while IFABP-PxK51 manifests a larger, 7.5-fold decrease. Both conjugates display a small increase in k_{cat} (1.5-fold). Molecular modeling suggests that the decreases in K_m' values for the new conjugates are most likely due to the formation of specific interactions between the substrate-derived α -carboxylate group and the ϵ -amino groups of the new lysine residues. Finally, it should be noted that the catalytic transamination reactions promoted by IFABP-PxK38 and IFABP-PxK51 are enantioselective, yielding L-glutamate with high enantiomeric purities ranging from 83 to 94% ee depending on the amino acid substrate employed. These levels of enantioselectivity are comparable to those previously obtained with the conjugate IFABP-Px that lacks the engineered lysines. In particular, using α -ketoglutarate and phenylalanine as substrates, glutamate was obtained from IFABP-Px, IFABP-PxK38, and IFABP-PxK51 in 93% ee, 92% ee, and 87% ee, respectively. Using α -ketoglutarate and tyrosine as substrates, glutamate was obtained from the same conjugates in 91% ee, 92% ee, and 92% ee, respectively. Thus, the above kinetic results clearly indicate that the new lysine residues are participating in catalysis and are having a positive influence on catalytic transamination without eroding the enantioselectivity observed with the parent conjugate, IFABP-Px.

To gain insight into how the introduced lysine residues were interacting with the catalytic center, mechanistic studies were undertaken. IFABP-PxK38 and IFABP-PxK51 (both in their pyridoxamine forms) were incubated with excess α -ketoglutarate. Due to the absence of an amino acid substrate, only half of the catalytic cycle can be accomplished, resulting in the conversion of the pyridoxamine cofactor to the corresponding aldehyde. The UV absorbance spectra of these catalyst forms, displayed in Figure 2, showed a band at 422–428 nm, which is characteristic of a pyridoxal–Schiff base complex (Shaltiel and Cortijo, 1970; Metzler et al., 1980). The fluorescence excitation spectra (excitation at 300–500 nm; emission at 510 nm) shown in Figure 3 revealed a corresponding band at 421 nm (Shaltiel and Cortijo, 1970; Metzler et al., 1980). After reduction of the Schiff base to a secondary amine with sodium borohydride, the absorbance and

**Figure 3.** Fluorescence excitation spectra of IFABP conjugates (ex at 300–500 nm; em at 510 nm; IFABP-PxK38 dotted line; IFABP-PxK51 dashed; IFABP-Px solid; all $10 \mu\text{M}$ in 20 mM HEPES, pH 7.5). The insert shows the second derivatives of the spectra.

fluorescence bands disappeared. As a control, samples of the IFABP-Px conjugate without the lysine mutation were subjected to the same series of experiments. After reaction with α -ketoglutarate, this conjugate had a maximum in the UV absorption spectrum at 398 nm (Figure 2) and in the fluorescence excitation spectrum at 391 nm (Figure 3), both corresponding to the pyridoxal form (Kallen et al., 1985). Thus, while there are 15 lysine residues present in IFABP-Px, none of these are able to form a Schiff base with the covalently tethered pyridoxal. Presumably, as predicted from modeling experiments, none of these residues have a geometry suitable for Schiff base formation. Only in the case of the lysines introduced by design does Schiff base formation occur.

Additional evidence for Schiff base formation between the engineered lysine residues and the pyridoxal cofactor was obtained via electrospray ionization mass spectroscopy; data for these experiments is summarized in Table 2. Analysis of samples of IFABP-PxK38 and IFABP-PxK51 following treatment with excess α -ketoglutarate and borohydride revealed a mass loss of 17 m/z compared to the pyridoxamine forms of these conjugates. This is consistent with the loss of ammonia (NH_3) that would occur upon intramolecular Schiff base formation with the active site lysine residue. Treatment of IFABP-Px (without a lysine mutation) under similar conditions followed by mass spectrometric analysis resulted in a loss of 1 m/z compared to the amine form, consistent with the simple reduction of the aldehyde to the corresponding alcohol.

Finally, in addition to playing a role in Schiff base formation, the engineered lysine residues also appear to participate in catalysis as possible proton donors or acceptors. In Figure 4 the pH dependence of the initial rate of transamination and the enantiomeric ratio of IFABP-PxK38 are shown; similar bell-shaped curves were found in the case of IFABP-PxK51. In contrast, the pH dependence of IFABP-Px (lacking a lysine mutation) catalyzed transamination, measured under the

Figure 4. Top: The initial rate and enantiomeric ratio of the IFABP-PxK38 catalyzed transamination depend on the pH value ($pK_{S1} = 5.5$, $pK_{S2} = 9.8$). IFABP-PxK51 revealed a similar curve with $pK_{S1} = 7.2$ and $pK_{S2} = 9.8$. For comparison, native aspartate aminotransferase shows values of $pK_{S1} = 6.7$ – 7.2 and $pK_{S2} = 9.4$ – 10.3 for the pH dependence of k_{cat} in the transamination of α -ketoglutarate and L-aspartate or L-cysteinesulfinate (Gloss and Kirsch, 1995). Bottom: The initial rate and enantiomeric ratio of the IFABP-Px (without a lysine mutation) catalyzed transamination reaction.

same reaction conditions, was linear for both rate and selectivity with a negative slope toward higher pH values. Interestingly, the bell-shaped pH dependence manifested by IFABP-PxK38 and IFABP-PxK51 is similar to that of natural transaminases; clearly the lysine residues introduced into these protein conjugates are influencing catalysis. The plots of the enantiomeric ratio vs pH of IFABP-PxK38 and -PxK51 show a sharp maximum in contrast to that observed with IFABP-Px. Such results suggest that the engineered lysine residues may be directly involved in the protonation of the aldimine intermediate and in determining the enantioselectivity of the reaction.

It is helpful to place the results obtained here with the lysine-containing conjugates into context with earlier work using fatty acid binding proteins. In our initial work, a fatty acid binding protein was derivatized with the pyridoxamine using the same reagent as employed here (Kuang et al., 1996). The resulting construct promoted the reductive amination of various α -ketoacids with significant enantioselectivity but at a rate that was actually slower than that mediated by the free cofactor. Subsequent work in which the pyridoxamine was positioned at several sites within the cavity showed that the cofactor was highly sensitive to its location within the protein host (Kuang et al., 1997). IFABP-PX60 was estimated to be at least 9.4 times faster than the original conjugate in a single turnover reaction in which α -ketoglutarate was reductively aminated to glutamic acid and examined after 24 h. These results prompted us to perform a kinetic analysis of the single turnover reaction promoted by IFABP-PX60 as well as to examine the

potential for this construct to undergo catalytic turnover in which the net transformation would be the transamination reaction shown in eq 1 (Kuang et al., 1998). Interestingly, it was found that the single turnover reaction was accelerated 62-fold relative to free pyridoxamine when measured at a single substrate concentration (50 mM α -ketoglutarate). Further analysis of the concentration dependence under catalytic conditions enabled values for k_{cat}' and K_M' to be determined. Comparison of these values with those for the simple pyridoxamine-catalyzed reaction showed a significant decrease in K_M' (41-fold) and a modest increase in k_{cat}' (9-fold) leading to an overall increase in catalytic efficiency, k_{cat}'/K_M' , of 360-fold. It should be noted that this rate enhancement in the catalytic reaction occurred in concert with significant enantioselectivity (>90% ee). While the increased catalytic efficiency obtained with IFABP-PX60 was exciting, it is important to emphasize that the role of the protein in this conjugate is limited to serving as a chiral, shape-selective recognition element. In particular, residues that participate in the acid/base chemistry and in modulating the reactivity of cofactor-bound intermediates that would exist in a typical enzyme active site are not present in IFABP-PX60. It was with this in mind that we sought to introduce into the IFABP-PX60 scaffold, lysine residues that could participate in covalent catalysis.

The results presented here highlight the successful design and assembly of two catalytic systems based on a protein scaffold that function via covalent catalysis. The interaction of the protein scaffold with the catalytic group was demonstrated by several spectroscopic methods. The introduced lysine residues change the pH profile and the kinetic parameters. The catalytic efficiency increased as much as 4200-fold over that of the free cofactor which is a rate acceleration comparable to that achieved with early examples of catalytic antibodies (Tramontano et al., 1986; Pollack et al., 1986). These semisynthetic aminotransferases are the first examples of bioconjugates designed for covalent catalysis. While the increase in catalytic efficiency due to the lysine residues reported here is only modest, this is not surprising given the absence of additional residues normally present in transaminases that are thought to modulate cofactor/substrate reactivity. Nevertheless, the ability to rationally design catalytic systems that mimic features of enzymatic processes (e.g., covalent catalysis, pH dependence) is a significant achievement. Thus, this approach illustrates the utility of mechanistic information and structural analysis for catalyst design as well as the enormous flexibility that can be harnessed using a combination of chemical and genetic (chemogenetic) methods.

ACKNOWLEDGMENT

We thank L. J. Banaszak and M. R. Lees for their support with the site-directed mutagenesis and D. P. Cistola for providing pMON-IFABP. The Minnesota Supercomputing Institute provided computer time for the modeling. This work was supported by the National Science Foundation (CHE9807495) and a fellowship of the Deutsche Akademische Austauschdienst (NATO-Programm).

Surface-Linked Liposomal Antigen Induces IgE-Selective Unresponsiveness Regardless of the Lipid Components of Liposomes

Yoshio Nakano,[†] Masahito Mori,[†] Shouichi Nishinohara,[†] Yusaku Takita,[‡] Seishiro Naito,[§] Hiroshi Kato,[§] Maiko Taneichi,^{||} Katsutoshi Komuro,[§] and Tetsuya Uchida^{*,§}

Received October 1, 2000; Revised Manuscript Received January 26, 2001

We have previously reported that antigen coupled with liposomes induced antigen-specific and IgE-selective unresponsiveness in mice. This antigen preparation was investigated for application in a novel vaccine protocol to induce minimal IgE synthesis. In this study, ovalbumin (OVA)–liposome conjugates were made using liposomes of four different lipid components, including unsaturated carrier lipid and three different saturated carrier lipids, after which the induction of anti-OVA antibody production was investigated in mice. All of the OVA–liposome conjugates induced IgE-selective unresponsiveness. The membrane fluidity of liposomes, as measured by detecting changes in the fluorescence polarization of a 1,6-diphenyl-1,3,5-hexatriene (DPH) probe located in the bilayers, was significantly higher in liposomes consisting of unsaturated carrier lipids than those of the other liposomes consisting of saturated carrier lipids. The highest titer of anti-OVA IgG was observed in mice immunized with OVA–liposomes made using liposomes consisting of unsaturated carrier lipids. In addition, among these OVA–liposomes, the one possessing the longest carbon chain induced the lowest IgG antibody production. These results suggest that the membrane fluidity of liposomes might affect the adjuvant effect of liposomes but not the induction of IgE-selective unresponsiveness in immunizations with surface-linked liposomal antigens.

INTRODUCTION

Adjuvants play a key role in the development of novel vaccines, particularly for vaccine antigens with weak immunogenicity. Aluminum-containing compounds such as hydroxides and phosphates (alum) are the only adjuvants currently approved for clinical use. However, alum is known to stimulate only humoral responses (1) and is known to induce IgE antibody production, which elicits an allergic response in the vaccinee (2). Therefore, the availability of improved adjuvants suitable for clinical use is highly desirable. Among the candidates for adjuvants for novel vaccines, liposomes are garnering attention as carriers (vehicles) of antigens because they are known to act as powerful adjuvants when physically associated with a protein antigen (3–6). Most of the liposomal vaccines proposed have been made by antigen entrapment within the aqueous lumen of liposomes (7). However, it is known that differential immune responses are induced by encapsulated and surface-linked liposomal antigens in both humoral- (8) and cell-mediated (9) immunity. We have previously reported that surface-linked liposomal antigens induce antigen-specific IgG

antibody production but not antigen-specific IgE antibody production (10). Thus, surface-linked liposomal antigens are expected to serve as a novel protocol for the development of vaccines to induce minimal allergic response.

In this study, ovalbumin–liposome conjugates were made using liposomes of four different lipid components, and the induction of antibody production by these conjugates was investigated in mice. The effect of liposomal composition on adjuvanticity has been investigated in many different studies (11–14). However, the more specific effect of this composition on IgE unresponsiveness has been more rarely addressed. This study was aimed at correlating liposomal composition and the induction of IgE-unresponsiveness by surface-coupled liposomal antigens.

MATERIALS AND METHODS

Experimental Animals. BALB/c mice (8 weeks of age, female) were purchased from Charles River (Yokohama, Kanagawa, Japan).

Chemicals. All phospholipids were obtained from NOF Co., Tokyo, Japan. Reagent grades of cholesterol and 1,6-diphenyl-1,3,5-hexatriene (DPH) were purchased from Wako Pure Chemicals Co., Osaka, Japan.

Liposomal Antigen. Ovalbumin (OVA, Grade VII) was purchased from Sigma (St. Louis, MO).

Liposomes. The liposomes consisting the four different components used in this study are listed in Table 1. The crude liposome solution was passed through a membrane filter (Nucleopore polycarbonate filter, Coster, Cambridge, MA) with a pore size of 0.2 μ m. The diameter of liposomes was analyzed using a NICOMP 370 Submicron Particle Sizer (Pacific Scientific, Silver Spring, MD).

Preparation of Fluorescence-Labeled Liposomes.

Fluorescence-labeled liposomes containing phospholipids consisting of an oleoyl group acting as an acyl chain were prepared as follows: 76.9 mg (97.88 μM) of DOPC, 54.6 mg (73.41 μM) of DOPE, 39.0 mg (48.94 μM) of DOPG, and 66.2 mg (171.29 μM) of cholesterol were dissolved in 2.37 mL of a solvent mixture (chloroform/methanol/water = 65/25/4 by volume), and then 0.2635 mL of 4.3 M DPH in chloroform solution was added. After a vigorous mixing, solvents were removed completely under reduced pressure, followed by the addition of 5 mL of 1 mM phosphate buffer (pH 6.0) containing 8.5% of sucrose to make a lipid vesicle suspension. The suspension was then extruded through a polycarbonate filter (0.2 μm) to adjust the liposome size. The lipid concentration of the resulting liposomes was 4.7 wt % (78.3 mM). Fluorescence-labeled liposomes containing phospholipids that consisted of a myristoyl group, palmitoyl group, or stearoyl group acting as the acyl chain were prepared by the same described above.

Fluorescence Measurement. Fluorescence depolarization of DPH was measured according to the method described by Lents et al. (15) using a Hitachi F-2000 spectrophotometer equipped with a temperature-controlled cuvette holder. DPH was excited at 360 nm, and its fluorescence was measured at 428 nm using an UV-39 instrument filter UV-39 to cutoff wavelengths below 390 nm. The degree of fluorescence polarization was calculated from the formula

$$P = (I_{VV} - I_{VH}G)/(I_{VV} + I_{VH}G)$$

where I_{VV} and I_{VH} are the observed fluorescence intensities measured with polarizers parallel and perpendicular to the vertically polarized exciting beam, respectively, and G is a correction factor for the transmission efficiency of vertically and horizontally polarized light. A 3-mL portion of 1 mM phosphate buffer (pH 6.0) containing 8.5% sucrose was mixed well with 0.3 mL of the liposome suspension prepared above. The mixture was then allowed to stand at 37 °C for 5 min before measurement. Three samples were prepared from each liposome suspension.

Coupling of OVA to Liposomes. Liposomal conjugates with OVA (OVA-liposome) via glutaraldehyde were prepared as described previously (10). Briefly, to a mixture of 90 mg of liposomes and 6 mg of OVA in 2.5 mL of phosphate buffer (pH 7.2) was added 0.5 mL of 2.5% glutaraldehyde solution in drops. The mixture was stirred gently for 1 h at 37 °C, and then 0.5 mL of 3 M glycine-NaOH (pH 7.2) was added to block excess

aldehyde groups. The mixture was then incubated overnight at 4 °C. The liposome-coupled OVA and uncoupled OVA in the resulting solution were separated using CL-4B column chromatography (Pharmacia Fine Chemical Co., Upsala, Sweden). The amount of lipid in the liposomal fraction was measured using a phospholipid content assay kit (Phospholipid-Test-Wako: Wako Pure Chemical Industries, Osaka, Japan). The OVA-liposome solution was adjusted to 10 mg lipid/mL and kept at 4 °C until use. For the measurement of OVA coupled to liposome, radiolabeled OVA ([methyl- ^{14}C]: purchased from New England Nuclear, Boston, MA) was mixed with cold OVA and used for coupling with liposome and for determining the calibration curve. The radioactivity of the resulting OVA-liposome solution was counted by using a calibration curve.

Immunization. Mice were immunized intraperitoneally (i.p.) with OVA-liposome at a dose of 2 mg lipid/200 μL /mouse. Control mice received i.p. injection with plain OVA solution in phosphate-buffered saline (PBS, pH. 7.2) at a dose of 140 μg OVA/200 μL /mouse. Four weeks after primary immunization, mice were boosted in the same manner as that used for primary immunization. For the measurement of serum antibodies, mice were bled from the tail vein.

Measurement of Serum Antibodies. Six weeks after primary immunization, serum anti-OVA IgG and IgG isotypes were determined by ELISA using HRP-labeled goat anti-mouse IgG (H+L), IgG1, IgG2a, IgG2b, and IgG3 (Zymed lab., San Francisco, CA). OVA-specific IgE was determined by monoclonal antibody-captured ELISA using monoclonal antibody against murine IgE produced by clone B1E3.

Spleen Cell Culture. Six weeks after primary immunization, spleen cells (SC) were taken from mice and suspended in RPMI-1640 containing 10% FCS at a cell density of $5 \times 10^6/\text{mL}$. In the preliminary examination, OVA at a final concentration of 1 mg/mL and a 24-h culture period was found to be optimal for the production of IFN- γ and IL-2. The cell suspension was plated at 100 μL per well onto a 96-well culture plate (No. 3072, Becton Dickinson Labware, Franklin Lakes, NJ), and 100 μL of 2 mg/mL OVA solution in the same media was added to each well. After incubation for 24 h in a CO_2 incubator, the culture supernatants were assayed for IFN- γ and IL-2.

Cytokine ELISA. Concentrations of IFN- γ and IL-2 in the culture supernatants were measured using a Biotrak mouse ELISA system (Amersham International, Buckinghamshire, UK). All test samples were assayed in duplicate, and the standard error (SE) in each test was less than 5% of the mean value.

Statistic Analysis. The Student's t-test was employed for the statistical analysis.

RESULTS

Liposome Diameter, Amount of OVA Coupled to Liposomes, and Polarization of DPH. There were no significant difference in diameter and in the amounts of OVA coupled to liposomes in OVA-liposome conjugates between the four liposome formulation (Table 2). Figure 1 shows fluorescence polarization degree of each liposome preparation determined at 37 °C. The degree of fluorescence polarization in "Oleoyl" liposomes, consisting of unsaturated fatty acids, was significantly lower than that in the other three liposomes, consisting of saturated fatty acids. In addition, a significant difference in the degree of fluorescence polarization was also observed among three liposomes consisting of saturated fatty acids.

Table 2. Liposome Diameter and Amount of OVA Coupled to Liposome^{a,b}

liposome formulation	diameter, nm (mean $\pm$ SD)	OVA, mg/10 liposome (mean $\pm$ SD)
myristoyl	241.2 $\pm$ 65.7	0.68 $\pm$ 0.04
palmitoyl	249.5 $\pm$ 50.2	0.70 $\pm$ 0.08
stearoyl	237.3 $\pm$ 54.6	0.59 $\pm$ 0.06

^a The diameter of liposomes was analyzed using a NICOMP 370 Submicron Particle Sizer. Data represent mean and SD of three independent measurements. ^b The amount of OVA coupled to liposome was measured using radiolabeled OVA as described in Materials and Methods. Data represent mean and SD of three independent measurements.

Figure 1. Fluorescence polarization degree in the liposomes with four different lipid formulations. The degree of fluorescence polarization at 37 °C was calculated as described in Materials and Methods. Data represent mean and SE of the triplicate measurements. Asterisk, $P < 0.000001$ compared with "Myristoyl" group; two asterisks, $P < 0.001$ compared with "Palmitoyl" group; three asterisks, $P < 0.01$ compared with "Stearoyl" group.

Anti-OVA Antibody Production in Mice Immunized with OVA-Liposome. Mice were immunized with OVA-liposome conjugates made using four different liposome formulations, and anti-OVA antibody production was investigated. Anti-OVA IgE antibody production was not observed in any of the OVA-liposome-immune groups (data not shown). As shown in Figure 2a, conjugates made using "Oleoyl" liposomes induced a significantly higher level of anti-OVA IgG antibody production as compared with those induced by the other three conjugates. Among the other three conjugates, those made using "Stearoyl" liposomes induced the lowest level of anti-OVA IgG antibody although the levels were higher than those of the control group, which received injections with plain OVA solution. The proportion of anti-OVA IgG isotype antibodies also varied among the immunization groups (Figure 2b). In mice immunized with OVA-liposome conjugates made using "Myristoyl", "Palmitoyl", and "Stearoyl" liposomes, the anti-OVA IgG response was dominated by IgG1 production; 80.8%, 75.9%, and 80.0% of the total anti-OVA IgG, respectively. In contrast, in mice immunized with OVA-liposome conjugates made using "Oleoyl" liposomes, IgG1 was 54.5% of the total anti-OVA IgG, while the rest were IgG2a (20.2%), IgG2b (21.2%), and IgG3 (4.0%).

Figure 2. Anti-OVA antibody production in mice. Six weeks after primary immunization, mice were bled from the tail vein and serum anti-OVA antibodies were measured. **a**, Titers of serum anti-OVA IgG. Data represent mean and SE of five mice per group. Asterisk, $P < 0.005$ compared with "Myristoyl" group; two asterisks, $P < 0.05$ compared with "Myristoyl" group and "Stearoyl" group; three asterisks, $P < 0.001$ compared with OVA-liposome-immune groups. **b**, Percentage anti-OVA IgG isotype response. The same serum samples in Figure 2a were assayed for the anti-OVA IgG isotype. Data represent percentage of the total anti-OVA IgG.

Cytokine Production by Spleen Cells of Mice Immunized with OVA-Liposome. Six weeks after primary immunization, cytokine production by SC of mice after *in vitro* restimulation with OVA was investigated. Correlating well with the results of anti-OVA IgG antibody production *in vivo* (Figure 2a), the level of IFN- γ produced by the SC of mice immunized with OVA-liposome made using "Oleoyl" liposomes was significantly higher than that in the other three groups (Figure 3). There were no significant differences in IL-2 production among the four immunization groups.

DISCUSSION

In the present study, liposomes with four different formulations were used to prepare OVA-liposome conjugates. All of the conjugates induced IgE-selective

Figure 3. Cytokine production by SC of mice immunized with OVA. Six weeks after primary immunization, SC of mice were cultured in vitro with OVA, and IFN- γ and IL-2 in the supernatants were measured thereafter. Data represent mean and SE of five mice per group. Asterisk, $P < 0.005$ compared with "Myristoyl", "Palmitoyl", or "Stearoyl" group. ■, IFN- γ . □, IL-2.

unresponsiveness. Among liposomes with the four different formulations, the fluorescence polarization values of the Oleoyl liposomes were significantly lower than those of the other three liposome preparations (Figure 1). The decrease in fluorescence polarization values can be interpreted as being due to an increase in mobility of the hydrophobic region of phospholipid bilayers in the membranes. OVA-liposome conjugates made using Oleoyl liposomes induced a significantly higher level of anti-OVA IgG antibody production (Figure 2a). In contrast, OVA-liposome made using Stearoyl liposome induced the lowest level of anti-OVA IgG antibody production. Among the four liposome preparations, only the Oleoyl liposomes consisted of unsaturated fatty acids. Membrane mobility would be higher in liposomes prepared using unsaturated fatty acid than in those liposomes prepared using saturated fatty acids. The chain length of the three saturated fatty acids used in the present study, Myristoyl, Palmitoyl, and Stearoyl, are 14, 16, and 18, respectively. In general, the shorter the acyl chain length, the higher the membrane mobility. Taken together, the membrane mobility of liposomes may correlate with liposomal adjuvanticity in immunizations with surface-coupled antigens of liposomes.

The results obtained in the present study differ from those mentioned in the review by Gregoriadis (3) in two points: (1) the adjuvanticity of liposomes does not depend on any specific vesicle characteristic (e.g., composition, size, surface charge, etc.). However, in this study, the adjuvant effects of liposomes differed strikingly among the different liposome formulations; (2) liposomal adjuvanticity occurs during primary immunization and is observed with most IgG subclasses with no apparent shift observed in subclass responses as compared with responses obtained with the free antigen. However in the present study, an increased production of IgG2a and IgG2b was observed in mice immunized with OVA-liposome made using Oleoyl liposomes (Figure 2a). These difference may be due to Gregoriadis and co-workers having used liposome-encapsulated antigen. In fact,

Shahum and Therien (8) have claimed that liposomal antigens differently influence the activation of the immune system depending on the mode of association of the antigen with the liposomal vehicle, whether it is by encapsulation or surface linkage. The present results further demonstrates that, even among surface-linked antigens of liposomes, the adjuvanticity of liposomes differs among specific vesicle characteristics (e.g., composition).

There are two types of processes for the mechanism of liposome uptake into cultured cells: phagocytosis and fusion (15). The differential fluidity of liposomes may affect the phagocytosis by antigen-presenting cells. In the group of mice immunized with OVA-liposome made using Oleoyl liposomes, a significantly higher level of IFN- γ production was observed as compared with that in the other groups (Figure 3). In the course of macrophage-T cell interactions, IFN- γ secreted from T cells may activate macrophages to increase phagocytic activity and antigen processing, which may result in the increased antigen recognition by T cells and an enhancement of antibody production.

Thus, in the present study, liposomes with different formulations were used to prepare OVA-liposome conjugates, and the induction of anti-OVA antibody production was investigated in mice. The liposomal adjuvanticity was strikingly different among different formulations of liposomes, although all of the OVA-liposome conjugates induced IgE-selective unresponsiveness. These results suggest that liposomal adjuvanticity, membrane mobility, or the lipid formulation of the liposomes did not affect the effect of the surface-coupled liposomal antigens on the induction of IgE-selective unresponsiveness. Efforts to clarify the mechanism of the induction of IgE-selective unresponsiveness with surface-coupled antigens of liposomes are in progress.

ACKNOWLEDGMENT

This work was supported in part by a grant from The Japan Health Sciences Foundation (Research on Health Sciences focusing on Drug Innovation).

Synthesis of the First Ferrocene-Labeled Dideoxynucleotide and Its Use for 3'-Redox End-Labeling of 5'-Modified Single-Stranded Oligonucleotides

Agnès Anne,* Bernard Blanc, and Jacques Moiroux

Laboratoire d'Électrochimie Moléculaire, Unité Mixte de Recherche Université-CNRS No 7591, Université de Paris 7 - Denis Diderot, 2 place Jussieu, 75251 Paris Cedex 05, France . Received October 18, 2000

The target ferrocene-labeled dideoxynucleotide compound 5-[*N*-(β -ferrocenyl-propanoyl)3-amino-propyn-1-yl]-2',3'-dideoxyuridine 5'-triphosphate, Fc-ddUTP, was synthesized and tested with terminal deoxynucleotidyl transferase for enzymatic 3'-redox-active end-labeling of 5'-phosphorylated single-stranded oligodeoxynucleotides. Starting from readily available 5-iodouridine and 3-ferrocenylpropanoic acid, the synthetic strategy elaborated here follows a mild multistep route. Each step involves reliable methods, and all ferrocene intermediates can be easily purified. Enzymatic 3'-ferrocene end-labeling of 5'-phosphorylated oligonucleotides is remarkably efficient, and 3'-ferrocene-labeled oligonucleotides can thus be prepared in sufficient amounts for further use in surface modifications.

Redox-active labeling of DNA has received recent substantial attention (1–14). In this regard, ferrocene-ended single stranded DNA oligomers have emerged as important versatile tools for the investigation of nucleic acids. In particular, ferrocene–oligodeoxynucleotide (ODN) conjugates have been recognized as viable alternatives to the use of radioactive isotopes in traditional DNA sequencing techniques, and their usefulness as hybridization redox probes for electrochemical sensing of target DNA/RNA sequences has been demonstrated in a number of modern applications (6–11). More specifically, ferrocene-labeled ODNs are routinely finding utility in the development and miniaturization of bioelectronic gene-sensing systems (12, 13).

A great, yet nonexploited, potential lies in the development of ferrocene-ended DNA probes bearing at the other terminus a function able to create a stable attachment to solid supports, surfaces and biomolecules. To our knowledge, only one group has been interested to address this promising research area. In this context, Letsinger et al. can be acknowledged for the pioneering synthesis of a 5'-ferrocene-nucleotide 3'-thiol-ended adsorbate for chemisorption onto gold surfaces and characterization of a redox-active nucleotide monolayer (14). However, despite the potential interest recognized by the authors in preparing redox-active oligonucleotide molecular assemblies on well-defined surfaces, it appears that the proposed chemical synthetic strategy for introducing a ferrocene label and a chemical functionality within an individual nucleotide was not expanded any further to oligonucleotides. Their strategy which focuses primarily on the construction of a ferrocene-labeled phosphoramidite for subsequent coupling to a nucleotide by standard automated DNA solid-phase synthesis suffers from a serious drawback: the ferrocene subunit does not suitably withstand the chemical oxidation step conditions required (iodine in basic THF/H₂O) in the coupling cycle. As noted in ref 14, the bound-ferrocene is readily converted into its corresponding ferrocenium form. However,

in the absence of an appropriate reductant, ferrocenium cations are well-known to rapidly hydrolyze in neutral/basic media with only partial regeneration of the parent ferrocene (15–17). Therefore, failure sequences lacking the ferrocene function inevitably are formed as byproducts, thus affecting product yield and reproducibility. While the phosphoramidite method generally offers the versatility of incorporating a metal complex at any site along the synthetic ODN (3, 18), postmodifications of a functionalized oligonucleotide after standard solid-phase synthesis are more appropriate approaches for incorporation of the sensitive ferrocene functionality (6, 10).

As part of an ongoing program on the investigation of the dynamic properties of biopolymer chains end-tethered to surfaces (19, 20), our interest was focused on developing redox-active ferrocene end-labeled DNA oligomers having a transformable monophosphate group at the 5'-end. The phosphate at this terminus is of importance since it can be used directly for ready attachment to amino-bearing surfaces through phosphoramidate linkages while preserving the integrity of the DNA single-strand sequence. Moreover, this 5'-end group can be profitably exploited for diverse bioconjugations and extension modifications (21, 22). Our approach to these complex labeled oligonucleotides combines key features that make it well-suited for preparation of 3'-ferrocene-5'-phosphorylated oligonucleotides that vary considerably in nature and length, from short ODNs accessible by chemical synthesis to enzymatically synthesized long nucleic acid sequences. Specifically, the route involves enzymatic 3'-end-labeling of presynthesized 5'-phosphorylated oligonucleotides that leaves the 5'-end intact and makes use of terminal deoxynucleotidyl transferase (terminal transferase, TDT). Terminal transferase catalyzes a template-independent addition of deoxyribonucleoside triphosphates to the 3'-OH ends of nucleic acids (23, 24). The enzyme accepts also a number of deoxynucleoside triphosphates containing modified base and/or sugar moieties. In this regard, C-5 labeled uridine 2',3'-dideoxynucleotides (ddUTPs) comprise a unique class of monomer substrates that are compatible with polymerase enzymes, and due to lack of the 3'-hydroxyl

functionality on the 2'-deoxyribose, offer a unique way to add a single label group such as biotin and digoxigenin (25, 26) or fluorophore groups (27, 28), to a DNA fragment. These labeled nucleotides are to date critical compounds in DNA sequencing techniques and antiviral chemotherapy (29, 30), as well as in molecular biology and biochemistry studies. Thus it seemed to us quite reasonable to expect a tolerance of terminal transferase to modification of the uracyl base moiety with a ferrocene unit.

As noted recently in a comprehensive review, no general and high-yielding route for preparing 2',3'-dideoxynucleosides 5'-triphosphates is currently available, but a renewed interest in the synthesis of these important compounds is highly expected (31). We felt that application of modern synthetic organic methodologies utilized in 2,3'-dideoxyuridines (ddUs) chemistry (29, 30) coupled with recent methods of analysis for the detection and isolation of nucleoside triphosphates would lead to a useful synthetic approach to ferrocene-labeled 2',3'-dideoxynucleoside triphosphates. In this paper, we describe the complete chemical synthesis of a first representative of the series, 5-[*N*-(β -ferrocenyl-propanoyl) 3-amino-propyn-1-yl]-2',3'-dideoxyuridine 5'-triphosphate, Fc-ddUTP, from inexpensive 5-iodo-2'-deoxyuridine. All reactions utilize readily available reagents and standard laboratory conditions. We further demonstrate that Fc-ddUTP is an excellent substrate for terminal deoxynucleotidyl transferase, a commercially available enzyme, and can be employed for a routine preparation of redox active 3'-end-labeled DNA probes.

EXPERIMENTAL SECTION

Ferrocenylmethyltrimethylammonium iodide was purchased from Strem Chemicals and from Aldrich Chemical Co. 5-Iodo-2'-deoxyuridine and propargylamine were purchased from Aldrich Chemical Co. Tetra-*n*-butylammonium dihydrogenophosphate (NBu₄KH₂PO₄) (99+%) was purchased from Fluka. Tri-*n*-butylammonium pyrophosphate ((HNBu₃)₂H₂P₂O₇) was obtained from Sigma Chemical Co. Other chemicals were obtained from commercial sources and were reagent grade or better quality and used as received. All solvents were anhydrous unless otherwise noted.

Terminal deoxynucleotidyl transferase (EC 2.7.7.31), TDT, and tailing reaction buffer were purchased from Roche Molecular Biochemicals (Boehringer, Mannheim). Synthetic 5'-phosphorylated oligonucleotides (sodium salts) were purchased from ESGS Cybergene (Evry, France) and were HPLC purified grade products. Centricon-30 YM cellulose membranes were purchased from Amicon.

Unless otherwise specified, all reactions were carried out in oven-dried glassware under argon atmosphere. All the ferrocene compounds prepared in this work were stored in vacuo (over P₂O₅) at ambient temperature, protected from light, and dried for at least 12 h before first use.

Chromatography. RP high-performance liquid chromatography (HPLC) was performed on a system equipped with two Gilson HPLC pumps (Model 305 and 306), a Gilson 119 UV-vis detector operating at 260 or 270 nm. Pump control and data processing used a Rainin Dynamax chromatographic software package (Macintosh).

For nonionic ferrocenes, analytical HPLC was carried out on a Waters (Milford, MA) Novapak C₁₈ (4 μ m, 3.9 mm i.d. $\times$ 15 cm) column with a linear gradient elution from 35% to 75% acetonitrile in water in 30 min (system

I). For other analytical runs, HPLC solutions were as follows: solvent A, 10% acetonitrile in aqueous KH₂PO₄ (20 mM) and NBu₄KH₂PO₄ (5 mM), pH adjusted to 7.5 with KOH; solvent B, acetonitrile. HPLC on a Novapak C₁₈ was performed isocratically with 25% B (system II) or following a linear gradient elution from 10 to 40% B in 60 min (system III). Purification of ferrocene-end-labeled oligonucleotides was carried out by HPLC on a Nucleosil 120C₁₈ (5 μ m, 4.6 mm i.d. $\times$ 15 cm) column (20 μ L loop) following a linear gradient elution from 25% to 35% B in 20 min (system IV). For other experiments performed on a Nucleosil 120C₁₈, the following conditions were used: solvent A, 10% acetonitrile in aqueous triethylammonium acetate, Et₃NH⁺, AcO⁻ (TEAA, 0.1 M) pH adjusted to 7.0 with acetic acid; solvent B, acetonitrile, (100 μ L loop). Elutions were done with a linear gradient from 2.5% to 25% B over 30 min (system V). For all HPLC runs the flow rate was 0.8 mL/min.

Thin-layer chromatography (TLC) analyses were performed on 0.25 mm silica gel Polygram SIL G/UV₂₅₄ plates. Preparative column chromatography was carried over Magerey-Nagel silica gel (0.063–0.2 mm), or over Sigma Chemical Co. ion-exchange DEAE cellulose or DOWEX 50WX4–100 (H⁺ form, strongly acidic) resins.

A 1 M solution of triethylammonium hydrogenocarbonate Et₃NH⁺, HCO₃⁻ (TEAC) was prepared by bubbling CO₂ through an aqueous mixture of triethylamine until the organic layer disappeared and adjusted to pH 7.5 with Et₃N.

Spectrometries. ¹H and proton-decoupled ¹³C NMR spectra were recorded on a Bruker AM-200 spectrometer operating at 200 and 50.3 MHz, respectively, in CDCl₃, CD₃OD, and/or DMSO-*d*₆. Chemical shifts are reported in parts per million relative to the solvents' residual protons CDCl₃ δ 7.27 ppm, CD₃OD, 3.31 ppm, DMSO-*d*₆ 2.50 ppm for ¹H experiments and the center line of CDCl₃ (77.00 ppm) CD₃OD (49.00) for ¹³C NMR experiments. ³¹P NMR spectra were recorded on a Bruker AM-400 spectrometer operating at 161.9 MHz in D₂O and referenced to 85% H₃PO₄.

Fast atom bombardment (FAB) mass spectra were obtained in the negative ion mode from the Ecole Normale Supérieure, Département de Chimie (Paris, France) using "magic bullet" (MB) as matrix. Matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry was performed on a PerSeptive Biosystems Inc. Voyager Elite instrument, operating in the negative mode using 3-hydroxypicolinic acid in diammonium citrate as the matrix and 355-nm pulsed light (49). External calibration was carried out using HPLC de-salted 5'-p-(dT)₁₀ (system V) in the above matrix.

UV-visible spectra and optical density (OD) were measured on a Hewlett-Packard HP 8452 diode array spectrophotometer. The quantity and yield of the ferrocene-nucleotides was determined by measuring the OD₂₉₀ of aqueous solutions of ferrocene-nucleotides and taking the value of ϵ_{290} for Fc-ddU **7** (ϵ_{290} = 9500 M⁻¹ cm⁻¹) as a standard value for **8–11**.

3-Ferrocenylpropanoic Acid (1). 3-Ferrocenylpropanoic acid **1** was prepared from ferrocenylmethyltrimethylammonium iodide following an adaptation of the three-step procedure reported in the past (50). The main modification is that ferrocenylmethylmalonic diethyl ester obtained in the first step was rigorously purified by fractional distillation before use. Without that additional purification step, we have found that the ferrocene monocarboxylic **1** could not be obtained as a clean sample.

A solution of diethyl malonate (8.8 g, 55 mmol) in 25

mL of absolute ethanol was added dropwise to a well-stirred solution containing freshly cut sodium (1.26 g, 55 mmol) in 50 mL of absolute ethanol. After complete addition, ferrocenylmethyltrimethylammonium iodide (19.3 g, 50 mmol) was added. The solution was heated under reflux for 72 h. After cooling to ambient temperature, the reaction mixture was diluted with water (200 mL), neutralized with 1 N HCl, and then extracted with two 100-mL portions of diethyl ether. The combined extracts were washed with saturated aqueous sodium hydrogenocarbonate, dried over magnesium sulfate, filtered, and evaporated to give an oily residue that was subjected to fractional distillation under reduced pressure. Discarding the first colorless fraction corresponding to residual diethyl malonate, the desired ferrocenylmethylmalonic diethyl ester was distilled as an orange oil (3 mmHg, 139–141 °C) which slowly solidified on standing (12.1 g, 68%). ¹H NMR (CDCl₃) δ 4.19 (q, 4H, OCH₂), 4.13 (s, 5 H, CpH), 4.08 (m, 4 H, CpH), 3.46 (t, *J* = 7.45 Hz, 1H, CH), 2.97 (d, *J* = 7.45 Hz, 2H, FcCH₂), 1.25 (t, *J* = 7.13 Hz, 6H, CH₃). ¹³C NMR (CDCl₃) δ 168.87, 84.55, 68.52, 67.57, 61.24, 54.15, 29.15, 13.96.

Ferrocenylmethylmalonic ester (10.7 g, 30 mmol) was saponified in 25 mL of 6 N potassium hydroxide in 90% aqueous ethanol under reflux for 24 h. The reaction mixture was diluted with water (150 mL) and extracted with two 100-mL portions of diethyl ether. The aqueous phase was neutralized with 6 N HCl. After addition of diethyl ether (150 mL), the mixture was cautiously acidified with 6 N HCl under stirring until extraction with ether. The organic extract was washed with water, dried over magnesium sulfate, and evaporated to obtain 2-ferrocenylmethyl malonic acid (8.2 g, 90%). ¹H NMR (DMSO-*d*₆) δ 12.73 (br s, 2H, COOH), 4.2–4.0 (m, 9H, CpH), 3.32 (t, *J* = 7.33 Hz, 1H, CH), 2.79 (d, *J* = 7.33 Hz, 2H, FcCH₂).

A sample of 2-ferrocenylmethyl malonic acid (7.6 g, 35 mmol) was heated at 150–160 °C for 0.5 h. The resulting residue was then purified by column chromatography on silica gel in chloroform/methanol, CHCl₃/MeOH (95:5) to afford analytically pure 3-ferrocenylpropanoic acid **1** (6.0 g, 93%). mp 121–122 °C (116–118 °C (50), 119–120 °C (51)). ¹H NMR (CDCl₃) δ 4.2–4.05 (m, 9H, CpH), 2.75–2.55 (m, 4H, FcCH₂CH₂). ¹³C NMR (DMSO-*d*₆) δ 174.08, 87.73, 68.30, 67.67, 66.94, 34.98, 24.31.

5-*N*-(β-Ferrocenyl-propanoyl)-3-amino-1-propyne (2). To a stirred solution of ferrocene **1** (5.16 g, 20 mmol) in 200 mL of dichloromethane were added 1-hydroxybenzotriazole (HOBT) (270 mg, 2 mmol) and propargylamine (2.06 mL, 40 mmol). After addition of 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride, EDC (4.22 g, 22 mmol), the mixture was allowed to react under stirring for 24 h at ambient temperature. The solution was successively washed with three 100-mL portions of 0.5 M H₂SO₄, water (100 mL), and saturated aqueous sodium hydrogenocarbonate. The organic phase was dried over magnesium sulfate, and the solvent was removed under reduced pressure. The solid residue was chromatographed on silica gel in CHCl₃/MeOH (95:5), yielding analytically pure ferrocene conjugate **2** (5.54 g, 94%). mp 78–79 °C. ¹H NMR (CHCl₃) δ 5.56 (br s, 1H, CONH), 4.3–3.9 (m, 11H, CpH + NHCH₂), 2.70 (m, 2H, FcCH₂), 2.38 (m, 2H, CH₂CO), 2.23 (t, *J* = 2.55 Hz, 1H, CH). ¹³C NMR (CD₃OD) δ 175.14, 88.79, 80.60, 72.12, 69.48, 68.96, 68.30, 38.27, 29.39, 26.63.

5-[*N*-(β-Ferrocenyl-propanoyl)-3-amino-propyn-1-yl]-2'-deoxyuridine (3) (Fc-dU). To a stirred solution of 5-iodo-2'-deoxyuridine (3.54 g, 10 mmol) in 50 mL of degassed DMF were added cuprous iodide (CuI) (38 mg,

0.2 mmol) and ferrocene **2** in excess (7.38 g, 25 mmol). The solution was stirred for 30 min at ambient temperature at which time triethylamine (Et₃N) (2.78 mL, 20 mmol) and tetrakis(triphenylphosphine)palladium(0) (PhP₃)₄Pd (116 mg, 0.1 mmol) were added. After stirring of the solution for 48 h, CuI (0.2 mmol) and (PhP₃)₄Pd (0.1 mmol) were added anew followed by addition of Et₃N (20 mmol). The reaction mixture was allowed to stir for another 24 h. At this point, TLC (CHCl₃/MeOH (85:15)) indicated quantitative conversion of the nucleoside reagent (*R*_f 0.42) to give the desired nucleoside–ferrocene product **3** (*R*_f 0.51). The solution was concentrated under vacuum at a temperature maintained at ≤35 °C, and the liquid residue was separated on silica gel. A first yellow fraction containing remaining starting ferrocene was eluted with CHCl₃/MeOH (95:5). A second yellow fraction was eluted with CHCl₃/MeOH (85:15), affording the desired product contaminated with a small amount of triethylammonium iodide. Crystallization from acetonitrile yielded analytically pure **3** (3.76 g, 72%). mp 196–198 °C (with some decomposition). ¹H NMR (CD₃OD) δ 8.30 (s, 1H, H-6), 6.24 (app t, *J* = 6.6 Hz, 1H, H-1'), 4.40 (m, 1H, H-3'), 4.2–4.0 (m, 11H, CpH + NHCH₂), 3.94 (m, 1H, H-4'), 3.85–3.70 (m, 2H, H-5'), 2.65 (m, 2H, FcCH₂), 2.42 (m, 2H, CH₂CO), 2.4–2.1 (m, 2H, H-2'). ¹³C NMR (CD₃OD) δ 175.16, 164.52, 151.11, 145.38, 99.94, 90.07, 89.15, 88.80, 87.03, 75.18, 72.07, 69.50, 68.97, 68.34, 62.62, 41.71, 38.36, 30.43, 26.63. HPLC (system I), retention time, *t*_r = 5.88 min.

A second chromatography using chloroform was performed on crude collected ferrocene **2** and allowed recovery of 2.95 g (67% from starting excess) of an essentially pure sample which could be used without further purification for a next preparation of **3**.

5'-O-(tert-Butyldimethylsilyl)-5-[*N*-(β-ferrocenyl-propanoyl)-3-amino-propyn-1-yl]-2'-deoxyuridine (4) (Fc-dU-5'TBDMS). Ferrocene–nucleoside **3** (1.56 g, 3 mmol) and imidazole (0.51 g, 7.5 mmol) were dissolved in 30 mL of DMF under stirring. To the solution was added *tert*-butyldimethylsilyl chloride (0.57 g, 3.75 mmol). The reaction mixture was stirred with the exclusion of moisture at ambient temperature for 1 h. The solvent was removed under vacuum at a temperature maintained at ≤35 °C, and the yellow residue was purified by column chromatography on silica gel in ethyl acetate/cyclohexane (95:5). Isolation of the major yellow component afforded the desired 5'-monosilylated ferrocene–nucleoside **4** as an orange solid (1.62 g, 85%). mp 165–166 °C. ¹H NMR (CD₃OD) δ 8.12 (s, 1H, H-6), 6.24 (dd, *J* = 7.45, 6.00 Hz, 1H, H-1'), 4.46 (m, 1H, H-3'), 4.2–4.0 (m, 12H, CpH + NHCH₂ + H-4'), 3.94 (dd, *J* = 11.50, 2.33 Hz, 1 H, H-5'), 3.84 (dd, *J* = 11.50, 2.59 Hz, 1H, H-5'), 2.66 (m, 2H, FcCH₂), 2.40 (m, 2H, CH₂CO), 2.4–2.1 (m, 2H, H-2'), 0.97 (s, 9H, *t*-BuSi), 0.19 (m, 6H, CH₃Si). ¹³C NMR (10% DMSO-*d*₆ in CD₃OD) 174.28, 163.85, 150.83, 144.35, 99.89, 90.67, 89.22, 89.02, 87.00, 75.60, 72.54, 69.56, 68.95, 68.33, 64.57, 42.22, 38.11, 30.27, 26.74, 26.44, 16.33, –4.90, –5.02. HPLC (system I) *t*_r = 19.49 min.

5'-O-(tert-Butyldimethylsilyl)-3'-O-(phenoxythiocarbonyl)-5-[*N*-(β-ferrocenyl-propanoyl)-3-amino-propyn-1-yl]-2'-deoxyuridine (5). (Fc-dU-5'TBDMS-3'PTC). To a solution of **4** (1.50 g, 2.36 mmol) in 3 mL of dichloromethane containing 1.4 mL of pyridine (17.3 mmol), cooled to 0 °C, was added dropwise a solution of phenoxythiocarbonyl chloride (0.94 mL, 6.84 mmol) in 3 mL of dichloromethane over a period of 30 min. After complete addition, the reaction mixture was stirred at ambient temperature for 2 h. At this point, TLC (ethyl acetate/cyclohexane (80:20)) showed the complete absence

of the starting nucleoside **4** (R_f 0.27) and its replacement by the thioacylated nucleoside **5** (R_f 0.63) and a byproduct (R_f 0.83). The solution was diluted with 100 mL of dichloromethane, washed successively with three 100-mL portions of 0.5 M H_2SO_4 , water, and brine. After drying over magnesium sulfate, the solvent was removed under vacuum to give a solid residue which was chromatographed on silica gel. Elution with ethyl acetate/cyclohexane (95:5) afforded the desired product **5** (1.10 g, 60%) as an orange amorphous solid. ^1H NMR (CD_3OD) δ 8.13 (s, 1H, H-6), 7.5–7.0 (m, 5H, ArH), 6.32 (dd, J = 8.7, 5.5 Hz, 1H, H-1'), 5.79 (app d, J = 5.6 Hz, 1H, H-3'), 4.46 (m, 1H, H-4'), 4.15–4.0 (m, 13H, CpH + $NHCH_2$ + H-5'), 2.65 (m, 2H, $FcCH_2$), 2.41 (m, 2H, CH_2CO), 2.9–2.2 (m, 2H, H-2'), 0.97 (s, 9H, t -BuSi), 0.19 (s, 3H, CH_3Si), 0.17 (s, 3H, CH_3Si). HPLC (system I) t_r = 34.22 min.

5'-O-(tert-Butyldimethylsilyl)-5-[N-(β -ferrocenylpropanoyl)-3-amino-propyn-1-yl]-2',3'-dideoxyuridine (6) (Fc-5'TBDMs-ddU). A well-stirred mixture of **5** (1.10 g, 1.42 mmol) and tributyltin hydride (0.42 mL, 1.56 mmol) in 70 mL of benzene was degassed for 30 min. After addition of 2,2'-azobis(2-methylpropionitrile) (AIBN) (23 mg, 0.14 mmol), the stirring reaction mixture was heated to reflux for 90 min. Solvent removal under reduced pressure gave a residue which was chromatographed on silica gel in ethyl acetate/cyclohexane (80:20), yielding the expected deoxygenated product **6** (0.46 g, 52%) as an orange amorphous solid. ^1H NMR (CD_3OD) δ 8.19 (s, 1H, H-6), 5.99 (m, 1H, H-1'), 4.2–4.0 (m, 13H, CpH + $NHCH_2$ + H-4' + H-5'), 3.77 (dd, J = 11.7, 2.81 Hz, 1H, H-5'), 2.65 (m, 2H, $FcCH_2$), 2.41 (m, 3H, CH_2CO + H-2'), 2.05–1.95 (m, 3H, H-2' + H-3'), 0.97 (s, 9H, t -BuSi), 0.17 (s, 6H, CH_3Si). HPLC (system I) t_r = 25.89 min.

5-[N-(β -Ferrocenylpropanoyl)-3-amino-propyn-1-yl]-2',3'-dideoxyuridine (7) (Fc-ddU). Product **6** (0.80 g, 1.29 mmol) was reacted with tetrabutylammonium fluoride in THF (1 M solution, 6.4 mL, 6.4 mmol) for 30 min. At this point, TLC (ethyl acetate–cyclohexane (80:20)) indicated complete disappearance of the starting nucleoside **6** (R_f 0.45) into the desired deprotected product **7** (R_f 0.07). After solvent removal, the residue was chromatographed on silica gel in $CHCl_3/MeOH$ (90:10). Fractions containing **7** were combined and concentrated under vacuum to give a viscous liquid which was taken up in 100 mL of acetonitrile. After washing with six 100 mL portions of cyclohexane which removed silylated byproducts, the acetonitrile phase was evaporated under vacuum yielding **7** (0.60 g, 92%) as an amorphous orange solid. ^1H NMR (CD_3OD) δ 8.44 (s, 1H, H-6), 6.01 (dd, J = 6.6, 3.0 Hz, 1H, H-1'), 4.2–4.0 (m, 12H, CpH + $NHCH_2$ + H-4'), 3.91 (dd, J = 12.2, 2.9 Hz, 1H, H-5'), 3.69 (dd, J = 12.2, 3.5 Hz, 1H, H-5'), 2.65 (m, 2H, $FcCH_2$), 2.41 (m, 3H, CH_2CO + H-2'), 2.2–1.9 (m, 3H, H-2' + H-3'). ^{13}C NMR (CD_3OD) δ 175.03, 164.65, 151.09, 145.56, 99.11, 89.81, 88.81, 88.20, 83.32, 75.43, 69.50, 68.94, 68.32, 63.26, 38.30, 33.85, 30.50, 26.56, 25.41. HPLC (system I) t_r = 7.81 min.

5-[N-(β -Ferrocenylpropanoyl)-3-amino-propyn-1-yl]-2',3'-dideoxyuridine 5'-monophosphate (9) (Fc-ddUP) as Morpholinium Salt. A 0.4 M stock solution of β -cyanoethyl phosphate pyridinium salt in pyridine was prepared by the procedure of Tener (46).

Nucleoside-ferrocene **7** (300 mg, 0.6 mmol) was dissolved in 3 mL of degassed anhydrous pyridine containing β -cyanoethyl phosphate in excess (3 mL of the stock solution, 1.2 mmol). To this solution was added dicyclohexylcarbodiimide (DCC) (495 mg, 2.4 mmol). The reac-

tion mixture was stirred at ambient temperature for 48 h. At this point, HPLC (system II) showed the quantitative conversion of the starting nucleoside (t_r = 7.1 min) into the less hydrophobic β -cyanoethyl phosphate derivative **8** (t_r = 6.5 min). To the solution was added 12 mL of water, and the mixture was stirred at ambient temperature for 1 h. The precipitate of N,N' -dicyclohexylurea was removed by filtration and washed well with water. The filtrate and washings were combined and concentrated under vacuum. The resulting residue was purified from excess undecomposed phosphorylating reagent by chromatography on DEAE cellulose using 0.1 M triethylammonium hydrogenocarbonate (TEAC) as the eluant. The yellow eluate was collected and lyophilized to afford intermediate **8** as a chromatographically pure solid: ^{31}P (D_2O) δ 0.96 (s, 1P, P_α).

The solid was dissolved in 30 mL of 9 N aqueous ammonia, and the solution was heated at 55 °C for 1 h. At this point, HPLC (system II) indicated conversion of the intermediate **8** into the expected monophosphate product **9** Fc-ddUP (t_r = 4.6 min) contaminated as shown by ^{31}P NMR spectroscopy with what appeared to be the corresponding diphosphate derivative. The solution was concentrated under vacuum and the residue was passed onto a DEAE (HCO_3^- form). The column was eluted with a linear gradient of TEAC (0.0 to 0.4 M, pH 7.5). Appropriate fractions were dried by lyophilization, and excess salt was removed by repeated lyophilization with deionized water to yield the triethylammonium salt of Fc-ddUP. An aqueous solution of Fc-ddUP was then applied to a Dowex 50 WX4 cation-exchange column (morpholinium form) and eluted with H_2O . The solution was lyophilized to afford morpholinium ferrocene-2',3'-dideoxyuridine phosphate **9**. The isolated yield (58%, based on starting **7**) was determined by optical density measurement. Attempts to separate the product from a phosphorus impurity gave the monophosphate compound, still not completely pure. The content of "morpholine" was determined to be 1.1 equiv by ^1H NMR. ^1H NMR (CD_3OD) δ 8.32 (s, 1H, H-6), 6.01 (m, 1H, H-1'), 4.27 (m, 1H, H-4'), 4.20–4.05 (m, 11H, CpH + $NHCH_2$), 4.03 (m, 2H, H-5'), 3.79 (br s, 1.1 $\times$ 8H, CH_2 morpholinium), 2.65 (m, 2H, $FcCH_2$), 2.55–2.35 (m, 3H, CH_2CO + H-2'), 2.25–1.95 (m, 3H, H-2' + H-3'). ^{13}C NMR (CD_3OD) δ 175.17, 164.71, 151.29, 145.39, 99.63, 90.08, 89.95, 88.10, 82.26 (d, J = 8.8 Hz, 1H, C-4'), 75.65, 69.51, 69.02, 68.29, 66.85 (d, $J_{C,P}$ = 4.8 Hz, 1H, C-5'), 65.98, 45.04 (morpholinium), 38.27, 33.18, 30.65, 26.62, 26.37. ^{31}P NMR (D_2O) δ 2.07 (s, 1P, P_α). HPLC (system II) t_r = 4.6 min. FAB-MS (–) data: m/z ($M - H$) $^-$, 584.0, $[C_{25}H_{27}N_3O_8PFe]H_3$ requires 584.1.

^{31}P NMR signals from what appears to be the diphosphate are as follows: δ –8.7 (d, 1P, J = 21 Hz, P_β), –13.2 (d, 1P, J = 21 Hz, P_α).

5-[N-(β -Ferrocenylpropanoyl)-3-amino-propyn-1-yl]-2',3'-dideoxyuridine 5'-triphosphate (9) (Fc-ddUTP) as Triethylammonium Salt. A solution of the monophosphate **9** (168 mg, 0.25 mmol) in water (2.5 mL) was mixed with *tert*-butyl alcohol (2.5 mL) and morpholine (85 μ L, 1 mmol). To the stirred refluxing solution was added a solution of N,N' -dicyclohexylcarbodiimide (206 mg, 1 mol) in *tert*-butyl alcohol dropwise over a period of 1.5 h. As shown by HPLC analysis, the quantitative formation of the phosphoromorpholidate **10** (system II, t_r = 6.2 min) was obtained after an additional 1 h. The reaction mixture was then cooled and evaporated under reduced pressure. The residue was dissolved in water (20 mL) and filtered; the solid was washed with an additional portion of water (5 mL). The combined

aqueous portions were extracted with diethyl ether (3×20 mL) and then coevaporated under reduced pressure with pyridine and finally benzene.

A solution of 47 mg of the above solid in dry DMSO (1.4 mL) was added slowly to a solution of tri-*n*-butylammonium pyrophosphate (101 mg, 0.28 mmol) in dry DMSO (0.4 mL), and the mixture was stirred under an inert atmosphere at ambient temperature for 3 days. The resulting solution was applied to a DEAE cellulose column (HCO_3^- form). The column was washed with water until the absorbance of the effluent fell to zero and then eluted with a linear gradient of triethylammonium hydrogenocarbonate (0.1 to 0.4 M). Appropriate fractions (0.2–0.3 M) monitored by HPLC for phosphorus content were pooled and lyophilized to yield Fc-ddUTP which was finally purified by HPLC on Nucleosil C₁₈ (system V). The isolated yield was determined by optical density measurement (0.12 mmol, 48%). The content of "triethylamine" was determined to be 3.2 equiv by ^1H NMR. ^1H NMR (CD_3OD) δ 8.24 (s, 1H, H-6), 6.01 (m, 1H, H-1'), 4.28 (m, 1H, H-4'), 4.20–4.05 (m, 11H, + CpH + NHCH_2), 4.04 (m, 2H, H-5'), 2.87 (m, 3.2×6 H, CH_2 triethylammonium), 2.63 and 2.48 (A_2B_2 system, 4H, $\text{FcCH}_2\text{CH}_2\text{CO}$), 2.38 (m, 1H, + H-2'), 2.20–2.00 (m, 3H, H-2' + H-3'), 1.18 (m, 3.2×3 H, CH_3 triethylammonium). ^{31}P NMR (D_2O) δ -9.80 (d, 1P, $J = 20$ Hz, P_γ), -10.1 (d, 1P, $J = 20$ Hz, P_α), -22.1 (t, 1P, $J = 20$ Hz, P_β). HPLC (system II), $t_r = 5.5$ min. FAB-MS (–) data: m/z ($\text{M} - \text{H}$) $^-$, 744.0, [$\text{C}_{25}\text{H}_{27}\text{N}_3\text{O}_{14}\text{P}_3\text{Fe}$] H_3 requires 744.0; ($\text{M} - 2\text{H} + \text{Na}$) $^-$, 766.0, [$\text{C}_{25}\text{H}_{27}\text{N}_3\text{O}_{14}\text{P}_3\text{Fe}$] H_2Na requires 766.0; ($\text{M} - 3\text{H} + 2\text{Na}$) $^-$, 788.0, [$\text{C}_{25}\text{H}_{27}\text{N}_3\text{O}_{14}\text{P}_3\text{Fe}$] HNa_2 requires 788.0.

5'-Phosphorylated Oligonucleotides Containing a 3'-Terminal ddU-Fc (5'-p-(dT)₁₀-ddU-Fc-3'). In a typical experiment, approximately 20 nmol of 5'-phosphorylated ODN 5'-p-(dT)₁₀ (23 μM) and 200 nmol of Fc-ddUTP (0.23 mM) in tailing buffer (850 μL) containing 25 mM Tris-HCl and 100 mM potassium cacodylate, pH 7.2, 1 mM CoCl_2 and 0.2 mM dithiothreitol were mixed with 500 units of terminal deoxynucleotidyl transferase (20 μL). The reaction was incubated for 30 min at 37 °C. The enzyme was then removed by filtration through a Centricon 30 YM cellulose membrane (30000 MW cutoff). For complete recovery of the ferrocene-labeled oligonucleotide, the membrane unit was washed by successive dilutions with water and filtrations (5×500 μL). The filtrates were concentrated by lyophilization and purified by HPLC using a linear gradient of sodium phosphate buffer (system IV) to remove reaction buffer components and excess Fc-ddUTP ($t_r = 7.7$ min). Appropriate fractions ($t_r = 13.8$ min) were collected in sterile Eppendorf tubes and were lyophilized to afford the oligonucleotide extended from the 3'-end with a ddU-Fc label (5'-p-(dT)₁₀-ddU-Fc-3') in a ca. 75–80% yield. Quantitation was done from the HPLC peak integral at 270 nm, the molar extinction coefficient being the sum of the estimated molar extinction coefficient for 5'-p-(dT)₁₀ ($\epsilon_{270} = 97800 \text{ M}^{-1} \text{ cm}^{-1}$) (9) and of the molar extinction coefficient of the Fc-ddU moiety ($\epsilon_{270} = 6640 \text{ M}^{-1} \text{ cm}^{-1}$) which was determined separately. Finally, the purified ferrocene-labeled DNA probe was desalted using a linear gradient of TEAA in acetonitrile buffer (system V, $t_r = 22.5$ min) prior to MALDI-TOF analysis. MS (MALDI-TOF) (–) data: m/z ($\text{M} - \text{H}$) $^-$, 3623.8, $\text{C}_{125}\text{H}_{157}\text{N}_{23}\text{O}_{78}\text{P}_{11}\text{Fe}$ requires 3624.5.

RESULTS AND DISCUSSION

Synthesis and Characterization of C-5 Ferrocene Nucleosides and Nucleotides. Of major concern for

Scheme 1

successful 3'-end-labeling of single-stranded DNAs is the appropriate choice of the linkage between the label and the uridine base in the C-5 labeled nucleotide substrate. For the Fc-ddUTP species we chose to synthesize (Scheme 1), the precise positioning of the ferrocene label is ensured through a triple-bonded cross-linking to the base. This structural feature originally designed by Prober et al. (32) is actually found in a variety of commercially available C-5 modified chain terminators. While the rigid triple bond is expected to reduce the interaction between the label and the nucleotide, the alkynyl $\text{C}=\text{CH}-\text{CH}_2-\text{NH}-\text{C}(\text{O})-(\text{CH}_2)_2$ arm we selected for Fc-ddUTP generally minimizes interference with enzyme activity. Choice of this linker arm would also offer an interesting redox-labeled nucleotide endowed with the low redox potential of an alkyl ferrocene derivative. Finally, because the C-5 positions of uridines are not involved in the Watson–Crick base pairing, the ferrocene label is expected not to interfere with probe hybridization, a criteria of major importance for development of valuable ferrocene-labeled DNA probes.

Our synthetic approach to the target compound Fc-ddUTP follows a chemical route which consists of three main stages: (a) synthesis of a C-5 ferrocene-labeled 2'-deoxyuridine precursor Fc-dU (Scheme 2); (b) specific 3'-deoxyoxygenation to Fc-ddU (Scheme 3); (c) triphosphorylation of the 5'-end via the monophosphate form Fc-ddUP (Scheme 4). This strategy capitalizes on well-established and mild methodologies in uridine chemistry that we anticipated to be compatible with the ferrocene unit. As a second main advantage, the route starts from inexpensive and readily available materials. In particular, 5-iodo-2'-deoxyuridine was selected for modification because of its commercial availability and current use at the gram level. Additionally, incorporation of the ferrocene label facilitates the purification work because of its hydrophobicity and coloration, therefore providing a quick entry to a variety of new ferrocene-nucleosides.

Scheme 2^a

^a (a) EDC, HOBT, CH_2Cl_2 ; (b) $(\text{PPh}_3)_4\text{Pd}$, CuI, Et_3N , DMF.

As outlined in Scheme 2, the synthetic stage to Fc-dU **3** relies on the classical palladium-mediated coupling methodology of terminal alkynes with 5-iodo-nucleosides. The starting 5-*N*-(β -ferrocenyl-propanoyl)-3-amino-1-propyne linker **2** was readily prepared by carbodiimide EDC-mediated condensation reaction of 3-ferrocenylpropanoic acid **1** with propargylamine in dichloromethane. The presence of 1-hydroxybenzotriazole (HOBT) as an additive was necessary for efficient reaction. This afforded **2** in an excellent isolated yield (94%) and purity. An improved synthesis of **1** is given in the Experimental Section.

Coupling of alkyne **2** with 5-iodo-2'-deoxyuridine was carried out in DMF following the Pd(0)-catalyzed methodology reported by Hobbs (33). It seemed from literature observations that formation of the cyclized furano pyrimidin-2-one byproduct which generally occurs under the Sonogashira Pd(II)-catalyzed coupling reactions (33–35) would be prevented. Indeed, at ambient temperature and using the (PhP₃)₄Pd/CuI catalytic system, the coupling reaction proceeded cleanly to give FcdU as the sole ferrocene-containing nucleoside. Compound Fc-dU was readily isolated by silica gel chromatography followed by crystallization in 72% yield. Its structure and purity were confirmed by ¹H NMR and ¹³C NMR spectra and reversed-phase (RP) HPLC.

Our route for specific chemical 3'-deoxygenation of ferrocene-2'-deoxyuridine Fc-dU to the corresponding ferrocene-2',3'-dideoxyuridine Fc-ddU involves the classical and mild four-step sequence: selective-protection of the 5'-hydroxyl function, thioacylation followed by radical-induced reductive cleavage, and deprotection (36) (Scheme 3). We chose to protect the 5'-hydroxy of Fc-dU with the *tert*-butyl-dimethyl silyl TBDMS group to avoid acid conditions during deprotection since 2',3' dideoxyuridines are acid labile (37, 38). Thus, Fc-dU was treated with *tert*-butylchlorodimethylsilane (TBDMSCl) in the presence of imidazole in DMF to give the 5'-O-TBDMS derivative **4** which was obtained after chromatographic separation from minor amounts (<5%) of the 3',5'-bis-silylated product in 85% yield. The removal of the 3'-hydroxy group of ferrocene-nucleoside **4** was basically achieved by adaptation of the Barton–McCombie deoxygenation procedure of alcohols (39) as modified by Robins et al. for nucleosides (36). Accordingly, **4** was converted in a first step into its 3'-(phenyl thionocarbonate) ester **5** using phenoxythiocarbonyl chloride (PTC-Cl).

However, it appeared that the acetonitrile/4-dimethylaminopyridine catalytic system classically used for thioacylation of hindered alcohols (36) was unsuitable for large-scale preparation of **5**. In addition to the limited solubility of **4** in acetonitrile, thioacylation of **4** was complicated by formation of a ferrocene-nucleoside byproduct in an approximate 50% amount. This product is believed to be the corresponding O²,3'-anhydronucleoside derivative of **4** (Figure 1), judging from the marked downfield position of the H-3' (δ 5.75 ppm) signal, slightly displaced 0.06 ppm upfield from the corresponding signal in the ester **5**, and the absence of the aromatic phenoxy signals in the NMR spectrum of a byproduct chromatography fraction. Similar O²,3'-anhydronucleosides have been reported in the literature and can be obtained by direct treatment with various reagents of the appropriate 2'-deoxyuridine but also by base treatment of the corresponding 3'-O-thiocarbonyl-nucleoside precursor (40–42). The low yield and the difficulty of purification of the desired **5** led us to use alternate conditions for the 3'-thioacylation step of **4**. In dichloromethane and in the presence of ~7 mol equiv of pyridine (43), O²,3'-cyclo-

Figure 1. Ferrocene-cyclonucleoside byproduct formed during thioacylation of **4**.

nucleoside formation could be reduced to less than 10%, possibly due to the shorter reaction times (<2 h). 3'-O-(Phenoxythiocarbonyl)ferrocene-nucleoside **5** was obtained as the major product and was isolated in this work in 62% (pure) as an amorphous solid.

Compound **5** was then smoothly deoxygenated with commercial tri-*n*-butyltin hydride (Bu₃SnH) and a catalytic amount of 2,2'-azobisisobutyronitrile (AIBN). The best chemical yield in the desired 2',3'-dideoxyuridine product **6** was obtained after a short heating at benzene reflux under argon. Under such conditions, no dethiation or alcohol byproducts were detected. Interestingly, the plausible unwanted hydrostannylation of the yne function (44) was also fully prevented. After purification by silica gel chromatography, the deoxygenated **6** whose structure was confirmed by ¹H and ¹³C NMR spectra was obtained in a 56% (pure) yield.

Removal of the silyl protecting group from **6** was then easily achieved by treatment with ~5 mol equiv of tetrabutylammonium fluoride (TBAF) in tetrahydrofuran for 30 min at ambient temperature. This afforded the desired deprotected ferrocene-2',3'-dideoxyuridine Fc-ddU in excellent yield. Full characterization of the compound is described in the Experimental Section. All physical data confirm the structure.

Scheme 4^a

^a (a) β -Cyanoethyl phosphate, DCC, pyridine; (b) aq NH_3 (c) DCC, morpholine, *t*-BuOH/ H_2O ; (d) $(\text{HNBu}_3)_2\text{H}_2\text{P}_2\text{O}_7$, DMSO.

5'-Phosphorylated Ferrocene-2',3'-dideoxyuridines. Several methods have been described for the chemical preparation of nucleoside triphosphates in the literature (31). Most of them involve the coupling of a pyrophosphate with an activated nucleoside monophosphate. Of the commonly used methods a priori compatible with the ferrocene subunit, we judged that the Moffatt phosphoromorpholidate coupling approach (45) would offer the mildest and most practical route to ferrocene–nucleoside triphosphate Fc-ddUTP **11** from **7** via the monophosphate derivative **9** (Scheme 4).

All phosphorylation reactions (**7** to **11**) were monitored by RP-HPLC, and chemical modifications were characterized by ^{31}P NMR spectroscopy of the products in crude and/or isolated pure forms. The free 5'-hydroxyl group of Fc-ddU was first phosphorylated by condensation with β -cyanoethyl phosphate (46) in the presence of *N,N*-dicyclohexylcarbodiimide (DCC) in anhydrous pyridine to afford the 5'-(β -cyanoethyl phosphate) sodium salt intermediate **8** in essentially quantitative yield. The ^{31}P NMR spectrum of **8** obtained after purification on DEAE cellulose anion-exchange chromatography showed one signal at 0.96 ppm corresponding to α -phosphorus. The β -cyanoethyl group of the intermediate **8** was removed in concentrated ammonia at 55 °C for 1 h to afford crude ferrocene–nucleoside 5'-phosphate **9**. The presence of two doublets centered at -8.7 ppm and -13.2 ppm in the ^{31}P NMR spectrum of the reaction mixture suggested the formation of the ferrocene–nucleoside diphosphate as a minor byproduct (<5%). Purification of the product on DEAE cellulose followed by chromatography on DOWEX 50 WX4 cation-exchange resin yielded the morpholinium salt of **9** (58% yield, based on starting **7**, UV–visible determination) which was used without further purification. The presence of the 5'-monophosphate group was proved by the singlet found at 2.1 ppm in the ^{31}P NMR spectrum of **9**. The structure of compound **9** was verified by ^1H NMR spectroscopy and confirmed by its negative-ion FAB spectrum which displayed the $[\text{M} - \text{H}]^-$ ion at m/z 504 as the base peak.

Monophosphate **9** was then converted into its activated 5'-phosphomorpholidate derivative **10** in quantitative yield by refluxing with morpholine in the presence of DCC in aqueous *tert*-butyl alcohol (45). In agreement with the proposed intermediate **10** (Scheme 4) was the observation of a new singlet at 4.9 ppm in the ^{31}P NMR spectrum of the crude product obtained after an aqueous

workup procedure (45, 47). The solid was rigorously dried and treated with a 5 equiv of commercial tri-*n*-butylammonium pyrophosphate $(\text{HNBu}_3)_2\text{H}_2\text{P}_2\text{O}_7$ in dry DMSO for 3 days. This yielded a crude product that was first purified by anion-exchange chromatography to yield a crude sample of ferrocene nucleoside 5'-triphosphate, Fc-ddUTP, **11**. Compound **11** could be further purified and desalted by HPLC using the volatile triethylammonium acetate (TEAA) buffer as eluant.

Chromatography thus provided spectroscopically pure **11** as a triethylammonium salt in 48% yield. In particular, the ^{31}P NMR spectrum only showed the three characteristic phosphorus atom signals due to the triphosphate chain with the expected P–P geminal coupling. The structure of compound **11** was also confirmed by its negative-ion FAB-MS.

Synthesis of 5'-Phosphorylated Oligonucleotides Containing a 3'-Terminal Ferrocene Label. To obtain uniformly successful results in 3'-end-tailing experiments, an important practical problem we studied preliminarily was the quality of the starting single-stranded 5'-phosphate-labeled oligonucleotide products supplied by ODN manufacturers. As it is known, the purity of crude unlabeled synthetic oligonucleotides depends on the length of the sequence to synthesize. The main impurities that are difficult to separate from (*n*)-mer (*n* nucleotides in length) are the *n* – 1 and *n* – 2 congener species (called runts of synthesis). In addition to these contaminants, chemical phosphorylation, which is achieved during solid-phase oligonucleotide syntheses using phosphoramidites, is often nonquantitative. Runts and unphosphorylated 5'-OH-ODN sequences cannot be eliminated through a simple desalting step and should be removed using purification methods. After reversed phase HPLC or ion-exchange HPLC, the 5'-modified oligonucleotide with the correct length and label is usually provided from the manufacturer as a HPLC-grade product.

Therefore, we developed a fast and informative C_{18} RP-HPLC analytical method for routine quality control of these 5'-modified synthetic products (up to 20 bases). HPLC traces A and B in Figure 2 clearly illustrate the high degree of variability in quality encountered among two HPLC-grade 5'-phosphorylated ODNs differing only in their commercial origin. As evidenced from HPLC profiles, some products regarded by their manufacturers as "gold standard" are actually unsuitable samples for most experiments due to high contamination with the parent 5'-hydroxylated sequence (slower-eluting species, trace A) and not well-resolved secondary structures. Nevertheless we have found that HPLC-grade 5'-phosphorylated products from ESGS Cybergene were practically free of impurities, their purity being >85% (Figure 3, trace B) in complete agreement with the analytical certificate of the provider.

An optimized 3'-ferrocene end-labeling procedure using terminal deoxynucleotidyl transferase TDT was set up at the 20 nmol scale of a HPLC-purified 5'-phosphorylated oligonucleotide of defined length (10-mer 5'-p-(dT)₁₀ sequence, ~ 2 OD₂₆₀ units) by adaptation of the standard protocol reported by Roychoudhury and Wu (48). The enzymatic incorporation reaction of the redox-labeled dideoxynucleotide Fc-ddUTP at the 3'-terminus of the oligonucleotide (eq 1) was analyzed by C_{18} RP-HPLC

using a linear gradient of acetonitrile in phosphate buffer,

Figure 2. RP-HPLC Profiles of Commercial HPLC-Purified Grade 5'-Phosphorylated Oligonucleotides. 5'-p-(dT)₂₀ sample provided (A) from Genset (B) from ESGS Cybergene. Column: Nucleosil C₁₈, 120 Å; eluant A: 10% acetonitrile in 0.1 M aqueous triethylammonium acetate, pH 7.0; solvent B, acetonitrile, linear gradient 2.5–25% B in 30 min, flow-rate 0.8 mL/min.

Figure 3. Analytical HPLC Control of 3'-End-labeling of 5'-Phosphorylated Oligonucleotide with Fc-ddUTP. Reaction mixture 200 nmol Fc-ddUTP + 20 nmol 5'-p-(dT)₁₀ in enzymatic buffer at 37 °C: (A) before TDT addition; (B) 30 min after TDT addition and after first Centricon-30 membrane ultrafiltration. Column: Novapak C₁₈, 60 Å; solvent A, 10% acetonitrile in aqueous KH₂PO₄ (20 mM) and NBu₄KH₂PO₄ (5 mM), pH 7.5; solvent B, acetonitrile, linear gradient 10–40% B in 60 min, flow-rate 0.8 mL/min.

at different times, after removal of the TDT enzyme by ultrafiltration on 30000 molecular weight cutoff membrane. As demonstrated in Figure 3, a rapid and complete ferrocene-labeling of the 10-mer sequence (trace A, retention time 34.4 min) could be achieved when using approximately 10-fold molar excess of Fc-ddUTP (traces A and B, retention time 32.0 min). Under our analytical reversed-phase HPLC conditions, the oligonucleotide extended at its 3'-end by a single hydrophobic ferrocene-nucleoside label Fc-ddU (trace B, retention time 43.9 min)

was a quite slower-eluting species than Fc-ddUTP. This interesting chromatographic separation feature was also obtained at the preparative scale level using a similar appropriate chromatographic system (see Experimental Section for details), and thus made purification of the ferrocenylated-oligonucleotide from excess Fc-ddUTP and other fastest eluting reaction contaminants a facile and efficient step. The final yield in ferrocenylated-oligonucleotide 5'-p-(dT)₁₀-ddU-Fc-3' product was about 75–80% (based on starting oligonucleotide) as determined from HPLC peak integral, and purity was confirmed by HPLC quality control method. Finally, the ferrocenylated-oligonucleotide sample was desalted from the chromatographic phosphate salts by RP-HPLC with volatile TEAA buffer and lyophilized. The identity of the Fc-ddU-terminated oligonucleotide product was confirmed by matrix-assisted laser desorption/ionization/time-of-flight (MALDI-TOF) mass spectrometry in the negative mode, using the carboxylic acid 3-hydroxypicolinic acid (3-HPA)/diammonium citrate as a useful two component matrix for detection of the molecular ion peak, (M – H)[–] of labeled 5'-p-(dT)₁₀ (49).

In conclusion, by starting from the readily available 5-iodouridine and ferrocene-alkyne **2** we developed an efficient synthetic approach for preparing the first ferrocene-labeled dideoxynucleotide Fc-ddUTP **11**. Although the overall yield of Fc-ddUTP cannot be regarded as outstanding (<10%), the methods presented here are reliable and all ferrocene intermediates can be easily purified. It is worth emphasizing that the ferrocene-dideoxynucleoside intermediate Fc-ddU **7** can be prepared in gram batches and that the target compound Fc-ddUTP can be obtained pure in practical quantities for incorporation into single-stranded DNA. Our results also clearly show that enzymatic 3'-ferrocene end-labeling of small 5'-phosphorylated synthetic oligonucleotides with TDT using Fc-ddUTP as a substrate is a highly efficient reaction which can be extended with great promise to larger and more complex 5'-modified oligomers. Finally, by proving that significant quantities of 3'-ferrocene-labeled oligonucleotides can be prepared, this work sets the stage for our studies of various redox-labeled DNA probes required for attaching monolayers of interesting redox-active oligonucleotide on surfaces.

ACKNOWLEDGMENT

The authors are thankful to Agnès Bouchardon for technical help with HPLC.

Chemical and Biochemical Issues Related to X-ray Crystallography of the Ligand-Binding Domain of Estrogen Receptor α

Steven W. Goldstein, Jon Bordner, Lise R. Hoth, and Kieran F. Geoghegan*

Pfizer Global Research and Development, Eastern Point Road, Groton, Connecticut 06340. Received October 19, 2000; Revised Manuscript Received February 2, 2001

Careful attention to technical issues preceded successful crystallography of the ligand-binding domain of estrogen receptor α (ER α) complexed with CP-336156, a nonsteroidal estrogen agonist/antagonist. An affinity column based on immobilized estradiol was prepared according to the scheme of Greene et al. (Greene, G. L., Nolan, C., Engler, J. P., and Jensen, E. V. (1980) *Proc. Natl. Acad. Sci. U.S.A.* 77, 5115–5119). It was shown by X-ray crystallography that the major and less polar isomer of the affinity column precursor was 17 α -((S)-2',3'-epoxyprop-1'-yl)estra-1,3,5(10)-triene-3,17 β -diol. This diastereomer was coupled to Thiopropyl Sepharose, with coupling monitored by observing loss of the phenolic absorption band of estradiol from the reaction supernatant, and gave an affinity matrix containing about 9 μ mol of estradiol per milliliter of wet gel. Recombinant ER α ligand binding domain was selectively removed from *E. coli* cell lysate by binding to the column and was partly S-carboxymethylated by treatment with iodoacetic acid while bound to the column as described by previous workers. After being eluted from the column as a complex with drug, the receptor fragment was shown by mass spectrometry to be a mixture of differently modified forms. It was further S-carboxymethylated in solution, after which anion-exchange chromatography was used to isolate protein in which two of the four cysteine residues were S-carboxymethylated. This material, which afforded diffraction-quality crystals, was subjected to digestion with trypsin and peptide mapping analysis by HPLC coupled with mass spectrometry. For this experiment, the two previously unmodified cysteines were alkylated with 4-vinylpyridine to allow definitive identification. It was shown that Cys-417 and Cys-530 were S-carboxymethylated in the crystallized protein, while Cys-381 and Cys-447 remained unmodified. Close attention to such technical issues may be important in structural studies of other nuclear receptors, a very important class of potential drug targets.

INTRODUCTION

ER¹ belong to the nuclear receptor superfamily and are composed of discrete ligand-binding and DNA-binding domains. There are two principal isoforms, ER α and ER β . In the presence of 17 β -estradiol or another agonist, the receptors associate with accessory proteins known as coactivators to mediate the effects on gene expression that are the end-point of estrogen action in many cells or tissues. Details of these interactions have only recently begun to be elucidated (1–3).

Crystallographic structural biology is one of the approaches being used to scrutinize this complex machinery. Structures have been reported for the ligand-binding domains of ER α (4–6) and ER β (7) complexed separately with agonist ligands (17 β -estradiol and diethylstilbestrol) and drugs of the class called selective estrogen receptor modulators (SERMs) (tamoxifen and raloxifene; for reviews of this drug class, see refs 8–10). The results illustrate brilliantly how internal details of a protein–ligand interaction can modulate the protein's external conformation, as the packing site of the C-terminal structural element helix 12 is different in the agonist and SERM complexes. They complement other demonstra-

tions that the nature of the ligand governs the types of interactions with coactivators available to the receptor and that this underlies the differences in action between agonists and SERMs. The results with ER form part of a more general picture that is emerging of how ligand–protein interactions modulate the function of nuclear receptors (11).

Isolation of ER from natural or recombinant sources is necessary in many studies and an essential precursor to crystal growth. Affinity chromatography has been an important technical asset, as the high affinity of ER for immobilized derivatives of estradiol allows single-step isolations (12). The same high affinity, however, has also been a detriment, as conditions that are probably at least partly denaturing have been needed to elute bound receptor from columns. In all four publications to date describing crystallography of ER–ligand complexes (4–7), a single specific affinity matrix (13) and generally similar procedures have been used.

In most of these published procedures, the receptor fragment was partly S-carboxymethylated while it was immobilized on the affinity column. When this was not done, the resulting structure contained an artifactual intermolecular disulfide (5). The exact outcome of these treatments has not been described in every case, and it has largely been left unstated but assumed that the modifications have no bearing on the substance of the results. We present peptide mapping analysis of a homogeneous protein preparation from which crystals were grown, data that clearly show the extent and

location of the modifications in the protein that we crystallized.

Our experience with these various technical issues came as we prepared recombinant ER α ligand-binding domain complexed with CP-336156 (lasofoxifene) (14, 15) for crystallography. The structural results (J. Pandit et al., unpublished) will appear elsewhere. Some technical aspects of the task of obtaining crystallographic-quality material were unusually subtle and challenging, and included elements not fully described in existing literature. Among these were crystallographic determination of the absolute conformation of the estradiol derivative needed to make the affinity column, details of its immobilization to Thiopropyl Sepharose, and the isolation of incompletely but uniformly S-carboxymethylated ER α protein. This note describes our experience with these key steps preceding successful crystal growth and structure analysis.

EXPERIMENTAL PROCEDURES

Synthesis of 17 α -Epoxypropylestradiol. 17 α -(2'-Propen-1'-yl)estra-1,3,5(10)-triene-3,17 β -diol (1). To 100 mL of a 1 M allylmagnesium chloride solution in ether (100 mmol) was added a solution of estrone (4.05 g, 15.0 mmol) and THF (100 mL) over 20 min. The reaction was heated to reflux for 3 h and then allowed to cool to room temperature overnight. After pouring into an aqueous solution of ammonium chloride (250 mL) and extracting with ether (2 $\times$ 150 mL), the combined organic fraction was washed sequentially with water (100 mL), 5% NaHCO₃ (50 mL), and brine (100 mL) and then dried over MgSO₄ and concentrated to give the title compound (4.48 g, 96%). Recrystallization from ethyl acetate/cyclohexane afforded a single diastereomer, mp 106–107 °C (dec). ¹H NMR (CDCl₃) δ 0.90 (s, 3H), 1.2–1.7 (multiplets, 9H), 1.86 (ddt, J = 2.7, 2.7, 12.5 Hz, 1H), 1.97 (m, 1H), 2.11 (m, 1H), 2.24 (dd, J = 7.1, 13.5 Hz, 1H), 2.29 (m, 1H), 2.35 (dd, J = 7.1, 13.5 Hz, 1H), 2.79 (d, J = 5.0 Hz, 2H), 5.18 (m, 2H), 5.98 (ddt, J = 7.3, 10, 17 Hz, 1H), 6.53 (d, J = 2.7 Hz, 1H), 6.60 (dd, J = 2.7, 8.4 Hz, 1H), 7.12 (d, J = 8.4 Hz, 1H). MS (APCI) 295 (M-17, 100), 253 (18). ¹³C NMR (CDCl₃) δ 14.6, 23.7, 26.5, 27.7, 29.9, 32.0, 35.1, 39.8, 42.0, 44.0, 46.7, 49.8, 82.8, 112.9, 115.5, 119.5, 126.7, 132.8, 135.0, 138.5, 153.6. Anal. Calcd for C₂₁H₂₈O₂·¹/₃EtOAc: C, 79.00; H, 9.04. Found: C, 78.78; H, 8.87.

3-(tert-Butyldimethylsilyloxy)-17 α -(2'-Propen-1'-yl)estra-1,3,5(10)-triene-3,17 β -ol (2). To a solution of tert-butyldimethylsilyl chloride (1.68 g, 11.1 mmol), imidazole (1.58 g, 23.2 mmol), and DMF (7 mL) was added **1** (9.01 mmol), and the reaction was heated to 35 °C for 3 h. An additional portion of silyl chloride (0.80 g, 11.6 mmol) was added, and the reaction was heated an additional 2 h at 35 °C. After cooling to room temperature, the reaction was poured into 2% aqueous NaHCO₃ (200 mL) and extracted with ethyl acetate (2 $\times$ 100 mL). The combined organic layer was washed with water (100 mL) and brine (100 mL), dried (MgSO₄), and concentrated to give an oil. This was chromatographed on silica gel with 5% ethyl acetate/hexane to give the title compound (3.61 g, 94%) isolated as an oil. ¹H NMR (CDCl₃) δ 0.16 (s, 6H), 0.89 (s, 3H), 0.95 (s, 9H), 1.2–1.7 (multiplets, 9H), 1.86 (ddt, J = 2.7, 2.7, 12.5 Hz, 1H), 1.97 (m, 1H), 2.11 (m, 1H), 2.24 (dd, J = 7.1, 13.5 Hz, 1H), 2.29 (m, 1H), 2.35 (dd, J = 7.1, 13.5 Hz, 1H), 2.79 (d, J = 5.0 Hz, 2H), 5.18 (m, 2H), 5.98 (ddt, J = 7.3, 10, 17 Hz, 1H), 6.53 (d, J = 2.5 Hz, 1H), 6.57 (dd, J = 2.5, 8.3 Hz, 1H), 7.10 (d, J = 8.3 Hz, 1H).

17 α -((R,S)-2',3'-Epoxyprop-1'-yl)estra-1,3,5(10)-triene-3,17 β -diol (3). To a solution of **2** (3.61 g, 8.47 mmol) and

methylene chloride (85 mL) was added mCPBA (2.93 g, 17.0 mmol). After stirring overnight, the reaction was diluted with an additional 100 mL of methylene chloride and then washed sequentially with 2% KI (aqueous, 100 mL) and 10% aqueous sodium bisulfite (100 mL). The remaining solution was dried (MgSO₄) and concentrated to give an oil which was chromatographed on silica gel (40% ethyl/hexane) to give two compounds (only clean fractions were collected): less polar diastereomer, 1.38 g; more polar diastereomer, 0.47 g.

These compounds were not further characterized, but rather a solution of the less polar isomer (1.38 g, 3.12 mmol) and THF (10 mL) was treated with tetrabutylammonium fluoride (4.6 mL, 1 M in THF) at 0 °C. After 5 min the ice bath was removed and the reaction allowed to warm to room temperature. It was then diluted with ethyl acetate and washed with 5% NaHCO₃ (2 $\times$ 50 mL) and brine (50 mL). This was dried over MgSO₄ and concentrated to give a solid. Purification on silica gel with 60% ether/hexane gave the title compound as a white solid; mp 202–203 °C. ¹H NMR (CDCl₃) δ 0.90 (s, 3H), 1.2–1.7 (m, 9H), 1.85 (m, 1H), 2.10 (m, 2H), 2.27 (m, 1H), 2.36 (br s, 1H), 2.53 (dd, J = 2.8, 4.9 Hz, 1H), 2.80 (m, 2H), 2.85 (dd, J = 4.2, 4.9 Hz, 1H), 3.26 (m, 1H), 4.72 (br s, 1H), 6.53 (d, J = 2.7 Hz, 1H), 6.59 (dd, J = 2.7, 8.3 Hz, 1H), 7.11 (d, J = 8.3 Hz, 1H). ¹³C NMR (CDCl₃) δ 14.0, 23.6, 26.4, 27.6, 29.8, 31.7, 35.0, 39.3, 39.7, 44.0, 46.8, 47.7, 49.7, 50.3, 83.7, 112.9, 115.4, 126.7, 132.8, 138.5, 153.5. Anal. Calcd for C₂₁H₂₈O₃: C, 76.79; H, 8.59. Found: C, 76.48; H, 8.65.

Crystallography of the Resolved Less Polar Isomer of 17 α -Epoxypropylestradiol. Light yellow crystals of the purified less polar isomer were grown by slow evaporation from acetonitrile. A representative crystal (0.24 $\times$ 0.26 $\times$ 0.44 mm) was surveyed and a 1 Å data set collected on a Siemens R4/sealed tube diffractometer using copper radiation (λ = 1.54178 Å) at room temperature. All crystallographic calculations were facilitated by the SHELXTL system. The crystal belonged to the monoclinic space group $P2_1$ with the following cell dimensions: a = 6.824(1), b = 26.662(2), c = 9.839 Å, β = 100.67(1)°, V = 1759.2(2) Å³. There were two molecules in the asymmetric unit (Z = 4). The structure was phased using direct methods and refined routinely to a R -index of 4.96%. Hydrogen positions were calculated wherever possible. The methyl hydrogens and hydrogens on oxygen were located by difference Fourier techniques. A final difference map revealed no missing or misplaced electron density (0.22, -0.28 eÅ⁻³).

Preparation of the Affinity Matrix. With minor variations, the coupling procedure was based on the method used by Salman et al. (16) to immobilize 17 α -(6'-iodohex-1'-ynyl)estr-4-en-17 β -ol-3-one on Thiopropyl Sepharose. Solutions and buffers were not bubbled with N₂ before use in the present work, and coupling was monitored by observing the phenolic 280 nm absorption band of the intended ligand rather than by chemical assay of the beads.

To generate the free-thiol form of Thiopropyl Sepharose 6B (Amersham Pharmacia Biotech), 9 g of the dry resin was slurried in 50 mL of 0.3 M NaHCO₃, 1.1 mM EDTA, pH 8.4 containing 1.1 g of DTT, and the resulting mixture in a screw-capped polypropylene tube was inverted slowly and continuously for 1 h at 22 °C. After this, the resin was washed on a coarse glass sinter with (i) an aqueous solution made to 3 L containing 18 mL of acetic acid, 87.7 g of sodium chloride, and 1.1 g of disodium EDTA, and (ii) 300 mL of 0.3 M NaHCO₃, 1.1 mM EDTA, pH 9.2.

The reduced, filtered, and washed Thiopropyl Sepharose

beads (now containing 0.48–0.84 mmol of reactive thiol, according to the manufacturer's specifications) were then added to a 50 mL polypropylene screw-cap tube containing 81 mg (0.25 mmol) of **3** dissolved in 18 mL of DMF. Some spontaneous warming of the mixture was noticed. This addition was followed by 30 mL of 0.3 M NaHCO₃, 1.1 mM EDTA, pH 9.2, after which a small portion of the mixture (about 0.05 mL) was quickly withdrawn, and the full tube was capped. The sample withdrawn was centrifuged to pellet the suspended beads, and the absorption spectrum of the supernatant (0.02 mL diluted by addition to 1 mL of aqueous sodium phosphate buffer, pH 7.4) was recorded. The local maximum near 280 nm due to the phenol absorption band had an absorbance of 0.12 in a 1 cm cuvette.

The reaction mixture was inverted slowly and continuously overnight at 22 °C, after which a check of the absorption spectrum of the supernatant from a small sample (done as before) showed no trace of the phenol band. This indicated complete attachment of the estradiol derivative to the resin. The beads were filtered on a coarse sinter and washed with 300 mL of 0.3 M NaHCO₃, 1.1 mM EDTA, pH 9.2, after which they were added to a solution of 0.16 g of iodoacetamide in 45 mL of 0.3 M NaHCO₃, 1.1 mM EDTA, pH 8.4, in a screw-capped polypropylene tube. The resulting slurry was inverted continuously and slowly for 1 h at 22 °C to alkylate remaining free thiol groups on the Thiopropyl Sepharose and then washed in turn with 0.3 L of each of the following: (i) 0.3 M NaHCO₃, 1.1 mM EDTA, pH 8.4, also containing 1.5 g of DTT; (ii) the same solution without DTT; (iii) 0.05 M Tris HCl, pH 7.4; (iv) water; (v) 25% methanol in water; (vi) 50% methanol in water; (vii) 70% methanol in water. The beads were then stored at 4 °C as a slurry in 70% methanol in water.

The absorption spectrum of a slurry of a small portion of the derivatized beads in sodium phosphate buffer, pH 7.4, clearly showed the presence of the phenol absorption band of the immobilized estradiol derivative. Based on complete coupling of the epoxide to Thiopropyl Sepharose, the gel was calculated to contain 9 μ mol of estradiol per milliliter.

Estradiol Affinity Chromatography. This step was performed at 22 °C using the method of Hegy et al. (17) for the most part, but with important modifications after ER α was eluted from the affinity column. A 11.4 g amount of *Escherichia coli* cells harboring the expression construct for ER α was resuspended in 50 mL of 0.1 M Tris HCl, 0.1 M KCl, 1 mM EDTA, 4 mM DTT, pH 8.5, containing leupeptin (25 μ g/mL) and aprotinin (5 μ g/mL), and lysed by sonication on ice (4 $\times$ 45 s treatment at power setting 4 with a 40% duty cycle using a Branson Sonifier). The lysate was centrifuged at 18 000g for 30 min, the pellet was discarded, and the supernatant was recovered and centrifuged again in the same way. The resulting clarified 50 mL sample was loaded (0.5 mL/min) onto a 5 mL column of the estradiol-Sepharose affinity medium previously equilibrated with lysis buffer. After loading, the column was washed sequentially at 1 mL/min with 25 mL of lysis buffer, 25 mL of 0.05 M Tris HCl, 0.7 M KCl, 1 mM EDTA, 1 mM DTT, pH 8.5, and 25 mL of 0.01 M Tris HCl, pH 8.1. After this, the column was treated (0.5 mL/min) with 18 mL of 5 mM iodoacetic acid in 0.01 M Tris HCl, pH 8.1, made by 1:200 dilution of a 1 M solution of iodoacetic acid in 1 M Tris base with 0.01 M Tris HCl, pH 8.1. Flow was then stopped, and the column (protected from light) was allowed to stand at 22 °C for 18 h. It was then washed (1 mL/min in each case) with 25 mL of 0.01 M Tris HCl, pH 8.1, and with

25 mL of 0.05 M Tris HCl, 0.25 M NaSCN, 1 mM EDTA, 1 mM DTT, 10% DMF, pH 8.5. Finally, bound ER α was eluted (0.5 mL/min) as a broad peak using 50 μ M CP-336156 in the same buffer, and a 60 mL product pool was recovered.

Mass spectrometry (see Results) showed that the eluted protein was unevenly carboxymethylated. Following dialysis against 0.02 M Tris HCl, 5 mM DTT, pH 8.2, the product (32 mg of ER α in 42 mL) was further treated with 10 mM iodoacetic acid for 2 h at 22 °C under argon in the dark. The reaction was followed by mass spectrometry with the objective of maximizing the yield of twice-carboxymethylated ER α and was stopped by adding DTT to 20 mM. The product was then dialyzed against 0.02 M Tris HCl, 5 mM DTT, pH 8.2, and fractionated by anion-exchange chromatography on a MonoQ HR 10/10 column (Amersham Pharmacia Biotech) using a NaCl gradient in 0.02 M Tris HCl, pH 8.2. The main peak consisting of twice-carboxymethylated ER α was isolated and used for crystal growth trials. Digestion and peptide mapping to locate the sites of S-carboxymethylation were performed as described below.

Mass Spectrometry. Mass spectra of intact proteins were obtained using an open-access system (Dr. J. G. Stroh) consisting of a PE Sciex API 100 single-quadrupole spectrometer with electrospray sample interface. Multistage MS of tryptic digests was obtained using a Finnigan LCQ ion-trap spectrometer interfaced with a Hewlett-Packard Model 1090 HPLC (see below).

Tryptic Digestion. Purified complex of ER α with CP-336156 (0.6 mg in 1.2 mL) was desalted by RP-HPLC on a Poros R2/H 2.1/30 column as described (18), and the protein peak (now lacking drug) in two equal aliquots was dried in a centrifugal concentrator (SpeedVac, Savant). To the dried residue of one portion in a microfuge tube was added 0.05 mL of 0.25 M Tris HCl, 6 M GnHCl, 1 mM EDTA, 5 mM DTT, pH 8.8. The sample was flushed with argon, closed, incubated at 37 °C for 2 h, and then allowed to come to 22 °C and treated with 1 μ L of a 10% solution of 4-vinylpyridine in ethanol, giving a final concentration of 4-vinylpyridine of about 0.02 M. The tube was purged with argon and stored in the dark at 22 °C for 30 min, after which the sample was again desalted by RP-HPLC and dried in the SpeedVac. The dried sample was redissolved in 0.05 mL of 0.4 M NH₄HCO₃, 8 M urea, pH 8.5 and incubated for 1 h at 37 °C. It was then diluted to 0.2 mL with water, giving final concentrations of 0.1 M NH₄HCO₃ and 2 M urea. Trypsin (Promega chemically modified) was added to give a 1:50 ratio of trypsin to ER α , the sample was incubated for 2 h at 37 °C, and a further addition of trypsin was made to give a 1:25 ratio of trypsin to ER α . Digestion was then allowed to continue for 18 h at 37 °C. Digests were then analyzed by LC-MS using a Vydac C18 narrowbore column (type 218TP52) and the Finnigan LCQ. Solvents were A: 0.1% TFA, and B: 0.085% TFA in acetonitrile.

RESULTS

Synthesis and Crystallography. 17 α -Epoxypropyl-estradiol was prepared as described by el Garrouj et al. (19) (Scheme 1). Briefly, estrone was treated with excess allyl Grignard to give a single diastereomeric tertiary alcohol (**1**) after recrystallization. The phenolic hydroxy was then protected as the *tert*-butyldimethyl silyl ether (**2**), the terminal olefin was oxidized with mCPBA, and the intermediate silyloxy epoxides were separated chromatographically into pure fractions. These products were not fully characterized, but the major diastereomer was subjected to desilylation with fluoride ion to give **3**,

Figure 1. Crystallographically defined structure of 17 α -((*S*)-2',3'-epoxyprop-1'-yl)estra-1,3,5(10)-triene-3,17 β -diol. Two views of the molecule are shown. In the upper molecule, the A ring with the 3-hydroxyl group is to the right and the epoxide is to the extreme left. In the lower molecule, the A ring is at the lower left and the epoxide is to the extreme right.

Scheme 1

crystallized, and identified as *S* at the epoxide (Figure 1) by crystallography (see Experimental Procedures). This compound was then coupled to the solid support.

Coupling. Complete disappearance of the absorption band corresponding to estradiol from the supernatant of the coupling reaction indicated quantitative attachment of the steroid epoxide to Thiopropyl Sepharose (see Experimental Section). The product was stored as a slurry in 70% methanol at 4 °C and performed well after several months of storage.

Affinity Chromatography and Modification of Cysteines. A 29 kDa protein fragment consisting of methionine followed by residues 301–553 of ER α (SWISS-PROT accession P03372; see Figure 2 for the amino acid sequence) was expressed as a soluble intracellular protein in *E. coli* and purified by affinity chromatography on immobilized estradiol (Figure 3). ER α was treated with iodoacetic acid while bound to the column, as described by other groups reporting successful crystallization of an ER–ligand complex (4, 6, 7). After elution of the ER α with CP-336156, anion-exchange chromatography on MonoQ resolved the complex into three main peaks (Figure 4A), and ES-MS (Figure 4B) showed that about 5% of the polypeptide was unmodified, 60% was singly

Figure 2. The amino acid sequence of recombinant ER α ligand-binding domain numbered according to the full-length sequence of ER α . Theoretical masses: unmodified protein 28 852 Da; once-carboxymethylated 28 910 Da; twice-carboxymethylated 28 968 Da; three times carboxymethylated 29 026 Da. An initiator methionine preceded this sequence, but was absent from the purified product.

carboxymethylated, and 35% was doubly carboxymethylated. Size-exclusion chromatography on a Superdex 75 HR 10/30 column showed that the protein was a dimer of the 29 kDa subunits (data not shown), and ES-MS of the MonoQ peaks (not shown) showed that these were (in order of elution) homodimer of singly carboxymethylated ER α , heterodimer of once- and twice-modified ER α , and homodimer of twice-carboxymethylated ER α .

In an effort to make the protein more homogeneous, it was treated in solution with iodoacetic acid (see Experimental Section). ES-MS was used to follow pilot reactions, and it was found that double carboxymethylation was readily accessible, while a third *S*-carboxymethylation would require more forcing conditions to be completed. A 33 mg sample in 43 mL was therefore treated with 0.02 M iodoacetic acid (2 h, 22 °C) until twice-carboxymethylated product was predominant (mass of 28 970 in Figure 4C). The reaction was quenched with DTT, and anion-exchange chromatography on MonoQ

Figure 3. SDS-polyacrylamide gel electrophoresis showing affinity chromatography of ER α ligand binding domain on a column packed with the Thiopropyl Sepharose conjugate of **3**. The procedure used was essentially that described in reference (17).

(Figure 4D) resolved the product into a minor peak (heterodimer of once- and twice-carboxymethylated ER α) and a major peak which was the homodimer of twice-carboxymethylated ER α (mass observed 28 971 Da) (Figure 4D, inset). The purified twice-alkylated protein was then used successfully for crystal growth.

Identification of S-Carboxymethylation Sites. To allow definitive assignment of the modification sites, the two remaining cysteines were S-pyridylethylated using 4-vinylpyridine before the protein was digested with trypsin and subjected to LC-MS peptide mapping. Having each of the four cysteines in one of two stable, alkylated forms created the possibility of showing conclusively which were carboxymethylated and which were unmodified in the crystallized ER α .

LC-coupled mass analysis was conducted using a Finnigan LCQ ion-trap spectrometer. The instrument was programmed to enable data-dependent multistage analysis of any mass peak exceeding a threshold, including a narrow-range scan that allowed confident assignment of its mass and subsequent analysis of a sequence-related pattern of fragment ions created by collision-induced dissociation in the ion trap (20). Postrun analysis of the data using the SEQUEST algorithm (21) frequently allows a peptide corresponding to the experimental ion to be identified even in a large database, with the best success tending to come for peptides of about 8–20 amino acids. For known protein sequences, if used with due care, this analysis is as reliable as chemical peptide sequencing.

Using a combination of automated and manual interpretation, peptides accounting for all but a few small fragments of ER α were accounted for in the peptide map (Figure 5). The SEQUEST program was run more than once to search for Cys-containing peptides modified by S-carboxymethylation (+58 Da) and for Cys-containing peptides modified by S-pyridylethylation (+103 Da), and UV and mass peaks unaccounted for after this process were interpreted manually by reference to the sequence.

Figure 4. Use of anion-exchange chromatography and mass spectrometry to analyze the extent of S-carboxymethylation in ER α and to isolate twice S-carboxymethylated ER α . (A) Analytical fractionation on MonoQ HR 5/5 of ER α after elution from estradiol-Sepharose by CP-336156. Peak labels indicate indications from mass spectrometry; e.g., 1CM-2CM indicates a heterodimer of once- and twice-carboxymethylated ER α . (B) ES-MS of the protein sample applied to MonoQ in panel A. (C) ES-MS of ER α subjected to further treatment with iodoacetic acid in solution, but before the anion-exchange step in the next panel. (D) Preparative anion-exchange chromatography on MonoQ HR 10/10 of the ER α after the secondary treatment with iodoacetic acid. Inset: ES-MS of the material purified in the major peak, showing that twice-carboxymethylated ER α (mass theor. 28 968 Da) is the major component.

Cys-417 and Cys-530 were detected only in the S-carboxymethylated form, showing that these were the two cysteines that were alkylated in the crystallized ER α . Cys-381 and Cys-447 were detected only in S-pyridylethylated form, showing that they were unmodified in the crystallized protein.

DISCUSSION

The preparation of protein–drug complexes for crystallography is often quite straightforward. Drug is added to soluble protein, and a concentrated solution of the complex is combined with a range of solutions that often induce protein crystallization. Conditions that yield

Figure 5. LC-MS peptide mapping of a tryptic digest of ER α ligand binding domain, S-alkylated with iodoacetic acid first and subsequently with 4-vinylpyridene. Cysteine-containing peptides were detected with Cys in either S-carboxymethyl or S-pyridylethyl form, as indicated on the figure.

acceptable crystals are ultimately discovered by a combination of strategy and chance.

This method does not appear to have worked so far with ER, as no published reports describe success with it, and we were also unsuccessful with it. Instead (4–7), ER ligand-binding domain has been allowed to bind to the affinity matrix introduced by Greene et al. (13), treated while bound to the affinity medium with iodoacetic acid to alkylate some of the four sulfhydryl groups in each polypeptide and then eluted from the column with soluble ligand in a buffer containing 0.25 M NaSCN, a chaotrope and potential denaturant, as well as (in one case) 10% DMF. Why this method works when the conventional one does not is open to speculation. An important possibility is that the ER binding site must be fully occupied with ligand, and that this is not achieved by adding ligand to protein in solution. It is possible, for example, that the column method monomerizes the ER fragment, forcing each polypeptide to be separately displaced from the column by soluble hormone or drug and so giving full occupancy.

The Greene affinity column is not the first affinity matrix applied to ER isolation. Vonderhaar and Mueller (22) prepared 17 α -n-propylthiol estradiol which was immobilized on polyvinyl-(N-phenylenemalimide) at a level of 0.08 mmol/g of dried resin (presumably about 0.03

mmol/mL of drained wet gel, or 3% of the ligand density of material made according to Greene). The same authors made another affinity medium in which estradiol was immobilized by diazotization at the 2 or 4 position, although this was unstable on storage. Both their products removed estrogen receptor from a homogenate of rat uterus, but the high affinity exhibited by the receptor for these media caused difficulty.

Estradiol bound to ER α is wholly engulfed by the protein (4), and it is difficult to see how estradiol immobilized through an A ring atom can be an effective affinity ligand if immobilized ligand is bound in the same orientation as soluble ligand. Sica et al. (23) tried other linkages of estradiol to agarose through A ring substituents, but the resulting media were ineffective. Among the many options that they examined, better success came from coupling 17 β -estradiol hemisuccinate to amino groups on an immobilized amino acid copolymer. Bound receptor was eluted by warming the medium to 30 °C in the presence of soluble estradiol. Efforts to produce media based on immobilized estradiol have continued; for example, a detailed discussion of a medium prepared using 17 β -estradiol 17-hemisuccinate linked to bovine serum albumin and immobilized on agarose appeared in reference (24).

Greene et al. (13, 25) described the synthetic plan (Scheme 1) for preparing the affinity medium used by all workers so far reporting crystal structures and showed that bound receptor could be eluted by soluble ligand in a buffer containing 10% DMF and 0.25–0.50 M sodium thiocyanate. We followed this general track to obtain the crystal structure of ER α complexed with CP-336156 (not shown here), but made departures from and additions to previously described methods.

17 α -Epoxypropylestradiol is the key reagent required to prepare the affinity column. Its diastereomers at the epoxide center have previously been used in attempts to prepare compounds that bind irreversibly to ER (19, 26) and were shown to differ not only in their chromatographic properties but also in their affinities for ER. To the best of our knowledge, the stereochemical identities of the two isomers have not previously been reported. The diastereomers were prepared and resolved by chromatography as described (19), and crystals suitable for X-ray diffraction were prepared by slowly evaporating a solution of **3** in acetonitrile. Analysis of the diffraction pattern identified **3** as the (S) epoxide (Figure 1), and this compound was used to prepare the affinity matrix by coupling it to Thiopropyl Sepharose.

Proteins with free cysteines are problematic for crystal growth, because long incubations of droplets create the risk of disulfide formation that destroys molecular homogeneity. For example, when cysteines were left unmodified in ER α , crystals were still obtained but an artifactual intermolecular disulfide was present in the final structure (5). This problem was avoided by the two groups who treated the column-bound protein with iodoacetic acid (4, 6). In addressing these problems, we encountered important issues that have not been discussed in detail elsewhere. The first was that ER α eluted from the affinity column with CP-336156 was inhomogeneous with respect to charge (Figure 4A) and mass (Figure 4B). As homogeneity is so highly valued in efforts to grow protein crystals, we “topped up” the chemical modification of cysteines by treating the protein–drug complex in solution with iodoacetic acid until doubly S-carboxymethylated ER α was the major species (Figure

4C). Anion-exchange chromatography was then used to purify the doubly S-alkylated form (Figure 4D), and this was the protein used to grow diffraction-quality crystals.

The main question is how many and which cysteines need to be carboxymethylated in order to allow crystal growth. Peptide mapping of a tryptic digest was used to determine which cysteines had been modified in our ER α cocrystallized with CP-336156. Cys-417 and Cys-530 were found to be S-carboxymethylated, and Cys-381 and Cys-447 were found not to be (Figure 5; also, see Figure 2 for the amino acid sequence of the recombinant ER α).

This result indicated a difference between our results and those of Brzozowski et al. (4). Their paper indicated only that Cys-381 was uniformly modified and Cys-447 was not modified. Their protein–ligand complexes were prepared as described in Hegy et al. (17), which states that triply carboxymethylated ER α with Cys-447 unmodified was the main product in their protein separately cocrystallized with estradiol and raloxifene. The crystal structures show that Cys-447 is sufficiently buried to be highly unlikely to react with iodoacetic acid in the folded protein. Thus it would appear that crystallizable forms of ER α described so far are those in which Cys-447 is unmodified, Cys-417 and Cys-530 are modified, and Cys-381 either is or is not modified. In the protein as used by Shiau et al. (6) (Protein Data Bank accession 3ERD), carboxymethylation was modeled into the X-ray structure on the basis of electron density at Cys-417 and Cys-530, but the detailed results of protein chemical analyses were not reported in the paper (although ES-MS was stated to have been done on the modified protein).

All of the above represents discussion in detail of material that some will consider purely technical and even marginal. To this it can only be replied that nuclear receptors represent a very large family of molecules of enormous biological significance, and that analysis of their structures is a process now in its infancy. The gains represented by work on a small number of nuclear receptors now need to be followed by success with more family members. The sharing of detailed experimental information can often be helpful and occasionally essential in accelerating such progress.

ACKNOWLEDGMENT

We thank Dr. P. K. LeMotte for providing cells expressing the recombinant fragment of ER.

Synthesis and Preclinical Characterization of a Paclitaxel Prodrug with Improved Antitumor Activity and Water Solubility

Andreas Niethammer, Gerhard Gaedicke, Holger N. Lode, and Wolfgang Wrasidlo*

Otto-Heubner Zentrum für Kinder- und Jugendmedizin der Charité, Department of Pediatrics

. Received October 23, 2000; Revised Manuscript Received February 12, 2001

The development of novel chemotherapy strategies based on prodrugs remains a major challenge for effective treatment of malignancies. We tested the hypothesis that this can be achieved by a prodrug of paclitaxel where one biologically active center, represented by the C7 hydroxyl group, was blocked by a dihydroxypropyl side chain which can be hydrolytically cleaved by a pH-dependent, slow-release mechanism. The prodrug was synthesized by condensation of solketal chloroformate with the C7 hydroxyl group of paclitaxel followed by a ring-opening reaction to the dihydroxyl derivative. The cytotoxicity of the prodrug was similar to paclitaxel, when tested in vitro against a variety of human tumor cell lines. In vitro cell cycle analysis indicated that concentrations within the micromolar range of both drug and prodrug are required to induce sufficient G2M arrest. The hydrophilic paclitaxel prodrug proved to be more than 50-fold more water soluble than the parental drug and effectively converted to paclitaxel by pH dependent hydrolysis. Importantly, the prodrug could be used at a 3-fold higher maximum tolerated dose (MTD) and revealed a markedly improved antitumor activity in mice compared to paclitaxel. Taken together, our results demonstrate, that a hydrolytically activated paclitaxel prodrug exhibits greater water solubility and superior antitumor activity than the parental drug.

INTRODUCTION

Paclitaxel is an anticancer agent with established value for clinical application (1) including breast, lung, and ovarian cancer (2–8). However, limited response rates, significant side effects, and low solubility of this drug remain as major obstacles for its optimally effective use in cancer therapy.

The chemical structure of paclitaxel, a natural product obtained from the bark of the pacific yew tree (*Taxus brevifolia*), was first described by Wani et al. in 1971 (9). Like taxotere and unlike other anti-microtubule drugs, such as vinca alkaloids, colchicine, or podophyllotoxin, paclitaxel promotes the irreversible polymerization of tubulin (10–15). The stable and thus dysfunctional microtubules disrupt cell division by cell cycle arrest in the premitotic G2 and the mitotic phases, the so-called G2M-arrest, which is the primary cytotoxic mechanism of this drug (16). A second cytotoxic mechanism of paclitaxel is to assist the induction of tumor necrosis factor α , an event unrelated to the polymerization of microtubules (17). The scope of paclitaxel's therapeutic use, especially in combination with other drugs, has been extensively reviewed (36, 37). Importantly, systemic use of paclitaxel in large doses is limited primarily by hematologic toxicity and neurotoxicity. Life-threatening hypersensitivity reactions are reported in 1–3% of patients despite appropriate premedication including dexamethasone, histamine H2 antagonists, and diphenhydramine (18, 19, 35). A second limitation of paclitaxel chemotherapy is neutropenia, starting usually 10 days

after induction of treatment with neutrophil counts below 500/ μ L in the majority of cases. Severe neutropenia can usually be avoided with doses of less than 200 mg/m² (1, 19). Neutropenia seems to be more severe with longer infusion times (4, 20). The third common side effect of paclitaxel is dose dependent neurotoxicity, characterized by peripheral symmetric distal loss of sensation, pain, and paresthesia. More severe adverse effects occur at dosages above 250 mg/m² such as motor and autonomic dysfunction as well as myopathy (26, 27). These symptoms are often judged to be the most discomforting side effects experienced by the patient. Thus, neurotoxicity and neutropenia are considered as principle dose-limiting factors of paclitaxel (19, 21, 22).

In view of these limitations of paclitaxel chemotherapy, novel prodrug design maintaining antitumor activity combined with fewer side effects is imperative to allow the administration of larger doses of paclitaxel or to diminish side effects. Indeed, the chemical modification of the paclitaxel molecule to achieve better tolerance and efficacy has been the goal of numerous projects (23, 33). One such approach is to induce molecular modifications to release paclitaxel by enzymatic or other physicochemical mechanisms. Thus a strategy was developed based on antibody-directed enzymes for prodrug activation, commonly referred to as ADEPT (23). However, in spite of promising initial results, this strategy is severely limited by antigenic heterogeneity and immunogenicity of the antibody–enzyme constructs used for tumor targeting.

An alternative strategy for tumor specific prodrug activation is provided by acidic conditions in the tumor microenvironment, a common characteristic of many solid tumors (24–29). Here, we describe a novel chemotherapeutic strategy using a hydrolytically activated prodrug with dramatically improved water solubility, allowing the

delivery of higher doses of active drug to the tumor with less toxicity. We demonstrate for the first time that a modified paclitaxel prodrug with slow and pH-dependent release of parental drug exhibits clearly superior antitumor activity in preclinical models. This method of conjugating a natural compound using a multifunctional linker can also be used to couple targeting molecules such as monoclonal antibodies to generate other types of bioconjugates.

MATERIAL AND METHODS

The paclitaxel prodrug was synthesized in two steps:

1. Utilization of the 2' and 7 hydroxyl groups via a condensation with 2,2-dimethyl-1,3-dioxolane-4-methanol chloroformate (solketal chloroformate) to form the bi-functional carbonate intermediate.

2. This intermediate was then hydrolyzed to remove the 2' carbonate and open the acetal ring to form the final dihydroxypropyl carboxy paclitaxel. The following procedure describes the detailed preparation.

Synthesis of the Paclitaxel Prodrug. 2',7-[Bis-(2'',3''-isopropylidene-glycerol carboxy)]paclitaxel was synthesized in dry glassware, under a nitrogen atmosphere: paclitaxel (5.0 mg, 5.86×10^{-3} mmol) was dissolved in CH_2Cl_2 (250 μL) and cooled to minus 70 °C. Solketal chloroformate (22.8 mg, 0.117 mmol) was added to the solution, followed by addition of dry pyridine (7.1 mL, 87.8×10^{-3} mmol). The reaction was completed after 4.5 h at room temperature. The reaction mixture was diluted with CH_2Cl_2 (1.0 mL) and brine (1 $\times$ 2.0 mL). The organic layer was dried over MgSO_4 , filtered, and then reduced to 100 mL volume under a flow of N_2 . The resulting solution was purified by preparative HPLC to yield 5.2 mg of 2',7-[bis(2'',3''-isopropylidene-glycerol carboxy)]paclitaxel (76.5%). Purity by HPLC was greater than 98%.

Proof of structure by ^1H NMR (500 MHz, CDCl_3): δ 8.13 (d, 2H, *o*-C(O) *pH*), 7.75 (d, 2H, *o*-NHC(O) *pH*), 7.62 (t, 1H, *p*-OC(O) *pH*), 7.53–7.49 (band, 3H), 7.43–7.35 (band, 7H), 6.91 (t, 1H, NH), 6.35 (s, 1H, C(10)-H), 6.27 (t, 1H, C(13)-H), 5.99 (t, 1H, C(3')-H), 5.96 (d, 1H, C(2)-H), 5.51 (dd, 1H, C(7)-H), 5.44 (dd, 1H, C(2')-H), 4.39–4.25 (band, 3H), 4.24–4.10 (band, 7H), 3.96 (d, 1H), 3.85 (dd, 1H), 3.75 (m, 1H), 2.61 (p, 1H, C(6)-H), 2.46 (d, 3H, C(4)-OAc), 2.41 (m, 1H), 2.23 (m, 1H), 2.14 (d, 3H, C(10)-OAc), 2.01 (s, 3H, C(12)-CH₃), 1.97 (m, 1H), 1.81 (s, 3H, C(8)-CH₃), 1.41 (d, 3H), 1.38 (s, 3H), 1.35 (d, 6H), 1.21 (s, 3H, C(15)-CH₃), 1.16 (s, 3H, C(15)-CH₃).

7-(2'',3''-Dihydroxypropyl carboxy)paclitaxel: To a solution of 2',7-[bis(2'',3''-isopropylidene-glycerol carboxy)]paclitaxel (5.0 mg, 5.86×10^{-3} mmol) in tetrahydrofuran (THF) (100 μL) was added 1 N HCl (100 μL) at room temperature. The reaction was stirred at 35 °C for 3 h to give complete conversion to 2',7-[bis-2'',3''-dihydroxypropyl carboxy)]paclitaxel. At this point the reaction was stopped and the product isolated by preparative HPLC following an aqueous workup. After allowing the reaction to reach ambient temperature, it was diluted with THF (1.0 mL) and then washed with brine (3 $\times$ 2.0 mL). The organic layer was dried over MgSO_4 and filtered and the volume reduced to about 100 mL volume under a flow of N_2 (g) followed by the addition of 0.1 M KH_2PO_4 (100 μL , pH = 6.0) at room temperature. The reaction was stirred at ambient temperature for 24 h, diluted with THF (1.0 mL), and washed with brine (3 $\times$ 2.0 mL). The organic layer was dried over MgSO_4 , filtered, and reduced in volume to approximately 100 mL. The resulting solution was purified by preparative HPLC

Figure 1. Schematic depicting structure and hydrolytic activation of paclitaxel prodrug. The hydroxyl group in position 7 of paclitaxel was masked by a hydrophilic side chain (*). The resulting 7-(2'',3''-dihydroxypropyl carboxy)paclitaxel is activated, pH-dependently, by hydrolytic cleavage of the carbonate moiety, resulting in active paclitaxel, dihydroxypropanol, and CO_2 .

to yield 4.7 mg of 7-(2'',3''-dihydroxypropyl carboxy)paclitaxel (82.5%). Purity by HPLC was greater than 99%.

Proof of structure by ^1H NMR (500 MHz, CDCl_3): δ 8.11 (d, 2H, *o*-C(O) *pH*), 7.76 (d, 2H, *o*-NHC(O) *pH*), 7.62 (t, 1H, *p*-OC(O) *pH*), 7.52–7.48 (band, 5H), 7.43–7.34 (band, 5H), 7.03 (d, 1H, NH), 6.26 (s, 1H, C(10)-H), 6.19 (t, 1H, C(13)-H), 5.80 (dd, 1H, C(3')-H), 5.67 (d, 1H, C(2)-H), 5.42 (dd, 1H, C(7)-H), 4.95 (d, 1H, C(5)-H), 4.80 (d, 1H, C(2')-H), 4.58–4.39 (dd, 1H, C(2'')-H), 3.72–3.59 (band, 5H), 2.67 (m, 1H, C(6)-H), 2.39 (s, 3H, C(4)-OAc), 2.36–2.29 (band, 3H), 2.22 (d, 4H), 1.98–1.93 (band, 2H), 1.83 (s, 3H, C(4)-OAc), 1.82 (s, 3H, C(11), CH₃), 1.23 (s, 3H, C(15)-CH₃), 1.16 (s, 3H, C(15)-CH₃).

^{13}C NMR (500 MHz, CDCl_3): 201.28, 201.18, 172.85, 171.58, 171.44, 170.70, 167.48, 166.95, 154.46, 154.34, 141.41, 141.34, 138.18, 134.00, 133.84, 132.73, 132.20, 130.37, 129.27, 129.21, 128.93, 128.54, 127.26, 84.02, 81.15, 78.62, 77.48, 77.23, 76.97, 76.57, 76.24, 76.19, 76.12, 74.40, 73.31, 72.39, 70.02, 69.06, 62.96, 62.77, 56.19, 56.16, 55.21, 47.25, 43.47, 35.76, 33.42, 26.80, 22.72, 21.18, 21.12, 21.07, 14.82, 10.92; FAB/MS (NBA/CsI) *m/e* 1104, $\text{M} + \text{Cs}^+$ calculated for $\text{C}_{51}\text{H}_{57}\text{NO}_{18}$ 1104.30; UV_{max} 230 nm (ϵ 27891), min 274 nm (ϵ 1489).

The structure of the prodrug and one mechanism of activation is depicted in Figure 1.

Solubility and Partition Coefficients of Paclitaxel and Paclitaxel Prodrug in Octanol/Water. Solubility was determined by sonicating drug and prodrug for 15 min in water at room temperature, followed by centrifugation at 10000g for 2 min. The supernatants were then analyzed by HPLC.

The partition coefficients (octanol/water) were determined by vortexing the mixtures for 10 min. The concentrations in each layer were then determined by HPLC. Coefficients were calculated according to $[C]_{\text{octanol}}/[C]_{\text{water}}$.

Cytotoxicity. Antiproliferative activities of the prodrug and paclitaxel were determined using the XTT cytotoxicity assay. This assay has been described in detail elsewhere (30). Briefly, 1×10^4 cells/well were added to

96 well microtiter plates and incubated for 24 h before addition of drug at concentrations ranging from 1×10^{-4} to 1×10^{-12} mol/L by direct addition from stock solutions prepared in DMSO. After 72 h, XTT (2,3-bis(2-methoxy-4-nitro-5-sulphophenyl)-5-[(phenylamino)carbonyl]-2H-tetrazolium hydroxide) was added to a final concentration of 280 $\mu\text{g/mL}$. The plates were then incubated for 4 h, and the inhibition of cell proliferation was quantified by determining the absorbance at 450 nm with a microplate reader (Molecular Devices, San Diego, CA). The drug concentration which inhibited growth by 50% (IC_{50}) was calculated from duplicate runs.

Stem cell toxicity was determined by a standard Salmon assay, which has been described in detail before (31, 32). Briefly, CD34 positive stem cells from cord blood were cultured in soft agar plates, followed by an incubation of various concentrations of prodrug and paclitaxel for a period of two weeks (37 °C, 5% CO_2). Stem cell toxicity was evaluated by colony counting.

Cell Cycle Analysis by Flow Cytometry. The human neuroblastoma cell line SK-N-SH was used as a model to determine the percentage of cells in G2/M phase as a function of prodrug concentration and time. Tumor cells were fixed and permeabilized in the presence of 70% ethanol. Cells were centrifuged (1000g, 5 min) and resuspended in phosphate-buffered saline (PBS, pH 7.4). To reduce background staining, RNase A (0.3 mg/mL) was added, followed by specific DNA staining using propidium iodide (50 $\mu\text{g/mL}$). The DNA histograms were determined using a Beckton-Dickenson FACS scan.

Animals and Experimental Tumor Xenograft Nude Mouse Models. Male athymic Ncr-nu (nu/nu) mice were obtained from Harlan Sprague Dawley (Indianapolis, IN) at 6–8 weeks of age. Animals were housed in the pathogen-free mouse colony at our institution in groups of four mice each. Mice were fed ad libitum on standard mouse laboratory chow. Animal experiments were performed according to the NIH Guide for The Care and Use of Laboratory animals.

Evaluation of Maximum Tolerated Dose (MTD). For this study, MTD was defined as the treatment dose at which all animals survived without significant weight loss, i.e., less than 15% as compared to the control. The MTD for protaxoid and paclitaxel was determined in Balb/c mice, which were injected iv with increasing concentrations of either of these drugs. Doses used included 10, 20, 40, 60 mg/kg in case of the protaxoid and 8, 10, 12, 14, 16, and 18 mg/kg in case of paclitaxel. A total of 80 animals were used, and each group consisted of eight mice. Body weight was monitored and the MTD defined as a >15% loss in body weight compared to controls treated with PBS.

Treatment of Human Tumor Xenografts. Three groups of eight mice each were selected randomly for each treatment regimen (PBS, paclitaxel, and prodrug) with each tumor cell line. MT-39, MDA-MB-468, OVCAR-3, and PC-3 tumor cell lines were harvested, and 2×10^6 cells were injected subcutaneously in 200 μL Hanks medium in the right front flank.

Mice were examined daily, and the tumors were measured in two dimensions with a microcaliper. Established tumors with mean areas of about 20–50 mm^2 were treated with a vehicle control containing DMSO, chremophore, ethanol, and PBS (8%, 6%, 6%, 80%), paclitaxel prodrug (40 mg/kg), and paclitaxel (16 mg/kg), four times on alternative days. Primary tumor size was determined by microcaliper measurements three times weekly and calculated according to width $\times$ length $\times$ 2/3.

Statistics. Differences between experimental findings were analyzed by the students t-test. Differences were considered statistically significant with p values of <0.05 .

RESULTS

Design of a Prodrug Based on Paclitaxel Activated by a pH-Dependent Mechanism. Carbonates of paclitaxel with hydrophilic group substitutions were shown to be more soluble in water and inert to tubulin (33). Based on this observation, a paclitaxel prodrug was designed and synthesized with a pH-dependent cleavable dihydroxypropyl carbonoxyl group ($-\text{O}-\text{CO}-\text{O}-\text{CH}_2-\text{CH}(\text{OH})-\text{CH}_2\text{OH}$) attached to the C7 position by a carbonate bond. This group is hydrolytically cleaved (Figure 1). The structure was designed based on its superior physiochemical characteristics including slow drug release, substantially increased aqueous solubility, nontoxic metabolites, and a route of synthesis with a high yield. The solubility of this compound was increased more than 50-fold over that of paclitaxel (<0.004 mg/mL) (data not shown). Furthermore, this modification was demonstrated to abrogate paclitaxel-specific activities including the polymerization of tubulin to microtubules in the presence of GTP and inhibition of the depolymerization caused by CaCl_2 in vitro (data not shown).

Solubility and Partition Coefficients of Paclitaxel and Paclitaxel Prodrug in Octanol/Water. The solubility determined for the paclitaxel prodrug was 8.7×10^{-4} M, while paclitaxel revealed a solubility of $<1.5 \times 10^{-5}$ M, making the prodrug 50-fold more water soluble than its parental compound. The partition coefficients in octanol/water was determined as 120 for the prodrug and >10000 for paclitaxel, respectively.

Analysis of Paclitaxel Prodrug Stability and Storage Life. The characterizations of this novel paclitaxel prodrug involved the assessment of stability and storage life in its formulation for intravenous infusion. Importantly, the prodrug was found to be stable to hydrolysis at ambient temperature in its formulation for intravenous infusion for at least 24 h with less than 5% conversion after 48 h.

Evaluation of Cytotoxic Potential and Mechanism against human Cancer and Nonmalignant Cell Lines. To assess cytotoxicity and selectivity for malignant cells over normal cells, paclitaxel prodrug and paclitaxel were tested against a range of malignant and nonmalignant cell lines in vitro (Figure 2). The IC_{50} values observed reveal similar potencies and selectivities for prodrug and drug. The selectivity as defined by an increased cytotoxic potential against malignant cells over normal cells is maintained for the paclitaxel prodrug, which is consistent with an activity based on paclitaxel release (33).

Based on the side effects observed with paclitaxel chemotherapy including agranulocytosis and thrombocytopenia, the toxicity of paclitaxel and the prodrug against hematopoietic stem cells was determined (Figure 3). Two separate sets of experiments demonstrated a 1.0 to 1.5 log decrease in stem cell toxicity of the paclitaxel prodrug in contrast to paclitaxel. No colonies grew in the presence of 1×10^{-5} M concentration of both drugs. Cell colonies were counted starting in the presence of 1×10^{-7} M paclitaxel and at 5×10^{-6} M concentration of prodrug. The number of colonies counted at a prodrug concentration of 1×10^{-6} was equivalent to the colonies counted at a paclitaxel concentration of 5×10^{-8} .

Cell Cycle Analysis by Flow Cytometry. Cell cycle analysis of SK-N-SH tumor cells following incubation

Figure 2. Cytotoxicity of paclitaxel prodrug and paclitaxel. The cytotoxic potential of paclitaxel prodrug and paclitaxel was tested against a variety of malignant and nonmalignant human cell lines. IC₅₀ values were determined as the molarity at which 50% of tumor cell viability was observed after 72 h exposure under standard tissue culture conditions.

Figure 3. Effect of paclitaxel prodrug and paclitaxel on hematopoietic stem cells. This assay was performed to test the in vitro toxicity of the prodrug and the parental compound on human stem cells. Colonies were counted in duplicates after two weeks of exposure (solid line, paclitaxel; dashed line, paclitaxel prodrug).

with paclitaxel prodrug revealed the prodrug to induce G2M arrest, a mechanism described for paclitaxel which is a prerequisite for synergisms in combination therapies. Importantly, a drug concentration within the micromolar range is required over a period of 24h in vitro to induce G2M-arrest of 40% (Figure 4). These results are similar to those obtained under the same conditions for paclitaxel (data not shown). These findings strongly emphasize that high concentration levels of paclitaxel or paclitaxel prodrug are required over an extended period of time to elicit a strong antitumor effect.

Evaluation of MTD and Antitumor Efficacy in Mice. The preclinical evaluation of paclitaxel prodrug involved the determination of antitumor activity in

Figure 4. Effect of paclitaxel prodrug on the cell cycle of malignant cells. The percentage of human neuroblastoma (SK-N-SH) cells in G2M phase was determined at varying concentrations of paclitaxel prodrug over time. G2M phase was determined by flow cytometry after DNA staining with propidium iodide. Data points are mean values of triplicate flow cytometry analysis of each sample. The deviations of each scan were within 5%.

human tumor xenograft models and the maximum tolerated dose (MTD) as defined by a loss in body weight of <20%. Typically, Balb/c mice were injected with increasing amounts of paclitaxel prodrug, and the body weight of individual animals was monitored over time. These experiments resulted in a MTD for paclitaxel prodrug of 40 mg/kg, contrasting with a MTD of 16 mg/kg for paclitaxel and consistent with a 2.5-fold decrease in toxicity in mice achieved by our prodrug design. At these dosages all animals survived for more than eight weeks.

Figure 5. Regression and suppression of growth of established primary tumors by treatment with paclitaxel prodrug. Ncr-nu (nu/nu) mice ($n = 8$) with established subcutaneous human primary tumors were treated with intraperitoneal injections of paclitaxel prodrug (40 mg/kg) (closed circle) and compared to controls treated with paclitaxel (16 mg/kg) (open triangle) or vehicle control (closed square). Primary tumor growth was monitored by microcaliper measurements over time and tumor size calculated according to width $\times$ length $\times$ 2/3. Figures represent mean values and standard deviations for each experimental group of mice for human prostate carcinoma PC-3 (A), human ovarian carcinoma OVCAR-3 (B), human mammary carcinoma MDA MB 469 (C), and human colon carcinoma MT-39 (D). The differences between experimental groups treated with paclitaxel prodrug and controls treated with paclitaxel (open triangle) or vehicle control (closed square) was statistically significant ($+ = p < 0.05$).

Subsequently, the antitumor activity of the prodrug compared to paclitaxel was determined when administered at the MTD in four different human tumor xenograft models using prostate, colon, breast, and ovarian cancer cell lines in nude mice (Figure 5A–D). The paclitaxel prodrug administered four times every other day at the MTD induced tumor regression or significant reduction in tumor growth in all four tumor models. This was in contrast to paclitaxel and the vehicle control, which were ineffective in this regard. For example, the growth of the PC-3 human prostate carcinoma cell line regressed until day 47 to an average tumor surface area of 18 mm² with a standard deviation of 9.5 mm². In contrast, treatment with paclitaxel failed to inhibit extensive tumor growth, and the mice had to be sacrificed 35 days after treatment initiation. Average tumor surface area at that time was 111 mm² as compared to 170 mm² for the vehicle control with a standard deviation of 9 mm² (Figure 5A). The ovarian carcinoma cell line OVCAR-3 revealed an average tumor surface area of 48 mm² (SD 8 mm²) on day 34, as compared to 78 mm² when treated with paclitaxel (Figure 5B). The treatment of the mammary cancer cell line MDA-MB-468 with the prodrug led to an average regression in tumor size from 30 mm² at initiation of treatment to 22 mm² at day 63. In contrast, the treatment with paclitaxel showed no significant difference compared to the vehicle control (Figure 5C). The treatment of the human colon carcinoma cell line MT-39 led to a tumor surface area of 45 mm² on day

29 versus 47 mm² at initiation of treatment and compared to 105 mm² following treatment with paclitaxel (Figure 5D).

DISCUSSION

The addition of paclitaxel to the repertoire of chemotherapeutic drugs offers a significant improvement in outcome and quality of life for patients suffering from a number of solid tumors, including breast, prostate, and ovarian cancer. However, the usefulness of paclitaxel is limited by its toxicity and the development of drug resistance. Here, we describe a novel prodrug designed to deliver paclitaxel via a sustained in vivo release mechanism with the intent to use larger doses or similar doses with lower toxicity. This design included modifications to increase water solubility. We demonstrated in four preclinical human tumor xenograft models an increase of the maximum-tolerated (MTD) dose for the paclitaxel prodrug by a factor of 2.5 over that of active paclitaxel, facilitating the use of higher dosages of paclitaxel prodrug in mice. This reduction in toxicity is also reflected by a 100 times lower stem cell toxicity of the prodrug as compared to the parental drug. This is important, since one of the dose limiting toxicities of paclitaxel is the induction of neutropenia. In addition, the prodrug was at least equally effective as paclitaxel against tumor cell lines in vitro. This finding also translated into improved antitumor effects of the paclitaxel prodrug over paclitaxel in four different human

tumor xenograft models. Three possible mechanisms may be involved in the superior effect of paclitaxel prodrug over parental paclitaxel.

First, higher doses of the prodrug lead to an increase in the maximum plasma levels of both the prodrug and subsequently released drug which may ensure a favorable tissue distribution, resulting in higher concentrations of the prodrug in the tumor microenvironment. Sufficient concentration levels of paclitaxel prodrug are most important for achieving G2M arrest, the primary effect of paclitaxel on malignant cells (15). This was clearly demonstrated in vitro as the paclitaxel prodrug elicited a significant G2M arrest at a concentration of 1 μ M after 24 h of incubation (Figure 4). Therefore, the exposure of tumor tissue to high prodrug concentration over a long period of time appears to be a most critical parameter for effective therapy with such protaxoids. This finding is of particular interest for combination chemotherapy strategies using paclitaxel prodrug with improved efficacy in the induction of G2M arrest, thereby increasing the susceptibility of cancer cells to subsequent attacks by other cytotoxic compounds or irradiation, all of which induce DNA damage. Such combination strategies should clearly enhance synergistic effects, which were already described for paclitaxel (16, 34).

Second, the 50-fold increase in water solubility achieved by the unique prodrug design involving the addition of a hydrophilic side chain decreases protein binding and increases the amount of free drug, thereby further improving tissue penetration. This increase in solubility may allow infusion of the prodrug requiring dramatically lower amounts of additives such as ethanol and Cremaphore EL, the later being associated with infusion related hypersensitivity reactions (35). Also, the total infusion volume to deliver a therapeutic dose of prodrug can be decreased and therefore volume associated problems can be avoided particularly in patients with renal insufficiency.

Third, it is known that favorable activation of the protaxoid in tissue is influenced by high or low pH. Therefore, preferential activation of the prodrug might occur pH dependent in malignant tumors (25, 27–29).

In summary, we described the synthesis and preclinical characterization of a novel prodrug of paclitaxel with increased water solubility and a pH-dependent hydrolytic mechanism of activation. Preclinical evaluation of the protaxoid clearly indicated decreased toxicity in vivo as demonstrated by a substantial increase in MTD over the parental drug. Furthermore, treatment of established subcutaneous xenografts of four different human malignancies resulted in marked suppression of tumor growth in athymic mice treated at the MTD. These findings provide a basis for clinical evaluation of hydrolytically activated paclitaxel prodrug in Phase I/II trials.

ACKNOWLEDGMENT

We like to thank Biophysica for providing large quantities of the paclitaxel prodrug. We thank Prof. R. Reisfeld for the critical review of the manuscript and helpful discussions.

A Robust Method for the Preparation and Purification of Antibody/Streptavidin Conjugates

Mark D. Hylarides,[†] Robert W. Mallett,[†] and Damon L. Meyer[‡]

NeoRx Corporation, 410 W. Harrison Street, Seattle, Washington 98119, and Seattle Genetics, Inc., 22215 26th Avenue SE, Bothell, Washington 98021 . Received October 26, 2000; Revised Manuscript Received January 26, 2001

The many uses of antibody–protein conjugates, especially antibody–streptavidin conjugates, give rise to the need for a reliable conjugation method offering reasonable yields and reproducible quality. We describe a method for preparing antibody–streptavidin conjugates that has consistently produced conjugates of quality and in sufficient quantity to be used in the clinical development and evaluation of the Pretarget delivery system. In this method antibody disulfides are reduced to generate reactive thiols, and maleimides are linked to streptavidin with the heterobifunctional cross-linking agent, SMCC. The two activated proteins are then mixed briefly before the conjugation is terminated with an oxidizing agent that reforms disulfides from unreacted thiols. The preponderance of the conjugate produced is 1:1 and 1:2 Ab:SA conjugate. This fraction is isolated from unconjugated proteins and high molecular weight byproduct by iminobiotin affinity and ion-exchange chromatography. The resulting conjugate is at least 90% 1:1 + 1:2 Ab:SA conjugate, contains no SA or Ab, and is produced reproducibly in 37% yield.

INTRODUCTION

Protein conjugates of monoclonal and polyclonal antibodies are used in many in vitro and in vivo applications. Researchers at NeoRx Corporation have investigated an approach to the treatment of solid and hematologic malignancies, “Pretarget” technology, which makes use of antibody–streptavidin conjugates to localize therapeutic radionuclides to tumors (1). The antibody causes the conjugate to localize at antigen bearing disease sites; the streptavidin captures subsequently administered biotinylated radionuclide chelates. This strategy has been shown (1–12) to circumvent the dose-limiting toxicity associated with covalent delivery of radionuclides by labeled antibodies (13–18).

Recent literature (9, 11, 12, 19, Pierce Catalog) offers a plethora of methods for the covalent conjugation of proteins. These methods produce conjugates with a wide range of yields and purity and are often incompletely characterized with respect to reproducibility and scalability. The conjugation method described in this report was used throughout the development and evaluation of the Pretarget delivery system and has been compared with a number of other conjugation methods either in the laboratory or in the literature. It meets the key criteria for the development of Pretarget: it produces a high yield (relative to other available methods) of 1:1 + 1:2 Ab:SA conjugate; it succeeds on scales from a few milligrams to tens of grams; and it succeeds, with some optimization, for many different antibodies.

The ideal targeting vehicles for the Pretarget method and many other applications are fusion proteins, which are homogeneous, and which, given a suitable expression system, may be prepared in large quantities at minimal cost. However, synthetic conjugates may be preferable during the investigation of a combined-function protein

because development of a suitable expression system for a fusion protein can be a lengthy and uncertain process. Furthermore, synthetic conjugation methods offer a relatively straightforward process for generating conjugates with a range of properties such as specificity, molecular weight, and binding valency to find out which are most suitable, and to aid the design of an optimal fusion protein. Hence, antibody–protein conjugation methods, and especially antibody–streptavidin conjugation methods can be helpful in the evaluation of new therapeutic modalities.

Streptavidin is a 52 kD tetrameric protein produced by *Streptomyces avidinii* that is commercially available in high purity and shows good in vivo stability (20, 21). The strong interaction and rapid association between streptavidin and biotin ($K_d = 10^{-15}$ M) are ideal for capture of the biotinylated radionuclide chelate (^{90}Y DOTA biotin) from circulation at the low concentrations reaching the disease site following systemic administration (20). Streptavidin was chosen in preference to avidin as a receptor because it is not glycosylated and has a reported lower retention in normal tissue (22).

The murine NR-LU-10 antibody recognizes a noninternalizing 40 kD glycoprotein antigen abundantly expressed on carcinomas of the lung, colon, breast, prostate, and ovary (23, 24). This antibody has been studied both in animals and in human clinical trials (25, 26).

The conjugation method takes advantage of thiols generated by reducing disulfides in IgG's. These thiols react with maleimides placed on the surface of streptavidin at an appropriate loading by reaction with SMCC. The reduced IgG and the maleimide-functionalized streptavidin are combined at an equimolar ratio, and the progress of the reaction is monitored by size exclusion chromatography. At an optimal reaction time, when the modified proteins are maximally consumed, but before too much high molecular weight byproduct has formed, the reaction is terminated by addition of the oxidizing

[†] NeoRx Corporation.

[‡] Seattle Genetics, Inc.

agent sodium tetrathionate, which reforms disulfides from unreacted thiols. Thus, the proteins are conjugated through thioether and amide linkages.

While the conditions described represent an optimum incorporation of reactants into usable conjugate, the reactants are not entirely consumed; some streptavidin remains underivatized with SMCC and, hence, unreactive. Consequently, the final conjugation reaction mixture contains, in addition to usable conjugate, unreacted streptavidin, unreacted antibody, and cross-linked byproduct. The purification procedure separates the three impurities in two steps. Unreacted antibody is removed by iminobiotin affinity chromatography. Unreacted streptavidin is removed by ion-exchange chromatography under conditions at which conjugate binds to the matrix but streptavidin does not. Cross-linked byproduct is separated by careful elution of the desired 1:1 + 1:2 conjugate from the ion-exchange matrix (after the streptavidin has flowed through) at a salt concentration at which the cross-linked byproduct remains immobilized on the matrix.

Conjugates produced using this process were evaluated in LS-180 and SW1222 nude mouse xenograft models. The conjugates show favorable pharmacokinetic properties and biodistribution.

MATERIALS AND METHODS

DL-Dithiothreitol (DTT), 5,5-dithiobis(2-nitrobenzoic acid) (DTNB), 2-iminobiotin *N*-hydroxysuccinimide, and sodium tetrathionate dihydrate were purchased from Sigma (St. Louis, MO). Succinimidyl 4-(*N*-maleimido-methyl)cyclohexane 1-carboxylate (SMCC) was purchased from Pierce (Rockford, IL). Recombinant core streptavidin (SA) was purchased from Boehringer Mannheim (Mannheim, Germany). The monoclonal antibody, NR-LU-10, was prepared by Boehringer Ingelheim for exclusive use by NeoRx Corporation. Coarse G-25 Sephadex chromatography matrix was purchased from Pharmacia LKB (Piscataway, NJ). Epoxy-activated Marcoprep chromatography support 45–90 μ m was purchased from Bio-Rad (Hercules, Ca) and supplied as a dry powder. *N*-(3-Aminopropyl)-1,3-propanediamine was purchased from Aldrich (Milwaukee, WI). Fractogel EMD TMAE-650 (M) was purchased from EM Separations (Wakefield, RI). Calcium- and magnesium-free phosphate-buffered saline (PBS) was from BioWhittaker (Walkersville, MD). Preparative chromatography was done using XK series columns on a Pharmacia FPLC system. LS-180 cells were obtained from ATCC (Rockville, MD).

Size Exclusion Chromatography. Analytical size exclusion chromatography (SEC) was performed on a Beckman 114M HPLC system fitted with a 9.4 mm $\times$ 250 mm Zorbax GF-250 column (MacMod Analytical, Inc., Chadds Ford, PA) using Borwin data processing software. The mobile phase consisted of 20 mM phosphate, pH 6.8 plus 0.5M NaCl at a flow rate of 1.0 mL/min. The effluent was monitored at 254 nm.

Immunoreactivity. Immunoreactivity of the conjugate was determined using a competitive ELISA (27). Briefly, a solution of crude LS-180 cell extract was allowed to dry onto 96 well microtiter plates as the target. Peroxidase-labeled NR-LU-10 was used as the competitor and reporting agent at a concentration that gave OD values of 0.5 at 490 nm. NR-LU-10 and NR-LU-10/SA were serially diluted into aliquots of optimized NR-LU-10/HRP conjugate and reacted with the antigen-coated microtiter plate for 1 h at room temperature. The microtiter plates were washed, and a substrate solution

of ABTS was added, incubated for 30 min, and then read at 490 nm on a Molecular Devices Spectra Max Plus spectrophotometer.

Polyacrylamide Gel Electrophoresis. PAGE analyses were done using the Mini-PROTEAN II system from Bio-Rad Laboratories (Hercules, CA). All electrophoresis was done using the procedure reported by Laemmli (28) using 5% acrylamide with sodium dodecyl sulfate (SDS). Samples were not boiled prior to electrophoresis, to maintain the tetrameric form of streptavidin. IEF gels were run on a PHAST system from Pharmacia. Precast IEF gels resolving proteins with isoelectric points between pH 3 and 9 were used in all evaluations, under the running conditions recommended by Pharmacia.

Molecular Weight Determination. Molecular weights of NR-LU-10/SA conjugates were determined using a Zorbax GF-250 column connected in series with a Varian Star 9040 refractive index detector and a MiniDawn light scattering instrument (Wyatt Technologies, Santa Barbara, CA). This method involves no assumptions regarding protein shape. Molecular weights were determined as described by Wyatt (29) using a dn/dc value of 0.185 for a protein in an aqueous buffer solution.

Iminobiotin Affinity Matrix Preparation. Immobilized iminobiotin affinity matrix was prepared by suspending a known amount of the dry Marcoprep epoxy-activated matrix in dry methanol. *N*-(3-Aminopropyl)-1,3-propanediamine was added to the slurry at 10 mmol/g of dry matrix. An excess of triethylamine was added, and the slurry was continuously rotated on a Buchi RE 111 rotary evaporator. After 16 h, an equal volume of 1.0 M Tris pH 10.6 buffer was added, and the slurry was rotated for an additional 2 h. The slurry was filtered, washed with several volumes of H₂O, resuspended in 0.1 M H₂SO₄, and rotated for an additional 16 h to hydrolyze any residual epoxide residues. After filtration and H₂O wash, the matrix was resuspended in 0.5 M sodium borate, pH 8.0 buffer, and 50 μ mol of 2-iminobiotin *N*-hydroxysuccinimide hydrobromide was added per gram of dry gel. The reaction mixture was rotated overnight, filtered, and washed with alternate cycles of 1.0 M acetic acid and 1.0 M NaOH. The affinity matrix was capable of binding 3.0 mg of SA/mL of packed bed volume. Iminobiotin resin, available from Pierce, is suitable for this purification, but its expense precluded use on large scale.

Affinity Purification of Streptavidin. Recombinant streptavidin (SA), $pI = 7.3$; $A_{280}^{1\%} = 34$, was supplied as a lyophilized powder. Removal of excipients, endotoxin, and residual proteases was accomplished by affinity purification using immobilized iminobiotin. Lyophilized SA (500 mg) was reconstituted in 50 mM glycine buffer pH 9.0, 0.5 M NaCl, and applied to a sanitized 5.0 cm $\times$ 10 cm (196 mL) iminobiotin affinity column which was preequilibrated in the SA reconstitution buffer. After the 280 nm absorbance returned to baseline, the column was washed with five additional column volumes of buffer. SA was eluted with 0.1 M acetate buffer, pH 3.0, 0.1 M NaCl, buffer-exchanged into PBS, and concentrated using an Amicon 1 ft² 10 kDa molecular weight cut off CH2 spiral ultrafiltration system. Following concentration, 370 mg of purified SA was recovered at 23.0 mg/mL.

Preparation of SMCC-Derivatized Streptavidin. Streptavidin, 368 mg (7.08 μ mol), was diluted to 20 mg/mL in PBS, and 1.84 mL (10% v/v) sodium borate buffer, 0.5 M pH 8.0, was added to increase the pH to 8.0. SMCC (7.10 mg, 21.24 μ mol, or 3 $\times$ over SA mol/mol) in 1.17 mL of DMSO was added to the gently stirring SA solution and reacted for 30–60 min at room temperature. The

solution was then loaded onto a 2.6 cm $\times$ 42 cm Sephadex G-25 size exclusion column equilibrated with PBS at 8.0 mL/min, and the effluent was monitored at 254 nm. SMCC-derivatized SA (368 mg) was collected at the void volume in 71 mL of PBS. The extent of maleimide derivatization (MSR) was determined using cysteine followed by DTNB (30). Briefly, a known quantity of SMCC-SA was reacted with excess cysteine for 15 min. The amount of cysteine consumed by maleimide was determined by treating the solution with DTNB and subtracting the sample OD₄₁₂ at pH 8.0 from that of a cysteine control.

DTT-Reduced NR-LU-10. NR-LU-10 at 23.4 mg/mL (819 mg), $pI = 6.2$; $A_{280}^{1\%} = 14$, was reduced by treatment with 25 mM DTT. After incubation for 30 min, residual DTT was removed by gel filtration as described above using a 2.6 $\times$ 42 cm G-25 column with helium-sparged PBS, containing 1 mM DTPA at 8.0 mL/min. A quantitative yield of reduced NR-LU-10 was recovered from the column in 795 mL. The thiol content of the antibody was measured using DTNB at pH 8.0 ($\epsilon = 13\,600\text{ cm}^{-1}\text{M}^{-1}$).

NR-LU-10/SA Conjugate. Equimolar amounts of DTT-reduced NR-LU-10 (824 mg) and SMCC-SA (286 mg) were diluted to 110 mL each (24 μM) with He-sparged PBS. The two components were combined simultaneously over a 2 min period into a sterile 250 mL container using a P-1 peristaltic pump (Pharmacia LKB) to obtain a final protein concentration of 5.0 mg/mL. The stirred protein solution was monitored by HPLC SEC to evaluate the extent of the conjugation reaction. After 45 min, the reaction was quenched, and the remaining reduced disulfides were reoxidized, by the addition of solid sodium tetrathionate dihydrate to a final concentration of 5 mM.

NR-LU-10/SA Conjugate Purification. For conjugate purification, glycine was added to the crude reaction mixture to obtain a concentration of 50 mM, NaCl was added to bring the total NaCl concentration to about 500 mM, and the pH was adjusted to 9.0 by addition of 1.0 M NaOH while stirring. The extinction coefficient for a 0.1% solution of an equimolar mixture of NR-LU-10 and SA is 2.0, which also corresponds to the extinction coefficient of a 1:1 NR-LU-10/SA conjugate. For simplicity, this value was used in all purification steps to estimate process yield.

A 5.0 cm $\times$ 7.5 cm (147 mL) iminobiotin affinity column was prepared and equilibrated in 50 mM glycine buffer pH 9.0 containing 0.5 M NaCl. Crude conjugate solution (255 mL), pH 9.0, with a conductance of 34 mS/cm was loaded onto the iminobiotin column at 8.0 mL/min. Conjugate products and residual streptavidin bound to the matrix while unreacted NR-LU-10 and tetrathionate were collected in the flow-through. After the column was washed with five additional column volumes of equilibration buffer, 715 mg of bound material was eluted in 550 mL at 1.3 mg/mL with 0.2 M sodium acetate buffer, pH 4.0 containing 0.4 M NaCl. The pH of the eluted material was adjusted to 5.0 with 0.5 M borate buffer, pH 8.0 for storage.

Following iminobiotin affinity purification, the product was buffer exchanged into 50 mM NaPi buffer pH 9.0 using a CH2 spiral diafiltration cartridge with a 30 kDa cutoff yielding 609 mg in 420 mL of buffer. The material (<3 mS/cm) was loaded onto a preequilibrated TMAE column (2.6 $\times$ 5.6 cm), monitored at 280 nm, and washed until the eluate OD₂₈₀ returned to baseline to remove all residual SA. Purified conjugate (413 mg) was recovered from the matrix by elution with 130 mL of 50 mM NaPi buffer containing 90 mM NaCl (15.6 mS/cm) resulting

Figure 1. Formation of NR-LU-10/SA conjugate using SMCC.

in an overall product yield of 37%. After recovery of desired conjugate, higher molecular weight cross-linked conjugates could be removed from the column by washing with 50 mM NaPi buffer containing 250 mM NaCl.

RESULTS

The conjugation scheme utilizes the heterobifunctional cross-linker, succinimidyl 4-(N-maleimidomethyl)cyclohexane-1-carboxylate (SMCC), to form a stable amide/thioether linkage between antibody and streptavidin (32) (Figure 1). SMCC was chosen as the cross-linker since it reacts rapidly and quantitatively and is commercially available, and the molar substitution ratio (maleimides per SA) could be readily determined after SA derivatization.

SMCC Derivatization of SA. Treatment of SA with a 3-fold molar excess of SMCC yielded a molar substitution ratio (MSR) of 1.5–1.8 maleimides per SA. SA and SMCC-SA both eluted from the SEC column at 10 min, but SMCC-SA showed an additional minor peak at 9 min (<10%) corresponding to dimerized SA (Figure 2). On SDS PAGE, underivatized SA migrated mainly as a single band midway down the resolving portion of the gel, while SMCC-SA migrated as multiple bands (Figure 3, lanes 6, 7). This “ladder” effect reflects the alteration of the charge of the SA rather than a change in molecular weight. Because SA was not boiled in SDS, PAGE migration was not a direct reflection of molecular weight. Maleimides on SA were stable in PBS over an 8 h period at 25 °C. However, measurable hydrolysis occurred over 20 h. SMCC-functionalized SA was stored frozen indefinitely at $-70\text{ }^{\circ}\text{C}$.

Reduction of NR-LU-10. Reduction of NR-LU-10 with 25 mM DTT (33) resulted in the formation of 9–12 reactive thiols as determined by DTNB. Use of N₂-sparged buffer and DTPA greatly reduced the thiol reoxidation rate so that the reduced NR-LU-10 could be stored at 25 °C for up to 8 h prior to conjugation without significant loss of reactive thiols. No difference was observed between the reduced and nonreduced forms of NR-LU-10 by SEC (Figure 4) or SDS PAGE (Figure 3, lanes 4 and 5). Noncovalent interactions maintain the

Figure 2. Size exclusion HPLC profile of SA (top) and SMCC-SA (bottom).

Figure 3. 5% SDS PAGE (nonboiled) of final purified NR-LU-10/SA conjugate (lane 1), conjugate after iminobiotin purification (lane 2), crude conjugate (lane 3), DTT-reduced NR-LU-10 (lane 4), NR-LU-10 (lane 5), SMCC-SA (lane 6), and SA (lane 7).

heavy-heavy and heavy-light chain association while the disulfides are reduced, unless the samples are boiled in SDS.

Conjugation of NR-LU-10 to SMCC-SA. The extent of the conjugation reaction was observed in the SEC profiles of the reaction mixture at 2 and 40 min (Figure 5). Reaction progress is indicated by consumption of SMCC-SA in the reaction mixture. In this reaction 50% of the 10.0 min peak, SMCC-SA, was consumed after 40 min. The consumption of NR-LU-10 is more difficult to quantitate by SEC because the free antibody peak elutes as an unresolved shoulder on the 8.2 min conjugate peak. Higher consumption of SA in the reaction mixture leads to the accumulation of a high molecular weight cross-linked species that appears before the desired monosubstituted conjugate peak at 7.5 min in the SEC trace.

The effect of changing the SMCC offering can be seen in an SDS PAGE analysis of the reaction mixture comparing conjugations performed with SA-SMCC prepared at different offering levels (Figure 6). The maximum yield of desired monosubstituted conjugate occurred at a 3:1 molar offering of SMCC to SA. A lower offering of SMCC to SA gave lower overall conjugate yields due

to a decreased consumption of SA. A higher SMCC derivatization resulted in increased consumption of

Table 1. SEC Retention Times of Conjugation Reaction Mixture Components

component	ret time (min)
streptavidin	10.0
NR-LU-10	8.4
1:1 conjugate	8.2
1:2 conjugate	7.6
high molecular weight byproduct	<7.6

SMCC-SA yet lower desired product yield due to formation of higher molecular weight cross-linked species. Addition of 3 equiv of SMCC to SA provided a good balance between conjugation efficiency and percent desired conjugates. All reactions in this study were done at room temperature for 1 h at a total protein concentration of 5.0 mg/mL. If the conjugation reaction was allowed to proceed for longer times a steady increase in the percentage of cross-linked products was observed until these species dominated the reaction mixture.

Conjugate Purification. Removal of residual NR-LU-10 from the crude reaction mixture was accomplished by employing the pH dependent binding of iminobiotin (IB) to SA (34). Anion-exchange chromatography (Fractogel) was used to remove SA and enrich product purity by removal of most HMW species. Using the initial phosphate buffer conditions described, the anion-exchange matrix retained conjugate products while unconjugated SA was collected in the flow-through. Desired conjugate was eluted by increasing the NaCl concentration in the eluting buffer in a single step to 90 mM. Fractionation and analysis of the collected eluate (not shown) indicates that the fraction of high molecular weight byproduct increases as the elution progresses, so it is possible to obtain conjugate with reduced levels of this contaminant by judicious pooling. Eluate was pooled so that the total quantity of high molecular weight material was no more than 10% of the total conjugate mixture, to maximize yield without adversely affecting in vivo performance of the conjugate. Residual high molecular weight byproduct was washed from the column with 250 mM NaCl. The purity of the conjugate was determined at each step by SEC (Figure 7). Byproducts were also analyzed to ensure that loss of desired conjugate was minimized. The product contained no detectable streptavidin or NR-LU 10 and about 7% high molecular weight byproduct.

In Vitro Characterization. HPLC Analysis/SDS PAGE. SEC retention times of each of the components present in the conjugation mixture are given in Table 1.

Conjugate and SA were analyzed by SDS PAGE under nonboiled conditions to avoid dissociation into monomeric species (Figure 3). SDS-PAGE analysis of crude conjugate showed bands corresponding to unreacted SA, NR-LU-10, and conjugate products. After iminobiotin puri-

Figure 8. Native 5% PAGE of NR-LU-10 (lane 1), crude NR-LU-10/SA conjugate (lane 2), conjugate after iminobiotin purification (lane 3), conjugate after ion exchange purification (lane 4).

Figure 9. Competitive ELISA of NR-LU-10 vs. NR-LU-10/SA on LS-180 cell extracts.

fication, the IgG band was absent; after anion exchange purification, the SA band was absent leaving desired conjugate and a small percentage of cross-linked conjugates. The band migrating like NR-LU-10 in the final product was produced by the SDS treatment since the corresponding native gel shows only product bands (Figure 8).

Immunoreactivity/Biotin Binding/IEF. Competitive ELISA indicated that NR-LU-10/SA conjugate was 71% as immunoreactive as unmodified NR-LU-10 (Figure 9). Biodistribution studies in tumor-bearing nude mouse xenografts demonstrated the antigen-mediated localization of this conjugate (5, 6). The observed minimal disruption of the antibody's antigen binding capability

Figure 10. IEF gel (pI 3–9) of markers (lane 1), NR-LU-10 (lane 2), SA (lane 3), and NR-LU-10/SA (lane 4).

indicated that NR-LU-10 was not impaired by derivatization through thiol moieties. This has been the case with most antibodies we have tested. The conjugate bound 4.5 biotins per conjugate molecule as determined using a HABA displacement assay (31), reflecting the retention of biotin binding function of the conjugate, and the portion of conjugate that contains >1 streptavidin moiety per conjugate molecule. Conjugate and starting materials were also analyzed by IEF on a pH 3–9 gel (Figure 10).

Laser Light Scattering Analysis. The molecular weight of purified conjugate eluting at 8.22 min by SEC HPLC was determined using laser light scattering analysis. The 210 kDa value obtained corresponds closely with the theoretical value of 202 kDa. The peak eluting as a front shoulder at 7.57 min had an average molecular weight of 260 kDa which corresponds closely to the theoretical 254 kDa value for the disubstituted conjugate.

DISCUSSION

The conjugation method described here has been guided by the pharmacologic behavior of radiolabeled conjugate and by the Pretarget delivery. Although the degree of heterogeneity with respect to attachment site is not characterized, the molecular weight heterogeneity is inferred from the molecular weight profile determined by static light scattering measurements. Biodistribution studies indicate that the presence of greater than 10% cross-linked material has a measurable effect on pharmacokinetics, while complete elimination of cross-linked material, and even 1:2 conjugate, (at substantial sacrifice in yield), does not improve the observed biodistribution. Hence, the method has been developed to produce the highest possible yield of experimentally suitable conjugate.

Cross-linkers other than SMCC have also been used successfully. The SA-maleimide reacts rapidly with antibody thiols. This conjugation rate can vary with different antibodies, as well as with concentration. For antibodies that react more rapidly, it may be impossible to follow the progress of the conjugation because the time required for two consecutive SEC analyses may be longer than the optimum reaction time, leading to over-reaction and excess cross-linking. In these cases less reactive thiol-selective cross-linkers such as α -halo-carbonyls may be preferable to SMCC. While instability of maleimide-derived thioethers has been reported by other researchers, conjugates prepared in our laboratory have remained apparently unchanged for extended periods at 4 °C and neutral pH.

One factor that directly affects the yield of conjugate is the loading level of maleimide on streptavidin as

described in Results. Lower yields of 1:1 + 1:2 conjugate are also obtained in either of two modified methods. If the antibody is conjugated through thiols synthetically attached by the use of thiolating agents such as iminothiolane or SPDP, the conjugation reaction mixture is more heterogeneous, and the preponderance of 1:1 and 1:2 conjugate is much smaller. Likewise, if the antibody is insufficiently reduced so that less than ~ 8 thiols/Ab are generated, the conjugation reaction proceeds more slowly, and the products are substantially more heterogeneous. These observations suggest that a single thiol on the antibody is substantially more reactive than the others and that this reactive thiol is released from its disulfide more slowly or at greater reducing agent concentration than the others. Hence, if the antibody is only partially reduced, the "reactive" thiol is not available, and the conjugation is a competition between a number of less reactive thiols.

Another key aspect of this conjugation method rests with the ion-exchange purification. Despite repeated attempts in our laboratory, purification by preparative SEC HPLC uniformly results in a dramatic decrease in yield. Determination of suitable ion-exchange conditions for conjugation of a new antibody involves three basic steps. First, pH and ionic strength conditions must be determined at which the conjugate binds to the matrix while streptavidin does not. If such conditions cannot be found, an additional purification step must be incorporated, namely affinity chromatography with Protein A or Protein G, which retains IgG containing species, but not streptavidin. Second, conjugate is bound to the matrix and then eluted with a linear NaCl gradient to identify the NaCl concentration at which conjugate is released from the matrix. Third, a series of step gradient elutions is performed. Both the eluate and the fraction that remains bound (subsequently eluted with 250 mM NaCl) are analyzed by SEC to identify a step gradient that will elute the maximum quantity of 1:1 + 1:2 conjugate with an acceptable level of high molecular weight component.

This conjugation method appears to be adaptable to the conjugation of enzymes and other proteins to antibodies (35). The purification of conjugates by size exclusion chromatography as reported is useful for preparation of small quantities of high quality conjugates. However, optimized ion-exchange procedures combined with affinity chromatography is more applicable to preparation of large quantities of conjugates. The two primary limitations in applying the conjugation method to proteins other than streptavidin are that the protein contain no reactive thiols and that the protein be insensitive (function and structural integrity) to lysine modification.

A number of reports describe methods for preparation of antibody/streptavidin conjugates (9, 11, 12, 19). We find that the method described in this paper is superior because of its reliability, yield, scalability, the quality of conjugate produced, and its adaptability to different antibodies and proteins. The conjugation method described in this paper enabled the preclinical development and optimization of the Pretarget delivery system. It was also used for preparation of conjugate employed in the clinical investigation of the therapeutic modality in hundreds of patients. While the method may be suboptimal for production of a pharmaceutical product because of its expense and the heterogeneity of the conjugate, it has been nonetheless invaluable in evaluating the utility of the Pretarget delivery system and in optimizing it. Less efficient conjugation methods would have been incapable of producing the required quantity and quality of material to fulfill this function.

A Polar Substituent-Containing Acylation Agent for the Radioiodination of Internalizing Monoclonal Antibodies: *N*-Succinimidyl 4-Guanidinomethyl-3-[¹³¹I]iodobenzoate ([¹³¹I]SGMIB)

Ganesan Vaidyanathan,* Donna J. Affleck, Jean Li, Phil Welsh, and Michael R. Zalutsky

Department of Radiology, Duke University Medical Center, Durham, North Carolina 27710. Received November 10, 2000; Revised Manuscript Received February 15, 2001

The objective of this study was to develop an acylation agent for the radioiodination of monoclonal antibodies that would maximize retention of the label in tumor cells following receptor- or antigen-mediated internalization. The strategy taken was to add a polar substituent to the labeled aromatic ring to impede transport of labeled catabolites across lysosomal and cell membranes after antibody degradation. Preparation of unlabeled *N*-succinimidyl 4-guanidinomethyl-3-iodobenzoate (SGMIB) was achieved in six steps from 3-iodo-4-methylbenzoic acid. Preparation of 4-guanidinomethyl-3-[¹³¹I]-iodobenzoic acid from the silicon precursor, 4-(*N*¹,*N*²-bis-*tert*-butyloxycarbonyl)guanidinomethyl-3-trimethylsilylbenzoic acid proceeded in less than 5% radiochemical yield. A more successful approach was to prepare [¹³¹I]SGMIB directly from the tin precursor, *N*-succinimidyl 4-(*N*¹,*N*²-bis-*tert*-butyloxycarbonyl)guanidinomethyl-3-trimethylstannylbenzoate, which was achieved in 60–65% radiochemical yield. A rapidly internalizing anti-epidermal growth factor receptor variant III antibody L8A4 was labeled using [¹³¹I]SGMIB in 65% conjugation efficiency and with preservation of immunoreactivity. Paired-label in vitro internalization assays demonstrated that the amount of radioactivity retained in cells after internalization for L8A4 labeled with [¹³¹I]SGMIB was 3–4-fold higher than that for L8A4 labeled with ¹²⁵I using either Iodogen or [¹²⁵I]SIPC. Catabolite assays documented that the increased retention of radioiodine in tumor cells for antibody labeled using [¹³¹I]-SGMIB was due to positively charged, low molecular weight species. These results suggest that [¹³¹I]-SGMIB warrants further evaluation as a reagent for labeling internalizing antibodies.

INTRODUCTION

Monoclonal antibodies (mAb¹) that bind to cell membrane associated molecules are often internalized into the cell, thereby exposing the mAb to intracellular catabolic processes including lysosomal proteolysis. For radiolabeled mAbs, intracellular processing can result in loss of label from the target cell, with the magnitude of this effect dependent on the nature of the radionuclide and the labeling method (Govindan et al., 1999; Kobayashi et al., 2000; Reist et al., 1999). After lysosomal catabolism, radioactivity from radiometalated mAbs is generally trapped in the cell in contrast to activity from directly

radioiodinated mAbs which escapes from the cell in the form of monoiodotyrosine (Press et al., 1996).

To surmount this problem, residualizing labeling methods have been pursued for protein radioiodination that involve labeled templates that are inert to lysosomal digestion and not transported across lysosomal or cell membranes. The first generation of such labels contained nonmetabolizable carbohydrate residues as their main feature, for example, tyramine–cellobiose (TCB) and inulin–tyramine (Ali et al., 1990; Maxwell et al., 1988; Pittman et al., 1983; Thorpe et al., 1993). Although these reagents enhanced cellular retention of radioiodinated proteins after internalization, this approach also results in considerable protein cross-linking, diminished immunoreactivity, and in many cases, poor protein conjugation efficiencies (Ali et al., 1988; Moerlein et al., 1988; Schilling et al., 1992; Reist et al., 1995; Stein et al., 1995). Because mAb–DTPA–radiometal conjugates exhibit good retention of the radiometal in tumor cells (Kobayashi et al., 2000), Govindan et al. (1999) developed an acylation agent consisting of DTPA coupled to a radioiodinated, proteolytically inert, D-amino acid peptide. An increase of up to 3-fold in cellular retention of radioiodine in vitro was achieved for two internalizing mAbs labeled using this method in comparison to those labeled using Chloramine-T.

Another strategy for residualization of activity within tumor cells has attempted to exploit the fact that exocytosis of catabolites by passive transport across the membrane can be minimized if they are charged species.

Chart 1

Lysosomal pH is ~ 5 , and molecules containing basic functionalities would be protonated under these conditions and thus should be trapped within the cells. The feasibility of increasing the tumor retention of mAbs by labeling them with positively charged templates has been demonstrated (Reist et al., 1996; 1997). The acylation agent, *N*-succinimidyl 5-[¹³¹I]iodopyridine-3-carboxylate ([¹³¹I]SIPC; Chart 1; Garg et al., 1991; 1993), contains a basic nitrogen in its structure and was shown to be protonated at lysosomal pH. Indeed, the intracellular retention of a mAb labeled with SIPC increased up to 65% in vitro, compared with the same mAb radioiodinated using Iodogen or *N*-succinimidyl 3-[¹³¹I]iodobenzoate; however, the advantage was only observed at time points less than 24 h ([¹³¹I]SIB, Reist et al., 1996). Similar differences were seen in vivo, but the enhanced tumor retention associated with SIPC labeling was again a transient effect.

Guanidines have a pK_a of about 13 and thus a substantially higher proportion of guanidine-substituted molecules should be protonated than those with most other basic moieties such as the pyridine nitrogen present in SIPC. On this basis, we hypothesized that higher and more prolonged tumor retention might be achievable if the radioactive catabolites of an internalizing mAb contained a guanidine function. Herein we describe the synthesis of *N*-succinimidyl 4-guanidinomethyl-3-[¹³¹I]iodobenzoate ([¹³¹I]SGMIB), derived from the attachment of a guanidinomethyl group to SIB. Its use for labeling mAb L8A4, which rapidly internalizes after binding to the mutant epidermal growth factor receptor variant III (EGFRvIII; Wikstrand et al., 1995), is also described.

MATERIALS AND METHODS

General. All chemicals were purchased from Aldrich unless otherwise noted. *N*-Succinimidyl 5-iodopyridine-3-carboxylate and 5-iodonicotinic acid were prepared as reported before (Garg et al. 1991; Vaidyanathan et al., 2000). Sodium [¹²⁵I]iodide and sodium [¹³¹I]iodide with specific activities of 2200 Ci/mmol and 1200 Ci/mmol, respectively, were obtained from DuPont-New England Nuclear. Radioiodinated SIPC was prepared according to previously published procedures (Garg et al. 1991).

Melting points were determined on a Haake Buchler apparatus and were uncorrected. High-pressure liquid chromatography was performed using one of two systems: (1) a Beckman System Gold HPLC equipped with a Model 126 programable solvent module, a Model 168 diode array detector, a Model 170 radioisotope detector,

and a Model 406 analog interface module; or (2) a Perkin-Elmer Series 4 Liquid Chromatograph connected to a Perkin-Elmer LC-95 UV/visible spectrophotometer detector and a Perkin-Elmer LCI-100 Laboratory Computing Integrator. Methods were programmed using a Perkin-Elmer 6312 display terminal. For reversed-phase chromatography, a Waters μ Bondapak C18 (10 μ m, 3.9 $\times$ 300 mm) column or a 3.9 $\times$ 300 mm Bondclone 10 (10 μ m) C18 column (Phenomenex, Torrance, CA) was used. Normal-phase HPLC was done on a 4.6 $\times$ 250 mm Partisil (10 μ m) silica column (Alltech, Deerfield, IL). Size-exclusion HPLC was performed using a 7.5 mm $\times$ 60 cm Tosohaas TSKgel G3000 SW (10 μ m) gel filtration column (Montgomeryville, PA) eluted with PBS at 1 mL/min. Aluminum-backed sheets (Silica gel 60 F₂₅₄) were used for analytical TLC, and normal-phase column chromatography was performed using silica gel 60, both obtained from EM Science (Gibbstown, NJ). Column chromatographic fractions were collected using a Gilson model 203 micro fraction collector (Middleton, WI) or an ISCO Foxy 200 fraction collector (Lincoln, NE), and the products were identified by TLC. In some cases, an ISCO UA-6 UV-vis detector was placed between the column outlet and the fraction collector to identify products. Preparative thick layer chromatography was performed using 20 $\times$ 20 cm, 1000 μ m plates (Whatman, Clifton, NJ). Before applying the sample, the plates were run in ethyl acetate to remove any adsorbed impurities. Radio-TLC was initially analyzed using a System 200 Imaging Scanner (BioScan, Washington, DC); sheets were then cut into strips and counted using an automated gamma counter (LKB 1282, Wallac, Finland). Proton NMR spectra (300 MHz) were obtained on a Varian Mercury 300 spectrometer or a General Electric Midfield GN-300 spectrometer. Chemical shifts are reported in δ units; solvent peaks were referenced appropriately. Mass spectra were obtained on a Hewlett-Packard GC/MS/DS Model HP-5988A instrument or on a JEOL SX-102 high-resolution mass spectrometer. Elemental analyses were provided by Galbraith Laboratories (Knoxville, TN).

Cells, mAb, and Culture Conditions. Murine IgG₁ L8A4 is a mAb which reacts specifically with the 145 kDa deletion mutant EGFRvIII molecule found on multiple human malignancies including gliomas and breast carcinomas (Wikstrand et al., 1995). The EGFRvIII-expressing cell line used for these studies was U87 MG/EGFR which was established from U87 MG cells by transfection with EGFRvIII cDNA (Nishikawa et al., 1994). In cell culture, this line expresses an average of 4–13 $\times$ 10⁵ EGFRvIII molecules per cell (Reist et al., 1997). Cells were grown in zinc option media (Life Technologies, Inc., Grand Island, NY) containing 10% fetal calf serum and Geneticin sulfate (600 mg/mL).

2-(Trimethylsilyl)ethyl (3-Iodo-4-methyl)benzoate (1). To a solution of 3-iodo-4-methylbenzoic acid (1.17 g, 4.5 mmol) in dry ethyl acetate (20 mL) at room temperature were added DMAP (34 mg, 0.3 mmol), 2-trimethylsilyl ethanol (990 mg; 8.4 mmol), and DCC (1.65 g; 8.2 mmol) in that order. The mixture was stirred at room temperature overnight, adsorbed on silica gel, and chromatographed (0–5% EtOAc/hexane) to yield 1.22 g (74%) of an oil: ¹H NMR (CDCl₃): δ 0.08 (s, 9H), 1.13 (m, 2H), 2.48 (s, 3H), 4.40 (m, 2H), 7.29 (d, 1H), 7.95 (d, 1H), 8.46 (s, 1H). MS (FAB⁺), m/z : 362 (M⁺).

2-(Trimethylsilyl)ethyl (3-Iodo-4-bromomethyl)benzoate (2). A mixture of **1** (970 mg, 2.7 mmol), NBS (477 mg; 2.7 mmol), and benzoyl peroxide (5–6 mg) in dry CCl₄ (15 mL) was refluxed for 3–4 h. The mixture was cooled to room temperature, the precipitate was

filtered off, and CCl_4 was evaporated from the filtrate. Column chromatography using hexane followed by 1% EtOAc in hexane afforded 400 mg (34%) of an oil. ^1H NMR (CDCl_3): δ 0.08 (s, 9H), 1.13 (m, 2H), 4.41 (m, 2H), 4.60 (s, 2H), 7.52 (d, 1H), 7.96 (d, 1H), 8.50 (s, 1H). MS (CI), m/z : 458 and 460 ($\text{M} + \text{NH}_4^+$), 413 and 415, 378, 362. This compound was used in the next step without extensive purification.

2-(Trimethylsilyl)ethyl 4-[N^1,N^2 -Bis(*tert*-butyloxy-carbonyl)guanidinomethyl]-3-iodobenzoate (3). The title compound was prepared from **2** as reported before (Vaidyanathan and Zalutsky, 1997). ^1H NMR (CDCl_3) δ 0.08 (s, 9H), 1.14 (t, 2H), 1.25 (s, 9H), 1.47 (s, 9H), 4.41 (t, 2H), 5.22 (s, 2H), 7.05 (d, 1H), 7.95 (d, 1H), 8.45 (s, 1H), 9.45 (br s, 2H). HRMS (FAB $^+$) Calcd for $\text{C}_{24}\text{H}_{39}\text{IN}_3\text{O}_6\text{Si}$ (MH^+): 620.1653. Found: 620.1649. Anal. Calcd for $\text{C}_{24}\text{H}_{38}\text{IN}_3\text{O}_6\text{Si}$: C, 46.53; H, 6.18; N, 6.78. Found: C, 46.66; H, 6.25; N, 6.76.

4-[N^1,N^2 -Bis(*tert*-butyloxycarbonyl)guanidinomethyl]-3-iodobenzoic Acid (4). To a solution of **3** (160 mg; 0.26 mmol) in dry DMF (5 mL, Pierce) was added TBAF (1 M in THF, 0.36 mL), and the solution was stirred at room-temperature overnight. The reaction mixture was partitioned between EtOAc and water, and the crude product was purified by preparative TLC using 50% EtOAc/hexane to afford 26 mg (20%) of an off-white solid: mp 133–135 °C. ^1H NMR (CDCl_3) δ 1.24 (s, 9H), 1.50 (s, 9H), 5.16 (s, 2H), 6.93 (d, 1H), 7.76 (d, 1H), 8.22 (s, 1H), 9.5 (br d, 2H). MS (FAB $^+$), m/z : 520 (MH^+), 464, 406.

4-Guanidinomethyl-3-iodobenzoic Acid (5). To 14.1 mg (27 μmol) of **4** in 1 mL of EtOAc at room temperature was added 45–50 mg of SnCl_4 (Miel and Rault, 1997), and the solution was stirred for 3–4 h. Ethyl acetate was removed under aspirator vacuum using a rotary evaporator, and the residue was further subjected to rotary evaporation under high vacuum. The residue was triturated with ether to get an oil in almost quantitative yield: ^1H NMR (CD_3OD) δ 4.48 (s, 2H), 7.45 (d, 1H), 8.20 (dd, 1H), 8.51 (d, 1H). MS (ESI), m/z : 359 ($\text{MH} + \text{K}^+$), 320 (MH^+), 261. HRMS (FAB $^+$) Calcd for $\text{C}_9\text{H}_{11}\text{IN}_3\text{O}_2$ (MH^+): 319.9896. Found: 319.9895 $\pm$ 0.0014 ($n = 2$).

***N*-Succinimidyl 4-[N^1,N^2 -Bis(*tert*-butyloxycarbonyl)guanidinomethyl]-3-iodobenzoate (6).** To a mixture of **4** (117 mg, 0.23 mmol) and *N*-hydroxysuccinimide (34 mg, 0.3 mmol) in dry THF (5 mL) was added DCC (47 mg; 0.23 mmol), and the mixture was stirred at room-temperature overnight. The precipitated DCU was filtered, and the filtrate concentrated. The residue was subjected to preparative TLC using 25% EtOAc/hexane to yield 75 mg (54%) of a solid: mp 225–230 °C (decomp). ^1H NMR (CD_3OD) δ 1.30 (s, 9H), 1.47 (s, 9H), 2.92 (s, 4H), 5.25 (s, 2H), 7.09 (d, 1H), 8.05 (d, 1H), 8.59 (s, 1H), 9.44 (br d, 2H). MS (ES), m/z : 617 (MH^+), 561, 505. HRMS (FAB $^+$) Calcd for $\text{C}_{23}\text{H}_{30}\text{IN}_4\text{O}_8$ (MH^+): 617.1108. Found: 617.1100 $\pm$ 0.0025 ($n = 2$).

***N*-Succinimidyl 4-Guanidinomethyl-3-iodobenzoate (7).** A sample of this compound was prepared for use as an HPLC standard by the treatment of **6** (about 5 mg) with TFA (0.1 mL) at room temperature for 5–10 min. TFA was evaporated, and the residue was triturated with ethyl acetate: ^1H NMR (CD_3CN) δ 2.86 (s, 4H), 4.40 (d, 2H), 7.48 (d, 1H), 8.19 (d, 1H), 8.82 (s, 1H). MS (ES), m/z : 417 (MH^+).

3-Methyl-4-(trimethylsilyl)benzoic Acid (8). To a solution of 3-bromo-4-methylbenzoic acid (1.26 g, 5.9 mmol) in dry THF (30 mL) at -78 °C was added dropwise a solution of *n*-BuLi in hexanes (6.9 mL, of 1.6 M, 11 mmol), and the mixture was stirred for 15 min at -78

°C. Chlorotrimethylsilane (1.79 g, 16.6 mmol) was added gradually to the above mixture. The reaction mixture was gradually warmed and was stirred overnight at room temperature. The THF was evaporated, and the residue was partitioned between EtOAc and water. The crude product was chromatographed using a stepwise gradient of 10–50% EtOAc/hexane to yield 340 mg of a crystalline solid: mp 134–136 °C. ^1H NMR (CDCl_3) δ 0.37 (s, 9H), 2.53 (s, 3H), 7.25 (d, 1H), 7.98 (d, 1H), 8.20 (s, 1H). MS (CI), m/z : 226 ($\text{M} + \text{NH}_4^+$), 209 (MH^+). Anal. Calcd for $\text{C}_{11}\text{H}_{16}\text{O}_2\text{Si}$: C, 63.42; H, 7.74. Found: C, 64.08; H, 7.75.

2-(Trimethylsilyl)ethyl (4-Methyl-3-trimethylsilyl)benzoate (9). The title compound was prepared from **8** (433 mg, 2 mmol) by a procedure similar to that used for the preparation of **1**, affording 335 mg (52%) of an oil: ^1H NMR (CDCl_3) δ 0.09 (s, 9H), 0.35 (s, 9H), 1.13 (m, 2H), 2.50 (s, 3H), 4.41 (m, 2H), 7.21 (d, 1H), 7.92 (d, 1H), 8.12 (s, 1H). This compound was used in the next step without extensive purification.

2-(Trimethylsilyl)ethyl (4-Bromomethyl-3-trimethylsilyl)benzoate (10). Compound **10** was prepared from **9** (319 mg, ~ 1 mmol) following a procedure similar to that used for the preparation of **2** yielding 195 mg (48%) of an oil: ^1H NMR (CDCl_3) δ 0.09 (s, 9H), 0.35 (s, 9H), 1.13 (m, 2H), 4.42 (m, 2H), 4.63 (s, 2H), 7.52 (d, 1H), 8.02 (d, 1H), 8.18 (s, 1H). MS (CI), m/z : 404 and 406 ($\text{M} + \text{NH}_4^+$), 386, 388 (MH^+), 376 and 378, 361 and 363. Anal. Calcd for $\text{C}_{16}\text{H}_{27}\text{BrO}_2\text{Si}_2$: C, 49.60; H, 7.02. Found: C, 49.00; H, 6.94.

2-(Trimethylsilyl)ethyl 4-[N^1,N^2 -Bis(*tert*-butyloxy-carbonyl)guanidinomethyl]-3-(trimethylsilyl)benzoate (11). This compound was prepared from **10** as reported before (Vaidyanathan and Zalutsky, 1997). ^1H NMR (CDCl_3) δ 0.08 (s, 9H), 0.40 (s, 9H), 1.14 (t, 2H), 1.26 (s, 9H), 1.41 (s, 9H), 4.41 (t, 2H), 5.37 (s, 2H), 7.05 (d, 1H), 7.95 (d, 1H), 8.18 (s, 1H), 9.45 (br s, 2H). HRMS (FAB $^+$) Calcd for $\text{C}_{27}\text{H}_{49}\text{N}_3\text{O}_6\text{Si}_2$ (MH^+): 566.3082. Found: 566.3069. Anal. Calcd for $\text{C}_{27}\text{H}_{47}\text{N}_3\text{O}_6\text{Si}_2$: C, 57.31; H, 8.37; N, 7.42. Found: C, 57.23; H, 8.33; N, 7.28.

4-[N^1,N^2 -Bis(*tert*-butyloxycarbonyl)guanidinomethyl]-3-(trimethylsilyl)benzoic Acid (12). THF was evaporated from a solution of TBAF (0.7 mL of 1 mM), and the residue was dried under vacuum. A solution of **11** (367 mg, 0.65 mmol) in DMF (10 mL) was added to the above, and the resultant solution was stirred overnight at room temperature. The reaction mixture was partitioned between water and EtOAc, and the pooled EtOAc layer was washed, dried, and concentrated. Chromatography of the crude product using a stepwise gradient of 30% EtOAc/hexane to 100% EtOAc yielded 170 mg (56%) of a solid: mp 223–228 °C (decomp). ^1H NMR (CDCl_3) δ 0.41 (s, 9H), 1.27 (s, 9H), 1.42 (s, 9H), 5.38 (s, 2H), 7.05 (d, 1H), 7.95 (d, 1H), 8.17 (s, 1H), 9.45 (br s, 2H). MS (FAB $^+$), m/z : 466 (MH^+). HRMS (FAB $^+$) Calcd for $\text{C}_{22}\text{H}_{36}\text{N}_3\text{O}_6\text{Si}$ (MH^+): 466.2373. Found: 466.2363.

2-(Trimethylsilyl)ethyl 4-[N^1,N^2 -Bis(*tert*-butyloxy-carbonyl)guanidinomethyl]-3-(trimethylstannyl)benzoate (13). A mixture of **3** (787 mg, 1.3 mmol), hexamethylditin (2.1 g, 6.4 mmol), and $(\text{Ph}_3\text{P})_2\text{PdCl}_2$ (425 mg, 0.6 mmol) in 35 mL of dry dioxane was heated under reflux for 1 h. The dark slurry was filtered through a bed of Celite, and the filtrate was concentrated. The residue was initially subjected to column chromatography using 0–10% EtOAc/hexane to obtain 211 mg of an oil. This was further purified by preparative TLC using 8% EtOAc/hexane to obtain 83 mg (10%) of a clear oil: ^1H NMR (CDCl_3) δ 0.07 (s, 9H), 0.40 (s, 9H [$^{119}\text{Sn}-\text{H}$, d]), 1.16 (m, 2H), 1.25 (s, 9H), 1.45 (s, 9H), 4.42 (m, 2H), 5.24 (s, 2H), 7.02 (d, 1H), 7.94 (d, 1H), 8.10 (s, 1H), 9.46 (br s,

2H). MS (FAB⁺), *m/z*: cluster peaks at 658 (MH⁺) and several others.

4-[N¹,N²-Bis(*tert*-butyloxycarbonyl)guanidinomethyl]-3-(trimethylstannyl)benzoic Acid (14**).** The solvent was evaporated from 0.3 mL of a 1 M solution of TBAF in THF, and the residue was dried using a vacuum pump for several hours. The TBAF residue was redissolved in 0.3 mL of dry DMSO, and the resultant solution was added to a vial containing 78 mg (0.12 mmol) of **13**. The reaction mixture was stirred overnight at room temperature. Aqueous workup and preparative TLC of the crude product using EtOAc gave 30 mg (45%) of a solid: mp 162–165 °C (decomp). ¹H NMR (CDCl₃) δ 0.42 (s, 9H [¹¹⁹Sn–H, d]), 1.26 (s, 9H), 1.44 (s, 9H), 5.28 (s, 2H), 7.06 (d, 1H), 7.95 (d, 1H), 8.11 (s, 1H), 9.42 (br s, 2H). MS (FAB⁺), *m/z*: cluster peaks at 558 (MH⁺), 502, 356. HRMS (FAB⁺) Calcd for C₂₂H₃₆N₃O₆¹¹⁸Sn (MH⁺): 556.1620. Found: 556.1643.

N-Succinimidyl 4-[N¹,N²-Bis(*tert*-butyloxycarbonyl)guanidinomethyl]-3-(trimethylstannyl)benzoate (15**).** A mixture of **14** (22 mg, 39 μmol), *N*-hydroxy-succinimide (12 mg, 0.1 mmol), and 1-cyclohexyl-3-(2-morpholinoethyl)carbodiimide metho-*p*-toluenesulfonate (39 mg, 0.1 mmol) in 0.5 mL of dry THF was stirred at room temperature for 5–6 h. The reaction mixture was filtered, and the crude mixture obtained from concentrating the filtrate was chromatographed (preparative TLC) using 35% EtOAc/hexane to yield 23 mg (90%) of a colorless oil: ¹H NMR (CDCl₃) δ 0.40 (s, 9H [¹¹⁹Sn–H, d]), 1.29 (s, 9H), 1.42 (s, 9H), 2.90 (s, 4H), 5.28 (s, 2H), 7.08 (d, 1H), 8.03 (d, 1H), 8.17 (s, 1H), 9.42 (br d, 2H). MS (FAB⁺), *m/z*: cluster peaks at 655 (MH⁺), 455. HRMS (FAB⁺) Calcd for C₂₆H₃₉N₄O₈¹²⁰Sn (MH⁺): 655.1790. Found: 655.1787 ± 0.0019 (*n* = 4).

Unlabeled Glycine and Lysine Conjugates of Potential Acid Metabolites. These conjugates were prepared on a small scale for use as HPLC standards. The products were isolated by semipreparative reversed-phase HPLC and were characterized by mass spectrometry. For HPLC, a C18 column (Bondclone) was eluted with the following gradient consisting of 0.2% (v/v) HOAc in water (A) and 0.2% (v/v) HOAc in methanol (B) at 1 mL/min: 5% B for 15 min, 70% B for 10 min, and then held at 70% B for 5 min. Radioiodinated forms of these potential catabolites were also prepared similarly from the corresponding labeled esters and had the same retention times as the unlabeled compounds.

Lysine Conjugate of 4-Guanidinomethyl-3-iodobenzoic Acid. To a solution of **6** (3.3 mg, 5.4 μmol) in 60 μL of THF was added a solution of *N*-α-Boc-lysine in 0.1 M borate buffer, pH 8.5 (2 mg in 5 μL, 8.1 μmol). The mixture was stirred overnight at room temperature. THF was evaporated, and the residue was treated at room temperature for 10 min with 100 μL of TFA. TFA was evaporated, and the residue was triturated with methanol. Finally, portions of a solution of the residual mixture were injected onto HPLC and the product (*t*_R = 14 min) was isolated. MS (FAB⁺), *m/z*: 448 (MH⁺), 390, 330.

Glycine Conjugate of 4-Guanidinomethyl-3-iodobenzoic Acid. To 1.8 mg (4.4 μmol) of **7** was added 25 μL of THF followed by a solution of glycine in 0.1 M borate, pH 8.5 (0.6 mg, 8 μmol). The hazy reaction mixture was stirred overnight at room temperature, and the product was isolated by reversed-phase HPLC (*t*_R = 22 min). MS (FAB⁺), *m/z*: 379 (MH⁺).

Lysine Conjugate of 5-Iodonitrocinic Acid. A solution of SIPC (5.6 mg, 16 μmol) in 90 μL of THF was treated at room temperature with 10 μL of a solution of *N*-α-Boc-lysine in 0.1 M borate buffer, pH 8.5 (4 mg, 8.1

μmol), and the mixture was stirred overnight at room temperature. Deprotection with TFA and HPLC purification were accomplished as described above (*t*_R = 27.6 min). MS (FAB⁺), *m/z*: 378 (MH⁺).

Glycine Conjugate of 5-Iodonitrocinic Acid. Glycine in borate buffer, pH 8.5 (2.5 mg in 50 μL, 33 μmol) was added to a solution of SIPC (5 mg, 14.4 μmol) in 90 μL of THF, and the mixture was stirred at room temperature overnight. The product was isolated by semipreparative HPLC as above (*t*_R = 26.3 min). MS (FAB⁺), *m/z*: 307 (MH⁺).

4-Guanidinomethyl-3-[¹³¹I]iodobenzoic Acid ([¹³¹I]5**).** (A) From **12**. The radioiodination of **12** to give [¹³¹I]**5** was attempted following conditions used for the preparation of [¹³¹I]MIBG from its silicon precursor (Vaidyanathan and Zalutsky, 1993a). To 100–200 μCi of ¹³¹I in 1–2 μL of 0.1 N NaOH in a Reacti vial was added a solution of NCS in TFA (0.4 mg in 10 μL) followed by 0.2 mg of **12** in 5 μL of TFA. The vial was vortexed, and the reaction was allowed to proceed for 5 min at room temperature. The mixture was injected onto a C18 column (Bondapak) and eluted with 90:10 water/acetonitrile each containing 0.1% TFA (w/v) at a flow rate of 1 mL/min. Less than 5% of the injected activity eluted with a retention time (14–15 min) corresponding to that of **5**.

(B) From **14**. A solution of **14** in CHCl₃ (~0.3 mg in 10 μL) was added to a 1/2-dram vial, and the CHCl₃ was evaporated using argon. To this was added about 0.5 mCi of ¹³¹I in 1 μL of 0.1 N NaOH followed by a solution of NCS in HOAc (0.4 mg in 20 μL). The mixture was heated in an oil bath at 70 °C for 10 min, 5 μL of TFA was added, and the mixture was heated for an additional 5 min. The contents of the vial were injected onto a C18 HPLC column (Bondapak) and eluted with a gradient of 0.1% TFA (w/v) in water (A) and acetonitrile (B) at 1 mL/min. The gradient had an initial composition of 5% B for 5 min, and the percentage of B was increased linearly to 90% over 15 min and maintained at that value for another 5 min. More than 95% of the injected radioactivity was associated with the only radioactive peak observed, which had a retention time (15.5 min) corresponding to that of **5**. The retention times of **4** and **14** under these HPLC conditions were 22.4 and 20.7 min, respectively.

N-Succinimidyl 4-[N¹,N²-Bis(*tert*-butyloxycarbonyl)guanidinomethyl]-3-[¹³¹I]iodobenzoate ([¹³¹I]6**).** To a Reacti vial containing 1–2 mCi of ¹³¹I in 1–3 μL of 0.1 N NaOH was added a solution of 3% (v/v) HOAc in CHCl₃ (3 μL), 30% (w/v) *tert*-butyl hydroperoxide in CHCl₃ (5 μL, dried with a few crystals of Na₂SO₄), and a solution of **15** in CHCl₃ (0.2 mg in 15 μL). The reaction mixture was stirred at room temperature for 30 min. The product [¹³¹I]**6** (*t*_R = 16 min) was isolated in 55–60% radiochemical yield by normal-phase HPLC using a Partisil column eluted with 30/70 (v/v) EtOAc/hexane containing 0.12% (v/v) HOAc at 1 mL/min.

N-Succinimidyl 4-Guanidinomethyl-3-[¹³¹I]iodobenzoate ([¹³¹I]7**).** The solvents from HPLC fractions containing [¹³¹I]**6** were evaporated, and the residual activity was transferred to a 1/2-dram vial and further concentrated to dryness. TFA (50–100 μL) was added to the above vial, and the reaction was allowed to proceed for 5 min at room temperature. TFA was evaporated, and the residue was triturated 3 times with EtOAc. This activity was used as such for mAb labeling.

Radiolabeling of L8A4 mAb. (A) *Iodogen Method.* This was performed as described previously (Reist et al., 1996). To a 1/2-dram vial coated with 10 μg of Iodogen was added a solution of L8A4 in phosphate buffer, pH

7.14 (100 μ L, $\sim$ 2 mg/mL), and 1–2 μ L of ^{131} I (0.2–0.5 mCi) in 0.1 N NaOH. The mixture was incubated at room temperature for 20 min and the labeled mAb was isolated by gel filtration over a PD10 column (Pharmacia) eluted with PBS.

(B) *Conjugation of 4-Guanidinomethyl-3-[^{131} I]iodobenzoic Acid Using EDC.* A 200 mM solution of EDC in 100 mM MES buffered saline pH 4.7 (Pierce) was prepared. To 0.5–1.0 mCi of [^{131} I]**5** in a $1/2$ -dram vial was added 5 μ L of the EDC solution followed by 5 μ L of sulfo *N*-hydroxysuccinimide (20 mM in MES). The vial was vortexed, and the reaction was allowed to proceed for 5 min at room temperature. Unreacted EDC was quenched by adding 5 μ L of 750 mM sodium acetate, and 50 μ L of L8A4 (375 mg) in pH 8.5, 0.1 M borate buffer was added. The mixture was incubated for 30 min at room temperature, and the labeled mAb was isolated by gel filtration chromatography as described above.

(C) *Acylation with N-Succinimidyl 5-[^{125} I]iodo-pyridine-3-carboxylate, N-Succinimidyl 4-[N^1,N^2 -Bis(*tert*-butoxy-carbonyl)guanidinomethyl]-3-[^{131} I]iodobenzoate or N-Succinimidyl 4-Guanidinomethyl-3-[^{131} I]iodobenzoate.* A solution of L8A4 in 0.1 M borate buffer pH 8.5 (50 μ L, 3 mg/mL) was added to about 1 mCi of [^{125} I]SIPC, [^{131} I]**6**, or [^{131} I]**7**, respectively, and the mixture was incubated for 20 min at room temperature. Labeled proteins were isolated using a PD10 column.

Evaluation of Immunoreactivity. The immunoreactivity of radiolabeled L8A4 was evaluated using a magnetic bead assay using beads coated with the extracellular domain of EGFRvIII or to control for nonspecific binding, BSA, as described (Foulon et al., 2000). Assays were done in paired-label format using two mAb preparations, one labeled with ^{125} I (SIPC or Iodogen) and the other with ^{131} I (GMIBA-EDC, SGMIB–Boc, or SGMIB). To increasing volumes (12.5, 25, and 50 μ L) of both positive- and negative-control beads in triplicate were added 5 ng (10 μ L) each of the two labeled mAbs. The immunoreactive fractions were calculated by plotting the reciprocals of the percent specific binding against the reciprocals of the bead volumes (Lindmo et al., 1984).

Internalization Assays. These assays were performed in either a single- or paired-label format using U87 MGDEGFR plated at a density of 5×10^5 cells per well in 3 mL. After an overnight incubation at 37 °C, the cells were allowed to equilibrate at 4 °C for 30 min. The medium was removed and fresh medium containing about 1 μ Ci (0.5–1.0 μ g, in mAb excess) of each labeled L8A4 preparation in 2 mL was added, and the cells were incubated for 1 h at 4 °C. Cells were washed with cold medium to remove unbound activity, and fresh zinc option medium supplemented with 10% fetal calf serum was added. Cells were brought to 37 °C and processed in triplicate at 0, 1, 2, 4, 8, 16, and 24 h. Cells were centrifuged, and the supernatants were removed. The surface-bound activity was removed by washing the cells twice with pH 2 zinc option medium. Finally, the cells were harvested and solubilized in 0.5 mL of 0.5 N NaOH. The supernatants, acid washes, and the cell pellets were all counted in an automated gamma counter. The number of counts in each compartment (released, cell surface, internalized) were expressed as the percentage of the activity initially bound to the cells immediately after the 1 h incubation at 4 °C.

Catabolism of L8A4 Labeled with [^{125} I]SIPC and [^{131} I]SGMIB by U87 MGDEGFR Cells. To determine the nature of the labeled catabolites present inside the cell and in the cell culture supernatant, an internalization assay was performed as above using 3–5 μ Ci of each

labeled mAb. After removing the surface-bound activity with acid washing, the cell pellets were lysed with 200 μ L of 0.5% NP40 in PBS containing aprotinin (0.02 mg/mL), leupeptin (0.05 mg/mL), PMSF (4 mM), and pepstatin (0.07 mg/mL) for 10 min at room temperature. The membranes were pelleted by centrifugation, and the lysates were isolated.

High molecular weight components in lysates and cell culture supernatants were analyzed by size-exclusion HPLC using a TSK column eluted with 0.1 M sodium phosphate, 0.05% sodium azide, pH 6.8 at 1 mL/min. Fractions of 0.25 mL were collected and counted for ^{125} I and ^{131} I in an automated gamma counter, and the activity was plotted versus time. For comparison, gel filtration standards (BioRad) were also run under identical conditions. To determine the low molecular weight catabolites, cell lysates and supernatants at each time point were filtered through Centricon-10 tubes (Amicon; 10,000 MW cut off). The filtrates and the cartridges were counted for radioactivity, prior to HPLC analyses of the filtrates, to determine the proportion of low and high molecular weight component at each time point. Filtrates were analyzed by reversed-phase chromatography using a C18 column (Bondclone) eluted with a mobile phase gradient consisting of 0.2% HOAc each in water (solvent A) and methanol (solvent B) at a flow rate of 1 mL/min. The mobile phase was maintained initially at 5% B for 15 min and then increased linearly to 70% B over 10 min, and then kept at that composition for another 5 min. Fractions of 0.25 mL were collected and counted for radioactivity. Under these HPLC conditions, the retention times of INA, INA-glycine, INA-lysine, GMIBA, GMIBA-glycine, GMIBA-lysine were 29.9, 27.5, 26.5, 23.0, 22.0, and 14.0 min, respectively.

Octanol–Water Partition Coefficient. [^{125} I]INA was prepared by incubating [^{125} I]SIPC (50–100 μ Ci) with 1 mL of 1 N NaOH at room temperature for 1 h. This mixture was extracted twice with 1 mL of EtOAc to remove any unreacted ester. The pH of the aqueous layer was adjusted to about 6 with 1 N HCl, and [^{125} I]INA was extracted with EtOAc. The partition coefficient was determined at both lysosomal and physiological pH using PBS at pH 4.75 and 7.4, respectively. The buffer and octanol were each saturated with the other before use. A few thousand counts each of [^{125} I]INA and [^{131} I]GMIBA in 5–10 μ L PBS were added in triplicate to a mixture of 1 mL each of octanol and buffer, and the contents were thoroughly mixed by vortexing for a few minutes. The layers were separated by centrifugation. A 50 μ L aliquot of each layer in duplicate was withdrawn from each tube and counted for radioactivity, and the ratios of activities in octanol and buffer were calculated.

RESULTS AND DISCUSSION

Perhaps the most widely known radiopharmaceutical bearing a guanidinoaryl substituent is *m*-iodobenzylguanidine (Chart 1) which has been utilized for cardiac applications as well as the diagnosis and treatment of neuroendocrine tumors such as neuroblastoma (Tepmongkol and Heyman, 1999). This compound has shown excellent stability in vivo and rapid clearance from normal tissues. Thus, in designing a guanidino-substituted protein acylation agent, it might be ideal to select a compound incorporating the structural features of both SIB and MIBG and with a 1,3,5-substitution pattern. However, we embarked on the preparation of a 1,3,4-system due to the ready availability of 3-iodo-4-methylbenzoic acid. The synthetic strategy utilized for the

Scheme 1^a

preparation of unlabeled SGMIB is presented in Scheme 1. Attempts to prepare 4-(*N*¹,*N*²-bis-*tert*-butoxycarbonyl)guanidinomethyl-3-iodobenzoic acid directly from 4-bromomethyl-3-iodobenzoic acid based on a previously described approach (Vaidyanathan and Zalutsky, 1997) were unsuccessful. For this reason, the acid moiety was first protected as a 2-(trimethylsilyl)ethyl (TMSE) ester. Benzylic bromination of **1** and subsequent guanidinylation yielded **3**. Removal of the TMSE group from **3**, and the reesterification of the resultant acid with *N*-hydroxysuccinimide afforded the active ester **6**. Both **4** and **6** were converted to the respective free guanidines by treatment with TFA, or SnCl₄ (Miel and Rault, 1997).

Because NCA [¹³¹I]MIBG has been prepared in excellent yields from its silicon precursor (Vaidyanathan and Zalutsky, 1993a), initial efforts were directed toward the preparation of a silicon derivative from which 4-guanidinomethyl-3-iodobenzoic acid (GMIBA, **5**) or its active ester could be obtained. Scheme 2 shows the synthesis of 4-(*N*¹,*N*²-bis-*tert*-butoxycarbonyl)guanidinomethyl-3-(trimethylsilyl)benzoic acid (**12**). Because the radioiodination of **12** to give [¹³¹I]**5** was not successful (vide infra), no attempts were made to prepare the *N*-hydroxysuccinimide ester. Compound **12** was prepared essentially following the approach taken to prepare the iodo counterpart. The starting material **8** was synthesized from 3-iodo-4-methylbenzoic acid via lithium/iodide exchange and subsequent silylation. In the case of the tin precursor **15**, the intermediate **3** was first stannylated using a modified Stille coupling protocol (Wigerinck et al., 1993;

Scheme 3). The resultant compound **13** was deprotected to **14** and converted to **15** following the methods used for the preparation of iodo derivatives.

Radioiodination of **12** under conditions used for the preparation of [^{131}I]MIBG from its silicon precursor (Vaidyanathan and Zalutsky, 1993a) gave [^{131}I]**5** in less than 5% radiochemical yield. Difficulty in the synthesis of radioiodinated 3-guanidinomethyl-5-iodopyridine from its silicon precursor was encountered earlier (Vaidyanathan et al., 1998a). While electronic factors might have been the reason for failure in the above instance, steric hindrance from the *o*-guanidinomethyl group may have contributed to the lower yields in the present situation. However, it was possible to convert **14** to [^{131}I]**5** in a one-pot reaction, by sequential radioiodination and deprotection, in an overall radiochemical yield of more than 90%. This radioiodination was performed at 70 °C in HOAc and lead to removal of a significant proportion of the Boc group; however, the mixture was further treated with TFA to ensure complete deprotection.

Preparation of [^{131}I]**7** from **15** in a similar fashion was not attempted because the active *N*-hydroxysuccinimidyl ester functionality is not expected to survive the reversed-phase HPLC and/or the subsequent concentration of the HPLC fraction. To avoid this, milder conditions for the radioiodination of **15** were sought. Radioiodinated IUdR and its fluorinated analogue FIAU have been prepared by a iododestannylation route under mild, but high yielding, conditions (Vaidyanathan and Zalutsky, 1998b). However, only modest yields were obtained when attempts were made to convert **15** to [^{131}I]**6** under these conditions. On the other hand, a radiochemical yield of 55–60% was obtained for the reaction when conditions used for the preparation of [^{131}I]SIB (Zalutsky and Narula, 1987) were adapted. Compound [^{131}I]**6** was isolated by normal-phase HPLC, and after deprotection, investigated for labeling mAbs.

Compound [^{131}I]**5** was initially pursued for mAb labeling because of the questionable stability of the *N*-succinimidyl function to TFA, the reagent used to convert [^{131}I]**6** to [^{131}I]**7**. Coupling of [^{131}I]**5** to mAb L8A4 under conditions reported for the EDC-mediated conjugation of carboxylic acids to protein (Davis and Preston, 1981; Sehgal and Vijay, 1994) was not successful. Therefore, conditions for EDC-mediated coupling were first optimized using [^{131}I]iodobenzoic acid (Vaidyanathan and Zalutsky, 1993b) and then applied for labeling L8A4 with [^{131}I]**5**. Consistent conjugation efficiencies of 35–40% were obtained with specific activities of 0.5–2.0 $\mu\text{Ci}/\mu\text{g}$. The immunoreactive fraction for L8A4 labeled by this method was similar to that labeled using Iodogen and was in the range of 75–80% and size-exclusion HPLC revealed less than 5% of aggregates (Figure 1). Nonetheless, this approach was not pursued because of the greater simplicity and higher yields anticipated with the *N*-succinimidyl ester acylation agents.

Initially, we attempted to label mAbs directly with [^{131}I]**6**, the *N*-succinimidyl ester with a protected guanidine functionality. It was anticipated that the protecting groups would be cleaved within the lysosomal compartment due to the susceptibility of the Boc group to acidic environments; carbamate groups have been used in the design of prodrugs (Hansen et al., 1991). Although it is an active ester, [^{131}I]**6** could be coupled to L8A4 in only 10–15% yield, presumably due to its high lipophilicity from the presence of Boc protecting groups, resulting in poor solubility in aqueous buffers. While this method yielded labeled mAb with immunoreactive fractions of about 80% and no obvious protein cross-linking, only low specific activities were obtained due to poor coupling yields. Thus, it was necessary to convert [^{131}I]**6** to [^{131}I]**7**. A pilot study was undertaken to test the stability of the

Figure 1. Size-exclusion HPLC radiochromatogram of L8A4 mAb labeled with ^{131}I using Iodogen (dotted line), [^{131}I]SGMIB (solid line), and [^{131}I]GMIBA using EDC-mediated coupling (dashed line).

N-hydroxysuccinimidyl ester to TFA using SIB as a model compound. No significant degradation of SIB in the presence of TFA was seen for up to 30 min at room temperature by TLC. Subsequently, it was demonstrated that [^{131}I]**6** could also be converted to [^{131}I]**7** without any adverse effects. Labeling of L8A4 with [^{131}I]**7** (SGMIB) resulted in 60–65% coupling yields with specific activities of 0.5–2.0 $\mu\text{Ci}/\mu\text{g}$. This method did not produce any observable cross-linking, and the immunoreactive fraction of ^{131}I -labeled L8A4 was more than 80%.

To test the hypothesis that the presence of a highly polar guanidine function in the structure of radioiodinated acylation agents will enhance the intracellular retention of activity for mAbs labeled with these molecules, internalization assays were performed with mAb L8A4 and the EGFRvIII-expressing U87 MGDEGFR cell line. In the first study, L8A4 labeled with the Boc-protected SGMIB analogue and Iodogen were compared in paired-label format. As shown in Figure 2, the percentage of activity retained inside the cell for L8A4 labeled using [^{131}I]**6** was higher than that for L8A4 labeled via Iodogen at all time points. At 16 h, the value for the former ($25.9 \pm 1.3\%$) was 3.5-fold higher than that for the latter ($7.5 \pm 0.4\%$). The activity pattern in the supernatant over this period was complementary to that observed for internalized activity. We speculate that the higher intracellular retention of activity for L8A4 labeled via [^{131}I]**6** reflects the removal of Boc groups from the prosthetic group within the lysosomal compartment generating the cationic guanidine moiety.

The results from a second paired-label study comparing the internalization of L8A4 labeled with [^{131}I]**7** versus that labeled using Iodogen is depicted in Figure 3. Again, L8A4 labeled with [^{131}I]**7** demonstrated significantly higher amounts of internalized activity and lower supernatant counts compared with the Iodogen-labeled mAb, with 3 to 4 times higher intracellular activity observed with SGMIB labeling at later time points. These results are in marked contrast to those obtained when this mAb was labeled using SIPC (Reist et al., 1996). In that study, SIPC offered no advantage compared with Iodogen in terms of intracellular counts after 8 h; however, it should be noted that a different EGFRvIII-expressing cell line (HC2 20 d2) was used in that study. A final experiment was performed in a paired-label format to directly compare the intracellular retention of radioiodine activity

Figure 2. Paired-label in vitro internalization of L8A4 by U87 MGDEGFR cells. L8A4 radioiodinated with ¹²⁵I via Iodogen method (●) and with ¹³¹I using Boc-SGMIB (○). (A) Percentage of radioactivity initially bound to cells retained intracellularly. (B) Percentage of radioactivity initially bound to the cells recovered from the cell culture supernatant.

in U87 MGDEGFR cells incubated with L8A4 labeled with ¹³¹I using SGMIB and ¹²⁵I using SIPC. At all time points, intracellularly trapped activity from L8A4 labeled with SGMIB was significantly higher than that from mAb labeled with SIPC. Use of the guanidino-substituted acylation reagent resulted in about 3 times higher internalized counts at the 16 and 24 h time points (Figure 4).

We next investigated whether the increased intracellular retention of iodine activity indeed was related to the nature of the catabolites generated during the processing of mAbs labeled using SGMIB. As a first step, the percentage of low molecular weight catabolites associated with the cell lysates was determined by passage through a 10 kDa filter for L8A4 labeled via SGMIB and SIPC. As summarized in Table 1, a considerably higher percentage of the low molecular weight catabolites that were generated from SGMIB-labeled mAb were recovered from the cell lysates. By 8 h, a nearly 20 times higher fraction of low molecular weight catabolites were found in the cell lysates with SGMIB labeling with the difference increasing to a factor of about 75 by 24 h. The trends observed for L8A4 labeled with SIPC were similar to those observed previously with a different EGFRvIII-expressing cell line (Reist et al., 1996). These results demonstrate that SGMIB labeling yields catabolites that remain inside the cell to a considerably greater extent than seen with mAb labeled via SIPC.

The percentage of the total radioiodine activity that was present in the cell culture supernatant and cell

Figure 3. Paired-label in vitro internalization of L8A4 by U87 MGDEGFR cells. L8A4 radioiodinated with ¹²⁵I via Iodogen method (●) and with ¹³¹I using [¹³¹I]SGMIB (○). (A) Percentage of radioactivity initially bound to cells retained intracellularly. (B) Percentage of radioactivity initially bound to the cells recovered from the cell culture supernatant.

lysates in the form of low molecular weight catabolites also was calculated, and the results are summarized in Table 2. At early time points, low molecular weight species accounted for only a small fraction of the total activity, and in the cell culture supernatant, the contribution of low molecular weight species was similar for mAb labeled by reaction with SIPC and SGMIB. However, clear differences were observed between the two labeling methods in the cell lysate. With SIPC, low molecular weight species accounted for less than 6% of the radioiodine activity recovered from the cells. In contrast, 45 to 64% of the radioactivity present in the cells after 8–24 h incubation at 37 °C was in the form of low molecular weight molecules. These results demonstrate that the increased intracellular retention observed for mAb L8A4 labeled via SGMIB in the internalization assays is due to low molecular weight degradation products.

Previous studies have shown that for mAbs labeled using SIB and similar reagents, the primary low molecular weight catabolites are the free acid as well as its glycine and lysine conjugates (Garg et al., 1995). The higher intracellular retention of low molecular weight species from mAbs labeled with SGMIB compared to those labeled with SIPC is consistent with the relative polarity of their expected catabolites. Retention times on reversed-phase HPLC (vide supra) indicate that GMIBA, GMIBA–glycine, and GMIBA–lysine are all more polar than INA and its corresponding derivatives. The higher polarity of GMIBA compared with INA was confirmed

Figure 4. Paired-label in vitro internalization of L8A4 by U87 MG/EGFR cells. L8A4 radioiodinated with ^{125}I using [^{125}I]SIPC (●) and with ^{131}I using [^{131}I]SGMIB (○). (A) Percentage of radioactivity initially bound to cells retained intracellularly. (B) Percentage of radioactivity initially bound to the cells recovered from the cell culture supernatant.

Table 1. Low Molecular Weight Catabolites Retained by H898 Cells Following Paired-Label Intracellular Processing of L8A4 Labeled Using [^{131}I]SGMIB and with [^{125}I]SIPC

time (h)	low molecular weight catabolites retained in the cell (percent of total)	
	SGMIB	SIPC
1	12.6	6.14
2	40.0	9.72
4	56.9	7.65
8	58.9	3.01
16	29.3	0.63
24	14.9	0.20

by measuring their octanol/saline partition coefficients at physiologic and lysosomal pH (pH 4.75). At a pH of 7.4, GMIBA had a partition coefficient (0.02 ± 0.00), three times smaller than that for INA (0.06 ± 0.00). The difference was even more pronounced at lysosomal pH (GMIBA 0.06 ± 0.00 ; INA 1.63 ± 0.01). Thus, INA probably exists predominantly as an uncharged molecule at lysosomal pH, whereas it may exist as a zwitter ion at physiologic pH. On the other hand, the guanidine function of GMIBA is likely to exist in its protonated form at both pH values.

The catabolism of mAb L8A4 labeled with [^{131}I]SGMIB and [^{125}I]SIPC following exposure to U87 MG/EGFR cells in vitro was evaluated by HPLC. Size exclusion HPLC failed to detect any aggregates in the mAb preparations used in these studies and less than 1% of the activity was associated with low molecular weight

Table 2. Percent of Total Activity Associated with Low Molecular Weight Catabolites in Cell Lysate and Cell Culture Supernatant

time (h)	supernatant ^a (%)		cell lysate ^a (%)

^a (Activity in the low mw fraction $\times$ 100)/(activity in the low mw fraction + activity in the high mw fraction).

Figure 5. Size-exclusion HPLC of radioiodine activity recovered from cell lysates after 1 h incubation with L8A4 mAb labeled with ^{125}I using SIPC (●) and labeled with ^{131}I using SGMIB (○). Retention times of molecular weight standards are indicated.

species. Size-exclusion HPLC of the cell lysate at 1 h showed that both radionuclides were primarily associated with a peak with a retention time of about 300 kDa (Figure 5) and a similar pattern was observed in cell lysate samples obtained at latter time points. Because of the lack of mAb dimers in the preparations used in this experiment, it is likely that the 300 kDa species represents a monomeric complex between mAb L8A4 and the 145 kDa EGFRvIII.

Analysis of reversed-phase HPLC radiochromatograms indicated that the predominant low molecular weight catabolites present in the cell culture supernatant at 2 h from the SGMIB labeled mAb were the free acid, GMIBA, and a peak eluting at the void volume. We speculate that this peak could be either free iodide, or more likely, the glucuronide conjugate (Laznick and Laznickova, 1999). At 4 h, a peak corresponding to GMIBA-glycine became apparent, and it was the predominant peak present in the supernatant at 24 h. The major peak at 2 h from the SIPC labeled mAb eluted in the void volume, and there were also two minor peaks corresponding to INA and INA-lysine. The intensity of the peak corresponding to INA-lysine increased with time, and by 24 h, it was the only major peak present in the cell culture supernatant.

Up until the 24 h time period, GMIBA-glycine was the only predominant peak that could be detected in the cell lysates for mAb labeled using SGMIB (Figure 6); however, the only peak seen at 24 h eluted in the void volume. From SIPC-labeled mAb, the major peak at 2 h has a retention time corresponding to that of INA while

Figure 6. Reversed-phase HPLC of low molecular weight species recovered from cell lysates 8 h after incubation with L8A4 mAb labeled with ¹²⁵I using SIPC (●) and that labeled with ¹³¹I using SGMIB (○). Retention times of potential catabolites indicated are those of authentic standards.

at 4 h, two peaks were seen, one corresponding to INA-lysine and the other, an unidentified more polar peak ($t_R = 20$ min). This peak was the significant component at 8 h in addition to a lower level of INA-lysine (Figure 6). At 24 h, there were two peaks near the void volume, one coeluting with the only SGMIB-labeled mAb catabolite, and the other unidentified peak eluted slightly earlier.

Although it is difficult to fully account for these catabolic patterns, it is clear that no lysine conjugate of GMIBA was detected. In contrast, INA-lysine was one of the major metabolites from SIPC labeled mAb, and similar lysine conjugates have been observed in the degradation of mAbs labeled on lysine ϵ -amino groups with other molecules (Duncan and Welch, 1993; Arano et al., 1995; Rogers et al., 1995). It appears that when mAbs labeled using SGMIB are degraded, free GMIBA is released from the protein itself and then further converted to the glycine conjugate, a normal pathway for the metabolism of aromatic carboxylic acids seen earlier with SIB-labeled mAbs (Garg et al., 1995). This suggests that the amide bond between GMIBA and the lysine on the mAb (or its lower molecular weight protein degradation product) is more susceptible to cleavage within the cell than the bond created when the mAbs were labeled using SIPC. Nonetheless, the retention of the GMIBA-glycine conjugate inside the cell after proteolysis of the mAb is consistent with the highly basic nature of its guanidino substituent.

In summary, a method has been developed for the preparation of SGMIB, an acylation agent containing a polar guanidine function, via a tin precursor. The anti-EGFRvIII mAb L8A4 could be radioiodinated efficiently using SGMIB with preservation of immunoreactivity and without any protein cross-linking. Internalization assays demonstrated that radioiodination of this mAb using SGMIB significantly enhanced the retention of radioiodine activity in EGFRvIII tumor cells after mAb internalization. Catabolism studies showed that this behavior was likely related to the generation of highly polar catabolites which were trapped within the cell. Experiments are in progress in mice with EGFRvIII-expressing tumors to determine whether SGMIB will be a useful reagent for labeling internalizing mAbs such as L8A4.

ACKNOWLEDGMENT

This work was supported by Grants CA42324, CA78417, and NS20023 from the National Institutes of Health. We thank Dr. Darell Bigner from the Department of Pathology, Duke University Medical Center, for providing the L8A4 mAb and the U87 MGDEGFR cell line.

Fluorine-Substituted Ligands for the Peroxisome Proliferator-Activated Receptor Gamma (PPAR γ): Potential Imaging Agents for Metastatic Tumors

Sung-Hoon Kim,[†] Stephanie D. Jonson,[‡] Michael J. Welch,[‡] and John A. Katzenellenbogen^{*,†}

Department of Chemistry, University of Illinois, Urbana, Illinois 61801, and Division of Radiological Sciences, Washington University School of Medicine, St. Louis, Missouri 63110. Received December 22, 2000; Revised Manuscript Received March 19, 2001

The peroxisome proliferator-activated receptor gamma (PPAR γ), a primary regulator of lipid metabolism, is present in many tumor cell lines and animal tumor systems and, in some cases, can mediate effective antitumor therapy with potent synthetic ligands. In an approach to image tumors with positron-emission tomography (PET) based on their content of PPAR γ , we have synthesized two fluorine-substituted analogues of a high affinity ligand from the phenylpropanoic acid class. The analogue having the highest affinity for PPAR γ was labeled with the positron-emitting radionuclide fluorine-18. In tissue distribution studies in normal rats and in SCID mice bearing human breast tumor xenografts, this compound did not show evidence of receptor-mediated uptake. The prospects for using PPAR γ as a target for imaging tumors may be limited by the low receptor concentrations in tumors and by the pharmacokinetic behavior of this class of ligands, which appears to be more favorable for therapy than for imaging.

The peroxisome proliferator-activated receptor gamma (PPAR γ), formerly considered together with its paralogs PPAR α and PPAR δ to be an orphan receptor, is now known to be a primary regulator of lipid metabolism, capable of inducing differentiation and lipid storage in preadipocytes (1, 2). More recently, endogenous ligands (prostaglandin-J's and unsaturated fatty acids) (3, 4) as well as potent synthetic ligands for PPAR γ have been identified (5).

PPAR γ appears to play an intriguing role in cancer, because PPAR γ ligands can induce certain cancer cell lines (namely, liposarcomas) to stop proliferating, lose their malignant character, and undergo terminal differentiation to adipocytes (6–9). Thus, these ligands might provide a novel route to therapy. PPAR γ levels, assayed by immunohistochemistry, are also elevated in other tumor cells, including several breast cancer cell lines (7), and in animal tumor models for breast cancer, receptor levels were especially high in metastases. When tested in some of the breast cancer cell lines, PPAR γ ligands again induced tumor cell differentiation, but not all cell lines that were PPAR γ positive responded. The key to responsiveness may be the state of PPAR γ phosphorylation in the tumor cells; the receptor phosphorylated on S112 is much less responsive to ligand than the nonphosphorylated receptor (10) and has lower affinity for ligands (11), whereas both are detected equally well by the antibody used in the PPAR γ immunoassay. Thus, it appears that PPAR γ might be a novel target for tumor therapy, but one in which responsiveness is determined

not only by the presence of the receptor, but its presence in a dephosphorylated form capable of responding to ligand.

In such a situation, functional imaging could play a critical role: The selective uptake of appropriate PPAR γ ligands, developed as *in vivo* radiotracers, could be used to identify those tumors containing receptors that have retained their ability to bind PPAR γ ligands. These might be the tumors more likely to show a favorable response to therapy with PPAR γ ligands. Thus, as has proved to be the case with estrogen receptor-based imaging of breast tumors (12–14), functional imaging of tumors based on their content of ligand-binding PPAR γ might enable hormonal therapy to be directed to those patients most likely to benefit. In this manner, time would not be lost in providing alternative therapies with higher morbidity to those who are unlikely to respond.

The affinity of endogenous ligands for PPAR γ , unsaturated fatty acids or prostaglandin J's (3,4), is only in the micromolar range, too low to be useful for imaging. However, a number of synthetic ligands, exemplified by the 5-substituted-thiazolidine-2,4-diones (15, 16) and the 2-aryloxy-3-phenylpropanoic acids (17, 18) have been identified as potent, high affinity PPAR γ ligands (Scheme 1). As targets in this first study, we selected compounds **9** and **22** as fluorine-substituted analogues of one of the most potent and selective PPAR γ ligand from the 3-phenylpropanoic acid class (SB 213 068, Scheme 1). The sites of fluorine substitution were selected to make these compounds reasonable analogues of the parent ligand and to allow for the introduction of a fluorine-18 label by a fluoride ion displacement reaction late in the synthetic sequence. In compound **9**, fluorine substitution is made by replacing the *N*-methyl group with a 2-fluoroethyl substituent, and in compound **22**, fluorine substitution is on C(2) of the α -ethoxy substituent of the parent ligand. The former, *N*-(2-fluoroethyl) for *N*-methyl substitution, has been used frequently in the design of

ligands for imaging neuroreceptors by PET (19, 20). It is of note that the parent compound, SB 213 068, also has good potency and relatively rapid blood clearance rates. The latter, in particular, is an important consideration for achieving the good contrast between target and nontarget areas needed for imaging.

We have synthesized these compounds, determined their binding affinity toward receptors in the PPAR family, prepared the highest affinity analogue labeled with the positron-emitting radionuclide fluorine-18, and conducted tissue distribution studies on this analogue in two animal model systems. Despite the high binding affinity of the best analogue (**22**), its tissue distribution does not show evidence of receptor-mediated uptake. This and the pharmacokinetic factors that characterize most high affinity/high potency ligands from these and other classes suggest that PPAR γ is likely to be a challenging target for tumor imaging by PET.

EXPERIMENTAL SECTION

Materials and Methods. All reactions using water- and air-sensitive reagents were carried out under N₂ atmosphere with dry solvents. Solvents were distilled under N₂ as follows: pyridine from KOH, tetrahydrofuran (THF) from sodium benzophenone ketyl, dimethylformamide (DMF) from MgSO₄. All other reagents were purchased from commercial suppliers and used without further purification. Reaction were monitored using thin-layer chromatography (TLC), performed on 0.255 mm silica gel plates containing F-254 indicator, with visualization under UV light (254 nm). Flash chromatography was performed using Woelm 32–63 μ m silica gel packing unless otherwise noted. Methods for the preparation of methanesulfonyloxyethanol (21), *tert*-butyldimethylsilyloxyethanol (22), methyl 2-phenoxydiethylphosphonoacetate (23), and methyl 2-diazodiethylphosphonoacetate (23) have been described in the cited literatures.

¹H NMR and ¹³C NMR spectra were recorded on Varian U400 and U500 instruments. NMR spectra chemical shifts (δ) are reported in parts per million downfield from TMS and referenced with either TMS internal standard for CDCl₃, MeOH-*d*₄, acetone-*d*₆, or

DMSO-*d*₆. NMR coupling constants are reported in Hertz. Low-resolution electron impact mass spectra and fast-atom bombardment mass spectra were obtained on Finnigan MAT CH-5 and ZAB-SE spectrometers, respectively. High-resolution mass spectra were obtained on a VG 70-SE-4E spectrometer.

2-[Di(2-hydroxyethyl)amino]benzoxazole (1). To the solution of 2-chlorobenzoxazole (1.22 g, 7.95 mmol) in the mixture of THF (15 mL) and DMF (5 mL) at room temperature was added diethanolamine (1.8 mL, 18.8 mmol). The reaction mixture was stirred for 3 h at the same temperature and then poured into ethyl acetate (50 mL) and water (50 mL). The organic layer was separated, extracted with ethyl acetate (50 mL $\times$ 3), dried over MgSO₄, filtered, and evaporated to give compound **1** (1.2 g, 68%) as a white solid: mp 109–110 °C; ¹H NMR (methanol-*d*₄, 500 MHz) δ 3.75 (t, $J = 5.5$ Hz, 4H), 3.84 (t, $J = 5.5$ Hz, 4H), 7.04 (t, $J = 7.5$ Hz, 1H), 7.15 (t, $J = 7.5$ Hz, 1H); MS (FAB) (%) m/z 223 ($M^+ + 1$, 100), 155 (28), 119.

2-[(2-(Methanesulfonyloxy)ethyl-2-hydroxyethyl)-amino]benzoxazole (2). To the solution of compound **1** (1.30 g, 5.86 mmol) in pyridine (5 mL) was added dropwise methanesulfonyl chloride (340 mg, 2.97 mmol) at 0–5 °C with a small syringe. After stirring continuously for 30 min, the same amount of MsCl was once more added to the reaction mixture. After an additional 30 min, the reaction mixture was added to 20 mL of water and extracted with ethyl acetate (30 mL $\times$ 3). The ethyl acetate solution was washed with brine, dried over MgSO₄, and concentrated in vacuo. The column chromatography on silica gel with ethyl acetate as eluent gave the desired compound **2** (850 mg, 48%) as a liquid together with unreacted starting material **1** (309 mg, 23%) and 2-[bis(2-methanesulfonyloxyethyl)amino]benzoxazole (580 mg, 25%). Spectra for compound **2**: ¹H NMR (CDCl₃, 500 MHz) δ 2.99 (s, 3H), 3.78 (t, $J = 5.5$ Hz, 2H, CH₂OH), 3.92–3.95 (m, 4H, CH₂NCH₂), 4.52 (t, $J = 5.5$ Hz, 2H, MsOCH₂), 7.08 (t, $J = 7.5$ Hz, 1H), 7.17 (t, $J = 7.5$ Hz, 1H), 7.27 (d, $J = 8.0$ Hz, 1H), 7.34 (d, $J = 8.0$ Hz, 1H); ¹³C NMR (CDCl₃, 125 MHz) δ 37.51, 49.56, 53.22, 61.40, 67.06, 109.02, 116.39, 121.08, 124.30,

142.50, 148.81, 162.19; MS (FAB) (%) m/z 301 ($M^+ + 1$, 100), 223 (100), 205 (50), 119 (33).

4-[2-[Benzoxazol-2-yl-(2-hydroxyethyl)amino]ethoxy]benzaldehyde (3). (A) To the suspension of NaH (58 mg, 1.44 mmol, 60%) in DMF (5 mL) was added portionwise *p*-hydroxybenzaldehyde (168 mg, 1.38 mmol) at 0 °C. To this solution was added compound **2** (375 mg, 1.25 mmol) at room temperature, and the reaction was heated at 80 °C for 5 h. The solution was poured into water (10 mL), and the solid precipitate was collected by filtration and chromatographed on silica gel with the mixture of CH_2Cl_2 and EtOAc (1:2) to afford a trace of 2-morpholinobenzoxazole and title compound **3** (350 mg, 86%) as a colorless liquid: ^1H NMR ($CDCl_3$, 500 MHz) δ 3.84 (t, $J = 5.5$ Hz, 2H, NCH_2CH_2OH), 3.95 (t, $J = 5.5$ Hz, 2H, NCH_2CH_2OH), 4.01 (t, $J = 5.5$ Hz, 2H, NCH_2CH_2OAr), 4.36 (t, $J = 5.5$ Hz, 2H, NCH_2CH_2OAr), 6.97 (d, $J = 8.5$ Hz, 2H), 7.08 (t, $J = 7.5$ Hz, 1H), 7.15 (t, $J = 8.0$ Hz, 1H), 7.24 (d, $J = 8.0$ Hz, 1H), 7.33 (d, $J = 8.0$ Hz, 1H), 7.79 (d, $J = 8.5$ Hz, 2H), 9.84 (s, 1H, CHO); ^{13}C NMR ($CDCl_3$, 125 MHz) δ 49.45, 53.31, 61.17, 66.38, 108.92, 114.73, 116.14, 120.84, 124.19, 130.24, 132.03, 142.67, 148.76, 163.29, 190.89; MS (EI) (%) m/z 327 (M^+ , 100), 224 (20), 205 (24), 161 (15).

(B) The mixture of **12** (924 mg, 2.28 mmol), K_2CO_3 (400 mg), and ethylene carbonate (300 mg, 3.41 mmol) in DMF (2 mL) was heated at 110 °C for 4 h. When compound **12** was no longer present upon TLC analysis, water (15 mL) was added to the reaction mixture, and the products were extracted with ethyl acetate (50 mL $\times$ 3), dried over $MgSO_4$, and concentrated under reduced pressure. The residue was chromatographed on SiO_2 column with EtOAc as an eluent to give title compound **3** (520 mg, 70%).

4-[2-[Benzoxazol-2-yl-(2-trimethylsilyloxyethyl)amino]ethoxy]benzaldehyde (4). A solution of compound **3** (287 mg, 0.88 mmol), $TMSCl$ (115 mg, 1.06 mmol), and triethylamine (107 mg, 1.06 mmol) in THF at room temperature was stirred for 4 h and then filtered and evaporated under vacuum to give title compound **4** (350 mg, 100%) as a colorless liquid. ^1H NMR ($CDCl_3$, 500 MHz) δ 0.09 (s, 9H), 3.81 (t, $J = 5.5$ Hz, 2H, NCH_2CH_2OTMS), 3.89 (t, $J = 5.5$ Hz, 2H, NCH_2CH_2OTMS), 4.07 (t, $J = 5.5$ Hz, 2H, NCH_2CH_2OAr), 4.38 (t, $J = 5.5$ Hz, 2H, NCH_2CH_2OAr), 7.00–7.04 (m, 3H), 7.17 (t, $J = 7.5$ Hz, 1H), 7.26 (d, $J = 7.5$ Hz, 1H), 7.37 (d, $J = 7.5$ Hz, 1H), 7.82 (d, $J = 9.0$ Hz, 2H), 9.80 (s, 1H, CHO); ^{13}C NMR ($CDCl_3$, 125 MHz) δ -0.64, 49.54, 52.47, 60.75, 66.31, 108.82, 114.73, 114.76, 116.18, 120.65, 121.31, 124.13, 130.22, 132.05, 148.19, 163.54, 190.80.

Methyl 3-[4-[2-[Benzoxazol-2-yl-(2-hydroxyethyl)amino]ethoxy]phenyl]-2-phenoxyacrylate (5). To the solution of methyl 2-phenoxy-2-diethylphosphonoacetate (261 mg, 0.86 mmol) in THF (15 mL) was added portionwise NaH (38 mg, 0.95 mmol, 60% mineral oil dispersion) at 0 °C. When gas evolution ceased, a solution of compound **4** (345 mg, 0.87 mmol) in THF (5 mL) was added dropwise. After stirring for 5 h, water (50 mL) was added to the reaction mixture, and the pH of the aqueous solution was adjusted to 2 with 0.1 M HCl. An EtOAc extract (30 mL $\times$ 3) was washed with brine, dried ($MgSO_4$), and evaporated to give title compound **5** ($E:Z = 1:1$) (309 mg, 75%) as a colorless liquid. ^1H NMR ($CDCl_3$, 400 MHz) [most peaks are doubled because of the geometric isomers] δ 3.65, 3.76 (s, combined, 3H, CH_3O), 3.82, 3.85 (t, $J = 5.5$ Hz, combined, 2H, CH_2OH), 3.90–4.02 (m, 4H, CH_2NCH_2), 4.26, 4.30 (t, $J = 5.5$ Hz, 2H, NCH_2CH_2OAr), 6.70 (s, 0.5H, *E*-olefinic H), 6.80–7.64 (m, 13.5H, *Z*-olefinic H and ArH); MS (EI) (%) m/z

474 (M^+ , 10), 430 (15), 326 (18), 296 (44), 205 (60), 161 (100), 147 (77).

Methyl 3-[4-[2-[Benzoxazol-2-yl-(2-hydroxyethyl)amino]ethoxy]phenyl]-2-phenoxypropanoate (6). The mixture of compound **5** (309 mg, 0.65 mmol) and Pd/C (10%, 3 mg) in MeOH (20 mL) was placed under 30 psi of H_2 in a Parr shaker and agitated at room temperature for 20 h. Filtration and solvent evaporation afforded the title compound **6** (306 mg, 99%) as a colorless liquid. ^1H NMR ($CDCl_3$, 400 MHz) δ 3.15 (dd, $J = 17.0$, 5.2 Hz, 1H, $ArCH_aH_bCH$), 3.19 (dd, $J = 17.0$, 7.6 Hz, 1H, $ArCH_aH_bCH$), 3.67 (s, 3H), 3.90 (t, $J = 5.2$ Hz, 2H, NCH_2CH_2OH), 3.96 (t, $J = 5.2$ Hz, 2H, NCH_2CH_2OH), 4.00 (t, $J = 5.2$ Hz, 2H, NCH_2CH_2OAr), 4.28 (t, $J = 5.2$ Hz, 2H, NCH_2CH_2OAr), 4.74 (dd, $J = 7.6$, 5.2 Hz, 1H, $ArCH_2CH$), 6.79–6.83 (m, 4H), 6.92–7.07 (m, 2H), 7.17–7.41 (m, 7H); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 38.08, 49.75, 52.18, 53.67, 61.37, 65.97, 77.68, 108.89, 114.22, 115.04, 115.83, 120.98, 121.61, 124.22, 129.00, 129.41, 130.48, 141.62, 148.29, 156.94, 157.49, 161.99, 171.56; MS (EI) (%) m/z 476 (M^+ , 18), 432 (22), 205 (56), 161 (100), 135 (68).

Methyl 3-[4-[2-[Benzoxazol-2-yl-(2-methanesulfonyloxyethyl)amino]ethoxy]phenyl]-2-phenoxypropanoate (7). To the solution of compound **6** (255 mg, 0.54 mmol) in pyridine (5 mL) was added methanesulfonyl chloride (41.0 μ L, 0.54 mmol) with a microsyringe at 0–5 °C. When starting material was no longer detected by TLC, the reaction mixture poured into water (30 mL), extracted with EtOAc (20 mL $\times$ 3), washed with 1 N HCl solution, brine, and water, and dried over $MgSO_4$. Evaporation of solvent under pressure gave the title compound **7** (210 mg, 71%) as a colorless liquid. ^1H NMR ($CDCl_3$, 500 MHz) δ 2.93 (s, 3H), 3.13–3.21 (m, 2H, $ArCH_2CH$), 3.70 (s, 3H), 3.98–4.10 (m, 4H, CH_2NCH_2), 4.24 (t, $J = 5.5$ Hz, 2H, NCH_2CH_2OAr), 4.55 (t, $J = 5.5$ Hz, 2H, NCH_2CH_2OMs), 4.74 (dd, $J = 7.5$, 5.5 Hz, 1H, $ArCH_2CH$), 6.80–6.83 (m, 4H), 6.94 (t, $J = 7.5$ Hz, 1H), 7.04 (t, $J = 7.5$ Hz, 1H), 7.16–7.28 (m, 6H), 7.36 (d, $J = 7.5$ Hz, 1H); ^{13}C NMR ($CDCl_3$, 125 MHz) δ 37.42, 38.22, 49.57, 49.80, 52.28, 66.24, 66.96, 77.89, 108.99, 114.36, 115.21, 116.49, 120.98, 121.76, 124.23, 129.01, 129.57, 130.63, 142.88, 148.91, 157.32, 157.70, 161.44, 171.71; MS (EI) (%) m/z 554 (M^+ , 1.2), 476 (32), 275 (26), 205 (100), 161 (42).

Methyl 3-[4-[2-[Benzoxazol-2-yl-(2-fluoroethyl)amino]ethoxy]phenyl]-2-phenoxypropanoate (8). To a solution of *n*-Bu₄NF (62 μ L, 0.1 M CH_2Cl_2 solution) in DMSO (0.2 mL), preheated to 90 °C, was added compound **7** (28 mg, 0.05 mmol) dissolved in DMSO (0.2 mL) through a microsyringe, and heating was continued for 10 min. A lot of solid deposited upon addition of water (5 mL). After the solvent was decanted, the residue was chromatographed on silica gel (1 $\times$ 3 cm), with an ether eluent. 4-[2-[(benzoxazol-2-yl)amino]ethoxy]benzaldehyde (4 mg, 18%) eluted in the first 20 mL, and the desired fluorinated title compound **8** (16 mg, 67%) in the next 25 mL, as a colorless oil. A small amount of unreacted starting material (4 mg, 14%) was eluted with ethyl acetate. ^1H NMR ($CDCl_3$, 400 MHz) δ 3.14 (dd, $J = 18.0$, 5.2 Hz, 1H, $ArCH_aH_b$), 3.19 (dd, $J = 18.0$, 7.6 Hz, 1H, $ArCH_aH_b$), 3.67 (s, 3H), 4.00 (tt, $J = 25.6$, 4.8 Hz, 2H, FCH_2CH_2N), 4.02 (t, $J = 5.6$ Hz, 2H, $ArOCH_2CH_2N$), 4.25 (t, $J = 5.6$ Hz, 2H, $ArOCH_2CH_2N$), 4.75 (tt, $J = 47.6$, 4.8 Hz, 2H, FCH_2CH_2N), 4.74 (dd, $J = 7.6$, 5.2 Hz, 1H, $ArCH_2CH$), 6.80–6.83 (m, 4H), 6.94 (t, $J = 7.6$ Hz, 1H), 7.02 (t, $J = 7.6$ Hz, 1H), 7.15–7.27 (m, 6H), 7.37 (d, $J = 7.6$ Hz, 1H); ^{13}C NMR ($CDCl_3$, 125 MHz) δ 38.24, 49.51, 50.48 (d, $J = 20$ Hz), 52.27, 66.13, 77.96, 82.12 (d, $J = 168.5$ Hz, FCH_2), 108.88, 114.39, 115.24, 116.31, 120.73,

121.76, 124.13, 128.86, 129.56, 130.57, 136.10, 142.81, 148.70, 157.46, 157.72, 171.92; MS (FAB) (%) m/z 479 ($M^+ + 1$, 100), 155 (46), 135 (40), 119 (93).

3-[4-[2-(Benzoxazol-2-yl)-(2-fluoroethyl)amino]ethoxy]phenyl-2-phenoxypropionic Acid (9). The mixture of compound **8** (6 mg, 0.011 mmol), 2 N NaOH (0.2 mL), and MeOH (0.4 mL) was stirred for 2.5 h at room temperature and then diluted with water (0.5 mL). White solid was deposited by adjusting the pH to 2–3 with 1 N HCl. Isolation of this material by filtration gave the title compound **9** (5 mg) as an off-white solid: mp 73–75 °C; ^1H NMR (acetone- d_6 , 500 MHz) δ 2.81 (brs, 1H, OH and H_2O), 3.15 (dd, $J = 14.5$, 8.0 Hz, 1H, ArCH_aH_b), 3.21 (dd, $J = 14.5$, 5.0 Hz, 1H, ArCH_aH_b), 3.99–4.06 (m, 4H, CH_2NCH_2 -), 4.30 (t, $J = 6.0$ Hz, 2H, $\text{ArOCH}_2\text{CH}_2\text{N}$), 4.77 (tt, $J = 47.5$, 5.5 Hz, 2H, $\text{FCH}_2\text{-CH}_2\text{N}$), 4.86 (dd, $J = 8.0$, 5.0 Hz, 1H, ArCH_2CH), 6.86–6.91 (m, 5H), 7.00 (t, $J = 7.5$ Hz, 1H), 7.14 (t, $J = 7.5$ Hz, 1H), 7.21–7.31 (m, 6H); ^{13}C NMR (CDCl_3 , 125 MHz) δ 37.77, 48.79, 49.87 (d, $J = 22$ Hz), 65.53, 77.26, 82.66 (d, $J = 165.0$ Hz, FCH_2), 108.70, 114.24, 115.10, 116.03, 120.35, 121.16, 123.84, 129.34, 130.58, 143.66, 149.08, 157.64; FABMS m/z (%) 465 ($M^+ + 1$, 98), 207 (35), 119 (100), 115 (45); FABHRMS Calcd/Found for $\text{C}_{26}\text{H}_{26}\text{FN}_2\text{O}_5$ ($M + \text{H}^+$) 465.18256/465.18257.

2-(2-Hydroxyamino)benzoxazole (10). To a solution of 2-chlorobenzoxazole (3.30 g, 21.5 mmol) in THF (30 mL) was added 2-hydroxyethylamine (2.70 g, 45.0 mmol) at room temperature. The mixture was stirred for 2 h, poured into water (200 mL), and extracted with EtOAc (50 mL $\times$ 3). The extract was dried over MgSO_4 and evaporated under reduced pressure to give title compound **10** (3.53 g, 92%) as a white solid: mp 156–157 °C; ^1H NMR (methanol- d_4 , 500 MHz) δ 3.45 (t, $J = 6.0$ Hz, 2H), 3.74 (t, $J = 6.0$ Hz, 2H), 6.99–7.25 (m, 4H, ArH); MS (EI) m/z (%) 178 (M^+ , 57), 147 (97), 134 (100).

2-(2-Methanesulfonyloxyamino)benzoxazole (11). To a solution of compound **10** (2.0 g, 11.2 mmol) in pyridine (5 mL) was added methanesulfonyl chloride (1.3 g, 11.3 mmol) through a microsyringe at room temperature. After stirring for 2 h, the mixture was poured into water (30 mL) and extracted with EtOAc (20 mL $\times$ 3). The extract was washed with 0.1 N HCl solution and brine, dried (MgSO_4), and concentrated under reduced pressure. The residue was chromatographed on SiO_2 with ether to give title compound **11** (2.15 g, 86%) as a colorless solid; mp 94–95 °C; ^1H NMR (CDCl_3 , 400 MHz) δ 3.01 (s, 3H), 3.84 (t, $J = 4.8$ Hz, 2H), 4.82 (t, $J = 4.8$ Hz, 2H, $\text{CH}_2\text{-OMs}$), 7.05 (t, $J = 8.0$ Hz, 1H), 7.18 (t, $J = 8.0$ Hz, 1H), 7.26 (d, $J = 8.0$ Hz, 1H), 7.36 (d, $J = 8.0$ Hz, 1H); MS (EI) m/z (%) 256 (M^+ , 34), 177 (32), 160 (47), 147 (100).

4-[2-[(Benzoxazol-2-yl)amino]ethoxy]benzaldehyde (12). To the suspension of NaH (95 mg, 2.38 mmol, 60%) in DMF (15 mL) was added portionwise *p*-hydroxybenzaldehyde (280 mg, 2.28 mmol) at 0 °C. To this solution was added compound **11** (580 mg, 2.27 mmol) at room temperature, and the mixture was heated at 80 °C for 5 h. The solution was poured into water (40 mL), and the solid that deposited was collected by filtration to give the title compound **12** (510 mg, 80%) as a colorless solid; mp 115–116 °C; ^1H NMR (acetone- d_6 , 500 MHz) δ 3.90 (t, $J = 5.5$ Hz, 2H, NHCH_2), 4.41 (t, $J = 5.5$ Hz, 2H, CH_2OAr), 7.00 (t, $J = 7.5$ Hz, 1H), 7.11–7.28 (m, 6H, NH and ArH), 7.86 (d, $J = 9.0$ Hz, 2H), 9.89 (s, 1H, CHO); MS (FAB) m/z (%) 283 ($M^+ + 1$, 100), 118 (77).

Methyl 2-(2-Methanesulfonyloxy)ethoxy-2-diethylphosphonoacetate (13). The mixture of methyl 2-diazo-2-diethylphosphonoacetate (0.5 g, 2.12 mmol), 2-methanesulfonyloxyethyl alcohol (0.59 g, 4.24 mmol), and

rhodium(II) acetate (10 mg, 2.26×10^{-5} mol, 1 mol %) in the solvent mixture of benzene (15 mL) and chloroform (7 mL) was refluxed for 8 h. Evaporation of the solvent, followed by chromatography of the residue on SiO_2 with EtOAc gave the title compound **13** (580 mg, 79%) as a colorless liquid. ^1H NMR (CDCl_3 , 500 MHz) δ 1.30–1.35 (m, 6H, $2 \times (\text{OCH}_2\text{CH}_3)$), 3.10 (s, 3H), 3.82 (s, 3H), 3.83–3.87 (m, 1H, $\text{MsOCH}_2\text{CH}_a\text{H}_b$), 3.94–3.98 (m, 1H, $\text{MsOCH}_2\text{-CH}_a\text{H}_b$), 4.12–4.24 (m, 4H, $2 \times (\text{OCH}_2\text{CH}_3)$), 4.33 (d, $J = 18.5$ Hz, 1H, POCH), 4.42 (t, $J = 4.5$ Hz, 2H, MsOCH_2); ^{13}C NMR (CDCl_3 , 125 MHz) δ 16.35, 16.39 (2C, $2 \times (\text{OCH}_2\text{CH}_3)$), 37.78, 52.82 (1C, OMe), 63.85 (d, 1C, $J = 6.5$ Hz, P(O) (OCH_2CH_3)), 63.95 (d, 1C, $J = 6.5$ Hz, P(O) (OCH_2CH_3)), 68.76, 70.33, 76.44 (d, 1C, $J = 156.5$, POCH), 167.34; MS (FAB) m/z (%) 349 ($M^+ + 1$, 100); FABHRMS Calcd/Found for $\text{C}_{10}\text{H}_{21}\text{PSO}_9$ ($M + \text{H}^+$) 349.0723/349.0722.

Methyl 2-(2-Fluoroethoxy)-2-diethylphosphonoacetate (14). The method described for the preparation of compound **13**, using 2-fluoroethanol in place of 2-mesyloxyethanol, furnished the desired product **14** as a colorless liquid (yield 91%); ^1H NMR (CDCl_3 , 500 MHz) δ 1.30–1.36 (m, 6H, $2 \times (\text{OCH}_2\text{CH}_3)$), 3.83 (s, 3H), 3.79–3.91 (m, 1H, $\text{FCH}_2\text{CH}_a\text{H}_b$), 3.92–4.01 (m, 1H, $\text{FCH}_2\text{-CH}_a\text{H}_b$), 4.19–4.27 (m, 4H, $2 \times (\text{OCH}_2\text{CH}_3)$), 4.45 (d, $J = 19$ Hz, 1H, POCH), 4.51–4.60 (m, 1H, $\text{FCH}_a\text{CH}_b\text{CH}_2$), 4.60–4.70 (m, 1H, $\text{FCH}_a\text{CH}_b\text{CH}_2$); ^{13}C NMR (CDCl_3 , 125 MHz) δ 16.32, 16.37 (2C, $2 \times (\text{OCH}_2\text{CH}_3)$), 52.74 (1C, OMe), 63.90 (d, 1C, $J = 6.5$ Hz, FCH_2CH_2), 71.57 (d, 1C, $J = 12$ Hz, P(O) (OCH_2CH_3)), 71.72 (d, 1C, $J = 12$ Hz, P(O) (OCH_2CH_3)), 77.18 (d, 1C, $J = 156.6$, POCH), 82.82 (d, 1C, $J = 169.4$ Hz, FCH_2), 167.65; MS (FAB) m/z (%) 273 ($M^+ + 1$, 100); FABHRMS Calcd/Found for $\text{C}_9\text{H}_{18}\text{-PO}_6$ ($M + \text{H}^+$) 273.0903/273.0903.

Methyl 2-(2-*tert*-Butyldimethylsilyloxy)ethoxy-2-diethylphosphonoacetate (15). The method described for the preparation of compound **13**, using 2-(*tert*-butyldimethylsilyloxy)ethanol in place of 2-mesyloxyethanol, furnished the desired product **15** as a colorless oil (yield 66%); ^1H NMR (CDCl_3 , 500 MHz) δ 0.05 (s, 6H), 0.89 (s, 9H), 1.32–1.36 (m, 6H, $2 \times (\text{OCH}_2\text{CH}_3)$), 3.61–3.67 (m, 1H, $\text{SiOCH}_a\text{H}_b\text{CH}_2$), 3.72–3.83 (m, 6H, OCH_3 , $\text{SiOCH}_a\text{-H}_b\text{CH}_2$), 4.20–4.24 (m, 4H, $2 \times (\text{OCH}_2\text{CH}_3)$), 4.56 (d, $J = 19$ Hz, 1H, POCH); ^{13}C NMR (CDCl_3 , 125 MHz) δ 16.32, 16.37 (2C, $2 \times (\text{OCH}_2\text{CH}_3)$), 52.74 (1C, OMe), 63.90 (d, 1C, $J = 6.5$ Hz, FCH_2CH_2), 71.57 (d, 1C, $J = 12$ Hz, P(O) (OCH_2CH_3)), 71.72 (d, 1C, $J = 12$ Hz, P(O) (OCH_2CH_3)), 77.18 (d, 1C, $J = 156.6$, POCH), 82.82 (d, 1C, $J = 169.4$ Hz, FCH_2), 167.65; MS (FAB) m/z (%) 273 ($M^+ + 1$, 100); ^{13}C NMR (CDCl_3 , 125 MHz) δ -5.49, -5.42, 16.35, 16.40 (2C, $2 \times (\text{OCH}_2\text{CH}_3)$), 18.24, 25.82, 52.74 (1C, OMe), 62.87 (SiOCH_2), 63.67, 63.73 (2C, P(O) (OCH_2CH_3)), 73.75, 73.84, 77.28 (d, 1C, $J = 155.6$, POCH), 168.06; MS (FAB) m/z (%) 385 ($M^+ + 1$, 100).

2-(2-Benzoxazolylmethylamino)ethanol (16). Reaction of 2-chlorobenzoxazole with *N*-methylethanolamine, according to the method described for the preparation of **10**, furnished the desired product **16** as a colorless solid after recrystallization from EtOAc; mp 61–62 °C (lit. (24) 62–63 °C); yield 86%; ^1H NMR (CDCl_3 , 400 MHz) δ 3.22 (s, 3H, NCH_3), 3.67 (t, $J = 5.5$ Hz, 2H), 3.90 (t, $J = 5.5$ Hz, 2H), 4.25 (brs, 1H, OH), 6.96 (t, $J = 7.5$ Hz, 1H), 7.00 (t, $J = 7.5$ Hz, 1H), 7.23 (d, $J = 7.5$ Hz, 1H), 7.30 (d, $J = 7.5$ Hz, 1H); ^{13}C NMR (CDCl_3 , 125 MHz) δ 36.64, 53.20, 60.55, 108.61, 115.71, 120.35, 123.86, 142.66, 148.65, 163.05; MS (FAB) 193 ($M^+ + 1$, 100) 161 (10).

2-[(*N*-Methyl-2-methanesulfonyloxyethyl)amino]benzoxazole (17). Mesylation, according to the method

described for the preparation of **11**, furnished the desired product as a colorless solid; mp 95–96 °C (lit. (24) 97–98 °C); yield 71%; ^1H NMR (CDCl_3 , 400 MHz) δ 3.00 (s, 3H, NCH_3), 3.31 (s, 3H), 3.91 (t, $J = 5.5$ Hz, 2H), 4.52 (t, $J = 5.5$ Hz, 2H), 7.02 (t, $J = 7.5$ Hz, 1H), 7.18 (t, $J = 7.5$ Hz, 1H), 7.28 (d, $J = 7.5$ Hz, 1H), 7.35 (d, $J = 7.5$ Hz, 1H); MS (FAB) 271 ($\text{M}^+ + 1$, 100) 161 (10), 119 (6).

4-[2-(2-Benzoxazolylmethylamino)ethoxy]-benzaldehyde (18). Reaction of mesylate **17** with *p*-hydroxybenzaldehyde, according to the method described for the preparation of compound **12**, furnished the desired product **18** as a colorless solid (yield 96%); mp 90–91 °C (lit. (24) 96–98 °C); ^1H NMR (CDCl_3 , 500 MHz) δ 3.36 (s, 3H, NCH_3), 3.99 (t, $J = 5.5$ Hz, 2H, NHCH_2), 4.36 (t, $J = 5.5$ Hz, 2H, CH_2OAr), 7.00 (d, $J = 8.5$ Hz, 2H), 7.03 (t, $J = 7.5$ Hz, 1H), 7.16 (t, $J = 7.5$ Hz, 1H), 7.26 (d, $J = 7.5$ Hz, 1H), 7.36 (d, $J = 7.5$ Hz, 1H), 7.83 (d, $J = 8.5$ Hz, 2H), 9.88 (s, 1H, CHO); ^{13}C NMR (CDCl_3 , 125 MHz) δ 37.48, 49.94, 66.47, 108.78, 114.75, 116.20, 120.57, 124.09, 130.31, 132.05, 149.01, 158.20, 162.28, 163.40, 190.76; MS (FAB) m/z (%) 297 ($\text{M}^+ + 1$, 100), 175 (24), 119 (28).

Methyl 3-{4-[2-[Benzoxazol-2-yl-methylamino]ethoxy]phenyl}-2-(2-fluoroethoxy)acrylate (19). (A) The compound **19** was prepared from the reaction of aldehyde **18** and phosphonate **14**, as described in the preparation of compound **5**. The geometric isomers were separated by silica gel column chromatography with a mixture of EtOAc and hexane (1:1.2) as eluent. *Z*-isomer: colorless liquid; yield 58%; ^1H NMR (CDCl_3 , 400 MHz) δ 3.35 (s, 3H), 3.83 (s, 3H), 3.96 (t, $J = 5.2$ Hz, 2H, CH_2N), 4.18 (two pseudotriplets, $J = 30$ Hz, 2H, $\text{FCH}_2\text{CH}_2\text{O}$), 4.29 (t, $J = 5.2$ Hz, 2H, $\text{ArOCH}_2\text{CH}_2\text{N}$), 4.67 (two pseudotriplets, $J = 47.6$ Hz, 2H, $\text{FCH}_2\text{CH}_2\text{O}$), 6.88 (d, $J = 8.8$ Hz, 2H), 7.00 (s, 1H, vinyl H), 7.01 (t, $J = 8.0$ Hz, 1H), 7.14 (t, $J = 8.0$ Hz, 1H), 7.26 (d, $J = 8.0$ Hz, 1H), 7.36 (d, $J = 8.0$ Hz, 1H), 7.75 (d, $J = 8.8$ Hz, 2H); ^{13}C NMR (CDCl_3 , 100 MHz) δ 37.33, 49.87, 52.01, 66.04, 70.42 (d, $J = 19$ Hz, 1C, FCH_2CH_2), 82.41 (d, $J = 169.0$ Hz, FCH_2), 108.60, 114.34, 115.96, 120.32, 123.87, 124.79, 126.08, 132.02, 141.84, 148.79, 158.98, 164.75; FABMS m/z (%) 415 ($\text{M}^+ + 1$, 100), 175 (64); FABHRMS Calcd/Found for $\text{C}_{22}\text{H}_{24}\text{FN}_2\text{O}_5$ ($\text{M} + \text{H}^+$) 414.1671/414.1669.

E-isomer: colorless liquid; yield 34%; ^1H NMR (CDCl_3 , 400 MHz) δ 3.35 (s, 3H), 3.69 (s, 3H), 3.95 (t, $J = 5.6$ Hz, 2H, CH_2N), 4.08 (two pseudotriplets, $J = 27.6$ Hz, 2H, $\text{FCH}_2\text{CH}_2\text{O}$), 4.26 (t, $J = 5.6$ Hz, 2H, $\text{ArOCH}_2\text{CH}_2\text{N}$), 4.72 (two pseudotriplets, $J = 47.2$ Hz, 2H, $\text{FCH}_2\text{CH}_2\text{O}$), 6.21 (s, 1H, vinyl H), 6.82 (d, $J = 8.8$ Hz, 2H), 7.01 (t, $J = 8.0$ Hz, 1H), 7.15 (d, $J = 8.8$ Hz, 2H), 7.16 (t, $J = 8.0$ Hz, 1H), 7.26 (d, $J = 8.0$ Hz, 1H), 7.35 (d, $J = 8.0$ Hz, 1H); FABMS m/z (%) 415 ($\text{M}^+ + 1$, 50), 175 (25), 154 (100); FABHRMS Calcd/Found for $\text{C}_{22}\text{H}_{24}\text{FN}_2\text{O}_5$ ($\text{M} + \text{H}^+$) 414.1671/414.1669.

(B) The title compound **19** was also prepared by the reaction of compound **25** (30 mg, 0.06 mmol) and tetrabutylammonium fluoride (0.07 mL of a 1 M solution in THF) in DMSO (0.5 mL) at 80 °C for 10 min as described in the preparation of compound **9**. The *Z*- and *E*-isomers were obtained in the ratio of 33% and 21%, using the same purification procedure stated in preparation A, above.

3-{4-[2-[Benzoxazol-2-yl-methylamino]ethoxy]phenyl}-2-(2-fluoroethoxy)acrylic Acid (20; 20(*E*) and 20(*Z*)). Hydrolysis of the separated *E* and *Z* isomers of ester **19**, according to the method described for the preparation of compound **9**, with a reaction time of 1 h, gave the *E* and *Z* isomers of acid **20**. *Z*-isomer: mp 154–

155 °C; yield 92%; ^1H NMR (methanol- d_4 , 500 MHz) δ 3.30 (s, 3H), 3.96 (t, $J = 5.0$ Hz, 2H, CH_2N), 4.14 (tt, $J = 30.5$ Hz, 2H, $\text{FCH}_2\text{CH}_2\text{O}$), 4.30 (t, $J = 5.0$ Hz, 2H, $\text{ArOCH}_2\text{CH}_2\text{N}$), 4.63 (tt, $J = 47.6$ Hz, 2H, $\text{FCH}_2\text{CH}_2\text{O}$), 6.90 (d, $J = 9.0$ Hz, 2H), 7.00 (s, 1H, vinyl H), 7.03 (t, $J = 8.0$ Hz, 1H), 7.16 (t, $J = 8.0$ Hz, 1H), 7.27 (d, $J = 8.0$ Hz, 1H), 7.30 (d, $J = 8.0$ Hz, 1H), 7.75 (d, $J = 9.0$ Hz, 2H); ^{13}C NMR (methanol- d_4 , 500 MHz) δ 35.74, 49.37, 65.30, 70.31 (d, $J = 19$ Hz, FCH_2CH_2), 82.39 (d, $J = 168.5$ Hz, FCH_2), 108.53, 114.14, 115.07, 120.57, 123.87, 124.00, 126.41, 131.80, 142.38, 142.48, 148.65, 159.22, 166.17, 166.28; FABMS m/z (%) 401 ($\text{M}^+ + 1$, 100), 175 (50); FABHRMS Calcd/Found for $\text{C}_{21}\text{H}_{22}\text{FN}_2\text{O}_5$ ($\text{M} + \text{H}^+$) 401.1514/401.1513.

E-isomer: mp 128–129 °C; yield 90%; ^1H NMR (methanol- d_4 , 500 MHz) δ 3.29 (s, 3H), 3.94 (t, $J = 5.5$ Hz, 2H, CH_2N), 4.07 (tt, $J = 21.0$ Hz, 2H, $\text{FCH}_2\text{CH}_2\text{O}$), 4.25 (t, $J = 5.5$ Hz, 2H, $\text{ArOCH}_2\text{CH}_2\text{N}$), 4.67 (tt, $J = 47.5$ Hz, 2H, $\text{FCH}_2\text{CH}_2\text{O}$), 6.18 (s, 1H, vinyl H), 6.82 (d, $J = 8.5$ Hz, 2H), 7.03 (t, $J = 8.0$ Hz, 1H), 7.16 (t, $J = 8.0$ Hz, 1H), 7.20 (d, $J = 8.5$ Hz, 1H), 7.27 (d, $J = 8.0$ Hz, 1H), 7.30 (d, $J = 8.0$ Hz, 1H); ^{13}C NMR (methanol- d_4 , 500 MHz) δ 35.74, 49.44, 65.30, 68.22 (d, $J = 20$ Hz, FCH_2CH_2), 81.35 (d, $J = 168.5$ Hz, FCH_2), 108.56, 110.54, 113.75, 115.03, 120.59, 123.89, 127.26, 129.65, 142.29, 146.20, 148.62, 157.70, 162.69, 166.18; FABMS m/z (%) 401 ($\text{M}^+ + 1$, 100), 175 (23), 155 (38), 119 (69); FABHRMS Calcd/Found for $\text{C}_{21}\text{H}_{22}\text{FN}_2\text{O}_5$ ($\text{M} + \text{H}^+$) 401.1514/401.1513.

Methyl 3-{4-[2-[Benzoxazol-2-yl-methylamino]ethoxy]phenyl}-2-(2-fluoroethoxy)propanoate (21). (A) The title compound **21** was prepared by hydrogenation of the isomeric unsaturated esters **19**, as described in the preparation of compound **6**: Colorless liquid; yield ~ 100%; ^1H NMR (CDCl_3 , 500 MHz) δ 2.96 (dd, $J = 14.5$, 8.0 Hz, 1H, ArCH_aH_b), 3.01 (dd, $J = 14.5$, 5.0 Hz, 1H, ArCH_aH_b), 3.35 (s, 3H), 3.58 (double multiplet, $J = 27.5$ Hz, 1H, $\text{FCH}_2\text{CH}_a\text{H}_b$), 3.70 (s, 3H), 3.79 (double multiplet, $J = 27.5$ Hz, 1H, $\text{FCH}_2\text{CH}_a\text{H}_b$), 3.95 (t, $J = 5.0$ Hz, 2H, $\text{ArOCH}_2\text{CH}_2\text{N}$), 4.06 (dd, $J = 8.0$, 5.0 Hz, 1H, ArCH_2CH), 4.24 (t, $J = 5.0$ Hz, 2H, $\text{ArOCH}_2\text{CH}_2\text{N}$), 4.49 (double multiplet, $J = 53$ Hz, 2H, $\text{FCH}_2\text{CH}_2\text{N}$), 6.80 (d, $J = 8.0$ Hz, 2H), 7.01 (t, $J = 7.5$ Hz, 1H), 7.13–7.18 (m, 3H), 7.26 (d, $J = 7.5$ Hz, 1H), 7.36 (d, $J = 7.5$ Hz, 1H); ^{13}C NMR (CDCl_3 , 125 MHz) δ 37.46, 38.33, 50.12, 51.96, 66.17, 69.87 (d, $J = 20$ Hz, FCH_2CH_2), 80.86, 82.93 (d, $J = 169.5$ Hz, FCH_2CH_2), 108.76, 114.28, 116.07, 116.54, 120.47, 124.04, 129.39, 130.49, 144.61, 148.90, 157.32, 172.36; MS (FAB) (%) m/z 417 ($\text{M}^+ + 1$, 45), 154 (100), 136 (62); FABHRMS Calcd/Found for $\text{C}_{22}\text{H}_{26}\text{FN}_2\text{O}_5$ ($\text{M} + \text{H}^+$) 417.1825/417.1825.

(B) This compound was also prepared by the reaction of compound **26** (30 mg, 0.06 mmol) and TBAF (0.07 mL, 1 M THF solution) in DMSO (0.5 mL) at 80 °C for 10 min, followed by chromatography on SiO_2 with ether as eluent, as described in the preparation of compound **5** (12 mg, 48%).

3-{4-[2-[Benzoxazol-2-yl-methylamino]ethoxy]phenyl}-2-(2-fluoroethoxy)propionic Acid (22). Hydrolysis of ester **21**, according to the method described for the preparation of compound **9**, with a reaction time of 30 min, gave the acid **22**: colorless solid; mp 106–107 °C; yield 91%; ^1H NMR (methanol- d_4 , 500 MHz) δ 2.89 (dd, $J = 14.0$, 8.0 Hz, 1H, ArCH_aH_b), 2.99 (dd, $J = 14.0$, 4.5 Hz, 1H, ArCH_aH_b), 3.28 (s, 3H), 3.57 (double multiplet, $J = 28.5$ Hz, 1H, $\text{FCH}_2\text{CH}_a\text{H}_b$), 3.76 (double multiplet, $J = 28.5$ Hz, 1H, $\text{FCH}_2\text{CH}_a\text{H}_b$), 3.93 (t, $J = 5.0$ Hz, 2H, $\text{ArOCH}_2\text{CH}_2\text{N}$), 4.07 (dd, $J = 8.0$, 4.5 Hz, 1H, ArCH_2CH), 4.23 (t, $J = 5.0$ Hz, 2H, $\text{ArOCH}_2\text{CH}_2\text{N}$), 4.43 (double multiplet, $J = 48$ Hz, 2H, $\text{FCH}_2\text{CH}_2\text{N}$), 6.80 (d, $J = 8.0$

Hz, 2H), 7.03 (t, $J = 7.5$ Hz, 1H), 7.13–7.18 (m, 3H), 7.27 (d, $J = 7.5$ Hz, 1H), 7.30 (d, $J = 7.5$ Hz, 1H); ^{13}C NMR (CDCl_3 , 125 MHz) δ 35.74, 37.75, 49.50, 65.29, 69.56 (d, $J = 20$ Hz, FCH_2CH_2), 80.26, 82.55 (d, $J = 167.6$ Hz, $\text{F-CH}_2\text{CH}_2$), 108.55, 113.92, 115.01, 120.58, 123.88, 129.67, 130.21, 142.25, 148.61, 157.37, 166.28, 174.11; MS (FAB) (%) m/z 403 ($\text{M}^+ + 1$, 100), 175 (32) FABHRMS Calcd/Found for $\text{C}_{21}\text{H}_{23}\text{FN}_2\text{O}_5$ ($\text{M} + \text{H}^+$) 403.1669/403.1669.

Methyl 3-{4-[2-[Benzoxazol-2-yl-methylamino]-ethoxy]phenyl}-2-(2-dimethyl-*tert*-butylsilyloxy-ethoxy)propanoate (23). Condensation of aldehyde **18** with phosphonate **15**, according to the method described for the preparation of compound **5**, furnished the desired product **23** as a colorless liquid (yield 90%). ^1H NMR (CDCl_3 , 500 MHz) [Peaks are doubled because of geometric isomerism] δ 0.05, 0.09 (s, combined, 6H), 0.89, 0.90 (s, combined, 9H), 3.34, 3.35 (s, combined, 3H, NCH_3), 3.67, 3.81 (s, combined, 3H), 3.88–4.00 (m, 6H, NCH_2 , $\text{CH}_2\text{CH}_2\text{OSi}$), 4.25, 4.29 (t, $J = 5.0$ Hz, combined, 2H, ArOCH_2), 6.14 (s, 0.4H, *E*-vinyl H), 6.93 (s, 0.6H, *Z*-vinyl H), 6.80–7.78 (m, 8H); MS (FAB) (%) m/z 527 ($\text{M}^+ + 1$, 100), 175 (60), 148 (47).

Methyl 3-{4-[2-[Benzoxazol-2-yl-methylamino]-ethoxy]phenyl}-2-(2-hydroxyethoxy)propanoate (24). The mixture of TBS ether **23** (158 mg, 0.3 mmol) and acetic acid (1.4 mL) in THF–water (2 mL, 2:1, v/v) was stirred for 5 h at 45 °C. CH_2Cl_2 (20 mL) was added to the reaction mixture, which was then washed with sat. NaHCO_3 solution, brine, and water. After drying the extract over MgSO_4 , evaporation gave the title compound **24** (103 mg, 88%) as a colorless liquid. ^1H NMR (CDCl_3 , 500 MHz) [Peaks are doubled because of geometric isomerism] δ 3.34 (s, 3H, NCH_3), 3.67, 3.83 (s, combined, 3H), 3.80–3.83 (m, 1.2H, *Z*-isomer, CH_2OH), 3.90–4.00 (m, 4.8H, NCH_2 , OCH_2 of *E* and *Z*, and CH_2OH of *E*), 4.25, 4.29 (t, $J = 6.5$ Hz, combined, 2H, ArOCH_2), 6.22 (s, 0.4H, *E*-vinyl H), 6.80–7.78 (m, 8.4H, *Z*-vinyl H and ArH); MS (FAB) (%) m/z 413 ($\text{M}^+ + 1$, 100), 175 (59).

Methyl 3-{4-[2-[Benzoxazol-2-yl-methylamino]-ethoxy]phenyl}-2-(2-methanesulfonyloxyethoxy)acrylate (25). (A) Reaction of aldehyde **18** with phosphonate **13**, according to the method described for the preparation of compound **5**, furnished the desired product **25** as a mixture of geometric isomers that was separated by SiO_2 column chromatography with EtOAc as eluent, giving 51% (*Z*-isomer) and 27% (*E*-isomer). *E*-isomer: colorless liquid; ^1H NMR (CDCl_3 , 500 MHz) δ 3.12 (s, 3H), 3.35 (s, 3H, NCH_3), 3.67 (s, 3H, OCH_3), 3.95 (t, $J = 5.5$ Hz, 2H, NCH_2), 4.10–4.12 (m, 2H, $\text{OCH}_2\text{CH}_2\text{OMs}$), 4.26 (t, $J = 5.5$ Hz, 2H), 4.54–4.56 (m, 2H, $\text{OCH}_2\text{CH}_2\text{OMs}$), 6.23 (s, 1H, *E*-vinyl H), 6.82 (d, $J = 8.0$ Hz, 2H), 7.00 (t, $J = 7.5$ Hz, 1H), 7.15 (d, $J = 8.0$ Hz, 2H), 7.16 (t, $J = 7.5$ Hz, 1H), 7.26 (d, $J = 7.5$ Hz, 1H), 7.36 (d, $J = 7.5$ Hz, 1H); ^{13}C NMR (CDCl_3 , 100 MHz) δ 37.45, 37.83, 50.67, 52.67, 52.09, 66.19, 67.08, 67.73, 108.75, 113.92, 114.15, 114.62, 116.11, 120.47, 124.03, 126.50, 130.02, 132.15, 144.82, 148.98, 157.94, 164.21; MS (FAB) (%) m/z 491 ($\text{M}^+ + 1$, 50), 381 (28), 175 (100).

Z-isomer: colorless liquid; ^1H NMR (CDCl_3 , 500 MHz) δ 2.98 (s, 3H), 3.35 (s, 3H, NCH_3), 3.83 (s, 3H, OCH_3), 3.96 (t, $J = 5.5$ Hz, 2H, NCH_2), 4.21–4.22 (m, 2H, $\text{OCH}_2\text{CH}_2\text{OMs}$), 4.30 (t, $J = 5.5$ Hz, 2H, ArOCH_2), 4.48–4.50 (m, 2H, $\text{OCH}_2\text{CH}_2\text{OMs}$), 6.89 (d, $J = 8.5$ Hz, 2H), 7.01 (t, $J = 7.5$ Hz, 1H), 7.01 (s, 1H, *Z*-vinyl H, overlap with ArH of benzoxazole), 7.16 (t, $J = 7.5$ Hz, 2H), 7.26 (d, $J = 7.5$ Hz, 1H), 7.36 (d, $J = 7.5$ Hz, 1H), 7.72 (d, $J = 8.5$ Hz, 1H); ^{13}C NMR (CDCl_3 , 100 MHz) δ 37.45, 37.59, 49.99, 52.23, 66.23, 68.62, 68.95, 108.77, 114.45, 114.62, 116.14, 116.63, 120.48, 124.03, 125.21, 126.00, 132.16, 141.73,

149.00, 159.34, 164.73; MS (FAB) (%) m/z 491 ($\text{M}^+ + 1$, 50), 381 (28), 175 (100).

(B) The title compound was also prepared by the reaction of the isomeric mixture of alcohols **24** (100 mg, 0.26 mmol) and methanesulfonyl chloride (30 mg, 0.26 mmol) in pyridine (2 mL) at room temperature, as described in the preparation of **11** (yield 87%).

Methyl 3-{4-[2-[Benzoxazol-2-yl-methylamino]-ethoxy]phenyl}-2-(2-methanesulfonyloxy-ethoxy)propanoate (26). Hydrogenation of the unsaturated ester **25**, according to the method described for the preparation of compound **6**, furnished the desired product **26** as a colorless liquid (yield ~ 100%); ^1H NMR (CDCl_3 , 500 MHz) δ 2.91 (s, 3H, OSO_2CH_3), 2.91 (dd, 1H, $J = 8.5$, 14.5 Hz, ArCH_aHCH), 3.01 (dd, 1H, $J = 4.5$, 14.5 Hz, ArCHH_bCH), 3.33 (s, 3H, NCH_3), 3.53–3.57 (m, 1H, $\text{OCH}_a\text{HCH}_2\text{OMs}$), 3.70 (s, 3H), 3.80–3.84 (m, 1H, $\text{OCHH}_b\text{CH}_2\text{OMs}$), 3.93 (t, $J = 5.0$ Hz, 2H CH_2N), 4.06 (dd, $J = 4.5$, 8.5 Hz, 1H, ArCH_2CH), 4.22 (t, $J = 5.0$ Hz, 2H, $\text{NCH}_2\text{CH}_2\text{OAr}$), 4.28–4.30 (m, 2H, CH_2OMs), 6.83 (d, $J = 9.0$ Hz, 2H), 7.00 (t, $J = 7.5$ Hz, 1H), 7.10 (d, $J = 9.0$ Hz, 2H), 7.15 (t, $J = 7.5$ Hz, 1H), 7.24 (d, $J = 7.5$ Hz, 1H), 7.34 (d, $J = 7.5$ Hz, 1H); ^{13}C NMR (CDCl_3 , 125 MHz) δ 37.40, 37.52, 38.22, 50.06, 52.03, 66.19, 68.47, 68.96, 80.63, 108.73, 114.36, 116.09, 120.39, 123.98, 129.07, 130.44, 143.38, 149.00, 157.43, 162.44, 172.04; MS (FAB) (%) m/z 493 ($\text{M}^+ + 1$, 100), 175 (99), 148 (47).

Radiochemical Synthesis of Compound [^{18}F]-22.

Proton bombardment of $\text{H}_2[^{18}\text{O}]\text{O}$ yielded no-carrier added [^{18}F]fluoride. Tetrabutylammonium [^{18}F]fluoride ($\text{n-Bu}_4\text{N}[^{18}\text{F}]\text{F}$) was obtained by the addition of [^{18}F]fluoride in $\text{H}_2[^{18}\text{O}]\text{O}$ to 2.6 μL of $\text{n-tetrabutylammonium hydroxide}$ (1 M in H_2O). The water was removed by azeotropic distillation upon three successive additions of acetonitrile while heating at 110 °C under N_2 . With 200 μL of THF, $\text{n-Bu}_4\text{N}[^{18}\text{F}]\text{F}$ was transferred to a reactivial containing 1.5 mg of compound **20**. Typically 80–90% of the activity was transferred. The reactivial was capped and immersed in an 80 °C oil bath for 30 min to effect incorporation. After cooling for 3 min, the reaction mixture was loaded directly onto a Florisil “plug” (Pasteur pipet filled with ca. 100 mg of Florisil above a Kimwipe plug) and eluted (45:55 hexane, 1:19 2-propanol/ CH_2Cl_2 with 0.1% TFA added) into a flask. Activity in the flask, Florisil “plug” and reactivial was counted to determine the yield of fluoride incorporation (typically 65–90%). The [^{18}F]fluorine-substituted methyl ester [^{18}F]-**21** was purified by normal phase semipreparative HPLC (45:55 hexane, 1:19 2-propanol/ CH_2Cl_2 with 0.1% TFA added) on a silica column (Mag 9, 0.9 cm $\times$ 50 cm, Whatman) under isocratic conditions of 5 mL/min. The eluent was monitored by UV (254 nm) and radioactive (NaI/Tl) detection. The filtrate was loaded into the injection loop through a 0.45 μm filter. The filter was washed with an additional 1.0 mL of eluent (stated above) prior to injection. The fractions that corresponded to the fluorine-substituted methyl ester [^{18}F]-**21** were combined, counted, and concentrated under reduced pressure. To this sample of [^{18}F]-**21** was added 100 μL of MeOH and 25 μL of 10% NaOH solution. After heating for 15 min at 80 °C, the solution was acidified with 100 μL of 1 N HCl, extracted with 2 mL of 1:19 hexane/ CH_2Cl_2 (v/v), and passed directly through a MgSO_4 plug (Pasteur pipet with ca. 100 mg MgSO_4 above a Kimwipe plug). The plug was washed with an additional 1 mL of HPLC eluent (35:65 hexane, 1:19 2-propanol/ CH_2Cl_2 with 0.1% TFA added). The filtrate, MgSO_4 plug, and reaction flask were then counted to determine the deprotection yield (typically 80–90%). The filtrate was loaded onto a semipreparative

^a Reagents and conditions: (a) diethanolamine, THF-DMF (3:1), 3 h, rt, 68%; (b) MsCl, pyr, 30 min, 0–5 °C, 48%; (c) NaH, DMF, *p*-hydroxybenzaldehyde, 8 °C, 86%; (d) TMSCl, TEA, THF, rt, 4 h, ~100%; (e) methyl 2-phenoxy-2-diethylphosphonoacetate, NaH, THF, 5 °C, 75%; (f) 10% Pd/C, H₂, MeOH, 99%; (g) MsCl, pyr, 0–5 °C, 71%; (h) TBAF, DMSO, 90 °C, 10 min, 67%; (i) 2 N NaOH, MeOH, rt, 2.5 h, 98%.

HPLC column (as specified above) through a 0.45 μm filter. An additional 1.0 mL of HPLC eluent was washed through the filter prior to injection onto the column. The fractions containing the desired fluoroacid [**¹⁸F]-**22** were combined, counted, concentrated under reduced pressure, and counted again. Typically, the overall radiochemical yield (two reactions and two purifications) was 20–30% decay corrected from n-Bu₄N[**¹⁸F]F. The entire synthesis and purification processes, starting from H₂[**¹⁸O]O, typically required 2.5–3.5 h.******

Tissue Distribution Studies of Compound [¹⁸F]-**22** in Rats and Mice.** All animal experiments were conducted in compliance with the Guidelines for the Care and Use of Research Animals established by Washington University's Animal Studies Committee. Animal doses were prepared by removing HPLC solvent under reduced pressure from collected fractions containing purified [**¹⁸F]-**22**. The radiolabeled compound was then dissolved in absolute EtOH and diluted with isotonic saline to give a 10% EtOH:90% saline solution.****

Anesthetized mature female Sprague-Dawley rats (200–225 g) were injected via the tail vein with either 30 μCi (normal dose) or 5 μCi (low dose) in a volume of 100 μL. The animals receiving a blocking dose were coinjected with 34 μg of unlabeled compound **22** (dissolved in 15% EtOH:85% saline) along with [**¹⁸F]-**22** giving a total injection volume of ca. 200 μL. Animals were sacrificed by decapitation at 1 h after receiving either a normal dose, low dose, or a normal dose with block, while animals sacrificed at 3 h received a low dose with or without block. Blood and tissues were removed, weighed, and counted in a Beckman Gamma 8000 counter. The upper and lower small intestine were voided of their contents, after being removed from the animal, by applying gentle pressure along the length of the tissue with a blunt instrument. Brown fat was removed from between the shoulder blades, while white fat was sampled from alongside the kidneys. Brown fat differs from white fat in appearance having a slightly darker color and a more solid and lumpy consistency.**

In female SCID mice (ca. 4 months, 20 g), 1 × 10⁷ MCF-7 cells (in 100 μL) were implanted bilaterally by subcutaneous injection in the left and right flanks. By

this method, two tumors were grown in each animal. These cells are a human line that is estrogen receptor-positive and require estradiol for growth; therefore, a 1.7 mg/60 day release pellet of estradiol (Innovative Research of America, Sarasota, FL) was inserted into the side of the neck of each animal. After 4 weeks of tumor growth, the biodistribution study of [**¹⁸F]-**22** in the tumor bearing animals was performed. Anesthetized SCID mice were injected via the tail vein with either 32 μCi (normal dose) or 5 μCi (low dose) in a volume of 100 μL. The animals receiving a blocking dose were coinjected with 29 μg of unlabeled compound **22** along with [**¹⁸F]-**22** giving a total injection volume of ca. 200 μL. Animals were sacrificed by decapitation at 1 h after receiving either a normal dose, low dose, or a normal dose with block, while animals sacrificed at 3 h received a low dose. A 3 h block was not included in the study due to a fewer number of tumor bearing animals. Tissue sampling and handling were as stated for the rats, except the gallbladder and tumors were harvested from the mice.****

RESULTS

Chemical Synthesis. Ultimately, labeling of the PPARγ ligands with the positron emitter fluorine-18 is to be done by fluoride ion displacement of a suitable leaving group on a precursor molecule. Therefore, we designed a synthetic route to both of the fluorine-substituted ligands that furnished such a reactive intermediate (**7** and **26**).

Synthesis of 3-[4-[2-[Benzoxazol-2-yl-(2-fluoroethyl)amino]ethoxy]phenyl]-2-phenoxypropionic Acid (9**).** As shown in Scheme 2, compound **7**, the precursor needed for preparation of the ultimate fluorine-substituted product **9**, was synthesized in seven steps from 2-chlorobenzoxazole, using a modification of known methods (17, 24). The reaction of diethanolamine with 2-chlorobenzoxazole gave the tertiary amine diol **1**. The monomethanesulfonate **2** (mesylate) could be prepared quite selectively by two sequential additions of 0.5 equiv of methanesulfonyl chloride. Sulfonate displacement with *p*-hydroxybenzaldehyde, followed by protection of the free hydroxyl group in intermediate **3** as the trimethylsilyl ether, gave the protected aldehyde **4**. A somewhat more

Scheme 3^a

^a Reagents and conditions: (a) ethanolamine, THF, rt, 92%; (b) MsCl, pyr, rt, 2 h, 86%; (c) NaH, DMF, *p*-hydroxybenzaldehyde, 80 °C, 80%; (d) ethylene carbonate, K₂CO₃, DMF, 110 °C, 70%.

Scheme 4

controlled and efficient route to the hydroxyaldehyde **3** is shown in Scheme 3. Continuing in Scheme 2, Horner–Emmons addition of methyl 2-phenoxycarbonylphosphonate to the aldehyde **4** (**23**) and subsequent hydrogenation of enoate **5**, followed by mesylation of hydroxyester **6**, provided the fluorination precursor **7**. This mesylate is relatively unstable and needs to be used soon after its preparation.

The crucial fluoride ion substitution reaction was examined using reagents (tetrabutylammonium fluoride (TBAF) or potassium 2.2.2 Kryptofix) and conditions (90 °C in DMSO or THF) suitable for ¹⁸F labeling (25). The best conditions proved to be TBAF in DMSO at 90 °C, and under these conditions, the displacement reaction, product isolation, and purification steps could be accomplished in ca. 2 h. The product of the fluorine substitution step consisted of the desired fluorinated methyl ester (**8**, 67%), together with small amounts of an undesired byproduct (18%) and unreacted starting material (**7**) (14%). Hydrolysis of methyl ester **8** with methanolic NaOH solution proceeded under mild conditions to give the desired fluorine-substituted phenylpropanoic acid **9** in 98% yield.

Synthesis of 3-{4-[2-[Benzoxazol-2-yl-methylamino]ethoxy]phenyl}-2-(2-fluoroethoxy)propionic Acid (22**).** To synthesize compound **22**, the fluorination precursor to the second PPAR_γ ligand, aldehyde **18** and the matched Horner–Emmons reagents **13**–**15** were prepared, as shown in Schemes 4 and 5, according to literature methods (21–23).

We first obtained an authentic sample of the final product (**22**) by the condensation of aldehyde **18** with the fluoroethylphosphonate **14**, followed by hydrogenation of the enoate **19** and hydrolysis of ester **21** (Scheme 6, right side). However, this approach is not practical for synthesis of the labeled material, because of the short half-life of fluorine-18.

Scheme 5^a

^a Reagents and conditions: (a) *N*-methylhydroxyethylamine, THF, rt, 86%; (b) MsCl, pyr, rt, 71%; (c) NaH, *p*-hydroxybenzaldehyde, DMF, 96%.

The number of steps following the introduction of fluorine could be reduced by using the methanesulfonyloxyethyl analogue **13** in place of the fluoroethylphosphonate **14**, to give the enoate–methanesulfonate **25** (Scheme 6, left side). Alternatively, this compound can be prepared from aldehyde **18** and the TBS-protected phosphonate **15**, through compounds **23** and **24**. All of these unsaturated esters (**19**, **23**–**25**) were mixtures of *E*- and *Z*-isomers that could be separated by chromatography. Hydrogenation of enoate **25** (30 psi) over Pd/C afforded the saturated ester **26**. Fluoride substitution on either the unsaturated methanesulfonates **25** (as separated *E*- and *Z*-isomers) or the saturated methanesulfonate **26** with TBAF in DMSO at 80 °C for 10 min furnished the corresponding fluorine-substituted products **19** and **21** in around ca. 50% yields. The final acids, **20(E)**, **20(Z)**, and **22**, were obtained after mild alkaline hydrolysis.

Binding Affinity Determinations. The binding affinity of four fluorine-substituted ligands (**9**, **20(E)**, **20(Z)**, and **22**) for PPAR_γ, PPAR_α, and PPAR_δ was determined in a competitive radiometric scintillation proximity assay, as previously described (26,27), using receptor preparations consisting of the ligand binding domains of the three PPARs, expressed in *E. coli*. The results are shown in Table 1.

The two alkenes, **20(E)** and **20(Z)**, have low affinity, especially the *Z*-isomer. Of the remaining two, the *O*-fluoroethyl compound **22** is the better, having a *K_i* value of 7 nM for PPAR_γ, 25 nM for PPAR_α, and much lower affinity for PPAR_δ. Because the concentration of receptors used in this assay (5 nM) is rather high with respect to the *K_i* value (7 nM), the *K_d* value is, in fact, considerably lower, possibly as low as 5 nM. By comparison with the *K_d* value of the parent compound SB 213 068 (Scheme 1), one can see that substitution of fluorine on the α-ethoxy group (as in compound **22**) has only a small effect on the binding, which is consistent with established structural and functional tolerance at the α position (17, 18). By contrast, substitution of the *N*-

20(E)	210	830	>10000

^a Determined by competitive binding, as described in refs 26, 27. Values represent the mean of replicate experiments.

methyl group with an *N*-(2-fluoroethyl) group reduces affinity substantially. The effect of alterations in *N*-substitution has not been widely investigated in this series (16, 17), and our result suggests that this site might not be very tolerant of structural changes.

It is of note that compounds **9** and **22** are racemates. On the basis of results in related series (28–30), it is likely that the *S* enantiomers of both compounds are responsible for most of the binding of their racemates to PPAR γ .

Synthesis of PPAR γ Ligand 22 in Fluorine-18 Labeled Form ([¹⁸F]-22). Because of its higher affinity for PPAR γ and its reasonable selectivity with respect to binding to the other two PPAR subtypes, we selected ligand **22** for preparation in fluorine-18 labeled form. The labeling reaction followed the same procedure as did the synthesis of the unlabeled compound, simply with substitution of fluorine-18 at the tracer level for fluorine-19 at the macroscopic level.

Fluorine-18 was generated from an oxygen-18 water target in a ¹⁸O(p,n)¹⁸F reaction and converted to tetrabutylammonium [¹⁸F]fluoride, using methodology described by us previously (25). At the tracer level, fluoride ion substitution on the methanesulfonate precursor **26** proceeded well, with more than 65% incorporation of radioactivity occurring within 30 min at 80 °C. The methyl ester intermediate **21** was purified by HPLC to remove unreacted starting material, OH-substituted byproduct, and a small amount of ester hydrolysis product, and the purified ester (**21**) was then saponified and the product

acid **22** repurified by HPLC. These normal-phase chromatographic purifications were facilitated by the good separation of the desired product ([¹⁸F]-**22**) from the precursors and byproducts. The overall radiochemical yield was 20–30% decay corrected, and the entire synthesis and purification, starting from H₂[¹⁸O]O, took 2.5–3.5 h.

Tissue Distribution Studies on [¹⁸F]-22. We evaluated the tissue distribution of compound [¹⁸F]-**22** in two animal model systems, adult male rats and SCID mice containing human MCF-7 tumor xenografts (Tables 2 and 3). Animals were injected IV with the indicated dose of compound [¹⁸F]-**22** alone, or, in the case of blocking studies, together with an excess of unlabeled compound **22** to block receptor-mediated uptake. In some cases, a lower dose of compound [¹⁸F]-**22** was used to ascertain that uptake was not being limited by receptor saturation. Tissue distribution was determined at the indicated times (1 or 3 h postinjection). On the basis of mRNA expression, the normal tissues having the highest PPAR γ levels are brown and white adipose tissue; significant levels are also found in the spleen and the mucosa of the duodenum (2, 31, 32). MCF-7 cells have significant levels of PPAR γ , so one would expect these receptors to be present in these xenografts (7). If the tissue distribution of this ligand were to be guided by its binding to PPAR γ , one would expect to see selective uptake in these target tissues (or tumor) that is displaceable by coinjection of an excess of the unlabeled ligand.

The distribution of compound [¹⁸F]-**22** in mature male rats (Table 2) shows no evidence of target tissue selective uptake. Very high levels are found in liver and kidney. In the presumed target tissues that we could evaluate, namely white and brown fat and spleen, there is some evidence of blockable uptake, but it is not statistically significant nor different from that of some other tissues (e.g., muscle, heart). Overall uptake at these target sites is also low, with uptake in spleen and white fat being the same as muscle, uptake in brown fat being somewhat higher, but only comparable to that of heart. There is no clear evidence that any of the tissue uptake in the

^a Normal dose is 32 μ Ci/animal, low dose is 5 μ Ci; blocked dose includes 29 μ g unlabeled compound **22**. ^b Number of animals given at head of each column, except where otherwise noted. ^c n = 3. ^d n = 4. ^e The contents of the small intestine were voided.

unblocked experiments is limited by receptor saturation, because none of the uptake values in the 1 h low dose experiment is significantly greater than the 1 h normal dose experiment. We were unable to evaluate the uptake into intestinal mucosa because of the very high levels of radioactivity in the intestinal contents, presumed to be due to hepatobiliary excretion of metabolites derived from compound [¹⁸F]-22.

Tissue distribution studies of compound [¹⁸F]-22 in SCID mice bearing MCF-7 xenografts is given in Table 3. Because mice are smaller animals, all of the uptake values, expressed as % ID/g tissue, are greater in mice than they are in rats. Again, high uptake is seen in liver and kidney, and, as well, in lung. The very high uptake seen in the gall bladder is consistent with the hepatobiliary excretion route of this compound. (Note: because rats do not have a gall bladder, uptake at this site could not be evaluated.) Uptake in normal target tissues (white and brown fat, and spleen) is also low in the SCID mice, again being similar to that in muscle and heart. There is no evidence that the uptake can be blocked with excess unlabeled ligand. Uptake in the tumors is no different than in the target tissues and is neither selective nor blockable.

DISCUSSION

The presence of PPAR γ receptors in certain cancer cell lines and experimental tumor systems, and the utility of PPAR γ ligands in treating some cancers, offers the tantalizing prospect that this receptor might be useful as a target for in vivo tumor imaging using PET with PPAR γ ligands labeled with positron-emitting radionuclides. If successful, the results of such imaging might

be useful in selecting those patients most likely to benefit from PPAR γ -based hormone therapy.

In this initial study, we have synthesized two fluorine-substituted analogues from the phenylpropionic acid class as high affinity ligands for PPAR γ . The particular parent ligand (SB 213068) that we selected for fluorine substitution, compound **22**, appeared to have a good combination of high binding affinity, good in vivo potency, and an adequate rate of clearance to permit the development of good target to nontarget tissue contrast during the lifetime of the radionuclide fluorine-18 ($t_{1/2}$ = 110 min). Both of the fluorine-substituted analogues **9** and **22** retain good affinity for PPAR γ , with the fluoroethoxy analogue **22** having somewhat higher affinity than the *N*-fluoroethyl analogue **9**. It was on the basis of this higher affinity that we chose to prepare compound **22** in fluorine-18 labeled form. The radiolabeling reaction proceeded in a reasonable manner and furnished sufficient material for tissue distribution studies in female rats and in female SCID mice bearing human breast tumor (MCF-7) xenografts. The distribution of activity, however, was not consistent with selective uptake or retention by PPAR γ , by either normal target tissue or tumor, suggesting that higher performing radiopharmaceuticals will be needed to achieve the type of selective uptake required for imaging applications.

PPAR γ ligands with higher affinity than the parent ligand used in this study have been described recently (5, 30, 33, 34). In particular, members of the novel tyrosine-benzophenone class (such as GI 262570) have significantly higher affinity, and they show high potency in vivo. In this respect, these newer ligands would appear to hold new promise as parent systems for the develop-

ment of fluorine-18 labeled PPAR γ -based imaging agents. The use of the high affinity enantiomer should also increase receptor binding affinity (28–30), which might also improve target tissue uptake selectivity. Nevertheless, both the low PPAR γ titer in tumors and the pharmacokinetic behavior of PPAR γ ligands are likely to prove to be limiting in the development of imaging agents for this receptor.

In general, there is a parallelism between the in vivo potency of PPAR γ ligands and their extent of plasma protein binding, which correlates in an inverse fashion with their clearance rates. Members of the highest affinity tyrosine–benzophenone class, in particular, have serum half-lives of several hours, which is thought to contribute to their high in vivo potency. By contrast, long serum half-lives are generally considered unfavorable for the development of good target to nontarget contrast during the lifetime of the radionuclide. For these reasons, we believe that it will be a significant challenge to develop effective radiopharmaceuticals to image PPAR γ .

ACKNOWLEDGMENT

We are grateful for support of this research through a grant from the Department of Energy (DE FG02 86ER60401). We thank Tim Willson and Brad Henke (Glaxo Wellcome) for advice on the design and synthesis of high affinity PPAR γ ligands. Receptor binding studies were performed by Lisa Leesnitzer and Steve Blanchard at Glaxo Wellcome, Research Triangle Park, NC. NMR spectra were obtained in the Varian Oxford Instrument Center for Excellence in NMR Laboratory. Funding for this instrumentation was provided in part from the W.M. Keck Foundation and the National Science Foundation (NSF CHE 96-10502). Mass spectra were obtained on instruments supported by grants from the National Institute of General Medical Sciences (GM 27029), the National Institute of Health (RR 01575), and the National Science Foundation (PCM 8121494).

Incorporation of an Aldehyde Function in Oligonucleotides

Jean-Marc Tilquin, Michel Dechamps, and Etienne Sonveaux*

Laboratoire de Chimie Thérapeutique et de Radiopharmacie, Université Catholique de Louvain, 73, Avenue Emmanuel Mounier, p. b. CMFA 7340, B-1200 Bruxelles, Belgium. Received June 1, 2000; Revised Manuscript Received November 15, 2000

A nucleotide-like phosphoramidite building block that has the nucleic base replaced by the *tert*-butyldimethylsilyl-protected styrene glycol was synthesized. After the automatic synthesis of an oligonucleotide incorporating this synthon, the benzaldehyde function was generated by fluoride deprotection and oxidation by sodium periodate. In a similar manner, an oligonucleotide where a nucleic base was replaced by the $(\text{CH}_2)_8\text{CH}=\text{O}$ chain was synthesized and conjugated with biotin derivatives.

INTRODUCTION

The aldehyde function is often used to couple biopolymers to other molecules by the process of reductive amination. In a typical reaction, this function is condensed with an amino group to form an imine bond, reduced in situ by sodium cyanoborohydride, under slightly acidic conditions (Lane, 1975 and recent examples: Westfall et al., 1998; Maruyama et al., 1998; Bentley et al., 1998; Zhao et al., 1999). A fully irreversible linkage is so obtained. The imine bond itself is quite labile. More stable links are obtained using hydroxylamines, hydrazines, and semicarbazides as nucleophiles. Stable oximes and semicarbazones functions are indeed present in well-established drugs such as cefuroxime and nitrofurantoin. The chemical properties of the aldehyde adducts are such that a tuning of the reversibility of the cross-link is thus possible. This is of prime importance if the in vivo targeting and delivery of a molecule of interest is envisioned.

Modification of oligonucleotides (ODNs) through incorporation of an appropriate molecule such as intercalating agent, nonnatural analogue of nucleic bases, metal chelating agent, fluorescent dye, etc., has been widely used to obtain functionalized ODNs as tools for biological and biophysical studies (Shinozuka et al., 2000 and references therein). The coupling of ODN's to cellular penetration enhancing polymers or peptides is also an important topic in the antisense ODN field (Lemaitre et al., 1987; Bongartz et al., 1994; Soukchareun et al., 1998; Peyrottes et al., 1998; Aubert et al., 2000).

Aldehyde functions were rarely introduced in ODNs. It is surprising, as reductive amination is largely used in protein chemistry and does not interfere with the functions present in DNA. The reason is probably that suitable aldehyde building blocks for automatic ODN synthesis are not currently available (Dechamps and Sonveaux, 1998). Aldehyde functions are randomly generated on DNA by depurination: these are the apurinic sites or, more broadly, the abasic sites. Abasic sites condense with hydroxylamine and methoxyamine to form rather stable adducts (Coombs and Livingston, 1969; Talpaert-Borlé and Liuzzi, 1983; Liuzzi and Talpaert-

Borlé, 1985; Liuzzi et al., 1987; Vasseur et al., 1986). When a ribose residue is introduced at the 3' or 5'-end of an ODN (by a 3'-5' or a 5'-5' linkage, respectively), the sodium periodate oxidation of the glycol function gives a dialdehyde that can be coupled with, for example, polylysine (Agrawal et al., 1986; Lemaitre et al., 1987). The intermediate dialdehyde is, however, prone to β -elimination in basic media (Nadeau et al., 1984). Postsynthetic 3', 5', or internal functionalizations of ODNs by aldehyde functions have also been reported (Kremsky et al., 1987; Urata and Akagi, 1993; Trévisiol et al., 1997). It should, however, be more practical to have at one's disposal aldehyde phosphoramidite building blocks mimicking nucleotides, especially if ODNs bearing multiple aldehyde functions are required. This could allow the polylabeling of ODNs (e.g., Teigelkamp et al., 1993). More specifically, a series of aldehyde functions situated at the end of an antisense ODN could in principle allow attachment of a bouquet of fusogenic peptides to mimic the viral proteins responsible for the cellular penetration of viruses. The influenza virus, for example, needs the concerted action of numerous fusogenic peptides to induce membrane destabilization and fusion (Chernomordik et al., 1998). Devising a method to replace a nucleic acid base by a benzaldehyde motif also opens perspectives in hybridization-triggered cross-linking. Formaldehyde (Chaw and al., 1980; Huang and Hopkins, 1993), acetaldehyde (Matsuda et al., 1998), and glucose (Bucala et al., 1984) react with DNA. Inside a double helix, an aldehyde function placed in the right position on one strand could form an adduct with the exocyclic amino function of cytosine, adenine, or guanine on the other strand (Gao and Orgel, 1999) and could, if the reaction is exoergonic, enhance the stability of the duplex. The testing of these ideas required easy access to aldehyde-oligonucleotides. This paper describes the synthesis of two phosphoramidite building blocks tailored for the construction of such ODNs.

EXPERIMENTAL PROCEDURES

The proportions in solvent and eluent mixtures are expressed as volumic fractions. The NMR spectra were recorded on a 200 MHz instrument, except when otherwise stated. Chemical shifts are given in ppm relative to TMS (^1H , ^{13}C) or phosphoric acid (^{31}P).

3,5-Di-O-*p*-chlorobenzoyl-1,2-dideoxy-1-(4-vinylphenyl)- β (and α)-D-ribofuranose (3a). Commercial 4-bromostyrene is stabilized by sterically hindered catechols. Such contaminants have to be removed in order to allow the formation of the Grignard reagent. 4-Bromostyrene (25 mL) was thus diluted by dichloromethane (75 mL), this solution was washed with 1 M NaOH (3 $\times$), dried (MgSO₄), filtered, and concentrated, and the residue was distilled under vacuum (bp 88 °C, 0.2 mmHg). The so-purified 4-bromostyrene was used immediately.

A solution of 4-bromostyrene (2.56 g, 14 mmol) in dry ether (10 mL) was added dropwise to a suspension of magnesium (0.374 g, 15.4 mmol) in the same solvent (40 mL) (the reaction was started with iodine and a few drops of the halide solution). After 2 h stirring, cadmium chloride (1.608 g, 8.75 mmol, dried at 100 °C for 1 h) was added portionwise. The mixture was further stirred for 1 h at RT. Solid 3,5-di-O-*p*-chlorobenzoyl-1,2-dideoxy-1-chloro-D-ribofuranose **1** was then added (1.5 g, 3.5 mmol, synthesized according to Fox et al., 1961. See also Ness et al., 1961 for the first step of this synthesis). After 40 h, cold water was added, the organic phase was collected, and the aqueous phase was washed with toluene (2 $\times$ 100 mL). The gathered organic extracts were washed with NaHCO₃ (5%) and water (2 $\times$), dried on MgSO₄, filtered, and evaporated under vacuum. The isomers were isolated by flash chromatography on silica (eluent: hexane/ethyl acetate 19:1), giving an amount of pure β epimer (10%), a mixture of β and α (18%) epimers, and an amount of pure, slower eluting α epimer (22%). A major side-product was *p*-chlorobenzoyl furfuryl alcohol, obtained from **1** by two successive β -eliminations.

¹H β epimer (ppm, CDCl₃): 2.2 (1H, H_{2'}, ddd, $J_{gem} = 13.5$ Hz, $J_{2'-1} = 10.8$ Hz, $J_{2'-3} = 6.3$ Hz), 2.55 (1H, H_{2''}, m, $J_{gem} = 13.5$ Hz, $J_{2''-1} = 5.1$ Hz), 4.5 (1H, H₄, m), 4.65 (2H, H₅, m), 5.2 (2H, H₁ and one of the olefinic CH₂'s, m), 5.6 (1H, H₃, m, $J_{3-2'} = 6.3$ Hz), 5.75 (1H, the second olefinic CH₂, d, $J_{vic} = 17.7$ Hz), 6.7 (1H, isolated olefinic CH, dd, $J_{vic1} = 17.7$ Hz, $J_{vic2} = 10.8$ Hz), 7.2–7.5 (8H, phenyl and *p*-chlorobenzoyl, m), 7.95 and 8.0 (4H, *p*-chlorobenzoyl, 2 $\times$ d, $J = 8.5$ Hz).

¹³C β epimer (ppm, CDCl₃): 41.90 (C₂), 65.54 (C₅), 78.12 (C₃), 81.06 (C₁), 83.29 (C₄), 114.54 (olefinic CH₂), 126.50 to 131.56 and 136.89 to 140.59 (11 resolved signals, aromatics and olefinic CH), 165.63 and 165.84 (2 $\times$ C=O).

¹H α epimer (ppm, CDCl₃, 300 MHz NMR): 2.34 (1H, H_{2''}, ddd, $J_{gem} = 14.0$ Hz, $J_{2''-1} = 5.5$ Hz, $J_{2''-3} = 3.5$ Hz), 2.89 (1H, H_{2'}, m, $J_{gem} = 14.0$ Hz, $J_{2'-1} = 7.2$ Hz, $J_{2'-3} = 6.5$ Hz), 4.58 (2H, H₅, m), 4.65 (1H, H₄, m), 5.27 (1H, one of the olefinic CH₂'s, d, $J_{vic} = 10.7$ Hz), 5.38 (1H, H₁, pseudo-t, $J_{1-2'} = 7.2$ Hz, $J_{1-2''} = 5.5$ Hz), 5.58 (1H, H₃, m, $J_{3-4} = 3.1$ Hz, $J_{3-2'} = 6.5$ Hz, $J_{3-2''} = 3.5$ Hz), 5.76 (1H, the second olefinic CH₂'s, d, $J = 17.6$ Hz), 6.73 (1H, isolated olefinic CH, q, $J_{vic1} = 17.6$ Hz, $J_{vic2} = 10.7$ Hz), 7.30–7.45 (8H, phenyl and *p*-chlorobenzoyl, m), 7.64 and 8.01 (4H, *p*-chlorobenzoyl, 2 $\times$ d, $J = 8.5$ Hz).

¹³C α epimer (ppm, CDCl₃): 40.11 (C₂), 64.75 (C₅), 76.69 (C₃), 79.94 (C₁), 81.99 (C₄), 113.99 (olefinic CH₂), 125.66 to 131.11 and 136.40 to 141.85 (13 signals, aromatics and olefinic CH), 165.13 and 165.45 (2 $\times$ C=O).

(2R,3S,5S)-1,3-O-Bis(*p*-chlorobenzoyl)-1,2,3,5-tetrahydroxy-2,5-anhydropentadec-14-ene (3b). This stereoisomer (β epimer) was obtained along the same lines. Yield, 30%. Anal. (C₂₉H₃₄Cl₂O₅) C, H.

Reference Compounds: 3,5-O-Bis(*p*-chlorobenzoyl)-1,2-dideoxy-1-(phenyl)- β (and α)-D-ribofuranose (3c). These compounds were also obtained by the

same procedure, except that the sugar derivative was condensed to the cadmium compound in a hot (40 °C) THF/benzene solution (1:1), distilling ether out of the reaction mixture (1 h). The crude mixture was chromatographed on silica (eluent: ethyl acetate/petroleum ether 1:20), giving a crop of pure α anomer as fast-migrating product, followed by the α/β mixture. The two constituents of this last fraction were separated by thin-layer chromatography, eluting three times consecutively with ethyl acetate/petroleum ether 1:15 ($R_f \alpha = 0.23$; $R_f \beta = 0.20$). Total yield 50% (*O*-*p*-chlorobenzoylfurfuryl alcohol was a major side-product). Yield of the α anomer (mp 232–233 °C): 37%. Yield of the β anomer (mp 227–228 °C): 13%.

The β anomer was also synthesized by a stereospecific method, starting from β -1-phenyl-1-deoxy-D-ribofuranose (Klein et al., 1971), by deoxygenation at position 2 followed by acylation (Robins et al., 1983). The properties of the compound obtained by this stereospecific synthesis were identical to those of the slow-eluting isomer.

500 MHz NMR data:

¹H β epimer (ppm, CDCl₃): 2.23 (1H, H_{2'}, ddd, $J_{gem} = 13.7$ Hz, $J_{2'-1} = 10.9$ Hz, $J_{2'-3} = 6.1$ Hz), 2.55 (1H, H_{2''}, m, $J_{gem} = 13.7$ Hz, $J_{2''-1} = 5.1$ Hz, $J_{2''-3} = 1.0$ Hz) (lit., 100 MHz: Millican et al., 1984: H_{2'} and H_{2''}: 2.05–2.70), 4.53 (1H, H₄, m), 4.66 (2H, H₅, m) (lit., ibidem: H₄ and H₅: 4.50–4.80), 5.26 (1H, H₁, dd, $J_{1-2'} = 10.9$ Hz, $J_{1-2''} = 5.1$ Hz) (lit., ibidem: H₁: 5.51–5.30, $J_{1-2'} = 9$ Hz, $J_{1-2''} = 5$ Hz), 5.60 (1H, H₃, m, $J_{3-4} = 1.5$ Hz, $J_{3-2'} = 6.1$ Hz, $J_{3-2''} = 1.0$ Hz) (lit., ibidem: H₃: 5.5–5.7), 7.24–7.46 (9H, phenyl and *p*-chlorobenzoyl, m), 7.95 and 8.02 (4H, *p*-chlorobenzoyl, 2 $\times$ d, $J = 8.5$ Hz).

¹³C β epimer (ppm, CDCl₃) (DEPT): 42.22 (C₂, t) (lit., ibidem: C₂, 41.6), 65.80 (C₅, t) (lit., ibidem: C₅, 64.9), 78.32 (C₃, d) (lit., ibidem: C₃, 82.8), 81.55 (C₁, d) (lit., ibidem: C₁, 80.8), 83.51 (C₄, d) (lit., ibidem: C₄, 77.4), 126.53 to 131.84 and 140.41 to 141.13 (12 signals, aromatics), 166.01 and 166.26 (C=O, s).

¹H α epimer (ppm, CDCl₃): 2.35 (1H, H_{2''}, ddd, $J_{gem} = 13.7$ Hz, $J_{2''-1} = 5.5$ Hz, $J_{2''-3} = 3.7$ Hz), 2.90 (1H, H_{2'}, m, $J_{gem} = 13.7$ Hz, $J_{2'-1} = 7.0$ Hz, $J_{2'-3} = 6.9$ Hz), 4.58 (2H, H₅, m), 4.67 (1H, H₄, m), 5.38 (1H, H₁, pseudo-t, $J_{1-2'} = 7.0$ Hz, $J_{1-2''} = 5.5$ Hz), 5.58 (1H, H₃, m, $J_{3-4} = 3.2$ Hz, $J_{3-2'} = 6.9$ Hz, $J_{3-2''} = 3.7$ Hz), 7.25–7.41 (9H, phenyl and *p*-chlorobenzoyl, m), 7.64 and 8.01 (4H, *p*-chlorobenzoyl, 2 $\times$ d, $J = 8.5$ Hz).

¹³C α epimer (ppm, CDCl₃) (DEPT): 40.68 (C₂, t), 65.49 (C₅, t), 78.05 (C₃, d), 80.83 (C₁, d), 82.70 (C₄, d), 126.17 to 131.72 and 140.40 to 142.95 (12 signals, aromatics), 165.85 and 166.18 (C=O, s).

3,5-O-Bis(*p*-chlorobenzoyl)-1,2-dideoxy-1-[4-(1,2-dihydroxyethyl)phenyl]- β -D-ribofuranose (4a). Compound **3a β** (1.8 mmol) was dissolved in an dichloromethane/acetone/water mixture (2:9:1, 35 mL) kept at 0 °C. *N*-methylmorpholin *N*-oxide (3 mmol) was added, followed by osmium tetroxide (0.16 mmol, i.e., 2 mL of a 2.5 (weight %) solution in *tert*-butyl alcohol). The mixture was magnetically stirred and the progress of the reaction was followed by TLC. (CH₂Cl₂/CH₃OH, 95:5; **3a**, $R_f = 0.8$, **4**, $R_f = 0.1$). The mixture was evaporated after 8 h and partitioned between water and CH₂Cl₂. The organic phase was dried (MgSO₄), filtered, and evaporated. The compound was purified by column chromatography (eluent, CH₂Cl₂). Yield: 94%. Anal. (C₂₇H₂₄Cl₂O₇) C, H.

¹H NMR (ppm, CDCl₃): 2.2 (1H, H_{2'}, m), 2.5 (1H, H_{2''}, dd, $J_{gem} = 13.5$ Hz, $J_{2''-1} = 5$ Hz), 3.25 (2H, broad band, 2 $\times$ OH), 3.55 (1H, one of the two diastereotopic CH₂-OH's, pseudo-t, $J_{gem} = 10.5$ Hz, $J_{vic} = 7.5$ Hz), 3.7 (1H,

the second of the two diastereotopic CH_2OH 's, dd, $J_{\text{gem}} = 10.5$ Hz, $J_{\text{vic}} = 3$ Hz), 4.5 (1H, H_4 , m), 4.6 (2H, H_5 , m), 4.75 (1H, CHOH , dd, $J_{\text{vic1}} = 7.5$ Hz, $J_{\text{vic2}} = 3$ Hz), 5.2 (1H, H_1 , dd, $J_{1-2'} = 11$ Hz, $J_{1-2''} = 5$ Hz), 5.6 (1H, H_3 , m, $J_{3-2'} = 5.5$ Hz), 7.25–7.5 (8H, phenyl and *p*-chlorobenzoyl, m), 7.95 and 8.0 (4H, *p*-chlorobenzoyl, $2 \times \text{d}$, $J = 9$ Hz).

As a further proof of structure, **4a** (0.18 g, 0.34 mmol) was oxidized by NaIO_4 (2.13 g, 10 mmol, 1.5 h, RT) in THF/phosphate buffer pH 7 (125 mL, 1:4) to give the corresponding aldehyde in quantitative yield. The ^1H NMR of the aldehyde (CDCl_3) featured the lack of the $\text{CH}(\text{OH})\text{CH}_2(\text{OH})$ signals, the appearance of the $\text{CH}=\text{O}$ signal at 10 ppm integrating for 1 proton, and the modification of the aromatic CH absorptions, appearing now as two sets of three doublets (12H, $J = \text{ca. } 9$ Hz) in the 7.3–7.7 and the 7.8–8.1 ppm ranges, respectively.

(2R,3S,5S)-1,3-O-Bis(*p*-chlorobenzoyl)-1,2,3,5,14,15-hexahydroxy-2,5-anhydropentadecane (4b). The oxidation was performed as for **4a**. Yield, 90%. Anal. ($\text{C}_{29}\text{H}_{36}\text{Cl}_2\text{O}_7$) C, H.

5-O-[(4,4'-Dimethoxy)triphenylmethyl]-1,2-dideoxy-1-{4-[1,2-bis(*tert*-butyldimethylsilyloxy)ethyl]phenyl}- β -D-ribofuranose (7a). The reaction was performed under argon under magnetic stirring. The diol **4a** (0.313 g, 0.6 mmol) was dissolved in dry DMF (5 mL), and dried imidazole (0.401 g, 6 mmol) was added, followed by *tert*-butyldimethylsilyl chloride (0.355 g, 2.4 mmol). The progress of the reaction was followed by TLC (eluent CHCl_3 , R_f **4a** = 0.1, R_f **5a** = 0.6). After 48 h, the mixture was partitioned between water (15 mL) and CH_2Cl_2 (15 mL). The organic phase was washed ($3 \times$) with water, dried (MgSO_4), filtered, and evaporated to give the silylated derivative **5a**.

^1H NMR (ppm, CDCl_3): 0.0–0.2 (12H, $\text{Si}(\text{CH}_3)_2$), 0.9–0.95 (18H, $\text{SiC}(\text{CH}_3)_3$), 2.3 (1H, $\text{H}_{2'}$, ddd, $J_{\text{gem}} = 14$ Hz, $J_{2'-1} = 11$ Hz, $J_{2'-3} = 6$ Hz), 2.6 (1H, $\text{H}_{2''}$, dd, $J_{\text{gem}} = 14$ Hz, $J_{2''-1} = 5$ Hz), 3.55 (1H, one of the two diastereotopic CH_2OSi 's, dd, $J_{\text{gem}} = 10$ Hz, $J_{\text{vic}} = 5$ Hz), 3.7 (1H, the second of the two diastereotopic CH_2OSi 's, dd, $J_{\text{gem}} = 10$ Hz, $J_{\text{vic}} = 7$ Hz), 4.6 (1H, H_4 , m), 4.7 (3H, H_5 and CHOSi , m), 5.3 (1H, H_1 , dd, $J_{1-2'} = 11$ Hz, $J_{1-2''} = 5$ Hz), 5.6 (1H, H_3 , m, $J_{3-2'} = 6$ Hz), 7.3–7.6 (8H, phenyl and *p*-chlorobenzoyl, m), 8.0 and 8.1 (4H, *p*-chlorobenzoyl, $2 \times \text{d}$, $J = 9$ Hz).

Compound **5a** (0.405 g) was deacylated by stirring 10 h in a mixture of dichloromethane (5 mL) and hydrazine hydrate (1 mL). The reaction mixture was evaporated, the residue dissolved in ether, and the solution washed with water (3×20 mL). The organic phase was dried (MgSO_4), filtered, and evaporated to leave **6a**.

^1H NMR (ppm, CDCl_3): –0.06, –0.05, –0.04, and 0.05 (12H, diastereotopic $\text{Si}(\text{CH}_3)_2$), 0.85 and 0.87 (18H, $\text{SiC}(\text{CH}_3)_3$), 2.0 (1H, $\text{H}_{2'}$, ddd, $J_{\text{gem}} = 13$ Hz, $J_{2'-1} = 10$ Hz, $J_{2'-3} = 6$ Hz), 2.2 (1H, $\text{H}_{2''}$, ddd, $J_{\text{gem}} = 13$ Hz, $J_{2''-1} = 6$ Hz, $J_{2''-3} = \text{ca. } 2$ Hz), 2.5 (2H, OH, broad signal), 3.4–3.9 (4H, diastereotopic CH_2OSi 's and H_5 , m), 4.0 (1H, H_4 , m), 4.4 (1H, H_3 , m, $J_{3-2'} = 6$ Hz, $J_{3-2''} = J_{3-4} = \text{ca. } 2$ Hz), 4.7 (1H, CHOSi , dd, $J_{\text{vic1}} = 5$ Hz, $J_{\text{vic2}} = 7$ Hz), 5.15 (1H, H_1 , dd, $J_{1-2'} = 10$ Hz, $J_{1-2''} = 6$ Hz), 7.15–7.35 (4H, aromatics, $2 \times \text{d}$, $J_{\text{vic}} = 8.5$ Hz).

Compound **6a** (0.204 g, 0.43 mmol) was coevaporated three times with dry pyridine and then stirred for 3 h with dimethoxytrityl chloride (0.194 g, 0.57 mmol) in pyridine (15 mL). Methanol (15 mL) was added to quench the residual chloride (during 10 min), followed by dichloromethane (15 mL), and the mixture was extracted three times with NaHCO_3 (5%), to eliminate the pyridinium hydrochloride. The organic phase was dried (MgSO_4),

filtered, and evaporated. The residue was chromatographed on silica (eluent $\text{CH}_2\text{Cl}_2/\text{CH}_3\text{OH}$ 98:2 + a few drops of triethylamine). Overall yield: 0.255 g, 0.33 mmol, 55%). Anal. ($\text{C}_{46}\text{H}_{64}\text{O}_7\text{Si}_2$) C, H.

^1H NMR (ppm, CDCl_3): –0.1 to 0.1 (12H, diastereotopic $\text{Si}(\text{CH}_3)_2$), 0.8–0.9 (18H, $\text{SiC}(\text{CH}_3)_3$), 1.9–2.1 (1H, $\text{H}_{2'}$ and OH, m), 2.2 (1H, $\text{H}_{2''}$, ddd, $J_{\text{gem}} = 12.3$ Hz, $J_{2''-1} = 5.4$ Hz, $J_{2''-3} = \text{ca. } 2$ Hz), 3.3 (1H, H_5 , dd, $J_{\text{gem}} = 10$ Hz, $J_{\text{vic}} = 5.4$ Hz), 3.4 (1H, $\text{H}_{5'}$, dd, $J_{\text{gem}} = 10$ Hz, $J_{\text{vic}} = 4.3$ Hz), 3.5 (1H, one of the diastereotopic CH_2OSi , dd, $J_{\text{gem}} = 10$ Hz, $J_{\text{vic}} = 4.8$ Hz), 3.6 (1H, the second diastereotopic CH_2OSi , dd, $J_{\text{gem}} = 10$ Hz, $J_{\text{vic}} = 7$ Hz), 3.8 (6H, OCH_3), 4.0 (1H, H_4 , m), 4.4 (1H, H_3 , m), 4.7 (1H, CHOSi , dd, $J_{\text{vic1}} = 4.8$ Hz, $J_{\text{vic2}} = 7$ Hz), 5.15 (1H, H_1 , dd, $J_{1-2'} = 10$ Hz, $J_{1-2''} = 5.4$ Hz), 6.8 (4H, DMTr, d, $J = 8.5$ Hz), 7.15–7.55 (13H, aromatics).

(2R,3S,5S)-1-O-(4,4'-dimethoxytrityl)-14,15-O-bis-(*tert*-butyldimethylsilyl)-1,2,3,5,14,15-hexahydroxy-2,5-anhydropentadecane (7b). This compound was obtained by the same procedure. Yield, 61%. Anal. ($\text{C}_{48}\text{H}_{76}\text{O}_7\text{Si}_2$) C, H.

3-{5-O-[(4,4'-Dimethoxy)triphenylmethyl]-1,2-dideoxy-1-{4-[1,2-bis(*tert*-butyldimethylsilyloxy)ethyl]phenyl}- β -D-ribofuranosyl}-2-methoxy}(N,N'-diisopropylamino)phosphine (8a). The reaction was performed under argon. Compound **7a** (0.178 g, 0.23 mmol) was coevaporated three times with acetonitrile, dried under high vacuum (2 h), and dissolved in dry CH_2Cl_2 (10 mL) containing diisopropylammonium tetrazolide (0.022 g, 0.13 mmol). Methyl tetraisopropylphosphorodiamidite (0.064 g, 0.24 mmol) was added. The mixture was magnetically stirred for 2 h [control by TLC, hexane/ $\text{N}(\text{CH}_2\text{CH}_3)_3$, 6:1]. Sodium bicarbonate (5%, 10 mL) was added. The organic phase was washed with a phosphate buffer (pH 7, 10 mL) and then with brine (sat., 10 mL), dried (MgSO_4), filtered, and evaporated. The residue was chromatographed on silica [eluent: hexane/ $\text{N}(\text{CH}_2\text{CH}_3)_3$, 6:1, R_f of **8a** = 0.7]. Yield, 60%. ^{31}P NMR, $\delta = 148.536$ and 148.366 ppm. Anal. ($\text{C}_{53}\text{H}_{80}\text{NO}_8\text{PSi}_2$) C, H, N.

^1H NMR (ppm, CDCl_3): –0.1 to 0.1 (12H, diastereotopic $\text{Si}(\text{CH}_3)_2$), 0.8–0.9 (18H, $\text{SiC}(\text{CH}_3)_3$), 1.0–1.3 (12H, $\text{NCH}(\text{CH}_3)_2$, m), 1.9–2.5 (2H, $\text{H}_{2'}$ and $\text{H}_{2''}$, m), 3.2 (2H, H_5 , m), 3.3 and 3.4 (3H, OCH_3 of the two diastereoisomers, $2 \times \text{d}$, $J_{\text{H-P}} = 13$ Hz), 3.6 (4H, CH_2OSi and $\text{NCH}(\text{CH}_3)_2$), 3.8 (6H, OCH_3), 4.2 (1H, H_4 , m), 4.5 (1H, H_3 , m), 4.7 (1H, CHOSi , m), 5.2 (1H, H_1 , m), 6.8 (4H, DMTr, d, $J = 8.5$ Hz), 7.15–7.55 (13H, aromatics).

3-[2R,3S,5S)-1-O-(4,4'-dimethoxytrityl)-14,15-O-bis-(*tert*-butyldimethylsilyl)-1,2,5,14,15-pentahydroxy-2,5-anhydro]pentadecoxy}-2(cyanoethoxy), (N,N'-diisopropylamino)phosphine (8b). The same protocol was used, engaging 0.06 mmol of diisopropylammonium tetrazolide and 0.12 mmol of bis(diisopropylamino)(β -cyanoethoxy)phosphine. Yield, 70%. ^{31}P NMR, $\delta = 148.811$ and 148.641 ppm. Anal. ($\text{C}_{57}\text{H}_{93}\text{N}_2\text{O}_8\text{PSi}_2$) C, H, N.

Synthesis and Purification of Oligonucleotides 9a,b. Building blocks **8a,b** were introduced at the X position in the sequence d(GTCGTGAC-X-GGGAAAAC) by automatic synthesis. The trityl-on oligomer was deprotected by the classical sequence of thiophenol (only for **9a**), concentrated ammonia (50 °C), and tetrabutylammonium fluoride (THF, 0.1 M). The oligomer was then desalted (Pharmacia NAP-10), adsorbed on a C-18 cartridge (Pharmacia Oligo-Pak), and eluted by detritylation (2% aqueous trifluoroacetic acid). A final purification, when needed, was performed by anion-exchange chromatography (Pharmacia Mono Q column), followed by desalting (NAP-10).

Oxidation of 9a,b to 10a,b and Titration by NaBT₄.

The aldehyde function was generated from the vicinal diol according to the protocol of Bayard et al. (1984).

Oligonucleotide **9a** (2.8 nmoles) was oxidized by NaIO₄ (2.5 μ L of 1.6 mM solution in 0.02 M sodium acetate buffer, pH 4.75) at 4 °C for 5 h in the dark. Ethylene glycol was added to destroy the excess NaIO₄. The aldehyde function was then reduced in situ by NaBT₄ (+ 2.5 μ L of 10 mM solution in 0.01 M sodium borate buffer, pH 9). The excess hydride was decomposed by the addition of acetate buffer. The yield of tritium incorporation was determined by passing the sample through two successive NAP-10 cartridges, isolating the high molecular weight fraction and determining both the A₂₆₀ (2.5 nmol of DNA recovered) and the immobilized tritium content (2.37 nmol, by scintillation counting). The tritium incorporation yield was thus 95%. The yield of **10b**, obtained by the same procedure, was quantitative.

Synthesis of 11 and 12. A solution of NaIO₄ (120 mM) in phosphate buffer (20 mM, pH 7) was made. It was degassed by helium (to avoid overoxidation of the aldehyde to be obtained). This solution (1 mL) was added to the glycol-oligonucleotide **9b** (100 OD in 25 μ L). The reaction was stopped after 30 min in the dark at room temperature by desalting on NAP-10. The success of the reaction was checked by reversed phase HPLC [BIORAD Bio-Sil C₁₈ HL 150 $\times$ 4.6 mm column. Linear gradient of eluent B (triethylammonium acetate 0.1 M in CH₃CN: H₂O, 60:40) in eluent A (triethylammonium acetate 0.1 M in CH₃CN:H₂O, 5:95), from 0 to 30% in 25 min. Flow, 1 mL/min]. The retention times were 15.4 and 16.3 min for **9b** and **10b**, respectively. The solution of the aldehyde-oligomer was not kept, but immediately used for the next step.

A solution of biotin hydrazide (Sigma, 10 μ L, 15 mM) and acetate buffer (5 μ L, 500 mM, pH 5) and a solution of sodium cyanoborohydride (5 μ L, 100 mM in acetate buffer) were added to the aldehyde-oligonucleotide **10b** dissolved in water (1.5 mmol in 500 μ L). The mixture was desalted on NAP-10 after 2 h at room temperature. The conjugate **11** was isolated by semipreparative HPLC, under the same conditions as indicated above.

Similarly, a solution of D-biotinyl-1,8-diamino-3,6-dioxaoctane (Boehringer Mannheim, 10 μ L, 15 mM) and phosphate buffer (100 μ L, 20 mM, pH 6.8) and a solution of sodium cyanoborohydride (10 μ L, 5 mM in water) were added to the aldehyde-oligonucleotide **10b** dissolved in water (1.5 nmol in 200 μ L). After 4 h at room temperature, the mixture was diluted by water to 500 μ L and desalted on NAP-5. The conjugate **12** was also isolated by semipreparative HPLC.

A titration of conjugate **12** by avidin was performed. Aliquots of a solution of avidin (Sigma, 5.2 nmol/mL of sites of complexation) were added to solutions of the biotin-oligonucleotide conjugate (66 pmol of oligonucleotide in 200 μ L). Each solution was ultrafiltrated (ULTRAFREE-MC from Millipore, membrane UFC-3-LTK, cutoff 30.000), and the filtrate was checked by HPLC. Oligomer **9b** was used as a not-retained internal standard. The addition of 65 pmol of avidin sites of complexation was necessary to completely retain the biotinylated oligomer on the filter.

RESULTS AND DISCUSSION

Proper Protection of the Aldehyde Function. The conditions of automatic DNA synthesis should arm an

unprotected aldehyde (nucleophilic attack of the P(III) derivatives on the carbonyl, oxidation of the aldehyde by iodine, and possible Cannizzaro reaction in the strongly basic conditions used for full deprotection). A classical acetal protection is not convenient, as it would be cleaved during the detritylation steps. Our strategy was to use a bis-silylated glycol as a precursor of aldehyde. ODNs can be treated with aqueous sodium periodate without degradation, as reported in the Introduction. This reagent selectively oxidizes glycols. A glycol is of course not compatible with the conditions of automatic synthesis. The OHs have to be properly protected. *tert*-Butyldimethylsilyl protection is used to cap the 2'-OH in solid-supported RNA synthesis (Wu and Ogilvie, 1990). A reasonable strategy leading to aldehyde-ODNs was thus to use a phosphoramidite synthon incorporating a *O,O'*-bis(*tert*-butyldimethylsilyl)glycol function.

Synthesis. The synthesis started with the coupling of organocadmium compounds **2a,b** with the highly electrophilic anomeric carbon of the deoxyribofuranosyl chloride **1** (Scheme 1). This type of coupling was pioneered in the hexose field (Hurd and Holysz, 1950) and expanded later in the ribose series (Klein et al., 1971). The yields were, however, low, ca. 20%. We and others have successfully used this method for the synthesis of various C-nucleosides in the deoxyribofuranose series, with, in our hands, yields higher than 80% (François et al., 1994; Chaudhuri and Kool, 1995; Ren et al., 1996; Dechamps and Sonveaux, 1998; Strässler et al., 1999). The coupling is not stereoselective, a mixture of α and β isomers being obtained. The formation of the *p*-styrenylmagnesium bromide, the obligate precursor of the corresponding organocadmium compound **2a**, proved to be impossible if *p*-bromostyrene was not freed from its radical trap stabilizers. The determination of the configuration of **3a,b** needed a detailed study, the Karplus equation being difficult to use (Chaudhuri and Kool, 1995) because of the flexibility of the deoxyribofuranose ring (François et al., 1990). *O,O'*-Dibenzoyl α and β 1-phenyl-1,2-dideoxy-D-ribofuranoses (e.g., **3c**) are known compounds, but their NMR spectra were not reported in sufficient detail (Millican et al., 1984; Gunning et al., 1985). For the sake of recording reference NMR spectra, we thus also obtained by our method the mixture of α -**3c** and β -**3c** and separated them by chromatography, and we synthesized independently β -**3c** by a reported stereospecific procedure (the route used the stereospecific synthesis of β -1-phenyl-1-deoxy-D-ribofuranose, followed by deoxygenation at position 2 and benzylation) (Klein et al., 1971; Robins et al., 1983). The stereoisomers α -**3a,b** and β -**3a,b**, separated by chromatography, were then easily identified by comparison. The synthesis was pursued with pure stereoisomers in order to simplify the analysis of the spectral data. On a practical point of view, if the method is used for labeling purpose only, the synthesis could be pursued on the mixture of epimers. We chose the less abundant β epimer because it corresponds to the configuration of natural nucleotides, a point of importance if hybridization-triggered cross-linking is envisioned. Osmium tetroxide oxidation (Jacobsen et al., 1988), followed by silyl capping, gave the fully protected nucleoside analogues **5a,b**. Selective aminolysis of the ester functions of **5a,b** led to **6a,b**, that were dimethoxytritylated on the primary alcohol function and then phosphitylated. Compounds **8a,b** are building blocks tailored for the automatic phosphoramidite-type DNA synthesis.

Scheme 1

We incorporated **8a,b** at the **X** position in the sequence GTCGTGAC-**X**-GGGAAAAC. The trityl-on oligomer was cleaved from the glass beads by concentrated ammonia, fully deprotected, and purified to homogeneity by anion-exchange chromatography. The oxidation of the glycol by sodium periodate, followed by the titration of the generated aldehyde function by NaBT₄, proved that the yields of these reactions were practically quantitative.

We also synthesized the biotine conjugates **11** and **12**, to demonstrate that the aldehyde function of the oligonucleotides can be coupled with amino compounds by reductive amination. The biotinylated oligomers were quantitatively captured by avidin.

CONCLUSION

We thus described a practical method to introduce an aldehyde function and perform a reductive amination at any position in an ODN. Both 3' and 5' ends of the ODN remain free for further functionalization or ³²P labeling.

The synthesis of the first peptide–oligonucleotide conjugate designed to coordinate chromium(III) is reported. The overall goal of this work is to synthesize di-deoxynucleotides tethered with chromium(III)-coordinating appendages to model chromium–DNA–protein cross-links, which are a type of DNA lesion that may be involved in chromium-induced cancers. The conjugate dGp(NHCH₂CH₂S-Ac-Gly-Ser-Gly-OH)G was made by coupling the peptide, ClAc-Gly-Ser-Gly-OH, and dinucleotide, dGp(NHCH₂CH₂SH)G, through a thioether moiety. The conjugate was characterized by HPLC and mass spectrometry. Previously reported methods for small-scale solid-phase synthesis of peptides and dinucleotide were unsuitable; therefore, gram-scale solution-phase methods were developed. We also report the gram-scale syntheses of two other serine-containing peptides, ClAc-βAla-Ser-Gly-OH and ClAc-Ser-Gly-OH, and three histidine-containing peptides, ClAc-Gly-His-Gly-OH, ClAc-βAla-His-Gly-OH, and ClAc-His-Gly-OH. The synthesis and characterization of chromium-containing peptide–oligonucleotide conjugates will ultimately help us to understand chromium–DNA interactions at a molecular level, which is necessary before we can determine how chromium causes cancer.

INTRODUCTION

Peptide oligonucleotide conjugates have been synthesized for a variety of applications, providing control of cellular uptake and intracellular delivery of oligonucleotides, improvement of DNA or RNA binding, creation and modification of artificial nucleases, and enhancement of nuclease resistance of oligonucleotides (1). We are interested in synthesizing peptide oligonucleotide conjugates to ultimately model chromium–DNA–protein cross-links, which are a type of DNA lesion that may be involved in chromium-induced cancers.

Chromium is a carcinogenic metal that may produce DNA damage by two different pathways: oxidative DNA

damage by high valent chromium intermediates and free radicals, and adduct formation by low valent chromium(III). We are investigating the covalent interaction between Cr(III) and DNA. Amino acid–Cr(III)–DNA adducts and Cr(III)-containing DNA–protein cross-links (Cr-DPC) have been reported in cells (2, 3), animals (4, 5), and humans (6) exposed to Cr(VI) compounds. These Cr-containing DNA lesions are mutagenic (7) and are likely to be involved in Cr-induced cancers because they are more slowly repaired than strand breaks (2).

Although Cr(III)–DNA adducts have been detected and quantitated in bulk DNA from cells and animals, there is still very little information available about their structures. Chromium(III) will associate electrostatically with the phosphate backbone. This noncovalent interaction can be disrupted by EDTA or high NaCl (8). There

Figure 1. Peptide–dinucleotide conjugate.

is growing evidence that Cr(III) also associates with guanine bases *in vitro* (9–15), which is consistent with the preference for guanine coordination shown by platinum (16), cobalt and barium (17), and nickel (18).

The overall goal of this work is to synthesize di-deoxynucleotides tethered with Cr(III)-coordinating appendages to model Cr-DPCs. A tethered Cr(III) will optimize metal DNA interactions by localizing the metal in the coordination environment of the nucleotide and will produce a more stable complex for crystallization and structural characterization. The synthesis of a series of Cr–DNA–peptide conjugates will help us to explain the difference in stabilities between Cr(III) coordination to the nucleotide versus the phosphate backbone. It will also help us to understand the stereochemical and electronic effects of different amino acids when they complete the coordination environment of Cr(III). Characterization of these conjugates will elucidate the mechanisms of Cr(III)-induced mutations. An understanding of chromium–DNA interactions at the molecular level is necessary before we can ultimately determine how chromium causes cancer.

The design of our initial targets is based on current knowledge of Cr–DNA–protein cross-links. The DNA portion contains guanine dinucleotides because of their known ability to bind metals described above. A series of peptide tethers were made, differing in length, with either serine-glycine or histidine-glycine sequences for the Cr(III)-binding region because these were among the amino acids found in Cr-DPC in cultured cells (3, 19, 20). In these first series of conjugates the tether has been attached to the phosphate bridge of the dinucleotide so that the phosphate oxygen will be blocked from association with Cr(III), thus favoring the coordination of Cr(III) to the guanine bases. Future conjugates will contain the tether attached to the 5'-OH group (21) or the base residue such as the N4-position of cytosine (22).

RESULTS AND DISCUSSION

Herein we describe the synthesis of our first peptide–dinucleotide conjugate, dGp(NHCH₂CH₂S-Ac-Gly-Ser-Gly)G (**1**), specifically designed to bind chromium(III) (Figure 1). We anticipate chromium to bind strongly to the C-terminal peptide sequence, -Ser-Gly-OH. This will serve as a tether holding chromium in proximity to the dinucleotide to allow for the isolation and characterization of the complex. Conjugate **1** was made by the Fragment Conjugation method (1), in that the peptide and dinucleotide were synthesized separately and then coupled through the thioether moiety (Scheme 1). While both the functionalized peptide ClAc-Gly-Ser-Gly-OH (**2**) and dinucleotide dGp(NHCH₂CH₂SH)G (**3**) can be synthesized by solid-phase methods, we found this approach to be unsuitable for our needs. To crystallize and char-

Scheme 1. Fragment Conjugation

acterize the chromium complex, we envision that gram quantities of **1** will be necessary, and the high cost and small scale of solid-phase methods made this approach uneconomical. Therefore, our first goal was to develop gram-scale solution-phase methods for the synthesis of the peptide and dinucleotide fragments.

The synthesis of peptide **2** is outlined in Scheme 2. Diisopropylcarbodiimide (DIC) and *N*-hydroxysuccinimide (HOSu) were originally used for the coupling of Cbz-Ser(OtBu)-OH (**4**) to H-Gly-OtBu. However, at multigram scales, the diisopropylurea (DIU) byproduct became problematic. The large amounts of DIU were removed by precipitation from cold CH₂Cl₂ followed by normal-phase column chromatography. However, these methods proved inefficient, and often repeated chromatography was necessary which made this procedure impractical. A superior procedure was found in the mixed anhydride approach. Using isobutyl chloroformate to activate the carboxylic acid moiety of **4**, the reaction with H-Gly-OtBu was clean and efficient. The byproducts, isobutanol and *N*-methylmorpholine (NMM), were easily removed in the workup. Column chromatography was not necessary, and near quantitative yields of dipeptide **5** were obtained. Removal of the benzyloxycarbonyl (Cbz) protecting group by catalytic reduction was straightforward and could be done quantitatively on a multigram scale also without chromatographic purification. These steps were repeated for the subsequent coupling of glycine and chloroacetic acid. The protecting groups were then removed by treatment with TFA, and the final peptide was purified by preparative reversed-phase HPLC.¹ Tetrapeptide **2** was isolated in over 90% yield on a 3-g scale. Two other peptides were made by this method, ClAc-βAla-Ser-Gly-OH (**7**) and ClAc-Ser-Gly-OH (**8**), representing a longer and shorter version of peptide **2**, respectively. These peptides were designed to investigate the ideal tether length between the peptide and dinucleotide binding regions.

The three corresponding histidine peptides, ClAc-Gly-His-Gly-OH (**12**), ClAc-βAla-His-Gly-OH (**13**), and ClAc-His-Gly-OH (**14**), were made by the method outlined in Scheme 3. Due to known problems with imidazole protecting groups (23), we chose to adapt standard solid-

¹ Reversed-phase HPLC: Varian Dynamax C-18 column, 41.4 × 250 mm, 8 μm, 100 Å; solvent A: 0.1% trifluoroacetic acid (TFA) in water; solvent B: 0.1% TFA in 90/10 acetonitrile/water; gradient: 0–30% solvent B over 30 min at 50 mL/min; UV detection at 220 nm.

Scheme 2. Synthesis of ClAc-GlySerGly-OH (2)**Scheme 3. Synthesis of ClAc-GlyHisGly-OH (12)**

phase Fmoc methods for the synthesis of these peptides. Peptide couplings were achieved with the commercially available HBTU reagent (2-(1*H*-benzotriazol-1-yl 1,1,3,3-tetramethyluronium hexafluorophosphate), and the protected peptide intermediates were purified by normal-phase column chromatography. The Fmoc protecting group was removed by treatment with diethylamine (DEA) in THF. The free-amine peptides were separated from the dibenzofulvene byproduct by precipitation from cold hexanes. After the chloroacetylation step, the peptides were deprotected with TFA and purified by prep-HPLC.¹ All three histidine peptides were produced on a 3- to 5-g scale in overall yields ranging from 85 to 92%. In due course, all six peptides will be conjugated to the functionalized dinucleotide **3** to produce a series of peptide–dinucleotide conjugates. These conjugates will then be incubated with chromium(III) to study chromium–DNA binding.

Our synthetic approach to the functionalized dinucleotide fragment **3** was inspired by the solid-phase synthesis reported by Fidanza and McLaughlin (24). In our solution-phase synthesis, both guanine nucleoside pieces **16** and **17** were synthesized from DMT-ibu-deoxyguanosine (**15**) which is commercially available and relatively inexpensive (Scheme 4). Treatment of **15** with PCl_3 and triazole afforded the corresponding H-phosphonate **16**, which was isolated and purified as the triethylammonium bicarbonate salt (25, 26). H-Phosphonate **16** could be made on a 3-g scale and purified by normal-phase column chromatography using a gradient of 0–10%

Scheme 4. Dinucleotide Synthesis

MeOH in CHCl_3 in an overall yield of 85%. Nucleoside **17** was made from **15** by acetylating the 3'-hydroxy group followed by the removal of the 5'-DMT protecting group. Nucleoside **17** was also purified by normal-phase chromatography (0–3% MeOH in CHCl_3) and could be

Scheme 5. Dinucleotide Functionalization

prepared on a gram scale in over 90% yield from **15**. The coupling of **16** and **17** was accomplished with adamantanecarbonyl chloride (AdCOCl) in a mixture of acetonitrile and pyridine. The timing for this reaction is critical due to the reactivity of the acylated phosphonate intermediate. H-Phosphonate **16** is treated with AdCOCl and pyridine under anhydrous conditions for 25 s and is then immediately quenched with an anhydrous solution of **17** in acetonitrile. The bis-acyl phosphite (**27**) and trimetaphosphite (**28**) byproducts from this reaction continue to make the scale-up difficult. Currently, we have been able to produce dinucleotide **18** in 65% yield on a 500 mg scale. This dinucleotide was characterized by mass-spec² and 2D NMR (COSY).

The functionalization of the H-phosphonate moiety in **18** was accomplished through oxidation with CCl₄ in the presence of cystamine (Scheme 5). The terminal amine was subsequently acetylated to facilitate its isolation and purification by normal-phase chromatography (0–3% MeOH in CHCl₃). Compound **19** was isolated in 46% yield on a 500 mg scale, and characterized by mass-spec³ and

² Compound **18** mass-spec: monoisotopic mass $M = 1064.4$, calculated for C₅₁H₅₇N₁₂O₁₄P₂; Found MH⁺ at 1065, MNa⁺ at 1087, and [M – H][–] at 1063.

³ Compound **19** mass-spec: monoisotopic mass $M = 1256.4$, calculated for C₅₇H₆₉N₁₂O₁₅PS₂; Found MH⁺ at 1257, MNa⁺ at 1279, and [M – H][–] at 1255.

⁴ Reversed-phase HPLC: Varian Dynamax C-18 column, 41.4 × 250 mm, 8 μm, 100 Å; solvent A: 50 mM HCO₂NH₄ in water (pH ~ 6); solvent B: 90/10 acetonitrile/solvent A; gradient: 0–20% solvent B over 20 min at 50 mL/min; UV detection at 220 nm.

⁵ Compound **20** mass-spec: monoisotopic mass $M = 730.2$, calculated for C₂₄H₃₅N₁₂O₉PS₂; Found MH⁺ at 731, MNa⁺ at 753, and [M – H][–] at 729.

⁶ Compound **3** mass-spec: monoisotopic mass $M = 655.2$, calculated for C₂₂H₃₀N₁₁O₉PS; Found MH⁺ at 656 and [M – H][–] at 654.

⁷ Reversed-phase HPLC: Varian Dynamax C-18 column, 41.4 × 250 mm, 8 μm, 100 Å; solvent A: 50 mM HCO₂NH₄ in water (pH ~ 6); solvent B: 90/10 acetonitrile/solvent A; gradient: 5–15% solvent B over 40 min at 50 mL/min; UV detection at 220 nm.

⁸ Compound **1** mass-spec: monoisotopic mass $M = 914.2$, calculated for C₃₁H₄₃N₁₄O₁₅PS; Found MNa⁺ at 937 and [M – H][–] at 913.

2D NMR (COSY and ROESY). Removal of the isobutryl and acetyl protecting groups was accomplished on a small scale by heating with concentrated NH₄OH at 45 °C for 2 h. The crude product was then treated with 2.5% Cl₃COOH/CH₂Cl₂ to remove the DMT group and then purified by reverse-phase HPLC⁴ to afford approximately 23 mg of compound **20**.⁵ The disulfide moiety was reduced with dithiothreitol (DTT), and the crude product **3**⁶ was then treated with an excess of peptide **2** at pH ~ 10. Approximately 3 mg of peptide–dinucleotide conjugate **1** was isolated by reverse-phase HPLC⁷ and characterized by mass-spec.⁸

CONCLUSIONS

We have synthesized the first of a series of peptide–dinucleotide conjugates that will be used to study chromium(III)–DNA binding. The isolation and characterization of conjugate **1** validates our synthetic approach. Our continuing efforts are aimed at the gram-scale synthesis of **3** and its corresponding conjugates with peptides **2**, **7**, **8**, **12**, **13**, and **14**. With sufficient quantities of our peptide–dinucleotide conjugates in hand, we will then begin to explore their interaction with Cr(III).

ARTICLES

Syntheses of Curcumin Bioconjugates and Study of Their Antibacterial Activities against β -Lactamase-Producing Microorganisms

Sanjay Kumar, Upma Narain,[†] Snehlata Tripathi, and Krishna Misra*

Nucleic Acids Research Laboratory, Department of Chemistry, University of Allahabad, Allahabad-211 002, India. Received May 9, 2000; Revised Manuscript Received September 18, 2000

In the present study curcumin bioconjugates, viz. di-*O*-glycinoylcurcumin (**I**), di-*O*-glycinoyl-*C*⁴-glycylcurcumin (**II**), 5'-deoxy-5'-curcuminylylthymidine (5'-cur-T) (**IV**), and 2'-deoxy-2'-curcuminylyluridine (2'-cur-U) (**V**) have been synthesized and characterized by elemental analysis and ¹H NMR. The turmeric peptide (Tp) was isolated from the aqueous turmeric extract of the turmeric rhizome. The antibacterial activity of these four bioconjugates and also of the turmeric peptide and sodium salt of curcumin (**III**) have been tested particularly for β -lactamase-producing microorganisms.

INTRODUCTION

Most novel drug-delivery systems have stemmed from work on new polymers, lipid vesicles, cyclodextrins, prodrugs, and viral vectors. The rationale behind systemic drug delivery is to achieve greater efficacy with lower toxicity. Enhancing the specificity of therapeutic drugs and thereby improving their site-specific delivery is the primary goal of today's pharmaceutical industries. The past decade has seen extensive use of liposomes and lipid-based delivery systems to improve the pharmacological properties of a variety of drugs (1–7). The principal benefits afforded by therapeutic agents through their liposomal encapsulation were enhanced plasma circulation lifetimes, increased delivery to specific sites, and changes in tissue distribution, which can result in reduced toxic effects.

Lipid–oligonucleotide complexes can provide levels of encapsulation, but their size and charge severely impair their ability to distribute systemically after parenteral administration and subsequently extravasate to the disease site. As a result, this type of liposomal carrier has a limited utility for the treatment of systemic diseases (8).

Keeping this rationale in mind, a bioconjugate can be synthesized composed of a nucleoside and any suitable molecule which should itself be active against inflammatory disorders, and it must be devoid of any charge. Nucleosides and amino acids rapidly cross the plasma membrane of the cells by a facilitated transport mechanism (9), thus gaining rapid entry into the cells. The curcumin molecule, meeting such requirements, was chosen for this dual purpose. It is the main coloring component of turmeric, the rhizome of the plant *Curcuma*

longa linn. Curcumin (1,7-bis(4-hydroxy-5-methoxyphenyl)-1,6-heptadiene-3,5-dione/diferuloyl methane) has been used for centuries as a traditional medicine for external/internal wounds, liver diseases (particularly jaundice), blood purification, and inflamed joints (rheumatoid arthritis) (10–13). It has been reported to have antioxidant properties (14, 15). Turmeric and curcumin have been shown to inhibit carcinogen-induced mutation in the Ames assay and the formation of tumors in several experimental systems, suggesting antiinitiating and/or antipromoting activity against several chemical carcinogens (16–20). Recently, it has been reported to decrease total cholesterol and LDL cholesterol levels in serum and also to increase the beneficial HDL cholesterol level. Curcumin is reported to inhibit the proliferation of HUVEC (human umbilical vein endothelial cells); therefore, it could turn out to be a useful compound for the development of novel anticancer therapy (21). It has also been claimed that curcumin inhibits HIV-I integrase protein, thus potentially preventing HIV-I from infecting CD-4 and CD-8 cells (22). The other attractive features of curcumin to explore as a vulnerary agent is that, despite being eaten daily for centuries in Asian countries, curcumin has not been reported to be toxic (11).

Curcumin has an interesting structure with two phenolic groups and one active methylene function, which are potential sites for attaching biomolecules. There is not much scope for structural variation in the curcumin molecule in order to enhance its activity, since it is reported that blocking the phenolic groups decreases its antioxidant activity; therefore, phenolic groups appear to be the sites involved in enzymatic activity at receptor sites. The double bonds are essential for proper conformational flexibility of the molecule.

However, its meager absorption through the intestinal wall on oral intake needs to be improved in order to achieve significant concentration inside the cells for appropriate activity. One of the most easily accessible approaches is to make bioconjugates of this molecule by

covalent attachment with ligands to promote entry into the pathogen cell. Since glycine and uridine are essential components of bacterial cell wall, when linked covalently to curcumin they may act as carrier molecules and thereby increase the intracellular delivery of curcumin.

Henceforth, the nucleoside–curcumin bioconjugates and amino acid–curcumin bioconjugates can serve a dual purpose of systemic delivery as well as a therapeutic agent against viral diseases. The size of these molecules as compared to liposomes ($>1\text{--}2\text{ }\mu\text{m}$) is small enough to get thorough passage in pulmonary capillaries, and the approach for improving the uptake involves such a design that would allow enzyme-mediated transformation of the bioconjugate within the target organ. The conjugate bonds reported herein in the case of amino acid–curcumin are exclusively enzyme sensitive to cause a positive systemic delivery. During the present work, a number of such conjugates have been synthesized, e.g., di-*O*-glycinoylcurcumin (**I**), di-*O*-glycinoyl-*C*⁴-glycylcurcumin (**II**), 5'-deoxy-5'-curcuminythymidine (5'-cur-T) (**IV**), and 2'-deoxy-2'-curcuminyluridine (2'-cur-U) (**V**), and tested against a number of Gram-positive and Gram-negative bacteria isolated from clinical specimens.

MATERIALS AND METHODS

All solvents used were thoroughly dried and distilled prior to use. Curcumin, glycine, allyl bromide, and triphenyl phosphite were purchased from Merck-Schuchardt, Germany. Nucleosides were purchased from Sigma Chemical Company, St. Louis, MO. Mueller–Hinton broth, agar, and sterile disks were purchased from Hi Media Laboratory Ltd, Mumbai, India. The water-soluble turmeric peptide (Tp) was purified from aqueous turmeric extract, lyophilized, and stored at $-30\text{ }^{\circ}\text{C}$.

Mueller–Hinton broth and agar have been selected for testing aerobic and facultative anaerobic bacterial isolates for fastidious organisms such as *Streptococci* and *Peptococci*. The agar was supplemented with 5% defibrinated blood. The microsusceptibility tests were standardized at pH 7.4, and agar and broth were incubated in an ambient air incubator at $37\text{ }^{\circ}\text{C}$.

The inoculum was prepared from broth culture that had been incubated for 4–6 h, when growth was considered in the logarithmic phase. Amoxyclave, taken as standard drug, is a combination of amoxicillin and clavulanate.

Experimental Guidelines To Determine Zone of Inhibition by Kirby–Baur's Method (24). 100 mg each of **I**, **II**, **III**, **IV**, **V**, curcumin, and peptide were weighed and dissolved in 10 mL of acetone. From this stock solution, serial dilutions were performed to get 30, 15, 7.5, 3.75, 1.88, and $0.94\text{ }\mu\text{mol/mL}$ with acetone in sterile test tubes. Sterilized filter disks were dipped in these solutions and subsequently dried to remove acetone. Nutrient agar medium plates were prepared using Mueller–Hinton agar and allowed to solidify. Seven different bacterias were selected, viz. *Enterobacter cloacae*, *Peptococcus*, *Staphylococcus epidermidis*, *Staphylococcus saprophyticus*, *Micrococcus cocci*, *Staphylococcus aureus*, and *Streptococcus pyogenes* and 1 mL each of the bacteria's culture broth was added to the plates and spread with the help of a sterile spreader. The filter paper disks soaked in bacterial strain were placed aseptically over the inoculated plates using sterile forceps. The plates were incubated at $37\text{ }^{\circ}\text{C}$ for 18 h in upright position. The zone of inhibition was measured using scale.

Experimental Guidelines To Determine Mic by the Micro Dilution Broth Susceptibility Test. Dif-

ferent concentrations 30, 15, 7.5, 3.75, 1.88, and $0.94\text{ }\mu\text{mol/mL}$ of **I**, **II**, **III**, **IV**, **V**, curcumin, and turmeric peptide were prepared in sterile dry test tubes. Nutrient broth was prepared using Mueller–Hinton broth (M391), and 4.9 mL of it was added to each test tube and then sterilized after plugging. After cooling, 0.1 mL of each of the dilutions was added to the test tubes, and final volume was brought to 5.0 mL. To each of the test tubes was added 0.1 mL of bacterial culture broth. The test tubes were shaken to uniformly mix the inoculum with the broth. The tubes were incubated at $37\text{ }^{\circ}\text{C}$ for 18 h. Appearance of any turbidity shows that the compound is not able to inhibit the growth of bacteria, while no turbidity indicates the inhibition of microorganism by the sample.

1,7-Bis(4-*O*-glycinoyl-3-methoxyphenyl)-1,6-heptadiene-3,5-dione (I**).** Curcumin (368 mg; 1 mmol) was dissolved in dry pyridine, mixed with *N*-phthaloylglycinoyl chloride (536 mg; 2.4 mmol), and stirred at room temperature for 6 h. After the completion of reaction, the reaction mixture was poured into crushed ice and thoroughly extracted with EtOAc. The organic layer was concentrated and treated with ammonia: pyridine (9:1 v/v) for 1 min at room temperature. The organic layer was concentrated and purified by silica gel column chromatography using a DCM:methanol gradient, yield 40% (192 mg). The pure product was characterized by elemental data and ^1H NMR. Anal. Found: C, 62.05; H, 5.56; N, 5.61%. Calcd for $\text{C}_{25}\text{H}_{26}\text{O}_8\text{N}_2$: C, 62.17; H, 5.39; N, 5.80%. ^1H NMR (CDCl_3) δ = 3.70 (s, 6H, OCH_3), 4.13 (s, 2H, $\text{C}_4\text{-H}$), 4.49–4.61 (m, 4H, CH_2NH_2), 6.53 (d, 2H, $\text{C}_2\text{-H}$ and $\text{C}_6\text{-H}$), 6.85–7.08 (m, 6H, Ar-H), 7.53 (d, 2H, $\text{C}_1\text{-H}$ and $\text{C}_7\text{-H}$).

1,7-Bis(4-*O*-glycinoyl-3-methoxyphenyl)-1,6-heptadiene-*C*⁴-glycinoyl-3,5-dione (II**).** Curcumin (368 mg; 1 mmol) was dissolved in EtOH, NaOEt (containing 83 mg of metallic sodium; 3.6 mmol) was added dropwise for 10 min, and the reaction mixture was stirred at room temperature for 30 min. The resulting sodium salt was concentrated under vacuo, thoroughly washed with EtOH, dissolved in dry pyridine, mixed with *N*-phthaloylglycinoyl chloride (804 mg; 3.6 mmol), added to the reaction mixture, and stirred at room temperature for 6 h. After completion of reaction, the reaction mixture was poured into crushed ice and thoroughly extracted with EtOAc. The organic layer was concentrated and treated with ammonia:pyridine (9:1 v/v) for 1 min at room temperature. The reaction mixture was poured into crushed ice and extracted again with EtOAc. The organic layer was concentrated and purified by silica gel column chromatography using a DCM:methanol gradient, yield 38% (205 mg). The pure product was characterized by elemental data and ^1H NMR. Anal. Found: C, 59.88; H, 5.60; N, 7.51%. Calcd for $\text{C}_{27}\text{H}_{29}\text{O}_9\text{N}_3$: C, 60.04; H, 5.48; N, 7.78%. ^1H NMR (CDCl_3) δ = 3.73 (s, 6H, OCH_3), 4.05 (s, 1H, $\text{C}_4\text{-H}$), 4.43–4.79 (m, 6H, CH_2NH_2), 6.58 (d, 2H, $\text{C}_2\text{-H}$ and $\text{C}_6\text{-H}$), 6.81–7.03 (m, 6H, Ar-H), 7.56 (d, 2H, $\text{C}_1\text{-H}$ and $\text{C}_7\text{-H}$).

5'-Deoxy-5'-curcuminythymidine (IV**).** 5'-Deoxy-5'-bromothymidine (305 mg, 1 mmol), synthesized by a procedure developed in our laboratory (23), was dissolved in dry pyridine and mixed with **III** (627 mg, 1.3 mmol). The reaction mixture was stirred at room temperature for 8 h. The product was treated with 2 N alcoholic NaOH at room temperature for 45 min to afford 5'-deoxy-5'-curcuminythymidine by the usual workup procedure as described above, yield 40% (237 mg). The pure product was characterized by elemental data and ^1H NMR. Anal. Found: C, 62.59; H, 5.56; N, 4.54%.

Chart 1. ^1H NMR Assignments for **I**, **II**, **IV**, and **V**

Calcd for $\text{C}_{31}\text{H}_{32}\text{O}_{10}\text{N}_2$: C, 62.77; H, 5.40; N, 4.72%. ^1H NMR (CDCl_3) δ = 2.08 (s, 3H, C_5-CH_3 of **T**); 2.41–2.48, 2.62–2.67 (m, 2H, 2'-H); 3.37–3.41 (m, 1H, C_4-H of **Cur**); 3.59 (s, 6H, OCH_3); 3.91 (m, 2H, 5'-H); 4.06–4.09 (m, 1H, 4'-H); 5.41–5.49 (m, 1H, 3'-H); 6.39–6.43 (m, 1H, 1'-H); 6.51 (d, 2H, C_2-H and C_6-H of **Cur**); 6.79–7.13 (m, 6H, Ar-H); 7.54 (d, 2H, C_1-H and C_7-H); 7.73 (s, 1H, C_6-H of **T**).

2'-Deoxy-2'-curcuminylluridine (V). 2'-Deoxy-2'-chlorouridine (263 mg, 1 mmol), synthesized by the known procedure (22), was dissolved in dry pyridine and mixed with **Ia** (627 mg, 1.3 mmol). The reaction mixture was stirred at room temperature for 8 h. The product was treated with 2 N alic NaOH to get 2'-deoxy-2'-curcuminylluridine by the usual workup procedure as describe above, yield 40% (237 mg). The pure product was characterized by elemental data and ^1H NMR. Anal. Found: C, 60.37; H, 5.19; N, 4.66%. Calcd for $\text{C}_{30}\text{H}_{30}\text{O}_{11}\text{N}_2$: C, 60.55; H, 5.05; N, 4.71%. ^1H NMR (CDCl_3) δ = 2.46–2.59 (m, 1H, 2'-H); 3.34 (d, 1H, C_4-H of **Cur**); 3.62 (s, 6H, OCH_3); 3.69 (d, 2H, 5'-H); 4.11–4.16 (m, 1H, 4'-H); 5.13–5.15 (m, 1H, 3'-H); 5.81 (d, 1H, C_5-H of uridine); 6.34 (d, 1H, 1'-H); 6.59 (d, 2H, C_2-H and C_6-H of **Cur**); 6.98–7.23 (m, 6H, Ar-H); 7.51 (d, 2H, C_1-H and C_7-H of **Cur**); 7.78 (d, 1H, C_6-H of uridine).

RESULTS AND DISCUSSION

Schemes 1 and 2 show the experimental steps involved in the preparation of **I** and **II**, and **IV** and **V**, respectively. In the case of **II**, a strong base, NaOEt, was used whereas in the case of **I**, curcumin itself was treated with *N*-phthaloylglycinoyl chloride (Scheme 1).

5'-Deoxy-5'-curcuminylluridine (5'-cur-T) (**IV**) and 2'-deoxy-2'-curcuminylluridine (2'-cur-U) (**V**) were synthesized by adding 5'-deoxy-5'-bromothymidine and 2'-deoxy-2'-chlorouridine (23) to pyridine mixed with **III** as shown in (Scheme 2).

The antibacterial activity of bioconjugates **I**, **II**, **III**, **IV**, **V**, and **TP** were compared with curcumin from a known microdilution broth susceptibility test method. These were serially diluted (30, 15, 7.50, 3.75, 1.88, 0.94 $\mu\text{mol/mL}$) and added to Mueller–Hinton broth, after which a standardized bacterial suspension was added. One of the disks was kept free of antibiotic and served as growth control, and the other disks were inoculated with a calibrated suspension of microorganism to be tested and incubated at 37 °C for 18 h. The lowest concentration of curcumin bioconjugates in $\mu\text{mol/mL}$ that prevents the in vitro growth of microorganism is represented as MIC (minimum inhibitory concentration) (Table 1) and correlated with the zone of inhibition (Table 2).

Scheme 1

Scheme 2

Each test was performed in triplicate, and the MICs reported represent the result of at least two repetitions. Out of four, three bioconjugates (**I**, **II**, and **V**) show a positive result on multiresistant microorganisms. The

most encouraging result was found against *Streptococcus pyogenes*, with **I** having an MIC of $1.88 \mu\text{mol/mL}$, compared with one of the most widely marketed antibiotics, viz. Amoxycylav, that has an MIC of $7 \mu\text{mol/mL}$ (6

^a **I**: Di-O-glycinoylcurcumin, **II**: di-O-glycinoyl-C⁴-glycylcurcumin, **V**: 2'-deoxy-2'-curcuminylluridine (2'-cur-U), **Cs**: sodium salt of curcumin, **Cur**: curcumin, **T**: turmeric. ^b Zone of inhibition is reported with respect to serial dilution (30, 15, 7.5, 3.75, 1.88, 0.94 $\mu\text{mol/mL}$). ^c R: resistant (below 10 mm).

$\mu\text{mol/mL}$ reported). This shows that **I** is 3.7 times more effective than Amoxycylav.

The result of zone of inhibition is also encouraging, as the disk containing 30 μg of Amoxycylav was purchased and same amount of **I** was loaded on a separate disk. The zone of inhibition of Amoxycylav was found to be 20 mm while **I** showed 28 mm zone of inhibition. The MICs of **II**, **V**, and **III** were found between 4 and 8 $\mu\text{mol/mL}$ in most cases as compared to available antibiotics on the market having an MIC between 6 and 10 $\mu\text{mol/mL}$. **Ip** has a significant result against *Peptococcus*, MIC 3.75 $\mu\text{mol/mL}$. In comparison to the above results, curcumin and turmeric were found to be resistant in most cases except against *Streptococcus pyogenes* where curcumin shows MIC 15 $\mu\text{mol/mL}$. The results with 5'-deoxy-5'-curcuminyllthymidine (**IV**) were far from satisfactory against the selected bacterial strains, which may be due to the fact that thymidine is not a natural component of bacterial genome and hence unable to internalize in the bacterial cell wall (data not shown). The results suggest that amino acids glycine and D-alanine are natural components of the bacterial cell wall, thus the positive results of **I** and **II**, whereas the positive result of **V** is due to uridine, which is an essential component of the bacterial cell wall and thus well recognized by bacteria. However, the amino acid bioconjugates have been found to be bacteriologically more active (approximately two times) than nucleoside bioconjugates, since the former, in addition to being internalized like the latter, are also more water soluble. The hydrophilic nature of these bioconjugates may also help in active transport across cellular membrane. It is therefore anticipated that bioconjugates composed of D-alanine would give the best results. This work is in progress and will be published elsewhere.

CONCLUSION

Conventionally, antibiotics are used to kill bacteria or to halt their division with the intention of preventing replication of the bacterial genome, but overuse of antibiotics in humans and livestock has led to the rapid evolution of bacteria that are resistant to multiple drugs (25), and recently there has been a call for worldwide use

of antibiotic rotation schemes to conquer the problems of resistance (26). β -Lactamase present in bacterial cellular fluid hydrolyzes the amide bond of the β -lactam ring of penicillins and cephalosporins, producing acidic derivatives which have no antibacterial properties, thereby making the bacteria resistant to that particular antibiotic drug.

To develop a new armory of agents active against antibiotic-resistant bacteria, nonconventional antibiotics could be designed that can internalize themselves in the bacterial cell wall easily. The structures should be devoid of the β -lactam ring for better efficacy.

Curcumin, the main molecule studied in this paper, is reported to be capable of expanding the cell membrane in in vivo conditions in eukaryotic cells, inducing echinocytosis (27), and changes in cell shape are accompanied by transient exposure to phosphatidyl serine. Membrane asymmetry was recovered in the presence of aminophospholipid traslocase, which remains active in the presence of curcumin, thereby suggesting that curcumin is able to be transported if covalently attached to a molecule which can easily cross the cell wall both in eukaryotic and in prokaryotic cells. This fact is supported by the studies reported here, by curcumin bioconjugates, where curcumin is conjugated with a biomolecule which is the active part of either the bacterial genome, i.e., uridine (**V**), or of the bacterial cell wall, i.e., amino acids (**I** and **II**) gave excellent results, whereas **IV**, i.e., curcumin conjugated with thymidine, failed to show positive results since thymine is not a natural component of the bacterial genome, thus unable to internalize in the bacterial cell wall.

More such bioconjugates may be designed by keeping one of the components common to either the bacterial cell wall or bacterial genome conjugated with curcumin, thereby improving the efficiency of curcumin comprehensively at low doses, and may prove to be better systemic drugs by concentrating mainly on and around malignant and ill-fated cells by recognizing the bacterial cells. This study proves once again the efficacy of curcumin and its bioconjugates and their antibacterial properties.

The present work suggests that the need for nonantibiotic drugs (28) which may overcome antibiotic resis-

tance may be fulfilled in the near future. A new series of inexpensive and highly bioactive drugs with no toxicity may be in the offing.

Received September 14, 2000; Revised Manuscript Received January 28, 2001

To optimize the preparation of immunoliposomes, we investigated the coupling of thiolated IgG and BSA to liposomes using a novel group of coupling lipids. All lipids consist of cholesterol as membrane anchor and a thiol-reactive maleimide headgroup, linked by a spacer that differs in length and polarity (ethylene glycol, tetraethylene glycol, PEG 400, PEG 1000, dodecyl). In addition, lipids differ in the electrophilicity of the maleimide group (*p*- or *m*-maleimidobenzoic ester). In the case of BSA, coupling efficiency strongly depended on the electrophilicity of the maleimide group as well as on the spacer polarity: The less electrophilic meta constitution seems to be an advantage over the *p*-maleimidobenzoic ester, resulting in higher coupling efficiency. Polar spacers (tetraethylene glycol, 46%) achieved a higher coupling efficiency than a nonpolar spacer with approximately the same length (dodecyl, 15%). When liposomes containing coupling lipids with the spacers tetraethylene glycol, PEG 400, and PEG 1000 were linked to BSA, coupling efficiencies were in a medium range and similar (41–46%) but were lower for the short ethylene glycol spacer (30%). In contrast, for IgG coupling efficiencies correlated with increasing spacer length. Best results were obtained using coupling lipids with a long polar spacer (PEG 1000) (65%), whereas a coupling lipid bearing a short spacer (ethylene glycol) resulted in a low coupling efficiency of 12%.

INTRODUCTION

Encapsulation of chemotherapeutic drugs into liposomes has been shown to be an effective strategy to increase the pharmacological index, i.e., to increase the antitumor activity and to decrease adverse side effects (1–3). When liposomes are used as drug carriers, not only the drugs can be prevented from their rapid degradation but also passive and active targeting can be achieved.

Passive targeting is an accumulation of liposomes in tumors or in inflamed tissues, based on the effect that blood vessels in such tissues are very often leaky, so that liposomes can extravasate (4–6). These particular morphological changes in the vasculature of tumors and inflamed tissues are most probably caused by angiogenesis (7, 8). Passive targeting of liposomes can be enhanced by increasing their half-life in blood, because extravasation is more probable with prolonged circulation in the blood stream. The lifetime of liposomes in the blood stream can be extended by preventing their interactions with serum components (e.g., antibodies or complement factors). The adsorption of serum proteins (opsonization) results in an increased uptake of liposomes by cells of the mononuclear phagocyte system (MPS) (9). This process can be prevented by coating liposomes with long poly(ethylene glycol) (PEG) chains (10–12) or defined glycolipids (13, 14), e.g., monosialo gangliosids (sterical stabilization). Clinical studies with nontargeted sterically stabilized liposomes containing doxorubicin have been reported (15, 16). Meanwhile, liposomal doxorubicin and daunorubicin have been admitted to clinical approach.

In contrast to passive targeting, active targeting of liposomes is based on specific interactions between liposome-bound structures (mostly antibodies or Fab-

fragments, immunoliposomes) and their defined antigens on the cell surfaces, for example, immunoliposomes bearing antibodies against defined structures on human ovarian carcinoma cells, human breast cancer cells, human B-cell lymphoma, and many other targets (17–21). The interaction between immunoliposomes and their target structures depends on liposome half-life. Hence, investigations on sterical stabilization of immunoliposomes have been reported (22–25).

An important prerequisite for the preparation of immunoliposomes for clinical use is a highly reproducible and effective method for liposome–protein coupling, which can easily be performed. Different methods based on noncovalent and covalent protein coupling have been described (23, 26–29). A widespread strategy is the use of coupling lipids containing maleimide groups. This coupling procedure is based on the rapid reaction of proteins bearing thiol groups with the thiol-reactive maleimide moiety, linked to the liposome surface by a lipid anchor.

Maleimide derivatives have been shown to be immunogenic (30, 31). Nevertheless, coupling lipids con-

taining maleimide groups are widely used for immuno-liposome preparation (17, 19, 25, 32). A common method is the use of *N*-[4-(*p*-maleimidophenyl)butyl]phosphatidylethanolamine (MPB-PE), first described by Martin and Papahadjopoulos in 1982 (32). MPB-PE is a coupling lipid consisting of phosphatidylethanolamine as membrane anchor that is linked to a thiol-reactive maleimide group via a short butyryl spacer. Unfortunately, no systematic studies on the influence of variations of the spacer moiety and the thiol-reactive head-group of MPB-PE on coupling efficiency are available.

Recently, we synthesized a group of thiol-reactive coupling lipids based on cholesterol as lipid anchor and bearing different spacer moieties. These lipid derivatives vary in length and polarity of the spacer unit and in electrophilicity of the thiol-reactive maleimide group (33, 34). The aim of this study was to investigate the influence of these structural variations on the coupling efficiency of IgG and BSA to the respective liposomes.

MATERIALS AND METHODS

Materials. Egg-phosphatidylcholine (EPC) was purchased from Lipoid GmbH (Ludwigshafen, Germany). Cholesterol (isolated from lanolin and recrystallized from ethanol), dimethylformamide, and *N*-ethylmaleimide were from Fluka (Buchs, Switzerland). Bovine albumin fraction V (BSA), bovine IgG (reagent grade), 2-iminothiolane HCl (Traut's reagent), *N*-succinimidyl *S*-acetylthioacetate (SATA), 5,5'-dithiobis(2-nitrobenzoic acid) (Ellmans reagent), and hydroxylamine HCl grade I were purchased from Sigma (Deisenhofen, Germany). Chloroform, methanol, diisopropyl ether, 2-propanol, ethyl acetate, phosphoric acid (85%), cupric sulfate, HPTLC plates, and HEPES were obtained from Merck (Darmstadt, Germany). Sephadex G 25 superfine was purchased from Pharmacia (Uppsala, Sweden). The bicinchoninic acid protein assay kit (used with bovine serum albumin and bovine IgG, respectively, as standard) was obtained from Pierce (Rockford, IL).

Thiol-Reacting Coupling Lipids. The thiol-reactive lipids used in this study were prepared as described previously (33): In brief, lipids were synthesized by a linear reaction sequence starting from cholesterol hemisuccinate, obtained from cholesterol and succinic anhydride. Cholesterol hemisuccinate was converted into the respective acid chloride and esterified with a 10-fold excess of the respective α,ω -diol spacer to achieve monoacylation. After separation of the diester byproduct, the desired monoester product was esterified with the *m*- or *p*-maleimidobenzoic acid chloride. Structures and abbreviations of all lipids are shown in Figure 1.

Preparation of Liposomes. Liposomes were composed of EPC/cholesterol/coupling lipid at a molar ratio of 58.8:39.2:2. A mixture of the appropriate amounts of lipids (typically: 120 μ mol of total lipid) was dissolved in chloroform/2-propanol 2:1 (v/v) and evaporated to dryness by rotary evaporation at 40 °C. Afterward, the lipid film was rehydrated in 4 mL of HEPES buffer (20 mM HEPES, 135 mM NaCl, pH 6). The resulting lipid dispersion was extruded sequentially 15 times through polycarbonate membrane filters with a pore diameter of 400 nm and subsequently 15 times through filters with a pore diameter of 100 nm using a Lipofast Extruder (Avestin, Canada). The temperature during extrusion was 40 °C. The liposome dispersion was diluted with HEPES buffer (20 mM HEPES, 135 mM NaCl, pH 6) to a final lipid concentration of 10 mM.

Determination of Liposome Composition by HPTLC. Prior to chromatography, the liposome disper-

sion was diluted with 2-propanol at a ratio of 1:3 (v/v). Standard solutions of the respective coupling lipid dissolved in ethyl acetate were prepared from 0.25 to 1 mM. The HPTLC plates were prerun with a mobile phase of diisopropyl ether/ethyl acetate/methanol/acetic acid (20:10:1:0.2, v/v/v/v). Samples and standard solutions were applied to the HPTLC plates using a Linomat IV (Camag, Berlin). Then the plates were developed in the mobile phase mentioned above. After the plate was dried at 110 °C for 15 min on a heating plate, lipid spots were visualized by staining with cupric sulfate solution (10%, w/v) in phosphoric acid (85%). The HPTLC plate was dipped into the dye solution for 15 s and then dried on the heating plate (5 min at 110 °C and subsequently 10 min at 170 °C). Finally, the lipid spots were quantified using a densitometer (Camag, Berlin) at a wavelength of 420 nm.

Thiolation of Proteins with 2-Iminoethiolane. A 0.05 mM solution of BSA in phosphate buffer (0.1 M NaH₂PO₄, pH 8) was incubated with 2-iminoethiolane at a molar ratio of iminoethiolane/BSA of 15:1 for 60 min at room temperature. For the thiolation of IgG, a 20-fold excess of 2-iminoethiolane was added to a 0.04 mM solution of IgG in phosphate buffer. Unbound 2-iminoethiolane was separated from the protein by gel filtration using a 1 × 10 cm Sephadex G-25 superfine column (Pharmacia, Uppsala, Sweden). The products were eluted with sterile 0.1 M phosphate buffer (pH 8). The thiolated BSA or IgG were immediately used for covalent coupling.

The thiolation grade was measured using 5,5'-dithiobis(2-nitrobenzoic acid) (Ellman's reagent) as described by Benzinger et al. (34). A 20-fold excess of 2-iminoethiolane resulted in two to three thiol groups per IgG. In the case of BSA, the same thiol density was achieved by using a 15-fold excess of 2-iminoethiolane.

Thiolation of IgG with SATA. Just before use, 4 mg of *N*-succinimidyl *S*-acetylthioacetate (SATA) (35) was dissolved in 1 mL of dimethylformamide and added to 1

mL of a 0.04 mM IgG solution in 0.1 M phosphate buffer (pH8) at a SATA/IgG molar ratio of 7:1. A 7-fold excess of SATA was necessary to achieve the desired density of two to three thiol groups per protein. After 20 min of incubation at room temperature, IgG was separated from unreacted SATA by gel filtration with a Sephadex G-25 superfine column in 0.1 M phosphate buffer (pH 8).

Coupling of Proteins to Liposomes. For the covalent attachment of proteins to liposomes, 5 nmol of thiolated BSA or IgG, respectively, was added to 1 mL of freshly prepared 10 mM MCS-liposomes at a maleimide/protein molar ratio of 40:1. The pH was adjusted to 7.6, adding 0.01 N NaOH to the incubation mixture. The coupling reaction was carried out for 12 h at 4 °C under constant and gentle shaking and protection from light. Afterward, the liposomes were separated from unconjugated IgG or BSA, respectively, by ultracentrifugation at 30000g (40 min, 4 °C). The resulting pellet was redispersed in 10 mL of HEPES buffer (20 mM HEPES, 135 mM NaCl, pH 7.4) and ultracentrifuged for a second time (40 min, 30000g, 4 °C). Finally, the pellet was redispersed in 1 mL of HEPES buffer. Liposome dispersions were stored at 4 °C.

If SATA was used as thiolating agent, the IgG bearing the protected thiol groups were added to liposomes containing 2 mol % *m*-MCS-22. Hydroxylamine HCl (0.5 M hydroxylamine HCl, 25 mM EDTA, pH 8, 100 μ L/mL protein solution to be deacetylated) was added, the pH was adjusted to 7.6, and the mixture was incubated for 12 h at 4 °C under constant and gentle shaking. Afterward, the liposomes were separated from unconjugated IgG as described above.

Kinetics of the Coupling Reaction. SATA-thiolated IgG was added to liposomes containing 2 mol % *m*-MCS-22. The procedure was performed as described in the Experimental Section. Afterward, the liposome/protein mixture was divided into 18 samples and incubated at 4 °C. After 0.5, 1, 2, 4, 6, and 12 h, the coupling reaction was stopped by adding a 100-fold excess of *N*-ethylmaleimide to the incubation mixture. The samples were ultracentrifuged in order to separate liposomes from unconjugated protein (see above).

Characterization of Liposomes. The mean liposome size was analyzed by using a Nicomp 370 photon correlation spectroscopy system (Nicomp, St. Barbara, CA). Lipid phosphate was determined by the method of Eibl and Lands (36). For the quantification of protein (IgG or BSA, respectively), coupled to the liposomes, a commercially available BCA-assay (37) was used. Prior to the protein assay, lipids were separated from proteins according to the method of Wessel and Flügge (37). All results are given as coupling efficiency, i.e., the percentage of the added protein linked to liposomes.

RESULTS AND DISCUSSION

Preparation of Immunoliposomes. Just after the extrusion process, the size of the resulting liposomes containing the different coupling lipids were examined by photon correlation spectroscopy. The diameters of the resulting liposomes (as well as the liposomes containing no coupling lipid) were similar (85.8 ± 22.7 nm; all Gaussian distribution). Thus, the incorporation of coupling lipid neither influenced the liposome size considerably nor induced spontaneous aggregation.

Since knowledge of the stability of coupling lipids incorporated into liposomal bilayers is important, we analyzed the liposomal content of *m*-MCS-4 and *p*-MCS-4 by HPTLC after different time points and temperatures

Figure 2. Stability of *m*-MCS-4 and *p*-MCS-4, incorporated into liposomes, at 23 and 4 °C.

Figure 3. Influence of the mesomeric effect on the electrophilicity of *p*- and *m*-maleimido benzoic acid esters.

(4 and 23 °C). Lipid analysis immediately after preparation process proved that the liposomes regularly contained the full concentration of coupling lipid and no destruction of coupling lipid occurred. In contrast, coupling lipids were unstable during storage of the liposomes, especially at room temperature. At 23 °C, 5 days after liposome preparation only 53% of the initial content of *m*-MCS-4 and 24% of the content of *p*-MCS-4 were detected (Figure 2). At 4 °C, the stability of the coupling lipids is much higher: 14 days after liposome preparation nearly the entire content of *m*-MCS-4 (95%) and a high amount of *p*-MCS-4 (80%) were detected (see Figure 2). Thus, to achieve high and reproducible coupling results, the following protein-liposome coupling experiments were performed immediately after liposome preparation (for discussion of the different stability of *p*-MCS-4 and *m*-MCS-4, see the following paragraph).

Influence of the Electrophilicity of the Maleimide Group on Coupling Efficiency. The formation of a thioether linkage between a thiol group on a protein and a thiol-reactive maleimide group of a coupling lipid was expected to be faster and probably more efficient with increasing electrophilicity of the maleimide group. Thus, we compared the coupling efficiencies of two coupling lipids that contain the same spacer (tetraethylene glycol), but differ in the constitution of the maleimido benzoic esters (*m*- or *p*-maleimido benzoic acid esters, *m*-MCS-4 and *p*-MCS-4). The difference in structure of the maleimido benzoic acid esters influences their electrophilicity: *p*-Maleimido benzoic acid esters are more electrophilic than *m*-maleimido benzoic acid esters, caused by a stronger $-M$ (mesomeric) effect of the benzoic ester group on the maleimide group (Figure 3). Interestingly, we found that the less electrophilic (less reactive) coupling lipid *m*-MCS-4 resulted in a higher coupling efficiency ($46 \pm 7\%$) than the more electrophilic *p*-MCS-4 ($30 \pm 5\%$). This might be explained by the increasing susceptibility to (competing) nucleophiles (water) of the maleimide group with higher electrophilicity. This result

corresponds well with the lower stability of *p*-MCS-4 in aqueous environment (see Preparation of Immunoliposomes, above). In the following experiments, we only used the *m*-maleimido benzoic acid ester group as the thiol-reactive moiety because of its higher coupling efficiency.

Influence of Spacer Length and Polarity on Coupling Efficiency. Coupling of thiolated proteins using the commercially available lipid *N*-[4-(*p*-maleimidophenyl)butyryl]phosphatidylethanolamine (MPB-PE) is one of the most common methods to prepare immunoliposomes (32). The coupling lipid MPB-PE is based on phosphatidylethanolamine as lipid anchor, bearing a short nonpolar butyryl spacer. Previous experiments, coupling thiolated IgG with liposomes that consisted of DPPC, cholesterol, and MPB-PE or *m*-MCS-4, respectively, showed better results for *m*-MCS-4 (25%) than for MPB-PE (16%) (data not shown). We assume that a short nonpolar spacer might be disadvantageous for the coupling of thiolated proteins because it is not long enough to present the maleimide group at a sufficient distance from the liposome surface. Furthermore, a nonpolar spacer could interact with the hydrophobic part of the liposome bilayers, thereby reducing the effective distance between maleimide group and liposome surface. Both effects could reduce the accessibility of the thiol-reactive maleimide groups, especially to sterically hindered thiol groups. Considering the structure of the liposomal bilayer, a long and polar spacer (e.g., PEG) might be more suitable to present the thiol-reactive maleimide group at the liposome surface.

Polarity. We studied the influence of the spacer polarity on coupling efficiency by comparing *m*-MCS-4 and *m*-MCS-Do. *m*-MCS-Do (see Figure 1) is an isosteric analogue of *m*-MCS-4 that contains a nonpolar hydrocarbon chain with approximately the same length (C-12) as the tetraethylene glycol spacer of *m*-MCS-4. The use of *m*-MCS-4, containing a polar PEG spacer, resulted in a 3-fold higher coupling efficiency compared to *m*-MCS-Do ($46 \pm 7\%$ vs $15 \pm 5\%$). This striking difference is probably caused by the better accessibility of the thiol-reactive moiety, presented via the polar tetraethylene glycol spacer at the liposome surface. A polar spacer is more likely to penetrate the outer hydrophilic part of the bilayer and to project from the membrane. This result partly explains the different coupling efficiencies using *m*-MCS-4 and MPB-PE (see above).

Spacer Lengths. To evaluate the influence of different spacer lengths, we compared the coupling efficiencies of four lipids with systematic variations in their polar PEG spacer length (*m*-MCS-1, *m*-MCS-4, *m*-MCS-9, *m*-MCS-22).

The coupling of BSA to liposomes containing *m*-MCS-4, *m*-MCS-9, and *m*-MCS-22 resulted in medium and statistically similar coupling efficiencies (41–46%). As expected, the use of *m*-MCS-1 bearing a spacer of only one ethylene glycol unit resulted in a statistically significant lower coupling efficiency (30%) (Figure 4).

Using BSA, we achieved coupling efficiencies of no more than 46%. That means that a high percentage of thiolated BSA molecules are not available for the maleimide groups, although a 40-fold excess of coupling lipid was present in the liposomes. Probably many thiol groups on BSA were not accessible for the following reasons.

(i) Some of the thiol groups might be located in unfavorable positions (e.g., in folds and inaccessible regions of the protein).

(ii) Formation of disulfide bonds may reduce the coupling efficiency: Thiol groups either of the same or different BSA molecules can react with each other,

Figure 4. Influence of spacer length on coupling efficiencies of thiolated BSA to liposomes, containing *m*-MCS-1, *m*-MCS-4, *m*-MCS-9, or *m*-MCS-22.

Figure 5. Influence of spacer length of coupling efficiencies of thiolated IgG to liposomes, containing *m*-MCS-1, *m*-MCS-4, *m*-MCS-9, or *m*-MCS-22.

forming disulfide bonds and thereby reducing the number of free thiol groups.

(iii) There may be still some BSA-proteins that bear just one thiol group (although the mean thiol group density was adjusted “statistically” to two to three thiol groups per protein).

All these factors may reduce the number of free thiol groups presented by the BSA surface and therefore result in lower coupling efficiencies. Our results show that a minimal spacer length of about four ethylene glycol units seems to be decisive for the successful interaction with albumin.

In contrast to BSA, the coupling of IgG to liposomes containing *m*-MCS-1, *m*-MCS-4, *m*-MCS-9, or *m*-MCS-22 is more dependent on spacer length: Experiments using *m*-MCS-1 resulted in a low coupling efficiency (12%). Using the longer coupling lipids *m*-MCS-4 and *m*-MCS-9, we achieved coupling efficiencies in a medium range (*m*-MCS-4: 29%, *m*-MCS-9: 21%). The best results could be achieved by using liposomes containing *m*-MCS-22 (65%) (Figure 5).

The different profiles of BSA and IgG coupling can be explained by the different shapes of albumin and IgG. IgG are Y-shaped proteins, consisting of two heavy chains and two light chains, forming a complicated bulky three-dimensional structure. Probably many thiol groups, introduced to IgG, are hardly available for coupling because they are located in inaccessible regions of the antibody. Therefore, the long distances between the thiol group and the liposome surface that are fixed by the shape and the surface structure of IgG result in lower coupling efficiencies of lipids with short spacers. Only coupling lipids bearing long polar spacers such as PEG

Figure 6. Kinetics of the coupling reaction of SATA-thiolated IgG and liposomes, containing *m*-MCS-22.

1000 (*m*-MCS-22) are able to reach these hidden thiol groups.

The coupling efficiency of *m*-MCS-1 was higher for albumin than for IgG (12% vs 30%), whereas coupling lipids with spacers longer than one ethylene glycol unit resulted in similar coupling efficiencies (41–46%). This may be due to the fact that BSA, unlike IgG, is a more globular protein. Hence, thiol groups on the protein surface are easier to access and also short polar spacers may be able to reach these thiol groups.

In the case of *m*-MCS-22, coupling efficiency of albumin was lower than IgG (BSA 42% vs IgG 65%). This seems to be contradictory to the fact mentioned above but might be caused by the formation of disulfide bonds by BSA. This may result in the formation of dimers because thiol groups at the surface of BSA are well accessible. This effect is less probable for IgG because of the bulky Y-shaped structure of antibodies.

Thiolation Using SATA. The thiolating agent, so far used for all previous experiments, was 2-iminothiolane (Traut's reagent). Iminothiolane introduces thiol groups by reaction with the amino group of lysine, present in the proteins. The use of 2-iminothiolane is a cheap and easy method for protein thiolation; unfortunately, the thiol group of iminothiolane is unprotected, and therefore, the thiolated protein has to be used immediately for coupling.

To improve the coupling process, we used *N*-succinimidyl *S*-acetylthioacetate (SATA) as thiolating agent. SATA introduces thiol groups into proteins by a two-step reaction. Like iminothiolane, SATA reacts with the amino group of lysine and introduces acetylated thiol groups into the protein. In a second step prior to protein coupling the thiol groups have to be deacetylated under mild conditions by adding hydroxylamine. Under appropriate conditions, the intermediate acetylated thio-proteins can be stored for at least 1 month without loss of thiol groups (35).

We prepared immunoliposomes by coupling SATA-thiolated IgG with liposomes, containing 2% *m*-MCS-22. Apart from the method of thiolation, all steps were identical with the previous experiments. The coupling of IgG to *m*-MCS-22 liposomes using SATA resulted in a high coupling efficiency ($72 \pm 13\%$), which is statistically identical with the results achieved by 2-iminothiolane ($65 \pm 12\%$).

Kinetics of the Coupling Reaction. The thiol-reactive lipid bearing the longest PEG spacer (*m*-MCS-22) proved to be the best agent for IgG coupling. To optimize the protocol of immunoliposome preparation, the kinetic parameters of the coupling reaction of IgG to *m*-MCS-22 liposomes were determined.

The coupling of IgG to liposomes containing *m*-MCS-22 was characterized by a rapid increase of liposome bound proteins within the first 2 h, reaching a plateau between 2 and 4 h. There was no further change of coupling efficiency within the next 8 h (Figure 6). The kinetics show that the reaction of IgG with liposomes, containing *m*-MCS-22, is almost completed after 4 h; a longer incubation time does not enhance coupling efficiency. Hence, the duration of the coupling reaction can be drastically reduced from 12 h (standard protocol) to approximately 4 h, which is more convenient.

CONCLUSIONS

The coupling of a sufficient number of antibodies to liposomes in an effective and reproducible way is an important prerequisite for immunoliposome preparation. Therefore, we recently synthesized novel group of thiol-reactive lipids (33, 34) in order to optimize the preparation of immunoliposomes. These coupling lipids differ in length and polarity of the spacer moiety and in electrophilicity of the thiol-reactive maleimide group. The new coupling lipids can be used for effective coupling of IgG and BSA to the liposome surface. Spacer polarity, spacer length, and electrophilicity of the maleimide group are important determinants for the coupling process: Polar spacers achieved a higher coupling efficiency than non-polar spacers. The less electrophilic meta constitution of the maleimide group (*m*-MCS-4) seems to be in advantage over the more electrophilic para conformation (*p*-MCS-4), resulting in increased stability as well as higher coupling efficiencies. Interestingly the optimal PEG-spacer length for a high coupling efficiency depends on the proteins which are coupled to the liposomes. The best coupling efficiency for IgG was achieved by using *m*-MCS-22 (65%), a lipid bearing a long hydrophilic spacer moiety (PEG 1000). Moreover, the use of long polar spacers might be essential with regard to the preparation of sterically stabilized immunoliposomes (22–25). Studies on optimization of the coupling process demonstrated, that the thiolation of proteins using SATA or iminothiolane resulted in identical coupling efficiencies and that the reaction was completed after 2–4 h.

The novel coupling lipids used for these experiments were based on cholesterol as lipid anchor, but the findings might also be applied to future coupling lipids: Such lipids might be based on phosphatidylethanolamine or diacylglycerol as lipid anchor or may contain a less immunogenic thiol-reactive moiety, e.g., succinimidyl 6-(*N*-maleimido)-*n*-hexanoate (30). These novel thiol-reactive lipids may further help to optimize the design of immunoliposomes and improve tumor and tissue targeting.

ACKNOWLEDGMENT

We thank A. Regelin and U. F. Senge for critical reading of the manuscript. We thank J. T. Kley for his generous supply of the coupling lipids.

To improve the transfection efficiency of nonviral vector, we synthesized the starburst polyamidoamine dendrimer conjugates with α -, β -, and γ -cyclodextrins (CDE conjugates), expecting the synergistic effect of dendrimer and cyclodextrins (CyDs). The ^1H NMR spectroscopic data indicated that α -, β -, and γ -CyDs are covalently bound to dendrimer in a molar ratio of 1:1. The agarose gel electrophoretic studies revealed that CDE conjugates formed the complexes with plasmid DNA (pDNA) and protected the degradation of pDNA by DNase I in the same manner as dendrimer. CDE conjugates showed a potent luciferase gene expression, especially in the dendrimer conjugate with α -CyD (α -CDE conjugate) which provided the greatest transfection activity (approximately 100 times higher than those of dendrimer alone and of the physical mixture of dendrimer and α -CyD) in NIH3T3 and RAW264.7 cells. In addition, the gene transfer activity of α -CDE conjugate was superior to that of Lipofectin. The enhancing gene transfer effect of α -CDE conjugate may be attributable to not only increasing the cellular association, but also changing the intracellular trafficking of pDNA. These findings suggest that α -CDE conjugate could be a new preferable nonviral vector of pDNA.

INTRODUCTION

There are two categories of gene therapy vectors, i.e., viral vectors and nonviral vectors. Viral vectors take advantage of being a higher gene expression. However, they have a failing in which the virus replicates and the inflammatory reaction occurs. On the other hand, the nonviral vectors have many advantages over viral vectors, such as easy to manufacture, safety, low immunogenicity, and molecular attachment of targeting ligand (1, 2). However, the problem is that the efficiency of nonviral vector-mediated gene transfer to cells is markedly low, compared to the viral vectors. This is because of the lack of receptor recognition, endosome escape, and nuclear pore targeting (3). To date, several strategies to enhance the gene expression of nonviral vectors are being developed, e.g., the application of helper lipids, pH-sensitive lipids, cationic polymers, endosome-disruptive peptides, nuclear proteins, and nuclear localization signal, etc. (3–5). Starburst polyamidoamine dendrimer is a spherical, highly ordered, dendritic polymer with positively charged primary amino groups on the surface at physiological pH (6). Recently, their usefulness as nonviral vectors has been reported (7, 8). However, dendrimers with lower generations (generation 1–3) do not have a good gene transfer activity, whereas dendrimers with higher generations may exhibit cytotoxicity (9).

Cyclodextrins (CyDs) are cyclic (α -1,4)-linked oligosaccharides of α -D-glucopyranose containing a hydrophobic central cavity and hydrophilic outer surface (10–12). The most common CyDs are α -, β -, and γ -CyDs, which consist

of six, seven, and eight D-glucopyranose units, respectively. CyDs are known to form inclusion complexes with a variety of guest molecules in solution and in a solid state. The solubilization of lipophilic compounds by CyDs has many uses in pharmaceutical fields (13, 14), while CyDs at higher concentration induce hemolysis and decrease the integrity of the nasal and intestinal epithelial cells, leading to an increase in the permeability of impermeable drugs through the membrane (15–17). The dissolution of lipids by CyDs from biological membranes may be useful in the study of cellular biology, e.g., caveolae, rafts, and cholesterol transport (18–20). Recently, CyDs have also been applied to the gene transfer and the oligonucleotide delivery (21–24): (1) The cationic β -CyDs such as tertiary amino- β -CyD acted as a viral dispersant, which resulted in an increase in adenoviral transduction in human colon adenocarcinoma Caco-2 cells by enhancing both viral binding and internalization (21). (2) β -CyD increased the gene transfer in the lungs of rats (22). In addition, 2-hydroxypropyl- β -CyD (HP- β -CyD) and 2-hydroxyethyl- β -CyD (HE- β -CyD) increased the uptake of the antisense phosphorothioate oligodeoxynucleotides in human T cell leukemia H9 cell line, without cytotoxicity (23). 6-Deoxy-6-S- β -D-galactopyranosyl-6-thio-CyD improved the antiviral activity of the antisense phosphodiester oligonucleotide in human adenocarcinoma cells (24). Unfortunately, these enhancing effects of CyDs were not great.

The potential use of the conjugation with CyDs has been studied in the pharmaceutical field, e.g., the sulfonylurea LY237868 conjugate with α -CyD (25) and the epoxysuccinyl peptide conjugate with β -CyD (26) as antitumor agents and the bioactive peptide conjugates with CyDs as protease inhibitors (27). In our laboratory, the potential uses of CyD conjugates with biphenyl acetic acid and prednisolone for colon-specific drug delivery have been reported. (28, 29). To our knowledge, however, there is only one paper reporting the beneficial

¹ Abbreviation: CyDs, cyclodextrins; CDE conjugate, cyclodextrin–dendrimer conjugate; pDNA, plasmid DNA; dendrimer, Starburst polyamidoamine dendrimer; [^{32}P]pDNA, [^{32}P]-labeled plasmid DNA; FITC-pDNA, Fluorescein isothiocyanate labeled pDNA.

use of CyD conjugates for gene transfer; a new class of β -CyD-containing polymers was successful in the gene transfer in vitro (30). In the present study, we synthesized the potent new dendrimer conjugates with α -, β -, and γ -CyDs (CDE conjugates), in anticipation of the following synergic effect; i.e., (1) dendrimer has the abilities to complex with plasmid DNA (pDNA) and to enhance the cellular uptake of pDNA and (2) CyDs have a disrupting effect on biological membranes by the complexation with membrane constituents such as phospholipids and cholesterol. Thus, we investigated the effects of CDE conjugates on the gene transfer efficiency in the cells, and the enhancing effects were compared with commercial transfection reagents, Lipofectin and TransFast.

EXPERIMENTAL SECTION

Materials. α -, β -, and γ -CyDs were donated by Nihon Shokuhin Kako (Tokyo, Japan) and recrystallized from water. Starburst PAMAM dendrimer (ethylenediamine core, generation 2, the terminal amino groups = 16, molecular weight = 3256) was purchased from Aldrich Chemical (Tokyo, Japan). *p*-Toluenesulfonyl chloride and *p*-naphthalenesulfonyl chloride were purchased from Nakarai Tesque (Kyoto, Japan). Fetal calf serum (FCS) was purchased from Nichirei (Tokyo, Japan). Dulbecco's modified Eagle's medium and RPMI1640 media were obtained from Nissui Pharmaceuticals (Tokyo, Japan). TransFast and Lipofectin transfection reagents were obtained from Promega (Tokyo, Japan) and Life Technologies (Rockville, MD), respectively. The plasmid pGL3 control vector (luciferase reporter vector, pDNA) and DNase I were obtained from Promega (Tokyo, Japan). The purification of pDNA amplified in bacteria was carried out using QIAGEN EndoFree plasmid maxi kit (<0.1 EU/ μ g endotoxin). [α - ^{32} P]CTP was obtained from Amersham Pharmacia Biotech (Tokyo, Japan). Other chemicals and solvents were of analytical reagent grade.

Preparation of CDE Conjugates. The CDE conjugates were prepared by the method of Suh et al. (31). Monotosyl- α -CyD, monotosyl- β -CyD, and mononaphthalenesulfonyl- γ -CyD were prepared according to the methods of Brown et al. (32) and Melton et al. (33), respectively. The methanol solution containing dendrimer (0.39 mL, 2.6×10^{-5} mol) was added to a flask and evaporated under reduced pressure. Dimethyl sulfoxide (DMSO, 0.5 mL) was added into the flask and then the monotosyl- α -CyD (25 mg, 2.6×10^{-5} mol), monotosyl- β -CyD (30 mg, 2.6×10^{-5} mol), or mononaphthalenesulfonyl- γ -CyD (34 mg, 2.6×10^{-5} mol) was added, respectively. Under a stream of nitrogen gas, the mixture was stirred at 60 °C for 24 h. The α -, β -, and γ -CDE conjugates were purified by gel-filtration (TOSOH TSKGel HW-40S, Tokyo, Japan) and then precipitated with methanol. The gel filtration was carried out to remove the free and monotosylated or mononaphthalenesulfonylated CyDs. The methanol precipitation was conducted to remove the free dendrimer, because it is highly soluble in methanol whereas the CDE conjugates are less soluble in the solvent. The CDE conjugates gave ^1H NMR spectra consisting of protons of both CyDs and the dendrimer. The ratios of peak areas of the anomeric proton of CyDs and ethylene protons of the dendrimer were approximately 0.95–1.11, indicating that α -, β -, and γ -CyDs covalently bind to the dendrimer in a molar ratio of 1:1, as shown in Figure 1. α -CDE conjugate: yield: 18%; ^1H NMR (500 MHz, D_2O) δ (from TMS) 5.29 and 4.96 (H1, α -CyD), 3.94–3.61 (H3, H5, H6, α -CyD), 3.60–3.33 (H2, H4, α -CyD), 3.33–3.08 (dendrimer methylene), 3.08–2.94 (dendrimer methylene),

Figure 1. Chemical structure of CDE conjugates.

2.94–2.60 (dendrimer methylene), 2.60–2.43 (dendrimer methylene), 2.43–2.15 (dendrimer methylene). β -CDE conjugate: yield: 21%; ^1H NMR (500 MHz, D_2O) δ (from TMS), 4.96 (H1, β -CyD), 3.93–3.67 (H3, H5, H6, β -CyD), 3.59–3.40 (H2, H4, β -CyD), 3.34–3.08 (dendrimer methylene), 3.08–2.96 (dendrimer methylene), 2.96–2.62 (dendrimer methylene), 2.62–2.44 (dendrimer methylene), 2.44–2.22 (dendrimer methylene). γ -CDE conjugate: yield: 29%; ^1H NMR (500 MHz, D_2O) δ (from TMS) 5.29 and 5.00 (H1, γ -CyD), 3.91–3.60 (H3, H5, H6, γ -CyD), 3.60–3.39 (H2, H4, γ -CyD), 3.39–3.05 (dendrimer methylene), 3.05–2.97 (dendrimer methylene), 2.97–2.57 (dendrimer methylene), 2.57–2.39 (dendrimer methylene).

Gel Electrophoresis. Electrophoretic mobility of the pDNA complex with dendrimer or CDE conjugates was measured using a gel electrophoresis system. Varying amounts of dendrimer or CDE conjugates were mixed with 0.2 μ g of pDNA in Hank's balanced salt solution (HBSS, pH 7.4). Gel electrophoresis was carried out at room temperature in TBE (45 mM Tris-Borate, 1 mM EDTA) buffer (pH 8.0) in 1% (w/v) agarose gel (include 0.1 μ g/mL ethidium bromide) using Mupid system (Cosmo Bio, Tokyo, Japan) at 100 V for 50 min. pDNA bands were visualized by an UV illuminator.

Measurement of Particle Size. Dendrimer and α -CDE conjugate solutions (0.1 mL in HBSS) at various charge ratios were added to pDNA solution (20 μ g/1.5 mL in HBSS) and incubated for 15 min. Particle sizes of the pDNA complexes with dendrimer and α -CDE conjugate were determined by quasi-elastic (dynamic) light scattering using a Beckman Coulter N4 Plus machine (CA). The wavelength of the He–Ne laser used was 632.8 nm. The measurement was carried out at a fixed angle of 62.6°, and the measuring time was 102 s at 25 °C. The measurements were carried out at least in triplicates.

DNase I Protection Assay. The complexes of pDNA (0.2 μ g) with dendrimer or CDE conjugates were prepared as described above and then incubated for 2 h at 37 °C in the reaction buffer (pH 7.4, 10 mM Tris-HCl, 10 mM NaCl, 10 mM CaCl_2 , 6 mM MgCl_2 and 2 mM DTT, 0.2 μ g/mL bovine serum albumin) containing 0.1 unit/ μ L DNase I. After incubation, DNase I was inactivated by heating the solution at 70 °C for 10 min, and 1 μ L of EDTA (0.5 M) and 10 μ L of SDS (8% w/v) were added to each sample and incubated at 37 °C for 60 min to dissociate pDNA from the complexes. After the incubation, gel electrophoresis was carried out in the same manner as described in gel electrophoresis section.

Cell Culture. NIH3T3 cells, a mouse fibroblast cell line, and RAW264.7 cells, a mouse macrophage-like cell line, were obtained from the Japan Health Sciences Foundation (Osaka, Japan) and the Riken cell bank (Tsukuba, Japan), respectively. Both cell lines were grown in Dulbecco's modified Eagle's medium (include 1

$\times 10^5$ mU/mL penicillin, 0.1 mg/mL streptomycin) and RPMI1640 medium (include 4×10^5 mU/mL penicillin, 0.2 mg/mL streptomycin) supplemented with 10% (v/v) FCS at 37 °C in a humidified 5% CO₂ and 95% air atmosphere, respectively.

Transfection. Transfection of the complexes of pDNA with dendrimer, CDE conjugates, or the commercial cationic lipid transfection reagents (Lipofectin and TransFast) was performed and analyzed using the expression of pDNA containing firefly luciferase gene under the control of Rous sarcoma virus enhancer/promoters. One to two micrograms of purified pDNA (per dish of transfected cells) was mixed with dendrimer or conjugates at a variety of charge ratios from 1/0 to 1/200 (pDNA/the vectors). The pDNA/dendrimer or CDE conjugates were then allowed to stand for 15 min at room temperature. The cells (2×10^5 per 35 mm culture dish) were seeded 18 h before transfection and then washed two times with serum-free medium. Eight hundred microliters of serum-free medium containing pDNA or the complexes with the various vectors (equivalent to 2 μ g of pDNA) were added to each well and then incubated for 1 h at 37 °C. The culture medium (1.5 mL) supplemented with 10% (v/v) FCS was added to each well. The cells remained in culture for 6, 12, and 24 h before being harvested for analysis of the expression of the transfected pDNA. Control transfection was performed with TransFast and Lipofectin in the same manner as described above. The charge ratios of pDNA and TransFast and pDNA and Lipofectin were 1:1, at which the optimal transfection activity was observed under the present experimental conditions.

Measurement of Luciferase Activity. After transfection for 25 h, firefly luciferase content of the cell lysate was quantified, using the Promega luciferase assay reagent and a luminometer (Lumat LB9507, EG&G Berthold Japan, Tokyo, Japan). Absolute light emission generated from the luciferase enzyme reaction was determined. It was confirmed that CyDs and CDE conjugates have no influence on the luciferase assay under the experimental conditions. Total protein contents of the supernatant were determined by BCA protein assay kit (Pierce, Rockford, IL).

Cellular Association. pDNA was labeled with [α -³²P]-CTP using a nick translation kit II (Nippon Gene, Toyama, Japan) according to manufacturer's protocols. [³²P] labeled pDNA ([³²P]pDNA) was purified using QIAquick PCR purification Kit (Qiagen, Tokyo, Japan). NIH3T3 and RAW264.7 cells were cultured in 35-mm culture dish. The cells were washed two times with 1 mL of medium, and [³²P]pDNA (1 μ g/mL, 5.0×10^4 cpm/ μ L) with or without dendrimer and CDE conjugates was added. After incubation at 37 °C for the indicated time, the cells were washed two times with 0.5 mL of ice-cold phosphate-buffered saline (PBS) and then solubilized with 0.5 mL of 1 N NaOH and incubated for 2 h. One-half milliliter of the total solutions was added to Hionic-Flour (Packard Japan, Tokyo, Japan) and then taken for the determination of ³²P radioactivity using a liquid scintillation counter (Aloka LSC-5100, Tokyo, Japan). Nonspecific binding of labeled pDNA was defined as the binding to the dishes rather than the cells and then that count subtracted from the total binding to calculate the specific binding.

Confocal Microscopic Study. Fluorescein isothiocyanate (FITC) labeled pDNA (FITC-pDNA) was prepared using Mirus label ITTM fluorescein labeling kit (Madison, WI). FITC-pDNA/dendrimer or CDE conjugates were then allowed to stand for 15 min at room temperature.

The transfection was performed as described above. After 25 h incubation, the cells were rinsed two times with 2 mL of PBS (pH 7.4) and fixed with 3.7% (v/v) formaldehyde in PBS for 40 min. Then, the cells were washed two times with 2 mL of PBS, and the lipids were removed by washing with 2 mL of methanol (−20 °C) for 10 min and then followed by washing two times with 2 mL of PBS. The cells were scanned with a confocal fluorescence microscopic system (Olympus FV300-BX, Tokyo, Japan) with an argon ion laser (excitation wavelength, 488 nm).

Data Analysis. Data are given as means $\pm$ SEM. Statistical significance of mean coefficients was performed by analysis of variance followed by Student's-t test. *p*-Values for significance were set at 0.05.

RESULTS

Interaction between pDNA and CDE conjugates.

We first studied the complexation between pDNA and dendrimer or CDE conjugates using agarose electrophoresis. As shown in Figure 2A, the intensity of the band derived from pDNA decreased, with increasing the charge ratio of pDNA/dendrimer, and at the charge ratio of 1/1 the band disappeared. The similar patterns were observed in the α -, β -, and γ -CDE conjugate systems (Figures 2B,C,D). CyDs did not change the electrophoretic band pattern of pDNA (data not shown). These results suggested that CDE conjugates form the complex with pDNA in a manner similar to dendrimer.

DNase I Protection Assay. Condensation of pDNA by cationic polymers has been shown to protect supercoiled pDNA from degradation by DNase I. We examined the stabilizing effect of dendrimer or CDE conjugates on the degradation of pDNA via the endonuclease activity of DNase I. In the present study, the concentration of DNase I was 0.1 unit/ μ L, because the activity in human serum is 2×10^{-4} – 8.2×10^{-2} unit/ μ L (34). As shown in Figure 3, when pDNA alone was treated with DNase I, pDNA degraded into smaller size fractions. On the other hand, the addition of dendrimer or CDE conjugates increased the band intensity of pDNA with the increase in the charge ratio up to about 1/10, although the intensity decreased at higher ratios ($> 1/20$). Since CyDs alone possessed no protecting ability against the DNase I-catalyzed degradation of pDNA (data not shown), these results suggest that both dendrimer and CDE conjugates protect pDNA, and the optimal charge ratio exists in their protecting effects. The protecting mechanism may be same between dendrimer and CDE conjugates.

Transfection. The gene transfer efficiency of dendrimer and CDE conjugates was compared with that of commercial transfection reagents, TransFast and Lipofectin, which were employed as positive controls. Figures 4A and 4B show the transfection efficiency of CDE conjugates in NIH3T3 and RAW264.7 cells, respectively. When pDNA alone with or without CyDs was transfected in both cells, no luciferase activity was observed (data not shown). In NIH3T3 cells, the combination of pDNA/dendrimer (1/2) gave the luciferase activity of about 10^4 RLU/ μ g proteins. However, this activity was only slightly enhanced even when the charge ratio increased to 1/200. On the other hand, the combination of pDNA/CDE conjugates significantly increased the luciferase activity with increasing the charge ratio; especially, α -CDE conjugate enhanced the activity by approximately 100 times that of pDNA/dendrimer. At the charge ratios of 1/100 and 1/200, the luciferase activity of the α -CDE conjugate system was higher than that of the Lipofectin system, although it was lower than that of the TransFast

Figure 2. Agarose gel electrophoretic analysis of pDNA/dendrimer or pDNA/CDE conjugates using TBE buffer (pH 8.0). The solutions containing pDNA and dendrimer or CDE conjugates were incubated for 15 min at room temperature after slight agitation. The electrophoresis was performed at 100 V for about 50 min. A, dendrimer; B, α -CDE conjugate; C, β -CDE conjugate; D, γ -CDE conjugate.

system. In RAW264.7 cells, the same effect of CDE conjugates was observed, as shown in Figure 4B. Since the luciferase activity was saturated at the charge ratio of 1/100–1/200 (pDNA/CDE conjugate), the complex with the 1/200 charge ratio was employed in the following experiment. Figures 5A and 5B show the time-courses of the gene transfer ability of CDE conjugates in NIH3T3 and RAW264.7 cells, respectively. Of CDE conjugates, the great transfection activities of α -CDE were observed at 7, 13, 25 h after transfection in NIH3T3 cells and at 13 and 25 h in RAW264.7 cells, although their activities were inferior to those of TransFast. These results indicate that α -CDE conjugate has the superior transfection ability than β - and γ -CDE conjugates.

Next, we compared the transfection ability of CDE conjugates with that of the simple mixtures of dendrimer and CyDs. As shown in Figure 6, the luciferase activities of the physical mixtures were almost the same as those of dendrimer alone in both NIH3T3 and RAW264.7 cells. These results indicate that the covalent conjugation between dendrimer and CyDs is necessary for the induction of the efficient transfection activity.

Cellular Association of pDNA. The enhanced transfection effects of CDE conjugates may be attributable to the increasing cellular association and/or to changing the intracellular trafficking of pDNA. To clarify the mechanism for the higher transfection efficiency of the CDE conjugates, we examined the effects of dendrimer and CDE conjugates on the cellular association of pDNA to NIH3T3 and RAW264.7 cells, using [^{32} P]pDNA. As shown in Figure 7, the association of pDNA to the cells increased as the charge ratio increased up to about 1/2–1/5, and there was a good correlation between the cellular association and the luciferase activity. This suggests that

the cellular entry is a rate-limiting step for gene transfer in lower molar ratios. However, the association was saturated above the charge ratio of about 1/2–1/5 and was almost the same between the dendrimer and the CDE conjugates, which was inconsistent with the results of luciferase activity (Figures 4 and 5). CyDs showed no effects of the cellular association of pDNA under the experimental conditions, implying a lack of perturbing effect of CyDs on the barrier function of plasma membrane (data not shown). These results suggest that CDE conjugates, especially α -CDE conjugate, may change the trafficking of pDNA in the cells.

Intracellular Distribution of FITC-Labeled pDNA.

To examine the effects of α -CDE conjugate on the distribution of pDNA in the cells, we observed the cells under a confocal laser microscope after transfection of FITC-pDNA for 25 h in NIH3T3 cells. The results are shown in Figure 8. The transfection of pDNA alone gave no fluorescence in the cells (Figure 8A), reflecting a lower cellular uptake of pDNA. The pDNA/dendrimer system gave a moderate fluorescence in cytoplasm (Figure 8B). On the other hand, more intense fluorescence was observed in cytoplasm when α -CDE conjugate was used as a vector (Figure 8C). Separately, we revealed that dendrimer and CDE conjugates entered into the cells in terms of the endocytosis mechanism (data not shown). These results suggest that α -CDE conjugate may change the distribution of pDNA in the cells, possibly in terms of the increase in the release of pDNA from the endosome into cytoplasm after endocytosis. Furthermore, α -CDE conjugate gave the fluorescence similar to that of the dendrimer alone at the low charge ratio (1/5) of the complexes, whereas it gave the stronger fluorescence than that of the dendrimer alone at the higher charge

Figure 3. Effects of dendrimer and CDE conjugates on electrophoretic mobility of pDNA treated with DNase I. The complexes of pDNA/dendrimer or pDNA/CDE conjugates were incubated with 0.1 unit/ μ L DNase I for 2 h. After DNase I was inactivated at 70 °C for 10 min, 1 μ L of EDTA (0.5 M) and SDS (8% w/v) were added to each sample and incubated at 37 °C for 1 h to dissociate pDNA from the complexes. After incubation, gel electrophoresis was carried out at room temperature in TBE (45 mM Tris-Borate and 1 mM EDTA) buffer (pH 8.0) in 1% (w/v) agarose gel (include 0.1 μ g/mL ethidium bromide) using Mupid system at 100 V for 50 min. A, dendrimer; B, α -CDE conjugate; C, β -CDE conjugate; D, γ -CDE conjugate.

ratio (1/200), as shown in Figures 8D and 8E. These results support the preceding idea that α -CDE conjugate changes the distribution of pDNA in the cells.

DISCUSSION

We prepared three CDE conjugates in which α -, β -, and γ -CyDs were covalently bound to the dendrimer (generation 2) in a molar ratio of 1:1. These CDE conjugates may be unique as gene transfer vectors, because the only conjugates with β -CyD have been published (30). We revealed here that of three CDE conjugates, α -CDE conjugate possessed the greatest transfection activity. This activity was approximately more than 100-fold than that of dendrimer under an optimal condition.

There are three major barriers to cationic polymers-mediated transfection: (1) interactions between polyplexes and cell surfaces, (2) the endosomal release of polyplexes, and 3) entry of pDNA into the nucleus (35). None of the CyDs alone had the protecting ability of pDNA against DNase I, or the transfection activity at various concentrations, or the enhancing effects of the

cellular association of pDNA (data not shown). In addition, neither dendrimer alone nor the physical mixture of the dendrimer with CyDs showed the significant enhancing effect on the transfection activity (Figures 4–6). On the other hand, the complexes of pDNA with CDE conjugates, especially α -CDE conjugate, possessed a superior transfection activity over the dendrimer and the physical mixtures. The effects of the CDE conjugates on these barriers were investigated to gain an insight into the enhancing mechanism of α -CDE conjugate.

From the results of gel mobility shift assay, dendrimer formed the complexes with pDNA (Figure 2). This may be attributed to electrostatic interaction, because terminal amines of dendrimer are only partially protonated because of their low pK_a 6.9 (36), thereby interacting with negatively charged pDNA. However, this result was inconsistent with that of Fukowska-Latallio et al. (9), in which the pDNA migration is not retarded in the presence of dendrimers with the generation of 1 to 3. This discrepancy in the complexation of dendrimer with pDNA is not clear; possibly the pH value and components of

Figure 4. Transfection efficiency of the complexes of pDNA/dendrimer or pDNA/CDE conjugates complexes at various charge ratios in NIH3T3 cells (A) and RAW264.7 cells (B). The luciferase activity in cell lysates was determined 25 h after incubation with pDNA alone or various complexes. The charge ratios of pDNA and TransFast and pDNA and Lipofectin were 1:1; open column, dendrimer alone; dark hatched column, α-CDE conjugate; light hatched column, β-CDE conjugate; closed column, γ-CDE conjugate; shade column, TransFast and Lipofectin. buffers might be different. CDE conjugates formed the complex with pDNA in a similar manner as dendrimer (Figure 2), suggesting that the CyD moiety is not involved in the complexation, because the 15 terminal amino groups remain on surface of CDE conjugates. Therefore, it is apparent that the complexation ability of CDE conjugates with pDNA is not necessarily a crucial factor for the enhanced transfection activity of CDE conjugates, although the complexation is needed for the induction of transfection activity. Interestingly, the band driven from pDNA disappeared at the charge ratio of 1/1 (pDNA/CDE conjugates), at which the molar ratio of complexes of pDNA with CDE conjugates was about 1/700 (Figure 2). This suggests that the relatively larger and complicated complexes may be formed at more than 1/1 charge ratios. At the charge ratios of 1/100 and 1/200 (pDNA:CDE conjugates), the conjugates are largely in a free form, although their accurate fractions were unknown. The α-CDE conjugate in a free form may assist in the transfection by increasing the release of pDNA from endosome, due to its endosome-membrane perturbing effect, as shown in Figure 8. To examine the average size of the complex of pDNA with dendrimer or α-CDE conjugate, the diameter of the complex was measured by quasi-elastic (dynamic) light scattering (see Experimental Section). The mean diameters of the complexes of pDNA with dendrimer at the charge ratios of 1/0.5, 1/1, 1/2, 1/10,

Figure 5. Time course of transfection efficiency of the complexes of pDNA/dendrimer or pDNA/CDE conjugates complexes at the charge ratio of 1/200 in NIH3T3 cells (A) and RAW264.7 cells (B). The charge ratio of pDNA and TransFast was 1:1. ○, dendrimer alone; △, α-CDE conjugate; □, β-CDE conjugate; ▲, γ-CDE conjugate; ■, TransFast. Each point represents the mean $\pm$ SEM of 4. * p < 0.05, compared with dendrimer alone.

1/20, 1/100, and 1/200 (pDNA/vectors) were 794, 594, 737, 731, 804, 717, and 743 nm, respectively, and those with α-CDE conjugate were 781, 753, 718, 735, 761, 747, and 720 nm, respectively. Therefore, the diameter of the complex of pDNA with dendrimer or α-CDE conjugate was not significantly affected by the charge ratios, and there was an insignificant difference in the diameter between the complexes with dendrimer and the conjugate. These results suggest that morphology of the complexes of pDNA with dendrimer or α-CDE conjugate might be independent of the charge ratio, and both dendrimer and α-CDE conjugate may exist as a free form in the solution containing the complexes with the higher molar ratios.

The DNase I protection assay indicated that the pDNA/dendrimer and pDNA/CDE conjugates resist the nuclease-catalyzed degradation (Figure 3). These results were in agreement with the previous reports in which the nuclease-catalyzed degradation is inhibited by the complexation with poly-L-lysine, DC-cholesterol, and Lipofectin (37, 38). However, the optimum charge ratio for the stabilizing effect of CDE conjugates existed, suggesting that factors other than the electrical charge may be associated with the stabilizing effect, e.g., the mode of the complexes and the existence of free fraction of CDE conjugate. Furthermore, there was an insignificant difference in the stabilizing ability between dendrimer and CDE conjugates, indicating that the greater transfection activity of α-CDE conjugate cannot be ex-

Figure 6. Transfection efficiency of physical mixtures of pDNA and dendrimer or pDNA and CDE conjugates in NIH3T3 cells (A) and RAW264.7 cells (B). plained simply by the inhibition of the DNase I-catalyzed degradation of pDNA.

The entry of the complexes of pDNA with cationic polymers into the cell is the first step of transfection. In the present study, we confirmed a good correlation between cellular association and luciferase activity in lower charge ratios (1/0.2 to 1/2–1/5) of pDNA/CDE conjugates (Figure 7). This suggests that the cellular entry is rate-limiting step for gene transfer. However, no difference in the cellular association of pDNA between dendrimer and CDE conjugates was observed (Figure 7), suggesting that the conjugation of α -CyD with dendrimer, particularly in higher molar ratios, affects intracellular trafficking of pDNA. The fluorescence in cytoplasm was stronger when α -CDE conjugate was used, compared with dendrimer alone (Figure 8), supporting that α -CDE conjugate changes the distribution of pDNA in the cells, possibly in terms of the increase in the release of pDNA from the endosomes into cytoplasm. This hypothesis is based on facts that CyDs induce hemolysis and collapse of liposomes via the release of biological components, such as phospholipids and cholesterol from the membranes (15, 41, 42). It is well recognized that CyDs disrupt the liposomes composed of egg phosphatidylcholine or dipalmitoylphosphatidylcholine in the order of $\alpha > \beta > \gamma$ -CyD, whereas the incorporation of cholesterol into the liposomes changes the membrane-disrupting ability of CyDs in the order of $\beta > \alpha > \gamma$ -CyD (41). In addition, CyDs cause hemolysis of human erythrocytes in the order of $\beta > \alpha > \gamma$ -CyD (15). This difference can be explained by the fact that the species and amounts of released membrane components were dependent upon the cavity

Figure 7. Cellular associations of [α -³²P] labeled pDNA at various charge ratios in NIH3T3 cells (A) and RAW264.7 cells (B). $\circ$, dendrimer alone; Δ , α -CDE conjugate; $\square$, β -CDE conjugate; $\blacktriangle$, γ -CDE conjugate. Each point represents the mean $\pm$ SEM of three experiments.

size of CyDs, i.e., α -CyD extracted mainly phospholipids, β -CyD cholesterol, and γ -CyD both components in smaller amounts (43). However, since endosomal membranes have a relatively higher cholesterol content, the enhanced transfection activity of α -CDE conjugates could not simply be related to the membrane-disrupting effects of CyDs. Furthermore, α -CyD concentration (12 mM) to induce 50% hemolysis (43) is higher than that to enhance the transfection efficiency (for example, about 50 μ M in the charge ratio of 1/100). In addition, CDE conjugates at less than micromolar concentrations could not increase the calcein release from the egg phosphatidylcholine liposomes (data not shown). Therefore, the exact mechanism for the enhanced transfection activity of α -CDE conjugate is currently unclear, but it is apparent that the conjugate affects the intracellular trafficking of pDNA. Further studies are necessary to elucidate the enhancing mechanism of CDE conjugates, e.g., whether β -CDE and γ -CDE conjugates change the intracellular trafficking of pDNA, how the complexes of CDE conjugates with pDNA dissociate, and how pDNA enters into the nucleus, compared with those of dendrimer alone.

Under the present experimental conditions, no cytotoxicity of CDE conjugates and their complexes with pDNA was observed in NIH3T3 and RAW264.7 cells in WST-1 assay, up to the charge ratio of at least 1/800 (data not shown). Therefore, CDE conjugates, particularly α -CDE conjugate, have great advantages as nonviral vectors, i.e., an easy preparation, a superior transfection efficiency, and less cytotoxicity. In a preliminary study,

Figure 8. Confocal laser microscope images for the distribution of FITC-labeled pDNA in NIH3T3 cells after transfection of pDNA alone (A), the complex of pDNA/dendrimer at charge ratio of 1/200 (B), the complex of pDNA/ α -CDE conjugate complex at charge ratio of 1/200 (C), the complex of pDNA/dendrimer at charge ratio of 1/5 (D), and the complex of pDNA/ α -CDE conjugate complex at charge ratio of 1/5 (E). The cells were incubated with pDNA alone or the complexes for 25 h at 37 °C. Scale bars represent 25 μ m. The images shown are typical among similar ones in the several visual fields.

we prepared the α -CDE conjugates containing more than one CyD molecules (average α -CyD/dendrimer molar ratios of 1.8 and 3.2) and then evaluated their transfection activities. The luciferase activities after the transfection of the 1.0, 1.8, and 3.2 α -CDE conjugates in NIH3T3 cells were $3.69 \times 10^5 \pm 0.22 \times 10^5$, $4.82 \times 10^5 \pm 0.27 \times 10^5$, and $6.72 \times 10^5 \pm 0.31 \times 10^5$, respectively, at the charge ratio of 1/200. These results indicated that the transfection activity of pDNA/ α -CDE conjugate complex increased with the increasing of molar ratio of α -CyD/dendrimer.

In conclusion, the present findings suggest that α -CDE conjugate could be a preferable nonviral vector of plasmid DNA among CDE conjugates. This strategy is applicable to other cationic lipids and polymers such as poly-L-lysine and polyethylenimine, which are now under investigation.

ACKNOWLEDGMENT

We are very grateful to Prof. S. H. Lee at the Kunsan National University in Korea for teaching us the method to purify CDE conjugates. We thank Dr. Makoto Uemura for assistance with the light scattering experiments using a Beckman Coulter N4 Plus machine at the Kumamoto

Industrial Research Institute. This research was supported by a Grant-in-Aid from Tokyo Biochemical Research Foundation and a Grant-in-Aid for Encouragement of Young Scientists from the Ministry of Education, Science and Culture of Japan (12771464).

Significance of Substrate Hydrophobicity for Recognition by an Oligopeptide Transporter (PEPT1)

Ryoko Tateoka,[†] Hiroshi Abe,^{†,‡} Seiji Miyauchi,[†] Satoshi Shuto,[‡] Akira Matsuda,[‡] Michiya Kobayashi,[§] Katsumi Miyazaki,[§] and Naoki Kamo^{*,†}

Our previous paper [(1999) *Bioconjugate Chem.* 10, 24–31] pointed out that hydrophobicity of substrates/inhibitors plays an important role in the recognition by an oligopeptide transporter (PEPT1) expressed in the human intestinal epithelial cell line Caco-2. To determine the significance of that hydrophobicity, we have now synthesized dipeptide analogues conjugating the ϵ -amino group of Lys in Val-Lys with aliphatic carboxylic acids: acetic acid (C2), propanoic acid (C3), pentanoic acid (C5), hexanoic acid (C6), and decanoic acid (C10). The affinities of these conjugates were estimated by their inhibition of the accumulation rate of Gly-Sar, a well-established substrate for PEPT1. With the increase in length of the hydrocarbon chain of the conjugates, i.e., in the hydrophobicity of the conjugates, the inhibition strengthened. Dixon–Webb plot analysis of the inhibition by the C10-conjugated dipeptide showed competitive inhibition. The trans-stimulation effect of Val-Lys conjugated to C10 or C5 on the uptake of Ceftibuten was observed using rat brush border membrane vesicles. This findings showed that these conjugates are transportable substrates. These results confirmed that the hydrophobicity of substrates/inhibitor is one of the factors in the recognition by PEPT1.

INTRODUCTION

Dipeptide transporters in the small intestine play an important role in the efficient absorption of small peptides following the digestion of dietary proteins (1). In some cases, this transporter serves as a carrier of pharmacological-active peptide-like compound such as oral β -lactam antibiotics (2–4), an antineoplastic agent bestatin (5), and an angiotensin-converting enzyme (ACE) inhibitor (6, 7). Because of the structural diversity of the substrates, this oligopeptide transporter (PEPT1) is believed to have very broad specificity. It can therefore be used as a channel to increase the intestinal absorption of poorly absorbable drugs when these drugs are conjugated with a dipeptide or tripeptide core, thus making them recognizable to the transporter (8). On the basis of this idea, we synthesized dipeptide analogues conjugated at ϵ -amino group of Lys in Val-Lys or Lys-Sar with the fluorescent dyes, fluorescein isothiocyanate (FITC, abbreviated as Flu) or coumarin-3-carboxylic acid (Coum¹) (9). These dyes were employed as model drugs which are poorly absorbed.

Unfortunately, the fluorescent dipeptide analogues synthesized were not transported by the oligopeptide

transporter, PEPT1, in Caco-2 cells. Quite interestingly, however, they were recognized by PEPT1 and their affinity was very high; Val-Lys(Flu) inhibited competitively the Gly-Sar uptake by PEPT1 with the inhibition constant being as low as 5 μ M. Here, Val-Lys(Flu) stands for the fluorescent analogue where Flu is conjugated with the free NH_2 of Lys in the dipeptide, Val-Lys. Since the fluorescent dyes, Flu and Coum, are hydrophobic, the increase in the affinity to PEPT1 led us to hypothesize that the hydrophobicity is one of the important factors for the substrate recognition of PEPT1.

To check this hypothesis, we have synthesized dipeptide analogues conjugated with various linear aliphatic acids, by which we systematically changed the degree of the hydrophobicity only while leaving the peptide core unchanged; aliphatic acids were acetic acid (C2), propanoic acid (C3), pentanoic acid (C5), hexanoic acid (C6), and decanoic acid (C10). In the presence of these conjugates, Gly-Sar uptake by Caco-2 cells was measured. With an increase in the chain length, i.e., hydrophobicity, the conjugates more strongly inhibited the uptake. In addition, the conjugates preloaded inside the vesicles increased the uptake rate of Ceftibuten, a substrate, meaning that the conjugate can be transported by the transporter. We thus concluded that the hydrophobicity is one of factors in the substrate recognition by PEPT1.

MATERIALS AND METHODS

Materials. ¹⁴C-Glycylsarcosine ([¹⁴C]-Gly-Sar)(1.78 GBq/mmol) was purchased from NEN Life Science Products (Boston, MA). The culture medium (Dulbecco's modified Eagle's medium, nonessential amino acids) and fetal bovine serum (FBS) were purchased from GIBCO BRL Life Technologies (Grand Island, NY). Dehydrated THF was purchased from Kanto Chemical Co., Inc. (Tokyo, Japan). DMF was distilled from CaH_2 at reduced

¹ Abbreviations: Coum, coumarin-3-carboxylic acid; FITC, fluorescein isothiocyanate; Flu, fluorescein; Gly-Sar, glycylsarcosine; HEPES, *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid; MES, 2-(*N*-morpholino)ethanesulfonic acid; *n*, number of carbons of the acyl group of Val-Lys-linear aliphatic acid synthesized; Tris, Tris(hydroxymethyl)-aminomethane; WSCD, water-soluble carbodiimide (1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide).

pressure. Toluene and Et₂O were distilled from sodium metal/benzophenone ketyl. Unless otherwise stated, starting materials were obtained from commercial suppliers and were used without further purification. All amino acids were L-isomers. Boc-Val were purchased from Peptide Institute, Inc. (Osaka, Japan). Lys(Cbz)-O-*t*-Bu was purchased from Kokusan Chem. Co., Inc. (Tokyo, Japan). FITC was purchased from Molecular Probes, Inc. (Eugene, OR). Other chemicals used were of the highest purity available.

Synthesis. General Procedures. ¹H NMR spectra were obtained on a JEOL EX270 or Bruker ARX500, and were presented in ppm (δ) relative to either tetramethylsilane or the solvent signal as internal reference (CHCl₃, 7.27 ppm; DMSO, 2.49 ppm). Splitting patterns are designated as follows: s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet; br, broad. Analytical thin-layer chromatography was carried out on silica gel 60 F254 plates (Merck). Preparative column chromatography was performed on silica gel 60 (Merck, 70–230 mesh or 230–400 mesh). All reactions were performed under a nitrogen atmosphere, unless stated otherwise (9).

Boc-Val-Lys(Cbz)-O-*t*-Bu (1) and Boc-Val-Lys-O-*t*-Bu·HCl (2). The preparation and the characterization were described previously (9).

Boc-Val-Lys(C2)-O-*t*-Bu (3a). Acetic anhydride (101 μL, 1.07 mmol) was added to a solution of **2** (304 mg, 0.717 mmol) in DMF (15 mL), followed by Et₃N (100 mL, 0.717 mmol) at 0 °C, and the mixture was stirred at room temperature for 3 h. It was diluted with AcOEt (60 mL) and washed successively with 0.6 M citric acid (40 mL), H₂O (30 mL), aqueous saturated NaHCO₃ (30 mL), H₂O (30 mL), and brine (20 mL) and then dried (Na₂SO₄) and concentrated. The resulting residue was purified by column chromatography (SiO₂, 25:1 CHCl₃–MeOH) to give **3a** (248 mg, 81% as white amorphous): ¹H NMR (CD₃OD, 270 MHz) δ 0.94(3 H, d, *J* = 6.6 Hz, Val-CH₃), 0.99(3 H, d, *J* = 6.6 Hz, Val-CH₃), 1.16–1.89(24 H, overlapping m, 2 × *t*-Bu, Lys β, γ, δ-CH₂), 1.99 (3 H, s, Acetyl), 2.07–2.23 (1 H, m, Val β-CH), 3.11–3.33 (2 H, m, Lys ε-CH₂), 4.00 (1 H, dd, *J* = 5.9, 7.9 Hz, Val α-CH), 4.39 (1 H, dt, *J* = 4.6, 7.9 Hz, Lys α-CH), 5.14 (1 H, d, *J* = 7.9 Hz, Val α-NH), 6.16 (1 H, br s, Lys ε-NH), 6.70 (1 H, d, *J* = 7.3 Hz, Lys α-NH); FAB–HRMS calcd for [C₂₂H₄₁N₃O₆ + H]⁺ 444.3073, found 444.3080.

Boc-Val-Lys(C3)-O-*t*-Bu (3b). The product from **2** (302 mg, 0.712 mmol) and propanoic anhydride (137 μL, 1.04 mmol) was prepared using the procedure for **3a**. The crude product was purified by column chromatography (SiO₂, 40:1 CHCl₃–MeOH) to give **3b** (246 mg, 78% as white amorphous): ¹H NMR (CD₃OD, 270 MHz) δ 0.93–(3 H, d, *J* = 6.6 Hz, Val-CH₃), 0.98 (3 H, d, *J* = 6.6 Hz, Val-CH₃), 1.16 (3 H, t, *J* = 7.3 Hz, propanoyl-CH₃), 1.26–1.90 (24 H, overlapping m, 2 × *t*-Bu, Lys β, γ, δ-CH₂), 2.08 (1 H, m, Val β-CH), 2.21 (2 H, q, *J* = 7.3 Hz, propanoyl-CH₂), 3.28 (2 H, m, Lys ε-CH₂), 3.97 (1 H, dd, *J* = 5.9, 7.9 Hz, Val α-CH), 4.41 (1 H, dt, *J* = 4.6, 7.3 Hz, Lys α-CH), 5.13 (1 H, d, *J* = 7.9 Hz, Val α-NH), 5.90 (1 H, br s, Lys ε-NH), 6.62 (1 H, d, *J* = 7.3 Hz, Lys α-NH); FAB–HRMS calcd for [C₂₃H₄₃N₃O₆ + H]⁺ 458.3230, found 458.3225.

Boc-Val-Lys(C5)-O-*t*-Bu (3c). A solution of **2** (313 mg, 0.738 mmol), *n*-pentanoic acid (88 μL, 0.812 mmol), HOBt (304 mg, 1.47 mmol), and WSCD·HCl (162 mg, 0.848 mmol) in DMF (15 mL) was stirred at 0 °C for 15 min and then Et₃N (103 μL, 0.738 mmol) was added. After 30 min, the reaction mixture was warmed to room temperature and stirred for a further 2 h. It was diluted with EtOAc (60 mL), washed successively with 0.6 M

citric acid (50 mL), H₂O (30 mL), aqueous saturated NaHCO₃ (40 mL), H₂O (30 mL), and brine (30 mL), and then dried (Na₂SO₄) and concentrated. The resulting residue was purified by column chromatography (SiO₂, 35:1 CHCl₃–MeOH) to give **3c** (270 mg, 75% as a white solid): ¹H NMR (CDCl₃, 270 MHz) δ 0.91 (3 H, t, valeryl-CH₃), 0.93 (3 H, d, *J* = 7.3 Hz, Val-CH₃), 0.98 (3 H, d, *J* = 7.3 Hz, Val-CH₃), 1.17–1.89 (28 H, overlapping m, 2 × *t*-Bu, Lys β, γ, δ-CH₂, 2 × valeryl-CH₂), 2.11 (1 H, m, Val β-CH), 2.18 (3 H, t, *J* = 7.3 Hz, valeryl-CH₂), 3.21 (2 H, m, Lys ε-CH₂), 3.95 (1 H, dd, *J* = 2.6, 8.6 Hz, Val α-CH), 4.41 (1 H, dt, *J* = 4.6, 7.9 Hz, Lys α-CH), 5.10 (1 H, d, *J* = 8.6 Hz, Val α-CH), 5.83 (1 H, br s, Lys ε-NH), 6.56 (1 H, d, *J* = 7.3 Hz, Lys α-NH).

Boc-Val-Lys(C6)-O-*t*-Bu (3d). The product from **2** (289 mg, 0.682 mmol) and *n*-hexanoic acid (94 μL, 0.750 mmol) was prepared using the procedure described for **3c**. The crude product was purified by column chromatography (SiO₂, 60:1 CHCl₃–MeOH) to give **3d** (221 mg, 68% as white solid): ¹H NMR (CDCl₃, 270 MHz) δ 0.89(3 H, t, *J* = 6.9 Hz, hexanoyl-CH₃), 0.93 (3 H, d, *J* = 7.3 Hz, Val-CH₃), 0.98 (3 H, d, *J* = 6.9 Hz, Val-CH₃), 1.21–1.85 (30 H, overlapping m, 2 × *t*-Bu, Lys β, γ, δ-CH₂, 3 × hexanoyl-CH₂), 2.11 (1 H, m, Val β-CH), 2.17 (2 H, t, *J* = 7.3 Hz, hexanoyl-CH₂), 3.21 (2 H, m, Lys ε-CH₂), 3.96 (1 H, dd, *J* = 5.6, 8.3 Hz, Val α-CH), 4.42 (1 H, dt, *J* = 4.6, 7.9 Hz, Lys α-CH), 5.11 (1 H, d, *J* = 8.6 Hz, Val α-NH), 5.87 (1 H, br s, Lys ε-NH), 6.58 (1 H, d, *J* = 7.3 Hz, Lys α-NH); FAB–HRMS calcd for [C₂₆H₄₉N₃O₆ + H]⁺ 500.3700, found 500.3697.

Boc-Val-Lys(C10)-O-*t*-Bu (3e). This product was prepared using the procedure for **3c** with starting materials being **2** (252 mg, 0.594 mmol) and *n*-decanoic acid (126 μL, 0.653 mmol). The crude product was purified by column chromatography (SiO₂, 40:1 CHCl₃–MeOH) to give **3e** (252 mg, 76% as white solid): ¹H NMR (CDCl₃, 270 MHz) δ 0.87(3 H, t, *J* = 6.6 Hz, caproyl-CH₃), 0.93 (3 H, d, *J* = 6.8 Hz, Val-CH₃), 0.98 (3 H, d, *J* = 6.8 Hz, Val-CH₃), 1.26–1.89 (38 H, overlapping m, 2 × *t*-Bu, Lys β, γ, δ-CH₂, 7 × caproyl-CH₂), 2.17 (3 H, overlapping m, Val β-CH, caproyl-CH₂), 3.23 (2 H, m, Lys ε-CH₂), 3.95 (1 H, dd, *J* = 5.9 Hz, Val α-CH), 4.41 (1 H, dt, *J* = 5.0, 7.9 Hz, Lys α-CH), 5.11 (1 H, d, *J* = 8.6 Hz, Val α-NH), 5.87 (1 H, br s, Lys ε-NH), 6.58 (1 H, d, *J* = 7.3 Hz, Lys α-NH); FAB–HRMS calcd for [C₃₀H₅₇N₃O₆ + H]⁺ 556.4325, found 556.4337.

Val-Lys(C2)·HCl (4a). A solution of 4 M HCl/dioxane solution (10 mL) was added to a solution of **3a** (225 mg, 0.521 mmol) in THF (1 mL). After 30 min, the reaction mixture was evaporated under reduced pressure. The resulting residue was triturated with Et₂O and dried in vacuo to give **4a** (168 mg, 100% as white powder): ¹H NMR (DMSO, 270 MHz) δ 0.97 (6 H, d, *J* = 6.6 Hz, Val-CH₃), 1.26–1.85 (9 H, overlapping m, Lys β, γ, δ-CH₂, acetyl-C), 2.11 (1 H, m, Val β-CH), 3.01 (2 H, m, Lys ε-CH₂), 4.09 (1 H, t, *J* = 5.9 Hz, Val α-CH), 4.20 (1 H, m, Lys α-CH), 7.96 (1 H, m, Lys ε-NH), 8.22 (3 H, br, Val α-NH₃), 8.67–8.86 (1 H, m, Lys α-NH); FAB–HRMS calcd for [C₁₃H₂₅N₃O₄ + H]⁺ 288.1923, found 288.1923.

Val-Lys(C3)·HCl (4b). The desired product **4b** (173 mg, 100% as a white powder) was obtained from **3b** (227 mg, 0.512 mmol) in a similar manner as described for **4a**: ¹H NMR (DMSO, 270 MHz) δ 0.89–1.04 (9 H, overlapping m, Val-CH₃, propanoyl-CH₃), 1.19–1.93 (6 H, overlapping m, Lys β, γ, δ-CH₂), 2.07 (2 H, q, *J* = 7.3 Hz, propanoyl-CH₂), 2.15 (1 H, m, Val β-CH), 3.02 (2 H, m, Lys ε-CH₂), 4.09 (1 H, t, *J* = 5.9 Hz, Val α-CH), 4.24 (1 H, m, Lys α-CH), 7.86 (1 H, m, Lys ε-NH), 8.22 (3 H, br, Val α-NH₃),

8.56–8.99 (1 H, m, Lys α -NH); FAB–HRMS calcd for $[\text{C}_{14}\text{H}_{27}\text{N}_3\text{O}_4 + \text{H}]^+$ 302.2080, found 302.2070.

Val-Lys(C5)·HCl (4c). The desired product **4c** (195 mg, 100% as white powder) was obtained from **3c** (260 mg, 0.535 mmol) in a similar manner as **4a**: ^1H NMR (DMSO, 270 MHz) δ 0.86 (3 H, t, $J = 7.3$ Hz, valeryl-CH₃), 0.95 (6 H, d, $J = 6.6$ Hz, Val-CH₃), 1.04–1.91 (10 H, overlapping m Lys β , γ , δ -CH₂, 2 $\times$ valeryl-CH₂), 2.06 (2 H, t, $J = 7.3$ Hz, valeryl-CH₂), 2.15 (1 H, m, Val β -CH), 3.02 (2 H, m, Lys ϵ -CH₂), 3.68 (1 H, m, Val- α -CH), 4.18 (1 H, m, Lys α -CH), 7.90 (1 H, m, Lys ϵ -NH), 8.23 (3 H, br, Val α -NH₃), 8.71 (1 H, d, $J = 7.3$ Hz, Lys α -NH); FAB–HRMS calcd for $[\text{C}_{16}\text{H}_{31}\text{N}_3\text{O}_4 + \text{H}]^+$ 330.2393, found 330.2401.

Val-Lys(C6)·HCl (4d). The desired product **4d** (153 mg, 95% as white powder) was obtained from **3d** (206 mg, 0.424 mmol) in a similar manner as described for **4a**: ^1H NMR (DMSO, 270 MHz) δ 0.85 (3 H, t, $J = 6.6$ Hz, Hexanoyl-CH₃), 0.97 (6 H, d, $J = 6.6$ Hz, Val-CH₃), 1.13–1.84 (12 H, overlapping m, Lys β , γ , δ -CH₂, 3 $\times$ hexanoyl-CH₂), 2.05 (2 H, t, $J = 7.9$ Hz, Hexanoyl-CH₂), 2.13 (1 H, m, Val β -CH), 3.01 (2 H, m, Lys ϵ -CH₂), 4.11 (1 H, m, Val α -CH), 4.22 (1 H, m, Lys α -CH), 7.89 (1 H, m, Lys ϵ -NH), 8.21 (3 H, br, Val α -NH₃), 8.62–8.93 (1 H, m, Lys α -NH); FAB–HRMS calcd for $[\text{C}_{17}\text{H}_{33}\text{N}_3\text{O}_4 + \text{H}]^+$ 344.2549, found 344.2549.

Val-Lys(C10)·HCl (4e). The desired product **4e** (183 mg, 97% as a white powder) was obtained from **3e** (239 mg, 0.430 mmol) in a similar manner as **4a**: ^1H NMR (DMSO, 270 MHz) δ 0.86 (3 H, t, $J = 5.9$ Hz, caproyl-CH₃), 0.97 (6 H, d, $J = 6.6$ Hz, Val-CH₃), 1.23–1.76 (20 H, overlapping m, Lys β , γ , δ -CH₂, 7 $\times$ caproyl-CH₂), 2.04 (2 H, t, $J = 7.3$ Hz, caproyl-CH₂), 2.10 (1 H, m, Val β -CH), 3.01 (2 H, m, Lys ϵ -CH₂), 4.09 (1 H, m, Val α -CH), 4.23 (1 H, m, Lys α -CH), 7.86 (1 H, m, Lys ϵ -NH), 8.20 (3 H, br, Val α -NH₃), 8.66–8.85 (1 H, m, Lys α -NH); FAB–HRMS calcd for $[\text{C}_{21}\text{H}_{41}\text{N}_3\text{O}_4 + \text{H}]^+$ 400.3175, found 400.3172.

Cell Culture. Caco-2 cells (ATCC HTB-37) at passage 28 were purchased from the American Type Culture Collection. Although a detailed method was described previously (9), the followings are brief description. Cells were passaged in 75 cm² culture dish in a culture medium consisting of Dulbecco's modified Eagle's medium supplemented with nonessential amino acids (1%), fetal bovine serum (15%), HEPES (5 mM) and NaHCO₃ (2 g/L) without antibiotics. The cells were maintained at 37 °C in an atmosphere of 5% CO₂. Cells between the 30th and 40th passage were used in this study. At 80–90% confluence, cells were seeded using 0.02% EDTA and 0.05% trypsin at a density of 53000 cells/cm² on 60 mm plastic culture dishes. The cells were fed fresh medium every 3 days and were used between the 14th and 16th day for the transport studies.

Uptake Experiments in Monolayer Caco-2. The uptake of [¹⁴C]-Gly-Sar was essentially measured using the manner described elsewhere (9). Unless otherwise indicated, values were corrected for the protein content which was also the same as described elsewhere (9). Initial uptake rates were determined using a linear regression of the linear portion in Gly-Sar uptake vs time (measured at 5, 10, and 15 min).

Kinetic Analysis of Gly-Sar Uptake. The analysis was performed using a Michaelis–Menten type equation with the nonsaturable component described earlier (see eq 1) by an iterative nonlinear least-squares method using a MULTI program (10).

$$v = v_{\max}[\text{S}]/(K_m + [\text{S}]) + K_d[\text{S}] \quad (1)$$

where v represents the initial uptake rate of Gly-Sar; $v_{\max}$, the maximum uptake velocity; $[\text{S}]$, the concentration of Gly-Sar; K_m , Michaelis constant; K_d , the coefficient of the passive diffusion.

Counter-Transport Experiments. These were done using microvilli vesicles from rat intestine. The increase in the uptake rate of Ceftibuten, a substrate of PEPT1, was measured by preloading Val-Lys (C10 or C5) inside vesicles. The entire small intestine of male Wistar rats (250–300 g) was exised under anaesthesia with diethyl ether, and brush border membrane vesicles were isolated according to calcium chloride precipitation method of Kessler et al. (11) which was described previously in some length (12, 13). The purity of the vesicles was assessed by measuring the specific activity of alkaline phosphatase, and the enrichment was more than 12-fold. Membrane vesicles were suspended in an experimental buffer containing 20 mM MES/Tris (pH 5.5), 100 mM D-mannitol, and 100 mM KCl. Twenty microliters of the membrane vesicle suspension (10–15 mg protein/mL) was mixed with 20 μL of the same buffer containing 1 or 10 mM of the test chemical, followed by incubation for 1 h at 30 °C, to load the chemical inside the vesicle. Ceftibuten (400 μL of 1.1 mM solution of the buffer) was added to start the uptake. After designated time (usually 30 s), the uptake was terminated by diluting the mixture with 5 mL of ice-cold washing buffer (150 mM NaCl, 20 mM HEPES/Tris (pH 7.5)) followed by filtration through a Millipore filter (0.45 μm , 2.5 cm diameter; HAWP). The filter was immediately washed once with 10 mL of the ice-cold washing buffer. Ceftibuten trapped on the filter was extracted with 300 μL of mili-Q water using a bath-type sonicator. Nonspecific adsorption of Ceftibuten to the filter was estimated using the experimental buffer without vesicles. The binding was corrected and did not exceed 10% of the total uptake. The concentrations of Ceftibuten were determined by HPLC (L-6200, Hitachi Co. Tokyo) equipped with an UV detector L-4200 (Hitachi Co.). The HPLC conditions were: column, PR-18 (5 μm , 4.2 mm i.d. $\times$ 250 mm, Kanto Chemical Co., Tokyo); a mobile phase, acetonitrile/5 mM citric acid/100 mM KCl (pH 2.5); flow rate 0.7 mL/min; injection volume, 20 μL ; room temperature; detection wavelength, 262 nm.

RESULTS

Synthesis of Hydrophobic Dipeptide Analogues. Our preceding paper (9) suggested the following two points with regard to the substrate recognition by PEPT1: (1) the hydrophobic nature is important and (2) α -carboxyl group is more essential than α -amino group. To confirm the importance of the hydrophobicity, we synthesized hydrophobic dipeptide conjugates: ϵ -Amino group of Lys in Val-Lys was conjugated with aliphatic acids of varying hydrocarbon chain lengths such as acetic acid (C2), propanoic acid (C3), pentanoic acid (C5), hexanoic acid (C6), and decanoic acid (C10). We thus obtained peptide–conjugate homologues with varying hydrophobicity but with the dipeptide backbone kept constant. Val-Lys was selected as a core dipeptide because it is highly resistant to the hydrolysis by peptidase owing to the bulkiness of Val (14) and to the existence of the free amino group. We designated the Val-Lys conjugated to an aliphatic acid whose carbon number is n as Val-Lys(Cn).

Compound **6a** was synthesized from commercially available protected amino acids **1** and **2** (Scheme 1). To remove the Cbz-protecting group of **3**, we chose acetic acid as a reaction solvent since **4** was unstable and an

Scheme 1. Synthesis of Conjugates of Val-Lys with Linear Aliphatic Acids, Val-Lys(Cn)^a

^a Reagents: (i) WSCD·HCl, HOBT, DMAP, DMF; (ii) 10% Pd/C, AcOH, then ion-exchange resin; (iii) Ac₂O or (CH₃CH₂CO)₂O, Et₃N, DMF; (iv) CH₃(CH₂)_nCO₂H ($n = 3$ or 4 or 8), WSCD·HCl, Et₃N, DMF; (v) 4 M HCl/dioxane.

Figure 1. Inhibitory effects of Val-Lys conjugated with linear aliphatic acids, Val-Lys(Cn) on the uptake of 100 μM Gly-Sar, a good substrate for PEPT1. Here, n in Val-Lys(Cn) stands for the hydrocarbon numbers of conjugated linear aliphatic acids. Initial uptake rates of Gly-Sar were measured in the presence of 100 μM or 1 mM of Val-Lys (second and third bar, respectively), or 100 μM Val-Lys(Cn). Control means the uptake rate of 100 μM Gly-Sar.

undesired isomerization occurred in a neutral solution. After removal of Cbz-protecting group, the product was applied to a weakly acidic ion-exchange resin column, and **4** was obtained as a hydrochloride salt. Acylation of **4** at the ϵ -amino group gave **5a**. The desired compound **6a** was easily obtained from **5a** by removal of Boc and *tert*-butyl ester protecting group with 4 M HCl/dioxane. Similarly, other compounds **4b**, **4c**, **4d**, and **4e** were obtained.

The Importance of Hydrophobicity on Recognition by PEPT1. Gly-Sar is a good substrate of PEPT1 (15). Gly-Sar uptake kinetics by Caco-2 cells satisfactorily followed eq 1. The values of K_m and $v_{\max}$ were 0.84 mM and 0.54 nmol/min/mg protein, respectively. A reference (15) described that the rate obtained at 10 μM Gly-Sar was about 0.13 nmol/10 min/mg protein. Our kinetic data give 0.07 nmol/10 min/mg protein at this condition, which is consistent with those reported by previous authors (15).

The uptake rate of 100 μM Gly-Sar was measured in the presence of Val-Lys and various Val-Lys(Cn). The uptake rate of Gly-Sar was inhibited to be 30% of the control level by 1 mM Val-Lys, whereas 100 μM Val-Lys

slightly influenced the uptake rate of Gly-Sar (Figure 1). These are consistent with the reported affinity of Val-Lys for PEPT1. As n increases, Val-Lys(Cn) more potently inhibits the Gly-Sar uptake. The conjugates synthesized here are hydrophobic and thought to interact with membrane lipid bilayer, so there might be possibility that Val-Lys(Cn) inhibit the transport *nonspecifically*. The effect of glucose transport was, hence, examined using Val-Lys(C10) as a most potent inhibitor among the Val-Lys(Cn) synthesized. Uptake rate of 100 μM glucose was 0.23 nmol/mg protein/min as a control, while those in the presence of 50 or 100 μM of Val-Lys(C10) were 0.23 or 0.24 nmol/mg protein/min, respectively, suggesting that the inhibition of the conjugates may be specific to PEPT1.

To evaluate the kinetic type of inhibition by Val-Lys-(C10) which is the strongest, we performed Dixon-Webb plot analysis (16, 17). Results are detailed in Figure 2 where the three lines cross at one point, and the slopes of these lines in this Dixon plot were replotted against the reciprocals of the Gly-Sar concentrations. The slopes

Figure 2. Val-Lys(C10) is a competitive inhibitor of Gly-Sar uptake by PEPT1 as analyzed by Dixon–Webb plot. Gly-Sar uptakes were measured in the presence of varying concentrations of Val-Lys(C10) plotted in abscissa. Open circles, closed circles, and diamonds represent data obtained in the presence of 50, 100, and 200 μM Gly-Sar, respectively. It is noted that the three lines nearly cross at one point. The abscissa and ordinate value of this cross point means the inhibition constant (K_i) and the reciprocal of V_{max} for Gly-Sar uptake, respectively. From this cross point, K_i and V_{max} were estimated to be about 50 μM and 0.65 $\text{nmol}\cdot\text{min}^{-1}\cdot\text{mg}^{-1}$. This V_{max} value agrees well with 0.54 $\text{nmol}\cdot\text{min}^{-1}\cdot\text{mg}^{-1}$ that was obtained from eq 1 (see text). Inset shows the plot of the slope of this Dixon plot against the reciprocal concentration of Gly-Sar, indicating the proportional relationship. As described in the text, these data clearly show competitive inhibition.

were proportional to the reciprocals as shown in an inset. This shows the competitive inhibition of Gly-Sar by Val-Lys(C10). The inhibition constant (K_i) was calculated to be 50 μM . In a previous paper (9), we found that the K_i value of Val-Lys(Flu) is as small as 5 μM . Despite this, the present Val-Lys(C10) may be a strong inhibitor because the values of K_i or K_m reported for various peptide transporter systems are in the range of 1–10 mM (18–20).

Dipeptide conjugates (Val-Lys(Cn)) are, thus, verified to be recognized by PEPT1. We further examined the trans-stimulation effect of the conjugate on the substrate transport to determine directly whether the conjugate is a transportable substrate. This trans-stimulation experiment was employed by previous authors (21) to examine whether a test compound is a transport substrate. Cefutibuten was chosen as a PEPT1 transport substrate. As depicted in Figure 3, the initial uptake of cefutibuten was markedly enhanced in the vesicles preloaded with Gly-Sar or β -lactam antibiotics cephalixin, whereas not with valine. These mean that Cefutibuten is a good substrate for PEPT1, and show good control results. Cefutibuten uptake was enhanced about 2-fold by the preloading of 1 mM Val-Lys(C10) and more than 2-fold by 1 mM Val-Lys(C5), revealing that Val-Lys(Cn) are transport substrates of PEPT1. The reason C5 has larger effect than C10 is not clear; it might be caused by the difference of the intravesicle concentrations after the loading or by the cis-inhibition of C10 due to its higher affinity.

DISCUSSION

Figure 1 implies that more hydrophobic Val-Lys(Cn) inhibits the uptake of Gly-Sar more potently. Figure 2 shows that Val-Lys(C10) is a competitive inhibitor of Gly-Sar, meaning that Val-Lys(C10) interacts directly with the substrate binding site. Figure 3 implies that Val-Lys (C5 and C10) are substrates. These findings suggest the

Figure 3. Trans-stimulation effect of Val-Lys(C5) and Val-Lys(C10) on the uptake of Cefutibuten. The conjugate was preloaded into rat brush border membrane vesicles, followed by the Cefutibuten uptake experiments. In this figure, control means the uptake rate of 100 μM Cefutibuten, and its absolute value was 526 $\text{pmol}/30 \text{ s}/\text{mg}$ protein. Bars with 10 mM Gly-Sar and with 10 mM cephalixin show the stimulation of Cefutibuten uptake after Gly-Sar or cephalixin, well-established PEPT1 substrates, were preloaded. 10 mM valine, which is not a substrate, did not induce the stimulation. These are results of control experiments for the counter-transport experiments. ** indicates $P < 0.05$, significant differences from the control using Student t-test.

importance of hydrophobicity of the substrate recognition of PEPT1. The same suggestion was recognized previously (9) using fluorescent dipeptide analogues.

Here a question might arise that the significance of hydrophobic properties is found only in artificial substrates, and this might not be valid for physiological

Table 1. Correlation between Inhibition of Gly-Sar Uptake by Various Dipeptides and Their Hydrophobicity Indexes

dipeptide	hydrophobicity index ^a (kcal/mol)	uptake ^b (% of control)
Gly-Sar	—	100
Gly-Phe	4.7	20.6
Gly-Leu	3.8	19.4
Gly-Pro	0.8	30.1
Gly-Glu	-7.2	64.1
Ala-His	-1.4	79.0
Val-Lys	-6.2	36.1

^a Sum of hydrophobicity indexes of two amino acids composing the dipeptide. The hydrophobicity indexes are taken from ref 22.

^b Data were taken from ref 9. Initial uptake rate of 100 μ M Gly-Sar by Caco-2 cells was measured in the absence or presence of 1 mM of various dipeptides.

substrates. We measured the inhibition of Gly-X dipeptide on the Gly-Sar uptake (see Figure 2 in ref 9). The order of inhibition by X was Phe > Leu > Pro > Glu, which is consistent with the order of hydrophobicity of X. One way to express the degree of the hydrophobicity of amino acids is to evaluate the free energy changes from a hydrophobic medium of low dielectric constant to water, as was done by Engelman et al. (22). Table 1 lists the percent uptake of 100 μ M Gly-Sar inhibited by various dipeptides and the hydrophobicity indexes (sum of the free energy change of two amino acids composed of dipeptide). Dipeptides used are Gly-X, Val-Lys, and Ala-His. For those of Gly-X dipeptide, the inhibition shows fairly good linearity against the hydrophobicity indexes, the free energy change (plot not shown). The data points of Val-Lys and Ala-His, however, do not follow the line of Gly-X, suggesting that total hydrophobicity of dipeptide

is not important but that the hydrophobicity of the X residue of Y-X dipeptide might determine the affinity when Y is fixed. Similar results were obtained by Brandsch et al. (23) who investigated the decisive structural factors relevant for dipeptide-PEPT1 interaction by measuring the ability of Pro-X dipeptide derivatives to inhibit Gly-Sar transport in Caco-2 cells: They demonstrated that the affinity of dipeptide to PEPT1 is determined by the hydrophobicity of C-terminal amino acid. They further concluded that structural parameters which play an important role in Pro-X recognition is a rigidity of the structure, since the affinity of a dipeptide with much high rigidity, Pro-Pro is 8-fold higher than Pro-Ala. To confirm these aspects of importance of the hydrophobicity, however, would require testing many dipeptides other than those.

The most probable conformation of Val-Lys(C10) (in vacuo, 25 °C) was calculated by 20,000-step Monte Carlo conformational search using AMBER*, and the obtained conformation is shown in Figure 4. It is assumed that the dielectric constant within the membrane is small, so our calculation in vacuo was done. Three hydrogen bonds are formed: one is between NH₃ of Val and C=O of Lys, the second is between N of the peptide-bonding and C=O of the caproyl group, and the third is between NH₃ of Val and C=O of the caproyl. These hydrogen bonds give rise to the bend structure of Val-Lys(C10) shown in the figure. It is worthwhile to note that the inhibition becomes stronger with increase in *n*, and that the inhibition is still observed at the C10 conjugate (see Figure 1), suggesting that the hydrophobic moiety near the substrate-binding site is large enough to accommodate the C10 hydrocarbon chain. This observation and the simulated structure of Val-Lys(C10) led us to assume

**Figure 4.** Stereoview of the simulated structure of Val-Lys(C10) in vacuo. The red broken lines represent the hydrogen bonds.

that the hydrophobic moiety might be membrane phospholipids or a helix whose surface toward the inner pore of the PEPT1 is hydrophobic. The latter may be less probable because a series of hydrophobic amino residues might not be present at the surface toward the inner pore of the transporter.

Döring et al. (24) showed that ω -amino fatty acid was transported by PEPT1, indicating that the presence of a peptide bond in a substrate is not a structural requirement. In addition, removal of either the amino group or the carboxyl group in ω -amino fatty acid maintained the affinity of the compound for interaction with the transporter but abolished the capability for the transport. EC₅₀ values of hexylamine and octylamine were 6.19 and 0.37 mM, respectively. The values for hexanoic acid and octanoic acid were 2.75 and 1.36 mM. These facts also suggest the importance of hydrophobicity for the recognition by PEPT1.

Miyamoto et al. (25) reported the inhibition by various dipeptides or tripeptides on the Gly-Sar uptake into rabbit renal vesicles. Analysis focusing on the hydrophobicity showed a similar tendency although the data points are scattered (plot not shown). Moore et al. (26) found that hydrophobic oligonucleotide conjugates inhibit the Gly-Pro uptake by Caco-2 cells. Otto et al. (27) also showed the preference of hydrophobic dipeptides by primary culture cells from rat anterior pituitaries, although property of this dipeptide transporter is somewhat different from the PEPT system because of there being no recognition of captopril, thiorphan, and benzylpenicillin. The physiological meaning that peptides having hydrophobic amino acids have high affinity is not known at present. On the other hand, there is an opposite report of the oligopeptide transport in human fibrosarcoma cell line HT1080 when we analyze the data of Nakanishi et al. (28). We do not know the reason, but should take the difference of the transporter into consideration.

The present data suggest the existence of a hydrophobic moiety in PEPT1, and this moiety is composed of the substrate binding site because Val-Lys(C10), Val-Lys(C5), and probably other Val-Lys(Cn) are substrates. Bailey et al. (29) also suggested the presence of hydrophobic part of the substrate recognition. Identification of this moiety on a molecular basis will be further investigated, and its physiological meaning should be clarified. It has been shown that ω -amino fatty acids are transportable substrates under the condition that two charged groups are separated within a certain distance (24). This and the finding presented here may be an interesting clue to develop the transportable carrier conjugated with a poorly absorbable drug.

ACKNOWLEDGMENT

We thank Miss Momoko Satoh for her assistance. This investigation was supported in part by a Grant-in-Aid from the Ministry of Education, Science, Sports and Culture of Japan.

Energy-Transfer Cassette Labeling for Capillary Array Electrophoresis Short Tandem Repeat DNA Fragment Sizing

Lorenzo Berti,[†] Igor L. Medintz,[†] Jennifer Tom, and Richard A. Mathies*

Department of Chemistry, University of California, Berkeley, California 94720. Received December 8, 2000

Energy-transfer (ET) dye-labeled primers significantly improve fluorescent DNA detection because they permit excitation at a single common wavelength and they produce well separated and intense acceptor dye emission. Recently, a new ET cassette technology was developed [Berti, L. et al. (2001) *Anal. Biochem.* 292, 188–197] that can be used to label any PCR, sequencing, or other primer of interest. In this report we examine the utility of this ET cassette technology by labeling seven different short tandem repeat (STR) specific primers with each of the four ET cassettes and analyzing the PCR products generated on a MegaBACE-1000 capillary array electrophoresis system. More than 60 amplicons were generated and successfully analyzed with the ET cassette-labeled primers. Both forward and reverse primers were labeled for multiplex PCR amplification and analysis. Single base pair resolution was achieved with all four ET cassettes. This ET cassette-primer labeling procedure is ideally suited for creating four-color fluorescent ET primers for STR and other DNA assays where large numbers of different loci are analyzed including sequencing, genetic identification, gene mapping, loss of heterozygosity testing, and linkage analysis.

INTRODUCTION

Microsatellite DNA or short tandem repeat (STR) sequences have proven invaluable in many aspects of genomic analysis. The power of these microsatellite loci is derived from their high degree of polymorphism and genome-wide distribution (Edwards et al., 1991). There are more than 5200 mapped microsatellite loci available for human genomic studies (Dib et al., 1996). Microsatellite loci are important for gene discovery and genome mapping, genome wide searches for disease markers and susceptibility genes, parentage testing and forensic identification, clinical diagnosis, evolutionary studies, loss of heterozygosity testing associated with cancer diagnosis, and linkage analysis (March, 1999; Reed et al., 1994; Cornelis et al., 1998; Ober et al., 1998; Davies et al., 1994; Edwards et al., 1991; Wiegand et al., 2000; Chakraborty et al., 1999; Caskey et al., 1992; Medintz et al., 2000a).

The intrinsic nature of short tandem repeat DNA sequences dictates that their analysis is heavily reliant on electrophoretic sizing separations. STR analysis usually consists of a locus-specific PCR amplification followed by electrophoretic separation of the products (Mansfield et al., 1996; Cornelis et al., 1998; Medintz et al., 2000a). In order for STR-based genetic assays to be highly informative, large numbers of microsatellite loci have to be screened in thousands of individuals (Cornelis et al., 1998; Ober et al., 1998; Davies et al., 1994; March, 1999), and each study will require multicolor fluorescently labeled locus-specific primers. A steady progression of improved slab gel and capillary array electrophoresis (CAE) instruments have been developed that can increase the amount of information gathered from these loci (Kheterpal and Mathies, 1999; Meldrum 2000) including the MegaBACE-1000 CAE system and the ABI 3700 (Fox,

1999; Meldrum, 2000). Analyses on these instruments have relied, at least in part, on energy-transfer (ET) dye-labeling technology.

In comparison to single dye-labeled primers, ET labeling offers the advantages of excitation at a single common wavelength with distinctive and intense acceptor dye emission and matched electrophoretic mobilities of the labeled targets (Hung et al., 1997; Ju et al., 1995; 1996a). ET labeling is particularly well suited to multicolor fluorescence assays such as STR analysis requiring coanalysis of analyte and standard (Mansfield et al., 1998).

Our original ET primer constructs introduced the donor and acceptor dyes onto a modified primer, or spacer, after automated oligonucleotide synthesis, resulting in a lengthy synthetic procedure (Ju et al., 1995; Ju et al., 1996a). An ET cassette synthetic scheme allowing the attachment of an ET label to any primer has been developed (Ju et al., 1996b). However, this early procedure required synthesis of the cassette on the 5' end of the primer during automated synthesis and postsynthetic dye conjugation. A convenient and simple synthetic method for ET labeling any primer of interest would be valuable.

Recently, an approach was developed (Berti et al., 2001) for easily tagging any primer sequence or other target of interest with a reactive fluorescent ET cassette label. A schematic representation of such an ET cassette-labeled primer is presented in Figure 1A. In our construct, the ET cassette-labeled primer consists of three parts: the ET cassette itself, the primer, and the disulfide linker joining the two. The chemical structure of the reactive ET cassette is presented in Figure 1B. The cassette consists of a sugar–phosphate spacer with a 6-FAM (6-carboxyfluorescein) donor at the 3'-end, an acceptor dye linked to a modified T-base at the 5'-end of the spacer, and a mixed disulfide group for coupling to the 5'-end of a thiol-modified primer. The coupling reaction is a two-step process (see Figure 1C) consisting

of primer deprotection followed by conjugation with the ET cassette. By quantitative coupling to a thiol-activated M13-target primer through disulfide exchange, a four-color set of ET cassette-labeled M13-primers have been constructed and used for both PCR and DNA sequencing analysis. The acceptor dye emission intensities of primers produced in this manner are comparable to commercially available ET primers (Berti et al., 2001).

In this report we labeled seven STR specific primers in each of four colors with our ET cassettes and analyzed the amplicons generated from these primers on a MegaBACE-1000 CAE system. Amplicons from a primer set where either the forward or reverse primer was labeled were generated as well as amplicons from multiplex amplification mixtures. Single basepair (bp) resolution is easily achieved with amplicons generated from four-color ET cassette labeled STR primers. This study illustrates that this ET-cassette labeling technology is particularly well suited to microsatellite analysis and other fluorescent DNA assays where large numbers of custom-labeled ET primers are required.

MATERIALS AND METHODS

DNA. Purified K562 cell line DNA was purchased from Promega Corp. (Madison, WI). Universal CEPH (Centre d'Etude du Polymorphisme Humain) Donor DNA, catalog number NA10859, was purchased from the Coriell Cell Repository (Camden, NJ). A genomic DNA sample containing the previously characterized THO1 9.3/10 alleles was generously provided by G. Sensabaugh, School of Public Health, U. C. Berkeley (Wang et al., 1995; 1996).

ET Cassette Synthesis. Briefly, starting with a 6-FAM-labeled controlled-pore glass (CPG) column on an Applied Biosystems (Foster City, CA) 392 DNA Synthesizer, the 1',2'-dideoxyribose monomers, amino modified T-base, and a monomethoxytrityl (MMT)-protected 5'-amino-modifier group were added sequentially through standard phosphoramidite chemistry. Cassettes with both seven and eight 1',2'-dideoxyribose monomer spacings were synthesized for this study. The 6-FAM-labeled cassette precursor was cleaved from the CPG support by NH_4OH treatment. The trifluoroacetamide protecting

group on the amino-modified T-base was also removed by this NH_4OH treatment. Succinimidyl ester derivatives of the acceptor dyes were then conjugated with the amino modified T-base. The acceptor dyes 6-carboxyrhodamine-110 (R110, emission maximum at ~ 525 nm), 6-carboxyrhodamine-6G (R6G, emission maximum at ~ 555 nm), carboxytetramethylrhodamine (TAMRA, emission maximum at ~ 572 nm), and 6-carboxy-X-rhodamine (ROX, emission maximum at ~ 620 nm) were obtained from Molecular Probes (Eugene, OR). The donor 6-FAM dye has an emission maximum at ~ 497 nm. Unreacted dyes were removed by size exclusion chromatography on PD-10 cartridges (Amersham/Pharmacia Biotech, Piscataway, NJ), and then the MMT-5'-aminomodifier group was deprotected with aqueous acetic acid treatment. A sulfosuccinimidyl 6-[3'-(2-pyridyldithio)propionamido]-hexanoate (Sulfo-LC-SPDP) linker (Pierce, Rockford, IL) was then coupled to the amino-functionalized ET cassette, and the activated cassette was purified by reverse phase HPLC. A particular ET cassette is described by the abbreviation D-S_n-A, where D is the donor, A is the acceptor, and S_n indicates the number of sugar phosphate monomers constituting the spacer (Ju et al., 1995). The ET cassettes with R110 and TAMRA as the acceptor dyes utilized a spacer with eight sugar phosphates (S-8) while cassettes with R6G and ROX as the acceptors utilized seven sugar phosphate spacers (S-7). In this cassette format the modified T to which the acceptor dye is attached will function as part of the spacer. Therefore, the spacings for the cassettes used in this study are functionally nine and eight units, respectively. The donor-acceptor dye pairings and the sugar phosphate spacers in our current cassettes are similar to those found in commercially available M13 ET labeled primers. The donor-acceptor dye pairs and spacings were selected to maximize the acceptor emission intensity while minimizing the relative donor emission.

ET Cassette-Primer Conjugation. Primer sequences are presented in Table 1. Modified primers for ET cassette conjugation were purchased from Operon Technologies (Alameda, CA) with a 5'-protected thiol (C6 S-S modification) and the trityl protection groups already removed. Additional primers were obtained from GIBCO BRL (Gaithersburg, MD). The thiol primer, protected as a disulfide, was deprotected by incubating in a 0.17 M phosphate buffer pH 8.0 solution containing 0.04 M dithiothreitol (DTT) for 16 h at 37 °C in a MJ Research PTC-100 Programmable Thermal Cycler (Watertown, MA). The thiol-deprotected primers can be stored for prolonged periods of time in this same solution at -20 °C. Just prior to coupling, the thiol-deprotected primers were purified using a PD-10 cartridge. A typical primer-ET cassette coupling reaction was performed as

follows: equimolar amounts (~ 1 nmol) of activated ET cassette and purified thiol-deprotected primer are mixed together in a 0.5 μL Eppendorf tube, dried down in a vacuum centrifuge, and reconstituted in 20 μL of 20 mM phosphate buffer containing 1 mM EDTA pH 7.5 and incubated at 45 °C overnight in the thermal cycler. The ET cassette-conjugated primers were then purified by reverse phase HPLC and quantitated by UV spectroscopy. ET cassette-labeled primers were stored in 1X TE at -20 °C.

PCR Amplification. Fifty nanograms of genomic DNA was utilized for each PCR reaction along with 15 pmol of both the ET cassette label and appropriate reverse primer. Reactions utilized Qiagen PCR Master Mix (Valencia, CA). Reaction conditions used were as described for specific STR loci (Promega, 1998) on the MJ Research Thermal Cycler. Successful PCR was verified by agarose gel electrophoresis.

Sample Preparation and Sizing Standards. PCR amplicons were desalted using the Qiagen PCR Purification Kit. Samples were resolubilized in 50 μL of 0.5X TE buffer. Approximately 1 μL of sample was then mixed with 5 μL of 75% deionized formamide containing dye-labeled sizing markers at a concentration of 10 fM. The TET (tetrachlorofluorescein, emission maximum at ~ 538 nm) Mapmarker Sizing Standard consisting of 20 fragments (70, 80, 90, 100, 120, 140, 160, 180, 190, 200, 220, 240, 260, 280, 300, 320, 340, 360, 380, and 400 bp) was obtained from Bio Ventures Inc. (Murfreesboro, TN). The ET-400-R sizing standard obtained from Amersham/Pharmacia consists of 20 fragments (60, 90, 100, 120, 150, 160, 170, 190, 200, 220, 250, 270, 290, 300, 310, 330, 350, 360, 380, and 400 bp) labeled in an energy transfer format with FAM as the donor dye and ROX as the acceptor dye. Samples were placed in a 96-well microtiter injection plate and centrifuged for 5 s to remove air bubbles. Less than 10 min before injection, the samples were denatured at 95 °C for at least 5 min and immediately placed on ice.

Capillary Array Electrophoresis. A MegaBACE-1000 capillary array electrophoresis system (Molecular Dynamics, Sunnyvale, CA) was utilized for sizing separations (Fox, 1999; Medintz et al., 2000a; Meldrum, 2000). This CAE system contains 96 capillaries, each with a 40 cm length (Bashkin et al., 1996a,b). Long Read linear polyacrylamide matrix, LPA, containing 7 M urea in a Tris/Taps buffer, was obtained from Amersham/Pharmacia Biotech. The matrix was introduced into the capillaries at 400 psi for 200 s followed by pre-electrophoresis for 5 min at 10 kilovolts (kV). Denatured samples were introduced into the capillaries by electrokinetic injection for 45 s at 3 kV and then electrophoresed at 10 kV for 75 min. Fresh matrix was introduced into

the capillaries between each run. The instrument was set up to run in sequencing mode with the 488 nm laser only used for fluorescent excitation. Four-channel fluorescent detection was performed with the following emission wavelength detection ranges: Channel 1, 555 ± 10 nm; Channel 2, 520 ± 10 nm; Channel 3, ≥ 610 nm; and Channel 4, 580 ± 10 nm.

Data Analysis. Data were analyzed with Genetic Profiler Software Version 1.1 (Molecular Dynamics, Sunnyvale, CA). The raw signal data files were imported into the Genetic Profiler program where they underwent background subtraction using a spectral separation or cross-talk matrix. Unknown samples were sized against the DNA sizing ladders included in each capillary using a third-order local algorithm (Medintz et al., 2000a; Wedemayer et al., 2001).

RESULTS

Evaluation of ET Cassette-Labeled STR Amplicons. All the primers utilized in this study were successfully labeled in parallel with the four different ET cassettes. Amplicons were generated from the K562 DNA and the CEPH control DNA and were genotyped on the MegaBACE-1000 CAE instrument. Figure 2 presents the electropherograms generated by genotyping all the FAM-7-ROX-primer derived alleles amplified from the CEPH control DNA. As can be seen, each of the amplicons is clearly identified and genotyped even though the amount of PCR product utilized for these separations represents only 1/50th of the total amount of purified PCR amplicon. Furthermore, these strong signals are obtained in the ROX channel, which has the reddest absorption (~595 nm) and emission (~620 nm); without using ET-labeling the ROX emission would be more than 10-fold weaker (Medintz et al., 2000b; 2001). The spacings between determined allele sizes corresponds to 4-bp increments as predicted for the TPOX, THO1, D7S820, and vWA loci. The difference between labeling either the forward or reverse primer for the CSF1PO locus is only 0.2 bp. This very slight (0.06%) difference is achieved even though the DNA strands that are labeled and separated are distinct in sequence.

Since ET cassette-primer labeling results in the addition of the ET cassette to a modified primer, a slight difference in predicted versus determined fragment size is expected. The approximate sizes of the cassettes were predicted by taking the molecular weight of the cassette and dividing by the average molecular weight of a nucleotide (330 g/mol). Using this method, the predicted size of an S-8 cassette should range from 9.5 bp for the FAM-8-TAM cassette to 9.8 bp for the FAM-8-ROX primer. Use of an S-7 cassette will drop these predicted sizes into the 8.5 to 8.8 bp range. To determine the actual effect of ET cassette conjugation on fragment sizes,

amplicons were generated from the K562 genomic DNA. The predicted sizes of the alleles generated from K562 DNA with the corresponding unlabeled primers have been characterized (Promega Corp, 1998; www.cstl.nist.gov). Table 2 presents a comparison of the predicted K562 allele sizes at the seven loci with those determined using all 4 ET cassette-labeled primers. On average, the ET labeled alleles were increased in size by 12.0 to 18.1 bp for the THO1 9.3 allele and the D13S317 8 allele, respectively. The standard deviations of the four-color sizing values for each allele ranged from 0.29 for the vWA 16 allele to 0.85 for the 9 allele at the D7S820 locus.

Multiplex Amplification. To explore the utility of ET cassette-labeled primers for multiplex coamplification and analysis, three separate amplicons were generated in a single reaction. Using K562 DNA, amplicons were generated with the THO1 FAM-8-TAM, TPOX FAM-7-R110, and CSF1PO reverse FAM-8-R6G labeled primers. Figure 3 presents the separation and genotyping of this triplex analysis against the ET-400-R sizing ladder. All the expected amplicons were generated, and their sizing did not differ from values presented in Table 2.

Single Base-Pair Resolution. The original characterization of these disulfide ET cassettes showed through four-color sequencing of M13 DNA that single base-pair resolution is easily achieved (Berti et al., 2001). A similar test in the context of STR analysis was performed using a THO1 9.3/10 allele-containing sample that was genotyped with all four ET labels. The THO1 9.3 allele represents a common variant that differs from the 10 allele by only a single base, instead of the usual 4 bp repeat (Promega 1998; Wang et al., 1995; 1996). Figure 4 presents the genotyping of this sample with all ET cassette labeled THO1 primers. Single bp resolution between the two alleles is achieved for all four colors. The interallele size difference in every case is no more than 1/10th of a bp, or 0.04%.

Effects of S-7 and S-8 Sugar Phosphate Spacers. To determine the effects of cassettes containing different number of sugar phosphate spacers on electrophoretic separations, the CEPH sample was genotyped at the THO1 locus with FAM-7-TAM and FAM-8-TAM ET cassette labeled primers. The expected size differences for these two cassettes should be around 1 bp. Figure 5 presents the separation of the alleles generated in this experiment. The 4 bp difference between alleles is still-maintained while the difference caused by the change in spacer number is less than 1 bp. Similar results were obtained with K562 DNA for the same primers as well as for the D7S8 primer labeled with FAM-7-R110 and FAM-8-R110 cassettes (data not shown).

Figure 2. Panels A–G present electropherograms generated by genotyping all the FAM-7-ROX primer derived alleles amplified from the CEPH control DNA. Samples (red traces) were separated against the TET Mapmarker Sizing Standard (green traces) on the MegaBACE-1000 CAE system, and resulting data were analyzed using Genetic Profiler Version 1.1 software. The allele sizes as determined are displayed above the peaks. Peak signal strength range is 600–10000 fluorescence units.

DISCUSSION

This study was performed to explore the feasibility of using ET cassette labeling to tag any primer of interest in a multicolor fluorescent format. To accomplish this we

labeled seven different STR specific primers, each with four different ET cassette labels, and genotyped amplicons generated from these primers. Our ET cassette labeling methodology has numerous advantages. One can tag any primer of interest with any of the multicolor ET

Figure 3. Four-color electropherogram demonstrating multiplex coamplification and analysis. Three separate amplicons were generated in a single reaction using K562 DNA and the THO1 FAM-8-TAM, TPOX FAM-7-R110, and CSF1PO reverse FAM-8-R6G labeled primers. The THO1 (black), TPOX (blue), and CSF1PO (green) alleles were separated and sized against the ET-400-R Sizing Standard (red). Allele sizes are indicated above the peaks.

Figure 4. Genotyping of the 9.3/10 allele containing sample with all 4 ET cassette-labeled THO1 primers. The small peak just to the left of the first allele represents a PCR stutter artifact common in STR DNA typing of these loci (Medintz et al., 2000a; Promega, 1998). The red (ET-400-R) or green (TET Mapmarker) peaks at 200 and 220 bp are generated from the sizing standard. Cassettes used for labeling are indicated and the determined sizes are presented above the peaks.

cassette labels. Primers destined for ET cassette labeling can be obtained commercially with a 5' protected thiol modifier; the primer can be deprotected in one step and stored for subsequent tagging. This ET cassette labeling technology is easily adapted to 96 well parallel robotic preparation formats, and both the primer deprotection

and ET cassette labeling reactions can be performed with a PCR thermal cycler. Due to the high sensitivity obtained when using ET cassette labels, only small amounts of labeled amplicons are needed for actual analysis. This means that primer concentrations and reaction volumes can be substantially reduced.

Figure 5. Effect of S-7 and S-8 sugar phosphate spacers on the mobility shift. The CEPH sample was genotyped at the THO1 locus with primers that had been labeled with either the FAM-7-TAM (A) or the FAM-8-TAM (B) cassettes. Alleles appear in black against the TET sizing markers in green at 190 and 200 bp.

To demonstrate multiplex analysis we evaluated the amplicons generated from ET cassette-labeled primers on a MegaBACE-1000 CAE system. All primers were labeled in all four colors and alleles from K562 and the CEPH control DNA were successfully generated by PCR and analyzed for all seven primers. The addition of the ET cassettes to these primers was expected to increase the sizes of amplicons by approximately 8–10 bp. The results presented in Table 2 show that the actual average fragment size for each of the seven loci increases by 12.0 to 18.1 bp. However, the standard deviation between each of the four cassette labels for each primer is very small (0.29 to 0.85 bp). This indicates that the addition of any one of the ET cassettes to a primer will result in a very small sizing difference as compared to another ET cassette for that same primer. The effect of the ET cassette on predicted versus determined fragment sizes can be ascribed to the increased mass and bulk of the cassette, the difference in charge, as well as conformational influences. The fact that the TET Mapmarker has a single fluorescent label directly attached to each DNA strand as well as the noncassette structure of the ET-400-R ladder also have to be taken into account. These structural differences will influence electrophoretic migration rates and cause relative mobility differences. Additionally, the sizing markers are all present as single-stranded DNA fragments while the amplicon sample consists of both the labeled and unlabeled complementary DNA strand. Although the samples are denatured prior to analysis, this may still influence electrophoretic migration. However, these mobility shift effects can be easily corrected by labeling all the fragments in the separation with ET cassettes or through the use of mobility shift correction software.

The 4 bp incremental size difference between STR alleles is strictly maintained in this ET format (see Table 2 and Figures 2–5). Furthermore labeling either the forward or reverse primer does not alter sizing differences as evidenced by the 0.2 bp difference in amplicon size at the CSF1PO locus (Figure 2). This small difference is achieved even though the analyzed strands are distinct

in sequence. Finally, primers labeled in this manner are functional for multiplex coamplification and analysis. This is demonstrated through a triplex amplification and four-color genotyping analysis (Figure 3). Moreover, single bp resolution is easily achievable when using these primers (Figure 4).

An added benefit of this labeling format is the flexibility to choose ET cassettes with different numbers of dideoxyribose monomer spacers. This becomes important when analysis requires differentiating amplicons that migrate very close to one another (Hung et al., 1997). By utilizing cassettes with varying spacers to label different primers, coeluting amplicons can be forced to migrate separately. Adjustment of cassette monomer spacing will allow adjustment in the differences between predicted vs electrophoretic size of fragments. Additionally, varying the number of spacers in an ET pair can substantially increase or decrease the relative fluorescent emission of the acceptor dye (Hung et al., 1998). For instance, cassettes can be constructed that have very high acceptor dye emissions, ideal for sequencing, or very low donor spectral cross-talk, ideal for multiplex fragment sizing/genotyping analysis.

ET cassette primer labeling is not limited to STR analysis. This labeling format can be used in any other assay where fluorescent tagging of analyte is required. This includes microarray hybridization formats, allele specific amplification, as well as protein and cell labeling (Meldrum, 2000; Medintz et al., 2000b, 2001). Additionally, the ability to label any sequencing primer in a four-color ET cassette format will facilitate custom sequencing methods and plasmid vector formats beyond those containing the M13 sequence.

In summary, these experiments have successfully demonstrated the wide applicability of our ET cassette labeling method and the ease with which the ET cassette labeling technology can be used for fluorescent tagging of any DNA oligonucleotide target. This ET cassette labeling technology will increase, expand, and diversify fluorescent DNA analysis.

ACKNOWLEDGMENT

We thank Melanie Mahtani, Kristin Pirkola, and David Shen at Amersham-Pharmacia Biotech for assistance in using the Molecular Dynamics MegaBACE-1000 CAE system and for providing the Genetic Profiler software. The authors also thank G. Sensabaugh for providing genotyping samples. I.M. is supported by NIH Program Project grant P01 CA77664 in collaboration with Johns Hopkins University. Support for L.B. is provided by Amersham-Pharmacia Biotech, by NIH grant HG01399, and the Director, Office of Science, Office of Biological and Environmental Research of the U.S. Department of Energy under contract DE FG91ER61125.

Received May 21, 2001

Topoisomerase I is an ubiquitous DNA-cleaving enzyme and an important therapeutic target in cancer chemotherapy for camptothecins as well as for indolocarbazole antibiotics such as rebeccamycin. To achieve a sequence-specific cleavage of DNA by topoisomerase I, a triple helix-forming oligonucleotide was covalently linked to indolocarbazole-type topoisomerase I poisons. The three indolocarbazole-oligonucleotide conjugates investigated were able to direct topoisomerase I cleavage at a specific site based upon sequence recognition by triplex formation. The efficacy of topoisomerase I-mediated DNA cleavage depends markedly on the intrinsic potency of the drug. We show that DNA cleavage depends also upon the length of the linker arm between the triplex-forming oligonucleotide and the drug. Based on a known structure of the DNA-topoisomerase I complex, a molecular model of the oligonucleotide conjugates bound to the DNA-topoisomerase I complex was elaborated to facilitate the design of a potent topoisomerase I inhibitor-oligonucleotide conjugate with an optimized linker between the two moieties. The resulting oligonucleotide-indolocarbazole conjugate at 10 nM induced cleavage at the triple helix site 2-fold more efficiently than 5 μ M of free indolocarbazole, while the other drug-sensitive sites were not cleaved. The rational design of drug-oligonucleotide conjugates carrying a DNA topoisomerase poison may be exploited to improve the efficacy and selectivity of chemotherapeutic cancer treatments by targeting specific genes and reducing drug toxicity.

INTRODUCTION

Sequence-specific modulation of gene expression can be achieved by oligonucleotides that bind to double-helical DNA via triplex formation (1–5). These triple-helical DNA structures offer new prospects to modulate the interactions between proteins and DNA. Cleaving or cross-linking agents have been tethered to triple helix-forming oligonucleotides [TFOs] in order to target chemical reactions to specific sequences on DNA (1, 2, 6–12). An attractive option for biological applications would be the recruitment of a cellular enzyme whose action on DNA would be directed by triplex formation to perform a sequence-specific DNA cleavage. One such enzyme is topoisomerase I, which is an ubiquitous nuclear enzyme involved in the control of DNA topology (13).

The reaction of topoisomerase I with double-stranded DNA produces a covalent 3'-phosphotyrosyl adduct, usually referred to as the cleavage complex. Under physiological conditions, the covalent intermediate is barely detectable, because a fast religation step occurs after relaxation of DNA constraints. A number of drugs, such as the antitumor alkaloid camptothecin [CPT], can convert topoisomerase I into a cell poison by blocking the

relication step, thereby enhancing the formation of persistent DNA breaks responsible for cell death (13, 14). Apart from the camptothecins, several classes of antineoplastic drugs have been shown to stabilize DNA-topoisomerase I complexes. One of the most promising series of antitumor agents targeting topoisomerase I is represented by indolocarbazole analogues of the antibiotic rebeccamycin [RBC], which strongly stimulate topoisomerase I-mediated DNA cleavage (15–17). In contrast to the camptothecins, RBC and analogues intercalate in DNA even in the absence of topoisomerase I. Structure-activity relationship studies have provided key information concerning the stabilization of DNA-topoisomerase I covalent complexes by indolocarbazoles (15, 18–21).

These considerations prompted us to attach a rebeccamycin derivative to a TFO in order to recruit topoisomerase I and direct its cleavage to specific DNA sequences. Upon intercalation into DNA, the attached indolocarbazole chromophore can stabilize the triple-helical structure and, in addition, can direct the topoisomerase I enzymatic reaction to particular sites at proximity to the triple helix binding site (22, 23). In a previous study, Matteucci and co-workers (24) have shown that a triplex-forming oligonucleotide conjugated to camptothecin is able to direct topoisomerase I-mediated DNA cleavage to a specific site. In this study, three indolocarbazole derivatives, R6, R0, and R95 (see Figure 1 for chemical structures) were covalently attached to the 3'-end of a 16-nt triplex-forming oligonucleotide and their potencies for topoisomerase I recruitment compared. The

Figure 1. (A) Sequence of the TFOs and the 77-bp target used in this study. The TFO binds in the major groove to the oligopurine strand of the duplex and parallel to it. The target site is in bold and underlined. The 77-bp duplex target sequence was inserted between the *Bam*H I and *Eco*R I sites of pBSK(±). M = 5-methyl-2'-deoxycytidine, P = 5-propynyl-2'-deoxyuridine, rU = uridine, L6 = hexaethylene glycol, L3 = triethylene glycol, L2 = diethylene glycol. (B) Structure of the indolocarbazole-TFO derivatives used in this study. U = uracil. The TFO-R6/TFO-R0 was synthesized with the spacer linked at one end to the 3'-phosphate of the TFO and at the other end to a uridylic acid. The glycol function of the ribose was oxidized by NaIO_4 and reacted with the NH_2 group linked to the maleimide function of R6 or R0. For the synthesis of the TFO-R95 conjugate, the hexaethylene glycol linker at the 3'-end of the TFO was phosphorylated and after activation by *N*-methylimidazole, dipyridyl disulfide, and triphenylphosphine, it was reacted with the NH_2 -terminal group of the 1-aminopropyl side chain of the B cycle of R95 (see reference (22) for details).

compounds differ by the nature of their functional groups, which allowed us to use different types of linkage to tether them to the TFO.¹ These different conjugates were used to further investigate the parameters involved in the interaction between topoisomerase I and the triple-helical structure in order to rationally design topoisomerase I poison-oligonucleotide conjugates that efficiently cleave DNA at specific sites.

¹ Abbreviations: TFO = triplex-forming oligonucleotide, bp = base pair, nt = nucleotide, • = Watson-Crick base pairing, x = Hoogsteen or reverse Hoogsteen base pairing, ssDNA = single-stranded DNA, dsDNA = double-stranded DNA, PAGE = polyacrylamide gel electrophoresis, RBC = rebeccamycin, CPT = camptothecin, DNase I = deoxyribonuclease I, K_d = dissociation constant defined as: $K_d = ([\text{Duplex}][\text{Oligonucleotide}])/[\text{Triplex}]$, M = 5-methyl-2'-deoxycytidine, P = 5-propynyl-2'-deoxyuridine, rU = uridine, L2 = diethylene glycol, L3 = triethylene glycol, L6 = hexaethylene glycol.

EXPERIMENTAL PROCEDURES

Drugs, Oligonucleotides, and DNA Fragment. The synthesis of the indolocarbazoles R-6, R-0, and R-95 have been previously described (18, 22, 25). All the drugs were dissolved in dimethyl sulfoxide at 3 mg/mL and then diluted further with water. The final dimethyl sulfoxide concentration never exceeded 0.3% (v/v) in all assays. They were attached to the 3'-end of the TFO as described in Figure 1.

Oligonucleotides were purchased from Eurogentec and purified using quick spin columns and sephadex G-25 fine (Boehringer, Mannheim). Concentrations were determined spectrophotometrically at 25 °C using molar extinction coefficients at 260 nm calculated from a nearest-neighbor model (26).

The rebeccamycin derivatives-oligonucleotide conjugates were synthesized and purified as reported in (22) and their structure is shown in Figure 1. The NH_2 group

of the aliphatic chain of R-95 was covalently linked to the phosphorylated hexaethylene glycol linker arm at the 3' end of TFO (Figure 1B) [22]. The 3' phosphorylated oligonucleotide (150 μ g) was first precipitated as a hexadecyltrimethylammonium salt and the oligonucleotide salt was then dissolved in 50 μ L of dry DMSO. A 5 μ L sample of *N*-methylimidazole and 25 μ L each of dipyridyl disulfide and triphenylphosphine solutions [1.2 M DMSO] were added. After 15 min incubation at room temperature, 5 μ L of triethylamine was added followed by the drug solution [20 μ L, 30 mM in DMSO]. After 20 min, the oligonucleotide was precipitated with LiClO₄. Reverse phase HPLC using a linear acetonitrile gradient (5–80% CH₃CN in 0.2 M (NH₄)OAc) was used to separate the product from the initial oligonucleotide. A Lichrosorb C-18 column (4.6 $\times$ 25 cm) and Shimadzu CR4-A Chromopack instrument were used (average yield 60%). The product was eluted as a single peak absorbing both at 310 nm (oligonucleotide) and 410 nm (rebeccamycin) with a retention time of 11.4 min compared to 10.4 min for initial TFO.

To covalently link R6 or R0 to the 3'-end of the oligonucleotide, we used the 16-mer TFO bearing at the 3'-end an uridine linked through an poly(ethylene glycol) linker arm [22]. 300 nmoles of oligonucleotide (ethanol precipitated), and 6.5 mg of sodium periodate (NaIO₄) were dissolved in 100 μ L of 200 mM sodium acetate, pH 5.2. After 20 min incubation at room temperature and in the dark, 100 μ L of 2 M potassium chloride was added in order to precipitate the excess of periodate. The pellet was washed several times with 50 μ L of H₂O. All water phases were collected, and the oligonucleotide was precipitated with ethanol. It was then dissolved in 50 μ L of 200 mM NaOAc, pH 5.2 and added to 1 mg of the indolocarbazole compound R6 or R0 dissolved in 50 μ L of DMF. The solution was incubated for 12 h at 4 $^{\circ}$ C in the dark. After ethanol precipitation, the oligonucleotide was dissolved in water and treated with 0.5 mg of sodium borohydrate and again precipitated with ethanol. The conjugates were recovered by reverse phase HPLC with a Lichrosorb C-18 column (4.6 $\times$ 25 cm) using a linear acetonitrile gradient (5–40% CH₃CN in 0.2 M (NH₄)OAc) and a Shimadzu CR4-A Chromopack instrument (average yield 40%). The product was eluted as a single peak absorbing both at 310 nm (oligonucleotide) and 410 nm (rebeccamycin). Retention times: TFO-L2-R6, 13.1 min vs 11.1 min; TFO-L3-R6, 13.0 min vs 11.2 min; TFO-L6-R6, 13.6 min vs 11.7 min.; TFO-L6-R0, 13.0 min vs 11.7 min for the drug-free oligonucleotide.

All conjugates were analyzed by UV spectroscopy and gel electrophoresis under denaturing conditions. In each case, the ratio of $A_{310\text{ nm}}/A_{410\text{ nm}}$ from the UV-vis absorbance spectrum corresponded to a 1:1 oligonucleotide:rebeccamycin complex. On a 20% denaturing gel electrophoresis only one band migrating slower than the one of the initial TFO was observed. The band revealed blue fluorescence as the free rebeccamycin derivative.

The plasmid pBSK($\pm$) was bought from Promega, and the 77-bp target duplex was inserted between the *Bam* HI and *Eco* RI sites. The digestion of the plasmid by *Pvu*II and *Eco* RI yielded a 324-mer fragment suitable for 3'-end labeling by the Klenow polymerase and α [³²P]-ddATP (Amersham). The detailed procedures for isolation, purification and labeling of this duplex DNA fragment have been described previously (27).

Topoisomerase I Cleavage Assays. The radiolabeled 324-bp target duplex (50 nM) was incubated for 1 h at 30 $^{\circ}$ C, in 50 mM Tris-HCl, pH 7.5, 60 mM KCl, 10 mM

MgCl₂, 0.5 mM DTT, 0.1 mM EDTA, and 30 μ g of BSA, in the presence of the TFO (at the indicated concentration) in order to form the triplex (total reaction volume 20 μ L). To analyze the topoisomerase I DNA cleavage products, 10 units of enzyme (Life Sciences) were added to the duplex, preincubated as described above with either the TFO or/and the drugs, followed by incubation for 30 min at 30 $^{\circ}$ C. DNA-topoisomerase I cleavage complexes were dissociated by addition of SDS (final concentration 0.25%) and of proteinase K (Sigma) to 250 μ g/mL, followed by incubation for 30 min at 55 $^{\circ}$ C. After ethanol precipitation, all samples were resuspended in 6 μ L of formamide, heated at 90 $^{\circ}$ C for 4 min, and then chilled on ice for 4 min, before being loaded onto a denaturing 8% polyacrylamide gel [19:1 acrylamide:bisacrylamide] containing 7.5 M urea in 1xTBE buffer (50 mM Tris base, 55 mM boric acid, 1 mM EDTA). To quantitate the extent of cleavage, the gels were scanned with a Molecular Dynamics 445SI Phosphorimager. For the determination of cleavage levels, a normalization relative to total loading was performed.

RESULTS AND DISCUSSION

Prior to investigating the effects of triplex formation with oligonucleotides conjugated to topoisomerase I poisons on DNA cleavage by topoisomerase I, the ability of the conjugates to form the triple helix was determined.

Triple Helix Formation by TFO-RBC Conjugates. As previously described (22), modified 16-nt TFO, containing 5-propynyl-2'-deoxyuracils [P] and 5-methyl-2'-deoxycytosines [M] (Figure 1), can form a stable triple helix on the target sequence (Figure 1, bold and underlined), at 37 $^{\circ}$ C and at pH 7.2 in a buffer containing 50 mM KCl, 10 mM MgCl₂. We covalently attached the 3'-end of the oligonucleotide to the indolocarbazole derivatives R6, R0, and R95 as described in Figure 1B. Triplex formation involves major groove binding of the conjugates via recognition of the oligopurine strand of the duplex (28). The binding should allow the planar indolocarbazole ring to intercalate at the duplex/triplex junction as previously described for other intercalating agents (29, 30).

Initially the RBC derivatives were attached to the TFO by a hexaethylene glycol linker (L6). The choice for such a long linker chain was based on previously reported data suggesting that topoisomerase I protected both strands of DNA over a 15–19-bp region in which the cleavage site was centrally located (31). This suggested that the enzyme might need an accessible 7–9-bp double helical region around the cleavage site, and therefore we reasoned that a relatively long linker (L6) should be used to allow the drug to get access to the catalytic site of topoisomerase I and to prevent steric hindrance between the TFO and the enzyme. But as shown below, this linker can be further shortened to improve topoisomerase I-mediated cleavage on the basis of the crystal structure of topoisomerase I. The indolocarbazole drugs, R6, R0, and R95, bear different functional groups used to tether the indolocarbazole chromophore to the TFO. R0 and its glycosylated analogue R6 were attached through reaction of the NH₂ group on the nitrogen of the maleimide function with the ribose of an uridine attached at the 3'-end of the oligonucleotide through a linker arm (Figure 1). In contrast, the R95 derivative was linked to a phosphate attached to the hexaethyleneglycol linked to the 3'-end of TFO via the NH₂ group of the 1-aminopropyl side chain attached to the B cycle of the drug.

Figure 2. (A) Sequence analysis of the topoisomerase I-mediated cleavage products on the 324-bp target duplex (50 nM) 3'-end radiolabeled on the oligopyrimidine-containing strand. Adenine/guanine-specific Maxam–Gilbert chemical cleavage reactions were used as markers. The positions of the cleavage sites are indicated (sites *a* to *j*). Lane 1, target duplex; duplex incubated with topoisomerase I (10 units) in the absence (lane 2) or in the presence of 5 μ M camptothecin (lane 3), 5 μ M R95 (lane 4), 5 μ M R6 (lane 5), 5 μ M TFO (lane 6), 5 μ M TFO and R6 (lane 7), 5 μ M TFO-L6-R6 (lane 8), and 5 μ M TFO-R95 (lane 9). The triple helix region and the nucleotide positions along the radiolabeled oligopyrimidine strand are indicated. (B) The ratio between the intensity of cleavage in the presence of TFO-L6-R6 and the intensity in the presence of the untethered R6 is represented on a logarithmic scale at different sites along the DNA fragment used as a substrate for topoisomerase I cleavage (data from lanes 8 and 5 of Figure 2A).

The binding of the conjugated third strands to the duplex was analyzed by gel retardation experiments, and the affinity of the TFOs for the duplex was measured. The following dissociation constants (K_d) were determined (as described in (22)): TFO: $5.3 \pm 0.5 \mu\text{M}$; TFO-R6: $0.20 \pm 0.06 \mu\text{M}$; TFO-R0: $0.50 \pm 0.1 \mu\text{M}$; TFO-R95: $0.85 \pm 0.07 \mu\text{M}$. Only the RBC-conjugates were studied, because as intercalating agents the RBC derivatives could greatly modify the stability of the triplex. Indeed, all conjugates bind more strongly to the duplex than the corresponding drug-free oligonucleotide. These results showed that the TFO–drug conjugates formed stable triple helices in the absence of topoisomerase I. Of the three conjugates, only TFO–R6 and TFO–R0 are comparable, because they share the same type of attachment point to the TFO. A 2-fold higher binding affinity was observed with the R6 conjugate, presumably due to the presence of the β -glucose residue attached to the indole nitrogen on ring B, which has been previously shown to stabilize drug–DNA complexes in the case of the free drugs (19).

Topoisomerase I-Mediated DNA Cleavage in the Presence of the Triple Helix. The 3'-end-radiolabeled restriction fragment (324-bp) bearing the 16-bp triple helix target site was incubated in the presence of TFOs and topoisomerase I. After protease treatment, DNA

cleavage products were analyzed by denaturing polyacrylamide gel electrophoresis. Figure 2 shows the results obtained when using the duplex target labeled at the 3'-end of the oligopyrimidine-containing strand. We compared the different topoisomerase I poisons, R6, R95, and R0, and their TFO conjugates.

Lane 2 shows the cleavage pattern of topoisomerase I alone in the absence of TFO and topoisomerase I poisons. Two sites are present near the 3' triplex/duplex junction (sites *b*) and one near the 5' junction (site *a*). There are also several other sites at some distance from the triplex binding site. The indolocarbazoles R95 (lane 4) and R0 (data not shown) are weak topoisomerase I poisons and enhance only slightly topoisomerase I-mediated cleavage (15, 19). In the presence of R6 (lane 5), sites *b1* and *b2*, located at 4-bp and 7-bp from the 3' triplex end, respectively, are strongly enhanced, like that of site *a* on the 5'-side of the triplex at 8-bp from the 5' triplex end. Additional sites were also detected in the oligopyrimidine–oligopurine region and in the regions marked *c*, *d*, *e*, *f*, *g*, *h*, *i*, and *j* in Figure 2. Sequence analysis showed that most of these cleavage sites correspond to T $\downarrow$ G sites, in agreement with previous findings showing that RBC derivatives stimulate DNA cleavage by topoisomerase I

preferentially at sites having a T and a G on the 3'- and 5'-sides of the cleaved bond, respectively (15).

The topoisomerase I cleavage profile changed only slightly in the presence of the triplex formed with the untethered oligonucleotide TFO (lane 6 compared to lane 2). The formation of the triple helix protected the duplex against enzymatic cleavage in this region. Site *a* at 8-bp from the 5' duplex/triplex junction and sites *b* at the 3'-triplex/duplex junction were still present. The addition of R6 to the triplex (lane 7) restored cleavage at sites *a* and *b*. Again there were no cleavage sites in the triple helix region. It is interesting to observe that the presence of the triplex enhanced the cleavage at the site situated at 4-bp from the 3' triplex end (site *b1*) compared to cleavage at the *b2* site. This could be due to an increase of local drug concentration at this site as a consequence of its intercalation at the triplex/duplex junction. The very strong site characteristic of R6 at 33-bp from the 3'-end of the triplex was still present (region *c*), as well as the other sites *d* to *j*.

Triplex formation with the TFO-L6-R6 conjugate (lane 8) diminished the cleavage at sites located far away from the triple helix (*c*, *d*, *e*, *f*, *g*, *h*, *i*, *k*) and at site *a* on the 5'-side of the TFO. Only site *b1*, at the 3'-end of the triple helix, was maintained and enhanced. This is consistent with a sequence-specific recruitment of topoisomerase I by triplex formation with TFO conjugates bearing topoisomerase I poisons at the 3' end. The TFO bearing the drug R6 at the 3'-end favors DNA cleavage by the enzyme only on the 3'-side of the triplex and decreases the other characteristic sites of the drug: this is clearly due to the targeting of the drug by triplex formation specifically to the *b1* site at the 3'-end of the triple helix. In fact, the triple helix formed by the uncoupled oligonucleotide stimulates cleavage equally at the three sites adjacent to the triplex (lane 6, sites *a*, *b1*, and *b2*) and upon addition of the free drug, all the characteristic cleavage sites of the drug are present (lane 7, sites *a*, *b*, *c*, *d*, *e*, *f*, *g*, *h*, *i*, and *j*). In Figure 2B is shown the ratio of the intensities measured with the conjugate TFO-L6-R6 and the free drug (R6) at 5 μ M. Only site *b1* shows an enhanced cleavage whereas all other sites reveal a decrease in cleavage efficiency, demonstrating that the drug-TFO conjugate is able to target the topoisomerase I poison specifically near the triplex site and to increase the efficiency of cleavage of the agent at this site. The enhancement observed at site *b1* was 3-fold for the TFO-L6-R6 as compared to free R6. It was only 2.6-fold when compared to the TFO+R6 mixture at 5 μ M concentration. The decrease at site *b2* was 5- and 2-fold, respectively.

The TFO-R95 conjugate was much less potent at inhibiting topoisomerase I than its congener TFO-L6-R6 (compare lanes 9 and 8, Figure 2A). Nevertheless, cleavage at the expected site *b1* remained visible and enhanced. The cleavage at site *a* on the 5' end of the triple helix and at site *b2* located 7-bp away from the 3' end of the triplex was less efficient compared to the free R95 (lane 4). Again this is consistent with a triple helix-induced effect. As for the TFO-R95 conjugate, in the presence of the triplex formed by the TFO-R0 conjugate, cleavage was maintained only at site *b1* (data not shown).

Therefore, TFOs bearing topoisomerase I poisons at the 3'-end favor DNA cleavage by the enzyme only on the 3'-side of the triplex and decreases the other characteristic sites of the free drug. This is clearly due to the targeting of the poison by triplex formation specifically to site *b1* at 4-bp from the 3'-end of the triple helix.

The lower efficacy of TFO-R95 and TFO-R0 compared to TFO-R6 is entirely consistent with the data presented

Figure 3. Molecular model for the complex formed between the TFO-L3-R6 conjugate and the topoisomerase I bound to DNA. The atomic coordinates of the topoisomerase I/DNA complex published by Rebinbo et al. (32) were used to construct this model. The α -helix, β -sheets, and the backbone are colored in red, yellow, and brown, respectively. The duplex region of the DNA is represented in white; the double helix site involved in triple helix formation is represented in pink (oligopurine strand) and in light blue (oligopyrimidine strand). The third strand moiety of the TFO-L3-R6 conjugate is in yellow. The extended linker chain (L3) positions the drug moiety at 4-bp from the triplex/duplex junction with the indolocarbazole chromophore intercalated in the double helix at the cleavage site. The glucose moiety of the drug is located in the minor groove, in a suitable position to interact with the Arg364 residue of topoisomerase I. Closer view of the model showing the drug binding pocket around the topoisomerase cleavage site.

above indicating that R95 and R0 are much less efficient than R6 both in terms of triplex stabilization and stimulation of topoisomerase I cleavage. As mentioned above, TFO-R95 not only lacks the essential glucose residue but the F-ring on the indolocarbazole chromophore is oriented toward the minor groove, which is an unfavorable orientation for optimal topoisomerase I inhibition. The F ring is presumed to interfere with the DNA-enzyme complex from the major groove (19). This might explain why the cleavage efficiency of the R95 conjugate is poor. The cleavage profile obtained with R0 was similar to that found with R95. The absence of the sugar moiety is presumably the most important element

Figure 4. Sequence analysis of topoisomerase I-mediated cleavage products with R6 conjugates containing linker arms of different length. Adenine/guanine-specific Maxam–Gilbert chemical cleavage reactions were used as markers. The positions of the cleavage sites are indicated (sites *a* to *j*). Lane 1, target duplex; duplex incubated with topoisomerase I (10 units) in the absence (lane 2) or in the presence of 5 μ M TFO (lane 3), 5 μ M TFO-L2-R6 (lane 4), 5 μ M TFO-L3-R6 (lane 5), 5 μ M TFO-L6-R6 (lane 6), 5 μ M R6 (lane 7), and 5 μ M TFO and 5 μ M R6 (lane 8). The triple helix region and the nucleotide positions along the radiolabeled oligopyrimidine strand are indicated. The band with an asterisk corresponds to a labeling artifact and was used as loading control.

responsible for the weak effect on topoisomerase I because the results obtained with the conjugate TFO–R0 were comparable to those obtained with TFO–R95. This corroborates the findings that the sugar moiety is important for both binding to DNA and poisoning of topoisomerase I (15, 19).

At this stage, the results suggest that topoisomerase I recruitment by a TFO coupled to a potent poison can be achieved with RBC derivatives, with efficiencies corresponding to the potency of the free drug. Furthermore, we have shown that the attachment point of the poison to the TFO orients the drug in the drug/topoisomerase I/DNA complex and thus changes the intensity of DNA cleavage. The conjugates could thus be used to study the orientation of the drug in the ternary complex, by measuring the efficiency of cleavage as a function of the attachment point of the drug to the TFO.

Design of an Optimized Linker for Oligonucleotide–Rebeccamycin Conjugates. The reported crystal structure of the complex formed between a 22-bp DNA duplex and a large fragment of human topoisomerase I (32) allowed us to build a molecular model where the drug moiety of the TFO–R6 conjugate was positioned in the catalytic site of the enzyme. According to this model, a triplex could be formed without steric clash with topoisomerase I at the 3′-side of the cleavage site, while the 5′-side of the cleavage site was not accessible (Figure 3). A pyrimidine motif triple helix was docked into the crystal structure at 4-bp from the cleavage site, called *b1*, identified in Figure 2A. The indolocarbazole derivative was attached through the linker arm to the 3′-end of the TFO and placed in the cleavage site. The model in Figure 3 shows the intercalated indolocarbazole derivative with its methoxy-glucose moiety attached to the B-ring of the chromophore. The sugar lies in the minor groove, in a suitable position to interact with amino acid Arg364, and to a lesser extent with the Asp533 residue of topoisomerase I. This model was used to investigate further the influence of the linker chain between the TFO and the drug. The modeling suggested that a triethylene glycol linker (L3) would be more appropriate than the hexaethylene glycol linker (L6) to position the drug at the *b1* cleavage site on the 3′ side of the triplex. Moreover, this shorter linker should permit major groove binding of the TFO 4-bp away from the cleavage site without steric interference with topoisomerase I.

To test this prediction, we synthesized the conjugates TFO-L3-R6 and the analogue TFO-L2-R6 bearing a diethylene glycol linker (Figure 1B). Both conjugates were tested in parallel with the TFO-L6-R6 conjugate initially constructed.

The 324-bp restriction fragment bearing the 16-bp triple helix target site was incubated in the presence of the conjugates and topoisomerase I. After protease treatment, DNA cleavage products were analyzed by denaturing polyacrylamide gel electrophoresis (Figure 4A). Lane 2 shows the cleavage pattern of topoisomerase I alone in the absence of TFO and drugs. As above-described, the presence of the triple helix formed by the untethered oligonucleotide (lane 3) has only a slight effect on the topoisomerase I cleavage pattern. In the presence of the R6 compound alone (lane 7), the two sites *b1* and *b2* were detected on the 3′ side of the triplex site, as well as site *a* on the opposite side of the triplex. Additional sites were observed in the regions marked *c* to *j*. The addition of the TFO (lane 8) did not affect the cleavage profile seen with the free drug. The TFO–[L2, L3, L6]–R6 conjugates (lanes 4–6) enhanced cleavage specifically at site *b1*. Cleavage at sites *a* at the 5′ end of the triple helix and *b2* located 7-bp away from the 3′ end of the triplex are strongly reduced compared to the free R6 compound (lane 7), as the other sites *c* to *j*. Again this is consistent with a triple helix-induced effect. In the R6 series, the 9 atoms linker (L3) produced a 4- and 2.6-fold stronger topoisomerase I-mediated DNA cleavage than TFO–L2–R6 and TFO–L6–R6, respectively, and 8-fold stronger than R6 alone. The TFO–R6 conjugate with the shorter linker arm enhanced cleavage at site *b1* about 8 times as compared to free R6 and 3 times as compared to TFO+R6 at 5 μ M concentration.

The experimental data fully agrees with the modeling predictions: the triethylene glycol is the most appropriate linker to allow positioning of the R6 compound at the same site in the complex. Collectively, the data demonstrate that the elaboration of a conjugate molecule requires an optimization of the two linked components but also a precise design of the linker chain.

Concentration Effect. Next we studied the efficacy of the TFO–drug conjugate compared to that of the free drug. We compared topoisomerase I-mediated DNA cleavage in the presence of increasing concentrations of R6 (from 0.01 μ M to 5 μ M, Figure 5A, lanes 5 to 10) and of

TFO-L3-R6 (from 0.01 μ M to 1 μ M, lanes 11 to 15). The conjugate induces efficient cleavage even at a concentration as low as 0.01 μ M (lane 11) compared to R6 alone (lane 5). Figure 5B compares the percentage of cleavage in the presence of R6 (red circles) and in the presence of TFO-L3-R6 (blue triangles) at sites *h*, *c*, *b1*, and *a* as a function of the concentration. The R6 conjugate not only strongly enhanced topoisomerase I cleavage at the triplex site *b1* but it is 10-fold more efficient at 10 nM than the poison alone at the same concentration. In contrast, at sites other than *b1* cleavage was abolished.

CONCLUSION

The designed TFO-indolocarbazole conjugates are able to direct the action of the topoisomerase I poison to a specific site in vitro. They induce sequence-specific DNA cleavage by topoisomerase I. Upon binding of the TFO-drug conjugate to its specific target, DNA cleavage is strongly enhanced at the triplex/duplex junction where the poison is positioned and strongly decreased at other sites. Three novel aspects were studied. First, the combined computational and experimental approach helped to identify the determinants, predominantly drug inhibitory potency and length of the linker arm, which shape the TFO-directed DNA cleavage mediated by topoisomerase I. Second, the comparison between the R0 and R6 conjugates provides important information on the role of the sugar residue attached to the indolocarbazole chromophore. Third, the positioning of the drug by triplex formation increases its local concentration at this site, and thus the conjugates induce cleavage in the nanomolar concentration range as compared to micromolar for the free drug.

In the future, triple helix-directed targeting of antitumor-active topoisomerase I poisons, such as camptothecin and indolocarbazole analogues, may be exploited further to improve the efficacy of chemotherapeutic cancer treatments by reducing drug toxicity and targeting topoisomerase I-induced cleavage to appropriately chosen genes. In addition to their utilization as therapeutic tools, TFO conjugates could be used as research tools: these conjugates provide a new approach for understanding the interactions involved in the topoisomerase I/drug/DNA ternary complex. In fact, with this approach, by varying the attachment sites and the functional groups as well as the nature and length of the linker, the drug can be located in different and controlled orientations with respect to topoisomerase and DNA.

ACKNOWLEDGMENT

The authors thank Dr. J. L. Mergny, J.F. Riou, D. Praseuth, L. Lacroix, and C. Giovannangeli for helpful suggestions. This work was supported by grants (to P.B.A.) from the European Community and the Ligue Nationale Contre le Cancer; (to C.B.) from the from the Ligue Nationale Contre le Cancer (Comité du Nord).

Paramagnetic Water-Soluble Metallofullerenes Having the Highest Relaxivity for MRI Contrast Agents

Masahito Mikawa,[†] Haruhito Kato,[‡] Masafumi Okumura,[†] Michiko Narazaki,[†] Yoko Kanazawa,[†] Naoto Miwa,[†] and Hisanori Shinohara^{*,‡}

Basic Research Institute, Nihon Schering K.K., 6-64 Nishimiyahara 2-chome Yodogawa-ku, Osaka, 532-0004, Japan, and Department of Chemistry, Nagoya University, Nagoya, 464-8602, Japan. Received December 14, 2000; Revised Manuscript Received March 23, 2001

Water-soluble gadolinium (Gd) endohedral metallofullerenes have been synthesized as polyhydroxyl forms ($\text{Gd@C}_{82}(\text{OH})_n$, Gd-fullerenols) and their paramagnetic properties were evaluated by in vivo as well as in vitro for the novel magnetic resonance imaging (MRI) contrast agents for next generation. The in vitro water proton relaxivity, R_1 (the effect on $1/T_1$), of Gd-fullerenols is significantly higher (20-folds) than that of the commercial MRI contrast agent, Magnevist (gadolinium–diethylenetriaminepentaacetic acid, Gd-DTPA) at 1.0 T close to the common field of clinical MRI. This unusually high proton relaxivity of Gd-fullerenols leads to the highest signal enhancement at extremely lower Gd concentration in MRI studies. The strong signal was confirmed in vivo MRI at lung, liver, spleen, and kidney of CDF1 mice after i.v. administration of Gd-fullerenols at a dose of 5 μmol Gd/kg, which was 1/20 of the typical clinical dose (100 μmol Gd/kg) of Gd-DTPA.

INTRODUCTION

With the advent of gadolinium-chelate complex for a magnetic resonance imaging (MRI)¹ contrast agent, Magnevist (Gd-DTPA) (1, 2), where the contrast agent can induce extra proton spin relaxation due to the paramagnetic property, many efforts have been given for the design and development of new compounds, such as Eovist (Gd-3,6,9-triaza-3,6,9-tris(carboxymethyl)-4-(4-ethoxybenzyl)undecandicarboxylic acid, Gd-EOB-DTPA), ProHance (Gd-1,4,7-tris(carboxymethyl)-10-(2'-hydroxypropyl)-1,4,7,10-tetraazacyclododecane, Gd-HP-DOTA) or Omnican (Gd-diethylenetriaminepentaacetate-bis(methylamide), Gd-DTPA-BMA) (3–5). These agents have been used as a routine clinical tool to reveal anatomical details in vivo and to detect lesions for diagnosis. For the future real-time in vivo imaging of molecular/cellular diagnosis, many efforts have been given by using the fluorescent (6, 7) and nuclear imaging techniques (8, 9) as well as MRI technique (10–13). Although fluorescent technique can have excellent temporal resolution, a common shortcoming is limited depth penetration. The nuclear techniques are free from this limitation but suffer from the inherently lower spatial resolution. In contrast, the MRI technique has much less

limitation on the observation depth and spatial resolution. As compared to fluorescent and nuclear imaging techniques, however, molecular probe detection by magnetic resonance is several orders of magnitude less sensitive (14, 15). It is necessary, therefore, to accumulate more targeting probes or enforce its potential enhancing ability for molecular/cellular diagnosis by MRI. Thus, novel materials having strong proton relaxivity and a higher capacity for MR signal enhancement at a significantly lower concentration are required for the next generation.

Here we have investigated the possibility of application of novel materials, water-soluble Gd metallofullerenes ($\text{Gd@C}_{82}(\text{OH})_n$, Gd-fullerenols) (16–20), for MRI contrast agents, and have evaluated them in vivo as well as in vitro. Extremely high water proton relaxivity, R_1 (the effect on $1/T_1$), was obtained with $\text{Gd@C}_{82}(\text{OH})_{40}$, 81 ($\text{mM}^{-1} \text{s}^{-1}$) at 1.0 T and 25 °C which is more than 20 times as high as that of the commercial Gd-DTPA. This unusually high proton relaxivity of $\text{Gd@C}_{82}(\text{OH})_{40}$ led to the highest signal enhancement at significantly lower Gd concentration by in vitro and in vivo MRI studies so far reported.

MATERIALS AND METHODS

Gd@C₈₂. Soot containing Gd endohedral metallofullerenes such as Gd@C_{82} was produced by the direct current arc evaporation method (350 A, 21 V) of Gd/graphite composite rods (0.8 wt % Gd atom, Toyo Tanso Co.) under a 17 l/min flow of helium at 50 Torr, followed by Soxhlet extraction with carbon disulfide for 12 h (21, 22). The purification and isolation of Gd@C_{82} was achieved by the two-stage high performance liquid chromatography (HPLC) (23) with a Buckyprep column (20 mm dia $\times$ 300 mm, Nacalai Tesque). The purity of Gd@C_{82} (<99%) was analyzed by both HPLC and matrix-assisted laser desorption/ionization (MALDI) TOF mass spectrometry (Shimadzu Kompact MALDI V).

Gd@C₈₂(OH)_n. The water-soluble Gd metallofullerene ($\text{Gd@C}_{82}(\text{OH})_n$, Gd-fullerenols) was synthesized as poly-

¹ Abbreviations: MRI, magnetic resonance imaging; Gd, gadolinium; DTPA, diethylenetriaminepentaacetic acid; EOB-DTPA, 3,6,9-triaza-3,6,9-tris(carboxymethyl)-4-(4-ethoxybenzyl)undecandicarboxylic acid; HP-DOTA, 1,4,7-tris(carboxymethyl)-10-(2'-hydroxypropyl)-1,4,7,10-tetraazacyclododecane; DTPA-BMA, diethylenetriaminepentaacetate-bis(methylamide); TBAH, tetrabutylammonium hydroxide; ICP-AES, inductively coupled plasma atomic emission spectroscopy; RES, reticular-endothelial system.

hydroxyl forms by vigorously stirring a mixture of a toluene solution of isolated Gd@C_{82} (<99%, 0.1 g) and a 50 wt % aqueous NaOH solution containing a few drops of tetrabutylammonium hydroxide (40% in water, TBAH) or 15-crown-5 as catalyst at room temperature under ambient conditions (24, 25). Within a few minutes, a brown sludge precipitated. After removal of toluene by decantation, the sludge and remaining aqueous solution was stirred with additional water for 1 night. The brown solution was added with MeOH to produce brown aqueous precipitates. The precipitation was rinsed with MeOH to ensure the removal of the catalyst and NaOH and was dissolved in water again to produce a brown solution which was put into cellulose dialyze tube (cut off MW = 500) in water for 1 week for complete removal of residual catalyst and NaOH. After freeze-drying, fine aqueous solution gave brown solid product Gd-fullerenols, $\text{Gd@C}_{82}(\text{OH})_n$.

On the basis of the elemental analysis and water contents, the average number of hydroxyl groups of $\text{Gd@C}_{82}(\text{OH})_n$ was obtained. The Gd concentration of the Gd-fullerenols solution was determined by using inductively coupled plasma atomic emission spectroscopy (ICP-AES, Seiko Electro Ind.) (26, 27). The sample for ICP-AES was prepared by the dilution with water. This preparation method was validated in comparison with the following two sample preparation methods. First, sample was digested in concentrated HNO_3 at 120 °C. Secondly, sample was digested in a mixture of concentrated H_2SO_4 and 30 % aqueous H_2O_2 (4:1 by volume) at 70 °C. Gd standards were made from a ICP standard solution (Wako Pure Chem.). The standards and samples were evaluated for intensity of their Gd emission line at 342.247 nm.

Proton Relaxivity. The proton relaxivities, R_1 and R_2 (the effect on $1/T_2$ as R_1 for T_1) of $\text{Gd@C}_{82}(\text{OH})_{40}$ in aqueous solution were determined by 0.47 T (Minispec, Bruker), 1.0 T (MAGNETOM Harmony, Siemens), and 4.7 T (Unity INOVA, Varian) at 25 ± 1 °C.

In Vitro MRI. The MRI phantom images of Gd-DTPA as well as $\text{Gd@C}_{82}(\text{OH})_{40}$ solutions at concentrations of 0.05, 0.1, and 0.2 mmol Gd/L were obtained at 4.7 T (Unity INOVA, Varian) by conventional spin-echo with pulse repetition time/echo time (TR/TE) = 300 ms/9 ms, field of view (FOV) = 10×10 cm², at 256×64 data, points zero-filled to 1024×1024 at 24 °C.

In Vivo MRI. In vivo MRI studies were performed after i.v. administration of $\text{Gd@C}_{82}(\text{OH})_{40}$ to CDF1 mice (ca. 20 g, female, 8 weeks age anesthetized with halothane (0.5–1%) and treated according to the Institutional Animal Care and Use Guidelines) at a dose of 5 μmol Gd/kg, which was 1/20 of the typical clinical dose (100 μmol Gd/kg) of Gd-DTPA ($n = 3$). The biodistribution studies at lung, liver, spleen, and kidney after i.v. administration of $\text{Gd@C}_{82}(\text{OH})_{40}$ ($n = 3$) was performed by Gd assay according to ICP-AES.

RESULTS AND DISCUSSIONS

Synthesis of Gd@C_{82} and $\text{Gd@C}_{82}(\text{OH})_n$. For the biomedical application of the metallofullerenes, modification to the water-soluble forms is essential. In this study, we employed the polyhydroxyl form for two reasons; one, for the simplicity of the synthesis, i.e., one-step procedure, and two, for the possibility of further molecular modifications such as conjugation of the bioreactive ligands. As the starting material of water-soluble metallofullerenes, highly purified Gd@C_{82} (<99%), which was achieved by the two-stage HPLC with a Buckyprep column (20 mm

Figure 1. MALDI-TOF mass spectrum of highly purified Gd@C_{82} (negative ion). The purity of Gd@C_{82} (<99%) was quantified by matrix-assisted laser desorption/ionization (MALDI) TOF mass spectrometry (Shimadzu Compact MALD IV).

Figure 2. Scheme of the synthesis of the water-soluble polyhydroxylated Gd@C_{82} , $\text{Gd@C}_{82}(\text{OH})_n$ (Gd-fullerenols) by the tetrabutylammonium hydroxide (40% in water, TBAH) phase-transfer reaction.

dia $\times$ 300 mm, nacalai tesque), was used. The purity was determined by HPLC and by matrix-assisted laser desorption/ionization (MALDI) TOF mass spectrometry (Figure 1). The polyhydroxylation of Gd@C_{82} to $\text{Gd@C}_{82}(\text{OH})_n$ (Gd-fullerenols) was performed by the tetrabutylammonium hydroxide (40% in water, TBAH) phase-transfer reaction as Figure 2. On the basis of the elemental analysis and water contents, the average number of hydroxyl groups of $\text{Gd@C}_{82}(\text{OH})_n$ was calculated to be approximately 40. The obtained Gd-fullerenols solution, whose Gd concentration was determined by the ICP-AES at 342.247 nm, was used for the further in vitro and in vivo MRI studies.

Table 1. Proton Relaxivities, R_1 and R_2 of $\text{Gd@C}_{82}(\text{OH})_{40}$ and Gd-DTPA at 0.47, 1.0, and 4.7 T, 25 °C and pH 7.5

[mM ⁻¹ s ⁻¹]	Gd@C ₈₂ (OH) ₄₀ ^a			Gd-DTPA ^b		
	0.47 T	1.0 T	4.7 T	0.47 T	1.0 T	4.7 T
R_1	67	81	31	3.8	3.9	3.8
R_2	79	108	131	4.2	6.2	5.9

^a The proton relaxivities R_1 and R_2 (the effect on $1/T_1$ and $1/T_2$) of $\text{Gd@C}_{82}(\text{OH})_{40}$ were determined at 0.47 T (Minispec, Bruker), 1.0 T (MAGNETOM Harmony, Siemens), and 4.7 T (Unity INOVA, Varian) at 25 °C. ^b The values of the conventional MRI contrast agent, Gd-DTPA (Magnevist), were also determined for comparison.

In Vitro MRI Study. The ability of proton relaxation enhancement of a paramagnetic compounds is commonly expressed by the term relaxivity, R_i , which is denoted as eq 1;

$$(1/T_i)_{\text{obsd}} = (1/T_i)_d + R_i \times [M] \quad i = 1, 2 \quad (1)$$

where $1/T_1$ and $1/T_2$, are the longitudinal and transverse relaxation rates of the solvent, $(1/T_i)_{\text{obsd}}$ is the observed value in the presence of the paramagnetic species, $(1/T_i)_d$ is the one in the absence of the paramagnetic species, and $[M]$ is the concentration of the paramagnetic species. The proton relaxivities, R_1 and R_2 of $\text{Gd@C}_{82}(\text{OH})_{40}$ determined at 0.47 T (Minispec, Bruker), 1.0 T (MAGNETOM Harmony, Siemens), and 4.7 T (Unity INOVA, Varian) at 25 ± 1 °C are summarized in Table 1 with the values of Gd-DTPA for comparison. R_1 of $\text{Gd@C}_{82}(\text{OH})_{40}$ is significantly higher than that of Gd-DTPA especially at 1.0 T which is the field strength of the common clinical MRI. Another important result is that R_2/R_1 is comparable to that of Gd-DTPA at lower field, which is one of the most crucial features for the T_1 -contrast agent. A Gd^{3+} ion with seven unpaired electrons in half filled 4f orbital has been known to exhibit a strong relaxation capability of proton nuclear spin of nearby water molecules. Earlier reports on R_1 measurements at 0.47 T gave lower values [20 mM⁻¹s⁻¹ (17) or 47 mM⁻¹s⁻¹ (18)] than that of our results (67 mM⁻¹s⁻¹). The factors causing the difference may be the number of the hydroxyl groups on the surface of fullerene cage and/or the differences in the aqueous environments, such as pH and ionic strength. Our preliminary results indicated the R_1 s of the Gd-fullerenols, obtained at 4.7 T at 37 °C, were significantly influenced by the pH and ionic strength. For example, a bell shape relation of R_1 vs pH was observed where maximal R_1 s values were from pH ca. 3 to pH ca. 8. R_1 values were lowered from 67 to 61 mM⁻¹s⁻¹ at 0.47 T when the NaCl concentration of Gd-fullerenol solution was changed from 0 to 1.0 M.

The conventional MRI contrast agents consisting of the Gd^{3+} -chelate complexes have one direct coordination window to a water molecule that rapidly exchanges with the bulk water molecules surrounding the Gd^{3+} ion, which leads to an efficient nuclear spin relaxation of solvent water molecules (3–5). In contrast, in $\text{Gd@C}_{82}(\text{OH})_n$ there are no water molecules which can form a direct coordination to the encaged Gd^{3+} ion. Although the details of the electronic and magnetic properties of the current Gd-fullerenols is not known at present, it is highly probable that $\text{Gd@C}_{82}(\text{OH})_n$ also has the paramagnetic property, as in the intact Gd@C_{82} fullerene (28), due to three electron transfer from Gd to the C_{82} fullerene cage [$\text{Gd}^{3+}@\text{C}_{82}(\text{OH})_n^{3-}$] with seven unpaired electrons in the Gd-4f orbitals inside the C_{82} cage and one on the cage (25). The encapsulated Gd^{3+}

Figure 3. T_1 -weighted MRI of $\text{Gd@C}_{82}(\text{OH})_{40}$ and Gd-DTPA phantom at the concentration of 0.05, 0.1, and 0.2 mmol Gd/L, respectively, by 4.7 T Unity INOVA (Varian, by conventional spin-echo with TR/TE = 300 ms/9 ms, FOV = 10×10 cm², 256×64 , points zero-filled to 1024×1024 , 24 °C) Extremely strong signals of $\text{Gd@C}_{82}(\text{OH})_{40}$ were demonstrated at the Gd concentration of 0.05 mM whereas Gd-DTPA of the same concentration showed only a slight enhancement of MRI signals as compared with pure water.

ion is unable to interact with the surface water directly. Therefore, the most plausible interpretation of the observed efficient relaxation of water protons is the dipolar interaction between these unpaired electrons and many water molecules surrounding the large spherical surface area of $\text{Gd}^{3+}@\text{C}_{82}(\text{OH})_n^{3-}$ with H side heading toward the negatively charged surface of the cage.

The present high values of relaxivity, R_1 , prompted us to carry out in vitro MRI phantom study of $\text{Gd@C}_{82}(\text{OH})_{40}$ with the expectation that the sufficient MRI signal enhancement should be obtained at lower Gd concentration than that required for Gd-DTPA. The measurement was performed by the T_1 -weighted spin-echo method and was evaluated according to the following relation (29):

$$\text{signal intensity} \propto \rho (1 - e^{-\text{TR}/T_1})e^{-\text{TE}/T_2} \quad (2)$$

where the symbols of ρ is proton density.

An extremely strong MRI signal enhancement was observed for $\text{Gd@C}_{82}(\text{OH})_n$ at the Gd concentration of 0.05 mM whereas Gd-DTPA at the same concentration showed only a slight enhancement as compared with pure water (Figure 3). These MRI data were consistent with the high R_1 and R_2 values in Table 1.

In Vivo MRI Study. The biodistribution studies after in vivo MRI were performed by Gd assay according to ICP-AES after i.v. administration of $\text{Gd@C}_{82}(\text{OH})_{40}$ to CDF1 mice (ca. 20 g, female, 8 weeks age). As shown in Figure 4 a, stronger signal in the T_1 -weighted image was obtained at lung, liver, spleen, and kidney after i.v. administration of $\text{Gd@C}_{82}(\text{OH})_{40}$ at a dose of 5 $\mu\text{mol Gd/kg}$ ($n = 3$), which was 1/20 of the typical clinical dose of Gd-DTPA (100 $\mu\text{mol Gd/kg}$). The signal intensity had good correspondence with the concentration of $\text{Gd@C}_{82}(\text{OH})_{40}$ found in these organs (Figure 4b and Figure 5). The biodistribution indicated that the $\text{Gd@C}_{82}(\text{OH})_{40}$ tends to be entrapped in the reticular-endothelial system (RES) supposedly by forming large particles by aggregation or by the interaction with the plasma components such as albumin (5, 15). This result of biodistribution suggested the potential of $\text{Gd@C}_{82}(\text{OH})_{40}$ as a RES specific MRI contrast agent. It was reported that the biodistribution of the other metallofullerenols, e.g., $\text{Ho@C}_{82}(\text{OH})_n$, showed an accumulation greater than 10% within bone tissues (19, 20). If it holds for the present system, $\text{Gd@C}_{82}(\text{OH})_n$ may accumulate in bone tissues, which

Figure 4. (a) T_1 -weighted MRI of CDF1 mice before and 30 min after i.v. administration of $\text{Gd@C}_{82}(\text{OH})_{40}$ via tail vein as the dose of $5 \mu\text{mol Gd/kg}$ [which was 1/20 of a typical clinical dose of Gd-DTPA ($100 \mu\text{mol Gd/kg}$)] ($n = 3$), and (b) its time dependent signal intensity change in various organs. MRI conditions: 4.7 T Unity INOVA (Varian), at $\text{TR/TE} = 300 \text{ ms}/11 \text{ ms}$. At 30 min. after i.v. administration of $\text{Gd@C}_{82}(\text{OH})_{40}$, enormous signal enhancement was observed at lung, liver, spleen, and kidney (Figure 4(b)).

Figure 5. Biodistribution of Gd in CDF1 mice at 30 min, 1 h, and 24 h after i.v. administration of $\text{Gd@C}_{82}(\text{OH})_{40}$. Assay of Gd ions was carried out by ICP. The signal enhancement shown in Figure 3 had good correspondence with the concentration of $\text{Gd@C}_{82}(\text{OH})_{40}$ found in these organs (Figure 4a and Figure 4b). The biodistribution indicated that the $\text{Gd@C}_{82}(\text{OH})_{40}$ tends to be entrapped in the reticular-endothelial system (RES), such as lung, liver, and spleen.

might not be well-tolerable. To avoid bone uptake and to target specific tissues, further surface modification may be required.

In the utilization of Gd-chelate complexes for the RES agents, one must be apprehensive of the possible in vivo Gd^{3+} dissociation. In contrast, $\text{Gd@C}_{82}(\text{OH})_{40}$ has much less potency of toxicity because of its solid carbon cage structure. The unique fullerene structure of $\text{Gd@C}_{82}(\text{OH})_{40}$ protects the central metal atom from the outer environments, hence scarce release of Gd^{3+} from the entrapped fullerene cage. Furthermore, our preliminary 3-D MR contrast-enhanced angiography clearly demonstrated rat blood vessels within a few minutes after i.v. administration of Gd-fullerenols at the dose of $10 \mu\text{mol Gd/kg}$. It is very likely that this angiogram can be further improved by simple modification on the fullerene surface for the prolongation of the blood circulation period and the avoidance of RES uptake.

The present paramagnetic water-soluble metallofullerenes (Gd-fullerenols), which have extremely strong MR signal enhancement ability, will be applied as novel MRI contrast agents for the present anatomical and functional imaging. Furthermore, this will be a promising novel core material of MRI probes for high-quality molecular/cellular and future genetic imaging for next generation.

Immunological Properties of Uricase Conjugated to Neutral Soluble Polymers

Paolo Caliceti,* Oddone Schiavon, and Francesco M. Veronese

Department of Pharmaceutical Sciences, University of Padua, Via F. Marzolo, 5 Padova, Italy. Received September 25, 2000

For a comparative study of immunological properties of protein–polymer conjugates, uricase was modified with (a) poly(*N*-vinylpyrrolidone) 6000 Da, (b) poly(*N*-acriloylmorpholine) 6000 Da, (c) branched monomethoxypoly(ethylene glycol) 10000 Da, and (d) linear monomethoxypoly(ethylene glycol) 5000 Da. Spectroscopic studies performed by UV, fluorescence, and circular dichroism did not show any relevant difference in protein conformation among the native and the conjugates. Immunological studies showed that both uricase antigenicity and immunogenicity were altered by polymer conjugation to an extent that depended upon the polymer composition; in particular, monomethoxypoly(ethylene glycol) 10000 Da remarkably reduced the protein antigenicity, while unexpectedly, the poly(*N*-vinylpyrrolidone) derivative presented higher antigenicity than the native protein. In Balb/c mice, the native protein elicited a rapid and intense immunoresponse whereas all the conjugates induced a lower production of anti-native uricase antibodies. The rank order of immunogenicity was native uricase > uricase–poly(*N*-vinylpyrrolidone) ≥ uricase–poly(*N*-acriloylmorpholine) > uricase–monomethoxypoly(ethylene glycol) 5000 Da > uricase–monomethoxypoly(ethylene glycol) 10000 Da. The four conjugates also induced anti polymer immunoresponse. Anti poly(*N*-vinylpyrrolidone) and anti poly(*N*-acriloylmorpholine) antibodies were generated from the first immunization while low levels of anti polymer antibodies were found with both poly(ethylene glycol) conjugates only after the second immunization.

INTRODUCTION

Polymer conjugation has so far been successfully used to enhance the therapeutic potential of many pharmacologically active proteins and peptides since it allows for the alteration of their physicochemical and biological properties improving permanence in circulation, stability, and solubility and reducing immunogenicity (1–3).

Immunological properties of conjugates are of primary importance for their therapeutic application, but a number of items should be taken into consideration regarding both the conjugate components: polymer and protein (4).

Although absence of immunogenicity is a general prerequisite for the polymers used in drug modification, some of them were shown to present inherent immunogenic character because of their repetitive structure or high molecular weight. Examples are polyamino acids, polyacryloyl peptides, and polysaccharides (5, 6). Furthermore, in some cases, conjugation can provoke a dramatic change of polymer immunological properties. Low or nonimmunogenic macromolecules can in fact acquire haptogenic character by conjugation with immunogenic compounds. Poly(hydroxyethylstarch), poly(lysine), poly(ornithine), and dextrans, for example, were found to gain relevant antigenicity and immunogenicity after coupling with proteins and peptides (7–9). Also, poly(hydroxyethylacrylate), a polymer largely investigated for drug conjugation, was found to acquire unexpected immunogenicity after binding to oligopeptides, and anti poly(ethylene glycol) antibodies were generated using PEG-

superoxide dismutase and PEG-ovoalbumin although this polymer is nonimmunogenic when administered alone (10, 11).

As far as the protein side is concerned, reduction of immunogenicity often represents the target of conjugation when medical application of proteins entails the risk of severe immunoresponse. However, it is worth noting that although protein immunogenicity can be improved by modification with several macromolecules this result cannot be considered a general consequence of polymer coupling. Dextrans, for example, have been found to ameliorate the immunogenic behavior of many proteins, but paradoxically, in some cases they increase the protein immunogenicity as reported with bovine serum albumin or chicken serum albumin. (12, 13). Increased immunogenicity was also observed when polymer coupling induces partial modification of protein structure or dissociation into subunits that can be accompanied by introduction of neo-antigens (2).

Another interesting immunological aspect of polymer binding is the possibility to obtain derivatives that modulate the immunoresponse toward allergens. In this regard, several studies demonstrated that polymer conjugation can switch immunogenic proteins into tolerogenic compounds, providing new therapeutic perspectives (14).

These features indicate that conjugation can reflect in immunological properties of the derivatives, which can be quite different from those of the starting protein and polymer. These are often unpredictable since, as already reported in the literature, they depend on a number of parameters.

In the framework of this research field, we carried out an immunological characterization of synthetic polymers

recently developed in our laboratory for protein conjugation: monofunctional poly(*N*-vinylpyrrolidone) (PVP) (15), poly(*N*-acryloilmorpholine) (PACM) (16), and a branched form of poly(ethylene glycol) (PEG2) (17). These polymers were selected because they possess physicochemical properties similar to the most used linear PEG 5000 Da, namely solubility, chemical stability, monofunctionality in reaction, and absence of charge. However, these polymers were found to confer to proteins different physicochemical and biopharmaceutical properties (18).

For the present comparative investigation, derivatives of uricase, an immunogenic protein of outstanding therapeutic value, bearing a close number of PVP, PACM, PEG2, and PEG were prepared and spectroscopic studies and antigenic and immunogenic characterizations were carried out on the native enzyme and the four conjugates.

EXPERIMENTAL SECTION

Uricase from *Candida utilis* was obtained from Toyobo (Osaka, Japan). [^3H]Succinimidyl propionate was from Amersham International (Amersham, U.K.) and Instagel for radioactivity determinations from Canberra Packard (Groningen, The Netherlands). The gel filtration Superose columns and the FPLC system were supplied by Pharmacia Biotech (Uppsala, Sweden); the ultrafiltration system was from Amicon Inc. (Beverly, MA). The alkaline phosphatase conjugated goat anti mouse IgG, IgM, and [IgG + IgM] were from Sigma (St. Louis, MO). All other reagents, of analytical grade, were purchased by Fluka (Buchs, Switzerland). Male Balb/c mice, weighing 24 ± 2 g and fed ad libitum, obtained from Charles River (Calco, Italy), were used for in vivo experiments. Animal treatments were performed according to institutional European guidelines.

Polymer Preparation and Activation. Succinimidyl ester activated linear monomethoxypoly(ethylene glycol) MW 5000 Da (PEG 5000) and branched monomethoxypoly(ethylene glycol) MW 10000 Da (PEG 10000) were prepared as previously reported (17, 19). Carboxy-terminating poly(*N*-vinylpyrrolidone) MW 6000 Da (PVP) and poly(*N*-acryloilmorpholine) MW 6000 Da (PACM) were synthesized, fractionated, and activated according to methods previously described (15, 16).

Preparation of Protein-Polymer Conjugates. Uric acid (77 μmol) was dissolved in 1 mL of 0.2 M borate buffer, pH 8.0 containing 10 mg of uricase. Proper amounts of activated polymer (77 mg of PEG 5000, 270 mg of PEG 10000, 115 mg of PVP, or 140 mg of PACM) were added to the protein solution under vigorous stirring. The reaction mixture was gently stirred for 1 h at room temperature, and 9 mL of 0.1 M borate buffer pH 8.0 was added. The solution was ultrafiltered with an Amicon system using a 10000 Da cut off membrane to reach a volume of 1 mL and the solution diluted with 5 mL of the same buffer and further ultrafiltered. The ultrafiltration procedure was repeated three times. The solution was finally loaded on a gel filtration Superose 12 preparative column that was eluted with 10 mM phosphate buffer, 0.15 M NaCl, pH 7.2 (PBS). The eluate was analyzed by OD at 280 nm for protein content, by iodine assay for polymer determination (20), and by enzyme activity (21). The protein-polymer conjugate peak was concentrated by ultrafiltration, and the protein concentration was determined by biuret assay (22). The degree of modification was estimated by a trinitrobenzenesulfonic acid based colorimetric method (23).

Preparation of Tritium-Labeled Derivatives. [^3H]Succinimidylpropionate (10 μg , 519 mCi/mg) was added

under stirring to 0.5 mL of 0.2 M borate buffer, pH 8.0, containing 5 mg of native uricase or equimolar amounts of its conjugates. The solution was gently stirred for 1 h at room temperature and then loaded on an analytical Superose 6 column eluted with PBS. The eluted fractions were analyzed for protein content by OD at 280 nm, enzyme activity, polymer content, and radioactivity using the Instagel cocktail. The radioactive peak corresponding to the [^3H]-labeled uricase or its conjugates was collected and protein concentration and radioactivity were assessed.

Spectroscopic Evaluations. The spectroscopic characterizations were carried out using solutions of 0.38 μM of native or polymer conjugated uricase in PBS. The circular dichroism spectra were recorded in the range of 200–250 nm while fluorescence spectra were determined in the range of 300–440 nm by excitation at 276 nm.

ELISA Determinations. ELISA microplates were incubated overnight at 4 °C with 100 μL /well of coating solution (0.1 M NaHCO_3 , pH 9.5) containing 1 $\mu\text{g}/\text{mL}$ of antigen. The wells were washed three times with 200 μL of PBS, 0.05% Tween, pH 7.2 (PBS-T) and then incubated for 2 h at room temperature with 200 μL of 0.1 M NaHCO_3 , pH 9.5, containing 50 $\mu\text{g}/\text{mL}$ of bovine serum albumin. The wells, washed as described above, were incubated for 2 h at room temperature with 100 μL of serum samples serially diluted in PBS-T and, after further washing, for 2 h with 100 μL of alkaline phosphatase conjugated goat anti mouse antibodies (anti IgG or anti IgM or anti [IgG + IgM]) properly diluted in PBS-T. The wells were washed as above and 100 μL of 1 M diethanolamine, MgCl_2 , pH 9.8, containing 1 mg/mL of *p*-nitrophenol phosphate (Sigma¹⁰⁴). The enzymatic reaction was stopped after 1 h by addition of 50 μL of 3 N NaOH and the o.d. at 405 nm was determined.

Antigen Coating Estimation. The amount of adsorbed protein on the well surface was estimated as follows: 200 μL of coating solutions containing serial dilutions (0.05–5 $\mu\text{g}/\text{mL}$) of tritium-labeled native protein or equimolar concentrations of its tritium-labeled conjugates in 0.1 M NaHCO_3 , pH 9.5, were incubated overnight at 4 °C in the ELISA wells. The solutions were completely removed and conserved, and the wells were washed three times with 200 μL of PBS-T. The coating and the washing solutions were pooled, lyophilized, and examined for radioactivity content.

Antigenicity Determinations. Native uricase (10 μg) in 200 μL of PBS/complete Freund's adjuvant (50/50) were intraperitoneously injected into seven male Balb/c mice on day 0. The animals were intraperitoneously boosted on days 7, 14, 21, and 28 with 10 μg of native uricase dissolved in 200 μL of PBS/incomplete Freund's adjuvant (50/50). The blood was taken on day 35, pooled, and centrifuged, and the serum serially diluted in PBS-T was used for antigenicity determinations by ELISA. The assay was performed as described above using, for well coating, 0.2 $\mu\text{g}/\text{mL}$ of native uricase or equimolar dilutions of uricase-PEG, uricase-PEG2, uricase-PVP, or uricase-PACM.

Immunogenicity Evaluations. Fifty male Balb/c mice were divided into five groups of 10 animals and immunized on days 0, 4, and 11 with 10 μg of native uricase (group 1) or equimolar amounts of uricase-PEG (group 2), uricase-PEG2 (group 3), uricase-PVP (group 4), and uricase-PACM (group 5). The immunizing solutions were prepared by dissolution of the immunogen in 100 μL of PBS and 100 μL of Freund's adjuvant (complete adjuvant was used in the first immunization, incomplete adjuvant was used for boosting). The solutions were

intraperitoneously injected, and blood samples were taken by retrobulbar bleeding at scheduled times. The blood samples were centrifuged for 2 min at 3500 rpm, and the serum was properly diluted in PBS for ELISA.

Anti conjugate (whole construct) antibodies were assessed by ELISA using the corresponding uricase derivative for well coating. For the determination of anti native uricase antibodies the well coating was performed with native enzyme while for determination of anti-polymer antibodies, ribonuclease modified with PVP, PACM, PEG2, and PEG was used.

RESULTS AND DISCUSSION

To provide alternatives to monomethoxypoly(ethylene glycol) MW 5000 Da (PEG) for protein modification, we recently developed new soluble polymers: monofunctional poly(*N*-vinylpyrrolidone) MW 6000 (PVP), poly(*N*-acryloilmorpholine) MW 6000 Da (PACM), and a branched form of monomethoxypoly(ethylene glycol) MW 10000 Da (PEG2).

Previous studies showed that these macromolecules possess the prerequisites for medical application, and encouraging results were obtained in the conjugation of few protein models. Conjugation of these polymers endowed in fact proteins with improved biopharmaceutical and immunological properties (17, 18, 24, 25).

Aiming to investigate closely the immunological aspects of PVP, PACM, and PEG2 conjugation, we carried out a comparative study using uricase as protein model. Uricase conjugated to the most known linear PEG 5000 was used as a comparison model. PVP and PACM with MW 6000 Da were selected because they have a molecular weight similar to PEG 5000, the polymer of choice for protein modification. PEG2 was considered in order to investigate the influence of the polymer molecular weight and shape on the immunological properties of the conjugate. Uricase was chosen because, despite its therapeutic value in treatment of uric acid overproduction, it presents a poor immunogenic character that greatly limits its medical use. For this reason, dextran and PEG derivatives of uricase with improved immunogenic and biopharmaceutical properties were already prepared (26, 27).

Polymer Conjugation. Because of the comparative nature of this investigation, conjugates at a similar level of modification were prepared. To overcome the differences in reactivity of the polymer, which depend on both polymer activation degree and accessibility to the protein surface, different polymer/protein molar ratios were used in the conjugation reaction.

Table 1 reports the reaction conditions, degree of modification, and molecular mass of the various uricase species. In all of the derivatives, an average of 44 protein

**Figure 1.** Circular dichroism spectra of native uricase (—) and uricase-PVP (---).

amino groups were modified by polymer. This yielded an higher molecular mass in the case of the PEG2 conjugate with respect to the other ones because of the higher molecular weight of this polymer that is about twice that of PVP, PACM, and PEG. It is important to note that since PEG2 is a branched form of the linear PEG, the number of polymer chains bound to the protein surface corresponds to a double number with respect to the other single chain polymer conjugates.

In all preparations, the addition of uric acid in the reaction mixture allowed for partial maintenance of the enzyme activity (20–80% of the unmodified uricase) probably because the substrate prevents the conjugation at the active site region (28).

Structural Studies. Spectroscopic studies were carried out to investigate whether the polymer conjugation induced protein denaturation that would be reflected in increased protein antigenicity and immunogenicity.

Native uricase and the four polymer conjugates displayed identical UV-vis and fluorescence spectra indicating that no macroscopic changes in protein structure occurred by polymer attachment. Also, no differences were found among the CD spectra of the various uricase species demonstrating that the secondary structure of the protein was not affected to a detectable degree by polymer conjugation. As an example, the CD spectra of native uricase and uricase-PVP are reported in Figure 1. The maintenance of the protein structure after polymer modification seems to indicate that the generation of new protein determinants, which could convey poor immunogenic properties to the conjugates, is unlikely.

The spectroscopic data suggest also that the low enzyme activity of conjugates is not due to partial denaturation of uricase but most probably to masking of the active site by the polymer or to chemical modification of protein amino groups involved in the catalytic activity that takes place despite the use of uric acid.

Antigenic Properties. The antigenicity of native and conjugated uricase was estimated by ELISA using mouse anti serum enriched with anti native uricase antibodies.

In a preliminary study, the coating levels of the various enzyme forms on the ELISA microplate wells were

Figure 2. Antigenic profiles of native uricase (X), uricase-PVP (♦), uricase-PACM (■), uricase-PEG (◆), and uricase-PEG2 (●). $\pm$ SD was calculated on the basis of the values obtained with five experiments.

estimated using the following: [^{3} H]uricase, [^{3} H]uricase-PVP, [^{3} H]uricase-PACM, [^{3} H]uricase-PEG, and [^{3} H]uricase-PEG2. This was essential for a correct comparison of the results obtained with the native and the polymer conjugated protein. Comparable protein adhesion was obtained with the various uricase species provided that the protein concentration of the coating solutions was 0.2 μ g/mL.

The antigenic profiles of native and polymer modified uricase are depicted in Figure 2. The different behavior obtained with the conjugates underlines the influence of the structural and physicochemical properties of the polymers on the protein antigenic character. PACM, PEG, and PEG2 were found to reduce remarkably the uricase antigenicity. The reduction of uricase antigenicity obtained with both poly(ethylene glycol) derivatives confirms the known efficiency of these polymers in enhancing the antigenic character of this protein (29). PACM also was found to reduce the protein antigenicity although at a lower extent with respect to the poly(ethylene glycol)s.

Most probably, the reduction of protein antigenicity is due on one side to direct polymer masking of the protein epitopes and, on the other, to the steric hindrance of the polymer around the protein that prevents the antibody approach. Both of these events are strictly related to the physicochemical nature of the polymers that can be arranged on the protein surface in an extended or coiled conformation providing a different degree of hiding of the protein epitopes. Furthermore, these polymers possess a different capability to coordinate water molecules, which is reflected in different hydrodynamic volume of the conjugates. Therefore, the protein located in the hydrated polymeric core of the construct is differently accessible to the antibody interaction. To observe that the high efficiency of PEG2 in decreasing the uricase antigenicity with respect to the linear polymer is in agreement with the results obtained with other proteins (30). This can be ascribed to the higher molecular mass of polymer on the protein surface that efficiently enables it to mask the protein antigenic sites and reduces the approach of the antibodies to the protein structure as well as to prevent the proteolytic digestion (30).

Unexpected results were instead obtained with the PVP derivative. In this case, the protein antigenicity is about 2-folds higher than the native enzyme one. This intriguing result is in contrast with the data obtained in our laboratory with superoxide dismutase and ribonuclease where PVP conjugation lowered the protein antigenicity. The different behavior observed with uricase with respect to ribonuclease and superoxide dismutase demonstrates that the antigenic performance of the

Figure 3. Anti whole molecule immunogenic profiles. IgM + IgG levels toward native uricase, uricase-PVP, uricase-PACM, uricase-PEG, and uricase-PEG2. $\downarrow$: immunization time. *: undetectable values.

conjugate is strictly related to the protein properties. In this regard we must remember that studies reported in the literature indicate that also PVP-conjugated D-N-acetyl hexosamidase A can strongly interact with the anti native protein antibodies (4).

Conjugate Immunogenicity. The generation of antibodies against the native protein or the whole constructs was determined by ELISA using the various uricase forms for well coating and mouse serum obtained from the animals immunized with the corresponding conjugates.

The immunological profiles depicted in Figure 3 indicate that the derivatives present a lower immunogenicity with respect to the native uricase, though at a different degree from one another. Uricase-PVP and uricase-PACM are the most immunogenic conjugates since they stimulate a high production of antibodies from the first immunization, and similar to the native enzyme, high antibody levels were maintained for the length of the experiment. On the other hand, the PEG and PEG2 derivatives present a remarkably lower immunogenicity with respect to native uricase. The very low amount of antibodies elicited by the PEG2 conjugate is worthy of note.

Protein Immunogenicity. The anti native protein antibody levels obtained by animals immunized with the four conjugates were estimated and compared with the ones obtained with native uricase.

The anti native protein [IgG + IgM] time courses depicted in Figure 4 A point out the high immunogenicity of native uricase. Anti uricase antibodies were found from the first immunization, and the maximal immunoreponse was obtained after animal boosting. The separate evaluation of IgM and IgG (Figure 4B,C) indicated that native uricase could elicit a rapid and intense IgM production since after the first immunization, and high IgM levels were maintained for 10 weeks while high amounts of anti native uricase IgG were elicited after the second immunization and maintained throughout the experiment.

All the conjugates were found to stimulate a lower anti uricase immunoreponse with respect to the native protein, although a different behavior was obtained with the four derivatives. PVP was the least effective in reducing the protein immunogenicity; anti uricase IgM were generated from the first immunization and IgG from the second one. PACM was more effective than PVP in suppressing uricase immunogenicity. By treatment with

Figure 4. Anti native uricase immunogenic profiles: IgM + IgG(A), IgM (B), and IgG (C) immunoresponse after immunization with native uricase, uricase-PVP, uricase-PACM, uricase-PEG, and uricase-PEG2. ↓: immunization time. *: undetectable values.

PACM-uricase, anti protein IgM and IgG were detected only after the second immunization, and the reduction in immunoresponse was reduced to 2% of the native enzyme one. Even higher reduction in uricase immunogenicity was found with the linear PEG conjugate (below 1% of the native protein one). In this case, detectable amounts of anti native uricase IgM were determined only after the second immunization to disappear rapidly while

low amounts of IgG were generated after the third treatment. With the PEG2 derivative anti native protein IgM were not found, and negligible amounts of IgG were detected after the third immunization only.

Similar to what reported for the conjugate immunogenicity, the different immunogenic profiles depicted in Figure 4 can be explained with the different ability of the polymer to mask the protein epitopes and to prevent

Figure 5. Anti polymer immunogenic profiles: IgM + IgG(A), IgM (B), and IgG (C) immunoresponse after immunization with uricase-PVP, uricase-PAcM, uricase-PEG, and uricase-PEG2. ↓: immunization time. *: undetectable values.

the approach of the immunocompetent cells to the conjugate. Probably the unlike arrangement of the four polymers on the protein surface as well as their degree of hydration affect in a different way the uricase immunogenicity.

Also in this case, the immunogenic behavior of uricase-PVP is in contrast with the results previously obtained

in our laboratory with other proteins. Superoxide dismutase-PVP, for example, was found to be less immunogenic than the PEG derivative (24). However, the low effectiveness of PVP in reducing uricase immunogenicity could be related to the high immunogenic character of this protein as well as to a possible low in vivo stability of the protein induced by PVP attachment that could

induce the molecule dissociation into high immunogenic subunits.

The rapid and intense production of anti native uricase IgM obtained with uricase-PVP indicates that a T cell independent mechanism may be involved in antibody response while with the other conjugates the immunoresponse appears to take place by a T cell dependent mechanism only. On the basis of such a hypothesis, we can think that PAcM, linear PEG, and PEG2 can convey to the conjugates a different capability to interact with macrophages and different stability toward the cell proteolytic processing.

As far as the two poly(ethylene glycol) derivatives are concerned, the PEG2 conjugate presents an immunogenic character that is more convenient for therapeutic application as already observed in our laboratory (30).

Polymer Immunogenicity. Interesting results were obtained regarding the ability of the conjugates to induce anti polymer immunoresponse. For this study, ELISA microplate wells were coated with ribonuclease (RNase) extensively modified with the four polymers. To avoid misinterpretation of the results, the absence of antibody cross reactivity with native RNase was previously verified.

Figure 5 reports the anti-polymer immunogenic profiles obtained with the four uricase-polymer conjugates. Unexpectedly, all the conjugates were found to induce anti polymer immunoresponses although at different levels.

The PVP and PAcM conjugates were found to induce a relevant production of IgM soon after the first immunization, suggesting a T cell independent mechanism antibody response (Figure 5B), while high levels of anti polymer IgG were estimated after the second treatment (Figure 5C). On the contrary, PEG and PEG2 derivatives gave rise to slight and delayed anti polymer antibody production. In particular, the immunogenic profiles reported in parts B and C of Figure 5 show that low levels of anti PEG IgM and IgG were found by immunization with uricase-PEG after the second and the third boosting, respectively, while the PEG2 derivative stimulated only negligible amounts of anti polymer IgM and IgG.

These results indicate that despite the absence of inherent immunogenic character of the polymers used for the present investigation (7, 31, 32) their immunogenicity can significantly increase by linkage to proteins. In this regard, we must remember that conjugation to proteins generally induces a deep modification of polymer physicochemical properties that can be reflected in different immunological properties. Covalent binding of polymers to the protein surface achieves high molecular weight constructs that may result in partial loss of polymer flexibility and prolonged exposure to the biological environment due to their long permanence in circulation. These events could be the reason immunocompetent cells are stimulated at a greater extent to produce anti polymer antibodies.

With regard to the molecular weight, it is worth noting that this parameter is of primary importance in dictating polymer immunogenicity. Immunogenic character of many polymers has been, in fact, demonstrated to increase as their molecular mass increases as, for instance, in the case of poly(*N*-vinylpyrrolidone)s of high molecular weights that are definitely immunogenic (32, 33). In the case of conjugates, the protein in the core of the construct behaves as an anchoring point for the polymer so that the conjugate could virtually acquire the properties of a high mol wt polymer. This may contribute

to increase immunogenic character of the polymer after protein conjugation. However, this relationship between polymer immunogenicity and molecular weight is not a general rule since data reported in the literature indicate that poly(ethylene glycol) immunogenicity decreases as the molecular weight increases. This is in agreement with the lower anti polymer immunoresponse obtained with the PEG2 derivative relative to the PEG one (7).

CONCLUSIONS

The data reported in this paper demonstrate that the four polymers investigated here, PVP, PAcM linear and branched PEG, can improve the immunogenic character of uricase. However, despite their apparently similar physicochemical properties, they convey different immunological properties to the conjugates.

In particular, our data demonstrate that the immunogenic properties of the conjugates are strictly related to the protein structure. This is in agreement with that reported in the literature and explains the different results obtained in our laboratory with other protein models modified with the same polymers. In the case of uricase, the high protein immunogenicity is probably the reason for the low efficiency of PVP and PAcM in preventing the anti native protein immunoresponse. Furthermore, this protein can confer to the polymers haptogenic character allowing for stimulation of anti polymer antibody production.

On the other hand, our results underline the relevance of the polymer choice in fabrication of conjugates with suitable immunogenic properties. Polymer flexibility, extended or coiled conformation, hydrophilic/hydrophobic balance, water coordination, and arrangement on the protein surface, together with molecular weight and chemical structure, are, in fact, all parameters that dictate the immunological properties of the conjugate.

In conclusion, from the investigation reported here we can say that, although neutral amphiphilic polymers seem to possess suitable immunological properties on their own for protein modification, the immunogenic performance of conjugates is not easily predictable because of the complexity of the immunoresponse process. Accurate immunological investigations are therefore required in the development of any new derivative, and both protein and polymer immunogenicity before and after conjugation must be thoroughly investigated.

New TFO Conjugates Containing a Carminomycinone-Derived Chromophore

Massimo L. Capobianco,* Marcella De Champdoré,[†] Luca Francini,[‡] Stefano Lena, Anna Garbesi, and Federico Arcamone

ICOCEA-CNR, Via Gobetti 101, 40129 Bologna, Italy. Received November 8, 2000;

Revised Manuscript Received February 16, 2001

Conjugates obtained by linking the anthracycline intercalating chromophore to triple helix forming oligonucleotides (TFOs) have been used in a physicochemical study of the stability of triple helices with DNA sequences of pharmacological relevance. The intercalating moiety is represented by carminomycinone derivatives obtained upon O-demethylation and hydrolysis of the glycosidic linkage of daunomycin followed by the introduction of an alkylating residue at two different positions. Results of experiments with a polypurinic region present in the multidrug resistance (MDR) gene indicate that the stability of the triple helix is significantly enhanced by replacement of C's with ⁵-MeC's in the TFO sequences tested. The stability is not changed when a 3'-TpT is present in place of a 3'-CpG at the presumed intercalation site of the anthraquinone chromophore. The same carminomycinone derivatives were used for the preparation of conjugates able to form triple helices with the polypurine tract (PPT) present in the human integrated genome of HIV-1 infected cells. Three different TFOs (T₄^{Me}CT₄^{Me}CC, **C2**; T₄^{Me}CT₄^{Me}CC^{Me}CC^{Me}CCT, **C6**; and T₄^{Me}CT₄G₆, **G6**) were designed and linked to the anthraquinone moiety. These conjugates showed a significantly enhanced ability to bind the PPT region of HIV with respect to the nonconjugated TFOs.

INTRODUCTION

One promising new technique used to inhibit the expression of genes consists of the formation of a local triple helix able to interfere with the transcription machinery. Local triple helices can be formed by an exogenous oligonucleotide that binds to a DNA in its natural duplex form, providing it has the right recognition pattern for Hoogsteen's type of hydrogen bonds, i.e., a polypurine tract. Since the pioneering studies of Hélène and co-workers, this approach has been known as anti-gene methodology (1). Even if polypurine tracts of suitable length for selective recognition (14–20 bases) are relatively rare within genomes, they are often present in the control region of genes (indicating, perhaps, a possible natural mechanism of regulation). In general, triple helices have a rather low thermodynamic stability under physiological conditions of pH and temperature. However, stability may be enhanced, inter alia, by tagging an intercalating agent at one or both termini of the triplex-forming oligonucleotide (TFO). Using different derivatives of daunorubicin as intercalating moieties at pH values between 5.5 and 6.8, we have already increased from 16 to 20 °C the melting temperature of a triplex formed by a pyrimidinic T/C oligonucleotide with a DNA duplex featuring a polypurine region present in the *hMDR1* gene (2).

The first part of the present work studied the effect of replacing cytidines with 5-methyl-cytidines on the stabil-

ity at pH 7.0 of the same triplex used with the daunorubicin-derived TFO conjugates (2). Using the same model system, we also addressed the question of the possible dependence of the triplex stabilizing effect of this type of intercalator upon the base pair sequence of their putative intercalation site. The second part investigated the use of the same type of conjugation for increasing the thermal stability at pH 7.0 of triplexes formed with the polypurine tract (PPT) region of HIV-1 proviral DNA. This region of the proviral DNA is accessible to TFOs within cell nuclei (3, 4), but native oligonucleotides do not lead to stable triplexes under physiological conditions. Hence, some extra binding strength is needed to obtain a significant inhibition of transcription.

MATERIALS AND METHODS

General Methods. All chemicals were of commercial analytical grade and used as received.

The following abbreviations were used throughout the text: AcOH, acetic acid; DMF, *N,N*-dimethylformamide; DTT, 1,4-dithio-D,L-threitol (or 1,4-dithioerythritol); TEAA, triethylammonium acetate; TEAB triethylammonium bicarbonate; Tris, tris(hydroxymethyl)aminomethane.

HPLC Analysis and Purifications. HPLC analysis and purifications were performed on a Waters 600E Millipore system control equipped with a Waters 484 tuneable absorbance detector as previously described (2).

UV-Melting Experiments. Ultraviolet measurements and melting profiles were recorded on a Perkin-Elmer 554 spectrophotometer equipped with a MGW Lauda RC5 thermostat and a MGW Lauda R40/2 digital thermometer; heating was controlled by an electronic device generating a linear gradient of temperature of 0.5 °C/min. Samples were prepared by dissolving equimolar amounts of the duplex strand in 0.1 M Tris–AcOH buffer, 0.05 M NaCl, 0.01 M MgCl₂ at pH 7.0 at a concentration

of 1 or 2 μM per strand. The UV cuvettes were heated to 80 °C for 20–30 min and then slowly cooled (at least in 2–3 h) to room temperature to favor annealing; the conjugates were then added, and the cuvettes were again heated to 60 °C to favor the annealing of the third strand without destruction of the duplex. The cuvettes were then gently cooled to 4 °C. Condensation of moisture on the cell walls, in the range 4–20 °C, was prevented by flushing nitrogen.

Fluorescence Experiments. Fluorescence quenching experiments were monitored on a SPEX 3000 spectrofluorometer at room temperature with 1.25 mm slits, 455 and 495 nm filters, $\lambda_{\text{exc}} = 470$ nm; the emission was recorded in the interval 520–700 nm. Interference of water was electronically subtracted from the recorded spectra.

Electrophoretic Mobility Shift Assay. Electrophoresis was run using a 20% polyacrylamide gel in a thermostatic slab gel unit at 10 V/cm. The samples were prepared by mixing 1 μL of a 0.1 mM buffered solution of duplex with 0.8–1.5 μL of a 0.1 mM buffered solution of conjugate–TFO. The samples were then diluted with buffer to 5 μL and allowed to anneal at 15 or 36 °C overnight; 5 μL of a 50% sucrose solution was added, and the 10 μL samples were applied on the gel. A 0.1 M Tris–AcOH buffer, 0.05 M NaCl, 0.01 M MgCl_2 at pH 7.0 was used both for the preparation of samples and for the run.

Gel staining was obtained by soaking the gel with 0.01% stains-all dye in 1/1 (v/v) water/formamide. The gels were then directly digitalized on a PC scanner.

Synthesis and Purification of the Oligonucleotides. The oligodeoxynucleotides were prepared on a Pharmacia gene assembler II-plus using the manufacturers' protocols with commercially available amidites. The oligonucleotides were deblocked with 30% aqueous ammonia (16 h at 50 °C) and then purified by ion exchange on a Sephacel column (Pharmacia), eluting with a linear gradient from 0.05 to 1.5 M TEAB. The fractions were analyzed by HPLC, and those with purity greater than 90% were pooled together, evaporated several times with water, and then converted to the sodium salt by ion exchange with Dowex WX-8 resin in the sodium form.

Synthesis and Purification of Conjugates (Series A and B). Oligonucleotides containing the 5'-PS linkage were prepared using a modified (home-tested) protocol on a Pharmacia gene assembler II-plus employing dicyanoethyl-(*N,N*-diisopropyl)-phosphoramidite. After deblocking and night-standing on DTT (5 mg/mL), the crude compound was precipitated with 1-butanol (10 volumes); the oligonucleotide was then dried, converted to the sodium salt (as above), and lyophilized. The sodium salt of a 5'-PS-oligonucleotide (10 ODU about 75% pure by HPLC) was dissolved in 125 μL of DMF, 20 μL of water, 11 μL of 15-crown-5, 1 mg of anthracycline iodo derivatives (2), and 0.2 mg of DTT. The reaction mixture was kept in a sealed vial for 16 h in a thermostat at 45 °C. The crude mixture was purified from the excess of iodoalkylcarminomycinone by diluting the mixture with 150 μL of water and extracting the unreacted iodo derivative with a 85/15 v/v solution of dichloromethane/methanol. The pure conjugate was then recovered by purification of the aqueous solution on a reverse-phase silica gel column using a gradient of acetonitrile (0–30%) in a 0.1 M TEAA aqueous buffer. Usually 5–6 ODU of pure conjugate was obtained.

RESULTS AND DISCUSSION

Part 1: hMDR1 Target. The sequences of the TFOs and the target duplexes used in part 1 of this study are

^a The evidenced regions encompassing the intercalation site are common to both **DNA-2** and PPT duplex.

Figure 1. The two types of conjugates employed. The hexamethylene spacer is attached to the 5'-base of the ODN through a phosphorothioate (PS) linkage (2).

shown in Table 1, and the structures of the conjugates are presented in Figure 1. Our previous work (2) demonstrated that derivatization of **MDR-1** as in the compounds of the type shown in Figure 1 enhances the stability of the triplex with the **DNA-1** target (Table 1). In particular, we observed that, while the triplex formed at pH 6.8 by unconjugated **MDR-1** exhibited a T_m of 11 °C, the 4-O- and the 6-O-carminomycinone derivatives of the same TFO (**MDR-1-A** and **MDR-1-B**) melted at 27 and 31 °C, respectively. The increased stability of the triplex is related to a specific structure including both recognition of the PPT region by the complementary Hoogsteen strand and intercalation of the anthracycline chromophore. This was deduced from observation of the biphasic melting transition and gel mobility shift in electrophoretic experiments, together with the fluorescence quenching typical of the intercalation process. Fluorescence quenching was observed only as a consequence of the triple helix formation. First, to explore the possibility of further enhancing the stability of the triple helix by substituting the cytidines with the 5-methylcytidine's sequence, **MDR-2** was synthesized and linked to the appropriate carminomycinone derivatives, according to the procedure already described (2), to give **MDR-2-A** and **MDR-2-B**. Second, although the precise position of the intercalation of the tagged molecule in the triple-helical complex remains to be established, the length of the linker allows it to occur either at the interface between the duplex and the triplex region or, at most, one base pair away from it. As **DNA-1** exhibits a 3'-CpG next to the said interface, we evaluated the effect of the substitution of this structural element with, for example, a 3'-TpT as in **DNA-2**.

The stability of the triplexes formed by the TFOs and by the conjugates with **DNA-1** and **DNA-2** was studied by UV-melting experiments, and the results are summarized in Table 2. As expected, replacing the C's with 5-MeC's (**MDR-2** versus **MDR-1**) enhanced the stability of the triple helix by more than 12 °C at pH 7.0. The melting data also show that, at least for the conjugates of type **A**

or **B**, the identity of the base pairs present in the duplex at the duplex/triplex interface (i.e., at the putative intercalation site) played no role in the stabilization of the resulting triplex, as there is no appreciable difference in the effect on the *T_m* between targeting **DNA-1** or **DNA-2**. This finding is important in that it allows the extension of the applicability of this class of conjugates to the targeting of polypurinic regions devoid of a flanking 3'-

CpG motif (such as the PPT region of the HIV). The CpG sequence is considered to be the preferred intercalation site of the anthracyclines (5).

As described in our previous work (2), the formation of a triplex with daunorubicin-derived conjugates quenches the fluorescence signal of the anthraquinone moiety, as shown for the present sequences in Figure 2. This figure illustrates the increasing fluorescence quenching of **MDR-2-A** (2.0 μ M) at neutral pH, following the progressive addition of **DNA-1** (left panel) or **DNA-2** (right panel). The signals were recorded 5 min after each addition of a small volume of a concentrated duplex solution. Since the measurements were done at 22 °C, it is assumed that the triplex was the only stable species, the *T_m* of the complex being about 53 °C (Table 2). In both cases, the signal decreases regularly up to the addition of 1.05 molar equiv of the duplex, with a further negligible change upon the addition of a further 0.14 equiv. This last measurement was repeated, and found unchanged, after 6 h. Since we know from the value of

Figure 3. Reverse-phase (C-18) HPLC analysis of the crude reaction mixture at the end of the synthesis of **G6-B** (left panel). The three main peaks were separately collected and analyzed under denaturing conditions (6 M urea) by PAGE (right panel). They resulted mainly in the formation of various aggregates between the original **G6** and the desired **G6-B**.

Figure 4. Gel mobility shift experiments of the triplex formed by **C2-A**, **C2-B**, **C6-A**, and **C6-B** at pH 7.0 and 15 °C. Lane 1, 200 pmol of single-stranded **PPT-Py**. Lane 2, 200 pmol of the indicated conjugate-TFO. Lanes 3 and 8, 100 pmol of duplex **PPT**. Lane 4, 100 pmol of **dx-PPT** + 80 pmol of conjugate-TFO. Lane 5, duplex **PPT** + conjugate-TFO, both 100 pmol. Lane 6, 100 pmol of **dx-PPT** + 120 pmol of conjugate-TFO. Lane 7, 100 pmol of **dx-PPT** + 150 pmol of conjugate-TFO. Lane 9, 200 pmol of single-stranded **PPT-Pu**. Total applied volumes, 10 μ L per lane.

$T_m = 53$ °C and from the melting profile (not shown) that the triplex was the largely predominant species at the equilibrium at 22 °C, we may assume that the fluorescence signals recorded at the end of the two experiments are those of the intercalated chromophore. The quenching due to intercalation was 40% with **DNA-1** and 29% with **DNA-2**; this behavior reflects the known property of the daunomycin chromophore to modulate its fluorescence yield according to the structure of the intercalating site (5).

In summary, the above experimental findings demonstrate that, in the case of the *hMDR1* target, the conjugates between suitable derivatives containing the daunorubicin chromophore and a polypyrimidinic oligonucleotide containing methylated cytidines form triple helices which are stable at physiological pH; the high increase in thermal stability (+30 °C) with respect to the underivatized TFO is due to intercalation of the tagged aglycon moiety.

Part 2: The HIV-1 PPT Target. Since we demonstrated that daunomycinone conjugates were able to stabilize a triplex formed with a duplex featuring a TpT step at the 5' side of the purinic *hMDR1* region, we turned to the targeting of the PPT region of HIV-1. We

used as TFOs oligomers **C2**, **C6**, and **G6**, whose sequence is reported in Table 3 together with that of the target duplex. According to previous literature data (3), acridine-oligonucleotide conjugates with very similar structures selectively blocked RNA polymerase at this target HIV-PPT region in a transcription elongation experiment.

The base sequence of **C2** and **C6**, alternating normal and methylated cytidines, was designed to avoid the destabilization due to the presence of a row of protonated, self-repelling, 5-methylcytidines, particularly in the case of **C6** (6).

The attempt to select the best candidate for triplex formation at neutral pH, among the three unconjugated TFOs, did not lead to any conclusion, as gel electrophore-

Figure 5. Quenching of the fluorescence of conjugate **C2-A** upon addition of PPT duplex. Measurements were recorded in a buffer containing 100 mM Tris-HCl, 50 mM NaCl, 10 mM MgCl₂, and 2 μ M conjugates.

sis at low temperature failed to disclose the formation of a retarded species between these ODNs and the target PPT-duplex (**PPT-dx**). In the case of **G6**, the experiment was also hampered by the self-aggregation of this oligomer at the concentration used to load the gel (10 μ M). [This same sequence had been reported to form a triple helix with $T_m = 34$ °C at pH 6.2 and at lower concentration (3)]. Hence, all three oligonucleotides were used for the preparation of conjugates of series **A** and **B**, following the already reported procedure with minor modifications (2).

During HPLC purification of the final products, we observed, by RP-18 HPLC analysis of concentrated solutions at neutral pH, the formation of easily reversible aggregates with both **C6-A** and **C6-B**, possibly due to the presence of a "i-motif" (7, 8). These aggregates spontaneously disappeared at lower concentrations or at basic pH, and did not affect the binding experiments. On the contrary, during the purification of crude mixtures of **G6-A** and **G6-B**, we faced severe problems of conjugate aggregation with themselves and with the starting **G6**, making it practically impossible to isolate the desired product with the needed quality (Figure 3).

The formation of triple helices between the **C2** and **C6** conjugates of general structure **A** and **B** with the **PPT-dx** was investigated at 10 μ M concentrations of each partner by electrophoretic retardation experiments at 15 °C and pH 7.0. The results are shown in Figure 4. All four gels show that, upon increasing the amount of conjugate added, the duplex spot is less and less visible and a retarded product is formed in increasing amounts. With the **C2** conjugates, the retarded spot, corresponding to the triplex, is very close to that of the duplex, reflecting the small mass difference between the 50 base duplex and the 61 base triplex. Accordingly, the retardation is slightly improved with the **C6** conjugates. Staining was

used to detect the species present in the gel; thus, only a qualitative estimate of the binding phenomenon can be made, with the indication that, at pH 7, at 15 °C and 10 μ M concentrations, at least 50% of the duplex is converted into the triplex upon addition of 1.5 equiv of the conjugates. In all four cases, UV-melting experiments from 5 to 80 °C failed to reveal the biphasic profile that allows the assessment of the thermal stability of the triple-helical complex. Hence, the gel electrophoresis experiments were repeated at 36 °C, but again failed to show any evidence of retarded species with any of the conjugates. To prove that the retarded species detected at 15 °C were, indeed, the triplexes formed by the conjugates with the target duplex, we used fluorescence spectroscopy. In all cases, the intensity of the fluorescence signal of the conjugate decreased following the addition of increasing amounts of the duplex, as expected because of the intercalation of the chromophore moiety of the conjugate within the triple-helical complex. The results obtained with conjugate **C2-A** are shown in Figure 5. Furthermore, the initial fluorescence values were restored when, at the end of the "titrations" with the duplex, the pH of the solution was brought to 8.2, i.e., a condition that is incompatible with the existence of triplexes formed by cytidine-containing TFOs.

In summary, the experimental results for the HIV-1 PPT target indicated that conjugation of the anthracycline aglycons with (T,C)-containing TFOs (**C2** and **C6**) significantly enhances their binding affinity for the target, even though further stabilization will be required to obtain triple helices sufficiently stable under physiological conditions. Conjugation of (T,G)-containing TFOs with anthracycline derivatives strongly promotes self-association, at least with the **G6** conjugates, thus preventing their recognition of the PPT region.

Different Strategies for Formation of PEGylated EGF-Conjugated PEI/DNA Complexes for Targeted Gene Delivery

Thomas Blessing,* Malgorzata Kursa, Robert Holzhauser, Ralf Kircheis, and Ernst Wagner†

Institute of Medical Biochemistry, University of Vienna, Dr. Bohrgasse 9/3, A-1030 Vienna and Boehringer Ingelheim Austria, Dr. Boehringer Gasse 5-11, A-1121 Vienna, Austria. Received November 15, 2000; Revised Manuscript Received April 28, 2001

With the aim of generating gene delivery systems for tumor targeting, we have synthesized a conjugate consisting of polyethylenimine (PEI) covalently modified with epidermal growth factor (EGF) peptides. Transfection efficiency of the conjugate was evaluated and compared to native PEI in three tumor cell lines: KB epidermoid carcinoma cells, CMT-93 rectum carcinoma cells, and Renca-EGFR renal carcinoma cells. Depending on the tumor cell line, incorporation of EGF resulted in an up to 300-fold increased transfection efficiency. This ligand-mediated enhancement and competition with free EGF strongly suggested uptake of the complexes through the EGF receptor-mediated endocytosis pathway. Shielded particles being crucial for systemic gene delivery, we studied the effect of covalent surface modification of EGF–PEI/DNA complexes with a poly(ethylene glycol) (PEG) derivative. An alternative way for the formation of PEGylated EGF-containing complexes was also evaluated where EGF was projected away from PEI/DNA core complexes through a PEG linker. Both strategies led to shielded particles still able to efficiently transfect tumor cells in a receptor-dependent fashion. These PEGylated EGF-containing complexes were 10- to 100-fold more efficient than PEGylated complexes without EGF.

INTRODUCTION

Cancer gene therapy by systemic gene delivery would be a most attractive way for treatment of cancer. Approaching the tumor via blood circulation should allow several advantages over the local intratumoral injection such as reaching multiple distant metastases. Unfortunately, the required tumor-targeted gene delivery system does not exist yet. An ideal gene delivery system has to fulfill several criteria to access tumor tissue: (1) ligands able to mediate cell specific recognition and internalization into target cells must be incorporated; (2) the gene delivery system must be inert against nonspecific interactions with the biological environment such as blood components and nontarget cells.

Synthetic gene delivery systems have recently attracted much attention particularly those based on polyethylenimine (PEI) polymers. Native PEI polymers of various molecular weights and topological isomers have been shown to be efficient for transfection of eukaryotic cells (1–4), and receptor-mediated endocytosis was achieved by chemical modification of PEI backbone with ligands such as sugars (5–8), peptides (9), and proteins (10). PEI polymers have also been used for gene delivery in vivo (1, 11–17) and particularly for systemic delivery to the lung (18, 19). However, unspecific interactions of the DNA complexes with blood components and nontarget cells strongly reduce the applicability of complexes. Recently, our group reported tumor-targeted gene delivery based on transferrin–PEI conjugate (20, 21).

Surface modification of transferrin-containing complexes with hydrophilic poly(ethylene glycol) (PEG) polymers strongly reduced interactions with blood components and prolonged circulation in blood after systemic delivery. Moreover, PEGylated transferrin-containing complexes mediated gene expression in distant tumor and showed reduced tropism for the lung compared to nonmodified PEI/DNA complexes.

Epithelial growth factor (EGF) receptor is an attractive therapeutic target for tumor targeting because it is overexpressed in a high percentage of human carcinomas including glioblastoma and lung, liver, breast, head, neck, and bladder cancers (22). The natural EGF ligand is a 53-residue polypeptide that binds specifically and with high affinity (23) to the EGF receptor. The binding of EGF triggers the dimerization of the receptor and the clustering of EGF–EGF receptor into coated pits that are internalized.

With the aim of specific gene delivery to EGF receptor-bearing tumor cells we synthesized a EGF–PEI conjugate and tested its ability to deliver DNA in three carcinoma cell lines. Keeping in mind future systemic gene delivery, the effect of PEGylation of preformed EGF-containing complexes was studied. We also describe an alternative novel way to generate PEGylated ligand-containing complexes where ligands are projected away from core complexes through a PEG linker.

EXPERIMENTAL PROCEDURES

Chemicals. Branched polyethylenimine with an average molecular weight of 25 kDa (PEI 25K) was obtained from Aldrich (Vienna, Austria). For complex preparation, PEI 25K was diluted with water, neutralized with HCl solution, and used as a 0.43 mg/mL working solution (10 mM of amine functions, assuming a MW of 43 Da for the repeating unit). Linear polyethylenimine

(PEI 22K), kindly provided by Jean-Paul Behr (Faculté de Pharmacie, Illkirch, France) and commercially available from Euromedex (Exgen 500, Euromedex, Souffelweyersheim, France), was also used as a neutral 10 mM working solution. Succinimidyl 3-(2-pyridyldithio)propionate (SPDP) was purchased from Fluka (Buchs, Switzerland); chloroquine, 1,4-dithio-L-threitol (DTT), bovine serum albumin (BSA) from Sigma (St. Louis, MO); α -vinyl sulfone- ω -N-hydroxy succinimide ester poly(ethylene glycol) (VS-PEG-NHS, MW 3400), α -maleimide- ω -N-hydroxysuccinimide ester poly(ethylene glycol) (MAL-PEG-NHS, MW 3400) from Shearwater Polymers (Huntsville, AL); mouse epidermal growth factor (mEGF) from Serotec (Oxford, England); cell culture media, antibiotics, foetal calf serum (FCS), Geneticin (G418-sulfate) from Life Technologies (Gaithersburg, MD). Plasmid pCMVLuc (Photinus pyralis luciferase under control of the CMV enhancer/promoter) described in Plank et al. (24) was purified with the EndoFree Plasmid Kit from Qiagen (Hilden, Germany).

Synthesis of Thiol-Functionalized PEI 25K. PEI 25K was diluted in water, neutralized with 32% aqueous hydrochloric and subjected to gel filtration as described previously (10). To 50 mg of PEI 25K (1.16 mmol of amine functions, quantified by ninhydrine assay at 570 nm (25)) in 758 μ L was added 394 μ L of a 20 mM ethanolic solution of SPDP (2.5 mg, 7.9 μ mol). The reaction was carried out for 1 h at room temperature. Low molecular weight products were removed by gel filtration on a Sephadex G25 superfine (Pharmacia, Uppsala, Sweden; 300 $\times$ 10 mm column) in 0.25 M NaCl, 20 mM Hepes, pH 7.3. After dialysis and concentration under vacuum, a 720 μ L solution containing 0.97 mmol of PEI monomer (41.5 mg) with 4.2 μ mol of pyridyldithiopropionate linker (PDP; quantified spectrophotometrically at 343 nm by release of thiopyridone after reduction of an aliquot with excess DTT (26)) was obtained (i.e., ca. 2.5 PDP groups per PEI molecule). Half of this solution (20.7 mg PEI, 0.48 mmol of amine functions) was mixed under argon with an excess of DTT (73 μ mol) and was left to react for 1 h at room temperature. For removal of the low molecular weight products an additional gel filtration on a Sephadex G25 superfine (0.25 M NaCl, 20 mM Hepes pH 7.3; 100 $\times$ 10 mm) was performed yielding 1.5 mL of thiol-functionalized PEI 25K that contained 242 μ mol of PEI monomer (10.4 mg) modified with 1.25 μ mol of thiol functions (quantified by Ellman assay at 412 nm (27)); i.e., ca. three thiol groups per PEI molecule.

Synthesis of PDP- and Thiol-Functionalized mEGF. A solution of 4 mg mEGF (0.66 μ mol) in 1 mL of 16 mM Hepes buffer pH 7.9 was mixed with 3.1 mg of SPDP (10 μ mol) in 0.5 mL of ethanol. The reaction and the purification steps (see below) were carried out in the presence of ethanol (20–50%) to avoid precipitation of the PDP-functionalized product. The reaction was left to react for 3 h at room temperature. The functionalized peptide was purified by either dialysis (MWCO 1000; Spectra Por, Spectrum, Houston, TX) against 50% aqueous ethanol or gel filtration on a Sephadex G10 (Pharmacia, Uppsala, Sweden; 100 $\times$ 10 mm column) in 20 mM Hepes pH 7.3/20% ethanol.

The purified conjugate contained about 0.9 PDP group per mEGF peptide ($\pm$ 10%, depending on the preparation).

Thiol-functionalized mEGF (mEGF-SH) was obtained by reduction of an aliquot of mEGF-PDP (at a concentration of about 50 μ M) with DTT (1 mM) for 1 h under argon. Low molecular weight products were removed by gel filtration on a Sephadex G25 PD-10 column (Pharmacia, Uppsala, Sweden) in 20 mM Hepes pH 7.3/30%

ethanol. Quantification of thiol functions with Ellman assay indicated that the conjugate contained about one thiol group per mEGF peptide ($\pm$ 15%).

Synthesis of mEGF-PEI 25K Conjugate. Two solutions of PDP-functionalized mEGF were pooled, and 2 mL of the resulting solution that contained 4.2 mg EGF (0.69 μ mol) was modified with 0.56 μ mol of pyridyldithiopropionate linker was mixed under argon with 7.5 mg of thiol-functionalized PEI 25K (174 μ mol of amine functions, 0.9 μ mol thiol functions) in 1.08 mL of 0.25 M NaCl, 20 mM Hepes, pH 7.9. After 1 day at room temperature, the reaction mixture was loaded on a cation-exchange column (Macro-Prep High S, BioRad, München, Germany; 100 $\times$ 10 mm column) and was fractionated with a salt gradient from 0.5 to 3.0 M sodium chloride with a constant content of 20 mM Hepes, pH 7.3. The major amount of conjugate eluted between 2.7 and 3.0 M salt and was pooled. After dialysis against HBS (MWCO 6000–8000; Gibco BRL, Gaithersburg, MD) and concentration under vacuum, 6.5 mL of mEGF-PEI solution was obtained that contained 148 μ mol PEI of monomer (6.4 mg) modified with 0.32 μ mol of mEGF peptide (2.0 mg); i.e., approximately 1.3 mEGF peptides per PEI molecule. Before use, EGF conjugate samples were diluted to 10 mM PEI monomer.

Formation of PEI/DNA, mEGF-PEI/DNA, and PEGylated mEGF-PEI/DNA Complexes. DNA complexes used for the transfection of KB and Renca-EGFR cells were prepared as described by Boussif et al. (1) with some modifications. Briefly, 4 μ g of pCMVLuc plasmid (12 nmol of phosphate) and 7.2 μ L of a 10 mM PEI or EGF-PEI (72 nmol of amine functions) were each diluted in 100 μ L of the indicated buffer: HBS (Hepes buffered saline: 145 mM NaCl/20 mM Hepes pH 7.3), HBS 1/2 (HBS twice diluted with water) or 5 mM Hepes pH 7.3, and mixed together. After 15 min incubation an aliquot of the complex solution was added to the cells (100 μ L/well for example corresponding to 2 μ g DNA/well).

Complexes that were subsequently PEGylated were prepared in advance. Fifteen minutes after mixing DNA and polymer solutions, 0.6 μ L of a 6 mM VS-PEG-NHS (or MAL-PEG-NHS) stock solution in DMSO (3.6 nmol) was added and left to react overnight.

For titration of different N/P ratios on CMT-93 cells mEGF-PEI/DNA or PEI/DNA complexes were prepared by mixing 5 μ g of pCMVLuc plasmid, prediluted in 250 μ L of HBS, with different amounts of mEGF-PEI 25K or PEI 25K prediluted in 250 μ L of HBS (2.25 μ g of PEI corresponding for example at N/P 3.6).

Sequential Addition of Bifunctional PEG and mEGF-SH to PEI/DNA Complexes. pCMVLuc plasmid (20 μ g, 60 nmol of phosphate) and PEI (360 nmol of amine) were each diluted in 0.5 mL of the indicated buffer previously saturated with argon. The two solutions were gathered and mixed with argon stream. The mixture was kept under argon until the end of the protocol. After 15 min, 3 μ L of a 6 mM VS-PEG-NHS (or MAL-PEG-NHS) stock solution in DMSO (18 nmol) were added. Two hours later, various amounts of EGF-SH (between 7.2 and 144 pmol; as indicated in the Figure legend) were added to 200 μ L aliquots of the complex solution and left to react overnight.

Cells and Cell Culture. KB human epidermoid carcinoma cells (ATCC CCL-17) and CMT-93 murine rectum carcinoma cells (ATCC CCL-223) were cultured in DMEM medium supplemented with 10% FCS, 2 mM glutamine, 100 U/ml penicillin, and 100 μ g/mL streptomycin. Renca mouse renal carcinoma cells stably cotransfected with the plasmids pLTR-EGFR and pSV2neo (28)

(kindly provided by Winfried Wels, Georg-Speyer-Haus, Frankfurt am Main, Germany), named Renca-EGFR, were grown in RPMI-1640 medium supplemented with 10% FCS, 2 mM glutamine, 100 U/mL penicillin, 100 μ g/mL streptomycin, and 0.5 mg/mL Geneticin. All cell lines were maintained at 37 °C in a 5% CO₂ humidified atmosphere.

Transfection. One day before transfection, KB and Renca-EGFR cells were seeded at 4×10^4 cells per well in 24-well dishes. Prior to transfection, medium was removed and replaced with 1 mL (or as indicated in Figure legend) of fresh culture medium complemented with 10% FCS. Transfection complexes were added to the cells, and after 4 h incubation, transfection medium was removed and replaced by 1 mL fresh culture medium.

Murine CMT-93 cells were seeded at 5×10^5 cells per 25 cm² tissue culture flask 1 day before transfection. Prior to transfection, medium was removed and replaced by 2 mL of fresh culture medium complemented with 10% FCS. Transfection complexes (in 0.5 mL of HBS) were added to the cells. After 4 h incubation, transfection medium was removed and replaced by fresh culture medium.

The cells were grown for additional 20 h and then washed in PBS and lysed (0.25 M Tris·HCl pH 7.4, 0.1% Triton X-100). Luciferase activity and protein concentration were determined from aliquot of the lysate using a luminometer (Lumat LB9507, Berthold, Bad Wildbad, Germany) and Bio-Rad protein assay (Bio-Rad, Hercules, CA), respectively. Values are given as light units integrated over 10 s per mg of protein.

RESULTS

Synthesis of mEGF-PEI 25K Conjugate. mEGF was covalently coupled to the PEI backbone through a disulfide bridge as described in Experimental Procedures. Murine EGF can bind both the murine and human EGF receptor (29) and was chosen because it lacks lysine residues in its primary sequence and can react with SPDP-activated ester only through the N-terminus. It has been shown that the derivatization of this free amino group had little effect on EGF receptor binding compared to native EGF (30). Modification of this amino group with the heterobifunctional cross-linker SPDP (26) rendered the peptide poorly soluble, and ethanol had to be present in the reaction and purification steps. The reaction was carried out with an excess of SPDP (15 molar equiv excess) and led to a mEGF-PDP conjugate containing almost one linker per peptide. PEI with an average molecular weight of 25 kDa was also modified with SPDP and then treated with an excess of DTT. A thiol-functionalized PEI conjugate that contained approximately three thiol groups per PEI molecule was obtained. Reaction between thiol-functionalized PEI and mEGF-PDP followed by purification by cation-exchange chromatography resulted in a mEGF-PEI conjugate that contained 1.3 mEGF peptides per PEI molecule.

EGF Receptor-Mediated Gene Transfer in Various Carcinoma Cell Lines. Transfection efficiency of mEGF-PEI 25K-containing DNA complexes was compared with EGF-free PEI 25K/DNA complexes in three carcinoma cell lines (Figure 1). Formulation of complexes in three different Hepes buffers containing different concentrations of NaCl (Hepes: 0 mM, HBS 1/2: 75 mM and HBS: 150 mM) at a PEI-nitrogen to DNA-phosphate ratio of 6 (N/P = 6) resulted in complexes of various sizes (Table 1) which were tested in transfection experiments with Renca-EGFR cells (Figure 1A) and KB cells (Figure

Figure 1. EGF-mediated gene transfer to Renca-EGFR mouse renal, KB human epidermoid and CMT-93 murine rectum carcinoma cells. Renca-EGFR (A) and KB cells (B) were transfected with pCMVLuc plasmid (2 μ g/well) complexed with PEI 25K or mEGF-PEI 25K/PEI 25K (1:1) at a PEI (nitrogen)/DNA (phosphate) ratio of 6 (N/P = 6) in either 5 mM Hepes pH 7.3, HBS 1/2 or HBS. After 4 h, transfection medium was replaced with fresh culture medium and cells were grown for additional 20 h. Luciferase activity was measured as described in Experimental Procedures. Values are the mean $\pm$ SD of two independent experiments made in duplicate. (C) KB cells were transfected with various amounts of pCMVLuc plasmid (2 to 0.125 μ g per well) complexed with PEI 25K or mEGF-PEI 25K/PEI 25K (1:1) at N/P = 6 in HBS. Luciferase activity is the mean $\pm$ SD of two independent experiments made in duplicate. (D) CMT-93 cells were transfected with pCMVLuc plasmid (5 μ g/flask) complexed with various amounts of PEI 25K or EGF-PEI 25K (at indicated N/P ratios) in HBS. Luciferase activity is shown as mean $\pm$ SD of duplicate.

Table 1. Biophysical Characteristics of DNA Complexes and Their PEGylated Derivatives^a

	size (nm)			zeta (mV) Hepes
	Hepes	HBS 1/2	HBS	
PEI 25K	57 ± 14	116 ± 36	478 ± 111	+20.0 ± 1.7
PEI 25K + MAL-PEG-NHS	47 ± 11	96 ± 30	446 ± 118	-0.7 ± 1.1
PEI 25K + MAL-PEG-NHS + EGF-SH	49 ± 15	81 ± 23	403 ± 118	-0.6 ± 1.4
EGF-PEI 25K/PEI 25K	53 ± 12	447 ± 82	590 ± 132	+21.5 ± 2.3
EGF-PEI 25K/PEI 25K + MAL-PEG-NHS	48 ± 14	553 ± 128	> 1 μm	-0.6 ± 1.0
PEI 25K/PEI 22K	43 ± 11	~ 1 μm	~ 1 μm	+28.0 ± 2.5
PEI 25K/PEI 22K + MAL-PEG-NHS	42 ± 10	> 1 μm	> 1 μm	-0.1 ± 1.4

^a Complexes were prepared as described in Experimental Procedures in 1 mL total volume of the indicated buffer containing 20 μg DNA (for zeta potential measurement of PEI 25K/PEI 22K/DNA complexes DNA concentration was 50 μg/mL). Size and zeta potential of non-PEGylated and PEGylated complexes were measured 20 min and 18 h after their formation respectively, using a Zetasizer 3000HS (Malvern Instruments, Worcestershire, England). Three measurements were carried out per sample.

1B). EGF-containing DNA complexes showed a 5- to 300-fold increase in gene delivery efficiency compared to unmodified PEI/DNA complexes. This ligand-mediated enhancement was found for all formulations. Large complexes formulated in physiological salt concentration (HBS) were more efficient than small complexes prepared in salt-free medium (5 mM Hepes pH 7.3), similar as observed previously with other cell lines using transferrin-modified PEI/DNA complexes (31). Chemical ligation of mEGF to the PEI 25K backbone did not change the biophysical properties (size, zeta potential) of resulting complexes generated either in Hepes or HBS buffer (Table 1). This strongly suggests the expected biological involvement of EGF in the increase of gene expression. In contrast, in HBS 1/2, the difference of size between both type of complexes might also contribute to the improved gene expression.

Comparative transfection was also investigated with sub-micromolar amounts of DNA on KB cells (Figure 1C). Luciferase expression of PEI complexes generated in HBS dropped rapidly with the decrease of DNA amount while expression of EGF-PEI complexes remained relatively high.

Luciferase gene expression was examined as a function of the PEI-nitrogen to DNA-phosphate ratio used to generate the complexes. Gene expression in CMT-93 murine rectum carcinoma cells was strongly dependent on the N/P ratio (Figure 1D). Increasing the N/P ratio from 3.6 to 8.4 increased the efficiency of both EGF-containing and EGF-free DNA complexes by more than three orders of magnitude. There was a 3- to 30-fold ligand-mediated enhancement at all N/P ratios tested. With ligand-free complexes a drop in transfection efficacy was found at high N/P ratio correlating with some toxicity.

Small particles generated in salt-free medium led to low gene expression in comparison with large particles generated in HBS (Figures 1A and 1B). We tested whether the addition of an endosomolytic compound during the transfection could enhance the efficiency of small complexes. Therefore, the lysomotropic drug chloroquine was added during transfection in cell culture medium of Renca-EGFR cells at a concentration of 100 and 200 μM (Figure 2A). Addition of chloroquine resulted in a 100-fold increase of gene expression with both EGF-containing DNA complexes and EGF-free DNA complexes while the ligand-mediated enhancement remained approximately constant.

To test whether the EGF receptor was involved in EGF-PEI-mediated gene transfer, a competition assay was performed using small complexes formulated in salt-free medium. Addition of exogenous mEGF in cell culture medium during transfection of Renca-EGFR did not interfere with PEI/DNA receptor-independent gene trans-

Figure 2. (A) Chloroquine strongly enhances transfection efficiency of small particles generated in salt free medium on Renca-EGFR cells. Renca-EGFR were transfected with pCMVLuc plasmid (2 μg/well) complexed with PEI 25K or mEGF-PEI 25K/PEI 25K (1:1) at N/P = 6 in Hepes. Transfection was carried out in the presence of 0, 100, or 200 μM chloroquine. After 4 h, transfection medium was replaced with fresh culture medium and cells were grown for additional 20 h. Luciferase activity values are the mean ± SD of two independent experiments made in duplicate. (B) Competitive inhibition of EGF receptor-mediated gene transfer on Renca-EGFR cells. Renca-EGFR cells incubated in 0.5 mL of fresh culture medium containing 200 μM chloroquine were transfected with pCMVLuc plasmid (1 μg/well) complexed with PEI 25K or mEGF-PEI 25K/PEI 25K (1:1) at N/P = 6 in Hepes. For the inhibition and the control experiments transfection was carried out in the presence of free mEGF (12 μg/well) and BSA (12 μg/well), respectively. After 4 h, transfection medium was replaced with fresh medium and cells were grown for additional 20 h. Luciferase activity is shown as mean ± SD of duplicate.

fer (Figure 2B). However, competition of EGF-containing DNA complexes with free mEGF (100 molar equiv excess) decreased gene transfer efficacy down to nearly the values found for the receptor-independent transfection. On the other hand, addition of BSA, a protein that does not interact with EGFR, did not significantly affected gene transfer efficiency of both type of complexes. Taken together, competitive and comparative transfection ex-

Figure 3. Schematic presentation of alternatives for the formation of PEGylated ligand-containing DNA complexes. Strategy A: A ligand is covalently conjugated to a polycation (step 1). Condensation of DNA with this conjugate leads to ligand-containing DNA complexes (step 2) which are subsequently modified with a PEG derivative reacting with free amino groups of the polycation (step 3). Strategy B: DNA is condensed with a polycation (step 1), and the resulting complexes are modified by a heterobifunctional PEG which first reacts with amino groups of the polycation (step 2). Subsequently ligands are incorporated into the complexes by covalent conjugation with the distal end of the PEG (step 3). The latter strategy should allow a better accessibility of the grafted ligand for its receptor.

periments strongly suggested involvement of EGF receptor in gene delivery with EGF-PEI-based systems.

Transfection Efficiency of PEGylated EGF-Containing DNA Complexes. Targeted transfection particles for systemic gene delivery should have uncharged surface to avoid nonspecific electrostatic interaction with blood components and nontarget cells. On the other hand, DNA is usually efficiently condensed using an excess of polymer, giving rise to cationic particles. One way to overcome this dilemma is to covalently modify the surface of ligand-containing DNA complexes with an electro-neutral polymer such PEG (20) (Figure 3, strategy A). Coating the DNA particle with PEG shields its cationic surface and prevents interaction with macromolecules by steric hindrance. On the other hand PEG potentially might also shield small ligands bound to the polymer and thus preventing to some extent the binding to the receptor on the target cell. As described in strategy B (Figure 3), incorporation of the ligand at the distal end of PEGylated PEI/DNA complexes should allow better accessibility of the ligand for its receptor and thus should increase cellular internalization of DNA complexes.

These two strategies using EGF as ligand were evaluated with Renca-EGFR cells (Renca mouse renal carcinoma cells stably transfected with pLTR-EGFR plasmid carrying human EGF receptor cDNA (28)) and KB cells (human epidermoid carcinoma cells that endogenously express human EGF receptor). Transfection of Renca-EGFR was performed in the presence of chloroquine with small complexes formulated in salt free medium. It was previously observed that addition of chloroquine on Renca-EGFR cells increases considerably PEI-mediated gene transfection (Figure 2A), in contrast to KB cells where no beneficial effect is observed. PEGylation of PEI/DNA complexes dramatically decreased the zeta potential (which reflects the surface charge) close to the neutrality (Table 1) and was accompanied by a reduction of gene expression (Figure 4A). Addition of increasing amounts of thiol-functionalized mEGF to PEGylated complexes without changing their biophysical properties (size, zeta potential) increased gene transfection by two-orders of magnitude. In contrast, addition of the functionalized ligand to PEI/DNA complexes without reactive PEG linker had no effect. This finding strongly suggested that

EGF binding at the distal end of the PEG allows the delivery of PEGylated complexes in a ligand-dependent manner. We compared this strategy with the one previously developed in our group (20) (Figure 3, strategy A). As previously observed, EGF-PEI conjugate-containing DNA complexes were more efficient than those prepared with native PEI 25K. PEGylation of EGF-containing DNA complexes decreased the zeta potential close to the neutrality (Table 1) and also gene expression. This PEGylated complexes were still about 5-fold more effective than EGF-free PEI/DNA complexes but about one order less efficient than PEGylated complexes obtained according to strategy B (Figure 3).

The two strategies were also used for the delivery of PEGylated EGF-containing DNA complexes in KB cells in the absence of chloroquine (Figure 4B). Subsequent addition of PEG and thiol-functionalized EGF to PEI/DNA complexes generated in HBS 1/2 increased their efficiency by more than one order of magnitude. Complexes resulting from the PEGylation of EGF-PEI conjugate-containing DNA complexes showed approximately the same level of gene expression.

Transfection with Different PEI Polymers Complexes and Their PEGylated Derivatives. Among all available PEI, which differ by their average molecular weight and topology, linear PEI 22K had shown the most promising properties to deliver DNA (4, 18). We were interested to know whether the combination of PEI 22K with mEGF-PEI 25K could enhance the ligand-mediated gene delivery in our in vitro cell models. KB cells were transfected with various amount of DNA complexed with PEI 25K, EGF-PEI 25K/PEI 25K (1:1), PEI 25K/PEI 22K (1:1), or EGF-PEI 25K/PEI 22K (1:1) in HBS 1/2 at N/P = 6 (Figure 5A). Incorporation of PEI 22K in the preparation of ligand and ligand-free PEI 25K/DNA complexes strongly increased gene expression especially at low DNA amounts. At 60 ng of DNA, PEI 22K-containing complexes remained efficient (10^7 – 10^8 RLU/mg) whereas PEI 22K-free complexes showed only low activity. Interestingly, a ligand-dependent enhancement was observed with PEI 22K-containing complexes on KB cells but also on Renca-EGFR cells independently of the medium in which the complexes were prepared (Figure 5B).

Figure 4. Transfection efficiency of PEGylated EGF-containing DNA complexes on Renca-EGFR and KB cells. (A) Renca-EGFR cells incubated in fresh culture medium containing 200 μ M chloroquine were transfected with the following complexes generated as described in Experimental Procedures in HEPES buffer at a N/P ratio of 6 (2 μ g DNA/well). Column 1: PEI 25K/DNA; 2: PEI 25K/DNA modified with VS-PEG-NHS; 3, 4, and 5: as in 2 and subsequently modified with 14, 72, and 144 pmol of thiol-functionalized mEGF, respectively; 6: mEGF-PEI 25K/PEI 25K (1:1)/DNA; 7: mEGF-PEI 25K/PEI 25K (1:1)/DNA modified with VS-PEG-NHS; 8: as in 1 in the presence of 144 pmol mEGF in culture medium during the transfection. Luciferase activity values are the mean $\pm$ SD of two independent experiments made in duplicate. (B) KB cells incubated in fresh culture medium were transfected with the following complexes prepared in HBS 1/2 at a N/P ratio of 6 (2 μ g DNA/well). Column 1: PEI 25K/DNA; 2: PEI 25K/DNA modified with MAL-PEG-NHS; 3 and 4: as in 2 and subsequently modified with 72 pmol and 144 pmol of thiol-functionalized mEGF, respectively; 5: EGF-PEI 25K/PEI 25K (1:1)/DNA; 6: EGF-PEI 25K/PEI 25K (1:1)/DNA modified with MAL-PEG-NHS. Luciferase activity is shown as mean $\pm$ SD of duplicate.

Transfection efficiency of PEGylated EGF-containing PEI 25K/PEI 22K complexes was studied in KB cells (Figure 6). As observed previously with PEI 22K-free complexes (Figure 4B), subsequent addition of PEG and thiol-functionalized EGF to PEI/DNA complexes strongly increased transfection efficiency to a level comparable to the one obtained by PEGylation of EGF-containing DNA complexes.

Figure 5. Effect of different PEI polymers (linear PEI 22K versus branched PEI 25K) on transfection efficiency. Complexes were generated from a mixture of mEGF-PEI 25K and different PEIs and tested on KB and Renca-EGFR cells. (A) KB cells were transfected with various amounts of pCMVLuc plasmid (2 to 0.06 μ g per well) complexed with PEI 25K, mEGF-PEI 25K/PEI 25K (1:1), PEI 25K/PEI 22K (1:1) or mEGF-PEI 25K/PEI 22K (1:1) at N/P=6 in HBS 1/2. Luciferase activity is shown as mean $\pm$ s.d. of duplicate (* is $<10^3$ RLU/mg of protein). (B) Renca-EGFR cells were transfected with pCMVLuc plasmid (2 μ g/well) complexed with PEI 25K, mEGF-PEI 25K/PEI 25K (1:1), PEI 22K or mEGF-PEI 25K/PEI 22K (1:1) at N/P = 6 in either Hepes buffer (in the presence of 200 μ M chloroquine in cell culture medium during the transfection), HBS 1/2 or HBS. Luciferase activity is shown as mean $\pm$ SD of duplicate.

DISCUSSION

Our aim is to develop synthetic gene delivery systems that can be administered by intravenous application. One important aspect for the construction of such systems is the use of a convenient ligand able to mediate cell specific recognition and internalization into target cells. EGF receptor is overexpressed in many human tumors of epithelial origin and may therefore serve as a useful cell surface target (22). Gene delivery into EGF receptor-expressing cells was previously demonstrated using polylysine conjugates where receptor ligand (EGF or anti-EGF receptor antibody) and polylysine were covalently coupled (32, 33) or bound through a biotin/streptavidin linkage (34–36). Also other synthetic systems were

Figure 6. Transfection efficiency of PEGylated EGF-containing PEI 25K/PEI 22K complexes on KB cells. Complexes were prepared as described in Figure 4B with PEI 25K/PEI 22K (1:1) instead of PEI 25K (Columns 1–4) and EGF–PEI 25K/PEI 22K instead of EGF–PEI 25K/PEI 25K (Columns 5 and 6). Column 1: PEI 25K/PEI 22K/DNA; 2: PEI 25K/PEI 22K/DNA modified with MAL-PEG-NHS; 3 and 4: as in 2 and subsequently modified with 72 pmol and 144 pmol of thiol-functionalized mEGF respectively; 5: EGF–PEI 25K/PEI 22K/DNA; 6: EGF–PEI 25K/PEI 22K/DNA modified with MAL-PEG-NHS. Luciferase activity is shown as mean $\pm$ SD of duplicate.

described including chimeric TGF- α fusion protein (37) and EGF-containing liposomes (38, 39). In these cases gene delivery in EGF receptor-expressing cells was effective only in the presence of an endosomolytic agent such as chloroquine or inactivated adenovirus. Chloroquine would be difficult to apply *in vivo* at the required dose due to its toxicity. The use of inactivated adenovirus could lead to undesired immune problems inherent of the virus.

Recently some new polycations such as PEI (1) and polyamidoamine dendrimers (40, 41) have been described as particularly efficient gene delivery vectors without the need for additional endosomolytic agents. These cationic polymers share with chloroquine a strong buffering capacity that promotes escape of the complexes out of the endosomal compartment (1, 42). We combined the powerful gene delivery activity of PEI with the specificity of EGF-receptor binding by generating an EGF–PEI conjugate able to deliver DNA into tumor cells with considerably higher efficiency compared to the native PEI complexes. When EGF was incorporated in polyplexes, 10-fold lower amounts of DNA complexes were required for similar efficiency. High transfection ability with low dose of DNA is essential for *in vivo* application. This ligand-mediated enhancement and competition experiments performed with free EGF strongly suggest that EGF-containing DNA complexes are taken up specifically by the EGF-receptor mediated endocytosis pathway. This is also supported by recent data from our group by FACS analysis (Ogris et al., submitted to *AAPS Pharm Sci.*) where enhanced uptake of EGF-containing complexes was demonstrated.

For *in vivo* administration, small DNA particles are required for escape out of normal blood vessels to reach surrounding tissues such as hepatocytes (43) and much effort is applied in this direction (44–46). Preparation of EGF-polyplexes in salt-free buffer generates small particles that, however, are relatively inefficient. These complexes are not limited by the EGF receptor uptake

process, but by ineffective endosomal release, as suggested by the large increase of transfection efficiency in the presence of chloroquine. This finding is in good agreement with previous observations using transferrin-PEI particles (31). For tumor-targeted gene delivery the DNA particle size is less problematic because of the leakiness of the tumor vasculature. Indeed accumulation of large DNA complexes (approximately 500 nm) was observed recently in our group (20, 21). Therefore, we evaluated also EGF–PEI complexes of medium-large size. Interestingly linear PEI 22K but also in mixture with PEI 25K (1:1) was more efficient to deliver DNA than the branched PEI 25K alone, particularly at low DNA doses. Indeed, gene expression obtained with 60 ng of DNA complexed with EGF–PEI 25K/PEI 22K was higher (10^8 RLU/mg protein) even compared to much higher amounts (2 μ g) of EGF–PEI 25K/PEI 25K complexes (Figure 5).

Gene delivery systems for intravenous application must be inert against nonspecific interactions with biological environment such as nontarget cells and blood components in order to maintain their physical integrity and to avoid rapid elimination via activation of the immune system. Covalent surface modification of pre-formed polyplexes with PEG has been shown to strongly reduce nonspecific interactions with erythrocytes and plasma proteins (20) and it also reduces complement system activation (47). Incorporation of PEG in polyplexes was also achieved using block copolymer as condensing agent such polylysine–polysaccharide (48), polylysine–PEG (49–54), and PEI–PEG (55, 56). Major drawback of this latter strategy is the crowding effect of the neutral polymer that can hinder proper DNA condensation in dense particles (49, 55).

We evaluated two post-PEGylation strategies to generate shielded EGF-containing complexes, where EGF was either coupled to PEI (Figure 3A) or to the distal end of a PEG spacer arm (Figure 3B). In the latter strategy the ligand is incorporated at the final step of complex preparation. Optimal amounts of ligand giving best transfection efficiencies can be rapidly found. The later strategy should also allow a better accessibility of the ligand as suggested by studies on liposomes. Indeed, it was shown that incorporation of PEG in immunoliposomes can substantially weaken antigen/antibody interaction (57, 58). In contrast, coupling the ligand to the distal end of the PEG produced stabilized liposomes still allowing efficient binding to the target receptor (59, 60). We showed that both types of shielded EGF-containing complexes were effective to deliver DNA. Efficiencies were approximately 10- to 100-fold higher compared to EGF-free PEGylated complexes. In contrast to the published liposome work, the beneficial effect of grafting the ligand at the distal end of PEG compared to coupling to PEI and PEGylation was less clear with polyplexes. With small complexes this strategy (Figure 3B) resulted in 8-fold higher gene expression than with strategy illustrated in Figure 3A, but with large complexes efficacies were nearly similar. This strongly suggests that the PEG covalently coupled to the surface of EGF-containing PEI/DNA complexes only weakly interferes with the binding to the EGF-receptor. This is quite surprising knowing that a brush of PEG (MW 5000) extending out of the surface of liposomes has been described to have a thickness of 10 nm (61). Nevertheless, this is in line with a recent finding by Ogris et al. (submitted to *AAPS Pharm Sci.*) suggesting that PEGylation does not reduce internalization of EGF-containing complexes.

In summary we have generated EGF-containing polyplexes able to efficiently transfect cells in a receptor-dependent fashion. PEGylated EGF-containing complexes maintained high efficiency and are interesting candidates for in vivo evaluation in tumor models.

ACKNOWLEDGMENT

We thank Winfried Wels who provided us with Renca-EGFR cells. We are grateful to Sylvia Brunner and Lionel Wightman for careful review of the manuscript. This work was supported by grants from the European Community and the Austrian Science Foundation.

Mixed-Ligand Technetium(III) Complexes with Tetradentate/Monodentate NS₃/Isocyanide Coordination: A New Nonpolar Technetium Chelate System for the Design of Neutral and Lipophilic Complexes Stable in Vivo

H.-J. Pietzsch,^{*,†} A. Gupta,[†] R. Syhre,[†] P. Leibnitz,[‡] and H. Spies[†]

Forschungszentrum Rossendorf, Institut für Bioanorganische und Radiopharmazeutische Chemie, PF 510119, D-01314 Dresden, Germany, and Bundesanstalt für Materialforschung und -prüfung, Rudower Chaussee 5, Haus 8.15, D-12489 Berlin, Germany. Received November 15, 2000

Starting from the tripodal ligand 2,2',2''-nitrilotris(ethanethiol) (NS₃) and isocyanides (CNR) as co-ligands, neutral mixed-ligand technetium(III) complexes of the general formulation [Tc(NS₃)(CNR)] have been synthesized and characterized. The ⁹⁹Tc complexes can be obtained by a two-step reduction/substitution procedure starting from [TcO₄]⁻ via the phosphine-containing precursor complex [Tc(NS₃)(PMe₂Ph)]. As shown by X-ray structural analyses, the complexes adopt a nearly ideal trigonal-bipyramidal geometry with the trigonal plane formed by the three thiolate sulfurs of the tripodal ligand. The central nitrogen atom of the chelate ligand and the monodentate isocyanides occupy the apical positions. The no-carrier-added preparation of the corresponding ^{99m}Tc complexes was performed by a one-step procedure starting from ^{99m}[TcO₄]⁻ with stannous chloride as reducing agent. Biodistribution studies in the rat demonstrated for the nonpolar, lipophilic compounds a significant initial brain uptake. In vitro challenge experiments with glutathione clearly indicated that no transchelation reaction occurs. Furthermore, there were no indications for reoxidation of Tc(III) to Tc(V) species or pertechnetate. We propose this type of complexes as a useful tool in the design of lipophilic ^{99m}Tc or ¹⁸⁶Re/¹⁸⁸Re radiopharmaceuticals.

INTRODUCTION

Complexes of the γ -emitting nuclide technetium-99m find broad application in diagnostic nuclear medicine because of its optimal nuclide properties (1–4). To design new and broadly applicable “bioactive” Tc-99m radiopharmaceuticals able to be involved in metabolic processes or to bind to receptors, the radioactive metal has to be incorporated into biologically active molecules in form of chelates (5, 6). The most frequently used technetium compounds suitable for coupling the metal to biologically active molecules are square-pyramidal complexes of the oxo ion [Tc=O]³⁺ based on tetradentate N₂S₂ ligands (7, 8). In this context, the “3 + 1” mixed-ligand approach is of high interest too (9–11). Properties and thus the in vivo behavior of such complexes are strongly influenced by the presence of the quite polar [Tc=O]³⁺ unit. Whether such a polarity is beneficial or not is not obvious and depends on the requirements for specific radiotracers, e.g., for receptor targeting agents or for metabolic tracers. Another crucial point in tracer design is the stability of the respective Tc chelate toward ligand exchange in vivo. Recently, it was shown that the applicability of the “3 + 1” mixed-ligand Tc(V) chelates is limited because of their reaction with glutathione in vivo (12, 13). Thus, there is a considerable interest in alternative chelate systems that offer lower polarity and enhanced in vivo stability. Such systems are based on

oxo-free cores with the metal at lower oxidation states. Thus, Tc(I) carbonyl complexes resulting from the reaction of the organometallic Tc(I) aqua ion [Tc(OH)₂(CO)₃]⁺ as a precursor with either N-containing ligands, phosphines, or thioether ligands (14–19) are hopeful candidates for stable binding of Tc to peptides and other polar biomolecules.

Here we offer a new type of Tc(III) chelate formed by the tripodal 2,2',2''-nitrilotris(ethanethiol) and a monodentate isocyanide that should fulfill the requirements for a lipophilic, nonpolar building block stable against ligand exchange reaction in vivo. Part of the family of “n + 1” mixed-ligand technetium and rhenium species (20–22), such a “4 + 1” chelate offers the advantage of high versatility in conjugating biomolecules as described for the “3 + 1” series (23).

In the present paper, we report on the synthesis and structural analysis of ⁹⁹Tc complexes with simple isocyanides serving as models for functionalized derivatives. The no-carrier-added preparation of the analogous ^{99m}Tc complexes, studies on stability in aqueous solution and in plasma, as well as biodistribution studies in rats are dealt with.

EXPERIMENTAL PROCEDURES

General Methods. Dimethylphenylphosphine (PMe₂-Ph) was purchased from Aldrich. Isocyanides were obtained from Aldrich (benzyl isocyanide), Merck (cyclohexyl isocyanide), and Fluka (isocyanoacetic acid ethyl ester). All solvents and commercially available substances were of reagent grade and used without further purification. The tripodal ligand 2,2',2''-nitrilotris(ethane-

thiol) (NS_3) was prepared according to standard procedures starting from tris(2-chloroethyl)amine hydrochloride (22). ^{99}Tc as NH_4TcO_4 was obtained from Amersham as a 0.3 M aqueous solution. $^{99m}\text{TcO}_4^-$ was eluted from a commercial $^{99}\text{Mo}/^{99m}\text{Tc}$ generator (Mallinckrodt).

Instrumentation. Elemental analyses were performed on a LECO elemental analyzer CHNS-932. Melting points were obtained on a BOETIUS-Mikroheiztisch and are uncorrected. IR spectra were measured as KBr pellets on a Perkin-Elmer FTIR-spectrometer SPEC-TRUM 2000. UV/vis spectra were measured on a SPECORD S10 spectrometer from Carl Zeiss Jena.

^1H NMR spectra (400 MHz) were recorded on a Varian spectrometer INOVA-400. Samples were dissolved in deuterated chloroform at a concentration of ca. 2%. Chemical shifts are given as δ in ppm.

TLC and HPLC analyses were used to determine the radiochemical purity and stability of the preparations. TLC analyses were performed using silica gel strips (Kieselgel 60) developed with chloroform/acetone (6:1 v/v) as solvents. For HPLC studies, a Perkin-Elmer device consisting of a Turbo LC system with a quaternary pump (Series 200 LC Pump), a programmable absorbance detector model 785A, and a homemade γ -detector (Bohrloch NaI(Tl) crystal) was used. HPLC analyses were carried out with a Hypersil ODS column (250 $\times$ 4 mm) using a premixed eluent of 80% methanol and 20% 0.01 M phosphate buffer of pH 7.4 and a flow rate of 1.0 mL/min. The eluate from the column was monitored by UV absorbance at 254 nm for ^{99}Tc reference complexes or γ detection for the ^{99m}Tc complexes.

X-ray Data Collection and Processing. The X-ray data were collected at room temperature (293 K) on a SMART-CCD diffractometer (SIEMENS), using graphite-monochromatized Mo K_{α} radiation ($\lambda = 0.71073$ Å). A summary of the crystallographic data is given in Table 1. The positions of the non-hydrogen atoms were determined by the heavy atom technique. After anisotropic refinement of the positions of these, the hydrogen positions were calculated according to ideal geometries.

Empirical absorption corrections were made using ψ scans. Most of the calculations were carried out in the SHELXTL system with some local modifications.

Relevant bond lengths and angles are contained in Table 2. Atomic positional and thermal parameters, full lists of bond lengths and angles, and F_o/F_c values have been deposited at the Cambridge Crystallographic Data Centre (24).

Synthesis of [$^{99}\text{Tc}(\text{NS}_3)(\text{PMe}_2\text{Ph})$] – ($^{99}\text{Tc1}$). A 35 mg (0.25 mmol) sample of dimethylphenylphosphine and 20 mg (0.101 mmol) of 2,2',2''-nitritoltris(ethanethiol) were dissolved in 3 mL of ethanol. This solution was added to a solution of 20 mg (0.1 mmol) KTcO_4 in 2 mL of water/ethanol (2:1 v/v). The reaction mixture was acidified with three drops of acetic acid and was stirred at ambient temperature for 5 h. During this time, the color changed to deep-violet. The solvents were stripped in vacuo, and the complex was purified by column chromatography (column 10 $\times$ 250 mm, stationary phase silica gel 0.04–0.063 mm, eluent CHCl_3 /methanol 9:1 v/v). Recrystallization from chloroform/methanol (1:3 v/v) gave violet crystals of $^{99}\text{Tc1}$ suitable for X-ray structure analysis.

Yield: 31 mg (73% relative to KTcO_4). Mp = 221 °C. Anal. ($\text{C}_{14}\text{H}_{23}\text{NPS}_3\text{Tc}$) Calcd: C, 39.0; H, 5.3; N, 3.2; S, 22.3. Found: C, 39.1; H, 5.8; N, 3.3; S, 22.6. IR (KBr) (cm^{-1}): 943 and 901 ($\text{PhP}(\text{CH}_3)_2$). UV/vis (CHCl_3): λ_{max} ($\log \epsilon$) = 273 nm (4.2), 342 (3.8), 544 (2.9). ^1H NMR (400 MHz, CDCl_3): 1.91 (d, $\text{P}(\text{CH}_3)_2\text{Ph}$, 6H), 2.9 and 3.1 (m, $-\text{CH}_2\text{S}$, $-\text{CH}_2\text{N}$, 12H), 7.42 and 7.92 (m, $\text{P}(\text{CH}_3)_2\text{C}_6\text{H}_5$, 5H).

General Synthesis Procedure for the Complexes [$^{99}\text{Tc}(\text{NS}_3)(\text{CNR})$] – ($^{99}\text{Tc2}$ – $^{99}\text{Tc4}$). A 40 mg (0.093 mmol) sample of $^{99}\text{Tc1}$ was dissolved in 5 mL of chloroform. At ambient temperature, 0.232 mmol of the appropriate isocyanide, dissolved in 1 mL of chloroform, was added in one portion. The reaction mixture was refluxed for 1 h. TLC showed the presence of the appropriate products $^{99}\text{Tc2}$ – $^{99}\text{Tc4}$ and of unreacted $^{99}\text{Tc1}$. The isocyanide complexes were isolated by column chromatography (chromatography (column 10 $\times$ 250 mm, sta-

General Synthesis Procedure for the No-Carrier-Assisted Preparation of the Compounds $^{99}\text{Tc}(\text{NS}_3)(\text{CN-R})] - (^{99}\text{Tc2}-^{99}\text{Tc4})$. A solution of 20 μL of SnCl_2 (1.0–1.5 mg of $\text{SnCl}_2/5.0 \text{ mL}$ of 0.1 N HCl) was added to a mixture of 0.5 mL of pertechnetate solution (10–500 MBq generator eluate), 0.3 mL of propylene glycol, 0.2 mL of acetonitrile, 0.3–0.4 mg of 2,2',2''-nitrilotris-(ethanethiol), dissolved in ethanol, 0.05 mg of the appropriate isocyanide, dissolved in ethanol, and 0.02 mL of 0.1 M NaOH. The vial was closed, and the reaction solution was heated at 50–60 °C for 15 min. The labeling yields for all complexes were between 75% and 80% as established by HPLC analysis. The identity of the species obtained was confirmed by comparison with the HPLC profiles of ^{99}Tc analogues. After HPLC separation the radiochemical purity of the $^{99}\text{Tc}(\text{III})$ “4 + 1” complexes was about 95%.

Determination of Partition Coefficients. Partition coefficients of the ^{99}Tc complexes were determined by shake-flask method by mixing 0.5 mL of the complex solution (0.9% NaCl solution and 20% propylene glycol) and 0.5 mL of octanol and shaking for 5 min. After centrifugation aliquots of both phases were counted and the partition coefficient calculated.

Ligand Exchange (Challenge) Experiments with Glutathione (GSH). ^{99}mTc complexes, dissolved in a mixture of propylene glycol/MeOH (2:1 v/v), were diluted with an equivalent volume of an aqueous solution of 20 mM GSH containing 25% of propylene glycol immediately after HPLC separation, resulting in a final glutathione concentration of 10 mM. The analyses were performed by HPLC as described above.

Stability Studies in Plasma. A 50 μL sample of the appropriate ^{99}mTc complex solution (0.9% NaCl, 12% propylene glycol) was incubated in 200 μL of rat plasma at 37 °C. After an incubation time of 30 min, the samples were analyzed by HPLC with a Supelguard column (20 $\times$ 4.6 mm, 10 μm , flow rate 1.0 mL/min) using a linear gradient 95% A to 40% A in 15 min [(A) 2-propanol/0.1% trifluoroacetic acid (TFA) (10/90), (B) 2-propanol/0.1% TFA (90/10)].

Alternatively, the HPLC analyses were carried out with a PRP-3 column (Hamilton, 150 $\times$ 4 mm, 10 μm , flow rate 1.0 mL/min) using a linear gradient system [t (min)/% B]: (5/0), (10/70), (5/70) of 10 mM phosphate buffer (PBS) of pH 7.4 (A) and acetonitrile (B).

Biodistribution Studies. The animal studies in male Wistar rats (5–6 weeks old) were carried out according to the relevant national regulations. A 500 μL sample of ^{99}mTc complex solution (saline, propylene glycol 25%) was injected into the tail vein of rats. After the injection, the rats were sacrificed by heart puncture under ether anaesthesia 5 and 120 min p.i. Selected organs were isolated for weighing and counting. The accumulated radioactivity in the tissue of organs was calculated in terms of percentage of injected dose per organ as well as percent injected dose per gram blood.

RESULTS AND DISCUSSION

Technetium-99 Chemistry. The ^{99}Tc complexes $^{99}\text{Tc2}-^{99}\text{Tc4}$ were synthesized by a two-step procedure starting from pertechnetate(VII) via the phosphine-containing precursor $^{99}\text{Tc1}$ according to Scheme 1. To a mixture of pertechnetate(VII) and 2,2',2''-nitrilotris-(ethanethiol) (NS_3) was added an excess of dimethylphenylphosphine. The phosphine acts as a reducing agent as well as a coligand to yield $^{99}\text{Tc1}$. The complex can be isolated as an air-stable deep-violet powder. This Tc(III) phosphine derivative undergoes in chloroform solutions facile substitution to the corresponding neutral “4 + 1”-coordinated Tc(III) complexes $^{99}\text{Tc2}-^{99}\text{Tc4}$ of the general formulation $[\text{Tc}(\text{NS}_3)(\text{CN-R})]$ (Scheme 1).

Elemental analyses, as reported in the Experimental Section, are in agreement with the proposed formulation. IR spectra of Tc(III) complexes $^{99}\text{Tc2}-^{99}\text{Tc4}$ exhibit

Scheme 1

strong absorptions characteristic of the Tc–CN– stretching vibrations. No additional bands indicating the presence of the Tc=O core in the region 900–1000 cm⁻¹ are observed. The UV/vis spectra of ⁹⁹Tc2, ⁹⁹Tc3, and ⁹⁹Tc4 (recorded in chloroform) are characterized by intense bands at about 280 and 350 nm and less intense absorptions in the visible region (505–527 nm).

The Tc(III) complexes show sharp proton signals characteristic of diamagnetic compounds, in agreement with low-spin d⁴ t₂g configurations. NMR profiles confirm the solution structures of complexes ⁹⁹Tc1–⁹⁹Tc4 to be identical to solid-state structure found by X-ray analysis.

Five-coordinate Tc(III) complexes ⁹⁹Tc1–⁹⁹Tc4, as prototypic representatives of this novel class of neutral Tc(III) compounds, were studied by X-ray structure analysis. A summary of the crystallographic data is given in Table 1, and selected bond lengths and angles are cumulated in Table 2.

As illustrated in Figures 1–4, the complexes adopt a nearly ideal trigonal-bipyramidal geometry with the trigonal plane formed by the three thiolate sulfurs of the tripodal ligand. The central nitrogen atom of the chelate ligand and the phosphine phosphorus in ⁹⁹Tc1 or the monodendate isocyanide ligand in ⁹⁹Tc2–⁹⁹Tc4 occupy the apical positions.

The Tc–S_{thiolato} distances are restricted in a narrow range (2.21–2.24 Å) and compare well with those previously reported for trigonal bipyramidal [Tc(SR)₃(L)₂]-type complexes (SR = sterically hindered arenethiolates, L = small π-accepting molecules) (25, 26). The Tc–C distances are found in a narrow range between 1.93 and 1.94 Å.

The N2–Tc–C1 axis shows only slight deviation from linearity. Also the other angles of the inner coordination sphere are consistent with the t₂g arrangement.

Figure 1. Molecular structure of complex ⁹⁹Tc1.

Figure 2. Molecular structure of complex ⁹⁹Tc2.

Figure 3. Molecular structure of complex ⁹⁹Tc3.

Figure 4. Molecular structure of complex ⁹⁹Tc4.

The compounds constitute the second example of an Tc(III) complex with an “umbrella” ligand, a concept introduced by Davison and co-workers (27, 28). The “umbrella” in Davison’s complexes of the general formula [Tc(PS₃)(CN-R)] consists of a central phosphorus atom and three aromatic thiolate functions (PS₃), while in ^{99m}Tc2–^{99m}Tc4 three aliphatic thiolates and a central nitrogen form the “umbrella” ligand (NS₃).

Technetium-99m Chemistry and Biodistribution Studies. *No-Carrier-Added Preparation of the ^{99m}Tc Complexes.* The no-carrier-added preparation of the complexes ^{99m}Tc2–^{99m}Tc4 was performed by a one-step procedure starting from ^{99m}[TcO₄]⁻ with stannous chloride as reducing agent (Scheme 1). The yields were between 75% and 80% using unoptimized preparation conditions. In the appropriate reaction mixtures, a byproduct occurs that is not eluted from the Hypersil column. Therefore, TLC has to be used for determining the yields of the preparation. After HPLC separation, the

Table 3. HPLC and TLC Data^a of Complex Couples $^{99m}\text{Tc2}/^{99m}\text{Tc2}$, $^{99m}\text{Tc3}/^{99m}\text{Tc3}$, and $^{99m}\text{Tc4}/^{99m}\text{Tc4}$ (Partition Coefficients ($\log P$) of $^{99m}\text{Tc2}$ – $^{99m}\text{Tc4}$ in Comparison to the Data of Corresponding “3 + 1” Mixed-Ligand Oxotechnetium(V) Complexes [$\text{TcO}(\text{SCH}_2\text{CH}_2\text{N}(\text{CH}_3)\text{CH}_2\text{CH}_2\text{S})(\text{SR})$] Bearing the Same Substituent R (A–C))

^a Hypersil ODS: MeOH/0.01 M PBS pH 7.4, linear gradient 70–100% A in 5 min, TLC data: TLC aluminum sheets RP-18 (Merck); eluent, methanol/water (80/20).

radiochemical purity of the $^{99m}\text{Tc(III)}$ “4 + 1” complexes was determined by TLC and found to be about 95%.

To establish the structure of the ^{99m}Tc complexes, comparison by HPLC with the well characterized ^{99m}Tc analogues was pursued applying parallel radiometric and photometric detection. Thus, after co-injection of complexes $^{99m}\text{Tc2}$ and $^{99m}\text{Tc2}$, practically identical retention times were observed, while the recovery through the column was quantitative. Similarly, co-injections of the complex couples $^{99m}\text{Tc3}/^{99m}\text{Tc3}$ and $^{99m}\text{Tc4}/^{99m}\text{Tc4}$ led to identical t_R values for the respective compounds, revealing their structural analogy. t_R values of HPLC, R_f values of TLC, and partition coefficients (P) of the ^{99m}Tc complexes in the system octanol/saline are given in Table 3.

Examination of the octanol/water partition coefficients suggests high lipophilicity for the resulting Tc species. A comparison with the values of so-called “3 + 1” mixed-ligand oxotechnetium(V) complexes A–C of the general formula [$\text{TcO}(\text{SCH}_2\text{CH}_2\text{N}(\text{Me})\text{CH}_2\text{CH}_2\text{S})(\text{SR})$] (23) bearing the same substituent R (complex (A) benzyl, (B) cyclohexyl, (C) carbethoxymethylene) indicates considerably higher lipophilicity of the studied “4 + 1” complexes. These observations are consistent with the expectation that absence of an oxo group and better shielding of the metal will enhance the lipophilicity (Table 3).

Glutathione Challenge Experiments. Glutathione (GSH), the most abundant thiol compound in tissues, is present in almost all animal cells in relatively high concentrations (0.5–12 mM) (29, 30). Therefore, it has to be considered as a potential agent for transchelating reactions in vivo. In fact, Neirinckx et al. (31) pointed out that the intracellular reaction of the brain perfusion agent $^{99m}\text{Tc(V)}$ -HMPAO with GSH is responsible for the trapping of the radiopharmaceutical in the brain. GSH is also responsible for the in vivo reactivity of “3 + 1” mixed-ligand $^{99m}\text{Tc(V)}$ complexes that consist of a monodentate thiol ligand and a tridentate dithiol (9–11). Here, a ligand exchange in terms of the replacement of the monodentate ligand by GSH occurs in vivo and in vitro as recently shown (12, 13, 32). In view of these experiences, it would be useful to explore also the behavior of $^{99m}\text{Tc(III)}$ “4 + 1” complexes against GSH ligand-exchange reactions.

Saline-containing preparations of the ^{99m}Tc compounds were diluted with a 10 mM GSH solution immediately after HPLC purification. In all cases, no additional peaks of Tc-GSH mixed ligand species were observed in HPLC studies. These results clearly indicate that glutathione has no negative effect on the stability of ^{99m}Tc complexes in solutions. Obviously, no transchelation reaction by

Figure 5. HPLC pattern of the complex $^{99m}\text{Tc4}$; Supelguard column (20 $\times$ 4.6 mm, 10 μm , flow rate 1.0 mL/min) using a linear gradient 95% A to 40% A in 15 min [(A) 2-propanol/0.1% trifluoroacetic acid (TFA) (10/90); (B) 2-propanol/0.1% TFA (90/10)]; (A) 120 min incubation in rat erythrocyte hemolysate; (B) 120 min incubation in rat plasma.

GSH occurs in vitro. This behavior is considered to be an important advantage of the $^{99m}\text{Tc(III)}$ “4 + 1” complexes over mixed-ligand ^{99m}Tc oxocomplexes in the oxidation state +5.

Stability Studies in Plasma and in Rat Blood. For stability studies, the ^{99m}Tc complexes were incubated in rat blood and rat plasma for 120 min. After incubation, the blood was centrifuged and the supernatant plasma was separated from the erythrocytes. The plasma as well as the erythrocyte hemolysate were analyzed using a Supelguard column as described above. For the complexes $^{99m}\text{Tc2}$ – $^{99m}\text{Tc4}$ no additional peaks were observed, indicating some kind of decomposition, modification, or alteration of the complexes. There is also no tendency of these complexes to bind on plasma components.

To confirm these results, the plasma samples as well as the hemolysates were extracted with ethyl acetate. In this way, about 95% of the activity could be extracted. Analyzing the extracts by HPLC using a Hypersil column and by TLC as described in the Experimental Section only the parent compounds were detected. These results indicate that the $^{99m}\text{Tc(III)}$ “4 + 1” complexes behave absolutely stable in plasma and blood of rat for at least 120 min as illustrated for $^{99m}\text{Tc4}$ in Figure 5.

Biodistribution Studies in Rats. Data of the biodistribution studies of ^{99m}Tc complexes $^{99m}\text{Tc2}$ – $^{99m}\text{Tc4}$ are shown in Table 4. All three complexes show low radioactivity in blood at 5 min p.i., which thereafter decreases within 120 min to a similar extent. The neutral, lipophilic

$^{99m}\text{Tc4}$	5	0.13 $\pm$ 0.02	0.44 $\pm$ 0.07	0.6 $\pm$ 0.1	1.1 $\pm$ 0.4	5.2 $\pm$ 0.7	13.8 $\pm$ 1.6
	120	0.07 $\pm$ 0.01	<0.05	0.1 $\pm$ 0.01	0.5 $\pm$ 0.1	3.2 $\pm$ 1.7	13.6 $\pm$ 2.0

complexes can cross the blood–brain barrier. They show a significant initial brain uptake from 0.13 up to 1.1%, obtained for the most lipophilic cyclohexyl-substituted complex $^{99m}\text{Tc3}$ (logP 1.7). The complexes are quickly cleared from the brain. $^{99m}\text{Tc2}$, $^{99m}\text{Tc3}$, and $^{99m}\text{Tc4}$ are distributed predominantly to the liver with slightly increased retention after 120 min p.i. Except for the excretory organs, no prominent uptake and retention was observed. The compounds are stable in whole-blood of rats and reveal no affinity to protein components of rat plasma (Figure 5).

CONCLUSION

The tripodal, tetradentate ligand 2,2',2''-nitritoltris(ethanethiol) and isocyanides as co-ligands form nonpolar, lipophilic technetium complexes that contain sterically well shielded oxo-free Tc(III) ions. The monodentate isocyanide ligand enables easy functionalization in order to fine-tune physicochemical properties of the complexes or to link the chelate unit to biomolecules. ^{99m}Tc complexes can easily be prepared at no-carrier-added level in high radiochemical yield. There is no tendency of these complexes to bind on rat plasma components. In vitro challenge experiments with glutathione clearly indicate that no transchelation reaction occurs. This behavior is considered to be an important advantage over mixed-ligand ^{99m}Tc oxocomplexes in the oxidation state +5. Furthermore, there are no indications for reoxidation of Tc(III) to Tc(V) species or pertechnetate. Therefore, we propose the complexes as a useful tool in designing of lipophilic ^{99m}Tc or $^{186}\text{Re}/^{188}\text{Re}$ radiopharmaceuticals.

Several biological barriers, including significant liver uptake, limit the clinical application of radiolabeled antibodies in radioimmunoscintigraphy. Here, a general approach is described for radiolabeling of monoclonal antibodies conjugated with poly(ethylene glycol) (PEG). This strategy is demonstrated with C225, a monoclonal antibody directed against epidermal growth factor (EGF) receptor. We synthesized a heterofunctional PEG with one end attached to a radiometal chelator, diethylenetriaminepentaacetic acid (DTPA), and the other end to a protected thiol group, S-acetylthioacetate. After a deprotection step, the resulting DTPA-PEG-SH was conjugated to maleimide-activated C225 to yield DTPA-PEG-C225 conjugate. Characterization of DTPA-PEG-C225 with immunoprecipitation and Western blot analysis revealed that the conjugate was biologically active in binding to the EGF receptor in A431 cells. Competitive EGF receptor binding assay in MDA-MB-468 cells showed that DTPA-PEG-C225, with up to 60% of the amino groups in C225 substituted, retained 66% of C225's binding affinity. Moreover, DTPA-PEG-C225 with increasing degrees of NH₂ substitution from 20% to 70% retained the activity of C225 to induce apoptosis in DiFi cells. More importantly, DTPA-PEG-C225 demonstrated less nonspecific interaction than DTPA-C225. Pharmacokinetic analysis using ¹¹¹In-labeled compounds revealed narrower steady-state distribution of ¹¹¹In-DTPA-PEG-C225 than ¹¹¹In-DTPA-C225, probably due to reduced nonspecific binding of PEG-modified antibody to tissues. The terminal half-life (*t*_{1/2,γ}) of ¹¹¹In-DTPA-PEG-C225, 21.1 h, was shorter than that of ¹¹¹In-DTPA-C225, 52.9 h. These data suggest that ¹¹¹In-DTPA-PEG-C225 may provide better imaging characteristics than ¹¹¹In-DTPA-C225, and that using PEG as a linker between the monoclonal antibody and DTPA may be a promising strategy in optimizing the imaging characteristics of immunoscintigraphic agents.

INTRODUCTION

Radioimmunodetection for diagnostic purposes has many potential applications in the management of cancer patients. These applications include presurgical staging of extent of disease, postsurgical evaluation of residual disease, confirmation of viable tumors known by other methods, disclosure of occult recurrence, confirmation of tumor targeting of antibody to be used for immunotherapy, and assessment of therapeutic response (1, 2). Although the potential usefulness of radiolabeled monoclonal antibody (mAb)¹ is high, the actual progress concerning their clinical applications has not been satisfactory. Despite nearly 50 years of investigation and refinement, to date only one radiolabeled mAb has been approved by the FDA for use in humans (3). Limitations

of radioimmunodetection have been multifactorial, and include low uptake by tumor confined by biological barriers, unfavorable pharmacokinetics, and poor tumor-to-background ratio, etc. (1).

Among a wide range of isotopes applied to the labeling of antibodies, the majority are transition metals. It is evident that in order to obtain optimal imaging characteristics, it is necessary to achieve a high ratio of radioactivity between the tumor and normal tissues. Unfortunately, although immunoconjugates labeled with radiometals such as yttrium and indium usually have greater retention in cancer than the corresponding iodinated radioimmunoconjugates, they also tend to be retained in normal tissues, particularly the liver (4, 5). To decrease the rate of radiometal detachment from the mAb and reduce the subsequent hepatic uptake of the

¹ Abbreviations: mAb, monoclonal antibody; DTPA, diethylenetriaminepentaacetic acid; PEG, poly(ethylene glycol); EGF, epidermal growth factor; SATA, S-acetylthioacetate; GMBS, N-γ-maleimidobutyryloxysuccinimide ester; TNBS, 2,4,6-trinitrobenzenesulfonic acid; SDS, sodium dodecyl sulfate; MTT, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide; TFA, trifluoroacetic acid; TEA, triethylamine; MWCO, molecular weight cutoff; DMF, dimethylformamide; GPC, gel permeation chromatography; DMEM, Dulbecco's modified Eagle's medium; FBS, fetal bovine albumin; BSA, bovine serum albumin.

radiolabel, modified DTPA molecule (6) and also macrocyclic chelates, such as 1,4,7,10-tetraazacyclododecane-*N,N',N'',N'''*-tetraacetic acid (DOTA) (7), have been used to increase the stability of radiometal–chelate complexes. Chelates with labile linkers can also exhibit such favorable characteristics as high tumor accumulation, rapid blood clearance, and low liver uptake in animal experiments (8, 9). For example, a peptide linker, triglycyl-L-phenylthiourea, susceptible to hepatic endopeptidase activity was designed and inserted between DOTA and chimeric mAb L6 (9). The resulting immunoconjugate exhibited reduced liver uptake due to increased hepatocyte cleavage and excretion of the radiochelate (10).

A different conjugation strategy is to manipulate the biodistribution patterns of the antibodies by employing the uncharged, amphiphilic linear polymer poly(ethylene glycol) (PEG) as a linker between the monoclonal antibody and the metal chelators. PEG-modified proteins, antibodies, and liposomes have been shown to exhibit reduced liver uptake and increased blood circulation half-lives, resulting in improved biological activity (11–13). In this report, we present the synthesis of a DTPA-PEG conjugate of an anti-epidermal growth factor (EGF) receptor antibody, C225, its radiolabeling with indium-111, and the biological activities of the resulting immunoconjugate. EGF receptor is a transmembrane glycoprotein with an intracellular tyrosine kinase domain. EGF receptor is overexpressed on the cells of over one-third of all solid tumors, including bladder, breast, colon, ovarian, prostate, renal cell, and squamous cell (nonsmall cell lung and head and neck) carcinomas (14). C225 is a human–mouse chimeric monoclonal antibody directed against human EGF receptor. It specifically binds to the external domain of the receptor with an affinity comparable to the natural ligand. C225 has been demonstrated to inhibit the proliferation of a variety of human cancer cells stimulated by the transforming growth factor- α (TGF- α) and EGF receptor autocrine loop (15).

EXPERIMENTAL PROCEDURES

Materials. C225 was kindly provided by ImClone Systems Inc. (New York, NY). *t*-Boc-NH-PEG-NH₂ (MW 3400) was obtained from Shearwater Polymers, Inc. (Huntsville, AL). *N*-Succinimidyl *S*-acetylthioacetate (SATA), *N*- γ -maleimidobutyryloxysuccinimide ester (GMBS), 2,4,6-trinitrobenzenesulfonic acid (TNBS, 5% w/v aqueous solution), 5,5'-dithiobis(2-nitrobenzoic acid) (Ellman's Reagent), sodium dodecyl sulfate (SDS), 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), and PBS (0.01 M phosphate-buffered saline containing 138 mM NaCl, 2.7 mM KCl, pH 7.4) were purchased from Sigma Chemicals (St. Louis, MO). DTPA-dianhydride, trifluoroacetic acid (TFA, anhydrous), ninhydrin, triethylamine (TEA), and all the other solvents and reagents were purchased from Aldrich Chemical Co. (St. Louis, MO). All the chemicals and solvents were at least ACS grade and were used without further purification. Indium-111 radionuclide was obtained from Dupont-NEN (Boston, MA). PD-10 disposable column, Sephadex G-75 gel, and Sephacryl S-200 high-resolution gel were purchased from Amersham Pharmacia Biotech (Piscataway, NJ). Spectra/Pro 6 dialysis tubing [molecular weight cutoff (MWCO) 2000] and Centricon-YM-10 centrifugal filter devices (MWCO 10 000) were purchased from Fisher Scientific (Houston, TX). Silica gel 60 TLC plates were obtained from EM Sciences (Gibbstown, NJ).

DTPA-PEG-NH₂. To a stirred suspension of DTPA-dianhydride (143 mg, 0.4 mmol) in 4 mL of chloroform

were added TEA (81 mg, 0.8 mmol) and *t*-Boc-NH-PEG-NH₂ (340 mg, 0.1 mmol). The mixture was allowed to react at room temperature for 2 h. The reaction was followed by silica gel TLC using CHCl₃–MeOH (4:1 v/v) as the mobile phase; the plates were visualized by both iodine vapor and ninhydrin spray (0.1% ninhydrin solution in ethanol). TLC showed complete conversion of NH₂-PEG-NH-*t*-Boc (*R_f* = 0.55, purple in ninhydrin) to DTPA-PEG-NH-*t*-Boc (*R_f* = 0.4 with iodine vapor, negative in ninhydrin). After the reaction, the chloroform and TEA were removed under vacuum. The *t*-Boc protecting group was removed without purification by adding TFA (2 mL) to the resulting residue and stirring the mixture at room temperature for 4 h. The resulting DTPA-PEG-NH₂ was purified by dialysis against PBS and deionized water using dialysis tubing (MWCO, 2000). *R_f*: 0.18 (chloroform–methanol, 4:1 v/v; ninhydrin spray); yield: 360 mg, 95%.

DTPA-PEG-ATA. DTPA-PEG-NH₂ (182 mg, 0.05 mmol) was reacted with SATA (14 mg, 0.06 mmol) in chloroform at room temperature for 1 h, and then purified by dialysis (MWCO, 2000) and by gel filtration on a PD-10 column to afford DTPA-PEG-ATA, *R_f* = 0.27 (chloroform–methanol, 4:1 v/v; iodine vapor). ¹H NMR, 300 MHz, CDCl₃: 2.34 (s, 3H, CH₃COS-), 3.17–3.28 (m, 8H, -CH₂CH₂- in DTPA), 3.50 (s, 308H, -CH₂CH₂- in PEG with 77 repeating units). Anal Calcd for C₁₆₉H₃₃₇N₅O₅S: C, 52.54; H, 8.73; N, 1.81; S, 0.83. Found: C, 51.52; H, 8.90; N, 1.61; S, 0.81. Molecular mass determined by MALDI-TOF mass spectroscopy (BiFlexIII, Bruker Daltonics, Billerica, MA): 3750. No peaks of dimer or oligomers were found in the spectrum (data not shown). Yield: 180 mg, 92%.

DTPA-PEG-C225. Maleimide-activated C225 with different ratios of C225 to maleimide was prepared according to the following general procedure. To an aqueous solution of C225 (2.4 mg/mL; 4.8 mg, 0.032 μ mol) at room temperature were added aliquots of GMBS in dimethylformamide (DMF) (2.8 mg/mL). The mixture was stirred for 1 h, and then purified by gel filtration using a PD-10 column. Prior to conjugation with activated C225, the acetyl protecting group in DTPA-PEG-ATA was removed using hydroxylamine. For this purpose, an aliquot of NH₂OH (50 μ L) in 0.1 M Na₂HPO₄ (0.5 M) was added to a solution of DTPA-PEG-ATA (7.7 mg, 1.92 μ mol) in 0.1 M Na₂HPO₄ (pH 8.5, 0.5 mL), and then incubated at room temperature for 30 min. The resulting DTPA-PEG-SH containing free sulfhydryl group was then mixed with maleimide-activated C225 with a DTPA-PEG-SH-to-maleimide molar ratio of 2:1 and incubated at 4 °C overnight. The final product was separated from unreacted DTPA-PEG by gel filtration on a Sephacryl S-200 HR column (1.5 cm $\times$ 20 cm) with PBS as eluent. The presence of free sulfhydryl group was monitored using Ellman's agent (16).

DTPA-C225. DTPA-C225 was prepared using a previously described method (17). Briefly, DTPA-dianhydride (4.6 mg, 12.8 μ mol) was added to an aqueous solution of C225 (2.4 mg, 0.016 μ mol; 2.4 mg/mL). For reaction efficiency, the pH of the reaction solution was kept at 7–8 by adding 0.1 M Na₂HPO₄. After incubation at room temperature for 1 h, the solution was concentrated to half-volume on a Centricon-YM 10 centrifugal filter and purified from free DTPA by gel filtration on a PD-10 column.

Radiolabeling. Generally, 40 μ g of each antibody conjugate in 100 μ L of PBS was incubated with 350–400 μ Ci of ¹¹¹InCl₃ (in 20 μ L of 1 M sodium acetate buffer, pH 5.5) at room temperature for 15 min. The resulting radioisotopic product was purified from free indium-111

by gel filtration on a PD-10 column using PBS as the eluent. Fractions of 0.5 mL each were collected. The radioactivity of each fraction was measured by a radioisotope calibrator (Capintec Instruments, Ramsey, NJ). The protein content in each fraction was determined using a Bio-Rad protein assay kit according to the manufacturer's instruction (Bio-Rad Laboratories, Hercules, CA). The fractions containing the protein were combined. The radiochemical yield, expressed as a percentage of the radioactivity of the protein fractions to the total loaded radioactivity, was calculated. The radiochemical purity was determined by gel permeation chromatography (GPC).

Determination of Degree of Modification. The degree of substitution of C225 by maleimide was determined by quantifying the free amino groups remaining in the antibody using TNBS assay according to the published protocol (18). Briefly, samples were dissolved in 0.1 M sodium bicarbonate (pH 8.5) at a concentration of 20–200 μ g/mL. To 1 mL of each sample solution was added 0.5 mL of TNBS solution in 0.1 M sodium bicarbonate (0.01%, w/v). After incubation at 37 °C for 2 h, 0.5 mL of 10% SDS and 0.25 mL of 1 N HCl were sequentially added to each sample. The percentage of the reacted amino groups was determined by comparing the UV absorbance (335 nm) of the free amino groups in the modified antibody with that in the intact antibody.

Gel Permeation Chromatography. Analytical GPC was performed with a Waters HPLC system (Waters Corp., Milford, MA) consisting of a 2410 refractive index detector and a 2487 dual λ UV detector applying a TSK-G3000 PW 7.5 mm $\times$ 30 cm gel column (Tosoh Corp., Japan). Samples were eluted with PBS containing 0.1% LiBr at a flow rate of 1 mL/min, and the products were detected by the refractive index and UV absorbance at 254 nm. Radio-GPC was performed using an HPLC unit equipped with LDC pumps (Laboratory Data Control, Rivera Beach, FL), an LUDLUM radiometric detector (Measurement Inc., Sweetwater, TX), and an SP 8450 UV/VIS detector (Spectra-Physics, San Jose, CA). The samples were separated by a Phenomenex Biosep SEC-S3000 7.8 mm $\times$ 30 cm column, eluted with PBS containing 0.1% LiBr at a flow rate of 1 mL/min, and detected by radioactivity and UV absorbance at 254 nm.

Cell Lines. Human breast adenocarcinoma MDA-MB-468, human vulvar squamous carcinoma A431, and human colorectal carcinoma DiFi were maintained in 1:1 (v/v) Dulbecco's modified Eagle's medium (DMEM)/Ham's F-12 mixture supplemented with 10% fetal bovine serum (FBS) (Gibco Laboratories, Grand Island, NY) at 37 °C in 5% CO₂/95% air.

Competitive Binding Assay. MDA-MB-468 cells were seeded at 5×10^7 cells/well onto 12-well plates in 10% FBS medium and allowed to attach overnight. The medium was replaced by DMEM/F-12 medium plus 0.2% bovine serum albumin (BSA), and 1 μ g/mL of 1:30 ¹¹¹In-DTPA-PEG-C225 or ¹¹¹In-DTPA-C225 plus native C225 mAb at the indicated concentrations was added to the wells. After incubation at 37 °C for 2 h, the cells were washed 5 times with PBS containing 0.2% BSA. The cells were then trypsinized and transferred to 5 mL disposable culture tubes. The level of radioactivity in each tube was measured with a Cobra Auto-gamma Counter (Packard Instrument Co., Downers Grove, IL).

Immunoprecipitation and Western Blot Analysis. A431 cells were cultured with C225 or DTPA-PEG-C225 conjugates at 37 °C for 30 min, followed by washing the cells twice with cold PBS and lysis of the cells with a buffer containing 50 mM Tris-HCl, pH 7.4, 50 mM NaCl,

0.5% NP-40, 50 mM NaF, 1 mM Na₃PO₄, 1 mM phenylmethylsulfonyl fluoride, 25 μ g/mL leupeptin, and 25 μ g/mL aprotinin. The lysates were centrifuged at the full speed of a microcentrifuge for 15 min, and the supernatants were collected for protein concentration determination. Immunoprecipitation was performed by incubation of 100 μ g of cell lysate with 40 μ L of Sepharose 4B-conjugated protein A at room temperature for 1 h, followed by washing the immunoprecipitates 3 times with the lysing buffer and separation of immunoprecipitates with 7% polyacrylamide–SDS electrophoresis. Western blot was carried out by electronically transferring the samples into a nitrocellulose membrane and incubation of the membrane for 1 h with an anti-EGF receptor antibody. The EGF receptor signals in the membrane were developed by the ECL chemoluminescence detection kit (Amersham, Arlington Heights, IL).

MTT Assay. DiFi cells were seeded at 5×10^4 cells/well onto 24-well culture plates. Cell viability after 72 h treatment of the cells with C225 or DTPA-PEG-C225 was assayed by adding 50 μ L of 10 mg/mL MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] (Sigma) into 0.5 mL of culture medium and incubating the cells for 3 h at a 37 °C in a CO₂ incubator, followed by cell lysis with 500 μ L of lysis buffer containing 20% SDS in dimethylformamide/H₂O, pH 4.7, at 37 °C for more than 6 h. An optical absorbance of cell lysate was determined by measuring the cell lysate at a wavelength of 595 nm and normalizing the value with the corresponding control of untreated cells.

Pharmacokinetics. Nude mice (Harlan Sprague Dawley, Indianapolis, IN) were divided into two groups of three mice each and administered i.v. with 1:30 ¹¹¹In-DTPA-PEG-C225 at a dose of 1.5 μ g/mouse or with ¹¹¹In-DTPA-C225 at a dose of 5 μ g/mouse. At predetermined intervals, blood samples (30–60 μ L) were taken from the tail vein, and the radioactivity of each sample was measured with a gamma counter. The pharmacokinetic parameters for ¹¹¹In-DTPA-PEG-C225 and ¹¹¹In-DTPA-C225 were calculated from mean blood concentration values observed from the time of initial administration to 96 h after administration using WinNonlin 2.1 software (Scientific Consulting, Inc., Lexington, KY).

RESULTS AND DISCUSSION

Synthesis and Characterization. Previous studies have shown that an ¹¹¹In-labeled DTPA-mAb C225 specifically localizes in human cancer cell xenografts that overexpress EGF receptor (19). Phase I studies demonstrated that ¹¹¹In-DTPA-C225 was able to image squamous cell lung carcinoma expressing high levels of EGF receptor and metastases greater than 1 cm in diameter. However, considerable hepatic radioactivity was seen as a result of nonspecific uptake (20). The significant liver uptake made it difficult to visualize tumors or lesions inside or close to the liver. To overcome this drawback and optimize the imaging properties of C225, we sought to introduce flexible, linear PEG molecules into mAb C225 to reduce nonspecific interaction. In the past, attempts have been made in altering the pharmacological characteristics of mAbs by shielding the antibody with PEG or other synthetic polymers (21–23). Kitamura et al., for instance, reported the attachment of PEG (MW 5000) to murine mAb A7 and its F(ab')₂ fragment (21). These antibodies were radiolabeled with iodine-125 by the chloramine-T method. Both PEG-modified mAb and its fragment exhibited lower tissue-to-blood ratios in all resected organs than the parent antibodies, suggesting

Scheme 1. Synthesis of PEG-Modified C225 Monoclonal Antibody

reduced nonspecific interaction. Unfortunately, the tumor-to-blood ratio was also decreased after PEG modification. A similar study by Pedley et al. with PEG-modified and ¹²⁵I-labeled anti-CEA antibody A5B7 showed that the localization index was inferior to that of the unmodified antibody, and there was little increase in the tumor-to-blood ratio with time (22). A major problem of radioiodinated antibodies is the in vivo instability due to circulating dehalogenases, with the released radioiodine accumulating in the thyroid. We were also concerned with avoiding excessive manipulation of the mAb by both PEG modification and radioiodination procedures. Therefore, we were especially interested in developing a simple, one-step method to introduce both PEG molecules and radiometal chelators to mAbs such as C225.

Our approach was to conjugate the metal chelator DTPA through a PEG linker to C225 instead of attaching DTPA and PEG to the antibodies directly in a stepwise manner. The synthesis of a key intermediate, hetero-functional DTPA-PEG-ATA, with one end attached with a DTPA and the other with S-acetylthioacetate, is shown in Scheme 1. The sequence of reactions, i.e., the reaction with DTPA-dianhydride first, followed by deprotection and coupling with SATA, was necessary to achieve high yield. When t-Boc-NH-PEG-NH₂ was first coupled to SATA, the S-acetyl group was found to be unstable in the presence of TFA in the deprotection step. The prematurely released SH group could be easily destroyed by DTPA-dianhydride in the subsequent step. The 1:1 ratio of DTPA and ATA in DTPA-PEG-ATA was established by ¹H NMR analysis, elemental analysis, and by MALDI-TOF mass spectroscopic characterization. The theoretical ratio of integrals between -CH₂CH₂- in DTPA and CH₃- in ATA is 2.67. The ratio derived from NMR was 2.57, suggesting that the molar ratio of DTPA to ATA in DTPA-PEG-ATA was close to 1. The percentage weight

ratio of N to S in DTPA-PEG-ATA should be 2.18. The ratio derived from elemental analysis was 1.99. These data again confirm the 1:1 ratio of DTPA and ATA in DTPA-PEG-ATA. Finally, the calculated molecular mass of DTPA-PEG-ATA is 3770 Da; the molecular mass of the conjugate determined by MALDI-TOF mass spectroscopy was 3750 Da. No peaks of dimer and oligomers were found in the spectrum. These data support the proposed structure of DTPA-PEG-ATA. DTPA-PEG-ATA is stable for more than 6 months when stored as lyophilized powder at 4 °C.

DTPA-PEG-ATA was conveniently coupled to maleimide-activated C225 following a simple in situ deprotection step to release the free SH group (Scheme 1). Four DTPA-PEG-C225 conjugates with different degrees of C225 modification were synthesized. These conjugates were designated as 1:10, 1:20, 1:30, and 1:40 DTPA-PEG-C225, with the numbers being the molar ratios of antibody to GMBS in the maleimide-activating reaction. The physicochemical properties of the newly synthesized conjugates and some of the ¹¹¹In-labeled molecules are summarized in Table 1. Each C225 molecule contains approximately 50–60 free amino groups as measured by TNBS assay. In the 1:10, 1:20, 1:30, and 1:40 DTPA-PEG-C225 conjugates, approximately 20–25%, 40%, 60%, and 70% of amino groups were substituted, respectively. DTPA-C225 with DTPA directly attached to C225 mAb was also synthesized for the purpose of comparison (Table 1). Because DTPA-anhydride was readily hydrolyzed in aqueous media, coupling of DTPA directly to C225 was an inefficient reaction. Only 10–20% of the amino groups in C225 were substituted by DTPA when the molar ratio of DTPA-dianhydride to C225 reached 800:1.

Two PEG-modified antibody conjugates, 1:10 DTPA-PEG-C225 and 1:30 DTPA-PEG-C225, as well as DTPA-C225 were radiolabeled with indium-111. The radiochemical yields of the two ¹¹¹In-DTPA-PEG-C225 conjugates were over 70%, whereas the yield of ¹¹¹In-DTPA-C225 was only 40%. The lower yield with ¹¹¹In-DTPA-C225 reflects the fact that a large amount of DTPA was introduced into the coupling reaction between DTPA-dianhydride and C225. Although extensive purification procedures including ultracentrifugation and gel filtration on GPC column were used, DTPA-C225 could still be contaminated by trace amounts of DTPA molecules, leading to low labeling efficiency.

GPC was used to monitor the purity of C225 conjugates and ¹¹¹In-labeled C225 conjugates. As shown in Figures 1–3, coupling of PEG to C225 increased the hydrodynamic volume of C225. The retention time of intact C225 (6.0 min) on the TSK-G3000 column was shortened to 4.9 min for 1:30 DTPA-PEG-C225, suggesting that PEG molecules were chemically bound to the mAb (Figure 1). The GPC chromatogram of purified DTPA-PEG-C225 also indicated that gel filtration on the Sephacryl S-200 HR column adequately removed unconjugated C225. However, when 1:30 DTPA-PEG-C225 was labeled with indium-111, it gave two peaks in radio-GPC, with reten-

Table 1. Physicochemical Properties of DTPA-PEG-C225 Conjugates

C225 conjugates	molar ratio of C225 to GMBS	degree of NH ₂ substitution (%)	retention time in GPC (min)	radiochemical yield (%)	radiopurity (%)
1:10 DTPA-PEG-C225	1:10	20–25	6.1	>70	>97
1:20 DTPA-PEG-C225	1:20	40			
1:30 DTPA-PEG-C225	1:30	60	5.7	>70	>99
1:40 DTPA-PEG-C225	1:40	70

Figure 1. TSK-G3000 size-exclusion HPLC (UV absorbance at 254 nm) of native C225 mAb and 1:30 DTPA-PEG-C225 conjugate after purification on a Sephadex G-75 column. DTPA-PEG-C225 was eluted 1.1 min earlier than the native C225 mAb, revealing the conjugation of PEG molecules to the C225 mAb.

tion times of about 5.9 and 8.5 min, respectively (Figure 2A). The major peak at 5.9 min corresponded to 1:30 ^{111}In -DTPA-PEG-C225 while the minor peak at 8.5 min, which reflects a retention time identical to that of ^{111}In -DTPA-PEG (Figure 2B), was attributed to unconjugated DTPA-PEG. Thus, another gel filtration procedure was necessary to remove ^{111}In -DTPA-PEG. Radio-GPC chromatograms of purified 1:30 ^{111}In -DTPA-PEG-C225, 1:10 ^{111}In -DTPA-PEG-C225, and ^{111}In -DTPA-C225 are presented in Figure 3. The 1:30 and 1:10 conjugates were eluted at 5.7 and 6.1 min, respectively, reflecting shorter retention times than ^{111}In -DTPA-C225 (6.7 min). These results further confirmed that there were more PEG molecules attached to the 1:30 DTPA-PEG-C225 conjugate than to the 1:10 conjugate. The radiopurities of purified 1:30 ^{111}In -DTPA-PEG-C225, 1:10 ^{111}In -DTPA-PEG-C225, and ^{111}In -DTPA-C225 were >99%, >97%, and >99%, respectively (Table 1).

In Vitro Biological Functions. To determine whether PEG-modified C225 retains the binding affinity of the

parent mAb, we evaluated the *in vitro* biological properties of DTPA-PEG-C225 conjugates using three methods: competitive binding to human breast cancer MDA-MB-468 cells, immunoprecipitation of EGF receptor from human vulvar squamous carcinoma A431 cell lysates, and inhibition of growth of human colorectal carcinoma DiFi cells. All three cell lines express high levels of EGF receptor (24–26).

Studies on the cellular uptake of 1:30 ^{111}In -DTPA-PEG-C225 and ^{111}In -DTPA-C225 in MDA-MB-468 cells have shown that cell-associated radioactivity increased with increasing concentrations of radiolabeled C225. A plateau was reached at 2 $\mu\text{g/mL}$ for 1:30 ^{111}In -DTPA-PEG-C225 (data not shown). Therefore, a concentration of 1 $\mu\text{g/mL}$ for the radiolabeled C225 was chosen for the competitive binding assay. The binding of both 1:30 ^{111}In -DTPA-PEG-C225 and ^{111}In -DTPA-C225 to MDA-MB-468 cells was displaced by C225 in a dose-dependent manner, suggesting that the binding is EGF receptor specific (Figure 4). Furthermore, ^{111}In -DTPA-PEG-C225 was almost fully

Figure 2. Radio-gel permeation chromatography of (A) ^{111}In -labeled 1:30 DTPA-PEG-C225 prior to purification and (B) ^{111}In -DTPA-PEG. In panel A, the peak at 5.9 min corresponds to the DTPA-PEG-C225 conjugate, and the peak at 8.5 min, which is identical to the peak in panel B, corresponds to unreacted DTPA-PEG.

displaced by a 16-fold excess of C225, whereas ^{111}In -DTPA-C225 was only 80% displaced by a 16-fold excess of C225 and could not be fully displaced even by 40-fold excess of C225. The remaining 20% of cell-associated ^{111}In -DTPA-C225 represent nonspecific binding to the cells. These results suggest that modification of C225 with PEG reduced the nonspecific interaction of the antibody. When the contribution of nonspecific binding is taken into consideration and is deducted from the cell-associated radioactivity, 44% of ^{111}In -DTPA-C225 and 33% of 1:30 ^{111}In -DTPA-PEG-C225 remained bound to the cells when the concentration of native C225 mAb was equal to the concentration of the labeled molecules (1 $\mu\text{g}/\text{mL}$). This means that ^{111}In -DTPA-C225 retained about 88% of the receptor binding affinity of native C225, while 1:30 ^{111}In -DTPA-PEG-C225 retained about 66% of the binding affinity.

To further assess the receptor binding affinity of DTPA-PEG-C225 conjugates, the ability of DTPA-PEG-C225 conjugates to bind to EGF receptor was investigated in A431 cells, which express a very high level of EGF

Table 2. Pharmacokinetic Parameters of 1:30 ^{111}In -DTPA-PEG-C225 and ^{111}In -DTPA-C225

parameters ^a	DTPA-C225	DTPA-PEG-C225 (1:30)
A (% ID/mL)	11.7	11.3
B (% ID/mL)	14.8	37.3
C (% ID/mL)	13.3	7.6
α (h^{-1})	1.74	2.82
β (h^{-1})	0.08	0.10
γ (h^{-1})	0.01	0.03
$t_{1/2,\alpha}$ (h)	0.40	0.24
$t_{1/2,\beta}$ (h)	9.11	6.82
$t_{1/2,\gamma}$ (h)	52.9	21.1
V_1 (mL)	2.52	1.78
V_{ss} (mL)	5.41	2.94
CL (mL/h)	0.08	0.16
k_{10} (h^{-1})	0.03	0.09
k_{12} (h^{-1})	0.48	0.53
k_{21} (h^{-1})	1.24	2.27
k_{13} (h^{-1})	0.03	0.02
k_{31} (h^{-1})	0.04	0.04

^a % ID/mL is the injected dose per milliliter of blood. A, B, C, α , β , and γ are hybrid constants. V_1 and V_{ss} are volume distributions in the central compartment and at steady state (V_{ss}). CL is clearance. k_{10} , k_{12} , k_{21} , k_{13} , and k_{31} are microconstants.

receptors. The cells exposed to C225 or one of the three 1:10, 1:20, and 1:40 DTPA-PEG-C225 conjugates were lysed, followed by immunoprecipitation of the antibody-bound EGF receptor with protein A-Sepharose beads and visualization of the EGF receptors with Western blot analysis. The results shown in Figure 5 indicate that all three DTPA-PEG-C225 conjugates, with 20%, 50%, and up to 70% of the amino groups in C225 substituted, retained their EGF receptor binding activities. However, the amounts of EGF receptor immunoprecipitated by C225 conjugates decreased with increasing degree of substitution, indicating that the binding affinity of the PEG-modified C225 decreased with the increasing number of PEG molecules attached to the mAb.

The activities of DTPA-PEG-C225 conjugates were further assessed by an independent antiproliferation assay. We have previously reported that blocking EGF receptor tyrosine kinase activity with C225 leads to cell cycle arrest and subsequent cell death through apoptosis in DiFi cells (26). As shown in Figure 6, while the linker molecule PEG-DTPA itself had no effect on DiFi cell growth, all three conjugates, 1:10, 1:20, and 1:40 DTPA-PEG-C225, inhibited the tumor cell growth to the same extent as native C225, indicating that all conjugates were capable of inducing apoptosis in the DiFi human colon cancer cells (Figure 6).

Pharmacokinetics. The radioactivities of the blood samples obtained at different time intervals after i.v. injection of 1:30 ^{111}In -DTPA-PEG-C225 and ^{111}In -DTPA-C225 were measured with a gamma counter. Figure 7 plots blood radioactivity expressed as a percentage of injected dose per milliliter of blood (% ID/mL of blood) versus time following i.v. injection of radiolabeled C225. The profiles of both ^{111}In -DTPA-PEG-C225 and ^{111}In -DTPA-C225 fit well into three-compartment models, and can be mathematically described by the triexponential equations: $Ct = 11.3e^{-2.82t} + 37.3e^{-0.10t} + 7.6e^{-0.03t}$ and $Ct = 11.7e^{-1.74t} + 14.8e^{-0.08t} + 13.3e^{-0.01t}$, respectively, where Ct is % ID/mL of blood at any given time t .

The pharmacokinetic parameters of volume distributions in the central compartment (V_1) and at steady state (V_{ss}), clearance (CL), hybrid constants (A, B, C, α , β , and γ), and microconstants (k_{10} , k_{12} , k_{21} , k_{13} , and k_{31}) are summarized in Table 2. The volume distribution at steady state (V_{ss}) of 1:30 ^{111}In -DTPA-PEG-C225, 2.94 mL,

Figure 3. Radio-gel permeation chromatography of purified (A) ^{111}In -DTPA-C225, (B) 1:10 ^{111}In -DTPA-PEG-C225, and (C) 1:30 ^{111}In -DTPA-PEG-C225. The three molecules were eluted through a Phenomenex Bioseep SEC-S3000 column. The radiochemical purity of each conjugate was greater than 97%.

Figure 4. Competitive binding of ^{111}In -DTPA-C225 and 1:30 ^{111}In -DTPA-PEG-C225 with native C225 to MDA-MB-468 cells. The cells were incubated with 1 $\mu\text{g/mL}$ of each ^{111}In -labeled C225 conjugate plus unlabeled C225 at different concentrations. After incubation at 37 $^{\circ}\text{C}$ for 2 h, the cell-associated radioactivity was measured with a gamma counter. The data are expressed as counts per minute (CPM) as a percentage of control and presented as the means of triplicates with standard deviations.

was smaller than that of ^{111}In -DTPA-C225, 5.41 mL. The narrower distribution of PEG-modified molecules might be due to the reduced nonspecific binding of these molecules to tissues and the faster returning rate constant from tissues to the central compartment, reflected by the larger k_{21} . The elimination rate constant from the central compartment (k_{10}) and the clearance (CL) of 1:30 ^{111}In -DTPA-PEG-C225 were 0.09 h^{-1} and 0.16 mL/h, respectively, higher than those of ^{111}In -DTPA-C225, 0.03 h^{-1} and 0.08 mL/h, respectively. The terminal half-life ($t_{1/2,\gamma}$) of ^{111}In -DTPA-PEG-C225, 21.1 h, was shorter than that of ^{111}In -DTPA-C225, 52.9 h, resulting from its smaller volume distribution and faster clearance.

Figure 5. Immunoprecipitation of EGF receptor from A431 cells by C225 and its PEG conjugates. Western blotting with anti-EGF receptor antibody revealed the binding of DTPA-PEG-C225 molecules to EGF receptor in A431 cells. In 1:10, 1:20, and 1:40 DTPA-PEG-C225s, PEG molecules were attached to 25%, 50%, and 70% of the amino groups in C225, respectively. The asterisks represent different batches of DTPA-PEG-C225 with the same degree of substitution (1:20).

Because the molecular weight of C225 is relatively high (150 000), its modification with PEG (34 000) was not expected to have profound effects on its blood circulation time. Nevertheless, our finding that the terminal half-life of 1:30 ^{111}In -DTPA-PEG-C225 was actually shorter than that of ^{111}In -DTPA-C225 is somewhat unexpected. A possible explanation is in vivo cleavage of ^{111}In -DTPA-PEG from ^{111}In -DTPA-PEG-C225. The shortened blood retention of ^{111}In -DTPA-PEG-C225 could be advantageous in obtaining improved images of target organs (8–10).

SUMMARY

The procedures for synthesizing and radiolabeling DTPA-PEG-C225 are efficient and reproducible. DTPA-PEG-C225 retained its binding affinity to EGF receptor with reduced nonspecific interaction with cells, although

Figure 6. Blockage of DiFi cell growth by C225, DTPA-PEG-C225 conjugates, and free DTPA-PEG. The DiFi cells were exposed to the indicated reagents at concentrations of 20 nM. After 3 days of incubation, the numbers of surviving cells were measured by MTT assay. The results are presented as the means of triplicates with standard deviations.

Figure 7. Pharmacokinetics of ^{111}In -DTPA-C225 and 1:30 ^{111}In -DTPA-PEG-C225. Each mouse was given 1.5 μg of a radiotracer i.v. The blood samples were collected at different time intervals, and the radioactivity of each sample was measured. The data are expressed as percentages of injected dose per milliliter of blood (% ID/mL) and presented as the means of triplicates. The standard deviation for each time point is less than 10%. The profiles of both ^{111}In -DTPA-C225 and 1:30 ^{111}In -DTPA-PEG-C225 fit well into the three-compartment model.

a high degree of PEG modification appeared to interfere with the binding activity of the antibody. Modification of C225 with PEG (MW 3400), even at a high degree of substitution, did not appear to increase blood circulation time of the antibody. PEG-modified C225 is less widely distributed to normal tissues than C225 without PEG, suggesting reduced nonspecific binding of PEG-modified C225 to tissues. Taken together, our results suggest that this method, introducing DTPA through a PEG linker, may be a useful strategy in developing radioimmunodetection imaging agents. This approach should be applicable to the labeling of other mAbs as well as their F(ab')_2 , Fab' , and ScFv fragments.

Radiolytic degradation of radiolabeled compounds is a major challenge for the development of new therapeutic radiopharmaceuticals. The goal of this study is to explore the factors influencing the solution stability of a ^{90}Y -labeled DOTA-peptide conjugate (RP697), including the amount of total activity, the activity concentration, the stabilizer concentration, and the storage temperature. In general, the rate of radiolytic decomposition of RP697 is much slower at the lower activity concentration (<4 mCi/mL) than that at the higher concentration (>10 mCi/mL). RP697 remains relatively stable at the 20 mCi level and room temperature while it decomposes rapidly at the 100 mCi level under the same storage conditions. Radical scavengers, such as gentisic acid (GA) and ascorbic acid (AA), were used in combination with the low temperature (-78°C) to prevent the radiolytic decomposition of RP697. It was found that RP697 remains stable for at least 2 half-lives of ^{90}Y when GA or AA (10 mg for 20 mCi of ^{90}Y) is used as a stabilizer when the radiopharmaceutical composition is stored at -78°C . The stabilizer (GA and AA) can be added into the formulation either before or after radiolabeling. The post-labeling approach is particularly useful when the use of a large amount of the stabilizer interferes with the radiolabeling. The radiopharmaceutical composition developed in this study can also apply to other ^{90}Y -labeled DOTA-biomolecule conjugates. The amount of the stabilizer used in the radiopharmaceutical composition and storage temperature should be adjusted according to the sensitivity of the radiolabeled DOTA-biomolecule conjugate toward radiolytic decomposition.

INTRODUCTION

We have been interested in the development of new diagnostic and therapeutic radiopharmaceuticals based on small-molecule receptor ligands (1–18). In our previous contribution (19), we reported the synthesis of a DOTA-conjugated vitronectin receptor antagonist (SU015: 2-(1,4,7,10-tetraaza-4,7,10-tris(carboxymethyl)-1-cyclododecyl)-acetyl-Glu(cyclo{Lys-Arg-Gly-Asp-D-Phe})-cyclo{Lys-Arg-Gly-Asp-D-Phe}) and its ^{90}Y complex (RP697 in Figure 1). Through a series of radiolabeling experiments, we developed a formulation for routine preparations of RP697 in high yield with the radiochemical purity (RCP) of $>95\%$. However, RP697 prepared using this formulation was not stable over time at room temperature, particularly at high activity levels.

^{90}Y is an β -emitter with a 2.27 MeV β -particle and a 2.67 day half-life. Due to the high energy of the β -particle, the radiolabeled cyclic peptide is very susceptible to radiolytic decomposition. Since the tumor uptake of RP697 is largely dependent on the receptor binding of the two cyclic RGD-containing peptide motifs, radiolytic decomposition may lead to the decreased therapeutic efficacy and unwanted radiation toxicity to other normal organs such as liver and bone marrow. The mechanism for radiolytic decomposition is thought to be mediated by the formation of free radicals, such as superoxide ($\text{O}_2^\bullet$) and hydroxyl radicals ($\text{OH}^\bullet$), in the presence of a large amount of high-energy β -particles (20). Radical scavengers such as human serum albumin (HAS), gentisic acid (GA), and ascorbic acid (AA) have been used as stabilizers

Figure 1. Structure of RP697.

for the radiolabeled antibodies (21–23). It was also found that freezing the antibody after radiolabeling up to the time of administration could considerably improve the immunoreactivity by decreasing the diffusion and interaction of free radicals with the radiolabeled biomolecule (22).

The purpose of this study is to explore the factors influencing the solution stability of RP697, including the activity concentration, the total activity level, the stabilizer concentration, and the storage temperature. We have chosen AA and GA as stabilizers since they have been approved for pharmaceutical or radiopharmaceutical applications. The ultimate goal is to find the optimized radiopharmaceutical composition to maintain the solution stability of RP697. In principle, the radiopharmaceutical composition developed in this study should also apply to other ^{90}Y -labeled DOTA-biomolecule conjugates.

EXPERIMENTAL PROCEDURES

Materials. Acetic acid (ultrapure), ammonium hydroxide (ultrapure), ascorbic acid (sodium salt), diethylene-

triaminepentaacetic acid (DTPA), and gentisic acid (sodium salt) were purchased from either Aldrich or Sigma Chemical Co., and were used as received. $^{90}\text{YCl}_3$ (in 0.05 N HCl) was purchased from New England Nuclear Life Sciences, North Billerica, MA. The cyclic pentapeptide cyclo(Arg-Gly-Asp-D-Phe-Lys), as its trifluoroacetic acid (TFA) salt, was prepared according to the literature method (24). Synthesis of SU015, 2-(1,4,7,10-tetraaza-4,7,10-tris(carboxymethyl)-1-cyclododecyl)-acetyl-Glu(cyclo-{Lys-Arg-Gly-Asp-D-Phe})-cyclo{Lys-Arg-Gly-Asp-D-Phe}, as its trifluoroacetic acid (TFA) salt will be described in a companion paper (19).

General Procedure for the Synthesis of RP697.

To a shielded clean 5 mL vial containing 100 μg of SU015 and 0–10 mg of sodium gentisate (GA) or sodium ascorbate (AA) dissolved in 0.5 mL of 0.5 M ammonium acetate buffer (pH 8.0) was added 20–40 μL of $^{90}\text{YCl}_3$ stock solution (~ 20 mCi) in 0.05 N HCl. The reaction mixture was heated at 95–100 $^\circ\text{C}$ for 5 min. A sample of the resulting solution was diluted 20-fold with 2 mM DTPA solution (pH 5), and then analyzed by radio-HPLC and ITLC. Each condition was run twice, and the radiochemical purity (RCP) data are presented as an average of two independent measurements.

Analytical Methods. The HPLC method used a HP-1100 HPLC system with a UV/visible detector ($\lambda = 220$ nm), an IN-US radio-detector, and a Zorbax C₁₈ column (4.6 mm $\times$ 250 mm, 80 $\text{\AA}$ pore size). The flow rate was 1 mL/min. The mobile phase was isocratic from 0 to 18 min using 87% solvent A (0.025 M ammonium acetate buffer, pH 6.8) and 13% solvent B (acetonitrile), followed by an isocratic wash using 40% solvent A and 60% solvent B from 19 to 25 min. The retention time of RP697 is 14–16 min. The ITLC method used Gelman Sciences silica gel ITLC paper strips and a 1:1 mixture of acetone and saline as eluant. By this method, RP697 migrates to the solvent front while ^{90}Y colloid and ^{90}Y acetate remain at the origin. The corrected RCP for RP697 was calculated by subtracting the percentage of ^{90}Y colloid and ^{90}Y acetate obtained by ITLC from that obtained by radio-HPLC.

RESULTS

Room Temperature Stability of RP697 at Low Concentration (4 mCi/mL). In the first experiment, we prepared three RP697 vials according to the standard procedure. The first vial contains only 100 μg of SU015, the second vial contains 100 μg of SU015 and 5 mg of GA, and the third vial contains 100 μg of SU015 and 5 mg of sodium ascorbate (AA). After addition of 20 mCi of $^{90}\text{YCl}_3$ in each vial, the reaction mixtures were heated at 100 $^\circ\text{C}$ for 5 min. After radiolabeling, the resulting solution was diluted to a concentration of 4 mCi/mL with saline, and the solution stability of RP697 at room temperature was monitored by radio-HPLC over 6 days. Figure 2 shows a typical radio-HPLC chromatogram for RP697. The peak at 14 min is from RP697. The peak at ~ 3.5 min is probably from a combination of several hydrophilic ^{90}Y -containing species while the peak at 24 min is from more lipophilic ^{90}Y -containing species. Since most of the radioimpurities are less than 1%, no efforts were made for further characterization. Figure 3 shows the RCP change over time for RP697. It is clear that RP697 remains relatively stable (RCP = 96.5% at 0 h and 94% at 144 h post-labeling) in the presence of GA and AA while it decomposes rapidly in the absence of GA and RCP is only 86% at 6 days post-labeling.

GA Concentration and Solution Stability. In this experiment, RP697 was prepared according to the general

Figure 2. Typical radio-HPLC chromatogram of RP697.

Figure 3. Effect of stabilizers on solution stability of RP697 at room temperature. Each condition was run twice, and the radiochemical purity (RCP) data are presented as an average of two independent measurements.

Figure 4. Effect of GA concentration on solution stability of RP697 at room temperature. Each condition was run twice, and the radiochemical purity (RCP) data are presented as an average of two independent measurements.

procedure using two levels (2 and 10 mg) of GA and 100 μg of SU015 for 20 mCi of $^{90}\text{YCl}_3$. The total volume was 0.5 mL, and the activity concentration was 40 mCi/mL. After radiolabeling, the resulting solution was kept at room temperature, and the solution stability of RP697 was monitored by radio-HPLC over 6 days. Figure 4 shows the RCP change over 6 days for RP697. The RCP of RP697 decreased from 96.5% at 0 h to 93% at 144 h post-labeling when 10 mg of GA was used for 20 mCi of activity. The RCP dropped much more rapidly from 97% at 0 h to 65% at 144 h when only 2 mg of GA was used to stabilize 20 mCi of RP697. This suggests that 2 mg of GA is not sufficient to maintain RCP above 90% and 10 mg of GA is needed to stabilize RP697 over 2 half-lives of ^{90}Y . Compared to the results from the previous experiment, it seems that the rate of decomposition of RP697 is also dependent on the activity concentration.

Activity Level and Solution Stability of RP697.

In this experiment, we prepared two RP697 vials using two different levels of ^{90}Y . In one vial, it contained 10 mg of GA, 100 μg of SU015, and 20 mCi of $^{90}\text{YCl}_3$ (total

Figure 5. Effect of the activity concentration on solution stability of RP697 at room temperature. Each condition was run twice, and the radiochemical purity (RCP) data are presented as an average of two independent measurements.

Figure 6. Solution stability of RP697 at -78°C . Each condition was run twice, and the radiochemical purity (RCP) data are presented as an average of two independent measurements.

volume = 0.5 mL). In another vial, RP697 was prepared using 500 μg of SU015, 50 mg of GA, and 100 mCi of $^{90}\text{YCl}_3$ (total volume = 2.5 mL). After radiolabeling, the resulting solution was kept at room temperature, and the solution stability of RP697 was monitored by radio-HPLC over 6 days, as shown in Figure 5.

Solution Stability of RP697 at -78°C . RP697 was prepared using the standard radiolabeling procedure (100 μg of SU015, 10 mg of GA for 20 mCi of $^{90}\text{YCl}_3$, and heating at 100°C for 5 min). For the vials containing 100 and 200 mCi of activity, all the component levels were increased proportionally. For the vial using AA as the stabilizer, AA (200 mg/mL) was dissolved in 0.5 N ammonium acetate buffer (pH 7.4) and added to the reaction mixture (10 mg of AA for 20 mCi of ^{90}Y) after radiolabeling. After addition of AA, all the vials containing RP697 were kept in a dry ice box (-78°C). Samples of the reaction mixture were analyzed by HPLC at 0, 24, 56, and 138 h. Figure 6 shows the RCP change over 6 days for RP697. Apparently, RP697 can be stabilized by the combination use of a stabilizer and low-temperature storage at -78°C .

DISCUSSION

There has been great current interest in radiolabeled small peptides as therapeutic radiopharmaceuticals (25–27). In developing a new receptor-based therapeutic radiopharmaceutical, several factors need to be considered to satisfy the clinical need and to comply with FDA regulations. The therapeutic radiopharmaceutical must demonstrate therapeutic efficacy and favorable pharmacokinetics, including high and fast tumor uptake, high tumor-to-background ratio, long tumor residence time, and fast renal clearance. High tumor uptake and fast

renal clearance are particularly important to improve the tumor-to-background ratio and to reduce the radiation burden to other major organs (kidney, liver, and bone marrow). The new radiopharmaceutical must have high radiochemical purity (RCP $\geq 90\%$). Unlike diagnostic radiopharmaceuticals, therapeutic radiopharmaceuticals have to be manufactured and released under GMP (Good Manufacturing Practice) conditions, and delivered for clinic applications. Therefore, the new therapeutic radiopharmaceutical must retain its chemical and biological integrity during release and transportation.

Therapeutic radiopharmaceuticals comprising β -emitting radionuclides may undergo autoradiolysis during preparation, release, transportation, and storage. During radiolysis, emissions from the radionuclide attack the metal chelate, targeting the biomolecule, and other compounds in proximity, which results in inter- and intramolecular decomposition or destruction of the radiometal chelate or the biomolecule. Radioactivity, which is not linked to the targeting biomolecule, will accumulate in nontargeting tissues and lead to the unwanted radiation toxicity to nontargeting tissues. Thus, it is important that the radionuclide remains linked to the targeting moiety, and the specificity of the targeting biomolecule is preserved. As a matter of fact, a major challenge for the development of a therapeutic radiopharmaceutical is to stabilize the radiolabeled compound during radiolabeling, release, and transportation.

Radiolysis is caused by the formation of free radicals such as hydroxyl and superoxide radicals. Free radicals are very reactive toward organic molecules such as peptides. To prevent radiolysis and stabilize the radiolabeled biomolecule, a radical scavenger or radiolytic stabilizer is often used either during or after the radiolabeling. A stabilizer is often an antioxidant, which readily reacts with hydroxyl and superoxide radicals. In general, the stabilizer for the therapeutic radiopharmaceutical should have the following characteristics: low or no toxicity or immunoreactivity when it is used for human administration, no interference with the receptor binding of the radiolabeled compound to the target cells or tissue(s), and the ability to stabilize the therapeutic radiopharmaceutical for a reasonable period of time (preferably 2 half-lives of ^{90}Y) for preparation, release, storage, and transportation.

There are several commercially available antioxidants. Human serum albumin (HAS) has been used as a stabilizer for the radiolabeled antibodies (21–23). Ascorbic acid is an antioxidant, and an FDA-approved pharmaceutical suitable for human injection. Gentisic acid has been used as a stabilizer in $^{99\text{m}}\text{Tc}$ radiopharmaceutical formulations (28–30). The stabilizer can be added into a therapeutic radiopharmaceutical formulation either before or after the radiolabeling. For pre-labeling addition, the stabilizer is added before addition of $^{90}\text{YCl}_3$ stock solution. During the radiolabeling process, the stabilizer is subjected to a certain degree of thermal decomposition, particularly at elevated temperatures. For the post-labeling addition, the stabilizer is not exposed to the heating process; thereby it may have longer stabilizing effect and higher stabilizing efficiency. The post-labeling approach is particularly useful when the addition of a large amount of stabilizer in the radiopharmaceutical formulation interferes with the radiolabeling.

There are several factors influencing the solution stability of RP697. These include the amount of activity in each vial, the activity concentration, the relative amount of stabilizer, and the storage temperature. For example, the rate of radiolytic decomposition of RP697

is much slower at the activity concentration of 4 mCi/mL than that at a concentration of 40 mCi/mL (Figure 3). It needs 10 mg of GA or AA to maintain the RCP of RP697 (20 mCi) above 90% over 2 half-lives of ⁹⁰Y (Figure 4). RP697 remains relatively stable at room temperature if 10 mg of GA is used for 20 mCi of activity. It decomposes much faster when 50 mg of GA is used for 100 mCi of activity under the same storage conditions, even though the GA/activity ratio remains the same (Figure 5). Therefore, the solution stability data obtained from the low activity level (<20 mCi) cannot be simply extrapolated to high activity levels (>100 mCi).

In addition to the use of an antioxidant in the radiopharmaceutical formulation, storing the reaction mixture at low temperature (−78 °C/dry ice) also has a dramatic impact on the solution stability of RP697. For example, RP697 remains stable for at least 2 half-lives of ⁹⁰Y at −78 °C (Figure 6) while it decomposes rapidly at room temperature. Freezing the reaction mixture containing RP697 offers two advantages: stopping the diffusion of free radicals and slowing down the reaction kinetics between free radicals and radiolabeled cyclic peptide. Thus, it is recommended that the radiopharmaceutical be stored at low temperatures to avoid extensive radiolysis during release and transportation. The amount of antioxidant used in the radiopharmaceutical formulation and the storage temperature during release and transportation should be adjusted according to the sensitivity of a specific radiolabeled receptor ligand toward radiolytic decomposition.

CONCLUSIONS

In this study, we explored the factors influencing the solution stability of RP697, a ⁹⁰Y-labeled DOTA-peptide conjugate, and found that both the amount of total activity and the activity concentration have significant impact on the stability of the ⁹⁰Y-labeled cyclic peptide. The rate of radiolytic decomposition of RP697 is much slower at the lower activity concentration (<4 mCi/mL) than that at the higher concentration (>10 mCi/mL). RP697 remains relatively stable at room temperature when it is prepared at the 20 mCi level while it decomposes rapidly at the 100 mCi level under the same storage conditions. Therefore, the solution stability data obtained from the low activity level (<20 mCi) cannot be simply extrapolated to high activity levels (>100 mCi).

To prevent extensive radiolysis, we used both GA and AA as stabilizers. The stabilizer can be added into the formulation either before or after radiolabeling. For the post-labeling addition, the stabilizer is not exposed to the heating process; thereby it may have a longer stabilizing effect and higher stabilizing efficiency. The post-labeling approach is particularly useful when the addition of a large amount of stabilizer in the radiopharmaceutical formulation interferes with the radiolabeling of the DOTA-biomolecule conjugate.

^{90}Y and ^{177}Lu Labeling of a DOTA-Conjugated Vitronectin Receptor Antagonist Useful for Tumor Therapy

Shuang Liu,* Eric Cheung, Marisa C. Ziegler, Milind Rajopadhye, and D. Scott Edwards

Medical Imaging Division, DuPont Pharmaceuticals Company, 331 Treble Cove Road, North Billerica, Massachusetts 01862. Received November 30, 2000; Revised Manuscript Received March 30, 2001

The ^{90}Y and ^{177}Lu complexes (RP697 and RP688, respectively) of a DOTA-conjugated vitronectin receptor antagonist (SU015: 2-(1,4,7,10-tetraaza-4,7,10-tris(carboxymethyl)-1-cyclododecyl)acetyl-Glu-(cyclo{Lys-Arg-Gly-Asp-D-Phe})-cyclo{Lys-Arg-Gly-Asp-D-Phe}) were prepared by reacting SU015 with the radiometal chloride in ammonium acetate buffer (pH > 7.2) in the presence of an antioxidant (sodium gentisate, GA). Through a series of radiolabeling experiments, it was found that there are many factors influencing the rate of ^{90}Y chelation and the radiolabeling efficiency of SU015. These include the purity of SU015, the pH, reaction temperature, and heating time, as well as the presence of trace metal contaminants, such as Ca^{2+} , Fe^{3+} , and Zn^{2+} . The chelation of ^{90}Y by SU015 is slow, so that heating at elevated temperatures (50–100 °C) is needed to complete the ^{90}Y -labeling. The rate of ^{90}Y chelation is also dependent on the pH of the reaction mixture. Under optimized radiolabeling conditions (pH 7.2–7.8 and heating at 50–100 °C for 5–10 min), the minimum amount of SU015 required to achieve 95% RCP for RP697 is $\sim 25\text{ }\mu\text{g}$ for 20 mCi of $^{90}\text{YCl}_3$ corresponding to a SU015: ^{90}Y ratio of $\sim 30:1$.

INTRODUCTION

We have been interested in the development of diagnostic radiopharmaceuticals based on small molecule receptor ligands (1–15). We have been using a ternary ligand system for the $^{99\text{m}}\text{Tc}$ labeling of a variety of hydrazinonicotinamide-conjugated biomolecules (HYNIC-BM), including a GPIIb/IIIa receptor antagonist for thrombus imaging (1–8), and chemotactic peptides (9) and LTB_4 receptor antagonists for imaging infection and inflammation (12–14). In a separate communication (15), we report the $^{99\text{m}}\text{Tc}$ labeling of an HYNIC-conjugated vitronectin receptor antagonist (SQ168: 2-sulfonatobenzenesulfonic acid hydrazine of *N*-(6-hydrazinonicotinamido)-Glu(cyclo{Lys-Arg-Gly-Asp-D-Phe})-cyclo{Lys-Arg-Gly-Asp-D-Phe}) and biological properties of the complex [$^{99\text{m}}\text{Tc}(\text{SQ168})(\text{tricine})(\text{TPPTS})$] (RP593: TPPTS = trisodium triphenylphosphine-3,3',3''-trisulfonate). In the c-Neu Oncomouse tumor model (15), RP593 shows high tumor uptake and long tumor residence time (3.4% ID/g at 2 h and 1.5% ID/g at 24 h postinjection) and is excreted predominantly via the renal system. This suggests that the corresponding ^{90}Y and ^{177}Lu complexes have the potential as target-specific radiopharmaceuticals for tumor therapy.

As a continuation of our efforts in developing new peptide-based diagnostic and therapeutic radiopharmaceuticals, a DOTA-conjugated vitronectin receptor antagonist (Figure 1: SU015 = 2-(1,4,7,10-tetraaza-4,7,10-tris(carboxymethyl)-1-cyclododecyl)-acetyl-Glu(cyclo{Lys-Arg-Gly-Asp-D-Phe})-cyclo{Lys-Arg-Gly-Asp-D-Phe}) has been synthesized. In this report, we present the synthesis and characterization of its corresponding ^{90}Y and ^{177}Lu complexes (Figure 1: RP697 and RP688). Through a series of radiolabeling experiments, we developed a for-

mulation for routine preparations of RP697 and RP688. This formulation may be used for the ^{90}Y - and ^{177}Lu -labeling of other DOTA-conjugated biomolecules.

EXPERIMENTAL SECTION

Materials. Acetic acid (ultrapure), ammonium hydroxide (ultrapure), diethylenetriaminepentaacetic acid (DTPA), and sodium gentisate were purchased from either Aldrich or Sigma Chemical Co. and were used as received. $^{90}\text{YCl}_3$ (in 0.05 N HCl) was purchased from NEN Life Sciences, N. Billerica, MA. High specific activity $^{177}\text{LuCl}_3$ was obtained from University of Missouri Research Reactor, Columbia, MO. The cyclic pentapeptide, cyclo(Arg-Gly-Asp-D-Phe-Lys), as its trifluoroacetic acid (TFA) salt was prepared according to the literature method (16).

Synthesis of 2-(1,4,7,10-Tetraaza-4,7,10-tris(*tert*-butoxycarbonylmethyl)-1-cyclododecyl)acetyl-Glu-(cyclo{Lys-Arg-Gly-Asp-D-Phe})-cyclo{Lys-Arg-Gly-Asp-D-Phe}. To a solution of tris(*tert*-butyl)-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (45 mg, 0.078 mmol) in DMF (2 mL) were added HBTU (18 mg, 0.047 mmol) and Hunig's base (20 μL). The mixture was stirred for 15 min. To this were added a solution of Glu-(cyclo{Lys-Arg-Gly-Asp-D-Phe})-cyclo{Lys-Arg-Gly-Asp-D-Phe} (63 mg, 0.038 mmol) and Hunig's base (20 μL) in DMF (1 mL). The reaction mixture was allowed to stir under nitrogen at room-temperature overnight. The solvent was removed in vacuo, and the residue was triturated in ethyl acetate (10 mL), filtered, and washed with ethyl acetate to give the desired product (75.2 mg). Purification of the DOTA conjugate is achieved by preparative HPLC (Vydac reverse phase C_{18} column; solvent A: 0.1% TFA in water; solvent B: 0.1% TFA 90% aq. ACN). Removal of the mobile phase gave the product as a lyophilized solid. ES-MS: $m/z = 1873.9$ for $[\text{M} + \text{H}]^+$ ($\text{C}_{87}\text{H}_{138}\text{N}_{23}\text{O}_{23}$) and 937.2 for $[\text{M} + 2\text{H}]^{+2}$. The analytical HPLC method for the DOTA-conjugate used

Figure 1. Structures of SU015 and its yttrium and lutetium complexes.

a HP-1050 HPLC system with a Diode array detector ($\lambda = 220$ nm) and a Vydac C₁₈ column (4.6 mm $\times$ 250 mm, 80 Å pore size). The column temperature was 50 °C. The flow rate was 1 mL/min with the mobile phase starting 98% solvent A (0.1% TFA in water) and 2% solvent B (0.1% TFA in 90% acetonitrile) to 63.2% solvent A and 36.8% solvent B at 16 min. The retention time was 20.0 min, and the purity was 99%.

Synthesis of 2-(1,4,7,10-Tetraaza-4,7,10-tris(carboxymethyl)-1-cyclododecyl)-acetyl-Glu(cyclo{Lys-Arg-Gly-Asp-D-Phe})-cyclo{Lys-Arg-Gly-Asp-D-Phe} (SU015). A solution of 2-(1,4,7,10-tetraaza-4,7,10-tris(*tert*-butoxycarbonylmethyl)-1-cyclododecyl)acetyl-Glu(cyclo{Lys-Arg-Gly-Asp-D-Phe})-cyclo{Lys-Arg-Gly-Asp-D-Phe} (4.5 g, 2.4 mmol) in TFA (110 mL) was stirred at room temperature under nitrogen for 2 h. The solution was concentrated in vacuo, and the residue was purified by preparative HPLC (Vydac C₁₈ column; solvent A: 0.1% TFA in water; solvent B: 0.1% TFA 90% aq. ACN). Removal of the mobile phase gave the product as a lyophilized solid (1.5 g, tetra TFA salt). ES-MS: $m/z = 1703.8$ for $[M + H]^+$ (C₇₅H₁₁₄N₂₃O₂₃) and 853.0 for $[M + 2H]^{2+}$. The analytical HPLC method for SU015 used a HP-1050 HPLC system with a Diode array detector ($\lambda = 220$ nm) and a Vydac C₁₈ column (4.6 mm $\times$ 250 mm, 80 Å pore size). The column temperature was 50 °C. The flow rate was 1 mL/min with the mobile phase starting 98% solvent A (0.1% TFA in water) and 2% solvent B (0.1% TFA in 90% acetonitrile) to 63.2% solvent A and 36.8% solvent B at 16 min. The retention time was 13.4 min, and the purity was 97%.

A General Procedure for Synthesis of RP688 and RP697. To a shielded, clean 5 mL vial containing 100 μ g of SU015 and 1–10 mg of sodium gentisate (GA) dissolved in 0.5 mL of 0.5 M ammonium acetate buffer (pH = 7.0, 7.5, or 8.0) was added 10–40 μ L of ⁹⁰YCl₃ or ¹⁷⁷LuCl₃ solution (~ 20 mCi) in 0.05 N HCl. The reaction mixture was allowed to stand at room temperature or was heated at 50–100 °C for 5–30 min. For RP697, a sample of the resulting solution was diluted 20-fold with 4 mM DTPA solution (pH = 5) and then analyzed by HPLC (injection volume = 1–2 μ L) and by ITLC. For RP688, the resulting solution was used for HPLC analysis without dilution (injection volume = 3–5 μ L).

The HPLC method for analysis of RP688 and RP697 used a HP-1100 HPLC system with a UV/visible detector ($\lambda = 220$ nm), an IN-US radio-detector, and a Zorbax C₁₈ column (4.6 mm $\times$ 250 mm, 80 Å pore size). The flow rate was 1 mL/min with an isocratic mobile phase from 0 to 18 min using 87% solvent A (0.025 M ammonium acetate buffer, pH 6.8) and 13% solvent B (acetonitrile), followed by an isocratic wash using 40% of solvent A and 60% solvent B from 19 to 25 min. The ITLC method used Gelman Sciences silica gel ITLC paper strips and a 1:1 mixture of acetone and saline as eluant. By this method, RP697 and RP688 migrate to the solvent front while [⁹⁰Y]/[¹⁷⁷Lu]colloid and [⁹⁰Y]/[¹⁷⁷Lu]acetate remain at the origin.

Synthesis of [¹⁷⁵Lu]RP688 for LC-MS. To a clean 5 mL vial containing 5 mg of SU015, 10 mg of GA, and 10 mg of Lu(NO₃)₃·6H₂O was added 1.0 mL of 0.5 M ammonium acetate buffer (pH = 7.5). The reaction mixture was heated at 100 °C for 20 min. After cooling

Figure 2. Typical radio (top) and UV/vis (bottom) HPLC chromatograms for the reaction mixture containing RP697. The UV/vis trace was recorded by injecting the reaction mixture without dilution. There is a retention time difference (~ 1.0 min) for the two detectors since they were not synchronized.

to room temperature, a sample of the resulting solution was filtered, and the filtrate was analyzed by LC-MS. No further purification was performed for the LC-MS analysis.

The LC-MS spectra were collected using a HP1100 LC/MSD system with API-electrospray interface. The LC-MS method used a Zorbax C_{18} column (4.6 mm $\times$ 150 mm, 3.5 μm particle size) at a flow rate of 1 mL/min and a gradient mobile phase starting from 92% solvent A (10 mM ammonium acetate buffer, pH 7.0) and 8% solvent B (methanol) to 100% B at 23 min. The MSD parameters are as follows: detection mode: positive mass range: 600–2000; gain: 1.0; fragmentor: 30 V; gas temperature: 350 $^{\circ}\text{C}$; drying gas flow: 13 L/min; nebulizer pressure: 60 psig (max.); V capillary: 4000 V; UV/vis detector: $\lambda = 220$ nm.

RESULTS

Synthesis of RP688 and RP697. RP697 was prepared by reacting SU015 with $^{90}\text{YCl}_3$ in an ammonium acetate buffer (pH = 6.5–8) at 50–100 $^{\circ}\text{C}$. GA was used as a stabilizer to prevent radiolytic degradation of RP697. The total volume was always 0.5 mL, and the $^{90}\text{YCl}_3$ concentration was 40 mCi/mL. We typically used 100 μg of SU015 for 20 mCi of $^{90}\text{YCl}_3$ corresponding to a SU015: ^{90}Y ratio of $\sim 130:1$. The use of excess SU015 is to compensate for the presence of other trace metal contaminants. Under optimized conditions, RP697 can be prepared in high yield with the RCP > 95%. RP688 was prepared in a similar fashion by reacting SU015 with $^{177}\text{LuCl}_3$ (100 μg of SU015, 10 mg of GA for 20 mCi of $^{177}\text{LuCl}_3$, pH > 7.2, heating at 100 $^{\circ}\text{C}$ for 5 min).

HPLC Characterization. Figures 2 and 3 show typical HPLC (radio and UV) chromatograms for RP688 and RP697, both of which show only one radiometric peak. The retention time for RP688 and RP697 is almost identical under the same chromatographic conditions. There are several small peaks due to radioimpurities in the HPLC chromatogram of both RP688 and RP697. Since these radioimpurities are less than 1.0%, no further characterization was performed. Many attempts were made to use LC-MS for the characterization of the

Figure 3. Typical radio (top) and UV/vis (bottom) HPLC chromatograms for the reaction mixture containing RP688. There is a retention time difference (~ 1.0 min) for the two detectors since they were not synchronized.

reaction mixture containing RP697, but the results were often difficult to interpret, due to dilute concentration of RP697.

LC-MS Characterization of RP688. We have used LC-MS to determine the composition of RP688. To identify the peak due to RP688 in the UV profile, we also prepared the corresponding “cold” complex Lu(SU015) by reacting SU015 with excess of lutetium(III) nitrate in a 0.5 M ammonium acetate buffer (pH = 7.5). Figure 4 shows the UV/vis and MSD profiles for RP688 and ^{175}Lu (SU015). Figure 5 shows the LC-MS spectra of RP688 (bottom) and ^{175}Lu (SU015) (top). The LC-MS patterns of both complexes are identical except the difference in isotope. The LC-MS spectral data support the proposed structure (Figure 1). There are several other intense peaks due to complexes of trace metal contaminants in the reaction mixture containing RP688. The molecular weights (Table 1) corresponding to these peaks match those from Ca(SU015) ($t_R = 10.85$ – 10.91 min), Co(SU015) ($t_R = 10.05$ – 10.08 min), Zn(SU015) ($t_R = 10.11$ – 10.21 min), and Fe(SU015) ($t_R = 10.22$ – 10.32 min).

Buffer Concentration. In this experiment, we used 100 μg of SU015 and 10 mg of GA, 20 mCi of $^{90}\text{YCl}_3$, and ammonium acetate buffer (0.1, 0.25, or 0.5 M) to prepare RP697. The pH in the mixture was 7.2 after addition of $^{90}\text{YCl}_3$. The reaction mixture was heated at 100 $^{\circ}\text{C}$ for 10 min. Figure 6 shows that the buffer concentration does not have a significant impact on RCP as long as the pH is well controlled. The 0.5 M ammonium acetate buffer was chosen for the remaining radiolabeling experiments mainly due to its higher buffering capacity.

^{90}Y -Chelation Kinetics at Room Temperature. In this experiment, we explored the possibility of preparing RP697 by reacting 100 μg of SU015 with 20 mCi of $^{90}\text{YCl}_3$ in the presence of GA (10 mg) at room temperature. The pH in the reaction mixture was 6.6, 7.2, or 7.8 after addition of $^{90}\text{YCl}_3$. Samples of the reaction mixture were analyzed by radio-HPLC at 5, 30, 60, and 120 min. The RCP data are summarized in Figure 7. It is obvious that the rate of ^{90}Y chelation depends on the pH of the reaction mixture. At pH 6.6, the RCP for RP697 was only $\sim 60\%$ after 2 h at room temperature. It is possible to prepare RP697 with RCP > 90% at room temperature at pH > 7.0,

Figure 4. UV/vis ($\lambda = 220$ nm) and MSD profiles of the reaction mixture containing $[^{175}\text{Lu}]\text{RP688}$ (top) and RP688 (bottom).

Figure 5. LC-MS spectra for $[^{175}\text{Lu}]\text{RP688}$ (top) and RP688 (bottom). The y-axis represents intensity of the signal. The x-axis represents m/z ratio.

but the RCP of RP697 could not be further improved. The elevated temperatures are needed to complete the ^{90}Y chelation.

Preparation of RP697 at 50°C . In this experiment, we prepared RP697 using $100\ \mu\text{g}$ of SU015 and $10\ \text{mg}$ of GA for $20\ \text{mCi}$ of $^{90}\text{YCl}_3$. The pH in the mixture was 7.2 or 7.8 after addition of $^{90}\text{YCl}_3$. After heating at 50°C for 5, 10, and 30 min, a sample of the reaction mixture was analyzed by radio-HPLC and ITLC. It was found (Figure 8) that at pH 7.8 heating at 50°C for 5 min is sufficient

Figure 6. Effect of the buffer concentration on RCP of RP697 .

Figure 7. Room temperature ^{90}Y chelation kinetics at pH = 6.6, 7.2, and 7.8.

to achieve 95% RCP for RP697 . The maximum RCP was obtained by heating the reaction mixture at 50°C for 10 min.

Preparation of RP697 at 100°C . In this experiment, we prepared RP697 using $100\ \mu\text{g}$ of SU015 and $10\ \text{mg}$ of GA for $20\ \text{mCi}$ of $^{90}\text{YCl}_3$ at pH 6.6, 7.2 or 7.8. The reaction mixture was heated at 100°C for 5, 10, 15, and 30 min. Figure 9 shows the effect of heating time on the RCP of RP697 at different pH values. It is clear that 5 min heating is sufficient to complete the ^{90}Y chelation at pH 7.8. Prolonged heating is detrimental due to hydrolysis and radiolytic decomposition of the radiolabeled peptide.

^{90}Y -Labeling Efficiency of SU015 . We studied the ^{90}Y -labeling efficiency of SU015 by determining the minimal amount of SU015 required to achieve 95% RCP for RP697 . In this experiment, the heating temperature was 100°C and the heating time was 10 min. Figure 10

Figure 8. Effect of heating (at 50 °C) time on RCP of RP697 at pH 7.2 and 7.8.

Figure 9. Effect of heating (at 100 °C) time on RCP of RP697 at pH 6.6, 7.2, and 7.8.

Figure 10. Effect of the pH on radiolabeling efficiency.

shows RCP data for RP697 prepared using 25, 50, or 100 μg of SU015, 10 mg of GA, 20 mCi of $^{90}\text{YCl}_3$, at pH 6.6, 7.2, or 7.8. Obviously, the pH has dramatic impact on the ^{90}Y -labeling efficiency of SU015. At pH 7.2–7.8, the minimum amount of SU015 required to achieve 95% RCP for RP697 is about 25 μg for 20 mCi of $^{90}\text{YCl}_3$ corresponding to a SU015: ^{90}Y ratio of $\sim 30:1$.

DISCUSSION

Therapeutic radiopharmaceuticals are radiolabeled molecules designed to deliver therapeutic doses of ionizing radiation to specific disease sites (17). Most systemically administered therapeutic radiopharmaceuticals are small organic or inorganic compounds with definite composition. They can also be macromolecules such as monoclonal antibodies and antibody fragments labeled with a therapeutic radionuclide. Ideally, a therapeutic radiopharmaceutical should localize at the tumor sites in high concentration and deliver sufficient radiation dose to tumor cells, while clearing rapidly from the blood to minimize radiation damage to normal tissues.

While tumor imaging relies heavily on a high target-to-background ratio for the best contrast, tumor therapy depends largely on a high concentration of radioactivity for a long duration. Thus, the therapeutic radiopharmaceutical must have high and fast tumor uptake, high tumor-to-background ratio, long tumor residence time, and fast renal clearance. High tumor uptake and fast renal clearance are particularly important to a high tumor-to-background ratio and to reduce the radiation burden to other major organs (kidney, liver, and bone marrow). The new radiopharmaceutical must have high radiochemical purity (RCP $\geq 90\%$) and high solution stability. Unlike diagnostic radiopharmaceuticals, which are typically made by radiopharmacists before injection, therapeutic radiopharmaceuticals have to be manufactured and released under GMP (Good Manufacturing Practice) conditions. Therefore, the radiopharmaceutical must retain its chemical and biological integrity during release and transportation.

Choice of Biomolecules. Angiogenesis, the formation of new blood vessels, is a requirement for malignant tumor growth and metastasis (18–20). The angiogenic process depends on vascular endothelial cell migration and invasion, regulated by cell adhesion receptors (21–29). The integrin $\alpha\beta_3$ (vitronectin receptor) is such a cell adhesion receptor and interacts with proteins and peptides containing the RGD tripeptide recognition sequence. Many peptide vitronectin receptor antagonists have very high binding affinity for the vitronectin receptor and have been shown to be able to inhibit neovascularization, tumor-induced angiogenesis, and tumor growth (27–33). Recently, Kessler and co-workers (34, 35) reported two ^{125}I -labeled cyclic pentapeptides: 3- ^{125}I -D-Tyr⁴-cyclo(RGDyV) and 3- ^{125}I -D-Tyr⁴-cyclo(RGDyK(SAA1)) (SAA = sugar amino acid). It was found that 3- ^{125}I -D-Tyr⁴-cyclo(RGDyV) has fast hepatobiliary and renal excretion (34). The tumor/muscle and tumor/blood ratios for melanoma in nude mice were 5.5 and 9.5, respectively, at 60 min postinjection. Substitution of leucine with a SAA-functionalized lysine amino acid residue resulted in improved blood retention time, renal excretion, and better target-to-background ratio. A blocking study using 3 mg/kg of the $\alpha\beta_3$ selective cyclo(RGDfV) demonstrated that the localization of radioactivity in the tumor is due to $\alpha\beta_3$ binding.

In our previous communication (15), we reported a $^{99\text{m}}\text{Tc}$ -labeled vitronectin receptor antagonist (RP593) and its biological properties in two spontaneous tumor models (c-Neu Oncomouse and dog). The high tumor uptake and long tumor residence time (3.4% ID/g at 2 h and 1.5% ID/g at 24 h postinjection in the c-Neu Oncomouse tumor model) led us to prepare the corresponding ^{90}Y and ^{177}Lu complexes, which have the potential for radiotherapy of a wide spectrum of tumors.

Choice of Radionuclides. Identifying an appropriate isotope for radiotherapy is often a difficult task and requires weighing a variety of factors (36, 37). These include tumor uptake, blood clearance, duration of receptor binding, rate of radiation delivery, half-life and specific activity of the radionuclide, and the feasibility of large-scale production of the radionuclide in an economical fashion. The ultimate goal for a therapeutic radiopharmaceutical is to deliver the maximum amount of radiation dose to the tumor cells to achieve a cytotoxic effect without causing unmanageable side-effects.

The physical half-life of the therapeutic radionuclide should match the biological half-life of the radiopharmaceutical at the tumor site. If the half-life of the radionuclide is too short, much of the decay will have occurred

before the radiopharmaceutical has reached the maximum target/background ratio. In this situation, attaining a sufficient integrated tumor dose for cytotoxicity (>50 Gy) will prove problematic. On the other hand, too long a half-life would cause unnecessary radiation dose to normal tissues. Ideally, the radionuclide should have a long enough half-life to attain a minimum dose rate (>0.4 Gy/h) and to irradiate all the cells during the most radiation sensitive phases of the cell cycle. In addition, the half-life of the therapeutic radionuclide has to be long enough to allow adequate time for manufacturing, release, and transportation.

We are interested in ^{177}Lu and ^{90}Y for their opposite nuclear properties. ^{90}Y is a high-energy β -emitter ($E_{\text{max}} = 2.23$ MeV) and has a half-life of 2.67 days while ^{177}Lu is a low energy β -emitter ($E_{\text{max}} = 0.5$ MeV) with a half-life of 6.67 days. Yttrium and lutetium share similar coordination chemistry, and chelator technologies have been well established for the radiolabeling of biomolecules with these isotopes. Depending on the tumor size and location, the low energy β -emitter, ^{177}Lu , may be better for smaller metastases while the high-energy β -emitter, ^{90}Y , may be superior for large tumors.

Choice of BFC. Polyazamacrocycles have been widely used as BFCs for the radiolabeling of biomolecules with various radionuclides (36–52). We chose DOTA as the BFC for several reasons. The macrocyclic framework is well organized so that it forms yttrium and lutetium complexes with high thermodynamic stability and kinetic inertness (40, 41). The pK_a values of the carboxylic groups are in the range 2–5. Lower pK_a values result in less competition from proton, high stability of the metal complex, and minimum acid-assisted demetalation, even under acidic ($\text{pH} \leq 2$) conditions. Conjugation of biomolecules can be easily achieved using one of the carboxylic groups. The acetate groups attached to the nitrogen donor atoms have low molecular weight, and are very hydro-

**Figure 11.** Possible structures for reaction intermediates and Y(DOTA-MA).

philic. Therefore, the contribution of the BFC to the overall molecular weight of the DOTA-BM conjugate can be minimized. The high hydrophilicity improves the pharmacokinetics of the radiopharmaceutical.

Characterization of RP688 and RP697. For the past decade, HPLC has become a routine technique for quality control of various radiopharmaceuticals. The advantage of radio-HPLC is its capability to determine the RCP for RP688 and RP697, and to separate different $^{90}\text{Y}/^{177}\text{Lu}$ species in the reaction mixture. It is also a very powerful tool for separation of diastereomers. However, radio-HPLC also has its limitations. For example, it cannot be used for the assessment of the amount of [$^{90}\text{Y}/^{177}\text{Lu}$]colloid in the reaction mixture. Therefore, a TLC method is needed in combination with radio-HPLC to assess the radiochemical purity of the RP688 and RP697. In addition, a 4 mM DTPA solution ($\text{pH} = 5$) is recommended for dilution of the reaction mixture in order to accurately determine unchelated $^{90}\text{Y}/^{177}\text{Lu}$ during the standard quality control by HPLC (51). If DTPA is not used, the unchelated $^{90}\text{Y}/^{177}\text{Lu}$ will be readily bound to the column, thereby giving a false indication of the radiochemical purity of the radiopharmaceutical.

In this study, we used a reverse phase HPLC method to analyze RP688 and RP697. The mobile phase was isocratic at 13% organic solvent (acetonitrile) to maximize the separation of different radiometal-containing species. We also recorded the UV/vis ($\lambda = 220$ nm) profiles in order to assess the extent of trace metal contamination. Figures 2 and 3 show typical HPLC (both radio and UV/vis) chromatograms for RP688 and RP697, respectively. Both RP697 and RP688 show one radiometric peak. We

Figure 12. Possible structures of $\text{Y}(\text{DOTA-MA})^{2+}$, $\text{Y}(\text{DOTA-MA})^+$, and $\text{Y}(\text{DOTA-MA})$.

also tried several other reverse phase HPLC methods. In all the cases, RP697 and RP688 show only one radiometric peak, suggesting that they exist in solution as only one *detectable* isomeric form. RP688 and RP697 have almost identical retention time under the same chromatographic conditions, indicating that yttrium and lutetium share the same coordination chemistry in solution.

In the solid state, the complex $\text{Y}(\text{DOTA-MA})$ (MA = monoamide) has a square antiprismatic geometry with four amine-nitrogen, one carbonyl-oxygen, and three carboxylate-oxygen atoms bonding to the yttrium metal (52). In principle, there should be four possible isomers (**A–D** in Figure 11) for the complex $\text{Y}(\text{DOTA-MA})$. Isomers **A** and **B** are enantiomers and indistinguishable by the reverse phase HPLC method. Isomers **C** and **D** represent the other pair of enantiomers. Isomers **A** and **B** are close to square prismatic with the acetate arms in a different layout and the cyclododecane ring conformation being identical to those of **C** and **D**. Conjugation of an optically pure peptide will not produce extra isomers, but it may result in the formation of one predominant isomeric form. These four possible isomers are not enantiomers but diastereomers, which are theoretically expected to be separable using a reverse phase HPLC method, particularly with an isocratic mobile phase. The fact that both RP688 and RP697 showed only one radiometric peak in their radio-HPLC chromatograms suggests that they exist in solution as only one predominant isomer, and is consistent with the observation of only m-isomer in the solid state of the complex $\text{Y}(\text{DOTA-D-Phe-NH}_2)$ (52).

Factors Influencing ^{90}Y Chelation. There are many factors influencing the ^{90}Y chelation and RCP of RP697. These include the purity of SU015, the pH, reaction temperature and heating time, buffer agent and buffer concentration, stabilizing agent, as well as trace metal contaminants, such as Ca^{2+} , Fe^{3+} , and Zn^{2+} . The goal of this study was to explore the factors influencing the RCP and to prepare RP697 in high RCP to support preclinical studies.

Trace Metal Contaminants. DOTA and its derivatives form complexes with most divalent and trivalent metal ions. These metal complexes often have extremely high thermodynamic stability and kinetic inertness. As a matter of fact, one of the most important factors influencing the radiolabeling efficiency of a DOTA-BM conjugate is the presence of trace metal contaminants in the reaction mixture. The trace metal contaminants may come from the buffering agent, glass vials, stoppers,

the radiometal stock solution, and the stabilizing agent. To minimize the amount of contaminants, we always used acid-treated 5 mL glass vials, and Teflon-coated stoppers to prevent leaking of metal ions. If possible, all the reagents should be extra-pure.

Table 1 shows the maximum limits of trace metal contaminants (as of the production date) in the $^{90}\text{YCl}_3$ stock solution from NEN and the stability constants of their DOTA complexes (53–57). Most of the trace metals (Al, Ca, Ce, Co, Cr, Cu, Fe, La, Ni, Pb, Zn, and Zr) in the $^{90}\text{YCl}_3$ stock solution have the potential to influence the ^{90}Y labeling of a DOTA-BM conjugate. The actual metal contaminant concentration may not be as high as specified by the manufacturer, but the UV profile of the reaction mixture containing RP697 (Figure 2) shows that the concentration of total trace metal contaminants is much higher than that of ^{90}Y .

Unlike ^{90}Y , a generator-produced radionuclide, ^{177}Lu is a reactor-produced isotope, made by irradiating ^{176}Lu -enriched lutetium metal. While other trace metal contaminants can be separated, ^{176}Lu remains in the $^{177}\text{LuCl}_3$ stock solution (in 0.05 N HCl) after chromatographic purification. The specific activity for ^{177}Lu is ~ 20 Ci/mg. Although the specific activity of ^{177}Lu is much lower than that of ^{90}Y (~ 500 Ci/mg, carrier free), RP688 can be prepared using identical radiolabeling conditions as RP697 (100 μg SU015 and 10 mg of GA for 20 mCi of $^{177}\text{LuCl}_3$).

Recently, we reported a LC-MS method for the characterization of $^{99\text{m}}\text{Tc}$ -labeled bioconjugates at the tracer level (58). In this study, we used the same MSD parameters to analyze the reaction mixture containing RP688. We found several other metal complexes: including Ca-(SU015) ($t_R = 10.85\text{--}10.91$ min), Zn-(SU015) ($t_R = 10.11\text{--}10.21$ min), and Fe-(SU015) ($t_R = 10.22\text{--}10.32$ min). The concentration of RP688 is much lower than those of Ca-(SU015), Zn-(SU015), and Fe-(SU015). This is especially true when reagent grade ammonium acetate was used as the buffering agent and the Teflon-coated stoppers were not used for the radiolabeling.

^{90}Y Chelation Kinetics. We first explored the possibility of preparing RP697 at room temperature. We found that the ^{90}Y chelation is very much dependent on the pH of the reaction mixture. We also found that the buffer concentration does not have a significant impact on the ^{90}Y chelation as long as the pH is well controlled. While it is possible to prepare RP697 with RCP > 90% at room temperature at pH > 7.0, the RCP of RP697 could not be further improved. Thus, it is necessary to use elevated temperatures to complete the ^{90}Y chelation.

These results are consistent with those reported by Meares and co-workers (48). Higher temperature increases the rate of ^{90}Y chelation, but prolonged heating is detrimental to the RCP of RP697 due to hydrolysis and radiolytic decomposition. For example, heating at 50 °C for 5 min is sufficient to achieve 95% RCP for RP697 if the pH is 7.2–7.8 (Figure 8). However, the RCP can be increased by heating at 50 °C for > 10 min. At 100 °C, only 5 min is needed to complete the ^{90}Y chelation at pH 7.8, while the optimal heating time at pH 7.2 is 10 min. In addition, the pH also shows a dramatic impact on the ^{90}Y -labeling efficiency of SU015. At pH 7.2–7.8, the minimum amount of SU015 required to achieve 95% RCP for RP697 is $\sim 25\ \mu\text{g}$ for 20 mCi of $^{90}\text{YCl}_3$ corresponding to a SU015: ^{90}Y ratio of $\sim 30:1$.

Like DOTA, DOTA-MA (MA = monoamide) also exists in solution as its zwitterion form, and the conformation of the chelator is determined by the degree of protonation of DOTA-MA (59, 60). For example, the predominant form at pH 3.6–5.0 is $\text{H}_3(\text{DOTA-MA})^-$ while DOTA-MA exists primarily as $\text{H}_2(\text{DOTA-MA})^{2-}$ and $\text{H}(\text{DOTA-MA})^{3-}$ at pH > 7.0. The formation of $\text{Y}(\text{DOTA-MA})$ proceeds via two intermediate complexes: $\text{YH}_2(\text{DOTA-MA})^{2+}$ and $\text{YH}(\text{DOTA-MA})^+$. The rate-limiting step is most likely the proton transfer from $\text{YH}(\text{DOTA-MA})^+$ to form the eight-coordinated complex $\text{Y}(\text{DOTA-MA})$ since it requires a significant rearrangement of the macrocyclic ring, including rotation of C–C and C–N bonds and inversion of the N-atom. Once the proton is removed, chelation of the remaining three N-atoms will be fast to give the final product. Therefore, higher pH gives a faster chelation rate.

Different protonated intermediates of DOTA-MA form yttrium complexes with different structures (Figure 12). It is most likely that in the doubly protonated complex $\text{YH}_2(\text{DOTA-MA})^{2+}$, the Y atom is coordinated solely by one carbonyl and three carboxylate oxygens. Upon removal of one proton from the ring nitrogen to form the intermediate, $\text{YH}(\text{DOTA-MA})^+$, the Y atom moves toward the ring and becomes five-coordinated to four oxygen atoms and one ring nitrogen atom. Because of static interaction, the N-atom bonding to the metal is most likely to be the one trans to the protonated N-atom. With the removal of the last proton, the expected eight-coordinated complex $\text{Y}(\text{DOTA-MA})$, with a square antiprismatic coordination geometry, is formed.

CONCLUSIONS

In conclusion, we synthesized ^{90}Y and ^{177}Lu complexes (RP697 and RP688, respectively) of a DOTA-conjugated vitronectin receptor antagonist (SU015). Through a series of radiolabeling experiments, we found that there are many factors influencing the rate of ^{90}Y chelation and the labeling efficiency of SU015. These include the purity of the SU015, the pH, reaction temperature, and heating time, as well as trace metal contaminants, such as Ca^{2+} , Fe^{3+} and Zn^{2+} . Among them, pH is the most dominant factor. Compared to that of the corresponding DTPA analogues (58), the ^{90}Y chelation kinetics are slow and heating at elevated temperatures (50–100 °C) is needed to complete the ^{90}Y labeling. Under optimized radiolabeling conditions (pH 7.2–7.8 and heating at 50–100 °C for 5–10 min), the minimum amount of SU015 required to achieve 95% RCP for RP697 is $\sim 25\ \mu\text{g}$ for 20 mCi of $^{90}\text{YCl}_3$ corresponding to a SU015: ^{90}Y ratio of $\sim 30:1$. The formulation developed in this study may be used for the ^{90}Y and ^{177}Lu labeling of other DOTA-conjugated biomolecules.

Acknowledgment is made to Anthony R. Harris for the synthesis of DOTA-conjugated cyclic peptide (SU015).

In Vitro Gene Transfer with a Novel Galactosylated Spermine Bolaamphiphile

Jérôme Gaucheron, Catherine Santaella,[†] and Pierre Vierling*

Laboratoire de Chimie Bioorganique, UMR 6001 CNRS-Université de Nice Sophia-Antipolis, Faculté des Sciences, 06108 Nice Cédex 2, France. Received December 18, 2000; Revised Manuscript Received March 28, 2001

We describe the synthesis of a α -galacto- ω -spermine bolaamphiphile (GalSper) and report on the gene transfer mediated with lipoplexes it forms either when used alone or in conjunction with DOPE or with DOGS (Transfectam). Lipofection with GalSper was investigated with human HepG2 or murine BNL-CL2 hepatocytes expressing the asialo-glycoprotein (ASGP) receptor, which displays a high affinity for galactosyl residues, or with A549 cells which do not express ASGP. Although lower luciferase expression levels in BNL-CL2 and in HepG2 cells were obtained with GalSper/DOPE N/P 2.5 lipoplexes as compared with control DOGS/DOPE N/P 2.5 particles or with the more positively charged N/P 5 particles (yet through a different mechanism), specific receptor-mediated endocytosis of DNA can be achieved with this targeted cationic GalSper bolaamphiphile presenting a single galactose residue. The present work suggests that GalSper-based DNA formulations appear as promising synthetic vectors for specific gene delivery to ASGP(+) cells.

INTRODUCTION

Nonviral gene transfer devices hold considerable potential for gene therapy of inherited or acquired diseases. This has led over the past decade to the development of various (poly)cationic lipids and polymers which form with DNA lipoplexes (1–8) and polyplexes (3, 5, 8–15), respectively, through electrostatic interactions. These synthetic systems provide receptor-independent gene transfer into various cell types, as the cationized gene particles bind to the anionic proteoglycans which are expressed on the cell surface (16, 17).

Successful in vivo gene transfer and gene therapy will depend on the efficient delivery of genetic material to specific cells and its effective expression within these cells. Aiming at these goals, various cell-targeting ligands (transferrin (18), mannose, galactose and other oligosaccharides, RGD-peptides and other peptides, antibodies, folate; for a recent review, see ref 19) were conjugated to the DNA complexes in order to trigger receptor-mediated endocytosis. To our knowledge, only a few targetable lipids and targetable quaternary ammonium amphiphiles linked to sugar residues (20–23), for which a selective lipoplex-mediated gene transfer has been demonstrated (20–22), have been described. As part of our contribution into this field, we have performed the synthesis of a α -galacto- ω -spermine bolaamphiphile (GalSper in Scheme 1). The rationale for such a design is that it combines spermine, which is known to spontaneously compact a nucleic acid (lipospermines are among the cationic lipids tested so far the most efficient synthetic gene transfer agents) linked, through a hydrophobic group, to a galactosyl residue which serves as a molecular signal for cell targeting. As a high density of galactose residues (which is important for effective receptor-mediated gene transfer

(21)) can be provided on the lipoplex surface on compacting DNA with such bolaamphiphiles, the sugar moieties are likely to prevent the lipoplexes from aggregation, coating with serum lipophilic proteins and/or binding to the anionic proteoglycans of the extracellular matrix (16, 17).

Here we describe the synthesis of the GalSper bolaamphiphile (Scheme 1) and report on the gene transfer mediated with lipoplexes it forms either when used alone or in conjunction with DOPE (which, as colipid, was found in several cases to enhance the transfection activity of cationic lipids (24, 25)) or with DOGS (or Transfectam) (5). Lipofection with GalSper was investigated with various cells (human HepG2 or murine hepatocytes BNL-CL2) expressing the asialo-glycoprotein (ASGP) receptor, which displays a high affinity for galactosyl residues (20–22, 26–29), or not (A549 cells which derive from a human carcinoma). Although the remainder of our initial goal was not fully reached, GalSper constitutes a very promising lead molecule worth studying.

MATERIALS AND METHODS

Analytical Conditions, Chemicals, Expression Vectors, and Cells. Column chromatography purifications were carried out using Merck silica gel 60 (mesh 70–230) and/or Sephadex LH 20 gel (Aldrich). Thin-layer chromatography (TLC) analyses were performed on pre-coated silica gel F₂₅₄ plates (Merck) and visualized by UV light ($\lambda = 254$ nm) and by charring with KMnO₄, 50% MeOH–H₂SO₄, or ninhydrine. ¹H and ¹³C NMR spectra were recorded at 200 and 50.3 MHz, respectively, on a Bruker AC-200. Chemical shifts were measured relative to CHCl₃ (δ 7.27 ppm) or CH₃OD (δ 3.35 ppm) for ¹H, relative to CDCl₃ (δ 76.9 ppm) for ¹³C and expressed in ppm indirectly in relation to TMS. The following abbreviations are used to describe the signal multiplicities: s (singlet), d (doublet), t (triplet), q (quadruplet), and m (multiplet). Chemical shifts are listed as follows: shift in ppm (multiplicity, coupling, integration, and attribution). Electrospray ionization mass spectrometry

Scheme 1. Synthetic Route to the α -Galacto- ω -spermine Bolaamphiphile, GalSper

(ESI-MS) in positive and negative mode of GalSper was performed on a Finnigan MAT TSQ 7000 equipped with an atmospheric pressure ionization (API) source.

1-(2-Thioxo-thiazolidin-3-yl)-octadec-9-enyl-1-one was obtained from oleic acid chloride and 2-thiazoline-2-thiol according to ref 30. TLC ($\text{CH}_2\text{Cl}_2/\text{hexane}$: 1/1: v/v): R_f 0.46. ^1H NMR (CDCl_3): δ 0.89 (t, $^3J = 6.4$ Hz, 3H, CH_3); 1.18–1.50 (broad s, 20H, $(\text{CH}_2)_6\text{CH}_2\text{CH}=\text{CHCH}_2(\text{CH}_2)_4$); 1.50–1.72 (m, 2H, $\text{CH}_2\text{CH}_2\text{C}(\text{O})$); 1.90–2.12 (m, 4H, $=\text{CHCH}_2$); 3.23 (t, $^3J = 7.4$ Hz, 2H, $\text{CH}_2\text{C}(\text{O})$); 3.28 (t, $^3J = 7.5$ Hz, 2H, CH_2N); 4.57 (t, $^3J = 7.5$ Hz, 2H, CH_2S); 5.24–5.46 (m, 2H, CH). ^{13}C NMR (CDCl_3): δ 14.1 (CH_3); 22.7 (CH_3CH_2); 24.7 ($\text{CH}_2\text{CH}_2\text{C}(\text{O})$); 27.2, 27.3 ($=\text{CHCH}_2$); 28.3 (CH_2S); 29.1, 29.2, 29.4, 29.6, 29.7, 29.8 ($(\text{CH}_2)_4\text{CH}_2\text{CH}=\text{CHCH}_2(\text{CH}_2)_3$); 31.9 ($\text{CH}_3\text{CH}_2\text{CH}_2$); 38.6 ($\text{CH}_2\text{C}(\text{O})$); 56.2 (CH_2N); 129.7, 130.0 (CH), 175.0 ($\text{C}=\text{O}$); 201.6 ($\text{C}=\text{S}$).

The lipoplexes investigated here were prepared either from plasmid pTG11033 (pCMV-intronHMG-luciferase-SV40pA, 9514 bp) or from plasmid pTG11236 (pCMV-SV40-luciferase-SV40pA, 5739 bp). These plasmids contain the luciferase gene under the control of the CMV immediate early 1 promoter. Their endotoxin content (<1 endotoxin unit/mg of plasmid) was checked using a Limulus Amebocyte Lysate kit (Biogenic, France).

For in vitro transfection, epithelial A549 cells (from human pulmonary carcinoma), human hepatoma HepG2 cells or murine embryo BNL-CL2 hepatocytes were grown 24 h before the experiments in Dulbecco-modified Eagle culture medium (DMEM; Gibco-BRL), containing 10% foetal calf serum (FCS; Sigma), in 96-well plates (2×10^4 cells per well), in a wet (37°C) and 5% $\text{CO}_2/95\%$ air atmosphere.

Chemistry. *Synthesis of N-[11-(Sodium oxycarbonyl)-undecyl]-1-amino-1-deoxylactitol (1).* A solution of sodium 12-aminododecanoate (5.0 g, 23 mmol; Aldrich) in 60 mL of MeOH was added to lactose (5.0 g, 14 mmol; Aldrich) in 30 mL of H_2O . The resulting mixture was stirred during 18 h at room temperature and then heated at 55°C for 6 h. Then, sodium borohydride (570 mg, 15 mmol; Aldrich) was added at room temperature, and the resulting mixture was stirred during 12 h. After evaporation, the residue was chromatographed on a silica gel column (200 g, CHCl_3 to $\text{CHCl}_3/\text{MeOH}/\text{NH}_4\text{OH}$: 5/5/1.5: v/v/v) leading to 3.1 g (40%) of **1** as white powder. TLC ($\text{CHCl}_3/\text{MeOH}/\text{NH}_4\text{OH}$: 5/5/1.5: v/v/v): R_f 0.53. ^1H NMR(D_2O): δ

1.12–1.40 (broad s, 14H, $\text{N}(\text{CH}_2)_2(\text{CH}_2)_7$); 1.40–1.57 (m, 2H, $\text{CH}_2\text{CH}_2\text{C}(\text{O})$); 1.57–1.80 (m, 2H, NCH_2CH_2); 2.12 (t, $J = 7.3$ Hz, 2H, $\text{CH}_2\text{C}(\text{O})$); 2.91–3.19 (m, 4H, CH_2N); 3.19–4.29 (m, 12H, CHOH , CHO , CH_2OH); 4.46 (d, $J = 7.5$ Hz, 1H, Gal H1). ^{13}C NMR ($\text{CDCl}_3/\text{CD}_3\text{OD}/\text{NH}_4\text{OH}$): δ 26.1, 26.4, 27.7, 28.7, 28.8, 29.1 ($\text{NCH}_2(\text{CH}_2)_9$); 37.7 ($\text{CH}_2\text{C}(\text{O})$); 51.1 (CH_2N); 61.1 (CH_2OH); 62.0 (Gal C6); 68.8, 70.9, 71.1 (CHOH); 69.3 (Gal C4); 71.0 (Gal C2); 72.9 (Gal C3); 75.3 (Gal C5); 79.6 ($\text{OCH}(\text{CHOH})_2$); 103.1 (Gal C1); 182.0 ($\text{C}=\text{O}$).

Synthesis of N-[11-(Sodium oxycarbonyl)-undecyl]-N-oleoyl-1-amino-1-deoxylactitol (2). A solution of **1** (0.60 g, 1.05 mmol), 1-(2-thioxo-thiazolidin-3-yl)-octadec-9-enyl-1-one (0.76 g, 2.17 mmol), and NEt_3 (0.2 mL; 1.44 mmol) in 100 mL of DMF was stirred during 7 days at 60°C . After evaporation and chromatography on a silica gel column (30 g, CHCl_3 to $\text{CHCl}_3/\text{MeOH}/\text{NH}_4\text{OH}$: 6/4/0.5: v/v/v), 140 mg (15%) of **2** was obtained as a white powder. TLC ($\text{CHCl}_3/\text{MeOH}/\text{NH}_4\text{OH}$: 5/5/1.5: v/v/v): R_f 0.66. ^1H NMR (CD_3OD): δ 0.81 (t, $J = 6.4$ Hz, 3H, CH_3); 1.06–1.41 (broad s, 34H, $\text{N}(\text{CH}_2)_2(\text{CH}_2)_7$, $(\text{CH}_2)_4\text{CH}_2\text{CH}=\text{CHCH}_2(\text{CH}_2)_6$); 1.41–1.72 (m, 6H, $\text{CH}_2\text{CH}_2\text{C}(\text{O})$, NCH_2CH_2); 1.81–2.08 (m, 4H, $=\text{CHCH}_2$); 2.15 (t, $J = 7.3$ Hz, 2H, $\text{CH}_2\text{C}(\text{O})$); 2.24–2.47 (m, 2H, $\text{CH}_2\text{C}(\text{O})\text{N}$); 3.06–4.07 (16H, CHOH , CHO , CH_2OH , $\text{C}(\text{O})\text{NCH}_2$); 4.38 (d, $J = 7.5$ Hz, 1H, Gal H1); 5.16–5.35 (m, 2H, $=\text{CH}$). ^{13}C NMR (CD_3OD): δ 14.5 (CH_3); 23.7 (CH_3CH_2); 26.4 ($\text{CH}_2\text{CH}_2\text{C}(\text{O})\text{N}$); 26.6, 26.8, 27.8, 28.0, 28.5, 29.9, 30.3, 30.4, 30.6, 30.8 ($(\text{CH}_2)_9\text{CH}_2\text{C}(\text{O})$, $(\text{CH}_2)_4\text{CH}_2\text{CH}=\text{CHCH}_2(\text{CH}_2)_4$); 28.1 ($=\text{CHCH}_2$); 33.1 ($\text{CH}_3\text{CH}_2\text{CH}_2$); 34.1, 34.4 ($\text{CH}_2\text{C}(\text{O})\text{N}$); 36.2 ($\text{CH}_2\text{C}(\text{O})\text{O}$); 47.7, 50.5, 50.7, 51.7 (CH_2N); 62.5 (CH_2OH); 63.6 (Gal C6); 70.2, 70.3, 70.8, 71.9, 72.0, (CHOH); 72.7 (Gal C4); 72.9 (Gal C2); 74.9 (Gal C3); 77.2 (Gal C5); 83.6 ($\text{OCH}(\text{CHOH})_2$); 105.7 (Gal C1); 130.9, 131.0 (CH); 176.3, 176.4 ($\text{NC}(\text{O})$); 179.5 ($\text{C}(\text{O})\text{O}$). The doubling of some signals indicates the presence of conformational isomers due to restricted rotation of the amide bound.

Synthesis of GalSper. To a solution of spermine (250 mg, 1.20 mmol; Fluka), **3** (100 mg, 0.12 mmol), and 0.2 mL of NEt_3 (1.4 mmol) in 4 mL of DMF was added 60 mg of BOP (0.13 mmol; Novabiochem). After 1 h at room temperature, evaporation and chromatography on Sephadex LH20 (5 g, MeOH), GalSper (102 mg; 84%) was isolated as a white powder. ^1H NMR (CD_3OD): δ 0.86 (t,

$J = 6.4$ Hz, 3H, CH_3); 1.12–1.43 (broad s, 34H, $\text{N}(\text{CH}_2)_2-(\text{CH}_2)_7$, $(\text{CH}_2)_4\text{CH}_2\text{CH}=\text{CHCH}_2(\text{CH}_2)_6$); 1.43–1.82 (m, 14H, $\text{CH}_2\text{CH}_2\text{C}(=\text{O})$, $\text{N}(\text{H})\text{CH}_2\text{CH}_2$, NCH_2CH_2); 1.89–2.07 (m, 4H, $=\text{CHCH}_2$); 2.14 (t, $J = 7.3$ Hz, 2H, $\text{CH}_2\text{C}(=\text{O})\text{N}(\text{H})$); 2.24–2.51 (m, 2H, $\text{NC}(=\text{O})\text{CH}_2$); 2.51–2.89 (m, 10H, $\text{CH}_2\text{-NH}_2$, $\text{CH}_2\text{N}(\text{H})\text{CH}_2$); 3.19 (t, $J = 7.5$ Hz, $\text{C}(=\text{O})\text{N}(\text{H})\text{CH}_2$); 3.25–4.11 (16H, CHOH , CH_2OH , CHO , $\text{CH}_2\text{NC}(=\text{O})$); 4.44 (d, $J = 7.5$ Hz, 1H, Gal H1); 5.25–5.36 (m, 2H, $=\text{CH}$). ^{13}C NMR (CD_3OD): δ 14.4 (CH_3); 23.6 (CH_3CH_2); 27.0 ($\text{CH}_2\text{CH}_2\text{C}(=\text{O})\text{N}$); 26.5, 26.7, 27.9, 28.3, 30.1, 30.2, 30.3, 30.5, 30.7 ($(\text{CH}_2)_9\text{CH}_2\text{NC}(=\text{O})$, $\text{CH}_2\text{CH}_2\text{N}(\text{H})$, $(\text{CH}_2)_4\text{-CH}_2\text{CH}=\text{CHCH}_2(\text{CH}_2)_4$); 28.0 ($=\text{CHCH}_2$); 32.9 ($\text{CH}_3\text{-CH}_2\text{CH}_2$); 33.9, 34.2 ($\text{NC}(\text{O})\text{CH}_2$); 37.0 ($\text{CH}_2\text{C}(=\text{O})\text{NH}$); 37.8 ($\text{C}(=\text{O})\text{N}(\text{H})\text{CH}_2$); 40.2, 47.4, 47.8, 49.9, 50.0 ($\text{CH}_2\text{-NHCH}_2$, CH_2NH_2); 50.7, 51.8 ($\text{CH}_2\text{NC}(=\text{O})$); 62.4 ($\text{CH}_2\text{-OH}$); 63.6 (Gal C6); 70.0, 70.1, 70.7, 70.7, 71.8, 72.0 (CHOH); 72.7 (Gal C4); 73.0 (Gal C2); 74.7 (Gal C3); 77.0 (Gal C5); 83.6, 83.7 ($\text{OCH}(\text{CHOH})_2$); 105.6, 105.7 (Gal C1); 130.7, 130.8 ($=\text{CH}$); 170.4 ($\text{C}(=\text{O})\text{N}(\text{H})$); 176.1, 176.2 ($\text{NC}(=\text{O})$). The doubling of some signals indicates the presence of conformational isomers due to restricted rotation of the amide bond. ESI-MS: $m/z = 990.8$, in agreement with the calculated mass for $[\text{M}]^+ = \text{C}_{52}\text{H}_{103}\text{-N}_5\text{O}_{12}$.

Lipoplex Preparation and Characterization. The lipoplexes were prepared in 20 mM HEPES pH 7.5 and incubated with the cells at a DNA concentration of 0.1 to 2 $\mu\text{g}/\text{well}$. The GalSper-based DNA complexes are formulated by adding a desired volume of a micellar GalSper preparation at a concentration of 10 mg/mL in HEPES or a liposomal GalSper/DOPE (1:1) or GalSper/DOGS/DOPE (1:1:2) at a concentration of 10 mg/mL in HEPES to the desired volume of the DNA solution to reach a final DNA concentration of 0.1 mg/mL. Thus, for the preparation of the GalSper/DOPE/DNA complex of N/P ratio 5 and 0.1 mg/mL DNA, 50 μL of the GalSper/DOPE solution (10 mg/mL in EtOH) was transferred to a borosilicate glass tube (16 $\times$ 100 mm). The solvent was evaporated in a Rotavap evaporation system (45 $^\circ\text{C}$, 30 pm, 0.2 bar, 40 min). 50 μL of HEPES 20 mM, pH 7.5, was added to the film obtained. The preparation was vortexed for 12 h. Then, 47.9 μL of this preparation was added to 952.1 μL of DNA solution [100 μL of DNA (1 mg/mL) diluted with 852.1 μL of HEPES buffer]. This preparation was used for the following experiments.

The N/P ratio of 5 corresponds to the molar amount of cationic lipid necessary to have a ratio of 5 amino group nitrogens (for 1 mol of cationic lipid) per one phosphate in the DNA (330 Da mean Mw), as described elsewhere (26). The average sizes of the lipoplexes were measured by photon correlation spectroscopy using a Coulter N4Plus particle size analyzer. Each sample (0.5 μg of plasmid) was electrophoresed for about 90 min under 75 V, through a 0.8% agarose gel in TAE 1 x (Tris-acetate-EDTA) buffer and stained by spreading a 1 $\mu\text{L}/\text{mL}$ ethidium bromide (EtBr) solution in TAE buffer. The DNA was visualized in 200 mL of TAE buffer containing 20 μL of ethidium bromide (Sigma, 10 mg/mL) after photographing on a UV transilluminator. The plasmid integrity in each sample (0.25 μg) was confirmed by electrophoresis after decomplexing the lipoplex (10 μL of a plasmid 0.05 mg/mL) with sodium dodecyl sulfate (10 μL , 80 g/L).

In Vitro Transfection. A volume of DNA/lipospermine lipoplex (20, 10, 5, and 1 μL , respectively) was diluted to 100 μL in DMEM in order to obtain various amounts of DNA (2, 1, 0.5, and 0.1 μg , respectively) in the preparation. For the transfection experiments performed in the presence of serum, the lipoplex preparation

was diluted to 100 μL in DMEM supplemented with 10% FCS. The cell culture medium was removed and replaced by 100 μL of lipoplex/DMEM solution. For the transfection experiments performed in the presence of ASF, ASF (1 mg in 50 μL of DMEM) was added to the cells 10 min before the addition of the lipoplex preparation diluted to 50 μL in DMEM. After 4 and 24 h, 50 μL and 100 μL of DMEM supplemented with 30 and 10% FCS, respectively, were added. 48 h after transfection, the culture medium was discarded, and the cells were washed twice with 100 μL of PBS and then lysed with 50 μL of lysis buffer (Promega, Charbonnières, France). The lysates were frozen at -40 $^\circ\text{C}$ awaiting analysis of luciferase activity. This measurement was done for 10 s on 10 μL of the lysis mixture in a LB96P luminometer (Berthold, Evry, France) in dynamic mode, using the "Luciferase" determination system (Promega) in 96-well plates. The total protein concentration per well was determined by the BCA test (Pierce, Montluçon, France). For cells grown in the absence of lipoplexes, a well contains around 30–60 μg of proteins. Luciferase activity was calculated as fg of luciferase/mg of protein. The percentage of cell viability of the lipoplexes was calculated as the ratio of the total protein amount per well of the transfected cells relative to that measured for untreated cells $\times$ 100%. All transfection experiments were performed at least in triplicate and are expressed as the mean $\pm$ SEM. Statistical analyses were performed using a Student *t*-test.

RESULTS AND DISCUSSION

Synthesis. The synthesis of the galacto-lipospermines has been performed using the three-step procedure outlined in Scheme 1. Although the overall yields by which GalSper was obtained are low, this strategy remains nevertheless very advantageous, as it did not require protection/deprotection of the sugar and spermine residues. The first step consisted into the opening of lactose, a low cost disaccharide, by 12-amino dodecanoic acid, followed by the *in situ* NaBH_4 reduction of the imine formed. Acylation of amine **1** thus obtained with the mercaptothiazoline derivative of oleic acid for one week afforded compound **2**. Such mild acylating agents are selective for amino groups and obviate the need for protection of the sugar hydroxyls (30). The low reactivity of this acylating agent and of the starting amine **1**, and the hydrophilicity of compound **3** which complicates its purification, are likely to be responsible for the low yields of this synthesis. Spermine was then condensed onto the free acid function of **3** leading to GalSper in 85% yield. This step was performed in the presence of BOP as coupling agent and with a large excess of spermine in order to avoid the coupling of activated acid onto two amino groups of spermine. GalSper was purified by size-exclusion chromatography on Sephadex LH-20 and characterized by ^1H and ^{13}C NMR spectroscopy, and by electrospray ionization mass spectrometry in positive and negative mode.

Lipoplex Formation and Characterization. The capability of GalSper to condense DNA and to form lipoplexes was analyzed with or without an equimolar amount of DOPE or of DOGS. The sizes of the lipoplexes were analyzed by light scattering spectroscopy. These studies were performed with pTG11033 plasmid, also used for the *in vitro* transfection screening assays (see below). The procedure applied for the lipoplex preparation relies on the dilution from a GalSper micellar solution or from GalSper/DOPE (1:1) or GalSper/DOGS/DOPE (1:1:2) liposomes in buffer, using N/P ratios of 10,

Table 1. Mean Sizes Determined by Light Scattering Spectroscopy of the Lipoplexes Formed between Plasmid PTG11033 and GalSper, GalSper/DOPE (1:1), GalSper/DOGS/DOPE (1:1:2), or DOGS/DOPE (1:1), and Prepared in 20 mM HEPES pH 7.5

N/P ratio ^a	mean size (standard deviation) in nm

2.5	230 (80)	250 (70)	p ^c	p ^c
1.25	p ^c	p ^c	p ^c	p ^c
0.8	280 (100)	290 (70)	400 (140)	300 (140)

^a N = amine equivalents; P = plasmid phosphate equivalents. ^b Percent (%) of the overall population. ^c p = precipitate.

5, 2.5, 1.25, and 0.8 (*N* = number of lipid amines; *P* = number of DNA phosphates). Table 1 collects the mean particle sizes measured for the different lipoplexes. These formulations were also analyzed by gel electrophoresis (data not shown) which indicated the absence of "free" plasmid for *N/P* ratios from 10 to 1.25 and the presence of accessible plasmid to ethidium bromide in the case of the GalSper/DOGS/DOPE *N/P* 1.25 formulation and of all *N/P* 0.8 preparations.

When used alone, GalSper was able to condense DNA into lipoplexes with mean particle sizes in the 140–280 nm range, except for the *N/P* ratio of 1.25 for which a precipitate was observed. When an equimolar amount of DOPE was used for the formulation of the lipoplexes, similar results were obtained, although for *N/P* 10 and 5, larger-sized particles (~800 nm) were also detected. When the lipoplexes were formulated using a combination of GalSper, DOGS, and DOPE, polydispersed preparations of large-sized particles and precipitates were measured.

It is further noticeable that GalSper and GalSper/DOPE form lipoplexes that do not precipitate at a *N/P* ratio of 2.5 while most often precipitates were formed with (poly)cationic lipids for *N/P* 2.5 (7, 31) (e.g., see DOGS/DOPE in Table 1). This result is indeed worth being noted if *in vivo* uses of such formulations are contemplated.

In Vitro Transfection. Our main objective was to demonstrate that targeted lipoplexes formulated with the cationic GalSper bolaamphiphile were able to deliver specifically genes to cells expressing ASGP receptors. However, cationic lipids also provide receptor-independent gene transfer to such cells (see below). It was therefore necessary to determine the conditions under which a specific gene transfer can be obtained *in vitro* with the cationic GalSper. Toward these goals, the transfection potential of the various above-described GalSper pTG11033-lipoplexes was first screened *in vitro* on the human hepatoma HepG2 cells. These assays, using the luciferase-encoding plasmid, were performed in the presence of 10% foetal calf serum for 24 h. The transfection efficiency of the lipoplexes (expressed in fg of luciferase/mg of protein) was evaluated for gradual *N/P* ratios (0.8, 1.25, 2.5, 5, and 10) and various amounts of DNA (2, 1, 0.5, and 0.1 μ g/well) as compared to naked DNA and to the control lipoplexes based on DOGS/DOPE (1/1 mol) which are known to have a very high potential for gene transfection (32). Cells treated with naked DNA under equivalent conditions showed expression levels of 10^{-3} fg luciferase/mg of protein. The cell viability of the lipoplexes was also checked by determining the total protein amount per well of the transfected cells relative to that measured for untreated cells (for which the total protein amount per well is in a 30–50 μ g/well range).

The transfection and cell viability results are illustrated in Figure 1. These results indicate that GalSper, when used alone, is not an efficient gene transfer agent. Transfection was observed only for high *N/P* ratios and for the highest concentrations of plasmid tested (1 and 2 μ g/well). Furthermore, these formulations led to low levels of luciferase expression ($<2 \times 10^5$ fg luciferase/mg protein) and were rather cytotoxic (cell viability below 10%).

However, its transfection potential was substantially improved when the GalSper lipoplexes were coformulated with an equimolar amount of DOPE, highlighting again the unique properties of DOPE as helper lipid (7, 24, 25, 32). Luciferase expression levels in the 10^6 – 10^7 fg/mg protein were indeed measured for the *N/P* 5 and 2.5 formulations and for a DNA amount of 0.5 μ g/well. When compared to control DOGS/DOPE lipoplexes, GalSper/DOPE *N/P* 2.5 formulations were found to be more efficient than the *N/P* 2.5 reference (at least by 2 orders of magnitude, $p < 0.05$) in mediating gene transfer and expression. For *N/P* ratios ≥ 5 or ≤ 1.25 , GalSper/DOPE formulations were found to be statistically as efficient or less efficient than their corresponding DOGS/DOPE lipoplexes, respectively.

Coformulation of DOGS/DOPE lipoplexes (which transfect HepG2 cells through a nonspecific mechanism) with GalSper could also constitute a mean to obtain specific cell interactions and gene transfer. We found that the transfection levels of DOGS/DOPE remained statistically unaffected by replacing half of the molar amount of DOGS by the same molar amount of GalSper. However, this result does not inform on the entry pathway specificity of the vector.

Most importantly, this transfection screening suggests that GalSper/DOPE *N/P* 5 and 2.5 lipoplexes could trigger a receptor-mediated transfection, although such a mechanism of gene transfer is more likely to be observed with lipoplexes having lower electrical surface charge in order to minimize the transfection electrostatic pathway. Unfortunately, the electrically less charged GalSper/DOPE lipoplexes *N/P* 1.25 and 0.8 that should exhibit increased specific binding displayed luciferase expression levels that are too low to allow the detection of a receptor-mediated endocytosis pathway leading to gene expression. It should be noted that substantially higher levels of transfection were measured for GalSper/DOGS/DOPE *N/P* 1.25 and 0.8 as compared to their respective GalSper/DOPE ones. This most likely resulted, consequent to the replacement of GalSper by DOGS, from increased nonspecific binding to the negatively charged proteoglycans which are expressed by these adherent cells.

To demonstrate cell specific transfection with GalSper-based lipoplexes, we performed a series of experiments

Figure 1. Luciferase expression (bars) and cell viability (points) in HepG2 cells of the lipoplexes prepared in 20 mM HEPES pH 7.5 and made of GalSper, GalSper/DOPE (1:1), or GalSper/DOGS/DOPE (1:1:2) and plasmid pTG11033 (DNA) for various N/P ratios, as compared to control DOGS/DOPE (1:1). The transfection experiments were performed in DMEM supplemented with 10% fetal calf serum. The given means $\pm$ SEM were calculated from four independent experiments.

on ASGP expressing cells (HepG2 and BNL-CL2) in the absence and in the presence of an excess of asialofetuin (ASF, 20- and 10-fold molar excess over galactose for the N/P 2.5 and 5 formulations, respectively) which is a high affinity ligand of ASGP (20, 26). To show the effects of ASF on nonspecific-mediated transfection, we performed also a series of control experiments on A549 cells which do not express ASGP. Control experiments were also realized with DOGS/DOPE lipoplexes as nontargeted galactose lipoplexes. These transfection assays were performed (i) with lipoplexes formulated from the luciferase encoding plasmid pTG11236, (ii) with N/P 5 and 2.5 formulations, for the above-discussed reasons, and (iii) in the absence of serum, to avoid the possible inhibitory effects on ligand–receptor interactions that might be due to the serum constituents. The results are illustrated in Figure 2.

As compared with the first series of experiments on HepG2 cells which were run in the presence of serum, a surprisingly lower luciferase expression level was measured for the GalSper/DOPE N/P 2.5 in the absence of serum while for the other formulations higher or comparable levels were found, as expected. The surface of these lipoplexes most probably displays the highest galactose/cation ratio among the different formulations investigated. This formulation corresponds to lipoplexes having 0.83 equiv of galactose for 2.5 amines and one DNA phosphate while GalSper/DOGS/DOPE (1:1:2) N/P 2.5 lipoplexes for example contain only 0.36 equiv of galactose for 2.5 amines and one DNA phosphate. The interactions of the lipoplexes and the different serum constituents being highly dependent upon the nature and

residual charge of the lipoplex surface, one expect therefore substantial different biological behaviors for the lipoplexes.

Before interpreting unambiguously the transfection results on ASGP(+) cells with GalSper-based lipoplexes, it was essential to estimate the effects of ASF on nonspecific-mediated transfection. Although one expects that ASF has no determinant influence on transfection of (i) the ASGP(–) A549 cells mediated with any type of lipoplexes, or (ii) ASGP(+) cells mediated with the DOGS/DOPE lipoplexes, its interactions with the cell surface and/or with the positively charged lipoplexes are likely to interfere with the transfection process.

Concerning the effects of ASF on nonspecific-mediated transfection, our results did not demonstrate any systematic trend, these effects being rather cell- and lipoplex-type dependent. Indeed, and as expected, the presence of ASF had almost no effect (at most a 5-fold decrease, which is however statistically not significant) on the transfection of A549 and HepG2 cells with DOGS/DOPE lipoplexes (Figure 2). However, ASF induced a substantial transfection increase of the A549 cells (64-fold) mediated with the GalSper/DOPE N/P 5 formulation. In contrast, it decreased the nonspecific transfection (i) of the A549 cells mediated with the GalSper/DOGS/DOPE lipoplexes and (ii) of the BNL-CL2 cells mediated with the DOGS/DOPE lipoplexes, by a factor of 15 in the latter case (ASF was also found to inhibit the transfection of BNL-CL2 cells by PEI polyplexes (26)). Altogether, these data are taken to indicate that, to be unambiguously interpreted as a receptor-mediated transfection process, competition experiments with ASF should inhibit

Figure 2. Luciferase expression in ASGP(+) cells (human HepG2 and murine BNL-CL2 hepatocytes) and ASGP(−) cells (A549 cells deriving from a human carcinoma) of the lipoplexes prepared in 20 mM HEPES pH 7.5 in the presence of ASF (grey bars) or not (open bars). The lipoplexes were made of GalSper/DOPE (1:1) or GalSper/DOGS/DOPE (1:1:2) and plasmid pTG11236 (DNA) for N/P 2.5 and 5, as compared to control DOGS/DOPE (1:1). The lipoplexes were incubated at a concentration of 0.5 μ g DNA/well with the cells. The transfection experiments were performed in DMEM supplemented with 1 mg/well of ASF which was added to the cells 10 min before addition of the lipoplexes. The given means $\pm$ SEM were calculated from three independent experiments. * p < 0.05, ** p < 0.01 and *** p < 0.001 were carried out in a pairwise comparison.

transfection of the HepG2 and BNL-CL2 cells with the GalSper-based lipoplexes by a factor significantly larger than 5 for HepG2 and 15 for BNL-CL2 cells.

Concerning the transfection of HepG2 and BNL-CL2 cells with the GalSper/DOPE N/P 2.5 lipoplexes, ASF was found to significantly inhibit this process by a factor 25 and 100 (p < 0.05), respectively. This likely indicates a receptor-mediated endocytosis pathway for the transfection of these two cell types. This is further supported by the very low ability of the GalSper/DOPE N/P 2.5 lipoplexes to transfect the control A549 cells through a receptor-independent process. The galactosyl coat interferes with the binding of the cationic particles to the anionic cell surface, providing a shielding effect that was also observed with other glycosylated-DNA complexes (21, 26, 27). Very surprisingly, ASF induced a transfection increase of the BNL-CL2 (14-fold) and HepG2 cells (120-fold) when performed with the GalSper/DOPE N/P 5 lipoplexes, indicating rather that transfection of these ASGP(+) cells with such highly cationic complexes is mainly dominated by nonspecific electrostatic interactions which involve anionic cell proteoglycans (16, 17).

Concerning the transfection of the HepG2 cells with the GalSper/DOGS/DOPE N/P 2.5 lipoplexes, the 25-fold luciferase expression inhibition detected in the presence of ASF could also be attributed to partial blockade by ASF of the targeted cell entry of the plasmid. On the other hand, no ASF inhibition was detected for these lipoplexes in the case of the BNL-CL2 cells. These results indicate that GalSper/DOGS/DOPE N/P 2.5 lipoplexes can transfect cells through a receptor-dependent and/or a receptor-independent mechanism, and when the former cell entry pathway is blocked, the other one takes over. This is further supported by the larger propensity of the

BNL-CL2 cells, as compared with HepG2 and A549 cell lines, to be transfected by the cationic nontargeted DOGS/DOPE lipoplexes.

Although lower luciferase expression levels in BNL-CL2 and in HepG2 cells were obtained with GalSper/DOPE N/P 2.5 lipoplexes as compared with control DOGS/DOPE N/P 2.5 particles or with the more positively charged N/P 5 particles (yet through a different mechanism), specific receptor-mediated endocytosis of DNA can be achieved with this targeted cationic GalSper bolaamphiphile presenting a single galactose residue. The present work suggests that targetable lipopolyamines appear as promising synthetic vectors for specific gene delivery to ASGP(+) cells. Although encouraging, the transfection efficiency and the selectivity obtained here with this first head compound should however be improved.

ACKNOWLEDGMENT

We wish to thank Transgène, SA (Strasbourg, France) for their interest into this project and for financial support. Special thanks to Dr. B Cavallini (Transgène) for supplying plasmids.

A Convenient Solid-Phase Method for Synthesis of 3'-Conjugates of Oligonucleotides

Dmitry A. Stetsenko and Michael J. Gait*

Medical Research Council, Laboratory of Molecular Biology, Hills Road, Cambridge, CB2 2QH, U.K.
Received December 28, 2000

We present a new procedure for the preparation of 3'-conjugates of oligonucleotides through solid-phase synthesis. A suitable universal solid support was readily prepared using a series of peptide-like coupling reactions to incorporate first a spacer and then an L-homoserine branching unit. The N- α -position of the homoserine carries an Fmoc protecting group that is removed by treatment with piperidine to liberate an amino group suitable for attachment of the conjugate (e.g., small organic molecule, fluorescent group, cholesterol, biotin, amino acid, etc.) or for assembly of a short peptide. The side-chain hydroxyl group of the homoserine carries a trityl protecting group. After TFA deprotection, the hydroxyl group acts as the site for oligonucleotide assembly. An additional spacer, such as aminohexanoyl, may be incorporated easily between the conjugate molecule and the oligonucleotide. A number of examples of synthesis of 3'-conjugates of oligonucleotides and their analogues are described that involve standard automated oligonucleotide assembly and use of commercially available materials. The linkage between oligonucleotide and 3'-conjugate is chirally pure and is stable to conventional ammonia treatment used for oligonucleotide deprotection and release from the solid support. The homoserine-functionalized solid support system represents a simple and universal route to 3'-conjugates of oligonucleotides and their derivatives.

INTRODUCTION

Oligonucleotides and their analogues have found wide application for the sequence-specific inhibition of gene expression within cells (Crooke and Lebleu, 1993; Chadwick and Cardew, 1997; Stein and Krieg, 1998). One of their main limitations, however, has been their generally poor uptake by cells in culture in the absence of a carrier. This is because the predominant routes of cell entry involve adsorptive or fluid-phase endocytosis, which often result in difficulties in release of the oligonucleotides from endosomes and lysosomes into other cellular compartments (Stein and Narayan, 1996). Uptake may be enhanced by co-administration of certain additives of which cationic liposomes are the most popular (Bennett et al., 1992). In particular, these agents have been found to assist the release of oligonucleotides into the cytosol. Yet use of these reagents is often limited due to their cellular toxicity and their instability in the presence of serum. Further, there are very large variations in effectiveness of these reagents for a particular cell line (Kang et al., 1999).

An alternative approach to enhance cellular uptake is to conjugate the oligonucleotide to another molecule known for its ability to penetrate or interact with cell membranes. Such molecules include lipophilic compounds, e.g., cholesterol (Letsinger et al., 1989; Krieg et al., 1993), lipids (Shea et al., 1990), long-chain hydrocarbons (Rait et al., 2000), and cholic acid and folic acid (Harrison and Balasubramanian, 1997). Conjugates of polycations such as spermine (Kabanov et al., 1995), homopolymers such as poly(ethylene glycol) (Jäschke et al., 1994), and a range of peptides (see recent reviews:

Stetsenko et al., 2000; Tung and Stein, 2000) have also been suggested as carriers. In addition, other types of molecules have been conjugated to oligonucleotides in order to provide specific labels for tracking oligonucleotides diagnostically or within cells (such as biotin or fluorophores (Agrawal et al., 1986)) or to enhance binding to nucleic acids (such as acridine (Asseline and Thuong, 1989)).

Conjugations to oligonucleotides are usually carried out at either the 5' or 3' ends to prevent interference with the ability of the oligonucleotides to hybridize with complementary target sequences. Synthetically, conjugation has been most readily achieved at the 5'-end through attachment of an appropriate amino linker (Agrawal et al., 1986) or by the preparation of a suitable phosphoramidite that can be used during or at the end of oligonucleotide assembly (Nelson et al., 1989b; Misiura et al., 1990). However, 5'-modification precludes the ability of the oligonucleotide to be ^{32}P -labeled by 5'-phosphorylation. By contrast, conjugation at the 3'-end of an oligonucleotide not only permits 5'- ^{32}P -labeling but has the added advantage that 3'-modification usually results in significant protection of the oligonucleotide against attack by 3'-exonucleases, which are the major source of nucleases within serum and cells.

A number of methods for the preparation of 3'-conjugates of oligonucleotides have been published. Early methods have involved a post-assembly conjugation protocol. Since oligonucleotide synthesis is carried out usually by solid-phase assembly from the 3'-end to the 5'-end, most methods have involved the development of special linkages between the solid support and the 3'-end of the first residue. After assembly of the oligonucleotide, it is cleaved from the support to generate a specific functional group to which the desired molecule, label, or peptide is then conjugated. The most common functional

Figure 1. Examples of various solid supports used for preparation of oligonucleotide 3'-conjugates.

groups generated are primary amines (Nelson et al., 1989a; Asseline and Thuong, 1990; Nelson et al., 1992; Petrie et al., 1992) or thiols (Zuckerman et al., 1987; Bonfils and Thuong, 1991; Gupta et al., 1991).

Linear 3'-linkers are only useful for post-assembly conjugation once the oligonucleotide has been cleaved from the solid support. By contrast, a more general 3'-linker incorporates a chain branch where a convenient functional group, usually a protected amino group, is present on a sidearm. In principle, a branched linker should allow one (a) to introduce the conjugation molecule before assembly of the oligonucleotide, (b) to assemble the oligonucleotide first and carry out post-assembly conjugation after release into solution, or (c) to use the functionality to act as an attachment point for solid-phase conjugation or assembly of a peptide or other biomolecule prior to release of the oligonucleotide from the support (total solid-phase conjugate synthesis).

Examples of such branched linkers are shown in Figure 1. The two most commonly used branched 3'-linkers are those based on 3-amino-1,2-propane diol (type i) (Nelson et al., 1989a; Nelson, 1992, 1995) or 3-aminobutyl-1,3-propane diol (type ii) (Nelson et al., 1992; Nelson and Kent, 1995, 1999). In variations of this type of scaffold, a 3-O-aminopropyl glycerol linker has been used for the preparation of 3'-fluorescein conjugates of oligonucleotides (type iii) (Theisen et al., 1992) and a hexadecyl chain has been introduced at the 3'-end via a glyceryl linker (Rait et al., 2000). Similarly, a 3'-pyrene conjugate was prepared via a 1,3-propanediol linker (type iv) (Korshun et al., 1999). All of these types of linkers introduce chirality at the linker branch point. Further, synthesis of solid supports incorporating these linkers generally involves the prior multistep preparation of a specialized linker reagent for attachment to the support, sometimes leading to low linker loading.

Alternative linkers that are achiral have been suggested. Thus, the nonprochiral diethanolamine has been used for the synthesis of 3'-anthraquinone-conjugated oligonucleotides, where the conjugate is attached to the secondary amine (type v) (Lin and Matteucci, 1991; Lin and Matteucci, 1995). This method also requires prior preparation of a specialized conjugate reagent and the route is also not suitable for post-assembly conjugation. Another type of branched linker is based on *trans*-4-hydroxy-L-prolinol (type vi). Linker reagents containing, for example, cholesterol or acridine are attached through the secondary amino moiety of the linker leaving the secondary alcohol for attachment to the support and the primary alcohol as the oligonucleotide growth point (Reed et al., 1991; Gamper et al., 1993; Cheng et al., 1997). Although this linker is chirally pure and avoids the problem of racemates obtained with other linkers, the preparation of conjugates still requires the multistep synthesis of a specialized linker reagent for each conjugate type, and the route is not suitable for post-assembly functionalization.

We now describe a novel method for functionalization of solid supports suitable for synthesis of oligonucleotides conjugated at the 3'-end with a wide variety of labels or other functionalities. The synthetic route involves use of inexpensive, commercially available materials to prepare functionalized supports under standard conditions of solid-phase peptide synthesis and avoids the need for presynthesis of a complex linker reagent for each conjugate type. Examples are presented of solid-phase synthesis of a range of 3'-conjugated oligonucleotides starting from prefunctionalized supports carrying small organic groups 4-pentynoyl or 4-iodophenylacetyl, the fluorescent dye 5(6)-carboxyfluorescein, D-(+)-biotin, the amino acid cysteine, and the tripeptide (Lys)₃.

MATERIALS AND METHODS

Reagents and solvents were obtained from Sigma-Aldrich or Fluka (Poole, U.K.) unless otherwise mentioned. LCAA-CPG¹ 500 was obtained from Pierce. HATU was obtained from Applied Biosystems. 6-*N*-(9-Fluorenylmethoxycarbonyl)aminohehexanol (**1a**) is commercially available from Fluka. TLC plates (Kieselgel 60 F₂₅₄, Merck) were developed in 10% MeOH–CHCl₃. Oligodeoxyribonucleotide synthesis was carried out on a ABI 380B or 394 DNA/RNA synthesizer on a 0.2 or 1 μ mol scale using 2'-deoxynucleoside phosphoramidite reagent materials obtained from Cruachem (Scotland) or 2'-*O*-methyl ribonucleoside phosphoramidites obtained from Glen Research (via Cambio, Cambridge, U.K.) and standard synthetic procedures (Brown and Brown, 1991). Phosphorothiate linkages were incorporated by replacing the iodine oxidation step by sulfurization with the Beaucage reagent (Glen Research). *O*-*trans*-4-(*N*- α -Fmoc-*S*-*tert*-butylsulfenyl-L-cysteinyl)piperidyl *O*-2-cyanoethyl-*N,N*-diisopropylphosphoramidite (Stetsenko and Gait, 2000a,b) was used to prepare the 5'-cysteinyl-3'-carboxy-fluoresceinyl conjugate.

Reversed-phase HPLC of oligonucleotides and conjugates was carried out using a Phenomenex RP-C18 column (4.6 $\times$ 250 mm) and dual-wavelength (218 and 254 nm) UV detection using gradients of acetonitrile (0–2%, 5 min; 2–40%, 20 min; 40–100%, 25 min) in either 0.1 M ammonium acetate buffer, pH 7.0 (a), or 0.1 M triethylammonium acetate buffer, pH 7.0 (b). Ion-exchange HPLC was carried out using a NucleoPac PA-100 (Dionex) (9 $\times$ 250 mm) using gradients of sodium perchlorate (1–400 mM) in a buffer of 20 mM Tris·HCl (pH 6.8), 25% formamide, and at UV detection at 280 nm wavelength. The mass of each oligonucleotide was checked by MALDI-TOF mass spectrometry on a Perseptive Biosystems Voyager DE mass spectrometer in positive-ion mode as previously described (Farrow et al., 1998).

2-(2-*N*-(9-Fluorenylmethoxycarbonyl)aminoethoxy)ethanol (1b). 9-Fluorenylmethyl succinimidyl carbonate (16 g, 47.5 mmol) was dissolved in ethyl acetate (100 mL), and 2-(2-aminoethoxy)ethanol (6 mL, 60 mmol) was added dropwise with stirring during ca. 10 min. A yellow waxy precipitate was formed immediately that gradually dissolved while the reaction proceeded. The mixture was stirred for another 12 h, until TLC (5% MeOH in CHCl₃) showed complete disappearance of the starting carbonate. The solution was transferred to a separation funnel and washed successively with 5% (w/v) citric acid (2 $\times$ 75 mL), water (75 mL), 5% aqueous NaHCO₃ (2 $\times$ 75 mL), and brine and dried over anhydrous sodium sulfate. The solvent was then removed by evaporation in vacuo, and the compound was crystallized from ethyl acetate–hexane (2:1 v/v) to give bunches of white needles. After filtration and washing with cold ethyl acetate–hexane (1:1 v/v), a first portion of product (13.41 g, 86%) was obtained. Evaporation of the mother liquor gave a further 1.68 g of product. Total yield of the title product was 15.09 g (97%). TLC (5% MeOH in CHCl₃): *R*_f 0.35. MALDI-TOF MS (2,5-dihydroxybenzoic acid in MeOH, 10 mg mL⁻¹): [M + H]⁺ 328.35 (obsd), 328.38 (calcd), [M + Na]⁺ 350.19 (obsd), 350.36 (calcd),

[M + K]⁺ 366.13 (obsd), 366.34 (calcd). ¹H NMR (DMSO-*d*₆, δ , ppm): 3.13 (d, 2H, *J* = 4.9 Hz, CH₂), 3.33 (d, 2H, *J* = 5.8 Hz, CH₂), 3.40 (t, 2H, *J* = 5.2 Hz, CH₂), 3.46 (d, 2H, *J* = 5.7 Hz, CH₂), 4.20 (t, 1H, *J* = 6.2 Hz, 9-fluorene CH), 4.29 (d, 2H, *J* = 6.8 Hz, fluorenylCH₂), 4.59 (m, 1H, NH), 7.32 (t, 2H, *J* = 7.2 Hz, Fmoc aromatics), 7.4 (t, 2H, *J* = 7.4 Hz, Fmoc aromatics), 7.68 (d, 2H, *J* = 7.2 Hz, Fmoc aromatics), 7.88 (d, 2H, *J* = 7.5 Hz, Fmoc aromatics).

6-*N*-(9-Fluorenylmethoxycarbonyl)aminohehexyl Succinate (2a). 6-*N*-Fmoc-aminohehexanol (3.73 g, 11 mmol), succinic anhydride (1.49 g, 14.85 mmol), and 4-(dimethylamino)pyridine (134 mg, 1.1 mmol) were suspended in 75 mL of 1,2-dichloroethane, 5 mL of pyridine was added, and the mixture was refluxed for 24 h. The solution was then transferred to a separation funnel, washed successively with 0.5 M NaHSO₄ (3 $\times$ 50 mL), water (50 mL), 5% aqueous NaHCO₃ (3 $\times$ 50 mL), and brine, and dried over anhydrous sodium sulfate. The solvent was removed in vacuo, and the mixture was flash chromatographed on Kieselgel 60 column eluted with 1% MeOH in CHCl₃. The appropriate fractions were pooled and evaporated, and the residue was crystallized from ethyl acetate–hexane (2:1 v/v) mixture to give 4.31 g (89%) of the title compound. TLC (5% MeOH in CHCl₃): *R*_f 0.46. MALDI-TOF MS: [M + H]⁺ 439.85 (obsd), 440.51 (calcd), [M + Na]⁺ 461.84 (obsd), 462.49 (calcd), [M + K]⁺ 477.36 (obsd), 478.60 (calcd). ¹H NMR (DMSO-*d*₆, δ , ppm): 1.26 (m, 4H, CH₂), 1.37 (t, 2H, *J* = 6.1 Hz, CH₂), 1.53 (t, 2H, *J* = 6.4 Hz, CH₂), 2.47 (s, 4H, succinyl CH₂), 2.94 (t, 2H, *J* = 6.9 Hz, CH₂), 3.98 (t, 2H, *J* = 6.4 Hz, CH₂), 4.19 (t, 1H, *J* = 6.9 Hz, 9-fluorene CH), 4.28 (d, 2H, *J* = 6.8 Hz, fluorenyl CH₂), 7.31 (t, 2H, *J* = 7.4 Hz, Fmoc aromatics), 7.40 (t, 2H, *J* = 7.3 Hz, Fmoc aromatics), 7.67 (d, 2H, *J* = 7.3 Hz, Fmoc aromatics), 7.87 (d, 2H, *J* = 7.4 Hz, Fmoc aromatics).

2-(2-*N*-(9-Fluorenylmethoxycarbonyl)aminoethoxy)ethyl Succinate (2b). 2-(2-*N*-Fmoc-aminoethoxy)ethanol (3.93 g, 12 mmol), succinic anhydride (1.50 g, 15 mmol), and 4-(dimethylamino)pyridine (147 mg, 1.2 mmol) were suspended in anhydrous ethyl acetate (75 mL), containing 2 mL of pyridine, and the mixture was stirred at 60 °C for 12 h. After TLC revealed total consumption of the starting alcohol, the mixture was transferred to a separation funnel, washed successively with 0.5 M sodium hydrogen sulfate (3 $\times$ 50 mL), water (50 mL), 5% aqueous NaHCO₃ (3 $\times$ 50 mL), and brine, and dried over anhydrous Na₂SO₄. The solvent was removed in vacuo, and the mixture was flash chromatographed on Kieselgel 60 column eluted with 2% MeOH in CHCl₃. The appropriate fractions were pooled and evaporated, and the residue was crystallized from ethyl acetate–hexane (3:1 v/v) to give 3.9 g (76%) of the title compound. TLC (5% MeOH in CHCl₃): *R*_f 0.40. MALDI-TOF MS (2,5-dihydroxybenzoic acid in MeOH, 10 mg/mL): [M + H]⁺ 427.84 (obsd), 428.17 (calcd), [M + Na]⁺ 449.93 (obsd), 450.15 (calcd), [M + K]⁺ 465.83 (obsd), 466.13 (calcd). ¹H NMR (DMSO-*d*₆, δ , ppm): 1.47 (m, 4H, succinyl CH₂), 2.12 (t, 2H, *J* = 6.7 Hz, CH₂), 2.40 (t, 2H, *J* = 5.7 Hz, CH₂), 2.55 (t, 2H, *J* = 4.4 Hz, CH₂), 3.09 (t, 2H, *J* = 4.4 Hz, CH₂), 3.18 (t, 1H, *J* = 6.7 Hz, 9-fluorene CH), 3.27 (d, 2H, *J* = 6.8 Hz, fluorenylCH₂), 6.30 (t, 2H, *J* = 7.4 Hz, Fmoc aromatics), 6.39 (t, 2H, *J* = 7.3 Hz, Fmoc aromatics), 6.67 (d, 2H, *J* = 7.3 Hz, Fmoc aromatics), 6.86 (d, 2H, *J* = 7.4 Hz, Fmoc aromatics), 11.20 (s, 1H, COOH).

Fmoc-sarcosine-Functionalized LCAA-CPG-500 (S1). Fmoc-sarcosine (148 mg, 0.47 mmol) and HATU

¹ Abbreviations: CPG, controlled pore glass; DIEA, diisopropylethylamine; DMF, *N,N*-dimethylformamide; Dmt, dimethoxytrityl; Fmoc, 9-fluorenylmethoxycarbonyl; HATU, *O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate; LCAA, long-chain alkylamine; MALDI-TOF, matrix-assisted laser desorption ionisation time-of-flight; TFA, trifluoroacetic acid; Trt, trityl.

(162 mg, 0.43 mmol) were dissolved in DMF (4 mL), DIEA (81 μ L, 0.47 mmol) was added, and the mixture was shaken for 5 min. More DIEA (81 μ L, 0.47 mmol) was added, and the yellow solution was then poured onto LCAA-CPG-500 beads (2 g, 0.19 mmol, 94.8 μ mol g⁻¹ amino group loading, for example, obtained from Pierce). The slurry was kept for 1 h with occasional swirling, the solution was filtered, and the CPG beads were washed with DMF (2 $\times$ 5 mL) and acetonitrile (2 $\times$ 5 mL). The CPG was treated on the filter with equal volumes (2 mL of each) of capping solutions (Cap I: 20% acetic anhydride in THF, Cap II: 20% 1-methylimidazole and 40% 2,4,6-trimethylpyridine in THF) for 15 min, washed successively with DMF (5 $\times$ 5 mL), MeOH (5 $\times$ 5 mL), and diethyl ether (5 $\times$ 5 mL), and finally dried in vacuo. A total yield of 1.95 g of Fmoc-sarcosine LCAA-CPG-500 **S1** was obtained, with estimated loading of 92.1 μ mol g⁻¹ (97% substitution based on Fmoc group determination).

6-Fmoc-aminoethyl-succinyl-sarcosine LCAA-CPG-500 (S2a). The above support **S1** (1 g, 0.09 mmol) was treated with piperidine/DMF (2:8 v/v, 3 mL) for 15 min and washed with DMF (10 $\times$ 3 mL). 6-N-Fmoc-aminoethyl succinate (41 mg, 0.09 mmol) and HATU (32 mg, 0.08 mmol) were dissolved in DMF (2 mL), DIEA (16 μ L, 0.09 mmol) was added, and the mixture was shaken for 5 min. More DIEA (61 μ L, 0.09 mmol) was added, and the solution was then poured on the Fmoc-deprotected support **S1**. The slurry was kept for 1 h with occasional swirling, and the solution was filtered. The CPG beads were washed with DMF (2 $\times$ 3 mL) and acetonitrile (2 $\times$ 3 mL) and treated on the filter with equal volumes of capping solutions I and II (1.5 mL of each) for 15 min, washed successively with DMF (5 $\times$ 3 mL), MeOH (5 $\times$ 3 mL), and diethyl ether (5 $\times$ 3 mL), and finally dried in vacuo. A total of 1.01 g of 6-Fmoc-aminoethyl succinyl sarcosine LCAA-CPG-500 **S2a** was obtained with estimated loading of 74.3 μ mol g⁻¹ (90% substitution).

6-(N-Fmoc-O-trityl-homoseryl)aminoethyl-succinyl-sarcosine LCAA-CPG-500 (S3a). The above support **S2a** (1 g, 0.07 mol) was treated with piperidine/DMF (2:8 v/v, 3 mL) for 10 min and washed with DMF (10 $\times$ 3 mL). Fmoc-Hse(Trt)-OH (108 mg, 0.19 mmol, Novabiochem) and HATU (64 mg, 0.17 mmol) were dissolved in DMF (2 mL), DIEA (32 μ L, 0.19 mmol) was added, and the mixture was shaken for 5 min. More DIEA (32 μ L, 0.19 mmol) was added, and the solution was poured onto the Fmoc-deprotected support **S2a**. The slurry was kept for 1 h with occasional swirling, the solution was filtered, and the CPG beads were washed with DMF (2 $\times$ 3 mL) and acetonitrile (2 $\times$ 3 mL). The CPG was treated on the filter with equal volumes of capping solutions I and II (1.5 mL of each) for 15 min, washed successively with DMF (5 $\times$ 3 mL), MeOH (5 $\times$ 3 mL), and diethyl ether (5 $\times$ 3 mL), and finally dried in vacuo. A total of 0.96 g of 6-(N-Fmoc-O-trityl-homoseryl)aminoethyl-succinyl-sarcosine LCAA-CPG-500 **S3a** was obtained with estimated loading of 71.6 μ mol g⁻¹ (93% substitution).

2-(2-Fmoc-aminoethoxy)ethyl-succinyl-sarcosine LCAA-CPG-500 (S2b). A fresh batch of Fmoc-sarcosine LCAA-CPG-500 **S1** (4.74 g, 0.68 mmol, 0.144 mmol g⁻¹ amino groups) was treated with piperidine/DMF (2:8 v/v, 15 mL) for 15 min and washed with DMF (10 $\times$ 15 mL). 2-(2-Fmoc-aminoethoxy)ethyl succinate (146 mg, 0.34 mmol) and HATU (117 mg, 0.31 mmol) were dissolved in DMF (14 mL), DIEA (59 μ L, 0.34 mmol) was added, and the mixture was shaken for 5 min. More DIEA (59 μ L, 0.34 mmol) was added, and the solution was poured onto the Fmoc-deprotected support **S1**. The slurry was kept for 1 h with occasional swirling, the

solution was filtered, and the CPG beads were washed with DMF (2 $\times$ 15 mL) and acetonitrile (2 $\times$ 15 mL). The CPG was treated on the filter with equal volumes of capping solutions I and II (7.5 mL of each) for 15 min, washed successively with DMF (5 $\times$ 15 mL), MeOH (5 $\times$ 15 mL), and diethyl ether (5 $\times$ 15 mL), and finally dried in vacuo. A total of 4.71 g of 2-(2-Fmoc-aminoethoxy)-ethyl succinyl sarcosine LCAA-CPG-500 **S2b** was obtained with estimated loading of 62.2 μ mol g⁻¹ (96% substitution).

2-[2-(N-Fmoc-O-tritylhomoseryl)aminoethoxy]ethyl-succinyl-sarcosine LCAA-CPG-500 (S3b). The above support **S2b** (4.70 g, 0.30 mol) was treated with piperidine/DMF (15 mL) for 10 min and washed with DMF (10 $\times$ 15 mL). Fmoc-Hse(Trt)-OH (172 mg, 0.30 mmol) and HATU (101 mg, 0.27 mmol) were dissolved in DMF (14 mL), DIEA (51 μ L, 0.30 mmol) was added, and the mixture was shaken for 5 min. More DIEA (51 μ L, 0.30 mmol) was added, and the solution was poured onto the Fmoc-deprotected support **S2b**. The slurry was kept for 1 h with occasional swirling, the solution was filtered, and the CPG beads were washed with DMF (2 $\times$ 15 mL) and acetonitrile (2 $\times$ 15 mL). The CPG was treated on the filter with equal volumes of capping solutions I and II (7.5 mL of each) for 15 min, washed successively with DMF (5 $\times$ 15 mL), MeOH (5 $\times$ 15 mL), and diethyl ether (5 $\times$ 15 mL), and finally dried in vacuo. A total of 4.67 g of 2-[2-(N-Fmoc-O-trityl-homoseryl)-aminoethoxy]ethyl-succinyl-sarcosine LCAA-CPG-500 **S3b** was obtained with estimated loading of 47.5 μ mol g⁻¹ (85% substitution).

General Procedure for Synthesis of 3'-Modified LCAA-CPG-500 Supports S4 and S5 from S3a and S3b, Respectively, Exemplified for Preparation of 2-[2-(O,O'-Diacetylfluorescein-6-ylcarbonylhomoseryl)aminoethoxy]ethyl-succinyl-sarcosine LCAA-CPG-500 (S5a). Support **S3b** (0.46 g, 0.02 mmol) was treated with piperidine/DMF (2:8 v/v, 2 mL) for 10 min and washed with DMF (10 $\times$ 2 mL). 6-Carboxyfluorescein diacetate (100 mg, 0.23 mmol) and HATU (74 mg, 0.19 mmol) were dissolved in DMF (1.5 mL), DIEA (37 mL, 0.22 mmol) was added, and the mixture was shaken for 5 min. More DIEA (37 μ L, 0.22 mmol) was added, and the resulting brown solution was poured onto the Fmoc-deprotected support **S3b**. The slurry was kept for 1 h with occasional swirling, the solution was filtered, the CPG beads were washed with DMF (3 $\times$ 2 mL), and the washings were repeated. After 1 h, the CPG was filtered and washed with DMF (2 $\times$ 2 mL) and acetonitrile (2 $\times$ 2 mL). The CPG was treated on the filter with equal volumes of capping solutions I and II (1 mL of each) for 15 min and then washed with DMF (5 $\times$ 2 mL), MeOH (5 $\times$ 2 mL), and CH₂Cl₂ (2 $\times$ 2 mL). A solution of TFA in CH₂Cl₂ (3% v/v, 2 mL) was added, and beads were kept in contact with the acid for 1 min, washed with 3% TFA in CH₂Cl₂ (2 $\times$ 2 mL), MeOH (2 $\times$ 2 mL), CH₂Cl₂ (5 $\times$ 2 mL), and diethyl ether (3 $\times$ 2 mL), and finally dried in vacuo. A total of 0.45 g of 2-[2-(O,O'-diacetylfluorescein-6-ylcarbonylhomoseryl)aminoethoxy]ethyl-succinyl-sarcosine LCAA-CPG-500 **S5a** was obtained as colorless beads.

Other S4 Supports: 6-[N-(4-Pentynoyl)homoseryl]aminoethyl-succinyl-sarcosine LCAA-CPG-500 (S4a). Support **S3a** (0.2 g, 27.5 μ mol/g, 5.5 μ mol) was treated with piperidine/DMF (2:8 v/v, 0.5 mL) for 15 min and washed with DMF (10 $\times$ 0.5 mL). 4-Pentynoic acid (12 mg, 0.11 mmol) and HATU (38 mg, 0.10 mmol) were dissolved in DMF (0.3 mL), DIEA (19 μ L, 0.11 mmol) was added, and the mixture was shaken for 5 min. More

DIEA (19 μ L, 0.11 mmol) was added, and the yellow solution was then poured on Fmoc-deprotected support **S3a**. The CPG beads were washed, capped, treated with TFA in CH_2Cl_2 (3%), washed, and dried in vacuo to yield 0.18 g of 6-[*N*-(4-pentynoyl)homoseryl]aminoethylsuccinyl-sarcosine (**S4a**).

6-(Iodophenylacetylhomoseryl)aminoethylsuccinyl-sarcosine LCAA-CPG-500 (S4b). Support **S3a** (0.14 g, 60.8 μ mol/g, 8.7 μ mol) was treated with piperidine/DMF (2:8 v/v, 0.5 mL) for 15 min and washed with DMF (10 $\times$ 0.5 mL). 4-Iodophenylacetic acid (26 mg, 0.09 mmol) and HATU (30 mg, 0.08 mmol) were dissolved in DMF (0.3 mL), DIEA (15 μ L, 0.09 mmol) was added, and the mixture was shaken for 5 min. More DIEA (15 μ L, 0.09 mmol) was added, and the yellow solution was then poured on Fmoc-deprotected support **S3a**. The CPG beads were washed, capped, treated with TFA in CH_2Cl_2 (3%), washed, and dried in vacuo to yield 0.13 g of 6-[*N*-(4-iodophenylacetyl)homoseryl]aminoethylsuccinyl-sarcosine (**S4b**).

6-(*N*- α -Fmoc-*S*-tert-butylthiocysteinylhomoseryl)aminoethylsuccinyl-sarcosine LCAA-CPG-500 (S4c). Support **S3a** (0.5 g, 60.8 μ mol/g, 30.4 μ mol) was treated with piperidine/DMF (2:8 v/v, 2 mL) for 15 min and washed with DMF (10 $\times$ 2 mL). *N*- α -Fmoc-*S*-tert-butylcysteine pentafluorophenyl ester (179 mg, 0.3 mmol) and HOAt (41 mg, 0.3 mmol) were dissolved in DMF (1.2 mL), DIEA (52 μ L, 0.3 mmol) was added, the mixture was shaken for 5 min, and the yellow solution was then poured on Fmoc-deprotected support **S3a**. The CPG beads were washed, capped, treated with TFA in CH_2Cl_2 (3%), washed, and dried in vacuo to yield 0.48 g of 6-[*N*-(*N*- α -Fmoc-*S*-tert-butylcysteinyl)homoseryl]aminoethylsuccinyl-sarcosine LCAA-CPG-500, and the loading was estimated to be 56.6 μ mol/g (93%).

A Tripeptide S4 Support: 6-(*N*- α -Fmoc-Lys(Tfa)-Lys(Tfa)-Lys(Tfa)-homoseryl)aminoethylsuccinyl-sarcosine LCAA-CPG-500 (S4d). A batch of support **S3a** (0.25 g, 7.7 μ mol, 27.5 μ mol g⁻¹ substitution) was treated with piperidine/DMF (2:8 v/v, 1 mL) for 10 min and washed with DMF (10 $\times$ 1 mL). Fmoc-Lys(Tfa)-OH (36 mg, 0.08 mmol) and HATU (26 mg, 0.07 mmol) were dissolved in DMF (0.5 mL), DIEA (13 μ L, 0.08 mmol) was added, and the mixture was shaken for 5 min. More DIEA (13 μ L, 0.08 mmol) was added, and the solution was poured onto Fmoc-deprotected support **S3a**. The slurry was kept for 1 h with occasional swirling, the CPG beads were filtered off and washed with DMF (3 $\times$ 1 mL), and the procedure was repeated. After 1 h, the CPG beads were filtered off, washed with DMF (2 $\times$ 1 mL) and acetonitrile (2 $\times$ 1 mL), and treated on the filter with equal volumes of capping solutions I and II (0.5 mL of each) for 15 min, washed successively with DMF (5 $\times$ 1 mL), MeOH (5 $\times$ 1 mL), and diethyl ether (5 $\times$ 1 mL), and finally dried in vacuo to obtain 0.23 g of 6-(*N*- α -Fmoc-*N*- ϵ -Tfa-lysyl-*O*-tritylhomoseryl)aminoethylsuccinyl-sarcosine LCAA-CPG-500 with estimated loading 27.1 μ mol g⁻¹ (99% substitution). A portion of the above support (0.2 g, 5.4 μ mol) was treated with Fmoc-deprotected, coupled again with Fmoc-Lys(Tfa)-OH, capped, washed, and dried as before to yield 0.19 g of di-Lys support with an estimated loading 27.2 μ mol g⁻¹ (99% substitution). A third cycle of Fmoc deprotection, coupling, and capping and washing as before was followed by treatment with a solution of TFA in CH_2Cl_2 (3% v/v, 1 mL). The beads were kept in contact with acid for 1 min, washed with 3% TFA in CH_2Cl_2 (2 $\times$ 0.75 mL), MeOH (2 $\times$ 0.75 mL), CH_2Cl_2 (5 $\times$ 0.75 mL), and diethyl ether (3 $\times$ 0.75 mL), and finally dried in vacuo to give 0.18 g of 6-(*N*- α -Fmoc-Lys-

(Tfa)-Lys(Tfa)-Lys(Tfa)-homoseryl)aminoethylsuccinyl-sarcosine LCAA-CPG-500 **S4d** with estimated loading of 26.1 μ mol g⁻¹ (96% substitution).

Other S5 Supports: 2-[(2-Cholesterylloxycarbonylhomoseryl)aminoethoxy]ethylsuccinyl-sarcosine LCAA-CPG-500 (S5b). Support **S3b** (0.25 g, 0.01 mmol) Fmoc-deprotected and washed was treated with 2-cholesterylchloroformate (53 mg, 0.11 mmol) in CH_2Cl_2 (1 mL) and DIEA (40 μ L, 0.22 mmol) for 1 h, washed, capped, washed again, and dried to yield 0.24 g of 2-[(2-cholesterylloxycarbonylhomoseryl)aminoethoxy]ethylsuccinyl sarcosine LCAA-CPG-500 **S5b**.

6-(6-*N*-Fmoc-aminohexanoyl-*O*-tritylhomoseryl)aminoethylsuccinyl-sarcosine LCAA-CPG-500 (S6a). A batch of support **S3a** (0.25 g, 7.7 μ mol, 27.5 μ mol g⁻¹ substitution) was treated with piperidine/DMF (2:8 v/v, 1 mL) for 10 min and washed with DMF (10 $\times$ 1 mL). 6-Fmoc-aminohexanoic acid (27 mg, 0.08 mmol) and HATU (26 mg, 0.07 mmol) were dissolved in DMF (0.5 mL), DIEA (13 μ L, 0.08 mmol) was added, and the mixture was shaken for 5 min. More DIEA (13 μ L, 0.08 mmol) was added, and the solution was poured onto Fmoc-deprotected support **S3a**. The slurry was kept for 1 h with occasional swirling, the CPG beads were filtered off and washed with DMF (3 $\times$ 1 mL), and the procedure was repeated. After 1 h, the CPG beads were filtered off, washed with DMF (2 $\times$ 1 mL) and acetonitrile (2 $\times$ 1 mL), and treated on the filter with equal volumes of capping solutions I and II (0.5 mL of each) for 15 min, washed successively with DMF (5 $\times$ 1 mL), MeOH (5 $\times$ 1 mL), and diethyl ether (5 $\times$ 1 mL), and finally dried in vacuo. A total of 0.24 g of 6-(6-*N*-Fmoc-aminohexanoyl-*O*-tritylhomoseryl)aminoethylsuccinyl-sarcosine LCAA-CPG-500 **S6a** was obtained with estimated loading of 28.2 μ mol g⁻¹ (100% substitution).

2-[2-(6-*N*-Fmoc-aminohexanoyl-*O*-tritylhomoseryl)aminoethoxy]ethylsuccinyl-sarcosine LCAA-CPG-500 (S6b). Support **S3b** (0.50 g, 0.02 mmol) was treated analogously to the synthesis of support **S6a** to yield 0.49 g of 2-[2-(6-*N*-Fmoc-aminohexanoyl-*O*-tritylhomoseryl)aminoethoxy]ethylsuccinyl-sarcosine LCAA-CPG-500 **S6b** with estimated loading of 41.9 μ mol g⁻¹ (88% substitution).

Synthesis of 6-[*N*-(6-(Biotinylamino)hexanoyl)homoseryl]aminoethylsuccinyl-sarcosine LCAA-CPG-500 (S7a). Support **S6a** (0.1 g, 6.0 μ mol) was treated with piperidine/DMF (2:8 v/v, 0.5 mL) for 15 min and washed with DMF (10 $\times$ 0.5 mL). D-(+)-Biotin 4-nitrophenyl ester (44 mg, 0.12 mmol) and HOAt (16 mg, 0.12 mmol) were dissolved in DMF (0.25 mL), DIEA (25 μ L, 0.14 mmol) was added, and the mixture was shaken for 5 min. The yellow solution was then poured onto Fmoc-deprotected support **S6a**. The slurry was kept for 16 h with occasional swirling, and the CPG beads were filtered off, washed with DMF (2 $\times$ 0.5 mL) and acetonitrile (2 $\times$ 0.5 mL), treated on the filter with equal volumes of capping solutions I and II (0.25 mL of each) for 15 min, and washed successively with DMF (5 $\times$ 0.5 mL), MeOH (5 $\times$ 0.5 mL), and CH_2Cl_2 (2 $\times$ 0.5 mL). A solution of TFA in CH_2Cl_2 (3% v/v, 0.5 mL) was added, and the beads were kept in contact with acid for 1 min, washed with 3% TFA in CH_2Cl_2 (2 $\times$ 0.5 mL), MeOH (2 $\times$ 0.5 mL), CH_2Cl_2 (5 $\times$ 0.5 mL), and diethyl ether (3 $\times$ 0.5 mL), and finally dried in vacuo. A total of 0.1 g of 6-[*N*-(6-biotinylamino)hexanoyl]homoseryl]aminoethylsuccinyl-sarcosine LCAA-CPG-500 (**S7a**) was obtained.

2-[2-(*O*,*O'*-Diisobutyl-2,7-dichlorofluorescein-5(6)-ylcarbonylamino)hexanoylhomoseryl]aminoethoxy]ethylsuccinyl-sarcosine LCAA-CPG-500 (S8a).

Support **S6b** (0.25 g, 0.01 mmol) was Fmoc-deprotected and coupled with 2,7-dichloro-5(6)-carboxyfluorescein diacetate (50 mg, 0.1 mmol), washed, capped with a mixture of 10% v/v isobutyric anhydride solution in THF (0.5 mL) and Cap B solution (0.5 mL) for 30 min, and washed again as for the preparation of support **S5a**. A solution of TFA in CH₂Cl₂ (3% v/v, 1 mL) was added, and the beads were kept in contact with the acid for 1 min, washed with 3% TFA in CH₂Cl₂ (2 × 1 mL), MeOH (2 × 1 mL), CH₂Cl₂ (5 × 1 mL), and diethyl ether (3 × 1 mL), and finally dried in vacuo. A total of 0.23 g of 2-[2-(*O,O'*-diisobutryl-2,7-dichlorofluorescein-5(6)-ylcarbonylamino)hexanoylhomoserine]aminoethoxy]ethylsuccinyl-sarcosine LCAA-CPG-500 (**S8a**) was obtained as slightly yellow beads.

RESULTS

Preparation of Solid Supports. We wished to develop a method of functionalization of solid supports that has both flexibility and convenience. First, the chemical reactions should be readily carried out in high yield and with reagents that are either available commercially or simply prepared. Second, the method must be compatible in principle with conjugation either pre- or post-assembly of the oligonucleotide chain. Third, for pre-assembly conjugation, a wide range of conjugate molecules should be able to be introduced at a late stage in support functionalization and without need for a multistep synthesis of the conjugate reagent. Fourth, the linker should not be racemic as this will lead to formation of a mixture of conjugate diastereomers. Finally, the procedure must be flexible enough to allow a range of spacers to be included between oligonucleotide and conjugate for different applications. Such requirements are well met by peptide-type coupling reactions and use of linker molecules containing the 9-fluorenylmethoxycarbonyl group (Fmoc) protecting group that is removable under mild piperidine deprotection conditions, techniques standard in solid-phase peptide synthesis (Chan and White, 2000). Use of the Fmoc group allows for careful monitoring of the loading of the solid support at various stages of its preparation, due to the high UV absorbance of its piperidyl adduct.

In contrast to other strategies of pre-synthesis of complex linker reagents, we have applied the "submonomer" principle (Figliozzi et al., 1996), where small, economically prepared Fmoc-protected synthons are coupled sequentially by means of efficient peptide-like coupling reactions. For the crucial chain-branching agent, we chose the bifunctional amino acid L-homoserine which is chirally pure. Use of a single enantiomer of the amino acid excludes the possibility of multiple stereoisomer formation inevitable in the case of racemic linkers such as 3-amino-1,2-propanediol (Nelson et al., 1989). Further and as reported previously (Beltrán et al., 1997), the spacing of three carbon atoms between the hydroxyl and carbonyl groups in homoserine renders it incapable of β -elimination of a nucleotide substituent that is observed to occur under basic conditions for β -hydroxy amino acids such as serine or threonine. The hydroxyl group of homoserine is used as an anchoring point for growth of the oligonucleotide chain by reaction with the first nucleoside as its phosphoramidite derivative, whereas the α -amino group can be utilized as the site of attachment of the conjugate or other reporter group. Conjugates can be coupled directly to this amino group or after elongation with a spacer, such as 6-aminohexanoic acid.

Homoserine was suggested recently as a branching agent for the stepwise synthesis of 3'-peptide conjugates

of oligonucleotides but in this case required the four-step pre-synthesis of a glycyl dipeptide to avoid racemization expected to occur upon homoserine esterification of a hydroxybutyrate-substituted solid support (Antopolsky and Azharyev, 1999). By contrast in our route, we have used directly the commercially available, protected homoserine derivative, Fmoc-Hse(Trt)-OH, without further modification (Scheme 1).

Thus, a solid support such as LCAA-CPG is first functionalized to provide both spacing and suitable ammonia lability required for deprotection and cleavage of oligonucleotides from the support. This is carried out by coupling of amino-functionalized LCAA-CPG with a long-chain amino alcohol, such as 6-aminohexanol or 2-(2-aminoethoxy)ethanol esterified to the support via an ammonia-labile succinate linker. Whereas a 6-(4-methoxytrityl)aminohexyl succinate linker has been used previously to attach peptide nucleic acids to a solid support (Will et al., 1995), we decided to use stable, crystalline and easily synthesized compounds 6-Fmoc-aminohexyl and 2-(2-Fmoc-aminoethoxy)ethyl succinates (**2a** and **2b**) as building blocks in linker construction (Scheme 1). We found that amino alcohols containing less than four methylene units gave poor loadings when coupled to the solid support as succinate hemiesters, presumably due to intramolecular O–N migration (D. A. Stetsenko and M. J. Gait, unpublished results). However, both long-chain succinic acid hemiesters **2a** and **2b** were efficiently coupled to the LCAA-CPG-500 using the HATU/DIEA in situ activation protocol commonly used in solid-phase peptide synthesis (Chan and White, 2000) to give the solid supports **S2a** and **S2b**.

Subsequently, Fmoc-Hse(Trt)-OH was attached to the Fmoc-deprotected aminoester support by use of the same coupling method to give the homoserine supports **S3a** and **S3b**. Low reagent consumption and high loading efficiencies (routinely 40–70 $\mu\text{mol g}^{-1}$ based on incorporation of Fmoc) are worth noting in both cases. Since we found that the succinate linkage attached through a primary amino group on the LCAA-CPG support is progressively degraded by repetitive piperidine treatment, we introduced instead a sarcosine (*N*-methylglycine) unit between the succinyl group and solid support (**S1**), with consistently better results. Once again, this is introduced by the same peptide coupling reaction. The *O*-trityl protecting group on homoserine serves the dual purpose of preventing the acylation of the side-chain hydroxyl group during the coupling of the homoserine unit to the solid-phase and in the following capping reactions, as well as excluding the possibility of homoserine lactone formation during carboxyl group activation. The trityl group can be cleaved off prior to oligonucleotide synthesis by dilute trifluoroacetic acid treatment.

The Fmoc-homoserine-derivatized aminoalkyl succinate CPG supports **S3a** and **S3b** are now ready for conjugate synthesis by either pre- or post-assembly of the oligonucleotide chain. Since most types of conjugate are stable to the conditions of oligonucleotide synthesis and deprotection, we have concentrated on more convenient pre-assembly conjugation. Thus, we used the α -amino group of the homoserine for direct attachment of a variety of reporter groups (Scheme 1), once again via a peptide-type coupling reaction with the corresponding carboxylic acid of the reporter group. As examples, we have prepared a number of functionalized supports **S4** starting from support **S3a** that carries the aminohexyl spacer: the small organic groups 4-pentynoyl (**S4a**) or 4-iodophenylacetyl (**S4b**) or the amino acid derivative *N*- α -Fmoc-*S*-tert-butylthio-cysteine (**S4c**). Some other functionalized

Scheme 1

supports **S5** were prepared starting from the 2-aminoethoxyethyl-spaced support **S3b**: the fluorescent group 6-carboxyfluorescein (**S5a**) or the steroid cholesterol (**S5b**). In each case, the conjugation was carried out by piperidine treatment of the support to cleave off the Fmoc group, followed by reaction of the resultant primary amino group with the conjugate either as a carboxylic acid in the presence of HATU/DIEA or in the case of cholesterol, the corresponding chloroformate derivative.

As a monitor of the accessibility of the primary amino group and to demonstrate the feasibility of use of this type of support in the total synthesis of peptide-oligonucleotide conjugates, we assembled the short tripeptide Lys-Lys-Lys on the homoserine support **S4** using a *N*- ϵ -Tfa-protected Lys monomer and standard HATU/DIEA coupling conditions. The three coupling reactions proceeded in average coupling yield of 98.3% per cycle as judged by incorporation of the Fmoc group, to give support **S4d**.

Another option is to introduce a hexanoyl spacer between the homoserine and the reporter group. Thus coupling of Fmoc-amino hexanoic acid to the piperidine-treated support **3a** and **3b** afforded the extended supports **S6a** and **S6b** respectively (Scheme 2). Coupling with the appropriate reporter group or amino acid can now be carried out as before to give the supports **S7** and **S8**, respectively. Examples of these supports are those carrying biotin (**S7a**) or 2,7-dichloro-5(6)-carboxyfluorescein (**S8a**). In the case of biotin, the 4-nitrophenyl ester was used in the coupling reaction. In the case of 2,7-dichloro-5(6)-carboxyfluorescein, the *O,O'*-diacetate was found to be partially unstable under HATU/DIEA-mediated coupling conditions, leading to partial *N*-acetylation of support-bound amino groups. We therefore used iso-

butyric anhydride to cap any liberated phenolic groups on the conjugate.

It should be noted that in principle any reporter molecule that can be activated for reaction with an amino group (e.g., carboxylic, carbonic, isothiocyanate, or sulfonyl derivatives) can be coupled using the same technique. Thus, we have successfully loaded these supports with a large range of other functionalities such as the fluorescent group pyrene-1-ylacetic acid, lipophilic groups such as stearic and adamantane-1-acetic acids, ($\pm$)-lipoic acid, deoxycholic acid, as well as other amino acids such as His and Arg (data not shown).

Synthesis of 3'-Conjugated Oligonucleotides. To demonstrate the utility of these supports in solid-phase synthesis of 3'-conjugates of oligonucleotides we have carried out a number of oligonucleotide assemblies (Table 1). Starting from support **S4a** (4-pentynoyl), an 11-mer oligodeoxyribonucleotide was assembled by standard phosphoramidite synthesis (Dmt on). After ammonia deprotection, reversed-phase HPLC showed a large main product corresponding to the 5'-trityl-3'-pentynoyl oligonucleotide derivative (Figure 2a). MALDI-TOF mass spectrometry showed the expected mass for the desired product (Table 1). Note that the ammonia treatment of the support liberates the oligonucleotide as a 3'-phosphodiester that is linked to the homoserine moiety. The *N*- α -position of the homoserine carries the conjugate moiety (pentynoyl), and the carboxyl is linked as an amide to the detached spacer which remains as the corresponding alcohol (in this case 6-aminohexanol). Similarly, good results were obtained for synthesis of another 11-mer oligodeoxyribonucleotide starting from support **S4b** (4-iodophenylacetyl) and a 15-mer starting

from support **S4c** (*S*-tert-butylthiocysteinyl) (Figure 2b and Table 1).

Our recent goal has been to investigate antisense effects of the nuclease-stable and tight binding 2'-*O*-methyloligoribonucleotides against the HIV-1 TAR RNA target (Arzumanov and Gait, 1999; Mestre et al., 1999). Thus, starting from support **S5a** (6-carboxyfluorescein) that carries the 2-(2-aminoethoxy)ethyl linkage, a 12-mer anti-TAR 2'-*O*-methyloligoribonucleotide was synthesized. In this case, the trityl group was removed before ammonia deprotection and purification (Dmt off). Ion-exchange HPLC showed a major product of oligonucleotide-6-carboxyfluorescein conjugate (Figure 2c), once again with the correct mass (Table 1). Similarly, a 14-mer anti-TAR 2'-*O*-methyloligoribonucleotide was synthesized on support **S5b** (cholesterol) again with good results (Figure 2d). We also wished to prepare a 5',3'-bis-conjugate of the 2'-*O*-methyl anti-TAR 12-mer where the 3'-end was conjugated to 6-carboxyfluorescein, and the 5'-end was functionalized with a cysteine residue suitable for our recently described procedure for solution-phase conjugation to a peptide via "native ligation" (Stetsenko and Gait, 2000). Thus, starting from support **S5a**, the 12-mer 2'-*O*-methyl oligoribonucleotide was assembled and in a final coupling step the reagent *O*-4-(*N*-α-Fmoc-*S*-tert-butylsulfenyl-L-cysteinyl)piperidyl *O*-2-cyanoethyl-*N,N*-diisopropylphosphoramidite (Stetsenko

and Gait, 2000a,b) was used. After ammonia deprotection and cleavage from the support, HPLC showed again a major 3'-carboxyfluorescein-5'-cysteinyl conjugate product (Figure 2e and Table 1).

To demonstrate the potential for sequential peptide and oligonucleotide synthesis, a 10-mer 2'-*O*-methyl oligoribonucleotide was assembled on the tri-Lys support **S4d**. After ammonia deprotection and cleavage from the support, conditions which also result in removal of *N*-ε-trifluoroacetyl protecting groups from the Lys residues, HPLC showed an excellent yield of peptide-oligonucleotide conjugate (Figure 2f and Table 1).

To show that these methods are also compatible with phosphorothioate linkages in oligonucleotides, we prepared the 12-mer anti-TAR 2'-*O*-methyl oligoribonucleotide where three phosphorothioate linkages were introduced at the 5'-end by a standard sulfurization reaction in the assembly cycle. After ammonia deprotection, ion exchange HPLC showed a series of five closely eluting product peaks (data not shown) representing partial separation of the nine phosphorothioate diastereomers. The combined product showed the correct mass and a good yield (Table 1).

Two further oligonucleotide assemblies were also carried out on the supports containing an additional amino-hexyl spacer between conjugate and the homoserine branching point. Thus, a 10-mer oligodeoxyribonucleotide

Figure 2. Analytical HPLC of crude oligonucleotide 3'-conjugates synthesized on homoserine supports **S4-S8** (A-B, reversed-phase HPLC, C-F, ion-exchange HPLC, for HPLC conditions see Materials and Methods). (A) 5'-Dmt-d(GTTAGCCAGAG), **S4a** 4-pentynoyl; (B) 5'-Dmt-d(CCCAGGCTCAG), **S4b** 4-iodophenylacetyl; (C) 2'-OMe(CUCCCAGGCUCA), **S5a** 6-carboxyfluorescein; (D) 2'-OMe(CUCCCAGGCUCAAA), **S5b** cholesteryl; (E) 2'-OMe(CUCCCAGGCUCA), 5'-*S*-*tert*-butylthiocysteinyl, **S5a** 6-carboxyfluorescein; (F) 2'-OMe(CUCCCAGGCU), **S4d** lysine tripeptide.

was synthesized on support **S7a** (biotin) and a 12-mer 2'-*O*-methyl oligoribonucleotide on support **S8a** (2,7-dichloro-5(6)-carboxyfluorescein). In the case of the biotin-functionalized 10-mer oligonucleotide synthesis, HPLC of the deprotected product showed a main product peak with high yield (Table 1). In the case of the 2,7-dichloro-5(6)-carboxyfluorescein-functionalized 12-mer oligonucleotide, the main product peak in the HPLC was the desired conjugate that was obtained in 47.2% yield (Table 1). Additionally, we isolated some *N*-acetylated amino-hexanoylhomoserine oligonucleotide as a side product resulting from the dye coupling step (28.7% yield).

DISCUSSION

Previous methods for synthesis of 3'-conjugates of oligonucleotides either require the conjugation reaction to be carried out after oligonucleotide assembly and cleavage from the support (linear linkers) or generally require the multistep synthesis of a specialized linker incorporating the conjugate. Our synthetic route allows the flexibility for both pre- and post-assembly conjugation and without the requirement for a multistep synthesis of a specialized linker reagent. Post-assembly conjugation is achievable, if desired, by standard synthesis of an oligonucleotide starting from supports **S3a** or **S3b** followed by ammonia treatment. The resultant amino group on the homoserine could then be coupled to the conjugate

molecule in solution in an analogous way to the use of C3 or C7 3'-amino-modifier CPG supports available commercially (e.g., Glen Research).

We have concentrated instead on pre-assembly conjugation, since this has been harder to achieve by a general method in the past. We have demonstrated the ready ability to make supports containing a wide range of different functionalities (fluorescent, aromatic, aliphatic, amino acid, etc.). One obvious application would be in the preparation of bis-5',3'-fluorescent oligonucleotide probes for use in FRET or Taqman-type assays as an alternative to the commonly used 3-aminobutyl-1,3-propane diol 3'-linker (Mullah and Andrus, 1997). Similarly, we have shown the synthesis of a bis-conjugated 2'-*O*-methyl 12-mer oligonucleotide containing a 3'-carboxyfluorescein and a 5'-cysteine. The cysteine residue may be used for further conjugation to a thioester peptide by the method of native ligation we recently described (Stetsenko and Gait, 2000a). Another potential application of our technology would be in the parallel preparation of a range of 3'-conjugated oligonucleotides for use in combinatorial screening in diagnostic or therapeutic applications. In addition, the route allows one to vary the length between conjugated molecule(s) and oligonucleotide by choice of appropriate spacer molecule (e.g., amino acid or aminohexanoic acid).

A special case of conjugation is the synthesis of peptides linked through the 3'-end of the oligonucleotide. There have been a number of recent papers in this area aimed at preparing 3'-peptide conjugates or 3', 5'-bis conjugates. Post-assembly conjugation at the 3'-end has been most popular (Kahl et al., 1998; Kahl and Greenberg, 1999; Aubert et al., 2000). However, there is now renewed interest in total solid-phase oligonucleotide-3'-peptide synthesis. For example, a linear 3'-dimethyl-hydroxypropionic acid spacer was used for on column synthesis of 5'-dipeptide, 3'-amino acid conjugates of oligonucleotides (Schwope et al., 1999). A more general route of 3'-peptide conjugate synthesis involves attachment of the oligonucleotide to the support via the exocyclic amino group of a cytidine residue, synthesis of an oligonucleotide toward the 5'-direction and then synthesis of a short peptide (Gly-Gly-His shown) toward the 3'-direction after attachment of a 3'-aminolinker as a phosphoramidite reagent (De Napoli et al., 1999). A less cumbersome method involves attachment of the oligonucleotide to a peptide through a serine residue, but this route requires special allyl-protected nucleotide derivatives to avoid the use of basic conditions during oligonucleotide assembly and deprotection (Sakakura and Hayakawa, 2000). The most encouraging total synthesis route utilizes a 3-amino-1,2-propane diol linker attached to the support via one hydroxyl group and a succinate spacer. Sequential peptide and oligonucleotide assemblies are carried out on the two arms of the linker in turn (Antopolsky and Azhayev, 1999). Our new supports can be used in principle in such a total synthetic route, as demonstrated by our efficient assembly of a tripeptide conjugate Lys-Lys-Lys of an oligonucleotide. In addition to chiral purity and ease of preparation, another advantage of the use of our linker strategy is the ability to vary the length between oligonucleotide and peptide by use of aminohexanoic or other spacer.

In summary, we have presented a convenient and flexible method for the preparation of 3'-conjugates of oligonucleotides that should have wide synthetic, diagnostic, and therapeutic applications.

ACKNOWLEDGMENT

We thank Donna Williams and Richard Grenfell for oligonucleotide assemblies and purifications, Vladimir Korshun for helpful discussions, and Andrew Walsh for some HPLC purifications.

Avidin-dendrimer-(1B4M-Gd)₂₅₄: A Tumor-Targeting Therapeutic Agent for Gadolinium Neutron Capture Therapy of Intraperitoneal Disseminated Tumor Which Can Be Monitored by MRI

Hisataka Kobayashi,^{*,†} Satomi Kawamoto,[‡] Tsuneo Saga,[§] Noriko Sato,[§] Takayoshi Ishimori,[§] Junji Konishi,[§] Koji Ono,^{||} Kaori Togashi,[†] and Martin W. Brechbiel¹

Hitachi Medical Co., chaired, Department of Diagnostic and Interventional Imagiology, and Department of Nuclear Medicine and Diagnostic Imaging, Kyoto University, Kyoto 606-8507, Japan, Department of Radiology, Otsu Municipal Hospital, Otsu 520-0804, Japan, Research Reactor Institute, Kyoto University, Osaka 590-0494, Japan, and Radioimmune & Inorganic Chemistry Section, Radiation Oncology Branch, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20892. Received January 8, 2001; Revised Manuscript Received March 26, 2001

Peritoneal carcinomatosis is a late stage in cancer progress, for which no effective therapeutic modality exists. Targeting therapeutic agents to disseminated lesions may be a promising modality for treating peritoneal carcinomatosis. Gadolinium (^{157,155}Gd) is known to generate Auger and internal conversion electrons efficiently by irradiation with a neutron beam. Auger electrons from neutron-activated Gd(III) are strongly cytotoxic, but only when Gd(III) atoms have been internalized into the cells. In the present investigation, we have developed a quickly internalizing tumor-targeting system to deliver large quantities of Gd(III) atoms into tumor cells to generate the Auger emission with an external neutron beam. Simultaneously, one would be able to image its biodistribution by MRI with a shortened T1 relaxation time. Avidin-G6-(1B4M-Gd)₂₅₄ (Av-G6Gd) was synthesized from generation-6 polyamidoamine dendrimer, biotin, avidin, and 2-(*p*-isothiocyanatobenzyl)-6-methyl-diethylenetriaminepentaacetic acid (1B4M). The Av-G6Gd was radiolabeled with Gd(III) doped with ¹⁵³Gd. All of the 1B4M's on the conjugate were fully saturated with Gd(III) atoms. An *in vitro* internalization study showed that Av-G6Gd accumulated and was internalized into SHIN3 cells (a human ovarian cancer) 50- and 3.5-fold greater than Gd-DTPA (Magnevist) and G6-(1B4M-Gd)₂₅₆ (G6Gd). In addition, accumulation of Gd(III) in the cells was detected by the increased signal on T1-weighted MRI. A biodistribution study was performed in nude mice bearing intraperitoneally disseminated SHIN3 tumors. Av-G6Gd showed specific accumulation in the SHIN3 tumor (103% ID/g) 366- and 3.4-fold greater than Gd-DTPA (0.28% ID/g, *p* < 0.001) and G6Gd (30% ID/g, *p* < 0.001) 1 day after *i.p.* injection. Seventy-eight percent of the tumor-related radioactivity of Av-G6Gd in the SHIN3 tumor was located inside the cells. The SHIN3 tumor-to-normal tissue ratio was greater than 17:1 in all organs and increased up to 638:1 at 1 day after *i.p.* injection. In conclusion, a sufficient amount (162 ppm) of Av-G6Gd was accumulated and internalized into the SHIN3 cells both *in vitro* and *in vivo* to kill the cell using ^{157/155}Gd with external irradiation with an appropriate neutron beam while monitoring with MRI. Thus, Av-G6Gd may be a promising agent for Gd neutron capture therapy of peritoneal carcinomatosis. This reagent also has the potential to permit monitoring of its pharmacokinetic progress with MRI.

INTRODUCTION

Neutron capture therapy (NCT) is a biomedical therapy consisting of two steps: (1) uptake/accumulation of a neutron-absorbing and principally nontoxic substance preferentially in the tumor; followed by (2) conversion/activation of the nontoxic agent into a radiotoxic sub-

stance after the neutron capture reaction by selectively irradiating the tumor with a neutron beam (1–3). Two isotopes, ¹⁰B and ¹⁵⁷Gd, are of major interest because of their significant large capture cross sections (CCS). Although the vast majority of NCT research has involved various aspects of boron chemistry for BNCT, ¹⁵⁷Gd has also been suggested from theoretical and experimental studies with limited success (4–9). The ¹⁵⁷Gd nuclide has the following possible advantages over ¹⁰B. First, ¹⁵⁷Gd has a significantly large neutron CCS of 255 000 barns, compared with 3840 barns for ¹⁰B (9). Second, Gd(III) complexes have been employed clinically as MRI contrast agents. The potential to trace the *in vivo* pharmacokinetics of a Gd-NCT agent directly by MRI (10, 11) would be useful for planning the neutron irradiation and to predict the therapeutic effect.

Peritoneal carcinomatosis is a late manifestation of cancer progress. Therapeutic options for treatment of the widely spread tumors in the peritoneal cavity are limited to intravenous or *i.p.* chemotherapy, usually with unsat-

isfactory results. To treat peritoneal carcinomatosis effectively, targeted delivery of therapeutic agents to disseminated lesions may be a promising tactic. The Auger electrons from Gd-NCT are strongly cytotoxic, but only when the Gd(III) atoms have been internalized into the cells (12). Therefore, targeted delivery with effective internalization of the Gd(III)-containing agent into the cancer cells of disseminated tumors in the peritoneal cavity followed by neutron beam irradiation is a potential schema for therapy of peritoneal carcinomatosis (13).

Avidin is a quickly internalizing molecule into either normal hepatocytes or cancer cells, especially ovarian and colorectal adenocarcinoma cells, which expressed β -D-galactose receptors (14–17). Polyamidoamine dendrimers are a class of highly branched spherical polymers that are highly soluble in aqueous solution and possess a unique surface of primary amino groups (18, 19). The defined structure and large number of available surface terminal primary amino groups of polyamidoamine dendrimers have led to their use as substrates for the attachment of multiple chelating agents to a single antibody molecule (19–22), and for the preparation of novel MRI contrast agents (11, 23, 24). A combination of these components, therefore, appeared possible to provide a reagent suitable for Gd-NCT.

Herein, we report the preliminary results of our ongoing investigation to provide a quickly internalizing tumor-targeting reagent into cancer cells that can be monitored by MRI to deliver large quantities of Gd(III) atoms for Gd-NCT. We describe the preparation and characterization of a macromolecular construct comprised of avidin, polyamidoamine dendrimer, and a bifunctional DTPA derivative for complexing Gd(III), and its in vitro and in vivo targeting and internalization properties.

EXPERIMENTAL PROCEDURES

PAMAM Dendrimers. The generation-6 PAMAM dendrimer (G6) (Aldrich Chemical Co., Milwaukee, WI) with an ethylenediamine core, 256 primary terminal amino groups, and a molecular mass of 57 991 Da was used.

Biotinylation and Conjugation of Chelates to G6 Dendrimers. A 10 mg/mL aliquot of G6 (170 nmol) was dissolved in PBS, pH 7.4, and mixed with 510 nmol of sulfosuccinimidyl-6-(biotinamide) hexanoate (Bt) (NHS-LC-biotin, MW = 340; Pierce Chemical Co., Rockford, IL) at a molar ratio of 1:3, at room temperature for 30 min. The mixture was applied to a diafiltration membrane (Centricon 30, Amicon, Inc., Beverly, MA) to remove unbound Bt as well as to change buffer to 0.1 M phosphate buffer, pH 9. After purification, a small aliquot of biotinylated G6 (Bt-G6) was examined with a modified HABA assay, as described previously in detail (25, 26). In brief, the 2-(4'-hydroxyazobenzene)benzoic acid (HABA; Pierce Chemical Co.) reagent was prepared according to the manufacturer's instructions by adding 10 mg of avidin and 600 μ L of 10 mM HABA to 19.4 mL of PBS. One hundred microliters of serially diluted Bt-G6 solutions was added to 900 μ L of the avidin-HABA solution. Then, the absorbance was measured at 500 nm. Approximately 0.88 biotin was conjugated to each G6 molecule.

The biotinylated G6 was concentrated to $\sim$ 5 mg/mL and reacted with a 256-fold molar excess of 2-(*p*-isothiocyanatobenzyl)-6-methyl-diethylenetriaminepentaacetic acid (1B4M, MW = 555) (44 μ mol) at 40 $^{\circ}$ C. The reaction was maintained at pH 9 with 1 M NaOH for 24 h. Another additional equal amount of 1B4M was added

to the mixture after 24 h as a solid, and the pH was maintained as before for another 24 h. The resulting preparation was purified by diafiltration using a Centricon 30 (Amicon Co.). Approximately $98.5 \pm 1.8\%$ of the amine groups on the surface of the G6 dendrimer reacted with the 1B4M, as determined by ^{153}Gd (NEN DuPont, Boston, MA) labeling of the reacted samples (27). In brief, $\sim$ 500 000 cpm ($\sim$ 0.4 pmol) of ^{153}Gd citrate was added to $\sim$ 40 μ g/10 μ L ($\sim$ 160 pmol) of the reaction mixture before diafiltration and incubated in 0.2 M acetate buffer for 15 min at room temperature. Then, the bound fractions to the conjugates and free 1B4M were separated using a PD-10 column (Pharmacia) and counted, after which the numbers of 1B4M chelates bound to the conjugate were calculated from the count of the radioactivity in the bound fraction to the conjugates. The binding ability to the avidin–Sephacrose gel (Pierce Chemical Co.) of ^{153}Gd -labeled Bt-G6-(1B4M-Gd) $_{254}$ (MW = 240 000) was examined (17). In brief, 3 ng/0.1 μ Ci of Bt-G6-(1B4M-Gd) $_{254}$ was incubated with 0.5 mL of avidin–Sephacrose gel for 15 min at room temperature. Then the gel fraction was washed and separated from the supernatant using a paper filter. The radioactivity of both fractions was counted using a γ -counter (Aloka, Tokyo, Japan). Then 82% of the radioactivity of the ^{153}Gd -labeled Bt-G6-(1B4M-Gd) $_{254}$ sample was bound to the avidin–Sephacrose gel.

For a control drug, G6-(1B4M-Gd) $_{256}$ (G6Gd; MW = 240 000) was prepared without conjugation with biotin as described previously (28).

Preparation of Avidin-G6-(1B4M-Gd) $_{254}$ Agent. Approximately 37 mg (0.16 μ mol) of biotinylated G6-1B4M conjugate (containing 40 μ mol of 1B4M) was mixed with 40 μ mol of nonradioactive Gd(III) citrate in 0.3 M citrate buffer for 2 h at 40 $^{\circ}$ C. The unbound Gd(III) atoms in each preparation were removed by diafiltration using the Centricon 30 (Amicon Co.). The purified samples were mixed with a 2-fold molar excess of avidin (19 mg/0.31 μ mol) (Pierce Chemical Co.) and incubated for 15 min at room temperature.

Radiolabeling of Avidin-G6-(1B4M-Gd) $_{254}$. Carrier-free $^{153}\text{GdCl}_3$ was purchased from NEN DuPont (Boston), and 1 mg (containing 1.3 μ mol of 1B4M) of avidin-G6-(1B4M-Gd) $_{254}$ (Av-G6Gd) (3 nmol; MW = 300 000) conjugate was reacted with 40 μ Ci of ^{153}Gd citrate in 0.3 M citrate buffer at pH 5 for 30 min at room temperature. To remove any nonincorporated free radiometal, 10 μ L of 0.5 M EDTA (Nakarai, Tokyo, Japan) was added, and the product was purified by passage through a PD-10 column (Pharmacia, Uppsala, Sweden) eluted with PBS (pH 7.4).

The radiolabeling yields ranged from 67 to 79%. Eighty-two percent of the conjugated sample bound to biotin–Sephacrose gel (Pierce Chemical Co.).

DTPA (Nakarai, Tokyo, Japan) was also labeled with ^{153}Gd in 0.3 M citrate buffer for 15 min at room temperature.

Cell Lines and Animal Models. The SHIN3 cell line, obtained originally from a human ovarian cancer, was used for performing an in vitro internalization assay and also for generating in vivo intraperitoneal disseminating tumors in this study. The cell lines were grown in RPMI 1640 medium (GIBCO Laboratories, Grand Island, NY) containing 10% fetal bovine serum (FBS) (GIBCO Laboratories) and 0.03% L-glutamine at 37 $^{\circ}$ C in 5% CO_2 with 1 day doubling time.

The intraperitoneal tumor xenografts were established by i.p. injection of 4×10^6 cells suspended in 350 μ L of PBS into 7-week-old female BALB/c nude mice, which

Figure 1. Flowchart of the protocol for preparing Avidin-G6-(1B4M-Gd)₂₅₄.

Figure 2. Micro-MR image of SHIN3 cell pellets incubated with 4 μmol of Av-G6Gd, G6Gd, Gd-DTPA, or PBS [no Gd(III)] (upper row), and a solution (lower row) of Av-G6Gd containing the same concentration of Gd(III) as the cell pellet incubated with Av-G6Gd based on radioactivity, and a PBS solution was obtained using the 3D-SPGR method.

were feeding in the clean animal facility. Experiments with tumor-bearing mice were performed at 3–4 weeks after injection when the large numbers of tumors of ~ 2 mm diameter had grown in the peritoneal cavity, especially at the hilum of the spleen, the root of the mesenterium, and around the stomach. All the mice will be died with malignant ascites within 2 months after inoculation of SHIN3 cells.

Internalization Assay and Signal Changes on MRI. SHIN3 cells (5×10^5) were preseeded into 150 cm^2 dishes and cultured overnight in RPMI 1640 medium (Nissui Pharmaceutical Co., Tokyo, Japan) supplemented with 10% FBS (GIBCO) and 0.03% L-glutamine, in a 5% CO_2 environment. Subconfluent cells were incubated with 300 000 cpm/4 μmol of Gd of either ^{153}Gd -labeled Av-G6Gd, ^{153}Gd -labeled G6Gd, ^{153}Gd -DTPA, or PBS in 25 mL of RPMI 1640 medium with 10% FBS for 24 h at 37 $^\circ\text{C}$. The medium was removed, and cells were washed with 0.5 M Na_2HPO_4 /0.5 M NaH_2PO_4 , 0.1 M NaCl, pH 7.4, containing 0.53 mM EDTA and 0.05% trypsin (GIBCO). The membrane-bound radioactivity was removed by washing the cells with acidic solution (0.05 M glycine hydrochloride/0.1 M NaCl, pH 2.8). Radioactivity in the acid-resistant (internalized) and acid-sensitive (membrane-bound) fractions was counted using a γ -counter (Aloka, Tokyo, Japan). The percentages of the membrane-bound fraction and internalized fraction of the total added radioactivity were calculated.

Then, MR images of the cell pellets of each preparation incubated with Av-G6Gd, G6Gd, Gd-DTPA, PBS, or an Av-G6Gd solution containing the same concentration of Gd(III) as the cell pellet incubated with Av-G6Gd were obtained using the 3D-fast spoiled gradient echo technique (fSPGR) method. In brief, the fSPGR (TR/TE 150/4.2; flip angle 60 $^\circ$; 4 numbers of excitation) and 3D data acquisitions were used. The coronal images were reconstructed with 0.7-mm section thickness without gaps. The field of view was 8 $\times$ 6 cm, and the size of the matrix was 256 $\times$ 192. The signal intensities of cells in each preparation (quadricate) were measured. The regions of interest were set on each cell pellet, and their average intensities were analyzed (Advantage Windows, General Electric Medical System).

Furthermore, cells were added with the same volume of 20% SDS solution and solubilized at room temperature for 1 week. At that time, MR images of the cell solutions of each preparation were obtained using the same method described above.

Biodistribution and Internalization Study of Gadolinium into Tumor Cells. SHIN3 cancer cells [$(3-4) \times 10^6$] were injected i.p. into 7-week-old female BALB/c athymic mice. Groups of mice bearing i.p. tumors received an i.p. injection of 37 kBq (1 μCi) of ^{153}Gd -labeled Av-G6Gd, ^{153}Gd -labeled G6Gd, or ^{153}Gd -DTPA. The injected samples were added to nonradioactive Av-G6Gd or G6Gd (3.9 nmol), and the total gadolinium dose was

adjusted to approximately 1 $\mu\text{mol}/\text{mouse}$ (0.05 $\mu\text{mol}/\text{g}$). The mice were sacrificed at 4 or 24 h after the injection of radioactivity by ether inhalation ($n = 4-6$). Blood, i.p. disseminated tumors, and organs were removed and weighed, and their radioactivities were determined using a γ -counter. The percentages of injected dose per gram of tissue (% ID/g) were determined, and the results were normalized to a 20-g mouse. The tumor-to-normal tissue uptake ratios of the radioactivity were also calculated. To evaluate the internalized fraction of Gd(III) atoms in the SHIN3 cells *in vivo*, the removed tumors were incubated in 0.5 M $\text{Na}_2\text{HPO}_4/0.5$ M NaH_2PO_4 , 0.1 M NaCl, pH 7.4, containing 0.53 mM EDTA and 0.05% trypsin (GIBCO) for 15 min at 37 $^\circ\text{C}$ immediately after being weighed and γ -counted to obtain the single cell suspension. The membrane-bound radioactivity was removed by washing the cells with an acidic solution (0.05 M glycine hydrochloride/0.1 M NaCl, pH 2.8), after which the tumor cells were completely suspended in the solution. Radioactivity in the acid-resistant (internalized) and acid-sensitive (membrane-bound) fractions was counted using a γ -counter (Aloka). The percentages of the membrane-bound fraction and internalized fraction in the added radioactivity were calculated.

All animal experiments were carried out in accordance with the regulations of Kyoto University animal facility regarding animal care and handling.

Statistical Analysis. Statistical analysis was performed using the Student's *t*-test (Sigmatat, Jandel Scientific, San Rafael, CA).

RESULTS

Internalization Assay and Signal Changes on MRI. The *in vitro* internalization study showed that ^{153}Gd -labeled Av-G6Gd accumulated in the SHIN3 cells (3.2%) 50- and 3.5-fold greater than ^{153}Gd -DTPA (0.064%) and ^{153}Gd -labeled G6Gd (0.91%) 1 day after incubation, respectively. By T1-weighted MRI (Figure 1), the increase in the T1 signal of SHIN3 cells incubated with Av-G6Gd (545 ± 58) was significantly greater than that with Gd-DTPA (120 ± 42 ; $p < 0.01$) and G6Gd (276 ± 75 ; $p < 0.01$), but smaller than that of a stock solution of the Av-G6Gd containing the same concentration of Gd atoms (967 ± 104 ; $p < 0.01$) (Figure 2a). After solubilizing the SHIN3 cells with SDS, the signal intensities of the cell solution containing Av-G6Gd (560 ± 41) were not significantly different from that of the Av-G6Gd solution containing the same amount of Gd atoms (630 ± 107 ; $p = 0.27$) (Figure 2b).

Biodistribution Study. ^{153}Gd -labeled Av-G6Gd showed specific accumulation in the i.p. disseminated SHIN3 tumors (103% ID/g) 366- and 3.4-fold greater than Gd-DTPA (0.28% ID/g, $p < 0.001$) and G6Gd (30% ID/g, $p < 0.001$) 1 day after i.p. injection (Figure 3). The SHIN3 tumor-to-normal tissue ratio was greater than 17 for all organs. The SHIN3 tumor-to-blood ratio increased up to 638 at 1 day after i.p. injection (Figure 4). In addition, 78 and 93% of the tumor-related radioactivity of ^{153}Gd -labeled Av-G6Gd in SHIN3 tumors was located inside the cells at 6 h and 1 day postinjection, respectively (Figure 5). In contrast, 35 and 78% of the tumor-related radioactivity of ^{153}Gd -DTPA in SHIN3 tumors was located inside the cells at 6 h and 1 day postinjection, respectively ($p < 0.01$) (Figure 6).

DISCUSSION

In previous studies, gadolinium atoms chelated with DTPA or macrocyclic compounds were used for Gd-NCT

Figure 3. Plots of the signal intensity of cell pellets incubated with 4 μmol of Av-G6Gd, G6Gd, Gd-DTPA, or PBS [no Gd(III)], and a solution of Av-G6Gd containing the same concentration of Gd(III) as the cell pellet incubated with Av-G6Gd based on radioactivity, and a PBS solution was obtained using the 3D-SPGR method shown in Figure 1. The data are expressed as the mean signal intensity of four different sets of samples and standard deviation before (a) and after (b) solubilizing cells by SDS solution.

(5, 6, 8). When those compounds were injected either intravenously or intraperitoneally, they were located in extracellular fluid and rapidly cleared from the body. However, limited but significant therapeutic effects on tumor cells by irradiation with a neutron beam were reported (5, 6, 8, 29). In the present study, differences in pharmacokinetics between Gd-DTPA and Av-G6Gd were clearly demonstrated. Av-G6Gd specifically accumulated in the tumor cells and was internalized at 436-fold greater amounts than Gd-DTPA 1 day after injection. To the best of our knowledge, no successful internalization of massive numbers of Gd(III) atoms into cancer cells for targeted imaging or therapy has been previously reported. The internalized Gd(III) is theoretically more effective than extracellular Gd(III) atoms since the path length of the emitted Auger electrons, a major product of the neutron capture reaction, is so short.

In this study, Gd(III) accumulated at 162 ppm intracellularly, calculated on the basis of the ^{153}Gd radioactivity, in SHIN3 tumors *in vivo* at 1 day after injection, and 93% of Gd(III) was located in the SHIN3 cells. In a recent study, 400–800 ppm of extracellular Gd(III)-DTPA as well as 30–51 ppm of ^{10}B was reported as effective to kill cancer cells with neutron beam irradiation (30).

Figure 4. Biodistribution of ^{153}Gd -labeled Av-G6Gd (a), G6Gd (b), and Gd-DTPA (c) at 6 h (black bars) and 1 day (hatched bars) after i.p. injection in nude mice bearing SHIN3 intra-peritoneal disseminated tumors. The data are expressed as the mean percentages of injected dose per gram of normal tissues and standard deviation ($n = 4-6$). All data show significant differences ($p < 0.01$) compared with the appropriate group of data with Gd-DTPA.

Intracellular Gd(III) should be more cytotoxic than the extracellular Gd(III) because of the limited range of the high linear energy transfer Auger electron emission.

Figure 5. Plots of the serial SHIN3 tumor-to-normal tissue ratio of ^{153}Gd -labeled Av-G6Gd (black bars), G6Gd (hatched bars), and ^{153}Gd -labeled Gd-DTPA (white bars) 6 h (a) and 1 day (b) after i.p. injection. The data are expressed as the mean tumor-to-normal tissue ratio and standard deviation ($n = 4-6$). All data show significant differences between Av-G6Gd and G6Gd or Gd-DTPA ($p < 0.01$).

Therefore, the concentration of Gd(III) with Av-G6Gd in SHIN3 cells should be adequate for Gd-NCT. The use of $^{157/155}\text{Gd}$ enrichment would optimize this potential.

Av-G6Gd accumulation into the SHIN3 cells could also be evaluated by the signal change in the cell pellets by T1-weighted MRI. However, the T1 signal of Av-G6Gd in the SHIN3 cells was lower than that of Av-G6Gd in a PBS solution of the same Gd(III) concentration based on the ^{153}Gd radioactivity. In addition, when the Av-G6Gd-containing cells were solubilized with SDS solution, the T1 signals of the cell solution increased to be insignificantly different from the signal of the Av-G6Gd in PBS solution. Signal changes on the MRI with Gd(III) atoms are directly related to the interaction between Gd(III) atoms and free water molecules. In a recent study, the inconsistent change in T1-relaxation time/signals with Gd-DTPA in a solution containing macromolecular contents was discussed (31). Although a reported theory evaluated the changes of T1-relaxation time in the extracellular solution with macromolecules, when Av-G6Gd is internalized into cells, the Gd(III) atoms were not homogeneously located in the cell and thus did not increase the T1 signals.

Additionally, this observed discrepancy between radioactivity and the signal change on MRI may also be

Figure 6. Data of the internalized fraction and the cell-surface fraction of ^{153}Gd -labeled Av-G6Gd (black bars), G6Gd (hatched bars), and ^{153}Gd -labeled Gd-DTPA (white bars) 6 h (a) and 1 day (b) after i.p. injection in the SHIN3 tumors is plotted. The cell-surface radioactivity was determined using a wash with 0.53 mM DTPA and 0.05% trypsin (GIBCO Laboratories) for 15 min at 37 °C followed by an acid wash with 1 mL of 0.05 M glycine hydrochloride/0.1 M NaCl, pH 2.8, at 37 °C for 5 min. Then the cell pellets were separated from the supernatant by centrifugation and counted to determine the internalized fraction. The supernatants of trypsin/EDTA washing and acid washing were separately counted. Each data point was performed in quadruplicate, and the data were calculated as the mean percentage and standard deviation recovered in the supernatant, cell surface or internalized.

evidence that the Gd(III) atoms were internalized. No conventional imaging method has been able to evaluate intra- or extracellular localization of agents containing nonradioactive metal atoms *in vivo*. Detection of the cellular localization of Gd(III) atoms contained in Av-G6Gd was also possible by the discrepancy between MRI and scintigraphy and with the use of ^{111}In as an alternative to Gd(III).

In this study, we used the 3D-SPGR sequence rather than 2D-T1 spin-echo (SE) sequence because the minimal slice thickness of 2D-T1SE was a 2-mm slice with a 0.3-mm slice gap, too thick to evaluate the T1 signal of the cell pellets of approximately 2-mm thickness. In contrast, the 3D-SPGR allows a 0.7-mm slice without gaps and choice of the slice with maximal signal intensity to evaluate the T1 signal.

In conclusion, a massive number of Gd(III) atoms up to 162 ppm were specifically delivered into the intraperitoneally disseminated SHIN3 tumor cells with the

newly synthesized Av-G6Gd molecule for Gd-NCT. In addition, this reagent can be dynamically traced by MRI to optimize Gd-NCT protocols and then to address the associated dosimetry considerations.

BC010002O

Fluorescent Gramicidin Derivatives for Single-Molecule Fluorescence and Ion Channel Measurements

Tyler Loughheed, Vitali Borisenko, Christine E. Hand, and G. Andrew Woolley*

Department of Chemistry, 80 St. George Street, University of Toronto, Toronto, Ontario M5S 3H6, Canada. Received January 22, 2001; Revised Manuscript Received April 12, 2001

Single-molecule spectroscopies in combination with single-channel patch-clamp measurements have the potential for providing new information on ion channel gating processes. Fluorescent gramicidin derivatives could provide a means for calibrating such experiments since the structure of the open channel is known and the mechanism of gating (peptide dimerization) is generally agreed. We describe here the synthesis and characterization of two pairs of gramicidin derivatives that should prove useful for such studies. They contain robust fluorophores, undergo resonance energy transfer (FRET) when they dimerize, and have single-channel properties close to those of the wild-type channel.

INTRODUCTION

Ion channels have been subjects of intensive study ever since the demonstration of their central importance for the function of nerve and muscle tissue (1, 2). The molecular events underlying channel gating (opening and closing) are of particular interest (3, 4). The difficulty of producing large quantities of these proteins and the necessity of maintaining a membrane environment for their proper function have hampered NMR-based and X-ray-based structural studies (5–7).

Single-molecule fluorescence spectroscopy, in combination with site-specific fluorescent-labeling strategies and simultaneous electrical detection of ion flux, offers the potential for obtaining structural information on the gating process under near-native conditions (8, 9). The possibility of obtaining information on structural rearrangements accompanying gating using simultaneous fluorescence and electrical measurements under multichannel conditions has already been demonstrated by Isacoff and colleagues and by Cha and Bezanilla (10–13). Single-molecule optical measurements offer the possibility of more detailed structural analyses. For instance, substates in opening transitions, that might be obscured in a multichannel analysis, could be resolved (14). The potential of combined optical and electrical detection for providing new information on the structures and dynamics of single ion channels has been realized (15), and several reports demonstrating the feasibility of such studies have appeared (16–19). In particular, single-molecule fluorescence resonance energy transfer (FRET)¹ could provide a direct means for probing structural changes underlying channel gating. Several reports of single-molecule fluorescence resonance energy transfer (FRET) have now appeared (20–24).

To fully exploit the power of single-molecule optical methods to extract structural information on complex membrane proteins, it will be useful to have well-characterized model systems with which to calibrate the measurements (16). Changes in apparent FRET ef-

iciency can arise from several sources including reversible transitions to nonemitting states ('blinking') (25) and dye dynamics (26) (e.g., cis–trans isomerizations). Failure to account for different photostates can lead to errors in the interpretation of FRET experiments (27).

The ion channel formed by the peptide gramicidin (HCO-Val-Gly-Ala-D-Leu-Ala-D-Val-Val-D-Val-Trp-D-Leu-Trp-D-Leu-Trp-D-Leu-Trp-NHCH₂CH₂OH) meets the requirements of a model system for simultaneous optical and electrical detection of ion channel gating. The structure and function of the gramicidin channel are well-established (28–30). Indeed, simultaneous fluorescence and conductance measurements with gramicidin (in a multichannel configuration) were reported 25 years ago by Veatch and Stryer (31). This classic work helped establish the dimeric model for the gramicidin channel.

Gramicidin is hydrophobic and readily incorporates into bilayers when added to the aqueous phase nearby. Movement of gramicidin monomers in the plane of the membrane is relatively fast [diffusion rates measured using fluorescence recovery after photobleaching techniques are similar to those measured for fluorescently labeled lipids (32)]. The channel is formed upon association of two gramicidin monomers, one from each leaflet of the bilayer membrane, in an N-terminal to N-terminal (head-to-head) fashion (Figure 1) (28, 29, 33). The $\beta^{6.3}$ helical structure of the peptide provides a pore ~ 28 Å long and 4 Å in diameter that traverses the membrane when a dimer forms. The pore is lined by backbone amide groups and permits the transmembrane flux of small monovalent cations at maximum rates of 10^6 – 10^7 ions

Figure 1. Schematic diagram showing the dimerization of fluorescent gramicidin derivatives in a lipid bilayer. The bilayer is represented as two parallel lines. Dimerization provides a pathway for monovalent cations (small circles) through the membrane. This cation flux can be detected electrically at the single-channel level. Dimerization is also expected to permit efficient fluorescence resonance energy transfer (FRET) between donor (gram-R6G) and acceptor (gram-Cy5) peptides. In principle, this FRET signal could also be detected at the single-channel level.

per second. The channel is stabilized by six hydrogen bonds at the dimer junction. Channel closing is believed to be due to dissociation of the dimer into monomers. At 25 °C, the average lifetime of a dimer is on the order of 1 s (34, 35).

If gramicidin dimerization could be detected optically at the single-molecule level, one would expect the optical change to coincide with a change in ionic current, measured electrically, through the membrane. With fluorescently labeled gramicidin derivatives, optical detection of peptide dimerization should be possible by measuring resonance energy transfer that would occur between dyes with appropriate absorption and emission spectra. Figure 1 shows the process diagrammatically. Peptides bearing a donor dye are added to one side of a lipid bilayer and peptides bearing an acceptor dye to the other. Transmembrane ionic current is measured using conventional patch-clamp or BLM techniques, and dimerization is detected as a step increase in this current. Upon peptide dimerization, the donor and acceptor dyes are 50 Å or less apart, a distance that should lead to efficient resonance energy transfer for many donor–acceptor pairs (36).

We describe here the synthesis and characterization of two pairs of fluorescently labeled gramicidin derivatives that should prove useful for combined optical and electrical single-molecule studies. The synthetic methods are general and could be used to prepare other fluorescent gramicidin derivatives from commercially available amine-reactive dyes. We show that the derivatives incorporate into unilamellar lipid vesicles and into planar bilayers. Single-channel properties of the derivatives measured electrically in planar bilayers were found to be similar to those of the unmodified channel. When donor and acceptor peptides are incorporated into the same lipid vesicles, fluorescence resonance energy transfer was observed under conditions where the channel can be shown to be active using a diffusion potential assay.

Thus, the fluorescent gramicidin derivatives appear to have properties suitable for combined optical and electrical single-molecule experiments. Some further requirements for such experiments are considered.

MATERIALS AND METHODS

1. Synthesis of Gramicidin-EDA (Gram-EDA). The C-terminal end of gramicidin was derivatized as described previously to install a primary amino group (37). Briefly, commercial gramicidin D (38 mg, 20 μmol) was combined with *p*-nitrophenyl chloroformate (200 μmol) in dry tetrahydrofuran (2 mL) (4 °C), and then triethylamine (TEA) (100 μL) was added and the mixture stirred for 1 h at 4 °C. The resulting carbonate ester was filtered through Celite into a 100-fold molar excess of ethylenediamine in 2 mL of dimethylformamide (DMF). The product [gramicidin-ethylenediamine (gram-EDA)] was then separated by gel filtration using Sephadex LH-20 (2.5 × 20 cm gravity column) in methanol. The product was further purified using reverse-phase HPLC [Zorbax-RX-C8 column (4.6 × 250 mm), isocratic conditions, 80% MeOH/20% H₂O, 0.1% TFA adjusted to a pH of 3.0 with TEA, flow rate = 1 mL/min, retention time 6.2 min]. Electrospray mass spectrometry: gram-EDA = C₁₀₂H₁₄₇N₂₂O₁₈ (M+H⁺) calcd = 1969.4, obsd = 1969.5; TLC (C:M:W = 65:25:4): gramicidin *R_f* = 0.70, gram-EDA *R_f* = 0.47.

2. Synthesis of Gramicidin-Rhodamine-6G (Gram-R6G). Gramicidin-EDA (2.0 mg, 1.02 μmol) was dissolved in 1.0 mL of dry DMF in a round-bottom flask under a nitrogen atmosphere. To the stirring solution of gram-EDA was added 100 μL of dry TEA. In a separate reaction vessel, also under nitrogen, 1.0 mg (1.8 μmol) of (5/6)-carboxyrhodamine-6G-NHS ester (Molecular Probes) was dissolved in 1.0 mL of dry DMF. The gram-EDA solution was then added dropwise over a period of 1 h via syringe to the stirring dye solution. After the reaction had stirred

for 24 h, protected from light, the DMF was removed under high vacuum and the product resuspended in methanol and separated from unreacted dye using gel-filtration chromatography (LH-20 in methanol). The product was further purified using reverse-phase HPLC [Zorbax-RX-C8 column (4.6 × 250 mm), isocratic conditions, 80% MeOH/20% H₂O, 0.1% TFA adjusted to a pH of 3.0 with TEA, flow rate = 1 mL/min, retention time 11.6 min]. MALDI mass spectrometry: gram-R6G = C₁₂₉H₁₇₁N₂₄O₂₂ (M+H⁺) calcd = 2409.8, obsd = 2409.7; TLC (C:M:W = 65:25:4): gramicidin *R_f* = 0.70, gram-R6G *R_f* = 0.77.

3. Synthesis of Gramicidin-Cy5 (Gram-Cy5). Gramicidin-Cy5 was prepared in a manner similar to that described for gram-R6G. Gram-EDA (0.4 mg, 0.2 μmol) was mixed with 20 μL of dry TEA in 0.2 mL of dry DMF; then the contents of one vial (nominally 0.2–0.3 mg) of Cy5-NHS-ester (monoreactive)(Amersham Pharmacia Biotech) dissolved in 0.2 mL of dry DMF were added dropwise. This solution was stirred at room temperature overnight protected from light. The solvent was removed under high vacuum, and the residue was dissolved in 1 mL of methanol. The product was then purified by HPLC [Zorbax-C8 column (4.6 × 250 mm), isocratic conditions, 98% solvent A (0.1% TFA in 80% MeOH/20% H₂O)/2% solvent B (0.1% TFA in H₂O), flow rate = 1 mL/min, retention time 5.4 min]. MALDI mass spectrometry (negative ion mode): gram-Cy5 = C₁₃₅H₁₈₃N₂₄O₂₅S₂ calcd = 2606.2, obsd = 2605; TLC (C:M:W = 65:25:4): gramicidin *R_f* = 0.70, gram-Cy5 *R_f* = 0.44.

4. Synthesis of Gramicidin-PyMPO (Gram-PyMPO). PyMPO-NHS [1-(3-(succinimidylloxycarbonyl)-benzyl)-4-(5-(4-methoxyphenyl)oxazol-2-yl)pyridinium iodide] (Molecular Probes) (1.7 mg, 3 μmol) was combined with 0.17 mL of dry DMF, vortexed, and added slowly to 1 mL of dry DMF containing gram-EDA (1.2 mg, 1 μmol). After 1 h, dry TEA (20 μL, 0.14 mmol) was added, and the solution was stirred overnight at room temperature protected from light. The DMF was pumped off, and the product was purified by gel filtration using LH-20 in methanol. The product was further purified using reverse-phase HPLC [Zorbax-RX-C8 column (4.6 × 250 mm), isocratic conditions, 10% MeOH/90% solvent B (80% MeOH/20% H₂O, 0.1% TFA adjusted to a pH of 3.0 with TEA), flow rate = 1.2 mL/min, retention time 6.2 min]. MALDI mass spectrometry: gram-PyMPO = C₁₂₅H₁₆₃N₂₄O₂₁ (M⁺) calcd = 2337.7, obsd = 2336.9; TLC (C:M:W = 65:25:4): gramicidin *R_f* = 0.70, gram-PyMPO *R_f* = 0.76.

5. Synthesis of Gramicidin-ROX (Gram-ROX). ROX-NHS (5-carboxy-X-rhodamine-*N*-hydroxysuccinimidyl ester, Molecular Probes, 1.9 mg, 3 μmol) was reacted with gram-EDA using the same procedure as described for gram-PyMPO. After purification using the LH-20 column, the gram-ROX was further purified with a silica gel column (2 × 20 cm) using C:M:W = 65:25:4 as eluant. The desired product was the first band eluted. The product was then purified using reverse-phase HPLC [Zorbax-RX-C8 column (4.6 × 250 mm), isocratic conditions, 15% MeOH/85% solvent B (80% MeOH/20% H₂O, 0.1% TFA adjusted to a pH of 3.0 with TEA), flow rate = 1.2 mL/min, retention time 10 min]. MALDI mass spectrometry: gram-ROX = C₁₃₅H₁₇₅N₂₄O₂₂ (M+H⁺) calcd = 2485.9, obsd = 2485.5; TLC (C:M:W = 65:25:4): gramicidin *R_f* = 0.70, gram-ROX *R_f* = 0.72.

6. Fluorescence Measurements of Gramicidin Derivatives in Lipid Vesicles. Unilamellar lipid vesicles containing gramicidin derivatives were prepared as follows: An aliquot of dioleoylphosphatidylcholine (DOPC)

(Avanti Polar Lipids) (2 mg, 2.54 μmol) dissolved in methanol was added to a 1.5 mL Eppendorf tube containing either a given number of moles (e.g., 1 nmol) of an individual fluorescent gramicidin derivative or a 1:1 mixture (e.g., 0.5 nmol each) of two fluorescent gramicidin derivatives (total methanol volume = 400 μL). Concentrations of fluorescent gramicidins were determined by UV–Vis absorbance measurements of stock solutions in methanol (extinction coefficients used: gram-R6G = 92 000 at 520 nm, gram-Cy5 = 250 000 at 649 nm, gram-PyMPO = 26 000 at 415 nm, gram-ROX = 78 000 at 574 nm). Methanol was then removed under a gentle stream of dry nitrogen to form a thin lipid film, and the film was pumped under high vacuum for >2 h. The lipid/gramicidin film was resuspended in 400 μL of 400 mM KCl, 6.5 mM phosphate buffer, pH 7.0. Unilamellar vesicles containing fluorescent gramicidins were then formed by repeated extrusion (20 passes) of the lipid suspension through a polycarbonate membrane (Avanti Polar Lipids) with a pore diameter of 100 nm. Fluorescence measurements were made of vesicle solutions prepared from 1:1 mixtures of fluorescent gramicidins and compared to measurements of 1:1 mixtures of vesicle solutions prepared from pure fluorescent gramicidins. Final lipid concentrations and peptide concentrations are given in the figure legends. Steady-state fluorescence measurements were made using a Perkin-Elmer LS50B spectrofluorometer (equipped with a red-sensitive photomultiplier for Cy5 detection) and a 150 μL cuvette with 0.5 cm excitation and emission path lengths. All measurements were made at room temperature (23 ± 2 °C).

7. Fluorescence Detection of Diffusion Potentials Generated by Gramicidin in Lipid Vesicles. The establishment of a diffusion potential across lipid vesicle membranes was assayed using the potential-sensitive fluorescent dye safranin O (38). Unmodified gramicidin (0.1, 1, 3, 5, 50 nmol) was combined with lipid (32 μmol) in methanol. Vesicles were then prepared exactly as described above except that 500 μL of 200 mM KCl, 5 mM phosphate buffer, pH 7.0, was used. After extrusion through 100 nm polycarbonate filters, 20 μL of this vesicle solution was added to 3 mL of a solution of 340 mM sucrose, 5 mM phosphate buffer, pH 7.0, containing 1 μM safranin O (Aldrich). The fluorescence emission of safranin O was monitored at 581 nm (excitation 521 nm, 5 nm slits, 0.5 s response time).

8. Single-Channel Conductance Measurements of Gramicidin Derivatives. The general techniques for making single-channel conductance measurements of gramicidin derivatives have been described previously (39). A solution of 1 M CsCl, 5 mM BES, pH 7.0, was used as the electrolyte. Gramicidin derivatives were HPLC-purified at least twice (using the conditions given above) before use in single-channel measurements to ensure highly uniform conductance events (40). Peptides (~10 nM in methanol) were added to membranes formed from diphytanoylphosphatidylcholine/decane (50 mg/mL) (Avanti Polar Lipids). Membranes were formed by painting the lipid solution across a ~100 μm aperture in a polypropylene pipet tip mounted horizontally in a Teflon well. Silver/silver chloride electrodes were placed, one on either side of the membrane, and were connected to the CV-4B headstage of an Axopatch 1D patch-clamp amplifier (Axon Instruments) controlled by Synapse (Synergetic Research Systems) software that permitted transmembrane voltage to be set and current recorded using the same pair of electrodes. Current records were filtered

Figure 2. Chemical structures of gramicidin derivatives.

at 50 or 100 Hz, sampled at 1 kHz, stored directly to disk, and analyzed using Synapse and Igor (Wavemetrics Inc.) software.

RESULTS AND DISCUSSION

Synthesis of Fluorescently Labeled Peptides.

Gramicidin isolated from *Bacillus brevis* is a mixture of peptides (denoted gramicidin D) with the general structure formyl-Xxx-Gly-Ala-D-Leu-Ala-D-Val-Val-D-Val-Trp-D-Leu-Yyy-D-Leu-Trp-D-Leu-Trp-NHCH₂CH₂OH, where Xxx is Val or Ile and Yyy is Trp (gramicidin A), Phe (gramicidin B), or Tyr (gramicidin C) (Figure 2) (41). Previous work with fluorescent gramicidins (31, 32, 42–44) relied primarily on a dansylated (Tyr¹¹-O-dansyl) gramicidin C derivative. Although this derivative was reported to have channel properties similar to those of native gramicidin, modifications at position 11 in the sequence to install various fluorescent groups might not be generally well tolerated (28). We decided instead to focus on derivatization of the C-terminal end of the peptide since chemical modifications at this end (the membrane/solution interface) do not significantly affect the overall structure of the channel (29).

Chemical modifications were carried out on the mixture (gramicidin D) since it is predominantly (>80%) Val¹-gramicidin A and, in any case, all peptides are HPLC-purified after modification, which removes minor species. Val¹-gramicidin A has no functional groups suitable for reaction with typical fluorescent labeling reagents, so we first derivatized the C-terminal end to provide a convenient site for attachment of commercially available amine-reactive fluorescent labels (37).

To be useful for single-molecule work, fluorescent dyes must be robust (i.e., resistant to photobleaching). We therefore focused on cyanine-based and rhodamine-based dyes that have been used successfully for these purposes (45). In addition, for fluorescence resonance energy transfer (FRET) measurements, dyes with overlapping emission and excitation spectra are required (46). The amine-functionalized gramicidin (gram-EDA, Figure 2) was reacted with four different fluorescent labels (rhodamine-6G, Cy5, PyMPO, ROX) all purchased as *N*-hydroxysuccinimide esters. Each product was purified by gel filtration chromatography in methanol (the pep-

tides are not water soluble), followed by reverse-phase high-performance liquid chromatography (HPLC) to ensure that no unreacted gram-EDA or unreacted dye was present (40). Mass spectrometry [matrix-assisted laser desorption ionization (MALDI)], in addition to absorbance and fluorescence data, confirmed the identity of the products. The chemical structures of the four fluorescently labeled gramicidin derivatives are shown in Figure 2. In addition, uniform single-channel conductance properties (vide infra) are an excellent indication of purity (40).

Channel Formation in Lipid Vesicles. Before performing fluorescence measurements, we wished to ensure that the fluorescent gramicidins were incorporated into a membrane in a functional form. Accordingly, dilute solutions of the peptides were combined with lipid in methanol. Under these conditions, the peptides are expected to be predominantly monomeric (47). As the methanol is evaporated, the peptide forms an intimate mixture with the lipid. When aqueous buffer is then added and the lipid/peptide suspension is extruded through 100 nm polycarbonate filters, unilamellar lipid vesicles are expected to form with peptide incorporated in the single-helix (channel-forming) structure. Although gramicidin peptides are known to form intertwined double helices in organic solvents, these convert to the single-helix form in the presence of lipid (47). Polar organic solutions facilitate this conversion. In particular, trifluoroethanol has been reported to function well in this regard (48). However, we found that traces of TFE remaining after extensive drying led to interference with fluorescence measurements, particularly where membrane potential was assayed using safranin O (see below). Consequently, we used methanol as the solvent for mixing peptide and lipid.

Lipid vesicles of 100 nm diameter may be estimated to contain ~100 000 molecules of lipid taking an average area per lipid molecule of 0.6 nm² (49). If one takes 1 nmol of gramicidin and 2.5 μmol of lipid, an average of 40 gramicidin molecules per vesicle is obtained. This corresponds to a total surface density of gramicidin in the membrane of 2.3×10^{-13} mol/cm².² The fraction of dimeric (active channel) form will depend on the dimerization constant for the particular membrane type.

Dimerization constants have been estimated for the dansyl gramicidin C derivative in dioleoylphosphatidylcholine (DOPC)/decane membranes by Veatch et al. (31) to lie in the range of 10^{13} – 10^{14} cm²/mol. Values between 10^{14} (for 0 mV) and 10^{15} cm²/mol (for 200 mV) have been reported for gramicidin A by Bamberg and Lauser (35) based on current relaxation measurements also in DOPC/decane membranes (the voltage dependence arises from a voltage-induced thinning of the membrane). If we use the same range of values for the present case, 63–95% of the peptide is estimated to be in dimeric form. As the concentration of peptide is lowered, the equilibrium fraction of dimers decreases; however, even with only two gramicidin molecules per vesicle, ion transport should still be possible over time. Transport should not be possible in vesicles with less than two peptide molecules since one molecule cannot form a channel and molecules cannot move between vesicles assuming there is no vesicle fusion (50).

To test the prediction that active channels should be present in vesicles when two or more peptide molecules are present, we investigated whether a diffusion potential could be established across the vesicle membranes. Vesicles were prepared in 200 mM KCl solution and diluted into isotonic sucrose solution. Were a gramicidin channel present, K⁺ ions should diffuse out of the vesicle, but, since no other cations are present and gramicidin is impermeable to anions, a potential should develop, negative inside, that opposes K⁺ efflux. Development of this potential can be followed by observing the redistribution of the cationic fluorescent dye safranin O between aqueous and membrane-bound compartments (38). Figure 3 shows the fluorescence response observed with various concentrations of (unmodified) gramicidin per vesicle. The channel is clearly active. As expected, no fluorescence response is seen if equimolar NaCl is included in the external medium (data not shown), in keeping with the known ability of gramicidin to transport sodium ions.

Fluorescence Spectroscopy. Having established that the present procedure for incorporating gramicidin channels into lipid vesicles led to active channel species, we wished to examine the fluorescence properties of these channels and to test whether the fluorescent tags would serve as functional donor–acceptor pairs for use in fluorescence resonance energy transfer studies. Figure 4 shows normalized fluorescence excitation and emission spectra for each of the four fluorescent gramicidins incorporated (individually) into lipid vesicles. The small size of the lipid vesicles used (100 nm diameter) results in light scattering intensities at these wavelengths that can be readily separated from fluorescence (51).

To test for resonance energy transfer, two different types of sample containing vesicle-bound fluorescent gramicidins were prepared. In case A, a vesicle solution containing only donor peptide and a vesicle solution containing only acceptor peptide were prepared, and then these vesicle solutions were mixed in a 1:1 ratio. In case B, donor and acceptor peptides were mixed directly in a 1:1 ratio and then incorporated together into vesicles. The result is two solutions with equal concentrations of lipid, donor peptide, and acceptor peptide, but with different distributions of the donors and acceptors. Since the aqueous solubility of the peptides is very low, the peptides are not expected to redistribute between vesicles (50). In case A, the following molecular species may be present:

Figure 3. Fluorescence detection of channel formation in vesicles. At the time indicated by the arrow, K⁺-loaded vesicles alone (0) or K⁺-loaded vesicles containing gramicidin (average number of gramicidin molecules per vesicle is indicated) were added to K⁺-free buffer containing isotonic sucrose and the potential-sensitive dye safranin O. Concentrations are given under Materials and Methods. Fluorescence enhancement is observed as the dye associates with vesicle membranes in response to the development of a K⁺ diffusion potential (38).

Figure 4. (A) Excitation and emission spectra (normalized) of gram-R6G and gram-Cy5 in lipid vesicles: (— · —) gram-R6G excitation, (····) gram-R6G emission, (—) gram-Cy5 excitation, (— —) gram-Cy5 emission. (B) Excitation and emission spectra (normalized) of gram-PyMPO and gram-ROX in lipid vesicles: (— · —) gram-PyMPO excitation, (····) gram-PyMPO emission, (—) gram-ROX excitation, (— —) gram-ROX emission.

donor monomers, donor dimers, acceptor monomers, and acceptor dimers. In the premixed sample (case B), donor–acceptor dimers (i.e., FRET pairs) will also be present. Since the concentration of vesicles in these experiments is ~64 nM (6.4 mM DOPC present in vesicles of 100 000

² Forty molecules of peptide (6.6×10^{-23} mol) divided by the area of a 100 nm diameter vesicle (2.9×10^{-10} cm²).

Figure 5. (A) Fluorescence resonance energy transfer between gram-R6G and gram-Cy5: (—) gram-R6G (0.3 μ M) and gram-Cy5 (0.31 μ M) in separate vesicles (6.4 mM DOPC); (---) gram-R6G (0.31 μ M) and gram-Cy5 (0.34 μ M) in the same vesicles (6.4 mM DOPC), excitation at 490 nm, 10 nm slit widths. (B) Fluorescence resonance energy transfer between gram-PyMPO and gram-ROX: (—) gram-PyMPO (1.1 μ M) and gram-ROX (0.9 μ M) in separate vesicles (6.4 mM DOPC); (---) gram-PyMPO (1.3 μ M) and gram-ROX (1 μ M) in the same vesicles (6.4 mM DOPC), excitation at 422 nm, 15 nm slit widths.

molecules each), the average separation between vesicles is ~ 3000 Å. This value is much larger than the expected Förster distance (~ 50 Å) so that FRET should only be possible in case B, where donor and acceptor gramicidins are co-incorporated into the same vesicles.

Figure 5A compares the fluorescence spectra obtained in case A and case B for the gram-R6G/gram-Cy5 pair where the peptide:lipid ratio is $\sim 1:10\,000$. Figure 5B compares the spectra obtained with the gram-PyMPO/gram-ROX pair where the peptide:lipid ratio is $\sim 1:3200$. In each case, significant quenching of donor fluorescence is observed for case B, the premixed samples, in comparison to case A. Additional evidence for FRET is the enhancement of acceptor fluorescence in case B for each dye pair. Note that there is minimal direct excitation of the acceptor in the gram-R6G/gram-Cy5 case as compared to the gram-PyMPO/gram-ROX case. Energy transfer efficiencies were calculated by the method of Clegg et al. (52) using both donor quenching and acceptor enhancement data. Calculated transfer efficiencies were $\sim 23 \pm 5\%$ for the gram-R6G/gram-Cy5 pair and $60 \pm 10\%$ for the gram-PyMPO/gram-ROX pair for the particular conditions described in the legend to Figure 5. The lower transfer efficiency of the gram-R6G/gram-Cy5 pair is

consistent with a lower peptide-to-lipid ratio, and therefore a smaller fraction of dimers, for that case. Increasing the peptide-to-lipid ratio gave increasing FRET efficiencies as expected; however, with acceptor concentrations > 1 μ M, self-quenching of Cy5 was observed (data not shown).

In principle, FRET can also occur between donors and acceptors that are present in the same vesicle but not part of a donor/acceptor dimer. Such lateral energy transfer in lipid bilayers has been analyzed previously by several authors (53–56). While lateral FRET may be observed even when the average donor–acceptor distance exceeds the Förster distance severalfold (53), FRET will nevertheless occur most efficiently between donors and acceptors that are actually associated (55). The total surface density of gramicidin in the membrane in the present FRET experiments ranges from 5.8×10^{-14} to 2.3×10^{-13} mol/cm², which corresponds to average distances between noninteracting peptides in the range of 550–270 Å if they were monomeric and 750–380 Å if they were dimeric. These values are larger than the expected Förster distances for these dye pairs, and substantially larger than the distance between donor and acceptor dyes in a gramicidin dimer (~ 50 Å). Since the fluorescent gramicidin peptides are able to form active dimers as demonstrated by the conductance data in bilayers (vide infra), we expect the observed FRET to be due primarily to the presence of heterodimer (donor–acceptor) gramicidin channels rather than the mere coexistence of the donor and acceptor peptides in the same vesicles.

The observed energy transfer efficiency is affected not only by the ratio of dimers to monomers and the intrinsic efficiency for the particular dye pair as it occurs in the gramicidin dimer, but also by the fact that donors can be paired with donors as well as with acceptors. If we assume that the dimerization constants for all possible dimers [donor–donor, acceptor–donor (two orientations), acceptor–acceptor] are the same, then approximately half of all dimers present should be FRET pairs since the concentrations of donors and acceptors are approximately equal. Single-molecule FRET measurements with these systems would thus be expected to show approximately double the energy transfer efficiency determined from a macroscopic measurement on dimerized gramicidins.

Channel Formation in Black Lipid Membranes.

The single-channel properties of each of the fluorescent gramicidin derivatives were examined in planar lipid bilayers using 1 M CsCl as the electrolyte. Single-channel current recordings are shown in Figure 6. In general, the single-channel properties of all the derivatives are similar to native gramicidin channels measured under the same conditions (see Table 1) (57). This result is expected as the C-terminal modifications are not expected to affect channel function significantly (29). A distinguishing feature of the modified channels, however, is the small steplike current fluctuations superimposed on the main conducting level in each case (Figure 6). Steps in current recording are also observed with gramicidin-EDA of the same average duration (~ 50 ms) and are due to thermal cis–trans isomerization of the carbamate group that is introduced near the channel mouth that alters the position of the protonated amino group relative to the channel mouth (58). The size of the current steps is much smaller for the fluorescent derivatives than for gram-EDA because charges on the fluorescent groups are significantly further from the channel entrance [cf. (59)]. The variation of the step sizes between the different fluorescent derivatives is also expected since isomeriza-

Table 1. Single-Channel Properties of Fluorescent Gramicidin Derivatives

	gram A (<i>n</i> = 250)	gram-R6G (<i>n</i> = 96)	gram-Cy5 (<i>n</i> = 91)	gram-PyMPO (<i>n</i> = 23)	gram-ROX (<i>n</i> = 129)
mean lifetime ^a (s)	0.4	4	2.3	0.8	1.8
conductance ^b (pS)	46	45	45	45	43

^a Estimated as described in (63). ^b Measured at 200 mV, 1 M CsCl, using diphytanoylphosphatidylcholine/decane membranes. Errors are on the order 5%.

Figure 6. Representative single-channel current recordings of (a) gram-R6G, (b) gram-Cy5, (c) gram-PyMPO, and (d) gram-ROX in diphytanoylphosphatidylcholine membranes. The applied voltage was 200 mV, and 1 M CsCl was used as the electrolyte.

tion of the linkage connecting the fluorescent group to the rest of the peptide is likely to have different effects on ion access in each case. These small fluctuations may be considered signatures of the modified channels that distinguish them from possible gram-EDA or native gramicidin contaminants in the membrane. Isomerization might also be expected to affect FRET efficiency in time-resolved measurements on single molecules, and this feature of the modified channels might also provide an internal calibration for single-molecule optical measurements.

Toward Simultaneous Single-Molecule Optical and Electrical Measurements. Single-molecule electrical measurements with gramicidin and derivatives are straightforward and highly reproducible. The dye conjugates, with the exception of PyMPO, described here have been used successfully in single-molecule optical detection experiments previously, and we have demonstrated that the two pairs can undergo efficient FRET when channels form. Correlating a single-molecule FRET measurement with a channel opening event measured electrically will require that single active channels (dimeric channels) can be observed among nonconducting monomers in a planar bilayer. Single-channel measurements with gramicidin are typically performed at peptide-to-lipid ratios $<1:10^7$ (60). At these densities, individual molecules can be resolved by fluorescence imaging (8, 61). The ratio of dimers to monomers can be increased by altering lipid type or by adding certain detergents to the membranes (62). Asymmetric addition of donor peptides to one side of a planar bilayer and acceptor peptides to the other should ensure that the majority of channel openings occur between FRET pairs since transmembrane flip-flop of gramicidin peptides is slow (33). The fluorescent gramicidin channels presented here thus appear to have properties that should make them suit-

able for attempting simultaneous single-molecule optical and electrical measurements.

ACKNOWLEDGMENT

Design and Synthesis of Substrate and Internal Standard Conjugates for Profiling Enzyme Activity in the Sanfilippo Syndrome by Affinity Chromatography/Electrospray Ionization Mass Spectrometry

Scott A. Gerber,[†] František Tureček,^{*,†} and Michael H. Gelb^{*,†,‡}

Departments of Chemistry and Biochemistry, Bagley Hall, Box 351700, University of Washington, Seattle, Washington 98195-1700. Received January 22, 2001; Revised Manuscript Received May 17, 2001

We describe the design and synthesis of substrate and internal standard conjugates for application in profiling enzyme activity of the enzymes α -D-2-deoxy-2-*N*-sulfonamido-glucosamine sulfamidase, α -D-2-deoxy-2-*N*-acetyl-glucosamine hydrolase, acetyl-coenzymeA: α -D-2-deoxy-2-amino-glucosamine transferase, and α -D-2-deoxy-2-*N*-acetyl-glucosamine-6-sulfate sulfatase. Deficiency of any one of these enzymes results in a single clinical phenotype known as Sanfilippo syndrome. Such substrates have been proven effective in the confirmation of enzyme deficiency by a combination of affinity chromatography (AC) and electrospray ionization mass spectrometry (ESIMS), which forms the foundation for a new analytical technology (ACESIMS) of general interest and application to clinical and biomedical research.

INTRODUCTION

Affinity chromatography has become increasingly popular over the past several decades as a simple yet highly selective method for the purification of a wide assortment of biomolecules (1, 2). In particular, the use of biotin and its corresponding receptor proteins avidin and streptavidin is now quite common in laboratories focused on life science research (3, 4). As a result, there is a growing body of biotin-conjugate chemistry in the literature for the preparation of biotinyl derivatives for a host of applications. In our research (5), we are developing biotinylated enzyme–substrate conjugates as the foundation of a mass spectrometric method to determine clinically relevant enzyme velocities directly in crude cell lysates from children suspected of suffering from enzyme-deficient disease.

The lack of properly functioning enzyme activity due to genetic aberrations in the coding sequence of such enzymes is a common molecular basis for inherited disease (6). Although there are a variety of methods in the clinical laboratory used to biochemically confirm a diagnosis of enzyme deficiency, there exists to date no single, unifying method capable of determining multiple, unique enzyme activities simultaneously, in a single sample (multiplexing). Such a technology could allow for the rapid and prompt screening of newborns for the most common genetic diseases. This would be advantageous and beneficial in the prompt identification and treatment of possible afflictions and would lead to reduced exposure of young patients to repeated biopsies.

Our recent efforts to establish such a technology have been successfully applied to several enzyme-deficient diseases (5, 8). In our approach, biotinylated substrate conjugates are incubated with fibroblast lysate obtained from cultures of skin biopsies from either apparently normal or putatively affected individuals. Action of the enzyme of interest on the substrate portion of the conjugate compositionally modifies the substrate conjugate, resulting in a change in mass of the substrate. A known amount of internal standard is added that is chemically identical to the product generated by enzyme activity but with deuterium incorporated into the conjugate. The mixture of excess substrate, nondeuterated enzyme product, and internal standard is purified from the biological matrix by addition of streptavidin–agarose to the sample and washing with purified water. The biotinylated conjugates are then selectively eluted from the bound receptor by addition of excess free biotin acid. This eluant is transferred to an electrospray-ionization mass spectrometer for analysis. The absolute amount of product formed during the reaction is determined by calculating the ratio of product to internal standard ion currents observed in the mass spectrum. In addition, an enzyme initial velocity can be calculated by determining the moles of product generated during the time in which the initial velocity condition exists.

The design of our substrate conjugates starts with biotin as the molecular handle with which such conjugates can be simply and selectively purified from the biological sample. Biotin is in turn conjugated to sarcosine to form an *N*-methyl biotinamide motif which is resistant to the enzyme biotinidase (7), known to be present in biological samples such as serum. Biotinidase would otherwise cleave our handle from the remainder of the conjugate. Sarcosinyl biotin is further linked to a water-soluble polyether linker. The linker also serves to position the structurally distinct biotin away from the substrate to avoid steric discrimination by the targeted enzyme, avidin or streptavidin. The linker also provides

a location for facile synthetic incorporation of deuterium for internal standards. The length (i.e., mass) of the linker can also be adjusted to avoid mass redundancy with other conjugate pairs in a multiplex analysis. The amine terminus of the linker is attached to the substrate portion, either by direct conjugation to the substrate or by way of an adapter segment of variable composition for conjugation to a wide variety of substrate substructures.

In the present work, we describe the synthesis of substrate and internal standard conjugates used to profile the enzyme velocities involved in Sanfilippo syndrome. This approach has recently been shown to be successful in the confirmation of diagnoses for several diseases of enzyme deficiency, including the lysosomal storage disorder known as Sanfilippo syndrome (8). In this condition, deficiency of the four heparinoid-degrading enzymes α -D-2-deoxy-2-*N*-sulfonamido-glucosamine sulfamidase, α -D-2-deoxy-2-*N*-acetyl-glucosamine hydrolase, acetyl-coenzymeA: α -D-2-deoxy-2-amino-glucosamine transferase, and α -D-2-deoxy-2-*N*-acetyl-glucosamine-6-sulfate sulfatase results in a Sanfilippo subtype A, B, C, or D, respectively (9–12).

EXPERIMENTAL PROCEDURES

General. Reagent-grade chemicals (including solvents) were obtained from commercial vendors and were generally used without further purification. Anhydrous dimethylformamide and pyridine were purchased from Aldrich Chemical Co. (Milwaukee, WI), and used as received. Triethylamine was frequently redistilled from calcium hydride and stored under argon. HPLC-grade solvents were purchased from Fischer (Fair Lawn, NJ), and water for HPLC was purified at point-of-use by a Milli-Q water system (Millipore, Bedford, MA). Trifluoroacetic acid was purchased from Advanced Chemtech (Louisville, KY), and was added to HPLC solvents as required, followed by 0.2 μ m filtration. Triethylene glycol was purchased from Fluka (Buchs, Switzerland). Methyl *N*-methyl-*N*-biotinyl glycinate (7), 1-fluoro-2-deoxy-2-(*N*-trifluoroacetyl)-3,4,6-tri-*O*-acetyl-glucosamine (13), 1- α -(*p*-nitrophenyl)-2-deoxy-2-(*N*-trifluoroacetyl)-3,4,6-tri-*O*-acetyl-glucosamine (13), and 2,3,5,6-tetrafluorophenyl trifluoroacetate (14) were prepared according to the literature. All syntheses involving highly toxic materials (sodium cyanide etc.) were performed in a fume hood. Due caution is advised in reproducing these syntheses.

Spectral Analyses. ^1H NMR data were obtained on Bruker (Rheinstetten, Germany) spectrometers: AC-200 (200 MHz), AC-300 (300 MHz), or AC-500 (500 MHz). Proton chemical shifts are designated as parts-per-million (ppm) from tetramethylsilane (δ = 0.00 ppm). Mass spectral data were obtained using either a Kratos (Manchester, United Kingdom) HV-4 electrospray ionization-double-focusing (E/B) magnetic sector or Bruker Daltonics (Bremen, Germany) Esquire electrospray-ion trap mass spectrometers with standard, commercial interfaces. Methanol/acetic acid (99.5:0.5) was used as solvent, and contained 5 μM gramicidin S (average, doubly charged molecular weight $(\text{M}+2\text{H}^+)^{2+}$ = 571.6) to verify mass accuracy.

Chromatography. Silica gel chromatography was performed using 230–400 mesh 60 Å silica (Merck, Darmstadt, Germany). Thin-layer chromatography was performed on 60 Å silica with F_{254} , aluminum-backed plates (Merck) and visualized by UV at 254 nm, phosphomolybdic acid, iodine, or ninhydrin, as indicated. Reversed-phase HPLC separations were performed using a Vydac

(Hisperia, CA) semipreparative column (up to 5 mg total loading, 10 μm packing, 10 mm $\times$ 250 mm, catalog no. 218TP1010) at 3.0 mL/min, or a preparative column (up to 300 mg total loading, 10 μm packing, 22 mm $\times$ 250 mm, catalog no. 218TP1022) at 7 mL/min. Solvents were water/0.08% TFA (solvent A) and acetonitrile/0.08% TFA (solvent B), unless otherwise indicated. Common gradient conditions used were: (1) 2% A for 5 min, then a linear gradient from 2% to 35% B for 40 min; and (2) 5% A for 5 min, then a linear gradient from 5% to 55% B for 60 min, unless otherwise specified.

Quantification of Final Conjugates. Quantification of final substrate and internal standard conjugates was performed by ^1H NMR analysis in the presence of an internal standard. In a typical procedure, 6 μmol of dimethylformamide (10 μL of a 0.6 $\mu\text{mol}/\mu\text{L}$ anhydrous dimethylformamide in D_2O stock solution) was added to the conjugate of interest dissolved in 490 μL of D_2O in an NMR tube. Analysis by ^1H NMR was performed on the AC-500, setting the proton relaxation delay to 4 s to properly integrate a broad range of proton relaxation rates. The mole amount of conjugate was determined using the integrals of the aromatic protons on the conjugate of interest and the internal standard. After analysis, the D_2O and dimethylformamide were removed by lyophilization, and the sample was redissolved to the indicated final concentration with purified water and stored in aliquots at -20°C until use.

4,7-Dioxa-1,10-decanedinitrile (1a). To a stirred solution of 2% (w/v) sodium hydroxide (5 mL) and ethylene glycol (5.0 g, 81 mmol) at 0°C was added acrylonitrile (12.8 g, 243 mmol) over 10 min. The mixture was allowed to stir at 0°C for 1 h, followed by stirring overnight at room temperature. Dichloromethane (75 mL) was added, and the organic layer was washed $1\times$ (5 mL) with water and $2\times$ (5 mL each) with a dilute brine solution and dried (MgSO_4). The solvent was removed by rotary evaporation. The oily residue was treated with 25 mL of anhydrous ethanol, and the solvent was removed by rotary evaporation. This was repeated $2\times$ to remove excess unreacted acrylonitrile, followed by removal of solvent by rotary evaporation and drying in vacuo. The resulting clear, colorless oil (13.5 g, 97%) was used without further purification. R_f 0.59, 9:1 dichloromethane/methanol. ^1H NMR (CDCl_3) δ 3.75 (m, 4H), 3.69 (s, 4H), 2.64 (q, 4H). ESI-MS ($\text{M}+\text{Na}^+$): 191.02

4,8-Dioxa-1,11-undecanedinitrile (1b). As for **1a**, using 1,3-propanediol. Yield 95%, R_f 0.63, 9:1 dichloromethane/methanol. ^1H NMR (CDCl_3) δ 3.75 (m, 4H), 3.69 (s, 4H), 2.64 (q, 4H), 1.80 (m, 2H). ESI-MS ($\text{M}+\text{Na}^+$): 205.04.

4,7,10,13-Tetraoxa-1,16-hexadecanedinitrile (1c). As for **1a**, using triethylene glycol. Yield 92%, R_f 0.46, 9:1 dichloromethane/methanol. ^1H NMR (CDCl_3) δ 3.75 (m, 4H), 3.70 (s, 16H), 2.65 (q, 4H). ESI-MS ($\text{M}+\text{Na}^+$): 279.07.

[3,3,8,8- ^2H]-4,7-Dioxa-1,10-decanedinitrile (1a $_d$). Ethylene glycol (0.5 g, 8 mmol) was added to 0.1 g of dry potassium hydroxide in 20 mL of acetonitrile, followed by 1.4 g (24 mmol) of d_3 -acrylonitrile (Cambridge Isotope Laboratories, Andover, MA) with stirring overnight at room temperature. The reaction was filtered, and the solvent was removed by rotary evaporation to yield an oil. Final product was purified by silica chromatography (R_f 0.59, 9:1 chloroform/methanol) to yield 0.9 g (65%) of a colorless oil. ^1H NMR (CDCl_3) δ 3.69 (s, 4H), 2.64 (q, 4H). ESI-MS ($\text{M}+\text{Na}^+$): 195.03.

4,7-Dioxa-1,10-decanediamine (2a). Raney nickel (50 mg) was washed 5 times with anhydrous methanol by inversion and decantation and placed in 20 mL of

anhydrous methanol in a 50 mL screw-cap vial. A small hole (~3 mm) was drilled in the center of the cap, which was covered from the inside with a Teflon-lined rubber septum (2 mm thickness). **1a** (1 g, 6 mmol) was added, and the vial headspace was purged with H₂ gas via an 16-gauge needle piercing the septum. The cap was screwed on tightly, and the entire assembly was charged to 40 psi with H₂ gas through the needle and placed in a hot water bath (80 °C) for 4 h, after which the solid catalyst was removed by filtration over diatomaceous earth. The filtrate was dried by rotary evaporation to yield an oil which was purified by preparative reversed-phase HPLC (preparative column, gradient 0–10 min, 0% B; 10–50 min, 0–18% B, *t_R* = 18.4 min) to yield 94 mg (9%) of a colorless oil. ¹H NMR (D₂O) δ 3.59 (s, 4H), 3.56 (t, 4H), 1.66 (broad m, 8H). ESI-MS (M+H)⁺: 177.02.

[3,3,8,8-²H]-4,7-Dioxa-1,10-decanediamine (**2a_d**). As done previously for **2a**, using **1a_d**. Yield 11%. ¹H NMR (D₂O) δ 3.56 (s, 4H), 2.96 (t, 4H), 1.68 (t, 4H). ESI-MS (M+H)⁺: 181.14.

Diethyl 4,8-Dioxa-1,11-undecanedioate (**3b**). Nitrile **1b** (2 g, 12.0 mmol) was dissolved in 7 mL of 95% ethanol with stirring at 0 °C. Then 1.5 mL of concentrated sulfuric acid was added slowly over 5 min. The reaction was heated to reflux, and allowed to stir at reflux for 24 h. The mixture was cooled to room temperature, and the solvent was removed by rotary evaporation. The resulting material was extracted with 50 mL of methylene chloride, washed 2× with 5 mL of water and 3× with 5 mL of brine. The organic layer was dried (MgSO₄), and solvent was removed to yield an oil. The oil was dissolved in 95% ethanol with stirring at 0 °C. Concentrated sulfuric acid (1 mL) was added over 5 min, and the mixture was returned to reflux for an additional 24 h. The reaction was cooled, extracted, washed, and dried as done previously, and the final product was purified by silica chromatography (gradient dichloromethane/ethyl acetate/acetone) to yield 2.5 g (80%) of product as a colorless oil. *R_f* 0.76, 9:1 dichloromethane/methanol. ¹H NMR (CDCl₃) δ 4.14 (m, 4H), 3.73 (m, 4H), 3.60 (s, 4H), 2.58 (m, 4H), 1.78 (m, 2H), 1.26 (t, 6H). ESI-MS (M+H)⁺: 277.08, (M+Na)⁺: 299.12, (M+K)⁺: 315.11.

Diethyl 4,7,10,13-Tetraoxa-1,16-hexadecanedioate (**3c**). As done previously for **3b**, using nitrile **1c**. Yield 72%, *R_f* 0.59, 9:1 dichloromethane/methanol. ¹H NMR (CDCl₃) δ 4.14 (m, 4H), 3.73 (m, 4H), 3.60 (s, 12H), 2.58 (m, 4H), 1.26 (t, 6H). ESI-MS (M+H)⁺: 351.13, (M+Na)⁺: 373.16, (M+K)⁺: 389.19.

4,8-Dioxa-1,11-undecanediol (**4b**). Lithium aluminum hydride (0.66 g, 16.5 mmol) was slowly added to 100 mL of distilled [lithium aluminum hydride] tetrahydrofuran under argon with stirring at 0 °C. The suspension was allowed to warm to room temperature and stirred for an additional 15 min. **3b** (1.7 g, 6.5 mmol) (previously dried in vacuo in the presence of P₂O₅ and dissolved in 5 mL of distilled [lithium aluminum hydride] tetrahydrofuran) was added dropwise over 10 min. The mixture was stirred an additional 60 min, followed by cooling to 0 °C and dropwise addition of ethanol to quench excess hydride. Salts were precipitated by dropwise addition of saturated sodium sulfate solution with efficient stirring until a white precipitate formed (ca. 6 mL). The organic solvent was decanted, the white precipitate was triturated 4× with 15 mL of tetrahydrofuran, the combined organic extracts were removed by rotary evaporation to yield an oil which was redissolved in 10 mL of dichloromethane and dried (MgSO₄), and solvent was again removed. The final product was purified by silica chromatography

(dichloromethane/ethyl acetate/acetone) to yield 0.9 g (79%) of a colorless oil. *R_f* 0.46, 9:1 dichloromethane/methanol. ¹H NMR (CDCl₃) δ 3.74 (m, 4H), 3.66 (t, 4H), 3.59 (s, 4H), 2.90 (bs, 2H), 1.80 (m, 6H). ESI-MS (M+H)⁺: 193.16, (M+Na)⁺: 215.08.

4,7,10,13-Tetraoxa-1,16-hexadecanediol (**4c**). As done previously for **4b**, using **3c**. Yield 81%, *R_f* 0.33, 9:1 dichloromethane/methanol. ¹H NMR (CDCl₃) δ 3.72 (m, 4H), 3.60 (t, 12H), 3.59 (s, 4H), 2.65 (bs, 2H), 1.82 (m, 4H). ESI-MS (M+H)⁺: 267.21, (M+Na)⁺: 289.16.

4,8-Dioxa-1,11-dichloroundecane (**5b**). **4b** (1.1 g, 4.9 mmol, previously dried in vacuo in the presence of P₂O₅) was dissolved in 25 mL of dry [activated 4A Linde molecular sieves] benzene with stirring under argon. Distilled [CaH₂] pyridine (1.15 g, 14.6 mmol) was added, followed by cooling to 0 °C and dropwise addition of 1.8 g (14.6 mmol) of thionyl chloride in 5 mL of dry benzene. The mixture was warmed to 50 °C and allowed to stir under argon overnight, followed by cooling to 0 °C and addition of 7 mL of 3 M HCl with vigorous stirring. The organic layer was separated, washed 3× with dilute brine, and dried (Na₂SO₄), and solvent was removed by rotary evaporation to yield 1.2 g (86%) of a yellowish oil. The resulting product was used without further purification. *R_f* 0.82, 9:1 dichloromethane/methanol. ¹H NMR (CDCl₃) δ 3.63 (t, 4H), 3.54 (m, 8H), 2.02 (m, 4H), 1.83 (m, 2H). ESI-MS (M+H)⁺: 229.10, (M+Na)⁺: 251.18.

4,7,10,13-Tetraoxa-1,16-dichlorohexadecane (**5c**). As done previously for **5b**, using **4c**. Yield 81%, *R_f* 0.64, 9:1 dichloromethane/methanol. ¹H NMR (CDCl₃) δ 3.65 (t, 4H), 3.54 (m, 16H), 2.01 (m, 4H), 1.83 (m, 2H). ESI-MS (M+H)⁺: 229.10, (M+Na)⁺: 251.18, (M+K)⁺: 267.09.

4,8-Dioxa-1,11-undecanedinitrile (**6b**). Sodium cyanide (0.78 g, 15.5 mmol) in 6 mL of dimethyl sulfoxide was warmed to 80 °C with stirring. After 30 min, 1 g (3.9 mmol) of **5b** was added dropwise as a neat oil. After 2 h, the reaction was cooled slightly and treated with 10 mL of saturated sodium chloride solution, 5 mL of deionized water, and 50 mL of ethyl acetate. After extraction, the organic layer was washed 3× with a brine solution as before and dried (Na₂SO₄), followed by removal of solvent by rotary evaporation. The final product was purified by silica chromatography (gradient dichloromethane/ethyl acetate/acetone) to yield 0.6 g (64%) of product as a colorless oil. *R_f* 0.68, 9:1 dichloromethane/methanol. ¹H NMR (CDCl₃) δ 3.56–3.67 (m, 8H), 2.48 (t, 4H), 1.92 (qint, 4H), 1.81 (qint, 2H). ESI-MS (M+Na)⁺: 233.05.

4,7,10,13-Tetraoxa-1,16-hexadecanedinitrile (**6c**). As done previously for **6b**, using **5c**. Yield 68%, *R_f* 0.55, 9:1 dichloromethane/methanol. ¹H NMR (CDCl₃) δ 3.56–3.67 (m, 16H), 2.44 (t, 4H), 1.92 (qint, 4H). ESI-MS (M+Na)⁺: 307.14.

5,9-Dioxa-1,13-tridecanediamine (**7b**). Lithium aluminum hydride (0.87 g, 20.8 mmol) was carefully added to 150 mL of distilled [lithium aluminum hydride] tetrahydrofuran at 0 °C with stirring under an argon atmosphere. The suspension was heated to gentle reflux under argon for 30 min, followed by addition of 0.5 g (2.6 mmol) of **6b** (previously dried in vacuo in the presence of P₂O₅ and dissolved in 7 mL of distilled [lithium aluminum hydride] tetrahydrofuran) dropwise over 20 min while maintaining reflux by additional heat. After complete addition, the reaction was refluxed an additional 2 h, followed by cooling to 0 °C and dropwise addition of ethanol to quench excess hydride. Salts were precipitated by dropwise addition of saturated sodium sulfate solution with efficient stirring until a white precipitate formed (ca. 8 mL). The organic solvent was decanted, the white precipitate was triturated 4× with 15 mL of tetrahydro-

thian, and the combined organic extracts were evaporated by rotary evaporation to yield an oil which was redissolved in 20 mL of dichloromethane and dried (MgSO_4), and solvent was again removed. Final product was purified by preparative reversed-phase HPLC (gradient 0–10 min, 0% B; 10–50 min, 0–18% B; t_R = 20.5 min) to yield 0.35 g (71%) of a colorless oil. ^1H NMR (D_2O) δ 3.57 (s, 4H), 3.51 (t, 4H), 2.98 (t, 4H), 1.83 (m, 2H), 1.62 (m, 8H). ESI-MS ($\text{M}+\text{H}^+$) $^+$: 219.08.

[1,1,13,13- ^2H]-5,9-Dioxa-1,13-tridecanediamine (**7b_d**). As done previously for **7b**, except lithium aluminum deuteride was used in place of lithium aluminum hydride. Yield 74%. Preparative reversed-phase HPLC, gradient 0–10 min, 0% B; 10–50 min, 0–18% B; t_R = 20.7 min. ^1H NMR (D_2O) δ 3.57 (s, 4H), 3.51 (t, 4H), 1.62 (m, 8H). ESI-MS ($\text{M}+\text{H}^+$) $^+$: 223.11.

5,8,11,14-Tetraoxa-1,18-octadecanedi-amine (**7c**). As done previously for **7b** using **6c**. Yield 64%. Preparative reversed-phase HPLC, gradient 0–10 min, 0% B; 10–50 min, 0–18% B; t_R = 22.2 min. ^1H NMR (D_2O) δ 3.56 (s, 12H), 3.51 (t, 4H), 2.98 (t, 4H), 1.62 (m, 8H). ESI-MS ($\text{M}+\text{H}^+$) $^+$: 293.15.

[1,1,13,13- ^2H]-5,8,11,14-Tetraoxa-1,18-octadecanedi-amine (**7c_d**). As done previously for **7b_d** using **6c**. Yield 68%. Preparative reversed-phase HPLC, gradient 0–10 min, 0% B; 10–50 min, 0–18% B; t_R = 22.5 min. ^1H NMR (D_2O) δ 3.57 (s, 4H), 3.50 (t, 4H), 1.62 (m, 8H). ESI-MS ($\text{M}+\text{H}^+$) $^+$: 297.05.

7-Acetoxycoumarin-4-acetic Acid (**8**). To 100 mg (455 μmol) of 7-hydroxycoumarin-4-acetic acid in 2 mL of acetic anhydride with stirring at room temperature as a slurry was added 20 μL of boron trifluoride/diethyl etherate. A clear, homogeneous solution was observed after 2 min. After stirring for an additional 10 min, the mixture was diluted with 10 mL of water and shaken vigorously for 10 min to hydrolyze any mixed anhydride formed (R_f 0.87, dichloromethane/methanol/acetic acid 9:1:0.1). The resulting suspension was diluted with 30 mL of dichloromethane, washed 2 $\times$ with 10 mL of dilute brine solution, and dried (MgSO_4). The solvent was removed by rotary evaporation to yield a semisolid that was further dried in vacuo in the presence of KOH to yield 122 mg (96%) of product as an off-white solid. R_f 0.53, 9:1:0.1 dichloromethane/methanol/acetic acid. ^1H NMR (d_6 -DMSO) δ 7.74 (d, 1H), 7.29 (d, 1H), 7.17 (dd, 1H), 6.48 (s, 1H), 3.93 (s, 2H), 2.28 (s, 3H).

7-Acetoxycoumarin-4-acetic Acid *tert*-Butyl Ester (**9**). To 183 mg (1.5 mmol) of anhydrous magnesium sulfate in 4 mL of distilled [CaH_2] dichloromethane under argon was added 10 μL of concentrated sulfuric acid with stirring at room temperature. After 60 min, 146 μL (1.5 mmol) of distilled [CaH_2] *tert*-butyl alcohol was added, followed immediately by 50 mg (190 μmol) of **8** in 1 mL of distilled [CaH_2] dichloromethane. The reaction flask was tightly sealed and allowed to stir at room temperature for 15 h. The mixture was diluted with 50 mL of dichloromethane and filtered. Silica gel (1 g) was added to the filtrate, and the solvent was removed by rotary evaporation. The dried silica gel was loaded onto a silica column (dichloromethane), and the product was eluted (5:1 dichloromethane/ethyl acetate). After removal of solvent by rotary evaporation, the resulting product was dried in vacuo to yield 46 mg of a white solid (77%). R_f 0.91, 9:1 dichloromethane/methanol. ^1H NMR (d_6 -acetone) δ 7.77 (d, 1H), 7.16 (m, 2H), 6.41 (s, 1H), 3.88 (s, 2H), 2.29 (s, 3H), 1.43 (s, 9H).

7-Hydroxycoumarin-4-acetic Acid *tert*-Butyl Ester (**10**). To 470 mg of **9** in 8 mL of tetrahydrofuran with stirring at room temperature was added 3 mL of saturated

methanolic ammonia in a tightly sealed flask. The mixture was allowed to stir for an additional 3 h, followed by dilution with 25 mL of dichloromethane, addition of 2.0 g of silica gel, and removal of solvent by rotary evaporation. The resulting silica gel mixture was loaded onto a silica column (dichloromethane), and eluted (5:1 dichloromethane/acetone). Purified fractions were combined, and solvent was removed to yield 390 mg of a white solid (96%). R_f 0.68, 9:1 dichloromethane/methanol. ^1H NMR (d_6 -acetone) δ 9.42 (s, 1H), 7.58 (d, 1H), 6.87 (dd, 1H), 6.76 (d, 1H), 6.17 (s, 1H), 3.80 (s, 2H), 1.41 (s, 9H).

7-O- α -D-(2-Deoxy-2-*N*-trifluoroacetamido-3,4,6-tri-O-acetyl glucopyranos-1-yl)-coumarin-4-acetic Acid *tert*-Butyl Ester (**11**). This compound was prepared as described in the literature (13). 7-Trimethylsilyloxy-4-*tert*-butoxyacetic acid ester was prepared as described for 7-hydroxycoumarin using **10** that was previously dried in vacuo in the presence of P_2O_5 , and used without characterization. R_f 0.89 (α -anomer), 0.44 (β -anomer); 9:1 dichloromethane/methanol; UV. α -Anomer: ^1H NMR (d_6 -acetone) δ 8.75 (d, 1H), 7.77 (d, 1H), 7.26 (m, 2H), 6.36 (s, 1H), 6.03 (d, J = 3.7 Hz, 1H), 5.61 (t, 1H), 5.24 (t, 1H), 4.68 (td, 1H), 4.32 (t, 1H), 4.24 (dd, 1H), 4.14 (dd, 1H), 3.90 (s, 2H), 2.06 (s, 3H), 2.03 (s, 3H), 2.01 (s, 3H), 1.47 (s, 9H).

7-O- α -D-(2-Deoxy-2-*N*-trifluoroacetamido-3,4,6-tri-O-acetyl glucopyranos-1-yl)-coumarin-4-acetic Acid (**12**). To 54 mg (82 μmol) of **11** (previously dried in vacuo overnight in the presence of P_2O_5) in 8 mL of distilled [CaH_2] dichloromethane was added 0.5 mL of distilled [P_2O_5] trifluoroacetic acid with stirring under argon. The mixture was warmed to 50 $^\circ\text{C}$ and allowed to stir overnight, followed by removal of solvent by rotary evaporation using a water bath at room temperature (~ 20 $^\circ\text{C}$) in a rotary evaporator previously flushed with dry nitrogen for 45 min. The resulting semisolid was rediluted with 5 mL of distilled dichloromethane and again dried by rotary evaporation. This was repeated twice, followed by addition of 5 mL of dichloromethane and 0.4 g of silica gel, and the solvent was removed by rotary evaporation. The resulting powder was loaded onto a short silica column (dichloromethane), and the final product was eluted (gradient dichloromethane/acetone/methanol). After removal of solvent by rotary evaporation, the final product was dried in vacuo to yield an off-white solid that was triturated in 1 mL of ether and dried by vacuum centrifugation to yield 41 mg (82%) of product. R_f 0.28, 9:1:0.1 dichloromethane/methanol/acetic acid. ^1H NMR (d_6 -acetone) δ 8.70 (d, 1H), 7.75 (d, 1H), 7.20 (m, 2H), 6.35 (s, 1H), 5.96 (d, J = 3.6 Hz, 1H), 5.56 (t, 1H), 5.19 (t, 1H), 4.62 (m, 1H), 4.28 (t, 1H), 4.18 (dd, 1H), 4.09 (dd, 1H), 3.93 (s, 2H), 2.00 (s, 3H), 1.99 (s, 3H), 1.96 (s, 3H).

Conjugate of **12** and **7b** (**13b**). To 5 mg (8.3 μmol) of **12** (previously dried in vacuo in the presence of P_2O_5) in a dry, 4 mL screw-cap vial was added 300 μL of anhydrous dimethylformamide under argon. The vial was agitated by orbital shaking to effect dissolution, followed by vacuum centrifugation to remove solvent. This was repeated, followed by additional drying in vacuo overnight in the presence of P_2O_5 . The film was dissolved in 300 μL of anhydrous dimethylformamide, followed by addition of 7 μL (17 μmol) of anhydrous pyridine and three Linde type-4A molecular sieves (previously dried for 48 h at 150 $^\circ\text{C}$). After orbital shaking for 2 h at room temperature, the solution was treated with 3 μL of tetrafluorophenyl trifluoroacetate and agitated for an additional 45 min. The solution was removed from the vial with a dry syringe and transferred to another 4 mL

screw-cap vial containing 10 mg (50 μ mol) of **7b** (previously dried in vacuo in the presence of P_2O_5), three activated molecular sieves, and 10 μ L of dry, distilled $[CaH_2]$ triethylamine in 200 μ L of anhydrous dimethylformamide under argon. After 2 h of additional agitation, the molecular sieves were washed with 0.5 mL of methanol, and the combined solvents were removed by vacuum centrifugation to yield a crude film which was redissolved in purified water. The pH was adjusted to 3–4 with trifluoroacetic acid, and the product was purified by reversed-phase HPLC [preparative column, gradient (2), t_R = 44.1 min]. The final product was dried by vacuum centrifugation to yield 5.5 mg (85%) of a thin, colorless film. ^1H NMR (d_6 -acetone) δ 8.75 (d, 1H), 7.84 (m, 1H), 7.20 (m, 2H), 6.3 (s, 1H), 5.96 (d, 1H), 5.56 (t, 1H), 5.20 (t, 1H), 4.62 (m, 1H), 4.28 (dd, 1H), 4.1 (m, 1H), 4.10 (dd, 1H), 3.78 (s, 2H), 3.34–3.65 (broad m, 12H), 3.24 (t, 2H), 2.02 (s, 3H), 1.98 (s, 3H), 1.96 (s, 3H), 1.83 (m, 6H), 1.45 (m, 4H). ESI-MS ($M+H^+$) $^+$: 804.70.

Conjugate of 12 and 7b_d (13b_d). As done previously for **13b**, using **7b_d**. Yield 82%, preparative column, gradient (2), t_R = 44.4 min. ^1H NMR (d_6 -acetone) δ 8.75 (d, 1H), 7.84 (m, 1H), 7.20 (m, 2H), 6.3 (s, 1H), 5.96 (d, 1H), 5.56 (t, 1H), 5.20 (t, 1H), 4.62 (m, 1H), 4.28 (dd, 1H), 4.1 (m, 1H), 4.10 (dd, 1H), 3.78 (s, 2H), 3.34–3.65 (broad m, 8H), 2.02 (s, 3H), 1.98 (s, 3H), 1.96 (s, 3H), 1.83 (m, 6H), 1.45 (m, 4H). ESI-MS ($M+H^+$) $^+$: 808.73.

Conjugate of 12 and 7c (13c). As done previously for **13b**, using **7c** (81%). Preparative column, gradient (2), t_R = 44.7 min. ^1H NMR (d_6 -acetone) δ 8.75 (d, 1H), 7.84 (m, 1H), 7.20 (m, 2H), 6.3 (s, 1H), 5.96 (d, 1H), 5.56 (t, 1H), 5.20 (t, 1H), 4.62 (m, 1H), 4.28 (dd, 1H), 4.1 (m, 1H), 4.10 (dd, 1H), 3.78 (s, 2H), 3.34–3.65 (broad m, 18H), 3.24 (t, 2H), 2.02 (s, 3H), 1.98 (s, 3H), 1.96 (s, 3H), 1.83 (m, 4H), 1.45 (m, 4H). ESI-MS ($M+H^+$) $^+$: 878.59.

Conjugate of 12 and 7c_d (13c_d). As done previously for **13b**, using **7c_d**. Yield 84%, preparative column, gradient (2), t_R = 44.9 min. ^1H NMR (d_6 -acetone) δ 8.75 (d, 1H), 7.84 (m, 1H), 7.20 (m, 2H), 6.3 (s, 1H), 5.96 (d, 1H), 5.56 (t, 1H), 5.20 (t, 1H), 4.62 (m, 1H), 4.28 (dd, 1H), 4.1 (m, 1H), 4.10 (dd, 1H), 3.78 (s, 2H), 3.34–3.65 (broad m, 16H), 2.02 (s, 3H), 1.98 (s, 3H), 1.96 (s, 3H), 1.83 (m, 4H), 1.45 (m, 4H). ESI-MS ($M+H^+$) $^+$: 882.61.

N-Methyl-N-biotinyl Glycine (14). The title compound was prepared by a modification of the method of Wilbur (7). Methyl N-methyl-N-biotinyl glycinate (7) was hydrolyzed in a mixture of 31 mL of methanol and 10 mL of 1 N sodium hydroxide at room temperature with stirring for 1 h. The mixture was diluted with 50 mL of 50% methanol/water and neutralized with cation-exchange resin, hydrogen form (BioRad). The solution was filtered, the resin was washed (3 $\times$ 50 mL) with 50% methanol/water, and the solvents were removed by rotary evaporation to yield 1.6 g (90%) of N-methyl-N-biotinyl glycine as an off-white solid. ^1H NMR (CD_3OD) δ 4.49 (m, 1H), 4.32 (m, 1H), 4.11 (d, 2H), 3.22 (m, 1H), 3.04 (d, 3H), 2.93 (dd, 1H), 2.71 (d, 1H), 2.39 (dt, 2H), 1.69 (m, 4H), 1.49 (m, 2H). ESI-MS ($M+H^+$) $^+$: 316.2.

Tetrafluorophenyl N-Methyl-N-biotinyl Glycinate (15). In a modification of a procedure by Wilbur (7), 2.5 mg (7.4 μ mol) of **14** (previously dried in vacuo in the presence of P_2O_5) was dissolved in 0.2 mL of anhydrous dimethylformamide containing three Linde type-4A molecular sieves (previously dried for 48 h at 150 $^{\circ}C$) by orbital shaking, under argon atmosphere. Then 5 μ L of distilled $[CaH_2]$ triethylamine was added, followed after 2 h of orbital shaking by 1.5 μ L (8.8 μ mol) of tetrafluorophenyl trifluoroacetate. The formation of active ester (15–30 min) was monitored by silica TLC (R_f 0.5, 5:1 dichloro-

methane/methanol, UV) with brief drying of the spotted TLC plate with a stream of air prior to development. The active ester was used within 1 h and without further purification or characterization.

1-[N-(N-Methyl-N-biotinyl glycine)amido]-5,9-dioxo-13-tridecanamine (16). **7b** (42 mg, 0.2 mmol) was dried in vacuo in the presence of P_2O_5 overnight prior to use, followed by dissolution in 200 μ L of anhydrous dimethylformamide by orbital shaking under argon. Three Linde type-4A molecular sieves (previously dried for 48 h at 150 $^{\circ}C$) were added, followed by 5 μ L (0.03 mmol) of distilled $[CaH_2]$ triethylamine. After 2 h of orbital shaking, **15** [freshly prepared from 10 mg (0.03 mmol) of **14**, in dimethylformamide] was added dropwise by dry syringe, and the reaction was allowed to proceed for 1 h at room temperature while mixing with orbital shaking. The molecular sieves were removed from the reaction vessel and rinsed with 0.5 mL of methanol, and the combined organic solvents were removed by vacuum centrifugation at room temperature. The residue was reconstituted in water, the pH was adjusted to 3–4 with trifluoroacetic acid, and the final product was purified by reversed-phase HPLC (preparative column, gradient 0–5 min, 0% B, 5–60 min, 0–26% B, t_R = 47.2 min) and dried by vacuum centrifugation to yield 13 mg (82%) of a thin, colorless film. ^1H NMR (D_2O) δ 4.49 (m, 1H), 4.32 (m, 1H), 4.08 (d, 2H), 3.55 (m, 8H), 3.41 (t, 2H), 3.22 (m, 1H), 3.04 (d, 3H), 2.93 (dd, 1H), 2.88 (t, 2H), 2.71 (d, 1H), 2.39 (dt, 2H), 1.81 (m, 2H), 1.69 (m, 4H), 1.60 (m, 8H), 1.49 (m, 2H). ESI-MS ($M+H^+$) $^+$: 516.33.

Conjugate of 15 and 13b (17b). To 5.5 mg (6.8 μ mol) of **13b** (previously dried in vacuo in the presence of P_2O_5) in a dry, 4 mL screw-cap vial was added 300 μ L of anhydrous dimethylformamide under argon. The vial was agitated by orbital shaking to effect dissolution, followed by vacuum centrifugation to remove solvent. This was repeated, followed by additional drying in vacuo overnight in the presence of P_2O_5 . The film was dissolved in 200 μ L of anhydrous dimethylformamide, followed by 5 μ L of dry, distilled $[CaH_2]$ triethylamine and three Linde type-4A molecular sieves (previously dried for 48 h at 150 $^{\circ}C$) under argon. The mixture was agitated by orbital shaking for 2 h at room temperature, followed by addition of **15** [prepared from 2.2 mg (7 μ mol) of **14**, in dimethylformamide]. After shaking for an additional 2 h, the molecular sieves were removed from the reaction vessel and rinsed with 0.5 mL of methanol, and the combined organic solvents were removed by vacuum centrifugation at room temperature. The resulting residue was reconstituted in water, the pH was adjusted to 3–4 with trifluoroacetic acid, and the product was purified by reversed-phase HPLC [preparative column, gradient (2), t_R = 52.4 min] and dried by vacuum centrifugation to yield 4.5 mg (62%) of a thin, colorless film. ^1H NMR (d_6 -acetone) δ 8.82 (d, 1H), 7.89 (m, 1H), 7.22 (m, 2H), 6.36 (s, 1H), 6.00 (d, 1H), 5.62 (t, 1H), 5.22 (t, 1H), 4.68 (m, 1H), 4.60 (m, 1H), 4.41 (m, 1H), 4.33 (dd, 1H), 4.24 (m, 1H), 4.15 (dd, 1H), 4.04 (d, 2H), 3.80 (s, 2H), 3.40–3.65 (broad m, 10H), 3.25 (m, 3H), 3.08 (d, 3H), 2.99 (dd, 1H), 2.80 (d, 1H), 2.40 (dt, 2H), 2.02 (s, 3H), 1.98 (s, 3H), 1.96 (s, 3H), 1.83 (m, 4H), 1.70 (m, 4H), 1.45 (m, 6H). ESI-MS ($M+H^+$) $^+$: 1101.55, ($M+2H^+$) $^{2+}$: 551.62.

Conjugate of 15 and 13b_d (17b_d). As prepared previously for **17b**, using **13b_d**. Yield 70%, preparative column, gradient (2), t_R = 52.5 min. ^1H NMR (d_6 -acetone) δ 8.82 (d, 1H), 7.89 (m, 1H), 7.22 (m, 2H), 6.36 (s, 1H), 6.00 (d, 1H), 5.62 (t, 1H), 5.22 (t, 1H), 4.68 (m, 1H), 4.60 (m, 1H), 4.41 (m, 1H), 4.33 (dd, 1H), 4.24 (m, 1H), 4.15 (dd, 1H), 4.04 (d, 2H), 3.80 (s, 2H), 3.40–3.65 (broad m, 8H), 3.24

(m, 1H), 3.08 (d, 3H), 2.99 (dd, 1H), 2.80 (d, 1H), 2.40 (dt, 2H), 2.02 (s, 3H), 1.98 (s, 3H), 1.96 (s, 3H), 1.83 (m, 4H), 1.70 (m, 4H), 1.45 (m, 6H). ESI-MS ($\text{M}+\text{H}^+$): 1105.65, ($\text{M}+2\text{H}^+$): 553.58.

Conjugate of 15 and 13c (17c). As prepared previously for 17b, using 13c. Yield 65%, preparative column, gradient (2), $t_R = 52.7$ min. ^1H NMR (d_6 -acetone) δ 8.82 (d, 1H), 7.89 (m, 1H), 7.22 (m, 2H), 6.36 (s, 1H), 6.00 (d, 1H), 5.62 (t, 1H), 5.22 (t, 1H), 4.68 (m, 1H), 4.60 (m, 1H), 4.41 (m, 1H), 4.33 (dd, 1H), 4.24 (m, 1H), 4.15 (dd, 1H), 4.04 (d, 2H), 3.80 (s, 2H), 3.40–3.65 (broad m, 18H), 3.25 (m, 3H), 3.08 (d, 3H), 2.99 (dd, 1H), 2.80 (d, 1H), 2.40 (dt, 2H), 2.02 (s, 3H), 1.98 (s, 3H), 1.96 (s, 3H), 1.83 (m, 4H), 1.70 (m, 4H), 1.45 (m, 6H). ESI-MS ($\text{M}+\text{H}^+$): 1175.79, ($\text{M}+2\text{H}^+$): 588.67.

Conjugate of 15 and 13c_d (17c_d). As prepared previously for 17b, using 13c_d. Yield 68%, preparative column, gradient (2), $t_R = 53.0$ min. ^1H NMR (d_6 -acetone) δ 8.82 (d, 1H), 7.89 (m, 1H), 7.22 (m, 2H), 6.36 (s, 1H), 6.00 (d, 1H), 5.62 (t, 1H), 5.22 (t, 1H), 4.68 (m, 1H), 4.60 (m, 1H), 4.41 (m, 1H), 4.33 (dd, 1H), 4.24 (m, 1H), 4.15 (dd, 1H), 4.04 (d, 2H), 3.80 (s, 2H), 3.40–3.65 (broad m, 16H), 3.24 (m, 1H), 3.08 (d, 3H), 2.99 (dd, 1H), 2.80 (d, 1H), 2.40 (dt, 2H), 2.02 (s, 3H), 1.98 (s, 3H), 1.96 (s, 3H), 1.83 (m, 4H), 1.70 (m, 4H), 1.45 (m, 6H). ESI-MS ($\text{M}+\text{H}^+$): 1179.59, ($\text{M}+2\text{H}^+$): 590.51.

**p-Aminophenyl- α -D-2-deoxy-2-acetamidogluco-
pyranoside (20).** p-Nitrophenyl- α -D-2-deoxy-2-acetamidogluco-
pyranoside (18, 20 mg, 0.07 mmol, Sigma) was added to 5 mg of palladium on activated carbon (previously washed with methanol by inversion and decantation) in 3 mL of methanol with stirring in a 5 mL septum-lined

vial. The septum was pierced by a 16-gauge needle, through which the vial headspace was purged with H_2 gas. H_2 gas was allowed to slowly bubble through the solution for 2 h with stirring. After 45 min, all noncatalyst material was dissolved. The catalyst was removed by filtration over diatomaceous earth (Celite). The solvent was removed by rotary evaporation, and the product was further dried in vacuo to yield 18 mg of an off-white solid (90%). ^1H NMR (D_2O) δ 7.24 (d, 2H), 7.16 (d, 2H), 5.44 (d, 1H), 4.02 (dd, 1H), 3.88 (t, 1H), 3.68 (m, 3H), 3.49 (t, 1H), 1.97 (s, 3H). ESI-MS ($\text{M}+\text{H}^+$): 313.22.

**p-Aminophenyl- α -D-(2-deoxy-2-N-trifluoroacetamido)-
3,4,6-tri-O-acetylglucopyranoside (21).** As done previously for 20, using 19 which was prepared by the method of Voznyi et al. (13). Yield 86%, R_f 0.55, 2:1 dichloromethane/ethyl acetate, UV, ninhydrin. ^1H NMR (CDCl_3) δ 7.35 (d, 2H), 6.92 (d, 2H), 6.77 (d, 1H), 5.69 (d, $J = 3.1$ Hz, 1H), 5.48 (t, 1H), 5.26 (t, 1H), 5.50 (td, 1H), 4.22 (dd, 1H), 4.01 (m, 2H), 2.07 (s, 3H), 2.05 (s, 3H), 2.04 (s, 3H). ESI-MS ($\text{M}+\text{H}^+$): 493.29.

**p-Acrylamidophenyl- α -D-2-deoxy-2-acetamidogluco-
pyranoside (23).** 20 (10 mg, 0.03 mmol) was added to 15 mL of methanol and 100 μL of triethylamine was added with stirring. The solution was chilled in an ice bath. Acryloyl chloride (15 mg, 0.17 mmol) was dissolved in 2 mL of distilled [CaH_2] dichloromethane and added dropwise to the stirred solution over 5 min. The reaction was allowed to return to room temperature, followed by 2 h of stirring. The solution was treated with successive anion (hydroxide form) and cation (proton form) exchange resins until neutral pH was obtained with moist pH paper. Solvent was removed by rotary evaporation to yield an off-white

Scheme 2

solid (11 mg, 95%). ^1H NMR (D_2O) δ 7.36 (d, 2H), 7.03 (d, 2H), 6.32 (dd, 1H), 6.23 (d, 1H), 5.78 (d, 1H), 5.50 (d, 1H), 4.02 (dd, 1H), 3.88 (t, 1H), 3.68 (m, 3H), 3.49 (t, 1H), 1.94 (s, 3H). ESI-MS ($\text{M}+\text{Na}^+$) $^+$: 389.14.

p-Acrylamidophenyl- α -D-(2-deoxy-2-*N*-trifluoroacetamido)-3,4,6-tri-*O*-acetylglucopyranoside (**24**). As prepared previously for **23**, using **21**. Yield 87%, R_f 0.63, 9:1 dichloromethane/methanol. ^1H NMR (CDCl_3) δ 7.51 (d, 2H), 7.05 (d, 2H), 6.41 (d, 2H), 6.18 (dd, 1H), 5.75 (dd, 1H), 5.04 (d, 1H), 5.48 (t, 1H), 5.25 (t, 1H), 4.45 (td, 1H), 4.26 (dd, 1H), 4.08 (m, 2H), 2.06 (s, 3H), 2.03 (s, 3H), 2.01 (s, 3H).

p-Acrylamidophenyl- β -D-galactopyranoside (**25**). As prepared previously for **23**, using *p*-aminophenyl- β -D-galactopyranoside (**22**, Sigma). Yield 97%. ^1H NMR (*d*-7-dimethylformamide) δ 10.28 (s, 1H), 7.69 (d, 2H), 7.03 (d, 2H), 6.52 (dd, 1H), 6.27 (dd, 1H), 5.69 (dd, 1H), 5.18 (s, 1H), 4.83 (d, J = 10.3 Hz, 1H), 4.79 (s, 1H), 4.77 (s, 1H), 4.55 (s, 1H), 3.93 (t, 1H), 3.77 (m, 1H), 3.70 (m, 1H), 3.58 (m, 1H), 3.39 (s, 2H).

Michael Addition Product of 2a and 23 (26). **23** (20 mg, 0.07 mmol) was added to a stirred solution of 80 mg (0.35 mmol) of **2a** in 5 mL of 0.2 M sodium carbonate, pH 10.5, warmed to 37 °C. The reaction was allowed to continue for 3 days at 37 °C, after which the solution was neutralized with dilute trifluoroacetic acid in water, concentrated by rotary evaporation, and purified by reversed-phase HPLC (preparative column, gradient 0–10 min, 0% B, 10–50 min, 0–19% B, t_R = 33.5 min). The purified product was dried by vacuum centrifugation

to yield 14.4 mg (38%) as a film. ^1H NMR (D_2O) δ 7.33 (d, 2H), 7.22 (d, 2H), 5.88 (d, 1H), 3.76 (t, 1H), 3.70 (m, 3H), 3.58 (m, 8H), 3.47 (m, 1H), 3.32 (m, 3H), 3.05 (t, 2H), 2.94 (t, 2H), 2.80 (t, 2H), 1.95 (s, 3H), 1.72 (m, 2H), 1.60 (m, 6H). ESI-MS ($\text{M}+\text{H}^+$) $^+$: 543.19, ($\text{M}+2\text{H}^+$) $^{2+}$: 272.09.

Michael Addition Product of 2ad and 25 (27). As done previously for **26**, using **25** and **2ad**. Yield 42%, preparative reversed-phase HPLC, gradient 0–10 min, 0% B, 10–50 min, 0–19% B, t_R = 32.9 min. ^1H NMR (*d*-7-dimethylformamide) δ 10.49 (s, 1H), 7.73 (d, 2H), 7.10 (d, 2H), 4.91 (d, 1H), 3.96 (d, 1H), 3.75 (m, 3H), 3.68 (m, 2H), 3.61 (m, 4H), 3.45 (m, 2H), 3.30 (s, 2H), 3.20 (s, 2H), 3.01 (t, 2H). ESI-MS ($\text{M}+\text{H}^+$) $^+$: 506.23, ($\text{M}+2\text{H}^+$) $^{2+}$: 253.60.

Michael Addition Product of 7ba and 23 (28). As done previously for **26**, using **23** and **7ba**. Yield 36%, preparative reversed-phase HPLC, gradient 0–10 min, 0% B, 10–50 min, 0–19% B, t_R = 33.8 min. ^1H NMR (D_2O) δ 7.33 (d, 2H), 7.22 (d, 2H), 5.88 (d, 1H), 3.76 (t, 1H), 3.70 (m, 3H), 3.58 (m, 8H), 3.47 (m, 1H), 3.32 (m, 3H), 3.05 (t, 2H), 2.94 (t, 2H), 2.80 (t, 2H), 1.95 (s, 3H), 1.72 (m, 2H), 1.60 (m, 6H). ESI-MS ($\text{M}+\text{H}^+$) $^+$: 589.25, ($\text{M}+2\text{H}^+$) $^{2+}$: 295.22.

Michael Addition Product of 16 and 24 (SFC Substrate) (29). As done previously for **26**, using **24** and **16**, except 3 mL of 0.2 M sodium carbonate was used, and **16** was added as a solution in 2 mL of methanol. Yield 32%, preparative reversed-phase HPLC, gradient 0–5 min, 0% B, 5–60 min, 0–22% B, t_R = 40.2 min, broadly eluting.

Scheme 3

Scheme 4

¹H NMR (D₂O) δ 7.40 (d, 2H), 7.18 (d, 2H), 5.82 (d, 1H), 4.57 (m, 1H), 4.38 (m, 1H), 4.07 (t, 1H), 4.05 (d, 2H), 3.80 (m, 3H), 3.55 (m, 10H), 3.38 (t, 2H), 3.32 (m, 3H), 3.05 (t, 2H), 3.00 (d, 3H), 2.94 (t, 2H), 2.80 (t, 2H), 2.40 (dt, 2H), 1.72 (m, 2H), 1.60 (m, 12H). Conjugate of 15 and 27 (SFB Substrate) (30). To 3 mg (5.5 μ mol) of **26** previously dried in vacuo overnight in the presence of P₂O₅ was added 200 μ L of anhydrous dimethylformamide and three Linde type-4A molecular sieves (previously dried for 48 h at 150 °C) under argon to redissolve and further dry the film. Dry, distilled

[CaH₂] triethylamine was added (2 μ L), followed after 2 h of orbital shaking by **15** [prepared from 2 mg (5.5 μ mol) of **14**]. After an additional 2 h of orbital shaking, the molecular sieves were removed and washed with 0.5 mL of methanol, and the combined solvents were removed by vacuum centrifugation. The final product was purified by reversed-phase HPLC [preparative column, gradient (1), t_R = 30.5 min] and dried by vacuum centrifugation to yield 4.6 mg of a clear film (62%). After quantitation by ¹H NMR, the conjugate was diluted in purified water to 2.0 mM final concentration and frozen in aliquots at -20 °C until use. ¹H NMR (D₂O) δ 7.45 (d, 2H), 7.18 (d,

Conjugate of 15 and 28 (SFC Internal Standard) (32). As done previously for **30** using **28**. Yield 68%, preparative reversed-phase HPLC, gradient 0–5 min, 0% B, 5–60 min, 0–22% B, $t_R = 41.8$ min, broadly eluting. After quantitation by ¹H NMR, the conjugate was diluted in purified water to 1.0 mM final concentration and frozen in aliquots at -20°C until use. ¹H NMR (D_2O) δ 7.42 (d, 2H), 7.18 (d, 2H), 5.58 (d, 1H), 4.57 (m, 1H), 4.38 (m, 1H), 4.11 (m, 2H), 4.05 (d, 3H), 3.80 (m, 1H), 3.55 (m, 9H), 3.41 (t, 2H), 3.26 (m, 1H), 3.00 (d, 3H), 2.98 (dd, 1H), 2.90 (t, 2H), 2.77 (dd, 1H), 2.40 (dt, 2H), 2.05 (s, 3H), 1.78 (m, 6H), 1.60 (m, 8H), 1.42 (m, 2H). ESI-MS ($M+H^+$)⁺: 886.77, ($M+2H^+$)²⁺: 443.64.

SFB Internal Standard Conjugate (33). **31** (1.8 mg) was dissolved in 2 mL of 100 mM Tris-HCl, 10 mM $MgCl_2$ buffer, pH 7.3, with stirring at 37°C . Recombinant β -D-

galactosidase (10 units, Sigma) was added, and after 12 h of additional stirring at 37°C , the mixture was acidified to pH 3–4 with trifluoroacetic acid and concentrated by rotary evaporation to 0.75 mL. The final product was purified by reversed-phase HPLC [semipreparative column, gradient (1), $t_R = 41.3$ min] and dried by vacuum centrifugation to yield 1.3 mg (89%) of a film. After quantitation by ¹H NMR, the conjugate was diluted in purified water to 1.0 mM final concentration and frozen in aliquots at -20°C until use. ¹H NMR (D_2O) δ 7.18 (d, 2H), 6.79 (d, 2H), 5.58 (d, 1H), 4.57 (m, 1H), 4.38 (m, 1H), 3.97 (d, 2H), 3.55 (m, 8H), 3.41 (t, 2H), 3.26 (m, 1H), 3.00 (d, 3H), 2.98 (dd, 1H), 2.90 (t, 2H), 2.77 (dd, 1H), 2.40 (dt, 2H), 1.68 (m, 2H), 1.60 (m, 6H), 1.42 (m, 2H). ESI-MS ($M+H^+$)⁺: 641.51.

Deprotection of Conjugate 17b (34b). To **17b** was added 1 mL of saturated ammonia in methanol and 0.35 mL of 2 M ammonium hydroxide with stirring. The solution was heated to 45°C and allowed to stir overnight, followed by removal of solvent by vacuum centrifugation, redissolution in purified water, and pH adjustment to 3 with dilute trifluoroacetic acid and purification by reversed-phase HPLC [semipreparative column, gradient (2), $t_R = 32.0$ min]. The final product was dried by vacuum centrifugation to yield 3 mg (90%) as a thin, colorless film. ¹H NMR (D_2O) δ 7.71 (d, 1H), 7.26 (d, 1H), 7.19 (dd, 1H), 6.37 (s, 1H), 5.99 (d, 1H), 4.57 (m, 1H), 4.38 (m, 1H), 4.09 (t, 1H), 4.05 (d, 2H), 3.85 (s, 2H), 3.75 (m, 3H), 3.60 (m, 10H), 3.41 (t, 2H), 3.26 (m, 5H), 3.00 (d, 3H), 2.98 (dd, 1H), 2.77 (dd, 1H), 2.40 (dt, 2H), 1.69

Scheme 6

(t, 2H), 1.55 (broad m, 12H), 1.42 (m, 2H). ESI-MS ($M+H^+$): 879.79, ($M+2H^+$): 440.41.

Deprotection of Conjugate 17b_d (34b_d). As done previously for 17b, using 17b_d. Yield 82%, semipreparative column, gradient (2), $t_R = 32.2$ min. ^1H NMR (D_2O) δ 7.71 (d, 1H), 7.26 (d, 1H), 7.19 (dd, 1H), 6.37 (s, 1H), 5.99 (d, 1H), 4.57 (m, 1H), 4.38 (m, 1H), 4.09 (t, 1H), 4.05 (d, 2H), 3.85 (s, 2H), 3.75 (m, 3H), 3.60 (m, 10H), 3.41 (t, 2H), 3.26 (m, 1H), 3.00 (d, 3H), 2.98 (dd, 1H), 2.77 (dd, 1H), 2.40 (dt, 2H), 1.69 (t, 2H), 1.55 (broad m, 12H), 1.42 (m, 2H). ESI-MS ($M+H^+$): 883.77, ($M+2H^+$): 442.42.

Deprotection of Conjugate 17c (34c). As done previously for 17b, using 17c. Yield 92%, semipreparative column, gradient (2), $t_R = 32.6$ min. ^1H NMR (D_2O) δ 7.71 (d, 1H), 7.26 (d, 1H), 7.19 (dd, 1H), 6.37 (s, 1H), 5.99 (d, 1H), 4.57 (m, 1H), 4.38 (m, 1H), 4.09 (t, 1H), 4.05 (d, 2H), 3.85 (s, 2H), 3.75 (m, 3H), 3.60 (m, 18H), 3.41 (t, 2H), 3.26 (m, 5H), 3.00 (d, 3H), 2.98 (dd, 1H), 2.77 (dd, 1H), 2.40 (dt, 2H), 1.55 (broad m, 12H), 1.42 (m, 2H). ESI-MS ($M+H^+$): 953.74, ($M+2H^+$): 477.47.

Deprotection of Conjugate 17c_d (SFA Internal Standard Conjugate) (34c_d). As done previously for 17b, using 17c_d. Yield 88%, semipreparative column, gradient (2), $t_R = 32.8$ min. ^1H NMR (D_2O) δ 7.71 (d, 1H), 7.26 (d, 1H), 7.19 (dd, 1H), 6.37 (s, 1H), 5.99 (d, 1H), 4.57 (m, 1H), 4.38 (m, 1H), 4.09 (t, 1H), 4.05 (d, 2H), 3.85 (s, 2H), 3.75 (m, 3H), 3.60 (m, 18H), 3.41 (t, 2H), 3.26 (m, 1H), 3.00 (d, 3H), 2.98 (dd, 1H), 2.77 (dd, 1H), 2.40 (dt, 2H), 1.55 (broad m, 12H), 1.42 (m, 2H). ESI-MS ($M+H^+$): 957.67, ($M+2H^+$): 479.43.

N-Acetylation of 34b (35b). To 3 mg (3.7 μmol) of 34b in 0.75 mL of purified water was added 4 mg (37 μmol) of sodium carbonate with stirring, followed after complete dissolution by 2 μL (18 μmol) of acetic anhydride. The reaction was allowed to stir for 4 h at room temperature, followed by adjustment of the pH to 3 with dilute

trifluoroacetic acid and purification by reversed-phase HPLC [semipreparative column, gradient (2), $t_R = 34.3$ min]. The final product was dried by vacuum centrifugation to yield 3 mg (95%) as a thin, colorless film. ^1H NMR (D_2O) δ 7.67 (d, 1H), 7.12 (m, 2H), 7.19 (dd, 1H), 6.28 (s, 1H), 5.62 (d, 1H), 4.57 (m, 1H), 4.38 (m, 1H), 4.05 (dd, 1H), 4.00 (d, 2H), 3.88 (t, 1H), 3.75 (s, 2H), 3.68 (s, 2H), 3.59 (m, 1H), 3.52 (m, 1H), 3.45 (m, 8H), 3.23 (m, 5H), 3.00 (d, 3H), 2.88 (dd, 1H), 2.75 (dd, 1H), 2.40 (dt, 2H), 1.97 (s, 3H), 1.69 (t, 2H), 1.55 (broad m, 12H), 1.42 (m, 2H). ESI-MS ($M+H^+$): 921.81, ($M+Na^+$): 943.85, ($M+2Na^+$): 483.47.

N-Acetylation of 34b_d (SFD Internal Standard Conjugate) (35b_d). As done previously for 34b, using 34b_d. Yield 94%, semipreparative column, gradient (2), $t_R = 34.7$ min. ^1H NMR (D_2O) δ 7.67 (d, 1H), 7.12 (m, 2H), 7.19 (dd, 1H), 6.28 (s, 1H), 5.62 (d, 1H), 4.57 (m, 1H), 4.38 (m, 1H), 4.05 (dd, 1H), 4.00 (d, 2H), 3.88 (t, 1H), 3.75 (s, 2H), 3.68 (s, 2H), 3.59 (m, 1H), 3.52 (m, 1H), 3.45 (m, 8H), 3.23 (m, 1H), 3.00 (d, 3H), 2.88 (dd, 1H), 2.75 (dd, 1H), 2.40 (dt, 2H), 1.97 (s, 3H), 1.69 (t, 2H), 1.55 (broad m, 12H), 1.42 (m, 2H). ESI-MS ($M+H^+$): 925.87, ($M+Na^+$): 947.79.

N-Sulfation of 34c (SFA Substrate Conjugate) (36). To 2.5 mg (2.6 μmol) of 34c in 0.5 mL of purified water was added 3 mg (29 μmol) of sodium carbonate with stirring at room temperature, followed after complete dissolution by 2 mg (13 μmol) of sulfur trioxide-pyridine complex (Lancaster, Lancaster, U.K.). The reaction was allowed to stir for 4 h at room temperature, followed by adjustment of the pH to 3 with dilute trifluoroacetic acid. The mixture was first purified by reversed-phase HPLC using TFA [semipreparative column, gradient (2), $t_R = 42.6$ min], and the correct product fractions were concentrated by vacuum centrifugation to 0.5–1 mL and repurified by reversed-phase HPLC without TFA [semipreparative column, gradient (2), $t_R = 20.5$ min, broadly eluting]. The

Scheme 7

product fractions were again concentrated to 1.0 mL and applied to a short column (300 mg) of AG MP-1 cation-exchange resin, sodium form. The column was washed with 7 mL of purified water, and the combined eluants were concentrated to 1 mL and lyophilized to give 2.0 mg (72%) of an off-white powder. ¹H NMR (D₂O) δ 7.70 (d, 1H), 7.26 (d, 1H), 7.19 (dd, 1H), 6.36 (s, 1H), 6.00 (d, 1H), 4.55 (m, 1H), 4.37 (m, 1H), 4.05 (d, 2H), 3.85 (m, 3H), 3.75 (m, 3H), 3.60 (m, 18H), 3.41 (t, 2H), 3.26 (m, 5H), 3.00 (d, 3H), 2.98 (dd, 1H), 2.77 (dd, 1H), 2.40 (dt, 2H), 1.55 (broad m, 12H), 1.42 (m, 2H). ESI-MS (M+H)⁺: 1056.81, (M-Na)⁺: 1032.20.

N-Acetyl-glucosamine-6-O-sulfation of 35b (SFD Substrate Conjugate) (37). 4.5 mg (4.9 μmol) of **35b** was dissolved in 300 μL of anhydrous dimethylformamide under argon. The solvent was then removed by vacuum centrifugation. This was repeated, followed by drying overnight in vacuo in the presence of P₂O₅. The film was redissolved in 400 μL of deuterio-dimethylformamide (d₇) in the presence of three Linde type-4A molecular sieves (previously dried for 48 h at 150 °C) under argon. Then 10 μL of deuterio-pyridine (d₅) was added, and the mixture was allowed to agitate by orbital shaking for 30 min, followed by transfer to an NMR tube (previously dried for 48 h at 150 °C) containing a single activated molecular sieve. A stock solution of 1 μmol/μL sulfur trioxide-pyridine complex in deuterio-dimethylformamide was added in 3 μL aliquots followed by mixing by inversion for 30 min and ¹H NMR analysis to determine the extent of reaction.

The extent of reaction was evaluated by chemical shift change of the *N*-acetyl-glucosamine C-6 methylene protons upon sulfation. These protons shift from a broad singlet at 3.82 ppm to two *pro*-chiral multiplets at 4.06 and 4.17 ppm. Mono-sulfation of the unprotected substrate stops at 55–65% sulfation of the conjugate. Above this level, nonspecific di- and tri-*O*-sulfation occurred. A total of 27 μL (27 μmol) of sulfur trioxide-pyridine solution was used to obtain 60% sulfation.

The reaction solution was rinsed from the NMR tube with methanol. The molecular sieve was washed with methanol, and the combined solvents were removed by vacuum centrifugation. The resultant film was reconstituted with purified water, and the mixture was purified by reversed-phase HPLC without TFA [semipreparative column, gradient (2), *t_R* = 23.0 min, broadly eluting]. The product fractions were combined and concentrated by vacuum centrifugation to 1 mL and applied to a short-column (300 mg) AG MP-1 cation-exchange resin (sodium form). The column was washed with 7 mL of purified water, and the combined eluants were concentrated to 1 mL and lyophilized to yield 2 mg (45%) of an off-white powder. ¹H NMR (D₂O) δ 7.71 (d, 1H), 7.20 (m, 2H), 6.46 (s, 1H), 5.69 (d, 1H), 4.55 (m, 1H), 4.35 (m, 1H), 4.20 (s, 2H), 4.15 (dd, 1H), 4.04 (d, 2H), 3.99 (m, 2H), 3.82 (d, 2H), 3.66 (t, 1H), 3.55 (m, 16H), 3.22 (m, 5H), 3.00 (d, 3H), 2.98 (dd, 1H), 2.77 (dd, 1H), 2.40 (dt, 2H), 2.01 (s, 3H), 1.71 (m, 2H), 1.55 (broad m, 12H), 1.42 (m, 2H). ESI-MS (M+H)⁺: 1023.79, (M-Na)⁺: 999.75.

Scheme 8

RESULTS AND DISCUSSION

Preparation of Deuteratable, Polyether Diamine

Linkers. As described in the Introduction, our enzyme analysis methodology makes use of a linker substructure, both deuterated and nondeuterated, to connect biotin to a particular substrate. Our initial attempts at linker synthesis were based on the use of 4,7,10-trioxa-1,13-tridecane diamine as a linker in a substrate conjugate made previously (5). The octa-deuterio form of that diamine was synthesized by Michael addition of d_2 (O-D) -ethylene glycol and d_3 -acrylonitrile in D_2O . While this reaction produced the desired product in good yield and with little loss of deuterium, the subsequent reduction product was obtained in very low yield (due mostly to elimination of the Michael adduct), and with considerable exchange of the deuterium α to the cyano group. A procedure described previously (15) for the preparation of a polyether dichloride was modified to generate a diamine in good overall yield and with little or no loss of incorporated deuterium (Scheme 1). The diamine linkers used in the present study are prepared from 1,3-propanediol and triethylene glycol. However, identical methods were used to produce polyether diamines from ethylene, diethylene, and tetraethylene glycols. In addition, this procedure allows for a variety of levels of stable isotopic substitution (e.g., using commercially available d_4 -ethylene glycol, d_3 -acrylonitrile, or ^{13}C and/or ^{15}N sodium cyanide) to increase the linker mass by up to +24 amu, in 2 amu increments. Due to issues of scale, we resorted to preparative reversed-phase HPLC purification of the final diamine products, using UV detection at 210 nm. Vacuum distillation may be preferred when linkers are prepared in greater quantity.

Synthesis of Glucosamine-Coumarin Acid Glycoconjugates for Profiling Enzyme Activity in Sanfilippo Subtypes A and D. Our original chemistry to produce substrates for the enzymes relevant to Sanfilippo subtypes A and D was based on the attachment of the linker to the appropriate *p*-acrylamidophenyl glycosides (see below). These conjugates were found to be resistant to enzyme action. Due to the lack of information in the literature concerning the substrate specificity of these enzymes, we opted to conservatively modify the 4-methylumbelliferyl glycoconjugates previously reported as substrates for these enzymes (16, 17). We used glycosides of umbelliferyl-4-acetic acid to further conjugate this substrate substructure to different linkers (Scheme 2), and, ultimately, to sarosinyl biotin (Scheme 3). Synthesis of the protected 7-hydroxy-coumarin-4-*tert*-butoxy acetate **10** and subsequent coupling of the trimethylsilyl ether of **10** with 1-fluoro-2-deoxy-2-(*N*-trifluoroacetyl)-3,4,6-tri-*O*-acetyl-glucosamine gave a mixture of **11** and **12** (partially deprotected by boron trifluoride-etherate in the coupling reaction to form **11**). The remaining **11** was easily deprotected without cleavage of the glycosidic linkage under anhydrous conditions using dry trifluoroacetic acid. The overall yield of the desired α -anomer was consistent with earlier syntheses of analogous 4-methylumbelliferyl glycoconjugates (13) (Scheme 2).

Activation and conjugation of **12** to diamines **7** yielded little or no product with a variety of coupling reagents, including DCC, EDC, and PYBOP under standard coupling conditions. When care was taken to azeotropically dry the starting material, and when activation was performed using 2,3,5,6-tetrafluorophenyl trifluoroacetate in the presence of an inert drying agent such as

molecular sieves, the active ester of **12** was consistently produced in very high yields. Several such successful reactions were performed in *d*-7-dimethylformamide in an NMR tube and monitored by ¹H NMR chemical shift change of the α-carboxylic acid methylene protons from 3.92 to 4.73 ppm upon activation. Although attempts to purify and isolate this activated intermediate were unsuccessful, in situ formation of the active ester and coupling to the diamines **7** consistently produced the desired amide products in at least 85% yield.

Further conjugation of the products **13** to sarcosinyl biotin was performed by a similar route involving careful preparation of tetrafluorophenyl *N*-methyl-*N*-biotinyl glycinate via a minor modification of a procedure by Wilbur (7) (Scheme 3). From this point, removal of protecting groups (Scheme 7) and functionalization of the carbohydrate (Schemes 7 and 8) ultimately afford the desired substrate and internal standard conjugates for profiling enzyme activity in Sanfilippo subtypes A and D (**34cd**, **35b_a**, **36**, and **37**). It should be noted that sulfation of the primary *N*-acetyl glucosamine hydroxyl of **35b** without additional steps to protect the secondary alcohols was performed by addition of sulfur trioxide–pyridine to the substrate in deuterated dimethylformamide in sub-stoichiometric amounts, and the reaction was monitored by ¹H NMR. Although the total amount of sulfating reagent required was in roughly 3-fold excess, addition of this amount in one portion yielded multiply sulfated products. Furthermore, mono-sulfation of the carbohydrate was uniform until roughly 40% of the starting material remained. At this point, di- and tri-sulfation occurred, despite a considerable quantity of unsulfated starting material remaining.

Synthesis of *p*-Amidophenyl Glycoconjugates for Profiling Enzyme Activity Involved in Sanfilippo Subtypes B and C. The commercial availability of some *p*-nitrophenyl glycoconjugates initially led our synthetic efforts. Synthesis of the substrate for Sanfilippo subtype C led us to the chemistry by Voznyi et al. (13) for the preparation of commercially unavailable 2-amino carbohydrate conjugates. Reduction and acrylation of such conjugates by the method of Romanowska (18) was achieved in good yield (Scheme 4). However, the following Michael addition to diamines **2** was much less successful (Scheme 5). Final coupling to sarcosinyl biotin was effected by active ester chemistry described above (Scheme 6).

Application of ACESIMS to Sanfilippo Syndrome. The use of the above substrate and internal standard conjugates for ACESIMS profiling of enzyme velocities involved in the Sanfilippo syndrome will be described elsewhere (ref 8). The ACESIMS methodology has been demonstrated to be rapid, sensitive, and accurate in confirming diagnoses of Sanfilippo subtypes. In addition, the ACESIMS approach has allowed all four Sanfilippo enzymes to be profiled in two duplex incubations, reducing the number of assays required. Owing to the sensitivity of ESI-MS, ACESIMS enzyme velocities have been calculated using 3.5 μg of patient total cell protein (obtained from ~2500 fibroblasts), requiring only 400 ng of substrate conjugate per assay. Although multistep synthesis is required to prepare these ACESIMS conjugates, several thousand assays can be performed per milligram of substrate. In addition, the modular nature of ACESIMS substructures allows for combinations of previously prepared deuterated and nondeuterated linkers, substrates, and sarcosinyl biotin to develop conjugates for a host of clinical and biomedical applications.

Department of Radiation Oncology, University of Washington, Seattle, Washington 98195.

Received January 31, 2001; Revised Manuscript Received April 27, 2001

An investigation was conducted in which the stabilities of four structurally different biotin derivatives were assessed with regard to biotinamide bond hydrolysis by the enzyme biotinidase. The biotin derivatives studied contained an extra methylene in the valeric acid chain of biotin (i.e., homobiotin), or contained conjugated amino acids having hydroxymethylene, carboxylate, or acetate functionalities on a methylene alpha to the biotinamide bond. The biotinidase hydrolysis assay was conducted on biotin derivatives that were radioiodinated at high specific activity, and then subjected to diluted human serum at 37 °C for 2 h. After incubation, assessment of biotinamide bond hydrolysis by biotinidase was readily achieved by measuring the percentage of radioactivity that did not bind with avidin. As controls, an unsubstituted biotin derivative which is rapidly cleaved by biotinidase and an *N*-methyl-substituted biotin derivative which is stable to biotinidase cleavage were included in the study. The results indicate that increasing the distance from the biotin ring structure to the biotinamide bond by one methylene only decreases the rate of biotinidase cleavage, but does not block it. The data obtained also indicate that placing a hydroxymethylene, carboxylate, or acetate alpha to the biotinamide bond is effective in blocking the biotinamide hydrolysis reaction. These data, in combination with data previously obtained, which indicate that biotin derivatives containing hydroxymethylene or carboxylate moieties retain the slow dissociation rate of biotin from avidin and streptavidin [Wilbur, D. S., et al. (2000) *Bioconjugate Chem.* 11, 569–583], strongly support incorporation of these structural features into biotin derivatives being used for in vivo targeting applications.

INTRODUCTION

Radiolabeled derivatives of biotin are being developed for application to "pretargeting" in targeted radiotherapy of cancer (1–5). A design criterion for radiolabeled biotin derivatives used in vivo is that they must be stabilized toward degradation by the enzyme biotinidase (6). Biotinidase is present in serum and tissues of both animals and humans in nanomolar concentrations (6). It is believed that the primary function of this enzyme is to cleave the biotinamide bond linking biotin (vitamin H) and lysine in biocytin (7, 8), such that the essential vitamin can be recycled. Biocytin is released after peptidase degradation of carboxylase enzymes containing biotin (9). An important finding is that biotinidase is not specific for cleaving the biotinamide bond in biocytin (10). This fact led us, and other investigators (11–14), to evaluate the effect of structural changes in biotin derivatives on blocking the biotinamide cleaving action of biotinidase. It was previously reported that an *N*-methylbiotinamide functionality, introduced by conjugation of biotin with *N*-methylglycine (sarcosine), completely blocked biotinidase cleavage of the biotinamide bond (12). Studies in our laboratory confirmed that biotin conjugated with sarcosine, and other *N*-methyl linker molecules, blocked the actions of biotinidase in mouse and human serum (15).

In this investigation, we have extended our previous studies evaluating variations in functional groups in

biotin conjugates for blocking biotinidase activity. The studies were primarily directed at biotin conjugates which contain hydroxymethylene and carboxylate substituents alpha to the biotinamide bond (e.g., **4b** and **5b**). However, two other biotin derivatives were prepared to provide a better understanding of the structural features required for blocking biotinidase cleavage, and two more biotin derivatives were prepared as standards. Similar to the hydroxymethylene and carboxylate derivatives, one of the biotin derivatives tested contained an acetate substituent alpha to the biotinamide bond (**6b**). In another biotin derivative, there was an additional methylene in the valeric side chain of biotin (i.e., homobiotin derivative **3c**). As standards for comparison, an unmodified biotin derivative that is rapidly cleaved by biotinidase (**1c**) and a *N*-methylbiotinamide derivative (**2c**) which is stable to cleavage by biotinidase were included in the study. As in previously studied biotin derivatives, 4,7,10-trioxatridecane-1,13-diamine was incorporated as a linker to aid in water solubilization (16). All of the biotin derivatives tested were radioiodinated to high specific activity to permit evaluation of the biotinidase cleavage. Reported herein are: (a) the syntheses of precursors to the radioiodinated biotin derivatives targeted for testing, (b) syntheses of iodinated HPLC standards, (c) radioiodination methods used, and (d) results obtained from the biotinidase assay.

EXPERIMENTAL PROCEDURES

General. All chemicals purchased from commercial sources were analytical grade or better and were used without further purification unless noted. Most of the reagents used were obtained from Aldrich Chemical Co.

(Milwaukee, WI). Biotin was obtained from Sigma Chemicals (St. Louis, MO). 4,7,10-Trioxa-1,13-tridecanediamine and sarcosine methyl ester were obtained from Fluka (St. Louis, MO). 2,3,5,6-Tetrafluorophenyl trifluoroacetate (TFP-OTFA)¹ was prepared as previously described (17). *O*-*tert*-Butyl-L-serine methyl ester hydrochloride, L-aspartic acid β -*tert*-butyl ester, and L-aspartic acid α -*tert*-butyl ester were obtained from Calbiochem-Novabiochem Corp. (San Diego, CA). Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μ m) prior to use. Silica gel chromatography was conducted with 70–230 mesh 60 Å silica gel (Aldrich Chemical Co.). Microcon-30 centrifugation concentrators were obtained from Amicon (Beverly, MA). Melting points were obtained in open capillary tubes on a Mel-Temp II apparatus with a Fluke 51 K/J electronic thermometer, and are uncorrected.

Radioactive Materials. Standard methods for safely using radionuclides of iodine were employed (18). Na¹²⁵I was purchased from NEN/Dupont (Billerica, MA) as high-pH, high-concentration solutions in 0.1 N NaOH. Measurement of ¹²⁵I was accomplished on the Capintec CRC-15R or a Capintec CRC-6A Radioisotope Calibrator. Radioactive samples were counted in a LOGIC Model 111B Gamma Counter (Abbott Laboratories, Chicago, IL).

Spectral Analyses. ¹H NMR were obtained on either a Bruker AC-200 (200 MHz) or a Bruker AC-500 (500 MHz) instrument. Chemical shifts are expressed as ppm using tetramethylsilane as internal standard (δ = 0.0 ppm). IR data were obtained on a Perkin-Elmer 1420 infrared spectrophotometer. Mass spectral data (both low resolution and high resolution) of most compounds prepared in this study were obtained on a PerSeptive Biosystems Mariner Electrospray Time-of-Flight Mass Spectrometer (ESI-TOF). For analysis, the samples were dissolved in 50:50 MeOH/H₂O and were introduced by an integral syringe infusion pump. Some mass spectral data (low resolution) were obtained on a VG Analytical (Manchester, England) VG-70 SEQ mass spectrometer with associated 11250J Data System. These mass spectral data were obtained by fast atom bombardment (FAB⁺) in a matrix of 2-hydroxyethyl disulfide (2-HEDS) and poly(ethylene glycol) 300 or 600 containing thioglycolate. High-resolution mass spectral data were used for compound identification. Compounds containing Sn isotopes had five matching isotopic masses, but only one is provided as identification. ¹H NMR and HPLC were used to assess the purity of nonradioactive compounds (these data are provided in the Supporting Information).

Chromatography. HPLC separations of nonradioactive compounds were obtained on a Hewlett-Packard quaternary 1050 gradient pumping system with a variable-wavelength UV detector (254 nm) and a Varex ELSD MKIII evaporative light-scattering detector. Analyses of the HPLC data were conducted on Hewlett-Packard HPLC ChemStation software. All reactions were monitored by HPLC. Reversed-phase HPLC chromatography was carried out using an Alltech Altima C-18 column (5 μ m, 250 mm $\times$ 4.6 mm) using a gradient solvent system at a flow rate of 1 mL/min. A gradient of

MeOH and H₂O/0.1% HOAc was used. Starting with 40% MeOH, the initial solvent mixture was held for 2 min; then the gradient was increased to 100% MeOH over the next 10 min, then held at 100% MeOH for 8 min. Retention times (*t*_R) under these conditions for biotin conjugates are provided with the compound experimental data.

HPLC separations of radioiodinated biotin derivatives were conducted using a gradient system which consisted of two Beckman model 110B pumps, a Beckman 420 controller, a Beckman model 153 UV detector (254 nm), and a Beckman model 170 radioisotope detector. The separations were obtained using HPLC conditions described for gradient I, above, except water was used in place of H₂O/0.1% HOAc.

The following compounds were prepared as previously described: **1a**, **1b**, [¹²⁵I]**1c**, **2a**, **2b**, [¹²⁵I]**2c**, (**15**); **7** (**19**); **8a**, **8b** (**15**); **10**, **11**, **12**, **13** (**19**); **20** (**20**); **27** (**21**). Biotin-NHS ester, **9**, was provided as a gift from Quanta BioDesign (Powell, OH).

N-(13-(*p*-Tri-*n*-butylstannylbenzoylamino)-4,7,10-trioxatridecanyl)homobiotinamide, 3a. To a 0.203 g (0.50 mmol) quantity of the TFP ester of homobiotin, **7**, dissolved in 10 mL of DMF was added 70 μ L (50.8 mg, 0.50 mmol) of Et₃N, then 0.307 g (0.51 mmol) of **8a**. The reaction was stirred at room temperature for 1 h, and the DMF was removed under vacuum. The crude residue was loaded onto a silica column and eluted with EtOAc, and then mixtures of EtOAc/MeOH. The product eluted with 4:1 EtOAc/MeOH. Evaporation of the solvent provided 0.380 g (0.44 mmol, 89%) of **3a** as a colorless solid, mp 106–107 °C. ¹H NMR 500 MHz (CD₃OD): 0.88 (t, *J* = 7.0 Hz, 9H), 1.10 (t, *J* = 8.1 Hz, 6H), 1.30–1.45 (m, 12H), 1.53–1.63 (m, 10H), 1.68–1.75 (m, 2H), 1.85–1.90 (m, 2H), 2.16 (t, *J* = 7.3 Hz, 2H), 2.69 (d, *J* = 13.3 Hz, 1H), 2.90 (dd, *J* = 5.1, 12.5 Hz, 1H), 3.15–3.19 (m, 1H), 3.23 (t, *J* = 6.6 Hz, 2H), 3.47 (t, *J* = 6.6 Hz, 4H), 3.52–3.54 (m, 2H), 3.57–3.64 (m, 6H), 4.27 (dd, *J* = 4.4, 8.1 Hz, 1H), 4.46 (dd, *J* = 4.4, 8.1 Hz, 1H), 7.54 (d, *J* = 8.1 Hz, 2H), 7.74 (d, *J* = 8.1 Hz, 2H). HRMS calcd for C₄₀H₇₁N₄O₆SSn (M + H)⁺: 853.4090. Found: 853.4112 (Sn-118). HPLC: *t*_R = 16.9 min.

N-(13-(*p*-Iodobenzoylamino)-4,7,10-trioxatridecanyl)homobiotinamide, 3b. To a 0.244 g (0.60 mmol) quantity of the TFP ester of homobiotin, **7**, dissolved in 10 mL of DMF was added 84 μ L (61 mg, 0.60 mmol) of Et₃N, then 0.268 g (0.61 mmol) of **8b**. The reaction was stirred at room temperature for 1 h, and the DMF was removed under vacuum. The crude residue was loaded onto a silica column and eluted with EtOAc, then mixtures of EtOAc/MeOH. The product eluted with 4:1 EtOAc/MeOH. Evaporation of the solvent provided 0.30 g (0.43 mmol, 72%) of **3b** as a colorless solid, mp 124–125 °C. ¹H NMR 500 MHz (CD₃OD): δ 1.33–1.45 (m, 6H), 1.54–1.62 (m, 4H), 1.73 (t, *J* = 6.6 Hz, 2H), 1.87 (t, *J* = 6.3 Hz, 2H), 2.16 (t, *J* = 7.3 Hz, 2H), 2.69 (d, *J* = 13.2 Hz, 1H), 2.91 (dd, *J* = 5.2, 12.5 Hz, 1H), 3.15–3.18 (m, 1H), 3.23 (t, *J* = 7.0 Hz, 2H), 3.44–3.49 (m, 4H), 3.53–3.63 (m, 8H), 4.28 (dd, *J* = 4.4, 8.1 Hz, 1H), 4.47 (dd, *J* = 4.4, 8.1 Hz, 1H), 7.56 (d, *J* = 8.8 Hz, 2H), 7.83 (d, *J* = 8.1 Hz, 2H). HRMS calcd for C₂₈H₄₄N₄O₆SI (M + H)⁺: 691.2026. Found: 691.2051. HPLC: *t*_R = 12.3 min.

Preparation of Biotin Derivatives 17–19 and 21–23. A 0.24 mmol quantity of a biotin-amino acid derivative (**11**, **12**, or **13**) was combined with 50 μ L (0.36 mmol) of Et₃N in 5 mL of DMF. The mixture was cooled to 4 °C, 69 mg (0.27 mmol) of TFP-OTFA was added, and then the mixture was allowed to stir for 30 min at 4 °C. An additional 40 μ L (0.29 mmol) of Et₃N was added, followed

¹ Abbreviations: Av, avidin; BSA, bovine serum albumin; cpm, counts per minute; DIP, direct insertion probe; EI, electron impact; 2-HEDS, 2-hydroxyethyl sulfide; HOHgBz, hydroxymercuribenzoic acid; *nca*, no-carrier-added; NCS, *N*-chlorosuccinimide; NHS, *N*-hydroxysuccinimide; PBS, phosphate-buffered saline; rt, room temperature; SAv, streptavidin; *t*-Boc, *tert*-butoxycarbonyl; TFA, trifluoroacetic acid; TFP, tetrafluorophenyl; TFP-OTFA, tetrafluorophenyl trifluoroacetate.

by addition of 0.24 mmol of **8b** or **20**. The reaction mixture was allowed to come to room temperature and was stirred for an additional hour at that temperature. The mixture was concentrated under vacuum, and purified over a silica gel column (2.5 cm $\times$ 22 cm). The column was first eluted with EtOAc, then with increasing amounts (i.e., 10–40%) of methanol in EtOAc.

2-(N-Biotinoyl)-1-(N'-(13'-p-iodobenzoylamino)-4',7',10'-trioxatridecaneamino)-L-serine-O-tert-butyl Ether, 17. This compound was obtained as a colorless oil in 45% yield. ^1H NMR 200 MHz (CD_3OD): δ 1.17 (s, 9H), 1.44 (m, 4H), 1.67 (m, 6H), 1.87 (m, 2H), 2.29 (t, J = 7.3 Hz, 2H), 2.69 (d, 2H), 2.90 (dd, J = 5.1, 12.5 Hz, 1H), 3.30 (m, 6H), 3.55 (m, 10H), 4.30 (m, 1H), 4.39 (m, 1H), 4.48 (m, 1H), 7.56 (d, J = 8.4 Hz, 2H), 7.83 (d, J = 8.8 Hz, 2H). HRMS calcd for $\text{C}_{34}\text{H}_{55}\text{IN}_5\text{O}_8\text{S}$ ($\text{M} + \text{H}$) $^+$: 820.2816. Found: 820.2806. HPLC: t_{R} = 13.2 min.

2-(N-Biotinoyl)-1-(N'-(13'-p-iodobenzoylamino)-4',7',10'-trioxatridecaneamino)-L-aspartate-4-O-tert-butyl Ester, 18. This compound was obtained as a colorless solid in 65% yield, mp 165–167 $^\circ\text{C}$. ^1H NMR 200 MHz (CD_3OD): δ 1.43 (s, 9H), 1.72 (m, 3H), 1.87 (m, 3H), 2.26 (t, J = 6.9 Hz, 1H), 2.59 (m, 2H), 2.79 (d, J = 6.2 Hz, 2H), 2.89 (d, J = 4.7 Hz, 1H), 2.95 (d, J = 4.7 Hz, 1H), 3.31 (m, 8H), 3.51 (m, 4H), 3.61 (m, 8H), 4.30 (m, 1H), 4.48 (m, 1H), 4.66 (m, 1H), 7.56 (d, J = 8.4 Hz, 2H), 7.83 (d, J = 8.4 Hz, 2H). HRMS calcd for $\text{C}_{35}\text{H}_{55}\text{IN}_5\text{O}_9\text{S}$ ($\text{M} + \text{H}$) $^+$: 848.2765. Found: 848.2742. HPLC: t_{R} = 12.9 min.

2-(N-Biotinoyl)-4-(N'-(13'-p-iodobenzoylamino)-4',7',10'-trioxatridecaneamino)-L-aspartate-1-O-tert-butyl Ester, 19. This compound was obtained as a colorless oil in 35% yield. ^1H NMR 200 MHz (CD_3OD): δ 1.44 (s, 9H), 1.71 (m, 3H), 1.89 (m, 3H), 2.24 (t, J = 7.3 Hz, 1H), 2.68 (m, 2H), 2.86 (d, J = 3.3 Hz, 1H), 2.99 (d, J = 3.3 Hz, 1H), 3.30 (m, 8H), 3.49 (m, 4H), 3.62 (m, 8H), 4.30 (m, 1H), 4.41 (m, 1H), 4.63 (m, 1H), 7.57 (d, J = 8.8 Hz, 2H), 7.84 (d, J = 8.8 Hz, 2H). HRMS calcd for $\text{C}_{35}\text{H}_{55}\text{IN}_5\text{O}_9\text{S}$ ($\text{M} + \text{H}$) $^+$: 848.2765. Found: 848.2767. HPLC: t_{R} = 12.8 min.

2-(N-Biotinoyl)-1-(N'-(13'-tert-butoxycarbonylamino)-4',7',10'-trioxatridecaneamino)-L-serine-O-tert-butyl Ether, 21. This compound was obtained as a colorless oil in 82% yield. ^1H NMR 200 MHz (CD_3OD): δ 1.18 (s, 9H), 1.43 (s, 9H), 1.72 (m, 10H), 2.30 (t, J = 6.9 Hz, 2H), 2.70 (d, 1H), 2.94 (dd, J = 5.1, 12.5 Hz, 1H), 3.12 (t, J = 6.9 Hz, 2H), 3.22 (m, 1H), 3.30 (m, 4H), 3.35 (s, 2H), 3.52 (m, 4H), 3.61 (m, 6H), 4.30 (m, 1H), 4.40 (t, J = 5.5 Hz, 1H), 4.49 (m, 1H). HRMS calcd for $\text{C}_{32}\text{H}_{60}\text{N}_5\text{O}_9\text{S}$ ($\text{M} + \text{H}$) $^+$: 690.4112. Found: 690.4117. HPLC: t_{R} = 12.5 min.

2-(N-Biotinoyl)-1-(N'-(13'-tert-butoxycarbonylamino)-4',7',10'-trioxatridecaneamino)-L-aspartate-4-O-tert-butyl Ester, 22. This compound was obtained as a colorless oil in 52% yield. ^1H NMR 200 MHz (CD_3OD): δ 1.44 (s, 18H), 1.74 (m, 8H), 2.09 (t, 2H), 2.54 (m, 2H), 2.79 (d, J = 6.2 Hz, 1H), 2.89 (d, J = 4.7 Hz, 1H), 2.95 (d, J = 4.7 Hz, 1H), 3.11 (t, J = 6.9 Hz, 2H), 3.31 (m, 8H), 3.51 (t, J = 6.2 Hz, 3H), 3.61 (m, 8H), 4.30 (m, 1H), 4.48 (m, 1H), 4.66 (m, 1H). HRMS calcd for $\text{C}_{33}\text{H}_{60}\text{N}_5\text{O}_{10}\text{S}$ ($\text{M} + \text{H}$) $^+$: 718.4061. Found: 718.4045. HPLC: t_{R} = 12.5 min.

2-(N-Biotinoyl)-4-(N'-(13'-tert-butoxycarbonylamino)-4',7',10'-trioxatridecaneamino)-L-aspartate-1-O-tert-butyl Ester, 23. This compound was obtained as a colorless oil in 59% yield. ^1H NMR 200 MHz ($\text{DMSO}-d_6$): δ 1.37 (s, 18H), 1.50 (m, 2H), 1.58 (m, 8H), 2.09 (t, 2H), 2.44 (m, 4H), 2.54 (m, 2H), 2.82 (m, 1H), 2.95 (m, 2H), 3.07 (m, 2H), 3.48 (m, 10H), 4.13 (m, 1H), 4.31 (m, 1H),

4.42 (m, 1H), 6.39 (d, J = 10.6 Hz, 2H), 6.75 (t, 5.9 Hz, 1H), 7.88 (t, J = 5.5 Hz, 1H), 8.04 (d, J = 7.7 Hz, 1H). HRMS calcd for $\text{C}_{33}\text{H}_{60}\text{N}_5\text{O}_{10}\text{S}$ ($\text{M} + \text{H}$) $^+$: 718.4061. Found: 718.4060. HPLC: t_{R} = 12.3 min.

Preparation of 4a, 5a, and 6a. For each of the *p*-iodo compounds **17**, **18**, and **19**, 2 mL of neat TFA was added and stirred for 10 min (the serine compound **17** was stirred for 30 min). The mixture was evaporated and dried on high vacuum overnight (yield $\sim$ 99%). The isolated biotin derivatives were washed several times with ether to remove any remaining TFA.

2-(N-Biotinoyl)-1-(N'-(13'-p-iodobenzoylamino)-4',7',10'-trioxatridecaneamino)-L-serine, 4a. This compound was obtained in nearly quantitative yield as a colorless oil. ^1H NMR 200 MHz (CD_3OD): δ 1.65 (s, 2H), 1.44 (m, 4H), 1.67 (m, 6H), 1.87 (m, 2H), 2.29 (t, J = 7.3 Hz, 2H), 2.69 (d, J = 12.5 Hz, 2H), 2.90 (dd, J = 4.7, 12.5 Hz, 1H), 3.01 (d, 1H), 3.30 (m, 6H), 3.55 (m, 10H), 4.30 (m, 1H), 4.39 (m, 1H), 4.48 (m, 1H), 7.56 (d, J = 8.8 Hz, 2H), 7.83 (d, J = 8.8 Hz, 2H). HRMS calcd for $\text{C}_{30}\text{H}_{47}\text{IN}_5\text{NaO}_8\text{S}$ ($\text{M} + \text{H}$) $^+$: 764.2190. Found: 764.2179. HPLC: t_{R} = 11.4 min.

2-(N-Biotinoyl)-1-(N'-(13'-p-iodobenzoylamino)-4',7',10'-trioxatridecaneamino)-L-aspartate, 5a. This compound was obtained in nearly quantitative yield as a colorless oil. ^1H NMR 200 MHz (CD_3OD): δ 1.72 (m, 3H), 1.87 (m, 3H), 2.26 (t, J = 7.3 Hz, 1H), 2.59 (m, 2H), 2.79 (m, 2H), 2.89 (d, J = 3.3 Hz, 1H), 2.95 (d, J = 3.3 Hz, 1H), 3.31 (m, 8H), 3.51 (t, J = 6.2 Hz, 4H), 3.61 (m, 8H), 4.30 (m, 1H), 4.48 (m, 1H), 4.66 (m, 1H), 7.56 (d, J = 8.4 Hz, 2H), 7.83 (d, J = 8.4 Hz, 2H). HRMS calcd for $\text{C}_{31}\text{H}_{46}\text{IN}_5\text{NaO}_9\text{S}$ ($\text{M} + \text{Na}$) $^+$: 814.1958. Found: 814.1937. HPLC: t_{R} = 11.6 min.

2-(N-Biotinoyl)-4-(N'-(13'-p-iodobenzoylamino)-4',7',10'-trioxatridecaneamino)-L-aspartate, 6a. This compound was obtained in 99% yield as a colorless oil. ^1H NMR 200 MHz (CD_3OD): δ 1.28 (s, 2H), 1.71 (m, 3H), 1.89 (m, 3H), 2.24 (t, 2H), 2.68 (m, 1H), 2.86 (d, J = 4.7 Hz, 1H), 2.99 (d, J = 4.7 Hz, 1H), 3.30 (m, 8H), 3.49 (m, 4H), 3.62 (m, 8H), 4.30 (m, 1H), 4.41 (m, 1H), 4.63 (m, 1H), 7.57 (d, J = 8.7 Hz, 2H), 7.84 (d, J = 8.7 Hz, 2H). HRMS calcd for $\text{C}_{31}\text{H}_{46}\text{IN}_5\text{NaO}_9\text{S}$ ($\text{M} + \text{Na}$) $^+$: 814.1958. Found: 814.1957. HPLC: t_{R} = 11.5 min.

Preparation of [^{125}I]3c. To 50 μL of a 1 mg/mL solution of **3a** was added 1–5 μL of Na^{125}I in 0.1 N NaOH, followed by 10 μL of a 1 mg/mL solution of NCS in MeOH. After 2 min, 10 μL of a 1 mg/mL aqueous sodium metabisulfite solution was added. The reaction mixture was then drawn into a syringe for purification by HPLC. The radioiodinated [^{125}I]3c was obtained from the HPLC effluent in 13% yield.

Preparation of [^{125}I]4b, [^{125}I]5b, and [^{125}I]6b using N-Hydroxysuccinimide *p*-[^{125}I]iodobenzoate, 27. The syntheses were accomplished from the N-*t*-Boc derivatives **21**, **22**, and **23** as depicted in Scheme 3. The steps involved are as follows.

Removal of *t*-Boc Protecting Group in Situ To Prepare 24, 25, and 26. A 100 μg quantity of biotin derivative **21**, **22**, or **23** in 100 μL of MeOH was evaporated to dryness, and 100 μL TFA was added. This solution was stirred for 30 min, and the TFA was evaporated under a stream of argon to yield **24**, **25**, and **26** as TFA salts. The TFA salt residues were diluted with 30 μL of DMF and 20 μL of triethylamine.

Preparation of [^{125}I]27. To 50 μL of HPLC-purified *p*-tri-*n*-butylstannylbenzoate *N*-hydroxysuccinimide ester (**21**) in MeOH/5% HOAc was added 3 μL (1.68 mCi) of Na^{125}I followed by 10 μL of 1 mg/mL NCS in MeOH. After 10 min at room temperature, 10 μL of a 1 mg/mL solution

Table 1. Biotin Derivatives Prepared

of sodium metabisulfite was added to quench the reaction. The mixture was then reduced to dryness under a stream of argon, and 50 μ L of DMF was added.

Radiolabeling of Biotin Derivatives. To the basic solution containing **24**, **25**, or **26** in DMF was added 15 μ L of [¹²⁵I]**27**. After 30 min at room temperature, the entire reaction mixture was injected on the HPLC column and eluted. The major radioactivity peaks were collected. The percent of radioactivity in the peak corresponding to the iodo standards (**4a**, **5a**, **6a**) on the HPLC chromatogram was noted ([¹²⁵I]**4b**, 43%; [¹²⁵I]**5b**, 44%; [¹²⁵I]**6b**, 46%). The isolated radiochemical yields were as follows: [¹²⁵I]**4b**, 25%; [¹²⁵I]**5b**, 29%; [¹²⁵I]**6b**, 31%.

Measurement of Biotinidase Cleavage. The same experimental conditions were used as previously reported (15). Briefly, the radiolabeled biotin derivative was diluted to obtain approximately 5000 cpm per 10 μ L in a well counter. To a 0.5 mL aliquot of diluted serum (1:10 with 20 mM phosphate buffer, pH 6.8) was added 10 μ L of the HPLC-purified radiolabeled biotin derivative in MeOH. Each tube was lightly vortexed and placed in a 37 $^{\circ}$ C heating block. After the desired time (e.g., 2 h), the vials were removed, and 40 μ L of 2 mM 4-(hydroxymercuri)benzoic acid (HOHgBz), sodium salt in H₂O, was added to inhibit biotinidase. To that solution was added an excess of avidin (40 μ L; 0.24 mg), and it was incubated at 37 $^{\circ}$ C for another 30 min. The solution was split into two 200 μ L aliquots, and the samples were transferred

to two Microcon-30 filters and centrifuged at 3000g for 10 min. The material remaining on the filter was washed with 4 $\times$ 100 μ L of phosphate buffer, concentrating by centrifugation each time. The top and bottom (containing filtrate and washes) of the Microcon-30 were counted in a well counter. The ratio of nonbound counts (bottom) to the total counts (top and bottom) was calculated to determine the percent of the biotin derivative that had been cleaved. As a control, this procedure was repeated as above except that the 4-(hydroxymercuri)benzoic acid was added prior to the radiolabeled biotin derivative to inhibit biotinidase activity.

RESULTS

Synthesis and Radioiodination of Biotin Derivatives. The biotin derivatives synthesized for the study are shown in Table 1. Radioiodinated derivatives ([¹²⁵I]**1c**, [¹²⁵I]**2c**, [¹²⁵I]**3c**, [¹²⁵I]**4b**, [¹²⁵I]**5b**, and [¹²⁵I]**6b**) were prepared for evaluation in the biotinidase assay. The arylstannane derivatives (**1a**, **2a**, **3a**) were prepared as precursors for radioiodination, and nonradioactive iodo-phenyl derivatives (**1b**, **2b**, **3b**, **4a**, **5a**, and **6a**) were prepared for use as HPLC standards. Syntheses of homobiotin-stannylbenzoate derivative **3a** and the homobiotin-iodobenzoate derivative **3b** were accomplished using the same synthetic approach as previously described for **1a**, **2a**, **1b**, and **2b** (15). The synthetic route employed is shown in Scheme 1. In the syntheses, homobiotin tetra-

fluorophenyl (TFP) ester, **7**, was generated in situ by reaction of homobiotin with TFP-OTFA (**19**), and was subsequently reacted with one of the substituted benzoyldiaminotrioxatridecane adducts, **8a** or **8b**, to provide **3a** and **3b** in 89% and 72% overall yield, respectively.

Syntheses of iodo-HPLC standards **4a**, **5a**, and **6a** were accomplished as shown in Scheme 2. The biotin-amino acid adducts **10–13** were prepared from reaction of the *N*-hydroxysuccinimide ester of biotin **9** with the corresponding *t*-Bu-protected amino acids, followed by in situ preparation of the tetrafluorophenyl (TFP) esters **14–16** as previously described (19). The *p*-iodobenzoyl adduct of trioxadamine, **8b**, was then reacted with the TFP esters to provide the adducts **17**, **18**, and **19** in 45%, 65%, and 35% yield, respectively. Subsequent conversion of *tert*-butyl ether/ester adducts to the desired **4a**, **5a**, and **6a** was accomplished in neat trifluoroacetic acid (TFA) in nearly quantitative yield.

High specific activity radioiodination was required for the biotinidase assay. Radioiodinated derivatives **1c**, **2c**, and **3c** were obtained by reaction of HPLC-purified stannylbenzoyl derivatives **1a**, **2a**, and **3a** with no-carrier-added (*nca*) Na¹²⁵I in MeOH/1% HOAc using *N*-chlorosuccinimide (NCS) as the oxidant (15). After radiolabeling, the radioiodinated biotin derivatives [¹²⁵I]**1c**, [¹²⁵I]**2c**, and [¹²⁵I]**3c** were purified by HPLC to rid them of radiochemical contaminants that might interfere with interpretation of the biotinidase assay results. In an effort to improve on the initial studies, which employed two HPLC purification steps in the preparation of [¹²⁵I]**1c**, [¹²⁵I]**2c**, and [¹²⁵I]**3c**, an alternate method that had only one HPLC purification step was used to prepare the subsequent radioiodinated derivatives [¹²⁵I]**4b**, [¹²⁵I]**5b**, and [¹²⁵I]**6b**. In the alternate method (Scheme 3), radioiodination was accomplished by preparing *p*-[¹²⁵I]iodobenzoate *N*-hydroxysuccinimide (NHS) ester, [¹²⁵I]**27**, from the stannylbenzoate NHS ester (**21**), followed by reaction with the amino-biotin derivatives **24–26**. The amino-biotin derivatives **24–26** were prepared in situ by removal of the *t*-Boc groups from **21–23** using neat TFA. Although it was anticipated that the desired products would be obtained in high yield using the alternate

approach, this was not found to be the case. Indeed, several products were obtained in the conjugation reactions, such that purification by HPLC gave only moderate (25–31%) yields of radiolabeled products. Identification of the desired radioiodinated products was obtained by HPLC retention time comparison of, and coelution with, the nonradioactive iodo standards. As an example, an HPLC radiochromatogram of the product mixture obtained in the reaction of **25** with [¹²⁵I]**27** is shown in Figure 1A. An HPLC chromatogram of the nonradioactive **5b** using UV detection is shown in Figure 1B. Since the elution of samples through the radioactivity detector is approximately 0.2 min after the UV detector at the flow rate used, a good correlation of the standard and radiolabeled product was obtained. Co-injection of the iodo standard **5b** further confirmed the identity. All isolated radiolabeled biotin derivatives were single peaks after reinjection on the radio-HPLC.

Biotinidase Assay. The isolated radioiodinated biotin derivatives [¹²⁵I]**1c**, [¹²⁵I]**2c**, [¹²⁵I]**3c**, [¹²⁵I]**4b**, [¹²⁵I]**5b**, and [¹²⁵I]**6b** were evaluated in an assay which determined the amount of radioactivity that bound avidin after the samples were incubated in human serum. This biotinidase cleavage assay is based on the fact that hydrolysis of the biotinamide bond results in separation of the biotin moiety from the radioactivity, which can be measured as a lack of radioactivity binding with avidin. Since the active site of biotinidase contains a sulfhydryl moiety, the biotinidase enzymatic activity can be quenched with the addition of hydroxymercuribenzoic acid (HOHgBz) (22). Thus, a comparison of the amount of avidin binding in the absence or presence of HOHgBz provides confirmation that the lack of binding (i.e., free radioactivity) was due to enzymatic activity.

In an initial evaluation (Table 2, assay 1), biotinidase cleavage of the homobiotin derivative [¹²⁵I]**3c** was compared with a biotin derivative, [¹²⁵I]**1c**, which had previously been shown to be rapidly degraded, and a second derivative, [¹²⁵I]**2c**, which had been shown to be highly resistant to degradation (15). In a second evaluation (Table 2, assay 2), biotin derivatives having substituents alpha to the biotinamide bond ([¹²⁵I]**4b**, [¹²⁵I]**5b**, [¹²⁵I]**6b**)

were evaluated. In the analyses, radiolabeled biotin derivatives were incubated in diluted (10%) human serum for 2 h at 37 °C. Following that, HOHgBz was added to quench the reaction, and a phosphate-buffered saline (PBS) solution containing a large excess of avidin was added to that mixture. The biotin derivative was allowed to bind with avidin over a 30 min period at 37 °C. Assessment of the percent of radioactivity that did not bind with avidin was obtained by sizing ultrafiltration separation (Microcon-30). The radiolabeled biotin that was not hydrolyzed remained with the avidin in the top of the Microcon-30, whereas the cleaved material filtered through the membrane. In separate analyses, serum was treated with HOHgBz prior to incubation with the radioiodinated biotin derivative. Duplicate runs were conducted, except for the homobiotin derivative **3c**, which was conducted in triplicate.

DISCUSSION

We are pursuing the development of radiolabeled biotin derivatives for application to the diagnosis and therapy of cancer using the monoclonal antibody-based “pre-targeting method”. During our investigations, and similar investigations of other research groups, it has become apparent that it is essential for application of biotin

derivatives *in vivo* that they be designed to block the enzymatic action of the enzyme biotinidase (8, 10, 23, 24). Although biotinidase stabilization is an essential design feature in new biotin reagents for *in vivo* application, it is also important that biotinidase cleavage be blocked without affecting the high binding affinity of biotin with avidin (Av) and streptavidin (SAv). Following the lead of other investigators (12) in our previous biotin design studies, we found that conversion of the biotinamide bond into a *N*-methylbiotinamide bond blocked cleavage of that bond (15). More recently, we developed a method for evaluating the relative rates of association and dissociation of biotin derivatives from Av and SAv using size-exclusion HPLC (25). Using the HPLC analysis, we evaluated a number of biotin conjugates, including a biotin adduct that contained the *N*-methyl moiety, biotin-sarcosine (19). Unfortunately, it was found that the derivative containing a *N*-methylbiotinamide structure had a more rapid dissociation rate from Av and SAv than biotin conjugates that lacked this structural feature. Not surprisingly, it was found that any alteration of the valeric acid side chain or the biotinamide bond in biotin derivatives resulted in an increased dissociation rate. The studies demonstrated that the dissociation rates were minimally affected when biotin conjugates contained an unaltered biotin moiety linked to molecules (e.g., amino

Table 2. Percentage of Radioiodinated Biotin Derivatives Filtered in the Presence of Avidin after being Incubated in Diluted Human Serum at 37 °C for 2h^a

radioiodinated biotin derivative	group 1 w/o HOHgBz ^b	group 2 with HOHgBz ^c
assay 1		
1c	90.4 ± 0.8	3.8 ± 0.8
2c	5.5 ± 0.0	4.3 ± 0.0
3c	12.3 ± 0.1	3.4 ± 1.6
assay 2		
1c	87.6 ± 1.9 ^d	2.2 ^e
2c	3.0 ± 0.1	1.9 ± 0.0
4b	2.9 ± 0.4	2.8 ± 0.1
5b	1.6 ± 0.0	3.2 ± 0.2
6b	1.9 ± 2.1	1.5 ± 0.1

^a All values represent the percentage of radioactivity filtered through a Microcon-30 centrifugation unit (i.e., not retained by binding with avidin or nonspecifically bound). The activity that filtered through is considered as cleaved from biotin by biotinidase. The values are an average of duplicate assays ± the standard deviation, except for **3c**, which is the average of triplicate assays. Human serum was obtained 1–2 days prior to the assay (refrigerated at 4 °C) and was diluted to 10% of its original composition with 0.9% sterile saline. ^b Assay 1 values represent activity filtered from diluted, but untreated (i.e., without addition of HOHgBz), serum after an excess of avidin was added. ^c Assay 2 values represent activity filtered from diluted and HOHgBz-treated serum after an excess of avidin was added. ^d A similar value (90%) was obtained when this assay was conducted without avidin. Thus, for **1c**, it appears that as much as 10% is retained by nonspecific adherence. ^e One sample was tested.

acids) that had a substituent on a methylene group alpha to the biotinamide bond. As might be expected, large substituents alpha to the biotinamide bond significantly increased dissociation rates, but less sterically bulky groups, e.g., methyl, hydroxymethylene, and carboxylate, had little effect on the dissociation rates. Importantly, previous studies demonstrated that having a methyl substituent alpha to the biotinamide bond decreased the rate of biotinidase cleavage, but did not block it (19).

This investigation was primarily conducted to determine if biotin-amino acid adducts containing the small substituents carboxylate, hydroxymethylene, and acetate were stable to biotinidase cleavage. Prior to the study, we believed there would be a good likelihood of obtaining biotinidase stability. This belief was based on our previous studies and information in the literature relating to structural features of biotin conjugates and stability toward biotinidase cleavage (10, 11, 23, 26–30). Perhaps the most relevant data were reported by Rosebrough, which indicated that an α -carboxylate can block biotinidase activity (11). In that study, the stability toward biotinidase hydrolysis was examined in biotin adducts of deferroxamine, either directly coupled or containing *N*- ϵ -lysyl and cysteinyl linkers. High stability to biotinidase hydrolysis was only demonstrated in the biotin derivative that contained a cysteine linker, which has a carboxylate alpha to the biotinamide bond.

The data on biotinidase cleavage obtained in this study indicate that the substituents hydroxymethylene, carboxylate, and acetate, when placed on a linker molecule alpha to the biotinamide bond, completely block biotinidase activity. These results correlate well with data previously published. The finding that homobiotin is hydrolyzed at a slow rate is consistent with the results reported by Pispas that alterations in the valeric acid chain “almost completely blocked biotinidase activity” (10). However, the increased dissociation rate demonstrated for homobiotin derivatives (19) eliminates it from being an optimal candidate for in vivo use. Foulon et al.

(14, 31) have described the use of norbiotinamine conjugates for blocking the biotinidase activity. Based on our studies with norbiotin derivatives (19), it might be expected that an unfavorable dissociation rate from avidin and SAV would be obtained with these conjugates, making them nonoptimal as well. In this investigation, we included a biotin derivative that contains an acetate moiety alpha to the biotinamide bond (**6b**) even though it was known that this structural feature increased the dissociation rate from Av and SAV, because it was of interest to determine if larger substituents blocked biotinidase. The fact that it completely blocked biotinidase activity suggests that any group larger than a methyl blocks biotinidase activity. The α -acetate might be considered to be isosteric with the *o*-aminobenzoic acid which had been previously shown to block biotinidase activity (26). Although we have not examined the dissociation rate of the biotin-*o*-aminobenzoic acid adduct, it might also be expected to have an increased dissociation rate based on our previous studies.

There are likely to be other structural features of biotin derivatives that will both block biotinidase activity and exhibit the slow dissociation rate with Av and SAV. For example, a linker containing an ethyl group alpha to the biotinamide bond would be a good candidate. We did not evaluate that compound in this study as we felt it would be more lipophilic than desired for in vivo applications. In contrast to our studies, where the evaluation of biotinidase activity of biotin conjugates was based on preparation of targeted high specific activity radioiodinated biotin derivatives, it is likely that optimal structural features may be predictable in the future through molecular modeling techniques. Biotinidase has been isolated, and information on the nature of the binding pocket is being obtained (26, 32). The sequence and cDNA cloning of biotinidase have been completed (33), and more information about its binding pocket is being learned by homology data with other enzymes (34). At this time, we believe that biotin derivatives containing a carboxylate or hydroxymethylene moiety alpha to the biotinamide bond are the best candidates for developing reagents for in vivo application.

ACKNOWLEDGMENT

We are grateful for the financial support provided by the Department of Energy, Medical Applications and Biophysical Research Division, Office of Biological and Environmental Research, under Grant DE-FG03-98ER62572. We thank Quanta BioDesign for their generous gift of biotin-NHS ester used in the studies.

^{99m}Tc-Labeling of a Hydrazinonicotinamide-Conjugated Vitronectin Receptor Antagonist Useful for Imaging Tumors

Shuang Liu,* D. Scott Edwards, Marisa C. Ziegler, Anthony R. Harris, Stuart J. Hemingway, and John A. Barrett

Medical Imaging Division, DuPont Pharmaceuticals Company, 331 Treble Cove Road, North Billerica, Massachusetts 01862. Received February 5, 2001; Revised Manuscript Received March 29, 2001

This report describes the ^{99m}Tc labeling of a HYNIC-conjugated vitronectin receptor antagonist (SQ168 = [2-[[[5-[carboonyl]-2-pyridinyl]hydrazono]methyl]benzenesulfonic acid]-Glu(cyclo{Lys-Arg-Gly-Asp-D-Phe})-cyclo{Lys-Arg-Gly-Asp-D-Phe}). The ternary ligand complex [^{99m}Tc(SQ168)(tricine)(TPPTS)] (RP593) was prepared using a non-SnCl₂-containing formulation. The corresponding ^{99m}Tc analogue, [^{99m}Tc]RP593, was also prepared and characterized by HPLC and LC-MS. A HPLC concordance experiment using RP593 and [^{99m}Tc]RP593 showed that the same technetium complex was prepared at both the tracer and macroscopic levels. The LC-MS data is completely consistent with the 1:1:1:1 composition for Tc:SQ168:tricine:TPPTS and provides direct evidence that the two radiometric peaks in the radio-HPLC chromatogram of RP593 are indeed due to the resolution of diastereomers. In an in vitro receptor binding assay, [^{99m}Tc]RP593 was shown to have comparable binding affinity for the vitronectin receptor to that of SQ168 itself.

INTRODUCTION

There is currently a considerable interest in labeling small biomolecules with ^{99m}Tc for the development of target specific imaging agents (1–10). For the last several years, we have been using 6-hydrazinonicotinamide (HYNIC) as a bifunctional coupling agent for the ^{99m}Tc-labeling of small biomolecules (BM), including a GPIIb/IIIa receptor antagonist for thrombus imaging (11–18), a chemotactic peptide (19), and LTB₄ receptor antagonists for imaging infection and inflammation (20–22). It was found that the combination of HYNIC-BM, tricine, and TPPTS (trisodium triphenylphosphine-3,3',3''-trisulfonate) produces a unique and versatile ternary ligand system which forms technetium complexes, [^{99m}Tc(HYNIC-BM)(tricine)(TPPTS)] with high solution stability and only two detectable isomeric forms. As a continuation of our efforts in developing new target-specific diagnostic radiopharmaceuticals, we now describe the ^{99m}Tc-labeling of a vitronectin receptor antagonist (Figure 1: SQ168 = [2-[[[5-[carboonyl]-2-pyridinyl]hydrazono]methyl]benzenesulfonic acid]-Glu(cyclo{Lys-Arg-Gly-Asp-D-Phe})-cyclo{Lys-Arg-Gly-Asp-D-Phe}).

The ternary ligand complex [^{99m}Tc(SQ168)(tricine)(TPPTS)] (Figure 1: RP593) was prepared using a non-SnCl₂-containing formulation (23) and was characterized using a reversed phase HPLC method. The corresponding ^{99m}Tc analogue, [^{99m}Tc]RP593, was also prepared and characterized by HPLC and LC-MS. A HPLC concordance experiment using RP593 and [^{99m}Tc]RP593 showed that the same complex was prepared at both the tracer and macroscopic levels. In an in vitro receptor binding assay, [^{99m}Tc]RP593 was shown to have comparable binding affinity for the vitronectin receptor as SQ168. Apparently, the attachment of the technetium chelate does not have significant effect on the receptor binding affinity. RP593

has been evaluated in two spontaneous tumor models (c-Neu oncomouse and dog) for its potential use as a new radiopharmaceutical for imaging tumors. The biological properties of RP593 have been described in our previous communications (24, 25).

EXPERIMENTAL SECTION

Materials. Succinic acid, TPPTS (trisodium triphenylphosphine-3,3',3''-trisulfonate), and tricine were purchased from Aldrich Chemical Co. TPPTS was purified according to the literature method (26). The cyclic pentapeptide, cyclo(Arg-Gly-Asp-D-Phe-Lys), was prepared according to the literature method (27). Synthesis of SQ168 has been reported as a separate communication (28). Na^{99m}TcO₄ was obtained from a commercial DuPont Pharma ⁹⁹Mo/^{99m}Tc generator, N. Billerica, MA.

Analytical Methods. HPLC methods used a HP 1100 system, a homemade NaI radiometric detector, a Zorbax C₁₈ column (4.6 mm × 250 mm) at a flow rate of 1 mL/min. In method 1, the mobile phase was isocratic at 0–18 min using 90% solvent A (95:5 (v:v) = 0.025 M ammonium acetate buffer (pH = 6.8):acetonitrile) and 10% solvent B (95:5 (v:v) = acetonitrile: 0.025 M ammonium acetate buffer, pH = 6.8), followed by an isocratic wash using 40% solvent A and 60% solvent B at 19–25 min. In method 2, the gradient mobile phase started from 92% solvent A (0.025 M succinate buffer, pH = 5.0) and 8% solvent B (acetonitrile) to 80% solvent A and 20% solvent B at 25 min. The mobile phase was isocratic at 26–31 min using 60% solvent B. The ITLC method used Gelman Sciences silica gel ITLC paper strips and 1:1 mixture of acetone and saline as eluant. Using this ITLC method, the radiolabeled peptide and [^{99m}Tc]pertechnetate migrate while the [^{99m}Tc]colloid remains at the origin.

LC-MS Methods. LC-MS spectral data were collected using a HP1100 LC/MSD system with an API-electrospray interface. The LC-MS method used a Zorbax C₁₈ column (4.6 mm × 150 mm, 3.5 μm particle size) and a mobile phase gradient starting from 92% solvent A (10 mM ammonium acetate buffer, pH 7.0) and 8% solvent

UV detector:	λ = 280 nm

B (methanol) to 100% B at 23 min at a flow rate of 1 mL/min. The MSD parameters are listed in Table 1.

Synthesis of RP593. RP593 was prepared according to the published procedure (13) with a slight modification. To a lyophilized vial containing 5 mg of TPPTS, 6.5 mg of tricine, 40 mg of mannitol, 38.5 mg of disodium succinate hexahydrate, 12.7 mg of succinic acid, and 0.1 mg of pluronic acid (0.1%); pH = 4.8) was added 0.5 mL of SQ168 solution (40 µg/mL in water). The vial was placed into a lead pig. To the vial was added 1.0 mL of Na[^{99m}TcO₄] solution (50 mCi/mL) in saline. The reconstituted vial was heated at 100 °C for 10 min in a lead-shielded water bath. After heating, the vial was placed back into the lead pig and allowed to stand at room

temperature for ~10 min. A sample of the resulting solution was analyzed by the radio-HPLC (method 1) and ITLC.

Solution Stability Studies. For solution stability in the kit matrix, RP593 was first prepared, and samples of the resulting reaction were analyzed by HPLC (method 1) at *t* = 0, 2, 4, and 6 h postlabeling. For HPLC-purified RP593, the two peaks at 9.3 and 12 min were collected into a 25 mL round-bottom flask. Solvents were removed using a rotary evaporator. The residue was dissolved in saline and samples of the resulting solution were analyzed by HPLC (method 1) at 0, 2, 4, and 6 h postpurification.

[⁹⁹Tc]RP593. To a clean 10 mL vial were added 1.5 mg of SQ168, 84 mg of tricine, 49 mg of TPPTS, 1.2 mg of NH₄[⁹⁹TcO₄] in 0.4 mL of H₂O, and 1.5 mL of 25 mM succinate buffer (pH = 5.0). The reaction mixture was heated in a 100 °C water bath for 30 min. After the mixture was cooled to room temperature, the product was separated by HPLC (method 2). The collections of the two peaks due to [⁹⁹Tc]RP593 were combined, and volatiles were removed under reduced pressure. The residue was then desalted using the same HPLC method using water as mobile phase A. Removal of the solvent gave the product, [⁹⁹Tc]RP593.

Immobilized Human Placental $\alpha\beta 3$ Receptor ELISA Assay. The placental $\alpha\beta 3$ receptors were isolated according to the published method (29). The assay conditions were developed and validated using [^{125}I]-vitronectin. Assay validation included Scatchard format analysis ($n = 3$) where receptor number (B_{max}) and K_d (affinity) were determined. Three standards (vitronectin, $\alpha\beta 3$ antibody, LM609, and $\alpha\beta 5$ antibody, P1F6) have been evaluated for IC_{50} determination. Briefly, the method involves immobilizing previously isolated receptors in 96 well plates (EIA/RIA, CORNING Costar) and incubating overnight. The plates are then blocked with 1% bovine serum albumin. During this time, compounds to be tested were prepared in 10 nM biotinylated vitronectin ([B]Vn) solution and were dispensed into a reservoir plate. Blocking buffer is removed, wells were washed, and then compound/[B]Vn mixture was pipetted. Incubation is carried out for 30 min at room temperature. The unbound material was removed, and wells were washed. [B]Vn binding was qualified using goat anti-biotin alkaline phosphatase conjugated antibody (GAB). Unbound GAB was removed, wells were washed, and phosphatase enzyme assay was performed. Enzyme product was detected via spectrophotometry ($\lambda = 405 \text{ nm}$) for subsequent IC_{50} determination. All concentrations of the tested compound were run in triplicate. Four independent measurements were made for [^{99}Tc]RP593. The IC_{50} value was calculated by fitting the percent inhibition values to a regression line.

RESULTS AND DISCUSSION

Angiogenesis, the formation of new blood vessels, is a requirement for malignant tumor growth and metastasis (30–32). The angiogenic process depends on vascular endothelial cell migration and invasion, regulated by cell adhesion receptors. The integrin $\alpha\beta 3$ (vitronectin receptor) is such a cell adhesion receptor and interacts with proteins and peptides containing the RGD tripeptide recognition sequence (33–42). In general, the level of expression of $\alpha\beta 3$ receptor is low on most cell types and is greatly increased in remodeling and growing tissues (43). Many peptide vitronectin receptor antagonists have high binding affinity for the vitronectin receptor and have been shown to be able to inhibit neovascularization, tumor-induced angiogenesis, and tumor growth (40–46). Therefore, these vitronectin receptor antagonists can serve as targeting molecules for diagnosis and radiotherapy of a wide spectrum of tumors.

Recently, Kessler and co-workers (47, 48) reported two ^{125}I -labeled cyclic pentapeptides: 3- ^{125}I -D-Tyr⁴-cyclo-(RGDyV) and 3- ^{125}I -D-Tyr⁴-cyclo-(RGDyK(SAA1)) (SAA = sugar amino acid). It was found that 3- ^{125}I -D-Tyr⁴-cyclo-(RGDyV) has fast hepatobiliary and renal excretion (47). The tumor/muscle and tumor/blood ratios for melanoma in nude mice were 5.5 and 9.5, respectively, at 60 min postinjection. Substitution of leucine with a SAA-functionalized lysine amino acid residue resulted in improved blood retention time, renal excretion, and better target-to-background ratio. A blocking study using 3 mg/kg of the $\alpha\beta 3$ selective cyclo(RGDfV) demonstrated that the localization of radioactivity in the tumor is due to $\alpha\beta 3$ receptor binding (48).

For diagnostic purposes $^{99\text{m}}\text{Tc}$ is more desirable than ^{125}I due to its easy availability, low cost, and ideal nuclear characteristics, which better match the rapid blood clearance and fast tumor accumulation of small peptides. Therefore, a series of RGD-containing peptide conjugates have been prepared for the development of a target-

Figure 2. A typical radio-HPLC chromatogram of RP593 (method 1).

Figure 3. Solution stability of RP593 in the kit matrix and after HPLC purification.

specific tumor imaging agent (24, 25). In the c-Neu Oncomouse tumor model, RP593 shows high tumor uptake and long tumor residence time (3.4% ID/g at 2 h and 1.5% ID/g at 24 h postinjection) and is excreted predominantly via the renal system. As an extension of these efforts, we present the synthesis and characterization of the ternary ligand $^{99\text{m}}\text{Tc}$ complex (Figure 1: RP593) of a HYNIC-conjugated vitronectin receptor antagonist (Figure 1: SQ168).

Synthesis of RP593. In this study, RP593 was prepared according to the published procedure (23) using a non-SnCl₂-containing formulation. The radiolabeling was achieved by adding 1.0 mL of generator eluant (50 mCi of Na[$^{99\text{m}}\text{TcO}_4$]) and heating at 100 °C for 10 min. The radiochemical purity (RCP) for RP593 is usually $\geq 90\%$. The formation of [$^{99\text{m}}\text{Tc}$]colloid is minimal ($<0.5\%$). Very high specific activity ($\sim 10000 \text{ mCi}/\mu\text{mol}$) can be achieved for RP593 without postlabeling purification.

HPLC Characterization. A reverse phase HPLC method was used for characterization of RP593. Figure 2 shows a typical radio-HPLC chromatogram. The small peak at $\sim 23 \text{ min}$ is due to a combination of several radio-impurities. Since most of radio-impurities in the RP593 kit are less than 1.0%, no further characterization was performed. The technetium chelate moiety is chiral, due to the tricine ligand being prochiral and should be formed in an equal mixture of D and L enantiomers. These enantiomers in combination with the chiral centers on the peptide backbone should result in two diastereomers, which are separable using a reverse phase HPLC method. Therefore, it is not surprising that RP593 shows two radiometric peaks in its radio-HPLC chromatogram and the area ratio of these two peaks is always close to 1:1.

Solution Stability Studies. We also examined the solution stability of RP593. Figure 3 shows the plot of RCP vs time for RP593 both in kit matrix and in the

Figure 4. The HPLC concordance (method 2) for RP593 (top) and ^{99m}Tc RP593 (bottom).

dilute solution after HPLC purification. It is clear that RP593 remains stable for at least 6 h both in the kit matrix and after HPLC purification.

Synthesis of ^{99m}Tc RP593. ^{99m}Tc RP593 was prepared in one step by reacting $[\text{NH}_4][^{99m}\text{TcO}_4]$ with SQ168 in the

Figure 5. UV (top) and MSD (bottom) profiles for ^{99m}Tc RP593.

presence of excess tricine and TPPTS. Unlike that of RP593, the yield for ^{99m}Tc RP593 is low (<30% by UV). After purification (method 2) and desalting, ^{99m}Tc RP593 was obtained only in milligram quantity, which is not enough for extensive NMR studies. However, sufficient material was obtained for the HPLC concordance experiment, *in vitro* receptor binding assay, and LC-MS characterization.

HPLC Concordance Experiment. The HPLC concordance experiment is a very useful supplementary method for compositional and structural determination

Figure 6. LC-MS spectra of the two isomers of ^{99m}Tc RP593.

of a new radiopharmaceutical. In this study, we used the identical chromatographic conditions for the HPLC analysis of both RP593 and [^{99}Tc]RP593. Figure 4 shows HPLC chromatograms of RP593 (top) and [^{99}Tc]RP593 (bottom). It is clearly demonstrated that the same complexes were prepared at the tracer ($^{99\text{m}}\text{Tc}$) and macroscopic (^{99}Tc) levels.

LC-MS Characterization of [^{99}Tc]RP593. In our previous communication, we reported a simple LC-MS method for the characterization of $^{99\text{m}}\text{Tc}$ radiopharmaceuticals at the tracer level (49). When we used the same MSD parameters for characterization of [^{99}Tc]RP593, only the triprotonated molecular ion, $(M + 3)^{3+}$ ($m/z = 743.8$) and the diprotonated molecular ion, $(M + 2)^{2+}$ ($m/z = 1114.8$) were observed in the LC-MS spectrum. This suggests that the original fragmentor voltage was too high. When the fragmentor voltage was lowered from 30 to 15 V, the monoprotonated molecular ion, $(M + 1)^+$, peak at $m/z = 2229.2$ for $[\text{C}_{89}\text{H}_{115}\text{N}_{23}\text{O}_{31}\text{PS}_3\text{Tc}]^+$ became obvious; but the diprotonated and triprotonated molecular ions remain predominant in the LC-MS spectrum. The observation of the predominant diprotonated and triprotonated molecular ions is also characteristic of the unlabeled HYNIC-BM conjugate, SQ168. The LC-MS data support the proposed structure (Figure 1) and is completely consistent with the 1:1:1:1 composition for Tc:SQ168:tricine:TPPTS. [^{99}Tc]RP593 shows two peaks in both the UV and MSD profiles (Figure 5). Both peaks show almost identical fragmentation patterns and the same molecular ions (Figure 6). This provides direct evidence for the conclusion that the two radiometric peaks in the radio-HPLC chromatogram of RP593 are indeed due to the resolution of diastereomers.

In Vitro Receptor Binding of [^{99}Tc]RP593. In an in vitro binding assay, [^{99}Tc]RP593 was able to effectively compete with 10 nM biotinylated vitronectin ([B]Vn) with IC_{50} of 1.7 ± 0.5 nM ($n = 4$). Compared to the corresponding unlabeled cyclic peptide, which has an IC_{50} of 0.6 ± 0.4 nM ($n = 4$), [^{99}Tc]RP593 remains a high affinity vitronectin receptor antagonist. The $^{99\text{m}}\text{Tc}$ -labeling did not significantly alter the binding affinity even though the molecular weight is significantly increased after radiolabeling.

CONCLUSION

In this report, we described the $^{99\text{m}}\text{Tc}$ labeling of a HYNIC-conjugated vitronectin receptor antagonist. The ternary ligand complex [$^{99\text{m}}\text{Tc}(\text{SQ168})(\text{tricine})(\text{TPPTS})$] (RP593) was prepared in high radiochemical purity and high specific activity using a non-SnCl₂ formulation. RP593 was stable in solution for at least 6 h postlabeling. The corresponding ^{99}Tc analogue, [^{99}Tc]RP593, was also prepared and characterized by HPLC and LC-MS. A HPLC concordance experiment using RP593 and [^{99}Tc]RP593 showed that the same technetium complex was prepared at both the tracer and macroscopic levels. The LC-MS data is completely consistent with the 1:1:1:1 composition for Tc:SQ168:tricine:TPPTS. In an in vitro receptor-binding assay, [^{99}Tc]RP593 had a similar binding affinity (within the experimental error) for the vitronectin receptor to that of the unlabeled cyclic peptide (SQ168).

Acknowledgment is made to Dr. M. Rajopadhye and Anthony R. Harris for the synthesis of hydrazinonicotinamide-conjugated cyclic peptide (SQ168).

Synthesis and Characterization of Two ^{111}In -Labeled DTPA–Peptide Conjugates

Shuang Liu* and D. Scott Edwards

Medical Imaging Division, DuPont Pharmaceuticals Company, 331 Treble Cove Road, North Billerica, Massachusetts 01862. Received February 5, 2001; Revised Manuscript Received April 20, 2001

This report describes the synthesis and characterization of two ^{111}In -labeled DTPA–peptide conjugates (DTPA–MA and DTPA–BA). It is surprising to find that $^{111}\text{In}(\text{DTPA–MA})$ and $^{111}\text{In}(\text{DTPA–BA})$ are more hydrophilic than their corresponding ^{90}Y analogues, suggesting a different coordination sphere in ^{111}In and ^{90}Y complexes of the same DTPA–peptide conjugate. By a reversed phase HPLC method, both $^{111}\text{In}(\text{DTPA–MA})$ and $^{111}\text{In}(\text{DTPA–BA})$ showed only one radiometric peak in their respective HPLC chromatogram due to a rapid interconversion of different isomers (particularly *cis* and *trans* isomers for $^{111}\text{In}(\text{DTPA–MA})$; *cis-cis*, *cis-trans*, *trans-cis*, and *trans-trans* isomers for $^{111}\text{In}(\text{DTPA–BA})$). The interconversion of different isomers involves the “wagging” of the diethylenetriamine backbone, “shuffling” of the NO or NO₂ donor sets, and a rapid inversion at the terminal amine–nitrogen atoms.

INTRODUCTION

There is currently a considerable interest in radiolabeled biomolecules (BM) as target-specific radiopharmaceuticals for the diagnosis and treatment of cancer (1–7). DTPA (diethylenetriaminepentaacetic acid) and its analogues have been used as bifunctional chelators (BFCs) for the radiolabeling of various biomolecules, including antibodies, antibody fragments, and small peptides (8–27). This has been reviewed recently (26). While the ^{90}Y -labeled BFC–BM conjugates are used for tumor therapy, the ^{111}In -labeled BFC–BM conjugates are often used as an imageable surrogate for the purpose of dosimetry determination and therapy monitoring (27–36).

In our previous communication (37), we reported two ^{90}Y -labeled DTPA-conjugated cyclic peptides: DTPA–MA and DTPA–BA (Figure 1). It was found that the complex $^{90}\text{Y}(\text{DTPA–MA})$ exists in solution as a mixture of two detectable isomers, which slowly interconvert at room temperature. The interconversion of two isomers involves a rapid exchange of “wrapping isomers” via the “wagging” of the diethylenetriamine backbone, “shuffling” of the two NO₂ donor sets, and the inversion at the terminal amine–nitrogen atom. For the complex $^{90}\text{Y}(\text{DTPA–BA})$, the interconversion of different isomers is much faster due to the weak bonding of two carbonyl–oxygen donors. The complex $^{90}\text{Y}(\text{DTPA–BA})$ shows only one broad radiometric peak in its HPLC chromatogram. The interconversion of different isomers is intramolecular via a partial dissociative mechanism and is consistent with the lack of kinetic inertness of ^{90}Y -labeled DTPA–BM conjugates.

As an extension of our efforts in understanding of the solution chemistry of the radiolabeled DTPA–BM conjugates, we describe the synthesis and characterization of ^{111}In complexes of DTPA–MA and DTPA–BA. The purpose is to compare the ^{111}In -labeled DTPA–BM conjugates with their corresponding ^{90}Y analogues with

respect to hydrophilicity and isomerism. We prepared the ^{111}In complexes by reacting DTPA–MA or DTPA–BA with $^{111}\text{InCl}_3$ in the 0.5 M ammonium acetate buffer (pH = 6.0) at room temperature and characterized them using a reversed phase HPLC method. It was surprising to find that both $^{111}\text{In}(\text{DTPA–MA})$ and $^{111}\text{In}(\text{DTPA–BA})$ are more hydrophilic than their respective ^{90}Y analogues. Unlike the complex $^{90}\text{Y}(\text{DTPA–MA})$, $^{111}\text{In}(\text{DTPA–MA})$ showed only one radiometric peak in its HPLC chromatogram due to a more rapid interconversion of *cis*- and *trans*-isomers.

EXPERIMENTAL SECTION

Materials. Acetic acid (ultrapure), ammonium hydroxide (ultrapure), and diethylenetriaminepentaacetic acid cyclic dianhydride were purchased from either Aldrich or Sigma Chemical Co. and were used as received. $^{90}\text{YCl}_3$ (in 0.05 N HCl) and $^{111}\text{InCl}_3$ (in 0.05 N HCl) were purchased from New England Nuclear, N. Billerica, MA. The DTPA–peptide conjugates, cyclo(Arg–Gly–Asp–D–Phe–Lys)DTPA (DTPA–MA) and [cyclo(Arg–Gly–Asp–D–Phe–Lys)]₂DTPA (DTPA–BA) and their ^{90}Y complexes have been described in our previous communication (37).

Synthesis of $^{111}\text{In}(\text{DTPA–MA})$ and $^{111}\text{In}(\text{DTPA–BA})$. To a lead-shielded clean 5 mL vial containing 50 μg of DTPA–MA or DTPA–BA in 1 mL of 0.5 M ammonium acetate buffer (pH = 6.0) was added 5–10 μL of $^{111}\text{InCl}_3$ stock solution (~ 1 mCi) in 0.05 N HCl. The reaction mixture was allowed to stand at room temperature for 10–30 min. A sample of the resulting solution was then analyzed by HPLC (gradient A for $^{111}\text{In}(\text{DTPA–MA})$ and gradient B for $^{111}\text{In}(\text{DTPA–BA})$) and by ITLC.

The HPLC method used a HP-1100 HPLC system with a UV/visible detector ($\lambda = 230$ nm), an IN–US radio-detector, and a Zorbax C₁₈ column (4.6 mm $\times$ 250 mm, 80 Å pore size). The flow rate was 1 mL/min with a gradient mobile phase. For $^{111}\text{In}(\text{DTPA–MA})$, the gradient started from 95% solvent A (95:5 mixture of 25 mM ammonium acetate buffer, pH 6.8, and acetonitrile) and 5% solvent B (50:50 mixture of 25 mM ammonium acetate buffer, pH 6.8, and acetonitrile) to 90% of solvent

Figure 1. Structures of DTPA-MA (top) and DTPA-BA (bottom).

A and 10% solvent B at 24 min. For $^{111}\text{In}(\text{DTPA-BA})$, the gradient started from 85% solvent A and 15% solvent B to 80% of solvent A and 20% solvent B at 18 min. The ITLC method used Gelman Sciences silica gel ITLC paper strips and 1:1 mixture of acetone and saline as eluant. By this method, $^{111}\text{In}(\text{DTPA-MA})$ and $^{111}\text{In}(\text{DTPA-BA})$ migrate to the solvent front while ^{111}In colloid and ^{111}In -acetate remain at the origin.

RESULTS

Synthesis of $^{111}\text{In}(\text{DTPA-MA})$ and $^{111}\text{In}(\text{DTPA-BA})$.

$^{111}\text{In}(\text{DTPA-MA})$ and $^{111}\text{In}(\text{DTPA-BA})$ were prepared by reacting DTPA-MA and DTPA-BA, respectively, with $^{111}\text{InCl}_3$ in the 0.5 M ammonium acetate buffer (pH = 6.0) at room temperature. Both $^{111}\text{In}(\text{DTPA-MA})$ and $^{111}\text{In}(\text{DTPA-BA})$ could be prepared in high yield (RCP > 95%) by reacting 50 μg of DTPA conjugate with 1.0 mCi of $^{111}\text{InCl}_3$. The ^{111}In -chelation was almost instantaneous for both DTPA-MA and DTPA-BA. This is consistent with the results reported in the literature (22, 23). Both $^{111}\text{In}(\text{DTPA-MA})$ and $^{111}\text{In}(\text{DTPA-BA})$ are stable in solution for at least 24 h without significant decomposition.

HPLC Characterization of $^{111}\text{In}(\text{DTPA-MA})$. For the past decade, HPLC has become a routine technique for quality control of various radiopharmaceuticals. The advantage of radio-HPLC is its capability to determine the radiochemical purity (RCP) of the radiopharmaceutical and to separate different radiolabeled species in the reaction mixture. It is also a very powerful tool for separation of different isomers such as diastereomers. In this study, we used a reversed phase HPLC method to analyze reaction mixtures containing $^{111}\text{In}(\text{DTPA-MA})$. For comparison purpose, we also prepared the complex $^{90}\text{Y}(\text{DTPA-MA})$. Both complexes were analyzed under identical chromatographic conditions. Figure 2 shows typical radio-HPLC chromatograms of $^{90}\text{Y}(\text{DTPA-MA})$ (top) and $^{111}\text{In}(\text{DTPA-MA})$ (bottom). Apparently, the

Figure 2. Typical radio-HPLC chromatograms for $^{90}\text{Y}(\text{DTPA-MA})$ (top) and $^{111}\text{In}(\text{DTPA-MA})$ (bottom) using method 1.

hydrophilicity of $^{111}\text{In}(\text{DTPA-MA})$ is higher than that of $^{90}\text{Y}(\text{DTPA-MA})$, reflecting the difference in their coordination chemistry. Unlike $^{90}\text{Y}(\text{DTPA-MA})$, which shows two radiometric peaks due to the resolution of *cis*- and

Figure 3. Typical radio-HPLC chromatograms for $^{90}\text{Y}(\text{DTPA}-\text{BA})$ (top) and $^{111}\text{In}(\text{DTPA}-\text{BA})$ (bottom) using method 2.

trans-isomers, $^{111}\text{In}(\text{DTPA}-\text{MA})$ shows only one radiometric peak at ~ 11.5 min. We tried several other reversed phase HPLC methods. In all the cases, $^{111}\text{In}(\text{DTPA}-\text{MA})$ always shows only one radiometric peak, suggesting that the complex $^{111}\text{In}(\text{DTPA}-\text{MA})$ indeed exists as one *detectable* isomer in solution.

HPLC Characterization of $^{111}\text{In}(\text{DTPA}-\text{BA})$. We used a slightly different gradient mobile phase when analyzing $^{111}\text{In}(\text{DTPA}-\text{BA})$ by HPLC due to its higher lipophilicity. We also prepared the complex $^{90}\text{Y}(\text{DTPA}-\text{MA})$. Complexes $^{111}\text{In}(\text{DTPA}-\text{BA})$ and $^{90}\text{Y}(\text{DTPA}-\text{BA})$ were analyzed using the same HPLC method. Figure 3 shows typical radio-HPLC chromatograms of $^{90}\text{Y}(\text{DTPA}-\text{BA})$ (top) and $^{111}\text{In}(\text{DTPA}-\text{BA})$ (bottom). Like $^{111}\text{In}(\text{DTPA}-\text{MA})$, $^{111}\text{In}(\text{DTPA}-\text{BA})$ shows one radiometric peak in its HPLC chromatogram. The retention time of $^{111}\text{In}(\text{DTPA}-\text{BA})$ is ~ 4 min shorter than that of the corresponding yttrium analogue, $^{90}\text{Y}(\text{DTPA}-\text{BA})$, suggesting a higher hydrophilicity for $^{111}\text{In}(\text{DTPA}-\text{BA})$.

DISCUSSION

Previously, we reported the synthesis and characterization of two ^{90}Y -labeled DTPA-conjugated cyclic peptides: DTPA-MA and DTPA-BA (37). It was found that the complex $^{90}\text{Y}(\text{DTPA}-\text{MA})$ exists in solution as a mixture of two *detectable* isomers (Figure 4), which slowly interconvert at room temperature. In the complex $^{90}\text{Y}(\text{DTPA}-\text{MA})$, DTPA-MA is octadentate with three amine-nitrogen, one carbonyl-oxygen, and four carboxylate-oxygen donors binding to the metal center. Although there is a rapid exchange of "wrapping isomers" via the "wagging" of the diethylenetriamine backbone and "shuffling" of the two NO_2 donor sets, the inversion at the terminal amine-nitrogen atoms is slow at room temper-

Figure 4. Relative orientations of the acetamide group in $^{90}\text{Y}(\text{DTPA}-\text{MA})$ (top) and $^{111}\text{In}(\text{DTPA}-\text{MA})$ (bottom).

ature so that the *cis* and *trans* isomers in $^{90}\text{Y}(\text{DTPA}-\text{MA})$ is detectable by radio-HPLC. Therefore, the complex $^{90}\text{Y}(\text{DTPA}-\text{MA})$ shows two peaks in its HPLC chromatogram (Figure 2).

In^{3+} has an ionic radius of $0.75 \text{ \AA}$ (38), which is smaller than that of Y^{3+} ($0.87 \text{ \AA}$). The coordination number for In^{3+} is typically 6 or 7. Only a few eight coordinated In^{3+} complexes are known (39, 40). Since In^{3+} is smaller, DTPA-MA is likely heptadentate with three amine-nitrogen and four carboxylate-oxygen donors binding to the metal center while the carbonyl-oxygen remains uncoordinated (Figure 4). The presence of the uncoordinated carbonyl-oxygen makes the complex $^{111}\text{In}(\text{DTPA}-\text{MA})$ more hydrophilic than its eight-coordinated analogue, $^{90}\text{Y}(\text{DTPA}-\text{MA})$. This is consistent with the shorter retention time of $^{111}\text{In}(\text{DTPA}-\text{MA})$ as compared to the average of the two isomers of $^{90}\text{Y}(\text{DTPA}-\text{MA})$. If they were to share the same coordination sphere, the complex $^{111}\text{In}(\text{DTPA}-\text{MA})$ should have the same retention time and chromatographic patterns as $^{90}\text{Y}(\text{DTPA}-\text{MA})$ under identical chromatographic conditions.

There are two possible orientations (*cis* and *trans*) for the acetamide group in $^{111}\text{In}(\text{DTPA}-\text{MA})$ relative to the acetate arm at the central nitrogen atom (Figure 4). The amide carbonyl-oxygen is most likely not bound to the metal center, which makes it easier for the NO donor set to become dissociated momentarily. Once the NO donor set becomes dissociated from the metal ion, it is possible for the terminal amine-nitrogen atom to undergo a rapid inversion. This leads to the rapid interconversion of the *cis*- and *trans* isomers. The presence of a single peak suggests that the complex $^{111}\text{In}(\text{DTPA}-\text{MA})$ exist in solution as only one *detectable* isomer at room temperature. Since $^{111}\text{In}(\text{DTPA}-\text{MA})$ remains stable for at least 24 h at room temperature, it is reasonable to assume that the remaining part of the DTPA-MA is firmly bonded to In^{3+} when the NO donor atoms become dissociated and the terminal amine-nitrogen atom undergoes a rapid inversion.

Like $^{111}\text{In}(\text{DTPA}-\text{MA})$, $^{111}\text{In}(\text{DTPA}-\text{BA})$ also shows a single peak in its HPLC chromatogram due to rapid exchange of different possible isomers (Figure 5). Compared to that of $^{90}\text{Y}(\text{DTPA}-\text{BA})$, the retention time of $^{111}\text{In}(\text{DTPA}-\text{BA})$ is ~ 4 min shorter under identical chromatographic conditions (Figure 3). The peak width (~ 0.6 min) for $^{111}\text{In}(\text{DTPA}-\text{BA})$ is also smaller than that (~ 3 min) of $^{90}\text{Y}(\text{DTPA}-\text{BA})$, suggesting a much faster exchange between different isomers. If these two complexes were to share the same coordination sphere, $^{111}\text{In}(\text{DTPA}-\text{BA})$ should have the same retention time as that of $^{90}\text{Y}(\text{DTPA}-\text{BA})$.

Figure 5. Relative orientations of the two acetamide groups in $^{90}\text{Y}(\text{DTPA-BA})$ (top) and $^{111}\text{In}(\text{DTPA-BA})$ (bottom).

CONCLUSIONS

In this report, we presented the synthesis and HPLC characterization of ^{111}In -labeled DTPA–peptide conjugates (DTPA–MA and DTPA–BA). By a reversed phase HPLC method, we found that complexes $^{111}\text{In}(\text{DTPA-MA})$ and $^{111}\text{In}(\text{DTPA-BA})$ are more hydrophilic than their respective ^{90}Y analogues, $^{90}\text{Y}(\text{DTPA-MA})$ and $^{90}\text{Y}(\text{DTPA-BA})$. Since $^{111}\text{In}(\text{DTPA-MA})$ and $^{90}\text{Y}(\text{DTPA-MA})$ share the same biomolecule, the difference in hydrophilicity strongly suggests that these two complexes have different coordination spheres. These results have significant implications for ^{90}Y - and ^{111}In -labeled DTPA–biomolecule conjugates. For radiolabeled antibodies, the attachment of the metal chelate (radionuclide and BFC) normally does not disturb the tertiary structure of the polypeptide, and the biological properties are not significantly affected. For small biomolecules, however, the metal chelate contributes greatly to the overall size and molecular weight of the radiolabeled biomolecule. Differences in the coordination chemistry may result in biological nonequivalence between the ^{90}Y - and ^{111}In -labeled DTPA–biomolecule conjugates. Thus, the choice of the bifunctional chelator should be those which form ^{90}Y and ^{111}In complexes with the same coordination sphere.

Both $^{111}\text{In}(\text{DTPA-MA})$ and $^{111}\text{In}(\text{DTPA-BA})$ showed one radiometric peak in their respective HPLC chromatograms due to a rapid interconversion of different isomers. The interconversion of different isomers involves the “wagging” of the diethylenetriamine backbone, “shuffling” of the NO or NO₂ donor sets, and a rapid inversion at the terminal amine-nitrogen atoms. Therefore, the presence of different isomeric forms may not impose a significant problem with respect to the difference in

biological properties of these isomers. The most critical issue in using DTPA as a bifunctional chelator is the low kinetic inertness. Once the ^{111}In -labeled DTPA–BM conjugate is injected into a biological system, the presence of biologically important metal ions such as Ca^{2+} , Cu^{2+} , Fe^{2+} , and Zn^{2+} , is expected to have a significant impact on the biological fate of the ^{111}In -labeled DTPA–biomolecule conjugate. These metal ions can compete with ^{111}In for the DTPA–BM conjugate due to their high concentration. Once ^{111}In is dissociated from the DTPA–biomolecule conjugate, it will most likely deposit in bone. It is not surprising that many ^{111}In -labeled DTPA–biomolecule conjugates often show high bone activity. Thus, the design of new BFCs should be focused on those which form indium and lanthanide complexes with high thermodynamic stability and more importantly kinetic inertness.

Acknowledgment is made to Dr. M. Rajopadhye and Kirsten L. Overoye for the synthesis of DTPA–conjugated cyclic peptides (DTPA–MA and DTPA–BA).

Nucleosides and Nucleotides. 208. Alternate-Strand Triple-Helix Formation by the 3'-3'-Linked Oligodeoxynucleotides with the Anthraquinonyl Group at the Junction Point[†]

Yoshihito Ueno, Mai Mikawa, Shuichi Hoshika, and Akira Matsuda*

Graduate School of Pharmaceutical Sciences, Hokkaido University, Kita-12, Nishi-6, Kita-ku, Sapporo 060-0812, Japan. Received February 20, 2001; Revised Manuscript Received April 17, 2001

The synthesis of 3'-3'-linked oligodeoxynucleotides (ODNs) with the anthraquinonyl group at the junction point is described. The ODNs were synthesized on a DNA synthesizer using a controlled pore glass (CPG) carrying pentaerythritol that has an intercalator at one of the four hydroxymethyl groups. Stability of the triplexes with the target duplexes was studied by thermal denaturation. The 3'-3'-linked ODNs with the anthraquinonyl group enhanced the thermal stability of the triplexes when compared with those without the intercalator and the unmodified nonamer **10**. It was found that the ODNs **12** and **13** carrying the anthraquinonyl groups can form thermally stable triplexes by skipping two or three extra base pairs between two binding domains of the target duplexes. The ability of the 3'-3'-linked ODNs to inhibit cleavage of the target DNA **22** by the restriction enzyme Hind III was tested. It was found that the 3'-3'-linked ODN **16** with the anthraquinonyl group at the junction point inhibited the cleavage by the enzyme more effectively than the nonamer **14** and the 3'-3'-linked ODN **15** without the intercalator.

INTRODUCTION

In the antigene strategy proposed to control gene transcription, an oligopyrimidine-oligopurine sequence of double-helical DNA is recognized by a third-strand oligodeoxynucleotide (ODN) that binds to the major groove of the DNA and forms a local triple helix (triplex) (1). Depending on the orientation of the third strand, two major classes of triplexes are identified. When the third strand consists mainly of pyrimidines, Hoogsteen-type Py-PuPy base triplets (T-AT and C⁺-GC) are formed in which the third strand is parallel to the purine strand of the target duplex (2, 3). When the third strand is predominantly purines, reverse Hoogsteen-type Pu-PuPy base triplets (G-GC and A-AT) are formed in which the third strand is antiparallel to the purine strand of the target duplex (4, 5). However, target sequences in the antigene strategy are very restricted. Since the thermal stability of the triplexes is generally lower than that of the duplexes under physiological conditions, an oligopurine cluster with fairly long chain lengths is required for stable triplex formation. In addition, formation of the pyrimidine motif triplex needs conditions of low pH (pH < 6.0), because unmodified cytosine residues, if present in the third strand, must be protonated to bind with guanine of the G:C duplex (2, 6).

Several approaches have been described to overcome this limitation. If the target duplex is composed of two adjacent and alternating oligopurine-oligopyrimidine tracts, the duplex can form a triplex with a single-strand ODN which pairs with oligopurine sequences on alternate strands by crossover in the major groove (7–24). This so-called “alternate-strand triplex” or “switched triplex” can

be formed in two distinct ways. By combining both Hoogsteen and reverse Hoogsteen motifs (7–14), the natural ODNs with oligopurine-oligopyrimidine sequences such as 5'-oligopurine-oligopyrimidine-3' or 5'-oligopyrimidine-oligopurine-3' can be used as the third strand. In the second approach, only one set of motifs (Hoogsteen or reverse Hoogsteen motif) (15–24) is employed, namely, the 3'- and 3'- or 5'- and 5'-ends of two ODN fragments have to be connected using a suitable linker. The different possibilities for “alternate-strand triplex” formation in the latter case are shown in Figure 1. When the oligopyrimidine sequence follows the oligopurine sequence, the 3'-3'-linked and the 5'-5'-linked ODNs can form the parallel (a) and antiparallel (b) triplexes with the target duplex by Hoogsteen and reverse Hoogsteen hydrogen bonds, respectively. On the other hand, when the oligopurine sequence follows the oligopyrimidine sequence, the 5'-5'-linked and the 3'-3'-linked ODNs can form the parallel (c) and antiparallel (d) triplexes with the target duplex by Hoogsteen and reverse Hoogsteen hydrogen bonds, respectively.

On the other hand, it is known that ODNs carrying intercalators, such as acridine (25–29), oxazolopyridocarbazole (30), benzopyridoindole (31, 32), and perylene (33) enhance the thermal stability of the triplexes. We recently reported the synthesis of branched ODNs with a pentaerythritol at the branch points (34). The ODNs formed thermally stable parallel and antiparallel triplexes with the single strand ODNs. On the basis of this information, we planned a synthesis of a 3'-3'-linked ODN with an intercalator at the junction point. We reasoned that the intercalator would stabilize the triplex by intercalating between the base pairs of the target duplex as shown in Figure 2. Since pentaerythritol has four equivalent hydroxymethyl groups, we envisaged that if we could synthesize the controlled pore glass (CPG) with pentaerythritol carrying an intercalator at one of the four hydroxymethyl groups, we would be able to conveniently

synthesize the 3'-3'-linked ODN with the intercalator at the junction point as shown in Scheme 1.

In this paper, we report the synthesis of the 3'-3'-linked ODN with the anthraquinonyl group at the junction point. The thermal stability of the triplexes between these ODNs and the target DNAs, and the ability of the 3'-3'-

linked ODNs to inhibit cleavage of a target DNA by a restriction enzyme, are also studied.

RESULTS AND DISCUSSION

Synthesis. The CPG with pentaerythritol that has the anthraquinonyl group was synthesized as shown in Scheme 2. First, 2-[(*tert*-butyldiphenylsilyl)oxymethyl]-2-(hydroxymethyl)-1,3-propanediol (**1**) (**33**) was treated with 2 equiv of 4,4'-dimethoxytrityl chloride (DMTrCl) in pyridine to give the *O*-bis(DMTr) derivative **2** in 87% yield. Compound **2** was converted into a carbonylimidazolid, which was reacted with ethylenediamine or 1,4-diaminobutane to produce **3a** or **3b** in 81 or 76% yield, respectively. Protection of the primary amino group of **3b** with a trifluoroacetyl group followed by desilylation by tetrabutylammonium fluoride (TBAF) gave **5**. Compound **5** was modified to the corresponding 3'-succinate **6**, which was reacted with CPG to give a solid support containing **6** (23 $\mu\text{mol/g}$). At the same time, **3a** or **3b** was treated with anthraquinone-2-carboxylic acid in the presence of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (WSCl) in DMF to afford **7a** or **7b** in 51 or 83% yield, respectively. After removal of the TBDPS groups, **8a** and **8b** were modified to the corresponding 3'-succinates **9a** and **9b**, which were reacted with CPG to give solid supports containing **9a** (20 $\mu\text{mol/g}$) and **9b** (30 $\mu\text{mol/g}$), respectively.

The 3'-3'-linked ODNs **11–13**, **15**, **16**, which consist of thymidine (T) and 5-methyl-2'-deoxycytidine (M), were synthesized on a DNA synthesizer (Figure 3a). The fully protected ODNs (each 1 μmol) linked to the solid support were treated with concentrated NH_4OH at 55 $^\circ\text{C}$ for 16 h. Purification by C-18 HPLC gave the ODNs **11**, **12**, **13**, **15**, and **16** in 52, 41, 44, 31, and 33 OD_{260} units, respectively. These ODNs were analyzed by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF/MS), and the observed molecular weights supported their structures.

Studies of Triplex Formation by Thermal Denaturation. The stability of the triplexes was studied by thermal denaturation in a buffer of 0.01 M sodium phosphate (both at pH 6.9 and 6.0) containing 0.5 M NaCl

Scheme 2^a

Figure 3. Sequences of ODNs and the target duplexes.

and 0.02 M MgCl_2 . Sequences of target duplexes used in this study are shown in Figure 3b. The DNAs 17–21 have oligopurine sequences, one on each strand of the duplexes, that can be recognized by the ODNs 10–13. The DNAs 18–21 also have extra base pairs between the two binding domains that do not participate in Hoogsteen base pair interactions with the third strands and will be spanned by the linker groups. The sequences of the binding domains are symmetrical. One equivalent of the 3'-3'-linked ODNs or two equivalents of the control ODN 10 to the target DNAs was used for the thermal denaturation.

Figure 4 shows melting profiles of the triplexes between the ODN 13 and the DNA 20 at pH 6.9 (I) and at pH 6.0 (II), and between the ODN 10 and the DNA 17 at pH 6.9 (III), respectively. The T_m s are listed in Table 1. The T_m for the control triplex between the ODN 10 and the DNA 17 was not detected at pH 6.9 and was 18.2 °C at pH 6.0. All 3'-3'-linked ODNs with and without the anthraquinonyl group enhanced the thermal stability of the triplexes at both pH 6.9 and 6.0 as compared with the control ODN 10. The T_m values of the triplexes at pH 6.0 were greater than those at pH 6.9. The ODNs 12 and 13 with intercalators at the junction points more

^a Experimental conditions are described in the Experimental Procedures. ND: not detected. —: not determined.

efficiently stabilized the triplexes as compared with the 3'-3'-linked ODN 11. Addition of 3 μM sodium anthraquinone-2-sulfonate to a solution containing the ODN 11 and the DNA 18 did not influence the T_m s of the triplexes at either pH 6.9 ($T_m < 8$ °C) or pH 6.0 ($T_m = 28.8$ °C). Thus, it was found that the attachment of the intercalator directly to the ODNs was important for the efficient thermal stabilization of the triplexes.

Thermal denaturation was performed by changing extra base pairs between two binding domains of the target duplexes. With the ODN 11 as the third strand, the highest T_m (11.6 °C at pH 6.9 and 38.3 °C at pH 6.0) was obtained for the DNA 20 which has three extra base pairs between the two binding domains. When the ODN 12 with the *N*-(anthraquinonylcarbonyl)aminoethyl group was used as the third strand, the highest T_m (17.1 °C at pH 6.9 and 45.0 °C at pH 6.0) was obtained for the DNA 19 which has two extra base pairs between the two binding domains. On the other hand, when the ODN 13

Figure 5. Specific inhibition of Hind III cleavage by the ODNs **14** (lanes 3–7), **15** (lanes 8–13), or **16** (lanes 14–21). Experimental conditions are described in the Experimental Procedures.

with *N*-(anthraquinonylcarbonyl)aminobutyl group was used as the third strand, the highest T_m (16.7 °C at pH 6.9 and 46.0 °C at pH 6.0) was obtained for the DNA **20**. Consequently, the ODNs **11**, **12**, and **13** can form thermally stable triplexes by skipping two or three base pairs between the two binding domains of the target duplexes. The ODN **12** with the ethylenediamine linker was found to be useful for skipping two extra base pairs while the ODN **13** with the diaminobutane linker was useful for skipping three extra base pairs. The difference between the ODNs **12** and **13** is due to the difference in the length of the linker groups between the intercalators and the ODNs.

Inhibition of Restriction Endonuclease Cleavage via Triplex Formation. We next tested the ability of the 3'-3'-linked ODNs to inhibit cleavage of a target DNA by a restriction endonuclease. The restriction enzyme Hind III recognizes the palindromic 6 bp sequence 5'-AAGCTT-3'/3'-AAGCTT-5' and cleaves the two strands in a symmetric way. We designed a 30 bp DNA containing Hind III recognition site as a target duplex (Figure 3b). It involves oligopurine sequences, one on each strand of it, that can be recognized by the third strand. The nonamer **14**, the 3'-3'-linked ODN **15**, and the 3'-3'-linked ODN **16** with the anthraquinonyl group at the junction point were used as the third strands.

The stabilities of the triplexes between the DNA **22** and ODNs **14**, **15**, or **16** were studied by thermal denaturation in a buffer of 10 mM sodium phosphate (pH 6.9)¹ containing 500 mM NaCl and 20 mM MgCl₂. The T_m s for the triplexes between the DNA **22** and ODNs **14**, **15**, or **16** were 20.5, 47.8, or 53.0 °C, respectively.

Inhibition of Hind III cleavage via the triplex formation was studied. A series of experiments was carried out at 37 °C in a 10 mM HEPES buffer (pH 6.9) containing 100 mM NaCl, 10 mM MgCl₂, and 1 mM DTT. Increasing amounts of the third strands were added to the DNA **22**, labeled at one 5'-end by ³²P, and the solutions were preincubated at 37 °C for 30 min before addition of the

Figure 6. Specific inhibition of Hind III cleavage by triplex formation: plots of percentage cleavage of the DNA fragment versus the concentration of ODN in the reaction mixture. The symbols on the plot indicate the ODNs **14** (■), **15** (▲), and **16** (●).

restriction enzyme. After incubated at 37 °C for 3 h, the products were analyzed by polyacrylamide gel electrophoresis under denaturing conditions (Figure 5). Densities of radioactivity of the gel were visualized by a Bio-imaging analyzer. As shown in Figure 6, cleavage was inhibited in a dose-dependent manner. It was found that the 3'-3'-linked ODN **15** inhibited the cleavage by the enzyme more effectively than the nonamer **14**. Furthermore, the 3'-3'-linked ODN **16** with the intercalator at the junction point inhibited the cleavage more effectively than the ODN **15**.

To show that inhibition was due to the interaction of the ODNs with the target DNA rather than with the restriction enzyme, a parallel experiment was carried out with the DNA **23**, which contains one restriction site for Hind III but no sequence fully complementary to that of the ODN **16**. It was found that the ODN **16** does not inhibit the cleavage of the DNA **23** by the enzyme at all (data not shown). Thus, inhibition of the cleavage was

¹ The enzyme reactions using Hind III are usually carried out at pH 7.5. Since the parallel-type triple-helix is thermally unstable at pH 7.5, the enzyme assay was done at pH 6.9.

found to be not due to the ODNs binding to the enzyme but to triplex formation at the binding site of the enzyme.

CONCLUSION

In this paper, we reported the synthesis of the 3'-3'-linked ODNs with the anthraquinonyl group at the junction point. Stability of the triplex was studied by thermal denaturation. The 3'-3'-linked ODNs with the anthraquinonyl group enhanced the thermal stability of the triplexes as compared with those without the intercalator and the unmodified nonamer **10**. Furthermore, it was found that the ODNs **12** and **13** can form the thermally stable triplexes by skipping two or three extra base pairs between the two binding domains of the target duplexes. We tested the ability of the 3'-3'-linked ODNs to inhibit cleavage of the DNA **22** by the restriction enzyme Hind III. It was found that the 3'-3'-linked ODN **16** with the anthraquinonyl group at the junction point inhibited the cleavage by the enzyme more effectively than the nonamer **14** and the 3'-3'-linked ODN **15** without the intercalator. Thus, the 3'-3'-linked ODN with the intercalator at the junction point may be useful as the antigene ODN to the DNAs, which have the alternating oligopurine-oligopyrimidine sequences on them.

EXPERIMENTAL PROCEDURES

General Remarks. NMR spectra were recorded at 270 or 400 MHz (^1H) and at 100 MHz (^{13}C). Chemical shifts (δ) and coupling constants (J) are reported in ppm downfield from TMS and in Hz, respectively. Mass spectra were obtained by fast atom bombardment (FAB) method. Thin-layer chromatography was done on Merck coated plates 60F₂₅₄. The silica gel used for column chromatography was Merck silica gel 5715.

2-[(*tert*-Butyldiphenylsilyl)oxymethyl]-1,3-O-bis(4,4'-dimethoxytrityl)-2-(hydroxymethyl)-1,3-propanediol (2**).** A mixture of 2-[(*tert*-butyldiphenylsilyl)oxymethyl]-2-(hydroxymethyl)-1,3-propanediol (**1**) (7.49 g, 20.0 mmol) (**34**) and DMTrCl (14.9 g, 44.0 mmol) in pyridine (100 mL) was stirred at room temperature. After 30 min, the mixture was concentrated in vacuo and was taken in EtOAc, which was washed with aqueous NaHCO₃ (saturated) and brine, dried (Na₂SO₄), and concentrated. The residue was purified by column chromatography (SiO₂, 17–20% EtOAc in hexane) to give **2** (17.0 g, 87% as a white foam): FAB-MS m/z 977 (M^+); ^1H NMR (270 MHz, CDCl₃) δ 7.52–6.63 (m, 36H), 3.73 (s, 12H), 3.78–3.71 (m, 6H), 3.67 (d, J = 5.9, 2H), 2.56 (t, J = 5.9, 1H), 0.85 (s, 9H). 2-[[*N*-(2-Aminoethyl)carbamoyl]oxymethyl]-2-[(*tert*-butyldiphenylsilyl)oxymethyl]-1,3-O-bis(4,4'-dimethoxytrityl)-1,3-propanediol (3a**).** *N,N'*-Carbonyldiimidazole (608 mg, 3.75 mmol) and DMAP (37 mg, 0.30 mmol) were added to a solution of **2** (1.47 g, 1.50 mmol) in DMF (15 mL), and the mixture was stirred at room temperature. After 24 h, 1,2-diaminoethane (1.34 mL, 20.0 mmol) was added to the mixture, which was stirred at room temperature. After 24 h, the mixture was partitioned between EtOAc and H₂O. The organic layer was washed with brine, dried (Na₂SO₄), and concentrated. The residue was purified by column chromatography (SiO₂, 5% MeOH in CHCl₃ containing 1% Et₃N) to give **3a** (1.30 g, 81% as a white foam): ^1H NMR (400 MHz, CDCl₃) δ 7.52–6.48 (m, 36H), 4.54 (m, 1H), 4.18 (s, 2H), 3.75 (s, 14H), 3.27 (s, 4H), 3.14 (m, 2H), 2.74 (m, 2H), 0.85 (s, 9H); ^{13}C NMR (100 MHz, CDCl₃) δ 158.10,

144.98, 135.97, 135.56, 130.14, 129.39, 128.14, 127.53, 127.45, 126.37, 112.83, 85.70, 77.21, 55.13, 26.81, 19.23. Anal. Calcd for C₆₆H₇₂N₂O₉Si·1/2H₂O: C, 73.78; H, 6.85; N, 2.61. Found: C, 73.69; H, 6.83; N, 2.69.

2-[[*N*-(4-Aminobutyl)carbamoyl]oxymethyl]-2-[(*tert*-butyldiphenylsilyl)oxymethyl]-1,3-O-bis(4,4'-dimethoxytrityl)-1,3-propanediol (3b**).** Compound **2** (4.89 g, 5.00 mmol) was aminobutylcarbamoylated by using 1,4-diaminobutane (5.00 mL, 50.0 mmol) as described in the preparation of **3a** to give **3b** (4.14 g, 76% as a white foam): ^1H NMR (270 MHz, CDCl₃) δ 7.52–6.68 (m, 36H), 4.42 (t, J = 5.3, 1H), 4.17 (s, 2H), 3.74 (s, 14H), 3.27 (s, 4H), 3.10 (m, 2H), 2.66 (m, 2H), 1.44 (m, 4H), 0.85 (s, 9H); ^{13}C NMR (100 MHz, CDCl₃) δ 158.08, 144.98, 135.96, 135.52, 130.11, 129.36, 128.11, 127.50, 127.41, 126.33, 112.80, 85.67, 55.09, 46.07, 26.79, 19.20.

2-[(*tert*-Butyldiphenylsilyl)oxymethyl]-1,3-O-bis(4,4'-dimethoxytrityl)-2-[[*N*-(4-(trifluoroacetamido)butyl)carbamoyl]oxymethyl]-1,3-propanediol (4**).** A mixture of **3b** (1.06 g, 1.00 mmol), ethyl trifluoroacetate (357 μL , 3.00 mmol), and Et₃N (418 μL , 3.00 mmol) in DMF (10 mL) was stirred at room temperature. After 4 h, the mixture was partitioned between EtOAc and H₂O. The organic layer was washed with brine, dried (Na₂SO₄), and concentrated. The residue was purified by column chromatography (SiO₂, 40% EtOAc in hexane) to give **4** (916 mg, 77% as a white foam): FAB-MS m/z 1188 (M^+); ^1H NMR (400 MHz, CDCl₃) δ 7.53–6.69 (m, 36H), 4.25 (t, J = 5.9, 2H), 4.17 (s, 2H), 3.75 (s, 12H), 3.73 (s, 2H), 3.33 (m, 2H), 3.10 (m, 2H), 3.27 (s, 4H), 1.49 (m, 4H), 0.84 (s, 9H). ^{13}C NMR (100 MHz, CDCl₃) δ 158.08, 156.46, 144.95, 135.91, 135.52, 133.20, 130.12, 129.39, 128.08, 127.51, 127.43, 126.37, 112.82, 85.68, 65.11, 63.33, 61.92, 60.36, 55.11, 45.55, 40.08, 39.51, 27.51, 26.77, 25.70, 21.04, 19.19, 14.21. HRMS calcd for C₇₀H₇₆F₃N₂O₁₀Si: 1189.5221. Found: 1189.5210. Anal. Calcd for C₇₀H₇₅F₃N₂O₁₀Si·1/2H₂O: C, 70.15; H, 6.39; F, 4.76; N, 2.34. Found: C, 70.19; H, 6.51; F, 4.92; N, 2.27.

1,3-O-Bis(4,4'-dimethoxytrityl)-2-(hydroxymethyl)-2-[[*N*-(4-(trifluoroacetamido)butyl)carbamoyl]oxymethyl]-1,3-propanediol (5**).** A mixture of **4** (629 mg, 0.530 mmol) and TBAF (1 M in THF, 1.06 mL, 1.06 mmol) in THF (6 mL) was stirred at room temperature for 24 h. The mixture was partitioned between EtOAc and H₂O. The organic layer was washed with brine, dried (Na₂SO₄), and evaporated under reduced pressure. The residue was purified by column chromatography (SiO₂, 33–100% EtOAc in hexane) to give **5** (413 mg, 82% as a white foam): FAB-MS m/z 950 (M^+); ^1H NMR (400 MHz, CDCl₃) δ 7.34–6.75 (m, 26H), 4.46 (t, J = 6.1, 1H), 4.11 (s, 2H), 3.78 (s, 12H), 3.49 (d, J = 6.9, 2H), 3.36 (m, 2H), 3.15 (m, 2H), 3.24 (s, 4H), 2.60 (t, J = 6.9, 1H), 1.52 (m, 4H); ^{13}C NMR (100 MHz, CDCl₃) δ 158.18, 156.85, 144.64, 135.58, 130.05, 127.98, 127.62, 126.54, 117.20, 112.92, 85.93, 77.20, 63.81, 63.36, 61.60, 55.10, 45.41, 40.12, 39.38, 27.21, 26.69. HRMS calcd for C₅₄H₅₇F₃N₂O₁₀: 950.3962, found 950.3976. Anal. Calcd for C₅₄H₅₇F₃N₂O₁₀·3/2H₂O: C, 66.31; H, 6.18; F, 5.83; N, 2.86. Found: C, 66.46; H, 6.12; F, 5.73; N, 2.76.

1,3-O-Bis(4,4'-dimethoxytrityl)-2-[(*O*-succinyl)oxymethyl]-2-[[*N*-(4-(trifluoroacetamido)butyl)carbamoyl]oxymethyl]-1,3-propanediol (6**).** A mixture of **5** (190 mg, 0.200 mmol), succinic anhydride (60 mg, 0.600 mmol), and DMAP (25 mg, 0.200 mmol) in pyridine (2 mL) was stirred at room temperature. After 5 days, the mixture was partitioned between EtOAc and H₂O. The organic layer was washed with aqueous NaHCO₃ (saturated) and brine, dried (Na₂SO₄), and concentrated. The residue was purified by column chromatography (SiO₂,

80–100% EtOAc in hexane, then 0–30% MeOH in EtOAc) to give **6** (204 mg, 97% as a white foam): FAB-MS m/z 1050 (M^+); ^1H NMR (270 MHz, $CDCl_3$) δ 7.34–6.72 (m, 26H), 3.99 (s, 4H), 3.76 (s, 12H), 3.32–3.14 (m, 8H), 2.04 (m, 4H), 1.53 (m, 4H). HRMS calcd for $C_{58}H_{61}F_3N_2O_{13}$ 1050.4125, found 1050.4120.

2-[[N-[2-(2-Anthraquinonylcarbonyl)aminoethyl]-carbamoyl]oxymethyl]-2-[(*tert*-butyldiphenylsilyl)-oxymethyl]-1,3-O-bis(4,4'-dimethoxytrityl)-1,3-propanediol (7a). A mixture of **3a** (532 mg, 0.50 mmol), anthraquinone-2-carboxylic acid (151 mg, 0.60 mmol), and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (WSCl) (115 mg, 0.600 mmol) in DMF (5 mL) was stirred at room temperature. After 3 days, the mixture was diluted with EtOAc. The organic layer was washed with aqueous $NaHCO_3$ (saturated) and brine, dried (Na_2SO_4), and concentrated. The residue was purified by column chromatography (SiO_2 , 40–50% EtOAc in hexane) to give **7a** (329 mg, 51% as a pale yellow foam): FAB-MS m/z 1298 (M^+); ^1H NMR (270 MHz, $CDCl_3$) δ 8.64–7.77 (m, 7H), 7.51–6.67 (m, 36H), 4.54 (m, 2H), 4.23 (s, 2H), 3.71 (s, 14H), 3.55 (m, 2H), 3.37 (m, 2H), 3.29 (s, 4H), 0.84 (s, 9H). HRMS calcd for $C_{81}H_{79}N_2O_{12}Si$: 1299.5402, found: 1299.5370. Anal. Calcd for $C_{81}H_{78}N_2O_{12}Si$: C, 74.86; H, 6.05; N, 2.16. Found: C, 74.67; H, 6.14; N, 2.15.

2-[[N-[4-(2-Anthraquinonylcarbonyl)aminobutyl]-carbamoyl]oxymethyl]-2-[(*tert*-butyldiphenylsilyl)-oxymethyl]-1,3-O-bis(4,4'-dimethoxytrityl)-1,3-propanediol (7b). Compound **3b** (1.09 g, 1.00 mmol) was anthraquinonylcarbonylated as described in the preparation of **7a** to give **7b** (1.11 g, 83% as a pale brown foam): FAB-MS m/z 1325 (M^+); ^1H NMR (270 MHz, $CDCl_3$) δ 8.65–7.81 (m, 7H), 7.53–6.68 (m, 36H), 4.28 (m, 2H), 4.20 (s, 2H), 3.73 (s, 14H), 3.48 (m, 2H), 3.17 (m, 2H), 3.27 (s, 4H), 1.54 (m, 4H), 0.84 (s, 9H). 2-[[N-[2-(2-Anthraquinonylcarbonyl)aminoethyl]-carbamoyl]oxymethyl]-1,3-O-bis(4,4'-dimethoxytrityl)-2-(hydroxymethyl)-1,3-propanediol (8a). Compound **7a** (110 mg, 86 μ mol) was desilylated as described in the preparation of **5** to give **8a** (67 mg, 74% as a pale yellow foam): FAB-MS m/z 1060 (M^+); ^1H NMR (270 MHz, $CDCl_3$) δ 8.62–7.77 (m, 7H), 7.33–6.73 (m, 26H), 4.85 (m, 2H), 4.20 (s, 2H), 3.75 (s, 12H), 3.60 (m, 2H), 3.44 (m, 2H), 3.52 (m, 2H), 3.26 (s, 4H), 2.49 (m, 1H). HRMS calcd for $C_{65}H_{60}N_2O_{12}$: 1060.4146, found: 1060.4160. Anal. Calcd for $C_{65}H_{60}N_2O_{12} \cdot H_2O$: C, 72.34; H, 5.79; N, 2.60. Found: C, 72.35; H, 5.99; N, 2.51.

2-[[N-[4-(2-Anthraquinonylcarbonyl)aminobutyl]-carbamoyl]oxymethyl]-1,3-O-bis(4,4'-dimethoxytrityl)-2-(hydroxymethyl)-1,3-propanediol (8b). Compound **7b** (663 mg, 0.50 mmol) was desilylated as described in the preparation of **5** to give **8b** (489 mg, 90% as a pale yellow foam): FAB-MS m/z 1089 (M^+); ^1H NMR (400 MHz, $CDCl_3$) δ 8.60–7.79 (m, 7H), 7.34–6.74 (m, 26H), 4.55 (t, J = 6.1, 2H), 4.14 (s, 2H), 3.76 (s, 12H), 3.53 (m, 4H), 3.28 (s, 4H), 3.52–3.21 (m, 2H), 2.70 (m, 1H), 1.66–1.59 (m, 4H). HRMS calcd for $C_{67}H_{65}N_2O_{12}$: 1089.4537, found: 1089.4540. Anal. Calcd for $C_{67}H_{64}N_2O_{12} \cdot H_2O$: C, 72.67; H, 6.01; N, 2.53. Found: C, 72.65; H, 6.20; N, 2.36.

2-[[N-[2-(2-Anthraquinonylcarbonyl)aminoethyl]-carbamoyl]oxymethyl]-1,3-O-bis(4,4'-dimethoxytrityl)-2-[(*O*-succinyl)oxymethyl]-1,3-propanediol (9a). Compound **8a** (64 mg, 60 μ mol) was succinylated as described in the preparation of **6** to give **9a** (46 mg, 65%

as a pale brown foam): FAB-MS m/z 1160 (M^+); ^1H NMR (270 MHz, $CDCl_3$) δ 8.59–7.74 (m, 7H), 7.30–6.70 (m, 26H), 4.00 (s, 4H), 3.72 (s, 12H), 3.56–3.29 (m, 4H), 3.21 (s, 4H), 2.36 (m, 4H). HRMS calcd for $C_{89}H_{64}N_2O_{15}$: 1160.4306, found: 1160.4320.

2-[[N-[4-(2-Anthraquinonylcarbonyl)aminobutyl]-carbamoyl]oxymethyl]-1,3-O-bis(4,4'-dimethoxytrityl)-2-[(*O*-succinyl)oxymethyl]-1,3-propanediol (9b). Compound **8b** (161 mg, 148 μ mol) was succinylated as described in the preparation of **6** to give **9b** (116 mg, 66% as a pale yellow foam): FAB-MS m/z 1189 (M^+); ^1H NMR (400 MHz, $CDCl_3$) δ 8.65–7.80 (m, 7H), 7.33–6.72 (m, 26H), 4.69 (m, 1H), 4.04 (s, 2H), 4.03 (s, 2H), 3.78 (s, 12H), 3.50 (m, 2H), 3.24 (s, 4H), 3.20 (m, 2H), 2.50–2.44 (m, 4H), 1.66–1.59 (m, 4H). HRMS calcd for $C_{71}H_{69}N_2O_{15}$: 1189.4697, found: 1189.4680.

Synthesis of the Controlled Pore Glass Support with 6, 9a, or 9b. Aminopropyl controlled pore glass (510 mg, 46 μ mol, 89.8 μ mol/g, CPG Inc.) was added to a solution of **6** (191 mg, 182 μ mol) and WSCI (35 mg, 182 μ mol) in DMF (5 mL), and the mixture was kept at room temperature for 3 days. After the resin was washed with pyridine, 1 mL of a capping solution (0.1 M DMAP in pyridine:Ac₂O = 9:1) was added, and the whole was kept at room temperature for 14 h. The resin was washed with EtOH and acetone and was dried under vacuum. The amount of loaded nucleoside **6** to the solid support is 23 μ mol/g from the calculation of released dimethoxytrityl cation by a solution of 70% $HClO_4$:EtOH (3:2, v/v). In a similar manner, the solid supports with **9a** and **9b** were obtained in 20 and 30 μ mol/g of loading amounts.

Synthesis of ODNs. ODNs were synthesized on a DNA synthesizer (Applied Biosystem Model 392) by the phosphoramidite method. Each oligonucleotide linked to the resin was treated with concentrated NH_4OH at 55 $^{\circ}C$ for 16 h, and the released ODN was purified by reversed-phase HPLC, using a J'sphere ODS M80 column (4.6 $\times$ 150 mm, YMC) with a linear gradient of CH_3CN (from 10 to 35% over 20 min) in 0.1 M triethylammonium acetate (TEAA, pH 7.0) to give a deprotected ODN **11** (52), **12** (41), **13** (44), **15** (31), and **16** (33). The yields are indicated in parentheses as OD units at 260 nm starting from 1 μ mol scale.

Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry. Spectra were obtained on a Voyager Elite reflection time-of-flight mass spectrometry (PerSeptive Biosystems, Inc., Framingham, MA) equipped with a nitrogen laser (337 nm, 3-ns pulse). 3-Hydroxypicolinic acid (HPA), dissolved in H_2O to give a saturated solution at room temperature, was used as the matrix. Time-to-mass conversion was achieved by calibration by using the peak representing the C^+ cation of the charged derivative to be analyzed. ODN **11**: calculated mass, 5715.11; observed mass, 5715.03. ODN **12**: calculated mass, 5921.11; observed mass, 5921.05. ODN **13**: calculated mass, 5949.14; observed mass, 5952.77. ODN **15**: calculated mass, 5719.05; observed mass, 5718.70. ODN **16**: calculated mass, 5953.08; observed mass, 5952.99.

Thermal Denaturation. The solution that contained the oligonucleotide (3 μ M) and the target duplex (3 μ M) in a buffer of 0.01 M sodium phosphate (both pH 6.9 and 6.0), 0.5 M NaCl, and 0.02 M $MgCl_2$ was heated at 60 $^{\circ}C$ for 5 min and then cooled gradually to an appropriate temperature and used for the thermal denaturation study. Thermal-induced transitions of each mixture were monitored at 260 nm on a Perkin-Elmer Lambda2S. Sample temperature was increased 0.5 $^{\circ}C$ /min.

Enzymatic Assay. Enzymatic assays were performed in a 10 mM HEPES buffer (pH 6.9) containing 100 mM NaCl, 10 mM MgCl₂, and 1 mM DTT. Various amounts of the third strands were added to the DNA **22** (1 pmol), labeled at one 5'-end by ³²P, and the solutions were preincubated at 37 °C for 30 min. Fifteen units of Hind III (Nippon Gene) was added to each solution, and the mixture (total 10 μL) was incubated at 37 °C for 3 h. Aliquot (3 μL) of the reaction mixture was separated and added to a loading solution (8 M urea, 0.1% xylene cyanol, 0.1% bromophenol blue, 10 μL); then the mixture was heated at 95 °C for 5 min. The solution was analyzed by electrophoresis on 20% polyacrylamide gel containing 7 M urea. Densities of radioactivity of the gel were visualized by a Bio-imaging analyzer (Bas 2000, Fuji Co., Ltd).

ACKNOWLEDGMENT

This work was supported in part by a Grant-in-Aid for Encouragement of Young Scientists from the Ministry of Education, Science, Sports, and Culture of Japan and a Grant from the "Research for the Future" Program of the Japan Society for the Promotion of Science (JSPS-RFTF97I00301). We thank Y. Misawa (Hokkaido University) for technical assistance.

Synthesis of a novel sulfhydryl-specific, tetraammine Ru(II)polypyridyl complex, $[\text{Ru}(\text{II})(\text{NH}_3)_4(1,10\text{-phenanthroline-5-maleimide})](\text{PF}_6)_2$, which exhibits environment-sensitive electrochemical properties is described. When conjugated to an allosteric site in a genetically engineered mutant of maltose binding protein, the formal potential of the conjugated redox probe is shifted to higher potential upon maltose binding. The magnitude of this potential shift was used to measure maltose affinity of the protein-redox conjugate complex and to monitor maltose concentration in solution. These results are presented in context of reagentless biosensing.

INTRODUCTION

Development of reagentless biosensors is a goal of many scientific communities (1–11). Such sensors combine analyte recognition with a change in an intrinsic property of the sensor upon analyte binding. Recently, fluorescence allosteric signal transduction (FAST) has been demonstrated as a viable approach toward reagentless biosensing (12, 13). Using this approach, an environment-sensitive fluorophore was conjugated to genetically engineered maltose binding protein (MBP) at a site distinct from the binding site for maltose but which underwent local environmental changes upon binding maltose. As a result, fluorescence intensity of the conjugated fluorophore was shown to be dependent upon maltose concentration. Because electrochemical-based detection strategies offer complimentary advantages compared to fluorescence-based strategies (14–18), we were motivated to explore an analogous electrochemical approach. Drawing on Ru(II) polypyridyl chemistry (19), we proposed that a sulfhydryl-specific tetraammine Ru(II)polypyridyl derivative would be a viable redox conjugate for this application based on its expected environmental sensitivity, accessibility of the Ru(II/III) electrochemistry in aqueous media, and insensitivity to oxygen (20). Reported here is the synthesis and structural characterization of a new electroactive sulfhydryl-reactive reagent $[\text{Ru}(\text{II})(\text{NH}_3)_4(1,10\text{-phenanthroline-5-maleimide})](\text{PF}_6)_2$. In addition, environment-sensitive cyclic voltammetry of the unconjugated reagent and maltose-sensitive cyclic voltammetry of the protein-bound conjugate is demonstrated.

EXPERIMENTAL PROCEDURES

Materials. 5-Amino-1,10-phenanthroline (Polysciences, Inc.); maleic anhydride, $[\text{NH}_4](\text{PF}_6)$, acetonitrile, ethyl alcohol, nitrobenzene, dimethylformamide (DMF), $[\text{N}(n\text{-C}_4\text{H}_9)_4](\text{PF}_6)$ (TBAH), and $[\text{Ru}(\text{NH}_3)_5\text{Cl}]\text{Cl}_2$ (Aldrich); and zinc amalgam (GFS Chemicals) were used as received. $[\text{Ru}(\text{NH}_3)_5(\text{H}_2\text{O})](\text{PF}_6)_2$ was prepared as reported (20). The genetically engineered maltose binding proteins were isolated and purified as previously described (12).

Measurements. Electrochemical experiments using a three-electrode configuration in a one-compartment cell were conducted using a potentiostat (EG&G Princeton Applied Research, model 263) using CorrWare software (Scribner Associates, Inc., version 2.1b). For measurements in organic solvents, 0.1 M $[\text{N}(n\text{-C}_4\text{H}_9)_4](\text{PF}_6)$ (TBAH) was used as the electrolyte, Ag/AgNO₃ (0.1 M TBAH and 0.01 M AgNO₃ in CH₃CN) was used as the reference electrode which was calibrated with ferrocene using the Fe(II/III) redox couple at 0.4 V vs SCE, and a platinum-coated niobium wire was used as the counter electrode. Aqueous measurements were conducted using a Ag/AgCl reference electrode and a platinum-coated niobium wire counter electrode. A 1.6-mm diameter platinum disk electrode was used as the working electrode for voltammetry of the unconjugated Ru(II) complex. A 3.0-mm diameter glassy carbon electrode was used as the working electrode for voltammetry of the protein-conjugated Ru complex. Spectroscopic experiments were conducted using a UV–vis spectrophotometer (Cary 4G).

Synthesis. *1,10-Phenanthroline-5-maleimide*. On the basis of modified literature preparations for similar maleimides (21, 22), 400 mg (2.05 mmol) of 5-amino-1,10-phenanthroline was added to 150 mL of CH_2Cl_2 . The solution was stirred at room temperature, and 1 g (10.2 mmol) of maleic anhydride was slowly added. After 72 h, 380 mg (64% yield) of a yellow precipitate was collected by vacuum filtration, washed with 3×100 mL of CH_2Cl_2 , and air-dried. The product was then added to 20 mL of acetic anhydride containing 2 g of sodium acetate. The solution was stirred and heated to 100 °C for 1 h. After the solution cooled to room temperature, 80 mL of ice-water was added and the solution was stirred until all of the acetic anhydride was consumed. The product was extracted with 3×100 mL CH_2Cl_2 , washed with 3×100 mL of water, and dried over MgSO_4 . The MgSO_4 was filtered off and the CH_2Cl_2 removed by rotoevaporation. The product was redissolved in 10 mL of CH_2Cl_2 , precipitated in 50 mL of hexanes, collected by vacuum filtration, and air-dried. The mass of the final product was 170 mg (30% overall yield). ^1H NMR (400 MHz, CDCl_3): 7.00 (s, 2H); 7.63 (m, 2H); 7.73 (s, 1H); 7.94 (d, 1H); 8.23 (d, 1H); 9.23 (m, 2H). Anal. Calcd for $\text{C}_{16}\text{H}_9\text{N}_3\text{O}_2 \cdot 0.5\text{H}_2\text{O}$: C, 67.60; H, 3.55; N, 14.78. Found: C, 67.75; H, 3.55; N, 14.38.

$[\text{Ru}(\text{NH}_3)_4(1,10\text{-Phenanthroline-5-maleimide})](\text{PF}_6)_2$. On the basis of a modified procedure for the preparation (20) of $[\text{Ru}(\text{NH}_3)_4(\text{bpy})](\text{PF}_6)_2$, 100 mg (0.202 mmol) of $[\text{Ru}(\text{NH}_3)_5(\text{H}_2\text{O})](\text{PF}_6)_2$ was added to 10 mL of argon-purged acetone. After the solution turned dark yellow (due to formation of $[\text{Ru}(\text{NH}_3)_5(\text{CH}_3\text{COCH}_3)]^{3+}$) (20), 63 mg (0.23 mmol) of 1,10-phenanthroline-5-maleimide was added. The solution turned deep purple and was stirred for 3 h at room temperature under Ar. The crude product was precipitated in 60 mL of stirring ether and collected by vacuum filtration. Purification was carried out by a series of precipitations. The crude product was redissolved in 10 mL of acetone and added to 150 mL of stirring CH_2Cl_2 . A red powder (30 mg) containing both the product and impurities (determined by NMR and cyclic voltammetry) was isolated by vacuum filtration. To the supernatant, 50 mL of ether was added and a second precipitate (44 mg of a red powder) was collected by vacuum filtration. Cyclic voltammetry revealed that an electroactive impurity with a redox couple centered at 120 mV vs SCE had been removed; however, NMR revealed ~10% excess free ligand. The precipitate was then redissolved in 2 mL of acetone and added with stirring to 50 mL of CH_2Cl_2 and chilled for 16 h. A red powder was collected by vacuum filtration, washed with 3×15 mL ether, and air-dried. The mass of the final product was 20 mg (20% overall yield). A dark red crystalline material can be obtained by slow evaporation of a concentrated acetone solution of product. ^1H NMR (400 MHz, CD_3CN): 9.43 (m, 2H); 8.43 (d, 1H); 8.15 (d, 1H), 8.13 (s, 1H), 7.88 (m, 1H), 7.83 (m, 1H), 7.17 (s, 2H), 2.92 (s, 6H), 1.48 (s, 6H). Anal. Calcd for $\text{C}_{16}\text{H}_{21}\text{F}_{12}\text{N}_7\text{O}_2\text{P}_2\text{Ru} \cdot 0.5\text{C}_3\text{H}_6\text{O}$: C, 27.53; H, 3.17; N, 12.84. Found: C, 27.14; H, 3.04; N, 12.41.

Protein Labeling. In a typical procedure, the protein concentration was 1 mg/mL in sodium phosphate buffer at pH 7. $[\text{Ru}(\text{NH}_3)_4(1,10\text{-phenanthroline-5-maleimide})](\text{PF}_6)_2$ was dissolved in CH_3CN . The Ru complex in solution was added to a rapidly stirring solution of protein. The organic solvent was kept below 5% of the total volume of the mixture, and the final Ru concentration was 5 to 10 times the molar protein concentration. The Ru complex and Ru-labeled protein were separated using gel filtration chromatography.

^a 200 mM in addition to 10 mM pH 7 phosphate buffer. ^b Formal potentials measured as the average of 2–4 cyclic voltammograms (10mV/s) ± 1 standard deviation. ^c Formal potentials measured as the average of 2–4 cyclic voltammograms (10mV/s) ± 1 standard deviation with 2-fold excess maltose. ^d The change in formal potential, ΔE , with excess 2-fold maltose.

Maltose Titration. For the detection of maltose, the concentration of Ru-labeled protein was 37–170 μM . A 3.0-mm diameter glassy carbon electrode was used as the working electrode for the voltammetry. The electrochemistry was conducted in a low-volume (200 μL) cell (BAS). Aliquots (1–2 μL) of a 2–10 mM solution of maltose were added to the protein solution. Two to four scans were measured at 10 mV/s for each maltose concentration. The formal potentials were calculated as the average of the cathodic and anodic peak potentials of the Ru(III/II) couple in the Ru-labeled protein and were plotted versus maltose concentration.

Simulations. Cyclic voltammograms were simulated using the DigiSim 2.1 (BAS). Default parameters were used in all simulations with $\alpha = 0.5$ and potential step = 0.005 V. The cyclic voltammograms were simulated at each concentration of maltose using the measured formal potentials of the Ru(III/II) couple for the unbound and maltose-saturated states of the protein (Table 1) and their respective concentrations defined by eq 2. The formal potentials from the simulated cyclic voltammograms were calculated as the average of the cathodic and anodic peak potentials and plotted versus maltose concentration.

RESULTS

To confirm environmental sensitivity of the Ru(II) maleimide complex, its spectroscopic and electrochemical properties were examined in a range of solvents with donor numbers (23) spanning 4.4 kcal/mol (nitrobenzene) to 26.6 kcal/mol (DMF) (Table 1). In Figure 1, the dependency of the formal potential of the Ru(II/III) redox couple, E_f , on solvent donor number (DN) is shown in comparison to that of the Fe(II/III) ferrocene redox couple which is environment-insensitive (24). As expected, the formal potential of the Ru(II/III) redox couple decreases with increasing donor number, reflecting the increase of electron density on Ru(II) metal center as a function of

Figure 1. Formal potential vs donor number of the Ru(II/III) redox couple of Ru(II)(NH₃)₄(1,10-phenanthroline-5-maleimide)](PF₆)₂ compared to that of the Fe(II/III) redox couple of ferrocene (27). The solvents listed with donor numbers (kcal/mol) are nitrobenzene (4.4), acetonitrile (14.1), acetone (17), ethanol (19), DMF (26.6), DMSO (29.8). Inset: Cyclic voltammograms of Ru(II)(NH₃)₄(1,10-phenanthroline-5-maleimide)](PF₆) in DMF and CH₃CN 0.1 M in [N(n-C₄H₉)₄](PF₆). 100 mV/s.

the hydrogen bonding (or electron donating) capacity of the solvent environment (12).

In the context of a protein environment (below), it is our supposition that conformational changes in proximity of a conjugated Ru(II) probe may change the extent of hydrogen bonding, resulting in changes in the observed formal potential.

Conjugation of the Ru(II) maleimide complex to the lone cysteine residue of genetically engineered *E. coli* maltose binding protein (MBP) was conducted in pH 7 buffer, with excess Ru complex removed by gel filtration chromatography. The extent of coupling was >95% based on titration of remaining free cysteines using Ellman's reagent and by comparison of the absorbance of the bound Ru complex ($\epsilon_{280} \sim 15000 \text{ M}^{-1} \text{ cm}^{-1}$, and $\epsilon_{490} \sim 5000 \text{ M}^{-1} \text{ cm}^{-1}$) to the absorbance of the protein ($\epsilon_{280} \sim 69000 \text{ M}^{-1} \text{ cm}^{-1}$). Two MBP variants, D95C and S233C, each containing a single cysteine mutation, were investigated. D95C, MBP containing an aspartic acid to cysteine mutation at position 95 (a site distinct from the maltose binding site), had previously demonstrated strong allosteric coupling of maltose binding with changes in fluorescence emission intensity of an environment-sensitive fluorescent conjugate (12). S233C, MBP containing a serine to cysteine mutation at position 233 (a site very close to or partially within the maltose binding site), had also previously demonstrated fluorescent reagentless maltose detection when conjugated with an environment-sensitive fluorophore (12).

Cyclic voltammetry for both Ru-conjugated MBP mutants was quasi-reversible at 10 mV/s with the ratio of anodic to the cathodic peak current equal to 1 (at a glassy carbon electrode in pH 7 sodium phosphate buffer) (Figure 2) and was stable upon successive scans in air-saturated solutions. The formal potential of the Ru(II/III) couple in Ru-MBP(D95C) changes as a function of maltose concentration in several different supporting electrolytes (Table 1). Potential shifts were not observed for Ru-MBP(S233C) or the unconjugated Ru(II) maleimide complex under similar conditions. In addition,

glucose at concentrations comparable to those used in maltose titrations resulted in no change in formal potential of the Ru(II/III) couple in Ru-MBP(D95C), owing to the small affinity of MBP for glucose (12).

DISCUSSION

As with the fluorescently labeled D95C analog (12), it is hypothesized that the increase in formal potential of the Ru(II/III) couple in Ru-MBP(D95C) results from a change in the local environment of the electrochemically active reporter group due to the conformational change in the protein upon maltose binding. The insensitivity of the formal potential of the Ru(II/III) conjugate in Ru-MBP(S233C) to maltose binding, even though a 2-fold increase in fluorescence intensity was observed in fluorescently labeled S233C upon maltose binding, likely reflects subtle differences in the resulting protein environment of the two probes and underscores the importance of further study in how proteins structurally accommodate conjugated probe molecules.

Assuming binding of maltose to Ru-MBP(D95C) is reversible (eq 1) the fraction of total protein with bound maltose as function of maltose concentration may be calculated from a binding isotherm (25), eq 2,

$$\text{fraction bound} = \frac{([P]_t + [M]_t + K_d) - \sqrt{([P]_t + [M]_t + K_d)^2 - 4[P]_t[M]_t}}{2[P]_t} \quad (2)$$

where $[P]_t$ is the total concentration of protein (bound and unbound), $[M]_t$ is the total concentration of maltose at each titration point, $K_d = 1.5 \mu\text{M}$ (12), and the fraction bound is given by $[\text{Ru-MBP(D95C)maltose}]/[P]_t$. Cyclic voltammograms were simulated over a range of maltose concentrations to explore the possibility that the observed

Figure 2. The titration of 75 μM Ru-conjugated MBP(D95C) mutant with maltose in a pH 7, 10 mM phosphate buffer with 0.2 M NaClO_4 . Formal potentials (measured as the average of the cathodic and anodic peak potentials ± 1 standard deviation) plotted vs [maltose]. The line is simulated data obtained as described in the Experimental Section using a binding isotherm (eq 2) with $K_d = 1.5 \mu\text{M}$ (12). Inset: Cyclic voltammogram (background subtracted) of the Ru-labeled MBP(D95C) (75 μM) at a working glassy carbon electrode with scan rate of 10 mV/s in a pH 7 buffer at an ionic strength of 0.2 M NaClO_4 with and without presence of 2-fold excess maltose.

shift in the formal potential could be correlated with the binding of maltose. In the simulation, the concentrations of bound and unbound forms of Ru-MBP(D95C) were determined from eq 2 for each maltose concentration. The cyclic voltammograms were simulated using values for the formal potentials of Ru-MBP(D95C) in both the unbound and maltose-saturated state. As can be seen in Figure 2, the simulated change in formal potential versus maltose concentration overlays the experimentally measured change in formal potential versus maltose concentration. The observable $\Delta E_f(\text{maltose})/\Delta E_f(\text{max})$, where $\Delta E_f(\text{maltose})$ is the change in formal potential of the Ru complex as a function of maltose concentration and $\Delta E_f(\text{max})$ is the maximum change in formal potential over the course of maltose titrations, reflects the fraction of MBP with bound maltose and may be used to quantitatively assess the affinity of MBP for maltose. The maximum change in formal potential as a function of maltose occupancy is somewhat dependent on electrolyte (Table 1), however, and may be due to the sensitivity of Ru complex electrochemistry to hydrogen-bonding and solvation (20).

In conclusion we have demonstrated that the new electroactive sulfhydryl-reactive reagent, $[\text{Ru}(\text{II})(\text{NH}_3)_4-(1,10\text{-phenanthroline-5-maleimide})](\text{PF}_6)_2$, can be implemented in an electrochemical allosteric signal transduction scheme (EAST) complementing fluorescence-based reagentless assay systems. At its current state of development, the EAST technique employed in this study was able to detect maltose at concentrations as low as 10 μM , whereas the fluorescence-based technique (FAST) (12) is able to detect maltose with a detection limit of 0.1 μM .

In existing enzyme-based electrochemical sensors, the main focus has been on the detection of glucose (26). Current enzyme-based electrochemical methods are able to monitor glucose over a wide range of concentrations (e.g., commercially available blood glucose sensors have working glucose concentration ranges of 1–30 mM) with detection limits as low as 0.1–1 μM (26). The predomi-

nant electrochemical detection scheme of glucose biosensors, however, involves the use of glucose oxidase which requires oxygen as an additional substrate and which, as an enzymatic mediator, may also be prone to inaccuracies due to matrix interferences. We are continuing to pursue the goal of reagentless biosensing through further development of the EAST technique and are currently designing new protein redox conjugates that undergo larger changes in formal potential upon analyte binding.

ACKNOWLEDGMENT

This work was performed while Scott Alan Trammell held a National Research Council Research Associateship Award at the Naval Research Laboratory. The research was supported by the Office of Naval Research and the Naval Research Laboratory.

TECHNICAL NOTES

Photoreduction of Autooxidized Albumin–Heme Hybrid in Saline Solution: Revival of Its O₂-Binding Ability

Akito Nakagawa, Teruyuki Komatsu, and Eishun Tsuchida*

Department of Polymer Chemistry, Advanced Research Institute for Science and Engineering, Waseda University, Tokyo 169-8555, Japan. Received September 5, 2000; Revised Manuscript Received January 20, 2001

Recombinant human serum albumin (rHSA) incorporating 2-[8-{*N*-(2-methylimidazolyl)}octanoyloxy-methyl]-5,10,15,20-tetrakis($\alpha,\alpha,\alpha,\alpha$ -*o*-pivalamido)phenylporphinatoiron(II)s (Fe(II)Ps) [rHSA–Fe(II)P] is a synthetic hemoprotein which can bind and release O₂ reversibly under physiological conditions (saline solution [NaCl]: 150 mM, pH 7.3) as do hemoglobin and myoglobin. However, the central ferrous ions of Fe(II)Ps are slowly oxidized to O₂-inactive ferric forms. Based on the UV–vis. absorption spectroscopy, the majority of the autooxidized Fe(III)Ps in albumin are determined to be six-coordinate high-spin complexes with a proximal imidazole and a chloride anion, which show ligand-to-metal charge transfer (LMCT) absorption at 330 nm. Interestingly, photoirradiation of this LMCT band under an argon atmosphere led to reduction of the central ferric iron of Fe(III)P, allowing the revival of the O₂-binding ability. The ratio of the photoreduction reached a maximum of 83%, which is probably due to the partial dissociation of the axial imidazole. The same photoirradiation under a CO atmosphere provides the corresponding carbonyl rHSA–Fe(II)P. Laser flash photolysis experiments revealed that the reduction was completed within 100 ns. The quantum yields (Φ) of these photoreductions were approximately 0.01.

INTRODUCTION

The ferrous complexes of protoporphyrin IX in hemoglobin (Hb) are slowly oxidized even in the bloodstream, converting to the O₂-inactive ferric forms. If one can reduce these iron(III) complexes by light irradiation, this becomes the easiest way to revive their O₂-binding abilities. From this point of view, reduction of the porphyrinatoiron(III)s has been of great interest for several decades. The ferric complexes of porphyrins normally coordinate with counteranions and show a ligand-to-metal charge transfer (LMCT) transition in the near UV region. It has been shown that, in organic solvents, photoirradiation of this LMCT absorption led to reduction of the central metal involving a radical dissociation (Bartocci et al., 1980; Brault et al., 1980; Hoshino et al., 1992,1998; Inamura et al., 1985; Ward et al., 1982). Henderikson et al., for example, revealed the clean photoreduction of tetraphenylporphinatoiron(III) halide ([Fe(III)TPP]⁺X[–]) by 355-nm irradiation in benzene (Henderikson et al., 1987). In aqueous media, however, the produced radicals easily react with the formed porphyrinatoiron(II), so that the ferrous complex is not accumulated. Only when hyaluronic acid coexists in phosphate-buffered saline solution, the self-organized fibers of amphiphilic Fe(III)TPP derivative could be reduced by the LMCT irradiation (Komatsu et al., 2000b).

On the other hand, recombinant human serum albumin (rHSA) incorporating eight 2-[8-{*N*-(2-methylimidazolyl)}octanoyloxymethyl]-5,10,15,20-tetrakis($\alpha,\alpha,\alpha,\alpha$ -

o-pivalamido)phenylporphinatoiron(II) (Fe(II)P) [rHSA–Fe(II)P] is a synthetic hemoprotein which can bind and release O₂ under physiological conditions (in aqueous media, pH 7.3, 37 °C) as do Hb and myoglobin (Mb) (Komatsu et al., 1999; 2000a; Tsuchida et al., 1997; 1999). The 5 wt % solution of this albumin–heme hybrid satisfies the physiological requirements for a red blood cell substitute. In fact, administration of this solution into hemorrhagic shock rats showed an increase in the renal cortical O₂-tensions and skeletal tissue O₂-tensions (Tsuchida et al., 2000). Nevertheless, the remaining problem with this rHSA–Fe(II)P is also the relatively short lifetime as an O₂-carrying vehicle. Autoxidation of the central ferrous ion of Fe(II)P takes place slowly through a proton-driven process (Momentau et al., 1994). We report herein for the first time the unique coordination structure of Fe(III)P in albumin and the photoreduction of rHSA–Fe(III)P by LMCT excitation, which allows revival of the O₂-binding ability. Laser flash

photolysis experiments also revealed that the reduction was completed within 100 ns.

EXPERIMENTAL PROCEDURES

Materials and Preparation. The synthetic heme, 2-[8-{*N*-(2-methylimidazolyl)}octanoyloxymethyl]-5,10,15,20-tetrakis(*o*-pivalamido)phenylporphyrinatoiron(II) (Fe(II)P) and the rHSA-Fe(II)P solution [rHSA/Fe(II)P = 1/8 (mol/mol), in phosphate-buffered saline (pH 7.4)] was prepared according to our previously reported procedures (Komatsu et al., 2000; Tsuchida et al., 1995). The recombinant human serum albumin (rHSA; 25 wt %) was obtained from the WelFide Corporation (Sumi et al., 1993). FeP concentrations of 20 μ M were normally used for the UV-vis. absorption spectral measurements (Shimadzu V-570 spectrometer) within the range of 300–700 nm. Upon addition of the rHSA-Fe(II)P solution to O₂, the absorption spectrum showed the typical O₂-adduct of Fe(II)P (λ_{max} : 426, 552 nm). After incubation of this dioxygenated rHSA-Fe(II)P at 40 °C for 24 h, all the Fe(II)P sites in rHSA are oxidized, giving rHSA-Fe(III)P with absorption maxima at 330, 423, and 565 nm.

Photoreduction of Fe(III)P Incorporated into rHSA. The photoirradiation of this oxidized rHSA-Fe(III)P solution was performed with a 250-W ultrahigh-pressure Hg arc-lamp (Ushio UCH-250) under an argon or a CO atmosphere in a dark room (25 °C). The Hg lamp was held in a special lamp housing (Koken Kogyo LHX-150), which was connected to a PSX-75 power supply. The light filtered by a U-370 colored filter was irradiated into the rHSA-Fe(III)P solution in a 10-mm cuvette with a constant distance of 7.5 cm. The UV-vis. absorption spectra of the solutions were measured at several intervals. The reduction rates were calculated from the Soret band absorption (A_s) divided by that of the 100% reduced form for the deoxy state (A_{deoxy} at 443 nm) or carbonyl state (A_{carboxy} at 427 nm). The quantum yield (Φ) was determined by the well-established procedure with an oxalight Fe(II) complex (Michaelson et al.).

Transient Absorption Spectroscopy. The transient absorption spectra after the laser flash photolysis were measured using an ICCD detector (ANDOR DH520-18F-WR) with an imaging monochromator (ORIEL MS-257). The excitation laser pulse was generated from the THG (355 nm; pulse width, 5 ns) of a Nd:YAG laser (Spectron SL803G-10). The pulse xenon flash lamp (10 W, 10 Hz, 100 ns pulse width) was used as the monitor light source. The path length of the cuvette was 10 mm, and all measurements were carried out using a two-channel simultaneous detection system (Tokyo Instruments, Ltd.) at 25 °C.

Resonance Raman Spectroscopy. Resonance Raman spectroscopy measurements were performed using a laser Raman spectrometer equipped with a CCD multichannel detector (JASCO NRS-2000). Excitation was carried out with the 457.9 nm line of an NEC GLG2162 Ar⁺ ion laser in a backscattering geometry at 25 °C. The FeP concentrations of 1 mM in special liquid cells were normally used for the measurements.

RESULTS AND DISCUSSION

Coordination Structure of Autooxidized Fe(III)P in Albumin. Although the rHSA-Fe(II)P hybrid can bind molecular O₂ reversibly under physiological conditions, the central ferrous ions of the Fe(II)Ps are slowly oxidized to O₂-inactive ferric forms by a proton-driven process (Momentau et al., 1994). This oxidation, namely

Figure 1. UV-vis absorption spectral changes in photoreduction of rHSA-Fe(III)P in phosphate-buffered saline (150 mM NaCl, pH 7.3) solution under argon atmosphere at 25 °C.

Table 1. Absorption Maxima of rHSA-Fe(III)P Solution with Sodium Halide (150 mM) at 25 °C

	electron negativity	LMCT (nm)	Soret (nm)	Q (nm)
F ⁻	4.0	330	423	566
Cl ⁻	3.0	330	423	565
Br ⁻	2.8	332	422	569
I ⁻	2.5	333	422	569

autoxidation, generally obeyed the first-order kinetics with a half-life of ca. 8 h at 25 °C (Tsuchida et al., 1997). The UV-vis absorption spectrum of the final compound showed maxima at 330, 423, and 565 nm. We have reported that the amphiphilic Fe(III)TPP derivative formed a five-coordinated high-spin complex with a chloride anion (Cl⁻) in phosphate-buffered saline solution (Fleischer et al., 1971; Komatsu et al., 2000b). However, this is not true for rHSA-Fe(III)P. On the basis of the absorption pattern, we determined that the dominant species of Fe(III)P in rHSA is an octahedral six-coordinate high-spin ferric complex with a Cl⁻ and an intramolecularly coordinated imidazole nitrogen (Figure 1, 3) (Shantha et al., 1998; Walker et al., 1976). In general, this type of six-coordination with sterically hindered imidazole, such as 1,2-dimethylimidazole (1,2-Me₂Im), is formed when a large excess of imidazole is present in the solution, because of the extremely low equilibrium constant of 1,2-DMIm to [Fe(III)TPP]⁺Cl⁻; 3.4 M⁻¹ (Walker et al., 1976). However, in albumin, each Fe(III)P molecule is incorporated into the small space of the hydrophobic domain, so that the six-coordination to the ferric complex is presumably formed. We assigned the small absorption band at 330 nm to a ligand-to-metal charge transfer (LMCT) transition between the central ferric ion and the Cl⁻ (Shantha et al., 1998). In the case of the five-coordinate high-spin [Fe(III)TPP]⁺Cl⁻, the LMCT absorption maxima shift to the lower energy with the decreasing electronegativity of the halides (I⁻ < Br⁻ < Cl⁻), while the Soret and Q-bands, which are π - π^* transitions, are not affected (Hendrikson et al., 1987; Komatsu et al., 2000). However, the λ_{max} of the LMCT absorption of the six-coordinated Fe(III)P in rHSA was constant versus the electron negativity of the counteranions ([X⁻]: 150 mM) (Table 1).

We then employed resonance Raman spectroscopy to detect the vibration stretching mode of the porphyrin ring

(ν_2) which is expected in the 1541–1554 cm^{-1} for the six-coordinated high-spin $[\text{Fe}(\text{III})\text{TPP}]^+\text{Cl}^-$ (1,2-Me₂Im) analogue (Parathati et al., 1987). The obvious absorption appeared in this region as double peaks at 1566 and 1547 cm^{-1} (not shown). The latter is likely to be the ν_2 band of the six-coordinate $\text{Fe}(\text{III})\text{P}$ in albumin.

Photoreduction of Autooxidized $\text{Fe}(\text{III})\text{Ps}$ in Albumin. The 365-nm irradiation of the saline solution of rHSA- $\text{Fe}(\text{III})\text{P}$ under argon atmosphere led to reduction of the central ferric ion; the visible absorption spectrum changed to the typical five-*N*-coordinate high-spin $\text{Fe}(\text{II})\text{P}$ complex (λ_{max} : 443, 542, and 565 nm) within 15 min (Figure 1). The isosbestic points (431, 461, 524, and 580 nm) throughout the measurement revealed that no side reactions occurred.

The following two results indicate that the photoreduction of rHSA- $\text{Fe}(\text{III})\text{P}$ occurs through the intramolecular electron transfer initiated by LMCT excitation. (i) In the absence of NaCl (in deionized water), the reduction proceeded by only 20%, suggesting that a Cl^- is essential for this reaction. (ii) The Soret band irradiation also reduced the ferric center, but by less than 40%. Irradiation of the LMCT band causes only the efficient reduction of the autooxidized rHSA- $\text{Fe}(\text{III})\text{P}$. Shantha and co-workers revealed that the coordination of 2-methylimidazole to $[\text{Fe}(\text{III})\text{TPP}]^+\text{Cl}^-$ results in a clean photoreduction of the central ferric ion by 407-nm irradiation (Shantha et al., 1998). They also inferred that a photoreactive state with a λ_{max} at 315–335 nm is responsible for this reduction.

For accumulation of the reduced $\text{Fe}(\text{II})\text{P}$, a radical scavenger should be present in the solution to avoid the back electron transfer. Actually, irreversible photoreduction of the molecular fibers of the amphiphilic $\text{Fe}(\text{III})\text{-TPP}$ derivative occurred only in a phosphate-buffered saline solution containing a small amount of hyaluronic acid (Komatsu et al., 2000). We can therefore assume that the albumin host itself, for instance, the amino acid residues located nearby $\text{Fe}(\text{III})\text{P}$, immediately traps the chloride radicals after the charge separation, then the reaction becomes irreversible. The most probable candidates are tyrosine and tryptophan. It is also remarkable that the photoreduction rate was not affected by the kinds of halide ions (I^- , Br^- , Cl^- , F^-).

Upon exposure of the aqueous solution of the photoreduced rHSA- $\text{Fe}(\text{II})\text{P}$ to O_2 , the UV-vis absorption spectrum changed to that of the dioxygenated complex (λ_{max} : 426, 552 nm). The O_2 coordination reversibly depended on the O_2 -partial pressure. An interesting observation is that the photoreduction rates reached a maximum of 83% (Figure 2). This is probably due to the base elimination in the ferric state; the imidazolyl group once dissociated from the central iron cannot coordinate again to the iron(III) center. This is consistent with our previously reported results on the reduction of the autooxidized rHSA- $\text{Fe}(\text{III})\text{P}$ by ascorbic acid with red blood cells (Tsuchida et al., 2000).

Photoirradiation into the LMCT band of the rHSA- $\text{Fe}(\text{III})\text{P}$ under CO atmosphere provides carbonyl rHSA- $\text{Fe}(\text{II})\text{P}$ (λ_{max} : 427, 540 nm) (Figure 3). CO coordinates with $\text{Fe}(\text{II})\text{P}$ immediately after the photoreduction of the central ferric ion, affording the stable carbonyl complexes. The reduction rate was estimated to be 93% under CO atmosphere. The real concentration of the carbonyl $\text{Fe}(\text{II})\text{P}$ in rHSA should not be as high, around 83%, because the Soret band absorption includes that of the five-coordinated $\text{Fe}(\text{II})\text{P}(\text{CO})$ complex without axial imidazole bonding, which has a large molecular coefficient.

Figure 2. UV-vis absorption spectral changes in photoreduction of rHSA- $\text{Fe}(\text{III})\text{P}$ in phosphate-buffered saline (150 mM NaCl, pH 7.3) solution under CO atmosphere at 25 °C.

Figure 3. Relationship between the reduction rate and the irradiation time of rHSA- $\text{Fe}(\text{III})\text{P}$ in phosphate-buffered saline (150 mM NaCl, pH 7.3) solution at 25 °C.

Laser flash photolysis at 355 nm (THG of Nd:YAG) of the deaerated aqueous rHSA- $\text{Fe}(\text{III})\text{P}$ solution showed that the photoreduction was finished within the duration of the laser pulse; the transient absorption spectral pattern measured at 100 ns after the pulse was in good agreement with the difference spectrum of the rHSA- $\text{Fe}(\text{II})\text{P}$ solution minus the autooxidized rHSA- $\text{Fe}(\text{III})\text{P}$ solution (Figure 4). The primary reaction step appears to be the homolytic cleavage of the axial Cl^- , and $\text{Fe}(\text{II})\text{P}$ with intramolecularly coordinated axial imidazole is immediately formed. The produced chloride radical should have reacted with the active hydrogen in the amino acid residues of rHSA.

The quantum yields (Φ) of this photoreduction system were determined to be 0.01 under a CO atmosphere and 0.008 in argon. Because the LMCT excitation state (LMCT^*) is located above the S_1 and S_2 states, the photoexcited species has two pathways for decaying (Figure 5). The first is quenching to the S_2 state with a rate constant of k_d , and the second one yields $\text{Fe}(\text{II})\text{P}$ via intramolecular electron transfer. Of course, the former decay is major, and the charge recombination to $\text{Fe}(\text{III})\text{-P}^+\text{Cl}^-$ with a rate constant of k_b is also a facile reaction which returns to the ground state. However, if the

Figure 4. Transient absorption spectrum of rHSA-Fe(III)P in phosphate-buffered saline (150 mM NaCl, pH 7.3) solution at 100 ns after the laser flash photolysis (355 nm) at 25 °C. The spectral pattern is in good agreement with the difference spectrum of rHSA-Fe(II)P minus rHSA-Fe(III)P.

Figure 5. Transient states and interconversion pathways for photoreduction of rHSA-Fe(III)P.

albumin cage traps the chloride radical, the photoinduced electron transfer to the ferric ion becomes irreversible. That is to say, the low quantum yield of this photoreduction is due to the high probabilities of (i) the deactivation of LMCT* to S₂, and (ii) back electron transfer between the ferrous ion and the chloride radical.

CONCLUSIONS

The autooxidized Fe(III)P in the albumin hybrid formed a unique six-coordinate high-spin ferric complex, which shows the LMCT absorption at 330 nm. Photoirradiation of this band under an argon atmosphere led to a clean reduction of Fe(III)P to revive its O₂-binding ability. The partial Fe(III)P which eliminates the axial base could not be reduced, because of the imidazole rebinding is probably interfered by the steric hindrance of the amino acid residues in the albumin interior. The relatively low quantum yield of this photoreduction may increase in the serum solution, because the biological system contains some scavengers for radicals. Picosecond laser flash photolysis experiments to reveal the detailed mechanism of this photoreduction are now in progress.

BIFUNCTIONAL CHELATORS FOR THERAPEUTIC LANTHANIDE RADIOPHARMACEUTICALS

The authors sincerely apologize to Dr. Garry E. Kiefer and co-workers for the oversight of their US patent no. 5587451, which was inadvertently omitted in reference to Chart 4 of this manuscript. US patent no. 6013793 disclosed the routes showing condensation of triethylene-tetraamine (TETA) with glyoxal, followed by oxidation with bromine and formation of a dicationic intermediate. In contrast, the monocationic intermediate depicted in Chart 4 is obtained from the condensation of TETA with dimethylformamide dimethyl acetal as described in US patent no. 5587451.

INTRODUCTION

Recent years have witnessed not only a growing understanding of the molecular basis of carbohydrate–protein interactions (1), but also a deeper appreciation of their importance in many biological processes. On cell surfaces, carbohydrate–protein interactions are involved in the mediation of important biological processes in which tissue cells, bacteria, and viruses recognize one another. Embryogenesis, cancer metastasis, inflammation, and bacterial and viral infection are all examples of biological events which involve the selective recognition of carbohydrates by proteins. However, isolated carbohydrate–protein interactions are typically very weak (2) with K_d values of the order of 10^{-3} to 10^{-6} M. Nature compensates for the weakness of these isolated interactions by tending to cluster together multiple copies of carbohydrate ligands and their receptors (3) in order to allow for stronger cooperative binding to take place—the so-called multivalent effect (4). This biological phenomenon is an important one to consider when planning how to capitalize on carbohydrate–protein interactions when developing a potentially new class of carbohydrate-based therapeutics.

In view of the important roles played by carbohydrate–protein interactions in disease states, it is hardly surprising that the exploitation of these interactions to develop a new generation of carbohydrate-based therapeutics is already well under way. For example, it is known (5) that the Shiga and cholera toxins, which have an AB_5 structure (6), gain entry to mammalian cells when the B_5 pentamer recognizes carbohydrates on the cell surface.

The recent demonstration by Bundle and co-workers (7) of a pentavalent carbohydrate ligand capable of inhibiting the binding of the B_5 subunit of the *Escherichia coli* O157: H7 Shiga-like toxin I with subnanomolar activity, is one of the most impressive applications of glycoscience to have been described in the literature to date.

The use of carbohydrates to inhibit a particular lectin-mediated process is not the only method by which carbohydrates can find therapeutic applications—indeed, carbohydrate-based cancer vaccines which are based on tumor-associated carbohydrate antigens, are an active area of research at present (8). Another area of contemporary interest is the carbohydrate-mediated delivery of drugs (9). Since cell-surface lectins are often displayed in a very cell-specific manner, it may be possible to use a carbohydrate, which is specifically recognized by a lectin found on the surface of a specific cell type, to direct an existing covalently attached drug molecule to the desired tissues in a selective manner. For example, an earlier study (10) has shown that the antiinflammatory, naproxen, when covalently attached to galactose-derivatized human serum albumin, can be delivered selectively to the liver—in preference to the kidneys—in rat models.

Recent years have witnessed the emergence of another approach by which the power of carbohydrates to target cell surfaces can be exploited in the selective delivery of drugs to their target tissues. Supramolecular chemists have long recognized (11) the ability of certain macrocyclic hosts to complex with complementary guests, including biologically important molecules (12). The macrocyclic hosts that have been studied traditionally by supramolecular chemists almost invariably lack a biologically recognizable component, however. So even if we discount the biological disadvantages associated with

many macrocycles, such as their lack of aqueous solubility and potential toxicities, they are, at best, limited in their biological potential. The possibility does exist, however, to modify many of these macrocyclic hosts chemically by grafting biorecognizable units—such as carbohydrates—onto their reactive functional groups. Thus, such a unique class of glycoconjugates would possess the potential to sequester a drug molecule noncovalently within their macrocyclic cavities and then rely upon their appended carbohydrate units to direct the glycoconjugate–drug complex to a specific tissue type, dictated by the choice of carbohydrate units displayed on the periphery of the macrocycle. This approach would dispense with one of the problems associated with conventional receptor-mediated glycotargeting—namely, the molecular structure of the drug molecule may have to be modified to allow it to be covalently attached to the glycoprotein, which could have serious consequences on the drug's potency. Even if it is not necessary to alter the structure of the drug molecule, covalently attaching the drug to a linker could still affect the drug's potency. Once the glycoconjugate–drug complex had located the specific target, the drug molecule would be released slowly into the cell membrane and adsorbed by the cell wherein it could fulfill its pharmacological purpose.

It is the prospect of this kind of scenario that has brought about a union of the disciplines practiced by supramolecular and carbohydrate chemists where the aim has been one of designing, synthesizing, and then determining the supramolecular and biochemical properties of these macrocyclic-based “intelligent” drug-delivery systems. This review will concentrate on recent developments in this relatively new field of glycoscience.

Design Considerations. The choice of macrocyclic host—which will become not only the host moiety but a scaffold for the attachment of the carbohydrate residues also—is an extremely important decision that has to be made at the outset by any researcher entering the field. Ideally, the starting macrocycle should be readily available and have appropriately positioned functional groups to allow for the facile attachment of carbohydrate residues. The macrocycle itself should display low pharmacological activity, and ideally, a high degree of biocompatibility. It is also advantageous if there is a well-developed literature dealing with the efficient chemical modification of the macrocycle. Another very important point for consideration is that the macrocycle should display a reasonably predictable propensity to complex with a wide range of guest molecules. The design of the macrocycle-based glycoconjugate must avoid the situation where its carbohydrate appendage(s), or any other part of the molecule for that matter, becomes bound inside the macrocyclic cavity in either an intramolecular or intermolecular sense, thus severely reducing the macrocycles' ability to complex with guest molecules. Indeed, weak complexation of a drug molecule by the macrocycle could result in the two becoming completely dissociated before the complex reaches its target. Therefore, it is advisable for chemists to design macrocyclic-based glycoconjugates which possess suitably strong association constants with their intended guest molecules.

The choice of carbohydrates to be covalently attached to the macrocycle will be determined by the desired lectin target of the neoglycoconjugate, whether for *in vivo* applications or simply model studies. Many of the compounds described in this review have been designed such that their interactions with plant lectins can be studied. Additionally, an emphasis has been placed by many researchers on producing homogeneous compounds which

Figure 1. (a) Condensed structural formulas of α -, β -, and γ -cyclodextrin, with the primary and secondary faces indicated. (b) Full structural formula of α -cyclodextrin.

possess a well-defined structure and a precise number of carbohydrate residues. The extra effort required to produce homogeneous compounds is probably worthwhile, since it can be difficult to reproduce accurately the composition of a heterogeneous mixture and evaluate it biologically.

When all the requirements and limitations are taken into consideration, it is perhaps hardly surprising that chemists in this area have chosen “tried-and-tested” macrocycles as the initial compounds for the construction of glycoconjugates. Since cyclodextrins, calixarenes, and calixresorcarenes all have rich and extremely well-documented synthetic and supramolecular chemistries, they have, thus far, been the macrocycles of choice for the construction of these glycoconjugates. This review will cover the research reported for each of these three classes of macrocycles in turn.

Cyclodextrins—Versatile Receptor Molecules. Cyclodextrins (CDs) (13) are cyclic oligosaccharides, composed of six, seven, or eight α -D-glucose units, and giving rise to α -, β -, and γ -CD, respectively. They have an overall shape reminiscent of a truncated cone. On account of their relatively hydrophobic interiors, CDs have the ability to form inclusion complexes with a wide range of substrates in aqueous solution. As CDs are obtained on an industrial scale by the enzymatic degradation of starch by bacterial microorganisms, they are readily available and relatively affordable. This important feature, combined with their inherently low toxicities and pharmacological activities, has meant that CDs are already finding applications in the pharmaceutical industry (14). The formation of inclusion complexes with drug molecules helps to enhance their solubilities, stabilities, and bioavailabilities—for example, to improve its solubility, the antiinflammatory drug, piroxicam, is commonly marketed in many European countries as its β -CD complex.

The physical properties of CDs can be altered upon their chemical modification. CDs contain two classes of free hydroxyl groups—the primary 6-OH groups are situated around the circumference of the narrower “primary face”, and the secondary 2- and 3-OH groups are located on the circumference of the wider “secondary face” (Figure 1). It is these hydroxyl groups, and their associated differences in reactivity, which provide the fundamental basis for the regioselective modification of CDs.

There are a limited number of examples of the chemical modification of CDs with bioactive molecules in an attempt to use the characteristics of the CD to improve the potency of a bioactive molecule. For example, the antitumor sulfonylurea LY237868 (1) has been attached (15) (Scheme 1) covalently to an α -CD derivative 2. The

Scheme 1. Reaction of the Antitumor Sulfonyl Urea 1 with the Modified CD Core 2 To Form the Cluster Compound 3 as a Mixture of Structural Isomers

resulting conjugate **3** is a mixture of isomers which contain approximately 14 sulfonylurea groups per CD molecule. Importantly, the attachment of these sulfonylurea groups to the α -CD core greatly increases the bulkiness of the conjugate, and it is thus less likely to pass through cell membranes. As a consequence, it has been possible to prove that the antitumor sulfonylurea blocks NADH oxidase activity on the external plasma membrane surface of HeLa cells and not in the interior of the cells. However, it is the prospect of utilizing recent advances in glycobiology which has done much to shape current research in this area. It is the possibility of employing CDs adorned with carbohydrate units to target cell surfaces selectively and thus to guide an included drug molecule to a desired site, which has been receiving the attention of many researchers of late.

Cyclodextrins Appended with One Carbohydrate. CDs adorned on their primary faces with one or more carbohydrate units have been known (16) since the mid 1960s. These branched CDs, which consist of an α -D-glucopyranosyl unit or a (1 $\rightarrow$ 4)- α -D-glucan connected to the 6-position of one or more of the α -D-glucopyranosyl units of the CD torus, are minor products formed during the action of *Bacillus macerans* cycloamylose glucotransferase on starch during the formation of native CDs. Researchers at the time were interested in these branched CDs, as they potentially offered advantages over native CDs in terms of solubility or substrate complexing ability, as well as being useful in studies of the enzymatic degradation of CDs. However, the tedious purification

procedures required to isolate these compounds prompted (17) the first chemical synthesis of the branched CD derivative **4**. Shortly thereafter, several research groups reported (18) the synthesis of the thio analogues of **4**—namely the 6-S- α -D-glucopyranosyl-6-thiocyclomaltoheptaose derivative **5**.

Although the ability of saccharide-branched CDs to complex with guest molecules had been investigated (19) sometime ago, it was not until the early 1990s that researchers recognized the potential of utilizing the carbohydrate appendage of a CD torus in order to direct the glycoconjugate toward a specific biological site.

Realizing the potential saccharide-branched CDs could have for the “vectorized transport of drugs”, Parrot-Lopez et al. began to develop synthetic methods to link carbohydrate units onto CD cores. However, the French group recognized an important limitation of the naturally occurring saccharide-branched CDs. Compounds such as **4**, where the carbohydrate appendage is connected directly to the CD torus through an O-glycosidic linkage, will probably not possess sufficient flexibility for the appendage to interact with the receptor. To circumvent this potential pitfall, a saccharide-branched CD was prepared (20) which relies upon a flexible C_9 spacer to attach the carbohydrate unit to the CD core. Thus, a carbohydrate derivative **6** (Scheme 2), containing a β -N-glucosidic linkage and a C_9 linker, terminated by a free carboxylic acid function, was prepared. Standard amide bond-forming chemistry (DCC/HOBt) was then used to attach **6** to mono-6-amino- β -CD (**7**), affording the target compound **8** in a 40% yield. ^1H NMR spectroscopic analyses of **8** revealed very little conformational perturbation of the CD toroidal protons in either $\text{DMSO}-d_6$ or D_2O as solvents, indicating that there is no interaction between the C_9 spacer arm and the hydrophobic cavity of the CD. Compound **8** was also found to have a much improved solubility (200 g L^{-1}) in water relative to that (19 g L^{-1}) of native β -CD. ^1H NMR spectroscopic evidence suggested that **8** can form an inclusion complex with the antihypertensive drug, nifedipine, although no association constant was reported for the complex. The same group also subsequently reported (21) the synthesis of β -N-galactoside, β -N-fucoside, and α -N-mannoside derivatives of **8**. Various biological experiments were then performed using some of these compounds. They indicated (22) that the β -N-galactosyl derivatives possess lower hemolytic properties than does the native β -CD, and that the β -N-galactosyl, β -N-fucosyl, and β -N-acetylglucosylamine derivatives display a certain cytotoxicity toward some human tumor cells.

Later work by Parrot-Lopez and co-workers (23) highlighted the fact that saccharide-branched CDs, with spacer arms between the appended carbohydrate units

4: X = O

5: X = S

Scheme 2. Synthesis of a CD Derivative Appended with One *N*-glucoside Unit at the End of an Alkyl Chain Spacer Arm**Scheme 3. Chemical–Enzymatic Synthesis of Mono-6-[Gal- β -1,4-GlcNAc- β -(1,6')-hexyl]amido-6-deoxy- β -CD **11****

and the CD torus, could be prepared efficiently, using a chemical–enzymatic strategy. The incorporation of an enzymatic step into the overall synthetic scheme would arguably allow access to these saccharide-branched CDs on a large scale, an issue which would have to be addressed should these compounds ever become of commercial interest. Peptide coupling (Scheme 3) of the GlcNAc derivative **9**, which contains a hexanoic acid

spacer arm, to mono-6-amino- β -CD (**7**) yields the product **10** in 28% yield. Enzymatic coupling of UDP-galactose to **10** in the presence of 4- β -galactosyltransferase affords mono-6-[Gal- β -1,4-GlcNAc- β -(1,6')-hexyl]amido-6-deoxy- β -CD (**11**) in 68% yield. Biological assays indicate that **11** can be recognized by the galactose-specific *Kluveromyces bulgaricus* cell wall lectin (K_b CWL), whereas the simpler GlcNAc derivative **10** is not recognized at all by this lectin.

The effects of the lengths of the spacer arm on the ability of monosaccharide-branched CDs to recognize lectins has been investigated by numerous researchers. Parrot-Lopez and co-workers (24) prepared a series of β -CD derivatives **12**, appended with a single *N*- β -D-

galactosyl unit at the end of a spacer arm of varying length ($n = 3–6$ or 9). The ability of these compounds to be recognized by the K_b CWL in a flocculation assay was then demonstrated. The results suggest that those compounds with short spacer arms are not recognized by K_b CWL as well as those compounds with long spacer arms. Another study, which deals briefly with the effects of spacer arm lengths on lectin recognition, has been performed by Hattori and co-workers (25). In this work, the technique of surface plasmon resonance (SPR) has been used to measure the rates of association and dissociation—information which allows the direct calculation of K_d —of various saccharide-branched CD derivatives with the lectin Concanavalin A (Con A), which is immobilized on a biosensor chip. One important conclusion from this investigation is that the α -glucosylgluconamide- β -CD **13** exhibits a significantly stronger interac-

tion with Con A than either of the simpler α -glucosyl- or α -maltosyl- β -CDs **4** and **14**. This result indicates that the carbohydrate appendage has to be spatially far enough removed from the CD core in order to enter into a strong interaction with Con A. However, it also indicates that the crucial terminal carbohydrate appendage must additionally have a certain degree of conformational freedom to help it interact with the Con A, which would explain why the α -glucosylgluconoamide- β -CD **13** experiences a much stronger interaction with Con A than does the α -maltosyl- β -CD **14**, which has a conformationally more restricted terminal α -glucopyranosyl residue. In the study of multivalent carbohydrate-protein interactions, the spacer arm length and relative spatial orientation of the appended carbohydrate ligand is of fundamental importance. Recent investigations (26) have focused upon the effect of these structural characteristics in a more systematic and detailed manner. It is probably fair to conclude that, in the area of saccharide-branched CDs, and indeed saccharide-branched macrocycles, the research carried out to date only begins to scratch the surface of understanding the subtleties of the relative spatial orientation of carbohydrate ligands, relative to their scaffolds and to each other.

Research performed (27) by the groups of Fernández and Defaye has resulted in the development of a route for the attachment of *N*-glycopeptide entities onto CD cores, utilizing thiourea formation. The glucosylamino acid derivative **15** shown in Scheme 4 was prepared in six steps from 1,2-*O*-isopropylidene- α -D-glucofuranose. Reaction of the free amino function in **15** with mono-6-isothiocyanato- β -CD **16**, followed by removal of the Boc-protecting group, affords the target compound **17** in high yield. The authors hope that this synthetic strategy will be efficient enough to allow the attachment of other more complex *N*-glycopeptide structures units onto CD cores.

Another interesting example of monofunctionalized CD derivatives has recently been published (28) by the same group. In this investigation, instead of functionalizing the CD core with a single carbohydrate appendage, it has been functionalized with a single dendritic wedge containing up to six carbohydrate units. As these compounds contain multiple copies of their carbohydrate ligands, they now possess the potential to exploit the so-called "multivalent" or "glycocluster" effects (4). Simpler compounds such as **18** and **19**, consisting of β -CD cores and monosubstituted with diantennary galactosyl and mannosyl moieties **19** had previously been described by Driguez and co-workers (29). The synthesis and use of glycodendrimers designed to exploit these effects, have been an active area of research in recent years. This topic has been reviewed elsewhere in detail (30). The synthetic

Scheme 4. The Attachment of a Simple *N*-glycopeptide to a CD Core

strategy of attaching carbohydrate-containing dendritic wedges to CD cores has several advantages. It allows the synthesis of a CD-based cluster containing multiple displays of carbohydrate units, without having to resort to more synthetically challenging perfunctionalizations of the CD core. Additionally, the binding ability of the CD core is also less likely to be perturbed relative to that of the corresponding native β -CD. The Franco-Spanish group have developed an efficient method for the construction of dendrons, substituted with mannosyl residues on their peripheries. Their synthesis, which uses the efficient and clean reaction of amines with isothiocyanates to form thioureas, allows the construction, in a convergent manner, of several mannose-containing dendrons, such as **20** shown in Scheme 5, with an isothiocyanate function at their focal points. Reaction of **20** with mono-6-amino- β -CD (**7**), followed by de-*O*-acetylation, affords the target compound **21**. A series of compounds containing various numbers (1–4 or 6) of mannosyl residues were prepared in a similar manner, and their

Scheme 5 The Attachment of a Dendritic Wedge Containing Six Mannosyl Residues at Its Periphery to a CD Core

abilities to interact with Con A were determined by an enzyme-linked lectin assay (ELLA). Although the results of this assay are not disclosed by the authors, they do mention that "IC₅₀ values for inhibition of Con A-yeast mannan binding reflected the expected amplification of lectin-binding strength for the higher-valent representatives". It was also observed that these mannosyl-coated β -CD-dendrimer constructs had an ability—which was similar to that observed for monobranched CDs—to solubilize the anticancer drug Taxotère.

Cyclodextrins Appended with Many Carbohydrates. The previously described example highlights the potential advantages that molecules displaying multiple carbohydrate ligands may have—namely the ability to interact with lectins with much stronger affinities than their monovalent counterparts. Research in the field of multivalent CDs to date has largely focused on the synthesis of persubstituted CDs, where each glucosyl residue of the CD torus has an appended carbohydrate ligand. Although CD derivatives of this type retain their inherent C_n symmetries, their perfunctionalization can pose very formidable synthetic problems.

The first chemical syntheses of CDs, persubstituted with carbohydrate appendages, were performed by Driguez co-workers (31) in 1994. The synthetic approach they utilized expands upon that used by them previously (18b) in the synthesis of the mono-branched CDs 5—i.e., simple nucleophilic displacement of a suitable leaving group in the 6-position(s) of β -CD with a thiolate anion. Reaction of the sodium salts **22** and **23** of both 1-thio- α - and 1-thio- β -D-galactopyranose, respectively, with per-6-bromo- β -CD

Scheme 6. The First Reported Synthesis of CDs Persubstituted on Their Primary Faces with Galactosyl Residues

24 affords (Scheme 6) the persubstituted products **25** and **26** in 50% and 80% yields, respectively.

Shortly afterward, Djedaïni-Pilard and co-workers (32) reported a more detailed account of the synthesis and host-guest binding properties of CDs, persubstituted with carbohydrate appendages. The French group was initially interested in comparing the water solubilities of CDs, persubstituted with carbohydrates, relative to those of monosaccharide-branched CDs and native CDs. Increased aqueous solubility could endow the modified CDs with an increased ability to bind drug molecules. Utilizing a strategy similar to that reported independently by Defaye (18a) and Driguez (18b) for the synthesis of **5**, the per-6-thio- α - and per-6-thio- β -D-glucopyranosyl derivatives **27** and **28** of CD were prepared.

Solubility studies indicated that these persubstituted CDs were more soluble than their monobranched counterparts, with the α -anomers being considerably more soluble than the corresponding β -anomers. An extensive NMR spectroscopic study of inclusion complexes formed between both the monosubstituted and persubstituted CD hosts and a series of drug molecules, was then performed. This investigation allowed the determination of association constants (K_a values) and binding orientations of the guests within the CD cavities—and, therefore, an estimation of the effect that the appended carbohydrate moieties have on the complexation ability of the CD cavity—and produced some initially unexpected results. Interestingly, it was found that *p*-nitrophenol, a well-known guest for β -CD, was found to form an exceptionally weak inclusion complex with **27**. This result was explained by the fact that β -CD prefers (33) to bind *p*-nitrophenol through its narrower primary face, suggesting that the bulky carbohydrate groups on the primary face of **27** present enough steric hindrance to prevent the complexation of the guest altogether. A different scenario is found in the complexation of the steroid, prednisolone, where 2D-ROSEY experiments suggest that it is complexed principally by **27** from the secondary face of its CD torus. However, the measured K_a value for the association of prednisolone with **27** in D₂O was only 200 M⁻¹, a value which is considerably

Scheme 7. Attachment of Seven *N*-Galactosyl Residues to a CD Core Using Amide Bond Formation as the Key Step

smaller than that (2000 M^{-1}) for the complexation of native β -CD with prednisolone. Molecular modeling of the native β -CD-prednisolone complex, using NMR-derived distance constraints, reveals that hydrogen bonding between the 6-hydroxyl groups of β -CD and the C-3 carbonyl group of prednisolone plays an important role in the stabilization of the complex. The absence of this interaction in the **27**/prednisolone complex may therefore account for the decrease in the K_a value.

Parrot-Lopez and co-workers (24) have expanded their synthetic studies on monobranched CDs such as **8** to investigations of persubstituted β -CD derivatives, adorned with seven *N*- β -D-galactosyl units at the end of a spacer arm. Reaction (Scheme 7) of 8.4 equiv of **29** with per-6-amino- β -CD (**30**), under standard amide bond-forming conditions, yields the fully substituted cluster compound **31**.

Our own research group has also used (34) amide bond formation as the key step in the synthesis of the *S*-glucosyl- and *S*-lactosyl CD-based clusters **32** and **33**,

Scheme 8. Preparation of CD-Based Clusters, Using the Reaction of Isothiocyanates with Primary Amines to Form Thioureas as the Key Step in the Attachment of the Carbohydrate Units to the CD Core

respectively. The lactose cluster **33** was shown to bind the nonsteroidal antiinflammatory, naproxen, in phosphate-buffered saline solution more weakly ($K_a = 165\text{ M}^{-1}$) than does β -CD ($K_a = 374\text{ M}^{-1}$) under identical conditions.

Another research group (35) in the US has utilized amide bond formation as the key step in the attachment of carbohydrate units to CD cores. However, in this research the carboxylic acid functions are located on the primary face of the CD and the amine functions on the appended carbohydrate units. Mixtures containing an average of five carbohydrates per CD and four carbohydrates per CD for the cases of α -CD and β -CD, respectively, were reported.

The clean and efficient reaction between amines and isothiocyanates to form thioureas, has been applied (36) by the research groups of Fernández and Defaye in the preparation of persubstituted CDs. The readily prepared carbohydrate isothiocyanates **34** and **35** (Scheme 8) react readily with per-6-amino- β -CD **30** to afford the fully substituted glycoclusters **36** and **37**, respectively, in good yields. The conditions required for this coupling reaction ($\text{Me}_2\text{CO}/\text{H}_2\text{O}/\text{NaHCO}_3$) result in partial deacetylation of the products, which are then fully deacetylated in a further step to afford the free cluster compounds.

Research groups led (37) by Roy and Santoyo-González have performed excellent and extensive investigations into both the syntheses and lectin-binding affinities of perglycosylated β -CD derivatives. In this research, perglycosylated β -CDs, containing four distinct linkage structures between the appended carbohydrate unit and the CD core have been prepared. The first set of CDs synthesized in this study are identical to **28**. The investigation was extended to the synthesis of the corresponding per- β -galactosides, per- β -*N*-acetylglucosamines and per- α -mannosides derivatives, all prepared by slightly differing methods to those described previously. To investigate further, the link between spacer arm length on the lectin binding abilities of the glycoconjugates, the second set of CDs were designed to incorporate a short CH_2CONH linker arm between the CD torus and the appended carbohydrate units. Reaction (Scheme 9) of per-6-amino- β -CD (**30**) with chloroacetic anhydride affords the heptachloro- β -CD derivative **38** in a near quantitative yield. When **38** is treated with the isothiuronium- β -D-glucoside **39**, the desired glycocluster **40** is obtained in excellent yield after de-*O*-acetylation. This synthetic methodology was repeated to obtain the β -galactosyl, β -*N*-acetylglucosamine, and α -mannosyl analogues of **40**. The third and fourth set of derivatives utilize *para*-substituted phenylmannosides only as the carbohydrate units.

Scheme 9. Reaction of Isothiuronium 39—Which Acts as a Latent Sulfur Nucleophile—with the Heptachloro- β -CD 38 to Afford, after Deprotection, the Persubstituted Cluster 40

Scheme 10. Synthesis of α -Mannosyl Clusters with Spacer Arms of Varying Lengths

Reaction of **41** (Scheme 10a) with per-6-iodo- β -CD (**42**), or reaction (Scheme 10b) of the isothiocyanate **43** with the extended β -CD core **44**, affords the two mannosyl derivatives **45** and **46**, respectively, with the obvious structural difference between these two compounds being the longer spacer arms present in **46**.

Various assays were then performed on these compounds. They indicated that (1) the cluster compounds are more effective inhibitors than the corresponding simple monosaccharide in competitive inhibition assays, (2) those clusters with longer spacer arms are more effective inhibitors than those with no spacer arms in competitive inhibition assays, and (3) the clusters can act as lectin cross-linking agents as a consequence of their multivalent nature. Unfortunately, the host–guest prop-

erties of none of these carbohydrate clusters have been, to our knowledge, reported by the authors yet. More recently, Roy and co-workers (38) have described the preparation of the protected persialylated β -CDs **47**, **48** and **49**, using similar synthetic methods to those described above.

Nucleophilic displacement reactions have also proven to be a very effective method for the attachment of carbohydrate units onto CDs. Research groups lead by

Scheme 11. Reaction of the *N*-Glucosyl Isothiuronium 50—Which Acts as a Latent Sulfur Nucleophile—with the Hepta-iodo- β -CD 51 To Afford the Persubstituted Cluster 52

Santoyo-González and Vargas-Berenguel have utilized (39) *N*-glycosyl isothiuronium derivatives—which act as latent thiolate nucleophiles—in the synthesis of CD-based cluster *N*-glycosides. Reaction (Scheme 11) of the isothiuronium derivative **50** with per-2,3-diacetyl-per-6-iodo- β -CD (**51**) in the presence of cesium carbonate affords, after reacylation, the persubstituted derivative **52**. Standard deacetylation is then employed to afford the final deprotected cluster. This synthetic strategy was employed to prepare the corresponding *N*-galactosyl, 2-acetamido-2-deoxy-*N*-glucosyl and *N*-mannosyl derivatives. A variation of this nucleophilic displacement strategy has been used (40) recently to construct clusters, such as the galactosyl cluster **53** which contains longer spacer arms bridging the gap between the CD core and its attached carbohydrate residues. Glucosylamino, lactosyl, and lactosylamino derivatives of this compound were also prepared and their abilities to inhibit the hemagglutination of blood cells by lectins was also reported in this investigation.

All CD-based carbohydrate clusters synthesized to date have involved the attachment of carbohydrate units onto the primary face of CDs, probably as a consequence of the relative ease of carrying out CD primary face synthetic modifications. The attachment of carbohydrate residues to the secondary face or both faces of CDs could have some potential advantages relative to their primary face-substituted counterparts. In addition, they present a considerable challenge in the preparation of chemically modified CDs. We have devised (41) a method for the perfunctionalization with carbohydrate residues of (1) the primary face, (2) the secondary face, and (3) both the primary and secondary faces, simultaneously, of β -CD. For the key step, our strategy relies upon (1) the well-known photoaddition of thiols to allyl ethers in an anti-Markovnikov fashion to yield thioethers, and (2) the fact that allyl ethers can be attached selectively to either or both the primary and secondary faces of CDs. The power of this methodology is demonstrated by the fact that the reaction (Scheme 12) of per-2,6-diallyl- β -CD (**54**) with an excess of β -D-thioglucose (**55**) in the presence of UV light from an Hg lamp affords, after deprotection, the fully substituted cluster compound **56** in a 70% yield. Derivatives persubstituted on either their primary or secondary faces *only* were also prepared in this straightforward manner.

Hattori and co-workers (42) have synthesized a per-substituted galactosyl cluster **57** and its monovalent analogue **58**. Using SPR-based techniques, they have estimated the binding constants of these two compounds with peanut lectin and found that the multivalent galactosyl cluster has an association constant ($K_a = 130000 \text{ M}^{-1}$) with the lectin approximately 16 times higher than that ($K_a = 8100 \text{ M}^{-1}$) of its monovalent analogue. SPR was also used to measure the association constants of the anticancer drug, doxorubicin with **58** ($K_a = 3100 \text{ M}^{-1}$) and with **57** ($K_a = 62000 \text{ M}^{-1}$). The Japanese group have suggested that the greatly increased K_a value

Scheme 12. Perfunctionalization of Both the Primary and Secondary Faces of a β -CD Core with 14 β -S-Glucosyl Residues

for the binding of doxorubicin with **57** is a consequence of the galactosyl appendages lowering significantly the rate of dissociation of doxorubicin from the CD cavity.

The use of 1,3-dipolar cycloadditions is perhaps an unusual choice of reaction to use as the key synthetic step in the attachment of carbohydrate units to CD cores. Nonetheless, Santoyo-González and co-workers (43) have prepared a galactosyl nitrile oxide derivative **59**, which, when reacted (Scheme 13) with the per-6-propargyl- β -CD derivative **60** in refluxing toluene, affords the cluster compound **61** in 79% yield. The isoxazole rings are formed in a regioselective manner, allowing the isolation of the isomerically pure compound **61**.

Calixarenes Appended with Carbohydrates. Calixarenes (**44**) are macrocyclic compounds commonly derived from the base-induced reaction of phenols with formaldehyde. They can exist in a conformation reminiscent of a basket or vase—indeed, the name calixarene is derived from a type of Greek vase called a calix. Although phenol-derived calixarenes have $[1_n]$ metacyclophane constitutions (Figure 2) and are commonly composed of four, six, or eight arene units, compounds containing other numbers of arene units are also known. All calixarenes discussed within this review contain four arenes per macrocycle and are therefore, broadly referred to as calix[4]arenes. Substituents located on the “wider rim” of the

Figure 2. (a) Condensed structural formulas for the calix[n]-arenes with the upper and lower rims of the bowl-shaped macrocycle indicated. (b) The complete structural representation of a calix[4]arene.

Scheme 13. The Use of 1,3-Dipolar Cycloaddition Reactions To Prepare a Persubstituted CD Cluster

calixarene are said to be situated on the “upper rim” of the macrocycle, while those on the “narrow rim” are said to be situated on the “lower rim” of the macrocycle. They possess an extensive host–guest chemistry, a property which makes them of potential interest to those researchers involved in developing molecular delivery vehicles. A multitude of metal cations, simple arenes, small neutral molecules and even C_{60} are all known examples of guests in both the solution and solid states—for complexation by calixarenes of varying sizes and shapes and with a range of functionalities. The literature of calixarenes has been reviewed extensively, and the reader should consult the monographs and reviews listed in ref 44 for more details.

In a pioneering study, Dondoni, Ungaro and co-workers (45) have developed methods for the attachment of carbohydrates onto calixarenes to form the so-called “calixsugars”. They anticipated that the attachment of carbohydrate substituents would induce water solubility upon the calixarene derivatives, thus opening up the possibility of being able to explore the supramolecular chemistry of calixarenes in water. They also realized that these compounds may have some useful role to play in the study of carbohydrate recognition processes. In their investigations, the Italian consortium developed synthetic routes to O-glycosyl calix[4]arene derivatives, examining how carbohydrates could be attached to both the upper and lower rims of calixarenes. The approach they have developed for the attachment of carbohydrate units to the lower rim of calix[4]arene **62** takes advantage of the

Scheme 14. The Use of the Mitsunobu Reaction in the Formation of Calix[4]arenes Mono- and Disubstituted with Protected Mannosyl Residues

Scheme 15. Preparation of a Tetragalactosyl Calix[4]arene Cluster

fact that, even although the phenolic hydroxyl groups are poor nucleophiles, they do possess acidic protons. This feature opens up the possibility to couple carbohydrates—unprotected at their anomeric centers—to the phenolic hydroxyl groups using Mitsunobu conditions. Thus, reaction (Scheme 14) of **62** with α -D-mannofuranose diacetone **63** under Mitsunobu conditions affords, in a stereospecific manner, the β -anomers of the mono- or disubstituted products **64** or **65**, depending on the number of equivalents of the acetonide used. Unfortunately, it was not possible to remove the protecting groups cleanly in order to afford the free mannosyl derivatives. Glycosylation of **62** with tetra-O-acetyl- α -D-glucopyranose under similar conditions produced a complex mixture of diastereoisomeric mono- and bis-glycosylated calixarenes—indicating clearly the limitations of using Mitsunobu conditions for the preparation of calixsugars. In an attempt to glycosylate the upper rim of calixarene derivatives, the Italian consortium have chosen calix[4]arene derivatives which are locked into

Scheme 16. The Formation of Tri- and Tetragalactosyl Calix[4]arenes by Wittig Reactions**Scheme 17. Reaction of β -Glucosyl Isothiocyanates with a Diaminocalix[4]arene To Form the Dithiurea Glucosyl Cluster**

cone conformations by four *O*-propyl groups on their lower rims. Hydroxymethyl substituents on the upper rims of these conformationally locked calix[4]arenes act as the glycosyl acceptors for thioglycoside glycosyl donors. After preparing bisglycoside-calix[4]arenes initially—only to find that these deprotected calixsugars were not water soluble—the consortium turned their attention to the synthesis of tetrakisglycoside-calix[4]arenes. Reaction (Scheme 15) of the thiogalactoside tetraacetate **66** with the protected calix[4]arene **67** affords, after deprotection, the tetrakis-*O*-galactosyl calix[4]arene **68**. This compound was found to be not only water soluble but also to act as a host toward charged guests such as D-glucosamine hydrochloride and the dihydrogenphosphate anion. Don-doni and co-workers (46) have also extended their synthetic methodology to prepare upper rim functionalized *O*-ketopyranosyl calix[4]arenes.

Concerned about the limitations imposed upon these calixarene-based carbohydrate clusters by the potentially acid labile glycosidic bonds linking the carbohydrate units to the macrocycle, Don-doni and co-workers (47) have developed another synthetic route in which the carbohydrate appendages are linked to the calixarene core by carbon–carbon bonds. Reaction (Scheme 16) of the diacetonegalactose phosphonium salt **69** with BuLi forms the corresponding phosphorane, which is then reacted with the tetraformylcalix[4]arene **70** to afford, after hydrogenation of the olefins, the tris- and tetragalactosides **71** and **72**, respectively, in a 1:1 ratio. Removal of the protecting groups in **72** by acid hydrolysis affords the free

Scheme 18. The Use of Suzuki Cross-Coupling Reactions To Prepare a Di- β -glucosyl Calix[4]arene

carbohydrate cluster **73**, which, however, is not soluble in water—further highlighting the problems of trying to modify calixarenes with appended carbohydrates to induce water solubility. Ribose analogues of these galactosyl clusters were also synthesized by the Italian group.

Santoyo-González and co-workers (48) have used the much tried-and-tested thiourea forming reaction for the attachment of carbohydrate residues to the lower rim of calixarenes. Reaction (Scheme 17) of the diamino-calix[4]arene **74** with the glucosyl isothiocyanate **34** affords, after deprotection, the bisglucosylthiourea-calix[4]arene **75**. This simple synthesis has been extended to the α -D-mannosyl, β -D-galactosyl, and D-lactosyl derivatives as well. No comments were made on the water-solubility of these particular carbohydrate clusters.

Another interesting route to calixarene-based carbohydrate clusters has been reported by Parrot-Lopez and co-workers (49). It relies upon Suzuki-type coupling reactions to attach the carbohydrate units to the upper

Scheme 19. Reaction of 2,3,4,5,6-Pentaacetyl-D-gluconyl Chloride **80 with the Diaminocalix[4]arene **74** To Afford, after Deacetylation, the Disubstituted Cluster **82****

rim of the calixarene scaffold and, at the same time, increase the cavity size of the calixarene. The diboronic acid calix[4]arene **77** can be prepared (Scheme 18) from the dibromide **76** by reaction with $n\text{-BuLi}$ and $\text{B}(\text{OMe})_3$ in THF. Cross-coupling reaction of **77** (2 equiv) with the 4-bromophenyl glycoside **78** using $\text{Pd}(\text{PPh}_3)_4$ as the catalyst afforded the bisglycosylated product **79** in 32% yield after deprotection. Removal of the acetate protecting groups proved to be troublesome, resulting in a yield of only 11% in the deprotection step. The same research group have also developed a "one-pot" synthesis of an analogous calix[4]arene, bearing one maltosyl unit. The water-solubilities of the calixarene-based carbohydrate clusters prepared in this study have not been discussed by the authors.

Lhoták and co-workers (50) have prepared some calixarene-based carbohydrate clusters with the aim of developing new molecular receptors, which, they claim, could have interesting properties on account of their chiral polyhydroxylated carbohydrate appendages. Their initial attempts to attach carbohydrate units to the lower rim of calix[4]arenes through amide bond formation

proved successful. Removal of the carbohydrate protecting groups, however, was not so easy. To circumvent this problem, they tried an alternative synthesis. 2,3,4,5,6-Penta-O-acetyl-D-gluconyl chloride **80**, which was prepared from sodium gluconate in two steps, is reacted (Scheme 19) with **74** to afford the protected compound **81** with two amide bonds in a 49% yield. Deacetylation (NaOMe/MeOH) afforded the deprotected compound **82** in an almost quantitative yield. Interestingly, **82** was found to dimerize in solution ($K_{\text{dimerization}} = 6300 \text{ M}^{-1}$ in CDCl_3), a process which presumably is occurring through intermolecular hydrogen bonding between carbohydrate residues. The complexing ability of **82** was investigated in CDCl_3 using 1-O-octyl- α -D-glucopyranoside ($K_a = 650 \text{ M}^{-1}$), 1-O-octyl- β -D-glucopyranoside ($K_a = 1050 \text{ M}^{-1}$), and 1-S-octyl- β -D-glucopyranoside ($K_a = 1000 \text{ M}^{-1}$) as guest molecules. Job plots indicated that 1:1 binding occurs between these guests and the host, although the dimerization of **82** must hamper a precise evaluation of the binding data presented. The authors are of the opinion that these binding constants are similar enough to discount any selectivity of the host toward these guests.

Roy and co-workers have also developed methods for the preparation of calixarene-based carbohydrate clusters. Realizing the lack of a suitable spacer arm between the calixarene scaffold and the carbohydrate appendages, and poor water solubility, in the calixarene-based clusters described so far, the Canadian group have designed compounds which circumvent these problems. In their initial communication (51), the Canadian group synthesized, in six steps, the calix[4]arene derivative **83**, which contains four spacer arms linked to the phenolic oxygen atoms of the calix[4]arenes' lower rim. The *N*-chloroacetyl groups present in **83** have been shown in Roy's laboratory to act as efficient substrates for the attachment of thiolated carbohydrates. Recalling their previous success in the synthesis of sialoside-coated glycodendrimers, they chose to attach α -thiolated sialosides onto the calixarene scaffold. Reaction (Scheme 20) of the thiol **84** with **83** afforded the protected cluster compound **85** in 65% yield. ^1H NMR spectroscopic evidence supports the hypothesis that the calixarene was completely substituted with four sialoside units. Deprotection of **85** afforded the final compound **86** in a quantitative yield. Fortunately, **86** was found to be fairly soluble in water (3 mg/mL). A turbidimetric analysis was performed, which indicated that **86** has a strong cross-linking ability with the lectin, wheat germ agglutinin.

The amphiphilic nature of calixarene-based carbohydrate clusters has been a hindrance to researchers in this

Scheme 20. Preparation of a Calix[4]arene-Based Tetrasialic Acid Cluster

Scheme 21. Attachment of Four α -N-Acetylgalactosyl Residues to the Lower Rim of a Tetraacid Chloride Calix[4]arene To Form the Tetra- α -N-acetylgalactosyl Cluster

field since it confers upon these compounds, at the very best, poor water solubility, and, more often than not, no solubility in water at all. However, Roy and co-workers (52) have taken advantage of the amphiphilic nature of calixarene-based carbohydrate clusters to prepare a new series of compounds which, on account of their hydrophobic upper rims, can be adsorbed onto the hydrophobic well surfaces in polystyrene microtiter plates. This observation means that amphiphilic carbohydrate cluster compounds of this particular design can be used as antigens in ELISA-type biological assays. The model carbohydrate **87**, chosen in this study, was based on the T_N antigen (GalNAc α 1 $\rightarrow$ O-Ser/Thr) without the O-Ser/Thr aglycon. The T_N antigen corresponds to one of the

Scheme 22. Preparation of an Octa- α -N-acetylgalactosyl Cluster

immunodominant epitopes found in human adenocarcinoma mucins—a class of large, heavily glycosylated glycoproteins associated with some cancerous tumors. Reaction (Scheme 21) of **87** with the readily prepared tetrachlorocalix[4]arene **88** afforded after deprotection, the tetravalent cluster **89**. A semiconvergent approach was then used to synthesize calixarenes with higher valencies. Reaction (Scheme 22) of the bromide **90**—prepared in four synthetic steps from **87**—with the extended calixarene core **91** yields the dendritic octameric cluster **92**. The synthesis has been expanded in an impressive manner to afford the hexadecamer cluster **93**. In all cases, the homogeneities of the cluster compounds were demonstrated by mass spectrometry or by NMR spectroscopy—a technique which was also used to verify that the compounds exist with the calixarene moieties

Figure 3. Condensed structural formula for the calix[4]-resorcarenes with the upper and lower rims of the bowl-shaped macrocycle indicated. A complete structural representation of a calix[4]resorcarene is also shown.

in their cone conformations. The relative lectin-binding properties of **89**, **92**, and **93** were measured with the lectin *Vicia villosa* agglutinin (VVA) which is known to bind α -D-GalNAc derivatives. In a solid-phase competitive inhibition experiment, compound **93** was found to be a very effective inhibitor ($IC_{50} = 13.4 \mu M$ —cf., a monovalent analogue with $IC_{50} = 158.3 \mu M$) of the binding of VVA with asialoglycophorin, which is a natural human blood group serotype.

Calixresorcarenes Appended with Carbohydrates.

Calixresorcarenes are a subdivision of calixarenes. Since the body of work concerning calixresorcarene-based carbohydrate clusters is unique, however, it merits having a separate subsection devoted to it. Calixresorcarenes are cyclo-oligomers (Figure 3) formed from the condensation of resorcinol with aldehydes to form macrocycles with comparable structural and host–guest properties to those of calixarenes. Calixresorcarenes exhibit similar binding and conformational properties to those of calixarenes. Consequently, they have been intensely studied (45, 53) receptors. Calix[4]resorcarenes possess eight resorcinic hydroxyl groups located on their upper rims. They serve as useful handles for the further chemical modification of these receptors. Additionally, they possess four “feet” attached to their lower rims. These feet are determined by the choice of aldehyde utilized in the synthesis of the receptor. These structural features, among others, make calixresorcarenes a useful and readily available choice of receptor for further elaboration with carbohydrate appendages.

Researchers led by Yasuhiro Aoyama have been the pioneers in the study of resorcarene-based carbohydrate clusters. In their first communication (54), this Japanese group reported the synthesis of an octagalactosyl calix-resorcarene-based cluster by reaction (Scheme 23) of the octaamine **94** with lactonolactone (**95**) to afford the galactosyl cluster **96** in a 79% yield. This compound—despite its amphiphilic nature—is soluble in water ($>0.1 M$). Dynamic light scattering experiments indicate that, in aqueous solution, it is monomeric at concentrations of $0.1 mM$, while it aggregates at concentrations of $\sim 1 mM$. When a quartz plate was dipped into an aqueous solution of **96**, electronic adsorption spectroscopy indicated that the galactosyl cluster was adsorbed onto its surface with a packing density of $3.5 nm^2$ per molecule. Additionally, it was also found that compound **96** cannot be rinsed off the plate by repeated washings with water: bases, pyridine, or amines, such as ethanolamine, are required in order to desorb the galactosyl cluster from the quartz plate. These results, supported by other experiments, indicate that compound **96** must be binding to the quartz surface through hydrogen bonding between the hydroxyl functions in the cluster and the silanol and silyl ether functionalities of the quartz surface. Another additional important experimental observation is that galactose and other carbohydrate compounds—when present in a large excess—cannot either inhibit the binding of the galactosyl cluster **96** to the quartz surface, or promote its desorption from the quartz surface. This result indicates that compound **96** must be binding to the quartz surface in a multivalent fashion, i.e., there exists a highly cooperative binding interaction between the hydroxy functions of the carbohydrate appendages of **96** and the many hydrogen bond donor/acceptor sites present on the quartz surface, resulting in the strong binding of the galactosyl cluster to the quartz surface. Additionally, compound **96** was found to form a stable 1:1 complex ($K_a = 2.2 \times 10^5 M^{-1}$) in aqueous solution with 8-anilidonaphthalene-1-sulfonate (ANS) which is located within the resorcarene cavity of **96**. Although ANS is not readily adsorbed onto a quartz surface, it is adsorbed onto this surface in the presence of compound **96**. Experiments have indicated that there is a 1:1 ratio of both ANS and **96** present on the surface. This evidence suggests that

Scheme 23. Formation of an Octagalactosyl Calix[4]resorcarene-Based Cluster **96** from the Octaamino Calix[4]resorcarene **94** and Lactonolactone **95**. Structural Formula for the Glucosyl Derivative (**97**) of **96** Is Also Shown, as Is the Cartoon Representation of Both of These Cluster Compounds

Figure 4. Schematic representation of the galactosyl cluster **96**, immobilized on a hydrophobic surface-plasmon-resonance (SPR) chip. When galactose-binding lectins are passed through the flow cell, they can bind to the immobilized **96**, inducing a refractive index change of the SPR chip.

compound **96** acts as a molecular delivery vehicle and has the ability to deliver guest molecules, with little or no affinity for a quartz surface, onto that same surface. However, since it is possible to remove the guest from the quartz surface by repeated washings, it is likely that the guest molecule is not completely encapsulated between the adsorbed galactosyl cluster and the surface.

The hydrophobicity of the alkyl chains present in the galactosyl cluster has been used (55) to form (Figure 4) a monolayer of compound **96** on a hydrophobic SPR sensor chip. Thus, the interaction of **96** with various compounds, such as lectins and other proteins, can be detected when a solution of these compounds is passed over the **96**-immobilized SPR chip. A strong interaction was detected between the galactosyl cluster and peanut agglutinin (PNA), a lectin which selectively binds galactosyl residues. A very weak interaction was, however, detected between the cluster and Con A, a lectin which selectively binds both mannosyl and glucosyl residues. Conversely, the analogous glucosyl cluster **97** was found to bind Con A but not PNA. The interaction of the clusters **96** and **97** with various monolayers has also been studied (56) using a quartz crystal microbalance. From this work, it has been reported that the clusters have a more favorable interaction with anionic and carbohydrate-based monolayers compared with cationic, zwitterionic, and nonionic monolayers.

Aoyama and co-workers (57) have also shown how these cluster compounds can be used to deliver guests to an immobilized Con A-Sepharose gel, purely as a consequence of carbohydrate-lectin interactions. Compound **96** and its glucosyl analogue **97** both form 1:1 complexes with the dye, eosin Y (**98**) with association constants of $K_a = 7.5 \times 10^5 \text{ M}^{-1}$ and $K_a = 1.8 \times 10^5 \text{ M}^{-1}$, respectively. In a simple series of experiments, the Japanese group have shown (Figure 5) that only the glucosyl cluster **97** can direct the adsorption of the guest dye **98** onto the surface of the Con A-Sepharose gel whereas the galactosyl cluster **96** cannot. Although, in reality, there is a certain amount of nonspecific binding interactions between the clusters and guest with the sepharose, the carbohydrate-lectin mediated binding is sufficiently strong to allow for a significant percentage of the guest in solution to be delivered to the Con A-Sepharose gel surface.

The Fukuoka group (58) have taken the concept of carbohydrate-directed delivery one step further and, in a most impressive piece of work, they have shown how their calixresorcurene-based carbohydrate clusters can be used to deliver guest molecules to cells. Although

Figure 5. Schematic representation of the use of the glucosyl cluster **97** to deliver the dye eosin Y **98** to the surface of sepharose immobilized Con A. The **97·98** complex forms a ternary complex with the Con A-immobilized on the sepharose. However, as the eosin Y is not completely encapsulated in the ternary complex, it can dissociate from the ternary complex, leaving the ConA·**97** complex.

carbohydrate-cell surface protein interactions are very specific, cells can also show high nonspecific affinities toward hydrophobic molecules. This problem is one which must be overcome if carbohydrate-protein interactions are to be the sole driving force for a delivery system. The Japanese group chose to study molecular delivery to hepatocyte cells (liver cells), which are known to contain a cell surface lectin—the asialoglycoprotein receptor—which specifically binds terminal galactose residues. As potential delivery vehicles, they chose the galactosyl and glucosyl clusters **96** and **97**, and as a suitable guest molecule, the fluorescent dye phloxine B (**99**). Both clusters were shown to form 1:1 complexes with **99** in phosphate-buffered saline solution with association constants of $2.0 \times 10^5 \text{ M}^{-1}$ and $2.1 \times 10^5 \text{ M}^{-1}$, respectively, for **96** and **97**. When a solution of the dye **99** was added to rat hepatoma (liver cancer) cells, these cells were found to fluoresce when viewed under a fluorescence microscope, indicating that the dye has been captured by the

cell as a consequence of nonspecific binding interactions. However, when a solution of **99** and the glucosyl cluster

97 is added to the cell (at a concentration where $\sim 100\%$ of the guest is bound by **97**), no fluorescence is detected from the cells, indicating that (1) the dye is so strongly bound by **97** that it is not available for nonspecific binding with the cell, and (2) that the glucosyl cluster is also not bound by the cell in a nonspecific manner. This hypothesis is further supported by the fact that the **96**·**99** complex is bound by the cells as a consequence of the interaction between the terminal galactosyl residues present in the cluster **96** and the asialoglycoprotein receptor on the cell surfaces, causing the cells to fluoresce when viewed under the fluorescence microscope. If mouse spleen cells—cells which lack the asialoglycoprotein receptor—are used in the experiment, then the galactosyl cluster **96** cannot deliver the dye **98** to the cells. Thus, it can be concluded that (1) the clusters **96** and **97** do not bind with the cells through nonspecific interactions, and that (2) the cluster **96** can bind with the hepatocyte cells through interaction with the cell-surface asialoglycoprotein receptor. This work highlights the important role that carbohydrates can play in the masking of hydrophobicity—in compounds such as **96**, it is only because its carbohydrate moieties mask the hydrophobicity of the calixresorcylene core sufficiently well that the carbohydrate-directed delivery of the guest dye to the cell surface is allowed to occur.

Compounds such as **96**, and its larger analogous cluster **100**, which contains 40 glucopyranosyl residues, have been shown (59) to bind various phosphate anions in water. Compound **96** also displays an interesting anion-induced agglutination. Phosphate salts such as $\text{Na}_2\text{HPO}_4/\text{NaH}_2\text{PO}_4$, D-ribose-5-phosphate and guanosine-5'-monophosphate induce the agglutination of **96**. ^{31}P NMR Spectroscopy was used to estimate the ratio of host:bound salt. In the same investigation, dynamic light scattering

Scheme 24. Formation of a Tetraglucosyl Cavitand-Based Cluster

has been utilized to demonstrate that Na_2HPO_4 can induce **96** to form aggregates which can grow up to μM -sized particles in a matter of minutes. This aggregation phenomena is almost certainly a consequence of hydrogen bonding interactions between the polyhydroxylated carbohydrate appendages of the cluster compounds and the phosphate anions, which, on account of their ability to interact with more than one cluster molecule at a time, can act as a supramolecular “glue”, sticking the clusters together. The Fukuoka group propose that the extended polyhydroxyl appendages in compounds such as **96** and **100** can act as a macrosolvent for anions, allowing these salts to be extracted from water into the unique environment of the cluster compounds.

Another carbohydrate cluster compound prepared by Aoyama and co-workers (60) has been constructed on a cavitand, i.e., a bowl-shaped macrocycle derived from calixresorcarenes. Reaction (Scheme 24) of the tetrathiol cavitand **101** with the bromide **102** affords, after deprotection, the tetraglucose cluster **103**. Maltosyl and maltotriosyl analogues of **103** have been prepared in a similar manner. These three cluster compounds were shown to bind ANS and found to interact with the lectin Con A.

CONCLUSIONS

The field of neoglycoconjugates based on cyclodextrin and calixarene cores is—at least as judged by the sheer number of recent publications—a blossoming one, with many challenges and opportunities available to researchers who can assume multidisciplinary mantles. To date, much effort has been directed toward the syntheses of neoglycoconjugates in feats which are by no means trivial—especially when recognition is granted to synthetic chemists for doing the notoriously difficult synthetic chemistry that surrounds CDs and calixarenes. It appears, however, that the synthetic problems associated with preparing these neoglycoconjugates have, to a large extent, been successfully overcome, thanks to the many varied and ingenious methods of syntheses now available to the talented synthetic chemist. By contrast, investigations of the molecular recognition properties of these neoglycoconjugates, and particularly their abilities to interact with lectins and cells, both in vitro and in vivo, have been few and far between. Thus, it seems obvious that, if the field of CD- and calixarene-based neoglycoconjugates is to continue to blossom, the emphasis in research must now be directed toward the physical and, most importantly of all, the biological evaluations of these compounds. Only when the biological chemistry is as well understood as the synthetic chemistry will the potential of this unique class of bioconjugates be truly realized and appreciated. The rewards for researchers who are willing and able to tackle real scientific issues surrounding

neoglycoconjugates in a multidisciplinary fashion are immense to say the very least.

ACKNOWLEDGMENT

We thank Dr. Bruce Turnbull for helpful discussions and Dr. Norma Stoddart for proof-reading the final manuscript. We also thank Anthony Pease for the design of the cover art work.

COMMUNICATIONS

Synthesis and Terminal Functionalization of a Polymerizable Phosphatidylethanolamine

Xue-Long Sun, Hongbo Liu, Janine M. Orban, Lijun Sun, and Elliot L. Chaikof[†]

Laboratory for Biomolecular Materials Research, Department of Surgery and Bioengineering, Emory University School of Medicine, Atlanta, Georgia 30322 and School of Chemical Engineering, Georgia Institute of Technology, Atlanta, Georgia 30320. Received March 10, 2001

We report the design and synthesis of bifunctional phospholipid conjugates, which contain a polymerizable acrylate group and a terminal linker, such as biotin or *N*-(ϵ -maleimidocaproyl) (EMC), to facilitate bioconjugation reactions. The lipid conjugate can be used to generate a multifunctional substrate-supported phospholipid film that is further stabilized via in-situ photocopolymerization.

INTRODUCTION

The generation of model lipid films that mimic cell surfaces have attracted considerable attention due to their potential as tools to probe intermolecular interactions and as bioactive coatings for sensor or medical implant applications (1, 2). Specifically, the fabrication of supported lipid membranes provides a practical method for the immobilization of transmembrane proteins, including those that serve as receptors, channels, or pores, as well as the incorporation of native or synthetic lipopeptides or glycolipids. Typically, phospholipids differing in chemical composition, saturation, and size have been utilized as the primary building blocks of the film structure (3–6). In the past two decades, lipids that contain a polymerizable group at the polar head (7–8), midchain (9), or chain terminus (6, 10–13) have been reported as a mechanism to stabilize vesicles, as well as other lipid assemblies.

We have previously reported a method to prepare stable, substrate-supported phospholipid films via in-situ photopolymerization of an acrylate functionalized phosphatidylcholine (mono-AcrylPC, **1**)¹ assembly (14–16). In the current study, we designed a novel polymerizable lipid, acrylate-functionalized phosphatidylethanolamine (mono-AcrylPE, **2**), in which the amino function can serve as a handle for further modifications. As shown in Figure 1, terminal groups, such as biotinyl and *N*-(ϵ -maleimidocaproyl) (EMC) were introduced by acylation of the amine

Figure 1. Model of a supported lipid assembly containing bifunctional phospholipid conjugates.

group of phosphatidylethanolamine. These linkers facilitate the incorporation of proteins or other target molecules via specific high affinity (biotin) interaction (17–20) or by covalent (EMC) attachment (21, 22). An example is also provided, in the case of generating a polymerizable lipid conjugate containing a fluorescent dye, which provides a mechanism for direct detection of the lipid membrane (18, 23–25). It is likely that a polymerized thin film composed of both mono-AcrylPC and mono-AcrylPE will be associated with enhanced protein binding efficiency due to inherently greater stability, compared with 2-D planar lipid assemblies that are stabilized solely by noncovalent interactions (14, 26, 27). Herein, we report the synthesis, characterization, and terminal functionalization of mono-AcrylPE (**2**).

EXPERIMENTAL PROCEDURES

General Methods. TLC was performed on Whatman silica gel aluminum-backed plates (F254, 250 μ m thickness) and detected by fluorescence quenching, sulfuric acid (10 vol % in methanol), or phosphomolybdic acid (20 wt % in ethanol). Column chromatography was performed on silica gel (Fisher Chemical, 200–425 mesh). ¹H and ¹³C NMR spectra were recorded at 300 and 75 MHz (Varian INOVA) in CDCl₃, CD₃OD (internal Me₄Si, δ = 0). Mass spectra (EI, FAB) were measured with a JEOL

JMS-SX 102/SX102A/E mass spectrometer. Confocal microscopy studies were performed on a Zeiss LSM510 Laser Confocal Microscope (Carl Zeiss, Inc., Germany) equipped with external argon (for excitation at 458, 488, and 514 nm), HeNe1 (for excitation at 543 nm), and HeNe2 (for excitation at 633 nm) lasers.

Material. Mono-AcryIPC (**1**) was prepared as described by Mara et al. (14). 3-*O*-(4-Methoxybenzyl)-*sn*-glycerol (**3**) was prepared from (+)-1,2-*O*-isopropylidene-glycerol according to the procedure described by Hebert et al (30).

1-*O*-Palmitoyl-3-*O*-(4-methoxybenzyl)-*sn*-glycerol (4**).** A solution of dicyclohexylcarbodiimide (3.7 g, 18.0 mmol) in dichloromethane (10 mL) was added dropwise over a period of 45 min at 0 °C to a solution of 3-*O*-(4-methoxybenzyl)-*sn*-glycerol (**3**) (2.0 g, 9.4 mmol), palmitic acid (2.7 g, 10.4 mmol), and *N,N*-(dimethylamino)pyridine (0.06 g, 0.5 mmol) in dichloromethane (60 mL). The reaction mixture was stirred for 18 h at room temperature under Ar atmosphere. Dicyclohexylurea was removed by filtering through Celite, and the filtrate was evaporated to give a residue, which was purified by column chromatography (SiO₂) using ethyl acetate-*n*-hexane (1:3) as eluent to afford **4** (3.0 g, 71%). ¹H NMR (CDCl₃) δ: 7.24 (d, 2 H, *J* = 9.0 Hz, Ph), 6.88 (d, 2 H, *J* = 9.0 Hz, Ph), 4.48 (s, 2 H, CH₂Ph), 4.14 (m, 1 H, CH), 4.00 (m, 1 H, CH), 3.80 (s, 3 H, OCH₃), 3.51–3.46 (m, 2 H, CH₂), 2.50 (d, 1 H, *J* = 5.1 Hz, OH), 2.31 (t, 2 H, *J* = 7.5 Hz, CH₂CO), 1.62–1.60 (m, 2 H, CH₂), 1.25 (br s, 24 H, CH₂ × 12), 0.87 (t, 3 H, *J* = 7.2 Hz, CH₃). HR-MS (EI) calcd for C₂₇H₄₆O₅: 450.33453; observed 450.33331 *m/z*.

1-*O*-Palmitoyl-2-*O*-(12-acryloyloxy)dodecanoyl-3-*O*-(4-methoxybenzyl)-*sn*-glycerol (5**).** A solution of dicyclohexylcarbodiimide (3.0 g, 13.4 mmol) in dichloromethane (10 mL) was added dropwise over a period of 20 min at room temperature to a solution of **4** (2.5 g, 5.5 mmol), 12-acryloyloxy-1-dodecanoic acid (1.67 g, 6.7 mmol), and *N,N*-(dimethylamino)pyridine (0.06 g, 0.45 mmol) in dichloromethane (30 mL). The reaction mixture was stirred for 18 h at room temperature under Ar atmosphere. Dicyclohexylurea was removed by filtering through Celite, and the filtrate was evaporated to give a residue, which was purified by column chromatography (SiO₂) using ethyl acetate-*n*-hexane (1:4) as eluent to afford **5** (3.0 g, 71%). ¹H NMR (CDCl₃) δ: 7.24 (d, 2 H, *J* = 9.0 Hz, Ph), 6.88 (d, 2 H, *J* = 9.0 Hz, Ph), 6.38 (dd, 1 H, *J* = 17.0, 1.5 Hz, CH=CH₂), 6.11 (dd, 1 H, *J* = 17.0, 10.5 Hz, CH=CH₂), 5.80 (dd, 1 H, *J* = 1.5, 10.5 Hz, CH=CH₂), 5.21 (m, 1 H, CH-2), 4.48 (d, 1 H, *J* = 11.7 Hz, CH₂Ph), 4.42 (d, 1 H, *J* = 11.7 Hz, CH₂Ph), 4.31 (dd, 1 H, *J* = 3.9, 12.0 Hz), 4.16 (dd, 1 H, *J* = 6.0, 9.9 Hz), 3.78 (s, 3 H, OCH₃), 3.54 (d, 2 H, *J* = 5.1 Hz), 2.33–2.24 (m, 4 H, CH₂CO × 2), 1.67–1.55 (m, 6 H, CH₂ × 3), 1.24 (br s, 38 H, CH₂ × 19), 0.89 (t, 3 H, *J* = 6.6 Hz, CH₃). ¹³C NMR (CDCl₃) δ: 173.94, 173.60, 166.61, 130.66, 128.81, 72.26, 64.89, 62.35, 61.52, 53.89, 34.55, 34.45, 34.28, 32.11, 29.88, 29.66, 29.60, 29.55, 29.43, 29.31, 28.77, 26.10, 25.07, 22.30, 14.30. HR-MS (EI) calcd for C₄₂H₇₀O₈-Li: 709.5231; observed 709.5211 *m/z*.

1-*O*-Palmitoyl-2-*O*-(12-acryloyloxy)dodecanoyl-*sn*-glycerol (6**).** To a solution of **5** (2.5 g, 4.2 mmol) in dichloromethane/water (18:1, 20 mL) was added 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (1.04 g, 4.6 mmol). The reaction mixture was stirred for 16 h at room temperature under Ar atmosphere. The reaction was quenched with NaHCO₃ and extracted with chloroform (20 mL × 3). The combined organic portion was dried over anhydrous Na₂SO₄ and the solvent evaporated to give a residue, which was purified by column chromatography

(SiO₂) using ethyl acetate-*n*-hexane (1:3) as eluent to afford **6** (1.4 g, 55%). ¹H NMR (CDCl₃) δ: 6.39 (dd, 1 H, *J* = 17.0, 1.2 Hz, CH=CH₂), 6.11 (dd, 1 H, *J* = 17.0, 10.8 Hz, CH=CH₂), 5.82 (dd, 1 H, *J* = 1.2, 10.8 Hz, CH=CH₂), 5.07 (m, 1 H, CH-2), 4.31 (dd, 1 H, *J* = 4.2, 12.0 Hz), 4.26 (dd, 1 H, *J* = 4.2, 13.2 Hz), 4.13 (t, 2 H, *J* = 6.9 Hz, CH₂O), 3.73 (t, 2 H, *J* = 4.2 Hz CH₂OH), 2.37–2.23 (m, 4 H, CH₂CO × 2), 1.67–1.60 (m, 6 H, CH₂ × 3), 1.24 (br s, 38 H, CH₂ × 19), 0.87 (t, 3 H, *J* = 7.2 Hz, CH₃). HR-MS (EI) calcd for C₃₄H₆₂O₇Li: 590.0035; observed 590.0021 *m/z*.

Trichloroethoxy 1-*O*-Palmitoyl-2-*O*-(12-acryloyloxy)dodecanoyl-*sn*-glycero-3-phosphoethylcarbamate (7**).** To an ice-cooled solution of dichloro(*N*-β,β,β-trichloroethoxycarbonyl-2-aminoethyl)phosphate (1.5 g, 4.4 mmol) in dichloromethane (15 mL) was added dropwise a solution of **6** (1.2 g, 2.1 mmol) and triethylamine (1.8 mL, 13.5 mmol) in dichloromethane (10 mL). The reaction mixture was stirred for 16 h at room temperature under Ar atmosphere and then washed with water (10 mL × 3). The organic portion was dried over anhydrous Na₂SO₄ and the solvent evaporated to give **7** as a light brown syrup (1.36 g, 71%), which showed high purity in ¹H NMR determination and was molybdenum blue positive on TLC (*R*_f = 0.8 CHCl₃/MeOH/H₂O, 65:25:1). Thus, this compound was used for the next reaction without further purification.

1-*O*-Palmitoyl-2-*O*-(12-acryloyloxy)dodecanoyl-*sn*-glycero-3-phosphoethanolamine (2**).** To a solution of crude **7** (1.0 g, 1.0 mmol) in acetic acid (10 mL) was added zinc dust (2.0 g). The reaction mixture was stirred for 20 h at room temperature. The reaction mixture was diluted with diethyl ether (30 mL) and filtered through Celite. The filtrate was washed with water and aqueous NaHCO₃ and dried over anhydrous Na₂SO₄. The solvent was then evaporated to give a residue, which was purified by column chromatography (SiO₂) using chloroform/methanol/water (65:25:4) as eluent to afford **2** (0.462 g, 62%). ¹H NMR (CDCl₃) δ: 8.51 (br, 3 H, NH₃⁺), 6.39 (dd, 1 H, *J* = 17.4, 1.0 Hz, CH=CH₂), 6.11 (dd, 1 H, *J* = 17.4, 10.5 Hz, CH=CH₂), 5.82 (dd, 1 H, *J* = 1.0, 10.5 Hz, CH=CH₂), 5.21 (m, 1 H, CH-2), 4.37 (dd, 1 H, *J* = 3.0, 12.3 Hz), 4.14 (t, 2 H, *J* = 6.6 Hz, CH₂O), 4.14–4.05 (m, 3 H), 3.94 (br, 2H, CH₂O), 3.16 (br, 2 H, CH₂N), 2.33–2.26 (m, 4 H, CH₂CO × 2), 1.68–1.57 (m, 6 H, CH₂ × 3), 1.24 (br s, 38 H, CH₂ × 19), 0.87 (t, 3 H, *J* = 6.6 Hz, CH₃). ¹³C NMR (CDCl₃) δ: 173.59, 173.29, 166.48, 130.59, 128.83, 70.50, 64.86, 64.63, 64.09, 62.75, 62.44, 40.61, 34.44, 34.26, 32.11, 29.50, 29.41, 28.81, 27.79, 26.14, 25.13, 25.07, 22.87, 14.30. FABMS (*m/z*): 728.6 [M + Na]⁺.

mono-AcrylPE-FITC (8**).** To a solution of **2** (50 mg, 0.071 mmol) in DMF (5 mL) was added triethylamine (0.1 mL, 0.71 mmol). After the solution was stirred for 30 min, a solution of fluorescent isothiocyanate (55 mg, 0.142 mmol) was added. The reaction mixture was stirred for 12 h at room temperature in the dark and then concentrated in a vacuum to give a residue, which was purified by column chromatography (SiO₂) using chloroform/methanol (4:1) as eluent to afford **8** (26 mg, 67%). ¹H NMR (CDCl₃) δ: 8.25 (br, 1 H, Ph), 7.25 (br, 1 H, Ph), 7.16–7.08 (m, 3 H, Ph), 6.68 (m, 4 H, Ph), 6.59 (dd, 1 H, *J* = 15.6, 1.5 Hz, CH=CH₂), 6.09 (dd, 1 H, *J* = 15.6, 10.5 Hz, CH=CH₂), 5.82 (dd, 1 H, *J* = 1.5, 10.5 Hz, CH=CH₂), 5.17 (m, 1 H, CH-2), 4.34 (dd, 1 H, *J* = 3.0, 12.3 Hz), 4.11 (t, 2 H, *J* = 6.6 Hz, CH₂O), 4.13–4.02 (m, 3 H), 3.94 (br, 2H, CH₂O), 3.36 (br, 2 H, CH₂N), 2.27–2.23 (m, 4 H, CH₂CO × 2), 1.66–1.54 (m, 6 H, CH₂ × 3), 1.24 (br s, 38 H, CH₂ × 19), 0.83 (t, 3 H, *J* = 6.6 Hz, CH₃). FABMS (*m/z*): 1096.2 [M + 1]⁺.

mono-AcrylPE-Biotin (9). To a solution of **2** (50 mg, 0.071 mmol) in DMF (5 mL) was added triethylamine (0.1 mL, 0.71 mmol). After the solution was stirred for 30 min, a solution of *N*-hydroxysuccinimidobiotin (36 mg, 0.11 mmol) was added. The reaction mixture was stirred for 24 h at room temperature and then concentrated in a vacuum to give a residue, which was purified by a Sephadex LH-20 column using methanol as eluent to afford **9** (17 mg, 53%). ¹H NMR (CDCl₃-CD₃OD) δ: 7.79 (br, 1 H, NH), 7.00 (br, 1 H, NH), 6.38 (dd, 1 H, *J* = 17.1, 1.0 Hz, CH=CH₂), 6.10 (dd, 1 H, *J* = 17.1, 10.5 Hz, CH=CH₂), 5.80 (dd, 1 H, *J* = 1.0, 10.5 Hz, CH=CH₂), 5.21 (m, 1 H, CH-2), 4.48 (m, 1 H), 4.35 (dd, 1 H, *J* = 3.0, 12.3 Hz), 4.32 (m, 1 H), 4.13 (t, 2 H, *J* = 6.6 Hz, CH₂O), 3.97 (br, 4 H), 3.24 (br, 1 H), 3.13–3.04 (br, 3 H), 2.31–2.20 (m, 5 H, CH₂CO), 1.70–1.57 (m, 6 H, CH₂ × 3), 1.24 (br s, 38 H, CH₂ × 19), 0.85 (t, 3 H, *J* = 6.9 Hz, CH₃). FABMS (*m/z*): 932 [M + 1]⁺.

mono-AcrylPE-EMC (10). To a solution of **2** (25 mg, 0.035 mmol) in DMF (5 mL) was added triethylamine (0.05 mL, 0.35 mmol). After the solution was stirred for 30 min, a solution of *N*-(ε-maleimidocaproyl)succinimide (22 mg, 0.11 mmol) was added. The reaction mixture was stirred for 24 h at room temperature and then concentrated in a vacuum to give a residue, which was purified by Sephadex LH-20 column using methanol as eluent to afford **10** (23 mg, 71%). ¹H NMR (CDCl₃) δ: 7.19 (br, 1 H, NH), 6.70 (s, 2 H, CH=CH), 6.39 (dd, 1 H, *J* = 17.4, 1.2 Hz, CH=CH₂), 6.11 (dd, 1 H, *J* = 17.4, 10.5 Hz, CH=CH₂), 5.81 (dd, 1 H, *J* = 1.2, 10.5 Hz, CH=CH₂), 5.21 (m, 1 H, CH-2), 4.37 (dd, 1 H, *J* = 3.0, 12.3 Hz), 4.29 (t, 1 H, *J* = 6.9 Hz), 4.14 (t, 2 H, *J* = 6.9 Hz, CH₂O), 4.07–4.01 (m, 3 H), 3.95 (br, 4 H), 3.15 (br, 5 H), 2.33–2.17 (m, 4 H, CH₂CO × 2), 1.68–1.57 (m, 6 H, CH₂ × 3), 1.24 (br s, 38 H, CH₂ × 19), 0.87 (t, 3 H, *J* = 6.6 Hz, CH₃). FABMS (*m/z*): 907.2 [M + 1]⁺.

RESULTS AND DISCUSSION

Unlike mixed diacyl phosphatidylcholine, mixed diacyl phosphatidylethanolamine could not be prepared directly from commercially available *lyso*-phospholipid because protection and deprotection of the ethanolamine requires additional steps (14, 29). Therefore, in this approach sequential acylation of the primary and secondary hydroxy groups of a 3-protected *sn*-glycerol was performed and followed by deprotection and phosphorylation with an *N*-protected phosphorylating agent. Subsequent global deprotection yielded the expected phospholipid.

The selective acylation of the primary hydroxy group in **3** (**30**) was performed with palmitic acid in the presence of coupling reagent dicyclohexylcarbodiimide (DCC) and *N,N*-(dimethylamino)pyridine (DMAP) to give monoester **4** and trace diester. Sequential acylation of **4** with 12-acryloxy-1-dodecanoic acid (**6**) provided a protected 1,2-diacyl-*sn*-glycerol (**5**). The *p*-methoxybenzyl (PMB) group was removed by treating it with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) to give 1,2-diacyl-*sn*-glycerol (**6**) in good yield. The phosphorylation of **6** with dichloro(*N*-β,β,β-trichloroethoxycarbonyl-2-aminoethyl)phosphate (**31**) afforded Troc-PE (**7**) which was used for the next reaction without purification. The Troc-protecting group was removed by treating crude **7** with zinc in acetic acid to yield the desired polymerizable mono-AcrylPE (**2**) as a white solid in 62% yield (Scheme 1). These compounds were characterized by NMR spectra. For example, the distinctive multiplet peaks at 5.10–5.00 ppm are characteristic of the proton at the C-2 position on the glycerol backbone of 1,2-diacylglycerol (**5**) (32), and the vinyl group of acrylate was confirmed at 6.38 (dd, 1 H), 6.11

Scheme 3. Photopolymerization of Mono-AcrylPE-FITC with Mono-AcrylPC on the Alginate Bead Surface

(dd, 1 H), 5.80 (dd, 1 H) ppm as an AMX spin system. Three additional methylene groups in compound **7** were assigned at 4.73 (2 H), 3.96 (2 H), and 3.47 (2 H) ppm as multiplet peaks. For compound **2**, the NH₃⁺ group was noted as a broad peak at 8.51 ppm (3 H) (33), and the vinyl group of acrylate was confirmed at 6.39 (dd, 1 H), 6.14 (dd, 1 H), 5.81 (dd, 1 H) ppm as an AMX spin system.

Treatment of mono-AcrylPE (**2**) with commercially available fluorescein isothiocyanate (FITC), *N*-hydroxy-succinimidobiotin (NHS-Biotin), and *N*-(ε-maleimidocaproyl)succinimide (EMCS) in the presence of triethylamine provided the desired conjugated lipid-AcrylPE-FITC (**8**), AcrylPE-Biotin (**9**), AcrylPE-EMC (**10**), all in good yield (Scheme 2). ¹H NMR spectra confirmed the anticipated structure of the lipid conjugates. Excluding lipid backbone protons, nine aromatic protons were

Figure 2. Fluorescent image of mono-AcrylPC and mono-AcrylPE-FITC coated alginate bead.

observed at 8.26 (m, 1 H), 7.40–7.30 (m, 1 H), 7.16–7.04 (m, 3 H), and 6.68–6.59 (m, 4 H) ppm for AcrylPE-FITC (**8**); two amido protons were noted at 7.79 (br, 1 H) and 7.00 (br, 1 H) ppm for AcrylPE-Biotin (**9**), and two olefin protons were observed at 6.67 (s, 2 H) ppm for AcrylPE-EMC (**10**).

Preliminary fabrication of mixed lipid films containing AcrylPE-FITC (**8**) and mono-AcrylPC (**1**) (**7**) was performed on the alkylated surface of alginate beads. Briefly, beads ($d = 300\ \mu\text{m}$) were incubated with a lipid vesicle solution composed of **8** and **1**, followed by photopolymerization using eosin Y (EY)/triethanolamine as coinitiator. The resultant beads were examined by confocal microscopy. As shown in Figure 2, the successful formation of the lipid film was confirmed by the presence of fluorescent activity on the surface of the beads while no such the activity was observed in the interior of the beads.

CONCLUSION

We have successfully developed a synthetic approach for generating bifunctional phospholipid conjugates containing both an acrylate functionality and a terminal linker, such as biotin or the *N*-(ϵ -maleimidocaproyl) functional group. These conjugates will enhance the capacity to generate stable, self-assembled, biologically functional and chemically heterogeneous, membrane-mimetic films.

ARTICLES

A Dumbbell-like Complex Formation for DNA Target Assay

Agnès Perrin, Thibault Martin, and Alain Theretz*

Unité mixte CNRS/bioMérieux, 46 Allée d'Italie, 69007 Lyon, France. Received September 18, 2000;
Revised Manuscript Received February 23, 2001

A simple and highly sensitive test for the detection of nucleic acid targets is described. It is based upon complex formation between a small-diameter magnetic particle and a larger and nonmagnetic particle through a hybridization reaction, what we have called a dumbbell-like complex. During the different steps, nonreacting nonmagnetic conjugates were eliminated by magnetic separation. At the end of the process, dumbbell complex number was estimated by counting under a microscope. Compared to the already described two-particle tests, our model was able to reach higher sensitivities, with a threshold typically in the amol/mL range (10^6 copies of HIV DNA/mL) without the need for complex instrumentation or genomic amplification reactions.

INTRODUCTION

Assays for the detection of nucleic acid targets useful in pathogen detection, identification, and susceptibility testing are increasingly used in diagnosis. Most of these use genomic amplification techniques such as polymerase chain reaction (PCR), nucleic acid sequence-based amplification (NASBA), and ligase chain reaction (LCR). These methods are able to reach the highest levels of sensitivity, but are known to be very susceptible to contamination and inhibitors. For these reasons, many papers are now dealing with the development of high-sensitivity methods which aim to avoid amplification steps. For example, authors have developed dedicated technologies and instrumentation based on piezoelectric (1) and SPR techniques (2, 3). Watts et al. (4) investigated the potential of a real-time optical sensor for hybridized DNA target quantification. They finally reached a sensitivity limit of 9.2 nM (12.1 ng). In (5), the authors conceived a DNA optical sensor. They used hybridization on a nucleic acid probe–magnetic bead conjugate to specifically extract DNA targets and, finally, used a chemiluminescent enzymatic detection which allowed them to reach the femtomole level. Another example of a DNA optical sensor was given by Piunno et al. (6), who described a hybridization bioassay on an optical fiber. Ethidium bromide was used for detection by fluorescence which allowed them to detect a minimum value of 86 ng of cDNA/mL. Other technologies including voltametric measurements were able to give good sensitivity. For instance, Hashimoto et al. (7) declared they have reached a detection threshold as low as 4×10^4 targets/mL, using a gold electrode modified with DNA probes. Flow cytometry was also used as a highly sensitive method to detect microspheres onto which stained DNA was captured (8), or to perform multiplexed DNA sequence analysis with fluorescent latex particles and oligonucleotides (9). Hakala et al. (10) detected single microparticles by time-

resolved fluorometry after specific capture of photoluminescent europium chelate labeled oligonucleotides. The ultimate sensitivity, i.e., hybridization of two single nucleic acid probes, was reached with techniques such as fluorescence correlation spectroscopy (11) or total internal reflection fluorescence microscopy (12), but analysis parameters (extremely limited volumes, low flow rate, very long analysis time) are not acceptable for medical diagnosis. As can be seen, even when good sensitivity is obtained, all these methods require the use of dedicated or complex instrumentation.

Alternately, the use of magnetic particles in immunoassays is expanding rapidly and is even becoming a generic technique known as ImmunoMagnetic Separation (IMS). Using this simple one-particle capture step, associated with sensitive detection methods such as chemiluminescence (13) or time-resolved fluorescence (14), authors significantly improved the sensitivity of conventional immunoassays. We also demonstrated the feasibility of a very sensitive Scanning Force Microscopic Immunoassay (SFMIA) associated with capture and detection of TSH antigens by the use of antibody–magnetic nanoparticle conjugates (15), which led to the detection of 1 amol of TSH/mL (i.e., 5×10^5 TSH molecules/mL). The presence of magnetic particles associated with a specific biological recognition event may also be evidenced by measuring parameters such as magnetic permeability (16) or magnetoresistance (17) with good sensitivity.

Other simple tests using two particles and aiming to have an acceptable to high level of sensitivity had already been described. Lim et al. (18) recently described an assay based on an agglutination inhibition principle test in tubes, using a large magnetic particle and a smaller colored latex particle. Detection is based upon direct observation by the user, and the sensitivity limit was said to be 16 μ g/mL of antibody (i.e., approximately 0.1 nmol/mL). Another judicious two-particle assay was proposed by Mizutani et al. (19), who studied the detected virus captured on microbeads using antibody-labeled magnetic nanoparticles. The reaction was quantified by the analy-

sis of interference fringes generated when focusing a laser beam onto concentrated nanoparticles: levels as low as 0.1 pg/mL of p24 antigen can be detected. Earlier, Kim et al. (20) described the same two-particle principle using a turbidimetric detection and obtained a sensitivity of 110 ng/mL of antibody (i.e., approximately 0.1 pmol/mL).

To our knowledge, very little work has been published on the use of the two-particle assay for nucleic acid target detection. Recently, Bains (21) described a simple agglutination format between dense and light particles which led to the detection of 10^5 DNA targets/mL in 6 h, using a sucrose density gradient and ultracentrifugation for the separation and quantification of complexes. Elghanian (22) proposed a selective colorimetric assay, based on the agglutination of modified gold nanoparticles in the presence of a DNA target which enabled detection of 10 fmol/test (3×10^{12} molecules/mL) of an oligonucleotide.

Here, we intend to describe a rapid and very simple two-particle test which has the advantage of using standard instrumentation and can detect DNA targets down to the attomole per milliliter range.

MATERIALS

Chemicals and Biochemicals. 1-Ethyl-[3-(3-dimethylamino)propyl]carbodiimide hydrochloride (EDC) and *N*-hydroxysulfosuccinimide sodium salt (NHSS) were from Fluka AG (Germany). Ethylene glycol and monoclonal anti-horseradish peroxidase (anti-HRP) antibodies and *o*-phenylenediamine (OPD) enzymatic substrate were obtained from Sigma Chemical Co. (St Louis, MO). Additional chemicals were respectively salmon sperm DNA from Boehringer, Triton X-100 from Sigma, and Tween 20 from Merck.

Oligonucleotides were obtained from Eurogentec (Belgium). The HRP modification was carried out at bio-Mérieux. Table 1 displays characteristics of oligonucleotides used throughout this paper, and Figure 1 visualizes which way the target is hybridized between both labeled nucleic acids.

Particles. Superparamagnetic streptavidin nanoparticles (145 nm diameter) were from Immunicon Corp. (Huntingdon, PA). Carboxylate polystyrene latex particles (850 nm diameter, 10.1% solids content) were obtained from Bangs Laboratories, Inc. (Fishers, IN).

Buffers. Particle coupling buffer consisted of 10 mM $\text{Na}_2\text{HPO}_4/\text{NaH}_2\text{PO}_4$, pH 6.8. Phosphate-buffered saline (PBS) was 50 mM $\text{Na}_2\text{HPO}_4/\text{NaH}_2\text{PO}_4$, pH 7.4, 0.15 M

NaCl. Particle conjugates blocking buffer was PBS, 40 mM ethanolamine, 0.05% Tween 20, and 0.5% bovine serum albumin. Particle conjugates storage buffer consisted of PBS, 0.05% Tween 20, 0.1% bovine serum albumin, and 0.05% sodium azide. Biotin binding buffer was 50 mM Tris, 100 mM NaCl, pH 7.5, and hybridization buffer was 10 mM Tris, pH 8.0, 1 mM EDTA, 1 M NaCl, 0.14 mg/mL salmon sperm DNA, and 0.05% Triton X-100.

METHODS

Synthesis of Anti-HRP/Bangs Particle Conjugates. EDC (0.1 mg) and NHSS (2 mg) were diluted in 0.4 mL of particle coupling buffer in the presence of 0.05 mg of anti-HRP antibodies. Then 10 mg of Bangs carboxylated polystyrene latex particles was added while stirring and incubated for 1 h at 37 °C. The reaction was stopped by the addition of 0.5 mL of particle conjugates blocking buffer, followed by centrifugation to precipitate microspheres (10 min at 8000 rpm). After resuspension in 0.5 mL of the blocking buffer, centrifugation was repeated once, and anti-HRP latex conjugates were finally resuspended in 0.1 mL of particle conjugates storage buffer. They were stable for several months at +4 °C.

³⁵S Radioactive Labeling of Oligonucleotides. Biotin-ODN1 was labeled with ³⁵S at its 3' end using the labeling kit from Boehringer Mannheim (Terminal Transferase 220582) and (α -³⁵S)ddATP from NEN. After incubation for 1 h at 37 °C, purification was carried out with Sephadex G25 QuickSpin columns also from Boehringer. The specific activity of the resulting 1 pmol/ μ L labeled oligonucleotide solution was measured on a liquid scintillation analyzer (1900TR) from Packard.

Synthesis of Biotin-ODN1/Immunicon Nanoparticle Conjugates. Solutions containing different concentrations of biotin-ODN1 oligonucleotides were obtained by mixing ³⁵S-labeled oligonucleotides with unlabeled (cold) oligonucleotides at known ratios. These solutions were then allowed to react for 1 h with 7×10^8 streptavidin-coated Immunicon particles in 1 mL of hybridization buffer. Excess oligonucleotides were eliminated by a series of rapid magnetizations and resuspensions in hybridization buffer. After resuspension in 0.2 mL of water, particle emission activity was measured. Knowledge of the specific activity, labeled/unlabeled oligonucleotide ratio, and remaining activity on the particles allows the calculation of the binding yield, i.e., the fraction of oligonucleotides retained on the particles. Within a maximal 8% error, no detectable loss of activity was found due to the presence of the particles, as the sum of activities measured in supernatant and on particles matched the total activity of the initial solution.

Formation of Immunicon–Bangs Dumbbells. The principle is described in Figure 2. It is known that hybridization in solution gives better reaction rates than in the solid phase, since the solid support introduces a diffusion limitation which significantly reduces kinetics (23). Hence, targets and ODN were incubated first, before introducing particles. Biotin-ODN1 (10^{12} molecules), HRP-ODN2 (6×10^{11} molecules), and an increasing number of targets (0 – 10^{10} molecules) were incubated in 1 mL of hybridization buffer for 1 h at 37 °C. Then, 7×10^8 particles of Immunicon streptavidin/magnetic particle conjugates were added and allowed to react with hybrids for 1 h at 37 °C.

Solutions were concentrated by magnetic attraction on rare earth magnets (NdFeB, diameter $\times$ height = 12 $\times$

Figure 2. Representative diagram of a dumbbell between one latex particle and one magnetic particle. First, biotin-ODN1, DNA target, and HRP-ODN2 are hybridized. Then, Immunicon magnetic particles are added for capture of hybrids. After magnetic separation, anti-HRP latex particles are incubated with the magnetic complex to form so-called dumbbells, i.e., a two-particle system for DNA capture and detection.

6 mm) for 20 min. Pellets were then resuspended with 6 mL of hybridization buffer.

A total of 10^7 anti-HRP/Bangs particle conjugates diluted in hybridization buffer were added for a final volume of 10 μ L. Incubation was carried out for 1 h at 37 $^{\circ}$ C.

Dumbbells and free magnetic nanoparticles were separated from unbound latex particles by magnetic attraction for 30 min. Pellets were resuspended once with 20 μ L of hybridization buffer and again isolated under a magnetic field. These were finally dispersed in 5 μ L of ethylene glycol. The role of this viscous solvent was to limit the particle's brownian motion, thereby making counting under a microscope easier.

The 5 μ L particle drops (V) were then deposited onto a Malassez cell defining small calibrated volumes (v) of a few picoliters. Such a cell is normally used for counting a number of cells or bacteria and turning it into a volumic concentration. After deposition of coverglasses onto the cell, latex particles were counted with an optical microscope (Olympus) equipped with a $\times 40$ lens, inside 10 compartments giving an average number of particles per compartment (n). The total number of particles (N) in the sample was extrapolated from this value ($N = nV/v$).

Dumbbell Analysis by Transmission Electron Microscopy (TEM). Purified dumbbells obtained with various target concentrations were deposited onto formvar carbon film TEM grids (Ted Pella Inc.) and analyzed on a Philips CM120 microscope under a 80 kV voltage. Controls were carried out to ensure that the drying process did not induce magnetic nanoparticle adsorption onto latexes. Also, samples were analyzed before and after magnetic separation to make sure that this step does not produce false dumbbells.

RESULTS

Characterization of Anti-HRP/Bangs Particle Conjugates by Size Measurement. To check that antibody grafting onto latexes did not induce aggregation, the size of grafted particles was measured by quasi-elastic light scattering using a Zetasizer 3000 (Malvern). No consequent diameter modification was measured before (883 ± 9 nm) and after coupling (905 ± 3 nm). Also, microscopic observation of conjugates revealed the absence of aggregates.

Immobilization Yield of Biotin-ODN1 onto Immunicon Nanoparticles. To avoid competition between free biotin-ODN1 in excess and those hybridized with

Figure 3. Binding yield of biotin-ODN1 onto streptavidin Immunicon particles as a function of the initial number of biotin-ODN1 molecules in solution estimated using radiolabeled oligonucleotides. Increasing concentrations of ^{35} S-labeled nucleotides are incubated in the presence of magnetic particles. After magnetic separation, the radioactivity is measured directly on the resuspended particle solution, and the number of nucleotides per particle is calculated.

targets, the binding capacity of streptavidin/Immunicon nanoparticles has to be greater than the total number of biotin-ODN1 molecules. In that perspective, the use of solutions containing radiolabeled biotin-ODN1 enabled an estimation of the fraction of ODNs that remained immobilized onto the particles. This binding yield is shown in Figure 3 as a function of the initial number of biotin-ODN molecules in solution.

With an initial number of 10^{12} biotin-ODN1 molecules, this figure indicates that the bonding yield is higher than 97%. Hence, there is no competition between free and hybridized biotin-ODN1 molecules in the dumbbell formation conditions: both are equally immobilized onto streptavidin/Immunicon nanoparticles. This biotin-ODN1/Immunicon particle ratio will thus be used throughout the following experiments.

Dumbbell Isolation Efficiency by Magnetic Separation. First, the efficiencies of magnetic nanoparticle conjugate separation and latex particle conjugate elimination were estimated separately.

Magnetic Nanoparticle Recovery Yield during the Magnetic Separation Step. A total of 100% of the Immunicon nanoparticles was extracted within 10 min when diluted in 1 mL of buffer, by placing the tube against a rare earth permanent magnet. This was determined by measuring the optical density of the particle solution before and after separation at 460 nm.

Latex Particle Elimination Yield. Solutions containing only latex particles at the same concentration as those used for dumbbell formation (10^7 particles in 10 μ L) were placed in the tube. Supernatant was discarded twice, and the remaining particles—later called washing noise—were counted under the microscope. An elimination yield of more than 99% was obtained. Considering the initial number of particles (10^7), the sensitivity of the assay is thus limited to less than 10^5 targets by this washing noise.

Separation of Dumbbells. The efficiency of dumbbell retention, in the presence of two types of particles at the same time, was estimated. The separation duration was extended to 30 min (instead of 10 min for isolated Immunicon particles) because of drag forces exerted on latex particles which are supposed to slow their motion.

To evaluate a possible loss of dumbbells between two separation cycles, the number of latex particles was

Figure 4. TEM analysis of dumbbells for increasing target numbers. (A) False dumbbells due to the nonspecific adsorption or the drying of a magnetic particle on latex (no magnetic separation or any other process). (B) No target in solution. (C) 10^7 targets. (D) 10^9 targets. (E) 10^{10} targets before magnetic separation. (F) Same sample as (E) (10^{10} targets) after magnetic separation.

evaluated in the same sample after the first and second separation steps. It was shown that as much as 50% of dumbbells can be lost in this way in the presence of 10^8 targets. Two possibilities can explain this loss: First, due to their low magnetic charge, some dumbbells are discarded while sucking up the supernatant, as the magnet can only exert weak magnetic forces. Second, the liquid meniscus also exerts strong capillary forces on the particle's spot and probably carries along the same poorly magnetic complexes.

Dumbbell Study by TEM. Electron microscopy is one of the few methods enabling observation of the structure of dumbbells. Controls ensure that the sample preparation drying step did not induce the formation of a large number of false dumbbells, i.e., nonspecific adsorption of one or several magnetic particles onto one latex. Contrary to the washing noise, these latex particles cannot be eliminated during magnetic washes since they are sensitive to the magnetic field as well as specific dumbbells. For this purpose, latexes, magnetic particles, and oligonucleotides were mixed briefly in the absence of targets, and immediately deposited onto grids. A few

isolated latexes were found to bear magnetic particles as shown in Figure 4A. In this figure, isolated Immunicon particles as well as latex are clearly defined. The structure of the magnetic particles is irregular and varies in shape and size. Some of them are seen on the bottom of the grid, and one seems to be immobilized on the latex. A kind of gel structure that may contain Immunicon particles is also often observed close to the latex. In any case, it was not possible to determine whether this false dumbbell was formed during the short contact time between particles before grid preparation, or during the drying itself. This phenomenon was limited, and the analytical method was not questioned.

Another control was performed to ensure that magnetic attraction did not induce the formation of false dumbbells by forcing the contact between both types of particles. A sample in the presence of 10^{10} targets was analyzed before (E) and after (F) separation. In both cases, latex aggregates are observed, proving that magnetic attraction is not in question. In panel E, salt deposits appear since the saline buffer was not eliminated from the sample as is the case for panel F.

Figure 5. Variation in the number of latex particles as a function of the number of targets in solution. First, biotin-ODN1, increasing concentrations of DNA targets, and HRP-ODN2 are hybridized. Then, Immunicon magnetic particles are added for capture of hybrids. After magnetic separation, anti-HRP latex particles are incubated to form dumbbells. These dumbbells and free magnetic particles are washed twice to eliminate unbound latexes, resuspended in ethylene glycol, and deposited in a Malassez cell for counting under a microscope, and finally particle numbers are determined as a function of initial DNA concentration.

Aggregate size varied as a function of target concentration. Images B (0 target), C (10^7 targets), D (10^9 targets), and F (10^{10} targets) demonstrate the evolution of the dumbbell format into a typical agglutination reaction. As a matter of fact, beyond 10^7 targets, the target/latex particle ratio is greater than 1, which led to the possibility for particles to bind to each other via several targets and several Immunicon particles.

Cluster size distribution is, of course, observed in each sample. As can be seen, latex particles are linked through the intermediate of magnetic nanoparticles. This confirms the specific aspect of the reaction and that these are not aggregates due to simple nonspecific adsorption between latex particles. These clusters are distinguishable from the few observed on the drying control sample. Also, a decrease in the number of isolated Immunicon particles on the bottom of the grid is observed as the target concentration increases, since more of them are involved specifically in dumbbells and immobilized onto latexes.

Assay Sensitivity. Increasing concentrations of targets were assayed, and the resulting dumbbells were counted under an optical microscope after depositing the sample in a Malassez cell. As a matter of fact, only the latex particles are seen and counted under the optical microscope. Magnetic nanoparticles are not visible and thus do not interfere with the measurement. Results are described in Figure 5. A weak error in particle counting can be attributed to the confusion between roughly spherical dusts and true colloids. Furthermore, the standard deviation on each concentration point—an average of 10 measurements on the same sample—is important (20–30%) since it was not possible for the experimenter to evaluate a very large amount of particles that would statistically better represent the sample.

The sensitivity threshold is defined as the minimal target concentration enabling a detection signal higher than that obtained for the background plus 3 times the standard deviation on the noise value to be reached. From this calculation, below 10^6 targets/mL, it was not possible to discriminate background from specific signals. About 7×10^4 latex particles were counted in this sample,

Figure 6. Evaluation of dumbbell formation yield, i.e., the percentage of latex counted at the end of the process over the number of targets. For each target concentration, the particle number obtained from Figure 5 after background subtraction is divided by the number of targets initially introduced in the solution.

representing 0.7% of the initial quantity. This background is essentially due to washing noise (latex particles not eliminated during the washing steps) for 0.1% (estimated as described in the section Dumbbell Isolation Efficiency by Magnetic Separation, by processing latex particles alone) and to false dumbbells (nonspecific adsorption of magnetic nanoparticles onto latex microspheres) for about 0.6%. Nonspecific interactions might be due to electrostatic or hydrophobic interactions between latexes and magnetic particles. TEM was used to ensure that the magnetic separation did not enhance false dumbbell formation to a significant extent.

A significant increase in the number of particles is observed under an optical microscope beyond 10^6 targets/mL, which represents a sensitivity threshold of 2 amol/mL. It is also observed that the presence of latexes becomes detectable by the naked eye beyond 10^8 targets/mL.

The reaction yield, i.e., the ratio between the number of specific dumbbells and the number of targets in solution, was estimated from Figure 5 by subtracting the background from the number of latex particles for each target concentration, and is depicted in Figure 6.

Best yields were obtained for low target concentrations, and did not exceed 5%. Such a result can be explained by method limitations described above. First of all, the capture of hybrids onto latex particles may be limited intrinsically by the affinity of the HRP/anti-HRP antibody system. Furthermore, TEM pictures showed that Immunicon particles are rough and not spherical, which probably enhances steric hindrance during the binding of the two particles. Also, the nonspecific latexes—false dumbbells plus washing noise—limit the sensitivity threshold.

Beyond 10^7 targets, as seen in the TEM section, there is statistically more than 1 target per latex, and the drawing in Figure 2 showing 1 latex and 1 magnetic particle per target is not representative. Clusters of particles are formed, leading to a drop in reaction yield.

DISCUSSION

As demonstrated, this assay reached a very high sensitivity threshold, in the attomole per milliliter range. It is easy to use, does not need complex instrumentation, and avoids tedious amplification techniques.

However, we identified several drawbacks which currently limit the overall sensitivity. Possible approaches to further enhance the assay performance are discussed below.

(a) Capture of hybrids on latex particles may be limited by the affinity of the HRP/anti-HRP antibody system. It would be worthwhile testing other systems that may have a better affinity: other antibody/antigen pairs or DNA-labeled particles.

Furthermore, on TEM pictures, Immunicon particles showed a bumpy structure which may induce steric hindrance and is probably not the most suitable for dumbbell formation. We would probably benefit from working with spherical and smooth magnetic particles. Currently, other commercial particles as well those synthesized in our lab are being tested.

(b) A large proportion of dumbbells—up to 50%—are lost during magnetic separation. The process has to be improved by developing specifically suited systems. Furthermore, particles with higher iron oxide contents would enable more magnetic dumbbells to be obtained, which are better retained on magnets. Nevertheless, attempts with larger and easily isolated particles such as Dynal (2.8 μm diameter) or Seradyn (1 μm diameter) gave no satisfactory sensitivity (detection threshold beyond 10^{10} targets/mL, data not shown). It is believed that the lower diffusion coefficient of larger linked particles limits their motion and, therefore, their binding rate onto latexes. On the other hand, testing with smaller and weakly magnetic particles from Miltenyi (50 nm diameter), used with High Gradient Magnetic Separation systems (24), led to intermediate results (10^7 targets/mL). In conclusion, particles easier to isolate than Immunicon, but whose size does not exceed 200 nm, should be a good choice.

(c) About 0.8% of the latexes initially introduced, resulting from the nonspecific interaction between magnetic nanoparticles and latex particles, are found in the samples in the absence of targets and, thus, restrict sensitivity. The formation of false dumbbells may be limited by working on treatments to reduce nonspecific adsorption of magnetic particles onto latexes.

Another possibility may be to use smaller latexes which are easier to carry in the magnetic fields and to retain on magnets while discarding supernatant. For the moment, assays in this direction show that it is necessary in this case to increase the number of latexes to maintain the same reactive surface, which finally induces an important level of background, which is harmful for sensitivity.

(d) The manual detection counting was shown to induce large standard deviations in the final results. It would be profitable and less tedious for the experimenter to set up an automated system enabling particles to be counted to a larger extent. Furthermore, the use of fluorescent particles would avoid the confusion between dusts and latexes. Besides, an interesting option would be to count particles using systems based on laser light scattering.

CONCLUSION

The assay described in this paper enabled a very high level of sensitivity for DNA target detection (10^6 molecules/mL) to be reached without the use of sophisticated technologies. With the reaction being detectable by the

naked eye beyond 108 targets/mL, applications may be considered for the rapid and sensitive assay of pathogenic material in difficult conditions, i.e., outside the analysis laboratory.

Optimizations are foreseen with the aim of pushing the sensitivity threshold one step beyond. This could allow the simple detection of pathogen nucleic acids, without the use of amplification techniques and their associated drawbacks. Applied to the identification of infectious diseases, this test could also have a high potential in early diagnosis and susceptibility testing. These results and experiments have been included in the bioMerieux patent 99/10675.

On the Preparation, Characterization, and Enzymatic Activity of Fungal Protease–Gold Colloid Bioconjugates

Anand Gole,[†] Chandravanu Dash,[‡] Chinmay Soman,[†] S. R. Sainkar,[†] Mala Rao,[‡] and Murali Sastry^{*,†}

Materials Chemistry and Biochemical Sciences Division, National Chemical Laboratory, Pune 411 008, India.
Received October 5, 2000; Revised Manuscript Received February 15, 2001

We present herein details pertaining to the preparation of bioconjugates of colloidal gold with aspartic protease from the fungus *Aspergillus saitoi* (F-prot) and their characterization and enzymatic activity. Simple mixing of the colloidal gold and protein solutions under protein-friendly conditions (pH = 3) followed by centrifugation (to remove uncomplexed gold nanoparticles and protein molecules) results in the formation of the fungal protease–gold nanoparticle conjugates. The protein–gold nanoparticle bioconjugate was redispersed in buffer solution and indicated the formation of efficient bioconjugates with intact native protein structures. The bioconjugates in solution were characterized by UV–vis spectroscopy, fluorescence spectroscopy, and biocatalytic activity measurements while drop-dried bioconjugate films on Si (111) substrates were characterized by scanning electron microscopy (SEM), energy dispersive analysis of X-rays (EDAX), and X-ray diffraction (XRD) measurements. Microscopy images do show some aggregate formation, but the intactness of the native structure of the enzyme in the bioconjugate material was verified by fluorescence and biocatalytic activity measurements. The enzyme retains substantial biocatalytic activity in the bioconjugate material and was comparable to that of free enzyme in solution.

INTRODUCTION

Colloid chemistry includes the study of a wide range of entities spanning micron-sized to nanometer-sized particles, the properties of the particles being vastly different from that of the bulk material. There has been a great deal of research in different areas of colloid chemistry, viz., protein chemistry, inorganic nanoparticles such as quantum dots, clay materials, interfaces, and membranes, to name a few. Combination of different branches of colloid chemistry is an important goal with exciting spin-offs expected in industrial, medical, and advanced materials applications. Potential applications in the food, chemical, and agriculture industries, markers in electron or standard light microscopy and medicine such as drug delivery systems, efficient immunosensing assays for early detection of diseases, etc., has seen an explosion in the research and design of a new class of materials commonly known as bioconjugates. Formation of bioconjugates by immobilization protocols into different 2D and 3D matrixes is currently a great challenge as far as the stability, accessibility, shelf life, transportation, cost, and ease of manufacturing etc. are concerned. An important requirement for immobilization is that the biomolecule in the bioconjugate material should remain in its natural form and should be able to carry out necessary functions as efficiently as in solution. To date, biomolecules such as proteins have been immobilized on/within various supports such as phospholipid bilayers,¹ self-assembled monolayers,² Langmuir–Blodgett films,³ polymer matrixes,⁴ the galleries of α -zirconium phosphates,⁵ in hydrophobic controlled pore-glasses,⁶ and in

films of thermally evaporated fatty lipids.⁷ All these systems deal with single protein immobilization protocols. In a different approach, Caruso and co-workers have demonstrated that the layer-by-layer (L-B-L) method can be used for the formation of multilayer protein–polymer conjugates.^{8a,b} In this method, electrostatic attraction between alternately deposited charged species of proteins and polyelectrolytes is used to form multilayer planar films.

Studies on using colloidal particles as a versatile and efficient three-dimensional (3-D) template for the immobilization of biomolecules has been recognized since the early 1980s.⁹ Immunomicrospheres, as one class of conjugate-colloids are called, can be defined as specially designed microscopic particles that have antibodies or similar molecules chemically bound to their surfaces.⁹ Appropriately coated colloidal particles can be used to react in a very specific way with antigens, target cells or viruses, depending on the type of antigen adsorbed on the microspheres. Immunomicrospheres have opened up new opportunities in the development of techniques for disease diagnosis and therapy.

A number of groups have studied the adsorption of proteins on both organic and inorganic colloidal particles. As an extension of planar surfaces, Caruso et al. have successfully extended the L-B-L technique to form multilayer protein layers on polymer colloidal systems.^{8c,d} The multilayers of proteins on colloidal particles increases the density of biomolecules and thus, their sensitivity in different applications. The stabilization of colloidal particles of polymers by proteins has been studied by Molina-Bolivar et al.¹⁰ Covalent attachment of immunoglobulins to the surface of polystyrene latex colloidal particles has also been demonstrated.¹¹ Schmitt et al.¹² have reported on a monomolecular layer of bovine serum albumin (BSA) on the surface of polystyrene (PS) latex particles. Elgersma et al. have demonstrated the

adsorption of BSA on positively and negatively charged polystyrene lattices.¹³

The interaction of noble metal colloidal particles such as gold and silver with proteins/enzymes as well as the study of the enzymatic activity of the nano-bioconjugates has also received attention. Natan and co-workers have studied in great depth cytochrome *c*–gold colloid conjugates as regards stability, protein orientation, and application in surface enhanced Raman scattering (SERS) and found that metal–protein–metal sandwiches offer benefits as reagents for protein SERS.¹⁴ Macdonald and Smith have studied the orientation of cytochrome *c* adsorbed on citrate-reduced silver colloids.¹⁵ Single molecule spectroscopy (SMS) of the hemoglobin molecule adsorbed on 100 nm sized citrate-reduced silver colloidal particles was achieved by SERS.¹⁶ Silver particle aggregation is necessary for this effect, and the protein molecules actually bind the Ag particle clusters together.¹⁶ In the area of metal nanoparticle–enzyme conjugate materials, Crumbliss, Stonehuerner, and co-workers have studied the formation and enzymatic activity of gold nanoparticles complexed with horseradish peroxidase^{17a} and xanthine oxidase^{17b} as well as glucose oxidase and carbonic anhydrase molecules.^{17c} A salient feature of their work is the demonstration that enzyme molecules are bound tightly to gold colloidal particles and retain significant biocatalytic activity in the conjugated form while the enzyme molecules denature on adsorption to planar surfaces of gold.^{17c}

As part of our ongoing investigation into the formation and catalytic activity of enzyme–bioconjugate materials,⁷ we investigate herein the immobilization of fungal protease (F-prot) molecules on 3-D supports such as colloidal gold particles, leading to the formation of efficient bioconjugates. We observe significant catalytic activity of the F-prot molecules in the F-prot–Au colloid bioconjugate material which indicates that the enzyme molecules are immobilized without distortion to the enzyme native structure. The bioconjugates of 35 Å colloidal gold particles with the enzyme F-prot are formed under enzyme-friendly conditions (at pH = 3) where the enzyme shows optimum catalytic activity. The bioconjugate was prepared by simple addition of the F-prot molecules to the colloidal gold solution held at pH = 3. Thereafter, the F-prot gold colloid solution was centrifuged to remove uncoordinated F-prot molecules in solution to yield the purified F-prot–Au colloid bioconjugate material. The purified F-prot–Au colloid bioconjugate material was resuspended in appropriate buffer solution after rinsing several times. UV–vis spectroscopy was used to monitor the surface derivatization before and after centrifugation/resuspension. The bioconjugate material were further characterized by scanning electron microscopy (SEM), energy dispersive analysis of X-rays (EDAX), X-ray diffraction (XRD), fluorescence spectroscopy, and biocatalytic activity measurements. The amount of F-prot on the colloidal gold surface was quantified by fluorescence spectroscopy and used for the determination of specific activity of the enzyme. The specific activities of the enzyme on the surface of colloidal gold and that of free enzyme in solution are comparable, indicating that the enzyme in the bioconjugate is in its active natural conformation. Presented below are details of the investigation.

EXPERIMENTAL SECTION

Chemicals. F-prot and hemoglobin were obtained from Sigma Chemicals and used without further purifi-

cation. Chloroauric acid and sodium borohydride were obtained from Aldrich Chemicals and used as received. All buffer salts were from standard commercial sources and of the highest quality available.

Colloidal Gold Synthesis. Colloidal gold was synthesized by the borohydride reduction of 1.25×10^{-4} M concentrated aqueous solution of chloroauric acid (HauCl_4). This process yields 35 ± 7 Å sized colloidal gold particles as shown previously by us.¹⁸ The colloidal solution was aged for a period of 12 h. The ruby red colored solution yielded an absorbance maximum at 518 nm.¹⁸

Formation of F-prot–Colloidal Gold Bioconjugates. A 10^{-6} M standard solution of the enzyme, F-prot (molecular weight ~ 37000 , pI ~ 9.5) was prepared in glycine·HCl (0.05 M, pH = 3) buffer. Different amounts of this standard solution were added to colloidal gold to yield an F-prot concentration of 10^{-7} , 10^{-8} , and 10^{-9} M in the conjugate solution. The pH of the colloidal gold solution was adjusted to 3 prior to addition of F-prot. This was done since F-prot shows optimum biocatalytic activity at pH = 3. The solution was kept for a period of 12 h at 4 °C and then centrifuged to remove uncoordinated F-prot and free gold particles in solution. The powder so obtained was rinsed several times with buffer solution and then resuspended in the pH = 3 buffer and stored at 4 °C for further experimentation.

UV–Vis Spectroscopy. The formation of the F-prot–gold colloid bioconjugate was studied by UV–vis spectroscopy using a Shimadzu dual-beam spectrophotometer (model UV-1601 PC) operated at a resolution of 1 nm. The absorbance band above 500 nm arising from excitation of the surface plasmon resonance in the gold particles^{18,19} and the resonance at 280 nm due to the π – π^* transition in the tryptophan and tyrosine residues of the enzyme²⁰ were monitored immediately after addition of F-prot to the gold solution as well as after centrifugation/resuspension. Three separate sets of F-prot–gold colloid bioconjugate solutions were prepared and tested for the above UV–vis signatures in order to check the reproducibility of the data.

Scanning Electron Microscopy (SEM) and Energy Dispersive Analysis of X-rays (EDAX). SEM and EDAX measurements were performed on a Leica Stereoscan-440 scanning electron microscopy (SEM) equipped with a Phoenix EDAX attachment. A drop-dried F-prot–gold colloid bioconjugate film (10^{-7} M F-prot in the bioconjugate solution) on Si (111) substrate was used for the analysis. SEM analysis was primarily used to observe the morphology of the bioconjugates in the film.

X-ray Diffraction Studies (XRD). A few drops of the centrifuged/resuspended F-prot–gold colloid bioconjugate solution were placed on 2 cm $\times$ 2 cm Si (111) substrates and dried in air. XRD measurements of these films were made on a Philips PW 1830 instrument operating at 40 kV voltage and a current of 30 mA with Cu K_α radiation. The size of the colloidal gold particles in the bioconjugate film was estimated from the peak width of the (111) Bragg reflection using the Debye–Scherrer formula.²¹

Tertiary Structure Studies. Fluorescence spectroscopy is a powerful tool to study the tertiary structure of proteins and enzymes. The fluorescence of the F-prot–gold colloid bioconjugate solution was studied using a Perkin-Elmer Luminescence Spectrometer (model LS 50B). The tryptophan and tyrosine residues in the enzyme were used for excitation at 280 nm, and the broad emission band having a maximum at about 336 nm was recorded.²² Fluorescence spectra of bare colloidal gold particles in water and that of the buffer used were also recorded as control experiments. As expected, these

controls did not show any emission in the region of interest (ca. 336 nm).

Estimation of Amount of F-prot in the Bioconjugate Composite System. The fluorescence emission intensities at ca. 336 nm²² due to excitation of tryptophan and tyrosine residues in the enzyme (absorption at 280 nm) were recorded for different concentrations of the free enzyme in buffer solution, and a calibration curve was obtained. The amount of F-prot in the different bioconjugate solutions prepared in this study was estimated by comparing the intensity of fluorescence emission at 336 nm in the bioconjugate solution with the calibration curve for this protein. The amount of F-prot estimated in this fashion was then used to calculate the specific activity of the enzyme in the bioconjugate solution.

Biocatalytic Activity Measurements. The biocatalytic activity of the centrifuged/resuspended F-prot–gold colloid bioconjugate solution was determined by reaction with a solution of hemoglobin (5 mg/mL) prepared in glycine·HCl buffer at pH = 3. F-prot is a proteolytic enzyme which acts on proteins such as hemoglobin²³ and has been successfully used by us in studies on thin films of the enzyme immobilized in fatty lipid films.^{7b} The enzyme fungal protease is not a well-studied system, and consequently information on specific chromogenic or fluorogenic substrates is not available. This has prompted us to use hemoglobin as a substrate in estimating the specific activity of the enzyme in the F-prot–gold colloid bioconjugate solution and of the free enzyme in solution. In a typical experiment to estimate the biocatalytic activity of the bioconjugate solution, 1 mL of the solution consisting of 100 μ L of the F-prot–gold colloid bioconjugate material and 0.9 mL of the buffer was reacted with 1 mL of the hemoglobin solution, and the reaction mixture was incubated at 37° C for 30 min. After the incubation time, 1.7 M perchloric acid was added to the reaction solution to precipitate the remaining hemoglobin. After 30 min, the precipitate was removed by centrifugation and the optical absorbance of the filtrate measured at 280 nm. F-prot digests hemoglobin and yields acid soluble products (tryptophan and tyrosine residues) which are readily detected by their strong UV signatures at 280 nm.²⁰ From the amount of F-prot estimated from the fluorescence studies, the specific activity of the enzyme was calculated. For comparison, the biocatalytic activity of similar concentration of free F-prot in solution was recorded. To check the reproducibility of the biocatalytic activity measurements, 10 separate measurements of the F-prot–gold colloid bioconjugate material were performed as mentioned above, and the average specific activity was calculated.

RESULTS AND DISCUSSION

The choice of colloidal gold in the formation of bioconjugates is dictated by a number of advantages which these particles display. The striking ruby red color of colloidal gold makes it an ideal medium for colorimetric determination of molecular recognition processes as has been demonstrated for the prototypical biotin–avidin interaction.²⁴ Colloidal gold has been used extensively by Mirkin, Letsinger and co-workers in the immobilization of oligonucleotides and detection of complementary base sequences by changes in the visible absorption spectra.²⁵ The surface of colloidal gold does not require modification for chemisorption of proteins/enzymes as in the case of organic colloids. The ease of characterization of colloidal gold by observing colorimetric changes upon immobilization of analytes from solution, its biocompatibility, the

Figure 1. (A) UV–vis spectra of the colloidal gold solution before (curve 1) and after addition of 10^{-6} M F-prot to the colloidal gold solution at pH = 3 (curve 2) to give an equilibrium concentration of 10^{-7} M of F-prot in the bioconjugate solution. (B) UV–vis spectra of F-prot–gold colloid bioconjugate solutions after centrifugation, rinsing and resuspension in pH = 3 buffer. The spectra corresponding to concentrations of F-prot in the starting bioconjugate solutions are curve 1– 10^{-7} M, curve 2– 10^{-8} M, and curve 3– 10^{-9} M.

stability of enzymes on colloidal gold particle surfaces (as also observed by Stonehuerner et al),¹⁷ the simplicity of bioconjugate formation by just addition of proteins/enzymes to the colloidal gold solution, and the fact that the surface does not require premodification has led to the choice of colloidal gold in the formation of bioconjugates of F-prot in this study.

Preparation of F-prot–Colloidal Gold Conjugates. The as-prepared pH of colloidal gold by the borohydride reduction procedure is ca. 9.¹⁵ The enzyme, F-prot, has a pI of about 9.5 and shows optimum catalytic activity at pH = 3,^{7b} and hence the pH of colloidal gold has to be lowered prior to addition of F-prot. As mentioned in the Experimental Section, 10^{-6} M standard solution of F-prot was prepared in glycine·HCl (0.05 M, pH = 3) buffer and added to colloidal gold solution at pH = 3, to form equilibrium F-prot solution concentrations of 10^{-7} , 10^{-8} , and 10^{-9} M, respectively. It is well-known that thiol groups bind to the gold surface via a covalent bond.¹⁸ Cysteine residues on the surface of F-prot molecules may thus bind to the colloidal gold particles via a thiolate linkage. Support for cysteine-mediated binding of enzyme to the gold colloids comes from the report of Sasaki et al.²⁶ who demonstrated that the functional protein, myosin subfragment 1, binds to gold thin films through an Au–S bond involving cysteine residues in the protein. It has been reported in the literature that alkylamine molecules form a weak covalent bond with colloidal gold surfaces.²⁷ Natan and co-workers indicate the role of the NH_2 group in lysine rich pockets for the binding of proteins to the colloidal gold surface.¹⁴ We believe that the binding of fungal protease to colloidal gold is covalent in nature and occurs either via the cysteine or lysine residues or a combination of both. The number of cysteine and lysine residues in the enzyme capable of binding to the gold particle surface would require detailed information regarding the amino acid sequence in F-prot which is not available at the moment.

Figure 1A shows the UV–vis spectra recorded from the gold colloidal solution before (curve 1) and after (curve 2) addition of the F-prot solution (overall F-prot concentration in the solution = 10^{-7} M). The spectra have been displaced vertically for clarity. The surface plasmon resonance due to gold can be clearly seen at about 520

Figure 2. (A) SEM image of a film of the F-prot–gold colloid bioconjugate material drop-dried on a Si (111) substrate (see text for details). (B) SEM image of an aggregate of F-prot and gold colloidal particles in a drop-dried film of bioconjugate material at higher magnification (see text for details).

nm¹⁸ for the as-prepared gold solution (curve 1, Figure 1A). On addition of F-prot, a broadening and red shift of the plasmon resonance is seen (curve 2, Figure 1A) and clearly indicates surface coordination of F-prot with the gold particles. The broadening of the plasmon resonance is also indicative of some degree of aggregation of the gold particles mediated by the protein molecules. The absorbance at about 280 nm seen prominently in the F-prot–gold colloid bioconjugate solution (curve 2, Figure 1A) is due to the π – π^* transitions in the tryptophan and tyrosine residues in the enzyme.²⁰ The spectra for other concentrations of F-prot (10^{-8} and 10^{-9}) gave similar features and are not shown for brevity. The bioconjugate solutions were stored for a period of 12 h at 4 °C before centrifugation and resuspension. UV–vis spectra of the F-prot–gold colloid bioconjugates recorded after centrifugation, rinsing, and resuspension in water for 10^{-7} , 10^{-8} , and 10^{-9} M F-prot in the starting bioconjugate solution are shown as curves 1–3, respectively, in Figure 1B. It is observed that both the surface plasmon resonance intensity from the gold particles as well as the concentration of F-prot molecules in the resuspended bioconjugate solution (as evidenced by the intensity of the absorption at 280 nm) scale with the concentration of F-prot molecules in the starting solution (i.e., the solution prepared prior to centrifugation). Thus, a larger number of gold particles are required to stabilize a greater concentration of F-prot molecules in solution and provides a simple recipe for increasing the loading factor of the enzyme molecules in the bioconjugate material. The magnitude of the absorbance at 280 nm in the case of 10^{-7} M F-prot–gold colloid bioconjugate material before centrifugation is about 0.3 absorbance units which is reduced to 0.06 absorbance units after centrifugation and resuspension. This is also true for other concentrations of F-prot in the bioconjugate material and indicates that the large decrease in intensity of this band is due to removal of uncoordinated F-prot molecules from the respective solutions. Three separate experiments each of bioconjugate formation, rinsing, and resuspension for the three concentrations of F-prot in the bioconjugate material were performed to check the reproducibility of the data. It was found that the curves and the absorbance at 280 nm (corresponding to that of F-prot in the

bioconjugate solution) agreed in the experiments to within 10%.

SEM and EDAX Measurements. Figures 2A and B show the SEM images of F-prot–gold colloid bioconjugate films formed by drop-drying the bioconjugate solution (10^{-7} M F-prot in the bioconjugate solution) on Si (111) substrates. A number of aggregates can be seen in the lower magnification image (Figure 2A) and is likely to be due to enzyme-induced cross-linking of the colloidal gold particles. Figure 2B gives a magnified view of one of the aggregates. On careful observation, it is seen that the aggregate is made up of dark and bright spots. EDAX spot measurements were performed, and the dark regions were found to be deficient in gold particles (but enhanced in protein concentration as evidenced by a large nitrogen signal) while the bright regions were rich in gold particles. Thus the SEM images indicate aggregates within the F-prot–gold colloid bioconjugate material with spatially separated regions of gold particles and protein molecules. We would like to add here that a similar surface morphology was observed by Caruso et al. in multilayer films of a polymer–anti-IgG composite material.²⁸

As mentioned above, EDAX measurements were performed on the above film and the average atomic percentage ratio of gold: nitrogen over the surface of the film was estimated to be 1:5 and that of gold:carbon was recorded to be 1:14. The nitrogen and carbon signals arise from the enzyme molecules and serve as a good indicators for the presence of enzyme in the F-prot–gold colloid bioconjugate material.

XRD Measurements. While formation of aggregates in the F-prot–gold colloid films is clearly seen in the SEM pictures (Figure 2), it was difficult to image the individual gold particles in the aggregates due to limited resolution of the instrument. It is well-known that the size of particles in such nano-structured films may be estimated from the line-broadening of Bragg reflections in the XRD patterns using the standard Debye–Scherrer formula.^{21,29} A few drops of the centrifuged/resuspended F-prot–colloidal gold bioconjugate solution (prepared from the 10^{-6} M F-prot starting solution) were placed on 2 cm $\times$ 2 cm Si (111) substrate and dried in air. Figure 3A shows the XRD pattern recorded from an F-prot–gold colloid

Figure 3. (A) XRD pattern of a film of the F-prot-gold colloidal solution on a Si(111) wafer prepared by a simple drop-drying method (see text for details). The solid line is a Lorentzian fit to the spectra. (B) Fluorescence spectra of F-prot solution at a concentration of 10^{-6} M at pH = 3 (curve 1), F-prot-colloidal gold bioconjugate solution at pH = 3 prepared from the 10^{-6} M concentration starting F-prot solution (curve 2) and F-prot solution at a concentration of 10^{-7} M at pH = 3 (curve 3). Fluorescence spectra from glycine-HCl buffer (0.05 M, pH = 3, curve 4), and bare gold colloidal solution (curve 5) as controls are also shown (see text for details).

bioconjugate film deposited on Si(111) wafer by drop-drying the 10^{-7} M F-prot bioconjugate solution. The (111) Bragg reflection from gold is clearly seen at a 2θ value of ca. 38.2° and has been fit to a Lorentzian (solid line, Figure 3A) to estimate the peak broadening. The size of the gold particles in the F-prot-gold colloidal bioconjugate film was calculated from the fit to be 250 Å. The size of as-prepared colloidal gold particles is about 35 Å,¹⁸ but on forming a bioconjugate with F-prot molecules, the size increases indicating a small amount of sintering of the particles. However, given that the enzyme on the surface of the colloidal gold particles is active (as explained subsequently in the section on biocatalytic activity measurements), enzyme aggregation may be ruled out.

Tertiary Structure Studies. The biocatalytic activity of the immobilized enzyme would, to a large extent, depend on the tertiary structure of the enzyme remaining unperturbed on the surface of colloidal gold. The tertiary structure of an enzyme can be checked monitoring the fluorescence emission from the tryptophan or tyrosine residues in the enzyme. This is a standard procedure, and we have used it to check the tertiary structure of F-prot on the surface of colloidal gold by excitation of the $\pi-\pi^*$ transition in the tryptophan and tyrosine residues at 280 nm.²² Figure 3B shows the fluorescence spectra recorded from 10^{-6} M and 10^{-7} M aqueous solutions of the free enzyme, F-prot, at pH = 3 (curves 1 and 3) as well as the fluorescence spectrum measured from the F-prot-colloidal gold bioconjugate solution prepared from the 10^{-6} M F-prot starting solution (curve 2). The intensity of absorbance maxima in all three solutions occurs at about 336 nm which indicates that the F-prot molecules in the bioconjugate solution are present in their natural configuration maintaining their tertiary structure. Therefore, even though aggregates were seen in the SEM images, fluorescence measurements show that the enzyme molecules in the aggregates maintain their tertiary structure. Control experiments were performed on the fluorescence from the glycine-HCl (0.05 M, pH = 3) buffer (Figure 3B, curve 4) and the bare colloidal gold solution (Figure 3B, curve 5) by excitation at 280 nm. It is observed that for these two controls, there is no

emission in the spectral region where the enzyme contributes (ca. 335 nm) to the signal. This result is important in obtaining a reliable estimate of the concentration of F-prot molecules in the redispersed F-prot-gold colloidal bioconjugate solution, as discussed below.

The fluorescence spectroscopy measurements of Figure 3B were used to quantify the amount of F-prot on the colloidal gold surface in the bioconjugate solution by comparing the intensity of the emission signal at 336 nm with the standard calibration curve. The calibration curve was obtained by plotting the fluorescence intensities of different concentrations of F-prot at pH = 3. The concentration of F-prot in the F-prot-gold colloidal bioconjugate system was calculated to be ca. 3.7×10^{-7} M and is an important number in the estimation of the specific activity of the bioconjugate solution and enables comparison of the activity of the enzyme in the bioconjugate material with that of the free enzyme in solution.

Biocatalytic Activity Measurements. The most important aspect in protein-colloidal bioconjugate systems is the retention of the biocatalytic activity after adsorption onto the nanoparticle surface. A 100 μ L volume of F-prot-gold colloidal bioconjugate solution (starting F-prot concentration in the bioconjugate material = 10^{-6} M) was reacted with hemoglobin as explained in the Experimental Section. The specific activity was calculated using the amount of enzyme estimated from the calibration curve (see Figure 3B and discussion above) and compared with that of free enzyme in solution under identical conditions. The specific activity of free enzyme in solution was 6.1 units, and that of the enzyme immobilized onto colloidal gold surface was 5.5 ± 0.4 units. (One unit of enzyme will produce a change in absorbance at 280 nm of 0.001 per minute at pH = 3.0 and 37 °C measured as acid soluble products using hemoglobin as the substrate).⁷ The value quoted for the specific activity of the enzyme in the bioconjugate solution is a statistical average over 10 separate measurements of freshly prepared solutions of the same concentration F-prot molecules in the bioconjugate. The small standard deviation shows that the results are highly reproducible. A comparison of the specific activities of the free enzyme and enzyme in the bioconjugate solution shows that there is not much decrease in the activity of the enzyme molecules in the bioconjugate system. This is a significant result and shows that the enzymes in the aggregates have not lost their biocatalytic activity and are possibly stabilized by the gold nanoparticles.

Conclusions. F-prot-gold colloidal bioconjugates have been prepared by simple addition of F-prot molecules to the colloidal gold solution. A microscopic analysis of the bioconjugate material showed the presence of aggregates of the enzyme, possibly cross-linked and stabilized by the gold particles. Even though aggregation of the protein was indicated, fluorescence and biocatalytic activity measurements clearly showed that the enzyme on the surface of colloidal gold retains its native confirmation and furthermore, that the specific activity of the enzyme in the bioconjugate was comparable to that of the free enzyme in solution.

Received October 17, 2000; Revised Manuscript Received April 2, 2001

The chemical nuclease metalloporphyrin (manganese(III) porphyrin) can cleave DNA irreversibly and can thus constitute a potential antitumor drug. However, these molecules show low permeability to cell surface membranes. We report here the conjugation of an amphipathic carrier peptide to improve considerably its cellular delivery. The metalloporphyrin–peptide conjugate can be internalized by cells within only 5 min of incubation with a yield as high as 80%. Furthermore, the metalloporphyrin–peptide conjugate is able to cleave in vitro high or low molecular weight DNA to the same extent as metalloporphyrin alone without affecting the sequence-specific cleaving activity of the porphyrin. The conjugate is 100-fold more efficient at inducing tumor cells death than the free metalloporphyrin via a mechanism involving genomic DNA cleavage. The results are promising for further therapeutic applications with antitumor drugs such as metalloporphyrin, and also with other existing drugs by using a carrier peptide system in order to improve the cellular uptake of such molecules.

INTRODUCTION

The major barrier to the development of drugs or gene therapies is their poor permeability to the cell membrane. To improve the delivery of these compounds, most research has been directed toward developing viral (1–3) or nonviral vectors (4–6). So far, gene delivery systems for cancer therapy have been restricted to the introduction of genes encoding for a missing protein or the tumor-suppressing protein p53 (7) as well as antisense strategies (8). However, no vectors have been specially designed for carrying small antitumor drugs except for one peptide-based shuttle recently developed for photodynamic therapy using the Chlorin e6 as antitumor agent (9). The efficiency of these drugs is ultimately dependent on their selective uptake and accumulation within cells or tissues. Therefore, the development and the use of optimal delivery shuttles represent an alternative and powerful approach to solve this problem.

We have recently shown that a primary amphipathic peptide Ac-M-G-L-G-L-H-L-L-V-L¹⁰-A-A-A-L-Q-G-A-K-K-K²⁰-R-K-V-Cya (where Ac and Cya are acetyl and cysteamide groups, respectively), where the hydrophobic and the hydrophilic domains correspond to a signal peptide and a nuclear localization sequence respectively, can promote cellular internalization of a covalently linked drug or a short nucleic acid (10, 11). This was first established using lucifer yellow as probe. Peptide-assisted internalization was almost complete within 3 min with a final localization which was mainly nuclear. This was later confirmed using a 26-mer antisense oligonucleotide

complementary to a mRNA encoding β subunits of Ca²⁺ channels (11). These results prompted us to try and carry a molecule which has been described to be biologically active and of potential interest for therapeutic applications and cancer therapy, namely metalloporphyrin (Mn-TMPyP).¹ This molecule has several major advantages: the first one lies in the fact that its cationic manganese derivative cleaves DNA irreversibly (12, 13) by a cleaving process in which no further ligation can be achieved by cellular ligases. Therefore, this manganese(III) porphyrin will become a potential antitumor drug after improvement of their cellular delivery. Moreover, this antitumor alternative approach is supported by results already described for other porphyrin families used for photodynamic or ultrasonic treatments in which they exhibited antitumor effect in vivo (14, 15). In our case, the metalloporphyrin is able to cleave DNA at A-T rich sites (at least three consecutive A-T base pairs) through binding in the DNA minor groove. The cleaving activity of the metalloporphyrin is generated by an oxidative reaction (pseudohydrolysis at the 5'C–H bond of the deoxyribose units of DNA) (16) leading to the appearance of 5' alcohol and 3' phosphate ends. This property also confers to these metalloporphyrins the ability to cleave DNA in vivo by using oxygen from air in combination with a cellular reductive agent similarly to bleomycin (17). Interestingly, porphyrin molecules show another advantage that lies

¹ Abbreviations used: Mn-TMPyP, manganese(III) derivative of *meso*-tetrakis(4-*N*-methylpyridiniumyl)porphyrin pentaacetate; trisMePyP-CH₂-I, *meso*-{5-[4-[3-(iodoacetamido)propyloxy]-phenyl]-10,15,20-tris(*N*-methylpyridiniumyl)}porphyrin; Mn-trisMePyP-CH₂-I, manganese(III) derivative of *meso*-{5-[4-[3-(iodoacetamido)propyloxy]-phenyl]-10,15,20-tris(*N*-methylpyridiniumyl)}porphyrin; KHSO₅, potassium hydrogen persulfate; NaBH₄, sodium tetrahydroborate; PS-NLS, peptide signal–nuclear localization sequence.

in the spectroscopic properties of the metal-free form. Although inactive from the biological point of view, they are strongly fluorescent and can thus be used to identify the intracellular domain where the porphyrin localizes.

Therefore, two types of conjugates have been synthesized: (i) a metal-free porphyrin-peptide (trisMePyP-CH₂-S-Peptide) to monitor cellular localization, and (ii) a metal bound porphyrin-peptide (Mn-trisMePyP-CH₂-S-Peptide) to determine cleavage activity. The latter conjugate is expected to be internalized by cells, as well as to cleave DNA and thus inhibit growth of tumor cells.

We present here the synthesis of the conjugates, the cellular localization of the metal-free porphyrin together with a comparison of the activity induced by free and peptide driven metalloporphyrin. We also demonstrate that the inhibition of leukemia cells is effectively due to the cleavage of genomic DNA by these metalloporphyrin-peptide conjugates.

EXPERIMENTAL PROCEDURES

Chemicals. Potassium monopersulfate (in fact, the triple salt 2KHSO₅·KHSO₄·K₂SO₄), NaBH₄, and Hepes were purchased from Sigma. Mn-TMPyP, *meso*-{5-[4-[3-(iodoacetamido)propyloxy]phenyl]-10,15,20-tris(*N*-methylpyridiniumyl)}porphyrin and its manganese derivative, Mn-trisMePyP-CH₂-I were synthesized as previously described (12, 18). T4 polynucleotide kinase and [γ -³²P]dATP were purchased from Boehringer Mannheim and Amersham Pharmacia Biotech, respectively. Oligodeoxynucleotides (called duplex ODN1 and ODN2, see Figure 9) were purchased from Genset SA, France. λ DNA, Bgl I, and EcoR I were purchased from GibcoBRL. Carrier peptides used in this work were synthesized by Fmoc solid-phase methods as already described (19).

Synthesis of the Conjugates. The purified peptide containing a thiol moiety at its C-terminus was dissolved in Hepes buffer (50 mM, pH = 8.2). Then, porphyrin (metal-free or manganese-complexed) owning an iodoacetamide function were added to peptide solution in the same buffer and stirred for 3 h. The corresponding conjugates were recovered after HPLC purification with triethylammonium acetate (20 mM, pH = 7.4) and acetonitrile (95%, 0.08% TFA) as the eluent. The HPLC was performed on Waters equipment (Milford, MA) with a C8 Aquapore RP300 column, semipreparative 220 $\times$ 10 mm, flow 5 mL/min (Brownlee Lab., Applied Biosystem Inc.). The characterization of the final products was achieved by fluorescence, Ellman test, amino acid analysis and mass spectrometry.

Identification of Peptide, Porphyrin, and Conjugates. Amino acids analysis was performed on the carrier peptide on a High Performance Analyzer (Model 7300, Beckman instruments, Fullerton, CA). For the analysis, 50 nmol of peptide was hydrolyzed in 0.2 mL of HCl 5.7 N containing 0.9% (v/v) of phenol at 110 °C under vacuum in sealed glass tubes.

Mass analyses of all compounds were performed on a MALDI-TOF mass spectrometer (Bruker Biflex III) equipped with a N₂ (337 nm; 3ns) laser system (LSI, VSL-337i). The instrument included a single-stage acceleration source, a delayed ion extraction, a two-stage gridless reflector. In all experiments, the ion accelerating voltage was 19 kV. The reflector voltage was set to 20 kV for the acquisition of normal reflector mass spectra. Time-to-mass conversion was achieved by external calibration using angiotensin ([MH]⁺, *m/z* 1046.54) and α -cyano-4-hydroxycinnamic acid (CHCA) ([2M + H]⁺, *m/z* 379.09) as references for the reflector mode and cytochrome *c* for the linear mode. Fifty picomoles (1 μ L of 50 μ M solution)

were used for each analysis. Saturated matrix solution of CHCA was prepared in the solvent system CH₃CN (50%)/H₂O with 0.01% TFA. A mixture of the peptide and matrix solutions (1:1 v/v) was applied to the target and allowed to dry in air before being introduced into the mass spectrometer. The pressure in the analyzer was better than 5 $\times$ 10⁻⁷ mbar.

Cell Culture and Cellular Localization. For this study, three different cellular types were used: human foreskin fibroblasts HS68, fibroblasts NIH 3T3, and murine lymphocytic leukemia L1210 were cultured at 37 °C as described previously (20, 21, 22).

Medium. L1210 lymphocytic cells were grown in nutrient medium RPMI 1640 (Life Sciences) supplemented with 10% of fetal calf serum, L-glutamine (2 mM/ml), and antibiotics such as penicilin (200 U/mL) and streptomycin (50 μ g/mL). DMEM (Dulbecco Modified Eagle's Medium) was used for fibroblast cells supplemented with 10% of foetal calf serum, L-glutamine, and the same antibiotics as mentioned above.

The cellular localization assays were performed on these three different cell types. HS68 and NIH 3T3 were grown on acid-washed coverslips and leukemia L1210 cells in 12-well plates. After a brief wash in PBS (Phosphate Buffer Saline), cells were incubated for 5 min with the porphyrin-peptide conjugate (λ_{exc} : 426 nm, λ_{em} : 660 nm) or 5 min to 2 h with the porphyrin alone (10 μ L at 10⁻⁵ M, dissolved in Hepes, 50 mM, pH 7.2) at 37 °C and then fixed in 3.7% formalin in PBS for 5 min. Coverslips were washed in water and mounted in 15% (w/v) Airvol 205, 33% glycerol in PBS. Hoechst dye (λ_{exc} : 345 nm, λ_{em} : 460 nm) (Sigma) was added for 1 min in the final wash step before mounting. For L1210 cells, localization assays were performed with the porphyrin or the conjugate (5 min at 10⁻⁵ M). Cells were resuspended directly into Airvol after centrifugation of cells (5 min at 1500 rpm). Cells were observed by confocal scanning laser microscopy. Images were acquired using a Leica confocal laser scanning microscope, equipped with a krypton-argon dual wavelength laser. Images were scanned at 512 $\times$ 512 pixel resolution with 12 bits per pixel. DNA staining was visualized with a normal fluorescence light source using a CCD low light sensitivity camera. For visualization of the porphyrin or the conjugate, Rhodamin filters were used.

Cleavage Experiments: λ Phage DNA. DNA of phage λ digested by Hind III (500 ng) dissolved in a solution of Tris (40 mM, pH 8) and NaCl (100 mM) was incubated with metalloporphyrin or the conjugate at room temperature for 15 min in a reaction volume of 7 μ L. Then, KHSO₅ (1 μ L at 10⁻² M) was added and allowed to react for 15 min and was stopped by 1 μ L of Hepes buffer (1 M, pH 8). All samples were subjected to NaBH₄ reduction (1 μ L at 1 M) for 1 h at ambient temperature. Samples were loaded on agarose gel (1.5%) and submitted to electrophoretic migration.

Cleavage Experiments: Oligodesoxyribonucleotides (ODN). ODN I and II (see Figure 7 for the sequences) were 5' end-labeled with [γ -³²P]dATP with T4 polynucleotide kinase for 1 h at 37 °C. Annealing of the complementarity ODNs I and II: 10 μ L of I stock solution (0.1 μ g/ μ L) was mixed with 10 μ L of II stock solution (0.1 μ g/ μ L), 4 μ L of Tris (40 mM, pH 8), EDTA (100 mM), and NaCl (100 mM). This saline buffer solution was heated at 95 °C for 5 min and allowed to slowly cool to ambient temperature before equilibration at 4 °C overnight. The concentration of duplex was 2.33 μ M. A preincubation of metalloporphyrin or the conjugate (at the selected concentration) with duplex (ODN I and II) was performed

Figure 1. Schema of the synthesis of the conjugates showing the structures of the metalloporphyrin derivatives and conjugates. The manganese derivatives exhibit four positive charges (three for the methylpyridiniumyl units and an additional for the manganese-(III) center).

in a reaction volume of 7 μL for 15 min at room temperature. KHSO_5 (1 μL at 10^{-2} M) was then added and after 15 min of reaction the cleavage reaction was stopped by 1 μL of Hepes buffer (1 M, pH 8). All samples were subjected to NaBH_4 reduction (1 μL at 1M) for 1 h at ambient temperature. The samples were ethanol-precipitated, dried as pellets and dissolved in the loading buffer. The samples were heated 2 min at 95 $^\circ\text{C}$ before loading on 20% denaturing polyacrylamide gel. The gel was dried and exposed for autoradiography.

Inhibition of Cell Growth Rate. The activity of the metalloporphyrin and the metalloporphyrin–peptide conjugate was tested against murine leukemia L1210 cells in vitro by a procedure already described (22). Briefly, metalloporphyrin, peptide or the conjugate were added directly to the culture medium and removed after 15 min with an initial cell density of 5×10^5 . The cells were then washed extensively with fresh medium and re-incubated at 37 $^\circ\text{C}$. After 12, 24, 48, 72, and 96 h of culture, cells were counted using either a cell counter (Coulter Counter ZM, Coulter Electronics Ltd, England) or by the trypan blue exclusion procedure. For the determination of the IC_{50} values, cells were counted after 48 h of culturing.

Analysis of Genomic DNA. L1210 cells were grown in 12-well plates until a cell density of exactly 10^6 cells. Porphyrin, or the conjugate, was then added directly to the culture medium for 15 min at 37 $^\circ\text{C}$ in a concentration range between 5 and 50 μM . After this time, cells were washed with fresh medium and re-incubated at 37 $^\circ\text{C}$ for 48 h. After a brief wash with PBS, cells were lysed in a buffer containing Tris 20 mM pH = 8, EDTA 20 mM, SDS

0.1% and proteinase K 100 $\mu\text{g}/\text{mL}$ (added just before lysis) and submitted to heating overnight at 55 $^\circ\text{C}$. Genomic DNA was isolated by phenol/chloroform/isoamyl alcohol (25/24/1) extraction followed by ethanol precipitation. Samples of DNA were incubated for 1 h at 37 $^\circ\text{C}$ in the presence of Rnase A (Dnase free) in order to eliminate persistent cellular RNA. DNA fragments obtained with this isolation procedure have a size less than 30 Kbp allowing for an agarose gel analysis.

RESULTS

Synthesis of the Conjugates. In this work one carrier peptide belonging to the PS-NLS family (10) has been examined. This peptide family is based on the juxtaposition of two types of sequences, a signal peptide, and a nuclear localization sequence. By combining these two sequences the resulting peptide has an amphipathic character, which allow it to cross cellular membranes. The carrier peptide has been designed in order to carry into cells small drugs and has already been used successfully for the delivery of antisens oligonucleotides via a covalent linkage (11, 23). This carrier peptide has the following sequence Ac-M-G-L-G-L-H-L-L-V-L¹⁰-A-A-A-L-Q-G-A-K-K-K²⁰-R-K-V-Cya. Owing to the presence of the C-terminal cysteamide group (including a free reactive SH) the peptide can be used for postsynthetic modifications, especially a covalent linkage to a cargo. This linkage can be easily achieved by the use of an iodoacetamide derivative of the molecule to be internalized. In this case, the cargo is a metal-free porphyrin (trisMePyP-CH₂-I) or its Mn(III) derivative (Mn-trisMePyP-CH₂-I), (Figure

Figure 2. HPLC profiles obtained for the crude conjugate (panel A) and for the purified conjugate (panel B).

Table 1. Characterization of the Porphyrin–Peptide Conjugates (trisMePyP–CH₂–S–Peptide and Mn-trisMePyP–CH₂–S-peptide) by Different Techniques^a

	% of elution (HPLC)	precipitation (ammonium sulfate)	fluorescence properties detected	Ellmann test
peptide	54	no		+++
porphyrin	62	no	porphyrin	—
metalloporphyrin	64	no	—	—
porphyrin–peptide conjugate	60	yes from 10%	porphyrin	—
metalloporphyrin–peptide conjugate	61	yes from 10%		—

^a After purification by HPLC (% of elution in acetonitrile) which already shows different retention times, these compounds have been characterized by ammonium sulfate precipitation, fluorescence, and Ellmann's test. Only the conjugates can be precipitated with ammonium sulfate. TrisMePyP–CH₂–S–Peptide can be detected by fluorescence of the porphyrin moiety while Mn-trisMePyP–CH₂–S–Peptide exhibit no fluorescence. The Ellmann procedure has been used to confirm the absence of any free SH group in the case of the porphyrin and conjugate samples. In these experiments, only the porphyrin with an iodoacetamide function was used.

Table 2. Amino Acid Analysis of the Carrier Peptide after Acidic Hydrolysis

	Gln	Gly	Ala	Val	Met	Leu	His	Lys	Arg
peptide	1 × 1.03	3 × 0.98	4 × 1.01	2 × 0.99	1 × 1	6 × 0.99	1 × 1.01	4 × 1.02	1 × 0.95

1). The peptide is conjugated with each porphyrin molecule for 3 h under basic conditions at room temperature. After purification by HPLC (Figure 2) the conjugates were identified by their absorption spectra in the visible (426 or 466 nm for the Mn(III) derivative). Ellman tests (24) did not indicate the presence of any free SH functions (See Table 1 for details). Further identification was achieved by amino acids analyses which revealed the expected composition of the carrier peptide (Table 2) and by mass spectrometry. Both conjugates showed the expected peaks at $m/z = 3344$ (theoretical 3346) and 3290 (theoretical 3291) for the metal-bound and metal-free compounds, respectively. This is illustrated in Figure 3 where the mass spectra of the two components forming the conjugate (metal bound form) are shown together with that of the final product. Note that the origin of the peak at $m/z = 3500$ (see Figure 3C) is unknown but very probably arises from an impurity found in the starting porphyrin derivative and which could not be removed by HPLC. As to the peak at $m/z = 3289$, it corresponds very probably to the Mn-free form produced by the ionization process.

Cellular Localization. Owing to the very low fluorescence emission yield of the Mn(III) form of porphyrin, these experiments were carried out only with the metal-free form of the porphyrin (trisMePyP–CH₂–I) and its

corresponding conjugate (trisMePyP–CH₂–S–Peptide). The cellular uptake was checked with two types of cells (fibroblasts and L1210). Both types of cells used showed very similar results. In both cases the cellular membranes are poorly permeable to porphyrin and only about 3% of the cells indicated a porphyrin uptake with a cytoplasmic localization after 2 h of incubation (Figure 4). Even after 24 h of incubation only about 20% of the cells show a porphyrin uptake. The influence of the iodoacetamide function was checked by using another porphyrin derivative without this function (trisMePyP), and no differences could be observed under the same experimental conditions.

When the porphyrin is covalently linked to the peptide, an incubation time of 5 min were sufficient for more than 80% uptake of this compound by cells, with the final localization being mainly nuclear (Figure 4). Closer examination of this figure also indicated that, besides the nuclear localization, the conjugate also remained in the cytoplasm.

Growth Inhibition and Cell Death. To determine whether the metalloporphyrin remains active against L1210 cells when linked to the peptide, experiments were also undertaken similarly to previously reported experiments for metalloporphyrin derivative (25). The results

Figure 3. MALDI-TOF mass analysis of the various compounds involved in the synthesis of the metalloporphyrin conjugate. A: Iodoacetamide porphyrin derivative as analyzed in a reflector mode. B: Peptide as analyzed in a linear mode. C: Conjugate as analyzed in a linear mode.

are shown on Figure 5 and indicate that, using our protocol (see methods "inhibition of cell growth rate"), the conjugation of porphyrin to the vector peptide induced, at least, a 100-fold increase of the activity. The IC_{50} (concentration which reduces by 50% after 48 h, the

L1210 cell growth as compared to control) value is 0.6 μM for the conjugate which has to be compared with $>50 \mu M$ for the metalloporphyrin alone. It must also be noted that using free metalloporphyrin to obtain a defined IC_{50} requires incubation throughout the time of experiment

Figure 4. Visualization by confocal microscopy of the fluorescent porphyrin derivative (trisMePyP-CH₂-I) after 5 min of incubation on human fibroblasts (HS68) at 37 °C. (A) porphyrin alone at 5 μ M (arrows indicate the nuclei). (B) porphyrin-peptide conjugate (trisMePyP-CH₂-S-peptide) at 5 μ M. (C) Same section as photo B but revealed by Hoechst 33258 to show the nuclei.

(48 h) leading to an IC₅₀ of 5 μ M. Also note that the peptide alone induced just a slight cell growth inhibition when at concentrations above 5×10^{-5} M. The consequence of conjugation of porphyrin to the peptide (see Figure 5), was also corroborated by following the inhibition of cell growth with time. Indeed, Figure 6 reveals that at a concentration of 0.5 μ M the conjugate inhibited almost totally the cell growth while the peptide or the metalloporphyrin alone did not show any significant difference compared with the reference.

Mechanism of Cell Growth Inhibition. *In Vitro DNA Cleavage.* To elucidate the mechanism of cell growth inhibition and evaluate the possible consequence of

conjugation on cleaving site selection, the effect of the metalloporphyrin- or the conjugate-induced cleavage of various double-stranded DNAs was studied. Figure 7 shows an agarose gel analysis of phage λ DNA (digested by Hind III) after incubation with metalloporphyrin (panel A), the conjugate (panel B), and the free peptide (panel C). Clearly, incubation of the DNA with the free peptide did not modify the migration profile. Comparison of panels A and B indicates that the metalloporphyrin cleavage efficiency is slightly improved when in the conjugate form (500 ng of DNA are fully cleaved with 4 μ M of conjugate while 8 μ M are required for free metalloporphyrin).

For the identification of the cleaving site (manganese porphyrin cleaves preferentially AT rich sites), the same experiment as above was carried out using double-stranded oligonucleotides previously reported (16) (Figure 8). These oligonucleotides have well-defined chemical structure (Figure 9): ODN 1 contains a single AAA site while this site has been modified into AGA for ODN 2. In contrast to the situation described above the cleaving activity of the conjugate appeared to be lower than that of the free form. In addition, it is also seen that when cleavage occurs it concerns the AAA site and that conjugation may improve the specificity for this site since no significant cleavage occurs for ODN 2 with the conjugate contrary to free metalloporphyrin (compare lanes 7 and 14 of Figure 8 panel B).

In Vivo DNA Cleavage. To deepen the understanding of cell growth inhibition, and also to make sure that this inhibition was effectively due to the genomic DNA cleavage, a comparative study with metalloporphyrin, peptide, or conjugate was carried out on L1210 cells. Cancerous cells have been treated by these compounds at three different concentrations, and the genomic DNA has been analyzed using agarose gel electrophoresis (Figure 10). All samples except for the conjugate showed a profile composed of large molecular weight DNA bands (≈ 24 kbp), smears (corresponding to genomic DNA fragments), and an intense band corresponding to low molecular weights DNAs (100 bp). For the metalloporphyrin or peptide alone, no DNA cleaving activity could be

Figure 5. Growth inhibition of cancerous cells (mouse leukemia, L1210) by the metalloporphyrin (Mn-trisMePyP-CH₂-I) and the metalloporphyrin-peptide conjugate (Mn-trisMePyP-CH₂-S-Peptide). After 15 min of incubation on cells at increasing concentrations (from 10^{-8} M to 5×10^{-5} M), cells were washed with PBS and incubated in culture medium for additional 48 h. Then, viable cells were counted with a coulter counter in order to determine the growth inhibition induced by metalloporphyrin (white bars), peptide (grey bars), and the conjugate (black bars).

Figure 6. Growth inhibition of cancerous cells (mouse leukemia, L1210) by the metalloporphyrin (Mn-trisMePyP-CH₂-I) and the metalloporphyrin-peptide conjugate (Mn-trisMePyP-CH₂-S-Peptide) at a concentration of 0.5 μ M versus time after 15 min of incubation. After washing with fresh medium cells were reincubated at 37 °C and after 12, 24, 48, 72, and 96 h of culture, cells were counted in order to follow the influence of these compounds during five cycles of cell division (L1210 division cycle $\approx$ 17 h). Symbols used: control (●), peptide (○), metalloporphyrin (▲), and metalloporphyrin-peptide conjugate (■). Initial number of cells for each sample was 10^5 .

detected, except when the peptide was at high concentration. This result is in good agreement with that obtained for the cell growth inhibition. As expected, only the conjugate could induce substantial DNA cleavage, and the profile was plainly different in comparison with peptide or metalloporphyrin (compare lanes from 2 to 7 and lanes from 8 to 10 in Figure 10). Here the appearance of low molecular weights band indicates a strong DNA cleaving activity.

DISCUSSION

In the present study we have shown that covalent linkage of metalloporphyrin to a carrier peptide facilitates its cellular uptake. Within 5 min most of the fluorescence arising from the metal-free porphyrin was localized in the nuclei of more than 80% of the cells. When nonassisted, about 2 h of incubation were required for internalization in a very reduced number of cells (about 3%) with a final localization, which was cytoplasmic and not nuclear. This indicates that, besides an improvement of the cellular uptake, the peptide also governed the final intracellular localization of the drug. It must be noted that this carrier system is actually the fastest one in comparison with the only shuttle used in an antitumor approach, which requires an incubation time of 6 h to deliver the drug to the nucleus (9). The fact that the peptide induced a nuclear localization of the porphyrin improved its biological activity as its target DNA is mostly within the nucleus.

The expected effect of peptide conjugation resulted in greater cell growth inhibition compared with the free form of the metalloporphyrin. Experiments were carried out on L1210 since this cell line has been already used for similar experiments with the metalloporphyrin and metalloporphyrin-ellipticine derivatives. The results presented here appeared to conflict with those previously reported for the IC₅₀ observed in the presence of the free

metalloporphyrin (IC₅₀ = 0.6 μ M). Indeed, in our experiments, nondriven metalloporphyrin appears to be almost inactive against L1210 cells. It must, however, be reminded that the incubation time used for the experiments reported here is considerably lower than that used in reference 25. To obtain the same activity as previously reported for the metalloporphyrin alone, an incubation time of 24 h is required. For the conjugate, 15 min of incubation was sufficient to inhibit cell growth at a concentration of about 0.5 μ M. Concerning the intrinsic toxicity induced by the peptide at high concentrations (>50 μ M), the present result is in line with previous observations made on mollicutes (26) and which were attributed to cell depolarization due to the formation of ionic channels (27).

As to the mechanism inducing cell growth inhibition activity in vitro, high molecular weight DNA cleaving experiments show that conjugation of metalloporphyrin enhances its cleaving activity. In fact, owing to the chemical structure of the vector peptide (it contains five positively charged residues) it appears logical that such a peptide will favor the interactions with nucleic acids. In addition, the metalloporphyrin cleaving activity has been shown to occur at the DNA minor groove (17), and the presence of the peptide increased its activity. These observations favor therefore the idea of the existence of a nonfolded conjugate since an α -helical conformation of the peptide cannot accommodate, for steric reasons, the minor groove.

For double-stranded oligonucleotides, containing or not, only one putative cleaving site, the situation differs from that found for high molecular weight DNA since nonbound metalloporphyrin appeared to be more efficient than the conjugate from the point of view of the cleavage. In addition, cleavage also occurred for the site-free oligonucleotide as already reported but for higher amounts of the cleaving agent. For the conjugate, significant

Figure 7. Agarose gel analysis of λ phage/Hind III DNA digestion by the metalloporphyrin Mn-trisMePyP-CH₂-I (A) and the metalloporphyrin-peptide conjugate Mn-trisMePyP-CH₂-S-peptide (B). The peptide alone (C) was checked as control and did not induce any DNA cleavage. Metalloporphyrin or metalloporphyrin-peptide conjugate were used at increasing concentrations (2, 4, 8, and 16 μ M). First, λ /Hind III DNA (500 ng) was composed of six fragments and was fully digested from 4 μ M in conjugate.

cleavage was observed only for the site-containing oligonucleotide. This result rather suggests that conjugation improves the specificity for the cleaving site. Although the reasons of the difference observed in vitro between high molecular weight DNA and oligonucleotides are still unclear, it is tempting to attribute this difference to a protecting role of the peptide. Such a hypothesis is supported by observations carried out on other primary amphipathic peptides containing the same hydrophilic domain as the peptide described here. In that case it was shown that this type of peptide can form complexes with nucleic acids and that the nucleic acid was coated by the peptide preventing thus digestion by nucleases (6, 28). The protective role of the peptide should be more efficient in the case of oligonucleotides rather than high molecular weight DNA. Moreover, in this latter case such a protection certainly also occur but owing to the length of this DNA, the number of specific cleaving sites is exceedingly high favoring thus the cleaving activity of the metalloporphyrin.

For genomic DNA extracted from cells beforehand treated by these compounds, the results we obtained indicate that only the conjugate was able to cleave DNA into cells. Thus, the presence of the peptide linked to the metalloporphyrin is fully needed in order to improve the cell delivery of this antitumor agent. Without this carrier, metalloporphyrin was unable to cross the cellular membrane of cells and therefore cannot act as a DNA cleaving agent. Moreover for the conjugate, the presence of the carrier peptide does not induce a loss of metalloporphyrin

Figure 8. Analysis by polyacrylamide gel electrophoresis of the cleavage of duplex ODN1 and ODN2 by the metalloporphyrin (Mn-trisMePyP-CH₂-I) and the conjugate (Mn-trisMePyP-CH₂-S-peptide) in order to verify the sequence specificity of the cleavage. (A): Duplex ODN1 with the sequence specific 3AT. Lane 1: molecular weights, 45, 36, and 21 bp. Lane 2: ODN1 alone. Lanes 3, 4, and 5: ODN1+ metalloporphyrin (with respectively 0.5, 2, and 8 equiv). Lane 6: ODN1 + carrier peptide. Lanes 7, 8, and 9: ODN1 + metalloporphyrin-peptide conjugate (with respectively 0.5, 2, and 8 equiv). Lane 10: ODN1 + BglI. Lane 11: molecular weights: 45, 36, and 21 bp. (B): Duplex ODN2 without the sequence specific 3AT. 1: molecular weights: 45, 36, and 21 bp. Lane 2: ODN2 alone. Lanes 3, 4, 5, 6, and 7: ODN2 + metalloporphyrin (with respectively 0.5, 1, 2, 4, and 8 equiv). Lane 8: ODN2 alone. Lane 9: ODN2 + carrier peptide. Lanes 10, 11, 12, 13, and 14: ODN2 + metalloporphyrin-peptide conjugate (with respectively 0.5, 1, 2, 4, and 8 equiv).

Figure 9. Sequence of the two duplex oligonucleotides (called ODN 1 and ODN 2) used in this study in order to determinate the sequence-specific cleavage activity of the metalloporphyrin.

activity after the cell delivery step. This result obviously shows the improvement of antitumor drug activity in terms of concentration and time of incubation by using such a carrier. One problem remaining for the development of useful manganese porphyrin as a chemical DNA restriction tool is that the (A-T)₃ cleaver affinity sequence is often encountered on random double-stranded DNA. One way to increase specificity toward a single site on DNA is to covalently link the metalloporphyrin to a sequence recognition agent, such as oligonucleotide or a peptide-nucleic acid (17, 29, 30). However, although these molecules were able to target a specific sequence of DNA in vitro, they still remained poorly permeable to cellular membrane. Future studies should concentrate on using such cleaver agent with a conjugate containing metalloporphyrin, oligonucleotide, and carrier peptide, which may promote cell uptake and highly specific DNA cleavage.

The use of a carrier peptide for drug delivery is rapidly becoming a very useful strategy. Either by complex formation between the carrier and the drug or by covalent linkage of the drug to a carrier peptide, cellular delivery

Figure 10. Agarose gel analysis (0.8%) of the genomic DNA extracted from cells beforehand treated or not with metalloporphyrin (Mn-trisMePyP-CH₂-I), peptide or metalloporphyrin-peptide conjugate (Mn-trisMePyP-CH₂-S-Peptide). L1210 cells have been incubated in the presence of the different compounds for 15 min, washed, and put back for growing at 37 °C during 48 h. Cell lysis and genomic DNA extraction have been performed as described in Materials and Methods. Lane 1: DNA extracted from nontreated cells. DNA extracted from cells treated with the peptide (lanes 2–4) or the metalloporphyrin (lanes 5–7) or the metalloporphyrin-peptide conjugate (lane 8–10) at 0.5, 5, and 50 μ M, respectively. Lanes 11 and 12: molecular weight markers corresponding to λ DNA/Hind III and 1 Kb DNA Ladder, respectively.

can be increased markedly. In the present case we have shown that the vector can improve considerably the cellular delivery of metalloporphyrin (by a factor of 100) with a reduced time of incubation (5 min). The increased "transfection" yield of about 80% resulted in higher metalloporphyrin activity. The mechanism of cell growth inhibition is certainly due to an increase of the DNA cleaving activity with a very distinct contrast between the metalloporphyrin alone and the conjugate. The mean reasons of this difference lies in a better cell uptake and peptide-induced improvement of the DNA binding of the metalloporphyrin. It is the first time that this has been shown *in vivo*. Furthermore, the carrier peptide appears to be a very promising strategy to improve the cellular delivery of other existing antitumor drugs including those already used in human therapy.

ACKNOWLEDGMENT

We thank Prof. M. Dorée for continuous support to this work. We also thank S. Gerbal-Chaloin for precious technical advice, E. Demey for mass spectra, and P. Rothwell for reading the manuscript and correcting the English. Further Studies on the Site-Specific Protein Modification by Microbial Transglutaminase

Haruya Sato,* Eiko Hayashi, Naoyuki Yamada, Masanobu Yatagai, and Yoshiyuki Takahara

Ajinomoto Company Inc., Pharmaceutical Research Laboratories, 1–1 Suzuki-cho, Kawasaki-ku, Kawasaki-shi, 210-8681, Japan. Received October 28, 2000; Revised Manuscript Received May 20, 2001

A guinea pig liver transglutaminase (G-TGase)-mediated procedure for the site-specific modification of chimeric proteins was recently reported. Here, an alternative method with advantages over the recent approach is described. This protocol utilizes a microbial transglutaminase (M-TGase) instead of the G-TGase as the catalyst. M-TGase, which has rather broad structural requirements as compared to the G-TGase, tends to catalyze an acyl transfer reaction between the γ -carboxamide group of an intact protein-bound glutamine residue and various primary amines. To demonstrate the applicability of the M-TGase-catalyzed protein modification in a drug delivery system, we have utilized recombinant human interleukin 2 (rhIL-2) as the target protein and two synthetic alkylamine derivatives of poly(ethyleneglycol) (PEG12; MW 12 kDa) and galactose-terminated triantennary glycosides ((Gal)₃) as the modifiers. For the M-TGase-catalyzed reaction with PEG12 and (Gal)₃, 1 mol of alkylamine was incorporated per mole of rhIL-2, respectively. Peptide mapping of (Gal)₃-modified rhIL-2 ((Gal)₃-rhIL-2) by liquid chromatography–electrospray ionization mass spectrometry (LC-ESI/MS) suggested that the Gln74 residue in rhIL-2 was site specifically modified with (Gal)₃. The PEG12–rhIL-2 and (Gal)₃–rhIL-2 conjugates retained full bioactivity relative to the unmodified rhIL-2. In pharmacokinetic studies, PEG12–rhIL-2 was eliminated more slowly from the circulation than rhIL-2, whereas (Gal)₃–rhIL-2 accumulated in the liver via hepatic asialoglycoprotein receptor binding. The results of this study expand the applicability of the TGase-catalyzed methodology for the preparation of protein conjugates for clinical use.

INTRODUCTION

Our goal is to develop methods for site-specific protein modification in order to generate protein conjugates for clinical use. The advent of recombinant DNA technology has brought with it the rapid development of protein therapeutics. Cytokines and other biological response modifiers, thrombolytics, adhesion molecules, agonist and antagonist peptide fragments of growth factors, and receptors all have widespread applications. The full exploitation of this new and powerful therapeutic armory requires solutions to several problems. First, most parenterally administered proteins are rapidly cleared from the circulation by the reticuloendothelial system, kidney, spleen, or liver. Second, the targeting efficiency of the administered proteins to the site of action is low. Attaching poly(ethyleneglycol) (PEG, also called polyoxyethylene (POE))¹ or an organ specific targeting device specifically to the proteins can improve the therapeutic utility by controlling the pharmacokinetic profiles in the body (1, 2, 3, 4). In this aspect, the product homogeneity can play an essential role in the licensing aspects of the protein conjugates as therapeutic agents.

The most popular method is the thiol-selective modification of an introduced cysteine residue by using site-directed mutagenesis and either maleimide-based or haloacetic-based reagents (5, 6, 7). A less popular method is the modification of vicinal OH and NH₂ groups on N-terminally introduced serine or threonine residues by using site-directed mutagenesis and aminooxy-function-alizing reagents (8, 9). In addition to the above methods,

we have recently devised a novel method for the site-specific incorporation of alkylamine derivatives into specific glutamine residues by using genetic engineering techniques and guinea pig liver transglutaminase (G-TGase) (10).

This method is superior to the aforementioned procedures, because of its special limitation to glutamine residues for the incorporation and its mild reaction conditions. In fact, thiol-reactive reagents can modify the side chains of histidine and lysine, and the α -amino groups of the peptide to a lesser extent, whereas N-terminal oxidation with periodate can potentially damage the protein. Furthermore, our G-TGase-catalyzed method is applicable to the dual and site-specific incorporation by using a special substrate sequence (TG2; AQQIVM) for G-TGase as the appended tag (11, 12). In fact, a chimeric protein of human interleukin 2 (rTG2-IL-2), in which TG2 was fused to the N-terminus of IL-2, was

dually and site-specifically modified with alkylamine derivatives of PEG (MW 10 kDa).

However, considering the therapeutic applications of our G-TGase-catalyzed method, one might fear some immunogenicity or antigenicity of the constructed chimeric proteins. To try to overcome the present limitations of our methodology, we have developed a more applicable method for the site-specific incorporation of alkylamines into intact proteins, by using a microbial transglutaminase (M-TGase) in place of G-TGase as the catalyst.

M-TGase, which is produced by the microorganism *Streptovorticillium sp.* strain s-8112, catalyzes the acyl transfer reaction between the γ -carboxyamides of glutamine residues in proteins and various primary amines in the same way as mammalian TGases (13, 14). The amino acid sequence of the M-TGase is very different from those of mammalian TGases. Furthermore, M-TGase has a rather broader substrate specificity for amine acceptor glutamine substrates in proteins than those of the mammalian TGases in our preliminary studies.

To demonstrate the usefulness of the M-TGase for constructing protein conjugates, we have selected recombinant human interleukin 2 (rhIL-2) as a target protein. Although none of the six glutamine residues in rhIL-2 were available as substrates for G-TGase, as described before (10) one reactive Gln residue, which could serve as a substrate for M-TGase, was identified in this paper. For conjugation studies, we have used two model substrates as the circulating carrier and the targeting device. One is a synthetic poly(ethyleneglycol) derivative (PEG12, MW: 12 kDa) with a straight chain alkylamine at one end, which is a useful polymer for prolonging the circulating lifetimes of proteins in vivo, as described before (10, 12). The other is a galactose-terminated triantennary glycoside with a straight chain alkylamine

at one end ((Gal)₃) (15). (Gal)₃ is an artificial ligand for the hepatic asialoglycoprotein receptor (ASGP-R), which is uniquely localized on hepatocytes and recognizes exposed and branched galactose residues on serum glycoproteins (16, 17). Since the uptake of glycoproteins by this receptor is both a high-affinity and high-capacity process, (Gal)₃ would be utilized as a homing device to target proteins specifically around hepatocytes.

We report here the stoichiometrically precise, site-specific incorporation of alkylamine derivatives (PEG12 and (Gal)₃) into intact rhIL-2 by using M-TGase. To demonstrate the modification site in rhIL-2, peptide mapping of (Gal)₃-modified rhIL-2 ((Gal)₃-rhIL-2) by liquid chromatography-electrospray ionization mass spectrometry (LC-ESI/MS) was carried out. We further compared the biological activities and the pharmacokinetic profiles of PEG12-modified rhIL-2 (PEG12-rhIL-2) and (Gal)₃-rhIL-2 to those of unmodified rhIL-2.

MATERIALS AND METHODS

Materials. M-TGase was purified from the culture supernatant of *Streptovorticillium sp.* s-8112 according to the modified method of Ando et al. (14). α -Carboxymethyl- ω -methoxypolyoxyethylene, with an average molecular weight of 12 kDa, was purchased from Nippon Oils & Fats Co., Ltd., Japan. rhIL-2 was purified from inclusion bodies, as described by Tsuji et al. (18). Other chemicals were of reagent grade.

Synthesis of PEG12. The artificial substrate PEG12 was synthesized from α -carboxymethyl- ω -methoxypolyoxyethylene and *N*-Boc-1,5-diaminopentane (Fluka, Buchs, Switzerland) as described (10).

Synthesis of (Gal)₃. The synthesis of (Gal)₃ was carried out according to the modified method of Murahashi et al. (15) as follows (Figure 1).

(a) Synthesis of 2-[2-(2-Aminoethoxy)ethoxy]ethanol. 2-[2-(2-Chloroethoxy)ethoxy]ethanol (36.5 mL, 251 mmol) was added to a solution of potassium phthalimide (50.6 g, 273 mmol) in dimethylformamide (300 mL), and the solution was stirred and heated with an oil bath (100 °C) for 17 h. The suspension was cooled to room temperature and was filtered to remove the precipitate. The filtrate was concentrated under reduced pressure and was extracted with dichloromethane (300 mL). The extract was concentrated under reduced pressure to afford *N*-[2-(2-hydroxyethoxy)ethoxy]ethylphthalimide as a yellow oil: ^1H NMR (300 MHz, CDCl_3) δ 2.58 (br, 1H), 3.51–3.57 (m, 2H), 3.57–3.71 (m, 2H), 3.72–3.80 (m, 2H), 3.87–3.96 (m, 2H), 7.68–7.80 (m, 2H), 7.82–7.90 (m, 2H); ^{13}C NMR (75 MHz, CDCl_3) δ 37.19, 61.72, 67.91, 69.98, 70.32, 72.43, 123.25, 132.06, 133.95, 168.34.

The above product was dissolved in ethanol (1.2 L). To this solution was added 80% hydrazine hydrate (16.8 mL, 277 mmol), and the mixture was mechanically stirred and heated under reflux for 2 h. The reaction mixture was cooled to room temperature and was filtered to remove the precipitate. The filtrate was concentrated under reduced pressure and was extracted with dichloromethane (500 mL). The extract was concentrated under reduced pressure to afford 2-[2-(2-aminoethoxy)ethoxy]ethanol as a yellow oil: yield 34.2 g; ^1H NMR (300 MHz, CDCl_3) δ 2.90 (t, $J = 5.2$ Hz, 2H), 3.18 (br, 3H), 3.53–3.70 (m, 8H), 3.70–3.77 (m, 2H); ^{13}C NMR (75 MHz, CDCl_3) δ 41.33, 61.46, 70.11, 70.35, 72.63, 72.66.

(b) Synthesis of 2-[2-[2-(Benzyloxycarbonylamino)ethoxy]ethoxy]ethanol. 2-[2-(2-Aminoethoxy)ethoxy]ethanol (34.2 g) was dissolved in distilled water (500 mL) and was cooled with an ice–water bath. To this solution were added alternately, in about five equal portions, sodium bicarbonate (19.5 g) and benzyloxycarbonyl chloride (125 mL, 33% solution in toluene), and the resulting mixture was stirred at room-temperature overnight. The reaction mixture was separated from the aqueous layer, which was extracted with ethyl acetate (100 mL) twice. The combined organic phases were washed with saturated aqueous sodium chloride, dried over anhydrous magnesium sulfate, and concentrated under reduced pressure. The residue was purified by column chromatography over silica gel, which was eluted with ethyl acetate to give 2-[2-[2-(benzyloxycarbonylamino)ethoxy]ethoxy]ethanol as a colorless oil; yield 32.1 g; ^1H NMR (300 MHz, CDCl_3) δ 2.58 (br, 1H), 3.35–3.44 (m, 2H), 3.54–3.67 (m, 8H), 3.71 (br, 2H); 5.10 (s, 2H), 5.47 (br, 1H), 7.27–7.42 (m, 5H); ^{13}C NMR (75 MHz, CDCl_3) δ 40.82, 61.65, 66.65, 70.08, 70.28, 70.34, 72.51, 128.05, 128.09, 128.46, 136.52, 156.43.

(c) Synthesis of 1-O-[2-[2-(Benzyloxycarbonylamino)ethoxy]ethoxy]ethyl- β -D-galactopyranose Tetraacetate. Thirty-two grams of 2-[2-[2-(benzyloxycarbonylamino)ethoxy]ethoxy]ethanol and 22 g of β -D-galactopyranose pentaacetate were dissolved in dichloromethane (400 mL), which was cooled in an ice–water bath. To this mixture was added a boron trifluoride diethyl ether complex (13.9 mL) dropwise, and the resulting mixture was stirred at room-temperature overnight. The reaction mixture was washed with saturated aqueous sodium bicarbonate, dried over anhydrous magnesium sulfate, and concentrated under reduced pressure. The crude product was purified by column chromatography over silica gel, which was eluted with ethyl acetate/*n*-hexane (1:1 $\rightarrow$ 2:1, v/v) to give 1-O-[2-[2-(benzyloxycarbonylamino)ethoxy]ethoxy]ethyl- β -D-galactopyranose tetraacetate as a colorless oil; yield 13.7 g; ^1H NMR (300 MHz, CDCl_3) δ 1.98 (s, 3H), 2.04 (s, 6H),

2.14 (s, 3H), 3.40 (dd, $J = 5.2, 10.4$ Hz, 2H); 3.52–3.78 (m, 9H), 3.85 (br t, $J_{\text{app}} = 7.1$ Hz, 1H), 3.95 (m, 1H), 4.06–4.24 (m, 2H), 4.52 (d, $J = 7.9$ Hz, 1H), 5.00 (dd, $J = 3.5, 10.3$ Hz, 1H), 5.11 (s, 2H), 5.20 (dd, $J = 7.9, 10.5$ Hz, 1H), 5.37 (br d, $J_{\text{app}} = 3.5$ Hz, 1H), 7.3–7.4 (m, 5H).

(d) 1-O-[2-(2-(Aminoethoxy)ethoxy)ethoxy]- β -D-galactopyranose Tetraacetate. To a solution of 1-O-[2-[2-(benzyloxycarbonylamino)ethoxy]ethoxy]ethyl- β -D-galactopyranose tetraacetate (13.7 g) in ethanol (300 mL) was added *p*-toluenesulfonic acid monohydrate (4.27 g). The mixture was added to 10% palladium on carbon (1.0 g) under argon and was stirred under atmospheric pressure of hydrogen at room-temperature overnight. After removing the hydrogen under reduced pressure and changing the atmosphere to argon, the reaction mixture was filtered to remove the palladium on carbon and was evaporated. The residue was dissolved in acetonitrile (300 mL), and the solution was evaporated under reduced pressure. This procedure was repeated twice to remove the residual ethanol. The residue was dissolved in acetonitrile (40 mL) again, and 4-methylmorpholine (2.5 mL) was added to this solution to afford a solution of 1-O-[2-(2-(aminoethoxy)ethoxy)ethyl- β -D-galactopyranose tetraacetate (solution A).

(e) Synthesis of *tert*-Butyloxycarbonyl-L-glutamyl-L-glutamic Acid α,γ -Benzyl Ester. Boc-L-Glu-OBzl (4.73 g, Peptide Institute, Inc., Osaka, Japan) and *N*-methylmorpholine (1.54 mL) were dissolved in tetrahydrofuran (100 mL). The solution was cooled with a dry ice–ethanol bath. Ethyl chloroformate (1.35 mL) was added, and the mixture was stirred for 5 min. To the reaction mixture was slowly added a mixture of L-Glu-(OBzl)-OBzl *p*-toulenesulfonate (7.0 g, Peptide Institute, Inc., Osaka, Japan) and *N*-methylmorpholine (1.54 mL) in dimethylformamide (50 mL). The dry ice–ethanol bath was removed and replaced with a sodium chloride–ice bath, and then the reaction mixture was stirred overnight and allowed to warm gradually to room temperature. The precipitate was removed by filtration, and the filtrate was concentrated under reduced pressure. The residue was dissolved in ethyl acetate and was washed successively with aqueous 10% citric acid, saturated aqueous sodium chloride, saturated aqueous sodium bicarbonate, and saturated aqueous sodium chloride. The organic phase was dried over anhydrous magnesium sulfate and was concentrated under reduced pressure to give 8.85 g of the *tert*-butyloxycarbonyl-L-glutamyl-L-glutamic acid α,γ -benzyl ester as pale yellow crystals; ^1H NMR (300 MHz, CDCl_3) δ 1.40 (s, 9H), 1.86–1.94 (m, 1H), 1.98–2.06 (m, 1H), 2.1–2.3 (m, 4H), 2.3–2.5 (m, 2H), 4.30–4.35 (m, 1H), 4.62–4.64 (m, 1H), 5.00–5.20 (m, 6H), 5.25 (d, $J = 7.0$ Hz, 1H), 6.41 (d, $J = 7.0$ Hz, 1H), 7.2–7.3 (m, 15H).

(f) Synthesis of Compound 1. *tert*-Butyloxycarbonyl-L-glutamyl-L-glutamic acid α,γ -benzyl ester (8.85 g) was dissolved in trifluoroacetic acid (25 mL), stirred for 3 h under room temperature, and then concentrated under reduced pressure. The residue was dissolved in ethanol (200 mL), and the solvent was evaporated under reduced pressure to remove the residual trifluoroacetic acid. After repetition of this procedure, the obtained residue was dissolved in methanol (25 mL) and was neutralized with *N*-methylmorpholine. The solvent was evaporated, and the residue was dissolved in dichloromethane (220 mL) (solution B).

N-Boc-6-aminoheptanoic acid (3.16 g) was dissolved in dichloromethane (220 mL) and was cooled with an ice–water bath. To this solution were added *N*-hydroxysuccinimide (1.73 g), dicyclohexylcarbodiimide (3.1 g), and solution B, and then the resulting mixture was stirred

at room temperature overnight. The precipitate was removed from the reaction mixture by filtration, and the filtrate was washed successively with aqueous 10 % citric acid, aqueous saturated sodium chloride, and aqueous 10 % sodium bicarbonate, dried with anhydrous magnesium sulfate, and was finally concentrated under reduced pressure. The crude product was purified by column chromatography over silica gel, which was eluted with *n*-hexane/ethyl acetate (1:1 → 1:2, v/v) to give compound **1** as a colorless solid; yield 4.24 g; ^1H NMR (300 MHz, CDCl_3) δ 1.30–1.34 (m, 2H), 1.39–1.48 (m, 11H), 1.60–1.64 (m, 2H), 1.93–2.06 (m, 2H), 2.13–2.26 (m, 6H), 2.34–2.48 (m, 2H), 3.06–3.10 (m, 2H), 4.55–4.65 (m, 3H), 5.06–5.20 (m, 6H), 6.50–6.60 (br, 2H), 7.3–7.4 (m, 15H).

(g) Synthesis of Compound 2. Ten percent of palladium on active carbon (900 mg) was added to the solution of compound **1** (4.24 g) in tetrahydrofuran (150 mL) and ethyl acetate (150 mL), and then the mixture was stirred under an atmospheric pressure of hydrogen at room-temperature overnight. The reaction mixture was filtered to remove the catalyst and was concentrated under reduced pressure to give compound **2** as a colorless solid; yield 3.39 g; ^1H NMR (300 MHz, CDCl_3) δ 1.34–1.52 (m, 13H), 1.61–1.67 (m, 2H), 1.91–2.00 (m, 2H), 2.15–2.24 (m, 2H), 2.26 (t, $J = 7.5$ Hz, 2H), 2.35–2.43 (m, 4H), 3.03 (t, $J = 7.0$ Hz, 2H), 4.39 (dd, $J = 5.0, 9.0$ Hz, 1H), 4.44 (dd, $J = 5.0, 9.0$ Hz, 1H).

(h) Synthesis of Compound 3. Compound **2** (3.39 g) was dissolved in dimethylformamide (20 mL) and was cooled with an ice–water bath. To this solution were added *N*-hydroxysuccinimide (2.58 g) and dicyclohexylcarbodiimide (4.63 g), and the mixture was stirred for several minutes with cooling, after which solution A (1-*O*-[2-[2-(aminoethoxy)ethoxy]ethyl]- β -D-galactopyranose tetraacetate in acetonitrile) was added. The resulting mixture was stirred and cooled in a water bath overnight. The precipitate was removed by filtration, and the supernatant was then concentrated under reduced pressure. The residue was dissolved in ethyl acetate (300 mL) and was washed successively with an aqueous 10% citric acid solution, aqueous saturated sodium chloride, and aqueous saturated sodium bicarbonate. The organic phase was dried over anhydrous magnesium sulfate and was concentrated under reduced pressure. The crude product was purified by column chromatography over silica gel, which was eluted with dichloromethane/methanol (20:1 → 15:1, v/v) to give compound **3** as a colorless solid; yield 5.87 g; ^1H NMR (300 MHz, CDCl_3) δ 1.30–1.36 (m, 2H), 1.42 (s, 9H), 1.46–1.52 (m, 2H), 1.60–1.66 (m, 2H), 2.01 (s, 9H), 2.02 (s, 9H), 2.04 (s, 9H), 2.09 (s, 9H), 2.2–2.4 (m, 2H), 3.08–3.12 (m, 2H), 3.5–3.6 (m, 34H), 3.70–3.75 (m, 6H), 3.93–3.98 (m, 6H), 4.10–4.20 (m, 6H), 4.38–4.43 (m, 2H), 4.55–4.57 (m, 3H), 4.72–4.76 (m, 1H), 5.02–5.06 (m, 3H), 5.17–5.22 (m, 3H), 5.39 (d, $J = 3.5$ Hz, 3H), 6.58–6.62 (m, 1H), 7.04–7.08 (m, 1H), 7.12–7.18 (m, 1H), 7.24–7.26 (m, 1H), 7.80–7.85 (m, 1H).

(i) Synthesis of (Gal)₃. Compound **3** (5.87 g) was dissolved in 50% trifluoroacetic acid in dichloromethane (50 mL), stirred for 1 h under room temperature, and then concentrated under reduced pressure. The residue was dissolved in ethanol (200 mL) and was concentrated under reduced pressure to remove the residual trifluoroacetic acid. After repetition of this procedure, the resulting residue was dissolved in dichloromethane (30 mL), cooled with an ice–water bath, and then neutralized with 28% sodium methoxide in methanol. The solvent was evaporated under reduced pressure, and the remaining solution was subjected to column chromatography

over silica gel (dichloromethane/methanol = 30/1 → 5/1, v/v). The obtained product was dissolved in methanol (85 mL) and was cooled with an ice–water bath. To this solution was added 28% sodium methoxide in methanol (320 μL). This mixture was removed from the cooling bath and was stirred at room temperature for 5 h. The resulting mixture was cooled with an ice–water bath and was neutralized with Dowex 50W cation-exchange resin that had been washed with methanol. The resin was then removed by filtration. The filtrate was concentrated under reduced pressure to give 1.95 g of (Gal)₃ as an amorphous solid. The purity of the (Gal)₃ was more than 95% as analyzed by RP-HPLC with an Inertsil ODS-2 column (4.6 $\times$ 150 mm; GL Sciences Inc.), which was developed by a linear gradient of 4–20% acetonitrile containing 0.1% TFA for 30 min at a flow rate of 1 mL/min; ESI-MS; ($M + H$)⁺ 1270.0 (MW 1269.4 Da).

M-TGase-Catalyzed Modification of rhIL-2. The M-TGase-catalyzed modification of rhIL-2 was carried out with the following concentrations of reagents in 0.2 M Tris/HCl (pH 7.5) at 25 °C for 12 h: PEG12 or (Gal)₃, 1.25 mM; protein, 5 μM ; and M-TGase, 0.18 units/mL. At the end of the incubation, the reaction mixtures were analyzed by SDS–PAGE under the same conditions used for rTG1-IL-2 (10). To remove the residual free PEG12 and (Gal)₃, the reaction mixtures were absorbed onto a Sep-Pak C8 cartridge (Millipore Co., Milford, MA) according to the same method used for rTG1-IL-2 (10). The eluted protein fractions were directly applied to a YMC-C8-AP column (4.6 $\times$ 150 mm; YMC Co., Ltd.), which was developed by a linear gradient of 54%–60% acetonitrile containing 0.1% TFA for 30 min at a flow rate of 1 mL/min. Each fraction was collected, and the different protein peaks were separately pooled and analyzed by reversed-phase HPLC (RP-HPLC) and SDS–PAGE. After the analysis, most of the main peak fractions were directly applied to a Molcut L LGC column (Millipore Co., Milford, MA), and the buffer was exchanged with Dulbecco's phosphate-buffered saline (D-PBS). The samples were used for bioactivity and pharmacokinetic studies. The remainder of the main fraction for (Gal)₃-rhIL-2 in the RP-HPLC was used for peptide mapping.

Protease Digestion of Modified and Unmodified rhIL-2. Protease digestions of (Gal)₃-rhIL-2 and rhIL-2 were done according to the modified method for rhIL-2 (18). One hundred micrograms of reduced and S-carboxymethylated (Gal)₃-rhIL-2 and rhIL-2 were each suspended in 180 μL of 0.05 M ammonium hydrogen carbonate buffer (pH 7.9) and were treated with 20 μL of V8 protease solution (Wako Pure Chemical Industries, Ltd., 100 $\mu\text{g}/\text{mL}$) for 22 h at 37 °C. After lyophilization of the reaction mixtures, the dry samples were respectively suspended in 45 μL of 0.05 M ammonium hydrogen carbonate buffer (pH 7.9) and were treated with 5 μL of L-1-(tosylamido)-2-phenylethyl chloromethyl ketone-treated trypsin (Sigma, 400 $\mu\text{g}/\text{mL}$) for 4 h at 37 °C.

ESI-MS Analysis. An LCQ iontrap mass spectrometer (Thermoquest Co., San Jose, CA) was used for all experiments. The MS detector settings are as follows: temperature of the heated capillary, 200 °C; spray voltage, 3 kV; scan range, 300–1850 m/z . The protease-digested peptides of modified and unmodified IL-2 were lyophilized to remove the buffer and were dissolved in 0.1% TFA. The lyophilized peptides were loaded onto a capillary chromatography column (Vydac C₁₈, 0.3 mm i.d. $\times$ 300 mm), and the separated peptides were subjected to an electrospray ion source in the LCQ spectrometer. To achieve a stable electrospray over the course of the gradient elution, 50% MeOH containing 1% acetic acid

was used as a sheath liquid at a flow rate of 3 $\mu\text{L}/\text{min}$. The elution conditions consisted of four successive linear increases of acetonitrile in 0.1% TFA, i.e., 4.5 to 4.5% in 10 min, 4.5 to 63% in 70 min, 63 to 81% in 5 min, and 81 to 81% in 5 min at a flow rate of 3 $\mu\text{L}/\text{min}$. Mass spectra were obtained by scanning the range of m/z 300–1850. The most abundant peptides were further analyzed by collisional-induced dissociation (CID) mass spectrometry.

In Vitro Biological Assays. The bioactivities of PEG12–rhIL-2, (Gal)₃–rhIL-2, and unmodified rhIL-2 were determined by using the IL-2 dependent murine cell line CTLL-2 (19). The amount of IL-2 activity was determined in units/mg by using the rhIL-2 standard (Collaborative Biomedical Products Co., Inc.) and was then expressed as the percent residual bioactivity as compared to the purified rhIL-2. All samples were tested in quadruplicate.

Pharmacokinetics of Modified rhIL-2. The modified and unmodified rhIL-2 were administered intravenously into male mice (C57BL/6, 6W, δ , Charles River Breeding Labs, Japan). At specific time intervals, described in the Results, the mice were bled and sacrificed, and the liver and kidney were excised. Blood was collected in heparin-coated 1.5 mL Eppendorf tubes. Plasma was immediately prepared by centrifugation at 4 $^{\circ}\text{C}$. Each organ was rinsed with ice-cold saline, weighed, and homogenized by adding enough isotonic phosphate buffer containing 0.2% BSA (pH 7.4) to yield a 10% homogenate (w/v). The IL-2 concentrations in plasma, liver, and kidney were determined by an ELISA procedure using the IL-2 Enzyme Immunoassay kit (Cayman Chemical Co., Michigan).

Analytical Methods. The M-TGase enzyme activity was measured by a colorimetric hydroxamate procedure with *N*-carbobenzoyl-L-glutamyl-glycine (20). SDS-PAGE was carried out with the PhastSystem (Amersham Pharmacia Biotech AB, Uppsala, Sweden) using a 20% (w/v) acrylamide gel under reducing conditions, according to the same procedure used for rTG1-IL-2 (10). The concentrations of the unmodified and modified forms of rhIL-2 were quantified by using an extinction coefficient (E_{280}) of $1.2 \times 10^4 \text{ M}^{-1}$. NMR spectra were determined at 300 MHz (^1H) with a spectrometer operating in the Fourier Transform (FT) mode. Chemical shifts are given in ppm (δ) relative to tetramethylsilane as the internal standard.

RESULTS

Synthesis of (Gal)₃. The synthesis of (Gal)₃ includes three stages (Figure 1). The first step involves the preparation of the building block of glutamic acids. The second stage involves the incorporation of the tri(ethylene glycol) spacer into β -D-galactopyranose tetraacetate. In the final stage, the galactopyranosyl-derivatized compounds are introduced into the building block of glutamic acids. The results of the ESI-MS and RP-HPLC analyses of the reaction product indicate that (Gal)₃ is consistent with the assigned structure.

M-TGase-Catalyzed PEG12-Modification of rhIL-2. Figure 2A shows the SDS-PAGE analysis of the PEG12-incorporated product for rhIL-2. In the presence of PEG12 and M-TGase, the rhIL-2 band migrating at about 15 kDa is decreased, and one broad band, migrating at about 35 kDa, is visible (lane 3). The higher molecular weight band that is slightly visible at about 38 kDa could be due to M-TGase (MW 37.8 kDa). Since the time course analysis of the reaction products by SDS-PAGE revealed only one new band (data not

Figure 2. SDS-PAGE analysis of the M-TGase-catalyzed PEG12- (A) and (Gal)₃- (B) modified rhIL-2. (A) Lane 1; MW Marker Lane 2; unmodified rhIL-2 Lane 3; rhIL-2 + PEG12 + M-TGase Lane 4; purified PEG12–rhIL-2 (B) Lane 1; MW Marker Lane 2; unmodified rhIL-2 Lane 3; rhIL-2 + (Gal)₃ + M-TGase Lane 4; purified (Gal)₃–rhIL-2

shown), the band migrating at 35 kDa presumably represents the PEG12-incorporated rhIL-2, with a molar ratio of 1:1. The attachment of one PEG12 molecule to rhIL-2 causes a greater increase in size than that predicted from its molecular mass, presumably due to the bulkiness of the PEG12–rhIL-2 conjugate (PEG12–rhIL-2). After the separation of the modified and unmodified rhIL-2 by RP-HPLC (data not shown), the isolated PEG12–rhIL-2 migrated as a single band at about 35 kDa in lane 4 (yield: 29%).

M-TGase-Catalyzed (Gal)₃-Modification of rhIL-2. Figure 2B shows the SDS-PAGE analysis of the (Gal)₃-incorporated product for rhIL-2. The electrophoretic pattern of the reaction mixture demonstrates that the rhIL-2 band migrating at 15 kDa is almost invisible, and one new band, migrating at 17 kDa, is present (lane 3), indicating that one mole of (Gal)₃ per rhIL-2 is incorporated by M-TGase, similar to the PEG12-modification. The attachment of one (Gal)₃ (MW; 1269 Da) caused a reasonable increase (about 1000 Da) in size, representing the single (Gal)₃-incorporated product of rhIL-2 ((Gal)₃–rhIL-2). The M-TGase band at 38 kDa is stronger than that for the PEG12-modification in Figure 2A, due to differences in the enzyme activity/mg of the M-TGase used for the individual reactions.

To characterize the (Gal)₃–rhIL-2, we carried out the separation of the modified and unmodified rhIL-2 by RP-HPLC (Figure 3). Two separate peaks (a and b) were observed. The large peak that eluted at about 12 min contained M-TGase and (Gal)₃. Peak b corresponds to the unmodified rhIL-2 (data not shown). The protein band from peak a, which migrates at 17 kDa (lane 4 in Figure 2(B)), corresponds to the (Gal)₃–rhIL-2. A fraction of peak a (yield: 20%) was collected and used for characterization. Although the incorporation efficiency of (Gal)₃ was higher than that of PEG12, as determined by the SDS-PAGE analysis of the reaction mixture, the yield of the (Gal)₃–rhIL-2 was inversely lower than that of PEG12–rhIL-2. The reason for the low recovery is assumed to be the insufficiency of the separation between (Gal)₃–rhIL-2 and unmodified IL-2 in the RP-HPLC.

ESI-MS Analysis of (Gal)₃–rhIL-2. Figure 4 shows the LC-ESI/MS chromatography of the protease-digested peptides containing Gln residues of rhIL-2 and (Gal)₃–rhIL-2. The identities of the respective peaks containing Gln residues, together with the theoretical and measured molecular masses, are displayed in Table 1.

A comparison of the chromatography derived from rhIL-2 and (Gal)₃–rhIL-2 reveals that only VT-1 (residues 69–76, VLNLAQSK) was not observed in (Gal)₃–

Figure 3. Purification of $(\text{Gal})_3$ -rhIL-2 on the YMC-C8AP column: a, peak containing $(\text{Gal})_3$ -rhIL-2; b, peak containing unmodified rhIL-2.

rhIL-2, and a new peak (VT-1(+ $(\text{Gal})_3$) was observed at 41 min. Since the ESI/MS spectra of the VT-1 (+ $(\text{Gal})_3$) gave a strong peak at m/z 1063.1, as the double-charged protonated molecular ion $[\text{M} + 2\text{H}]^{2+}$, predicted m/z ; 1063.5 Da) of the $(\text{Gal})_3$ -incorporated VT-1 ($(\text{Gal})_3$ ($\text{C}_{52}\text{H}_{96}\text{N}_6\text{O}_{29}$); MW 1269.2 Da, VT-1; MW 871.5 Da) (Figure 5), $(\text{Gal})_3$ was site-specifically incorporated at Gln74 in rhIL-2.

In Vitro Biological Assays. The bioactivities of PEG12-rhIL-2 and $(\text{Gal})_3$ -rhIL-2 are shown in Table 2.

The control, purified rhIL-2, has an activity of 1.43×10^7 units/mg as hIL-2. The bioactivities of PEG12-rhIL-2 and $(\text{Gal})_3$ -rhIL-2 are 1.35×10^7 units/mg (94%) and 1.53×10^7 units/mg (107%), respectively, indicating that both modified forms of rhIL-2 retain full bioactivity relative to rhIL-2.

Pharmacokinetic Studies. The blood plasma curves for PEG12-rhIL-2 and rhIL-2 given intravenously to mice are compared in Figure 6. PEG12-rhIL-2 showed a prolonged circulation half-life in comparison with unmodified rhIL-2. The α and β half-lives of rhIL-2 were 2.2 and 11 min, respectively. For PEG12-rhIL-2, these half-lives were increased to 8.8 and 75 min, respectively. The area under the plasma concentration vs time curve ($\text{AUC}_{0-\text{inf}}$) of PEG12-rhIL-2 (442 ng·h/mL) was about 10 times greater than that of unmodified rhIL-2 (46 ng·h/mL).

Figure 7 shows the tissue distribution of $(\text{Gal})_3$ -rhIL-2 and rhIL-2 after i.v. administration in mice. $(\text{Gal})_3$ -rhIL-2 predominantly accumulated in the liver, at about a 5-fold higher concentration than that of unmodified rhIL-2. When $(\text{Gal})_3$ -rhIL-2 was coadministered with asialoorosomucoid, which is a well-known high-affinity ligand for the hepatic ASGP-R, the liver accumulation of the conjugate was reduced to the same level as that of rhIL-2. This result indicates that the hepatic targeting of $(\text{Gal})_3$ -rhIL-2 is via the ASGP-R.

DISCUSSION

Selective protein drug delivery and targeting seek to achieve the optimal arrival of a drug at its site of action in a manner that is appropriate for the disease and the drug, which would lead to a significant reduction in the possibility of drug side effects. Controlling the circulating lifetimes or tissue distributions of therapeutic proteins is one of the main areas for developing drug delivery

systems. By using M-TGase as the catalyst, we have developed a new methodology for the site-specific incorporation of alkylamine derivatives of a hepatic targeting device ((Gal)₃) and PEG (PEG12) into intact proteins and controlling the pharmacokinetic profiles of the protein drugs.

The progress of our application study for the TGase-catalyzed modification of therapeutic proteins depends on the adoption of M-TGase instead of G-TGase as the catalyst. Although a few attempts have been made to characterize the substrate specificity of M-TGase, using synthetic peptide derivatives, the characterizations of the substrate recognition of the enzyme have not considered the tertiary structure (14, 21). From our preliminary studies, M-TGase has lower substrate specificity for the amine acceptor site around the Gln residues in proteins than G-TGase. In the case of the G-TGase-catalyzed modification studies for rhIL-2, there was a need to

**Figure 6.** Plasma concentration time courses of PEG12-rhIL-2 and rhIL-2 in mice. The plasma concentrations were determined by ELISA after intravenous administration (50 μ g as rhIL-2/kg) into C57BL/6 mice (6W, δ). Data are presented as means $\pm$ standard deviations.

construct a chimeric protein of hIL-2, in which the substrate peptide was fused to the N-terminus of hIL-2

Figure 7. Tissue distributions of (Gal)₃-rhIL-2 and rhIL-2 in mice. Each sample (50 μ g as rhIL-2/kg) was injected intravenously into mice, without or with asialoorosomucoid (1320 μ g/kg). After 2 min of circulation, the uptake by the liver and kidney and the remaining fraction in the serum were determined (percentage of the injected dose). Data are presented as means $\pm$ standard deviations.

(10). On the other hand, we could site-specifically incorporate alkylamine derivatives of PEG or a hepatic targeting device into intact rhIL-2 by using M-TGase. In fact, we have found a lot of other substrate proteins for M-TGase, such as human interleukin 6, human interferon α , and so on (data not shown). The reason for the lower substrate specificity of M-TGase is assumed to be as follows.

It is known that the catalysis of TGase takes place in an acylation-deacylation pathway; this reaction proceeds through the formation of Michaelis-type acyl-enzyme intermediates and the subsequent transfer of acyl-enzyme intermediates (22, 23). Specifically, there is evidence that these enzymes have extended active sites whose interactions with substrate peptides bear directly on their binding affinity for and/or their catalytic efficiency toward glutamine residues (24). These secondary interactions between the target proteins and the active site of TGase are thought to determine the reactivity for TGase. When compared with the structures of the two TGases, by Kanaji et al. (13), the secondary structure of the region around the active site Cys residue of M-TGase is similar to that of G-TGase, whereas the amino acid sequence of the M-TGase is very different from that of G-TGase. However, the molecular weight for M-TGase (37.9 kDa) is much smaller than those of the mammalian TGases, represented by G-TGase (76.6 kDa). Thus, the smaller M-TGase could easily interact with the substrate site of the target proteins, as compared to G-TGase, and the subsequent transfer of the acyl-enzyme intermediates results in the lower specificity toward glutamine residues. This characteristic of M-TGase is assumed to be a special feature among the TGases. To confirm the broad specificity of M-TGase for the Gln substrate in intact proteins, further systematic studies for its reactivity toward various proteins will be necessary.

Our characterization studies of (Gal)₃-rhIL-2 by LC-ESI/MS showed that the Gln74 residue in rhIL-2 was modified with (Gal)₃ in a site-specific manner. In addition, the LC-ESI/MS analysis of PEG12-rhIL-2 also showed that only the VT-1 fragment (residues 69–76) of rhIL-2 was site-specifically modified with PEG12 (data not shown). The consistent results of the incorporation site between (Gal)₃ and PEG12 indicate that only Gln74, out of the six Gln residues in rhIL-2 (Gln11, 13, 22, 57, 74, and 126), can be a substrate for M-TGase.

Table 3. Comparison of the Amino Acid Sequence Surrounding the Gln Residues in RhIL-2

Gln residues	sequence ^{a,b}	location
Gln11	APTSSST KKT Q LQLEHLLLDL	in helix A
Gln13	TSSST KKTQL Q LEHLLLDLQM	in helix A
Gln22	LQLEHLLLDL Q MILNGINNYK	in helix A
Gln57	PKKATELKHL Q CLEELKPLE	in helix B
Gln 74	KPLEEVLNLA Q SKNFHLRPRD	near helix B
Gln126	EFLNRWITFC Q SIISTLT-COOH	in helix D

^a The Gln residues in rhIL-2, as well as the charged amino acids, are printed in boldface. ^b The carboxy terminus of rhIL-2 is indicated by COOH

From the stereoview of the hIL-2 mutant (PDB Code: 3INK) represented by a Protein Data Bank program (25), all of the side-chains of the glutamine residues in hIL-2 are located in the exposed region. Since the location of reactive glutamine residues at the surface of the respective proteins is a common feature for TGase-catalyzed modifications, every glutamine residue in hIL-2 has the possibility of being an amine acceptor substrate in this category. Thus, the amino acid sequences surrounding the Gln residues in hIL-2 play a key role for the reactivity. In fact, the reactive Gln residues for TGase are located in a sequence containing a high proportion of charged and polar amino acids (26). Furthermore, in substrate proteins with known three-dimensional structures, i.e., melittin and glucagon, the reactive glutamine residues are located in an α -helix with positively charged amino acids clustered either NH₂- or COOH-terminally, relative to this residue (27, 28).

Table 3 shows the amino acid sequences and the secondary structures surrounding the Gln residues in hIL-2 (29, 30). Comparing the location of each Gln residue, the sequences around Gln57 and Gln74 would be most abundant in polar and (positively) charged amino acids. Thus, the site-specificity at Gln74 appears to be reasonable. Since it is impossible to derive a consensus sequence for the M-TGase-catalyzed modification at present, the reason for the reaction selectivity at Gln74 and not for Gln57 is immediately clear to us. The differences in the amino acid sequence and the peptide flexibility around Gln57 and Gln74 would dramatically affect the binding affinity for the acyl-enzyme intermediate between M-TGase and rhIL-2.

Our pharmacokinetic studies showed that the site-specific introduction of the PEG12 molecule prolonged the circulation lifetime of rhIL-2. To increase the time further, either enhancing the PEG length or adding multiple copies of PEG chains at one site would be necessary. In fact, this type of PEG-protein conjugate, in which one mole of high molecular weight (40 kDa) branched PEG is incorporated per mole of interferon α -2a, has shown sufficient prolongation in its pharmacokinetic profiles (31).

On the other hand, (Gal)₃-rhIL-2 could accumulate in the liver via the hepatic ASGP-R. To achieve hepatic delivery of proteins, many groups have synthesized galactosylated proteins, in which some galactose residues are covalently attached to the lysine side chains of the proteins (32, 33). However, since N-linked oligosaccharides containing multiple terminal Gal residues bind to the hepatic ASGP-R with high affinity, more Gal residues must be incorporated per target protein, which would reduce the bioactivity. Since such conjugates showed product heterogeneity and decreased bioactivity as compared to the unmodified proteins, it was difficult to develop them as therapeutic agents. Thus, the methodology for the hepatic targeting of proteins by using (Gal)₃

1) M-TGase-catalyzed modification of intact proteins

2) G-TGase-catalyzed modification of chimeric proteins

Figure 8. The strategy of the site-specific modification of proteins by the use of M-TGase (i) and G-TGase (ii).

would be generally applicable, as compared to the previous method, as detailed in the following points.

(i) This methodology can achieve the hepatic delivery of proteins with one point of incorporation of the ligand at a substrate Gln residue.

(ii) The incorporation of (Gal)₃ would not affect the function of the proteins.

In addition to the above points, (Gal)₃-mediated targeting has another advantage over the previous hepatic delivery systems. Although there are some reports of the utilization of artificial tri- or tetraantennary ligands for ASGP-R for hepatic targeting devices, these were developed for carrying DNAs, antisense oligonucleotides, cholesterol, and liposomes, but not proteins, into hepatocytes (34, 35, 36, 37). Then, they selected the highest affinity ligands (K_d , nanomolar affinity) for the devices to favor the efficient uptake of the molecules via ASGP-R-mediated endocytosis.

In contrast, (Gal)₃ is a lower affinity ligand for the ASGP-R (K_d , several hundreds nM to μ M affinity) as compared to the previous ligands. This affinity would be sufficient for binding to the ASGP-R after administration, but insufficient for internalization into hepatocytes. In fact, we found that the (Gal)₃ had a special feature that allowed it to escape from ASGP-R-mediated endocytosis after binding to the ASGP-R on hepatocytes in our preliminary studies, whereas the high-affinity ligand was rapidly internalized into the cells (data not shown).

Thus, (Gal)₃-protein conjugates would mainly accumulate around the extracellular region of hepatocytes, not within the cells. Since many endogenous proteins, such as cytokines, are produced and released to act locally, and since these types of molecules have multiple functions in the body, the delivery of systematically administered proteins to the site of action would be necessary to reduce the systemic toxicity. With this viewpoint, our hepatic targeting system is a potential methodology for developing therapeutic proteins toward liver diseases. To demonstrate the utility of the (Gal)₃ ligand as a hepatic targeting device, further studies, such as kinetic studies of the uptake of (Gal)₃-protein conjugates into hepatocytes, will be necessary.

On the basis of the previous observations and the present studies of TGase-catalyzed modification, the strategy of our site-specific modification of proteins can be described as follows (Figure 8). In cases where one would like to introduce alkylamine derivatives into intact proteins, M-TGase would be suitable for their modification (1). Even if the target protein lacks reactive Gln residues, the site-specific introduction is still possible, because a short substrate sequence for G-TGase can be genetically introduced at the terminus of the target

protein (2). This methodology can be generally applied to therapeutic proteins in cases where the incorporation of alkylamine derivatives does not affect the bioactivity of the proteins. Although alkylamine derivatives of PEG and an artificial ligand for the hepatic ASGP-R were employed as the modifier in this study, other functional alkylamines may be introduced to tailor the delivery and targeting of proteins. Furthermore, other kinds of TGases with different substrate specificities could be applicable for constructing protein conjugates.

In conclusion, we have successfully developed a new methodology for the site-specific modification of intact proteins by the use of M-TGase. The high homogeneity of the constructed conjugates and the ability to control the pharmacokinetic profiles will improve the therapeutic indices of proteins.

ACKNOWLEDGMENT

The authors are grateful to Dr. Yuji Iwashita for helpful discussions. We also thank Daisuke Ejima and Hiromi Sumikawa (Ajinomoto Co., Inc.) for their advice concerning purification study and structural information.

***N*-(2-Hydroxypropyl)methacrylamide Copolymer–6-(3-Aminopropyl)-ellipticine Conjugates. Synthesis, in Vitro, and Preliminary in Vivo Evaluation**

F. Searle,[†] S. Gac-Breton,[†] R. Keane,[†] S. Dimitrijevic,[†] S. Brocchini,[†] E. A. Sausville,[‡] and R. Duncan^{*,†}

Centre for Polymer Therapeutics, School of Pharmacy, University of London, 29/39 Brunswick Square, London WC1N 1AX, U.K., and Developmental Therapeutics Program, National Cancer Institute, EPN 843, Bethesda, Maryland 20892. Received December 13, 2000; Revised Manuscript Received July 11, 2001

Ellipticine derivatives have potential as anticancer drugs. Their clinical use has been limited, however, by poor solubility and host toxicity. As *N*-(2-hydroxypropyl)methacrylamide (HPMA) copolymer–anticancer conjugates are showing promise in early clinical trials, a series of novel HPMA copolymer conjugates have been prepared containing the 6-(3-aminopropyl)-ellipticine derivative (APE, NSC176328). Drug was linked to the polymer via GFLG or GG peptide side chains. To optimize biological behavior, HPMA copolymer–GFLG–APE conjugates with different drug loading (total APE: 2.3–7% w/w; free APE: <0.1% w/w) were synthesized. Conjugation of APE to HPMA copolymers considerably increased its aqueous solubility (>10-fold). HPMA copolymer–GG–APE did not liberate drug in the presence of isolated lysosomal enzymes (tritosomes), but HPMA copolymer–GFLG–APE released APE to a maximum of 60% after 5 h. The rate of drug release was influenced by drug loading; lower loading led to greater release. Whereas free APE (35 $\mu\text{g/mL}$) caused significant hemolysis (50% after 1 h), HPMA copolymer–APE conjugates were not hemolytic up to 300 $\mu\text{g/mL}$ (APE-equiv). As would be expected from its cellular pharmacokinetics, HPMA copolymer–GFLG–APE was >75 times less cytotoxic than free drug ($\text{IC}_{50} \sim 0.4 \mu\text{g/mL}$) against B16F10 melanoma in vitro. However, in vivo when tested in mice bearing s.c. B16F10 melanoma, HPMA copolymer–GFLG–APE (1–10 mg/kg single dose, APE-equiv) given i.p. was somewhat more active (highest *T/C* value of 143%) than free APE (1 mg/kg) (*T/C* = 127%). HPMA copolymer–APE conjugates warrant further evaluation as potential anticancer agents.

INTRODUCTION

Ellipticine, 5,11-dimethyl-6*H*-pyrido(4,3-*b*)carbazole (I, Figure 1) [reviewed in (1, 2)], is a potent cytotoxic agent with an IC_{50} in the range of 0.3–0.7 μM toward a variety of malignant cell lines in vitro (3). Its mechanisms of action include DNA intercalation (4), topoisomerase inhibition (5), and alkylation (1). Early clinical development was limited by poor drug solubility and in vivo host toxicities including hemolytic activity, decreased heart rate (1), and hepatotoxicity (6). A 9-hydroxy-2-methylellipticinium acetate derivative (II, Figure 1) did however show interesting clinical activity against thyroid and renal tumors, and bone metastases associated with breast cancer [reviewed in (1)]. These observations led us to propose the ellipticines as interesting candidates for evaluation in the form of polymer–drug conjugates.

Biocompatible, water-soluble polymers provide a useful platform for tumor-selective drug delivery. Conjugation of doxorubicin (7), paclitaxel (8), and camptothecin (9) to HPMA copolymers improves their water solubility and reduces drug toxicity. Additionally, after intravenous (i.v.) administration, such conjugates selectively accumulate in solid tumor tissue by the “enhanced perme-

Figure 1. Chemical structure of ellipticine (I), 9-hydroxy-2-methylellipticinium acetate (II), and 6-(3-aminopropyl)-ellipticine (III).

ability and retention” (EPR) effect (10–12). EPR-mediated targeting arises due to preferential extravasation of circulating conjugate as it passes through hyperpermeable, angiogenic, tumor vessels (12), and the absence of an effective tumor lymphatic drainage encourages intratumoral retention. Those factors found previously to be important for the preclinical optimal design of polymer–drug conjugate have been extensively reviewed (13–16). Several conjugates have now progressed successfully into Phase I/II clinical evaluation. The first, HPMA copolymer–GFLG–doxorubicin (PK1, FCE 28068), displayed greatly reduced toxicity compared to free doxorubicin (7), and also showed antitumor activity in

[‡] National Cancer Institute.

chemotherapy-refractory patients, even at relatively low doses (80, 120, 180 mg/m² doxorubicin-equiv) (17). The observed PK1 maximum tolerated dose (MTD) was 320 mg/m² doxorubicin-equiv, which is 4–5 times higher than the usual clinical dose of free doxorubicin (60–80 mg/m²) (17).

In this study, a series of HPMA copolymer–6-(3-amino-propyl)-ellipticine dihydrochloride (APE; NSC176328) (III, Figure 1) conjugates were synthesized with the aim of improving the water-solubility of ellipticine and also improving its therapeutic index. Conjugates were prepared by aminolysis of activated HPMA copolymer precursor (18) to give compounds with either a GFLG linker, since this peptide is degraded by the lysosomal thiol-dependent proteases (19, 20), or a potentially nonbio-degradable GG linker. The APE content of the conjugate was varied between 2.3 and 7% w/w to allow investigation of the effect of drug loading on conjugate properties. Hemolytic activity, cytotoxicity, and the rate of APE release in the presence of isolated lysosomal enzymes (tritosomes) were all assessed *in vitro*. Preliminary experiments were also conducted to evaluate the anti-tumor activity of HPMA copolymer–APE in a subcutaneous (s.c.) murine tumor model *in vivo*.

EXPERIMENTAL PROCEDURES

Materials. HPMA copolymers, carrying GG (5 mol %; $M_w \sim 30\,000$ and $M_w/M_n = 1.3\text{--}1.5$) or GFLG (either 5 or 10 mol %; $M_w \sim 30\,000$ and $M_w/M_n = 1.3\text{--}1.5$) peptide side chains, were supplied by Polymer Laboratories, Shrewsbury, U.K. The C-terminal amino acid in both peptide side chains was esterified with 4-nitrophenol, the content of displaceable activated ester being calculated from the extinction coefficient of bound 4-nitrophenol at 274 nm in dimethyl sulfoxide (DMSO) ($\epsilon = 9500\text{ L}\cdot\text{mol}^{-1}\cdot\text{cm}^{-1}$).

APE (NSC176328) was a gift from the National Cancer Institute, Washington, D.C. Dry solvents were supplied by Aldrich, U.K., and dispensed under argon. Chemicals were obtained from Aldrich, U.K., Fischer Chemicals, U.K., or BDH Ltd., U.K., unless otherwise stated.

Synthesis of HPMA Copolymer-GFLG(5 mol %)-APE (1a), HPMA Copolymer-GFLG(10 mol %)-APE (2a), and HPMA Copolymer-GG(5 mol %)-APE (3a) (Method 1). HPMA copolymer (1 equiv, calculated as 4-nitrophenyl ester) and APE (2 equiv) were dissolved in minimal volumes of dry DMSO. Triethylamine (2 equiv) was added to the copolymer solution to neutralize the hydrochloride protons of the APE solution which was added dropwise to the reaction mixture. Aminolysis was allowed to proceed for 5 h. To complete the aminolysis of any unreacted esters, 1-aminopropan-2-ol (2 equiv) was added to the reaction mixture (1 h). The DMSO was removed at room temperature under high vacuum and the residue redissolved in distilled water. The reaction mixture (comprising conjugate, 4-nitrophenol, and unreacted 1-aminopropan-2-ol and unreacted APE) was then dialyzed against distilled water (M_w cutoff 5000, solvent resistant grade, cellulose ester; Spectrapor, USA, Pierce and Warriner, U.K.). For small-scale preparations, an additional purification step was undertaken. The reaction mixture was applied to a PD10 (Sephadex G25) column in water and the void volume fraction collected and freeze-dried. For larger scale preparations, this step was omitted. Overall yields based on polymer weight were 60–75%.

Synthesis of HPMA Copolymer-GFLG(5 mol %)-APE (1b–d) (Method 2). HPMA copolymer-GPLG–p-

nitrophenol ester (5 mol %) (1 g) was dissolved with stirring in dry dimethylformamide (DMF) (25 mL). APE (84 mg, 0.75 equiv) was dissolved in dry DMSO (17 mL). The solutions were mixed, a small aliquot of each (5–10 μL) being retained for thin-layer chromatography (TLC). A dilute solution of dry triethylamine in dry DMF (1:100 v/v, 9.3 mL, 3:1 equiv to APE) was prepared for addition in aliquots (500 μL) at 5 min intervals to the reaction mixture. After each addition, with swirling, samples (10 μL) were taken into a 1 mL cuvette containing Dulbecco's phosphate-buffered saline (pH 7.0), and the initial absorbance at 400 nm was noted to follow the release of 4-nitrophenol (Shimadzu UV-1601 UV-visible spectrophotometer). The reaction mixture, initially pale yellow, decolorizes after the first six aliquots of triethylamine; then the yellow color progressively deepens. The absorbance at 400 nm reaches a plateau as triethylamine addition is completed, consistent with the displacement of the calculated amount of 4-nitrophenol (0.75 equiv). The disappearance of unbound APE was followed by thin-layer chromatography (TLC) [on Kieselgel ALU 60 F₂₅₄ silica gel plates from Merck, using chloroform/methanol/triethylamine 8:1:1 (v/v) as the mobile phase]. The reaction mixture was left overnight in the dark, and then quenched with dilute 1-aminopropan-2-ol (1:100 v/v in dry DMF, 2.2 mL) for 1 h. The solvents were evaporated under high vacuum at 30 °C, and the resulting gum was dissolved in distilled water (60 mL) and dialyzed against three changes of distilled water over 48 h (Spectrapor M_w cutoff 2000, solvent resistant). The contents of the dialysis tubing were freeze-dried to constant weight (750 mg). The content of APE in the preparation (wt %) was determined by UV at 295 nm using APE as a standard.

Determination of Impurities in HPMA Copolymer–APE Conjugates by HPLC. Samples of HPMA copolymer–APE conjugates (1–5 mg) or APE (1–10 μg) were dissolved in 900 μL of water. Doxorubicin (100 μL of a 0.3 g/L stock solution) was added to each sample as an internal standard. The pH of the samples was adjusted to 8.5 with ammonium formate buffer (200 μL , 1 M, pH 8.5), and then a mixture of chloroform/propan-2-ol at a ratio of 80:20 (8 mL) was added. Samples were thoroughly mixed by hand and then centrifuged at 2000g for 10 min. The lower organic layer was carefully removed and placed in glass test tubes. The solvent was evaporated under nitrogen and the dry residue dissolved in 200 μL of methanol/water 60:40 (v/v). APE content was determined by HPLC using a $\mu\text{Bondapak C}_{18}$ (150 mm $\times$ 3.9 mm) column and methanol/water 60:40 (v/v), pH 2.2, adjusted with *o*-phosphoric acid as the mobile phase delivered at 1 mL/min using an LKB Bromma 2150 HPLC pump. A UV detector (Spectroflow 783 Kratos analytical) with a fixed-wavelength filter (307 nm) was used to monitor APE, ellipticine, and doxorubicin.

Determination of the Solubility of APE and HPMA Copolymer-GFLG(5 mol %)-APE (1c) in Phosphate-Buffered Saline (PBS). A stock solution of APE in DMSO was prepared (0.1 mg/mL). To obtain a calibration curve (absorbance at 296 nm), samples were diluted using PBS to give an APE concentration range of 0–5 $\mu\text{g/mL}$. The maximum solubility of APE was determined at 37 °C or at room temperature by preparing a saturated solution in PBS (5 mL) with adjustment of the pH to 7.4 by addition of sodium hydroxide (0.1 M). Either at room temperature or at 37 °C (the saturated solution was left for 10 min to warm, the pH being rechecked) the solution was filtered through a 0.45 μm filter. Triplicate samples (10 μL) were then diluted in PBS (1 mL; 37 °C or room

temperature, respectively), and the absorbance at 296 nm was measured.

In similar experiments, the conjugate **1d** (50 mg) was dissolved in PBS (2 mL) at 37 °C with pH adjustment and equilibration for 10 min. A clear solution was obtained which was nevertheless filtered (to allow for equivalent losses) and treated as before.

Size Exclusion Chromatography (SEC). SEC analysis was performed using two TSK-gel columns in series (G3000 PW followed by G2000 PW) with a guard column (Progel PWXL) and a differential refractometer (Gilson 153 refractive index detector) and a UV-visible spectrophotometer (UV Savern Analytical SA6504) as detectors connected in series. A Tris buffer (Tris, 0.05 M; NaCl, 0.5 M) was used as the mobile phase, delivered at 1 mL/min by a Jasco PU-980 pump. PowerChrom AD Instrument software was used for recording the detector output signal and for analysis of the data.

Evaluation of HPMA Copolymer-APE Conjugate Degradation by Tritosomes (Rat Liver Lysosomal Enzymes). *Preparation of Tritosomes and Determination of Their Activity.* Rat liver lysosomal enzymes were prepared according to the method described by Trouet (21), and their protein content was determined using bicinchoninic acid assay (22). The tritosome protein content of the tritosomes used here was 1.7 mg/mL. Their proteolytic activity was determined by measuring the release of *p*-nitroanilide from *N*-benzoyl-Phe-Val-Arg-*p*-nitroanilide (23). Activity was 25 nM min⁻¹ (mg of protein)⁻¹.

Degradation Studies. HPMA copolymer-APE conjugates (at a concentration of 46 µg/mL APE-equiv) to give comparable substrate (peptide spacer-APE concentration) or APE (1–10 µg) were incubated at 37 °C in citrate-phosphate buffer containing 0.2% Triton X-100 (400 µL) in the presence of EDTA (100 µL, 10 mM) and GSH (100 µL, 50 mM). To start the degradation study, tritosomes warmed to 37 °C (200 µL) were added, and the tube was thoroughly mixed. Aliquots of reaction mixture were taken at times 0–10 h, immediately frozen in liquid nitrogen, and stored frozen in the dark until processed by HPLC.

HPLC Evaluation. The samples were mixed with distilled water (800 µL) and ammonium formate buffer (100 µL, 1 M, pH 8.5) and doxorubicin (100 µL of a 0.3 g/L solution) added as an internal standard. The content of free APE was then determined as described above. Throughout this procedure, samples have to be kept on ice because it was noticed that the APE degrades within the organic phase at room temperature to give ellipticine.

Evaluation of Rat Red Blood Cell Lysis. HPMA copolymer-GFLG-APE (**1a**, **1b**), HPMA copolymer-GG-APE (**3a**), APE, and ellipticine (final concentrations between 5 mg/mL and 1 µg/mL) were incubated at 37 °C with rat erythrocytes (2% w/v) for 1 or 24 h. Intact cells and debris were then removed by centrifugation (1500g, 10 min), and the supernatant was removed and used to assess hemoglobin release spectrophotometrically (at 550 nm) using a microtiter plate reader. Data were expressed as the percentage hemolysis observed compared with total hemolysis induced by Triton X-100 (0.5%).

Determination of In Vitro Cytotoxicity. In vitro cytotoxicity of APE and the conjugates was evaluated according to a standard, 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT), cell viability assay (24) using a B16F10 mouse melanoma cell line. B16F10 cells (10⁴) were seeded in 96-well microtiter plates and then left for 24 h to establish. APE or the HPMA copolymer-GFLG(5 mol %)-APE (**1c**) conjugate was

added in fresh medium (concentration range 0.01–70 µg/mL). Cells grown in medium alone were used as a control. After 67 h of incubation, MTT (20 µL of a 5 mg/mL solution) was added to each well, and the cells were incubated for a further 5 h. After removal of the medium, the precipitated formazan crystals were dissolved in spectroscopic grade DMSO (100 µL), and, after 30 min, the optical density was measured at 550 nm using a microtiter plate reader. Results are expressed as a percentage of cells grown in the absence of drug.

Antitumor Activity of APE and HPMA Copolymer-APE in Vivo. All experiments were conducted according to UKCCCR Guidelines governing experiments with neoplasia.

Male C57BL/6J mice were inoculated s.c. with 10⁵ viable B16F10 murine melanoma cells. Tumors were allowed to reach a palpable size (~50–70 mm² calculated from the product of the two longest diameters), and treatment (saline, free APE, or conjugate **1c** at doses calculated as APE-equiv) was administered by single-dose i.p. Mice were weighed daily, and the tumor growth was also monitored daily until tumor area reached the maximum allowable 289 mm². At this time or if the drugs used showed evidence of toxicity, the animals were humanely killed. Data are expressed as *T/C* values, i.e., the ratio of the mean time to tumor progression of the treated group to the mean time to tumor progression of the control group expressed as a percentage. Animal groups were statistically compared by a Student's *t*-test.

RESULTS AND DISCUSSION

Synthesis and Characterization. Successful conjugation of APE to HPMA copolymer intermediates was achieved using a standard aminolysis reaction (18) (Figure 2). This was predictable as the 3-dimensional structure of APE (Figure 3) shows that the primary amino group is free from any steric hindrance, standing well outside the plane formed by the unsaturated rings. Conjugates were synthesized to contain a range of APE loadings (Table 1). To maximize yield of conjugation, an improved conjugation method was used to prepare conjugates **1b–d**. In the small-scale pilot preparations (1–5 mg of polymer), 4-nitrophenol release (Figure 4) was in molar accordance with that expected. Maintenance of high concentrations of reagents in dry solvents and dropwise addition of the triethylamine to free the 3'-amino group of APE slowly from its hydrochloride salt (such that the copolymer remained in excess during the reaction) were both critical for successful conjugation. Also the use of 0.75 equiv of APE (method 2) instead of 2 equiv (as indicated in method 1) gave greatly improved yields of substitution of the peptide linker. For example, synthesis of conjugate **1a** had a yield of 25.7% compared with a minimum of 62.9% yield for synthesis of conjugates **1b–d**.

During the reaction, the disappearance of free APE and the appearance of conjugate were followed by TLC (*R_f* APE: 0.4, bound APE remains at the origin; *R_f* 4-nitrophenol: 0.9), and after dialysis no free APE was detectable by TLC. The higher sensitivity of the HPLC procedure showed that there was some free APE, and also small amounts of free ellipticine, present (Table 1). However, the amounts of these impurities detected represent <0.1% of the conjugate by weight, and <0.5% of the APE in the preparation was present as free drug—except in conjugate **1a** which contained 2.6% free APE related to the total APE. It is worth noting that conjugates **1b–d** prepared using method 2 contained lower

Figure 3. Three-dimensional structure of 6-(3-aminopropyl)-ellipticine.

amounts of free drug than seen when conjugates were synthesized using the original method.

SEC analysis confirmed that APE was conjugated to HPMA copolymers uniformly across the molecular weight range (Figure 5). Both RI and UV detection showed some evidence of aggregation (as indicated by the peak at 11 min). This is not surprising as APE is a hydrophobic drug and its planar aromatic structure would probably promote stacking between the drug molecules present on the polymer backbone. It has already been shown that side-chain chemical modification can influence the solution properties of HPMA copolymers (25).

Figure 4. Pilot study of displacement of *p*-nitrophenol from HPMA-GFLG(5 mol %)-ONp treated with 0.75 equiv of APE. Results derived from triplicate measurements of absorbance at 400 nm (SD $\pm$ 1.7%).

A major problem encountered with previous ellipticine derivatives was their limited solubility (26). Here it was found that the maximum solubility of APE at room temperature and 37 °C was 44.5 and 62.4 μ g/mL,

Figure 5. Size exclusion chromatograms of the polymer precursor after hydrolysis of the *p*-nitrophenyl ester and the resulting conjugate with APE, using a refractometer detector (a) and a UV detector (b). V_0 indicates the exclusion volume of the columns and V_t the total elution volume.

respectively. Drug conjugation to HPMA copolymers dramatically improved solubility. For example, the conjugate **1c** was still soluble at 37 °C at an APE-equiv concentration of 625.2 $\mu\text{g/mL}$. The APE concentration in solution increased at least 10-fold by its incorporation into the HPMA copolymer, and this observation is consistent with observations made following conjugation of HPMA copolymer to doxorubicin, camptothecin, or taxol (7–9).

Biological Properties of HPMA Copolymer-APE Conjugates. During incubation with tritosomes, HPMA copolymer-GFLG-APE conjugates (**1a**, **1b**, **2a**) released APE over time to a maximum of ~80% in 10 h (Figure 6). No peptidyl-APE degradation products were seen. Experiments involving HPMA copolymer-GG-APE (**3a**) as substrate or incubation of the above conjugates (**1a**, **1b**, **2a**) without enzyme showed no drug liberation. These results are in agreement with results obtained with HPMA copolymer-GFLG-doxorubicin conjugates. The diglycyl linker is not degraded by tritosomes, while the GFLG spacer released ~30% of doxorubicin after 10 h (20). In the case of HPMA copolymer-APE conjugates, drug loading clearly had an effect on the rate of APE release. The two conjugates (**1a**, **1b**) having a similar APE content (~7 wt %) released the same amount of drug during 10 h incubation (Figure 6). In contrast, conjugate **1a**, having an APE content of only 2.3 wt %, released 80% of APE over the same time interval. Recent studies (27) infer that HPMA copolymer-APE conjugates with a higher APE loading form in solution intramolecular micelles as observed in comparable systems (25), which would therefore be expected to limit enzyme accessibility to the peptidyl side chain. Ongoing studies are trying to

Figure 6. Percent of APE released from the conjugates HPMA-GFLG(5 mol %)-APE (**1a**, **1b**), HPMA-GFLG(10 mol %)-APE (**2a**), and HPMA-GG(5 mol %)-APE (**3a**). The numbers in boldface represent the samples incubated without tritosomes.

Figure 7. Percent of red blood cell lysis after 1 h incubation at 37 °C with APE and ellipticine at concentrations between 1 $\mu\text{g/L}$ and 5 g/L .

determine the drug loading that will produce an optimum therapeutic index in vivo. Using HPMA copolymer-doxorubicin conjugates and their evaluation in a murine L1210 (i.p.) model, it was shown that a slower doxorubicin release rate led to significantly improved efficacy in vivo (20). However, in the clinical setting, there is still a need to understand better how dose schedule and drug release rates can be best optimized to give maximum therapeutic index in the treatment of solid tumors.

Ellipticines cause significant red blood cell damage [attributed to interaction with negatively charged phospholipids in the membrane (28)], and hemolysis occurs in rhesus monkeys and beagles at doses of 3 mg/kg (28). Here APE and ellipticine caused 50% hemolysis (after 1 h) at 35 and 600 $\mu\text{g/mL}$, respectively (Figure 7). None of the conjugates tested (at concentrations up to 350 $\mu\text{g/mL}$ APE-equiv) demonstrated any in vitro hemolytic activity after either 1 h (Figure 8) or 24 h (data not shown). Polymer-bound APE must be sufficiently well-hidden within the polymer coil to minimize membrane interaction. This property of conjugated drug may lessen the risk of severe hepatic toxicity (as encountered in the Phase I trials of datelliptium) and avoid scheduling difficulties as encountered with elliptinium acetate [these toxicities are reviewed in (1)].

The IC_{50} value of APE was 0.4 $\mu\text{g/mL}$ against the B16F10 cell line (Figure 9). Conjugate **1c** was >75 times less active ($\text{IC}_{50} > 30 \mu\text{g/mL}$ APE-equiv—all cells were

Table 2. Antitumor Activity of APE and HPMA-GFLG(5 mol %)-APE Conjugate in Mice Bearing s.c. B16F10 Melanoma

treatment	dose ^a (mg/kg)	mean time to tumor progression (±SE)	T/C (%)	toxic deaths

Figure 8. Percent of red blood cell lysis after 1 h of incubation at 37 °C with HPMA-APE conjugates compared to the percent of red blood cell lysis obtained after 1 h of incubation with APE.

Figure 9. In vitro cytotoxicity on the B16F10 mouse melanoma cell line of APE and HPMA-GFLG (5 mol %)-APE (**1c**) at concentrations of APE between 0.01 and 70 μg/mL.

still viable at this concentration). The HPMA copolymer-APE conjugates (except conjugate **1a**) showed no significant activity in the NCI screen (29) ($t = 48$ h) up to a conjugate concentration of 50.1 μg/mL (~3.5 μg/mL APE-equiv) (NCI Developmental Therapeutics Program, unpublished results). Although conjugate **1a** did show some activity, this was simply attributable to free APE in the conjugate. These results illustrate the impossibility of adequately assessing polymer-drug potential using standard in vitro assays. Whereas free drug present in the culture medium can permeate cells within minutes, the conjugates enter cells slowly via the endocytic route, and, moreover, once internalized, the active drug is also liberated very slowly (30).

A s.c. B16F10 murine model, well standardized in terms of EPR-mediated targeting of PK1 (10), was chosen as a preliminary screen to evaluate the antitumor activity

of HPMA copolymer-APE. Despite lack of body weight loss (results not shown), three toxic deaths were recorded (Table 2) during dose escalation. The highest T/C seen for free APE (127%) was at a dose of 1 mg/kg. At the same dose (1 mg/kg APE-equiv), conjugate **1c** had a T/C = 143% (Table 2). Although the HPMA copolymer-APE showed better antitumor activity than APE for a dose of 1 mg/kg, this was not statistically significant ($p = 0.26$, Student's *t*-test). However, the moderate activity seen is not surprising knowing that a single dose of PK1 (given i.p.) is poorly active in the aggressive s.c. B16F10 tumor model (31). In this study, treatment with PK1 at doxorubicin doses of 5, 10, and 20 mg/kg produced T/C values in the range 98–175%, and i.v. treatment was necessary to obtain higher T/C values. The antitumor activity of the HPMA copolymer-APE conjugates presented here is promising when compared to that of other ellipticine analogues in the B16F10 model (32).

On dose escalation with HPMA copolymer-APE, unexpectedly a T/C value less than that seen for the 1 mg/kg dose was seen (Table 2). This phenomenon could be due to dose-dependent precipitation of the compounds in the peritoneal cavity, an increase of the liver clearance, a preferred accumulation site other than the tumor, or a significant decrease of the release of APE from the conjugate with increasing dose. A dose-dependent bio-distribution study will give an insight into the mechanism of action of the HPMA copolymer-APE conjugates.

The intracellular site of action of ellipticine drugs is not established unequivocally (33–36), but passage through the lysosomes [as indicated by granular cytoplasmic fluorescence and radiolocalization (37, 38)] does not preclude cytotoxicity. The preliminary in vivo studies reported here confirm that HPMA copolymer-APE does show antitumor activity. Further studies are needed to establish the magnitude and spectrum of activity using a panel of different murine and human tumors.

So far, only HPMA copolymer conjugates containing established antitumor agents such as doxorubicin, paclitaxel, camptothecin, and platinates [reviewed in (14)] have progressed to clinical trial. The polymer is proving its safety in man, and drug conjugation can be used to dramatically reduce the toxicity of bound drug; PK1 is ~5 times less toxic than doxorubicin (17). From these observations, it is clear that drug conjugation has the potential to assist the delivery of highly toxic natural product drugs and/or provide improved forms for promising antitumor agents that fail in either preclinical or early clinical development. The ellipticines are an example of the latter. Here HPMA copolymer-APE conjugates displayed improved solubility and reduced hemolytic activity and released APE in the presence of lysosomal enzymes. Preliminary experiments showed that they display antitumor activity in vivo, and although the activity seen was modest, the B16F10 model is particularly aggressive. A recent study on S16020-2 (an ellipticine analogue in clinical trial) using a much higher

multiple dosing regimen (up to 9 doses of 20 mg/kg) resulted in a similar activity ($T/C = 161\%$) (32). HPMA copolymer-Gly-Phe-Leu-Gly-APE warrants further biological evaluation (pharmacokinetics and pharmacology at its maximum tolerated dose) to determine their potential for clinical testing. Additionally, polymer conjugation could, in principle, also be usefully applied to other ellipticine derivatives, notably the potent 9-hydroxyellipticine that has an IC_{50} of $0.06 \mu M$ against L1210 cells in vitro (2 and references cited therein).

ACKNOWLEDGMENT

The National Cancer Institute supported this project and supplied APE. We also thank Professor H. Ringsdorf for helpful discussions.

Triple, MPEG-Conjugated, Helix-Forming Oligonucleotides (TRIPEGXs): Liquid-Phase Synthesis of Natural and Chimeric “All-Purine” Sequences Linked to High Molecular Weight Poly(ethylene glycols)

M. Ballico,[†] S. Drioli,[†] F. Morvan,[‡] L. Xodo,[§] and G. M. Bonora^{*,†}

Department of Chemical Science, Via Giorgieri 1, University of Trieste, 34127 Trieste, Italy, Laboratoire de Chimie Organique Biomoléculaire de Synthèse, UMR 5625 CNRS UMII, Université de Montpellier II, 34095 Montpellier Cedex 5, France, and Department of Biomedical Science and Technology, P.le Kolbe 4, University of Udine, 33100 Udine, Italy. Received March 8, 2001; Revised Manuscript Received July 10, 2001

Long “all-purine” oligonucleotides, up to the 20mer, known to be active as antigene effectors, conjugated to high molecular weight monomethoxy poly(ethylene glycol)s (MPEG)s, were successfully synthesized. Through a liquid-phase, MPEG-supported process, both natural and chimeric sequences containing selected phosphorothioate backbone modifications were obtained, purified, and characterized. To follow their cellular trafficking, a fluorescent probe was linked by soluble supported organic reactions to the 5'-terminus, and the efficiency of the different synthetic procedures for the introduction of a fluorescein moiety was compared. The usefulness of the fluorescent marker was estimated by laser confocal microscopy that ascertains that the MPEG-conjugation enhances the oligonucleotide capacity to cross the cellular membranes and to be accumulated inside the nuclei.

INTRODUCTION

The liquid-phase method, in which a soluble polymer supports the chemical synthesis of simple organic molecules, as well as of large biopolymers, has seen in these last years an explosion of successful applications (1). It is worth recalling that the replacement of insoluble cross-linked resins, such as those employed in the Merrifield-like solid-phase procedures, can solve the problems of converting solution-based reaction protocols for their use under heterogeneous conditions. Moreover, this methodology appears to tolerate an easy scaling-up of the process, as demanded by its commercial development (2). Among the investigated soluble polymers, the monomethoxy poly(ethylene glycol) (MPEG) is by far the most commonly used support, since its first application on peptide synthesis (3). Oligonucleotides were also synthesized through a MPEG-based approach (4), and even very recently a further development of their liquid-phase synthesis was proposed (5), proving the active interest in this methodology. In addition, a modified process was recently set up for the preparation of oligonucleotides chemically linked to high molecular weight MPEGs (6).

The conjugation of polymeric moieties to pharmacologically active molecules represents a promising approach to solve problems due to their *in vivo* lability and poor biodisposability (7). In particular, the oligonucleotides are characterized by a rapid enzymatic degradation and insufficient cellular uptake; however, once conjugated to a MPEG moiety, they are more resistant to nuclease digestion (6, 8). A critical mass value of the MPEG unit

is also observed: significant biological effects are recognized with increased molecular weights of the conjugated polymer (9). It must be stressed that the high viscosity, and poor reactivity, of the reacting polymer hampers an efficient postsynthetic conjugation of high molecular weight MPEG to oligonucleotides. In our case, since the liquid-phase procedure employs large MPEG chains as supports, the same MPEG unit can be left linked to the final oligonucleotide by using a chemical bond (a phosphodiester) that will not be hydrolyzed during the final deblocking procedure (6). This trick allows in principle the introduction of variable-mass MPEG on the synthesized nucleic acid chain.

As indicated by the first biological studies, the MPEG moiety does not impede the formation of the double helix between the linked oligonucleotide and the nucleic acid complementary target; moreover, its presence grants the natural degradative activity of the ubiquitous RNase H on the RNA part of the new duplex, once formed (10). As a further extension of these investigations, the formation of a triple helix between MPEG-conjugated oligonucleotides and a double-helical DNA target is of special interest (11). These MPEG-conjugated, triple helix forming oligonucleotides are dubbed TRIPEGXs. Their biological behavior is actually under investigation in cultured cells (12). As a testing sequence, an “all-purines” AG 13mer was initially preferred, since it recognizes a polypurine-polypyrimidine motif located in the human *bcr* promoter (13); successively, a longer AG 20mer active against the human Ki-ras oncogene that is overexpressed in many human tumors was synthesized (14). The synthesis of oligonucleotide chains bearing multiple guanosine sequences is not easy because their presence gives rise to low-solubility intermolecular structures (15) that make the chromatographic purifications difficult. The presence of a high-mass MPEG can reduce their intermolecular interaction and allows an easier produc-

tion of such molecules. In addition, the amphiphilic property of this polymer should improve the nuclear internalization of the conjugated oligonucleotide. Both uptake and intracellular distribution of oligonucleotides were examined by confocal laser microscopy of their fluorescein-labeled derivatives (16). Usually, the introduction of a fluorescent moiety is achieved through preformed building blocks or by postsynthetic modification of the oligomers (17–19), both at its extremity as well as along the chain. In our case, since the MPEG unit is linked at the 3'-extremity of the oligonucleotide, an efficient liquid-phase procedure for the postsynthetic modification of the 5'-OH extremity is demanded.

In conclusion, in the present paper we describe the liquid-phase synthesis of "all-purine" sequences conjugated to high molecular weight MPEG, natural or chimeric, i.e., bearing some phosphorothioate modifications selectively located along the backbone, to be used as antigene effectors. To study the oligonucleotide cellular uptake and internalization, further conjugation with a fluorescein derivative was investigated. The compatibility of fluorescein derivatives with the liquid-phase approach was examined, and compared with similar solid-phase approaches (20). Synthesis and purification of these molecules were discussed, and their characterization was reported. An example of the cellular internalization process of these fluorescent MPEG-oligonucleotides is also described.

EXPERIMENTAL PROCEDURES

Synthesis of the MPEG-Conjugated Oligonucleotides. The synthesis of the MPEG-conjugated oligonucleotides was performed following the phosphoramidite-based procedure previously described (6).

A 9000 Da molecular mass monomethoxy poly(ethylene glycol) (MPEG) was used for the 13mer oligonucleotide complementary to the pyrimidinic tract of the *bcr* sequence. In the case of the 20mer complementary to the human Ki-ras S5, a 10 000 Da MPEG was preferred. Both syntheses were performed on 1.0 g of MPEG, corresponding to an approximate 100 μ M scale. The reaction yields were calculated by spectrophotometric analysis of the MPEG-conjugates, using the absorption of the DMT group at 498 nm, as previously reported (6), when a new DMT-bearing molecule was added.

The five thioate substitutions along the anti-Ki ras sequence were obtained by dissolving, after each coupling step, the MPEG-conjugated, growing oligonucleotide in acetonitrile (10% w/v), and reacting it with 10 equiv of diethoxy-dithiocarbonyl-disulfide (DDD) from a 0.5 M solution in acetonitrile. After 15 min under stirring, the product was precipitated with TBME, filtered, washed with ether, and dried under vacuum over KOH pellets.

The fully protected, MPEG-conjugated oligonucleotides were deprotected through the standard two-step ammonia/acetic acid procedure. The final purification was achieved by an anion-exchange HPLC performed on a Mono Q HR 5/5 column. The starting eluent was a 0.05 M NaCl solution, pH 12.0. The MPEG-13mer was eluted with a 0.5 M NaCl solution, pH 12.0, the gradient ranging from 25 to 80% over 30 min. The MPEG-20mer was eluted with a 2.0 M NaCl solution, pH 12.0, the gradient ranging from 0 to 100% over 30 min. Both products were desalted by gel filtration on Sephadex G25-F columns eluted with MilliQ water.

Introduction of the Fluorescein Probe. The introduction of the fluorescein moiety on the MPEG-conjugated oligonucleotide was performed on the 5'-detrity-

lated derivative, OH-free. Three different procedures were investigated:

(a) *Reaction at the 5'-OH Terminal Group with N-Hydroxysuccinimidofluorescein (Fluo-Osu).* Fifty milligrams of 5'-detritylated, MPEG-conjugated oligonucleotide was dissolved in a 50 mL three-neck reactor equipped with self-sealing septa. The product was coevaporated twice from anhydrous acetonitrile, thoroughly desiccated by a rotating pump, and left under an argon atmosphere. Through the septa, 1.0 mL of solution containing 100 mg of Fluo-Osu, freshly prepared (40 equiv), and 20 mg of DMAP was injected; a few drops of anhydrous DMF were added to create a clear solution. The reaction mixture was left under stirring for 72 h, and the product was precipitated, under stirring in an ice bath, by addition of TBME. The MPEG-conjugate was washed with i PrOH and ether, recrystallized from EtOH, and dried under vacuum over KOH pellets.

(b) *Reaction at an NH₂ Group, Introduced at the 5'-Terminal Position, with the Fluo-Osu Derivative.* The 5'-terminal position was previously modified by introduction of an NH₂ group through a commercial "amino-modifier", namely, the 2-[2-(4-monomethoxytrityl)aminoethoxy]ethyl-(2-cyanoethyl)-(N,N-diisopropyl)-phosphoramidite (Glen Research). This synthesis was performed, as during the standard coupling step, by reacting 12 equiv, with respect to the free 5'-OH terminal groups, of the modifying phosphoramidite reagent dissolved in acetonitrile and 50 equiv of 1*H*-tetrazole on the same solvent, in anhydrous conditions, under an argon atmosphere. Fifty milligrams of MPEG-conjugated oligonucleotide in a total of 1.0 mL of anhydrous acetonitrile solution was employed. From the absorbance of the MMT group measured at 472 nm in p-TsOH 0.1 M in acetonitrile ($\epsilon = 17.600$), a 45% yield of reaction was measured.

After oxidation of the new phosphite bond, ammonia deprotection, and removal of the MMT 5'-amino-protecting group with an 80% (v/v) glacial acetic acid solution for 4 h, the MPEG derivative was lyophilized and reacted with 100 equiv of Fluo-Osu, as described in the previous procedure. The product was precipitated with TBME, washed with i PrOH and ether, and dried under vacuum over KOH pellets.

(c) *Reaction at the 5'-OH Terminal Group with a Fluo-Amidite Derivative.* Fifty milligrams of the 5'-detritylated, MPEG-conjugated oligonucleotide was extensively dehydrated, as reported, in a three-neck reactor equipped with self-sealing septa. Under an argon atmosphere, the solid was dissolved in a minimum amount of anhydrous acetonitrile. Successively, 6 equiv of the Fluo-amidite derivative, namely, the 1-DMT-2-(N-thiourea(di-O-pivaloyl-fluorescein)-4-aminobutyl)-propyl-3-O-(2-cyanoethyl)-(N,N-diisopropyl)-phosphoramidite (Glen Research), and 25 equiv of 1*H*-tetrazole were added, and left to react under stirring for 15 min in an overall 1.0 mL solution. The product was precipitated, after cooling, with TBME and washed. The final derivative was recrystallized from EtOH to remove all soluble byproducts and residual excess reagent. From the DMT absorption, a 97% condensation yield for the MPEG-13mer and an 89% yield for the MPEG-20mer were measured. The phosphite bond was oxidized by the usual procedure and the product fully deprotected under standard treatment.

Confocal Microscopy. Confocal microscopy experiments were performed following a standard propidium iodide (PI) staining of cells fixed on a glass slide. K562 cells, supplied by Dr. M. Giunta (University of Udine), were seeded in 12-well plates at a density of 0.8×10^5 cells in 600 μ L of RPMI medium supplemented with 10%

heat-inactivated fetal bovine serum 24 h before being added with the oligonucleotides. Cells were treated with free Fluo-13mer or Fluo-13mer-MPEG. After centrifugation, the cells were washed twice with PBS, spun on a glass slide, and fixed with 3% paraformaldehyde (PFA) for 20 min. After washing with 0.1 M glycine containing 0.02% sodium azide to remove PFA and Triton X-100 (0.1% in PBS), the cells were incubated with PI and RNase for 30 min at 37 °C in order to stain the nuclei. Then coverglasses were mounted on the glass slide with Mowiol 4-88 and Dabco (2.5%). Fixed K562 cells were analyzed with a Leica DM IRBE confocal imaging system. Diaphragm and fluorescence detection levels were adjusted to reduce to a minimum any interference between fluorescein and PI channels.

Characterization of the MPEG-Conjugated Oligonucleotide. The spectrophotometric analyses were performed on a Helios β UNICAM spectrophotometer.

^1H and ^{31}P NMR spectra were recorded on a JEOL EX 400 spectrometer, utilizing CDCl_3 (99.96%) as solvent and TMS and 85% phosphoric acid as internal standards.

MALDI-TOF mass spectra were recorded on a Voyager DE mass spectrometer (Perseptive Biosystems, Framingham, MA) equipped with a N_2 laser (337 nm). MALDI conditions are as follows: accelerating voltage, 24 000 V; guide wire, 0.05% of accelerating voltage; grid voltage, 94% of accelerating voltage; delay extraction time, 550 ms; and 256 scans averaged. Samples were mixed with trihydroxyacetate phenone (THAP) or 2,5-dihydroxybenzoic acid (DHB) as a matrix.

To ascertain the purity of MPEG-conjugated derivatives, TLC on silica gel 60 F254 was utilized with the eluant $\text{CHCl}_3/\text{EtOH} = 9:1$ (v/v). The purified compounds were evaluated by an analytical IE HPLC column (eluant: gradient of NaCl, at pH 12.0, from 0.05 to 0.6 M in 38 min for the MPEG-13mer and its shorter derivatives, and from 0.05 to 2.0 M in 25 min for the MPEG-20mer and its shorter derivatives). An FPLC apparatus (Pharmacia) equipped with a Mono Q HR 5/5 column was used. The purity of the longer MPEG-conjugated oligonucleotides was also investigated by the gel electrophoresis technique, in denaturing conditions, on 20% polyacrylamide. Conditions: 2 h of prerunning at 55 °C, 600 V, 25 mA, 15 W; 30 min of running at 55 °C, 600 V, 23 mA, 15 W. Staining with a "stains-all" solution: MPEG-conjugated oligonucleotides appear as blue bands.

Maxam and Gilbert G reaction for footprinting experiments was performed according to the standard procedure (21).

RESULTS AND DISCUSSION

Synthesis and Purification of "All-Purine" MPEG-Conjugated Oligonucleotides. The liquid-phase synthesis of TRIPEGXs was performed by the standard procedures described for similar compounds in a previous paper (6). Concentration, size of support, excess of reagents, and general procedures were followed with meticulousness for a safe comparison with earlier syntheses. A main difference was obviously introduced when a phosphorothioate substitution along the backbone was required. The sulfurizing agent was different from that described in a similar process (22); in this case, the DDD previously used for a large-scale liquid-phase production of fully thioate free oligonucleotides was employed (2). Its efficacy and convenience even in the production of a chimeric phosphate/thioate product were confirmed.

The sequences of the two MPEG-oligonucleotides to be synthesized are reported in Scheme 1. Obviously, the

20mer	5	3.0	3.4

conjugated, chimeric anti-Ki-ras 20mer shows the same number and position of thioates as in the free 20mer previously investigated (14). A main drawback was expected in these syntheses due to the presence of long, repeated stretch of guanines along the final sequence. Since it is well-known that guanine-rich chains have a strong propensity to form stable intermolecular aggregates, a positive effect was supposed to be given by a large unit of an amphiphilic polymer linked to the oligonucleotide chain, as in the case of the MPEG moiety. A first, positive response can be observed from the synthetic data reported for the two MPEG-conjugates (Table 1): it is quite clear that, under standard conditions, an almost quantitative yield during all the intermediate steps and a large amount of final, crude derivatives are obtained when a phosphoramidite-activated fluorescein is employed. The estimation of the expected ratio between natural phosphodiester and surrogate thioates in the case of the chimeric molecule, analyzed by ^{31}P NMR, confirmed the efficacy of the procedure within the experimental error (Table 2). In Figure 1 an example of a ^{31}P NMR spectrum of a chimeric, MPEG-conjugated oligonucleotide is reported.

The unfavorable intermolecular interactions of the synthesized derivatives were investigated in detail during the chromatographic purification. The accustomed reverse-phase HPLC was not adopted since the large MPEG component dominates the behavior of the conjugated molecules and gives a false uniform chromatographic pattern even in the presence of a mixture of products. Hence, a strong anionic support was preferred since the charge balance of different oligonucleotides is not suppressed by MPEG. As described in Figure 2, part A, the superimposition of selected products obtained during the overall synthetic production of the MPEG-13mer gives a clear image of the proceeding of the process. In Figure 2, part B, a similar chromatographic procedure, but on a preparative scale, shows that the higher sample concentration demanded by the larger operative scale generates some new late-running peaks, likely due to the aggregation of the single MPEG-conjugated chains. In fact, as reported in the inset, the product collected from those peaks, eluted once again in diluted, analytical conditions, gives a main peak superimposable to that of the pure,

Figure 1. ^{31}P NMR spectrum in CDCl_3 of crude, fully protected, chimeric MPEG-10mer.

Figure 2. Part A: Analytical IE HPLC (4 mg/mL) patterns of the crude MPEG-13mer and two shorter oligomers. Inset: Analytical IE HPLC of the purified and desalted MPEG-13mer. final product. The same features were given by the MPEG-20mer (noteworthy: the longest oligonucleotide conjugated to a high molecular weight MPEG unit so far obtained!). However, in this case, the chromatographic analysis and purification were made more troublesome due to the presence of the new chiral centers introduced

at the phosphorothioate level, and due to the consequent diastereomeric mixture that produced a multippeak pattern.

Gel electrophoresis analysis on denaturing, high-temperature, conditions (Figure 3) supports our belief in the efficiency of the proposed synthetic method. It is quite

Figure 3. Gel electrophoretic analysis on denaturing conditions of the MPEG-oligonucleotides.

clear that the polydispersity of the supporting MPEG does not allow a full investigation on the detailed composition of the final, purified compound. On the other hand, it ensures that only MPEG-conjugated derivatives are present, in which the nucleic acid component is expected to be homogeneous in length and composition on the basis of the analytical IE HPLC of the purified compounds (Figure 1, part A: inset).

An indirect determination of the final sequence of the TRIPEGXs was obtained by Maxam and Gilbert DMS/piperidine footprinting experiments with 50-mer duplexes containing the *bcr/abl* and Ki-ras target. It should be remembered that DMS reacts with guanine N7 only when this base is not involved in hydrogen bonding. We observed that all the guanines inside the targets were protected from chemical degradation, suggesting that the synthesized MPEG-conjugated oligonucleotides had the expected length and composition (data not shown).

Introduction of a Fluorescein Probe on the MPEG-Oligonucleotides. The purpose of this synthesis was to follow the cellular trafficking of the MPEG-conjugated oligonucleotides and to ascertain their nuclear accumulation, if any, since they are designed to interact with a double-helical, genomic DNA target.

Initially, the reaction of a Fluo-OSu molecule to form an ester bond with the free, terminal 5'-OH group of a simple conjugated dinucleotide was investigated. The same size of the supporting polymeric chain was utilized, namely, 9000 Da molecular mass. Taking advantage of the basic features of the liquid-phase procedure, a large excess of the activated fluorescein derivative was used to overcome the expected low reactivity of the system, but, even after repeated treatments, the final yield did not overcome a few percent reaction. The nucleophilicity of the terminal hydroxy group was clearly too low to permit the introduction of a satisfactory amount of the fluorescent probe. Hence, a more reactive amino group was introduced through a suitable, commercial linker using a phosphoramidite-based procedure. In this case, a good amount, even if not excellent, of linker was found to be present at the 5'-end of the MPEG-oligonucleotide. Successively, the higher nucleophilicity of the amino group allowed the isolation of a derivative bearing a larger amount of fluorescein, activated as previously described. A far better result, nearly quantitatively modified, was obtained by reacting a phosphoramidite-activated fluorescein with the MPEG-oligonucleotide,

Table 3. Yields of Introduction of the Fluorescein Derivatives on the Final, Crude MPEG-Oligonucleotides^a

once the 5'-DMT protecting group was removed. In this last reaction, a very high yield was obtained with the standard procedure utilized for the liquid-phase synthesis of the oligonucleotides (6). A further advantage derives from the reduced number of synthetic steps, since any previous introduction of an appropriate linker is avoided. The same reaction was performed on the larger, chimeric MPEG-20mer with similar results. In both cases, it must be reminded that these reactions were always performed on the crude, final mixture deriving from the liquid-phase synthesis of the MPEG-conjugates, since all the shorter, failure sequences were in advance, step-by-step, capped. Consequently, the only reacting chain able to bear a fluorescent probe was exclusively the longer, final sequence. In Table 3 yields of introduction of the fluorescein probes are reported.

A further advantage of this liquid-phase procedure was due to the spectral transparency of the MPEG support that allows an easy evaluation of the proceeding of the reaction through simple UV/Vis analyses. As an example, the UV spectrum of the fluorescent, fully deprotected MPEG-20mer is reported (Figure 4). Unfortunately, the ¹H NMR analysis of these products is difficult due to the low intensities of probes' signals and to their burial under those of the polymer.

Mass Characterization of MPEG-Conjugates. The correct sizes of the final MPEG-conjugated oligonucleotides were tentatively investigated by using MALDI mass spectroscopy. A set of crude, fully protected and deprotected final derivatives were analyzed, to establish if this technique could be convenient for their final characterization. It must be recalled that the electrospray (ESI) technique, proposed for the mass evaluation of similar compounds (23), in this case can be severely limited by the too large a size of the final conjugates. In our hands,

Figure 5. MALDI spectra of (A) starting MPEG and (B) fully protected MPEG-13mer (calculated mass = 14 952 Da).

the MALDI approach has disappointingly given only a partial reply. In particular, it was possible only to establish the mass of the fully protected MPEG-oligo, while any attempt was unsuccessful in the case of MPEG-oligos with charged linkages where only the signal corresponding to the starting MPEG was detected. A possible explanation is that MPEG is more easily ionized than the MPEG-oligos; hence, even a trace of MPEG present in the sample led to spectral suppression.

Typical MALDI spectra are reported in Figure 5.

Efficiency of MPEG-Conjugates as Fluorescent Probes. The fluorescent MPEG-oligonucleotides were tested in selected cell lines for their ability to penetrate the cellular membranes.

In the case of the MPEG-oligonucleotide in which the fluorescein moiety was linked through an ester bond, a low fluorescence intensity was initially observed inside the nucleus which rapidly disappeared, most probably for the hydrolysis of the probe and its removal from the cell.

A similar behavior was observed when the fluorescein molecules were joined to the oligonucleotide through an amide bond, following the previous introduction of an amino-linker at its 5'-extremity. Again, a rapid appearance of fluorescence was noticed inside the nucleus, but its intensity did not further increase, suggesting a reduced stability of the probe's bond.

With the third derivative, in which the chain was modified by a direct phosphorylation of the 5'-OH terminus with the proper fluorescein derivative, an increasing performance was recognized. In fact, a strong fluorescent emission from the nucleus was detected which augmented with time and stabilized at higher values after 72 h from the addition of the fluorescent MPEG-oligonucleotide. To demonstrate the efficiency of these fluorescent, high molecular weight, MPEG-conjugated oligonucleotides, their capacity to penetrate the cellular membranes and to internalize in the nuclei was investigated by laser confocal microscopy on leukemic K562 cells. Figure 6 shows typical confocal images of K562 cells exposed to 10 μ M fluorescein-labeled MPEG-13mer oligonucleotide for 2 and 6 h. The nuclei of the cells have been stained in red with propidium iodide. To evaluate the effect of MPEG on the transport of the 13mer in the cells, we compared the uptake of the unconjugated 13mer oligonucleotide (Fluo-13mer) with the uptake of the conjugated oligonucleotide (Fluo-13mer-MPEG). Panels A and B show that free Fluo-13mer is taken up by K562 cells, as indicated by the green light emitted from the

Figure 6. Confocal images of K522 cells exposed to free and MPEG-conjugated 13mer after 2 and 6 h, respectively.

perinuclear region. This suggests that the 13mer oligonucleotide is taken up by the cells and that it remains in the cytoplasm, after incubation times of 2 and 6 h. However, a close inspection of the nucleus in panel B suggests that after 6 h of exposition a small amount of oligonucleotide reached the nucleus, as indicated by the presence of a yellow crown. In fact, the presence of Fluo-13mer (emitting green light) in the nucleus (emitting red light) is detected by the emission of yellow light (green light plus red light). Panels C and D show the confocal images obtained with the MPEG-conjugated 13mer oligonucleotides. It can be seen that after 2 h of incubation Fluo-13mer-MPEG is present in the cytoplasm in large amount as indicated by the intense green fluorescent light color. Comparison of panels A and B with panels C and D indicates that MPEG facilitates the transport of the 13mer oligonucleotides into the cytoplasm of K562 cells. Interestingly, after 6 h of incubation, the nucleus of the cell appears stained in orange and yellow, clearly indicating that Fluo-13mer-MPEG has been internalized in the nucleus. In the case of free Fluo-13mer, after 6 h

of incubation with K562 cells, it was present in the nucleus only in trace amounts. We have extended the confocal analysis to other cell cultures (HeLa, Panc-1) and obtained substantially the same behavior. In conclusion, the conjugation to high molecular weight MPEG enhanced the oligonucleotide capacity not only to penetrate the cellular membranes but also to internalize in the nuclei. Since it is known that MPEG oligonucleotides do not lose their binding property (10), their use as effector molecules is now extensively investigated in our laboratories, and it will be the subject of a forthcoming paper (12).

In conclusion, the liquid-phase approach, based on the use of a soluble inert support, was conveniently utilized even for the production of quite large "all-purine" MPEG-conjugated oligonucleotides designed to act as active anti-gene agents. The demanded phosphorothioate units within the phosphodiester backbone were easily introduced at the desired positions. The synthetic approach adopted for these sequences apparently did not represent a serious obstacle to their efficient large-scale production. The purification of the final product was affordable, despite few drawbacks due to the residual presence of multimeric components resulting from the intermolecular interactions of G-rich sequences. The unique features of the supporting, large MPEG moiety were fully compatible with the further introduction of a fluorescent probe on the final conjugate, extremely useful to follow their cellular destination, and appeared to improve their cellular uptake with a specific nuclear accumulation.

Toward New Designed Proteins Derived from Bovine Pancreatic Trypsin Inhibitor (BPTI): Covalent Cross-Linking of Two 'Core Modules' by Oxime-Forming Ligation

Natàlia Carulla,[†] Clare Woodward,[‡] and George Barany^{*,†}

Department of Chemistry, University of Minnesota, Minneapolis, Minnesota 55455, and Department of Biochemistry, Molecular Biology, and Biophysics, University of Minnesota, St. Paul, Minnesota 55108. Received June 7, 2001; Revised Manuscript Received July 20, 2001

A 25-residue disulfide-cross-linked peptide, termed 'oxidized core module' (OxCM), that includes essentially all of the secondary structural elements of bovine pancreatic trypsin inhibitor (BPTI) most refractory to hydrogen exchange, was shown previously to favor nativelylike β -sheet structure [Carulla, N., Woodward, C., and Barany, G. (2000) Synthesis and Characterization of a β -Hairpin Peptide That Represents a 'Core Module' of Bovine Pancreatic Trypsin Inhibitor (BPTI). *Biochemistry* 39, 7927–7937]. The present work prepares to explore the hypothesis that the energies of nativelylike conformations, relative to other possible conformations, could be decreased further by covalent linkage of two OxCMs. Optimized syntheses of six ~50-residue OxCM dimers are reported herein, featuring appropriate monomer modifications followed by oxime-forming ligation chemistry to create covalent cross-links at various positions and with differing lengths. Several side reactions were recognized through this work, and modified procedures to lessen or mitigate their occurrence were developed. Particularly noteworthy, guanidine or urea denaturants that were included as peptide-solubilizing components for some reaction mixtures were proven to form adducts with glyoxylyl moieties, thus affecting rates and outcomes. All six synthetic OxCM dimers were characterized by 1D ^1H NMR; three of them showed considerable chemical shift dispersion suggestive of self-association and mutual stabilization between the monomer units.

INTRODUCTION

An 'oxidized core module' (OxCM),¹ which is a 25-residue disulfide-cross-linked peptide that includes essentially all of the secondary structural elements that in the full protein bovine pancreatic trypsin inhibitor (BPTI: 58 residues, 3 disulfides, Figure 1a) are most refractory to hydrogen exchange, has recently been designed, synthesized, and characterized (1). NMR analysis showed that OxCM favors nativelylike β -sheet structure in rapid equilibrium with populations of non-native β -sheets (1). Based on these encouraging observations, ways were sought to further stabilize nativelylike conformations in OxCM. The working hypothesis is that covalent linkage of two OxCMs may enhance self-association and mutual stabilization, resulting in a more compact, kinetically accessible, and thermodynamically favored structural ensemble resembling a protein native state. This design strategy was reinforced by findings about the full-length protein, i.e., a dimeric form of BPTI exists in solution and undergoes rapid association–dissociation (2, 3). Further, molecular modeling studies on dimeric BPTI indicate that the residues at the hydrophobic monomer–monomer interface are primarily in OxCM (4) (Figure 1b).

The chemistry chosen to link two OxCMs is oxime-forming ligation (5). In its most general form, this method

allows the joining of two unprotected peptide segments in an unambiguous manner by the chemoselective reaction of two unique and mutually reactive functionalities: (a) an (aminoxy)acetyl moiety and (b) any of a variety of carbonyl-containing moieties including aldehydes, methyl ketones, and α -oxo aldehydes (glyoxylyl

¹ Abbreviations used for amino acids and the designations of peptides follow the rules of the IUPAC–IUB Commission of Biochemical Nomenclature (34). Figure 1. Ribbon representations of (a) crystallographic structure of BPTI, showing positions of the three native disulfides and highlighting in dark blue those residues that correspond to the oxidized core module (OxCM), and (b) a model for the BPTI dimer, reorienting two BPTI structures from (a) in the way proposed by Zielenkiewicz et al. (4), but without repeating those authors' energy minimization calculations. Residues Arg¹⁷ in monomer I (left) and Leu²⁹ (nearer to Arg¹⁷) and Asn²⁴ (further from Arg¹⁷) in monomer II (right) are shown in red. Both diagrams in (a) and (b) were produced using the program MOLSCRIPT (33). (c) Representation of a simpler model for OxCM dimer that, unlike what is shown in (b), ignores the native twist of the β -sheet strands and suggests that Arg¹⁷ in monomer I is spatially closer to Asn²⁴ in monomer II. Block arrows are β -sheet strands (oriented N at tail to C at arrowhead), solid boldface ribbons are β -turns, and solid lines are the flexible loops including the disulfide bond that cyclizes each OxCM.

function). Oxime-forming ligations have been used primarily in the production of peptide dendrimers (5–7), 'template assisted synthetic proteins' (TASPs) (8, 9), and functional proteins such as the heterodimeric transcription factor cMyc-Max (10). When carried out intramolecularly, oxime-forming ligation provides macrocyclic peptides (11, 12). For the present application (Scheme 1), it was observed that the presence of guanidine hydrochloride (GdnHCl) or urea as denaturants in the buffers used to dissolve peptide materials altered the rates and outcomes of the ligations. The underlying chemistries were elucidated in a model tetrapeptide system, and the resultant insights were applied to

optimize conditions for oxime-forming ligations of BPTI core modules.

The chosen dimerization chemistry accommodates changes in the position of the cross-link (Figure 2a) and variations in the length of the cross-link (Figure 2b). Six examples of OxCM dimers were synthesized. One-dimensional proton (¹D ¹H) NMR was used as a qualitative criterion to gauge the extent of conformational families present in each OxCM dimer. Three dimers showed considerable chemical shift dispersion, and one of them is likely to be amenable for further structural characterization by multidimensional homo- and hetero-nuclear NMR methods.

EXPERIMENTAL PROCEDURES

General. Materials, instrumentation, and procedures for synthesis, spectroscopy, chromatography, and analysis are detailed in the Supporting Information; some of these follow precedents in earlier publications from our laboratories (13–15), and others are specific for this work. Refer to the Supporting Information for conditions A through I used in reversed-phase analytical or semi-preparative HPLC and conditions J and K for size-exclusion chromatography (SEC). The matrix used for sample analysis by matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) was α -cyano-4-hydroxycinnamic acid (4-HCCA; Hewlett-Packard, obtained as solution in methanol), diluted 1:1 with 0.1% TFA in CH₃CN/H₂O (1:1), whereas samples for electrospray mass spectrometry (ESMS) were infused in 0.2% acetic acid in CH₃CN/H₂O (1:1). The final isolated yields were calculated by comparison of amino acid analyses of the purified peptide to the initial loading of the resin. In describing core module monomers, capped monomers, and dimers, the notation presented in Figures 2, 3, and 8, and the accompanying text, is used. When closely related procedures were followed, this section provides representative descriptions while further characterizations are reported in the Supporting Information.

NMR Spectroscopy. NMR samples for the tetrapeptide model studies were 11 mM dissolved in ²H₂O at pH 4.6 (measured at electrode and uncorrected for isotope effects). ²H₂O was from Aldrich, and urea-¹⁵N₂ was from Cambridge Isotope Laboratories, Inc. (Andover, MA). GdnDCl-*d*₆ and urea-¹⁵N₂,*d*₄ were prepared respectively by dissolving GdnHCl or urea-¹⁵N₂ in an excess of ²H₂O, lyophilization, and repeating the solution/lyophilization cycle 3 more times. Experiments were performed at 25 °C on Varian 300, 500, 600, or 800 MHz Inova instruments, and the pulse sequences used were obtained from the Varian library (macros: gCOSY, gHMQC, and gHMBC). ¹H/¹H-gCOSY were acquired using 2K × 333 data points and a spectral width of 12 ppm in both dimensions. ¹H/¹³C-gHMQC and ¹H/¹³C-gHMBC were acquired using 2K × 512 data points and a spectral width of 12 ppm in the ¹H dimension and 240 ppm in the ¹³C dimension. ¹⁵N/¹H-gHMQC and ¹⁵N/¹H-gHMBC were acquired using 2K × 128 data points and a spectral width of 12 ppm in the ¹H dimension and 200 ppm in the ¹⁵N dimension. A shifted sine bell or a Gaussian function was applied to both dimensions during data processing.

NMR samples for the capped monomers were 0.3–0.5 mM, pH 4.5, and for the OxCM dimers were 0.2–0.4 mM, pH 2. The lyophilized pure peptides or proteins were dissolved in water at the desired pH and adjusted when required with aliquots of 0.1 N ²HCl/²H₂O or 0.1 N NaO²H/²H₂O. ¹H NMR spectra were obtained in 90:10 H₂O/²H₂O on a Varian 600 MHz Inova instrument.

Scheme 1. Synthesis of $I_{R17K(U)}-II_{L29K(J)}$ Dimer by Oxime-Forming Ligation To Connect Corresponding OxCM Monomers^a

^a See later in this paper (Figures 2 and 3 and accompanying text) for explanations of schematic and nomenclature conventions.

Proton chemical shifts of capped monomers were measured from an internal DSS standard defined as 0 ppm. NMR data acquisition and processing followed methods described previously (1).

The hydrogen isotope exchange rate for the most downfield amide proton resonance of $I_{R17K(U)}-II_{L29K(J)}$ was obtained by measuring peak integrals vs time in a series of 1D spectra at pH 2 and 5 °C (Supporting Information Figure 2). The pseudo-first-order rate constant was determined from nonlinear least-squares fit of an exponential rate equation to experimental data.

Peptide Synthesis. Starting with Fmoc-PAL-PEG-PS resin (13, 16) (1 g, 0.24 mmol/g, 0.24 mmol), the core module monomer linear sequences were assembled by automated Fmoc solid-phase synthesis using an Applied Biosystems Pioneer automated peptide synthesizer. Side-chain protecting groups were provided by appropriate *tert*-butyl (tBu) ethers and esters for Thr, Tyr, Asp, and Glu; *tert*-butoxycarbonyl (Boc) for Lys (when not part of cross-link); 2,2,5,7,8-pentamethylchroman-6-sulfonyl (Pmc) for Arg; 2,4,6-trimethoxybenzyl (Tmob) for Asn and Gln; and trityl (Trt) for Cys. Washes between chemical steps were carried out with DMF. Fmoc removal was achieved with piperidine/DMF (1:4, 5 min). Couplings of all residues other than Cys were 1 h, in DMF, as mediated by HBTU/HOBt/DIEA (4:4:8 equiv with respect to peptide-resin; 3.5 min preactivation) using 4 equiv of Fmoc-amino acids. Fmoc-Cys(Trt)-OPfp was used for 1 h, in DMF, to introduce Cys with minimal racemization (17). As expected, completed peptide-resins had a lower substitution (i.e., 0.12 mmol/g), due to weight gain from the peptide portion.

Peptide Synthesis of Core Module Monomers: $I_{R17K(U)}$, $I_{R17K(UG)}$, and $I_{R17Z(U)}$ (Supporting Information Scheme 1), and $II_{L29K(J)}$, $II_{L29K(JG)}$, $II_{L29Z(J)}$, and $II_{N24K(J)}$ (Supporting Information Scheme 2 and Figure 4). $I_{R17K(U)}$. In the linear core module sequence, Arg¹⁷ was replaced by Fmoc-Lys(Alloc)-OH. A portion of the completed peptide-resin (1 g, 0.12 mmol/g, 0.12 mmol) was washed with CH₂Cl₂ (10 × 0.5 min), and the *N*^ε-Alloc protecting group of Lys¹⁷ was cleaved under an argon atmosphere at 25 °C by adding Me₂NH·BH₃ (84.8 mg, 1.44 mmol, 12 equiv) in CH₂Cl₂ (4.7 mL), followed 1 min later by Pd(PPh₃)₄ (27.7 mg, 0.024 mmol, 0.2 equiv) in CH₂Cl₂ (0.8 mL). After 10 min treatment, the peptide-resin was drained and washed with CH₂Cl₂ (3 × 0.5 min),

and the deprotection procedure was repeated twice. The peptide-resin was then washed successively with CH₂Cl₂ (8 × 0.5 min), 0.2% TFA in CH₂Cl₂ (2 × 1 min), DIEA/CH₂Cl₂ (1:19) (3 × 1 min), and CH₂Cl₂ (5 × 0.5 min). An aliquot of the peptide-resin at this stage was cleaved, and analyzed by HPLC (*t*_R 16 min, condition D). The identity of the peptide in the HPLC peak was confirmed by MALDI-TOF analysis; calcd monoisotopic mass: 2826.4, found: 2827.6 [M+H]⁺.

The peptide-resin (1 g) with the Alloc group removed was placed into a column of the Applied Biosystems Pioneer synthesizer. Next, Boc-Aoa-OH (8 equiv) was incorporated onto the *N*^ε-amino side chain of Lys¹⁷ using PyAOP/HOAt/DIEA (8:8:16 equiv with respect to peptide-resin). Boc-Aoa-OH, PyAOP, and HOAt were weighed as solids into the same vial, and were dissolved by addition of equal volumes of 1 M DIEA-DMF and neat DMF; after a 3.5 min preactivation period, this mixture was added to the peptide-resin to initiate coupling. Two more such couplings were required to complete the incorporation of Boc-Aoa-OH.

Upon completion of on-resin steps, the dried protected peptide-resin was cleaved portion-wise with freshly prepared Reagent R [TFA/thioanisole/1,2-ethanedithiol/anisole (90:5:3:2)]. Peptide-resin (450 mg, 58.4 μmol of peptide) was treated with cleavage cocktail (5 mL) for 1 h at 25 °C. The filtrate was collected and set aside at 25 °C, while the remaining peptide-resin was cleaved twice more, 1 h each, with fresh cocktail (5 mL). The separate filtrates were concentrated under a stream of N₂, and Et₂O (~25 mL, freshly distilled from Na) was added at 0 °C with thorough agitation. The precipitated peptide was collected by low-speed centrifugation, washed with cold freshly distilled Et₂O (3 × 25 mL), and dissolved in ~100 mL of H₂O/CH₃CN (9:1) for lyophilization. The crude peptide (126 mg, 74% cleavage yield) was characterized by analytical HPLC (*t*_R 26.3 min, >90% purity; condition A), and the identity of the main HPLC peak was confirmed by MALDI-TOF analysis; calcd monoisotopic mass: 2899.45, found: 2900.32 [M+H]⁺. When the precipitated peptide was washed with reagent grade Et₂O from a can (not distilled), a byproduct was observed by HPLC (*t*_R 21 min; condition D) and the identity of this HPLC peak was confirmed by MALDI-TOF; found: 2940.1 [M+H]⁺ (40 amu above the expected mass).

To form the disulfide bridge, the crude reduced peptide (60 mg, 20.7 μ mol) was dissolved in 6 mL of 0.01 N aqueous HCl, and then ~300 mL of a mixture of dimethyl sulfoxide/6 M GdnHCl in 0.1 M sodium phosphate buffer, pH 7 (1:18), was added. The reaction was monitored by analytical HPLC (t_R 26.3 min and t_R 21.8 min for reduced and oxidized, respectively; condition A). After oxidation had gone to completion in 12 h at 25 °C, the mixture was concentrated over a 1 day period using an Amicon ultrafiltration cell (YM1 membrane, MWCO ~1000) (final volume ~25 mL). Crude oxidized peptide was loaded in five batches onto semipreparative HPLC (condition E). Purified peptide (10.2 mg, 6%) was characterized by analytical HPLC (t_R 21.8 min; condition A), amino acid analysis (Asp, 2.02; Thr, 0.93; Glu, 1.02; Gly, 3.02; Ala, 1.99; Val, 0.97; Ile, 1.35; Leu, 1.02; Tyr, 2.86; Phe 1.97; Lys, 2.92; Arg, 1.03), and MALDI-TOF; calcd monoisotopic mass: 2897.43, found: 2898.29 [M+H]⁺.

For synthesis and characterization of I_{R17K(U)} and I_{R17Z(U)}, see Supporting Information.

II_{L29K(J)}. In the linear core module sequence, Leu²⁹ was replaced by Fmoc-Lys(Alloc)-OH. Alloc deprotection was carried out in the same way as already described with the procedure for I_{R17K(U)}. Coupling of Fmoc-Ser(tBu)-OH toward II_{L29K(J)} was difficult, but accomplished by the same procedures used to add Boc-Aoa-OH toward I_{R17K(U)}. The N^α-Fmoc group of Ser was removed immediately before cleavage. The dried protected peptide-resin was cleaved essentially as described for I_{R17K(U)}, except that Reagent K [TFA/phenol/thioanisole/H₂O/1,2-ethanedithiol (82.5:5:5:5:2.5)] was used instead of Reagent R. The crude peptide (130 mg, 75% cleavage yield) was characterized by analytical HPLC (t_R 21 min, >90% purity; condition A), and the identity of the main HPLC peak was confirmed by ESMS analysis; calcd average mass: 2958.46, found: 2957.7 ± 1.3. When Reagent R was used to cleave the peptide-resin, a byproduct (~25% of major) was observed. This was analyzed and isolated by HPLC (t_R 22.8 min; condition A) and identified by ESMS; found: 3054.2 ± 0.6 (96 amu above the expected mass).

There follows a description of experimental details for three different scenarios matching Figure 4 and the accompanying text discussion.

Figure 4a. Crude reduced peptide was loaded in six batches, each of 20 mg/5 mL of 0.01 N aqueous HCl, onto semipreparative HPLC (condition F) (25 mg, 19% purification yield). To form the disulfide bridge, the pure reduced peptide (15 mg, 5 μ mol) was dissolved in 4 mL of 0.01 N aqueous HCl, ~200 mL of a mixture of dimethyl sulfoxide/2 M GdnHCl in 0.1 M sodium phosphate buffer, pH 7 (1:18), was added, and the reaction was stirred for 24 h at 25 °C. The reaction was monitored by analytical HPLC (t_R 22.8 min and t_R 18.5 min for reduced and oxidized, respectively; condition A). The identity of the oxidized peptide in the HPLC peak was confirmed by MALDI-TOF analysis; calcd monoisotopic mass: 2954.46, found: 2955.3 [M+H]⁺. Directly following disulfide bond formation and retaining the same milieu, the Ser residue branched off the Lys side chain was oxidized by adding aqueous sodium periodate (2 mL, 5 mM, 2 equiv). After 10 min reaction in the dark at 25 °C, the reaction was quenched with aqueous ethylene glycol (2 mL, 10 mM, 4 equiv). The resultant glyoxylyl peptide was characterized by analytical HPLC [t_R 18.6 min (P1) and 19 min (P2); ratio 2:9; condition A]. The reaction mixture (200 mL) was placed in an Amicon ultrafiltration cell (YM1 membrane, MWCO ~1000) that was part of an Amicon diafiltration setup. During diafiltration, H₂O was introduced into the cell while the buffer components (GdnHCl,

sodium phosphate) and undesired species (DMSO, periodate, ethylene glycol, and formaldehyde generated by the serine oxidation) were removed from the reaction mixture. After 600 mL of H₂O (3 times the volume of the reaction mixture) had passed through the cell, the mixture was concentrated (final volume ~50 mL) and finally lyophilized. Lyophilized peptide (17 mg, 10%) was characterized by analytical HPLC [t_R 19 min (P2); condition A], amino acid analysis (Asp, 1.99; Thr, 0.94; Glu, 1.01; Gly, 3.09; Ala, 1.99; Val, 0.86; Ile, 0.98; Tyr, 2.58; Phe, 1.92; Lys, 2.93; Arg, 2.03), ESMS; calcd average mass: 2925.39, found: 2942.6 ± 0.5 [18 amu (H₂O) above expected with glyoxylyl end group], 2924.7 ± 0.7 [expected], 2906.7 ± 0.2 [18 amu (H₂O) below expected with glyoxylyl end group], and by MALDI-TOF; calcd monoisotopic mass: 2923.43, found: 2924.1 [M+H]⁺.

Figure 4b. To form the disulfide bridge, the crude reduced peptide (60 mg, 20.2 μ mol) was dissolved in 6 mL of 0.01 N aqueous HCl, ~300 mL of a mixture of dimethyl sulfoxide/6 M GdnHCl in 0.1 M sodium phosphate buffer, pH 7 (1:18), was added, and the reaction was stirred for 24 h at 25 °C. The crude oxidized peptide was characterized by analytical HPLC (t_R 18.5 min, >90% purity; condition A), and the identity of the main peak was confirmed by MALDI-TOF analysis; calcd monoisotopic mass: 2954.46, found: 2955.3 [M+H]⁺. Directly following disulfide bond formation and retaining the same milieu, the Ser residue branched off the Lys side chain was oxidized by adding aqueous sodium periodate (3 mL, 13.5 mM, 2 equiv). After 10 min reaction in the dark at 25 °C, the reaction was quenched with aqueous ethylene glycol (3 mL, 27 mM, 4 equiv). The glyoxylyl peptide was characterized by analytical HPLC [t_R 18.6 min (P1) and 19 min (P2), ratio 1:1; condition A]. After periodate oxidation, the mixture was concentrated over a 1 day period using an Amicon ultrafiltration cell (YM1 membrane, MWCO ~1000) (final volume ~25 mL). Crude glyoxylyl peptide was loaded in five batches onto semipreparative HPLC (condition G) to provide separately analytical HPLC pure P1 and P2 which were each characterized by ESMS; calcd average mass: 2925.39, found: for P1, 2943.6 ± 1.2 [18 amu (H₂O) above], 2924.9 ± 0.5 [expected], 2906.4 ± 0.2 [18 amu (H₂O) below]; and for P2, 2942.6 ± 0.5 [18 amu (H₂O) above], 2924.7 ± 0.7 [expected], 2906.7 ± 0.2 [18 amu (H₂O) below]. Purified P1 and P2 were indistinguishable by MALDI-TOF; calcd monoisotopic mass: 2923.43, found: 2924.2 [M+H]⁺, and by amino acid analysis (Asp, 2.00; Thr, 0.80; Glu, 0.98; Gly, 3.08; Ala, 1.96; Val, 0.96; Ile, 1.62; Tyr, 2.78; Phe 1.98; Lys, 2.88; Arg, 2.08). Including fractions that had both components, the final overall isolated yield of P1 plus P2 was 34 mg (20%). When either pure P1 or pure P2 was dissolved in various solvent milieus, reequilibration occurred as described in the text.

Figure 4c. The same procedures as in the previous paragraph were followed, except that 6 M GdnHCl was replaced by 8 M urea. Purified peptide (34 mg, 20%) was characterized by analytical HPLC [t_R 19 min (P3); condition A], amino acid analysis (Asp, 2.20; Thr, 0.85; Glu, 1.15; Gly, 3.27; Ala, 2.32; Val, 0.81; Ile, 1.59; Tyr, 3.25; Phe 2.21; Lys, 3.31; Arg, 2.16), ESMS; calcd average mass: 2925.39, found: 2984.4 ± 1.4 [60 amu (urea) above], 2925.0 ± 0.9 [expected], 2906.7 ± 0.5 [18 amu (H₂O) below], and MALDI-TOF; calcd monoisotopic mass: 2923.43, found: 2924.7 [M+H]⁺.

For synthesis and characterization of II_{L29K(JG)}, II_{L29Z(J)}, and II_{N24K(J)}, see Supporting Information.

Tyr-Dpr(Ser)-Ala-Lys-NH₂. Starting with Fmoc-PAL-PEG-PS resin (1 g, 0.24 mmol/g, 0.24 mmol), the title

precursor to model tetrapeptide TP was assembled by Fmoc solid-phase synthesis using an Applied Biosystems Pioneer automated peptide synthesizer. As also done for synthesis of $\text{II}_{\text{L29K(J)}}$, the dipeptide building block Fmoc-Dpr(Boc-Ser(*t*Bu))-OH was incorporated at the third cycle. The dried protected peptide-resin (500 mg, 120 μmol) was cleaved using Reagent K. Crude reduced peptide was loaded onto semipreparative HPLC (condition H). Fractions with the desired peptide were pooled and lyophilized to provide a white powder (47 mg, 71%), pure by analytical HPLC (t_{R} 7.3 min; condition C), with the expected amino acid analysis (Ser, 0.80; Ala, 1.00; Tyr, 0.98; Lys, 0.95) and ESMS; calcd average mass: 552.62, found: 554.2 $[\text{M}+\text{H}]^+$.

Tyr-Dpr(Gxy)-Ala-Lys-NH₂. Purified Tyr-Dpr(Ser)-Ala-Lys-NH₂ (10 mg, 18.1 μmol) was dissolved in 10 mL of 0.1 M sodium phosphate buffer, pH 7, and then aqueous sodium periodate (0.1 mL, 0.36 M, 2 equiv) was added. After 10 min reaction in the dark, the reaction was quenched with aqueous ethylene glycol (0.1 mL, 0.72 M, 4 equiv). The crude glyoxylyl peptide, characterized by analytical HPLC [t_{R} 7.30 min (T1); condition C], was loaded in two batches onto semipreparative HPLC (condition H). Fractions with the desired peptide were pooled and lyophilized to provide a white powder (29 mg, 43%), characterized further by amino acid analysis (Ala, 1.00; Tyr, 0.70; Lys, 0.97) and ESMS; calcd average mass: 521.57, found: 540.2 $[\text{M}+\text{H}_2\text{O}+\text{H}]^+$, 522.2 $[\text{M}+\text{H}]^+$, 504.3 $[\text{M}-\text{H}_2\text{O}+\text{H}]^+$.

Corresponding oxidation experiments were carried out in the presence of GdnHCl or urea. In 2, 6, and 8.5 M GdnHCl in 0.1 M sodium phosphate buffer, pH 7, the peptide products were recognized by analytical HPLC [t_{R} 7.3 min (T1) and t_{R} 7.6 min (T3); ratio 4:1, 3:2, and 1:1, respectively; condition C] and characterized by HPLC/ESMS; calcd average mass: 521.57, found: for T1, 540.2 $[\text{M}+\text{H}_2\text{O}+\text{H}]^+$, 522.2 $[\text{M}+\text{H}]^+$, 504.3 $[\text{M}-\text{H}_2\text{O}+\text{H}]^+$; and for T3, 539.8 $[\text{M}+\text{H}_2\text{O}+\text{H}]^+$, 522.3 $[\text{M}+\text{H}]^+$, 504.1 $[\text{M}-\text{H}_2\text{O}+\text{H}]^+$. In 8 M urea in 0.1 M sodium phosphate buffer, pH 7, peptide product was recognized by analytical HPLC [t_{R} 7.4 min (T2); condition C] and characterized by HPLC/ESMS; calcd average mass: 521.57, found: 582.2 $[\text{M}+\text{urea}+\text{H}]^+$, 540.2 $[\text{M}+\text{H}_2\text{O}+\text{H}]^+$, 522.2 $[\text{M}+\text{H}]^+$, 504.3 $[\text{M}-\text{H}_2\text{O}+\text{H}]^+$.

Oxime-Forming Ligation Reactions. Capping of Monomers. (A) $\text{I}_{\text{R17K(U*)}}$. $\text{I}_{\text{R17K(U)}}$ (2.9 mg, 1 μmol) was dissolved in 1 mL of 0.01 N aqueous HCl, and acetone (10 μL , 136 μmol) was added. The reaction was complete at 25 °C within 30 s, as shown by analytical HPLC (t_{R} 25.1 min; condition A). Crude capped monomer was purified by semipreparative HPLC (condition I) to give 2 mg of $\text{I}_{\text{R17K(U*)}}$ as a white solid after lyophilization (70%, based on $\text{I}_{\text{R17K(U)}}$). Purified peptide was characterized by amino acid analysis (Asp, 2.00; Thr, 0.92; Glu, 1.07; Gly, 3.02; Ala, 2.00; Val, 0.96; Ile, 1.44; Leu, 1.01; Tyr, 2.71; Phe, 1.87; Lys, 2.91; Arg, 0.96) and MALDI-TOF; calcd monoisotopic mass: 2937.47, found: 2938.22 $[\text{M}+\text{H}]^+$.

For characterization of $\text{I}_{\text{R17K(U*G)}}$ and $\text{I}_{\text{R17Z(U*)}}$, see Supporting Information.

(B) $\text{II}_{\text{L29K(J*)}}$. $\text{II}_{\text{L29K(J)}}$ (2.9 mg, 1 μmol) was dissolved in 0.87 mL of 6 M GdnHCl in 0.1 M NaOAc buffer, pH 4.6, and then, $\text{CH}_3\text{ONH}_2\cdot\text{HCl}$ (25–30 wt % solution in water) (0.13 mL, 400 μmol) was added, and the reaction mixture was stirred for 24 h at 25 °C. Crude capped monomer was purified by semipreparative HPLC (condition G) to give 1.5 mg of $\text{II}_{\text{L29K(J*)}}$ as a white solid after lyophilization (50%, based on $\text{II}_{\text{L29K(J)}}$). Pure peptide was characterized by analytical HPLC (t_{R} 20.3 min; condition A), amino acid analysis (Asp, 2.04; Thr, 0.92; Glu, 1.01; Gly, 2.98; Ala,

1.99; Val, 0.97; Ile, 1.35; Tyr, 2.78; Phe, 1.97; Lys, 2.96; Arg, 2.03), and ESMS; calcd average mass: 2954.43, found: 2953.6 $\pm$ 1.4.

For characterization of $\text{II}_{\text{L29K(J*G)}}$, $\text{II}_{\text{L29Z(J*)}}$, and $\text{II}_{\text{N24K(J*)}}$, see Supporting Information.

Dimer Formation. $\text{I}_{\text{R17K(U)}}-\text{II}_{\text{L29K(J)}}$. Reaction was initiated by combining purified $\text{I}_{\text{R17K(U)}}$ (2.9 mg, 1 μmol) and $\text{II}_{\text{L29K(J)}}$ (P1 or P2) (2.9 mg, 1 μmol) in 1 mL of 6 M GdnHCl in 0.1 M NaOAc buffer, pH 4.6, and maintaining the reaction for 3 days at 25 °C while monitoring by analytical HPLC (Supporting Information Figure 1). Crude dimer was loaded in two batches for SEC (condition J) to give 3.3 mg of $\text{I}_{\text{R17K(U)}}-\text{II}_{\text{L29K(J)}}$ as a white solid after lyophilization (57%, based on $\text{I}_{\text{R17K(U)}}$). Pure peptide was characterized by analytical HPLC (t_{R} 29.2 min; condition B), amino acid analysis (Asp, 3.82; Thr, 1.67; Glu, 1.98; Gly, 5.94; Ala, 3.85; Val, 1.88; Ile, 3.11; Leu, 1.10; Tyr, 5.02; Phe, 3.65; Lys, 5.45; Arg, 2.86), and ESMS; calcd average mass: 5806.76, found: 5806.3 $\pm$ 1.6.

Contrasting to the optimal conditions to carry out the oxime-forming ligation given in the previous paragraph, when the reaction was initiated by combining $\text{I}_{\text{R17K(U)}}$ (2.9 mg, 1 μmol) and $\text{II}_{\text{L29K(J)}}$ (P3) (2.9 mg, 1 μmol) in 1 mL of 8 M urea in 0.1 M NaOAc buffer, pH 4.6, the reaction was extremely slow due to the low reactivity of P3 (see Figure 7, dotted line and accompanying text). Moreover, during that lengthy time period, $\text{I}_{\text{R17K(U)}}$ was mostly converted to the corresponding carbamylated byproduct, recognized by analytical HPLC (t_{R} 27.1 min; condition B) and identified by MALDI-TOF; found: 2941.09 $[\text{M}+\text{H}]^+$ (42.6 amu above the expected mass for $\text{I}_{\text{R17K(U)}}$).

For characterization of $\text{I}_{\text{R17Z(U)}}-\text{II}_{\text{L29K(J)}}$, $\text{I}_{\text{R17Z(U)}}-\text{II}_{\text{L29Z(J)}}$, $\text{I}_{\text{R17K(U)}}-\text{II}_{\text{L29K(JG)}}$, $\text{I}_{\text{R17K(UG)}}-\text{II}_{\text{L29K(JG)}}$, and $\text{I}_{\text{R17K(U)}}-\text{II}_{\text{N24K(J)}}$, see Supporting Information.

RESULTS AND DISCUSSION

Dimer Design Considerations: Positioning and Length of Cross-Link between Monomers. The general rationale for creating and studying dimers of OxCM has already been stated. Presented herein is an iterative design strategy that is integrated with the available chemical options dictated by the central choice of oxime formation in solution as the means to link two monomers (Scheme 1). Since an entirely rigorous nomenclature would be cumbersome, several intuitive pictorial and written shorthands are used to describe the target molecules (Figures 2 and 3).

The disulfide-bridged OxCM monomer comprises ~25 residues, and these are numbered to comply with the corresponding residues in native BPTI; e.g., the *N*-terminal Mpa and *C*-terminal Cys of OxCM are respectively 14 and 38 (Figure 3). Solid-phase methods to assemble such molecules, to cleave them from the support, and to produce the spanning disulfide bridge have already been described (1). As 2 monomers are linked to form a dimer of ~50 residues, symmetry is lost: the monomer which will be modified to include an (amino-oxy)acetyl (Aoa or U) residue is referred to as I, and the monomer which will eventually provide a glyoxylyl (Gxy or J) functionality is referred to as II. The choice of where to position the I–II cross-link is suggested by modeling studies of Zielenkiewicz et al. (4), which propose a large BPTI dimer interface involving numerous intermolecular hydrophobic contacts but only three intermolecular hydrogen bonds. The hydrophobic residues of BPTI involved in this antiparallel self-complementary association are primarily the ones also found in the OxCM. Inspection

(a)

(b)

Figure 2. Schematic representation of, and nomenclature system for, the six OxCM covalent dimers synthesized in this work, emphasizing (a) different positions of the cross-link and (b) different length cross-links between the monomers. See accompanying text for details. Each solid boldface ribbon depicts an OxCM, and the spanning disulfide bond between Mpa¹⁴ and Cys³⁸ is indicated by the solid line connecting the *N* and *C* termini. Arrows indicate residue numbers that are connected; the type I monomer is drawn directly beneath the type II monomer in all representations. All atoms in the cross-links, starting with the β -carbons, are shown. The dimer $I_{R17K(U)}-II_{L29K(J)}$ is drawn twice so that it can be compared to other dimers addressing points (a) and (b).

of the BPTI dimer model reveals that Arg¹⁷ in one monomer is near Leu²⁹ in the other monomer (Figure 1b). A simpler model that ignores the nativelike twist of the β -sheet strands suggests that Arg¹⁷ in one monomer is near Asn²⁴ in the other monomer (Figure 1c). Each of these residues (i.e., Arg¹⁷, Asn²⁴, Leu²⁹) can be replaced in the linear sequence by an orthogonally protected $N^{\alpha,\omega}$ -diamino C^{α} -monoacid, i.e., Lys or Dpr (Figure 3c–e). At the appropriate stage of the overall solid-phase synthesis process (see Supporting Information Schemes 1 and 2 and later text for details), the N^{ω} -amino group can be exposed selectively, and extended further to accomplish one or more of the following: (i) vary the linker length, i.e., by coupling a protected Gly residue (this is in addition to control of length by the earlier choice of Dpr vs Lys); (ii) for monomer I, ultimately introduce the Aoa functionality by coupling the corresponding protected building block; and (iii) for monomer II, couple a protected Ser derivative which serves as a precursor to the Gxy moiety that is established later by a periodate oxidation step carried out in solution.

Based on these principles and strategies, six OxCM dimers were assembled (Figure 2). All dimers replaced Arg¹⁷ in monomer I that would contribute the Aoa component of the oxime linkage. In one set of studies (Figure 2a), the ‘matching’ residue that was replaced in monomer II was either Leu²⁹ or Asn²⁴. In brief (details later), NMR studies show that the dimer with the oxime linkage between residue 17 in monomer I and residue 24 in monomer II, i.e., $I_{R17K(U)}-II_{N24K(J)}$, has less chemical shift dispersion than the dimer with the oxime linkage between residue 17 in monomer I and residue 29 in monomer II, i.e., $I_{R17K(U)}-II_{L29K(J)}$. Therefore, a further set of studies (Figure 2b) kept constant the *preferred* cross-linkage site between residue 17 in monomer I and residue 29 in monomer II, but varied from 10 to 22 atoms the cross-linking length (counting atoms between, but not including, the α -carbon of position 17 in I and the α -carbon of position 29 in II).

Synthesis of Core Module Monomers Suitable for Oxime-Forming Ligation. (A) Assembly, Cleavage, and Disulfide Formation in Unprotected OxCM Monomers

Figure 3. Amino acid sequences for (a) residues 14–38 in native BPTI, (b) OxCM [ref (1)]; underlined residues are different from the native sequence], (c) monomers of type I, replacing Arg¹⁷, (d) monomers of type II, replacing Leu²⁹, and (e) monomer of type II, replacing Asn²⁴. More detailed chemical structures drawn at the bottom include B (β -mercaptopropionic acid), X (α -amino-*n*-butyric acid), and the cross-linking substituents Γ and ϑ , for (c), (d), and (e). The glyoxylyl endgroup of ϑ is drawn in its aldehyde form to explain its reactivity in oxime-forming ligation; NMR experiments reported later prove that this endgroup exists in the hydrated dihydroxyacetyl form (see Figure 5a for accurate structure in a model peptide).

Containing the (Aminoxy)acetyl Functionality. Linear protected sequences were assembled by automated step-wise Fmoc solid-phase peptide chemistry starting with Fmoc-PAL-PEG-PS supports (Supporting Information Scheme 1). Leading to the eventual elaboration of the cross-link, the synthetic strategy next required on-resin

removal of an *N*^ε-Alloc protecting group from Lys¹⁷. Application of Pd(Ph₃)₄ (0.1 equiv) and Me₂NH·BH₃ (6 equiv) in CH₂Cl₂ (18) worked smoothly, and set the stage for addition of Boc-Aoa-OH to the liberated amino group. Couplings were sluggish and required repeat treatments; the best conditions used Boc-Aoa-OH (8 equiv) mediated by PyAOP (8 equiv) and DIEA (16 equiv) in DMF for 3 × 1 h to achieve a negative ninhydrin test result. The aforementioned series of steps gave monomer *I*_{R17K(U)} (see previous section for explanation of nomenclature); inter-polymer of one coupling/deprotection cycle of Fmoc-Gly-OH gave monomer *I*_{R17K(UG)}. Preparation of a third monomer of interest, i.e., *I*_{R17Z(U)}, was expedited because Fmoc-Dpr(Boc-Aoa)-OH, a commercially available building block, could be incorporated directly during the linear assembly.

Cleavages and manipulations of these peptides presented new challenges, due to the ready reactivity of the Aoa functionality with aldehydes and ketones to provide stable oxime derivatives. During routine work, peptides are precipitated from acidolytic cleavage cocktails by addition of ether; they may also become exposed to acetone either from glassware last washed with this solvent or from the dry ice/acetone baths used to shell-freeze aqueous samples before lyophilization (10). Often, a major byproduct was observed, present at a level comparable to or even higher than the desired Aoa-containing product. These byproducts all show a mass (ESMS) 40 amu above the expected, corresponding to addition of acetone (or propionaldehyde) and elimination of H₂O. Fortunately, such byproducts were eliminated entirely when the ether used to precipitate the peptide was freshly distilled from sodium, and when precautions were taken to avoid exposure to incidental or residual acetone. Cleavages were carried out conveniently using TFA/thioanisole/1,2-ethanedithiol/anisole (90:5:3:2) (Reagent R) (13), and provided the peptides with all free side chains including two thiols from the termini (Mpa¹⁴ and Cys³⁸-NH₂).

For OxCM, disulfide bond formation was carried out by dissolving the peptide in DMSO/2 M GdnHCl in 0.1 M phosphate buffer, pH 7 (1:18), for 24 h at 25 °C (1). However, the substitution of Arg¹⁷ by Γ (Figure 3) changes the solubility characteristics of the peptide, and a precipitate is observed as the oxidation proceeds under the previously optimized conditions. GdnHCl sometimes aids in solubilizing peptides as well as creating a denaturing environment that favors disulfide formation (19). Several GdnHCl concentrations (1–6 M) were tested, and the best results were obtained with DMSO/6 M GdnHCl in 0.1 M phosphate buffer, pH 7 (1:18), for 12 h at 25 °C. Other conditions, which varied pH (6 or 7) and/or used different percentages of DMSO without GdnHCl, were less satisfactory because disulfide product precipitated. Procedures concluded by concentration of reaction mixtures and peptide purification by reversed-phase HPLC. The overall isolated yield was typically 6%, based on the starting PAL-PEG-PS resin.

(B) Assembly, Cleavage, Disulfide Formation, and Periodate Oxidation of Unprotected OxCM Monomers Containing the Glyoxylyl Functionality. Again, linear protected sequences were assembled by automated step-wise Fmoc solid-phase peptide chemistry starting with Fmoc-PAL-PEG-PS supports (Supporting Information Scheme 2). Toward monomer *II*_{L29K(J)}, the *N*^ε-Alloc protecting group of Lys²⁹ was removed as already described, and Fmoc-Ser(*t*Bu)-OH was coupled as mediated by PyAOP/HOAt/DIEA. The *N*^ε-Fmoc group of Ser was removed from the resultant peptide-resin immediately

Figure 4. Chemistries and chromatographic analyses of three different scenarios that were followed to generate the disulfide bond and the glyoxylyl functionality in monomers of type II. Elucidation of accurate structures for P1, P2, and P3, based in part on studies with a model peptide TP, is covered extensively in the accompanying text.

before acidolytic cleavage. Toward monomer II_{L29K(JG)}, an additional coupling/deprotection cycle incorporated Fmoc-Gly-OH onto the N^ε-amine of Lys²⁹, prior to addition of Fmoc-Ser(*t*Bu)-OH. Finally, preparation of the II_{L29Z(J)} monomer featured direct incorporation of commercially available Fmoc-Dpr(Boc-Ser(*t*Bu))-OH.

The cleavage and further processing of these modified monomers revealed several unanticipated problems, which were systematically elucidated and circumvented. Recall

that a central part of the plan was to eventually oxidize the Ser residue with periodate in order to generate the glyoxylyl functionality. Acidolytic cleavage with Reagent R (composition given in the previous section) was invariably accompanied by formation of a byproduct, at a level typically 25% that of desired, which was shown by MALDI-TOF to have a mass 96 amu above what was expected. Moreover, the byproduct (as part of crude mixture) did not react further upon periodate treatment.

This information was consistent with a tentative conclusion that the byproduct is an *O*-trifluoroacetyl ester of the *N*-terminal serine residue, although an *N*-trifluoroacetyl species formed by $O \rightarrow N$ migration cannot be ruled out (20). Consistent with this hypothesis, and of obvious practical import, the trifluoroacetyl byproduct was not formed when cleavage was carried out with TFA/phenol/thioanisole/ H_2O /1,2-ethanedithiol (82.5:5:5:5:2.5) (Reagent K) (21). This result is attributed to the presence in the latter cocktail of water, which either scavenges any activated trifluoroacetyl species or hydrolyzes any ester that is produced.

Because of concerns about incompatibility of free thiols with the oxidation conditions planned for converting Ser to the glyoxylyl moiety (22), the disulfide-forming step was carried out next in the overall process. In turn, solubility considerations as already described made it necessary to add substantial levels of denaturants (GdnHCl or urea), along with the DMSO (5% v/v) used as the oxidizing reagent. Three scenarios were followed (Figure 4). In each case, peptide was first dissolved fully in 0.01 N aqueous HCl, next the mixture of pH 7 phosphate buffer, denaturant, and DMSO was added, and then disulfide formation was carried to completion (24 h, single major peak by HPLC). Subsequently, in the same milieu, $NaIO_4$ (2 equiv) was added, and 10 min later, oxidation was quenched with ethylene glycol (4 equiv) (23). HPLC analysis showed three products (P1, P2, and P3 in Figure 4), of which only P2 was later proven to correspond to the expected structure. The highest relative level of P2, i.e., ~80%, occurred when the crude peptide had been purified first, and then dissolved in 2 M GdnHCl (Figure 4a). When the crude peptide was used directly, the concentration of GdnHCl required for solubilization was higher, i.e., 6 M, and consequently the relative level of P2 dropped to ~50% (determined after the periodate step; Figure 4b). The byproduct in the experiments with GdnHCl was P1, for which the following properties were deduced: (i) the most intense ESMS peak corresponds to the aldehyde, and two other peaks, half the intensity of the major, correspond to the hydrated and dehydrated forms of the aldehyde; (ii) the unique MALDI-TOF signal corresponds to the aldehyde form; (iii) the byproduct was quite unreactive for the oxime-forming ligation step (see 'Synthesis of OxCM Dimers'); and (iv) the byproduct was converted to the desired P2, which has the anticipated good reactivity, by extensive diafiltration with H_2O (Figure 4a), albeit with reduction in the overall yield due to solubility problems. In contrast, ESMS data on the desired P2 showed that the most intense peak corresponds to the hydrated form of the aldehyde, while the intensities of the free aldehyde and the dehydrated form were about 1/3 and 1/6 respectively; MALDI-TOF analysis of P2 again showed only the aldehyde form. Finally, in experiments carried out in the presence of 8 M urea, neither P1 nor P2 formed, but the exclusive unwanted product was P3. Purified P3 had the following characteristics: (i) the most intense ESMS peak corresponds to the peptide aldehyde having reacted with urea (60 amu above what was expected), with the aldehyde form and the dehydrated forms also present each at about 1/4 intensity; (ii) the unique MALDI-TOF signal corresponds to the aldehyde form; and (iii) P3 was exceptionally unreactive for the oxime-forming ligation step (see 'Synthesis of OxCM Dimers').

Model Studies To Determine Structures of Byproducts Obtained after Periodate Oxidation in the Presence of Denaturants. To understand the formation of unexpected byproducts P1 and P3 after oxidation

Table 1. Effects of Denaturants on the Distribution of Products from Periodate Oxidation at pH 7 of Model Peptide H-Tyr-Dpr(Ser)-Ala-Lys-NH₂^a

milieu (aqueous buffer, denaturant)	T1	T2	T3
0.1 M phosphate, pH 7	100	0	0
2 M GdnHCl in 0.1 M phosphate, pH 7	82	0	18
6 M GdnHCl in 0.1 M phosphate, pH 7	63	0	37
8.5 M GdnHCl in 0.1 M phosphate, pH 7	49	0	51
8 M urea in 0.1 M phosphate, pH 7	0	100	0

^a Products are designated in order of HPLC elution, and relative amounts are expressed in percent so as to add up to 100%. As noted in the text, TP products T1, T2, and T3 correlate to type II monomer-derived products P2, P3, and P1, respectively.

of a Ser residue in the presence of GdnHCl or urea, the model peptide H-Tyr-Dpr(Ser)-Ala-Lys-NH₂ (corresponding to BPTI residues 23–26, with replacement of Asn²⁴) was synthesized and evaluated. Mirroring the results with the full 25-residue OxCM type II monomers, treatment of the model with periodate produced two products (T1, T3) with varying HPLC-reported ratios depending on the GdnHCl concentration (2–8.5 M) that was used, and a unique product (T2) when urea (8 M) was used (Table 1). In the absence of denaturant, only T1 formed, suggesting that this corresponds to the desired H-Tyr-Dpr(Gxy)-Ala-Lys-NH₂. Further supporting the correlations P1/T3, P2/T1, and P3/T2, HPLC/ESMS analysis was inconclusive about the true structures of T1 and T3, but supportive of T2 being a urea adduct.

The Gxy-containing T1 was readily purified, and then redissolved in each of three different milieus for NMR analysis: (a) ^2H_2O at pH 4.6, (b) 6 M GdnDCl-*d*₆ in ^2H_2O at pH 4.6, and (c) 8 M urea- $^{15}N_2d_4$ in ^2H_2O at pH 4.6. Milieu (a) allowed structural conclusions about pure T1, whereas milieu (b) promoted a rapid equilibration to a 3:2 ratio of T1 to T3 (confirmed by HPLC), and T1 was converted quantitatively to T2 within 12 h in milieu (c). From the NMR data and detailed interpretations that follow, it is concluded (for the tetrapeptide structure) that in T1, the terminal Gxy residue exists as the corresponding hydrate, i.e., a dihydroxyacetyl residue; that an amino group of guanidine reacts with the terminal aldehyde of Gxy to form a covalent hemiaminal adduct (two diastereomers) as exemplified in T3; and that the amino group of urea reacts in an analogous fashion as exemplified in T2 (Figure 5 shows all of the proposed structures, including numbering of key atoms in the positions of interest). It is highly likely that these structural inferences generalize to systems (P1, P2, and P3 in Figure 4) for which the observations were originally made. It is instructive to compare the NMR-established structural conclusions with the more ambiguous information from mass spectrometry; more specifically, MALDI-TOF suggested only the expected aldehyde structures (without the proper hydration), whereas the more "gentle" ESMS technique was clear only for the urea adduct, hinted at the aldehyde hydrate (major peak, but unhydrated and dehydrated species also noted), and entirely missed the guanidine adduct (unhydrated as major, and hydrated as well as dehydrated aldehyde forms as minor, all present). Since the environments of the rapidly equilibrating species in these samples change as they are prepared for and then analyzed by mass spectrometry, these findings are not especially surprising.

Supporting the structural conclusions, consider first the 1D ^1H NMR spectra (Figure 6), backed up by $^1H/^1H$ -gCOSY experiments which allowed assignments of all nonexchangeable hydrogen resonances (Supporting Information Table 1). The most significant differences are

Figure 5. Structures of (a) T1, the hydrated Gxy-containing model tetrapeptide, (b) T3, the two hemiaminal diastereomers obtained by reversible reaction of guanidine with the terminal aldehyde of the Gxy residue in T1, and (c) T2, the two hemiaminal diastereomers obtained by reversible reaction of urea with the terminal aldehyde of the Gxy residue in T1. Arrows identify key atoms in the structural identifications (see also Table 2).

between 5.4 and 5.8 ppm. In the absence of denaturants (Figure 6a), a unique singlet at 5.52 ppm is assigned to the H-C(2) proton of the dihydroxyacetyl residue [the former H-C(α) of Ser]. In an $^1\text{H}/^{13}\text{C}$ -HMQC experiment, the ^1H signal at 5.52 ppm correlates to a ^{13}C signal at 89.6 ppm, again consistent with a hydrated aldehyde (24) (Figure 5a). When spectra are recorded in the presence of GdnHCl- d_6 (Figure 6b), the singlet at 5.52 ppm was supplemented by two more signals, of equal height, at 5.71 and 5.72 ppm. The latter two signals had consistent chemical shifts regardless of what field strength (300, 500, 600, or 800 MHz) was used for spectral acquisition; hence, they are derived from two unique chemical environments rather than from splitting of a single resonance. Further information obtained from $^1\text{H}/^{13}\text{C}$ -HMQC and $^1\text{H}/^{13}\text{C}$ -HMBC spectra (Table 2) reprise the observations about T1 already noted, and provide a way to characterize structures of the two new species corresponding to T3. Thus, the ^1H signals at 5.71 and 5.72 ppm *both* correlated in $^1\text{H}/^{13}\text{C}$ -HMQC to the *same* ^{13}C signal at 76.8 ppm, consistent with a hemiaminal, and in $^1\text{H}/^{13}\text{C}$ -HMBC to *two* ^{13}C signals at 172.5 and 159.6 ppm. While the 172.5 ppm signal is assigned to the C(1) carbon (originally C=O of Ser), the 159.6 ppm peak is

particularly conclusive because it is derived from guanidine. The ^{13}C chemical shift is close to, but different from, 157.2 ppm, which is the shift of the carbon from GdnHCl itself (24). These data establish the covalent connectivity of the adduct (Figure 5b). The two close, but separate, ^1H peaks in the 1D NMR spectra are now readily explained by the chirality of C(2) after nucleophilic attack by a guanidine nitrogen on the Gxy aldehyde.

Spectroscopic examination of the Gxy-containing peptide in the presence of urea (Figure 6c) reveals similarities as well as differences from the same peptide in the presence of GdnHCl. The absence of a signal at 5.5 ppm is taken to mean that the aldehyde function of the model tetrapeptide had reacted quantitatively with urea. As before, ^1H signals at 5.57 and 5.61 ppm were assigned to the H-C(2) proton, correlated by $^1\text{H}/^{13}\text{C}$ -HMQC to the same ^{13}C signal at 76 ppm and by $^1\text{H}/^{13}\text{C}$ -HMBC to two ^{13}C signals at 175.3 ppm [assigned to the C(1) carbon] and 162.7 ppm [similar to the shift of urea itself at 163.5 ppm (24)]. Also as before, the two ^1H shifts are independent of field strength and explained by the chirality of C(2). The availability of [^{15}N]urea allowed correlation in $^1\text{H}/^{15}\text{N}$ -HMBC of the ^1H signals at 5.57 and 5.61 ppm, respectively, to ^{15}N signals at 100.8 and 101.0 ppm

Figure 6. ^1H NMR spectra, recorded at 500 MHz, of the purified Gxy-containing model tetrapeptide redissolved in (a) $^2\text{H}_2\text{O}$ at pH 4.6, (b) 6 M GdnDCl- d_6 in $^2\text{H}_2\text{O}$ at pH 4.6, and (c) 8 M urea- $^{15}\text{N}_2, d_4$ in $^2\text{H}_2\text{O}$ at pH 4.6. The proton resonance(s) of H-C(2) in each milieu is/are indicated in the spectra. Full ^1H assignments are compiled in Supporting Information Table 1. The residual H_2O signal was suppressed by use of presaturation techniques. The signal around 6.9 ppm in (b) corresponds to residual GdnHCl. In (c), the signal of residual protons from urea is not observed because urea exchanges rapidly with water, and the urea signal is saturated concomitant with H_2O suppression.

Table 2. Diagnostic ^1H , ^{13}C , and ^{15}N Chemical Shifts for H-Tyr-Dpr(Gxy)-Ala-Lys-NH $_2$, Recorded at 500 MHz in $^2\text{H}_2\text{O}$ at pH 4.6 in the Absence and Presence of Denaturants^a

residue	position	$^2\text{H}_2\text{O}$		6 M GdnDCl- d_6		8 M urea- $^{15}\text{N}_2, d_4$	
Gxy-derived	H-C(2)	5.52	5.52 ^b	5.71	5.72	5.57	5.61
	C(1) ^c	^d	^d	172.5	172.5	175.3	175.3
	C(2) ^e	89.6	89.7 ^b	76.8	76.8	76.0	76.0
denaturant-derived	N(1) ^f					101.0	100.8
	C(3) ^c			159.6	159.6	162.7	162.7

^a Refer to Figure 5 to define the atoms in the Ser to Gxy conversion, and the atoms derived from denaturants. Sample preparations are defined in the legend to Figure 6, and the ^1H chemical shifts in the first row of this table overlap with that figure. ^b These signals, which overlap those observed in $^2\text{H}_2\text{O}$ in the absence of denaturant, are attributed to the original species present in $^2\text{H}_2\text{O}$, and not to the Gdn adduct. ^c Chemical shifts of C(1) and C(3) were obtained from $^1\text{H}/^{13}\text{C}$ -HMBC experiments. ^d No correlation was observed between the H-C(2) proton and C(1) in the $^1\text{H}/^{13}\text{C}$ -HMBC experiment. Two bond coupling constants are small, and their observation depends on electronic properties of the bond. ^e Chemical shifts of C(2) were obtained from $^1\text{H}/^{13}\text{C}$ -HMQC experiments. ^f Chemical shifts of N(1) were obtained from $^1\text{H}/^{15}\text{N}$ -HMBC experiments.

(compared to ^{15}N of urea itself at 76 ppm), further supporting the urea adduct structure (Figure 5c). It is also plausible that additional stabilization could be provided by formation of a hydrogen bond involving the oxygen of $\text{O}=\text{C}(3)$ and the hydrogen of $\text{OH}-\text{C}(2)$; note this gives a six-membered ring.

The observations described in this and the preceding section are of considerable practical importance, given the subsequent goal to apply glyoxylyl-containing peptides for oxime-forming ligation reactions. In aqueous media, the glyoxylyl moiety itself exists in the dihydroxyacetyl (hydrated) form; this follows classical expectations about aldehyde chemistry and will not affect its ultimate reactivity with strong nucleophiles. Formation under mild aqueous conditions of the described *intermolecular* adducts of glyoxylyl functions with guanidine or urea is unprecedented and surprising due to the low nucleophilicities of guanidino or amide nitrogens. The high concentrations of denaturants do drive the equilibrium toward adduct, although in the case of guanidine, enough adduct reverts to the glyoxylyl species so that reactions with Aoa-containing products can proceed (albeit much slower; see next section). A review of organic literature

databases showed numerous examples of related transformations (i.e., amides or carbamates react with glyoxylyl or simpler aldehyde derivatives), although invariably under nonaqueous conditions with heating and/or long reaction times. The recent report by Rose et al. (25) of a rapid *intramolecular* cyclization (six-membered ring forms, specifically facilitated by structural constraint of the Pro residue), involving irreversible nucleophilic attack in aqueous media by a peptide amide nitrogen on an *N*-terminal glyoxylyl function, provides a somewhat analogous precedent to what was found in the present work.

Synthesis of OxCM Dimers: Oxime-Forming Ligation. At this stage of the work, methodologies were on hand to obtain both families of functionalized monomers that needed to be connected by an oxime-forming ligation, but the identification of covalent adducts between glyoxylyl moieties and either GdnHCl or urea denaturants was a source of concern. To create the desired OxCM dimers, it was necessary to react the functionalized monomers under acidic aqueous conditions at pH 4.6, based on literature precedents (5–7, 10). Several strategies were explored to combine $\text{I}_{\text{R17K(U)}}$ with

Figure 7. Oxime-forming reactions connecting I_{R17K(U)} and II_{L29K(J)} (1 mM each) as a function of time and denaturant. The denaturant used to solubilize components in the reaction mixture was 6 M GdnHCl (solid line), 8.5 M GdnHCl (dashed line), and 8 M urea (dotted line). The ordinate, expressed as a percentage, was calculated (based on HPLC areas) as the amount of I_{R17K(U)}-II_{L29K(J)} formed divided by the total amount of all species (product, starting materials, adducts of II with either GdnHCl or urea, and adduct of I with cyanate).

II_{L29K(J)}, in the context that the use of denaturants could not be avoided due to the need to keep peptide materials in solution. Later, the best procedures were extended to prepare the other dimers.

In one experiment, the Ser-containing precursor of II_{L29K(J)} was oxidized with periodate in 6 M GdnHCl in 0.1 M phosphate buffer, pH 7, generating a 1:1 ratio of P1 and P2 as already indicated (Figure 4). These two products were separated by semipreparative reversed-phase HPLC and separately dissolved in 6 M GdnHCl in 0.1 M NaOAc buffer, pH 4.6, for reaction with I_{R17K(U)}. There was an early burst of initial reactivity corresponding to P2 (free glyoxylyl) vs P1 (guanidine hemiaminal), i.e., 10% vs 2% of I_{R17K(U)}-II_{L29K(J)} formed after 3 min. However, within 1 h both reaction mixtures had equilibrated, so that regardless of whether pure P1 or pure P2 had been present at the outset, these materials were now in a 1:1 ratio. From this point on, the kinetics of the ligations were essentially the same in both reactions (Figure 7, solid line). The experiment was repeated at higher GdnHCl concentration, i.e., 8.5 M. In this case, equilibration within 1 h gave P1 and P2 in a ratio of 1.4:1, and the overall kinetics were slightly slower (Figure 7, dashed line). Experiments in the other direction, i.e., with lower GdnHCl concentration, were not feasible due to solubility problems. These data are consistent with the idea that the higher the concentration of GdnHCl, the more guanidine hemiaminal adduct (P1) is formed, and the slower the reaction. In another experiment, the peak obtained from periodate oxidation in the presence of 8 M urea, i.e., P3 (Figure 4c), was reacted with I_{R17K(U)} in 8 M urea in 0.1 M NaOAc buffer, pH 4.6. This reaction was the slowest of the experiments carried out (Figure 7, dotted line), and was accompanied by slow formation of a I_{R17K(U)}-derived byproduct which by MALDI-TOF was 42.6 amu higher than the starting monomer. It is known that in aqueous solution, urea is in equilibrium with ammonium cyanate (26, 27), and that cyanate reacts with amino groups to yield carbamyl derivatives (26). It is reasonable to propose that, over the long time course of reaction in the presence of urea [where the urea adduct

of II_{L29K(J)} is particularly unreactive], the Aoa moiety of I_{R17K(U)} eventually reacts with the slowly accumulating cyanate.

From these experiments, optimized conditions were established for the oxime-forming ligation. Equivalent amounts of purified I_{R17K(U)} and II_{L29K(J)} (the latter obtained from periodate oxidation in 6 M GdnHCl in 0.1 M phosphate buffer, pH 7) were combined in 6 M GdnHCl in 0.1 M NaOAc buffer, pH 4.6. The course of the reaction was followed by analytical reversed-phase HPLC (Supporting Information Figure 1); after 3 days, no appreciable further product was formed, and product was isolated in 57% yield after SEC purification. Five further dimers (Figure 2) were created by the identical protocols with comparable yields.

Evaluation of Conformational Integrity of OxCM Monomers Modified for Incorporation into Dimers.

Having developed chemical means to combine two OxCM monomers and form the corresponding dimers, it was also necessary to check that the antiparallel β -sheet conformations sampled by OxCM are not significantly perturbed by the structural modifications that later facilitate cross-linking. Accordingly, each monomer was appropriately 'capped', and characterized by a spectroscopic criterion the reliability of which had been established in earlier work (1). Monomers of type I, with an (aminooxy)-acetyl functionality, were treated with acetone, whereas monomers of type II, with a glyoxylyl functionality, were treated with CH₃ONH₂·HCl (Figure 8; note the '*' convention to indicate oxime capping).

For each capped monomer, the C α H chemical shifts were determined as a function of residue number, and the deviation from literature random coil values (28, 29) was calculated. The baseline experiment (Figure 8, red traces) was the previously reported analysis of OxCM (1), in which residues 25–28 (a turn in native BPTI) show a negative deviation (upfield shift), and residues 18–24 and 29–35 (strands in native BPTI) show positive deviations (downfield shift). I_{R17K(U*)}, I_{R17K(U*G)}, II_{L29K(J*)}, II_{L29K(J*G)}, and II_{L29Z(J*)} have C α H chemical shift deviations similar to OxCM both in the strands and in the turn (Figure 8), consistent with the conclusion that the structures of these monomers do not differ significantly from that observed in OxCM. However, I_{R17Z(U*)} has C α H chemical shift deviations similar to OxCM for turn residues but smaller C α H chemical shift deviations for strand residues. The latter result indicates that replacement of Arg¹⁷ in OxCM by the Dpr(Aoa) unit is a sufficiently drastic change to impact strand conformation. A more dramatic example for a poorly tolerated substitution was revealed with II_{N24K(J*)}, where surrounding the modified site at residue 24, residue 23 which was in a strand for OxCM now appears to be in a turn, and residue 25 which was in the OxCM turn now is indistinguishable from random.

Structural Characterization of the OxCM Dimers.

Each synthesized OxCM dimer was evaluated by ¹H NMR and size-exclusion chromatography. Synthetic dimers were dissolved to a concentration of 0.3 mM in CH₃CN/10 mM aqueous NaCl (1:19) at pH 2, and applied at 3 °C to a size-exclusion chromatography column made of cross-linked agarose and dextran. The salt and CH₃CN were included to suppress, respectively, ionic and hydrophobic interactions between the packing material and the proteins, whereas the pH was selected for consistency with what pilot NMR studies had shown to be most promising. Under these conditions, all synthesized proteins elute as a single peak in the order expected by their molecular weights, without any evidence for noncovalent association (i.e., they were physically monomeric, with

Figure 8. Along the right side are shown schematic representations, all drawn according to the same conventions used earlier (Figure 2), of capped monomers of (a) type I, replacing Arg¹⁷, and with acetone used to cap (aminoxy)acetyl functions; (b) type II, replacing Leu²⁹, and with CH₃ONH₂·HCl to cap glyoxylyl moieties; and (c) type II, replacing Asn²⁴, again capped with CH₃ONH₂·HCl. Each panel compares the CαH chemical shift deviations, obtained at pH 4.5 and 3 °C, of OxCM (red trace) to a capped monomer (black trace) defined and named underneath, with an asterisk (*) used to indicate the presence of the appropriate oxime cap.

the preceding term not to be confused with the “monomer/dimer” terminology used to describe the chemical constructs of this work) (Supporting Information Table 2).

The potential for folding of each protein variant was qualitatively assessed by 1D ¹H NMR spectra, recorded at 5 °C and pH 2 (Figure 9). Well-folded proteins have relatively narrow line widths, while conformational heterogeneity and increased internal mobility on the millisecond to microsecond time scale, which characterize molten globule and aggregated states, result in broad and/or heterogeneous line widths. Spectra of well-folded proteins are also characterized by pronounced chemical shift dispersion, which arises from the variety of unique, local magnetic environments present in a compact protein.

To evaluate the best position for the cross-link, I_{R17K(U)}–II_{N24K(J)} was compared to I_{R17K(U)}–II_{L29K(J)}. The former is characterized by broad proton line widths and negligible chemical shift dispersion (Figure 9a), whereas the latter shows narrower line widths and considerable chemical shift dispersion (Figure 9b). The problems with I_{R17K(U)}–

II_{N24K(J)} may have been anticipated by the NMR studies on II_{N24K(J*)} (see Figure 8c and accompanying discussion in previous section) which showed that replacement of Asn²⁴ changes the structure of the monomer itself. In addition, the present working model for the antiparallel BPTI dimerization interface shows Arg¹⁷ to be closer to Leu²⁹ (Figure 1b). Asn²⁴, which on the basis of a simpler two-dimensional representation (Figure 1c) was predicted to be close to Arg¹⁷, is now believed to be on the opposite side due to the natively like ‘twist’ of the β-sheets.

With the I₁₇–II₂₉ optimal cross-link position established, variations in the length of the cross-link were considered next. Although intuition suggested that self-association between covalently joined monomers might be improved if they were closer, experiments showed better results with longer cross-links. 1D ¹H NMR of I_{R17Z(U)}–II_{L29Z(J)} (Figure 9c) and I_{R17Z(U)}–II_{L29K(J)} (Figure 9d) show broad line widths and reduced chemical shift dispersion. These results can be explained in part by the NMR studies on I_{R17Z(U*)} (Figure 8a, left), which showed a decrease in structure for the strand residues with

Figure 9. Aromatic and amide regions of 1D ^1H NMR spectra at 600 MHz, obtained at pH 2 and 5 $^\circ\text{C}$, are shown for OxCM dimers (a) $\text{I}_{\text{R17K(U)}}\text{-II}_{\text{N24K(J)}}$, (b) $\text{I}_{\text{R17K(U)}}\text{-II}_{\text{L29K(J)}}$, (c) $\text{I}_{\text{R17Z(U)}}\text{-II}_{\text{L29Z(J)}}$, (d) $\text{I}_{\text{R17Z(U)}}\text{-II}_{\text{L29K(J)}}$, (e) $\text{I}_{\text{R17K(UG)}}\text{-II}_{\text{L29K(JG)}}$, and (f) $\text{I}_{\text{R17K(U)}}\text{-II}_{\text{L29K(JG)}}$.

respect to OxCM. In addition, unwanted steric interactions between monomers may be a factor. 1D ^1H NMR spectra of $\text{I}_{\text{R17K(UG)}}\text{-II}_{\text{L29K(JG)}}$ (Figure 9e) and $\text{I}_{\text{R17K(U)}}\text{-II}_{\text{L29K(JG)}}$ (Figure 9f) show narrower line widths and similar chemical shift dispersion, by comparison to $\text{I}_{\text{R17K(U)}}\text{-II}_{\text{L29K(J)}}$, demonstrating the advantages of a longer cross-link.

Preliminary Characterization of OxCM Dimers

$\text{I}_{\text{R17K(U)}}\text{-II}_{\text{L29K(J)}}$ and $\text{I}_{\text{R17K(UG)}}\text{-II}_{\text{L29K(JG)}}$. The first dimer that gave evidence of folded structure beyond what is inherent in the OxCM monomer was $\text{I}_{\text{R17K(U)}}\text{-II}_{\text{L29K(J)}}$. Strong evidence in further support of this conclusion comes from 1D $^1\text{H}/^2\text{H}$ isotope exchange studies at pH 2 and 5 $^\circ\text{C}$, monitored in the region 7.5–10.5 ppm where the amide protons resonate (Supporting Information Figure 2). While a subset ($\sim 36\%$) of the protons exchange within a day, the majority of the amides (particularly the more downfield ones) are still observable after 6 days. The most downfield NH at pH 2 and 5 $^\circ\text{C}$ (labeled 'a' in Supporting Information Figure 2) was sufficiently resolved from the amide envelope to allow determination of the hydrogen isotope exchange rate ($k_{\text{obs}} \sim 10^{-4} \text{ min}^{-1}$, $t_{1/2} \sim 110 \text{ h}$). By comparison, exchange of strand residues in OxCM ($t_{1/2} \sim 1 \text{ h}$, pH 4.1 and 6 $^\circ\text{C}$) is 2 orders of magnitude faster, and exchange in the most protected regions of a partially folded protein such as $[\text{14-38}]_{\text{Abu}}$ (30) ($t_{1/2} \sim 10 \text{ h}$, pH 4.6 and 1 $^\circ\text{C}$) is 1 order of magnitude faster.

Of additional promise, the 1D ^1H NMR spectrum of $\text{I}_{\text{R17K(U)}}\text{-II}_{\text{L29K(J)}}$ in $^2\text{H}_2\text{O}$ at pH 2 at 5 $^\circ\text{C}$ shows a characteristic singlet at the unusually upfield position of 0.35 ppm. This signal is likely due to a methyl group from an aliphatic residue side chain that is in a structured environment. As the temperature was increased to 60 $^\circ\text{C}$, the upfield signal decreased in a cooperative transition with an apparent $T_{\text{m}} \sim 39 \text{ }^\circ\text{C}$. By comparison, the transition of $[\text{14-38}]_{\text{Abu}}$ at pH 6 occurs at $\sim 19 \text{ }^\circ\text{C}$ (31).

Efforts to characterize the structure of the $\text{I}_{\text{R17K(U)}}\text{-II}_{\text{L29K(J)}}$ dimer further were stymied by the fact that relatively few cross-peaks were observed in the TOCSY spectra. These findings, while disappointing, reflect a situation preceded in the literature for partially folded proteins (32). One possible explanation recognizes multiple conformations in chemical exchange, leading to relatively short T_2 relaxation times which in turn broaden peaks to the extent that they are not recognized.

The iterative development of dimers to date culminates with $\text{I}_{\text{R17K(UG)}}\text{-II}_{\text{L29K(JG)}}$, the 1D ^1H NMR spectrum (Figure 9e) of which shows narrow line widths and good dispersion. TOCSY spectra show considerably more cross-peaks, allowing for optimism on the prospects for further structural analysis.

Conclusions. Optimized syntheses of six OxCM dimers via oxime-forming ligation have been worked out. Issues that have been investigated include practical aspects of the preparation and manipulation of (aminoxy)acetyl-functionalized peptides, as well as the effects of using denaturants (GdnHCl or urea) in the buffers to dissolve glyoxyl-functionalized peptides, or their precursor peptides, for further steps. In the latter regard, it is recommended to avoid the use of urea entirely, and to use GdnHCl only at the lowest possible concentration consistent with peptide solubility.

Three of the dimers, $\text{I}_{\text{R17K(U)}}\text{-II}_{\text{L29K(J)}}$, $\text{I}_{\text{R17K(U)}}\text{-II}_{\text{L29K(JG)}}$, and $\text{I}_{\text{R17K(UG)}}\text{-II}_{\text{L29K(JG)}}$, were judged by 1D ^1H NMR spectroscopy to show evidence of compact structure. Among them, $\text{I}_{\text{R17K(UG)}}\text{-II}_{\text{L29K(JG)}}$ seems to be particularly suited for further structural characterization. Such stud-

ies may ultimately validate the proposed strategy to create new proteins by combining core modules.

ACKNOWLEDGMENT

We thank Drs. Fernando Albericio, Jordi Alsina, Dominique Lelièvre, and Scott Yokum for helpful discussions on the synthetic work and Drs. David Live and Letitia Yao for help with NMR. NMR experiments were performed at the University of Minnesota High Field NMR Laboratory, and mass spectrometry data were collected at the University of Minnesota Mass Spectrometry Consortium for the Life Sciences. N.C. holds a Doctoral Dissertation Fellowship from the Graduate School of the University of Minnesota. Experimental work was supported by National Institutes of Health Grant GM 51628 (G.B. and C.W.).

Supporting Information Available: Detailed general materials, instrumentation, and procedures for synthesis, spectroscopy, chromatography, and analysis. Additional information about syntheses and characterizations of peptides not covered in the representative text descriptions. Figures documenting HPLC analysis to monitor oxime-forming ligation, and $^1\text{H}/^2\text{H}$ isotope exchange of the OxCM dimer $\text{I}_{\text{R17K(U)}}-\text{II}_{\text{L29K(J)}}$. Detailed schemes outlining syntheses and cleavages of OxCM monomers of type I and type II. Tables showing complete ^1H NMR assignments for the model peptide TP, and presenting elution behavior of the OxCM dimers on a SEC column (12 pages). This material is available free of charge via the Internet at <http://pubs.acs.org>.

Towards New Designed Proteins Derived from Bovine Pancreatic Trypsin Inhibitor (BPTI): Covalent Cross-linking of Two 'Core Modules' by Oxime-forming Ligation.

Bioconjugate Chemistry

SUPPORTING INFORMATION

CONFIDENTIAL

SUPPORTING INFORMATION

General. Fmoc-PAL-PEG-PS supports (initial loading 0.17–0.24 mmol/g) for peptide synthesis were obtained from Applied Biosystems (Foster City, CA). Protected Fmoc-amino acid derivatives and coupling reagents were from Applied Biosystems or Advanced Chemtech (Louisville, KY), S-Trt-mercaptopropionic acid was from Peptide International (Louisville, KY), Boc-Aoa-OH, Fmoc-Dpr(Boc-Aoa)-OH, Fmoc-Dpr(Boc-Ser(*t*Bu))-OH, and Fmoc-Asn(Tmob)-OH were from Novabiochem (San Diego, CA), and Fmoc-Gln(Tmob)-OH was from Bachem Bioscience (Philadelphia, PA). TFA, piperidine, and DIEA were obtained from Fisher (Pittsburgh, PA). GdnHCl and urea 'ultrapure reagents' were from Gibco BRL (Rockville, MD), and DMSO, sodium periodate, ethylene glycol, and $\text{CH}_3\text{ONH}_2\cdot\text{HCl}$ (25–30 wt % solution in water) 'ACS grade reagents' were from Aldrich (Milwaukee, WI). Et_2O was freshly distilled from Na.

Amino acid analyses were performed on a Beckman 6300 analyzer with a sulfated polystyrene cation-exchange column (0.4 cm x 21 cm). Peptide or protein samples were hydrolyzed in 6 N aqueous HCl plus one drop of liquefied phenol (to prevent degradation of Tyr), for 90 min at 155 °C. Cys was not quantitated and is therefore not reported. The Ile values were consistently low, due to incomplete hydrolysis of the peptide bond between Ile¹⁸ and Ile¹⁹.

Analytical HPLC of the core module monomers, capped monomers, and of the model tetrapeptide and its derivatives, was performed using a Vydac C₁₈ reversed-phase column (5 μm , 300 Å; 0.46 x 25 cm), and analytical HPLC of the core module dimers was performed using a Waters YMC C₄ reversed-phase column (5 μm , 200 Å; 0.46 x 25 cm), all on a Beckman instrument, configured with two 112 pumps and a 165 variable wavelength detector. UV detection was at 220 nm.

Condition A: linear gradients of 0.1% TFA in CH_3CN and 0.1% aqueous TFA were run, at 1.2 mL/min flow rate, from 1:9 to 2:3 over 30 min, then to 4:1 over the next 10 min.

Condition B: linear gradients of 0.1% TFA in CH_3CN and 0.1% aqueous TFA were run, at 1.2 mL/min flow rate, from 1:4 to 7:13 over 40 min, then to 4:1 over the next 10 min.

Towards New Designed Proteins Derived from Bovine Pancreatic Trypsin Inhibitor (BPTI): Covalent Cross-linking of Two 'Core Modules' by Oxime-forming Ligation.

Bioconjugate Chemistry

SUPPORTING INFORMATION

Condition C: linear gradients of 0.1% TFA in $\text{CH}_3\text{CN}-\text{H}_2\text{O}$ (3:2) and 0.1% aqueous TFA were run, at 1.2 mL/min flow rate, from 0:1 to 1:1 over 20 min, then to 4:1 over the next 10 min.

Condition D: linear gradients of 0.1% TFA in $\text{CH}_3\text{CN}-\text{H}_2\text{O}$ (3:2) and 0.1% aqueous TFA were run, at 1.2 mL/min flow rate, at 1:3 for 5 min, then to 1:1 over 30 min, then to 4:1 over the next 10 min.

Semipreparative HPLC was carried out on a Waters DeltaPrep 3000 using a Vydac semipreparative C_{18} reversed-phase column (10 μm , 300 Å; 1 x 25 cm). UV detection was at 220 nm.

Condition E: linear gradients of CH_3CN and 0.1% aqueous TFA were run, at 5 mL/min flow rate, from 0:1 for 10 min, then to 19:81 over the next 5 min, then to 27:73 over the next 120 min, and finally to 4:1 over the next 10 min.

Condition F: linear gradients of CH_3CN and 0.1% aqueous TFA were run, at 5 mL/min flow rate, from 4:21 for 5 min, then to 9:16 over the next 45 min, and finally to 4:1 over the next 10 min.

Condition G: linear gradients of CH_3CN and 0.1% aqueous TFA were run, at 5 mL/min flow rate, from 0:1 for 10 min, then to 17:83 over the next 5 min, then to 1:3 over the next 120 min, and finally to 4:1 over the next 10 min.

Condition H: linear gradients of $\text{CH}_3\text{CN}-\text{H}_2\text{O}$ (3:2) and 0.1% aqueous TFA were run, at 4 mL/min flow rate, from 0:1 to 3:17 over 20 min, then to 4:1 over the next 10 min.

Condition I: linear gradients of CH_3CN and 0.1% aqueous TFA were run, at 5 mL/min flow rate, from 0:1 for 10 min, then to 11:39 over the next 5 min, then to 3:7 over the next 120 min, and finally to 4:1 over the next 10 min.

Size exclusion chromatography (SEC) was performed using two Superdex Peptide HR 10/30 columns assembled in series, in an FPLC System (Pharmacia).

Condition J: injections of 500 μL were eluted with 0.1% TFA in $\text{CH}_3\text{CN}-\text{H}_2\text{O}$ (3:7), at 0.2 mL/min.

Condition K: injections of 25 μL were eluted with $\text{CH}_3\text{CN}-10\text{ mM}$ aqueous NaCl (1:19) at pH 2, at 0.2 mL/min.

MALDI-TOF mass spectrometric data were collected with a Bruker Biflex III instrument, equipped

Towards New Designed Proteins Derived from Bovine Pancreatic Trypsin Inhibitor (BPTI): Covalent Cross-linking of Two 'Core Modules' by Oxime-forming Ligation.

Bioconjugate Chemistry

SUPPORTING INFORMATION

with a N_2 -laser (337 nm, 3 nanosecond pulse length) and a microchannel plate (MCP) in the reflectron mode, positive polarity, with an accelerating potential of 19 kV. Each spectrum was the accumulation of 200 laser shots. External calibration was performed using human angiotensin II (monoisotopic mass 1046.5 $[M+H]^+$; Sigma) and adrenocorticotrophic hormone (ACTH) fragment 18-39 (monoisotopic mass 2465.2 $[M+H]^+$; Sigma). The matrix used for samples and standards was α -cyano-4-hydroxycinnamic acid (4-HCCA; Hewlett-Packard, obtained as solution in methanol), diluted 1:1 with 0.1% TFA in CH_3CN-H_2O (1:1). ESMS data were collected using a ThermoFinnigan LCQ Classic ion trap mass spectrometer equipped with an ESI source in full scan mode from 50-2000 m/z with a spray voltage setting of 4.0 kV and a heated capillary temperature of 200 °C. Samples were infused at a flow rate of 5 $\mu L/min$ in 0.2% acetic acid in CH_3CN-H_2O (1:1), using the syringe pump on the instrument. Deconvolution of multiply charged protein peaks was performed using ThermoFinnigan's BioMASS add-on tool in the Xcalibur software. Molecular masses were calculated with the GPMW Version 4.0 program.

Peptide synthesis of core module monomers: $I_{R17K(U)}$, $I_{R17K(UG)}$, and $I_{R17Z(U)}$ (Supporting Information Scheme 1), and $II_{L29K(J)}$, $II_{L29K(JG)}$, $II_{L29Z(J)}$, and $II_{N24K(J)}$ (Supporting Information Scheme 2 and Figure 4).

$I_{R17K(U)}$. The synthesis and characterization of this molecule is described in the main text.

$I_{R17K(UG)}$. The only difference between the procedure for this molecule, and for $I_{R17K(U)}$ described in the main text Experimental, was the extra incorporation of Fmoc-Gly-OH preceding Boc-Aoa-OH. As summarized in the main text, three repeat PyAOP/HOAt/DIEA (8:8:16 equiv with respect to peptide-resin)-mediated couplings in DMF, 1 h each, were required for the Fmoc-Gly-OH incorporation to go to completion. Pure peptide was characterized by analytical HPLC (t_R 22.8 min; condition A), amino acid analysis (Asp, 2.04; Thr, 0.93; Glu, 1.05; Gly, 4.07; Ala, 1.98; Val, 0.92; Ile, 1.17; Leu, 0.99; Tyr, 2.46; Phe 1.91; Lys, 2.87; Arg, 1.07), and MALDI-TOF; calcd monoisotopic mass: 2954.46, found: 2955.1 $[M+H]^+$.

Towards New Designed Proteins Derived from Bovine Pancreatic Trypsin Inhibitor (BPTI): Covalent Cross-linking of Two 'Core Modules' by Oxime-forming Ligation.

Bioconjugate Chemistry

SUPPORTING INFORMATION

I_{R17Z(U)}. In the linear core module sequence, Arg¹⁷ was replaced by Fmoc-Dpr(Boc-Aoa)-OH. Cleavage, disulfide bond formation, and purification followed as already described for I_{R17K(U)}. Pure peptide was characterized by analytical HPLC (*t_R* 22.5 min; condition A), amino acid analysis (Asp, 1.83; Thr, 0.91; Glu, 1.04; Gly, 3.14; Ala, 1.71; Val, 1.02; Ile, 1.18; Leu, 1.04; Tyr, 2.53; Phe 1.85; Lys, 1.83; Arg, 0.93), and MALDI-TOF; calcd monoisotopic mass: 2855.39, found: 2856.03 [M+H]⁺.

II_{L29K(J)}. The synthesis and characterization of this molecule is described in the main text.

II_{L29K(JG)}. The only difference between the procedure for this molecule, and for II_{L29K(J)} (Figure 4b) described in the main text Experimental, was the extra incorporation of Fmoc-Gly-OH preceding Fmoc-Ser(*t*Bu)-OH. As summarized in the main text, three repeat PyAOP/HOAt/DIEA (8:8:16 equiv with respect to peptide-resin)-mediated couplings in DMF, 1 h each, were required for the Fmoc-Gly-OH incorporation to go to completion. Semipreparative HPLC (condition G) provide *separately* analytical-HPLC pure P1 and P2 [*t_R* 18.4 min (P1) and *t_R* 18.8 min (P2); condition A]. Purified P1 and P2 were indistinguishable by amino acid analysis (Asp, 1.98; Thr, 0.91; Glu, 1.00; Gly, 3.99; Ala, 2.00; Val, 1.01; Ile, 1.37; Tyr, 2.86; Phe, 1.92; Lys, 2.79; Arg, 2.02) and MALDI-TOF; calcd monoisotopic mass: 2980.45, found: 2981.3 [M+H]⁺.

II_{L29Z(J)}. In the linear core module sequence, Leu²⁹ was replaced by Fmoc-Dpr(Boc-Ser(*t*Bu))-OH. Cleavage, disulfide bond formation, and purification followed as already described for II_{L29K(J)} (Figure 4b). Semipreparative HPLC (condition G) provide *separately* analytical-HPLC pure P1 and P2 [*t_R* 18.8 min (P1) and 19.2 (P2) min; condition A]. Purified P1 and P2 were indistinguishable by amino acid analysis (Asp, 2.01; Thr, 0.93; Glu, 1.00; Gly, 3.12; Ala, 1.99; Val, 0.94; Ile, 1.24; Tyr, 2.67; Phe 1.93; Lys, 1.94; Arg, 2.07) and MALDI-TOF; calcd monoisotopic mass: 2881.38, found: 2882.1 [M+H]⁺.

II_{N24K(J)}. The procedure for this molecule was essentially as described for II_{L29K(J)} (Figure 4b), except that Asn²⁴ was replaced by Fmoc-Lys(Alloc)-OH and Leu²⁹ was added normally. Semipreparative HPLC (condition G) provide *separately* analytical-HPLC pure P1 and P2 [*t_R* 20.8 min (P1) and 21.8 min (P2); condition A]. Purified P1 and P2 were indistinguishable by amino acid analysis (Asp, 1.01; Thr,

0.86; Glu, 1.02; Gly, 3.09; Ala, 1.98; Val, 0.96; Ile, 1.58; Leu, 1.00; Tyr, 2.57; Phe, 1.97; Lys, 2.97; Arg, 1.97) and MALDI-TOF; calcd monoisotopic mass: 2922.47, found: 2923.12 $[M+H]^+$.

Oxime-forming ligation reactions

Capping of monomers

I_{R17K(U*)}. The synthesis and characterization of this molecule is described in the main text.

I_{R17Z(U*)}. Pure peptide was characterized by analytical HPLC (t_R 27 min; condition A), amino acid analysis (Asp, 2.01; Thr, 0.92; Glu, 0.99; Gly, 3.01; Ala, 2.02; Val, 0.95; Ile, 1.11; Leu, 1.00; Tyr, 2.85; Phe, 1.96; Lys, 2.05; Arg, 1.05), and MALDI-TOF; calcd monoisotopic mass: 2895.42, found: 2896.09 $[M+H]^+$.

I_{R17K(U*G)}. Pure peptide was characterized by analytical HPLC (t_R 25.5 min; condition A), amino acid analysis (Asp, 1.99; Thr, 0.86; Glu, 1.03; Gly, 3.95; Ala, 2.02; Val, 0.99; Ile, 1.63; Leu, 1.03; Tyr, 2.78; Phe, 1.95; Lys, 2.91; Arg, 1.05), and MALDI-TOF; calcd monoisotopic mass: 2994.49, found: 2996.3 $[M+H]^+$.

II_{L29K(J*)}. The synthesis and characterization of this molecule is described in the main text.

II_{L29K(J*G)}. Pure peptide was characterized by analytical HPLC (t_R 21.3 min; condition A), amino acid analysis (Asp, 2.00; Thr, 1.03; Glu, 1.13; Gly, 3.89; Ala, 2.05; Val, 1.07; Ile, 1.40; Tyr, 2.89; Phe 2.01; Lys, 2.76; Arg, 1.87), and MALDI-TOF; calcd monoisotopic mass: 3009.47, found: 3010.9 $[M+H]^+$.

II_{L29Z(J*)}. Pure peptide was characterized by analytical HPLC (t_R 20.1 min; condition A), amino acid analysis (Asp, 1.96; Thr, 0.83; Glu, 1.06; Gly, 2.96; Ala, 1.97; Val, 0.98; Ile, 1.59; Tyr, 2.56; Phe, 1.87; Lys, 1.96; Arg, 2.06), and ESMS; calcd average mass: 2912.35, found: 2912.6 ± 1.4 .

II_{N24K(J*)}. Pure peptide was characterized by analytical HPLC (t_R 24.6 min; condition A), amino acid analysis (Asp, 1.14; Thr, 1.01; Glu, 1.25; Gly, 3.00; Ala, 1.78; Val, 1.13; Ile, 1.15; Leu, 1.15; Tyr, 2.45; Phe, 1.96; Lys, 2.56; Arg, 1.95), and MALDI-TOF; calcd monoisotopic mass: 2951.49, found: 2953.2 $[M+H]^+$.

Synthesis and Characterization of Membrane-Active GALA-OKT9 Conjugates

Jennifer Kuehne and Regina M. Murphy*

Department of Chemical Engineering, University of Wisconsin–Madison, 1415 Engineering Drive, Madison, Wisconsin 53706-1607. Received January 3, 2001; Revised Manuscript Received May 25, 2001

Cellular processing of immunotoxins is inefficient, limiting the overall effectiveness of current immunotoxin therapies. Specifically, translocation of ribosome-inactivating toxins across intracellular membranes is agonizingly slow. In one strategy to improve immunotoxin efficacy, membrane-active peptides are attached to immunotoxins to facilitate transfer of the toxic moiety across a cellular membrane to the cytosol. pH-sensitive peptides are of particular interest, as the membrane activity can be localized to the endosomal/lysosomal pathway, reducing nonspecific interactions at the cell surface. In this study, GALA, a pH-sensitive peptide that forms multimeric pores in membranes, was chemically attached to OKT9, an anti-transferrin receptor mAb. Conjugates were tested by measuring release of encapsulated dyes from liposomes to determine the extent to which the membrane-lytic properties of GALA were retained. The most significant feature affecting the lytic properties of GALA-OKT9 conjugates was the number of attached GALA per OKT9. Conjugates with a single GALA per OKT9 caused almost no leakage while conjugates with two or three GALA per OKT9 caused significant leakage in a concentration-dependent manner. Invariably, GALA-OKT9 conjugates were significantly less active than unconjugated GALA, attributable to a decrease both in partitioning and in surface aggregation. No improvement in membrane-lytic activity was achieved by using a longer, more flexible poly(ethylene glycol) cross-linker. Attachment of GALA via C- versus N-terminal linkage had no effect on membrane-lytic properties. Size-selective release of high molecular weight dextrans was almost identical for conjugated and unconjugated GALA, suggesting that GALA forms the same pore structure regardless of conjugation state.

INTRODUCTION

Immunotoxins are chimeric molecules with both targeting and toxic capabilities, of interest for treatment of diseases such as cancer, graft-vs-host disease, and AIDS. Targeting ability is derived from monoclonal antibodies, stable hormones, or carrier proteins, while toxic activity is typically conferred by plant or bacterial toxins. Ideally, immunotoxins bind with high specificity and affinity only to the targeted cell, while avoiding healthy tissue.

Even if immunotoxins bind tightly to the surface of targeted cells, cell death is not assured. Commonly used toxins (e.g., diphtheria toxin, gelonin, ricin, *Pseudomonas* exotoxin A) act at the ribosomal level to inactivate protein synthesis. Thus, the toxin must be correctly routed to the ribosome for cell death to occur. For immunotoxins targeted to specific cell-surface receptors, this involves receptor-mediated endocytosis into an appropriate intracellular vesicle, followed by translocation of the toxin across the vesicular membrane to the cytosol. Inefficient intracellular trafficking, e.g., immunotoxins traveling to lysosomes, results in a large reduction in utilization of the targeted toxin (1). In one study, it was estimated that ~10 million transferrin–gelonin immunotoxins are processed through a cell for each one that actually reaches the cytosol and inactivates protein synthesis (2). The slowest step by far appears to be translocation across the membrane (2, 3), and it has been suggested that strategies which improve toxin translocation rates could result in gains in immunotoxin efficacy (4).

Another delivery system that encounters membrane barriers is gene therapy. There are two main strategies for gene therapy: (1) lipofection, in which translocation occurs across the plasma membrane followed by transport into the nucleus; and (2) polyfection, in which internalization into an endosomal vesicle occurs, then translocation across the endosomal membrane, followed by transport to the nucleus (5). Molecules used to facilitate transport to the cell and across membranes include polycations, lipid-based DNA complexes, targeting ligands, and endosomolytic agents (5, 6). Further improvements in membrane translocation of gene therapy products are also needed.

In one strategy for improving membrane translocation of internalized macromolecules, membrane-disrupting peptides are linked to macromolecules via chemical conjugation or genetic fusion. pH-sensitive peptides are of particular interest, since membrane activity can be localized to the acidic endosomal/lysosomal system. The hypothesis is that perturbation of intracellular membranes by the peptide would lead to enhanced translocation of the attached macromolecule. A few studies in which this strategy was implemented to improve immunotoxin efficacy have been reported, with variable success. Decreases in IC_{50} (concentration required to inhibit protein synthesis by 50%) of 2–20-fold were observed for some peptide-modified immunotoxins relative to unmodified immunotoxins (7–9), but in other cases no effect or even a reduction in efficacy was observed (8, 9). Lorenzetti et al. compared the ability of three peptide–toxin fusion proteins to destabilize liposomes with their activity in protein synthesis inhibition assays, and observed no

strong correlation (9). In fact, the peptide–toxin combination that was most effective at destabilizing liposomes proved to be least effective at killing cells. Thus, although this strategy is appealing, greater mechanistic insight is needed to fulfill its promise. Specifically, the structure–activity relationship between peptide–conjugate design, membrane destabilization, and macromolecule translocation remains undefined.

In this report, we describe how the activity of a membrane-destabilizing peptide is affected by conjugation to a carrier protein. We chose as a model system the synthetic pH-sensitive peptide GALA chemically conjugated to an anti-transferrin antibody, OKT9. GALA converts from a random coil monomer at neutral pH to an amphipathic α -helix at pH 5 (10). When contacted with large unilamellar vesicles at acidic pH, GALA partitions into the lipid bilayer, forms pores of 8–12 monomers, and allows leakage of encapsulated small molecules. GALA also causes phospholipid flip-flop in large unilamellar vesicles and fusion of small vesicles (10–13). These properties make GALA an attractive candidate for investigation. In fact, GALA has been used successfully to improve delivery of genes (14) and antisense oligodeoxynucleotides (15), and may improve intracellular retention of Fabs in cancer cells (16). However, no detailed biophysical studies have been undertaken to establish the extent to which GALA's activity was retained upon attachment to macromolecules. The goals of this work are as follows: (1) to determine how cross-linker length, peptide:antibody ratio, and peptide orientation relate to the membrane activity of GALA-OKT9 conjugates; and (2) to compare membrane interaction properties of unconjugated versus conjugated GALA.

MATERIALS AND METHODS

Materials. GALA has the following sequence: WEAALAEALAEALAEHLAEALAEALAEALAA (10). A cysteine was added to the N- or C-terminus of GALA to add a chemically reactive sulfhydryl group. GALA, cys-GALA, and GALA-cys were purchased from American Peptide Co. (Sunnyvale, CA). Purity was greater than 90% by reverse-phase HPLC,¹ and identity was confirmed by mass spectroscopy. Hybridoma serum-free media (SFM) was purchased from Gibco (Gaithersburg, MD). *N*-Succinimidyl-3-(2-pyridyldithio)propionate (SPDP) was purchased from Pierce Chemical Co. (Rockford, IL), while maleimido-PEG₃₄₀₀-succinimidyl propionate (PEG) was purchased from Shearwater Polymers, Inc. (Huntsville, AL). 1-Palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC) and 1,2-dibromostearoyl-*sn*-glycero-3-phosphocholine (OBPC) were purchased from Avanti Polar-Lipids, Inc. (Alabaster, AL), aliquoted into 5 or 10 mg vials, dried under nitrogen, vacuum-desiccated for at least 2 h, and then stored under nitrogen at –20 °C. Neutral Texas-Red 3000 and 10 000 MW dextran were

Figure 1. Purification of an OKT9-GALA conjugate mixture. A representative HPLC chromatograph of an OKT9-SPDP-GALA conjugate mixture on a Zorbax GF-250 column. Conjugate used in testing was purified from aggregated conjugate and unreacted GALA.

purchased from Molecular Probes (Eugene, OR). All other reagents were purchased from Sigma (St. Louis, MO), unless otherwise stated.

Conjugate Production and Purification. mAb OKT9, a murine anti-transferrin receptor antibody, was purified on a protein G affinity column (Pharmacia Biotech, Piscataway, NJ) from supernatant of the hybridoma cell line CRL8021 (American Type Culture Collection, Rockville, MD) and then dialyzed into PBSA [3 mM KH₂PO₄, 7 mM K₂HPO₄·3H₂O, 140 mM NaCl, and 0.02% (w/v) NaN₃, pH 7.0]. To synthesize conjugates with disulfide linkers, 2 mg of SPDP was dissolved in DMSO, and then added in varying molar ratios to 2–3 mg of OKT9 (~1 mg/mL) in PBSA. SPDP and OKT9 were reacted for 30 min at 25 °C. Excess SPDP was removed by overnight dialysis in a 10K MWCO Slide-A-Lyzer (Pierce, Rockford, IL) against 1 L of PBE (0.1 M Na₂PO₄/NaHPO₄, pH 7.4, + 1 mM EDTA) at 4 °C. Alternatively, SPDP-modified OKT9 was separated from unreacted SPDP on a Zorbax GF-250 (Mac Mod Analytical, Chadds Ford, PA) size exclusion HPLC (running buffer PBE), and then concentrated to ~1 mg/mL by ultrafiltration with a YM10 filter (MWCO 10K, Millipore, Bedford, MA). To synthesize conjugates with PEG linkers, PEG was dissolved in ~1 mg/mL OKT9 and incubated for 1 h at 25 °C. Excess PEG was removed by Zorbax GF-250 size exclusion HPLC (running buffer PBE). After HPLC purification, PEG-modified OKT9 was concentrated to ~1 mg/mL by ultrafiltration. Modified OKT9 was mixed with a 5 molar excess of cys-GALA or GALA-cys and reacted for 4 h at 25 °C. OKT9-GALA conjugates were purified from unconjugated GALA by Zorbax GF-250 size exclusion HPLC (running buffer PBE). Approximately 75% of the conjugate peak was collected, to eliminate aggregates (Figure 1). Conjugate was stored at 4 °C overnight at a concentration of ~0.15 mg/mL and tested the following day. Conjugate concentration was determined by optical density measurements at 280 nm using an extinction coefficient of 1.4 mL/(mg·cm). As a control, sham-conjugation of OKT9 and cysteine-modified GALA, in the absence of cross-linker, was carried out under identical conditions.

The degree of SPDP modification was determined by quantifying the number of pyridine-2-thione groups released from OKT9 upon incubation with DTT (17). SPDP modification ranged from 0.8 to 3.4 SPDP per OKT9. The degree of PEG modification was determined from shifts in the HPLC retention time of PEG-modified OKT9 vs unmodified OKT9. Column calibration was

¹ Abbreviations: EDTA, ethylenediaminetetraacetic acid disodium salt; DMSO, dimethyl sulfoxide; DTT, dithiothreitol; HPLC, high-performance liquid chromatography; mAb, monoclonal antibody; MWCO, molecular weight cutoff; PEG, maleimido-PEG₃₄₀₀-succinimidyl propionate; OBPC, 1,2-dibromostearoyl-*sn*-glycero-3-phosphocholine; PBE, phosphate buffer with EDTA (0.1 M Na₂PO₄/NaHPO₄, pH 7.4, + 1 mM EDTA); PBS, phosphate-buffered saline (3 mM KH₂PO₄, 7 mM K₂HPO₄·3H₂O, 140 mM NaCl, pH 7.0); PBSA, phosphate-buffered saline with azide [3 mM KH₂PO₄, 7 mM K₂HPO₄·3H₂O, 140 mM NaCl, and 0.02% (w/v) NaN₃, pH 7.0]; POPC, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine; SDS, sodium dodecyl sulfate; SFM, serum-free media; SPDP, succinimidyl-3-(2-pyridyldithio)propionate.

determined using OKT9 (150 kDa), bovine serum albumin (68 kDa), and ovalbumin (43 kDa). A total of 0.5–4 PEG groups were attached per OKT9. The number of GALA attached per OKT9 was assumed equal to the degree of modification by the cross-linker, as the conjugation reaction was run with a 5-fold molar excess of cysteine-modified GALA.

Liposome Production. POPC and OBPC liposomes were prepared by extrusion. Briefly, lipids were rehydrated to a concentration of 10 mg/mL in an aqueous calcein (50 mM) solution at pH 7.0 in Tris buffer (1 mM EDTA and 20 mM Tris), or at pH 5.0 in citrate buffer (1 mM EDTA, 100 mM NaCl, 5.9 mM $C_6H_5O_7Na_3$, 4.5 mM $C_6H_8O_7$, pH adjusted with NaOH), or in an aqueous solution of neutral Texas-red 3000 or 10 000 MW dextran (0.167 mM) in citrate buffer, pH 5.0. After 30 min, the hydrated lipid suspension was subjected to 4–5 freeze–thaw cycles in an ethanol–dry ice bath and warm water bath, and then passed through a 0.1 μ m polycarbonate filter (Avanti Polar Lipids) 21 times. Liposomes were separated from unencapsulated calcein by Sephadex G-50 size exclusion chromatography or from unencapsulated dextran by Sephacryl S-400 size exclusion chromatography. Lipid concentration was determined using a Stewart assay (18). Liposome diameter was 100–150 nm, as measured by dynamic light scattering.

Calcein Leakage Assay. Leakage of encapsulated calcein from liposomes was used to determine the lytic ability of conjugates. Calcein is a self-quenching dye; release of encapsulated calcein from liposomes into buffer causes a reduction in concentration and a corresponding increase in fluorescence intensity. Fluorescence measurements were collected using a model M-3 Alphascan spectrofluorometer (Photon Technology International, South Brunswick, NJ) with excitation at 490 nm and emission at 520 nm. Conjugate was dialyzed into pH 5.0 citrate buffer using a 10K MWCO Slide-A-Lyzer for 3 h, with two buffer changes. Samples were prepared by mixing calcein-encapsulated liposomes (final lipid concentration 10 μ M) with varying molar ratios of conjugate, 1% (v/v) Triton-X 100 (100% leakage), or citrate (pH 5.0) buffer or PBS (pH 7.0) (0% leakage). Samples were briefly vortexed, and then left quiescent for 16 h at room temperature, which was sufficient time to allow equilibration (data not shown). Fluorescent intensity (FI) measurements were normalized as

$$\% \text{ leakage} = \frac{(FI_{\text{sample}} - FI_{\text{buffer}})}{(FI_{\text{triton}} - FI_{\text{buffer}})} \times 100 \quad (1)$$

Partitioning Assay. The partition coefficient of GALA-OKT9 conjugates (containing three GALA per OKT9 linked by SPDP) in liposomes was determined by incubating ^{125} I-labeled conjugate with dense liposomes, separating the lipid phase from the aqueous phase by centrifugation, and measuring the radioactivity associated with each phase. To facilitate centrifugal separation, dense liposomes were made with brominated lipids (OBPC) (19). Following the manufacturer's instructions, Iodobeads (Pierce, Rockford, IL) were used to radiolabel conjugate and antibody with $Na^{125}I$ (DuPont, New England Nuclear, Boston, MA). To deter nonspecific binding to tubes, 0.6 mL tubes were preincubated with 50 μ L of a 40 mg/mL bovine serum albumin/citrate buffer. Samples were prepared by mixing ~ 0.5 mg/mL ^{125} I-labeled conjugate or ^{125} I-labeled antibody in PBS, pH 7.0, with OBPC liposomes in citrate, pH 5.0, and then adding 450 μ L to the coated tubes (final lipid:antibody/conjugate

ratios of 1000 or 3000, final lipid concentration 10 μ M, final pH 5.0). After incubation for 16 h, samples were centrifuged at 7000g for 30 min followed by 16000g for 30 min. Centrifuged samples were separated by removing 250 μ L of supernatant (SN) from the remaining 250 μ L solution plus pelleted material (P). Radioactivity associated with SN and P was measured in a gamma counter. The partition coefficient, K_p , was calculated as

$$K_p = \frac{P_L}{P_W} = \frac{(CPM_P - CPM_{SN})}{2 \cdot CPM_{SN}} \quad (2)$$

where P_L = moles of peptide in the lipid phase per volume of solution and P_W = moles of peptide in the aqueous phase per volume of solution.

Model of GALA-Induced Calcein Leakage from Liposomes. GALA pore formation was modeled as a two-step process: (1) partitioning of the peptide into lipid phase and (2) surface aggregation. The equilibrium constant for partitioning between lipid and aqueous phases, K_p , is defined as

$$K_p = \left(\frac{P_L}{P_W} \right) \frac{1}{L_{\text{tot}}} = K'_p \frac{1}{L_{\text{tot}}} \quad (3)$$

where L_{tot} = moles of lipid per volume solution (10^{-5} M). It was assumed that peptides reversibly aggregate on the lipid surface, and that aggregates containing M or more peptides will leak. Total leakage, L_{∞} , is (20, 21)

$$L_{\infty} = \sum_{i=M}^N z_i A_i \quad (4)$$

where A_i = fraction of liposomes containing i peptides, z_i = probability that a liposome containing i peptides will include an aggregate of M or more peptides, and N = maximum allowable number of peptides per liposome. A_i is calculated from (20)

$$A_0 = (1 - T)^N \quad (5)$$

$$A_{i+1} = A_i \left(\frac{N-i}{i+1} \right) \left(\frac{T}{1-T} \right) \quad (6)$$

$$T = \frac{P_L}{NG_0} \quad (7)$$

subject to

$$\sum_{i=0}^N A_i = 1 \quad (8)$$

where G_0 = molar concentration of liposomes. z_i is calculated from (21)

$$z_i = P_i^{M-1} (M - MP_i + P_i) \quad (9)$$

$$P_i = \frac{1}{K_i + \sqrt{K_i^2 - 1}} \quad (10)$$

$$K_i = 1 + \frac{1}{4iK_s} \quad (11)$$

where K_s = the equilibrium constant for surface aggregation. We assumed $M = 10$ (20) and determined K_s and K_p from a least-squares fit to the leakage data. (Adjusting

M to 8 or 12 peptides affected the absolute values of K_S and K_P but did not change the relative ordering; data not shown.) For simplicity we neglected the effects of liposomal size distribution on leakage. Parameters were determined using the general purpose multiresponse parameter estimation program GREG (22, 23).

Dextran Leakage Assay. Leakage of 3000 or 10 000 MW dextrans from liposomes was used to determine whether conjugates formed size-selective pores. All work with Texas-red dextran was done with minimal light exposure to minimize photobleaching. Conjugates with three GALA per OKT9 cross-linked with SPDP were used in these experiments. Conjugate was dialyzed into pH 5.0 citrate buffer using a 10K MWCO Slide-A-Lyzer for 3 h, with two buffer changes. Samples were prepared by mixing dextran-encapsulated liposomes (final lipid concentration 10 μ M) with varying molar ratios of conjugate, 0.2% (w/v) SDS, or buffer. Conjugate samples were prepared at 50, 500, and 2000 lipid:conjugate ratios to span calcein leakage ranges from 20 to 100%, while cys-GALA samples were prepared at 200, 500, 2000, and 7000 lipid:peptide ratios to span calcein leakage ranges from 50 to 100%. Samples were briefly vortexed and left quiescent for 16 h at room temperature. Then 500 μ L aliquots were placed in a Microcon-100 (100K MWCO, Millipore, Bedford, MA) filtration unit and centrifuged at 5000*g* for 15 min to separate released dextran. The Microcon unit was removed, and 10 μ L of a 10% (w/v) SDS solution was added to retentate to lyse liposomes; then 500 μ L of citrate buffer was added. The filter was reversed and centrifuged for 10 min at 3000*g* to release all retained dextran. To account for SDS background fluorescence, filtrate samples were mixed with 10 μ L of 10% (w/v) SDS. The fluorescence intensity (FI) of each fraction was measured with excitation at 595 nm and emission at 610 nm. Control experiments in which buffer alone or SDS was added in place of the conjugate were conducted, and corrections were made for the SDS contribution to FI of each dextran sample. The fraction, f , of released dextran was determined as

$$f = \left(\frac{FI_{\text{filtrate}}}{FI_{\text{filtrate}} + FI_{\text{retentate}}} \right) \quad (12)$$

Results were normalized according to

$$\% \text{ leakage} = \frac{(f_{\text{sample}} - f_{\text{buffer}})}{(f_{\text{SDS}} - f_{\text{buffer}})} \times 100 \quad (13)$$

Dynamic Light Scattering. Dynamic light scattering was used to determine the size of liposomes before and after addition of conjugate at acid pH. Liposome samples were prepared by mixing various concentrations of conjugate with a constant 10 μ M lipid in pH 5.0 citrate buffer and then incubated for 16 h. Samples were filtered through a 0.45 μ m filter into dust-free light-scattering cuvettes, and then placed in a temperature-controlled bath (25 $^{\circ}$ C) of decahydronaphthalene. Dynamic light scattering measurements were collected with a Lexel (Fremont, CA) argon laser and a Malvern (Southborough, MA) 4700 C system as described in detail elsewhere (24). Three replicate measurements were taken at a 90 $^{\circ}$ scattering angle. Data were analyzed using CONTIN.

RESULTS

Effect of Conjugation Method on Retention of GALA Lytic Activity. At pH 5, GALA causes leakage of small molecules from egg phosphatidylcholine lipo-

Figure 2. Effect of derivatization on conjugate-induced leakage. Conjugate was mixed with calcein liposomes (final concentration 10 μ M lipid) and left quiescent for 16 h; then fluorescent measurements were obtained with excitation at 490 nm and emission at 520 nm. Percent leakage was calculated per eq 1. (A) OKT9-GALA conjugates were synthesized with 1 (●), 2 (■), and 3 (◆) GALA per OKT9 using a SPDP cross-linker. The data represent the average of 1–3 preparations of conjugate with 3–4 data points per lipid:conjugate ratio for each conjugate. Cys-GALA (▲) data are a single representative set of data with 3–4 data points per lipid:peptide ratio. Error bars are standard deviation of the average leakage from each separate conjugate preparation. Lines show model fits of the data. (B) The lipid:conjugate molar ratio was divided by the integer number of GALA per OKT9 to give the lipid:peptide ratio.

somes (12). A panel of conjugates was synthesized and tested to determine the extent of GALA's lytic activity retained upon attachment to OKT9. Effects of three variables were examined: number of GALA per OKT9, cross-linker type, and C- or N-terminal placement of the cysteine on GALA.

GALA-OKT9 conjugates with SPDP cross-linkers were synthesized with one, two, or three GALA per OKT9. Conjugates with a single GALA per OKT9 caused little leakage (Figure 2A), reaching only $14 \pm 3\%$ leakage at a 50:1 lipid:conjugate ratio. Conjugates with two or three GALA per OKT9 caused significant calcein leakage in a concentration-dependent manner, with the extent of leakage increasing with extent of derivatization (Figure 2A). Approximately 100% leakage was reached at ~ 100 lipid:conjugate ratio. Conjugated GALA was substantially less effective than unconjugated GALA (Figure 2A). For example, at least 7-fold greater concentration of GALA-OKT9 conjugate was required to cause 50% leakage compared to unconjugated GALA. At equivalent final leakage values, rates of leakage for conjugated and unconjugated GALA were similar (data not shown), demonstrating that the kinetics of GALA's interaction with liposomes are unchanged upon conjugation. Neither GALA nor OKT9-GALA caused leakage at pH 7, indicating that GALA did not lose its pH sensitivity upon conjugation (data not shown). Thus, GALA retains pH

Table 1. Model Fit Parameters^a

	$K_P (\times 10^3 \text{ M}^{-1})$	K_S
GALA	200 ± 100	$> 3^b$
OKT9-SPDP-3GALA	28 ± 0.6	0.8 ± 0.01
OKT9-SPDP-2GALA	7 ± 2	1.0 ± 0.5
OKT9-SPDP-1GALA	0.2 ± 2	0.1 ± 0.7
OKT9-PEG-3GALA	8 ± 1	0.7 ± 0.2
OKT9-PEG-2GALA	6 ± 4	0.3 ± 0.2
OKT9-PEG-1GALA	2 ± 1	0.2 ± 0.01

sensitivity, but only a fraction of its lytic activity, when multiple peptides are attached to an antibody.

The activity of conjugates was compared on a per-peptide basis (Figure 2B). Differences in activity among conjugates with one, two, or three GALA persist, showing that the greater efficacy of conjugates with greater degrees of derivatization observed in Figure 2A is not due solely to the increased number of peptides. The steepness of the curves, an indication of the extent of cooperative self-association, differs between GALA and OKT9-GALA conjugates. For example, the ratio of peptide concentration required to produce 90% versus 10% leakage (an indication of the sharpness of the transition) is ~ 5 for GALA but ~ 15 for OKT9-GALA.

To provide a more quantitative analysis of differences between unconjugated and conjugated GALA, data were fit to eqs 3–11. The model captured the lytic behavior of both unconjugated and conjugated GALA (Figure 2A). Coupling of GALA to OKT9 significantly reduced both the partition coefficient, K_P , and the surface aggregation constant, K_S (Table 1). The decrease in K_P , determined by evaluation of leakage data, could be due to an actual loss of partitioning into the membrane phase, or to a loss in the ability of membrane-bound conjugated GALA to form pores. To distinguish between these two possibilities, an independent measure of K_P was obtained by direct measurement of partitioning of conjugates with three GALA per OKT9 cross-linked via SPDP. The K_P for these conjugates was determined to be $(1.1 \pm 0.3) \times 10^4 \text{ M}^{-1}$, in reasonably good agreement with the K_P of $(2.8 \pm 0.06) \times 10^4 \text{ M}^{-1}$ from the fit to leakage data, demonstrating that the decrease in K_P was due to a true decrease in partitioning. The presence of GALA was essential for partitioning into the lipid; OKT9 alone did not associate with the lipid phase (data not shown). Thus, the reduction in lytic activity observed upon conjugation of GALA to OKT9 is due to a combination of decreased partitioning and decreased surface aggregation.

We hypothesized that retention of GALA activity upon conjugation could be improved by increasing the length and/or flexibility of the cross-linker. To test this, OKT9-GALA conjugates were synthesized with a cross-linker containing a poly(ethylene glycol) chain with an estimated end-to-end length of 60 Å, compared to a spacer arm length of 6.8 Å for SPDP. As with SPDP-cross-linked conjugates, PEG-cross-linked conjugates with three GALA per OKT9 caused the most leakage while conjugates with a single GALA per OKT9 caused the least (Figure 3). The PEG-cross-linked conjugates were slightly less effective than the SPDP cross-linker: conjugates with two GALA per OKT9 cross-linked with SPDP had similar lytic activity as conjugates with three GALA per OKT9 cross-linked with PEG. Values for K_P and K_S were determined by fitting the data to eqs 3–11. This analysis suggests

Figure 3. Effect of linker on conjugate-induced leakage. Samples were prepared as described in Figure 2. OKT9-GALA conjugates were made with 1 (●), 2 (■), or 3 (◆) GALA per OKT9 using a PEG cross-linker. Actual number of PEG linkers per OKT9 varied from 0.5 to 1.6 for “1”, 1.8–2.8 for “2”, and 2.4–3 for “3”. The data points represent 2–3 replicate conjugate preparations with 3–4 replicates at each lipid:conjugate ratio. Error bars show standard deviation of the average leakage from each conjugate preparation. Solid lines show model fit to data.

Figure 4. Effect of GALA cysteine placement on conjugate leakage ability. Samples were prepared as in Figure 2. OKT9-GALA conjugates were synthesized with either N-terminally modified GALA (closed symbols) or C-terminally modified GALA (open symbols) with either 1 (●), 2 (■), or 3 (◆) GALA per OKT9. Data points represent the average of 1–3 replicate conjugate preparations with 3–4 replicates at each lipid:conjugate ratio. Error bars show standard deviation of the average leakage from each conjugate preparation.

that the decreased lytic ability of PEG-cross-linked conjugates, like SPDP-cross-linked conjugates, relative to unconjugated GALA was due to reductions in both partitioning and surface aggregation.

When inserted in a membrane, GALA has a preferred orientation: 75% N-terminally and 25% C-terminally inserted (25). To determine if conjugated GALA retained a preferred orientation, OKT9-GALA conjugates synthesized with C- or N-terminal placement of cysteine on GALA were compared. Conjugates with two or three GALA per OKT9 produced identical leakage curves regardless of peptide orientation (Figure 4). Conjugates with a single GALA per OKT9 showed slight preference (increased lytic activity) for N-terminal insertion, the preferred peptidyl insertion. Thus, cross-linking of GALA at the C- or N-terminus does not strongly affect the lytic ability of GALA-OKT9 conjugates, which suggests that the preferred orientation observed in unconjugated GALA has little or no consequence for the lytic ability of conjugated GALA.

Mechanism of Enhanced Membrane Permeability. Membrane-inserted GALA self-associates into oligo-

mers of 8–12 monomers, forming pores with a hydrated channel 5–10 Å in diameter (20). Discrete pore formation is therefore believed to be the mechanism by which GALA allows leakage of liposomal contents. A similar mechanism could explain leakage with OKT9-GALA conjugates; in fact, a pore formation model was able to fit calcein leakage data. Alternatively, leakage could be due to liposomal break-up. To determine whether the observed leakage of calcein upon interaction with conjugates was due to catastrophic loss of liposome integrity, the size of liposomes in the presence of high concentrations of GALA or OKT9-GALA conjugate was measured by dynamic light scattering. Neither hydrodynamic diameter nor number concentration of liposomes (as measured by total scattering intensity) changed with addition of lytic quantities of GALA or OKT9-GALA conjugates (data not shown). These data demonstrate that neither micelle formation nor fusion of liposomes occurred to any detectable level and therefore complete liposome disruption could not explain the leakage data.

Alternatively, if pores of defined size were formed, then leakage of liposomal contents would be sensitive to the molecular size of the encapsulated markers. Size selectivity of pores was determined by measuring leakage of encapsulated 3000 and 10 000 MW dextran by conjugates with three GALA per OKT9 cross-linked with SPDP. For 3000 MW dextran, little to no leakage was observed until calcein leakage reached roughly 35% (Figure 5A). Above this, dextran leakage increased with increasing calcein leakage (decreasing lipid:peptide or conjugate ratio), reaching 60% dextran leakage at full calcein leakage. In contrast, essentially none of the 10 000 MW dextran was released (Figure 5B). Remarkably, the size selectivities for conjugated and free GALA were virtually identical. These data indicate that OKT9-GALA conjugates form size-selective pores similar to GALA pores. Interestingly, if GALA concentration is increased to 4–10-fold greater than that required for 100% calcein leakage, ~40% leakage of 10 000 MW dextran is observed (data not shown). This observation, together with the nonlinear shape of the data in Figure 5A, indicates that the average pore size increases as the GALA:lipid or OKT9-GALA:lipid ratio increases.

DISCUSSION

Synthesis of Membrane-Lytic Conjugates. The objectives of this work were to synthesize GALA-OKT9 conjugates that retained membrane activity and to compare the membrane-lytic activity of conjugates to unconjugated GALA. Three design parameters were evaluated: number of GALA per OKT9, choice of cross-linker, and orientation of attached GALA. The most significant parameter affecting retention of lytic activity was the number of GALA per OKT9. As shown in Figure 2A, conjugates containing two or three GALA per OKT9 caused dramatically increased leakage compared to conjugates with only one GALA, which were essentially inactive. Conjugates with 4–5 GALA per OKT9 contained a large fraction of aggregated protein, and thus were not further evaluated (data not shown). Thus, the optimum extent of derivatization is 2–3 GALA per OKT9.

Lytic ability was significantly reduced for conjugated GALA relative to unconjugated GALA (Figure 2A,B). A possible explanation could be that partitioning of conjugated GALA into the membrane and/or surface aggregation is hindered by the bulky antibody. We attempted to overcome this problem by synthesizing a GALA-OKT9 conjugate containing a long, flexible spacer. GALA-PEG-

Figure 5. Leakage of higher molecular weight compounds. Conjugate was mixed with liposomes (final concentration 10 μ M lipid) containing either 3000 or 10 000 MW Texas-Red-labeled dextran, left quiescent for 16 h, and then centrifuged in a 100 kDa MWCO Microcon to separate released dextran from encapsulated dextran. Fluorescent measurements were obtained with excitation at 595 nm and emission at 610 nm. Percent leakage was calculated with eq 1 using the fraction of released dextran as in eq 2. GALA-OKT9 conjugates with 3 SPDP per antibody made with cys-GALA were tested. Data represents individual data points of 3–4 replicates for 3 conjugate and 3 cys-GALA preparations. Error bars show standard deviation of the average leakage from a single conjugate or cys-GALA preparation. Cys-GALA leakage data (●) and conjugate leakage data (○) are shown for (A) 3000 MW dextran or (B) 10 000 MW dextran.

OKT9 conjugates performed no better than conjugates made with a short SPDP cross-linker (Figure 3). This could suggest that steric hindrance caused by close proximity of OKT9 and GALA is not a significant influence on GALA-OKT9 lytic activity, or alternatively that addition of the PEG linker was not sufficient to eliminate the steric hindrance effects of OKT9 on GALA.

Membrane-inserted GALA has a preferred orientation in liposomes, with 75% N-terminally inserted into liposomes (25). Other systems also show differential activity based on orientation. For example, chimeric toxins of restrictocin and a single-chain region of anti-(transferrin receptor) antibody have 3–12-fold increased cellular activity when restrictocin is attached with a C-terminal linkage compared to an N-terminal linkage (26). These results suggested that the orientation of conjugated GALA might affect the conjugate's lytic ability; however, no significant effect of orientation was observed. Nicol et al. (25) suggested two alternative interpretations of the preferred orientation of GALA in membranes: (1) all pores consist of 75% N-terminally inserted GALA and 25% C-terminally inserted GALA or (2) 75% of pores consist exclusively of N-terminally inserted GALA and 25% of pores consist exclusively of C-terminally inserted GALA. Based on our data, when GALA is forced into a single conformation, it can still cause leakage of liposomal

contents. Although this does not directly elucidate the behavior of unconjugated GALA, it suggests that unconjugated GALA could indeed form pores of exclusively one orientation.

Of the design parameters investigated, the most significant modifier of lytic ability is the number of GALA per OKT9. To our knowledge, no other study has specifically addressed this issue. If this proves to be generally true, then chemical conjugation would be preferable to genetic fusion as the mode of attachment for membrane-active peptides to proteins. Chemical conjugation provides a means to produce a protein studded with several copies of the active peptide; such a molecule cannot be produced easily by genetic means.

There are at least two plausible mechanisms by which increased derivatization might lead to improved lytic activity. If placement of multiple copies of GALA on a single macromolecule facilitates peptide self-association by rendering the reaction effectively intramolecular, one would expect K_s to increase with the extent of derivatization. As shown in Table 1, however, K_s is insensitive to the number of GALA per OKT9. Thus, increased activity cannot be attributed to intramolecular interactions of multiple GALA on a single mAb. Alternatively, conjugate association with liposomes could increase with the number of GALA per OKT9, perhaps due to an increase in the hydrophobicity of the conjugate. Under this mechanism, one would expect to see K_p increase with GALA content; in fact, this is exactly what is observed.

Mechanism of Interaction of GALA-OKT9 Conjugates with Liposomes. It is fairly well established that GALA inserts into membranes and forms oligomeric pores of defined size by an all-or-none mechanism (20), but it was not clear a priori that GALA-OKT9 conjugates would do the same. Kinetics of calcein leakage, liposome stability, and size selectivity of released molecules were investigated to determine how GALA-OKT9 conjugates interact with liposomes compared to unconjugated GALA. When compared at similar equilibrium extents of leakage, kinetics of calcein leakage for GALA and GALA-OKT9 conjugates were similar. Incubation of conjugates with liposomes did not change liposomal size, demonstrating that the conjugates did not cause liposomal fusion, micelle formation, or other catastrophic changes in liposome structure. Rather, leakage of liposomal contents must occur via formation of stable or transient structures in the lipid bilayer. GALA and GALA-OKT9 conjugates demonstrate similar size-selective release of encapsulated molecules, allowing passage of molecules up to 3000 MW, while generally excluding passage of 10 000 MW molecules. This strongly suggests that GALA and GALA-OKT9 conjugates form pores of similar diameter [~ 1 nm, (20)]. This is a very intriguing finding since GALA is attached to an antibody with a hydrodynamic diameter of ~ 11 nm; one might expect that GALA self-association must be disturbed in order to accommodate multiple bulky antibodies. This result suggests that GALA-GALA association in pores is under rather rigid geometric constraints. Some leakage of 10 000 MW dextran occurs with both GALA and GALA-OKT9 conjugates at high concentrations. This is indicative of a distribution of pore sizes, wherein the average size increases with increasing number of monomers per liposome, as proposed by Nicol et al. (27). Thus, the geometric constraints, although strong, are not absolute. Although it is established that GALA causes leakage via an all-or-none mechanism (20), we have no direct evidence of a similar mechanism with OKT9-GALA. Given that OKT9-GALA mimics unconjugated GALA with

respect to kinetics of leakage, liposome stability, and size selectivity, it is likely that OKT9-GALA causes leakage via an all-or-none mechanism as well.

Although unconjugated GALA and GALA-OKT9 conjugates appear to form similar structures in liposomes with identical size selectivity, there is still a substantial loss of activity upon conjugation. By fitting the data to a simple leakage model, we surmised that this loss is due to both decreased partitioning and decreased surface aggregation. The decreased partitioning of GALA-OKT9 conjugates is a true decrease in conjugate association with liposomes, because the value for K_p extracted from fitting the leakage data was consistent with that obtained by independent partitioning experiments. This indicates that the decrease in K_p established from the leakage data is due to a true decrease in partitioning of GALA-OKT9 conjugates into the membrane and not due to unproductive association of OKT9-GALA conjugates with lipid (i.e., association that does not lead to pore formation). In the conjugates, K_p increased substantially with the number of GALA per OKT9 but was not improved by the use of a long, flexible spacer arm. This leads us to speculate that reduced partitioning of conjugates is caused not by steric constraints but by reduced hydrophobicity of GALA-OKT9 conjugates relative to unconjugated GALA. Surface aggregation is reduced across-the-board for conjugates relative to GALA. The bulkiness of the OKT9 moiety might hinder GALA self-association; alternatively, self-association might occur just as readily, but be unproductive because the bulky antibody blocks some pores. Improved GALA-OKT9 conjugates could be generated by increasing partitioning and/or surface aggregation. Conjugates with a greater number of GALA, or a smaller targeting protein (e.g., Fab fragment), might have greater hydrophobicity and therefore increased partitioning. Attachment of a preformed GALA multimer to a single site on OKT9 might effectively increase surface aggregation.

To summarize, we have successfully synthesized membrane-active conjugates and shown that multiple GALA per OKT9 are required for membrane activity. These conjugates apparently form pores of defined size and relatively small diameter. Thus, it seems unlikely that, after internalization by a targeted cell, GALA-OKT9 conjugates would facilitate rampant transport of globular proteins across endosomal/lysosomal membranes via pores. However, this does not necessarily imply that GALA-OKT9 conjugates cannot facilitate translocation of proteins across these membranes. For example, GALA, as one component of a transfection mixture, successfully increased the transport of DNA to the cytosol (28, 29). The mechanism by which this transport occurred is unknown, but is hypothesized as destabilization of intracellular membranes. This hypothesis seems reasonable, especially since anti-endosomal acidification agents significantly reduced transport (28). Therefore, it seems likely that our membrane-active GALA-OKT9 conjugates could also destabilize endosomal/lysosomal membranes, facilitating translocation of co-internalized toxins to the cytosol. Experiments to test this hypothesis are underway.

Revised Manuscript Received April 12, 2001

Antibody fragments can be expressed at a high level in microbial systems, but they may have limited therapeutic value because they are rapidly eliminated from the body. We demonstrate here that site-specific conjugation or binding of bacterially derived Fab' to the long-lived protein serum albumin allows full retention of the antibody's binding characteristics while imparting the albumin's longevity in vivo. In rats the area under the curve for Fab' conjugated to rat serum albumin was 17-fold greater than for the control of Fab' conjugated to cysteine. Again, a bispecific F(ab')₂ with specificity for rat serum albumin showed an area under the curve about 8-fold greater than did a F(ab')₂ without specificity to albumin. Genetic fusions of scFv to albumin were similarly long-lived and could be expressed in yeast to provide the basis of a cost-effective production system.

INTRODUCTION

Antibodies are useful therapeutic agents because of their great specificity in binding to other molecules. Large volumes of low cost antibody are required to satisfy the large markets of common or chronic diseases. The ability of cultured cells or transgenic organisms to supply a large market with immunoglobulin at low cost is unproven so far. Expression of whole immunoglobulin G (IgG1)¹ has been reported in fungi (1, 2), but not at high level or on an industrial scale. Furthermore, the nonmammalian glycosylation pattern of IgG produced in fungi would be expected to show problems of immunogenicity and compromised function when injected into man.

Bacterial systems are a source of low-cost immunoglobulin fragments, such as Fab', F(ab')₂, or single chain Fv (scFv) (3). These molecules lack the Fc domain and its functions, for example, the interaction with FcRn that gives a long lifetime in vivo (4): the half-life in circulation in mammals of Fab' or F(ab')₂ is about 1% that of whole IgG (5), and the β -phase half-life (the time taken for half of the molecules in circulation to be eliminated) of Fab' is about 5% that of whole IgG (6). This rapid elimination of immunoglobulin fragments from the body can be disadvantageous where prolonged presence of the molecule is required, for instance, in order to provide prolonged therapeutic cover for inhibition of inflammatory cytokines. Extension of the half-life of antibody fragments such as Fab' or F(ab')₂ has been achieved by in vitro conjugation to one or more molecules of poly(ethylene glycol) (6, 7). In the present work, we have investigated an alternative approach to improving in vivo half-life that employs a natural polymer, namely serum

albumin. Albumin is abundant in both vascular and extravascular compartments and has a half-life of about 19 days (8) in man (similar to that of IgG1 at about 21 days (5)), though it is less in other species (about 2 days in rats, for example (8)). Albumin does not possess the noted ability of antibodies to specifically bind ligands, particularly those of high molecular weight.

We have investigated the potential of association of immunoglobulin fragments with albumin in three different ways: chemical cross-linking of the separate, low-cost components, albumin, and Fab'; genetic fusion, which would allow a one-step synthesis of the combination; noncovalent binding of an antibody species to endogenous albumin, an approach that could lead to a relatively small, low-cost protein therapeutic. The concept was validated since all three approaches were successful: each albumin-associated immunoglobulin fragment retained its antigen-binding capability while showing extended in vivo half-life.

EXPERIMENTAL SECTION

Preparation of Proteins. Rat serum albumin (RSA) was obtained from Sigma, St. Louis, MO (code A6272). Anti-RSA IgG F(ab')₂ was generated by pepsin (Sigma, St. Louis, MO) digestion (9) of IgG that was prepared from rabbit antiserum (ICN Biomedicals, Costa Mesa, CA) by affinity chromatography on (i) Gammabind plus Sepharose (following the instructions of the manufacturer, Amersham Pharmacia Biotech, Little Chalfont, UK, with elution of adsorbed protein by a buffer of acetic acid, 0.5 M, made to pH 3 by addition of sodium hydroxide), and then (ii) RSA-Sepharose (prepared by linking RSA to CNBr-activated's instructions). For RSA-Sepharose affinity chromatography, the sample (at pH 7) was loaded onto the column, which was preequilibrated in phosphate-buffered saline, and the RSA-binding component eluted in acetate buffer (0.5 M acetic acid, brought to pH 3 by addition of sodium hydroxide). Fractions eluted from each column were immediately neutralized by addition of trizma (2 M, pH 8). Control F(ab')₂ was

¹ Abbreviations: AUC, area under the curve; BMH, 1,6-bismaleimidohehexane; FcRn, neonatal Fc receptor; HSA, human serum albumin; IgG, immunoglobulin G; RSA, rat serum albumin; SDS PAGE, sodium dodecyl sulfate polyacrylamide electrophoresis; scFv, single chain Fv; TNF, tumour necrosis factor.

made by the same method, from rabbit anti-keyhole limpet haemocyanin antiserum. Recombinant anti-human Tumor Necrosis Factor α (TNF) and anti-cell surface marker $F(ab')_2$ and Fab' molecules were produced in *E. coli*, as described previously (6). Thiols were assayed as described previously (6).

Preparation of Conjugates. *Bispecific $F(ab')_2$.* Freshly reduced anti-RSA Fab' was incubated for 2 h at 21 °C in PE buffer (sodium phosphate, 0.1 M, pH 6, 2 mM ethylenediaminetetraacetate) with an 80-fold molar excess of 1,6-bismaleimidohexane (BMH, Perbio Science UK Ltd, Tattenhall). Excess BMH was removed by Sephadex G25M size exclusion chromatography ("PD10", Amersham Pharmacia Biotech, Little Chalfont, UK) in PE buffer, as per manufacturer's instructions. The derivatized anti-RSA Fab' was then incubated for 20 h at 21 °C with freshly reduced anti-TNF Fab' at a molar ratio of anti-RSA Fab':anti-TNF Fab':1:3.1. Purification of the bispecific anti-RSA–anti-TNF $F(ab')_2$ heterodimer was purified by affinity chromatography on RSA immobilized on Sephadex (as described above), followed by size exclusion chromatography in a buffer of 0.2 M sodium phosphate, pH 7, on Zorbax GF250 (Agilent Technologies, Palo Alto, CA), using an HP1090 HPLC (formerly Hewlett-Packard, currently Agilent Technologies, Palo Alto, CA), to remove anti-RSA Fab'. Overall yield (nonoptimized) was about 9%. Control monospecific anti-TNF $F(ab')_2$ homodimer was made in an analogous way and purified by gel filtration on Zorbax GF250 in a buffer of 0.2 M sodium phosphate, pH 7.

RSA-Fab'. RSA was reduced either by (a) incubation for 50 min at 37 °C in 5 mM 2-mercaptoethylamine (Sigma, St Louis, MO) in PE buffer, or (b) incubation for 40 min at 37 °C in a 3-fold molar excess of dithiothreitol (Sigma, St Louis, MO) in sodium acetate, 0.1 M, pH 5.9. Reduced RSA was reacted in PE buffer with a 21-fold excess of BMH in PE buffer for 100 min, 21 °C. Approximately 80% of reduced RSA reacted with BMH under these (nonoptimized) conditions. Derivatized RSA was reacted for 2 h at 21 °C with freshly reduced Fab' in the molar ratio, derivatized RSA:reduced Fab':1:1.4. The reaction mixture was first subjected to chromatography on Gammabind plus Sepharose (described above), pre-equilibrated in PE buffer. Adsorbed protein was eluted by acetic acid, 0.5 M, made to pH 3 by addition of sodium hydroxide. Eluted fractions were immediately neutralized by addition of 2 M trizma, pH 8. As expected of this protein G matrix, nonconjugated Fab' bound and was eluted by the pH 3 buffer, whereas the nonconjugated RSA did not bind at all and emerged in the flow-through. Conjugation of a single Fab' to one RSA molecule clearly affected its binding to the protein G on the matrix, for the conjugate emerged in the flow-through, just slightly later than (and overlapping with) the unconjugated RSA. More free RSA was removed from the conjugate by both: (i) a further cycle of chromatography on Gammabind plus (as above); (ii) gel permeation chromatography on a Zorbax GF250 HPLC column of size (described above). Overall yield (nonoptimized) was about 5%.

Control anti-TNF Fab'-cys conjugate was prepared by a similar approach: (i) derivatization of Fab' by BMH; (ii) incubation with a 22-fold molar excess of cysteine (Sigma, St Louis, MO). Purification was by chromatography on a 1 mL volume Mono S column using an FPLC apparatus (Amersham Pharmacia Biotech). Adsorbed protein were then eluted in a gradient of 0 to 250 mM sodium chloride in sodium acetate, 50 mM, pH 4.5. Overall yield (nonoptimized) was about 28%.

Figure 1. Structure of trimaleimide cross-linking agent.

Bivalent Conjugate RSA- $F(ab')_2$. This conjugate was made by use of the trimaleimide cross-linking agent N_α -[1,4,7-tris(carboxymethyl)-1,4,7-triaza-2-cyclononyl]butyl-aminosuccinoyl- N_ω -(maleimidopropanoyl)lysyl- N_ω -(maleimidopropanoyl)lysyl- N_ω -(maleimidopropanoyl)lysyl- N_ω -(maleimidopropanoyl)lysyl-L-lysine, illustrated in Figure 1. It was synthesized according to the method described previously (10), starting from 2-(4-aminobutyl)-1,4,7-triazacyclononane-1,4,7-triyltriacetic acid (11) and N6-[3-(2,5-dihydro-2,5-dioxo-1H-pyrrol-1-yl)-1-oxopropyl]-L-lysyl-N6-[3-(2,5-dihydro-2,5-dioxo-1H-pyrrol-1-yl)-1-oxopropyl]-L-lysyl-N6-[3-(2,5-dihydro-2,5-dioxo-1H-pyrrol-1-yl)-1-oxopropyl]-L-lysine (trifluoroacetate). Anti-cell surface marker Fab' PE buffer was reacted with this trimaleimide cross-linking agent for 3 h at 21 °C at a molar ratio cross-linker:Fab':1:2.56. Monomer, dimer, and trimer Fab'conjugates were resolved by chromatography on SP-Sepharose HP (Amersham Pharmacia Biotech, Little Chalfont, UK), being eluted by a gradient of 0 to 250 mM sodium chloride in 50 mM acetate, pH 4.5. The dimer (approximately 30% of the total material) was then reacted with freshly reduced RSA at molar ratio of 1:1, for 24 h at 21 °C. The RSA- $F(ab')_2$ was finally prepared by affinity chromatography on Gammabind plus Sepharose to remove free albumin, then on Blue Sepharose, to remove unconjugated $F(ab')_2$. The yield of this (nonoptimized) procedure was about 12%.

A control molecule of anti-cell surface marker $F(ab')_2$ (containing no RSA) was prepared by conjugating two freshly reduced Fab' molecules with BMH, in a manner analogous to conjugation of anti-TNF Fab' (see above).

Preparation of scFv-HSA Fusion Proteins. Oligonucleotides were designed that coded for fusions of scFv with the N-terminus of mature Human Serum Albumin (HSA), either directly (scFv-HSA) or via linkers positioned to physically separate the scFv from the albumin moiety. The linkers were a sequence of 3 repeats of (glycine)₄-serine (scFv-G4S-HSA); a sequence derived from the flexible upper (N-terminal) end of the human IgG1 hinge region, (scFv-UHL-HSA); or the C-domain from human Ig-kappa light chain (scFv-C_K-HSA). The orientation of variable domains in the scFv was V_L-V_H, except for scFv-C_K-HSA, in which the order was V_H-V_L. The scFv sequence was immediately preceded by a spacer of (glutamic acid-alanine)₂ as recommended by Sreerishna et al. (12) to alleviate possible problems of steric hindrance of pro-sequence-processing protease. An "EasySelect Pichia Expression" kit (Invitrogen, Carlsbad), with the plasmid pPIC, was used as per manufacturer's

instructions to express each type of fusion protein in shake flask culture. Each fusion protein was secreted into 30–40 mL of medium. Supernatant from each culture was adjusted to pH 7 by addition of 2 M sodium hydroxide, and applied to Blue Sepharose (Amersham Pharmacia Biotech, Little Chalfont, UK). Each construct bound and was eluted by sodium thiocyanate, 0.2 M in phosphate-buffered saline. Each protein was concentrated and the buffer exchanged to phosphate-buffered saline by use of an Amicon stirred cell concentrator (Millipore, Bedford, MA).

Analytical Procedures. Sodium dodecyl sulfate polyacrylamide electrophoresis (SDS PAGE) utilized precast SDS gels (Novex, San Diego, CA), run as per manufacturer's instructions. Protein bands were quantified after staining by Coomassie BBG (13). Protein sequencing was performed on an Applied Biosystems (Warrington, UK) model 470A or Procise 492 protein sequencer. A combination of approximations of molecular weight (by SDS PAGE) and quantity (by N-terminal sequencing) allowed determination of the stoichiometry of components in conjugates.

Surface plasmon resonance study of interactions with ligand was performed a BIACORE 2000 (Biacore AB, Stevenage, UK) on a CM5 Sensor Chip, with kinetic parameters calculated by use of BIAevaluation 3.0 software.

scFv-HSA fusion protein was bound to the chip surface by amine coupling chemistry to approximately 400 Response Units. The ligand, recombinant human TNF α , was passed across the immobilized molecule at concentrations between 0 nM to 120 nM. RSA-Fab' conjugate was captured by goat anti-human IgG F(ab')₂ fragment specific antibody (Jackson ImmunoResearch Labs Inc, West Grove) that was immobilized on the chip surface, prior to application of ligand. For the bispecific conjugate, anti-RSA-anti-TNF, affinity for TNF was assayed by capture of the conjugate by AffiniPure F(ab')₂ fragment, goat anti-rabbit IgG, F(ab')₂ fragment specific (Jackson ImmunoResearch Labs Inc, West Grove) that was immobilized on the chip surface, prior to application of the TNF α ligand. To assay the affinity of the bispecific conjugate for RSA, the ligand RSA was immobilized on the chip surface, and conjugate solution was passed over that.

RSA-F(ab')₂ and F(ab')₂ control were fluoresceinated prior to Scatchard analysis of binding, in which they were incubated with cells for 3 h at 4 °C for 3 h, before analysis by fluorescence activated cell sorting, using a FACScan flow cytometer (Becton Dickinson, Franklin Lakes).

Pharmacokinetic Analysis of the Conjugate. Proteins were labeled at the ϵ -amino groups of lysyl residues, using ¹²⁵I-labeled Bolton and Hunter reagent (Amersham International, Little Chalfont, UK) as follows. A 300 μ g amount of protein dissolved in 300–370 μ L of 0.1 M borate, pH 8, was mixed with 20 μ L of Bolton and Hunter solution in propan-2-ol (containing 9 MBq of ¹²⁵I) and incubated at 21 °C for 15 min. The reaction was then quenched by addition of 60 μ L solution of glycine, 1 M, in borate, 0.1 M, pH 8. After approximately 5 min reaction at 21 °C, the labeled protein was separated from other reagents by chromatography on Sephadex G25M using a PD10 column (Amersham Pharmacia, used as per manufacturer's instructions). In doing so, the buffer was exchanged for phosphate buffered saline. The specific activity of each preparation was calculated from estimates of protein concentration (estimated by absorption at 280 nm) and of radioactivity and was typically in the

range 0.45 to 0.54 μ Ci/ μ g. The radiolabeled samples were used directly after labeling.

A 20 μ g amount of ¹²⁵I-labeled or 180 μ g of unlabeled protein in solution in phosphate-buffered saline was injected into a tail vein of male Wistar rats (approximately 250 g each). Blood samples were taken periodically from the tail artery, with plasma prepared by heparinization and centrifugation. Radioactivity was detected in whole blood by gamma counting (using a Cobra II auto gamma, from Canberra Packard, Ontario). The percent injected dose (%ID) was calculated for each individual rat, based on standards and expressed as %ID/mL total blood volume. Data were analyzed by WinNonlin software (Pharsight Corp., Mountain View, CA). For this, a two-compartment model was used, except for Fab'-cys monitored by ELISA, where too few data were acquired due to rapid elimination and where a one-compartment model was used instead.

Phosphorimaging and quantification of radiolabeled samples on SDS PAGE utilized a Cyclone system with Optiquant software (Canberra Packard, Ontario). This enabled examination of the quality of radiolabeled protein in plasma throughout the experiments.

ELISA's used microtiter plates coated with the antigen recombinant human TNF α (Strathmann Biotech GMBH, Hannover). Detection was by rabbit anti-RSA (Cappel, obtained from ICN, Costa Mesa, CA) followed by goat anti-rabbit immunoglobulin Fc-peroxidase conjugate (Jackson ImmunoResearch Labs Inc, West Grove), or by goat anti-human kappa light chain (Southern Biotechnology Associates, Inc., Birmingham, AL) followed by donkey anti-goat immunoglobulin (H+L)-peroxidase conjugate (Jackson ImmunoResearch Labs Inc, West Grove). Quantification was by absorption at 630 nm, generated from 3,2',5',5'-tetramethylbenzidine (R and D Systems Europe, Abingdon, UK; 120 μ M in 10 mM acetate, pH 6) as a result of the activity of peroxidase.

Anti-TNF activity was assayed by the inhibition of killing of monolayered mouse L929 cells by recombinant human TNF α (Strathmann Biotech GMBH, Hannover, NH) in normal RPMI 1640 plus glutamine and 10% (v/v) foetal calf serum (both from Life Technologies, Paisley, UK). Cell survival was quantified as follows: the brown color produced by surviving cells from 50 μ g/mL 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (Sigma, St Louis, MO) in the culture medium at 37 °C for 4 h was extracted (by a solution of SDS, 20%, w/v, in 50% v/v in water, adjusted to pH 4.7 by addition of 50% acetic acid in 1 M hydrochloric acid) and quantified by absorbance at 570 nm; absorption at 630 nm was subtracted, and compared to standards from known amounts of TNF added to samples of cells, in the absence of TNF-neutralizing activity.

RESULTS

Characterization of Conjugates. The cysteinyl residue at position 34 of albumin is commonly engaged in formation of a mixed disulfide with molecules such as glutathione or free cysteine, but suitable reduction conditions can liberate that thiol without disrupting disulfides present elsewhere in the molecule (8). Reduction of albumin in such conditions increased the amount of free thiol from 0.15 in the original albumin preparation to between 0.95 and 0.97 mol of thiol per mol of albumin. Albumin dimers were not formed during derivatization by BMH, because the free cysteinyl 34 with which the BMH is presumed to react lies within a cleft in the albumin structure, and the 16.1 angstrom spacer arm of

Figure 2. Reduced SDS PAGE of conjugates and fusion proteins. Stain: Coomassie Brilliant Blue G in perchloric acid. Approximate apparent molecular weights (indicated) were determined by co-electrophoresis of standard proteins. Samples: a = RSA-anti-TNF Fab' conjugate; b = RSA-anti-TNF F(ab')₂ conjugate; c = bispecific anti-TNF-anti-RSA F(ab')₂; d = scFv-HSA fusion protein; e = scFv-G4S-HSA fusion protein; f = scFv-UHL-HSA fusion protein; g = scFv-C_K-HSA fusion protein.

the bifunctional BMH was too short to reach from within the cleft of one albumin molecule and penetrate the depth of the equivalent cleft in a second albumin molecule.

Again, the reducing conditions used here produced Fab' that contained only one free cysteinyl residue, near the C-terminus of the Fd chain (12). It was therefore possible to cross-link specific thiols in albumin and Fab' molecules, to make conjugates with defined stoichiometry. Methods for production of the various conjugates were not optimized, but provided sufficient material for subsequent experiments.

SDS PAGE (Figure 2) and N-terminal sequencing of preparations and of protein bands on blots from SDS PAGE confirmed that 1:1 molar ratios were achieved in conjugates of anti-TNF Fab' with RSA, and anti-TNF Fab' with anti-RSA Fab'. Similarly, one anti-TNF F(ab')₂ was covalently attached to one RSA molecule. Fab' molecules were conjugated through their Fd chain, as seen by generation of free light chain by reducing conditions in SDS PAGE, seen as a band of about 30 kDa apparent molecular weight. The H chain dimer from the bispecific F(ab')₂ appeared as a band of 40 to 50 kDa apparent molecular weight or as a species of very approximately 150 kDa apparent molecular weight when linked to RSA. The H chain-RSA from the Fab-RSA conjugate migrated as an approximately 100 kDa band but was accompanied by lesser a quantity of H chain-RSA dimer material (as can sometimes be seen upon electrophoresis of preparations of albumin alone – not shown), and some (putative) free albumin at an apparent molecular weight of about 65–70 kDa.

Four types of scFv-HSA fusion proteins were secreted into the medium of *Pichia pastoris* cultures. A single step of Blue Sepharose chromatography of culture supernatant provided fusion proteins of between 75% and 91% purity (see Figure 2), with mature HSA as the other component (presumably arising from proteolysis of linker). Yields of prepared proteins as $\mu\text{g/mL}$ of culture supernatant (mean of two experiments) were: scFv-HSA, 9.0 $\mu\text{g/mL}$; scFv-G4S-HSA, 8.5 $\mu\text{g/mL}$; scFv-UHL-HSA, 7.5 $\mu\text{g/mL}$; scFv-C_K linker, 7.8 $\mu\text{g/mL}$. Neither the nature of the linker nor the order of the variable domains in the scFv portion significantly affected levels of expression of

^a Data were analyzed using WinNonlin and a two-compartment model, except for Fab'-cys when a one-compartment model was used. AUC (0– ∞): area under the plasma concentration curve, or plasma residence time. ¹²⁵I: proteins monitored by gamma counting. ELISA1: TNF-binding material detected by anti-L chain. ELISA2: TNF-binding material detected by anti-albumin. L929: quantified by neutralization of TNF activity. For ¹²⁵I assay, $n = 5$ –7, others $n = 2$. Data shown for RSA and F(ab')₂ are means of four and two experiments, respectively.

fusion protein. N-Terminal protein sequencing revealed that the (Glu-Ala)₂ sequence lying N-terminal to the scFv domain was not removed by aminopeptidase activity (cf. ref 12).

Anti-TNF Fab' retained ligand binding activity in all conjugates and fusions (Table 1, and ELISA and L929 assay data, below). Similarly, affinity for cell surface ligand was retained by both the RSA-F(ab')₂ and the corresponding control F(ab')₂ conjugate. Scatchard analysis showed the presence of both low and high affinity binding sites (Table 1) with 40 000 and 20 000 RSA-F(ab')₂ binding sites per cell, respectively, and 125 000 and 50 000 F(ab')₂ binding sites per cell, respectively. Thus, association of Fab' with albumin did not decrease ligand binding affinity, though the 67 kDa albumin moiety hindered access to some binding sites present on a cell surface.

Pharmacokinetic Analysis of the Conjugate in Rat Plasma. As judged by phosphorimaging, all ¹²⁵I-labeled conjugates were stable in vivo (that is, the quality of the labeled protein remained constant throughout the experiment), with one exception. The exception was the ¹²⁵I-RSA-Fab' conjugate, in which some instability was

Figure 3. Pharmacokinetics of ^{125}I -labeled RSA, conjugates, and other immunoglobulins in rats. ^{125}I detected in plasma samples by gamma-counting. (■) RSA; (◆) RSA-Fab'; (●) Fab'-cys; (▲) F(ab')₂. For each, $n = 6$. Error bars: sem.

noted in vivo, whereby a species was generated with an apparent molecular weight similar to that of RSA on SDS PAGE. Experiments (not shown) indicated that this instability was artificial, coinciding with the presence of the covalently attached ^{125}I or to some other aspect of the labeling process. Nevertheless, phosphorimage analysis showed that even after 144 h in vivo the intact conjugate still represented about 30% of all labeled protein present. Data from phosphorimage analysis of rat plasma samples were used to correct gamma counting data from in vivo experiments with ^{125}I -labeled RSA-Fab', to reflect the quantity of ^{125}I in intact, labeled conjugate only. In rat plasma the intact ^{125}I -RSA-Fab' conjugate had a residence time, or an area under the curve (AUC), that was 17-fold greater than the Fab'-cys control in the same experiment in vivo (Figure 3 and Table 2). The longevity of the RSA-Fab' conjugate in vivo was confirmed by experiments using conjugate that was not labeled, by ELISA format or by L929 survival assay (Figure 4, Table

2). By these methods, the RSA-Fab' AUC was approximately 200-fold greater than that of the Fab'-cys, which was very rapidly eliminated.

Similarly, binding to endogenous albumin by ^{125}I -bispecific F(ab')₂ caused a 6-fold increase in AUC over that of the control in the same experiment, unispecific anti-TNF F(ab')₂, which did not bind albumin (Figure 5, Table 2). The residence time for the bispecific F(ab')₂ was approximately 70% that of RSA in the same experiment, though their $t_{1/2\beta}$ values were similar. The loss of bispecific F(ab')₂ in the first few minutes of the experiment was probably not due to failure to bind to endogenous albumin, for experiments (not shown) with anti-RSA Fab' showed that in vitro incubation with plasma prior to injection did not alter the residence time in vivo.

The residence times of three ^{125}I -labeled fusion proteins tested (scFv-HSA, scFv-G4S-HSA, and scFv-UHL-HSA) were similar to those of HSA and approximately 12-fold greater than those of ^{125}I -Fab'-cys control in the same

Figure 5. Pharmacokinetics of ^{125}I -labeled RSA, bispecific and unspecific $\text{F}(\text{ab}')_2$ in rats. ^{125}I detected in plasma samples by gamma counting. (■) RSA; (▲) anti-RSA-anti-TNF bispecific $\text{F}(\text{ab}')_2$; (▼) anti-TNF unspecific $\text{F}(\text{ab}')_2$. For each, $n = 5\text{--}7$. Error bars = sem.

Figure 6. Pharmacokinetics of ^{125}I -labeled HSA and fusion proteins in rats. ^{125}I detected in plasma samples by gamma counting. (◆) HSA; (●) scFv-HSA; (■) scFv-G4S-HSA; (▲) scFv-UHL-HSA. experiment (Figure 6, Table 2). In rats the residence time of scFv-HSA fusions was shorter than of RSA-Fab' conjugate, but this was taken to be because the albumin moiety dictates the longevity, and the heterologous HSA was only about half as persistent as the homologous RSA.

DISCUSSION

Data presented here show that association of immunoglobulin fragments with serum albumin, whether by conjugation, fusion or noncovalent binding, results in extended persistence in plasma *in vivo*, approaching that of albumin itself. The albumin moiety determined longevity, and in man the $t_{1/2\beta}$ of serum albumin is about 19 days in man (8) (compared to 2 to 2.5 days in rat (8)). Accordingly, in man an immunoglobulin–albumin molecule might persist for about the same time as would whole IgG1 ($t_{1/2\beta}$ = about 21 days in man (5)). Extended residence time of an agent *in vivo* can be beneficial in providing extended therapeutic cover. This goal of extending the half-life of Fab' has previously been achieved by attachment of poly(ethylene glycol), which gave 7- to 21-fold increase in AUC, depending on the amount of the

polymer that was attached (7). We show here that albumin provides an alternative to poly(ethylene glycol) as a conjugation partner. Any effect due to the albumin moiety, administered as part of a therapeutic agent, would be expected to be negligible: the role of albumin is in transportation of various molecules (such as steroid hormones, bile pigments and fatty acids) in circulation and in extravascular fluids and is normally present in plasma at about 50 mg/mL, in great excess over any administered therapeutic. In the present work defined conjugates were made *in vitro* by cross-linking through a specific site in each component, particularly a site in the Fab' molecule near its C-terminus, such that the Fab' ligand-binding properties are not adversely affected (6). Both Fab'(s) and albumin components can be produced at low cost by microbial systems and therefore provide the basis of an economic therapeutic molecule.

Additionally, we have illustrated an alternative possibility, namely that of genetically engineering novel albumin–immunoglobulin fusion proteins and expressing them in yeast cells. This approach has the extra advantage, compared to conjugation of immunoglobulin to albumin or PEG, that no *in vitro* conjugation step is required in the production process, which is therefore simpler. Expression of these fusion molecules in yeast was not fully optimized here, but it has considerable potential if it can approach the level of albumin production in yeast, which can be at a level of grams per liter (15, 16, 17). This level of expression makes industrial production of pharmaceutical grade protein economically feasible (16). The potential problems of antigenicity that surround yeast oligosaccharides when injected into mammals are avoided by excluding glycosylation sites from the fusion protein sequence—glycosylation is not required for prolonged serum half-life in this case, unlike for whole IgG (18).

Bispecific immunoglobulin that can bind to endogenous serum albumin provides a third strategy. Once injected, anti-albumin Fab' binds rapidly to endogenous albumin, whose concentration in plasma is about 0.6 mM. From the observed association and dissociation rates for anti-RSA (Table 1) it may be calculated that at equilibrium in serum only 4.4×10^{-3} % of bispecific $\text{F}(\text{ab}')_2$ would remain unbound to albumin. We have exemplified the bispecific molecule approach with a molecule made by chemical conjugation of components produced economically in microbial systems, but other forms of bispecific antibodies such as those reviewed by Cao and Suresh (19) would be expected to function in the same way.

Possibilities exist for further elaboration of the principles described here. These include use of alternative proteins to albumin, generation of both polyvalent and polyspecific immunoglobulins (by either chemical cross-linking or genetic fusion, or a combination of both), and engineering of additional function into the protein or the cross-linking agents. For instance, the trimaleimide cross-linker used here includes a macrocycle moiety capable of chelating any of a range of metal ions such as might be used for therapeutic or diagnostic purposes. The macrocycle illustrated (Figure 1) is able to chelate Indium.

In summary, we have shown that association of fragments or derivatives of immunoglobulin with albumin provides the basis of a system for production of a potentially low cost but long-lived therapeutic immunoglobulin.

Synthesis and Binding Properties of Oligo-2'-deoxyribonucleotides Covalently Linked to a Thiazole Orange Derivative

Eric Privat and Ulysse Asseline*

Centre de Biophysique Moléculaire, UPR 4301 CNRS. Affiliated with the University of Orléans and with INSERM, Rue Charles Sadron, 45071 Orléans Cedex 02, France. Received January 22, 2001; Revised Manuscript Received July 5, 2001

Thiazole orange label was coupled to the eighth phosphate of a pentadeca-2'-deoxyriboadenylate via a phosphoramidate linkage using different linkers. The stereoisomers were separated, and their absolute configurations were determined. Finally, the thiazole orange moiety was also linked to the tenth phosphate of icosathymidylates in both the α and the β series via a phosphoramidate linkage. Once again, the thiazole orange–icosathymidylate conjugates were obtained as pure stereoisomers. The binding properties of these oligo-2'-deoxyribonucleotide–thiazole orange conjugates with their complementary sequences were studied by absorption spectroscopy. The covalent attachment of the thiazole orange derivatives to the oligoadenylates stabilizes the complexes formed with both the DNA and RNA targets. On the contrary, when the thiazole orange is tethered to the oligo- α -thymidylate or oligo- β -thymidylate, no significant stabilization of the duplexes formed with poly r(A) can be observed.

INTRODUCTION

The rapidly increasing rate of sequencing has opened the way to greater progress in various research areas such as gene organization and function including research on the underlying genetic causes of inherited and acquired diseases with possible applications for their prevention and treatment, the detection of pathogens for clinical diagnoses, and finally food technology, agricultural, environmental, and forensic sciences. Base-pairing properties of nucleic acids are used, in most methods which involve the hybridization of a single-stranded oligonucleotide labeled probe, to detect a complementary target sequence in a complex nucleic acid mixture. The most commonly used hybridization assays employ a solid phase in order to facilitate the separation of bound from unbound analytes (1, 2). In contrast, assays that process in a homogeneous solution avoid problems such as nonspecific adsorption associated with the heterogeneous assays, but the separation of hybridized and free probes is required. The separation step can be eliminated by a probe whose signal changes upon hybridization (3, 4). Such probes could be used inside cells to detect their complementary sequences *in situ* directly on their RNA targets. The development of fluorescent or luminescent labeled oligonucleotides that display a modified signal upon hybridization with their target sequences has been the subject of intense research. Among the reported systems, molecular beacons are based on the quenching/dequenching of fluorescence. This system involves stem-loop-forming oligo-2'-deoxyribonucleotides bearing a fluorescent dye at one end and a quencher at the other end (5). Upon hybridization to the target sequence, the stem is dissociated and the distance between the fluorescent dye and the quencher is largely increased, generating an increase in fluorescence. Other methods utilize a change in the fluorescent emission wavelength, rather than in

the intensity alone. Among these are the fluorescence resonance energy transfer (FRET) between a donor and an acceptor dye (6, 7), and the luminescence resonance energy transfer (LRET) (8) between a sensitized lanthanide metal and an acceptor dye. Another example of the color-changing strategy involving a two-chromophore system is the utilization of excimer-forming chromophores such as pyrene (9, 10). The last strategy is based on modification of the signal generated by a single fluorescent or luminescent DNA binding agent linked to oligonucleotides upon hybridization with their target sequences. A minor groove binder, Hoechst 33258 (11, 12), and intercalating agents such as ruthenium complex (13) and oxazole orange (14, 15) have been covalently tethered to oligonucleotides, and fluorescent or luminescent, in the case of the ruthenium complex, signal increases were observed upon hybridization of these labeled probes. Following our previous work (16) and one report (17) concerning the fluorescent properties of thiazole orange-linker derivatives in interaction with single-stranded and double-stranded targets, we now describe the synthesis and binding properties of oligo-2'-deoxyribonucleotides covalently linked to thiazole orange. [During the course of this work, results on the fluorescent properties of thiazole orange–peptide nucleic acid conjugates were published (18–20).] Since the homodimeric thiazole orange (TOTO) was reported to intercalate in double-stranded DNA (21) and our previous work on oligo-2'-deoxyribonucleotide–acridine conjugates showed stronger stabilization of the duplex when the acridine moiety, an intercalator, is linked to an internucleotidic phosphate (22), we chose to tether the thiazole orange residue to an internucleotidic position of the oligonucleotide sequence.

EXPERIMENTAL PROCEDURES

General Methods. All solvents used were dried, distilled, and stored as described in ref 23. All chemicals were used as obtained unless otherwise stated. Cystamine dihydrochloride, 3-methylbenzothiazole-2-thione,

over 30 min, to a stirred solution of 1,11-dibromo-3,6,9-trioxaundecane **1** (1 g, 2.84 mmol) in anhydrous (freshly distilled) refluxing dioxane (3 mL) contained in a two-necked round-bottomed flask equipped with a reflux condenser and a dropping funnel and protected from the light. After 3 h of heating, the mixture was left under stirring for 16 h at room temperature, and then concentrated by evaporation. The residue was dissolved with a $\text{CH}_2\text{Cl}_2/\text{MeOH}$ mixture (97:3, v/v) (1 mL) and purified on a silica gel column using a $\text{CH}_2\text{Cl}_2/\text{MeOH}$ mixture (97:3, v/v, to 93:7, v/v) to give a colorless oil: yield 60% (0.315 g, 0.68 mmol); $R_f = 0.31$ using $\text{CH}_2\text{Cl}_2/\text{MeOH}$ (95:5, v/v) as eluent; ^1H NMR (CDCl_3) δ 2.98 (s, 3H, CH_3), 3.40–3.79 (m, 12H, CH_2O), 4.18 (t, 2H, $J = 4.77$ Hz, CH_2Br), 5.58 (t, 2H, $J = 4.75$ Hz, NCH_2), 7.90–7.95 (m, 2H, Ar), 8.16–8.18 (m, 1H, Ar), 8.30 (d, 1H, Ar, $J = 7.62$ Hz), 8.66 (d, 1H, Ar, $J = 9.03$ Hz), 10.2–10.5 (m, 1H, Ar); mass analysis, ESI, polarity positive; calculated for $\text{C}_{18}\text{H}_{25}\text{O}_3\text{NBr}$: $\text{M}+\text{H} = 384.3$, found 384.4.

Synthesis of *N*-(10-Iododecyl)-lepidine **3.** This compound was obtained following the procedure used for the preparation of *N*-(11-bromo-3,6,9-trioxaundecyl)-lepidine **2** except that 1,11-dibromo-3,6,9-trioxaundecane **1** was replaced by 1,10-diiododecane. Starting from lepidine (0.162 g, 1.17 mmol) and 1,10-diiododecane (1.12 g, 2.84 mmol), *N*-(10-iododecyl)-lepidine **3** was obtained with 65% yield (0.304 g, 0.74 mmol): $R_f = 0.23$ using $\text{CH}_2\text{Cl}_2/\text{MeOH}$ (95:5, v/v) as eluent; ^1H NMR (CDCl_3) δ 1.22–1.28 [m, 8H, $(\text{CH}_2)_4$], 1.29–1.33 (m, 2H, CH_2), 1.42–1.50 (m, 2H, CH_2), 1.73–1.79 (m, 2H, CH_2), 2.03–2.09 (m, 2H, CH_2), 2.99 (s, 3H, CH_3), 3.40–3.79 (m, 12H, CH_2O), 3.17 (t, 2H, $J = 7.5$ Hz, CH_2I), 5.24 (t, 2H, $J = 7.5$ Hz, NCH_2), 7.94–8.0 (m, 2H, Ar), 8.16–8.19 (m, 1H, Ar), 8.34 (d, 1H, Ar, $J = 8$ Hz, $J = 9.03$ Hz), 10.15 (d, 1H, Ar, $J = 6$ Hz); mass analysis, ESI, polarity positive; calculated for $\text{C}_{20}\text{H}_{29}\text{NI}$: $\text{M}+\text{H} = 410$, found 410.3.

Synthesis of *S*,3-Dimethylbenzothiazole-2-thiol **4.** *S*,3-Dimethylbenzothiazole-2-thiol **4** was obtained as reported in ref 27: yield 92% (5.97 g, 18.48 mmol); $R_f = 0.51$ using $\text{CH}_2\text{Cl}_2/\text{MeOH}$ (80:20, v/v) as eluent; mp = 152–154 °C; ^1H NMR ($\text{DMSO}-d_6$) δ 3.12 (s, 3H, SCH_3), 4.10 (s, 3H, NCH_3), 7.71 (t, 1H, $J = 7.8$ Hz), 7.82 (t, 1H, $J = 7.8$ Hz), 8.18 (d, $J = 8$ Hz, 1H), 8.40 (d, $J = 8$ Hz, 1H); mass analysis, ESI, polarity positive; calculated for $\text{C}_9\text{H}_{10}\text{NS}_2$: $\text{M}+\text{H} = 197$, found 196.6.

Synthesis of *N*-(11-Iodo-3,6,9-trioxaundecyl)-thiazole Orange **5.** *N*-(11-bromo-3,6,9-trioxaundecyl)-lepidine **2** (0.300 g, 0.65 mmol) and *S*,3-dimethylbenzothiazole-2-thiol **4** (0.303 g, 0.94 mmol) were dissolved in warm ethanol (4 mL) under stirring, and then triethylamine (200 μL , 1.5 mmol) was added to the solution. The red-colored mixture was protected from the light and left under stirring for 1 h at room temperature. The solvent was removed by evaporation, and the residue was purified on a silica gel column using a gradient of MeOH (0–3%) in CH_2Cl_2 to give a red powder: yield 35% (0.120 g, 0.22 mmol); $R_f = 0.77$ using $\text{CH}_2\text{Cl}_2/\text{MeOH}$ (80:20, v/v) as eluent; ^1H NMR (CDCl_3) δ 3.43–3.67 (m, 12H, CH_2O), 3.98 (t, 2H, $J = 5.16$ Hz, CH_2I), 4.00 (s, 3H, NCH_3), 4.71 (m, 2H, NCH_2), 6.72 (s, 1H, CH), 7.24–7.35 (m, 4H, Ar), 7.40–7.50 (m, 1H, Ar), 7.64–7.86 (m, 4H, Ar), 8.64 (d, $J = 7.5$ Hz, 1H, Ar); mass analysis, ESI, polarity positive; calculated for expected product $\text{C}_{26}\text{H}_{30}\text{BrN}_2\text{O}_3\text{S}$: $\text{M}+\text{H} = 530$, found 577.2, corresponds to $\text{C}_{26}\text{H}_{30}\text{IN}_2\text{O}_3\text{S}$. (These results indicate that halogen exchange occurred. This can be explained by the fact that the reaction between **2** and **4** to give **5** is performed in basic conditions in the presence of triethylamine.) mp = 117–118 °C.

Synthesis of *N*-(10-Iododecyl)-thiazole Orange **6.** This

compound was obtained following the procedure used for the preparation of *N*-(11-iodo-3,6,9-trioxaundecyl)-thiazole orange **5** except *N*-(11-bromo-3,6,9-trioxaundecyl)-lepidine **2** was replaced by *N*-(10-iododecyl)-lepidine **3**. Starting from 0.383 g (1 mmol) of *N*-(10-iododecyl)-lepidine **3** and 0.325 g (1 mmol) of *S*,3-dimethylbenzothiazole-2-thiol **4**, 0.208 g of 10-iododecylthiazole orange **6** was obtained: yield 62% (0.208 g, 0.29 mmol); $R_f = 0.46$ using $\text{CH}_2\text{Cl}_2/\text{MeOH}$ (90:10, v/v) as eluent; ^1H NMR (CD_3OD) δ 1.22–1.45 (m, 12H, $(\text{CH}_2)_6$), 1.75–1.78 (m, 2H, CH_2), 1.84–1.95 (m, 2H, CH_2), 3.15 (t, 2H, $J = 4.2$ Hz, CH_2I), 3.98 (s, 3H, NCH_3), 4.52 (t, 2H, $J = 4.5$ Hz, NCH_2), 6.72 (s, 1H, CH), 7.21–7.32 (m, 2H, Ar), 7.38–7.40 (m, 1H, Ar), 7.41–7.48 (m, 1H, Ar), 7.57–7.61 (m, 1H, Ar), 7.65–7.70 (m, 2H, Ar), 7.75–7.78 (m, 1H, Ar), 8.65 (d, $J = 4.8$ Hz, 1H, Ar), 8.90 (d, $J = 4.2$ Hz, 1H, Ar); mass analysis, ESI, polarity positive; calculated for $\text{C}_{28}\text{H}_{34}\text{IN}_2\text{S}$: $\text{M}+\text{H} = 558.1$, found 557.1; mp = 164–165 °C.

Synthesis of Pentadeca-2'-deoxyriboadenylates **19a, **19b**, **20a**, and **20b** Bearing a Thiazole Orange Derivative at the Eighth Internucleotidic Phosphate and Icosa- α -thymidylates **21a** and **21b** and Icosa- β -thymidylates **22a** and **22b** Bearing a Thiazole Orange Derivative at the Tenth Internucleotidic Phosphate (Scheme 2).** **Preparation of 5'-O-(4,4'-Dimethoxytrityl)- α -thymidine-3'-H-phosphonate **11**.** This synthesis was adapted from ref 28. To a stirred solution of 2-chloro-4H-1,3,2-benzodioxaphosphorin-4-one (1.39 g, 6.86 mmol) in a pyridine/ $\text{ClCH}_2\text{CH}_2\text{Cl}$ (90:10, v/v) mixture cooled to 0 °C was added slowly a solution of 5'-O-(4,4'-dimethoxytrityl)- α -thymidine, previously dried by coevaporation with anhydrous pyridine and kept under vacuum overnight (2.5 g, 4.6 mmol) in an anhydrous pyridine/ $\text{ClCH}_2\text{CH}_2\text{Cl}$ (50:50, v/v) mixture. The reaction was monitored by TLC on silica gel with $\text{CH}_2\text{Cl}_2/\text{MeOH}/\text{NEt}_3$ (90:9.5:0.5, v/v/v) as eluent. After 15 min, the starting material ($R_f = 0.54$) was fully transformed into a new compound having a lower R_f (0.31). The reaction mixture was poured into an $\text{NEt}_3/\text{H}_2\text{O}$ (20:80, v/v) mixture (100 mL) under vigorous stirring for 5 min. The reaction mixture was then extracted with CH_2Cl_2 (50 mL), twice. The organic phase was then washed with a saturated NaCl solution (15 mL), and the latter was back-extracted with CH_2Cl_2 (50 mL). The organic phases were pooled, dried over Na_2SO_4 , and concentrated under reduced pressure. The residue was purified on a silica gel column using a gradient of methanol in dichloromethane in the presence of triethylamine, $\text{CH}_2\text{Cl}_2/\text{NEt}_3$ (99.5:0.5, v/v) to $\text{CH}_2\text{Cl}_2/\text{MeOH}/\text{NEt}_3$ (94.5:5:0.5, v/v/v), as eluent to give a pale yellow solid: $R_{f11} = 0.62$ using $\text{CH}_2\text{Cl}_2/\text{MeOH}/\text{NEt}_3$ (79.5:20:0.5, v/v/v) as eluent; yield 40%, 1.3 g, 8.4 mmol; mass analysis, ESI, polarity negative; calculated for $\text{C}_{31}\text{H}_{32}\text{N}_2\text{O}_9\text{P}$: $\text{M}+\text{H} = 608$, found 607.3.

Preparation of Oligonucleotides **16, **17**, and **18** Bearing a Linker at the Central Phosphate Group and Separation of Their Diastereoisomers.** The oligo-2'-deoxyribonucleotides were assembled using classical phosphoramidite chemistry on a CPG support at a micromolar scale except that at the site selected for the introduction of the linker arm, a coupling step using H-phosphonate chemistry was manually performed. The CPG support involving α -thymidine, the phosphoramidite, and the H-phosphonate derivatives of α -thymidine was not commercially available. The first two were available in the laboratory, while the last one (compound **11**) was obtained as described above. The syntheses were performed as follows. At the end of the chain assembly of the hepta-2'-deoxyriboad-

Scheme 2. Synthesis of the Oligo-2'-deoxyribonucleotide-Thiazole Orange Conjugates **19a**, **19b**, **20a**, **20b**, **21a**, **21b**, **22a**, and **22b**

enylate **7**, the deca- α -thymidylate **8**, and the deca- β -thymidylate **9**, an additional detritylation step was

performed. N^6 -Benzoyl-5'-O-(4,4'-dimethoxytrityl)-2'-deoxyadenosine-3'-H-phosphonate **10** (0.033 g, 0.04 mmol) and

5'-O-(4,4'-dimethoxytrityl)- α -thymidine-3'-H-phosphonate **11** [or 5'-O-(4,4'-dimethoxytrityl)- β -thymidine-3'-H-phosphonate **12**] (0.04 g, 0.056 mmol) in a pyridine/CH₃CN (50:50, v/v) mixture (0.4 mL) and pivaloyl chloride (0.02 g, 0.166 mmol) in a pyridine/CH₃CN (50:50, v/v) mixture (0.5 mL) were then added simultaneously to the hepta-2'-deoxyriboadenylate, the deca- α -thymidylate, or the deca- β -thymidylate bound to the support. After a 2.5 min reaction, the solution was removed and the support washed with an anhydrous pyridine/CH₃CN (50:50, v/v) mixture (1 mL, 3 times). Then cystamine (0.165 g, 0.87 mmol) solubilized by a pyridine/CCl₄ (50:50, v/v) mixture (1 mL) was added. After 1 h, the solution was removed and the support washed with an anhydrous pyridine/CH₃CN (50:50, v/v) mixture (1 mL) 3 times and then with anhydrous CH₃CN (1 mL) 3 times. The support was treated with a mixture of capping solutions used on the synthesizer (0.5 mL each) for 10 min, washed with CH₃CN (1 mL, 4 times), and dried. The oligonucleotide chain assemblies were completed via phosphoramidite chemistry to give the fully protected pentadeca-2'-deoxyriboadenylate **13**, icoso- α -thymidylate **14**, and icoso- β -thymidylate **15** bound to the support bearing the linker at the central phosphates of the oligonucleotide chains. At the end of the chain assembly, an additional detritylation step was performed to deblock the 5'-terminal hydroxyl function. The deprotection step was completed by overnight concentrated ammonia treatment at 50 °C in the case of the oligo-2'-deoxyriboadenylates and at room temperature in the case of the oligothymidylates (in both cases, the support was discarded after a 2 h treatment). Purification was performed by ion exchange chromatography on a DEAE column (8 μ M, 100 mm $\times$ 10 mm, Waters) using a linear gradient of NaCl (0.075–0.525 M over 30 min) in 25 mM Tris-HCl, pH 7, buffer containing 10% MeOH. After the desalting steps, reversed-phase chromatography analyses were performed on a Lichrospher 100 RP (5 μ M) column (125 mm $\times$ 4 mm) from Merck with a linear gradient of CH₃CN (17.4–18.4% over 15 min) in 0.1 M aqueous triethylammonium acetate, pH 7, with a flow rate of 1 mL/min. Two roughly equivalent peaks with very close retention times (Rt) were obtained for both oligo-2'-deoxyribonucleotides with Rt_{16a} = 8 min, 24 s and Rt_{16b} = 9 min in the case of the oligo-2'-deoxyriboadenylates. In the case of oligothymidylate isomers, analyses were performed on the same column with the same buffer and flow rate but with different gradients of CH₃CN: 5–35% over 50 min for oligo- α -thymidylate isomers (Rt_{17a} = 19 min, 46 s; Rt_{17b} = 21 min, 40 s) and 12.5–20% over 30 min for oligo- β -thymidylate isomers (Rt_{18a} = 18 min, 52 s; Rt_{18b} = 19 min, 40 s).

Synthesis of Oligonucleotides 19a, 19b, 20a, 20b, 21a, 21b, 22a, and 22b by Coupling Thiazole Orange-Linker Derivatives 5 and 6 with the Oligonucleotides Bearing a Thiol Function Obtained after Treatment of Oligo-2'-deoxyribonucleotides 16a, 16b, 17, and 18 with a Reducing Agent. Solutions of **16a** and **16b**, d⁵(Ap)₇Ap*[NH-(CH₂)₂S-S-(CH₂)₂NHCOCH₃]A(pA)₆^{3'} (15 OD each), in 5% aqueous bicarbonate buffer, pH 9 (800 μ L), were degassed by bubbling argon. An aqueous tris(2-carboxyethyl)-phosphine (TCEP) solution (0.06 mg in 5 μ L of H₂O) was then added, and the solutions were vortexed for a few minutes. Finally, a DMF solution of thiazole orange-linker derivative **5** or **6** (1.5 mg in 800 μ L) was added. The solutions were vortexed and heated at 35–40 °C. The coupling reactions were controlled by reversed-phase analyses as follows. The oligonucleotides were recovered by centrifugation of an aliquot of the reaction mixture. The pellets were dissolved in water, and the red solutions

Figure 1. HPLC reversed-phase analysis of the coupling reaction between the pentadeca-2'-deoxyriboadenylate **16** (isomer mixture) and the thiazole orange-linker derivative **5** after 2 h incubation. Pentadeca-2'-deoxyriboadenylate-thiazole orange conjugates **19a** and **19b** are eluted with Rt_{19a} = 26 min, 48 s and Rt_{19b} = 28 min, 10 s, respectively. The inset shows the absorption spectrum, recorded between λ = 240 and λ = 600 nm, of the conjugate **19a**. The analysis was performed on a Lichrospher 100RP-18 (5 μ m) column (125 $\times$ 4 mm) using a linear gradient of CH₃CN in 0.1 M aqueous triethylammonium acetate buffer (pH 7) with a flow rate of 1 mL/min (12–36% over 45 min).

were analyzed by reversed-phase chromatography on the Lichrospher column described above with a linear gradient of CH₃CN (12–36% over 45 min) in 0.1 M aqueous triethylammonium acetate, pH 7, with a flow rate of 1 mL/min (Rt_{19a} = 19 min, 1 s; Rt_{19b} = 20 min, 5 s; Rt_{20a} = 30 min; Rt_{20b} = 31 min). The coupling reaction could be performed on the mixture of isomers of oligo-2'-deoxyriboadenylate (**16a** + **16b**), but separate coupling reactions on each isomer are required for determination of the stereochemistry of oligo-2'-deoxyriboadenylate-thiazole orange conjugates. Reversed-phase analysis of the coupling reaction between the oligo-2'-deoxyriboadenylate **16** and the thiazole orange-linker derivative **5**, after 2 h of incubation, is shown in Figure 1. The inset shows the absorption spectra, recorded between λ = 240 nm and λ = 600 nm, of the oligo-2'-deoxyriboadenylate-thiazole orange conjugates with a hydrophilic linker, **19a**. Usually the reaction was completed after 5–6 h of incubation: yield 50% after purification; mass analysis, ESI, polarity negative. Pentadeca-2'-deoxyriboadenylate-thiazole orange conjugates with a polymethylene linker: compounds **20a** and **20b**: calculated mass for C₁₈₀H₂₁₉O₇₂N₇₈S₂P₁₇: M–H = 5125.08, found 5125.26 $\pm$ 0.63 for compound **20a** and 5125.23 $\pm$ 0.63 for compound **20b**.

Solution of icoso- α -thymidylate **17** (20 OD, 0.11 μ mol) in 5% aqueous NaHCO₃, pH 9, buffer (800 μ L) was degassed by bubbling argon. Then an aqueous tris(2-carboxyethyl)phosphine (TCEP) solution (0.06 mg, 0.22 μ mol in 1 μ L of H₂O) was added, and the solutions were vortexed for a few minutes. After verification of the cleavage of the disulfide bridge by reversed-phase chromatography [Rt_{17a} = 17 min, 22 s; Rt_{17b} = 17 min, 42 s; and for the thiol derivatives, Rt = 17 min, 9 s; Rt = 17 min, 22 s on the Lichrospher column described above with a linear gradient of CH₃CN (0–24% over 15 min) in 0.1 M aqueous triethylammonium acetate, pH 7, with a flow rate of 1 mL/min], a DMF solution (1 mL) of thiazole orange-linker derivative **6** (1.5 mg, 2.2 $\times$ 10^{–6} mol) was added. The solutions were vortexed and heated at 35–40 °C. The coupling reactions were controlled by reversed-

Scheme 3. Isomer Identification

phase analyses as follows. The oligonucleotides were recovered by centrifugation. The pellets were dissolved in water, and the solutions were analyzed by reversed-phase chromatography on a Lichrospher column (the same as above) with a linear gradient of CH_3CN (0–40% over 50 min) in 0.1 M aqueous triethylammonium acetate, pH 7, with a flow rate of 1 mL/min. Two peaks corresponding to the R_p and S_p isomers were obtained ($R_{t_{21a}} = 34$ min, 40 s; $R_{t_{21b}} = 36$ min, 2 s). The coupling reactions were nearly complete after 5–6 h of reaction. The oligonucleotide–thiazole orange isomers **21a** and **21b** were purified by using a more flat gradient: yield 50% after purification; mass analysis, ESI, polarity negative. Icosa- β -thymidylate–thiazole orange conjugates **21a** and **21b**: calculated mass for $\text{C}_{230}\text{H}_{298}\text{O}_{167}\text{N}_{43}\text{S}_2\text{P}_{19}$: $M-H = 6509.74$, found mass 6509.64 ± 1.93 .

The icosa- β -thymidylate–thiazole orange conjugates **22a** and **22b** were obtained by using the isomer mixture of the icosa- β -thymidylate-linker derivative **18** and the thiazole orange-linker derivative **6**, and proceeding as reported for the preparation of the icosa- α -thymidylate–thiazole orange conjugates **21a** and **21b**. HPLC reversed-phase analyses were performed on a Lichrospher column

(the same as above) with a linear gradient of CH_3CN (20–30% over 30 min) in 0.1 M aqueous triethylammonium acetate, pH 7, with a flow rate of 1 mL/min. Two peaks corresponding to the R_p and S_p isomers were obtained ($R_{t_{22a}} = 12$ min, 42 s; $R_{t_{22b}} = 19$ min, 50 s).

Isomer Identification (Scheme 3). Preparation of Dinucleosides $d\text{-}5'\text{DMTrA}^{Bz}p^*(H)A^{Bz}Bz^{3'}$ **24a** and **24b**. To an anhydrous stirred pyridine solution (5 mL) of a mixture of N^6 -benzoyl-5'-O-(4,4'-dimethoxytrityl)-2'-deoxyriboadenosine-3'-H-phosphonate **10** (0.412 g, 0.5 mmol) and N^6 -benzoyl-3'-O-benzoyl-2'-deoxyriboadenosine **23** (0.230 g, 0.5 mmol), previously dried by coevaporation with anhydrous pyridine (20 mL, 3 times) and kept under vacuum overnight, was added pivaloyl chloride (0.180 g, 1.5 mmol) at room temperature. After 15 min of stirring, the reaction mixture was diluted with CH_2Cl_2 (50 mL), and the organic phase was washed with a 5% aqueous NaHCO_3 solution (50 mL). The aqueous phase was back-extracted with CH_2Cl_2 (50 mL), twice. The organic phases were then pooled, dried over Na_2SO_4 , filtered off, and concentrated under reduced pressure. The residue was solubilized with acetone and coevaporated with toluene (10 mL), 3 times, and then purified on a silica gel column

(ref. 109336 from Merck) using an ethyl acetate/acetone mixture (60:40, v/v) containing 0.2% acetic acid as eluent until the first isomer was eluted and then an ethyl acetate/acetone mixture (50:50, v/v) containing 0.2% acetic acid as eluent for the elution of the second isomer. After removal of the solvents by evaporation, the residual acetic acid was removed by co-evaporation with CH_3CN (3 mL), 3 times. Products corresponding to each pure dinucleoside-H-phosphonate isomer (0.2 g each) were obtained as pale yellow solids: $R_{24a} = 0.61$ and $R_{24b} = 0.53$ using $\text{CH}_2\text{Cl}_2/\text{iPrOH}$ (90:10, v/v) as eluent; $R_{24a} = 0.56$ and $R_{24b} = 0.53$ using $\text{CH}_2\text{Cl}_2/\text{MeOH}$ (90:10, v/v) as eluent; mass analysis, ESI, polarity positive; calculated mass for $\text{C}_{62}\text{H}_{55}\text{O}_{12}\text{N}_{10}\text{P}_{19}$: $M+H = 1163.4$, found mass 1163.3.

Preparation of Dinucleosides $d\text{-}^5\text{Ap}^*(S)\text{A}^3'$ 25a and 25b. To pyridine solutions (1 mL) of each pure dinucleoside-H-phosphonate (**24a** and **24b**) (0.02 g, 17.2 mmol), previously dried by co-evaporation with anhydrous pyridine (5 mL, 3 times), was added, at room temperature, under stirring, and in an argon atmosphere, a pyridine/ CS_2 (50:50, v/v) solution of S_8 (4.25 mg/mL) (2 mL) (32). After 1 h of stirring, the reaction mixtures were evaporated to dryness, and the residues were co-evaporated with toluene (5 mL), 3 times. The residues were solubilized with ethyl acetate (6–7 mL). The reaction mixtures were filtered and then washed with water (1–2 mL). The organic phases were concentrated to dryness, and an 80% solution of acetic acid in water (5 mL) was added. After 30 min, acetic acid was removed by evaporation. The residues obtained were solubilized with a 28% aqueous ammonia solution (4–5 mL) and left overnight at 50 °C. The reaction mixtures were evaporated to dryness. The residues were solubilized with water (7–8 mL), and the aqueous phases were extracted with ethyl acetate (3×1 mL): $R_{25a} = 0.53$ and $R_{25b} = 0.61$ using $\text{iPrOH}/\text{NH}_4\text{OH}/\text{H}_2\text{O}$ (70:20:10, v/v/v) as eluent; $R_{25a} = 0.17$ and $R_{25b} = 0.31$ using $\text{CH}_2\text{Cl}_2/\text{MeOH}$ (90:10, v/v) as eluent. The presence of the sulfur atom was confirmed by the obtention of pink-colored spots on TLC plates by spraying with a 2,6-dibromo-4-benzoquinone-*N*-chloroimine (DBPNC) solution in ethanol (2 mg/mL) and heating; mass analysis, ESI, polarity positive; calculated for $\text{C}_{20}\text{H}_{25}\text{N}_{10}\text{O}_7\text{SP}$: $M+H = 580.52$, found 581.1.

Preparation of Dinucleoside $d\text{-}^5\text{Ap}^*[\text{NH}(\text{CH}_2)_2\text{S-S}(\text{CH}_2)_2\text{-NHCOCH}_3]\text{A}^3'$ 26a and 26b. Both pure isomers **24a** and **24b** of the dinucleoside-H-phosphonate N^6 -benzoyl-5'-*O*-(4,4'-dimethoxytrityl)-2'-deoxyriboadenosyl- N^6 -benzoyl-3'-*O*-benzoyl-2'-deoxyriboadenosine-3'-H-phosphonate (0.035 g each, 0.03 mmol) were treated, separately, with cystamine (0.09 g, 0.6 mmol) solubilized by an anhydrous pyridine/ CCl_4 (50:50, v/v) mixture (1 mL) for 10 min over an argon atmosphere. The reaction mixture was concentrated to dryness and solubilized with CH_2Cl_2 (7–8 mL). The organic phase was washed with water (1–2 mL), dried over Na_2SO_4 , and concentrated to dryness. The residue was co-evaporated with anhydrous pyridine (3 mL, 3 times), and during the last evaporation, 1 mL of pyridine was kept in the flask. Acetic anhydride (0.93 g, 0.9 mmol) was added under stirring at room temperature. The reaction was monitored by TLC analysis using $\text{CH}_2\text{Cl}_2/\text{MeOH}$ (90:10, v/v) as eluent. When the reaction was completed, the reaction mixture was evaporated to dryness, co-evaporated with toluene, and purified by flash chromatography using a gradient of MeOH in CH_2Cl_2 (0–20%). An 80% acetic acid solution in water (3 mL) was then added. After 30 min of reaction at room temperature, the solution was evaporated to dryness and co-evaporated with toluene (3 mL), twice. The residue was

then treated with a 28% solution of aqueous ammonia in a MeOH/ H_2O (80:20, v/v) mixture at 50 °C overnight. After removal of the ammonia solution by evaporation, the residue was solubilized with water (3 mL), and the aqueous phase was extracted with ethyl acetate (0.5 mL), 3 times. Purification by reversed-phase chromatography was performed on a Lichrospher 100 RP (5 μM) column (125 mm $\times$ 4 mm) from Merck with a linear gradient of CH_3CN (10–35% over 50 min) in 0.1 M aqueous triethylammonium acetate, pH 7, with a flow rate of 1 mL/min: $R_{t26a} = 19$ min, 30 s; $R_{t26b} = 19$ min, 55 s; mass analysis, ESI, polarity positive; calculated for $\text{C}_{26}\text{H}_{37}\text{N}_{12}\text{O}_8\text{S}_2\text{P}$: $M+H = 741.76$, found 741.1.

RESULTS AND DISCUSSION

Synthesis of the Oligonucleotide-Thiazole Orange Conjugates. One report shows that the homodimeric thiazole orange TOTO bisintercalates in DNA with the linker in the minor groove (21). Since our previous work on oligo-2'-deoxyribonucleotide-acridine conjugates showed that stronger stabilization (therefore better intercalation) was observed when the intercalating residue was linked to an internucleotidic phosphate (22), we chose the same position for the linking of the thiazole orange moiety. Substitution at an internucleotidic position introduces a chirality at the phosphorus atom with the formation of two diastereoisomers (Figures 2 and 3). These oligonucleotides can be separated as pure isomers. When these oligonucleotides are hybridized with their complementary sequences, the substituent of one isomer protrudes in the direction of the minor groove, while the substituent of the other isomer points in the direction of the major groove. The CPK model indicates that a linker involving 14 atoms fixed on an internal phosphorous atom and on the nitrogen atom of the quinolinium ring of the thiazole orange residue would be suitable for the intercalation of the thiazole orange residue by either the minor or the major groove. We chose to attach the linker via a phosphoramidate linkage at the central phosphate of a pentadeca-2'-deoxyriboadenylate (Figure 2), an icoso- α -thymidylate, and an icoso- β -thymidylate (Figure 3) and to separate both isomers in order to study the influence of the stereochemistry at the phosphorus atom on the interactions of the oligonucleotide-thiazole orange conjugates with their complementary sequences. A linker involving a masked thiol function such as cystamine that can withstand the conditions required for the deprotection and purification steps of the oligonucleotide was chosen (29). After in situ cleavage of the disulfide bridge, the released thiol function was selectively reacted with a halogenoalkyl group linked at the nitrogen atom of the quinolinium ring of the thiazole orange. Of the 2 different linkers fixed on the thiazole orange, 1 was hydrophilic, derived from tetraethylene glycol (compound 5), and the other was hydrophobic with 10 methylene groups (compound 6). These thiazole orange-linker derivatives, 5 and 6, were reacted with each pure S_p and R_p isomer of the pentadeca-2'-deoxyriboadenylate 16 while only the thiazole orange derivative involving a polymethylene linker, 6, was reacted with the mixture of the S_p and R_p isomers of icoso- α -thymidylate 17 and with the mixture of the S_p and R_p isomers of icoso- β -thymidylate 18. S_p and R_p isomers of the icoso- α -thymidylate-thiazole orange conjugates and of the icoso- β -thymidylate-thiazole orange conjugates were then separated by reversed-phase chromatography.

Preparation of Thiazole Orange-Linker Derivatives 5 and 6. The preparation of thiazole orange-linker derivatives 5 and 6 (Scheme 1) was achieved by a

Figure 2. Structures of the pentadeca-2'-deoxyriboadenylate-thiazole orange conjugates **19a**, **19b**, **20a**, and **20b**.

procedure adapted from the literature (27, 30). The lepidine-linker derivatives **2** and **3** were obtained by reaction of lepidine with 1,11-dibromo-3,6,9-trioxaudecane **1** and 1,10-diiododecane, respectively. 1,11-Dibromo-3,6,9-trioxaudecane **1** was obtained by treatment of tetraethylene glycol with triphenylphosphine and BrCCl_3 . Reaction of the lepidine-linker derivatives **2** and **3** with *S*,3-dimethylbenzothiazole-2-thiol **4** (obtained by reaction of 3-methylbenzothiazole-2-thione with methyl iodide) led to the expected thiazole orange-linker derivatives **5** and **6**, respectively.

Synthesis of Oligo-2'-deoxyribonucleotide-Thiazole Orange Conjugates 19a, 19b, 20a, 20b, 21a, 21b, 22a, and 22b. This was achieved following Scheme 2. At the end of the chain assembly of hepta-2'-deoxyriboadenylate **7**, deca- α -thymidylate **8**, and deca- β -thymidylate **9**, an additional detritylation step was performed, and the fixation of the cystamine on the central phosphate of the oligo-2'-deoxyribonucleotide was achieved by performing an H-phosphonate coupling step, manually, including an oxidation step using a mixture of CCl_4 and cystamine in pyridine, at a position preselected for the attachment of the linker (31). Acetylation of the terminal primary amino function of the linker was performed in

order to prevent its phosphitilation during the assembling of the second parts of the oligonucleotide chains via phosphoramidite chemistry. This led to the fully protected pentadeca-2'-deoxyriboadenylate **13**, icoso- α -thymidylate **14**, and icoso- β -thymidylate **15** bound to the support and bearing the linker at the central phosphates. After deprotection and purification by ion-exchange chromatography, reversed-phase analyses of pentadeca-2'-deoxyriboadenylate **16**, icoso- α -thymidylate **17**, and icoso- β -thymidylate **18** bearing the linker at their central phosphate via a phosphoramidate linkage exhibited two roughly equivalent peaks with very close retention times (see Experimental Procedures). The pentadeca-2'-deoxyriboadenylate isomers **16a** (fast eluted) and **16b** (slowly eluted) were separated by reversed-phase chromatography (see Experimental Procedures for the conditions used) while the mixture of isomers was used in the case of icoso- α -thymidylate **17** and icoso- β -thymidylate **18** for the coupling step with the thiazole orange derivative **6**. Determination of the configuration was made for pentadeca-2'-deoxyriboadenylates **16a** and **16b** after their digestion by the nuclease P1 or snake venom phosphodiesterase followed by alkaline phosphatase treatment. Each hydrolysate was then compared with pure S_p or R_p

21a and 21b, T in α -anomeric position

22a and 22b, T in β -anomeric position

Figure 3. Structures of the icoso- α -thymidylate–thiazole orange conjugates **21** and **21b**, and the icoso- β -thymidylate–thiazole orange conjugates **22a** and **22b**.

isomer samples of the dinucleoside $d\text{-}5'\text{Ap}^*[\text{NH}(\text{CH}_2)_2\text{S}(\text{CH}_2)_2\text{NHCOCH}_3]\text{A}^{3'}$, whose stereochemistry was determined following the method reported in Scheme 3 and discussed in the next paragraph. The thiazole orange derivatives **5** and **6** were coupled with the released thiol function obtained after in situ treatment of pure isomers **16a** and **16b** of the pentadeca-2'-deoxyriboadenylate with a reducing agent (TCEP) to give the pentadeca-2'-deoxyriboadenylate–thiazole orange conjugates **19a** and **19b**, **20a** and **20b**, respectively. The same reaction was performed with the thiazole orange derivative **6** and a mixture of the isomers of icoso- α -thymidylate **17** or icoso- β -thymidylate **18** to give a mixture of the isomers of icoso- α -thymidylate–thiazole orange conjugates **21a** and **21b** and of icoso- β -thymidylate–thiazole orange conjugates **22a** and **22b**, respectively. The latter were then separated by chromatography.

Determination of the Configuration of Isomers 19a, 19b, 20a, and 20b of the Pentadeca-2'-deoxyriboadenylate–Thiazole Orange Conjugates. This was achieved as described in Scheme 3. The fully protected dinucleoside-H-phosphonate **24** was obtained following a procedure adapted from the literature (32) except that the benzoyl group was used for the protection of the 3'-

hydroxyl function. Dinucleoside isomers **24a** and **24b** were purified and separated by silica gel chromatography. A part of both pure dinucleoside-H-phosphonate isomers **24a** and **24b** was separately transformed (with retention of configuration at the phosphorus center) into pure dinucleoside phosphorothioates by treatment with S_8 in a pyridine/ CS_2 mixture. After deprotection and purification by reversed-phase chromatography, aliquots of both pure dinucleoside phosphorothioate isomers **25a** and **25b** were treated separately with P1 endonuclease and snake venom phosphodiesterase (SVP) and then with phosphatase alkaline (PA). Treatment with P1 + PA led to the full degradation of the S_p isomer into dA while the R_p isomer remained unchanged. On the contrary, treatment with SVP + PA led to full degradation of the R_p isomer into dA while the S_p isomer remained unchanged (33). These results showed that only dinucleoside phosphorothioate **25b** which comes from dinucleoside-H-phosphonate **24b** was cleaved by P1 + PA treatment while only dinucleoside phosphorothioate **25a** which comes from dinucleoside-H-phosphonate **24a** was cleaved by SVP + PA treatment. The remaining part of both pure dinucleoside-H-phosphonate isomers **24a** and **24b** was separately transformed (with inversion of configuration

at the phosphorus center) (34) into the dinucleoside d-⁵Ap*[NH(CH₂)₂S-S(CH₂)₂NHCOCH₃]₃A^{3'} **25a** and **25b** by treatment with cystamine in a CCl₄/pyridine mixture followed by an acetylation step. After deprotection, reversed-phase purification of the dinucleoside gave nearly equivalent peaks which correspond to diastereoisomers **25a** and **25b**. Both pure dinucleoside isomers **25a** and **25b** d-⁵Ap*[NH(CH₂)₂S-S(CH₂)₂NHCOCH₃]₃A^{3'} were used as a reference during analysis of the mixture obtained after nuclease degradation by either P1 + PA or SVP + PA of each pure isomer of the pentadecamers d-⁵(Ap)₇Ap[NH(CH₂)₂S-S(CH₂)₂NHCOCH₃]₃(Ap)₆A^{3'} **16a** and **16b**, thus allowing the determination of their configuration and subsequently those of all the pentadeca-2'-deoxyriboadenylate-thiazole orange conjugates described (**16a** gives dA + **25a**, and **16b** gives dA + **25b**). We then verified that the elution order for pentadeca-2'-deoxyriboadenylate-thiazole orange conjugates **19a** and **19b** was the same as that for oligonucleotides **16a** and **16b**. The same result was observed for oligo-2'-deoxyriboadenylates **20a** and **20b** with the hydrophobic linker. The coupling of **16a** with **5** and **6** gave **19a** and **20a**, respectively, while the coupling of **16b** with **5** and **6** gave **19b** and **20b**, respectively. From these results and in accordance with a literature report (35), we were able to conclude that the fast-eluted pentadeca-2'-deoxyriboadenylate-thiazole orange conjugates **19a** and **20a** have the *R_p* configuration while the slow-eluted conjugates **19b** and **20b** have the *S_p* configuration. When the conjugates with the *R_p* configuration are hybridized with their target sequences, the linker is directed toward the minor groove of the duplex while in the case of the conjugates with the *S_p* configuration the linker is directed toward the major groove.

Interaction with the Complementary Sequence.

The stabilizing effect of the thiazole orange residue on the hybridization of the thiazole orange-oligonucleotide conjugates with their complementary sequences was determined by absorption spectroscopy studies carried out between $\lambda = 240$ nm and $\lambda = 600$ nm in the case of the thiazole orange-oligonucleotide conjugates and between $\lambda = 240$ nm and $\lambda = 350$ nm in the case of the corresponding unmodified oligonucleotides used as references.
