Figure 6. Tumor, kidney, and liver activity of ^{64}Cu after 2 and 4 h postadministration of ^{64}Cu-DOTA-DY1-TATE generated by measuring ROIs from microPET images in control and blocked AR42J tumor-bearing SCID mice (A) and Lewis rats (B). Each bar presents two animals.

adrenals. However, the liver and blood uptake of ^{64}Cu-DOTA-DY1-TATE were significantly greater than for DOTA-^{125}I-DY1-TATE ($p < 0.01$). The high uptake in the blood at longer time points and the increasingly high uptake in the liver was problematic for ^{64}Cu-DOTA-DY1-TATE, suggesting that ^{64}Cu dissociated from the DOTA chelator (*21*). Research is ongoing to develop more stable chelators for copper radionuclides that have greater kinetic stability, and these will eventually be conjugated to somatostatin analogues (*22*). It is predicted that conjugating a chelator to DY1-TATE that forms a more stable Cu(II) complex than DOTA will significantly decrease accumulation in the blood, liver and kidneys.

The uptake of ^{64}Cu- and ^{125}I-labeled DOTA-DY1-TATE was not as high in somatostatin-receptor positive tissues as has been observed for other radiolabeled somatostatin analogues. Comparisons between the AR42J tumor-bearing rat model can only be made with CA20948 tumor-bearing rats, since to the best of our knowledge, uptake of radiolabeled somatostatin analogues has not yet been reported for the AR42J tumor-bearing rat model. Therefore, comparisons with other somatostatin-receptor positive tissues are presented here. For example, the uptake of ^{64}Cu-TETA-Y3-TATE in the rat pancreas was 9.35 ± 1.66 %ID/g in Lewis rats (*19*) at 1 h postinjection, compared to 1.49 ± 0.34 %ID/g for ^{64}Cu-DOTA-DY1-TATE and 0.85 ± 0.20 %ID/g for DOTA-^{125}I-DY1-TATE. A biodistribution study of ^{177}Lu-DOTA-Y3-TATE in Lewis rats showed a pancreas uptake of 10.49 ± 1.91 %ID/g (*23*). However, the uptake of the DOTA-DY1-TATE analogues in the pancreas was comparable or greater than ^{64}Cu-TETA-OC (0.86 ± 0.14 %ID/g) and ^{111}In-DTPA-OC (0.42 ± 0.09 %ID/g) (*15*). Compared to DTPA-^{125}I-DY1−OC (*4*), the pancreas and adrenal uptakes of DOTA-^{125}I-DY1-TATE were somewhat higher (pancreas: 0.85 vs ∼0.5 %ID/g, respectively; adrenal: 1.5 vs ∼1.0 %ID/g, respectively). This suggests that the octreotate analogues may be superior to the octreotide analogues, which has been previously been reported (*2*, *3*).

Although the radiometal-labeled DOTA/TETA-Y3-TATE analogues showed superior receptor-mediated uptake, these analogues do not allow the ability to label via a residualizing label with radiohalogens. Therefore, the use of the DY1 analogues opens possibilities for the radiotherapeutic application of radioiohalogened ligands in patients with somatostatin receptor-positive tumors.

MicroPET imaging of ^{64}Cu-DOTA-DY1-TATE in AR42J tumor-bearing mice and rats at 2 h postinjection showed higher amounts of activity in the liver and kidneys compared to other normal tissues (Figure 6). The tumor also had significant uptake and showed good contrast compared with receptor-negative background tissue in the neck and thigh tumors of the mouse, and the thigh tumors in the rat model. In the AR42J-tumor bearing Lewis rats, the somatostatin receptor-positive pituitary was visualized, whereas it was not visualized in the rat coinjected with a blocking dose. Quantification of the activity in the rat tumor, liver, and kidney was comparable to the relative amounts determined by traditional biodistribution. The quantification of the microPET images also demonstrated that the activity in the tumor was significantly blocked, and this decrease in uptake corresponded to the visual decrease in uptake delineated in the images. These data suggest that microPET may be used as an alternative to traditional multiple animal biodistribution studies for screening new positron-emitting radiopharmaceuticals.

CONCLUSIONS

The study presented here demonstrates that DOTA-DY1-TATE is a peptide that can be labeled with both metal and halogen radionuclides. The IC_{50} values for ^{64}Cu- and ^{125}I-labeled DOTA-DY1-TATE were comparable to ^{111}In-DPTA-OC, and these analogues showed somatostatin receptor-mediated uptake in normal and tumor tissues in vivo. DOTA-^{125}I-DY1-TATE appeared to remain in the tumor out to 4 h postinjection, suggesting that the iodine was possibly residualized in the tumor cells. Future studies include microPET imaging in the AR42J tumor-bearing rat model with DOTA-DY1-TATE labeled with other positron-emitting radionuclides such as ^{76}Br, ^{124}I, and ^{86}Y.

ACKNOWLEDGMENT

The authors wish to thank Lynne Jones, Nicole Mercer, Mu Wang, Virginia Richey, and John Engelbach for technical assistance, and W. Barry Edwards, Ph.D. (MetaPhore Pharmaceuticals) for helpful discussions. This research was supported by NIH Grant R01 CA64475 (C.J.A.). The production of copper radionuclides at Washington University is supported by a grant from the National Cancer Institute (R24 CA86307 − M. J. Welch, P. I.). MicroPET imaging is supported by NIH/NCI SAIRP grant (1R24 CA83060). We would also like to thank the Small Animal Imaging Core of the Alvin J. Siteman Cancer Center at Washington University and Barnes Jewish Hospital in St. Louis, MO for additional support of the microPET imaging. The core is supported by a NCI Cancer Center Support Grant (1P30 CA91842).

Human monoclonal antibodies are promising agents for the development of more selective anticancer therapeutics. However, the tumor-targeting efficiency of most anticancer antibodies is severely limited by their poor penetration into the tumor mass. Recent studies have shown that a peptide derived from the HIV TAT protein could improve the distribution of cytoplasmic reporter proteins when administered systemically as fusion proteins or cross-linked chimeras. In this article, we tested by quantitative biodistribtution analysis whether conjugation to TAT peptides could improve the tumor targeting properties of scFv(L19)-Cys: an engineered human antibody fragment specific for the ED-B domain of fibronectin, a marker located in the modified extracellular matrix surrounding tumor neovasculature. Our results show that TAT peptides, consisting either of L-amino acids or D-amino acids, can efficiently transduce target cells when conjugated to fluorophores and/or antibody fragments, suggesting a receptor-independent cell entry mechanism. However, conjugation of scFv(L19)-Cys to TAT peptides resulted in a severely reduced tumor targeting performance compared to the unconjugated antibody, as measured in murine F9 teratocarcinoma-bearing mice, after intravenous injection of the radiolabeled antibody preparations. Our results outline the usefulness of TAT peptides for the efficient in vitro transduction of cells with globular proteins. In particular, the use of TAT peptides composed of D-amino acids may significantly reduce proteolytic degradation. At the same time, the poor biodistribution properties of antibody−TAT conjugates cast doubts over the applicability of this methodology for the delivery of biopharmaceuticals in vivo.

INTRODUCTION

The development of better chemotherapeutic drugs for the treatment of solid tumors needs to address two main issues, which are currently limiting therapeutic efficacy. First, most anticancer drugs interfere with cell replication and consequently exhibit toxicity toward normal proliferating tissues. Thus, it would be desirable to increase the selectivity of chemotherapeutic agents, i.e., their preferential killing of tumor cells rather than normal cells (*1*). Second, low molecular weight cytotoxic drugs often localize more efficiently in normal tissues, rather than in tumors (*2*). This undesired property, which significantly limits the in vivo efficacy of promising drugs, may be attributed to the high interstitial pressure and to unfavorable blood flow properties within rapidly growing solid tumors (*3*−*5*).

The delivery of biocidal agents to the tumor by means of specific monoclonal antibody−drug conjugates may reverse the biodistribution properties of anticancer drugs and therefore result in improved anticancer selectivity. Indeed, Mylotarg (a monoclonal antibody specific for CD33, conjugated to calicheamicin) has been approved by the American Food and Drug Administration for the treatment of acute myeloid leukemia. Furthermore, Bexxar and Zevalin (two radiolabeled monoclonal antibodies specific for CD20) are expected to be approved by the FDA soon (*6*), while more than 700 antibody-based biopharmaceuticals are currently in clinical development by some 200 biotech companies (*7*). However, despite these promising developments, solid tumors have often proven to be relatively resistant to antibody-based therapies. Typically, antibodies penetrate tumors slowly, displaying good tumor:blood ratios only several hours after intravenous injection (*8*). Furthermore, the so-called "antigen barrier" may sequester the antibody in perivascular regions, preventing a homogeneous distribution within the tumor mass (*9*, *10*). In fact, in patients, typically, only 0.001−0.01% of the injected antibody dose accumulates per gram of solid tumor.

Vascular targeting, i.e., the selective delivery of therapeutic agents (e.g., antibody conjugates) to the tumor neovasculature, has been proposed as an avenue for overcoming the limitations of the antibody-mediated targeting of tumor cells (*11*, *12*). Markers on the tumor neovasculature should be readily accessible to intravenously administered antibody derivatives. There is a growing evidence that the selective damage of tumor neovasculature may lead to massive death of tumor cells, which rely on blood vessels for their supply of nutrients

and oxygen to satisfy their metabolic needs. It is estimated that more than 100 tumor cells rely on one endothelial cell for survival. Furthermore, angiogenesis (i.e., the formation of new blood vessels from preexisting ones) is a general feature in aggressive solid tumors, and a vascular targeting agent should be effective with different tumor types. Notably, angiogenesis plays an important role in relevant diseases other than cancer, including rheumatoid arthritis, psoriasis, and ocular disorders such as the exudative form of age-related macular degeneration and diabetic retinopathy (*13*).

Recently, we have reported on the tumor targeting properties of human monoclonal antibody fragments specific for the ED-B domain of fibronectin, a marker of angiogenesis (*14*−*17*). Antibodies specific to ED-B-containing fibronectin (B-FN) selectively target the neovasculature in vivo, as shown in animal models and in patients, thus opening the possibility to selectively deliver therapeutic molecules to new blood vessels.

The scFv(L19) antibody fragment, with picomolar affinity for the ED-B domain, was chemically coupled to a photosensitizer and mediated the selective and complete occlusion of ocular neovasculature in a rabbit model, after irradiation with near-infrared light (*18*). Nilsson et al. reported that the fusion protein of L19 with the extracellular domain of tissue factor mediates the selective thrombosis of new blood vessels, in different types of murine tumor models (*19*). Furthermore, promising therapeutic results have been obtained in rodents with scFv(L19)-cytokine fusion proteins (*20*, *21*).

B-FN is a marker of the modified ECM associated with the tumor enovasculature. Biodistribution studies have shown that crossing the endothelial cell layer of tumor blood vessels is a slow process and in fact limits the absolute tumor uptake of anti-ED-B antibody fragments, which are typically cleared from blood with half-lives of approximately 30 min (*17*, *35*).

Recently, the transacting transcriptional activater protein (TAT) has been described as a protein with the ability to enter and leave cells in by unconventional manner (classical cell entry mechanisms can be excluded), in a process termed protein transduction (*22*−*24*). TAT is a viral regulatory protein, isolated from human immunodeficiency virus 1 (HIV-1), which binds the viral nascent 5′ leader RNA hairpin transactivation response element (TAR) (*25*, *26*). The TAT sequence responsible for the transduction properties has been identified as the basic domain comprising residues 49−57 (RKKRRQRRR) (*27*), which contains a nuclear localization signal and is involved in the binding of TAR RNA.

In vitro studies with TAT peptides, labeled with fluorescein or magnetic beads, have demonstrated a rapid cell internalization of this peptide, with predominant nuclear localization (*27*, *28*). Furthermore, the intraperitoneal injection of mice with β-galactosidase fused to a TAT peptide resulted in the delivery of the biologically active fusion protein to all tissues in mice, including the brain (*29*). However, the X-Gal detection method used in this article did not allow a quantitative evaluation of targeting efficacy, but only a relative comparison with mice treated with unconjugated β-galactosidase. Nonetheless, these experiments generated excitement in the field of protein-based therapeutics (*30*), since epithelial structures and brain have proven rather impermeable to most proteins.

When an adenovirus was used to continuously express β-glucuronidase, fused to TAT peptide, only a modest increase of enzymatic activity was observed in tissues, as compared to the uptake properties of unmodified β-glucuronidase (*31*). Furthermore, quantitative biodistribution studies performed with ^{99m}Tc-labeled TAT peptide (GRKKRRQRRR) showed an initial whole body distribution, followed by rapid clearance by both renal and hepatobiliary excretion, with low uptake [<1% injected dose per gram of tissue; (%ID/g)] in normal organs not involved in the clearance process (*32*).

The aim of this work was to test whether a site-specific conjugation of TAT peptides to the high-affinity anti-ED-B antibody fragment scFv(L19) would result in improved crossing of endothelial barriers and, consequently, in enhanced tumor uptake. In this article, we show that both TAT peptides with the sequence CGISYGRKKRRQRRR (TAT), made of D- or L-amino acids, exhibited rapid uptake in cells. This peptide sequence corresponds to residues 44−57 of the TAT protein, to which an N-terminal cysteine residues had been appended to facilitate chemical modification. The peptides could be readily conjugated to cysteine-tagged scFv(L19), allowing for a site-specific modification of the antibody with full retention of immunoreactivity. Cell uptake studies of the scFv(L19)−TAT conjugate confirmed that this antibody derivative is taken up by cells, though with a different subcellular pattern. However, quantitative biodistribution experiments performed with radioiodinated scFv(L19)−TAT showed a significantly lower tumor uptake of the immunoconjugate (compared to the unmodified antibody), raising doubts on the usefulness of TAT sequence for the efficient transport of proteins to perivascular regions of tissues in vivo.

EXPERIMENTAL PROCEDURES

Cell Lines and Genes. F9 murine teratocarcinoma were used for the grafting of subcutaneous tumors (*17*)**.** The anti-ED-B human antibody fragment scFv(L19) has been described elsewhere (*16*). The human embryonic kidney (HEK) 293 cell line was obtained from American Type Culture Collection (ATCC; Rockville, MD).

Peptide Synthesis. Peptides (CGISYGRKKRRQRRR) were synthesized as described (*33*) using either all amino acids in L configuration or all D amino acids and amidation at the C-terminus. Peptides were analyzed and purified by C_{18} reversed-phase HPLC at a flow rate of 2 mL/min using as eluent 0.1% trifluoroacetic acid in water modified by a linear gradient of 20−100% methanol over 40 min. A single HPLC peak was observed for each peptide. Peptide identity was confirmed by MALDI-TOF (Protein Service Labor, ETH Zürich, Switzerland).

Cloning of scFv(L19)-Cys. To append residues GGGC at the C-terminus of scFv(L19), the gene coding for scFv(L19) was amplified with the primers *L19Xho1back* (5′ gta tct ctc gag aaa aga gag gtg cag ctg ttg gag tct ggg 3′) and *L19CNot1for* (5′ tta att cgc ggc cgc tca tta aca ccc gcc ccc ttt gat ttc cac ctt ggt ccc ttg 3′). The PCR product was cloned into the yeast *Pichia pastoris* expression vector pPIC9K (Invitrogen, Groningen, The Netherlands), using the *Xho*I/*Not*I sites of the vector.

Expression and Purification of L19Cys. *Pichia pastoris* cells were electroporated with the vector and plated on Minimal Dextrose histidine deficient (MD; Invitrogen) agar plates. The resulting colonies were plated on yeast extract peptone dextrose (YPD; Invitrogen) agar plates with increasing concentrations of G418 (neomycin). Clones of G418-resistant cells (>2 mg/mL) were screened for scFv(L19)-Cys expression by ELISA using biotinylated recombinant ED-B domain of fibronectin as antigen (*34*) and protein A conjugated to HRP as detection reagent (Sigma, Buchs, Switzerland). The

protein was produced in 2 L shaker flasks, using buffered methanol−complex medium (BMMY; Invitrogen) as expression medium and purified from the supernatant by affinity chromatography over antigen columns as previously described (*34*). After dialysis in 10 mM HEPES, pH 6.7, the protein was loaded onto a Resource-S cation exchange column (Amersham Pharmacia Biotech, Dübendorf, Switzerland) and eluted with a linear salt gradient. The homodimeric antibody fraction was collected, and the protein was analyzed by SDS−PAGE (both in reducing and nonreducing conditions) and in native conditions by fast protein liquid chromatography gel filtration on a Superdex S75 column (Amersham Pharmacia Biotech).

Antibody Conjugation. Tat-peptides were dissolved at 0.05 mg/mL in 50 mM phosphate, 100 mM NaCl (phosphate-buffered saline, PBS), at pH 6.5, and treated with a 8-fold molar excess of bis-maleimidohexane (BMH; Pierce, Bezons, France) in dimethylfomamide (DMF) (final concentration 10% (v/v) DMF) for 2 h at 4 °C. The mixture was applied to a small carboxymethyl (CM) sepharose cation exchange column (Amersham Pharmacia Biotech), and the peptide conjugate was eluted with 1 M NaCl. Prior to cross-linking, scFv(L19)-Cys (1 mg/ml) was reduced for 1 h at room temperature with 10 mM dithioerythritol (DTE; Sigma) in PBS, pH 7.4. After desalting on a PD-10 gel filtration column (Amersham Pharmacia Biotech), the reduced antibody was incubated for 2 h at 4 °C in PBS, pH 6.5, with a 10-fold molar excess of the peptide−BMH conjugate. ScFv(L19)−TAT conjugates were purified from unconjugated antibody and peptide on a CM-sepharose cation exchange column. ScFv(L19)-Cys−TAT conjugate was eluted at 50mM phosphate, 300 mM NaCl at pH 7.4. The conjugate was >95% pure as judged by SDS−PAGE.

Fluorescent Labeling of TAT Peptides. Fluorescein-5-maleimide (Molecular Probes, Leiden, The Netherlands) at 100 μM in 10% (v/v) dimethylformamide in PBS, pH 7.4, was incubated with 400 μM of TAT peptides or reduced glutathione as control for 60 min at room temperature. The reaction mixtures were analyzed by reversed-phase HPLC. A single fluorescent peak of equivalent intensity was detected in the reaction mixtures, and no unreacted fluorescein-5-maleimide could be detected. The reaction mixtures were used at 4 μM concentration (corresponding to 1 μM of fluorescently labeled peptide) for cell uptake experiments without further purification. Glutathione was labeled in a similar manner.

Fluorescent Labeling of scFv(L19)-Cys−TAT Immunoconjugates. ScFv(L19)-Cys was reacted with one vial of Cy5 monofunctional reactive dye (Amersham Pharmacia Biotech) according to the manufacturer's instructions, followed by a PD-10 gel filtration column. A portion of the fluorescently labeled antibody (antibody: Cy5 ratio = 0.6:1) was used as control in cell uptake experiments; the remaining portion was conjugated to TAT peptides as described in the section Antibody Conjugation. Immunoreactivity of the labeled antibody was measured by affinity chromatography as described (*17*) and was, in all cases, >89%. Furthermore, dilution series of conjugated and unconjugated antibody gave similar results in ELISA, using biotinylated ED-B as antigen. Cy5-labeled scFv(L19)-Cys and scFv(L19)-Cys−TAT conjugates were diluted with PBS to a final concentration of 0.1 mg/mL and used as 7-fold stock solution for cell uptake experiments. The protein concentration was determined by measurement of the absorbance at 280 and 650 nm and by Coomassie blue staining following SDS−PAGE.

Fluorescence Microscopy. HEK cells were grown on glass cover slips to 30−50% confluency. Fluorescently labeled peptides (1 μM), scFv(L19)-Cys (0.5 μM) or scFv(L19)-Cys−TAT conjugates (0.5 μM) were added to the culture medium. Cells were incubated for 15−30 min at 37 °C. After being washed three times with PBS, cells were fixed in 3% paraformaldehyde in PBS for 10 min at room temperature. Cells were rinsed with PBS and treated with 0.1M glycine in PBS, and nuclei were then stained with Dapi (Hoechst 33342) at 100 ng/mL. The cells were washed again, and then preparations were mounted in Mowiol (Calbiochem, Laufelfingen, Switzerland) and analyzed by confocal laser microscopy on a Zeiss LSM 410 inverted microscope (lasers: HeNe 633 nm, HeNe 543 nm, Ar 488/514 nm and ArUV 364 nm). Images were processed on a Silicon Graphics workstation using IMARIS, a 3D multichannel image processing software for confocal microscopic images (Bitplane, Zurich, Switzerland).

Biodistribution Experiments. Biodistribution experiments in mice bearing F9 tumors were performed as described (*17*). Briefly, scFv(L19)-Cys and purified scFv(L19)-Cys−TAT^{D} conjugates were radioiodinated with iodine-125, and approximately 2 mg (2−4 mCi) were injected into the tail vein of 12−14 weeks old, female SV129 mice (M&B A/S, Ry, Denmark) bearing subcutanously implanted F9 murine teratocarcinoma. Mice were sacrificed 1 h or 24 h after injection, the organs were weighed, and the radioactivity was counted. Targeting results of representative organs are expressed as percent injected dose per gram of tissue (%ID/g). Experiments were performed in agreement with Swiss regulations and under a "Tumor targeting" Project license issued to D. N. by the "Kantonales Veterinäramt des Kantons Zürich" (Bewilligung 80/2000). No free peptide was detectable in the injected solution as determined by radiography of dried SDS−PAGE gels. The immunoreactivity of the radiolabeled antibodies was determined by a radioimmunoassay, using ED-B as antigen and measuring the bound radioactivity. Blood and urine of the animals were collected at 1 h after injection to assess the serum stability of the injected scFv(L19)-Cys−TAT^{D} conjugate in vivo. Cells were spun down, and the supernatant was analyzed by SDS−PAGE, followed by radiography.

RESULTS

Localization of B-FN in Tumors. Quantitative biodistribution studies performed with the L19 antibody, specific to the ED-B domain of fibronectin, have shown that different antibody formats deliver different amounts of antibody to the tumor. In particular, antibody fragments with longer half-life in serum (e.g., diabodies, minibodies, IgG) mediate a higher accumulation in the tumor, as compared to scFv(L19) preparations (*16*, *35*). While these data suggest that B-FN is mainly localized in the subendothelial ECM and is therefore separated from the blood stream by a layer of endothelial cells, a formal demonstration has still been missing.

We investigated sections of murine F9 teratocarcinoma by confocal laser immunofluorescence microscopy using the L19 antibody. Figure 1A,B shows that B-FN (red) is located in the abluminal aspects of the tumor blood vessels (stained in green with an anti-actin antibody).

TAT Peptides and Cell Transduction. At the beginning of our work, it was not known whether TAT peptides, composed of D-amino acids rather than L-amino acids, would be capable of cell transduction. For practical

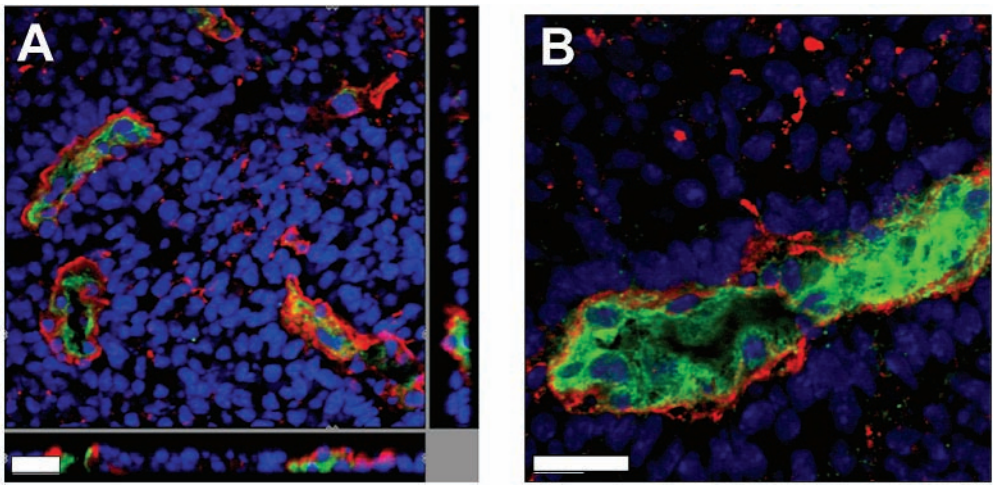

Figure 1. Three-color confocal fluorescence microscopic images of a murine F9 teratocarcinoma section stained with the L19 antibody (red) specific to the ED-B domain of fibronectin, a marker of angiogenesis. Cell nuclei are stained with DAPI (blue) while actin staining (green) outlines the endothelial cells of the tumor blood vessels. Bars: 20 mm.

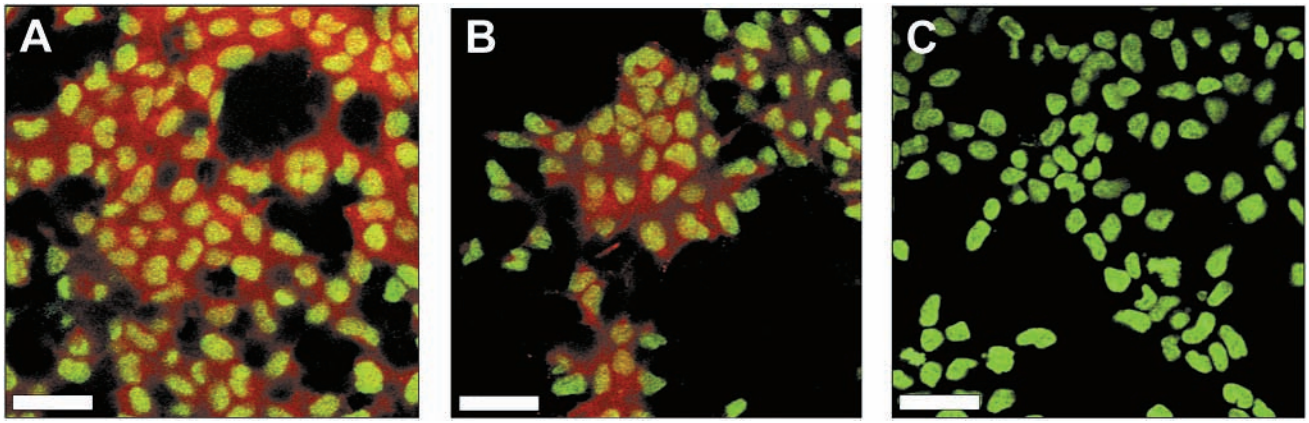

Figure 2. Confocal micrograph of intracellular accumulation of fluorescein labeled TAT peptides and fluorescein-labeled glutathione in HEK 293 cells. Cells were incubated for 15 min at 37 °C with either fluorescein−TAT^L (A), with fluorescein−TAT^D (B), or with fluorescein-labeled glutathione (C), all at 1 mM concentration. Panels show double staining of cells with fluorescein (red) and DAPI for visualization of cell nuclei (green). Bars: 40 mm.

applications, the resistance to proteolysis of TAT peptides composed of D-amino acids would offer significant advantages.

We synthesized the peptide CGISYGRKKRRQRRR (TAT), using either L- or D-amino acids (hereafter termed TAT^L and TAT^D). This peptide sequence had previously been shown to efficiently enter cells (*29*). The thiol group of the N-terminal cysteine residue was used for the stable conjugation of the peptide to maleimido-5-fluorescein. Figure 2A and 2B shows the results of cell uptake experiments, performed on human embryonic kidney cells (HEK 293) using fluorescein−peptide conjugates. Cell incubation with 1 μM fluorescein−TAT^L and fluorescein−TAT^D yielded a strong and homogeneous fluorescent cell staining within the cytoplasm and the nuclei, similar to the one previously reported for the L-peptide. Simultaneous confocal laser microscopic detection of DAPI staining of cell nuclei (Figure 2A−C) confirmed that virtually all the HEK 293 cells had taken up the peptide conjugates. By contrast, cell incubation with fluorescein−glutathione (used as negative control peptide) did not show a significant peptide uptake (Figure 2C).

The fact that fluorescein−TAT^L and fluorescein−TAT^D are taken up by cells with similar efficiency indicates a receptor-independent cell entry mechanism.

Antibody−TAT Peptide Conjugates and Cell Transduction. We used 1,6-bis-maleimidohexane as a homobifunctional cross-linker, to mediate the coupling of TAT^D to scFv(L19)-Cys (Figure 3A). A C-terminal cysteine residue had been appended to this antibody fragment, specific for the ED-B domain of fibronectin, a marker of angiogenesis (*14*, *15*), to allow its site-specific chemical modification, without loss of immunoreactivity (*36*−*38*). Similar to what has recently been described for other antibody fragments (*39*), we expressed scFv(L19)-Cys in *Pichia pastoris*, since this expression system provided yields which were significantly higher, compared to *E. coli*. The antibody fragment was purified to homogeneity by affinity chromatography, using an ED-B resin (*40*).

Figure 3B shows a nonreducing SDS−PAGE analysis of the scFv(L19)-Cys before and after conjugation to TAT^D. Lane 1 shows that approximately 50% of scFv-(L19)-Cys was present as a disulfide-bonded homodimer, which could be reduced using dithioerythritol (lane 2). Incubation of reduced scFv(L19)-Cys with an excess of the reaction product between TAT and a molar excess of 1,6-bis-maleimidohexane (TAT-BMH) resulted in the complete coupling of both TAT^L and TAT^D to the antibody fragment (lane 3). Unreacted TAT-BMH and antibody were separated from the scFv(L19)-Cys-TAT conjugates

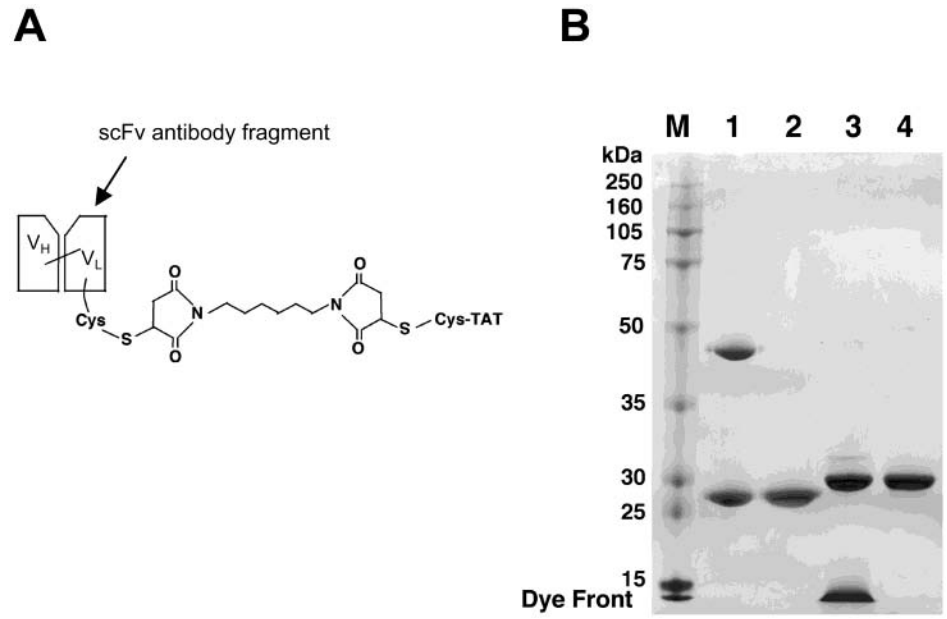

Figure 3. (A) Schematic representation of scFv(L19)-Cys conjugated to a TAT peptide by means of a bis-malimidohexane (BMH) cross-linker. The thioether bonds of cysteine residues are indicated. (B) Nonreducing SDS−PAGE analysis documenting the conjugation of scFv(L19)-Cys to TAT-peptides, using bis-maleimidohexane (BMH) as cross-linker. M: Molecular weight marker; Lane 1: scFv-(L19)-Cys; Lane 2: reduced scFv(L19)-Cys; Lane 3: Reaction mix after incubation of scFv(L19)Cys with TAT-BMH conjugate showing the band of the reacted scFv(L19)-Cys−TAT and the one of the unreacted TAT-BMH (used in molar excess); Lane 4: purified scFv-(L19)-Cys−TAT conjugate.

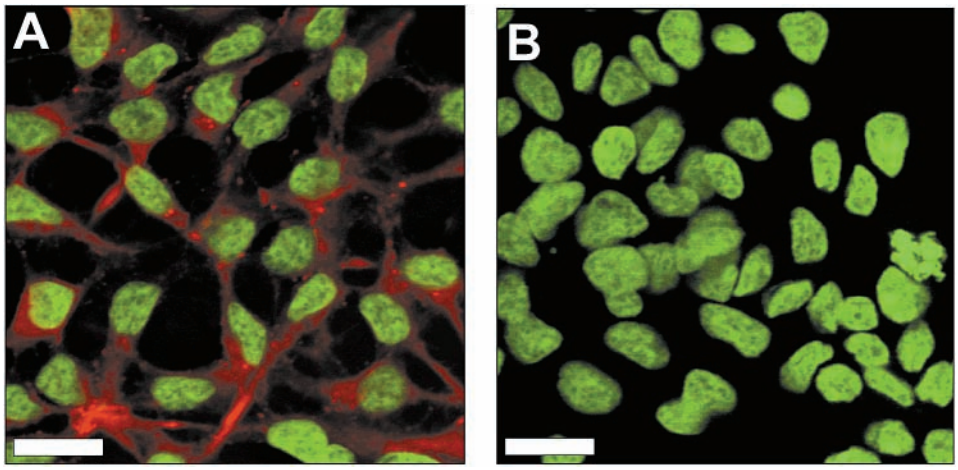

Figure 4. Confocal micrograph showing the intracellular accumulation of Cy5-labeled scFv(L19)-Cys−TAT^D as compared to the one of unconjugated, Cy5 labeled scFv(L19)-Cys. HEK 293 cells were incubated for 30 min at 37 °C with either Cy5-labeled scFv-(L19)-Cys−TAT^D or Cy5-labeled scFv(L19)-Cys (B). Panels show double labeling of cells with Cy5 (red) and the DAPI (green). Bars: 20 mM

by CM-sepharose cation exchange chromatography, yielding a pure antibody−peptide conjugate (lane 4).

To assay the cell transduction activity of the scFv(L19)-Cys-TAT, the scFv(L19)-Cys was labeled with the red fluorophore Cy5, prior to coupling to TAT. Fluorescence microscopic analysis of HEK 293 cells exposed to either Cy5-scFv(L19)-Cys−TAT^D (Figure 4A) or Cy5-scFv(L19)-Cys (Figure 4B) reveals that only the TAT-modified antibody is taken up by the cells. When compared to unconjugated TAT peptides (Figure 2), Cy5-scFv(L19)-Cys−TAT^D shows a compartmentalized cell uptake, which does not overlap with the nuclei.

Tumor Targeting Experiments. To test whether conjugation to TAT peptides could improve the tumor targeting properties of scFv(L19)-Cys, we performed quantitative biodistribution studies in in immunocompetent Sv129 mice, bearing a subcutaneously grafted syngeneic F9 teratocarcinoma. On the basis of the similar cell transduction properties of TAT^D and TAT^L, we decided to use TAT^D for all the following experiments, since this peptide is resistant to proteolysis. ScFv(L19)-Cys and scFv(L19)-Cys−TAT^D were radiolabeled with iodine-125 using the Iodogen method, to a specific activity of 0.5−1 μCi/μg. The labeled antibodies retained >86% immunoreactivity, as assessed by affinity chromatography and by radioimmunoassay (RIA) (*16*, *17*).

Mice were injected intravenously with 2 μg of fusion protein and sacrificed at an early and a late time point (1 h or 24 h) after injection. The in vivo stability of the radiolabeled proteins was confirmed by SDS−PAGE, followed by radiography, of blood and urine samples collected 1 h after injection. Table 1 shows the biodistribution results, expressed as percent injected dose per gram of tissue or fluid (%ID/g) for tumor, blood, and relevant organs. Unconjugated scFv(L19)-Cys showed a significant accumulation in tumors (tumor:blood ratio =

Table 1. Biodistribution of scFv(L19)-TAT^D and scFv(L19)-Cys[a]

	ScFv(L19)-Cys, %ID/g	ScFv(L19)-Cys-TAT^D, %ID/g
	1 Hour	
tumor	11.8 ± 1.4	4.1 ± 1.1
spleen	4.2 ± 0.3	11.8 ± 2.0

[a] Biodistribution results of SV129 mice bearing the F9 teratocarcinoma at 1 h and 24 h after injection with 2 mg of radioiodinated ScFv(L19)-Cys or ScFv(L19)-Cys−TAT^D conjugate. Antibody doses in the different organs are expressed as percent injected dose/gram tissue (%ID/g).

9.1:1 at 24 h), similar to what had previously been observed for scFv(L19) devoid of the C-terminal Cys residue (*16*, *17*, *41*). However, conjugation of scFv(L19)-Cys to TAT^D resulted in a severely reduced tumor targeting performance compared to the unconjugated antibody (with tumor:blood ratio = 2.5: 1 at 24 h).

Similar to scFv(L19) (*17*), scFv(L19)-Cys was cleared from circulation through the kidneys (Table 1). By contrast, scFv(L19)-Cys−TAT^D showed a rapid uptake in the liver at early time points, similar to the one reported in biodistribution studies for unconjugated TAT peptides (*32*). High liver, kidney, and spleen values persisted up to 24 h, whereby tumor values followed the levels of normal organs (Table 1). In summary, site-specific conjugation of scFv(L19)-Cys to TAT^D abolishes the tumor-targeting properties of this antibody fragment, while enhancing antibody uptake in the liver and in the spleen, without affecting the other normal organs.

DISCUSSION

In this article, we show for the first time that TAT^D and TAT^L have similar cell transduction behavior (Figure 2). This observation strongly supports the existence of a receptor-independent uptake mechanism, consistent with findings reported by other groups (*30*, *42*). The cell uptake of TAT^D may have practical consequences, since peptides made of D-amino acids are not proteolyzed, thus facilitating both in vitro and in vivo applications. Furthermore, D-peptides are not presented by MHC Class II molecules and should not elicit a cellular immune response (*43*).

Our experiments show that TAT also facilitates the uptake of chemically modified antibody fragments (Figure 4), compared to unmodified antibodies. However, the transduction of TAT-conjugated antibody fragments leads to a compartmentalized cell uptake, thus potentially limiting the applicability of TAT-based cell transduction technology either to smaller molecules or to highly bioactive macromolecules.

The most surprising finding of our study was the fact that TAT^D completely abolished the tumor targeting properties of scFv(L19), a human antibody fragment specific for a marker of angiogenesis. ScFv(L19) has previously shown excellent biodistributions in animal tumor models and has entered clinical trials for the immunoscintigraphic detection of tumors in patients with cancer. The inability of scFv(L19)-Cys−TAT^D to target tumors has to be attributed to an inefficient crossing of the endothelial cell layer lining tumor blood vessels (acting as a physical barrier to B-FN, located in the perivascular ECM), since this site-specific conjugate retains full immunoreactivity. The rapid liver uptake of scFv(L19)-Cys−TAT^D may further contribute to the observed lower tumor values (Table 1). Similar findings have been reported for an unconjugated radiolabeled TAT^L peptide, which have recently been investigated in quantitative biodistribution studies in mice (*32*).

The ability of scFv(L19) to target tumors has not been affected by conjugation of this antibody fragment to radionuclides (*16*, *17*), or small organic molecules (*18*, *40*, *41*). Furthermore, excellent biodistribution results in tumor-bearing mice were observed with scFv(L19) fused to a procoagulant protein domain (*19*) and to the cytokines interleukin-2 (*21*) and interleukin-12 (*20*), demonstrating the versatility of scFv(L19) as a tumor targeting vehicle.

However, we have recently found that fusion of scFv(L19) to the proangiogenic cytokine VEGF-165 (but not to the shorter isoformVEGF-121) completely abolished the tumor-targeting property of the antibody, while not significantly affecting blood clearance (*44*). VEGF-165 and VEGF-121 differ by a positively charged heparin-binding peptidic moiety, which is inserted in the VEGF-165 molecule by a mechanism of alternative splicing at the level of the pre-mRNA. The observation that the addition of positively charged moieties (such as TAT^D or VEGF-165) impair the tumor-targeting properties of antibody fragments prompts more quantitative investigations on the interplay between protein charge and vascular permeability.

The poor efficiency of TAT-mediated cell transduction in vivo has recently also been reported by other groups. Tremblay and co-workers showed that the direct delivery of a TAT−eGFP fusion protein to muscle tissue, using subcutaneous or intraarterial injections, only led to few positive fibers in the muscle periphery or surrounding the blood vessels (*45*). As mentioned previously, another study revealed that the continuous in vivo production of TAT−β-glucuronidase from adenovirally transduced hepatocytes only lead to moderately increased uptake of the enzyme in certain tissues (*31*). Some authors have suggested that misfolded proteins may be more amenable to TAT-mediated cell transduction (*46*, *47*). However, this avenue appears to be of little practical utility in biomedical applications, since it may no be able to meet Good Manufacturing Practice standards, required by regulatory authorizations.

The poor in vivo performance of TAT-modified antibodies suggests that other methodologies (such as fusion to vasoactive cytokines) may be more general avenues for improving antibody uptake in the tumor environment (*48*). In a broader perspective, the present article (and a previous related study, performed with unmodified TAT peptides (*32*)) underlines the need to perform quantitative biodistribution studies in animal models, when assessing the potential of TAT peptides and other cell transducing agents, as vehicles for crossing membrane barriers in vivo.

Liposomes are of interest as drug delivery tools for therapy of cancer and infectious diseases. We investigated conjugation of epidermal growth factor, EGF, to liposomes using the micelle-transfer method. EGF was conjugated to the distal end of PEG−DSPE lipid molecules in a micellar solution and the EGF−PEG−DSPE lipids were then transferred to preformed liposomes, either empty or containing the DNA-binding compound, water soluble acridine, WSA. We found that the optimal transfer conditions were a 1-h incubation at 60 °C. The final conjugate, ^{125}I-EGF−liposome−WSA, contained approximately 5 mol % PEG, 10−15 EGF molecules at the liposome surface, and 10^4 to 10^5 encapsulated WSA molecules could be loaded. The conjugate was shown to have EGF-receptor-specific cellular binding in cultured human glioma cells.

INTRODUCTION

Liposomes have gained considerable interest as drug delivery tool for therapy of cancer and infectious diseases. They have therapeutic advantages, such as the ability to deliver large amounts of drugs to specific sites, spare healthy tissue from toxic effects, and increase the systemic circulation time of the drug (*1*−*6*). However, one problem with liposomes is their poor stability in the circulatory system. To improve this, poly(ethylene glycol), PEG, is frequently used as a component in the lipid bilayer. PEG stabilizes the liposomes sterically and also effectively protects the liposomes from degradation by the reticuloendothelial system (RES) (*7*−*9*).

Specific accumulation of liposomal substances in tumor cells may be achieved by attachment of targeting agents to the liposomal surface. One way to gain both stability and specificity is to use PEG as a spacer and conjugate the targeting agent to the terminus of the polymer (*10*). We chose this approach and developed a conjugate of epidermal growth factor (EGF) attached to PEG-stabilized liposomes. EGF can be used as a tumor-seeking agent since the EGF receptor is overexpressed in many tumor cells including gliomas and squamos carcinomas (*11*). EGF is a stable protein with well-defined reaction sites for conjugation. It is also known that EGF undergoes receptor-mediated endocytosis, which brings the ligand−receptor complex inside the cell.

The compound Water-Soluble Boronated Acridine-1 (WSA) is a candidate drug for boron neutron capture therapy, BNCT (*12*), and can be actively loaded into liposomes using a pH-gradient procedure (*13*). WSA consists of a boron cage with 10 boron atoms coupled to a DNA intercalating acridine analogue and spermidine to achieve high water solubility. The compound is primarily developed for BNCT, and the stable nuclide, ^{10}B, produces a helium and a lithium ion after neutron capture-induced fission (*14*). Healthy tissue can potentially be saved since only the cells that take up the compound are affected by the ion particles (*15*).

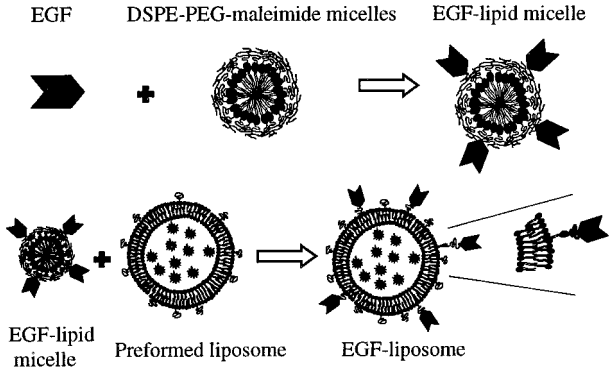

Figure 1. Schematic drawing of the micelle-transfer method. EGF is attached to DSPE−PEG−maleimide lipids in micelles via a thiol linkage. The EGF lipids, in the form of micelles, are mixed with preformed liposomes, and the EGF−PEG−DSPE molecules are thereby incorporated into the liposome membranes

We investigated the possibility to attach EGF to DSPC/cholesterol/DSPE−PEG liposomes, empty or loaded with the drug WSA, using the micelle transfer method (Figure 1). EGF was coupled to maleimide−PEG−DSPE molecules in micelles to achieve a protocol that can easily be adjusted to new targeting agents and new drugs (*16*). The EGF-conjugated micellar lipids were then incorporated into preformed liposomes (*17*). This approach is appealing since the development of new formulations can be reduced to only redesigning the conjugation or the loading step.

Optimizations of the micelle transfer conditions, i.e., time, temperature, and concentration, were performed. We studied the stability of the formulation regarding

ligand attachment and leakage of the encapsulated compound. The receptor specificity was analyzed by incubating the EGF liposome conjugate with U-343 MGa glioma cells (*18*) with either blocked or nonblocked receptors.

MATERIALS AND METHODS

Murine EGF, obtained from Chemicon International , was labeled with ^{125}I from Amersham Pharmacia Biotech, Uppsala, Sweden. The protein was modified with 2-iminothiolane (Traut's Reagent from Sigma, St. Louis, MO) to obtain thiol groups for conjugation. The Sephadex G-25 columns (NAP-5 columns), the Sephadex G-150 and Sepharose CL-4B gels used for separation, and the empty PD-10 columns were purchased from Amersham Pharmacia Biotech, Uppsala, Sweden. NHS-PEG(3400)-maleimide was purchased from Shearwater Polymers, Huntsville, AL, and 1,2-disteaoryl-*sn*-glycero-3-phosphatidylethanoleamine (DSPE) was obtained from Avanti Polar Lipids, Alabaster, AL. The lipids forming the liposomes 1,2 disteaoryl-*sn*-glycero-3-phosphatidylcholine (DSPC) and 1,2-disteaoryl-*sn*-glycero-3-phosphatidylethanolamine-*N*-[poly(ethylene glycol)-2000] (DSPE−PEG) were purchased from Avanti Polar Lipids. Cholesterol (Cho) was obtained from Sigma Aldrich (Stockholm, Sweden). The DNA binding compound, 1,8-diamino-4-*N*-3-[12-(*N*-9-acridinyl-3-aminopropyl)-*p*-carborane-1-yl]propyl-4-azo-octane hydrogen chloride (WSA, Water-Soluble Acridine Derivative) was produced as described (*12*).

The cell line, U-343 MGaCl2:6 (a subclone of U-343MG, hereafter referred to as U-343 MGa), was grown in Ham's F-10 medium supplemented with 10% FCS and PEST (penicillin 100 IU/mL and streptomycin 100 μg/mL), L-glutamine (2 mM), and amphotericin B (2.5 μg/mL) (all from Biochrom KG, Berlin, Germany). The cells were incubated at 37 °C in humidified air containing 5% CO_2.

Micelles. The micelles were composed of DSPE−PEG−maleimide lipids. NHS−PEG(3400)−maleimide was coupled to the phospholipid DSPE as described (*19*) and dried to form a lipid film. The micelles were formed by hydrating the dried lipid DSPE−PEG−maleimide film in Hepes buffer (20 mM with 150 mM NaCl pH 7.4) at a concentration above the critical micelle concentration, approximately 5 μM (*20*).

Liposomes. The liposomes were composed of DSPC: Cho (60:40 molar ratio), and they contained additionally 0, 3, or 5 mol % DSPE−PEG compared to total lipid. The liposomes were prepared by freeze thawing and extrusion (*13*). Mostly unilamellar liposomes with 100 nm diameter were produced. Liposomes loaded with the DNA binding agent WSA were identical to the above. The loading of WSA was performed using a pH gradient as described (*13*). Briefly, liposomes with an acidic interior (citrate buffer, 300 mM pH 4) were created, and the pH on the outside of the liposomes was raised to 7.8 with sodium carbonate. This pH gradient caused the WSA molecules to enter the liposomes actively and be trapped inside with a concentration up to 300 mM, which gives approximately 10^5 to 10^6 boron atoms per liposome (*13*). Liposomes with an acidic interior, but without WSA, were used in a control experiment.

Radiolabeling of EGF. EGF, diluted in 0.1 M sodium phosphate buffer (0.1 M NaCl, pH 7.5) (25−75 μL, 1 μg EGF/μL) was labeled with 2−7 MBq ^{125}I by the chloramine-T method. The desired amount of ^{125}I (1−5 μL) was added to the EGF solution and 10 μL chloramine-T (2 μg/μL in 0.1 M sodium phosphate buffer 0.1 M NaCl, pH 7.5) was added and mixed for 1 min. The reaction was stopped by 25 μL sodium metabisulfite 25 μL (2 μg/μL in 0.1 M sodium phosphate buffer 0.1 M NaCl, pH 7.5). The labeled protein was separated from reagents by gel filtration on a Sephadex G-25 column (NAP-5) and eluted in 500−600 μL with Traut's buffer (50 mM triehanolamine 0.15 M NaCl, 1 mM EDTA, pH 8).

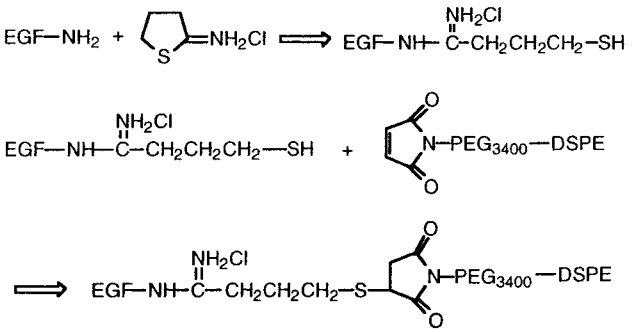

Figure 2. Scheme of the reactions of thiolation of EGF with Traut's reagent (2-iminothiolane) and the thiol conjugation of EGF−SH to maleimide−PEG−DSPE.

Conjugation of ^{125}I-EGF to Maleimide−PEG−DSPE in Micelles (Figure 2). The labeled protein was modified with an excess of Traut's reagent (300−700 μg) for 1h in room temperature (20−23 °C) under argon. Excess reagent was removed by gel filtration on a NAP-5 column eluted with 0.1 M sodium phosphate buffer (0.1 M NaCl, pH 7.5). The thiolated ^{125}I-EGF was mixed with the micelle solution at room-temperature overnight (16−24 h) at either 1:100 or 1:30, EGF: phospholipid molar ratio (PL concentration 0.35 to 0.12 mM). To remove unbound EGF, the sample was separated by gel filtration on a small (PD-10 size) column with Sephadex G-150 gel and eluted with HEPES buffer in 600 μL fractions. The fractions were measured on a gamma counter (1480 Wizard 3, Wallac, Turku, Finland), and the fraction of EGF conjugated to the micellar lipids was determined.

Transfer of ^{125}I-EGF−PEG−DSPE to Liposomes. The influence of various parameters on the rate and the amount of incorporated lipid was studied. The parameters were temperature (room temperature (RT), 37 °C, and 60 °C), lipid concentration (0.5−2.5 mM total lipid), the ratio of liposomal lipid to micellar lipid (1−5% micellar lipid:liposomal lipid), and concentration of PEG-DSPE in the preformed liposomes (0%, 3%, and 5% PEG). The amount of ^{125}I-EGF−PEG−DSPE incorporated was studied after 1, 4, and 24 h, and the same procedure was used for all experiments: ^{125}I-EGF−PEG−DSPE micelles were mixed with the liposome solution under the varying conditions and for the desired time. The transfer was performed in a heating block. After, EGF−liposomes were purified by gel filtration on a small column (PD-10 size) with Sepharose CL-4B gel, eluted with HEPES buffer. The fraction of ^{125}I-EGF−PEG−DSPE incorporated into the liposomes was determined by measuring the eluted fractions (0.5 mL) on a gamma counter. The final conjugates are hereafter referred to as ^{125}I-EGF−liposome−WSA for the loaded liposomes and ^{125}I-EGF−liposome for the unloaded.

Stability and Leakage. The stability of the conjugate was tested by incubation of the ^{125}I-EGF−liposome conjugate diluted in culture medium for up to 3 weeks in 4 °C or 1 week in 37 °C. After incubation, the sample was separated by gel filtration on a CL-4B column. The amount of ^{125}I found in the liposome fraction was determined and was assumed to constitute intact conjugate, and a comparison was made with the total amount of ^{125}I eluted from the column. The leakage of the

encapsulated compound was determined as described (*13*). Briefly, the liposomal sample was separated on a gel filtration column (NAP-5), and the absorbance of lysed separated sample was compared with the absorbance of the lysed initial sample.

Stability of EGF at Different Temperatures and Times. EGF (2.5 μg) was labeled with 10 MBq ^{125}I (as described above) and after purification incubated in HEPES buffer at RT, 37 °C, and 60 °C for 1 and 24 h. The binding activity was examined with U-343 MGa cells grown in small cell dishes (3 cm) with approximately 600000 cells in each dish. The cell dishes were first washed with serum-free medium and the ^{125}I-EGF samples were added (approximately 10 ng/dish). As a control, preincubated dishes with an excess of unlabeled EGF were used. After 30 min, the incubation media was removed, and the cells were washed 6 times with serum-free medium. The cells were trypsinized for 15 min and then resuspended in medium to a total volume of 1.5 mL per cell dish. Of this, 0.5 mL was used for cell counting and 1 mL was measured in a gamma counter to determine the bound radioactivity. The amount of bound ligand was determined and compared to untreated ^{125}I-EGF.

Displacement Test. A displacement study was made to analyze the specificity of the EGF–liposome conjugate. U-343 MGa cells were grown in 3-cm cell dishes, approximately 10^6 cells per dish. Loaded liposome conjugate, 0.5 mL (^{125}I-EGF–liposome–WSA), or unloaded liposome conjugate (^{125}I-EGF–liposome) was added to dishes with 0.5 mL of nonradioactive EGF at the concentration 0, 0.001, 0.01, 0.1, 1, 10, 100, 1000, or 10,000 ng/mL. The cells were incubated with the liposomes for 4 h, the incubation media was removed, and cells were washed six times with cold serum-free medium, trypsinized (trypsin EDTA), and resuspended (total volume 1.5 mL/dish). A volume of 0.5 mL was used for cell counting, and 1 mL was measured in the gamma counter to determine the amount of liposome conjugate bound to the cells. In the displacement study, the liposomal compounds were prepared as described above, and the following composition was used: 3% DSPE-PEG liposomes, 25 μg of EGF labeled with 50 MBq ^{125}I, conjugation overnight, transfer of micellar lipids at 60 °C for 16 h, 3% micellar lipid:liposomal lipid ratio for the unloaded liposomes, 5% micellar lipid:liposomal lipid ratio for the loaded liposomes (to compensate for the lower incorporation level, see Results).

RESULTS

Conjugation of ^{125}I-EGF to Maleimide–PEG–DSPE in Micelles. The coupling efficiency was determined by separating the ^{125}I-EGF micelle conjugate from free ^{125}I-EGF by gel filtration on a Sephadex G-150 column (Figure 3). Approximately 30% of the added ^{125}I-EGF was coupled to the micelles for both 1:100 and 1:30 molar ratio. The figure shows the 1:30 case; a similar pattern was obtained for the 1:100 case. This gives approximately 1 EGF /100 lipids for the highest molar ratio. The conjugation of thiolated ^{125}I-EGF to the maleimide groups on the lipids was shown to be thiol-specific (Figure 3).

Transfer of ^{125}I-EGF–PEG–DSPE to Liposomes. The ^{125}I-EGF–PEG–DSPE transfer efficiency into both WSA-loaded and -unloaded liposomes was examined during the conditions described below.

Temperature and Time. Three different temperatures were studied: RT, 37 °C, and 60 °C (Figure 4). We found

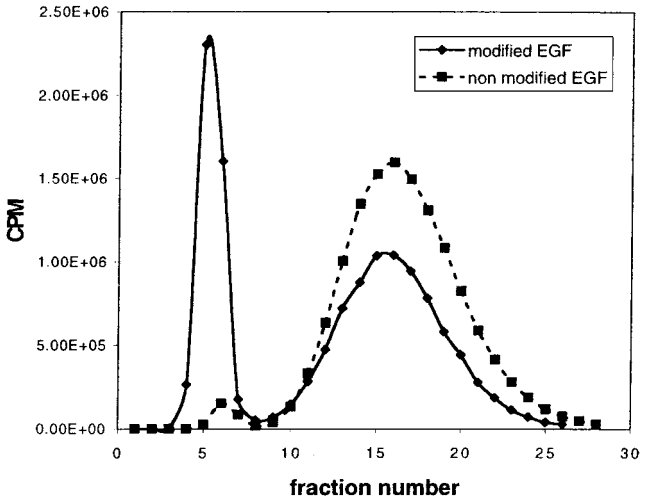

Figure 3. Gel filtration chromatogram for purification of ^{125}I-EGF–PEG micelles. The peak in fraction 4–8 represents the ^{125}I-EGF–PEG-lipid micelles. Fraction 10–25 is ^{125}I-EGF and ^{125}I. The solid line is the elution curve for ^{125}I-EGF modified with Traut's reagent to obtain a thiol group for conjugation to the maleimide group of the maleimide–PEG–DSPE lipid. The dotted line is the elution curve for unmodified ^{125}I-EGF and only a limited unspecific attachment (see fractions 6 and 7) to the maleimide group is seen.

that 60 °C was the best of the tested temperatures for the incorporation of EGF lipids into liposomes. At this temperature no further increase in the amount of incorporated ^{125}I-PEG–DSPE could be seen after 1 h. For RT and 37 °C, the amount incorporated increased with time, but was after 24 h still not as much as 60 °C at 1 h. A smaller amount of lipid was incorporated into the liposomes when the liposomes were loaded with the DNA binding compound WSA (Figure 4). After 1 h at 60 °C, about 30% of the added micellar lipid (Figure 4D) had entered in WSA-loaded liposomes whereas in empty liposomes, with the same PEG amount, this value was about 60% (Figure 4B). To test whether the acidic interior, pH 4, of the loaded liposomes affected their ability to incorporate EGF–lipids, unloaded liposomes with a similar acidic interior were used in control experiments. The level of incorporation at 60 °C (50%) was about the same as for nonacidic unloaded liposomes (data not shown), indicating that the lower level of incorporation in the loaded liposomes was not due to their acidic interior.

Different PEG–Lipid Concentrations in the Liposomes. The PEG–lipid ratio in the liposomes before transfer did not seem to affect the incorporation of ^{125}I-EGF–DSPE at 60 °C or RT (Figure 4A,B,C). Somewhat lower incorporation was seen at 60 °C for 1 and 4 h with 5% PEG, but this increased with time (Figure 4C). Transfer at 37 °C with 0% PEG gave lower incorporation than with 3% and 5% PEG during all studied times (Figure 4A,B,C). The overall transfer with WSA-loaded liposomes was much lower than for liposomes with no load (Figure 4D), as mentioned above. For the loaded liposomes, we chose to continue with 3% PEG since PEG–lipid is needed for the stability and at least after shorter transfer times, the larger amount, 5%, might reduce the incorporation of ^{125}I-EGF–PEG–DSPE.

Concentration Effects. The incorporation of ^{125}I-EGF–DSPE was analyzed as a function of the amount of added ^{125}I-EGF–DSPE. Three different concentrations of ^{125}I-EGF–DSPE were applied. A saturation effect could be seen since 3% and 5% ^{125}I-EGF–DSPE to liposomal lipid gave about the same incorporation, about twice the

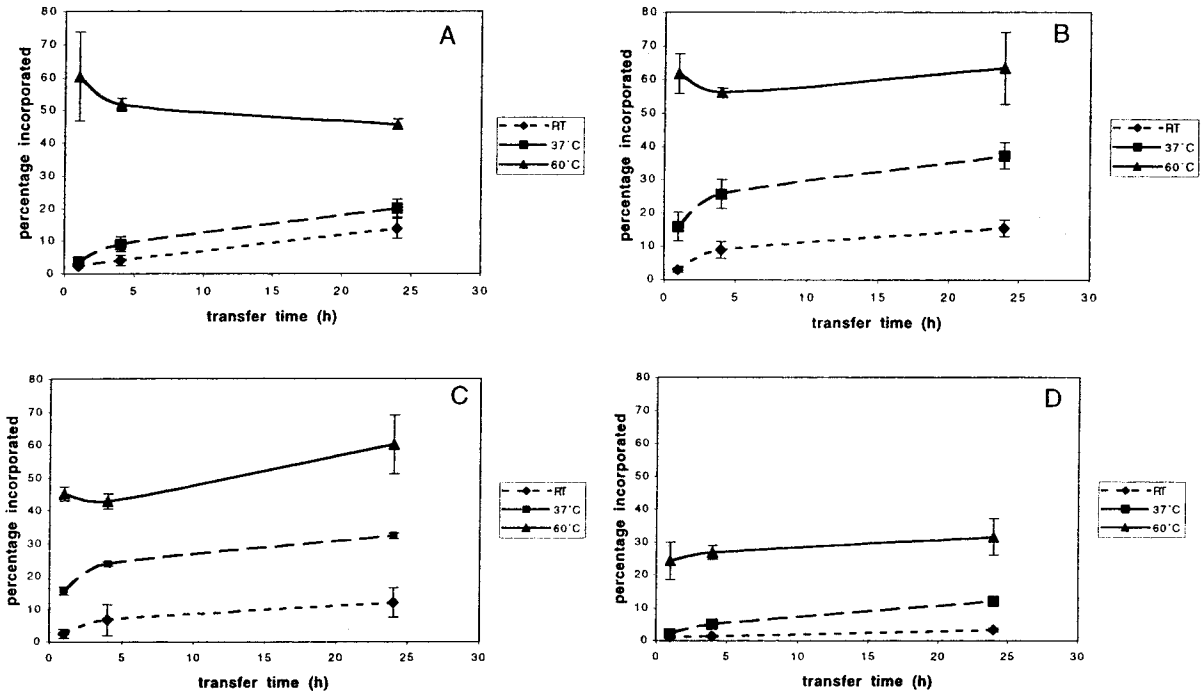

Figure 4. Incorporation ability of ^{125}I-EGF−PEG−DSPE lipid molecules into preformed liposomes. The percentage of added lipid incorporated in the liposome membrane was measured using the ^{125}I-label on EGF. The amount of added EGF lipid was 2.7% to total liposomal lipid. A: 0% PEG in the preformed liposomes, B: 3% PEG-DSPE to total lipid, C: 5% PEG-DSPE to total lipid, D: WSA loaded liposomes with 3% PEG-DSPE, to total lipid. Error bars represent maximal errors from double experiments.

Table 1. Micelle Transfer to Liposomes as a Function of the Percentage Micellar EGF−Lipid, ^{125}I-EGF−PEG−DSPE, to Liposome Lipid[a]

^{125}I-EGF−PEG−DSPE to liposome lipid, ratio	% incorporated	nmol EGF/ mmol lipid
0.01	66 ± 1	19 ± 1
0.03	52 ± 1	42 ± 2
0.05	35 ± 2	46 ± 1

[a] Incorporation was performed for 1 h in 60 °C and with an initial concentration of 3% PEG in the liposomes.

Table 2. Stability of the ^{125}I-EGF−Liposome−WSA Conjugate after Storage in Complete Culture Medium at Either 4 or 37 °C[a]

time	4 °C	37 °C
2 days	97%	90%
5 days	nd	85%
1 week	nd	79%
3 weeks	90%	nd

[a] The result is given as the percentage of total radioactivity that remained in the liposome fraction. nd = not determined.

amount of EGF incorporated compared to 1% (Table 1). The total lipid concentration in the reaction tube did not affect the incorporation of micelles when 3% ^{125}I-EGF−DSPE to liposomes was applied. No difference regarding the transfer could, in this case, be seen for 2.5 mM, 1 mM, and 0.5 mM total lipid (data not shown).

Stability and Leakage. The stability was rather good since 79% of the radioactivity remained in the liposome fraction after 1 week of incubation at 37 °C with ^{125}I-EGF−liposome−WSA diluted in complete culture medium (Table 2). Samples incubated for 3 weeks at 4 °C had 90% radioactivity in the liposome fraction. The leakage of WSA from the liposomes was about 12% at 60 °C after 1 h. At 37 °C, the leakage was about 10% after 24 h. No extra leakage due to the transfer process was observed for either temperature.

Stability of EGF at Different Temperatures and Times. The cell tests showed that the binding ability and receptor specificity of ^{125}I-EGF was almost unaltered for all studied times and temperatures during the micelle transfers. A slight decrease was however detected for 24 h in 60 °C (Figure 5).

Displacement Test. By adding high concentrations of EGF, it was possible to displace the binding of ^{125}I-EGF−liposomes almost completely (Figure 6) proving receptor specific binding. Specificity was also seen for ^{125}I-EGF−liposome−WSA. However, the fraction of nonreceptor specific binding of radioactivity increased to about 30% in the latter case. The reason for this increase in nonspecific binding is at present not clear, but it appears likely that the WSA in some way modifies the properties of the liposomes.

DISCUSSION

Here, we showed that EGF can be coupled to PEG-stabilized liposomes using the micelle transfer method. A transfer temperature of 60 °C produces higher amounts of liposome incorporated ^{125}I-EGF−PEG−DSPE than at room temperature or 37°C. This is not unexpected since the bilayer fluidity increases with increasing temperature. EGF loses nearly no biological activity at 60 °C. The leakage of WSA at 60 °C was higher than at 37 °C, but it was not severe enough to defend the use of 37 °C as transfer temperature.

The optimization studies included investigations of how the amount of PEG−lipid in the initial liposome preparation affected the incorporation of EGF-conjugated PEG−lipid. Three different PEG−lipid concentrations were tested in the preformed liposomes, and only small differences were observed between them. At short time scales, a somewhat lower level of incorporation was observed for the preparation containing the highest amount of PEG−lipid, i.e., 5 mol %. The incorporated amount increased, however, with time and reached after

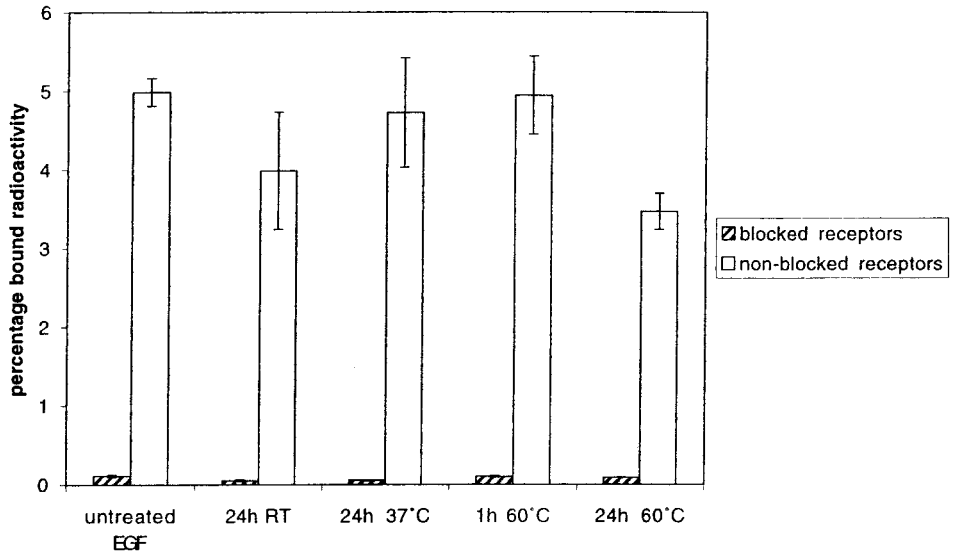

Figure 5. Test of the binding ability of temperature pretreated ^{125}I-EGF to cultured glioma cells. Binding was also tested on blocked receptors to ensure that receptor specificity did not change. An excess of unlabeled EGF was used to block the receptors in those cases. The cells were incubated with EGF for 30 min. Each bar corresponds to three cell dishes. Error bars represent maximal errors.

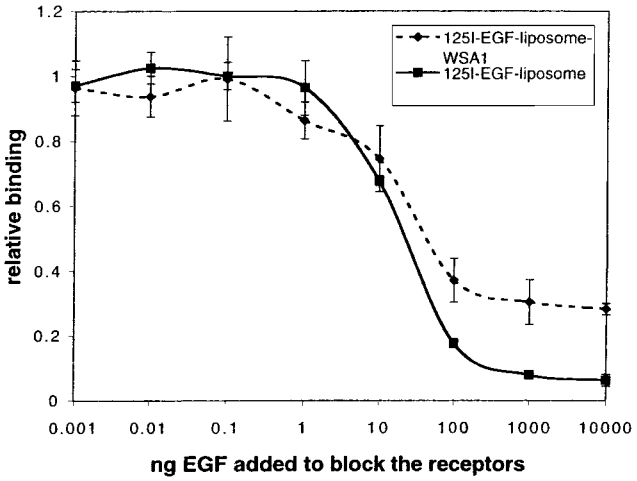

Figure 6. Test of binding specificity of ^{125}I-EGF–liposome–WSA conjugate and ^{125}I-EGF–liposome conjugate. The added amount of conjugate was the same, and increasing concentrations of unlabeled EGF displaced the binding to the EGF receptor. The incubation time was 4 h for both conjugates. For all studies the amount bound without blocking was normalized to unity. Error bars represent maximal errors; ^{125}I-EGF–liposome–WSA, $n = 6$, ^{125}I-EGF–liposome, $n = 3$.

24 h the same level as observed for 0 mol % and 3 mol %. Since an initial PEG–lipid concentration of 3 mol % gave the preferred final PEG–lipid content, we chose this concentration for our further experiments.

A clear difference in the transfer was observed between empty and WSA-loaded liposomes. The amount of incorporated EGF-conjugated PEG–lipid was significantly lower for liposomes containing WSA than for unloaded liposomes with the same PEG–lipid content. A similar study published by Ishida et al. (*16*) reported that the amount of DSPE–PEG in the preformed liposomes affects the ability of lipids to incorporate into liposomes. Ishida et al. also studied coupling of antibody to Caelyx/Doxil liposomes with the micelle transfer method. The results indicated a much lower transfer for liposomes loaded with drug than for empty liposomes with slightly lower PEG-lipid content (4% PEG–lipid vs 5% PEG–lipid). We do not rule out the possibility that the PEG–lipid concentration in the preformed liposomes may influence the amount of incorporation but believe that, at least in our case, the decrease in the transfer is mainly due to the content of the liposomes.

A final concentration of about 5 mol % PEG–lipid is desired for prolonged liposome circulation in vivo (*21*). With the unloaded liposomes, this can be achieved by using 3 mol % PEG–lipid in the liposomes before transfer and 3% micellar lipid to total lipid the transfer. With the loaded liposomes, we obtained about 4 mol % total PEG–lipid in the final conjugate. One way to increase the final PEG–lipid amount, and also the EGF amount, is to slightly increase the micelle lipid to total lipid ratio.

We studied liposomes with a radius of about 100 nm and such liposomes contain approximately 75000–80000 phospholipids per liposome (*19*). For these liposomes we managed to obtain about 10–15 EGF molecules /liposome. This amount is assumed to be enough to achieve a satisfactory cellular uptake of antibody-targeted liposomes (*10, 19*). However, the optimal amount of EGF molecules on the liposome surface needed for a high cell uptake, and desirable clearance from the systemic circulation, has to be studied in future in vitro and in vivo experiments.

In two earlier studies, direct coupling of EGF to phospholipids via disulfide bonds was used (*22, 23*). This approach would for our PEG-stabilized, long-circulating liposomes probably lead to lower binding to tumor cells since the ligand would be "buried" within the PEG-layer (*24*). Instead, we conjugated EGF to the PEG-part of the lipids, ending up with the targeting agent outside the PEG-layer of the liposomes. We chose to conjugate EGF to maleimide–PEG–DSPE, thereby also avoiding the problem of unstable disulfide bonds within the circulation.

The stability of the ^{125}I-EGF–liposome–WSA conjugate was good; besides, it could be stored at 4 °C for weeks. The stability at 37 °C was also acceptable and high enough for us to be sure that no significant spontaneous degradation occurred during the in vitro tests with cultured tumor cells.

The ^{125}I-EGF–liposome conjugate showed mainly EGF-receptor-specific binding to cultured glioma cells, as proven by displacement of the conjugate with increasing

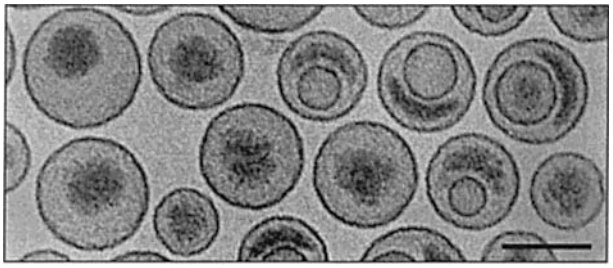

Figure 7. Cryo-Tem analysis picture of liposomes loaded with WSA. Bar represents 100 nm.

amounts of nonradioactive EGF. We cannot, at present, explain why the nonspecific binding of conjugates loaded with WSA was higher than that of the conjugate without WSA. There seems to be no disturbance of the liposome bilayer due to the load as shown in previous studies based on Cryo-TEM(*13*). The Cryo-TEM analyses showed intact liposomes with WSA crystals in the middle (Figure 7).

More studies on the cellular uptake, retention kinetics, and fate of the load are currently in progress.

CONCLUDING REMARKS

Although the problem with high uptake of liposomes by the RES system has been widely addressed during the last years (*7*−*9*), the dose-limiting organ for radionuclide therapy of malignancies using liposomes is still thought to be the liver (*25*). Further improvements are needed and one important factor is the tumor cell specificity of the liposomes. An active tumor targeting approach using antibodies, antibody fragments, or receptor ligands coupled to liposomes can hopefully increase the tumor specificity and decrease the dose to the liver. A binary system, such as BNCT, would give the opportunity to choose the area of neutron activation of boron and thereby further decrease the liver dose. Earlier reports on liposomes for BNCT lack specific tumor targeting ability (*3, 27*−*30*). Here, we presented a liposomal delivery vehicle for specific tumor targeting. We loaded about 10^5 to 10^6 boron atoms in each liposome, which is enough to make the liposomes interesting for therapy. It is known that 10^8 to 10^9 boron atoms are needed per tumor cell for therapeutic effect (*26*), and with the achieved number of boron atoms per liposome, it is realized that only 10^2 to 10^4 receptor interactions are needed per cell. The targeting ability will hopefully give the liposomes a much higher potential to find, bind, and inactivate tumor cells.

The procedure of the micelle-transfer method is attractive since the load and the targeting agent can be easily exchanged. We are currently developing DNA-binding compounds for halogen labeling, such as ^{211}At and ^{125}I, which may be exchanged for WSA used in this study. The use of EGF as a targeting molecule is at present being evaluated at our laboratory in a clinical study on bladder cancer patients. In this study, EGF−dextran (*31*) is used, but EGF-labeled liposomes might be applied if the penetration properties are found to be satisfactory.

In the previous study, we investigated the induction of ovalbumin (OVA)-specific antibody production in mice by OVA−liposome conjugates made using four different lipid components, including unsaturated carrier lipid and three different saturated carrier lipids. All of the OVA−liposome conjugates tested induced IgE-selective unresponsiveness. The highest titer of anti-OVA IgG was observed in mice immunized with OVA−liposomes made using liposomes with the highest membrane fluidity, suggesting that the membrane fluidity of liposomes affects their adjuvant effect. In this study, liposomes with five different cholesterol inclusions, ranging from 0% to 43% of the total lipid, were made, and the induction of OVA-specific antibody production by OVA−liposome conjugates was compared among these liposome preparations. In contrast to the results in the previous study, liposomes that contained no cholesterol and possessed the lowest membrane fluidity demonstrated the highest adjuvant effect for the induction of IgG antibody production. In addition, when the liposomes with four different lipid compositions were used, OVA−liposome conjugates made using liposomes that did not contain cholesterol induced significantly higher levels of anti-OVA IgG antibody production than did those made using liposomes that contained cholesterol and, further, induced significant production of anti-OVA IgE. These results suggest that cholesterol inclusion in liposomes affects both adjuvanticity for IgG production and regulatory effects on IgE synthesis by the surface-coupled antigen of liposomes.

INTRODUCTION

Vaccines are undoubtedly the most efficient tool for control or elimination of severe infectious diseases. Over the course of development of modern vaccines, weak immunogenicity presented a major difficulty (*1*). Consequently, the use of adjuvants became indispensable. Aluminum-containing compounds are, at present, the only adjuvants approved for clinical use. However, they are not active with all immunogens, and they are known to induce production of IgE antibodies, which can cause allergic reactions in the vaccinee (*2*). To date, many adjuvant formulations have been developed, but only a few have been evaluated in clinical trials, mainly due to their toxicity and side effects (*3*). Among the candidates for adjuvants, liposomes have garnered recent attention for their capacity as carriers of vaccines (*4*−*8*). Most of the liposomal vaccines proposed have been made by antigen entrapment within the liposomal compartment (*5*). However, encapsulated and surface-linked liposomal antigens are known to induce differential immune responses (*9*). The capability to induce cellular immune response by a surface-linked, but not by encapsulated, liposomal antigen has been reported (*8*).

We previously reported that surface-linked liposomal antigen induced antigen-specific IgG, but not IgE, antibody production (*10*). This antigen modification was expected to serve as a novel protocol for the development of vaccines that would induce minimal allergic response. IgE-selective unresponsiveness was induced regardless of the coupling procedure of antigen and liposomes (*11*). In addition, differential adjuvant effects were obtained with antigen−liposome conjugates including differentially formulated liposomes, whereas IgE antibody production was not induced by the prepared conjugates (*12*).

Inclusion of cholesterol in the liposome formulation is known to affect the stability and adjuvanticity of liposomes (*7*, *13*). In this study, liposomes with different cholesterol inclusions were prepared and then coupled with antigens in order to investigate the induction of antigen-specific IgG and IgE antibody production. The aim of this study was to determine the correlation between cholesterol inclusion in liposomes and the induction of antibody production by surface-linked liposomal antigens.

MATERIALS AND METHODS

Experimental Animals. BALB/c mice (8 weeks of age, female) were purchased from Charles River (Yokohama, Kanagawa, Japan).

Chemicals. All phospholipids were obtained from NOF Co., Tokyo, Japan. Reagent grades of cholesterol and 1,6-diphenyl-1,3,5-hexatriene (DPH) were purchased from Wako Pure Chemical Co., Osaka, Japan.

Liposomal Antigen. Ovalbumin (OVA, Grade VII) was purchased from Sigma (St. Louis, MO).

Liposomes. The liposomes with different cholesterol inclusions used in this study are listed in Table 1. The liposomes consisting of four different components, with or without cholesterol, are listed in Table 2. The crude liposome solution was passed through a membrane filter (Nucleopore polycarbonate filter, Coster, Cambridge, MA) with a pore size of 0.2 μm. The diameter of liposomes was analyzed using a NICOMP 370 submicron particle sizer (Pacific Scientific, Silver Springs, MD). After filtration, the mean size and SE of liposomes listed in Tables 1 and 2 were 222.8 ± 10.1 and 224.0 ± 14.3 nm, respectively.

Preparation of Fluorescence-Labeled Liposomes. Fluorescence-labeled liposomes containing phospholipids were prepared as follows: DPPC, DPPE, DMPG, and cholesterol with the indicated molar ratio (Table 1) were dissolved in a mixture of solvents (chloroform/methanol/water = 65/25/4 by volume), and then 4.3 M DPH in chloroform solution was added. After vigorous mixing, solvents were removed completely under reduced pressure, followed by the addition of 1 mM phosphate buffer (pH 6.0) containing 8.5% sucrose to create a lipid vesicle suspension. The suspension was then extruded through a polycarbonate filter (0.2 μm) to adjust the liposome size. Fluorescence-labeled liposomes containing phospholipids that included a myristoyl group, palmitoyl group, or stearoyl group acting as the acyl chain were prepared by the same method.

Fluorescence Measurement. Fluorescence depolarization of DPH was measured according to the method described by Lents et al. (*14*) using a Hitachi F-2000 spectrophotometer equipped with a temperature-controlled cuvette holder. DPH was excited at 360 nm and its fluorescence was measured at 428 nm using an UV-

39 instrument filter UV-39 to cutoff wavelengths below 390 nm. The degree of fluorescence polarization was calculated from the formula

$$P = (I_{VV} - I_{VH}G)/(I_{VV} + I_{VH}G)$$

where I_{VV} and I_{VH} are the observed fluorescence intensities measured with polarizers parallel and perpendicular to the vertically polarized exciting beam, respectively, and G is a correction factor for the transmission efficiency of vertically and horizontally polarized light. A 3-mL portion of 1 mM phosphate buffer (pH 6.0) containing 8.5% sucrose was mixed well with 0.3 mL of the liposome suspension prepared as described previously. The mixture was then allowed to stand at 37 °C for 5 min before measurement. Samples from each liposome suspension were prepared in triplicate.

Coupling of OVA to Liposomes. Liposomal conjugates with OVA (OVA−liposome) via glutaraldehyde were prepared as follows: to a mixture of 90 mg of liposomes and 6 mg of OVA in 2.5 mL phosphate buffer (pH 7.2), 0.5 mL of 2.5% glutaraldehyde solution was added in drops. The mixture was stirred gently for 1 h at 37 °C, and then 0.5 mL of 3 M glycine-NaOH (pH 7.2) was added to block the excess aldehyde groups. The mixture was then incubated overnight at 4 °C. The liposome-coupled OVA and uncoupled OVA in the resulting solution were separated using CL-4B column chromatography (Pharmacia Fine Chemical Co., Upsala, Sweden). The amount of lipid in the liposomal fraction was measured using a phospholipid content assay kit (Phospholipid-Test-Wako, Wako Pure Chemical Co., Osaka, Japan). The OVA−liposome solution was adjusted to 10 mg lipid/mL and kept at 4 °C until use. For the measurement of OVA coupled to liposome, radiolabeled OVA ([methyl-^{14}C], purchased from New England Nuclear, Boston, MA) was mixed with cold OVA and then used for coupling with liposome and for determining the calibration curve. The radioactivity of the resulting OVA−liposome solution was counted using a calibration curve. The mean and SE of OVA coupled to liposomes listed in Tables 1 and 2 were 47.0 ± 2.2 and 47.8 ± 2.5 μg/mg of lipid, respectively. These results suggested that the variation in moles of phosphatidyl choline (4−8), phosphatidyl ethanolamine (3−6), and differential cholesterol inclusion in liposomes did not result in the differential coupling efficiency of OVA to liposomes.

Immunization. Mice were immunized intraperitoneally (ip) with OVA−liposome at a dose of 2 mg of lipid/200 μL/mouse. Four weeks after primary immunization, mice were boosted in the same manner as that used for primary immunization. For the measurement of serum antibodies, mice were bled from the tail vein.

Measurement of Serum Antibodies. Six weeks after primary immunization, serum anti-OVA IgG and IgG isotypes were determined by enzyme-linked immunosorbent assay (ELISA) using HRP-labeled goat anti-mouse IgG (Zymed Lab., San Francisco, CA). OVA-specific IgE was determined by monoclonal antibody-captured ELISA using monoclonal antibody against murine IgE produced by clone B1E3.

Preparation of SAC and CD4$^+$ T Cells. Spleen cell suspensions were prepared in RPMI-1640 containing 10% fetal calf serum (FCS). Cells (5×10^7) in 5 mL of medium containing 10% FCS were plated into 50-mm plastic tissue culture dishes (No. 3002, Becton-Dickinson Labware, Franklin Lakes, NJ) and incubated at 37 °C in a humidified 5% CO_2 atmosphere for 2 h. After culture, nonadherent cells were removed by vigorous washing in warm media, and adherent cells were then harvested with a cell scraper. CD4$^+$ T cell purification from SC of mice immunized with OVA−liposome was performed with the magnetic cell sorter system MACS, according to the manufacturer's protocol using anti-CD4 antibody-coated microbeads (Miltenyi Biotec GmbH, No. 492-01). CD4$^+$ T cells were suspended in RPMI-1640 containing 10% FCS at a cell density of 2×10^6/mL. In the preliminary examinations, OVA at a final concentration of 1 mg/mL, 24 h (Th1) and 96 h (Th2) culture period, respectively, were found to be optimal for cytokine production. The cell suspension was plated at 250 μL per well onto a 48-well culture plate (No. 3047, Becton-Dickinson Labware, Franklin Lakes, NJ), and 500 μL of 2 mg/mL OVA solution and 250 μL of 8×10^5/mL SAC in the same media was added. After incubation in a CO_2 incubator, the culture supernatants were collected and assayed for cytokines.

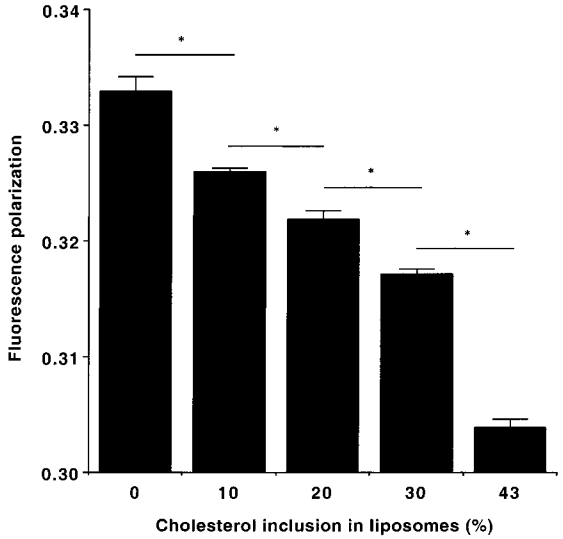

Figure 1. Degree of fluorescence polarization in the liposomes with five different cholesterol inclusions. The degree of fluorescence polarization at 37 °C was calculated as described in Materials and Methods. Data represent mean and SE of the triplicate measurements. (*) Significant ($p < 0.01$).

Cytokine Assays. IL-4 in the culture supernatant was measured using the Biotrak mouse ELISA system (Amersham International, Buckinghamshire, U.K.). All test samples were assayed in duplicate, and the standard error in each test was always less than 5% of the mean value.

Statistical Analysis. The Student's *t*-test was employed for the statistical analysis.

RESULTS

Membrane Fluidity of Liposomes. Figure 1 shows the degree of fluorescence polarization of the liposome preparations listed in Table 1. A significant difference was observed in the degree of fluorescence polarization among liposomes with different cholesterol inclusions. The increase in fluorescence polarization values can be interpreted as the result of a decrease in mobility of the hydrophobic region of phospholipid bilayers in the membranes. The results suggest that the membrane fluidity of liposomes correlated well with the amount of cholesterol contained, and liposomes containing no cholesterol showed the lowest membrane fluidity.

Anti-OVA Antibody Production in Mice Immunized with OVA−Liposome Prepared Using Liposomes with Different Cholesterol Inclusions. Lipo-

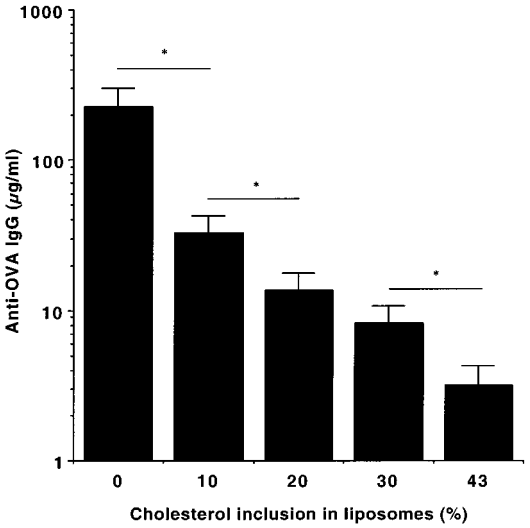

Figure 2. Anti-OVA antibody production in mice immunized with OVA−liposome made using liposomes with five different cholesterol inclusions. Six weeks after primary immunization, mice were bled from the tail vein, and serum anti-OVA IgG were measured. Data represent mean and SE of five mice per group. (*) Significant ($p < 0.01$).

somes in Figure 1 were coupled with OVA and inoculated into mice as described in Materials and Methods. Anti-OVA IgE antibody production was not observed in any of the groups of mice throughout the observation period (data not shown). On the other hand, anti-OVA IgG antibody production was induced in correlation with cholesterol inclusion in liposomes (Figure 2), and OVA−liposome prepared using liposome that contained no cholesterol induced the highest level of anti-OVA IgG antibody production.

Anti-OVA Antibody Production in Mice Immunized with OVA−Liposomes Made Using Liposomes with Four Different Lipid Formulations with or without Cholesterol. Liposomes of four different lipid formulations were prepared in the presence or absence of cholesterol as listed in Table 2, and the induction of anti-OVA IgG antibody production by OVA−liposome was investigated. OVA−liposome prepared using liposome consisting of unsaturated carrier lipids ("oleoyl" liposomes) induced the highest titer of anti-OVA IgG. Among OVA−liposomes prepared using liposomes consisting of saturated carrier lipids, the preparation using liposomes possessing the longest carbon chain ("stearoyl" liposomes) induced the lowest IgG antibody production when cholesterol was included in the liposomes (Figure 3a). On the other hand, OVA−liposome prepared using liposomes that did not contain cholesterol induced a significantly higher level of anti-OVA IgG antibody production than did those prepared using liposomes that contained cholesterol, except in the case of "oleoyl" liposomes. Interestingly, significant anti-OVA IgE antibody production was observed in mice immunized with OVA−liposome made using liposomes that did not contain cholesterol, except in the case of "palmitoyl" liposomes (Figure 3b).

Cytokine Production by Splenic CD4$^+$ T Cells of Mice Immunized with OVA−Liposome. Splenic CD4$^+$ cells were taken from mice in the previous experimental groups (Figure 3), and in vitro cytokine production was investigated. Because no cytokine production was observed in the absence of OVA under the culture conditions described in Materials and Methods, data shown in Figure 4 is considered to represent antigen-specific cytokine production. Significant levels of IL-4 production were observed in all groups of mice, and no correlation was found between in vitro T cell IL-4 production and in vivo anti-OVA IgE antibody production (Figure 3b). Similar results were obtained when production of IL-13 was monitored (data not shown).

DISCUSSION

In the present study, liposomes with five different cholesterol inclusions (Table 1) were used to make OVA−liposome conjugates, and induction of antigen-specific antibody production was monitored. All of the conjugates induced IgE-selective unresponsiveness. Among liposomes with five different cholesterol inclusions, membrane fluidity changed relative to the amount of cholesterol contained (Figure 1). The induction of IgG antibody production by OVA−liposome conjugates prepared using these liposomes correlated well with the membrane

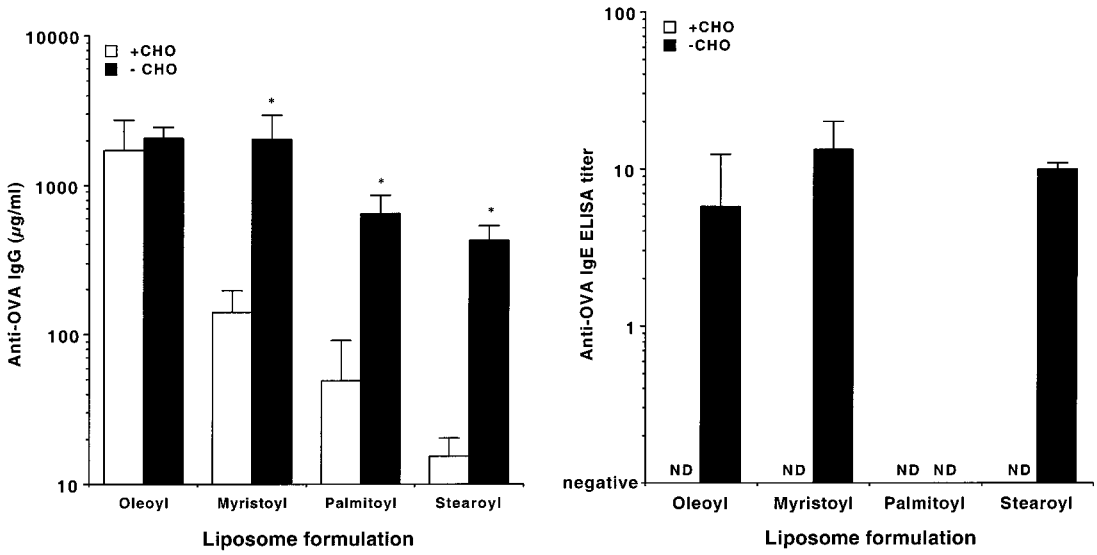

Figure 3. Anti-OVA antibody production in mice immunized with OVA−liposome made using liposomes with four different lipid formulations with (□) or without (■) cholesterol. Six weeks after primary immunization, mice were bled from the tail vein, and serum anti-OVA antibodies were measured: (a) IgG; (b) IgE. Data represent mean and SE of five mice per group. (*) Significant ($p < 0.01$) difference as compared with liposomes of the same formulation containing cholesterol. ND, not detected.

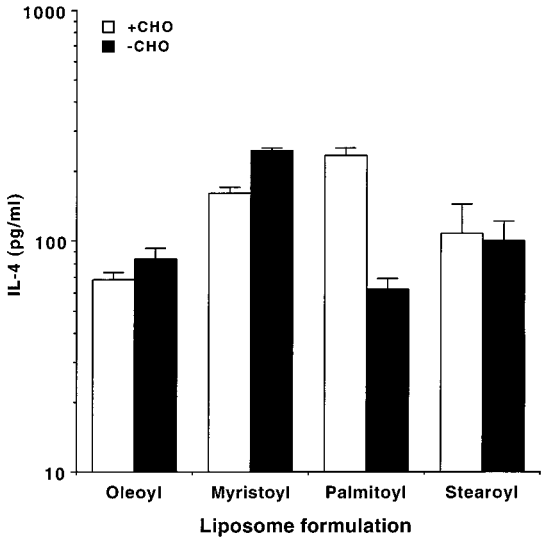

Figure 4. OVA-specific cytokine production by splenic $CD4^+$ T cells of mice immunized with OVA−liposome. Splenic $CD4^+$ T cells in the experiment shown in Figure 3 were stimulated with OVA as described in Materials and Methods, and IL-4 in the culture supernatants was monitored. Data represent mean IL-4 (pg/mL) and SE of five mice per group.

fluidity or with cholesterol inclusion in liposomes; OVA−liposome conjugates prepared using liposome that contained no cholesterol and possessed the lowest membrane mobility induced the highest level of anti-OVA IgG antibody production (Figure 2).

The results obtained in the present study differ from those obtained in the previous study (*12*); in the previous study, among liposomes with four different lipid components, the one possessing the highest membrane mobility displayed the highest adjuvant effect for the induction of IgG antibody production when cholesterol was included in all liposome preparations. We then prepared the same panel of liposomes as those used in the previous study in the presence or absence of cholesterol (Table 2) and investigated the induction of anti-OVA antibody production by OVA−liposome conjugates prepared using these liposome preparations. The results obtained using cholesterol-containing liposomes well-confirmed the results of the previous study (Figure 3a). On the other hand, in the cases of "myristoyl", "palmitoyl", and "stearoyl" liposomes, liposomes containing no cholesterol displayed significantly higher adjuvant effects than identically formulated liposomes containing cholesterol. Unexpectedly, OVA−liposome conjugates made using liposomes containing no cholesterol induced a significant production of anti-OVA IgE, except in the "palmitoyl" liposome group (Figure 3b). It is unlikely that IgE production was induced in those groups in relation to the induction of high titers of IgG antibody production, because in mice immunized with OVA−liposome prepared using "oleoyl" liposomes, IgE antibody production was induced only in the group of no-cholesterol liposomes, although a similar level of IgG antibody production was induced in both groups, regardless of the presence or absence of cholesterol in liposomes. Interestingly, among liposomes without cholesterol, IgE antibody production was not induced only in the group of mice immunized with "palmitoyl" liposomes. The results were in agreement with those shown in Figure 2; the liposome consisted mainly of palmitic acid (Table 1), and IgE production was not induced regardless of the inclusion of cholesterol. Although, at present, the mechanism of the induction of IgE-selective unresponsiveness by antigen−liposome conjugates remains unclear, the differential induction of IgE antibody production by OVA−liposome conjugates among liposomes with different lipid formulations, in the absence of cholesterol, could provide an insight into the mechanism. By the inclusion of cholesterol, liposomes are made more resistant to disintegration and biological degradation (*7*). Perhaps the change in the stability of liposomes caused by cholesterol inclusion affects both adjuvanticity and the capacity to induce IgE-selective unresponsiveness by antigen-coupled liposomes. Both IL-4 and IL-13 are known to play a key role in the induction of IgE antibody production (*15*). However, $CD4^+$ T cells of mice immunized with OVA−liposome produced IL-4 upon in vitro stimulation with OVA (Figure 4), regardless of in vivo IgE production (Figure 3b), showing that antigen-specific IL-4 production by T cells did not participate in the regulation of IgE production in mice immunized with OVA−liposome.

Thus, in the present study, liposomes with different cholesterol inclusions were used to prepare OVA−liposome conjugates, and the induction of anti-OVA antibody production was investigated in mice. The liposomal adjuvanticity for IgG and IgE antibody production was strikingly different among liposomes with different cholesterol inclusions. These results suggest that the cholesterol inclusion in liposomes affects adjuvanticity for IgG production and exerts regulatory effects on IgE synthesis by the surface-coupled antigen of liposomes.

Received October 18, 2001; Revised Manuscript Received February 25, 2002

Two kit preparations of the organometallic precursor $[^{188}Re(H_2O)_3(CO)_3]^+$ in aqueous media are presented. Method A uses gaseous carbon monoxide and amine borane ($BH_3{\cdot}NH_3$) as the reducing agent. In method B CO(g) is replaced by $K_2[H_3BCO_2]$ that releases carbon monoxide during hydrolysis. Both procedures afford the desired precursor in yields >85% after 10 min at 60 °C. HPLC and TLC analyses revealed 7 ± 3% of unreacted $^{188}ReO_4^-$ and <5% of colloidal $^{188}ReO_2$. Solutions of up to 14 GBq/mL Re-188 have been successfully carbonylated with these two methods. The syntheses of two tailor-made bifunctional ligand systems for the precursor $[^{188}Re(H_2O)_3(CO)_3]^+$ are presented. The tridentate chelates consist of a bis[imidazol-2-yl]methylamine or an iminodiacetic acid moiety, respectively. Both types of ligand systems have been prepared with alkyl spacers of different length and a pendent primary amino or carboxylic acid functionality, enabling the amidic linkage to biomolecules. The tridentate coordination of the ligands to the rhenium-tricarbonyl core could be elucidated on the macroscopic level by X-ray structure analyses and 1D and 2D NMR experiments of two representative model complexes. On the nca level, the ligands allow labeling yields >95% with $[^{188}Re(H_2O)_3(CO)_3]^+$ under mild reaction conditions (PBS buffer, 60 °C, 60 min) at ligand concentrations between 5×10^{-4} M and 5×10^{-5} M. Thus, specific activities of 22−220 GBq per μmol of ligand could be achieved. Incubation of the corresponding Re-188 complexes in human serum at 37 °C revealed stabilities between 80 ± 4% and 45 ± 10% at 24 h, respectively, and 63 ± 3% and 34 ± 3% at 48 h postincubation in human serum depending on the chelating system. Decomposition product was mainly $^{188}ReO_4^-$. The routine kit-preparation of the precursor $[^{188}Re(H_2O)_3(CO)_3]^+$ in combination with tailor-made ligand systems enables the organometallic labeling of biomolecules with unprecedented high specific activities.

INTRODUCTION

In the past years, the bioinorganic chemistry of rhenium has been developed toward novel applications in therapeutic nuclear medicine (*1*, *2*). Interests in this field origin from the fact, that the two particle emitting radioisotopes Re-186 and Re-188 have excellent physical decay properties for therapeutic applications (Re-186: $t_{1/2}$ = 89 h, β^- 1.07 MeV, γ 137 keV; Re-188: $t_{1/2}$ = 18 h, β^- 2.12 MeV, γ 155 keV). Furthermore, due to the generator technique, Re-188 is nowadays readily available carrier-free and at any time (*3*). In analogy to Tc-99m, most of the currently applied Re-186/188 labeling techniques use precursors or complexes in higher oxidation states (*4*, *5*). However, it is a fact that rhenium needs harsher conditions to be reduced from its original oxidation state +VII to lower oxidation states typically +V/+III. It is also frequently observed, that these rhenium complexes have a higher tendency reoxidize, than their technetium analogues. Therefore, kinetically more inert complexes containing technetium and rhenium in the low oxidation state +I have received more attention, recently (*6*−*10*). Soft metal centers show an increased kinetic inertness and a low affinity for hard nitrogen and oxygen donor groups, readily present in the blood serum. This characteristic protects the complexes in vivo against ligand dissociation and ligand exchange.

Our group has developed a fully aqueous-based kit preparation of the organometallic technetium precursor $[^{99m}Tc(H_2O)_3(CO)_3]^+$ under mild reaction conditions in the presence of gaseous carbon monoxide and sodium borohydrate (*11*). The formulation could be optimized in terms of kit-stability and commercial production due to substitution of both gaseous CO and $NaBH_4$ by $K_2[H_3BCO_2]$ (*12*). However, till today the corresponding Re-186/188 precursor $[^*Re(H_2O)_3(CO)_3]^+$ **1** was obtained only in low yields via the above-mentioned methods.

In the present work we describe two simple and fully aqueous-based synthetic routes to obtain the precursor $[^{188}Re(H_2O)_3(CO)_3]^+$ in high yields and with high specific activities. To translate the excellent specific activities on the labeling of biomolecules, tridentate bifunctional

ligand systems tailor-made for the precursors $[^{188}Re(H_2O)_3(CO)_3]^+$ have been synthesized. The first ligand system consists of bis[imidazol-2yl]methylamine chelate originally developed for copper(II) (*13*). To our knowledge this chelate system has never been tested and reacted with a soft, organometallic precursor. The second type of ligands consists of an iminodiacetic acid (IDA) moiety, which is well-known to form complexes with almost any metal of the fist and second transition row. Both chelating systems proved to be good candidates for facile bifunctionalization with spacers of different chain length bearing a terminal amino or carboxylic acid group for amidic linkage to carboxylic acid or primary amino group of biomolecules. On the other hand, they offer three potential coordination sites, forming multiple stable chelating rings with the rhenium-tricarbonyl center. The X-ray structures of two model complexes exemplify the coordinative features of these new ligand systems. In vitro plasma stabilities of the corresponding Re-188 complexes will be discussed.

MATERIALS AND METHODS

Solvents for syntheses were purchased from Aldrich Chemical Co. or Fluka, Buchs, Switzerland and were dried according to standard methods. Glycine **2**, 5-aminopentanoic acid **3**, and 10-aminoundecanoic acid **4** were purchased from Fluka. The precursor $(NEt_4)_2[ReBr_3(CO)_3]$ (*14*), *N-tert*-butyloxycarbonyldiaminopropane **5**, and *N-tert*-butyloxycarbonyldiaminohexane **6** (*15*), bis(imidazol-2-yl)nitromethane **7** (*16*), bis(imidazol-2-yl)-carboxymethylaminomethane **8a** (*13*), and $K_2[H_3BCO_2]$ (*12*) were synthesized according to the literature. Na-$[^{188}ReO_4]$ was eluted from a $^{188}W/^{188}Re$ generator (Oak Ridge National Laboratories, Oak Ridge, TN) using 0.9% saline. The elution volume (approximately 30 mL) was reduced to a total of 5 mL (max. 14 GBq/mL) using the method of Blower (*17*). HPLC analyses were performed on a Merck-Hitachi L-7000-system equipped with an L-7400 tunable absorption detector and a Berthold LB 506 B radiometric detector. HPLC solvents consisted of aqueous 0.05 M TEAP (triethylammonium phosphate) buffer, pH = 2.25 (solvent A) and methanol (solvent B). For the radiochemical analyses, a Macherey-Nagel C-18 reversed phase column (10 μm, 150 × 4.1 mm) was used. The HPLC system started with 100% of A from 0 to 3 min. The eluent switched at 3 min to 75% A and 25% B and at 9 min to 66% A and 34% B followed by a linear gradient 66% A/34% B to 100% B from 9 to 20 min. The gradient remained at 100% B for 2 min before switching back to 100% A. The flow rate was 1 mL/min. The thin-layer chromatography (TLC) system was performed using glass-backed silica gel plates (Merck $60F_{254}$, mobile phase of 99% methanol 1% concentrated HCl) and paper (Whatman No.1, mobile phase 99.5% methanol, 0.5% 6 M aqueous HCl). The plates were scanned with a Burkard RAYTEST RITA-3200 radioanalyzer. Radioactive samples were counted in a Camberra Packard COBRA II auto gamma well counter. Reactions with activities >500 MBq/mL have been performed in specially equipped lead-boxes with manipulators. Nuclear magnetic resonance spectra were recorded on a 300 MHz Varian Gemini 2000 spectrometer. The ^1H and ^{13}C chemical shifts are reported relative to residual solvent protons as a reference. IR spectra were recorded on a Perkin-Elmer FT-IR 16PC using KBr pellets. Elementary analyses were performed at the department of inorganic chemistry of the university of Zurich.

Preparation of Precursor $[^{188}Re(H_2O)_3(CO)_3]^+$, 1. Method A. A 5 mg amount of $BH_3{\cdot}NH_3$ was placed in 10 mL glass vial. The vial was sealed with an aluminum capped rubber stopper and flushed with CO for 20 min. The generator eluate (1 mL, 3−14 GBq/mL) was mixed with 6 μL of concentrated H_3PO_4 (98%) prior to the injection in the reaction vial. The vial was incubated at 60 °C for 15 min. Pressure from the evolving H_2 gas was balanced with a 20 mL syringe. The reaction was cooled on an ice bath. The final pH of the reaction solution was neutral. Yield: 85 ± 5% determined by means of HPLC and TLC. **Method B.** A 5 mg amount of $BH_3{\cdot}NH_3$ and 3 mg of $K_2[H_3BCO_2]$ were placed in 10 mL glass vial and flushed with nitrogen. The generator eluate (1 mL, 3−14 GBq/mL) was mixed with 6 μL of concentrated H_3PO_4 (98%) prior to the injection in the reaction vial. The vial was incubated at 60 °C for 15 min. Pressure from the evolving H_2 gas was balanced with a 20 mL syringe. The reaction was cooled on an ice bath. The final pH of the reaction solution was neutral. Yield: 80 ± 5% determined by means of HPLC and TLC.

Radiolabeling. The radioactive complexes were prepared according to the following general procedure: 450 μL of a solution of $[^{188}Re(H_2O)_3(CO)_3]^+$ and 50 μL of a 10^{-3} M, and 10^{-4} M, respectively, 950 μL of a solution of $[^{188}Re(H_2O)_3(CO)_3]^+$ and 50 μL of a 10^{-2} M, 10^{-3} M, and 10^{-4} M solution of the corresponding ligand in PBS buffer (0.1 M NaCl/0.05 M sodium phosphate buffered, pH = 6.5−7.5) were placed in a 10-mL glass vial under nitrogen. The vial was sealed and the reaction heated to 60 °C for 60 min and cooled on an ice bath.

In Vitro Plasma Stability. The solutions of the ^{188}Re complexes were adjusted with physiological saline to a concentration of 370 MBq/mL. Aliquots of 100 μL of these solutions were added to 400 μL human plasma and incubated at 37 °C. Aliquots were taken and analyzed after 1 h, 4, 24, and 48 h.

Preparation of Compound 8c and 8d. The ligands **8c/d** were synthesized according to the procedure described for **8a** (*13*) starting from the corresponding aminoalkyl carboxylic acid (n = 4, 10). Yields: 50−70%. Analytical data for ligand **8c** (n = 4): Calculated for $C_{12}H_{17}N_5O_2{\cdot}1.6$ HCl: C 44.81; H 5.83; N 21.77. Found C 44.91; H 5.95; N 22.35. ^1H NMR (D_2O): δ 7.41 (s, 4 H), 6.68 (s, 1 H), 3.51 (t, 2 H), 2.33 (t, 2 H) 1.82 (m, 2 H), 1.69 (m, 2 H). ^{13}C NMR (D_2O): δ 177.9, 143.3, 122.7, 53.7, 42.0, 34.2, 25.6, 23.2. MS (ES): m/z (%) 264 (60) [M + 1]. Analytical data for ligand **8d** (n = 10): Calculated for $C_{18}H_{29}N_5O_2{\cdot}1.7$ HCl: C 52.80; H 7.56; N 17.10. Found: C 52.63; H 7.03; N 17.27. ^1H NMR (D_2O): δ 7.50 (s, 4 H), 6.30 (s, 1 H), 2.82 (t, 2 H), 2.23 (t, 2 H), 1.6−1.4 (m, 4 H), 1.2−1.1 (broad m, 12 H). ^{13}C NMR (D_2O): δ 179.1, 135.9, 122.9, 66.8, 47.8, 35.6, 34.0, 28.5, 25.7, 24.4, 23.3. MS (ES): m/z (%) 348 (100) [M + 1].

Preparation of Compounds 9a and 9b. The compounds **9a/b** were synthesized according to the following, general procedure starting from the corresponding *N-tert*-butyloxycarbonyldiamines (n = 3, **5**, and n = 6, **6**). Bis-[imidazol-2-yl]nitromethane (500 mg, 2.2 mmol) was dissolved in 2.6 mL of 2 M NaOH. One equivalent of the corresponding mono Boc-protected diaminoalkane was added under vigorous stirring. The suspension was heated at 80 °C for 20 min, in which a clear orange solution was formed. After cooling on an ice bath, the almost colorless product precipitated. The pure product was filtered and dried under vacuum. Yields: 50−70%. Analytical data for compound **9a** (n = 3): Calculated for $C_{15}H_{24}N_6O_2$: C 56.23; H 7.55; N 26.23: Found: C 55.96; H 6.95; N 26.71. ^1H NMR (MeOH-d_4): δ 6.91 (s, 4 H), 4.99 (s, 1 H), 3.06 (t, 2 H), 2.46 (t, 2 H), 1.56 (q, 2 H), 1.33 (s, 9 H). ^{13}C NMR (MeOH-d_4): δ 162.3, 143.4, 121.5,

70.6, 51.6, 40.5, 33.8, 25.6, 24.2, 23.7. MS (ES): *m/z* (%) 321 (100) [$M + 1$]. Analytical data for compound **9b** ($n = 6$): Calculated for $C_{18}H_{30}N_6O_2$: C 59.64; H 8.34; N 23.19: Found: C 59.08; H 7.24; N 22.91. ^{1}H NMR (MeOH-d_4): δ 7.12 (s, 4 H), 5.01 (s, 1 H), 3.33 (t, 2 H), 2.53 (t, 2 H), 1.63 (m, 4 H), 1.40 (s, 4 H), 1.34 (s, 9 H). ^{13}C NMR (MeOH-d_4): δ 160.2, 144.4, 120.8, 66.2, 50.4, 42.5, 34.2, 28.6, 25.5, 25.1 23.4, 22.3, 20.1. MS (ES): *m/z* (%) 363 (100) [$M + 1$].

Preparation of Compounds 10a and 10b. Compounds **10a/b** were deprotected in 3 M HCl at 50 °C for 20 min. After removal of the solvent, the products could be obtained almost quantitatively in the hydrochloride form as pale rose powder. Yields >95%. Analytical data for ligand **10a** ($n = 3$): Calculated for $C_{10}H_{16}N_6 \cdot 4.5$ HCl: C, 31.0; H, 6.1; N, 21.7. Found: C, 31.1; H, 5.95; N, 21.5. ^{1}H NMR (MeOH-d_4): δ 7.58 (s, 4 H), 5.94 (s, 1 H), 3.16 (t, 2 H, 9 Hz), 2.81 (t, 2 H, 6 Hz), 1.95 (m, 2 H). ^{13}C NMR (MeOH-d_4): δ 139.6, 117.8, 57.7, 42.5, 39.4, 25.6. MS (ES): *m/z* (%) 221 (100) [$M + 1$]. Analytical data for ligand **10b** ($n = 6$): Calculated for $C_{13}H_{22}N_6 \cdot 4$ HCl: C, 38.3; H, 6.4; N, 20.6. Found: C, 37.9; H, 6.1; N, 20.2. ^{1}H NMR (MeOH-d_4): δ 7.51 (s, 4 H), 6.04 (s, 1 H), 2.96 (t, 2 H), 2.73 (t, 2 H), 1.62 (m, 2 H), 1.58 (m, 2 H), 1.33 (m, 4 H). ^{13}C NMR (MeOH-d_4): δ 140.4, 117.7, 56.7, 42.5, 34.2, 28.6, 25.7,23.6, 20.4. MS (ES): *m/z* (%) 263 (80) [$M + 1$].

Preparation Compounds 11a and 11b. The compounds **11a/b** were synthesized according to the following, general procedure using the corresponding amino alkyl carboxylic acid ($n = 4$, **3** and $n = 10$, **4**). A 1 g amount of 5-aminopentanoic acid **3** or 11-aminoundecanoic acid **4**, respectively, was dissolved in 100 mL of methanol together with 2.5 equiv of triethylamine. Methyl bromoacetate (2.1 equiv) was added over a period of 2 h at room temperature. The reaction was refluxed overnight. After removal of the solvent, the oily residue was purified by column chromatography (CH_2Cl_2/ethyl acetate: 4:1). The esters were saponified with 2 M NaOH under reflux for 60 min. The solution was neutralized with concentrated HCl and the solvent evaporated under reduced pressure. The residue was extracted twice with 5 mL of methanol to separate NaCl. After evaporation of the methanol the products were obtained as white solids. Yield: 40−60%. Analytical data for compound **11a** ($n = 4$): Calculated for $C_9H_{15}NO_6$: C 46.35; H 6.48; N 6.01. Found: C 45.85; H 5.53; N 5.92. ^{1}H NMR (MeOH-d_4): δ 3.38 (t, 2 H), 3.15 (s, 4 H), 3.04 (t, 2 H), 2.88 (q, 4 H). ^{13}C NMR (MeOH-d_4): δ 179.9, 171.5, 66.8, 56.2, 50.3, 33.1, 28.0. MS (ES): *m/z* (%) 234 (100) [$M + 1$]. Analytical data for compound **11b** ($n = 10$): Calculated for $C_{15}H_{27}NO_6$: C 56.77; H 8.57; N 4.41. Found: C 56.45; H 6.97; N 4.21.^{1}H NMR (D_2O): δ 3.41 (t, 2 H), 3.21 (s, 4 H), 2.62 (t, 2 H), 1.77 (m, 2 H), 1.6−1.1 (m, 14 H). ^{13}C NMR (D_2O): δ 177.0, 171.0, 56.0, 51.1, 35.3, 33.2, 33.0, 28.6, 28.3, 26.8, 25.0, 23.3. MS (ES): *m/z* (%) 318 (100) [$M + 1$].

Preparation of Compounds 12a/b and 13a/b. The compounds **13a/b** were synthesized according to the following, general procedure using the corresponding *N-tert*-butyloxycarbonyldiamines ($n = 3$, **5** and $n = 6$, **6**). The *N-tert*-butyloxycarbonyldiamines were dissolved in 50 mL of methanol together with 2 equiv of triethylamine. Methyl bromoacetate (2.1 equiv) was added over a period of 2 h at room temperature. The reaction was refluxed overnight. After removal of the solvent the oily residue was diluted with water and extracted three times with ethyl acetate. The organic layers were combined and dried over Na_2SO_4. After filtration and evaporation of the solvent, the crude products **12a/b** were checked by means of NMR and processed without purification. The crude products were dissolved in 3 M HCl and heated at 50 °C for 30 min. After removal of the solvent the residues were dissolved in 2 M NaOH and refluxed for 60 min. The solution was neutralized with concentrated HCl and the solvent evaporated under reduced pressure. The residue was extracted twice with 5 mL of methanol to separate NaCl. After evaporation of the methanol, the products were obtained as white solids. Yield: 40−60%. Analytical data for ligand **13a** ($n = 3$): Calculated for $C_7H_{14}N_2O_4 \cdot 0.3$NaCl: C 40.47; H 6.79; N 13.49. Found: C 40.64; H 7.21; N 13.91. ^{1}H NMR (D_2O): δ 3.53 (s, 4 H), 2.83 (t, 2 H), 2.74 (t, 2 H), 1.87 (q, 2 H). ^{13}C NMR (D_2O): δ 176.1, 94.3, 64.1, 60.5, 51.7 40.0, 33.8. MS (ES): *m/z* (%) 191 (100) [$M + 1$]. Analytical data for ligand **13b** ($n = 6$): Calculated for $C_{10}H_{20}N_2O_4 \cdot 0.2$NaCl: C 49.23; H 8.26; N 11.48. Found: C 49.11; H 7.38; N 11.96. ^{1}H NMR (D_2O): δ 3.53 (s, 4 H), 2.83 (t, 2 H), 2.74 (t, 2 H), 1.87 (q, 2 H), 1.4−1.2 (m, 6 H). ^{13}C NMR (D_2O): δ 179.0, 95.1, 60.2, 58.1, 53.9, 42.3, 34.4, 29.6. Preparation of Compound 8b. Compound **8a** (200 mg, 0.9 mmol) was dissolved in 10 mL of methanol. The solution was cooled to 0 °C on an ice bath before adding 60 μL (0.9 mmol) of $SOCl_2$. To the reaction solution was added 500 mg of molecular sieve, and the reaction was stirred overnight at room temperature. After filtration, the solvent was removed under reduced pressure to obtain the product. Yield 190 mg (90%). Analytical data: Calculated for $C_{10}H_{13}N_5O_2$: C 51.06; H 5.57; N 29.77. Found: C 51.12; H 4.98; N 29.24. ^{1}H NMR (D_2O): δ 7.12 (s, 4 H), 5.30 (s, 1 H), 3.67 (s, 3 H), 3.51 (s, 2 H). ^{13}C NMR (D_2O): 174.3, 138.1, 135.8 116.4, 56.7, 42.5. MS (ES): *m/z* (%) 236 (100) [$M + 1$].

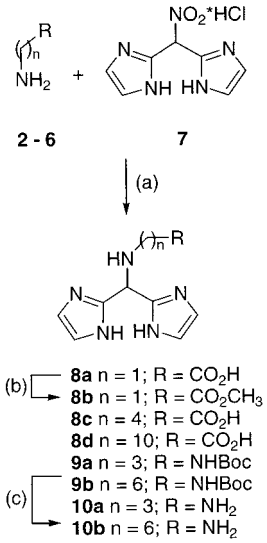
Preparation [Re(8b)(CO)$_3$]Br. $(NEt_4)_2[ReBr_3(CO)_3]$ (100 mg, 0.12 mmol) was dissolved in 5 mL of methanol. One equivalent of **8a** (30 mg) was added and the reaction stirred overnight at room temperature. The reaction was concentrated to 1 mL and layered with diethyl ether. The products crystallized completely after 3 days. Yield: 47 mg (65%). Analytical data: Calculated for $C_{13}H_{13}N_5O_5$-ReBr: C 26.67; H 2.24; N 11.96. Found: C 26.12; H 2.98; N 11.24. ^{1}H NMR (MeOH-d_4): δ 7.40 (d, 1 H, 1.5 Hz), 7,33(d, 1 H, 1.5 Hz), 7.22 (d, 1 H, 1.5 Hz), 7.20 (d, 1 H, 1.5 Hz), 6.20 (s, 1 H), 3.78 (s, 3H), 3.61 (s, 2 H). IR (KBr, cm^{-1}): 3420 (w), 2028 (vs), 1922 (vs), 1904 (vs), 1758 (m), 1290 (w), 1138 (m), 858 (w).

Preparation of [Re(13aH$^+$)(CO)$_3$]. $(NEt_4)_2[ReBr_3(CO)_3]$ (82 mg, 0.11 mmol) was dissolved in 5 mL of H_2O. Ligand **13a** (25 mg, 0.13 mmol) was added and the reaction heated at 70 °C for 2 h. Immediately after cooling to room temperature, the product crystallized almost quantitatively from the reaction solution. Yield: 48 mg (95%). Analytical data: Calculated for $C_{10}H_{13}N_2O_7Re \cdot 0.9H_2O$: C 25.25; H 3.14; N 5.89. Found: C 26.73; H 3.31; N 5.64. ^{1}H NMR (DMSO-d_6): δ 3.76 (d, 2 H, 16 Hz), 3.40 (d, 2 H, 16 Hz), 3.30 (t, 2 H), 3.28 (m, 2 H), 2.80 (t, 2 H). IR (KBr, cm^{-1}): 3446 (w), 2362 (w), 2018 (vs), 1902 (vs), 1870 (vs), 1654 (s), 1622 (s), 1394 (m), 548 (w).

RESULTS AND DISCUSSION

Contrary to the almost quantitative reductive carbonylation of $^{99m}TcO_4^-$ in the presence of BH_4^-, CO, and Na_2CO_3 in aqueous media, only traces of the desired Re-188 precursor were detected under these reaction conditions. Failure of this approach can presumably be explained by several facts: (i) Rhenium has a lower redox potential than technetium. (ii) Rhenium +V and/or +III intermediates presumably formed during the reductive

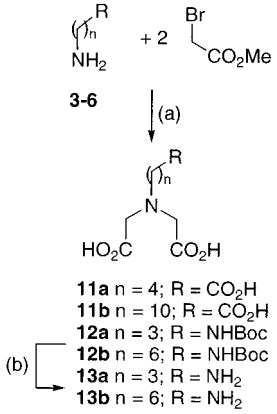
Scheme 1



carbonylation are unstable at basic pH. (iii) Under neutral/acidic conditions rhenium(III/IV) intermediates are stable but BH_4^- hydrolyzes fast. Thus, BH_4^- is not available for reduction of the metal center. To circumvent these problems, the water-soluble aminoborane, $BH_3{\cdot}NH_3$, was used instead of BH_4^-. Aminoborane is sufficiently stable under neutral/acidic conditions and is highly reducing.

The organometallic precursor $[^{188}Re(H_2O)_3(CO)_3]^+$ **1** was synthesized via two routes starting from $^{188}ReO_4^-$ in saline. Method A uses solid $BH_3{\cdot}NH_3$ as the reducing agent and gaseous carbon monoxide as the source of CO ligands. The perrhenate solution was acidified with concentrated phosphoric acid prior to injection in the reaction vial to maintain an acidic/neutral pH during the reaction. After 15 min at 60 °C, the reaction was completed (Scheme 1). The HPLC γ-trace revealed beside the peak of the desired product **1** (70 ± 10%; RT = 5 min) and remaining $^{188}ReO_4^-$ (7 ± 3%; RT = 10 min) a third peak of a byproduct with a retention time of 10.5 min (10 ± 5%). This byproduct of unknown composition can be converted into the precursor **1** by acidifying the carbonyl solution to pH < 2. TLC analysis of the carbonyl solution revealed only the peak of precursor **1** (85 ± 5%; $R_f = 0.4$) and $^{188}ReO_4^-$ (10 ± 2%; $R_f = 0.7$). Less than 5% colloidal $^{188}ReO_2$ was detected at the origin.

In method B, $K_2[H_3BCO_2]$ was used as a solid source of CO and $BH_3{\cdot}NH_3$ as the reducing agent. The perrhenate solution was also acidified with concentrated phosphoric acid previous to injection in the reaction vial. After 15 min at 60 °C, the yields and product distribution were similar to those in method A (Scheme 1). The amount of $BH_3{\cdot}NH_3/K_2[H_3BCO_2]$ and acid (concentrated H_3PO_4) was carefully balanced, to avoid fast hydrolysis of the boranes and to maintain a sufficient low pH to stabilize reduced rhenium intermediates. Using exclusively $K_2[H_3BCO_2]$ instead of $BH_3{\cdot}NH_3$ and CO(g) did not yield the desired precursor even if applied in large excess (10−50 mg per reaction vial). Furthermore, it was observed that, when reaction volume was increased (>1 mL), the yields of **1** dropped significantly. Since a concerted mechanism, where the reduction of the metal center and the CO addition take place almost simultaneously, is proposed for the carbonylation reaction (*12*), the availability of reducing agent and CO are limiting factors. Thus, a fast saturation of the aqueous solution with carbon monoxide can only be guaranteed if the volume of the solution is relatively small. Yet, solutions of up to 14 GBq/mL Re-188 could be successfully carbonylated with both methods.



The free precursor **1** is stable (>90%) for approximately 3 h at pH = 7−5. After this time, decomposition of the precursor and reformation of $^{188}ReO_4^-$ was observed in the absence of effectively coordinating and stabilizing ligands. Addition of radical scavenging coligand such as gentisic acid or ascorbic acid did not significantly improve the half-life of the precursor.

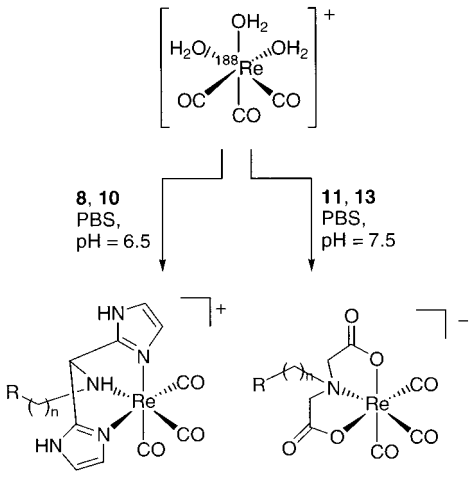
Scheme 3[a]



[a] Reagents and conditions: (a) MeOH, NEt_3, reflux, 15 h; 2 M NaOH; (b) 3 M HCl, 50 °C.

To translate the excellent yields and specific activities of precursor **1** on the radiolabeling of biomolecules such as peptides and proteins, novel, bifunctional ligand systems have been developed. Ligands **8** and **10** could be produced in a straightforward synthetic approach. Bifunctionalization of the chelate system was achieved by reacting the previously *mono N*-Boc-protected diamines or commercially available amino alkyl carboxylic acids with bis(imidazol-2-yl)nitromethane in the presence of aqueous NaOH (Scheme 2). Under these conditions, the nitro group is displaced by the nucleophilic amino group forming the corresponding N_α-substituted 2,2′-bis-(imidazolyl)methanes. Deprotection of the Boc group was accomplished in 3 M HCl at 50 °C (Scheme 3). The $^1H/^{13}C$ NMR and mass spectra and elemental analyses confirmed the composition and the symmetric structure of the ligands. In all compounds the four C−H protons of the imidazole rings are chemically equivalent, forming singlets around 7 ppm.

Ligands **11** and **13** could be produced in two and three steps, respectively. The chelating moiety was built up by a double alkylation of the primary amino group with methyl bromoacetate in the presence of triethylamine in good yields. Subsequent saponification of the ester groups and/or deprotection of the *N*-Boc group afforded the bifunctional IDA derivatives (Scheme 3). The $^1H/^{13}C$ NMR

Scheme 4

and mass spectra and elemental analyses confirmed the composition and the structures of the ligands.

Radiolabeling and in Vitro Stability. Radiolabeling of ligands **8/10** and **10/13** with precursor **1** was performed in PBS buffer at pH 6.5−7.5 (Scheme 4). Different labeling conditions have been tested. Short incubation at higher temperature (10 min, 100 °C) or longer incubation at lower temperature (37 °C, 3 h) revealed almost complete consumption of **1**, but it was observed that under these conditions the reformation of perrhenate prohibits labeling yields better than 40% of the initial activity. The best conditions for radiolabeling were found to be 60 °C for 60 min in PBS. All tested ligand systems formed single species with the precursor **1**.

Plotting the labeling yields of the different chelate systems as a function of ligand concentration revealed steep sigmoid curves (Figure 1). Generally the 2,2′-diimidazolylmethylamine chelates (**8**/**10**) yielded the corresponding Re-188 complexes at 1 order of magnitude lower concentration (5×10^{-5}M) than the IDA-chelates (5×10^{-4}M for **11**/**13**). At these concentrations, labeling yields >95% in respect to $[^{188}Re(OH_2)_3(CO)_3]^+$ and specific activities of up to 220 GBq/μmol ligand (based on initial activity of 14 GBq/mL $^{188}ReO_4^-$) could be achieved. The pendent additional functional groups (CO_2H or NH_2) did not seem to have an influence on the labeling yields.

Stability of the Re-188 complexes was evaluated in human serum at 37 °C over a period of 48 h (Table 1). The $^{188}Re(CO)_3$ complexes with ligands **8**/**10** showed generally a higher stability (80 ± 4% 24 h and 63 ± 3% 48 h postincubation in human serum) than those with ligands **11**/**13** (45 ± 10% 24 h and 34 ± 3% 48 h postincubation in human serum). The TLC and HPLC analyses of aliquots of the incubated plasma samples revealed beside the intact complexes decomposition predominantly to $^{188}ReO_4^-$. Only minor transchelation and aggregation to plasma proteins have been observed (>4% of total activity).

Preparation and Analysis of Rhenium Complexes. To determine the coordinative features of the novel ligand systems, two representative rhenium model complexes with ligand **8b** and **13a** have been prepared and fully characterized including the X-ray structures. The complexes revealed almost identical retention times on the HPLC column ($[Re(\mathbf{8b})(CO)_3]^+$: 19.8 min; $[Re(\mathbf{13a})(CO)_3]$: 20.4 min) as the corresponding radioactive complexes ($[^{188}Re(\mathbf{8b})(CO)_3]^+$: 19.9 min; $[^{188}Re(\mathbf{13a})(CO)_3]$: 20.2 min) proving the identity of the complexes on the macroscopic and the nca level. Analysis of the ^{1}H NMR

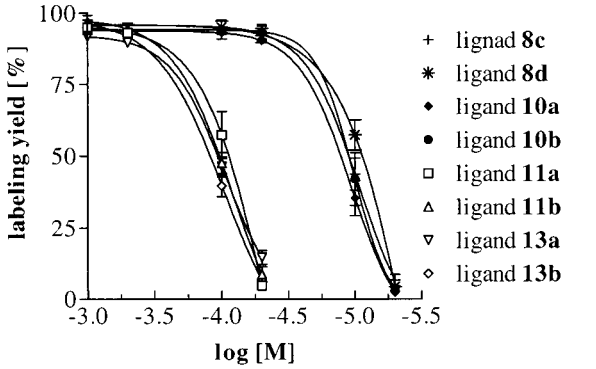


Figure 1. Labeling yield as a function of the ligand concentration in PBS buffer pH = 6.5 (ligands **8**/**10**) and pH = 7.5 (ligands **11**/**13**) 60 min, 60 °C.

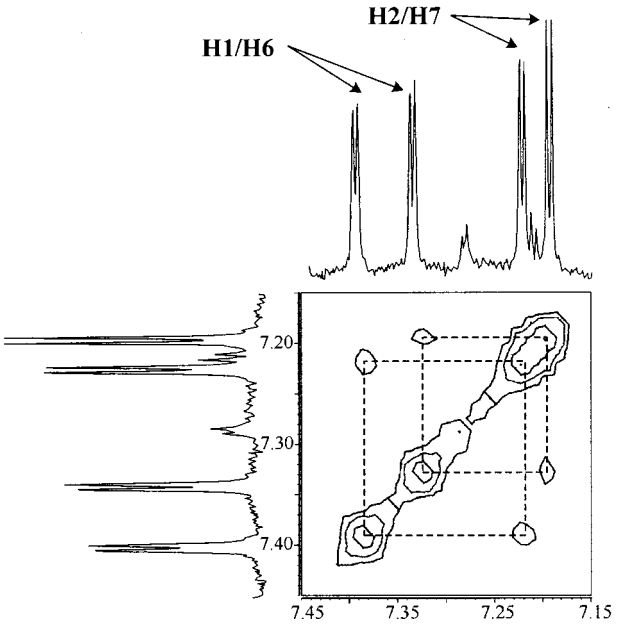

Figure 2. 2D proton NMR (COSY) of the aromatic region (imidazole protons) of complex $[Re(\mathbf{8b})(CO)_3]Br$. For proton numbering, see Figure 3.

spectrum of complex $[Re(\mathbf{8b})(CO)_3]Br$ showed four doublets with an intensity of one proton each. Two-dimensional NMR experiments (^{1}H/^{1}H COSY) revealed coupling between two pairs of protons (Figure 2) indicating an unsymmetrical coordination or structure of the complex.

A concluding explanation for this observation could be found after analysis of the X-ray structure. Crystals of X-ray quality could be grown by exchange of the bromide in complex $[Re(\mathbf{8b})(CO)_3]Br$ with the more bulky perchlorate anion. The ligand coordinates tridentately via the two imidazole rings and the secondary amino group

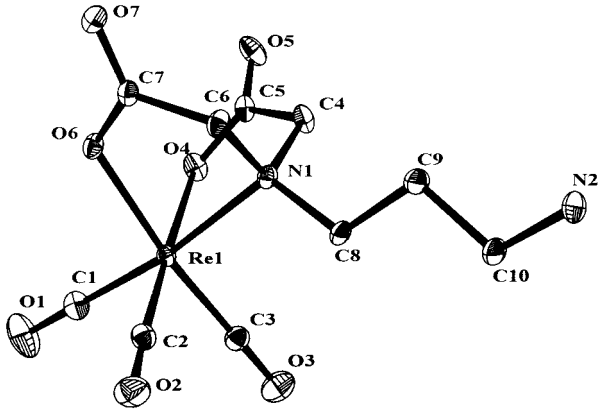

Figure 4. ORTEP (*18*) of the complex $[Re(\mathbf{13aH}^+)(CO)_3]$. H-atoms are omitted for clarity. Re(1)−C(1) 1.919(4) Å; Re(1)−O(4) 2.114(3) Å; Re(1)−O(6) 2.153(3) Å; Re(1)−N(1) 2.239(3) Å; C(2)−Re(1)−C(1) 87.74(17)°; C(3)−Re(1)−C(1) 88.40(17)°; C(2)−Re(1)−O(4) 173.96(13)°; O(4)−Re(1)−O(6) 78.19(11)°; O(4)−Re-(1)−N(1) 78.69(11)°; O(6)−Re(1)−N(1) 76.78(11)°.

as expected, forming two five-membered and one six-membered ring with the metal center (Figure 3). The structure clearly reveals the asymmetry of the ligand/complex after complexation. In respect to the N(3)−C(4) bond one of the imidazole rings is *trans* and one is *cis* oriented in respect to the acetyl methyl ester group (Figure 3). Clearly the orientation of the residue at the coordinated secondary amino group must be the reason for the chemical nonequivalence of the imidazole rings. The fact, that this NMR pattern was observed for all complexes with an N_α-substituted 2,2′-diimidazolylmethane amine ligand but not with the unsubstituted is a further evidence for this assumption. Temperature-dependent NMR experiments (20−90 °C) did not show a significant change of these patterns, proving the rigid and inert coordination of the ligand to the metal center. The IR spectrum of compound $[Re(\mathbf{8b})(CO)_3]Br$ showed the typical *fac*-$M(CO)_3$ pattern for the CO ligands at 2028 and 1922 cm^{-1}/1904 cm^{-1}. This is significantly blue-shifted, compared to the educt $(NEt_4)_2[ReBr_3(CO)_3]$ (2000 cm^{-1}, 1868 cm^{-1}).

The neutral complex $[Re(\mathbf{13aH}^+)(CO)_3]$ crystallized directly as colorless needles from the reaction medium (H_2O). Analysis of the ^1H NMR spectrum of complex $[Re(\mathbf{13aH}^+)(CO)_3]$ revealed a typical pattern of an AB system for the four protons of the coordinated IDA moiety. The previously identical NCH_2COO protons of the IDA moiety became nonequivalent upon rigid coordination to the metal center by virtue of their different chemical environment. The same spectroscopic features have been observed for all complexes with ligands **11** and **13** and were also reported for rhenium-tricarbonyl complexes of IDA-functionalized desoxyglucose and glucose derivatives (*19*). The IR spectrum of compound $[Re(\mathbf{13aH}^+)(CO)_3]$ showed M−CO stretch frequencies at 2018 and 1902 cm^{-1}. The X-ray structure confirmed the tridentate coordination of the ligand via the two carboxylates and the tertiary amino group (Figure 4).

CONCLUSION

The organometallic precursor $[^{188}Re(H_2O)_3(CO)_3]^+$ can now be prepared in a simple one-step synthesis in good yields and high specific activities. These procedures will allow the easy performance of therapeutic studies using the organometallic labeling approach. In fact in vitro experiments with Re-188 tricarbonyl-labeled antibodies against bladder cancer have shown the superior characteristic of the carbonyl technology compared to "classical" Re(V) methods (*20*). The novel, tridentate, bifunctional chelating systems presented in this work are versatile and offer the possibility to insert presumably any type (e.g. alkyl, poly(ethylene glycol), benzene) and length of spacer adaptable to different biomolecules. Particularly with ligands containing a bis(imidazole-2-yl)methylamine moiety high labeling yields should be possible at low ligand concentration.

ACKNOWLEDGMENT

We thank Judith Stahel, for her assistance in preparing the Re-188 complexes and Prof. Horst Bruchertseifer and Dr. Bernd Jäckel for generously providing Na-$[^{188}ReO_4]$. This work was supported by Mallinckrodt-Tyco Inc.

Received November 12, 2001; Revised Manuscript Received May 9, 2002

This study describes the synthesis, characterization, and reactivity of new methoxypoly(ethylene glycol) (mPEG) derivatives containing a thioimidoester reactive group. These activated polymers are able to react with the lysyl ϵ-amino groups of suitable proteins, generating an amidinated linkage and thereby preserving the protein's positive charge. mPEG derivatives of molecular weight 2000 and 5000 Da were used, and two spacer arms were prepared, introducing chains of different lengths between the hydroxyl group of the polymer and the thioimidate group. These mPEG derivatives were used to modify gelonin, a cytotoxic single-chain glycoprotein widely used in preparation of antitumoral conjugates, whose biological activity is strongly influenced by charge modification. The reactivity of mPEG thioimidates toward lysil ϵ-amino groups of gelonin was evaluated, and the results showed an increased degree of derivatization in proportion to the molar excesses of the polymer used and to the length of the alkyl spacer. Further studies showed that the thioimidate reactive is able to maintain gelonin's significant biological activity and immunogenicity. On the contrary, modification of the protein with N-hydroxysuccinimide derivative of mPEG strongly reduces the protein's cytotoxic activity. Evaluation of the pharmacokinetic behavior of native and PEG-grafted gelonin showed a marked increase in plasma half-life after protein PEGylation; in particular, the circulating life of the conjugates increased with increased molecular weight of the polymer used. The biodistribution test showed lower organ uptake after PEGylation, in particular by the liver and spleen.

INTRODUCTION

Ribosome-inactivating proteins (RIPs)[1] are a group of naturally occurring plant and fungal proteins that have been widely studied for their potential applications, especially as anticancer agents (*1*).

All RIPs exhibit RNA N-glycosidase activity, depurinating rRNA at a specific universally conserved position (i.e., cleavage of N-glycosidic bond of a specific adenine of 28S rRNA) (*2*). More recently, it has appeared that RIPs are also capable of inactivating many nonribosomal nucleic acid substrates (*3*) and hence can be considered polynucleotide:adenosine glycosidases. These insights have renewed interest in RIPs because understanding the enzymatic activity enhances exploitation of the properties and activities of RIPs for diverse applications. Indeed, such biomolecules are being exploited for designing immunotoxins/hormonotoxins obtained by chemical conjugation or by production of chimeric proteins using gene splicing DNA techniques (*4*, *5*). Other applications of therapeutic potential for nonconjugated RIPs lie in the treatment of some cancers (*5*) and AIDS (*6*, *7*) and as abortifaciens (*8*).

Gelonin, a protein extracted from the seeds of *Gelonium multiflorum*, is one of the most interesting RIPs and has been widely used in the preparation of conjugates directed against tumor epitopes (*9*, *10*) or as antiviral agent (*11*, *12*). Recently, it has also been suggested that gelonin has DNA-damaging activity, which may be responsible for the elimination of the parasite 6 kb extrachromosomal mitochondrial DNA of *Plasmodium falciparum*-infected erythrocytes (*13*−*15*).

Gelonin has been used by our group particularly in the preparation of conjugates with monoclonal antibodies using both new heterobifunctional linkers and noncovalent systems (*16*−*19*). Indeed, one favorable aspect of using gelonin is its low systemic toxicity (LD_{50} 40 mg/Kg body weight) and its low toxicity on intact cells (IC_{50} > 33 μM on HeLa) due to its incapability of penetrating cell membranes. Furthermore, it is rapidly removed from the bloodstream by kidney filtration (*20*). Clinical use of RIPs and related immunotoxins may be limited by the host immune response observed in patients after injection of RIPs, as reported in Lambert et al. (*21*). Allergic reaction and occasional anaphylactic response have, for example, been described for trichosanthin (*22*, *23*), and the same behavior has been found for gelonin (*24*). Specific antibodies against immunotoxins containing gelonin have been observed after infusion in monkeys;

high-titer antibody responses developed quickly, and sera from the infused monkeys were able to block the cytotoxicity of the immunotoxin (*24*).

To improve the behavior and thus the therapeutic efficacy of gelonin, alone or conjugated with a targeting moiety, we considered an approach to surface modification using a covalent coupling reaction with poly(ethylene glycol) (PEG) derivatives.

PEG is used to modify various proteins. PEG-grafted proteins exhibit increased stability, decreased immunogenicity, and increased circulating lives (*25*−*27*). Furthermore, PEG conjugates are more resistant to proteolysis, and in vivo activity can sometimes be enhanced despite a reduction in in vitro activities (*28*). The major problem of PEG conjugation of RIPs is their sensitivity to lysine modification. Some authors have reported a rapid decrease in the ability of several RIPs, and in particular gelonin, to inhibit protein synthesis after modification with SPDP or other reactives able to modify charge (*29*−*31*).

To obtain polymer conjugates with almost unaltered gelonin activity, we prepared novel derivatives of mPEG containing a thioimidoester reactive group. This reactive group is able to react with the protein lysyl ϵ-amino groups in physiological conditions (pH 7.5), generating an amidinated linkage and thus preserving the positive charge of the protein.

This paper describes the synthesis and chemical characterization of mPEG-thioimidates, with different molecular weights and different spacers between mPEG and thioimidate group**.** These reactives were applied to prepare different conjugates with gelonin. The conjugates were then purified and characterized in terms of molecular mass, in vitro activity, and immunogenicity. The pharmacokinetics and organ distribution were also studied.

EXPERIMENTAL PROCEDURES

Materials. mPEG 2000 and 5000 and mPEG succinimidyl succinate with M_r of 5 kDa (SS-5PEG) were purchased from Sigma Chemical Co. (St. Louis, MO). mPEG succinimidyl succinate with M_r of 20 kDa (SS-20PEG) was from Shearwaters Corp. (Huntsville, AL). Gelonin was extracted from seeds of Gelonium multiflorum and purified to mass homogenicity (M_r = 30 kDa) and characterized (*32, 33*). 2,4,6-trinitrobenzenesulfonic acid (TNBS) was from Serva (Heidelberg, Germany). All other reagents were purchased from Aldrich (Milwaukee, WI). Diethyl ether and tetrahydrofuran (THF) were dried over sodium benzophenone ketyl.

General Procedures. ^{1}H NMR spectra were recorded on a Bruker AC 200 instrument, operating at 200 MHz, with tetramethylsilane as internal standard. Ultraviolet spectra were recorded on a Beckman DU-70 spectrophotometer. The reactions were monitored by TLC on F_{254} silica gel precoated sheets (Merck, Milan, Italy); after development, the sheets were exposed to iodine vapor. Flash column chromatography was performed on 230−400 mesh silica gel (Merck).

Preparation of Sodium Naphthalene Solution. Naphthalene 2.6 g (20 mmol) was dissolved in 20 mL of dry THF under a nitrogen atmosphere dried by passing it through concentrated sulfuric acid and NaOH platelets in two washing bottles. About 0.5 g (22 mmol) of small clean pieces of sodium was then rapidly added, and the mixture was stirred for 2 h at room temperature under dry nitrogen.

Preparation of mPEG(CH$_2$)$_2$CN (1, 2). Five grams of mPEG 2000 (2.5 mmol) or 5000 (1 mmol) was dissolved in 100 mL of toluene and dried by removal of the water−toluene azeotrope. The solution was cooled to room temperature, concentrated, and then dissolved in 50 mL of dry THF. The sodium naphthalene solution prepared previously was added dropwise to the mPEG solution under dry nitrogen and stirring; addition continued until a persistent pale green solution was obtained. A solution of 3-bromopropionitrile (2 mL, 25 mmol in the case of mPEG 2000 or 830 μL, 10 mmol in the case of mPEG 5000) dissolved in 5 mL of dry THF was slowly added to the solution, and the reaction mixture was allowed to stand overnight at room temperature under dry nitrogen. The reaction mixture was concentrated under reduced pressure and filtered, and the filtrate was added dropwise into 100 mL of diethyl ether under stirring; the resulting solid was collected by filtration and purified. Derivative **1**, prepared from mPEG 2000, was purified by flash chromatography with elution in dichloromethane/methanol (96:4). The pure product was obtained with a yield of 60% (3 g): ^{1}H NMR ($CDCl_3$) 3.6 (s, mPEG backbone methylene), 3.3 (s, 3H, terminal mPEG methoxy), 2.6 (t, 2H, −O−CH$_2$−*CH$_2$*−CN). We obtained 2 g (40%) of derivative **2** after crystallization from diethyl ether; ^{1}H NMR ($CDCl_3$) 3.6 (s, mPEG backbone methylene), 3.3 (s, 3H, terminal mPEG methoxy), 2.5 (t, 2H, −O−CH$_2$−*CH$_2$*−CN).

Preparation of mPEG(CH$_2$)$_6$CN (3, 4). The same procedure used to prepare **1** and **2** was followed, using 7-bromoheptanenitrile (25-fold molar excess respect to mPEG). The crude products were purified by flash chromatography (dichoromethane/methanol, 93:7) to give **3** (85%): ^{1}H NMR ($CDCl_3$) 3.55 (s, mPEG backbone methylene), 3.4 (s, 3H, terminal mPEG methoxy), 2.34 (t, 2H, −CH$_2$−CN), 1.59 (m, 4H, −O−CH$_2$−*CH$_2$*−CH$_2$−CH$_2$−*CH$_2$*−CH$_2$−CN), 1.4 (m, 4H,-O−CH$_2$−CH$_2$−*CH$_2$*−*CH$_2$*−CH$_2$−CH$_2$−CN).

Derivative **4** was purified by flash chromatography with elution in dichloromethane/methanol 92:8 (yield 95%). The NMR spectrum was similar to that of compound **3**.

Preparation of mPEG−Thioimidate ester hydrochlorides (5−8). The thioimidate ester hydrochlorides **5**−**8** were obtained from the corresponding nitriles **1**−**4** by the Pinner synthesis (*34*). Hydrogen chloride gas, dried by being passed through concentrated sulfuric acid in two washing bottles, was bubbled through ice-cold ethanthiol (560 μL, 7.5 mmol). The nitrile (0.25 mmol) dissolved in anhydrous dichloromethane was quickly added to the cold solution under stirring; the flask was tightly stoppered and left overnight at 0 °C. Anhydrous cold diethyl ether was then added to the reaction mixture, which was left at −20 °C until a crystalline solid formed. The supernatant was decanted, and the precipitate was washed 3 times with anhydrous cold diethyl ether under argon and dried under reduced pressure at room temperature.

Compounds **5** (yield 85%) and **6** (yield 75%): ^{1}H NMR ($CDCl_3$) 3.6 (s, mPEG backbone methylene), 3.4 (s, 3H, terminal mPEG methoxy), 3.1 (t, 2H, −O−CH$_2$−*CH$_2$*−C=NH_2^+), 1.4 (t, 3H, S−CH$_2$−*CH$_3$*).

Compounds **7** and **8** (yield 95%): ^{1}H NMR ($CDCl_3$) 3.64 (s, mPEG backbone methylene), 3.4 (s, 3H, terminal mPEG methoxy), 2.9 (t, 2H, −*CH$_2$*−C=NH_2^+), 1.8 (m, 4H, −O−CH$_2$−*CH$_2$*−CH$_2$−CH$_2$−*CH$_2$*−CH$_2$−C=NH_2^+), 1.6−1.4 (m, 7H −O−CH$_2$−CH$_2$−*CH$_2$*−*CH$_2$*−CH$_2$−CH$_2$−C=NH_2^+, −S−CH$_2$−*CH$_3$*).

Polymers−Gelonin Conjugate Preparation. A solution of gelonin (5 mg/mL, 500 μL) in PBS-EDTA (100 mM sodium phosphate, 100 mM NaCl, 1 mM EDTA, pH 7.4), deaerated and flushed with argon, was added to

different molar excesses of the mPEG−thioimidate ester hydrochlorides (**5**−**8**). The solution was left for 1 h at room temperature under stirring. The molar ratio of activated mPEG to protein ranged from 2- to 50-fold. For comparison, gelonin was also modified with increasing excesses (from 2- to 50-fold) of the commercially available SS-5PEG, methoxypoly(ethylene glycol) succinimidyl succinate with a M_r of 5 kDa.

The unreacted PEG was removed using an Amicon system (Danvers, MA) with YM membranes (cutoff, 10 and 30 kDa). The crude conjugates were separated on a Zorbax Bio Series GF 250 column (250 × 9.4 mm) (Du Pont, Newtown, Connecticut) that was equilibrated and eluted with 0.01 M sodium phosphate, 0.1 M sodium sulfate, pH 7.0, eluting buffer, and flow rate 0.5 mL/min. The chromatographic procedures were performed at 20 °C. All the chromatograms were generated on a Merck-Hitachi 655A-12 Liquid Chromatographer equipped with a L5000 LC Controller (Merck), and the eluting fractions were monitored at 280 nm using a L4000 UV detector. Peak heights and areas were recorded and processed on a CBM-10A Shimadzu interface (Shimadzu, Milan, Italy).

The protein concentration was evaluated spectrophotometrically at 280 nm and also determined by a biuret assay.

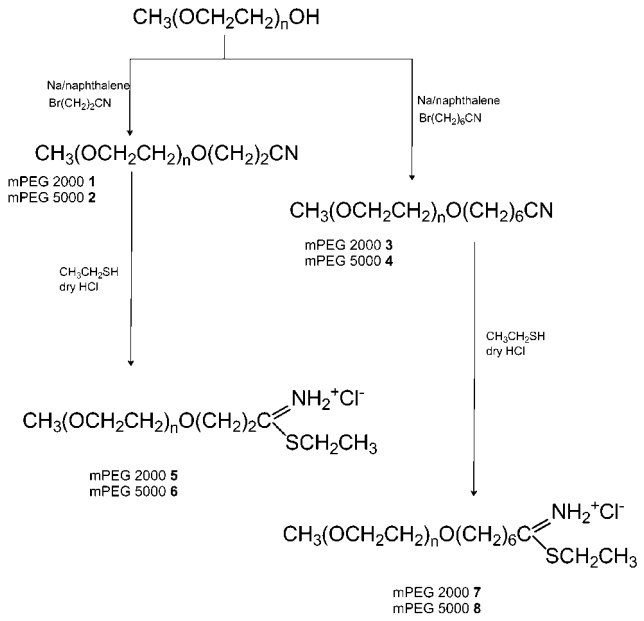
The extent of protein modification was evaluated colorimetrically following the Habeeb's method (*35*). The sample solution (1 mL) at protein concentration between 0.7 and 1 mg/mL was diluted with 1 mL of 4% sodium bicarbonate solution, and 1 mL of 0.1% 2,4,6-trinitrobenzenesulfonic acid (TNBS) solution was added. After 2 h at 40 °C, the reaction was stopped by the addition of sodium dodecyl sulfate and HCl. The absorption at 341 nm was correlated with the number of free amino groups ($\epsilon = 12400$).

Gelonin−PEG conjugates were analyzed by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS−PAGE) using 4−15% precast gels (Bio-Rad, Hercules, CA) in nonreducing conditions. Coomassie blue staining was used to visualize the proteins.

Protein Synthesis Inhibition Assay. The inhibitory activity of gelonin−PEG derivatives on cell-free protein synthesis was evaluated with a rabbit reticulocyte lysate prepared as described by Allen and Schweet (*36*). Gelonin, appropriately diluted, was added to a reaction mixture containing, in a final volume of 62.5 μL: 10 mM Tris/HCl buffer, pH 7.4, 100 mM ammonium acetate, 2 mM magnesium acetate, 1 mM ATP, 0.2 mM GTP, 15 mM phosphocreatine, 3 μg of creatine kinase, 0.05 mM amino acids (minus leucine), 3.3 kBq of L-^{14}C-leucine (Amersham International, Bucks, U.K.), and 25 μL of a rabbit reticulocyte lysate. Incubation was at 28 °C for 5 min. The reaction was arrested with 1 mL of 0.1 M potassium hydroxide, and two drops of hydrogen peroxide and 1 mL of 20% (w/v) of trichloroacetic acid were added. Precipitated proteins were collected on glass-fiber disks, and the radioactivity incorporated was measured with a β-counter (Beckman, Fullerton, CA) after addition of 5 mL of Ready Gel scintillation cocktail (Beckman) containing 0.7% acetic acid. Each experiment was carried out in duplicate. The concentration of RIP causing 50% inhibition of leucine incorporation (IC_{50}) was calculated by linear regression analysis. All tests were repeated three times.

Production of Antigelonin mAbs. Antigelonin mAbs were produced according to a standard immunization/fusion protocol using P3U1 myeloma cells (*37*). Hybrid cells were selected by culture in HAT (hypoxanthine aminopterin thymidine) medium 18 h after fusion. Hybridoma supernatants were screened by the enzyme-linked immunosorbent assay (ELISA) using gelonin-coated microtiter plates. For this study, we mixed three mAbs (B 3.1, A12, E17) that strongly reacted in ELISA assay with native gelonin. The culture medium for hybrids was RPMI 1640 supplemented with 10% FCS and 2 mM L-glutamine.

Immunoreactivity. The immunoreactivity was determined using a modification of the ELISA assay (*38*). Enzyme microtitration plates were coated with antigen (4 μg/well of RIP) solubilized in 50 mM sodium bicarbonate buffer, pH 9.6, and left overnight at 4 °C. The plates were washed 3 times with 0.14 M NaCl/5 mM sodium phosphate buffer, pH 7.5, containing 0.05% (v/v) Tween 20 (PBS-Tween), blocked with 200 μL/well of PBS-Tween containing 0.5 mg/mL bovine serum albumin for 60 min at 37 °C, and washed 3 times as described above. Specific mouse antisera mix was serially diluted in PBS-Tween, added to the antigen coated plates, and incubated for 3 h at 37 °C. Plates were washed 3 times and incubated with 200 μL of appropriately diluted secondary antibody (goat antimouse IgG conjugated with alkaline phosphatase, Sigma) in PBS-Tween for 1 h at 37 °C. Plates were washed 3 times as described above and incubated with 200 μL of 1 mg/mL 4-nitrophenyl phosphate disodium salt in diethanolamine buffer, pH 9.8, for 30 min a 37 °C. Absorbance was measured in a Bio-Rad microtiter plate reader at 405 nm.



Pharmacokinetics and Biodistribution. To evaluate the in vivo behavior of gelonin and mPEG modified protein, we prepared different conjugates using ^{125}I gelonin as tracer. The protein was labeled with ^{125}I by the iodogen method (*39*), and 250 MBq of ^{125}I gelonin (specific activity 166.15 MBq/μg) was added to a solution of unlabeled protein (10 mg/mL). The conjugates were prepared as previously described, reacting gelonin with a 5-fold molar excess of thioimidate derivatives **7** and **8** and with a 3-fold molar excess of SS-20PEG.

Pharmacokinetic studies were performed using female Balb/c mice (1 month old, 18−20 g; Charles River Italia, Milan, Italy), the mice drank water plus 0.2% (v/v) Lugol solution 3 days before and during the experiment to block thyroid iodine uptake. The animals were injected intravenously into the tail vein (groups of three animals each) with a single dose of ^{125}I-gelonin and of the mPEG−^{125}I-gelonin conjugates ranging from 7.5 to 9.1 MBq. The samples were diluted in a carrier solution of PBS pH 7.4 to a volume of 100 μL. Blood samples were taken from the retroorbital plexus and withdrawn into heparin-containing tubes at various times (0, 10, 15, 20, 30, 60, 90, 120, and 240 min and 24 h for conjugates and 0, 5, 10, 15, 30, and 45 min for gelonin). Experiments were repeated 3 times. The blood samples were precipitated rapidly with 1 mL of cold trichloroacetic acid (12.5%, w/v). The samples were counted directly in a gamma counter (L'ACN, Milan, Italy) and then centrifuged; the resultant pellets were counted and used to determine the pharmacokinetic parameters.

Pharmacokinetic parameters were determined from a two-compartmental model analysis using the Software KINETICA 2.00.200 (InnaPhase, Champs Sur Marne, France). Data were fitted using a compartmental open model. Elimination and distribution were represented by the following parameters: mean residence time (MRT), total body clearance (Cl), volume of distribution at steady state (V_{ss}), distribution, and elimination phases ($t_{1/2}^{\alpha}$, $t_{1/2}^{\beta}$).

Other groups of five animals each were similarly injected, and the liver, kidney, and spleen, were removed at different times (10, 30, 60, and 120 min, and 24 h).

Scheme 1

The organs were washed twice in physiological solution, wiped, weighed, and γ-counted. The counting was performed on intact organs and also after mechanical shattering to correctly measure radioactivity. The monitored radioactivity was recorded as concentration, in percent injected dose per gram of organ versus time and represented through histograms. The experiments were repeated 3 times.

Care and handling of the animals were in accordance with the provisions of the European Economic Community Council Directive 86/209 recognized and adopted by the Italian Government (approval Decree No. 230/95 B).

RESULTS

Chemistry. The mPEG−thioimidate ester hydrochlorides **5**−**8** were obtained as shown in Scheme 1. These activated polymers were prepared starting from mPEG of molecular weight 2000 and 5000 Da and were characterized by the presence of spacers of different lengths between the polymer chain and the reactive group.

Initially, the sodium naphthalene solution was prepared by stirring clean pieces of sodium with a slight excess of naphthalene in dry THF under nitrogen at room temperature (*40*). Then mPEG 2000 or 5000 was converted to the corresponding nitrile **1** or **2** by titration with sodium naphthalene to generate the alkoxide, followed by treatment with 3-bromopropionitrile. Derivative **1**, obtained from mPEG 2000, was easily purified by flash chromatography, but it was not possible to purify the corresponding nitrile **2** prepared from mPEG 5000 in the same way because it was impossible to discriminate the starting product from the obtained nitrile by TLC. Derivative **2** was thus purified by crystallization from diethyl ether. Compounds **3** and **4** were obtained in a similar way, using 7-bromoheptanenitrile instead of 3-bromopropionitrile and were easily purified by flash chromatography. Probably in this case, the presence of a hexamethylenic spacer between the PEG backbone and the nitrile group allowed better discrimination of derivatives **3** and **4** on gel chromatography. The corresponding thioimidates **5**−**8** were prepared throught the Pinner synthesis by addition of the nitrile to a solution of ethanthiol previously saturated with dry hydrogen chloride. The yield of activation was usually above 90% and was ascertained by NMR (integration of the peaks corresponding to the terminal mPEG−methoxy and to the methylene in α position to the thioimidate). The thioimidates required storage under very anhydrous conditions and were stored at −20 °C under dry argon. To maintain their reactivity unmodified, it is important to reduce exposure to atmospheric humidity because of the hygroscopicity of the compounds. Under these conditions they are stable for several months.

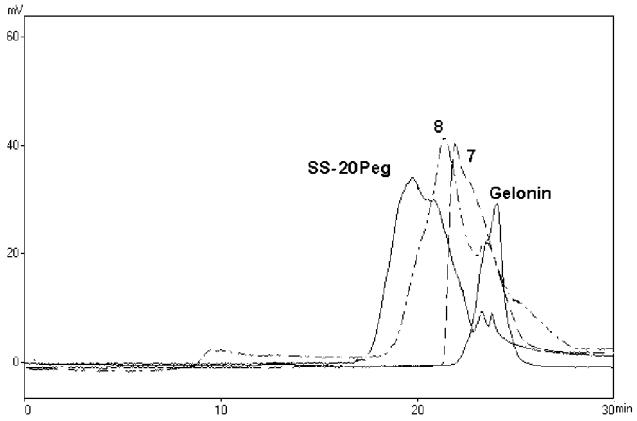


Figure 1. Molecular exclusion chromatographic profiles of gelonin and crude conjugates obtained by reaction with 5-fold molar excesses of compounds **7**, **8**, and SS-20PEG on gel-filtration column Zorbax Bio Series GF 250.

Reaction of mPEG−Thioimidate with Gelonin. The reactivity of the activated polymers **5**−**8** toward the protein lysyl ϵ−amino groups of gelonin, a 30 kDa cytotoxic single-chain glycoprotein, was evaluated. Gelonin was found to be composed of 258 amino acids and contains 21 lysine residues (*41*). The mPEG−thioimidate was added in various molar excesses (from 2- to 50-fold) to the solution of the protein (5 mg/mL) for 1 h at room temperature; the conjugates were then purified from the excess of mPEG by ultrafiltration. To remove the unreacted gelonin, we submitted the conjugates to molecular exclusion chromatography (Figure 1). This purification is necessary before submitting the samples to characterization assays and to in vitro tests.

The concentration of native or PEG-grafted protein was evaluated either spectrophotometrically at 280 nm or using biuret reaction.

The derivatization degree was estimated by titration of free amino groups by TNBS method. Figure 2 shows the number of modified amino groups of gelonin versus the different excesses of mPEG−thioimidates. From the figure, it is evident that the derivatization degree increases in proportion to the molar excess of mPEG used. This is particularly evident for derivatives **7** and **8**, characterized by the presence of a hexamethylenic spacer between the polymer backbone and the thioimidate reactive group, which was found to be more reactive toward the protein than derivatives **5** and **6**, characterized by a dimethylenic spacer. This behavior is more evident when the mPEG−thioimidate excess was increased from 10- to 50-fold. At 50-fold excess of **8**, for instance, 12 lysine residues were derivatized with compound **8** and only six with compound **6**. We also compared the reactivity of the thioimidates with that of the commercially available SS-5PEG (M_r, 5 kDa) characterized by the presence of a highly reactive succinimidyl ester reactive group, which generates an amidic bond by reaction with protein amino groups. As shown in Figure 2, compound **8** and SS-5PEG demonstrated a similar

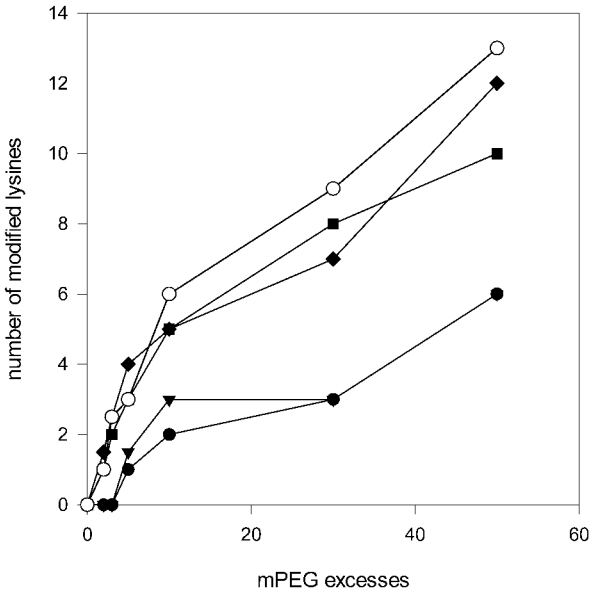

Figure 2. Reactivity of different mPEG−thioimidates toward gelonin. The activated polymer was added in molar excesses from 2- to 50-fold to solutions of the protein. The extent of protein modification was evaluated by titration of free amino groups by the TNBS method after purification from excess mPEG. The points represents the arithmetic means of three determinations; SDs (not reported) were <10% of the means. Solid circle compound, **5**; solid triangle pointing down, **6**; solid square, **7**; solid diamond, **8**; and outline circle, SS-5PEG.

behavior using excesses of polymer, modifying up to 50% of the total lysines of gelonin.

To analyze the molecular weight of the protein after derivatization with the different mPEG-thioimidates, we analyzed the conjugates by SDS−PAGE electrophoresis.

Figure 3 shows the SDS−PAGE of the gelonin−PEG conjugates obtained by modifying the protein with different excesses of compound **7** and **8** and SS-20PEG (M_r, 20 kDa). The gel shows that, on increasing the number of mPEG molecules attached to gelonin, the size of the protein increased although a clear distribution in molecular weight was evident only for lower derivatization degrees. On increasing the linked PEG molecules, broader bands appeared. Bands relative to unreacted gelonin were evident only when lower mPEG excess was used.

Protein Synthesis Inhibition Activity and Immunoreactivity. Table 1 summarizes the characteristics of PEGylated gelonin in terms of derivatization degree, IC_{50} in a reticulocyte lysate cell free protein synthesis system, and antigelonin antiserum recognition.

The thioimidate linkers are able to maintain a higher activity than the N-hydroxysuccinate analogues. Gelonin

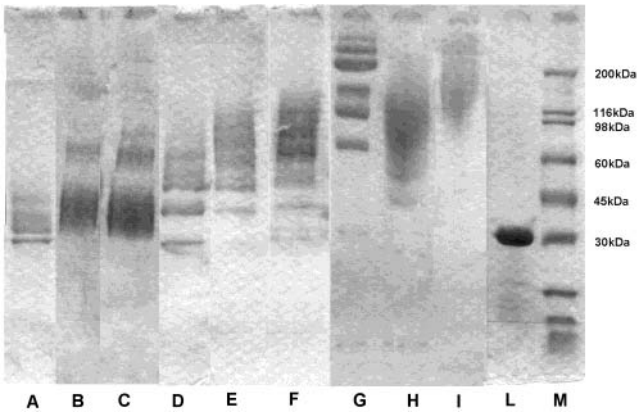

Figure 3. SDS−PAGE analysis of gelonin and conjugates obtained with increasing excesses of mPEG−thioimidates **7** and **8** and SS-20PEG. Samples were run on a 4−15% polyacrylamide gel under nonreducing conditions and Coomassie blue staining. Lanes A−C, conjugates obtained with molar excesses (5, 10, and 20) of compound **7**; lanes D−F, conjugates prepared using increasing excesses of compound **8** (5, 10, and 20); lanes G−I, conjugates prepared using increasing excesses of SS-20PEG (5, 10, and 20); lane L, gelonin; lane M, molecular markers. Molecular masses are expressed in kDa.

is a highly basic protein (pI, >9), and thus direct evaluation of surface charge modification (e.g., by IEF) is not realizable, but as demonstrated in a previous paper (*31*), a direct relationship between charge modification and loss of cell-free activity exists. Gelonin appeared very sensitive to modification of its RNA N-glycosidase activity; on increasing the derivatization degree over two lysyl groups, activity rapidly decreases. From the results in Table 1, the thioimidate linkage appears able to maintain 50% of native activity for a derivatization degree of three groups, while only 18% was evident using N-hydroxysuccinate analogue under the same conditions. An increase in M_r over 5 kDa is responsible for a rapid fall of gelonin activity: in fact, just one PEG group of 20 kDa can reduce the toxic activity to 12% of initial values.

Immunoreactivity is strongly affected by PEG length; a PEG 2 kDa chain is not able, in any of the conditions tested, to reduce antibody recognition by more than 68% (compounds **5**, **7**), while an increase in M_r to 5 kDa reduces recognition to 37%. A further increase in M_r (SS-20 PEG) give not a detectable reaction at any antiserum dilution.

Pharmacokinetic Studies and Organ Disposition. The influence of the PEG protein modification on circulation time was studied after intravenous bolus administration of native and modified gelonin to Balb/c mice. The RIP was radiolabeled with ^{125}I and the samples injected i.v. to groups of mice; blood samples were collected at

Table 1. Inhibition of Protein Synthesis in a Cell-Free System and Immunoreactivity of Gelonin and PEG Derivatives[a]

PEG reactive	modified[b] Lys	IC_{50}[c]	% immunoreactivity[d]	PEG reactive	modified[b] Lys	IC_{50}[c]	% immunoreactivity[d]
5	2	0.41	76	**6**	2	0.33	60
	4	0.57	72		3	0.89	55
	6	3.73	70		6	3.9	45
7	2	0.36	76	**8**	2	0.35	64
	4	1.13	70		3	0.66	54
	6	3.82	70		6	2.63	43
	10	>5.33	68		10	>5.33	37
SS-5 PEG	3	1.73	53	SS-20 PEG	1	2.62	n.d.
	6	>5.3	40		2	4.50	n.d.
	10	>5.33	38		4	>5.33	n.d.

The points represent the means of three separate determinations. [a] n.d. not detectable. [b] The degree of derivatization was detected by the TNBS method and electrophoresis. [c] The IC_{50} (concentration giving 50% inhibition of protein synthesis) expressed in nM was assayed on rabbit reticulocyte lysate. Gelonin has a IC_{50} value of 0.31 nM. [d] The relative immunoreactivity (100% for pure gelonin) was obtained using a specific antiserum and assayed on ELISA test.

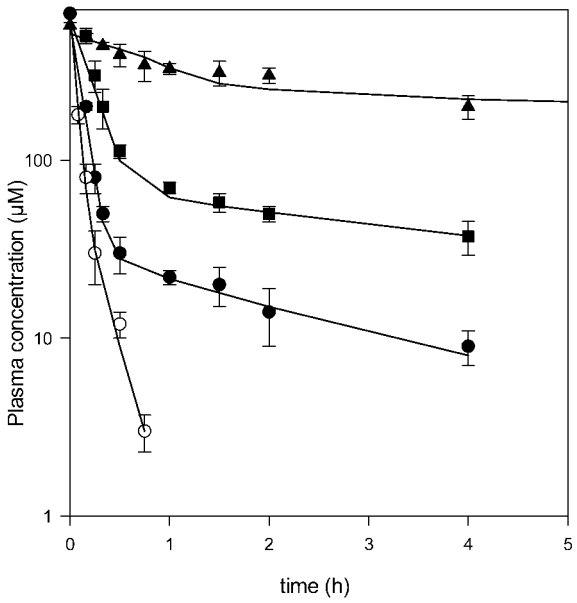

Figure 4. Pharmacokinetic profiles following an intravenous bolus injection of radiolabeled gelonin and mPEG conjugates in mice. The reported data are the arithmetic means of three determinations, and SDs are indicated. Outline circle, gelonin; solid circle, conjugate obtained with compound **7**; solid square, conjugate obtained with compound **8**; solid triangle, conjugate obtained with SS-20PEG.

intervals and radioactivity determined. Since similar behavior in in vitro tests of compounds **5** and **6** versus compounds **7** and **8** was found, the analysis on animals were performed only on thioimidate **7** and **8** and with SS-PEG 20 kDa in order to have a comparison for the highest M_r.

Figure 4 shows the pharmacokinetic profiles of gelonin and conjugates obtained with compound **7**, **8**, and SS-20PEG. The gelonin rapidly disappears from blood circulation ($t_{1/2}^{\alpha}$ is 2 min and $t_{1/2}^{\beta}$ is 13 min, see Table 2), while an increase in molecular mass and hydrophilic radius (from 30 kDa for gelonin to 36, 45, and 70 kDa for conjugates with **7**, **8**, and SS-20PEG, respectively) increases survival time. Following a bicompartmental model for 2 and 5 kDa PEG conjugates, the distribution phase appears rapid ($t_{1/2}^{\alpha}$ of 4 and 7 min), but a progressive decrease in elimination is evident ($t_{1/2}^{\beta}$ from 70 to 273 min). Different behavior appeared when the conjugate M_r increased above the glomerular sieving threshold: the $t_{1/2}^{\alpha}$ increased to 44 min and the $t_{1/2}^{\beta}$ up to 25 h. The mean residence time also reflects the slow elimination from the body due to PEGylation; MRT increases in a quadratic mode, from 10 min for gelonin to 94, 324, and 2073 min for the conjugates.

The levels of accumulation of native and PEG modified gelonin sampled in the organs involved in toxin removal (liver kidney and spleen) after i.v. administration of conjugates are shown in Figure 5. These values are expressed as percentages of the dose per gram of tissue and were sampled up to 24 h after injection. The pattern of biodistribution confirms the pharmacokinetic profiles; gelonin is rapidly removed from the body by kidney filtration, and an increase in molecular mass proportionally decreases kidney uptake and increases liver and spleen uptake. Specific accumulation in these RES organs is reduced progressively for 5 kDa and for 20 kDa mPEG conjugates, with a proportional increase in blood survival time.

DISCUSSION

Targeting of toxins is one of the approaches to the selective removal of cancer or viruses. The major problems encountered in the use of toxin as therapeutic agents are due to nonspecific toxicity, low blood-residence time, and immunogenicity induced by the toxin moiety. The main way to solve these problems is to construct recombinant RIPs or in to use soluble hydrophilic masking polymers (*42*, *43*).

The present study aimed to evaluate the characteristics of mPEG derivatives able to generate a stable linkage and to increase the immunological and pharmacokinetic properties of the RIP gelonin, chosen as model protein sensitive to surface modification. This RIP has been exploited in therapeutic application both in immunotoxin preparation and as such: several interesting studies have recently been reported (*9*, *42*, *44*) as well as other relevant applications of gelonin in the treatment of tumors, involving the use of new techniques such as shock wave permeabilization or photochemical internalization (*45*−*47*).

Several methods of activating PEG to obtain protein conjugates have been described (*48*), but some of them change the total charge of the modified protein, in some cases reducing its biological activity. In contrast, the imido ester derivatives of mPEG, described in a patent (*49*), after reaction with the amino groups of proteins, lead to a charged amidine group without altering the positive charge of the protein.

Several amidination experiments, using, for example, alcohol dehydrogenase, carbonic anhydrase, trypsin, or lysozime, have demonstrated that retention of the surface charge distribution favors preservation of the tertiary and quaternary structure of proteins, and thus retention of their biological activities (*50*).

By studying the amidination mechanism of proteins, it has been found that the imidic esters lead to the desired amidinated proteins at a pH > 9, while for pH values below 8, the formation of cross-linked products is favored (*51*). At pH values normally used for the modification of proteins, the imidic ester generated a mixture of reaction products. On the contrary, using a thioimidate derivative such as S-methylthioacetimidate (*52*), it has been shown that amidination of a standard protein can be obtained even at pH 6 without any side reaction or cross-linking. At this pH, complete modification of all gelonin accessible lysines can be achieved. It has been suggested that reaction of the imidoester RX−C(R)═NH2$^+$ (X = O or S) with protein amino groups leads to a tetrahedral intermediate. Using imidic esters (X = O)

Table 2. Pharmacokinetic Parameters[a]

	$t_{1/2}^{\alpha}$ (min)	$t_{1/2}^{\beta}$ (min)	MRT (min)	V_{ss} (ml)	Cl (ml h^{-1})
gelonin	2.25 ± 0.22	13.27 ± 1.2	10.16 ± 2	0.129 ± 0.02	0.76 ± 0.12
conjugate with compound **7**	4.40 ± 0.8	70.67 ± 3.5	94.05 ± 8.1	0.308 ± 0.11	0.196 ± 0.2
conjugate with compound **8**	7.58 ± 1.5	273.18 ± 15.2	324.98 ± 32	0.063 ± 0.01	0.0118 ± 0.004
conjugate with SS-20 PEG	43.91 ± 4.7	1489.16 ± 23.9	2073.06 ± 45	0.017 ± 0.013	$4.9\ 10^{-4} \pm 3.5\ 10^{-5}$

[a] Pharmacokinetic parameters (means ± S.D.) of gelonin and conjugates obtained with mPEG of different molecular mass obtained after i.v. administration in mice (n = 3 each). The values were obtained by adopting a two-compartment open pharmacokinetic model.

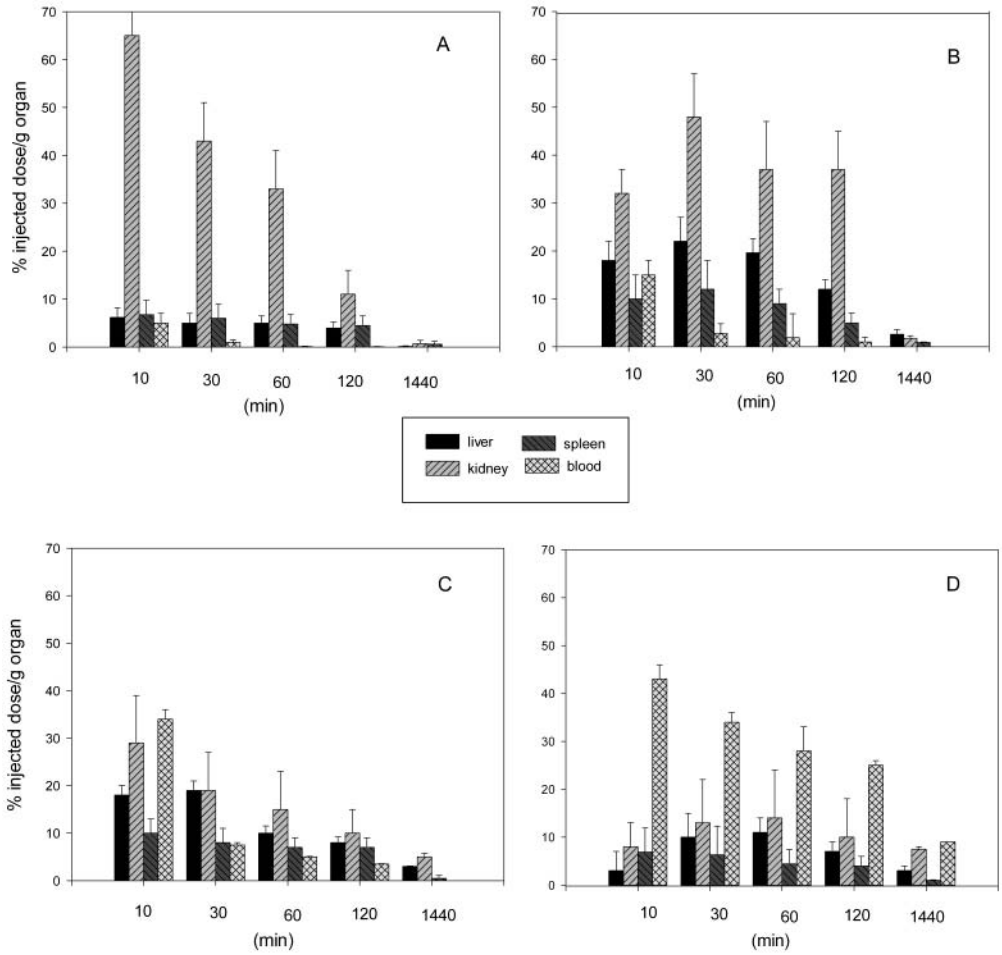

Figure 5. Disposition profiles in elimination organs after intravenous administration in mice: native gelonin (panel A); conjugates with compounds **7**, **8**, and SS-20PEG are shown in panel B, C, and D, respectively. SDs values are reported.

below pH 8, the protonation and elimination of the amino group leading to protein cross-linked derivatives prevails. A better leaving group, such as the thioimidate reagents (X = S), should favor elimination of the alkanethiolated group even at a low pH (pH 7.5−8), preferentially giving the desired amidinate protein (*52*).

Our thioimidate derivatives of mPEG have shown good reactivity at neutral pH, quite similar to that of commercially available mPEG−SS. This was particularly evident for compounds **7** and **8**, which have a hexamethylene spacer group between mPEG and the reactive moiety. The length of this lipophilic and flexible arm is also very important, since the PEG−hexamethylene−thioimidate derivative is much more reactive than the dimethylene ones toward the exposed amino groups of the protein.

Although PEGylation of proteins usually leads to a decrease in the in vitro activity, due to charge or surface modification, in vivo activity can sometimes be enhanced. This is probably due to the increase in blood circulation and thus the increased diffusion in the perfused organs. This behavior is confirmed by the PEGylation of the RIP trichosanthin (*23*). In this case, native RIP and mutants were linked by a thioether linkage on specific cystein groups. In all cases, and both with 5 and with 20 kDa mPEGs, a drastic decrease in enzymatic activity appeared (10−20-fold) with a marked decrease in immunogenicity. In our hands, the N-hydroxysuccinimide derivatives 5 kDa PEG also strongly reduce gelonin activity, and this confirms our and other authors' results (*31*, *53*). Thioimidate reactives, on the contrary, are able to maintain the activity of gelonin at least three times better than N-hydroxysuccinimide reactives.

The results also show that a polymeric chain of high M_r is not suitable because, even at lower derivatization degree, the length of mPEG 20 kDa is sufficient to completely inhibit accessibility to the catalytic site. The hindrance induced by this chain toward specific antiserum is complete in all conditions, and the pharmacokinetics and tissue distribution confirm the longest retention in the blood circulation. The better candidate appears to have a 5 kDa PEG chain that, as reviewed by the authors (*54*), has been extensively used for many proteins of therapeutic interest. A mean of three groups of compound **8** allows significant biological activity to be maintained, reduces immunogenicity to one-half of the initial value, and greatly extends circulatory life (MRT of 5.4 h vs 10 min for gelonin). This value is confirmed by a lower RES organs uptake.

In conclusion, we have shown that novel PEG derivatives are able to increase the behavior of RIPs, maintaining RNA N-glycosidase activity at high levels. This may make gelonin a better therapeutic candidate; in particular, the improvement in immunological properties makes it possible for a panel of toxin/immunotoxin to be administered. This approach has been applied in treating both tumors and HIV, with an evident increase in therapeutic results (*21*, *55*−*57*). In order not to reduce the activity of gelonin with other derivatization steps, conjugation with targeting molecules could utilize the noncovalent interaction, as described by the author elsewhere (*18*).

Identification of Two Tamoxifen Target Proteins by Photolabeling with 4-(2-Morpholinoethoxy)benzophenone

Fabienne Mésange,[†] Mohamed Sebbar,[†] Joël Capdevielle,[‡] Jean-Claude Guillemot,[‡] Pascual Ferrara,[‡] Francis Bayard,[†] Marc Poirot,[†] and Jean-Charles Faye*[,†]

INSERM U397 Institut Claudius Regaud 20-24 rue du pont Saint Pierre 31052 Toulouse Cedex, France, and Laboratoire de biochimie des protéines, Sanofi Synthélabo, Labège Innopole, BP 137, 31676 Labège Cedex, France. Received December 3, 2001; Revised Manuscript Received April 9, 2002

Our quest to identify target proteins involved in the activity of tamoxifen led to the design of photoaffinity ligand analogues of tamoxifen able to cross-link such proteins. A new tritiated photoprobe, 4-(2-morpholinoethoxy)benzophenone (MBoPE), was synthesized and used to identify proteins involved in tamoxifen binding in rat liver. MBoPE, which has structural features in common with the potential antagonist of the intracellular histamine receptor (*N*,*N*-diethyl-2-[(4-phenylmethyl)phenoxy]ethanamine HCl: DPPE) is unable to bind the estrogen receptor although it does compete with tamoxifen for an antiestrogen binding site (AEBS). This tritiated benzophenone derivative was obtained by metal-catalyzed halogen−tritium replacement reaction. Because of its high specific activity, four target proteins could be photolabeled, three of which were identified with M_r of 60 000, 49 500, and 14 000, while the fourth at 27 500 was in too low an amount and could not be sequenced. The 49.5 kDa protein corresponded by mass spectrometry to the microsomal epoxide hydrolase already identified with an aryl azide photoprobe [Mesange, F., et al. (1998) *Biochem. J. 334,* 107−112]. The 60 and 14 kDa proteins were identified as the carboxylesterase (ES10) and the liver fatty acid binding protein (L-FABP), respectively. The inhibitory effect of tamoxifen on carboxylesterase activity and the competitive efficacy of oleic acid on [^{3}H]tamoxifen binding suggest that both proteins are AEBS subunits. Moreover, treatment of hepatocytes with antisense mRNA directed against ES10 or L-FABP abolished both tamoxifen and MBoPE binding. On the basis of previous pharmacological arguments, the 27.5 kDa protein might correspond to the sigma I receptor. Altogether, these results confirm that the microsomal epoxide hydrolase is a target for tamoxifen and provide evidence of two new target proteins implicated in cell lipid metabolism.

INTRODUCTION

The antiestrogen tamoxifen has few known noxious side effects and has become the world's second most widely used antitumor drug. It was initially designed as an antagonist of binding of the steroid hormone estradiol to the estrogen receptor (ER). Given the ubiquitous presence of antiestrogen binding sites (AEBS) that specifically bind triphenylethylenic antiestrogens such as tamoxifen with high affinity ($K_D = 10^{-9}$ M), several group (*1*−*5*) have focused attention on the potential existence of a protein or proteins that are different from ER and mediate several of the biological activities of tamoxifen (*6*, *7*). By developing specific AEBS-targeted ligands based on the tamoxifen backbone but without ER affinity, we (*8*, *9*) and others (*5*, *10*) have hypothesized that AEBS mediates estrogen receptor-independent biological activities of tamoxifen. Moreover, the AEBS prototypical ligand DPPE (*N*,*N*-diethyl-2-[(4-phenylmethyl)phenoxy]ethanamine HCl), which was expected to be a specific ligand of a new intracellular histamine receptor (*11*) has been shown to potentiate the chemotherapeutic index of cytotoxic drugs in vitro (*12*, *13*). Clinical trials have shown that DPPE, in association with cyclophosphamide or doxorubicin, is successful in the treatment of metastatic prostate cancer (*14*) and metastatic breast cancer (*15*). Further, this product has been shown, by acting in the liver by an estrogen receptor-independent pathway, to modulate the serum lipids in a manner similar to tamoxifen (*16*) Identification and characterization of the proteins is important to understand the side effects of tamoxifen and to design new drugs. For this reason, our group has worked to identify and purify AEBS using photolabeling strategies (*9*). On the basis of the structure of DPPE described by Brandes (*17*), an azido-photoaffinity tritiated ligand was used to identify microsomal epoxide hydrolase as a component of AEBS (*18*). Because of the low specific activity (2 Ci/mmol) obtained with this ligand, a tritiated photoactivable ligand, 4-(2-morpholinoethoxy)benzophenone, also named morpholino-benzoylphenoxy-ethanamine (MBoPE), was prepared having high specific activity (40 Ci/mmol). This photoactivable aryl ketone (*19*) was chemically more stable than the aryl azide previously used, was activated at 360 nm (with less protein damage), and inserted into unreactive C−H bonds in the presence of water. This tamoxifen-competing ligand could be employed after electrofocusing prepurification. By these techniques, specific photolabeling (competed by either tamoxifen or unlabeled MBoPE) of microsomal epoxide hydrolase was obtained, as previously reported (*18*), as well as the fatty acid binding protein L-FABP and the carboxylesterase ES10.

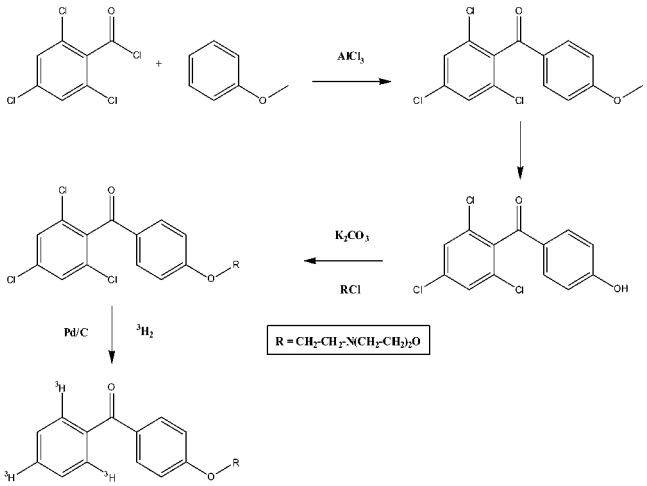

Figure 1. Outline of synthesis of [^{3}H] MBoBPE.

MATERIALS AND METHODS

Chemicals. [^{3}H]-Tamoxifen (specific activity 84 Ci/mmol) was from Amersham, and unlabeled steroids were from Steraloïd. Tamoxifen was a gift from Imperial Chemical Industries. Tris, KCl, sodium azide, glycerol, EDTA, dimethylformamide, and other reagents were obtained from Sigma.

Synthesis of Photosensitive Ligand MBoPE (Figure 1). *Synthesis of 2,4,6-Trichloro- 4′-methoxybenzophenone.* $AlCl_3$ (4 g, 30 mmol) was progressively added to a solution of anisole (2.2 g, 20 mmol) and 2,4,6-trichlorobenzoyl chloride (5 g, 20 mmol) in 50 mL of anhydrous dichloromethane at −80 °C in an inert atmosphere, and the reaction was monitored by TLC. The reaction mixture was gradually brought to ambient temperature and poured into a mixture of crushed ice and 0.1 N HCl (150 mL). The organic layer was collected, washed with water, dried (Na_2SO_4), and concentrated to yield 5.5 g of a white solid (87% yield, mp = 110−111 °C). Mass spectrum (70 eV) *m/e* (relative intensity) 315.6. ^{1}H NMR (100 MHz, DMSO-d_6), δ; 3.83 (s, 3H, OCH_3); 6.87 (d, 2H, arom); 7.26 (d, 2H, arom), 7.59 (d, 2H, arom). Anal. ($C_{14}H_9Cl_3O_2$) C, H, N, Cl.

Synthesis of 4-Hydroxyphenyl 2,4,6-Trichlorophenyl Ketone. One equivalent of 4-methoxyphenyl 2,4,6-trichlorophenyl ketone was heated to melting point at 250 °C with 10 equiv of pyridinium chloride. After 4 h, 30 mL of water were added followed by 30 mL of ether. The ether phase was washed with a 0.1 N solution of HCl, dried over Na_2SO_4, and evaporated. The phenolic product was recrystallized in 2-propanol (yield 70%). Mass spectrum (70 eV) *m/e* (relative intensity) 302.6. ^{1}H NMR (100 MHz, DMSO-d_6) δ; 6.82−7.59 (m, 6H, arom); 12.4 (s, 1H, OH phenolic, exchangeable with ^2H_2O). Anal. ($C_{14}H_9ClO_2$) C, H, N, Cl.

Synthesis of 4-(2-Morpholinoethoxy)phenyl 2,4,6-Trichlorophenyl Ketone. 4-Hydroxyphenyl 2,4,6-trichlorophenyl ketone was added (0.5 g, 1.6 mmol) to a solution of NaOH (200 mg, 4.8 mmol) in 15 mL of water. The mixture was boiled for 1 h. A total of 1.1 equiv of 2-morpholinoethyl chloride was added gradually to the mixture. After the sample was refluxed for 12 h, the reaction mixture was cooled and extracted with 30 mL of diethyl ether. The organic layer was washed with 3 × 10 mL of 0.1 N NaOH, and then with 3 × 10 mL of brine. The organic layer was extracted with 1.5 mL of 6 N HCl. The aqueous layer was evaporated, dried over P_2O_5, and recrystallized from ethanol (75% yield, mp = 110−111 °C). Mass spectrum (70 eV) *m/e* (relative intensity) 415.9. ^{1}H NMR (100 MHz, DMSO-d_6) δ; 3.47 (m, 4H, -N(CH_2-CH_2)$_2$O); 4.01 (m, 4H, -N(CH_2CH_2)$_2$O); 3.65−3.69 (t, 2H, J = 6.8 Hz) Ar−O−CH_2−CH_2−N; 4.40−4.53 (t, 2H, J = 6.05 Hz, Ar−O−CH_2−CH_2−N-); 6.93−6.96 (m, 2H, arom); 6.99−7.05 (m, 2H, arom), 7.23−7.41 (m, 2H, arom). Anal. ($C_{19}H_{19}Cl_4NO_3$) C, H, N, Cl.

Synthesis of 4-(2-Morpholinoethoxy)phenyl 2,4,6-^{3}H Phenyl Ketone. The tritiation was performed at the Commissariat à l'Energie Atomique (Saclay, France) by catalytic tritium exchange with $^3H_2$ over Pd/C (5%) in ethanol. The chemical and radiochemical purity of 4-(2-morpholinoethoxy) phenyl (2,4,6-^{3}H phenyl) ketone ([^{3}H]-MBoPE) was determined by HPLC under the following conditions: isocratic elution on a C18 RP column (254 × 4.6) licrosorb (Bishof, Germany) coupled to UV detection at 220 nm using 60% acetonitrile in ammonium acetate, pH 8. The specific activity of this compound, determined by quantitative HPLC, was 40 Ci/mmol. The mass of an injected sample was determined by comparing the integrated area of the eluted peak with an area calibration curve generated by injecting known weights of unlabeled MBoPE, and the activity of the eluting peak was determined by scintillation counting.

Preparation and Solubilization of Rat Liver Microsomes. Sprague−Dawley rats were ovarectomized by dorsal route at least three weeks before sacrifice by cervical dislocation. Livers were removed and the microsomes prepared and solubilized as previously described (*20*).

Preparation and Solubilization of Microsomes from Cultured Cells. All procedures were performed at 4 °C; 5 × 10^6 cells were pelleted by centrifugation at 1500 rpm for 15 min and washed with PBS. Homogenization was carried out by sonication in TTE buffer pH 7.4 (Tris-HCl 50 mM, EDTA 1.5 mM, thioglycerol 12 mM). The homogenate was centrifuged at 10000*g* for 20 min, and AEBS measurements obtained from the supernatant as previously described (*18*). The protein concentration was determined by the Bradford method (*21*).

Binding Studies. Binding studies were routinely performed with 200 μL aliquots of solubilized material. For the K_I determination, [^{3}H]tamoxifen or [^{3}H]MBoPE were incubated in the presence or absence of various concentrations of unlabeled compounds and in the presence of 1 μM estradiol to block ligand binding to estrogen receptors. After incubation (16 h at 4 °C), the bound and free radioligands were separated on Sephadex LH-20 columns (*20*). No-specific binding was determined in the presence of 1 μM tamoxifen, and its value was corrected according to the method of Rosenthal (*22*). The equilibrium dissociation constant (K_D) was determined with increasing tritiated ligand and calculated with the EBDA Ligand computer program (*23*).

Photoinactivation of the Tamoxifen Binding Capacity. After incubation of the soluble preparation for 18 h at 4 °C with 150 nM MboPE into 800 μL aliquots, the samples were UV-irradiated for various periods of time (8 W) at 365 nm. The residual [^{3}H]tamoxifen binding capacity was measured as described above, after elimination of the noncovalent bound ligand by passage through a Sephadex G25 column (Pharmacia). A control experiment was carried out in the absence of MBoPE to determine the UV induced protein degradation.

Electrofocusing. Solubilized microsomal proteins were subjected to liquid electrofocusing in a Rotofor Cell (Biorad). The 20 mM CHAPS supernatant of the microsomal extraction was mixed with 3 mL of pH 3−10 ampholytes and 2 mL of pH 5−8 ampholytes. Electrofocusing was performed for 6 h at 4 °C with power 12 W,

and the solution of each of 20 compartments was collected. After the pH was measured and adjusted to 7.4 with 100 mM Tris, each fraction was checked for [^{3}H]-tamoxifen and [^{3}H]MBoPE binding.

Photolabeling. The electrofocused fraction pH 6.7 was incubated for 18 h at 4 °C with [^{3}H]MBoPE (150 nM) in the presence or absence of tamoxifen (1 μM). UV irradiation was carried out for 45 min and the photolinked proteins precipitated with 10% TCA. After centrifugation at 12000*g*, the pellet was washed twice with ethanol/ether (v/v: 1/2), dried, and dissolved in electrophoresis sample buffer (50 mM Tris, pH 6.8, 100 mM dithiotreitol, 8% glycerol, 2% SDS). The radioactivity was determined before loading onto a polyacrylamide gel.

SDS−PAGE and Autoradiography. Samples were subjected to electrophoresis as described by Laemmli (*24*). Following protein migration, the gel was either rapidly stained (*25*) and cut in 5-mm slices, which were then crushed and proteolyzed with proteinase k (the radioactivity contained in 10000*g* supernatant was determined), or dried in the presence of Amplify (Amersham) and autoradiographed.

Proteolyses, Peptide Purifications, and Sequences. In-gel trypsinisation of the radioactive bands revealed by the autoradiogram was performed as previously described by Rosenfeld et al. (*25*). The peptides eluted from the polyacrylamide matrix were purified on a Brownlee Labs microgradient system on a C18 Ultrasphere column (250 × 2.1 mm). Elution was performed with a linear gradient of 5 to 70% acetonitrile, 0.1% TFA at a flow rate of 300 μL/min, and the peaks detected at 218 nm were manually collected.

Sequence analysis was performed on a gas-phase sequencer (470A, Applied Biosystems).

ORF Subcloning of Human Liver Fatty Acid Binding Protein. Total RNA from the hepato-carcinoma cell line SKHep-1 was obtained by a rapid guanidinium thiocyanate procedure (*26*). The cDNA encoding for the human L-FABP was acquired by RT-PCR of total RNA using the superscript preamplification system (GIBCO-BRL) with random hexamers for the reverse transcription step. Oligonucleotides with *Eco*RI and *Bam*HI restriction sites, matching the first 15 and last 16 bases of the ORF cDNA encoding the human L-FABP, respectively (*27*), were used for PCR. The amplification product was cloned in the *Eco*RI, *Bam*HI restriction sites of pSG5 vector (*28*) and sequenced by the dideoxy chain-termination technique (*29*).

Rat Liver Carboxylesterase. (ES10) cDNA (*30*) was a generous gift from Dr. M. Robbi (University of Brussels, Belgium). It should be subcloned in the pSG5 vector at the *Eco*RI restriction site.

Overproduction of Human L-FABP and ES10. Plasmids (1 μg) were transiently transfected in COS-7 cells using the DEAE-Dextran methodology, as previously described (*18*). Cells were harvested by scraping 48 h after transfection and sonicated in TTE buffer.

Enzyme ES10 Assays. Carboxylesterase activity was measured colorimetrically at 30 °C, using *p*-nitrophenylacetate as substrate, according to the procedure previously reported by Hosokawa (*31*). Assays were carried out on the solubilized microsomal subfraction of transiently transfected COS-7 cells. Increasing concentrations, up to 10^{-4} M, of tamoxifen were added and the concentration that inhibited 50% of the enzyme activity (IC_{50}) was determined.

Inhibition of Specific Protein Syntheses in SKHep-1 Cells. Inhibition of the synthesis of specific proteins was obtained by using an oligonucleotide antisense strategy

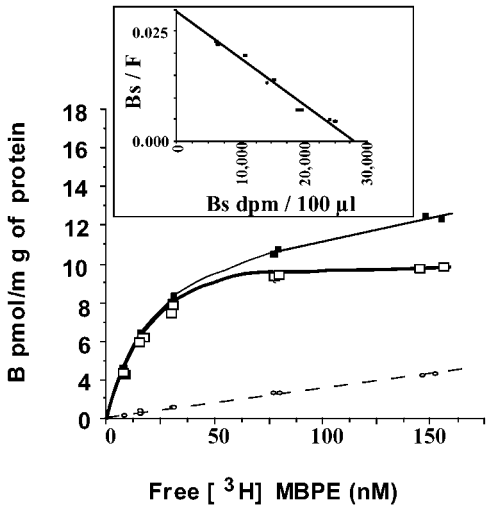

Figure 2. [^{3}H]MBoPE saturation binding curve on solubilized microsomes. Increasing concentrations of [^{3}H]MBoPE were incubated with 100 μL of solubilized microsomes as described in Materials and Methods (■) total binding (◇) unspecific binding in the presence of a 100-fold excess of either MBoPE or Tx (□) specific binding. The graph shown is representative of five independent experiments. The corresponding Scatchard representation of specific binding is shown in the inset.

with 18-mer oligonucleotides matching with the first 5′ translated codons of a protein encoding mRNA (*32*, *33*). The following oligodeoxynucleotides (ODN) were made: 3′-TACTCAAAGAGGCCGTT-5′ and 3′-TGCTACAC CGAGGCAG-5′ for human L-FABP and human carboxylesterase, respectively. Controls were carried out with randomized bases contained in the antisense ODN and with the 5′/3′ base inverted sequence of the antisense ODN.

The transfections of SKHep-1 with oligonucleotides (final concentration = 20 μM) were carried out using the cationic liposome lipofectin system according to the manufacturer's recommendations (Gibco BRL).

RESULTS

Binding Studies and Photoinactivation. As previously reported (*19*), MBoPE is able to compete with [^{3}H]-tamoxifen on AEBS of solubilized microsomes. The inhibitory efficacy of MBoPE on tamoxifen binding (K_I = 1.3 10^{-7} M) was determined by Dixon plots and was, in good agreement with the affinity of [^{3}H]MBoPE (K_D = 1.1 10^{-7} M), calculated from the results in Figure 2, with the EBDA ligand computer program (*23*).

The ability of MBoPE to inactivate photochemically tamoxifen binding was investigated on solubilized microsomes of rat liver as previously described (*9*). After as little as 5 min, MBoPE produces a covalent irreversible linkage to AEBS that inhibits [^{3}H]tamoxifen binding (Figure 3). In the absence of MBoPE, 100% of the tamoxifen binding is conserved for up to 30 min, showing that UV irradiation at 365 nm does not destroy the proteins but activates the photoprobe since only 50% of the sites remained accessible in its presence. The progressive decrease in residual tamoxifen binding indicates that the photolinkage of MBoPE is time dependent, thus enhancing the usefulness of this photoprobe for tamoxifen target labeling.

Purification of the Photolabeled Proteins. Because of its high specific activity, MBoPE has an advantage over the previous azido photoprobe (*9*) in that it can be used in the presence of free ligands to provide a nonspecific estimation and in binding studies after solubilization and

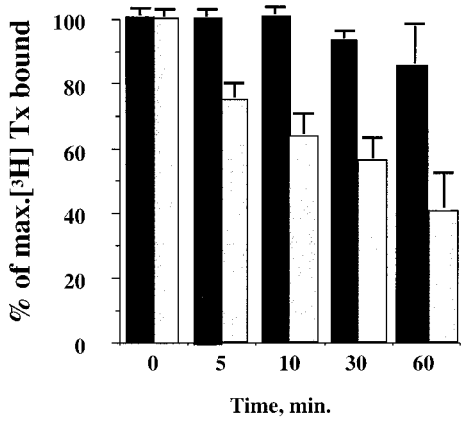

Figure 3. Photoinactivation of solubilized AEBS. Unlabeled MBoPE (500 nM) were incubated with solubilized AEBS extracts and subjected (grey bars) or not (black bars) to UV irradiation for 45 min. The residual [^{3}H]tamoxifen binding was determined after removal of free ligand on a PD10 column.

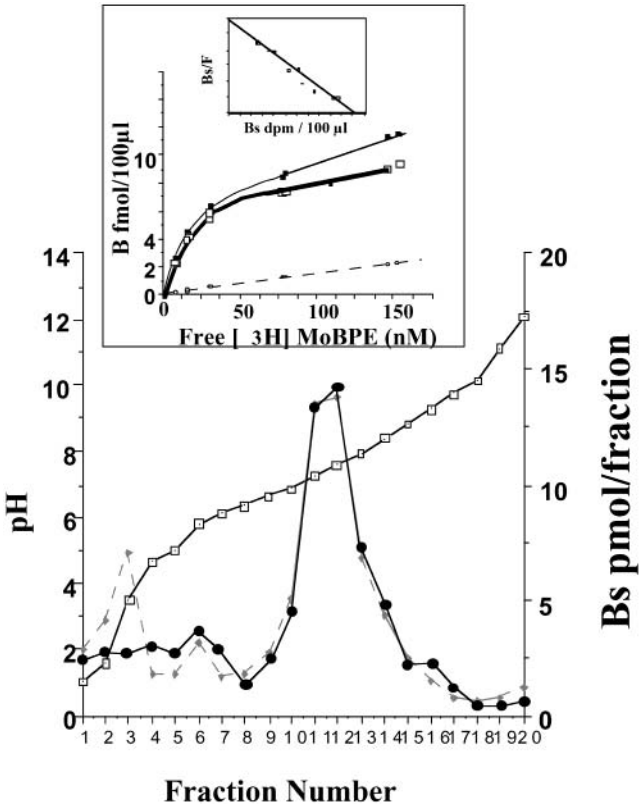

Figure 4. Specific binding studies after iso-electrofocusing. Isoelectrofocusing was performed with a rotofore on solubilized microsomal protein as described in Materials and Methods. Binding was carried out either with (●) [^{3}H]Tx (3 nM) or (♦) [^{3}H]MBoPE (100 nM) in the presence or absence of 1 μM unlabeled Tx. Inset: Scatchard analysis of the fraction 12.

electrofocusing. Similar binding patterns were found for tritiated tamoxifen and MBoPE (Figure 4), and the affinity parameters for tamoxifen and MBoPE (Figure 4; inset) were determined on fraction numbers 3 (pH = 3.2) and 12 (pH = 6.7). We were not able to obtain a saturation curve of binding with fraction 3, although K_D values similar to those observed in the crude extract were found for [^{3}H]Tx ($K_D = 3 \times 10^{-9}$ M) and [^{3}H]MBoPE ($K_D = 1 \times 10^{-7}$ M) with fraction 12 (Figure 4). This result is in good agreement with previous observations (*9*), which gave a pI of about 6.4 for AEBS when photolabeling, with another azido ligand, was carried out before chromatofocusing. The fraction with a pI = 6.7 was therefore used

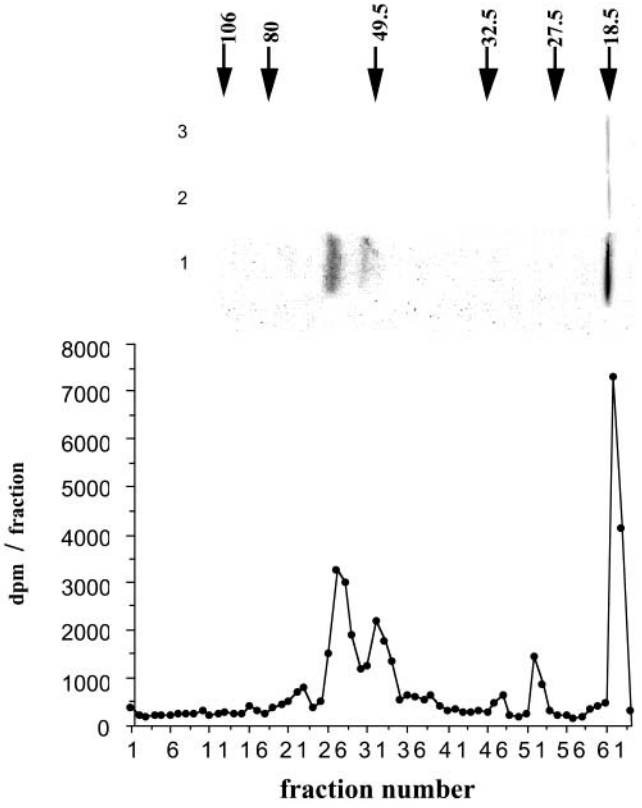

Figure 5. Photolabeling with [^{3}H]MBoPE after electrofocusing. The pH 6.7 fraction was incubated for 18 h at 4 °C with [^{3}H]-MBoPE (100 nM) in the absence (lane 1) or presence of unlabeled (lane 2) 10 μM MBoPE, (lane 3) 1 μM Tx. After UV irradiation at 360 nm, samples were TCA precipitated, solubilized with sample buffer, and subjected to SDS−PAGE on 10% gel. Bottom: specific radioactivity (lane 1 minus lane 3) determined by counting. Upper: the gel was fixed, incubated with Amplify, dried, and exposed for 23 days to the obtained autoradiogram.

for photolabeling and further purification steps. Acid-precipitable proteins were subjected to SDS−PAGE, and photolabeling was evaluated either by autoradiography or counting (Figure 5). Radioactive peaks were extracted and loaded onto polyacrylamide gels of 12 or 18% for bands corresponding to M_r of 60 000 and 49 500, or 14 000, respectively. The proteins were lightly fixed, stained, and directly trypsinized in the gel as described in Materials and Methods and in ref 27. The radioactive peak at M_r 49 500 corresponds, according to mass spectroscopy analyses, to the microsomal epoxide hydrolase previously reported (*18*). Eluted peptides, corresponding to the protein with apparent M_r of 60 000, were simultaneously analyzed by mass spectroscopy and purified by C18 reverse phase column HPLC. Two distinct peptides were sequenced according to the Edman method. The detected amino acid sequences were NLFHR, DAGAPTFMYEFEYR, corresponding to amino acids 220−224 and 418−431 of the rat carboxylesterase (ES-10) identified by Robbi et al. (*30*).

The theoretical molecular masses of these amino acid sequences correspond to two peaks observed in mass spectroscopy. These amino acid series exhibited 100% homology with sequences from the rat carboxylesterase ES 10.

The same experimental procedures were performed for the M_r 14 000 protein and two peptides were sequenced, namely, the MVTTFK and AMGLPEDLIQK amino acid sequences which exhibit 100% homology with sequences 91−96 and 21−31 of the rat liver fatty acid protein (L-

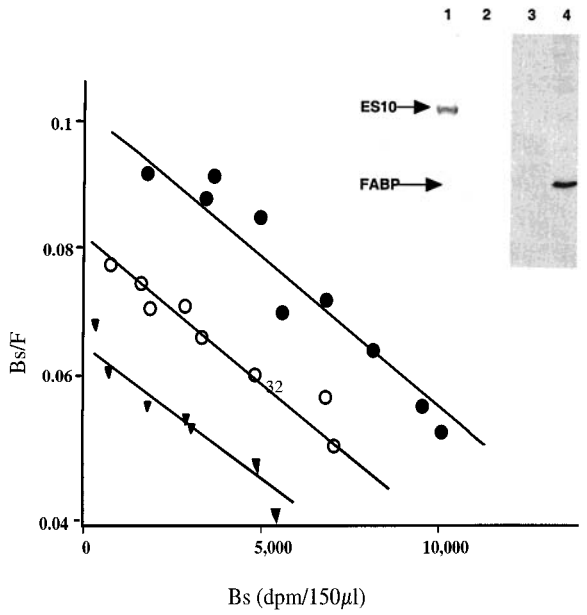

Figure 6. FABP and ES10 overexpressions: [^{3}H]Tx binding analyses of COS-7 transfected cells. Lane 1: transfected cells with ES10 cDNA (5 μg). Lanes 2 and 3 mock transfected cells. Lane 4: transfected cells with liver FABP cDNA (5 μg).

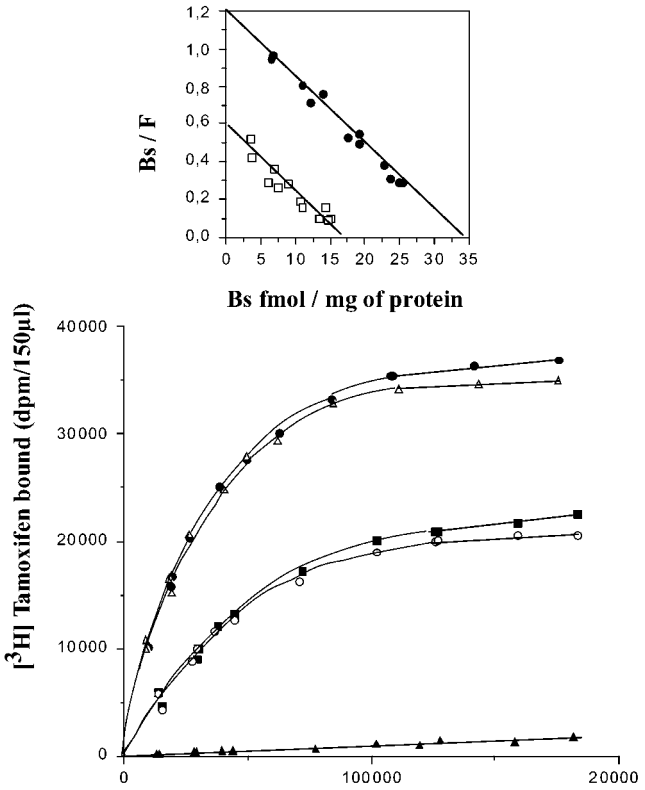

Figure 7. [^{3}H]Tx binding displacement with oleic acid. Competitions were performed on liver microsomal membrane proteins incubated with increasing concentrations of [^{3}H]Tx in the (●) absence and in the (□) presence of oleic acid (30 μM).

FABP), the full-length cDNA of which was isolated by Gordon et al. (*34*).

The radioactive peak seen at 27 500 (Figure 5) could not be further purified. We have previously shown that AEBS ligands exhibit structural similarities with sigma receptor ligands and bind with high affinity to the sigma I receptor (*35*) for which the reported molecular mass in the liver is 28 kDa (*36*).

Protein Overexpression. Binding Studies. To ensure that carboxylesterase and FABP belonged to the AEBS complex, their cDNA open reading frames were subcloned in the pSG5 vector and transiently transfected in COS-7 cells. The specific increase of AEBS was determined by [^{3}H]Tx Scatchard analyses and by binding studies of [^{3}H]-MBoPE at the single concentration of 150×10^{-9} M. As seen in Figure 6, although the protein overexpressions determined by Western blots were increased at least 10-fold, the endogenous proteins were not detected by antibodies under our conditions, and the increase in Tx binding to solubilized microsomes of transfected cells with carboxylesterase overexpression was 1.85-fold, and 1.4-fold in the case of FABP. As shown by Scatchard analysis, the overexpresion of each protein does not change the K_D of tamoxifen binding. Similar increases in binding site numbers were observed with tritiated MBoPE: 2.5−5.9 pmol/mg of protein for carboxylesterase and 2.5−5 pmol/mg of protein for FABP.

Competition for [^{3}H]Tx Binding by the p-Nitrophenylacetate and Oleic Acid Subtrates of Carboxylesterase and FABP, Respectively. Increasing concentrations of [^{3}H]Tx in the presence or absence of *p*-nitrophenylacetate or oleic acid were used to determined the competitive activities of these products. The solubilized microsomal fractions of the respective transfected cells were used as biological supports (rat liver and SKHep1 cells were also used without any modification of the results). Although the carboxylesterase substrate (*p*-nitrophenylacetate) did not compete with tamoxifen up to 10^{-3} M, the oleic acid at 3×10^{-8} M was able to significantly displace tamoxifen. As seen in Figure 7 the B_{max} decreased, whereas the K_D was unchanged by the competitor evidencing a inhibitory effect of the oleic acid on the tamoxifen binding. However, *p*-nitrophenylacetate, at concentrations exceeding 10^{-3} M, induced various problems of solubility (formation of aggregates in the test tube), binding saturability and reproducibility. To ensure that carboxylesterase was a tamoxifen target, its catalytic activity was therefore estimated in the presence of tamoxifen or MBoPE. Tamoxifen and MBoPE were apparently able to inhibit the catalysis of *p*-nitrophenylacetate by carboxylesterase with $IC_{50} = 20 \times 10^{-6}$ and 60×10^{-6} M, respectively.

Inhibition of Protein Expression by Antisense Oligonucleotides. Following our previous studies with the human hepatoma cell line SKHep1 for which the half-life (26 ± 2 h) and concentration of AEBS had previously been estimated (*18*), an antisense oligonucleotides strategy, directed against the corresponding human liver mRNA of the characterized proteins was chosen. Figure 8 shows the Scatchard plots of [^{3}H]Tx binding following various cell treatments. Controls were carried out with the corresponding scrambled and 5′/3′ inverted sequence oligonucleotides at the same concentration (20 μM). Antisense ODNs against L-FABP and ES10 were able to inhibit [^{3}H]Tx binding to a similar extent (50%) without any effect on the K_D, whereas the scrambled and inverted oligonucleotides had no effect, thus demonstrating the specificity of the inhibition. Binding of [^{3}H]-MBoPE at a single concentration (150×10^{-9} M) gave similar inhibition results (data not shown).

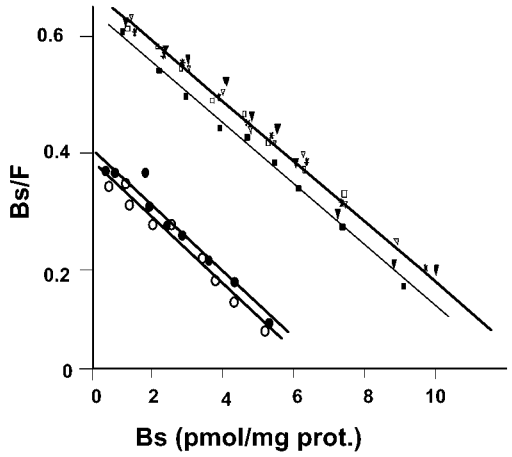

Figure 8. Inhibition of [^{3}H]Tx binding with oligonucleotides. Scatchard analyses of [^{3}H]Tx binding in SKHep-1 cells were carried out as in Figure 6. (▼) Control cells, (○) FABP antisense, (*) FABP scrambled ODN, (□) FABP inverted ODN, (●) ES10 antisense, (■) ES10 scrambled ODN, and (▽) ES10 inverted ODN.

DISCUSSION

Identifying the intracellular target proteins of tamoxifen constitutes an important step in understanding the mechanism of action of this antiestrogen. We have for several years been using a specific photolabeling strategy based on the highest affinity site for tamoxifen binding (AEBS). Microsomal epoxide hydrolase was the first protein shown to be a member of the AEBS (*18*). However, the low specific activity of the previous photoprobe has prevented the determination of other potential protein targets of tamoxifen in the protein complex with molecular mass between 100 and 700 kDa (*6*, *37*, *38*). Using products of the intestinal metabolism of triarylethylene antiestrogen (*39*), we synthesized a new radioactive photoprobe, named MBoPE, with a specific activity 20-fold higher than the former. This photoprobe has, in addition to epoxide hydrolase, led to the determination of two new proteins involved in tamoxifen binding. Although the overexpression of these proteins obtained by transient transfection of their ORF does not substantially increase the maximal binding (B_{max}) of tritiated tamoxifen, their inhibition with the antisense strategy suggests that the liver fatty acid binding protein (L-FABP) and liver carboxylesterase ES10 also belong to the heteropolypeptide AEBS. Moreover, while in both experiments only B_{max} was modified and the affinity (K_D) did not change, a tamoxifen interaction with the same binding site could be observed in each case. L-FAPB is widely expressed in liver, and photolabeling of this protein might be nonspecific. However, L-FABP is a cytosolic protein, and its concentration in the microsomal subcellular fraction is low. The involvement of FABP in AEBS has already been suggested by Hwang (*40*). We show here that the competition of [^{3}H]Tx with oleic acid in binding studies is noncompetitive, which would suggest different binding domains for tamoxifen and fatty acid. Altogether, the results obtained here show that L-FABP is a protein target of tamoxifen. Although its precise function remains unknown, it is assumed to be involved in the uptake, intracellular transport, compartmentalization, and metabolism of fatty acids. It is also involved in peroxisome proliferation and has been described as a specific mediator of the mitogenesis induced by two classes of carcinogenic peroxisome proliferators (*41*).

The microsomal carboxylesterase ES 10 is the second new protein we have shown to be a tamoxifen target. Its catalytic inhibition by tamoxifen and MBoPE accord with its belonging to AEBS. This protein is included in a family of at least four enzyme isoforms. All are glycoproteins of the high-mannose type, which are able to cleave simple aliphatic and aromatic esters (*42*). It has been suggested hat the enzyme might correspond to the activity of acyl coenzyme A cholesterol acyltransferase (ACAT) (*43*). In agreement with this hypothesis, we recently observed that tamoxifen was an inhibitor of ACAT in vitro and in vivo (C. Danthier, unpublished data), and the enzymatic activity of ES10 might require FABP as a cofactor.

Taken together, these data indicate that FABP and ES 10 are possible components of the antiestrogen binding site and suggest that one mode of action of tamoxifen would be to interfere with lipid metabolism in an estrogen receptor-independent mechanism. Moreover, it has recently been reported in yeast that sigma I receptor corresponds to the C7/C8 sterol isomerase implied in tamoxifen binding and activity (*36*, *44*), suggesting that this enzyme would be a part of AEBS. All these results suggest that tamoxifen interacts with a large heteroprotein complex, the molecular mass of which is probably about 700 kDa. Most of the proteins in this complex interfere with cholesterol biosynthesis, since we have shown that they are inhibited by tamoxifen. These results could explain the cholesterol downregulation reported in various experimental and therapeutic treatments (*45*).

ACKNOWLEDGMENT

This work was supported in part by grants from INSERM, ARC, Ligue nationale contre le cancer and Institut Claudius Regaud. (ES10) cDNA and antibodies are from Dr. M. Robbi (University of Brussels, Belgium).

Received December 14, 2001; Revised Manuscript Received February 18, 2002

Poly(ethylene glycol)s (PEGs) are potential drug carriers for improving the therapeutic index of anticancer agents. In this work, the anticancer drug methotrexate (MTX) was activated with *N*,*N*′-dicyclohexylcarbodiimide (DCC) and coupled to amino group bearing PEGs of MW 750, 2000, 5000, 10 000, 20 000, and 40 000. First, the activation process of MTX with DCC in the presence and absence of *N*-hydroxysuccinimide was analyzed through HPLC. Preincubation of methotrexate with DCC alone at 0 °C proved to be favorable with respect to the amount of activated species and the formation of byproducts. MTX−PEG conjugates were synthesized according to this procedure, isolated through size-exclusion chromatography, and characterized through analytical HPLC, MALDI-TOF spectrometry, and gel permeation chromatography. In a cell-free assay, all of the drug polymer conjugates inhibited the target enzyme of MTX, dihydrofolate reductase (DHFR), to a similar extent, but were not as active as free MTX. Additionally, incubation of the MTX−PEG40000 conjugate for 6 days at 37 °C in phosphate buffered saline (pH 7.4), in cell-conditioned medium, or in human serum revealed no significant release of methotrexate. These results, taken together, indicate that release of MTX from polymer conjugates is not necessary for an effective interaction with the active site of dihydrofolate reductase. Evaluation of the in vitro cytotoxicity of the MTX−PEG conjugates in two adherent and three suspension human tumor cell lines revealed that the IC_{50} values of the tested compounds increased with the size of the drug−polymer conjugates. The most effective compound tested in these assays was the free drug MTX itself (IC_{50} value ranging from ∼0.01 to 0.05 μM), while the IC_{50} values of the polymer conjugates were higher (IC_{50} value for MTX−PEG750, 2000 and 5000: ∼0.6−3 μM; for MTX-PEG10000 and 20000: ∼2−7 μM; and for MTX−PEG40000: > 6 μM). Subsequently, MTX−PEG5000, MTX−PEG20000, and MTX−PEG40000 were evaluated in a human mesothelioma MSTO-211H xenograft model, and their antitumor effects were compared with free methotrexate and the albumin conjugate MTX−HSA, a conjugate that is currently in phase II clinical trials. In contrast to the in vitro results, the high molecular weight MTX−PEG conjugates exhibited the highest in vivo antitumor activity: At a dose of 40 and 80 mg/kg MTX−PEG5000 was less active than MTX at its optimal dose of 100 mg/kg; MTX−PEG20000 at a dose of 40 mg/kg showed antitumor efficacy comparable to MTX, but MTX−PEG40000 at a dose of 20 mg/kg was superior to MTX and demonstrated antitumor activity of the same order as MTX−HSA (20 mg/kg).

INTRODUCTION

Methotrexate (MTX), a folic acid antagonist, is a widely used agent for the treatment of certain human cancers (*1*). The drug acts as an inhibitor of dihydrofolate reductase (DHFR), an essential enzyme in the biosynthesis of thymidylate, which is required for DNA replication (*2*).

The efficacy of MTX in anticancer chemotherapy is hampered by its very short plasma half-life. It is administered in relatively high doses, which often leads to drug resistance and causes nonspecific toxicities in normal proliferating cells, limiting the permissible dose of the drug. Adverse side effects may be minimized by targeted delivery of the drug directly to the tumor site. Various attempts have been made to enhance tumor selectivity of MTX by conjugating the anticancer agent to monoclonal antibodies that recognize tumor-associated antigens (*3*−*7*). However, this strategy of "active tumor targeting" is limited by an immune response against the employed murine antibodies as well as the presence of antigens in normal tissue and in the circulation. "Passive targeting" of the tumor can be achieved by coupling antineoplastic drugs to macromolecules because high molecular weight conjugates generally accumulate at the tumor site due to the "enhanced permeability and retention" (EPR) effect (*8*−*11*). Methotrexate has previously

been coupled to the biological polymers fibrinogen (*12*, *13*), gelatin (*14*), and serum albumin (*15*−*17*). The most promising of these compounds is a methotrexate albumin conjugate that exhibits excellent antiproliferative properties in vivo, while its systemic toxicity compared to the free drug is significantly reduced (*18*−*20*). The MTX−HSA conjugate has successfully been evaluated in phase I clinical studies (*21*, *22*) and is currently undergoing phase II clinical trials in Germany.

In recent years, the potential of synthetic macromolecules as carriers of cytotoxic drugs has attracted wide interest (*23*, *24*). Conjugates of various anticancer agents with soluble polymers such as dextrans (*25*), polypeptides (*26*, *27*), and especially with *N*-(2-hydroxypropyl)methacrylamide copolymer (HPMA) (*9*, *28*) and poly(ethylene glycol) (*29*) have been extensively investigated. MTX conjugates with poly(L-lysine) (*30*, *31*), dextran (*32*), or HPMA (*33*) have been synthesized demonstrating in vitro cytotoxicity against human tumor cell lines.

Among synthetic polymers, high molecular weight poly(ethylene glycol) (PEG) plays an outstanding role as a drug carrier. As a water-soluble, biocompatible, nontoxic, and nonimmunogenic material, it exhibits favorable pharmacokinetics and tissue distribution (*34*, *35*). A wide variety of biologically relevant molecules including proteins, enzymes, lipids, and low molecular weight drugs have been coupled to PEG to take advantage of these properties (*36*). PEG conjugates of the anticancer agents paclitaxel, camptothecin (*29*), and doxorubicin (*37*) have been designed to enhance the water-solubility and plasma half-life of the drugs. The camptothecin PEG conjugate Prothecan has recently been evaluated in a phase I clinical trial (*38*).

In this paper, we report on the synthesis, characterization, in vitro and in vivo evaluation of MTX−PEG conjugates ranging in their molecular weight from MW 750 up to MW 40 000.

EXPERIMENTAL SECTION

General. Methotrexate was provided by Klinge-Pharma GmbH, (Munich, FRG); mPEG-NH_2 (MW 750 and 2000) and H_2N-PEG-NH_2 (MW 10 000 and 20 000) were purchased from Rapp-Polymers (Tübingen, FRG); mPEG-NH_2 (MW 5000) was obtained from Shearwater-Polymers (Huntsville, USA); H_2N-PEG-NH_2 (MW 40000) was supplied by Richard B. Greenwald (ENZON Inc., New Jersey, USA); all other chemicals used were at least reagent grade and obtained from Sigma-Aldrich (Deisenhofen, FRG) or Merck (Darmstadt, FRG) and used without further purification. PBS buffer contained 0.004 M sodium phosphate and 0.15 M NaCl and was adjusted to pH 7.4. All the employed buffers were vacuum-filtered through a 0.2 μm membrane (Sartorius, Göttingen, FRG) before use.

Instrumentation. TLC analysis was performed on silica coated plates 60 F_{254} from Merck (Darmstadt, FRG); spots were visualized under UV light (254 and 366 nm). Column chromatography was carried out on silica gel (0.040−0.063 mm) from Merck (Darmstadt, FRG). NMR spectra were obtained on a Bruker ARX 300 (300 MHz) and a Bruker ARC (75.4 MHz) with TMS as internal standard. Mass spectra (ESI) were recorded on a Finnigan MAT 312. Reported M + 1 peaks were the major species in each case. If not otherwise indicated, HPLC analysis was performed on an apparatus consisting of a Kontron 422 pump and a Kontron 535 detector (at 370 nm). For peak integration, KromaSystem 2000 software (version 1.83 by Kontron BioTEK) was used.

Analysis of the Activation Process. Method A. A total of 4.54 mg of MTX (10 μmol) and 11.5 mg of NHS (10 mmol) were dissolved in 225 μL of dry DMF. The reaction was started by adding 200 μL of dry methanol and a solution of 2.06 mg of DCC (10 μmol) in 75 μL of DMF and stirring at room temperature for 18 h. Before HPLC analysis, the white precipitate was removed by centrifugation. **Method B:** 4.54 mg of MTX (10 μmol) were dissolved in 132.5 μL of dry DMF and cooled to 0 °C. The reaction was started by adding an ice-cold solution of 2.27 mg of DCC (11 μmol, 1.1 equiv) in 82.5 μL of DMF and stirring at 0 °C for 18 h. The white precipitate was removed by centrifugation. The supernatant was added to 200 μL of dry methanol or 2-methoxyethylamine, and the solution was stirred for 3 h at room temperature.

The product profiles of the above-described reactions were monitored by analytical HPLC on a Lichrosorb-CN column ([250 × 4], 5 μm, Merck, Darmstadt, FRG) with 30% methanol (v/v) in ammonium phosphate (pH 5.0) and a flow of 1 mL/min. A 50 μL sample of the reaction mixture was centrifuged to remove the white precipitate. The clear yellow supernatant was precipitated with 1 mL of diethyl ether. After centrifugation, the yellow precipitate was washed twice with 1 mL of diethyl ether and dissolved in 500 μL mobile phase.

General Procedure for the Preparative Scale Synthesis of MTX Derivatives. A solution of 454 mg of MTX (1.0 mmol) in 14 mL of dry DMF was kept at 0 °C and added to an ice-cold solution of 227 mg of DCC (1.1 mmol, 1.1 equiv) in 1 mL of dry DMF. After the sample was stirred at 0 °C for 18 h, the white precipitate was removed by centrifugation (4000 rpm, 4 °C, 10 min) and subsequent filtration over celite. The filtrate (∼15 mL) was added to an excess of the respective nucleophile to yield MTX esters or amides.

Synthesis of MTX Methylesters. The filtered solution of activated MTX was added to dry methanol (50 mL, gradient grade) and stirred at room temperature for 3 h. Methanol was removed by rotary evaporation (200 mbar, 40 °C), the crude product was precipitated with diethyl ether and dried in vacuo. Column chromatography on silica gel with 95:5 (v/v) THF/H_2O yielded some mixed fractions and three products: **MTX α-methylester 1** (108 mg); retention time (R_t) on analytical HPLC (Lichrosorb-CN column): 4.2 min, purity >98%; MS (ESI) m/z (M + 1) = 469.3; ^{1}H NMR (DMSO-d_6): δ(ppm) = 1.86−2.09 (m, 2H, β-CH_2), 2.28 (t, 2H, J = 6.4 Hz, γ-CH_2), 3.21 (s, 3H, NCH_3), 3.61 (s, 3H, OCH_3), 4.36 (m, 1H, α-CH), 4.78 (s, 2H, 9-CH_2), 6.61 (bs, 2H, 4-NH_2), 6.82 (d, 2H, J = 8.7 Hz, 3′-H, 5′-H), 7.42 (bs, 1H, 2-NH_2), 7.53 (bs, 1H, 2-NH_2), 7.74 (d, 2H, J = 8.7 Hz, 2′-H, 6′-H), 8.57 (s, 1H, 7-H), 8.70 (d, 1H, J = 6.0 Hz, 8′-NH); ^{13}C NMR (DMSO-d_6): δ(ppm) = 25.96 (C-β), 31.15 (C-γ), 38.97 (C-11), 51.54 (C-α), 52.24 (O-CH_3), 54.71 (C-9), 110.94 (C-3′, C-5′), 120.76 (C-1′), 121.27 (C-4a), 128.81 (C-2′, C-6′), 145.83 (C-6), 149.03 (C-7), 150.85 (C-4′), 155.05 (C-8a), 162.56 (C-4), 162.71 (C-2), 166.18 (C-7′), 171.10 (C-carboxyl), 174.75 (C-carboxyl). **MTX γ-methylester 2** (85 mg); HPLC (Lichrosorb-CN column): R_t = 3.3 min, purity >98%; MS (ESI) m/z (M + 1) = 469.2; ^{1}H NMR (DMSO-d_6): δ (ppm) = 1.86−2.17 (m, 2H, β-CH_2), 2.33−2.42 (m, 2H, γ-CH_2), 3.21 (s, 3H, NCH_3), 3.55 (s, 3H, OCH_3), 4.29 (m, 1H, α-CH), 4.80 (s, 2H, 9-CH_2), 6.63 (bs, 2H, 4-NH_2), 6.83 (d, 2H, J = 8.7 Hz, 3′-H, 5′-H), 7.50 (bs, 1H, 2-NH_2), 7.71 (d, 2H, J = 8.7 Hz, 2′-H, 6′-H; superimposed by one proton of 2-NH_2, bs, 1H), 8.02 (d, 1H, J = 7.5 Hz, 8′-NH), 8.57 (s, 1H, 7-H); ^{13}C NMR (DMSO-d_6): δ (ppm) = 26.71 (C-β), 30.27 (C-γ), 39.28 (C-11), 51.45 (C-α), 52.45 (γ-

OCH_3), 54.93 (C-9), 111.27 (C-3′, C-5′), 121.32 (C-4a), 121.55 (C-1′), 128.91 (C-2′, C-6′), 146.48 (C-6), 149.32 (C-7), 151.06 (C-4′), 155.00 (C-8a), 162.79 (C-4), 162.84 (C-2), 166.34 (C-7′), 173.29 (C-carboxyl), 174.24 (C-carboxyl).

MTX-Dimethylester 3 (12 mg); HPLC (Lichrosorb-CN column): $R_t = 10.2$ min, purity >96%; MS (ESI) m/z (M + 1) = 483.2; ^{1}H NMR (DMSO-d_6): δ (ppm) = 1.90−2.17 (m, 2H, β-CH_2), 2.43 (t, 2H, $J = 7.5$ Hz, γ-CH_2), 3.22 (s, 3H, NCH_3), 3.58 (s, 3H, α-OCH_3), 3.62 (s, 3H, γ-OCH_3), 4.41 (m, 1H, α-CH), 4.79 (s, 2H, 9-CH_2), 6.64 (bs, 2H, 4-NH_2), 6.83 (d, 2H, $J = 8.7$ Hz, 3′-H, 5′-H), 7.45 (bs, 1H, 2-NH_2), 7.73 (d, 2H, $J = 8.7$ Hz, 2′-H, 6′-H; superimposed by one proton of 2-NH_2, bs, 1H), 8.36 (d, 1H, $J = 7.5$ Hz, 8′-NH), 8.58 (s, 1H, 7-H); ^{13}C NMR (DMSO-d_6): δ (ppm) = 25.70 (C-β), 29.87 (C-γ), 39.05 (C-11), 51.25 (C-α), 51.67 (α-OCH_3), 51.73 (γ-OCH_3), 54.75 (C-9), 110.97 (C-3′, C-5′), 120.64 (C-1′), 121.31 (C-4a), 128.87 (C-2′, C-6′), 145.89 (C-6), 149.09 (C-7), 150.94 (C-4′), 155.08 (C-8a), 162.62 (C-4), 162.74 (C-2), 166.33 (C-7′), 172.50 (C-carboxyl), 172.64 (C-carboxyl).

Synthesis of MTX 2-Methoxyethylamides. The filtrate of the activated MTX solution was added to an excess of 2-methoxyethylamine (265 μl, 3 equiv) and stirred at room temperature for 3 h. The crude product was precipitated with diethyl ether from the DMF solution and dried in vacuo. Column chromatography on silica gel with 2:1 (v/v) ethyl acetate/methanol yielded three products: **MTX α-2-methoxyethylamide 4** (115 mg); HPLC (Lichrosorb-CN column): $R_t = 3.6$ min, purity > 98%; MS (ESI) m/z (M + 1) = 512.3; ^{1}H NMR (DMSO-d_6): δ (ppm) = 1.78−1.93 (m, 2H, β-CH_2), 1.98−2.19 (m, 2H, γ-CH_2), 3.18 (s, 3H, OCH_3), 3.20 (s, 3H, NCH_3), 3.22 (m, 2H, C$\underline{H}_2$O), 3.30 (t, 2H, $J = 5.7$ Hz, C$\underline{H}_2$−NH″), 4.17 (m, 1H, α-C$\underline{H}$), 4.77 (s, 2H, 9-CH_2), 6.63 (bs, 2H, 4-NH_2), 6.80 (d, 2H, $J = 8.7$ Hz, 3′−H, 5′−H), 7.43 (bs, 1H, 2-NH_2), 7.73 (bs, 1H, 2-NH_2), 7.78 (d, 2H, $J = 8.7$ Hz, 2′−H, 6′−H), 7.85 (t, 1H, $J = 5.7$ Hz, NH″), 8.55 (s, 1H, 7-H), 9.73 (bs,1H, 8′-NH); ^{13}C NMR (DMSO-d_6): δ (ppm) = 27.72 (C-β), 34.24 (C-γ), 38.14 C$\underline{H}_2$−NH″), 38.94 (C-11), 54.63 (C-α), 54.75 (C-9), 57.80 (O-C$\underline{H}_3$), 70.47 (C$\underline{H}_2$O), 110.98 (C-3′, C-5′), 121.32 (C-4a), 121.65 (C-1′), 128.84 (C-2′, C-6′), 145.90 (C-6), 149.01 (C-7), 150.60 (C-4′), 155.08 (C-8a), 162.59 (C-4), 162.75 (C-2), 165.85 (C-7′), 172.35 (C-carboxyl), 176.80 (C-carboxyl). **MTX γ-2-methoxyethylamide 5** (70 mg); HPLC (Lichrosorb-CN column): $R_t = 2.9$ min, purity >96%; MS (ESI) m/z (M + 1) = 512.4; ^{1}H NMR (DMSO-d_6): δ (ppm) = 1.78−2.19 (m, 2H, β-CH_2, γ-CH_2), 3.18 (s, 3H, OC$\underline{H}_3$), 3.19 (s, 3H, NCH_3), 3.11−3.16 (m, 2H, C$\underline{H}_2$O), 3.27 (t, 2H, $J = 5.7$ Hz, C$\underline{H}_2$−NH″), 3.99 (m, 1H, α-CH), 4.77 (s, 2H, 9-CH_2), 6.65 (bs, 2H, 4-NH_2), 6.83 (d, 2H, $J = 9.0$ Hz, 3′−H, 5′−H), 7,45 (bs, 1H, 2-NH_2), 7.60 (d, 1H, $J = 6.4$ Hz, 8′-NH), 7.63 (d, 2H, $J = 8.7$ Hz, 2′−H, 6′−H), 7.73 (bs, 1H, 2-NH_2), 8.01 (t, 1H, $J = 5.7$ Hz, NH″), 8.57 (s, 1H, 7-H); ^{13}C NMR (DMSO-d_6): δ (ppm) = 25.21 (C-β), 34.24 (C-γ), 38.14 (C$\underline{H}_2$−NH″), 38.94 (C-11), 54.63 (C-α), 54.75 (C-9), 57.80 (O-CH$_3$), 70.54 (C$\underline{H}_2$O), 111.16 (C-3′, C-5′), 121.33 (C-4a), 122.18 (C-1′), 128.10 (C-2′, C-6′), 145.91 (C-6), 149.01 (C-7), 150.57 (C-4′), 155.10 (C-8a), 162.61 (C-4), 162.76 (C-2), 164.80 (C-7′), 172.54 (C-carboxyl), 173.92 (C-carboxyl). **MTX bis-2-methoxyethylamide 6** (10 mg); HPLC (Lichrosorb-CN column): $R_t = 11.2$ min; purity >98%; MS (ESI) m/z (M + 1) = 569.4; ^{1}H NMR (DMSO-d_6): δ (ppm) = 1.74−2.20 (m, 4H, β-CH_2, γ-CH_2), 3.16−3.42 (m, 17H, NCH_3, C$\underline{H}_2$−NH″, C$\underline{H}_2$O, OC$\underline{H}_3$), 4.32 (m, 1H, α-CH), 4.79 (s, 2H, 9-CH_2), 6.62 (bs, 2H, 4-NH_2), 6.81 (d, 2H, $J = 8.7$ Hz, 3′−H, 5′−H), 7.45 (bs, 1H, one proton of 2-NH_2), 7.61−7.78 (m, 4H, 2′−H, 6′−H, one proton of 2-NH_2, NH″), 7.91 (t, 1H, $J = 5.1$ Hz, NH″), 8.04 (d, 1H, $J = 7.9$ Hz, 8′-NH), 8.56 (s, 1H, 7-H); ^{13}C NMR (DMSO-d_6): δ (ppm) = 24.45 (C-β), 27.63 (C-γ), 38.26 (C$\underline{H}_2$−NH″), 38.99 (C-11), 54.77 (C-9), 57.80 (OC$\underline{H}_3$), 70.40 (C$\underline{H}_2$O), 110.89 (C-3′, C-5′), 121.13 (C-1′), 121.31 (C-4a), 128.82 (C-2′, C-6′), 145.96 (C-6), 149.04 (C-7), 150.76 (C-4′), 155.05 (C-8a), 162.59 (C-4), 162.72 (C-2), 165.86 (C-7′), 170.61 (C-carboxyl), 171.87 (C-carboxyl).

Racemization Analysis of MTX Derivatives. The amount of D- and L- enantiomers of the isolated α- and γ-MTX derivatives (methylesters and 2-methoxyethylamides) synthesized according to the described procedure, was determined on the following chiral HPLC system: Nucleodex-β-OH column (Macherey & Nagel, Düren, FRG), mobile phase: 20% (v/v) acetonitrile in aqueous triethanolamine (10 g/L in water) adjusted to pH 7.0 with acetic acid, flow: 1 mL/min.

Preparation and Characterization of the MTX−PEG Conjugates. All conjugates were synthesized using the same procedure. Data for one experiment is described below. The final concentration of the conjugates was between 2 and 5 mM (with respect to MTX) as determined through the absorption at 372 nm with a UV−Vis spectrophotometer U-2000 from Hitachi ($\epsilon_{372} = 7400$ cm^{-1} M^{-1}). The conjugates were stored at −20 °C. The amount of free MTX in the conjugate solutions was < 2% as determined through analytical HPLC at 370 nm on a Nucleogel aqua-OH [40−8] column (300 × 7.7 mm, Macherey & Nagel, Düren, FRG) under isocratic conditions with 1 mL/min PBS buffer as mobile phase.

Synthesis of MTX−PEG40000. A total of 150 mg of MTX (0.33 mmol) and 75 mg of DCC (0.36 mmol; 1.1 equiv) were dissolved in 5.0 mL of DMF. The clear yellow solution was stirred for 18 h at 0 °C. The formed white precipitate was subsequently removed by centrifugation (4000 rpm, 10 min, 4 °C) and filtration over celite. The filtrate was added to 2200 mg of H_2N-PEG40000-NH_2 (0.11 mmol of NH_2 groups) and stirred at room temperature for 3 h. DMF was subsequently removed in high vacuo. The residue was dissolved in 30 mL of PBS buffer and purified through preparative FPLC performed on Sephadex G25 superfine (Pharmacia) with PBS buffer as mobile phase. Peak elutions were monitored at 280 nm using a LKB 8300-UVCORD monitor controlled by FPLC-Detector software (version 1.03, Pharmacia Biotech, Uppsala, Sweden). Concentration of the conjugate to a volume of approximately 25 mL to a final concentration of 5 mM was carried out with CENTRIPREP-10-concentrators from Amicon, FRG (30 min at 4 °C and 4500 rpm).

MALDI-TOF Spectrometry of the Conjugates MTX−PEG750−5000 and the Respective Free PEG Carriers. MALDI-TOF mass spectrometry was performed on a Bruker Reflex II spectrometer operating in the reflection mode at 21.50 kV. As matrix, α-cyano-4-hydroxycinnamic acid (10 mg/mL in methanol) was used. Calibration was performed using a standard of linear PEGs in THF (10 mg/mL). Polymeric samples were dissolved in methanol (5 mg/mL) and added to the matrix solution (1 μL each). After 1 μL of potassium chloride solution (1 mg/mL) was added, the mixture was placed on the stainless steel sample probe and allowed to dry.

Stability of MTX−PEG40000. The stability of MTX−PEG40000 at 37 °C was investigated in different media: (a) phosphate buffered saline (PBS buffer at pH 7.4), (b) cell-conditioned medium, and (c) human serum. The cell-conditioned medium was prepared by growing MCF-7 human breast cancer cells in RPMI 1640 medium (Bio Whittaker, Europe) containing 10% FCS at 37 °C for 48 h. After centrifugation, the supernatant was removed and

stored at −20 °C. A 5 mM stock solution of MTX−PEG40000 in PBS was diluted with the respective medium to a final concentration of 100 μM. The samples were incubated at 37 °C and then analyzed through anion-exchange chromatography on a BioLogic DuoFlow 1082 HPLC apparatus (Biorad Laboratories, Munich, FRG): HR − 5/20 column (Pharmacia Biotech, Uppsala, Sweden) filled with POROS 20 PI weak anion-exchanger (Perseptive Biosystems, Framingham, USA). The injection volume was 1 mL and the flow was 4 mL/min with 10 mM Tris-HCl and increasing NaCl concentration [buffer A: 10 mM Tris HCl (pH 7.5), buffer B: buffer A + 140 mM NaCl; buffer C: buffer A + 1 M NaCl)] according to the following method: 0−1.0 min (buffer A, isocratic); 1.0−7.0 min (linear gradient 100% buffer A to 100% buffer B); 7.0−18.0 min (linear gradient 100% buffer B to 100% buffer C); 18−21 min (buffer C, isocratic); 22−25 min (buffer A, isocratic). Peak elutions were detected at 370 nm with a Bischoff-Lambda1010 detector (Bischoff, Leonberg, FRG). The decrease in the height of the conjugate peak was monitored over 144 h in triplicate.

Cell Free Dihydrofolate Reductase (DHFR) Assay. The assay was adapted for 96 well-plates, and all solutions were freshly prepared. β-NADPH was dissolved in assay buffer (50 mM potassium phosphate, pH 7.5 containing 0.1% BSA) yielding the reaction buffer with a final concentration of 1×10^{-3} M β-NADPH. The bovine enzyme DHFR was dissolved in reaction buffer at a final concentration of 0.018 U/mL. A total of 100 μL of this assay solution containing β-NADPH and DHFR were transferred into each well, and then 13 μL of test compound (or assay buffer in the case of control) were added followed by 10 μL of tetrazolium salt (MTT, stock solution: 5 mg/mL in assay buffer). The enzymatic reaction was started by adding 10 μL of the substrate solution (10^{-2} M dihydrofolic acid in assay buffer). The plate was transferred immediately to the plate reader (Bio-Tek EL340, Deelux, Gödenstorf, FRG) to monitor the initial velocity of the kinetic process.

At room temperature, the increase of the absorption exhibits a plateau over a period of 10 min. This process is characterized by the initial velocity ($V_0 = dp/dt$) of the enzymatic reaction, which can be reduced by various inhibitors of the target enzyme DHFR. For dose−response curves, V_0 was plotted versus the concentration of MTX derivative. All experiments were performed in triplicate. Standard deviation was < 5%.

Cell Lines and Cytotoxic Assays. The leukemic cell lines HL-60 and THP-1 were purchased from the American Type Culture Collection (ATCC Rockville, Maryland, USA). The CCRF−CEM cell line was generously made available by Dr. G. Jansen (University Hospital Vrije Universiteit, Amsterdam, NL). The MCF-7 cell line was kindly provided by Prof. Dietel (Humboldt University Hospital Charité, Berlin, FRG) and the prostate cancer cell line DU-145 was obtained from the Cell Line Service (CLS, Heidelberg, FRG). Cell lines were maintained by weekly passages in their recommended medium supplemented with 10% fetal calf serum, FCS (Life Technologies, Eggenstein-Leopoldshafen, FRG). The leukemic cell lines, growing as suspension cultures, as well as the adherent prostate cancer cell line DU-145 were grown in RPMI 1640 medium, whereas the adherent cancer cell line MCF-7 was maintained in IMEMZO medium. The cytotoxicity experiments were performed in MEM medium. All basal media were supplemented with 10% FCS, 2 mM Glutamax I (Gibco, Paisly, UK), 100 IU/mL penicillin and 100 μg/mL streptomycin. RPMI 1640 and MEM medium were purchased from Sigma (Deisenhofen, FRG) and IMEMZO was obtained from Life Technologies (Eggenstein-Leopoldshafen, FRG). Cells were cultured at 37°C in a humidified atmosphere and gassed continuously with 5% CO_2 in air. All further ingredients were of reagent grade and purchased from Sigma (Deisenhofen, FRG). The WST-1 ready-to-use solution was obtained from Roche Diagnostics (Mannheim, FRG) and the BCA reagent for protein determination was purchased from Pierce, distributed by Bender & Hobein (Munich, FRG).

Adherent Cells. For the cytotoxicity experiments, growth medium was removed, and the cell layer was washed once with 2 mL of trypsin/EDTA solution before adding 1 mL of trypsin solution. After 5 min at 37 °C, cell detachment was almost complete, and the trypsinization process was stopped by adding 5 mL of medium containing 10% FCS. The cell number within the obtained cell suspension was determined by electronic cell volume measurements using a CASY 1 Cell counter + analyzer system, model TTC (Schärfe System, Reutlingen, FRG) equipped with a 60 μm capillary. Finally, cells were seeded at a density of approximately 5000 cells in 200 μL per well in 96-well flat bottom culture dishes (Greiner, Frickenhausen, FRG). The plates were incubated at 37 °C in a humidified atmosphere and gassed continuously with 5% CO_2 in air. After 1 day, when the cells were adherent to the dishes, the cultures were replenished with fresh medium containing the test substances at concentrations between 0.01 and 10 μM. The plates were incubated for the specified period of time (see Table 3) without further medium change. Within each assay, samples were prepared and measured for each concentration in triplicate or quadruplicate.

Protein Determination (BCA Assay). The two reagent solutions, A (bicinchoninic acid) and B (cupric sulfate), were mixed in a ratio of 1:50 directly before use to give the working solution. The medium was removed from the plates, the cells were carefully washed once with phosphate-buffered saline, and then 200 μL of working solution was transferred into each well. After the samples were incubated for 30 min at 37 °C, the absorption at 562 nm was determined. The mean value of each compound-treated group was calculated as a percentage of the control.

Suspension Cells. Suspension cells were grown in their recommended medium supplemented with 10% FCS. For the experiment, cells were centrifuged at 1200 rpm for 5 min at room temperature. The cell pellet was resuspended in growth medium, and the cell number was determined by electronic cell volume measurements using a CASY 1 Cell counter. A total of 100 μL of the cell suspensions were finally seeded at a density of approximately 5000 or 40 000 cells per well in 96-well, flat bottom culture dishes (Greiner, Frickenhausen, FRG). A total of 100 μL medium containing the test substances (final concentration 0.01−1 μM) were added immediately after seeding. The plates were incubated at 37 °C in a humidified atmosphere and gassed continuously with 5% CO_2 in air for the indicated growth period (see Table 3). All samples were prepared and measured in triplicate or quadruplicate for each concentration. Methotrexate was dissolved in 0.9% NaCl to obtain a final stock solution of 10^{-2} M, which was stored at −20 °C. All PEG derivatives of methotrexate were provided as 2 mM solution in PBS buffer (pH 7.4).

Cellular Dehydrogenase Activity (WST-1 Assay). The assay was carried out according to the manufacturer's instructions (Roche Diagnostics GmbH, Mannheim, FRG). Briefly, 20 μL of WST-1 reagent was added to the

cultures (200 μL/well) in the microtiter plates (96-wells) and incubated in a humidified atmosphere containing 5% CO_2 at 37 °C. The amount of formed formazan was quantified after 4 h by measuring the optical density in each well at 450 nm against a background control (absorption of culture medium plus WST-1 ready-to-use solution in the absence of cells) using a microtiter plate reader (Bio-Tek EL340, Deelux, Gödenstorf, FRG). The mean value of each treated group was calculated as percentage of the untreated control group.

Human Tumor Xenografts. For the in vivo testing of the conjugates in comparison with MTX and MTX−HSA, female NMRI nu/nu mice (M&B A/S, Denmark) were used. Mice were held in laminar flow shelves under sterile and standardized environmental conditions (25 ± 1 °C room temperature, 70 ± 3% relative humidity, 12-h light/dark cycle). They received autoclaved food and bedding (Ssniff Granulat S8/15', J. Rettenmaier & Söhne Faserstoffwerke, Ellwangen-Holzmühle, FRG) and acidified drinking water (pH 3.0) ad libitum. All animal experiments were performed under the auspices of the German Animal Protection Law.

The human mesothelioma MSTO-211H cells (Cell Lines Service, Heidelberg, FRG) were cultured in sterile tissue culture flasks with IMEMZO medium, supplemented with 10% FCS at 37 °C in a humidified atmosphere of 5% CO_2. The cells were passaged and expanded in number by trypsinization of cell monolayers, followed by replating an aliquot of cell suspension every 7 days. The culture medium was changed every 3−4 days. Cells in log-phase growth were harvested by trypsinization.

The cell number was determined with a cell counter (Beckmann-Coulter, Krefeld, FRG). The cells were centrifuged for 5 min at 1000 rpm, resuspended in sterile Ca^{2+}-, Mg^{2+}-free PBS-buffer and adjusted to 15 million cells/mL of buffer. Tumor cells were inoculated subcutaneously into the left flank of the animals using an inoculation volume of 0.2 mL. Each of the mice received 3×10^6 cells. In the control group the animals received 0.9% sterile saline solution.

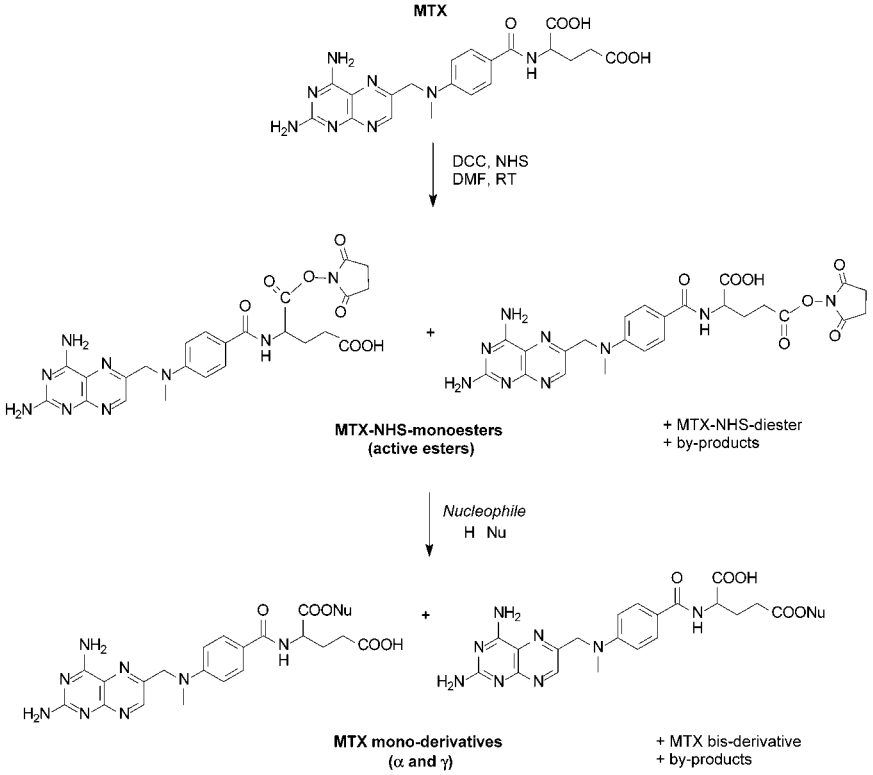
The treatment was started when tumor sizes had reached 20−50 mm^2. Between 6 and 8 mice were treated per dose group. Changes in tumor size and side effects were recorded. The tumor volume was calculated using the formula $(ab^2)/2$ (a = larger diameter of the tumor, b = smaller diameter of the tumor). Antitumor activity was assessed comparing the relative tumor volume of the treated (Tx/To; Tx = tumor volume on any given day, To = initial tumor volume) and the control group (C); the ratio between the mean of the relative tumor volumes of treated and that of control tumors × 100 resulted in T/C values (in %). The experiment was completed when tumor regrowth or severe side effects were observed.

In a first series, the experimental setting consisted of seven groups including one control group. Six animals were allocated to each group. The animals in control group 1 were treated with 0.9% saline solution. The animals in groups 2 and 3 were treated with MTX−PEG5000 a dose of 40 and 80 mg/kg, and in groups 4 and 5 the animals were treated with MTX−PEG20000 at a dose of 20 and 40 mg/kg, respectively. In group 6, the animals received 20 mg/kg of MTX-HSA, in group 7 MTX was administered at a dose of 100 mg/kg. All dosages are expressed in terms of MTX. Because of the high dose volumes in groups 3, 5, and 6, the application volume was split into two injections with an interval of 2 h. The animals in groups 1−5 were treated on day 1, 8, and 15, the animals in groups 6 and 7 were only treated on day 1 and 8 (because of the poor condition of the animals). Tumor size was measured on day 1, 4, 6, 8, 11, 13, 15, 18, and 20. The individual body weight of all animals was determined at study initiation and on day 1, 4, 6, 8, 11, 13, 15, 18, and 20. After a posttreatment observation period of 5 days, all animals were killed by CO_2 asphyxiation (day 20).

In a second series, the experimental setting consisted of five groups including one control group. Eight animals were allocated to each group. The animals in control group 1 were treated with 0.9% saline solution. The animals in groups 2 and 3 were treated with MTX−PEG40000 at doses of 10 and 20 mg/kg. In group 4, the animals received 20 mg/kg MTX−HSA and in group 5 MTX was administered at a dose of 100 mg/kg. Because of the high dose volume in group 4 the application volume of MTX−HSA was split into two injections with an interval of 2 h inbetween. The intravenous treatment was performed on day 1, 8, and 15. Tumor size was measured on day 0, 4, 6, 11, 13, 18, 20, 25, 27, 29, and 32. The individual body weight of all animals was determined at study initiation and on day 1, 4, 6, 8, 11, 13, 15, 18, 20, 22, 25, 27, 29, and 32. After a posttreatment observation period of 16 days the surviving animals in groups 2, 3, 4, and 5 were killed by CO_2 asphyxiation (day 32). The animals in the control group were killed on day 28 due to the size of the tumor.

CHEMISTRY

Activation of the carboxyl groups of methotrexate with *N,N'*-dicyclohexylcarbodiimide (DCC) and *N*-hydroxysuccinimide (NHS) for coupling the drug covalently to amino bearing molecules, such as peptides or proteins, is an established technique (*39*, *40*). Furthermore, the first macromolecular prodrug of methotrexate that has reached the clinic, the MTX−HSA conjugate, is synthesized using this procedure (*41*). The initially formed carbodiimide adducts react directly with *N*-hydroxysuccinimide to yield activated NHS esters that react with nucleophiles, e.g., amines, to stable amide derivatives (see Scheme 1).



Although frequently used, this active ester method not only yields the desired methotrexate α- and γ-isomers but also bis-derivatives and several byproducts due to rearrangement reactions (e.g., formation of *N*-acylisourea derivatives) (*39*). Especially the activated bis-derivatives of MTX are unfavorable compounds because they can lead to cross-linking of the carrier protein in the subsequent conjugation reaction.

Furthermore, optically pure *N*-benzoyl α-amino acids form oxazolone derivatives after activation of their α-carboxyl group, followed by racemization (*42*). Because the L-glutamic acid moiety in MTX is acylated by a benzoic acid derivative, the drug is postulated to undergo racemization whenever its α-carboxyl group is activated (*39*, *43*) resulting in the formation of the less active D-isomer of MTX (*44*).

Thus, our first goal was to understand the activation process in more detail and subsequently optimize the reaction conditions for obtaining better defined coupling products with macromolecular carriers.

Initially, several attempts were made to isolate the α- and γ- MTX−NHS active esters, but failed due to their high reactivity. In a second approach, methotrexate was reacted in DMF for 18 h at ambient temperature with 1 equiv of DCC and 1 equiv of NHS, and an excess of methanol was added to yield the stable methyl esters in situ. The reaction products were identified using analytical HPLC; reference samples of the MTX α-, γ- and dimethylester were obtained by preparative scale syn-

Scheme 1. Reaction Pathway of the Activation Process of Methotrexate (MTX) with *N,N′*-Dicyclohexylcarbodiimide (DCC) and *N*-Hydroxysuccinimide (NHS) in DMF[a]

[a] Active ester intermediates react immediately with nucleophiles to yield stable α- and γ- monoderivatives of MTX. In addition, the MTX bis-derivative and several byproducts are formed in small amounts.

thesis (as described in the Experimental Section) and characterized by NMR and mass spectrometry.

Not surprisingly, the product profile of this reaction was quite complex (see Figure 1a). Besides a high amount of unreacted MTX (∼55%, values determined through peak integration), we found the monoesters to be the predominant products (∼13% α- and ∼23% γ-derivative). Smaller amounts of MTX dimethylester were produced (∼4%) and also several byproducts (∼5%). At 0 °C, more than 75% MTX remained unchanged, while the amount of dimethylester was not significantly reduced (data not shown). In summary, this reaction cannot be considered to be ideal for a controlled coupling of MTX to macromolecular carriers. The rate of MTX-activation is below 50% and about 9% unfavorable byproducts are produced.

In a next step, the activation procedure was modified according to Kato et al. (*45*), who described a different mechanistic pathway for the reaction of methotrexate with DCC (see Scheme 2). In the absence of NHS and any other nucleophile, the formation of a cyclic anhydride is postulated when MTX is preincubated with DCC in DMF at 0 °C. The activated intermediate can then react with an added nucleophile (e.g., an alcohol or amine) to give stable MTX monoderivatives. MTX was incubated with 1.1 equivalents of DCC in DMF and stirred at 0 °C for 18 h. In contrast to the published procedure (*45*), the addition of tertiary amines (e.g., pyridine or triethylamine) was avoided because no influence of the base on the reaction progress could be detected (data not shown).

The white precipitate (probably *N,N′*-dicyclohexylurea) was removed, and the activated MTX was reacted with an excess of methanol for 3 h at room temperature. HPLC analysis of the crude product is shown in Figure 1b. In this case, only ∼35% of MTX remained unchanged. MTX α-methylester was the main product (∼37%), while ∼26% of the γ-methylester was formed. The amount of diester was reduced to ∼2%, and no other byproducts could be detected.

To reproduce these results, the above experiment was repeated with 2-methoxyethylamine acting as a nucleophilic model compound for methoxy-PEG-amines (mPEG-NH_2). Activated MTX was reacted with 3 equiv of the amine to yield ∼30% unchanged drug, ∼46% α-amide, ∼23% γ-amide, and ∼2% byproduct (see Figure 2).

The extent of racemization of L-MTX during the latter activation process was examined by chiral HPLC of the isolated α- and γ-methylesters as well as the α- and γ-2-methoxyethylamides. For the MTX α-methylester and both amides, we found complete racemization with almost 50% of each isomer, while the γ-methylester showed only approximately 35% D-isomer (chromatograms are shown in the supporting material).

PEG conjugates of L-methotrexate were prepared by coupling the drug to α-methoxy-poly(ethylene glycol)-ω-amine, mPEG-NH_2 (MW 750, 2000, and 5000), or α,ω-bis-amino poly(ethylene glycol) NH_2-PEG-NH_2 (MW 10 000, 20 000, and 40 000) according to the preincubation procedure (Scheme 3). The carboxyl groups of MTX were activated by preincubating MTX with 1.1 equivalents of DCC in dry DMF for 18 h at 0 °C. The activated intermediate (MTX*), presumably the cyclic MTX−anhydride, reacts with nucleophilic amino-PEGs yielding MTX−PEG conjugates that were isolated through preparative size-exclusion chromatography over Sephadex G-25 in phosphate buffered saline (pH 7.4). Analytical size-exclusion HPLC showed that the amount of free MTX in the conjugate solutions was <2%. Representative chromatograms are shown in the Supporting Information.

To obtain information about the loading ratio of the purified MTX−PEG conjugates, MALDI-TOF spectrometry was performed. A comparison of the MALDI-TOF

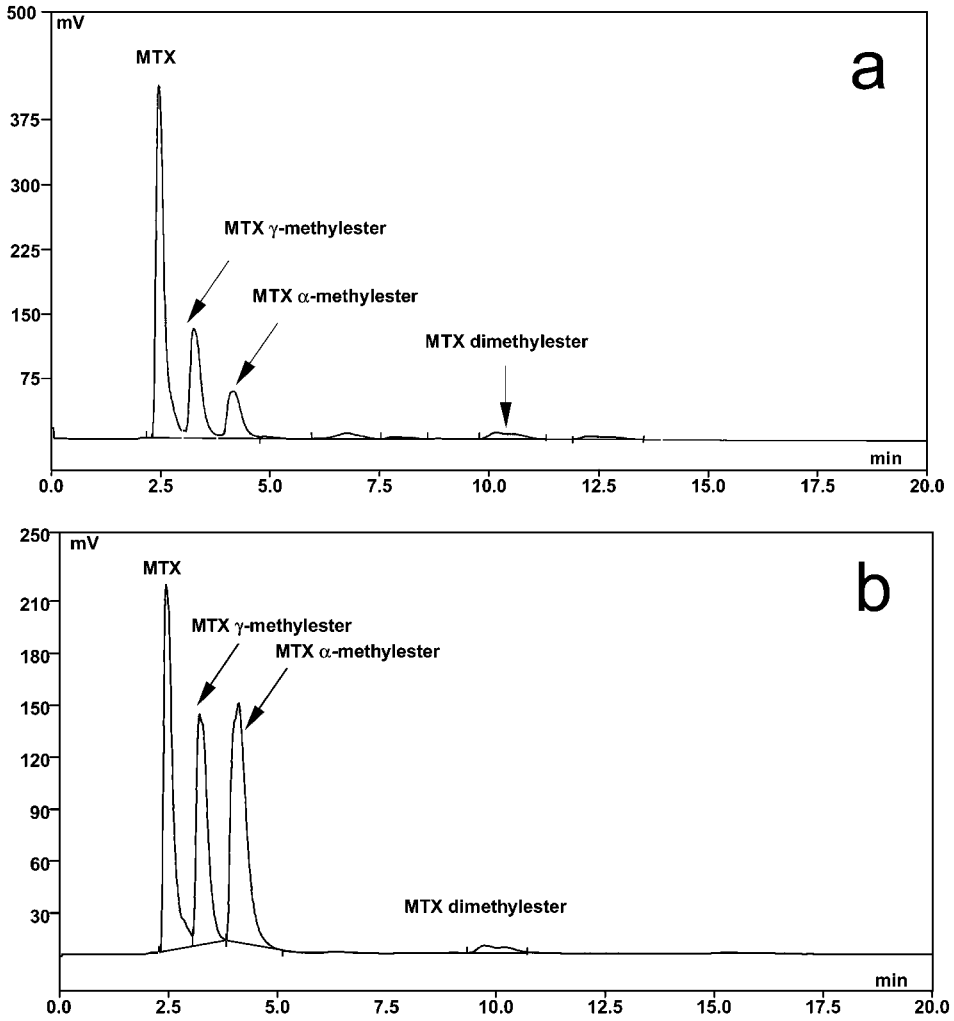


Figure 1. HPLC analysis of the product profile of the reaction of activated methotrexate (MTX) with methanol (Lichrosorb-CN column). (a) MTX reacted with 1 equiv of DCC, 1 equiv of NHS, and an excess of methanol for 18 h at ambient temperature. The crude product contains ~55% unchanged MTX, ~13% α-methylester, ~23% γ-methylester, ~4% dimethylester, and ~5% byproducts. (b) MTX preincubated with 1.1 equiv of DCC for 18 h at 0 °C and then reacted with an excess of methanol for 3 h at ambient temperature. The crude product contains ~35% unchanged MTX, ~37% α-methylester, ~26% γ-methylester, ~2% dimethylester. No byproducts were detected.

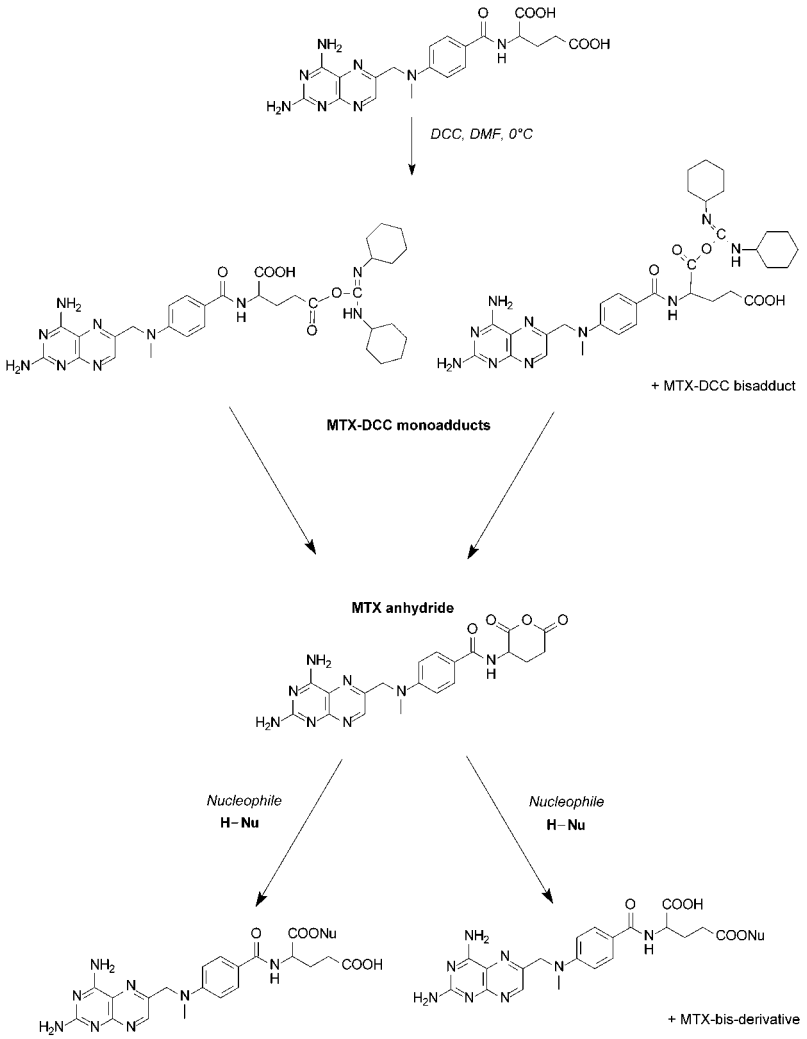
spectra of the low molecular weight MTX-PEG conjugates (MW 750−5000) with those of the respective amino-PEG carriers revealed a shift of 436 Da in the single mass peaks, indicating that the polymer conjugates carried exactly one MTX molecule (see mass spectra in the Supporting Information). Additionally, no subdistribution of unreacted PEG was observed in the mass spectra of the MTX−PEG conjugates confirming that the conjugate solutions contained no free amino-PEG. The calculated molecular weight Mw and Mn of the conjugates and the respective free carriers are summarized in Table 1.

Because MALDI-TOF spectrometry was not suitable for determining the mass distribution of modified high-molecular weight PEGs, we examined the high molecular weight conjugates (MTX−PEG10000−40000) through gel permeation chromatography (GPC). Unfortunately, the very polar compounds interacted strongly with the employed size-exclusion column (PLGel, Mixed-B, 5 μm; Polymer Laboratories, Darmstadt, FRG) so that their retention times could not be compared with any reference standards.



BIOLOGY

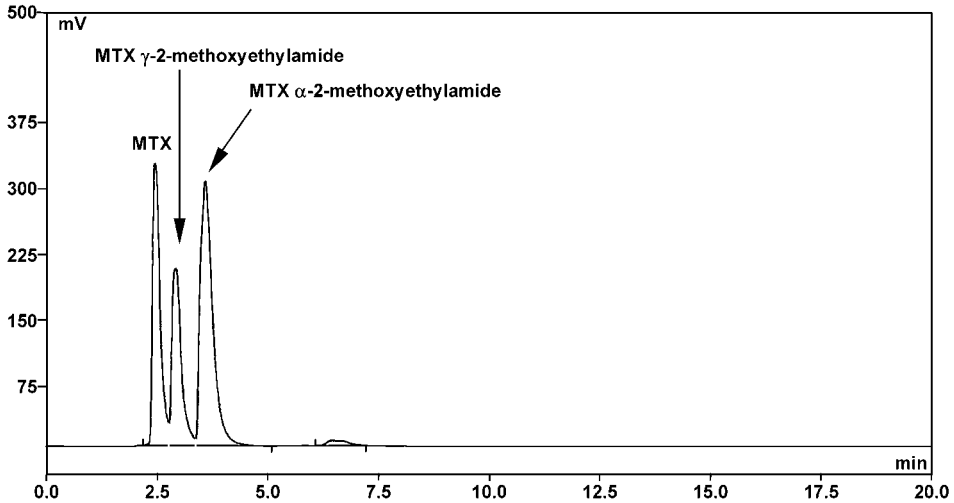
Inhibition of Dihydrofolate Reductase, DHFR. The inhibitory effect of MTX, MTX−PEG conjugates, and the respective free PEG carriers on the target enzyme DHFR was evaluated in a cell-free assay, which is based on the reduction of dihydrofolate to tetrahydrofolate by the enzyme DHFR in the presence of NADPH. The formed tetrahydrofolate is utilized simultaneously for the reduction of the tetrazolium salt MTT to formazan. During the reaction, the amount of formazan generated is monitored spectrophotometrically by determining the absorption at $\lambda = 595$ nm using a kinetic plate reader.

As expected, the free drug MTX showed a steep concentration response curve with an IC_{50} value of approximately 2 μM, while none of the amino-PEGs had an influence on enzyme activity (see Figure 3a). In contrast, all of the tested MTX−PEG conjugates inhibited the target enzyme DHFR (IC_{50} values in the range of 4−8 μM). Surprisingly, the molecular weight of the conjugates had no significant influence on the extent of enzyme inhibition (Figure 3b).

In vitro Cytotoxicity of MTX-PEG Conjugates. The in vitro efficacy of the MTX−PEG conjugates was tested in five human tumor cell lines: suspension CCRF−CEM, HL-60, and THP-1 human leukemia cells as well as adherent MCF-7 (human breast cancer) and DU-145 (human prostate cancer) cells. The metabolic activity of the suspension cells was determined using a WST-1

Scheme 2. Reaction Pathway of the Activation Process of MTX with DCC in DMF[a]

[a] The activation product is probably a cyclic MTX-anhydride that reacts with nucleophiles to yield stable α- and γ-monoderivatives of MTX. As a by-product, the MTX bis-derivative was produced in small amounts.



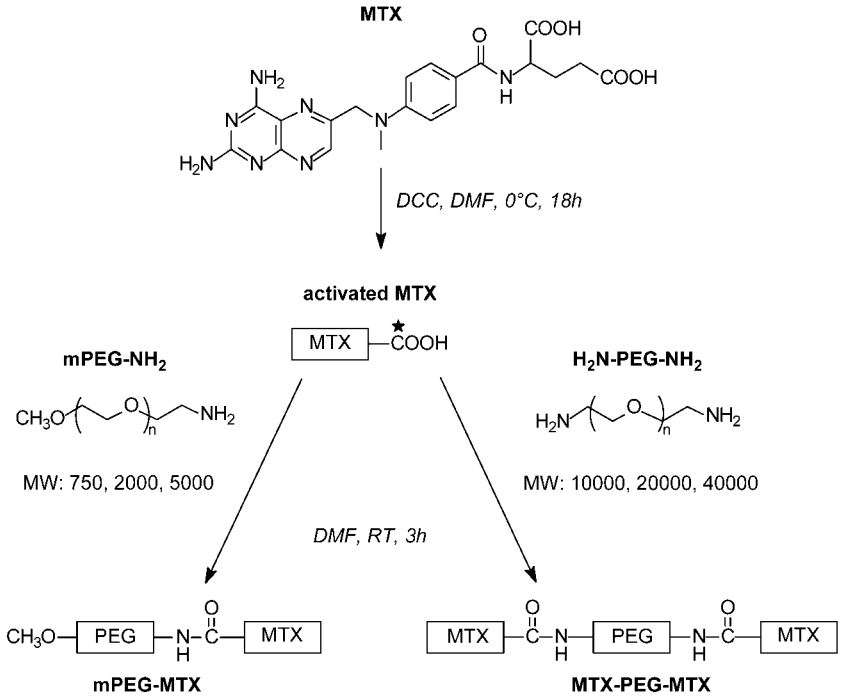


Figure 2. HPLC analysis of the product profile of the reaction of activated methotrexate (MTX) with 2-methoxyethylamine (Lichrosorb-CN column). MTX was preincubated with 1.1 equiv of DCC for 18 h at 0 °C and then reacted with an excess of 2-methoxyethylamine for 3 h at ambient temperature. The crude product contains ∼30% unchanged MTX, ∼46% MTX α-2-methoxyethylamide, ∼23% MTX γ-2-methoxyethylamide, and ∼2% byproduct.

assay, which is a colorimetric assay for the quantification of cell proliferation based on the cleavage and reduction of a water-soluble, stable tetrazolium salt WST-1 to formazan by cellular dehydrogenases. For the adherent cancer cell lines, the commercially available BCA (bicinchoninic acid) assay was performed to determine the total protein content per well as a parameter for overall vitality. This assay is based on the reduction of Cu^{2+} to

Scheme 3. Reaction Pathway for the Synthesis of MTX-PEG Conjugates: the Drug Is Activated with DCC in DMF[a]

[a] In a second step, the activated species reacts with the nucleophilic amino-PEGs to yield MTX−PEG amides.

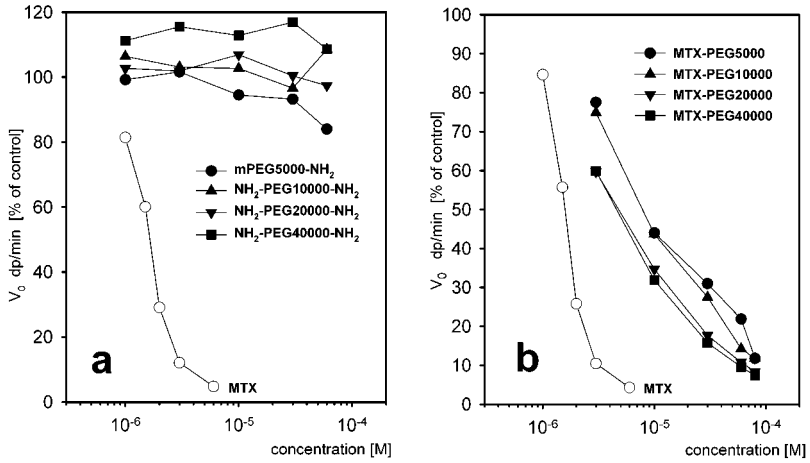

Figure 3. Effect of MTX and MTX−PEG conjugates on isolated dihydrofolate reductase in a cell-free assay. MTX, the unconjugated PEG carriers MW 5000−40000 (a) and the respective MTX-PEG conjugates (b) were tested for their ability to inhibit dihydrofolate reductase (DHFR) in a cell-free assay using 0.0180 U of DHFR per well.

Table 1. Molecular Weight Mw and Mn of Amino-PEG Carriers (MW 750−2000) and the Respective MTX−PEG Conjugates as Determined by MALDI-TOF Spectrometry

compound	Mw	Mn	Mw/Mn
mPEG750-NH_2	991	1024	1.03
mPEG2000-NH_2	2157	2183	1.01
mPEG5000-NH_2	5096	5167	1.01

time (days)	PBS buffer (pH 7.4) %	cell-conditioned medium %	human serum %
0	100.0 ± 3.4	100.0 ± 1.2	100.0 ± 2.7
3	95.3 ± 2.6	93.0 ± 4.1	90.8 ± 0.8
6	94.4 ± 1.9	94.3 ± 2.9	91.2 ± 2.4

[a] The decrease of the conjugate peak was monitored in triplicate.

Cu^+ by proteins in an alkaline medium (biuret reaction) and the highly sensitive and selective complexation of Cu^+ by bicinchoninic acid.

The results of the cell culture experiments are summarized in Table 3. The IC_{50} value for the free drug MTX ranged from 0.008 to 0.052 μM in the tested cell lines; cytotoxicity of the MTX-PEG conjugates was dependent on their molecular weight: IC_{50} values of the small conjugates (MW 750−5000) were between 0.5 and 2 μM, while the IC_{50} values for the high-molecular weight compounds (MW > 10000) were in the range of 3−10 μM or higher.

In Vivo Activity of MTX-PEG Conjugates in the MSTO-211H Mesothelioma Model in Nude Mice. In a first series of experiments, the antitumor effect of MTX−PEG5000 (at a dose of 40 and 80 mg/kg) and MTX−PEG20000 (20 and 40 mg/kg) was evaluated in a

Table 3. In Vitro Cytotoxicity of Methotrexate and MTX−PEG Conjugates against Various Human Tumor Cell Lines[a]

	IC_{50} (μM)

[a] The results obtained with either the WST-1 (suspension cultures) or BCA (adherent cell lines) assay were expressed in concentration−response-curves (CRC) relative to untreated controls (see Supporting Information). To determine the individual sensitivity of each cell line toward MTX or the different MTX conjugates, the IC_{50} value was read from the CRC. The IC_{50} value was defined as the concentration that caused a 50% reduction in cell numbers. [b] Incubation time: 3 days. [c] Incubation time: 7 days. [d] Incubation time: 6 days. [e] Incubation time: 5 days; n.d. = not determined. [f] IC_{50} value not reached.

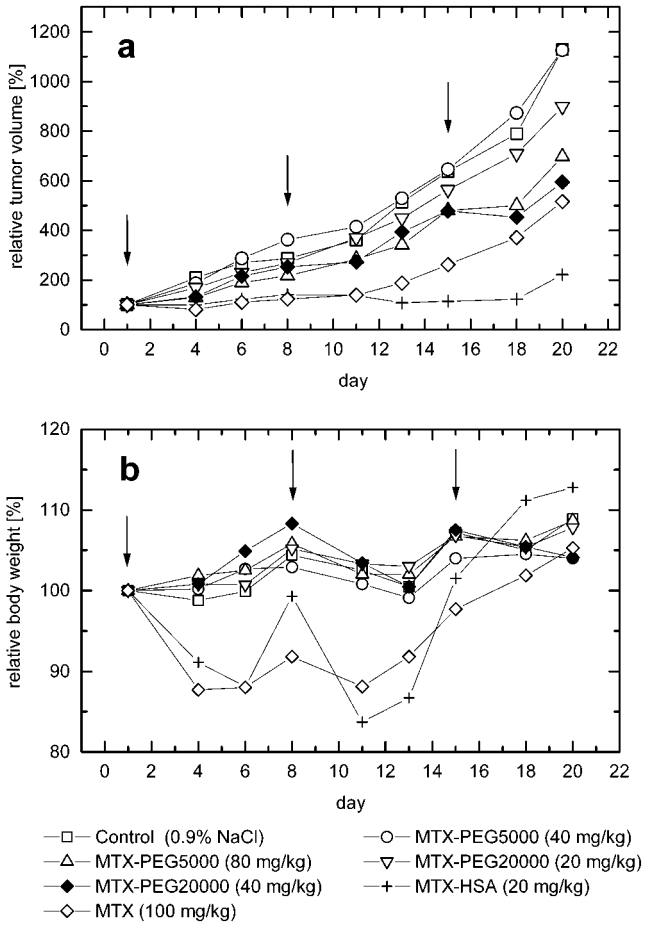

Figure 4. Tumor growth inhibition (a) and body weight loss (b) of subcutaneously inoculated human mesothelioma xenografts (MSTO-211H) in NMRI nu/nu mice treated on day 1, 8, and 15 with MTX, MTX-HSA, MTX-PEG5000, and MTX-PEG20000, respectively. Arrows indicate the days of treatment.

MSTO-211H mesothelioma model in nude mice in comparison to free MTX at the maximum tolerated dose (MTD) of 100 mg/kg and the reference conjugate MTX−HSA (20 mg/kg, MTD). The results of this study are summarized in Figure 4. MTX−PEG5000 exhibited a marginal effect on tumor growth even at a dose of 80 mg/kg. At 40 mg/kg, MTX−PEG20000 showed a tumor growth inhibition similar to free MTX at a dose of 100 mg/kg (MTD), while body weight loss was negligible indicating that the MTD of the MTX−PEG conjugate was not yet reached. A higher dose of MTX−PEG20000 conjugate could not be administered due to the high viscosity of the solution. In this experiment, therapy with MTX−HSA at 20 mg/kg (MTD) showed the highest antitumor effect.

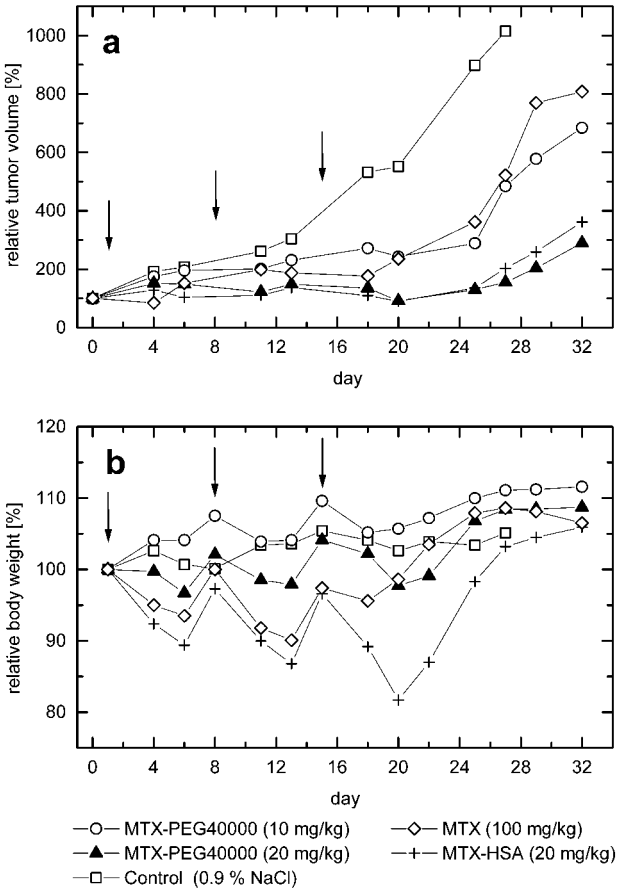

Figure 5. Tumor growth inhibition (a) and body weight loss (b) of subcutaneously inoculated human mesothelioma xenografts (MSTO-211H) in NMRI nu/nu mice treated on day 1, 8, and 15 with MTX, MTX−HSA, and MTX-PEG40000, respectively. Arrows indicate the days of treatment.

In a second series, we evaluated MTX−PEG40000 in the same human tumor xenograft model and compared its activity with MTX and MTX−HSA (Figure 5). Due to the high viscosity of the MTX−PEG40000 solution, the highest administered dose was limited to 20 mg/kg. MTX−PEG40000 at this dose demonstrated a good antitumor effect, which was significantly higher than under therapy with free MTX. Efficacy was comparable to MTX−HSA at its MTD (20 mg/kg), but no significant influence on body weight was observed (Figure 5b), indicating that the conjugate was well tolerated.

DISCUSSION

Methotrexate has frequently been coupled to macromolecular carriers such as antibodies or synthetic polymers by activation of its carboxyl groups using *N*,*N*′-dicyclohexylcarbodiimide (DCC) and/or *N*-hydroxysuccinimide (NHS) (*5*, *40*, *43*). However, the stereochemistry of the activation process and its implication for the composition of the resulting drug conjugates has not been adequately addressed.

A series of experiments revealed that activating MTX with DCC in the absence or presence of NHS followed by reaction with a nucleophile (methanol or 2-methoxyethylamine) produces a mixture of α- and γ-MTX derivatives as the main products with concomitant formation of byproducts such as the diester or diamide derivatives of MTX and probably *N*-acylurea derivatives that are commonly formed when activating carboxylic acids with DCC (*39*). Minimizing the formation of byproducts and maximizing yields is best achieved by preincubating MTX with DCC in the cold and in the absence of NHS and then directly adding the nucleophile.

As shown by chiral HPLC, racemization of the L-glutamate moiety of MTX takes place when activating the carboxyl groups with DCC in accord with the literature (*43*, *46*). Analysis of the isolated model compounds, i.e., the α- and γ-methylester as well as the α- and γ-2-methoxyethylamide derivatives of MTX, showed complete racemization of the MTX α-derivatives and the MTX-γ-amide. The MTX γ-methylester contained only ∼35% of the D-isomer.

Due to the observed stereochemical properties of the MTX model compounds, we can safely predict that the MTX−PEG conjugates, synthesized according to the same activation procedure, are mixtures of α- and γ-isomers and L- and D-enantiomers.

In our in vitro studies, we first examined to what extent the different MTX−PEG were able to inhibit the target enzyme dihydrofolate reductase (DHFR). Interestingly, the MTX−PEG conjugates showed very similar IC_{50} values in the DHFR assay demonstrating that the length of the polymer backbone does not have a significant influence on the inhibition of the target enzyme (see Figure 3). The lower activity of the MTX−PEG conjugates compared with free MTX is probably due to the partial derivatization of the alpha-carboxyl group of MTX; this free carboxyl group has shown to be important for the binding to DHFR. Derivatization at the γ-position is usually well tolerated, while the blocked α-carboxyl group leads to decreased cellular uptake and reduced enzyme inhibition (*47*, *48*). This explanation is supported by our results with α- and γ-methylester in the DHFR assay which show that the γ-methylester is more active than the α-methylester (see Supporting Information).

Although the ability of inhibiting the isolated cellular enzyme, DHFR, is very similar for all the tested MTX−PEG conjugates, cell culture experiments in five human tumor cell lines show a different picture: The molecular weight of the carrier molecule has a significant influence on the cytotoxic activity of the conjugates. Low-molecular weight conjugates (MW ≤ 5000) exhibit an IC_{50} value of around 0.5−3 μM, while conjugates of higher molecular weight are less active in the tested cell lines with IC_{50} values in the range of 2−7 or >10 μM. Free MTX is approximately 20- to 1000-fold more active than the MTX−PEG conjugates (see Table 3).

These differences are likely to be due to different rates of cellular uptake which occurs either by diffusion through the cell membrane, by active transport through the MTX specific amino acid carrier (*49*) or by endocytosis (*50*).

A noteworthy result of our studies was that the MTX−PEG conjugate with the lowest activity in vitro (MTX−PEG40000) was the most active compound in subsequent in vivo experiments in a mesothelioma xenograft model. At a dose of 20 mg/kg MTX−PEG40000 showed superior efficacy compared to free MTX at its optimal dose (100 mg/kg) but similar activity to the methotrexate albumin conjugate MTX−HSA (also at 20 mg/kg, MW of human serum albumin ∼66 500) (see Figure 5). Even at a tenth of the dose (10 mg/kg) compared to the free drug (100 mg/kg), MTX−PEG40000 was as active as MTX in this animal model. In contrast, MTX−PEG conjugates of MW 5000 (at 40 and 80 mg/kg) and MW 20 000 (at 20 and 40 mg/kg) were significantly or slightly less active than free MTX.

These results, taken together, emphasize the importance of the molecular weight of the drug polymer conjugate with respect to in vivo antitumor efficacy. As recently emphasized by Greenwald and coworkers for drug conjugates with PEGs, improved efficacy of the drug conjugates compared to the free drug is observed in vivo once the molecular weight of the PEG backbone exceeds MW 20 000 (*29*). The pathophysiology of tumor tissue, characterized by angiogenesis, hypervasculature, a defective vascular architecture and an impaired lymphatic drainage (known in the literature as enhanced permeability and retention of macromolecules, "EPR-effect") serves as a working model for explaining the targeting potential of macromolecules with MW > 20 000 for solid tumors (*11*).

An open issue regarding the mode of action of MTX polymer conjugates is the cleavability of the amide bond between the glutamate moiety of MTX and the amino group of PEG. Our stability studies show that less than 10% of MTX are released after 6 days when MTX−PEG40000 is incubated at 37 °C in PBS buffer, cell-conditioned medium or human serum indicating that large amounts of MTX are unlikely to be cleaved from the polymer extracellularly. A reasonable assumption is that a lysosomal enzyme, such as γ-glutamyl hydrolase (γ-GH, EC 3.4.19.9), cleaves the amide bond considering that this enzyme efficiently hydrolyzes the γ-glutamyl tail of folate and antifolate polyglutamates (*51*, *52*). Unfortunately, this enzyme is not commercially available to date. It will, however, be important to elucidate the cleavage mechanism of MTX−PEG and MTX−HSA conjugates in future work considering that the level of expression of lysosomal enzymes in solid tumors has a decisive effect on the efficacy of enzymatically cleavable drug polymer conjugates. This has recently been emphasized by Duncan et al.: PK1, a doxorubicin−HPMA copolymer, is stable in the bloodstream but releases doxorubicin through cleavage of a tetrapeptide bond by intracellularly or extracellularly secreted cysteine proteases such as cathepsin B. The in vivo activity of this conjugate is correlated with the amounts of cathepsin B levels found in tumor cells and tumor tissue (*53*).

In summary, the structure−activity relationships elaborated in this study emphasize that in the field of drug polymer conjugates a systematic comparison of in vitro and in vivo data is a critical step for selecting drug candidates for further preclinical assessment.

Supporting Information Available: Chromatograms of chiral HPLC showing the racemization of various MTX compounds (Figure 6); HPLC analysis and MALDI−TOF spectra of MTX−PEG conjugates (Figures 7 and 8); inhibitory effect of MTX compounds on DHFR (Figure 9); and dose−response curves of MTX PEG conjugates in various cells (Figures 10−12). This material is available free of charge via the Internet at http://pubs.acs.org.

The growth inhibitory effect of the compounds was determined by measuring the total protein content using the BCA assay.

Modifications in Synthesis Strategy Improve the Yield and Efficacy of Geldanamycin−Herceptin Immunoconjugates

Raya Mandler,[†] Hisataka Kobayashi,[†] Marie Y. Davis,[†] Thomas A. Waldmann,[†] and Martin W. Brechbiel*[,‡]

Metabolism Branch and the Chemistry Section, Radiation Oncology Branch, National Cancer Institute, NIH, Bethesda, Maryland 20982-1002. Received December 26, 2001; Revised Manuscript Received April 15, 2002

Geldanamycin (GA) was modified with *N*-*tert*-butyloxycarbonyl-1,3-diaminopropane to introduce a latent primary amine. After deprotection, this primary amine provided a site for introduction of a maleimide group that enabled linkage to proteins. This maleimido derivative of geldanamycin (GMB-APA-GA) was linked to the monoclonal antibody Herceptin after the antibody had been modified with Traut's reagent to introduce thiol groups. By this sequence, a new immunoconjugate (H:APA-GA) was generated that showed greater antiproliferative activity than the previously reported analogous immunoconjugate created with a 1,4-diaminobutane spacer derivative of geldanamycin to form an immunoconjugate, H:ABA-GA. Both immunoconjugates inhibited in vitro the growth of MDA-361/DYT2 cells, a cell line overexpressing the HER2 antigen, while Herceptin alone was ineffective. However, H:APA-GA showed better efficacy than H:ABA-GA (IC_{50} = 0.2 vs 0.58 mg/mL and cell doubling time >12 vs 6 days, respectively). Results of the in vivo therapy experiments in a xenograft model were consistent with the in vitro findings. Treatment with Herceptin prolonged the survival of the tumor-bearing mice when compared with the control group, but H:ABA-GA and H:APA-GA were each more efficacious than unmodified Herceptin. However, unlike H:ABA-GA, the immunoconjugate H:APA-GA caused stable tumor regression (in 25% of the recipients), showing a qualitative improvement with potential clinical relevance.

INTRODUCTION

Geldanamycin (GA)[1] (Figure 1) is a benzoquinoid ansamycin produced by the actinomycete *Streptomyces hygroscopicus* that is related to herbimycin A with a known cellular target being the cytosolic protein chaperone hsp90 (*1*). Upon binding to hsp90, GA inhibits its ability to protect cellular enzymes from proteasomal degradation and disrupting in this way many crucial cellular processes (*2*). Consequently, this molecule is extremely cytotoxic to a wide variety of cells, including neoplastic cells. While the antitumor potential of GA has long been recognized, clinical use of native GA has not been pursued due to the drug's severe toxicity and difficulties with aqueous formulation (*3*). Numerous GA analogues have been synthesized and studied in an effort to develop derivatives with improved therapeutic indices (*4*). These studies indicated that modifications at the 17 position on the quinone ring maintained anticancer activity at nanomolar range while reducing the overall toxicity (*3*, *4*). One of these derivatives, 17-allylamino-GA (Figure 1), is currently entering Phase II clinical trials to treat a variety of solid tumors (*5*, *6*).

Further reduction of GA systemic toxicity could potentially be achieved by selectively targeting and delivering an active GA species into malignant cells using a monoclonal antibody (mAb) as the targeting vehicle. Clearly, internalization is a prerequisite for successful application of such immunoconjugates (*7*). With the advances of therapeutic mAbs into clinical use, it is conceivable that mAbs that internalize efficiently could also be used as the targeting vehicle in such an application (*8*). Several tumor-targeting mAb's armed with small toxic compounds have already been clinically evaluated and one has been approved for therapy of AML in elderly patients (*9*, *10*).

In our present studies, Herceptin was chosen as the targeting mAb. This mAb was the first to be approved by the FDA for therapy of solid tumors (*11*). Herceptin specifically targets the membrane receptor HER2, a member of the epidermal growth factor receptor family. HER2 is overexpressed in approximately 30% of human gastric, lung, and breast carcinomas and is associated with poor prognosis. Blocking of HER2 activity or interfering with its expression was shown to inhibit proliferation and reduce tumor growth (*11*−*13*). Because HER2 stability and function depends on hsp90, this protein is highly sensitive to and is efficiently eliminated by GA (*14*). Herceptin has been previously shown to internalize upon binding to HER2. The conjugation with GA is through an acid-labile bond that should release the GA derivative once the endocytosed conjugate is shuttled into the lysosomes. In fact, our laboratories have already reported that such conjugates do deliver a more potent selective cytotoxic impact than use of just Herceptin (*15*−*17*).

Geldanamycin

17-GMB-ABA-GA

17-Allylamino-GA

Figure 1. Structures of geldanamycin, 17-GMB-ABA-GA, 17-allylamino-GA.

Conjugation of mAb's with GA has not been a straightforward process because GA lacks a suitable functional group for direct covalent linkage to protein. As recently reported by our laboratories, introduction of a primary amine group originating from modification at the 17 position has been successful and permitted subsequent addition of a heterobifunctional cross-linking reagent for conjugation of the modified GA to mAb's (*15*, *16*). By use of this chemistry, 17-GMB-ABA-GA (Figure 1) could be conjugated to Herceptin efficiently and reproducibly. The product immunoconjugate, H:ABA-GA, subsequently demonstrated a higher antiproliferative effect on HER2 overexpressing cells than unmodified Herceptin. H:ABA-GA was also shown to be specific for HER2-positive, but not for HER2-negative, cells. The choice of 17-GMB-ABA-GA rather than the more potent 17-GMB-APA-GA, butyl spacer versus propyl spacer, respectively, was the result of a compromise between activity and availability of the required GA derivative (*15*, *16*). While 17-APA-GA had higher antiproliferative activity than 17-ABA-GA, the preparation of 17-GMB-APA-GA has been problematic. Simple introduction of the amine via direct aminolysis with 1,3-diaminopropane yielded a complex mixture of byproducts (*15*). Exposure to silica during chromatography aggravated this condition, efficiently catalyzing the formation of a seven-membered imine ring from the distal amine and the quinone carbonyl, further complicating access to this derivative. Insertion of an additional methylene into the amine chain eliminated this cyclization (*15*) and thus provided 17-GMB-ABA-GA in excellent yield. This synthesis ultimately allowed for the synthesis of a very pure and active GA-mAb immunoconjugate. (*15*)

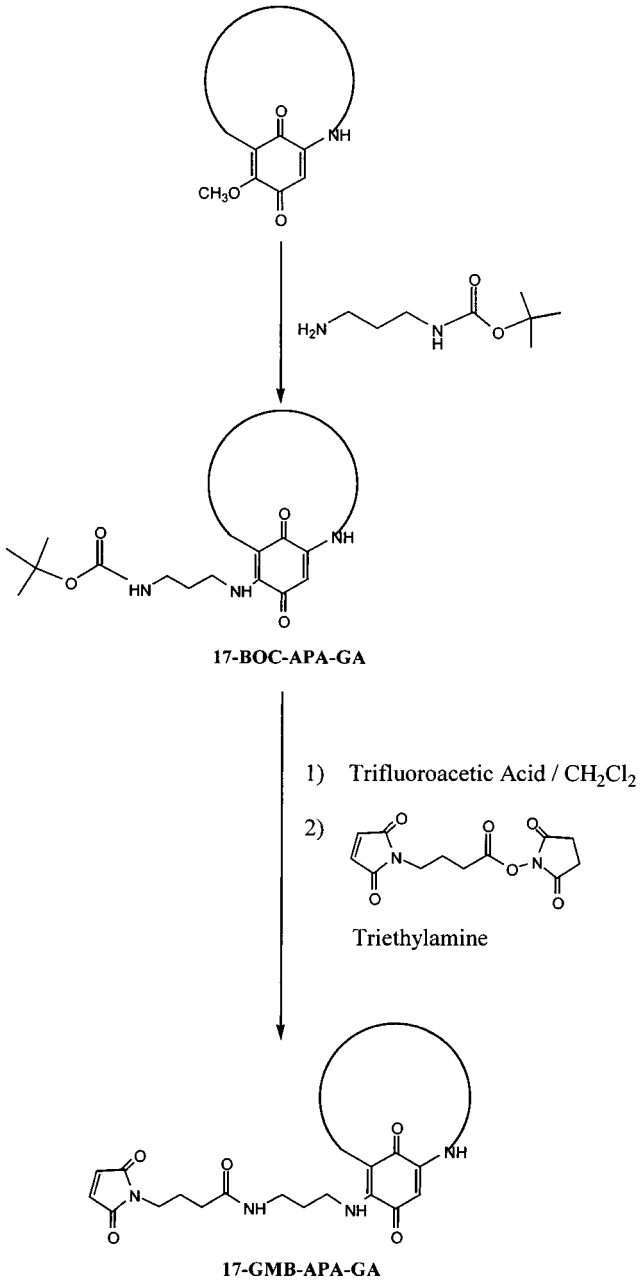

Figure 2. Synthesis of 17-GMB-APA-GA.

However, this strategy compromised the potency of the final immunoconjugate, prompting re-examination of the chemical strategies that had been employed.

Herein, we report on a successful modified synthesis strategy of 17-GMB-APA-GA (Figure 2), its conjugation to Herceptin, and an evaluation of this immunoconjugate's efficacy in vitro as well as in tumor-bearing mice.

EXPERIMENTAL PROCEDURES

Materials and Methods. All anhydrous solvents and reagents except where noted otherwise were obtained from Aldrich, Sigma, or Fluka and were used as received. The *N*-hydroxysuccinimidyl ester of 4-maleimidobutyric acid (GMB) was prepared by modification of a literature method (*18*). Geldanamycin (GA) was generously supplied by Edward A. Sausville and Gordon Cragg, NPG, DTP, DCTD, NCI. Triethylamine was distilled from CaH_2 prior to use.

^1H and ^{13}C NMR were obtained using a Varian Gemini 300 instrument, and chemical shifts are reported in ppm

on the δ scale relative to TMS, TSP, or solvent. Proton chemical shifts are annotated as follows: ppm (multiplicity, integral, coupling constant (Hz)). Chemical ionization mass spectra (CI-MS) were obtained on a Finnegan 3000 instrument. Fast atom bombardment mass spectra (FAB-MS) were obtained on an Extrel 4000 in the positive ion detection mode. Elemental analyses were performed by Atlantic Microlabs (Norcross, GA).

The MDA-361/DYT2 cell line was generously provided by Drs. Dajun Yang and Marc E. Lippman of The Lombardi Cancer Center, Georgetown University (Washington, DC) (*19*). The NIH3T3/HER cell line was generously provided by Dr. S. Aaronson, NIH (*20*). ^{125}I was obtained in the NaI form from Amersham Biosciences Corp. (Piscataway, NJ).

Caution: ^{125}I ($t_{1/2}$ = 59.4 day) is a γ-emitting radionuclide. Appropriate shielding and handling protocols should be in place when using this isotope. All protocols in which animals were used have been approved by the National Cancer Institute Animal Care and Use Committee.

17-(3-*tert*-Butyloxycarbonyl(aminopropyl)amino)-geldanamycin (17-*N*-BOC-APA-GA). GA (0.5 g, 0.89 mmol) was dissolved in $CHCl_3$ (300 mL), and *N*-*tert*-butyloxcarbonyl-1,3-diaminopropane (250 mg, 1.44 mmol) was added. The reaction was stirred shielded from light for 48 h, during which the initial golden yellow solution grew darker and an additional 100 mg (0.575 mmol) of the monoprotected diamine was added. After 96 h, the reaction was assayed by thin-layer chromatography (TLC) on silica (5% MeOH/$CHCl_3$). Despite the now dark purple appearance of the reaction, a distinct yellow component corresponding to GA was still evident by TLC, and another 100 mg of the protected diamine was added. After 120 h, the amount of GA remaining was deemed minimal by TLC, the reaction solution was concentrated to ca. 25 mL, and hexanes (ca. 450 mL) was added to precipitate the crude product. The suspension was placed at −20 °C for 24 h, after which the dark purple solid was collected on a Buchner funnel, washed with hexanes, and dried in vacuo in the absence of light. The pure 17-*N*-BOC-APA-GA was cleanly isolated by flash chromatography on silica (2.5 × 35 cm column) eluting with 1:99 MeOH/$CHCl_3$ (470 mg, 75%). ^{1}H NMR (300 MHz, $CDCl_3$, δ): 0.991 (br, d, 6H, J = 5.7 Hz), 1.432 (m, 1H), 1.456 (s, 9H), 1.803 (s, 3H), 1.835 (m, 2H), 2.028 (s, 3H), 2.410 (dd, 1H, J = 12.9, 10.8 Hz), 2.61−2.82 (m, 3H), 3.239 (m, 1H), 3.276 (s, 3H), 3.366 (s, 3H), 3.40−3.70 (m, 6H), 4.309 (d, 1H, J = 9.9 Hz), 4.693 (t, 2H, J = 6.3 Hz), 4.837 (br, s, 2H), 5.185 (s, 1H), 5.81−5.95 (m, 2H), 6.586 (t, 2H, J = 11.7 Hz, one proton obscured), 6.955 (d, 1H, J = 11.7 Hz), 7.267 (s, 1H), 9.167 (s, 1H). FAB-MS (nba/CsI) *m*/*e*: 704 (M^+). Anal. Calcd for $C_{36}H_{56}N_4O_{10}$: C, 61.33; H, 8.02; N, 7.95. Found: C, 61.45; H, 8.37; N, 7.72.

17-(3-(4-Maleimidobutyrcarboxamido)propyl-amino)geldanamycin (17-GMB-APA-GA). The 17-*N*-BOC-APA-GA (100 mg, 0.142 mmol) was dissolved in CH_2Cl_2 (100 mL) and treated with trifluoroacetic acid (10 mL) at room temperature for 1 h, after which TLC indicated that starting material was no longer present. The solution was rotary-evaporated at ambient temperature until near dry. The residue was taken up in CH_2Cl_2 (ca. 50 mL) and rotary-evaporated until near dry 3 times and then finally dried in vacuo for 24 h. The crude protonated amine was taken up in ethyl acetate (100 mL), and GMB (80 mg, 0.286 mmol) was added to the solution. Immediately thereafter, triethylamine (100 μL) was added, and the reaction was stirred in the dark for 24 h. At this point, TLC on silica with 10% MeOH/$CHCl_3$ indicated one major component, and the solvent was removed by rotary evaporation at ambient temperature. The product was isolated by flash chromatography on silica as described previously, eluting with 2% MeOH/$CHCl_3$ (90 mg, 83%). ^{1}H NMR (300 MHz, $CDCl_3$, δ): 0.990 (t, 6H, J = 7.5 Hz), 1.77−1.60 (m, 3H), 1.802 (s, 3H), 1.99−1.84 (m, 3H), 2.029 (s, 3H), 2.184 (t, 2H, J = 7.2 Hz), 2.44−2.32 (m, 2H), 2.61−2.80 (m, 3H), 3.275 (s, 3H), 3.48−3.38 (m, 2H), 3.367 (s, 3H), 3.38−3.66 (m, 6H), 4.314 (d, 1H, J = 9.9 Hz), 5.191 (s, 1H), 5.81−5.95 (m, 2H), 6.044 (t, 1H, J = 5.7 Hz), 6.588 (t, 1H, J = 11.4 Hz), 6.626 (t, 1H, J = 5.7 Hz), 6.726 (s, 2H), 6.956 (d, 1H, J = 12.0 Hz), 7.263 (s, 1H), 9.164 (s, 1H). FAB-MS (nba/prg/CsI) *m*/*e*: 767 (M^+). HR-FAB-MS *m*/*e*: 767.3742, error = −0.7 ppm. Anal. Calcd for $C_{39}H_{53}N_5O_{11}$: C, 60.99; H, 6.97; N, 9.12. Found: C, 61.18; H, 7.04; N, 8.97.

Conjugation of GA Derivatives (17-GMB-ABA-GA, 17-GMB-APA-GA) to Herceptin (H:ABA-GA, H:APA-GA). The conjugation was performed as previously reported (*15*, *16*). Herceptin was reacted with Traut's reagent at a molar ratio of 1:13. Excess Traut's reagent was removed by buffer exchange into conjugation buffer (50 mM HEPES, 150 mM NaCl, 10 mM EDTA (pH 7.0)). The molarity of the SH functionality groups after thiolation was determined by the method of the Ellman reaction at A_{412} (*16*). When compared with the molarity of the mAb itself, this value allowed calculation of the average reaction ratio of GA:mAb. The reaction conditions employed yielded an average of three thiol groups per protein molecule. Thereafter, 17-GMB-APA-GA (or 17-GMB-ABA-GA) was dissolved in DMSO (2 mg/mL) and was reacted with the mAb at ≥5-fold the concentration of the mAb's SH groups. The reaction mixture was kept in the dark at 25 °C for 1 h and then was dialyzed extensively (3 × 1 L during 48 h) against PBS without Ca^{2+}/Mg^{2+} at 4 °C. The presence of the GA moiety on the mAb was confirmed by spectrophotometric reading at A_{334}, as previously reported (*15*, *16*). All conjugates were filtered for sterility and were kept at 15−20 mg/mL, at 4 °C. Humanized anti-CD25 mAb (Zenapax, Hoffman-LaRoche) was similarly treated to produce a comparable immunoconjugate as previously reported (*16*).

Immunoreactivity and Cell Binding Assay. To establish that the conjugation did not compromise the mAb, antigen recognition and cell binding of the immunoconjugates were compared to native Herceptin. MDA-361/DYT2 cells as well as the HER2-transfectant cell line NIH3T3/HER were used as a source of HER2 for these assays. The transfectant cells were employed because they expressed a much higher receptor/cell number than MDA-361/DYT2 cells (2.3×10^6 vs 0.18×10^6 receptor/cell, respectively, as determined by Scatchard plot analysis) and thus provided conditions for a more accurate evaluation of antigen binding. Herceptin and H:APA-GA were each labeled using ^{125}I (7 mCi/mg of protein) employing a modified Chloramine-T method. Immunoreactivity was determined by a modified cell-binding assay (*21*, *22*). Aliquots of the ^{125}I-labeled H:APA-GA or parental Herceptin (2 ng/100 μL) were incubated in parallel with 5.0×10^5 to 2.0×10^6 NIH3T3/HER cells or 1.0×10^6 MDA-361/DYT2 cells for 2 h at 4 °C. Nonspecific binding was determined under conditions of excess antibody (25 μg of nonradiolabeled Herceptin). The K_d values for Herceptin and the GA immunoconjugate were obtained from the Scatchard plot analysis.

Evaluation of In Vitro Efficacy of H:APA-GA. MDA-361/DYT2 cells were seeded into six-well, flat-bottom plates at 5×10^4 cells/mL and allowed to adhere. Herceptin and the two GA immunoconjugates were each

added to the wells at 0.5 mg/mL (2 mL). Control treatments were PBS only (vehicle) and 1 μM BOC-APA-GA (2 mL). To calculate cell doubling times, cells were detached and counted every 48 h, for 12 days.

To establish an IC_{50} for the conjugates, MDA-361/DYT2 cells were seeded into 96-well plates and were treated with increasing concentrations of Herceptin and either of the two conjugates, as described previously (*15*, *16*). Cultures were allowed to grow until the PBS-treated controls reached 80% confluency. Cell growth was measured after fixing the cultures in all wells, staining the fixed cells with Crystal Violet, and reading the eluted dye at A_{540} (*15*).

Evaluation of Therapeutic Efficacy of the H:APA-GA with Human Xenografts in Athymic Mice. Six-week old athymic female mice (NCI, Frederick, MD) were inoculated sc with MDA-361/DYT2 cells (2×10^6/0.1 mL). These tumors are estrogen-dependent; therefore, E2 pellets (Innovative Research of America, Sarasota, FL) were inserted under the skin 24 h prior to tumor transplanation (0.72 β-estradiol, constant release for 60 days). When tumors reached 15−20 mm^3, the mice were randomly divided into groups ($n = 8$) and treatment was initiated. The treatment regimen was an ip dose of the immunoconjugate at 4 mg/Kg in PBS (0.2 mL) every 3 days for 120 days. The size of the tumors and their appearance was monitored and recorded during that time. Mice were terminated when the tumors reached ~1200 mm^3, if the tumor became necrotic, or if the animals showed signs of severe stress and illness.

RESULTS AND DISCUSSION

The synthesis of the 17-GMB-APA-GA (Figure 2) was performed using the mono-BOC-protected 1,3-diaminopropane. This completely eliminated the competing formation of the seven-membered ring that occurred with use of just the diamine. Thus, treatment of GA with *N-tert*-butyloxcarbonyl-1,3-diaminopropane (Figure 2) produced a dark purple solid that was isolated by precipitation with hexane and then easily purified by column chromatography on silica gel. The most effective reaction conditions involved a careful titration of the GA with the protected amine over several days while carefully following the progress of the reaction by TLC. Regardless of this care, isolation of a minor product that appeared to have added two equivalents of protected diamine (as determined by mass spectrometry) was still observed. This product was presumed to form from the addition of a second equivalent of the monoprotected diamine to the quinone carbonyl, forming an imine.

The rationale for using the *tert*-butylcarbamate (BOC) protecting group was that the formed primary amine would be efficiently protonated upon acidic removal of the BOC group and would effectively continue to inhibit the competing cyclization reaction. Although acidic deprotonation and interception of the amine was expected to lead to the desired product, this was not altogether assured. Deprotection with trifluoroacetic acid appeared to be extremely efficient. However, initial attempts to first directly generate the free amine and subsequently perform reactions with the *N*-hydroxysuccinic ester of γ-maleimidobutyric acid (GMB) led to capricious results. In contrast, reproducible results were only obtained by generating the free amine in situ as the final component of this reaction, concomitantly trapping the amine with the GMB. As such, routine production of the GA derivative, 17-GMB-ABA-GA, suitable for conjugation to proteins or peptides in reasonably large amounts was achieved in good yield and excellent purity.

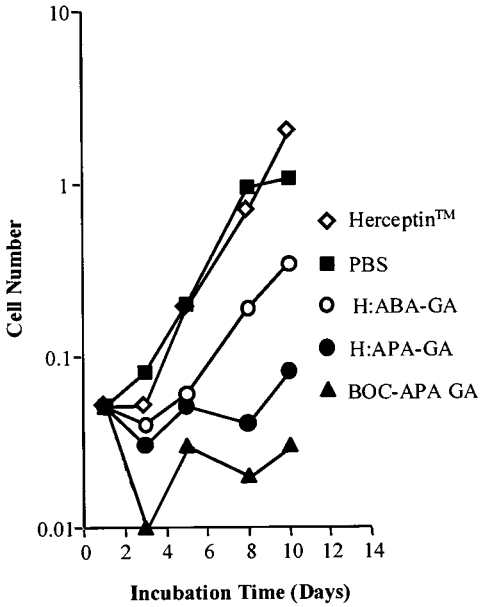

Figure 3. Effect of GA immunoconjugates on cellular growth rate of HER2-overexpressing cells. MDA-361/DYT2 cells were treated with 0.5 mg/mL Herceptin or GA immunoconjugate. Cell numbers were determined every 48 h, for 12 days. Cell doubling times for the PBS, Herceptin, H:ABA-GA, and H:APA-GA-treated cultures were 1.4, 1.6, 6.2, and greater than 12 days, respectively.

This product, as well as the previously reported 17-GMB-ABA-GA, were each conjugated to Herceptin, as described in the Experimental Procedures (*15*, *16*). Previously, the purity of the 17-GMB-ABA-GA had been assessed by analytical SE-HPLC and shown to be essentially congruent with Herceptin (*15*). This observation was duplicated by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE). Thus, in this current study, SDS−PAGE was employed to confirm the absences of conjugation reaction byproducts. All of the conjugates employed herein were found to be comparable to Herceptin as determined by SDS−PAGE (data not shown).

The immunoreactivity of H:APA-GA was not compromised by this conjugation process to any detectable level as measured in binding assays. The absolute amount of bound immunoconjugate to MDA-361/DYT2 cells was 13% ± 1% for both H:APA-GA and parental Herceptin using 1.0×10^6 cells. Binding was even higher (~91 ± 2% for Herceptin and H:APA-GA) when the assay was performed with NIH3T3/HER cells, consistent with the fact that the amount of HER2 antigen was higher on the surface of these cells. To support the characterization of the immunoconjugate, the K_d values for Herceptin and the H:APA-GA, as obtained from Scatchard plot analysis, were determined. The K_d values clearly were not significantly different, 4.2 ×and 3.8×10^{-9} M for H:APA-GA and Herceptin, respectively, and were consistent with previously reported values for Herceptin (*23*).

The biological activity of 17-APA-GA was reported to be approximately 3-fold higher than that of 17-ABA-GA (*16*). Thus, the immunoconjugate formed with 17-GMB-APA-GA, H:APA-GA, was expected to exert a stronger inhibitory activity compared with H:ABA-GA. The antiproliferative activity of the two immunoconjugates was evaluated using MDA-361/DYT2 cells and is displayed in Figure 3. Cell growth rate was measured in cultures treated with either 0.5 mg/mL of Herceptin, H:ABA-GA, or H:APA-GA. The effect of Herceptin alone was marginal

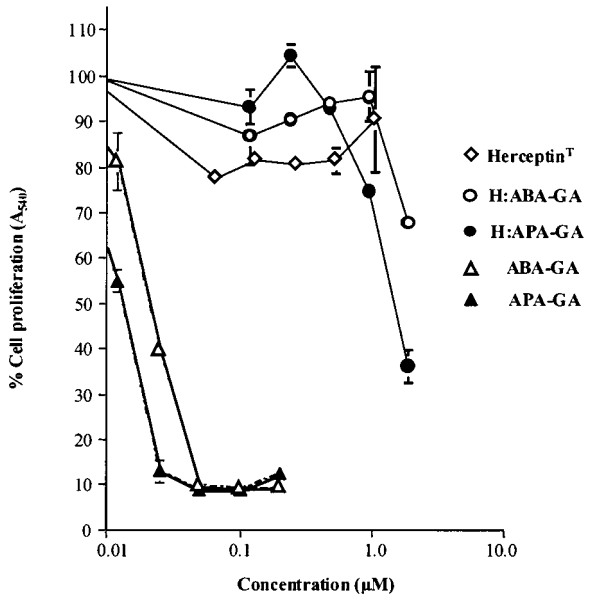

Figure 4. Dose−response curves obtained from MDA-361/DYT2 cultures treated with increasing concentrations of either Herceptin, GA immunoconjugates, or GA derivatives alone. Doses are expressed in molarity of GA moeity, other than in the Herceptin alone samples. All samples were run in duplicate and are presented with SD bars.

while both immunoconjugates inhibited cellular growth. As expected, the H:APA-GA showed higher efficacy than H:ABA-GA, maintaining the cultures at no apparent growth for 8 days. Cell doubling times for the control (PBS) and Herceptin-treated cultures were 1.4 and 1.6 days, respectively, while for H:ABA-GA this was 6.2 days. In contrast, the doubling time of the H:APA-GA-treated cultures exceeded 12 days. The IC_{50} values of H:APA-GA and H:ABA-GA were determined from seven separate experiments to be 0.2 ± 0.03 and 0.58 ± 0.02 mg/mL, respectively, and a representative experiment is shown in Figure 4. In contrast, IC_{50} values for native Herceptin could not be determined because the maximal inhibition of unmodified Herceptin reached only 25%, even at concentrations higher than 10 mg/mL (Figure 4).

The specificity of cell targeting was addressed in our earlier publications on GA immunoconjugates (*15*−*17*). In brief, anti-HER2:GA immunoconjugates were demonstrated to not inhibit proliferation of HER2-negative cells, such as the lymphocytic cell line HuT102. These immunoconjugates also did not inhibit the proliferation carcinoma cells with normal HER2 expression, such as A431 or MCF-7 cells. The inverse condition was also demonstrated, that is, that GA immunoconjugates comprised of irrelevant mAbs did not affect HER2-positive cells and that, in all cases, selective internalization was crucial for efficacy.

Concurrent with our ongoing studies, Kasuya et al. reported a similar finding concerning the isolable nature of the propylamine-derivatized GA via a protonation procedure that was used postreaction between GA and 1,3-diaminopropane (*24*). The procedure provided here is believed to offer some advantages in that complete obviation of the competing cyclization reaction was achieved and that both the carbamate-protected GA and protonated-deprotected GA are then readily available for subsequent chemical modification. While chromatographic separation steps were required to obtain the carbamate-protected GA as well as the 17-GMB-APA-GA in high purity, these operations were not difficult. In the case of the former compound, this did eliminate the consistently present impurity that arose from addition of a second molecule of reagent to GA.

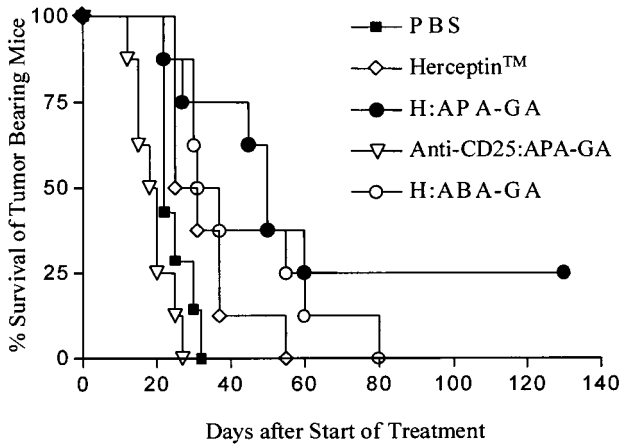

Figure 5. Effect of GA immunoconjugates on survival of MDA-361/DYT2 sc xenograft (15−20 mm^3) bearing athymic mice (n = 8/group). Reagents were given ip at 3 day intervals at 4 mg/kg and were continued for 3 months.

Recently, Kasuya et al. also reported the preparation of a GA immunoconjugate that targets ovarian cancer cells (*25*). They employed different chemistry creating a polymeric form of APA-GA with *N*-(2-hydroxyproply)-methacrylamide (HPMA) that could be conjugated to the anti-OA-3 mAb, OV-TL16. This conjugation strategy was designed to form a lysosomally degradable linkage that efficiently releases GA intracellularly. The linkage of 17-APA-GA to HPMA significantly reduced the antiproliferative activity, with a 40-fold increase of the IC_{50} value (19 μM in A2780 cells) and the final product (anti-OA-3:GA immunoconjugate) had modest activity, similar to the nonspecific conjugate of GA with bovine serum albumin.

H:ABA-GA and H:APA-GA were then tested for their in vivo efficacy in a xenograft model of MDA-361/DYT2 tumors that were transplanted sc into athymic mice. Therapy was initiated when tumors had reached a detectable size (15−20 mm^3) as described in the Experimental Procedures. The administration regimen was chosen to mimic a dose used in patients (4 mg/Kg) and corresponded to $t_{1/2}$ (*17*) (i.e., ip injections every 3 days through 120 days). Efficacy was determined on the basis of survival and tumor progression. As shown in Figure 5, the survival of Herceptin-treated recipients was prolonged compared with that of the placebo group. The H:ABA-GA and H:APA-GA conjugates prolonged survival even further, but neither Herceptin nor the H:ABA-GA were able to induce a complete, stable tumor regression. However, treatment with the H:APA-GA immunoconjugate induced permanent tumor regression in 2/8 recipients. No tumors were detectable by visual inspection, even after 4 months had elapsed, 1 month after the ip injection treatment had been halted. Thus, H:APA-GA was qualitatively superior to H:ABA-GA because this immunoconjugate could cure a fraction of the recipient mice while H:ABA-GA, in repeated experiments, was only able to retard tumor growth.

In this study, we have demonstrated that the strategy of BOC protecting and acid deprotection allowed production of large quantities of the desired 17-GMB-APA-GA in excellent purity. Thus, the previously encountered technical obstacles to larger-scale production of 17-APA-GA immunoconjugates have been eliminated. Conjugation of 17-GMB-APA-GA to the anti-HER2 mAb Herceptin resulted in an immunoconjugate with enhanced

antiproliferative action when compared with that of the native mAb. More importantly, this immunoconjugate is superior to the previously studied immunoconjugate, H:ABA-GA, and shows significantly improved efficacy in vivo.

ACKNOWLEDGMENT

The authors thank Robert Cohen and Mark Sliwkowski, Genentech Inc., for their generous supply of Herceptin, and the Laboratory of Analytical Chemistry, NIDDK, for their assistance in obtaining detailed mass spectra data for all of the geldanamycin derivatives.

Selective Adsorption of Serum Albumin on Biomedical Polyurethanes Modified by a Poly(ethylene oxide) Coupling-Polymer with Cibacron Blue (F3G-A) Endgroups

Dong-an Wang,*[,†,‡] Bao-lin Chen,[†,§] Jian Ji,[†] and Lin-xian Feng[†,||]

Department of Polymer Science and Engineering, Zhejiang University, Hangzhou, 310027, P. R. China, Department of Pharmaceutical Sciences, University of Tennessee Health Science Center, Memphis, Tennessee 38163, and Department of Chemistry, Inner Mongolia Hulunbeier Collage, Hailaer, 021008, P. R. China . Received January 22, 2002; Revised Manuscript Received April 3, 2002

A tri-*block*-coupling polymer, "PEO−MDI−PEO" ["poly(ethylene oxide)−4,4′-methylene diphenyl diisocyanate−poly(ethylene oxide)", abbreviated "MPEO"], was used to react with a triazine dye, Cibacron Blue F3G-A (ciba), in an alkaline environment. The product of this nucleophilic reaction was a penta-*block*-coupling polymer, "ciba-PEO-MDI-PEO-ciba" (abbreviated "cibaMPEO"). The cibaMPEO-modified poly(ether urethane) (PEU) surfaces were prepared by dip-coating and detected by XPS. The surface enrichment of both ciba endgroups and poly(ethylene oxide) spacer-arms was revealed. On the modified surfaces, bovine serum albumin (BSA)-adsorbing experiments were carried out, respectively, in the low and high BSA bulk-concentration solutions, and accordingly, the methods of radioactive ^{125}I-probe and ATR-FTIR were, respectively, employed for the characterization. The competitive adsorption of BSA and bovine serum fibrinogen (Fg) in the BSA−Fg binary solutions was also studied using a ^{125}I-probe, and through which the reversibly BSA-selective adsorption on cibaMPEO-modified PEU surfaces was confirmed. Finally, the improvement of blood-compatibility on the modified surfaces was verified by the plasma recalcification time (PRT) test.

INTRODUCTION

The implantable biomedical devices made of polymeric materials, such as blood-contacting intravascular catheters, have been extensively utilized for the interventional treatments in clinical practice. However, the surfaces of these devices may promote the in situ blood coagulation, microbial infections, and consequent inflammatory reactions (*1*, *2*). It is believed that these iatrogenic effects are likely to be mediated by adsorbed host proteins on the device surfaces (*3*, *4*). It is also widely accepted that albumin-coated surfaces can minimize those harmful effects (*5*, *6*). Thus, a series of novel surface-modifying additives (SMA) were specially designed to develop surfaces that would selectively bind the host albumin.

In our study, a triazine dye, Cibacron Blue F3G-A (abbreviated "ciba") (Schemes 1, 2) and the polymeric material poly(ethylene oxide) (PEO) were employed as the two main components of the SMA. Ciba possesses the capacity to selectively bind the host albumin. It is proposed that the binding of ciba to human serum albumin (HSA) is at the bilirubin-binding sites and ciba's binding to bovine serum albumin (BSA) is at the fatty acid-binding sites (*7*, *8*). PEO is a well-known and very useful biomaterial. Under aqueous physiological conditions, hydrophilic PEO has high kinetic chain mobility and large thermodynamical steric volume (*9*), leading to the repulsion of almost all kinds of foreign adherence and adsorption. Accordingly, for the SMA in our study, ciba was introduced as the functional endgroup, and the PEO chains were employed as the spacer-arms. We hypothesize that on the modified surface, ciba will selectively bind the host albumin, while the PEO will be resistant to the adsorption of the tangible humoral (particularly haemal) components such as proteins and cells. As the endgroup, ciba's presence on the blood−polymer interface would depend on the support from the hydrophilic PEO backbones, and the activity of ciba would also be provided by the mobility of PEO chains. Because of this proposed cooperative effect between the PEO spacer and ciba endgroup of SMA, the biocompatibility of the medical device was expected to be improved.

The SMA in our study is a penta-*block*-coupling polymer of "ciba−PEO−4,4′-methylene diphenyl diisocyanate (MDI)−PEO−ciba" (abbreviated "cibaMPEO") (Schemes 1, 2), which was a product of the nucleophilic reaction between ciba and the preproduct, a tri-*block*-coupling polymer of "PEO−MDI−PEO" (abbreviated "MPEO") (Scheme 1) (*10*, *11*). The matrix material of the medical device in this paper was poly(ether urethane) (PEU). The expedient dip-coating method of surface modification was selected. According to the conclusions from our earlier studies (*10*, *11*), H-bonds will be formed between the middle MDI-blocks of cibaMPEO and the "hard" blocks of PEU chains (Scheme 2), by which the stability of the coating can be ensured.

The adsorbing experiments of BSA and/or fibrinogen (Fg) were carried out on the modified surfaces. The systemic quantitative analysis was performed using attenuated total reflection (ATR) FT-IR spectroscopy (*12*, *13*) for the experiments with high BSA-bulk-concentra-

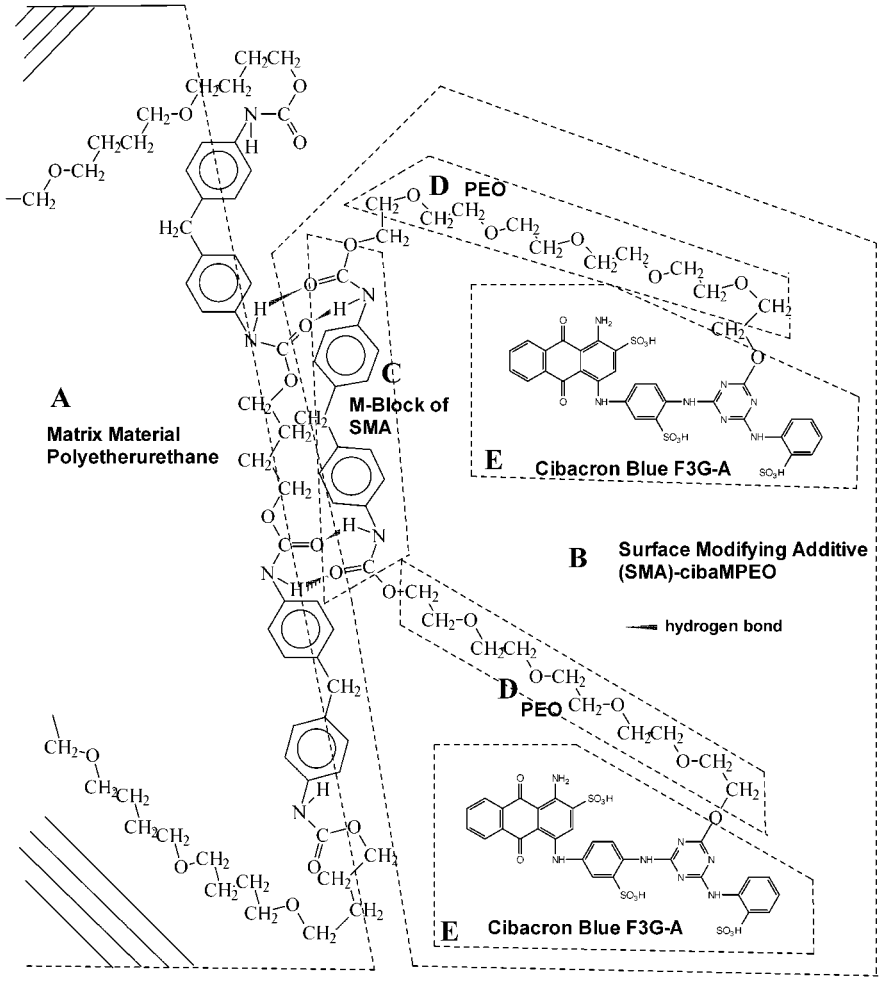
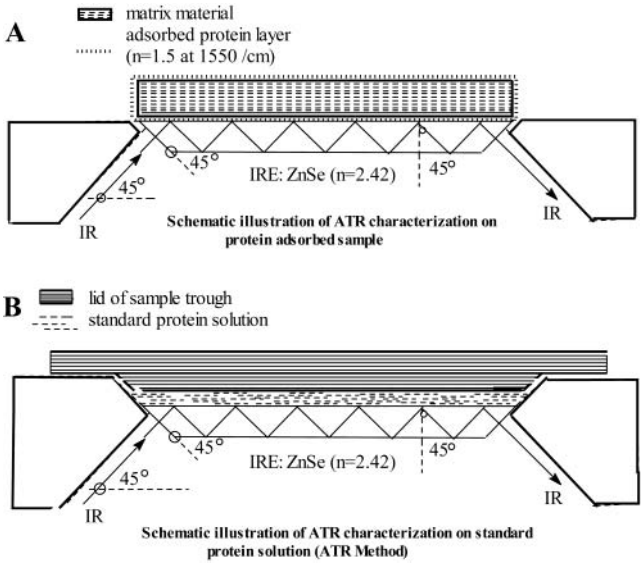
tion solutions and using a radioactive ^{125}I-labeled probe (*8*) for the experiments with low BSA- and/or Fg-bulk-concentration solutions. Finally, for characterization of anticoagulation, measurements of plasma recalcification time (PRT) (*14*) were carried out.

EXPERIMENTAL SECTION



Preparation of SMA−CibaMPEO and Modified PEU Surfaces. *Preparation of MPEO and CibaMPEO.*The synthesis and purification of MPEO (PEO MW 1000, 2000, 6000, and 10000; the corresponding MPEO were named MPEO1k, -2k, -6k, and -10k) were reported previously (*10*). The preparation of SMA−cibaMPEO (Scheme 1) was based on the nucleophilic substitution of the Cl^- on ciba (Cibacron Blue; purchased from Sigma Chemical Co., St. Louis, MO, C9534) by MPEO's hydroxyl endgroup (*15*). MPEO (MPEO1k, -2k, -6k, and 10k, respectively, 5.0 g) and ciba (accordingly 1.00, 0.5, 0.33, and 0.10 g) were dissolved in deionized water (10 mL) with NaOH (1.12 g) and anhydrous Na_2SO_4 (0.48 g). The mixture was moderately stirred at room temperature for 12 h. Ice-cold acetic acid (1.6 mL) was added to terminate the reaction by neutralizing the medium. The product was dried over magnesium sulfate and concentrated in vacuo. The residue was further dried under high vacuum overnight at 60 °C. The resulting blue powders were washed and filtered with tetrahydrofuran to remove the insoluble salts and unreacted ciba. Finally, graded precipitation was carried out with ethyl ether to isolate the desired blue products from the unreacted MPEO, which was monitored by the resulting color and GPC (Baseline 810 method, Waters). The corresponding final products were respectively named cibaMPEO1k, -2k, -6k, and 10k. ^{1}H NMR spectroscopy (500 MHz, AVANCE DMX500, Bruker; solvent DMSO-d_6, Aldrich) and XPS (ADXPS, VG Instruments) were used for characterization.

Preparation of CibaMPEO-Modified PEU Surfaces. The sheets (80 mm × 10 mm × 2 mm) of poly(ether urethane) (PEU, Pellethane 2363−80AE, Dow Chemical) were used as the matrix material, and the PEU pellets were used as the film-building additive (FBA) for coating. FBA−PEU has been extracted with alcohol in a soxhlet extractor for 72 h to remove the processing aid (stearamide additive) (*16*). The coating solution was obtained by dissolving SMA−cibaMPEO and FBA−PEU together into tetrahydrofuran and then diluting with equal volume of alcohol. The dosage ratio of cibaMPEO/PEU was 3:2 (w/w), and the concentration of cibaMPEO was 4% (w/v). The dip-coating process was performed on an electric lifter. The matrix-PEU sheets were vertically dipped into and then lifted out of the coating solution with constant speed followed by drying in a vacuum for 30 min. The process was repeated three times. Two kinds of control sample, which was respectively coated only with the FBA−PEU or only with MPEO/FBA−PEU, were also prepared. XPS was used to analyze the modified PEU surfaces (PEU-control, ctMPEO2k, ct-cibaMPEO1k, -2k, -6k, and -10k).



Preparation of Protein-Adsorbed Surfaces. *Proteins and Buffers.* Bovine serum albumin (BSA) was provided by Sigma (A-2153, protein content 96−99%, M_n 66,210, refraction index $n_2 = 1.5$ at infrared absorbance 1550 cm^{-1} (*12*)). Bovine serum fibrinogen (Fg) was also from Sigma (F-8630, protein content 74% (Biuret), clottable protein 87%, 10% sodium citrate, 15% NaCl). Fg was purified by dialysis with dialysis sacks (Sigma 250-7U, retains proteins with $M_n > 12000$) and stored under −20 °C. The tris(hydroxyethyl)methylaminomethane (A.R., abbreviated "Tris") and glycine (A.R., abbreviated "Gly") were from Shanghai Bio-Chem. Co. The buffers of "Tris-HCl" solution (6.057 g Tris/water 1000 mL, pH 7.35−7.40) and "Gly-NaOH" solution (6 g Gly/water 80 mL, pH 8.80) were prepared. The Gly-NaOH buffer was stored under 4 °C. All the water used was double-distilled deionized water.

Radioactive Protein Probe. Radioactive Na^{125}I (25 mCi, original radiointensity 160−180 mCi/mL, without reductives, $t_{1/2}$ = 59.7 d) was provided by the Institute of

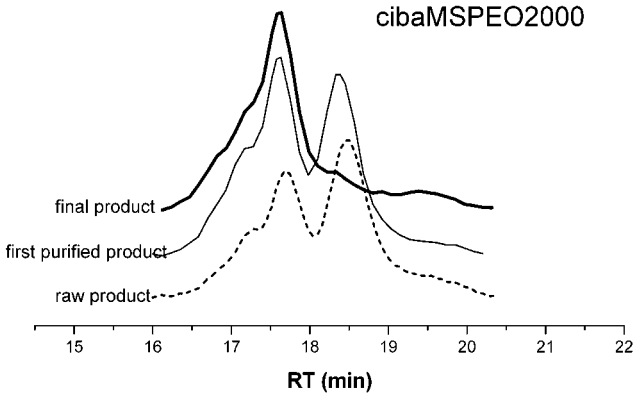

Figure 1. GPC spectra of cibaMPEO(2k) for the purification. The chromatographic peaks at approximately 17.5 min (RT) represent the product cibaMPEO; the peaks at approximately 18.5 min (RT) represent the unreacted MPEO.

Atomic Energy of China and was used within the first half of $t_{1/2}$. The preparation of ICl solution and the following ^{125}I-labeling of the protein were reported elsewhere (*17*). The radioactive protein probe was acquired by mixing the solution of protein (4 mg/0.1 mL) in Gly-NaOH into the solution of 0.01 mL of ICL/0.5 of mL Gly-NaOH/Na^{125}I (Na^{125}I dosage for BSA 0.2 mCi, for Fg 0.1 mCi) and then eluting with Tris-HCl through an alkali PS anion exchanger column (Shanghai Chemical Co.).

Protein Solutions. As for the protein-bulk-solution for adsorption and/or the protein-standard-solution for the calculation, the BSA, Fg, and the BSA−Fg binary solutions were respectively prepared in Tris-HCl buffer. The radioactive bulk solution was prepared by adding the radioactive protein probe into the solution containing 9 times as much non-radioiodine-labeled protein. The de-

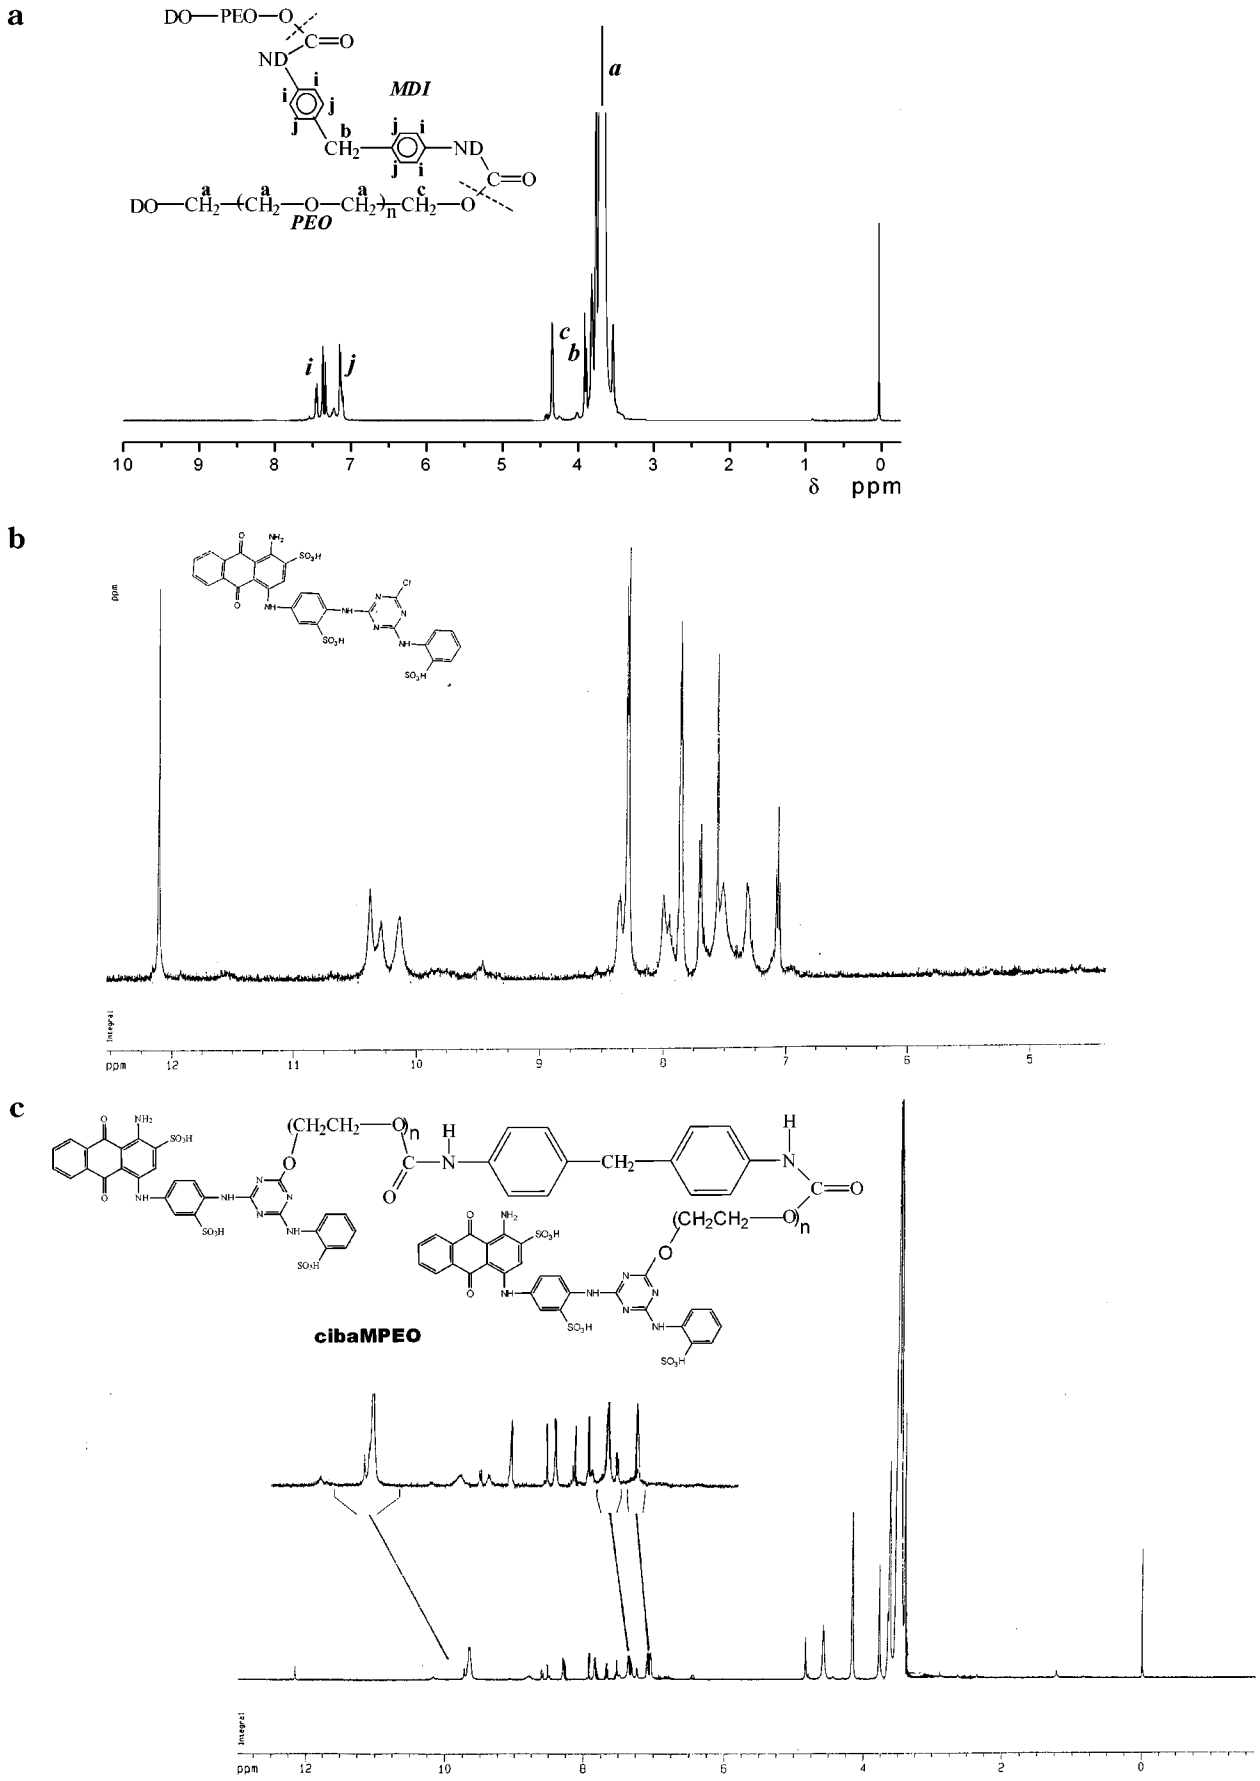

Figure 2. ^{1}H NMR spectra: (a) MPEO(2k), (b) Cibacron Blue F3G-A and (c) cibaMPEO(2k).

termination of concentration was performed through an ultraviolet (Beckman DU-50) method (*18*).

Adsorption Experiment. The modified sheets were previously equilibrated in water for 2 h, and the method

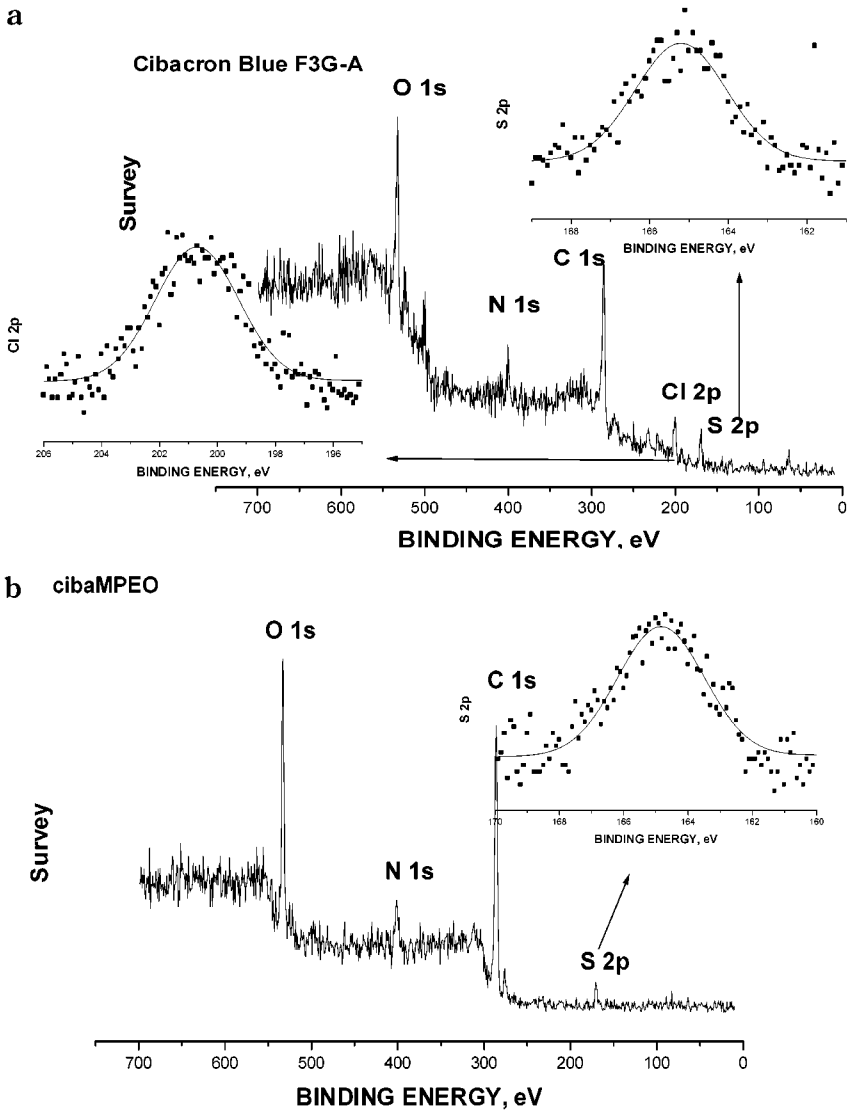

Figure 3. Survey XPS spectra of the powders: (a) Cibacron Blue F3G-A and (b) cibaMPEO(2k).

of adsorption followed a static immersing process in the protein-bulk-solution at 37 °C. After immersion, the residual solution on the surface of the samples was thoroughly removed by a centrifugal method instead of the popular rinsing method with protein-free buffer, to avoid the undesirable protein desorption by leaching and to maintain the original status on the polymer surfaces in the protein solution.

ATR-FTIR Analysis of BSA-Adsorbed Surfaces. ATR-FTIR (E.S.P., MAGNA-IR560, Nicolet; two types of ATR fittings respectively for solid samples (Scheme 3a) and solution (Scheme 3b); IRE crystal: ZnSe, sampling interface 80 mm × 10 mm, refractive index $n_1 = 2.42$, infrared internal reflecting angle *(θ)* 45°) was used to quantitatively characterize the adsorbed proteins (non-radioiodine-labeled). Thirty-two scans were performed. The blank sheet without BSA (or the solvent) was prescanned in a referenced infrared path to yield the background data, the corresponding BSA-adsorbed sample (or the protein solution) was scanned, and the nonprotein background was subtracted off automatically. The correct subtraction should make the region 1900−1720 cm^{-1} flat (*12*). BSA solutions (10.4 mg/mL and 30.6 mg/mL) were used as the parallel standard solution.

Static Isothermal Adsorption. The 5.0 mg/mL, 10.4 mg/mL, and 30.6 mg/mL BSA solutions were employed, and the time of adsorption was 30 min.

Static Adsorption Kinetics. The 30.6 mg/mL BSA solution was employed, and data at six time-points (0.5, 1, 5, 10, 30, and 60 min) were collected.

Adsorption Analysis of ^{125}I-Labeled Proteins A scintillation γ-ray counter (SN 682, Shanghai Institute of Atomic Nucleus) was used to quantitatively characterize the adsorbed proteins (radioiodine-labeled), and the data at six time-points (5, 10, 15, 30, 60, and 90 min) were respectively collected. The standard curve was obtained according to the radiocount from the standard ^{125}I-labeled protein solution.

Adsorption of ^{125}I-Labeled Proteins. The 0.4 mg/mL BSA solution and the 0.04 mg/mL Fg solution were respectively employed.

Selective Binding of Albumin in BSA−Fg Binary Protein System. Parallel adsorption on the same samples was carried out at the same time respectively in radioiodine-labeled BSA/nonlabeled Fg and nonlabeled BSA/radioiodine-labeled Fg binary solutions with the same protein concentrations. The compound results indicated the information of competitive adsorption. Two systems

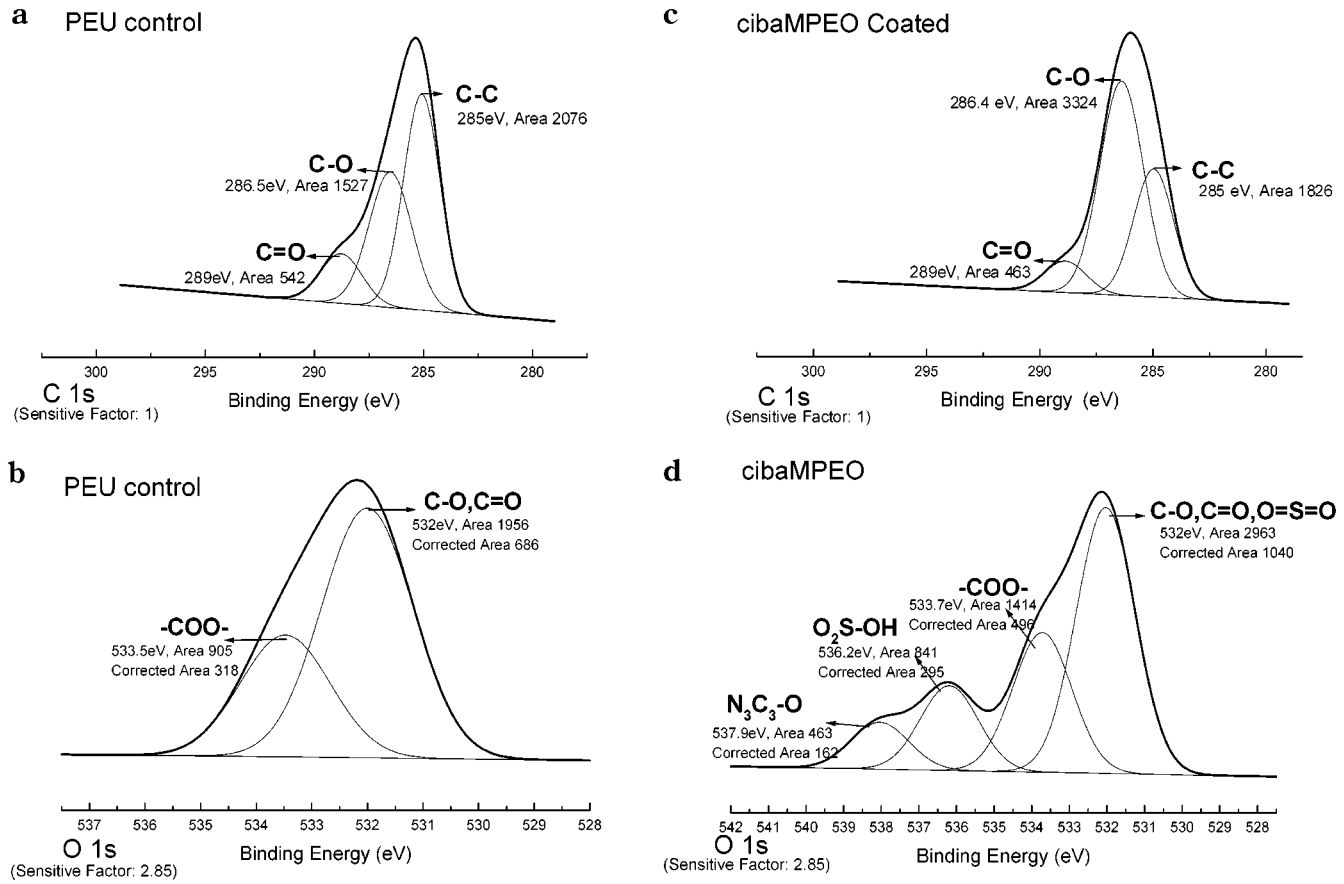

Figure 4. Curve-fit data of the XPS spectra: (a) and (b) respectively C 1s and O 1s peaks of PEU-control; (c) and (d) respectively C 1s and O 1s peaks of ct-cibaMPEO(2k).

of BSA−Fg binary solutions with the concentration of 0.8−0.02 and 0.8−0.06 (mg/mL) were employed, respectively.

Reversibility of Albumin Binding. After the samples had been immersed in 0.4 mg/mL radioiodine-labeled BSA solution for 60 min, the radioactive solution was replaced by non-radioiodine-labeled BSA solution with the same concentration. Then the data at three time-points, 5, 30, and 60 min (65, 90, and 120 min) were collected, respectively.

Plasma Recalcification Time Tests. Human plasma (0.1 mL, blood type B, Central Blood Bank of Hangzhou; containing ACD anticoagulant, without Ca^{2+}) and $CaCl_2$ solution (0.1 mL 0.025 mol/L) were respectively warmed to 37 °C and then were mixed in a test tube whose inner wall had been coated with the SMAs. At the same time, we began to stir the recalcified plasma with a small stainless steel hook and started to time it until the silky fibrin appeared. The duration was recorded as the plasma recalcification time (PRT).

RESULTS AND DISCUSSION

SMA−CibaMPEO and CibaMPEO-Modified PEU Surfaces. *Synthesis and Purification of SMA−CibaMPEO.* As described by Burton et al.,[15] following synthesis, the product was purified several times with ion exchanger. Finally, the dark blue polymeric powder of cibaMPEO was obtained. The GPC data (Figure 1, cibaMPEO2k) indicates that the ciba endgroups have changed the hydromechanical size of whole molecule dramatically, although the M_n of ciba is relatively small. The gradual flatting of the unreacted MPEOs' GPC peak at RT 18.4 min indicates that the product was purified. Figures 2a, 2b, and 2c are the ^1H NMR spectra of MPEO2k, ciba, and cibaMPEO2k, respectively, from which it can be observed that the spectrum of cibaMPEO combines all the typical peaks of ciba and MPEO. Moreover, when the XPS spectrain Figures 3a and 3b are compared, ciba powder and cibaMPEO2k powder, respectively, in the cibaMPEO2k spectrum (Figure 3b) the Cl-2p peak at approximately 201 eV has been eliminated, while the S-2p peak at approximately 165 eV is still present. All the data above indicate that the Cl^- of ciba has been nucleophilically substituted by the hydroxyl endgroup of MPEO and that the synthesis shown in Scheme 1 has been accomplished.

Surface Analysis on Modified PEU by XPS. From Figures 4a and 4c, the XPS C-1s region of PEU-control and ct-cibaMPEO2k, respectively, the ratio of C−O (286.5 eV)/C−C (285 eV) increases from 0.736 to 1.820. This ratio on PEU (on the soft blocks, poly(tetramethylene glycol)) is 2/3, while on cibaMPEO (on PEO segments) it is approximately 2; thus, the increase indicates the enrichment of PEO chains on the ct-cibaMPEOs. From Figures 4b and 4d, the XPS O-1s region of PEU-control and ct-cibaMPEO2k, respectively, it is indicated that the components of ciba have been introduced. Furthermore, the radiocount of O/C (has been corrected with the sensitive factor of oxygen 2.85) also has increased from 0.2422 to 0.3551. All of the data confirm the surface-content of both PEO and ciba.

ATR-FTIR Analysis of BSA-Adsorbed Surfaces. Due to the sensitivity and the operating conditions, the quantitative method of ATR-FTIR was specially used to deal with the BSA adsorption in the solution with a high BSA-bulk-concentration. In this paper, the concentration

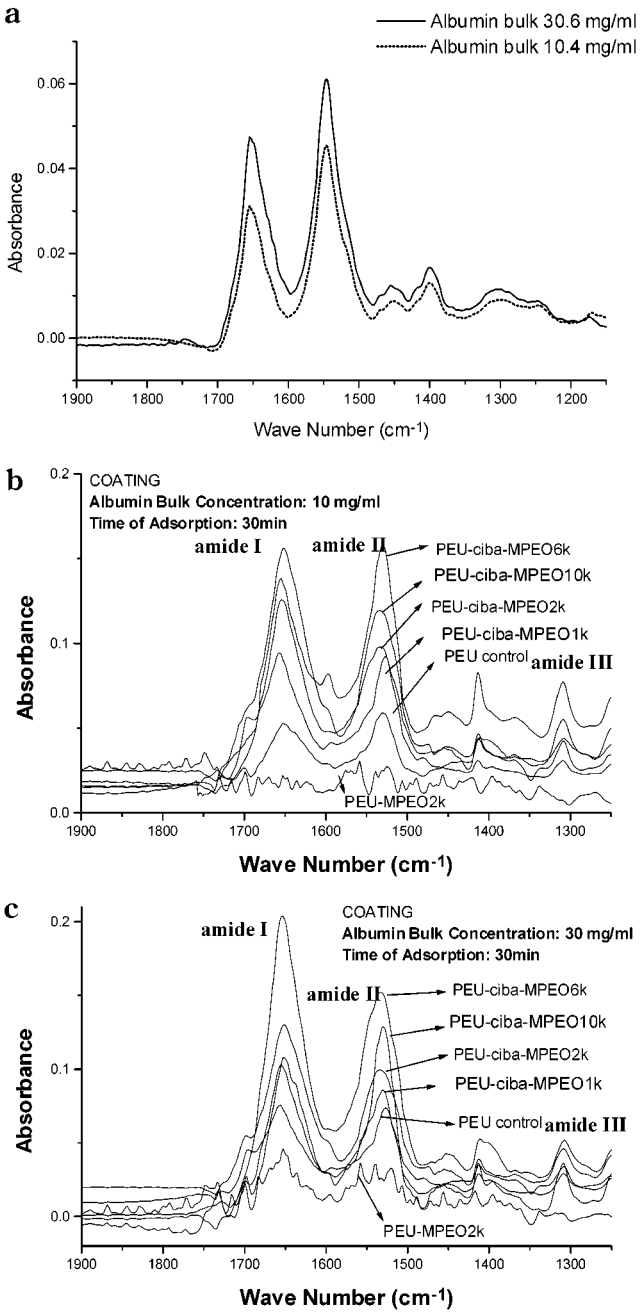

Figure 5. ATR−FT-IR spectra: (a) 30.6 mg/mL and 10.4 mg/ml standard BSA solution; ct-cibaMPEO(2k) from (b) 10.4 mg/mL BSA-bulk-solution and (c) 30.6 mg/ml BSA-bulk-solution.

was as high as 5.0−30.6 mg/mL. On the IR spectra, the integrated area of the protein-typical amide II band at 1550 cm^{-1} was obtained because its peak area can be related to the total amount of protein adsorbed at the interface (*19*, *20*). The horizontal baseline for integration was 1720−1480 cm^{-1}, and the region for integration was 1600−1480 cm^{-1} (*12*). The integrated area A_2 for BSA-adsorbed samples and A_s for standard solution is the average value of six parallel data.

The calculation of the adsorbing density on the modified PEU surfaces is based on the Tompkin equation (*21*),

$$\frac{A}{N}\frac{n_{21}E_0^2\epsilon}{\cos\theta}\int_0^\infty C(z)\exp\left(\frac{-2z}{d_p}\right)dz$$

where A is the integrated absorbance, N is the number of internal reflections, n_{21} is the index of refraction

equation can be simplified as $\Gamma = A_2C_sd_p/(2A_s)$, where Γ is the density of protein adsorption (μg/cm^2) and C_s is the concentration of standard protein solution.

Figure 5 shows the examples of ATR-FTIR spectra. Figures 5a, 5b, and 5c are respectively the spectra of BSA standard solutions, adsorbed BSA on the sample surfaces in 10.4 mg/mL bulk solution and that in 30.6 mg/mL bulk solution. Figure 6 is the isothermal curves of BSA-adsorption. It is observed that for all the samples, the relation between the amount of adsorbed BSA and the concentration of BSA-bulk-solution (5.0−30.6 mg/mL) is generally a linearly incremental change. In addition, the amount of adsorbed BSA on PEU-control was lower than that on the ct-cibaMPEOs, but higher than that on ctMPEO2k, which indicates the repulsion of the bare PEO chains to the BSA-adsorption and simultaneously demonstrated the outstanding BSA-binding capacity of ciba. The ascending BSA-adsorption from that on ct-cibaMPEO1k to that on ct-cibaMPEO6k indicates that the longer PEO chain is able to provide better support and higher mobility to ciba endgroups, which is due to the intrinsic property of PEO in aqueous environments (*9*). For ciba endgroups, better support from PEO will lead to a higher surface enrichment, and higher mobility means higher activity for BSA-binding. This cooperative effect between PEO spacer and ciba endgroup was approximately best achieved under a PEO-chain-length of 6000. Longer PEO chains such as in PEO10000 cannot significantly produce any more positive effects; on the contrary, the amount of ciba endgroups will inevitably decrease, which is the reason for less BSA-adsorption on ct-cibaMPEO10k than that on ct-cibaMPEO6k. Figure 7 shows the curves for static adsorption kinetics. In the case of 30.6 mg/mL BSA-bulk-concentration, the fast BSA-adsorption happens in the first minute, and then the adsorption slows down; for different samples, a larger amount of adsorbed BSA is obtained, the later the adsorbing saturation is reached.

Adsorption Analysis of ^{125}I-Labeled Proteins. *Adsorption and Reversible Binding of ^{125}I-Labeled BSA.* The amount of adsorbed BSA on each sample is shown in Figure 8. According to the comparison with the case of PEU-control, the PEO chains' repulsive performance and the ciba's BSA-binding capacity, as well as the PEO−ciba cooperative effect, are respectively confirmed by the BSA-adsorbing performances on the ctMPEO and ct-cibaMPEOs. The curves of adsorption under low BSA-

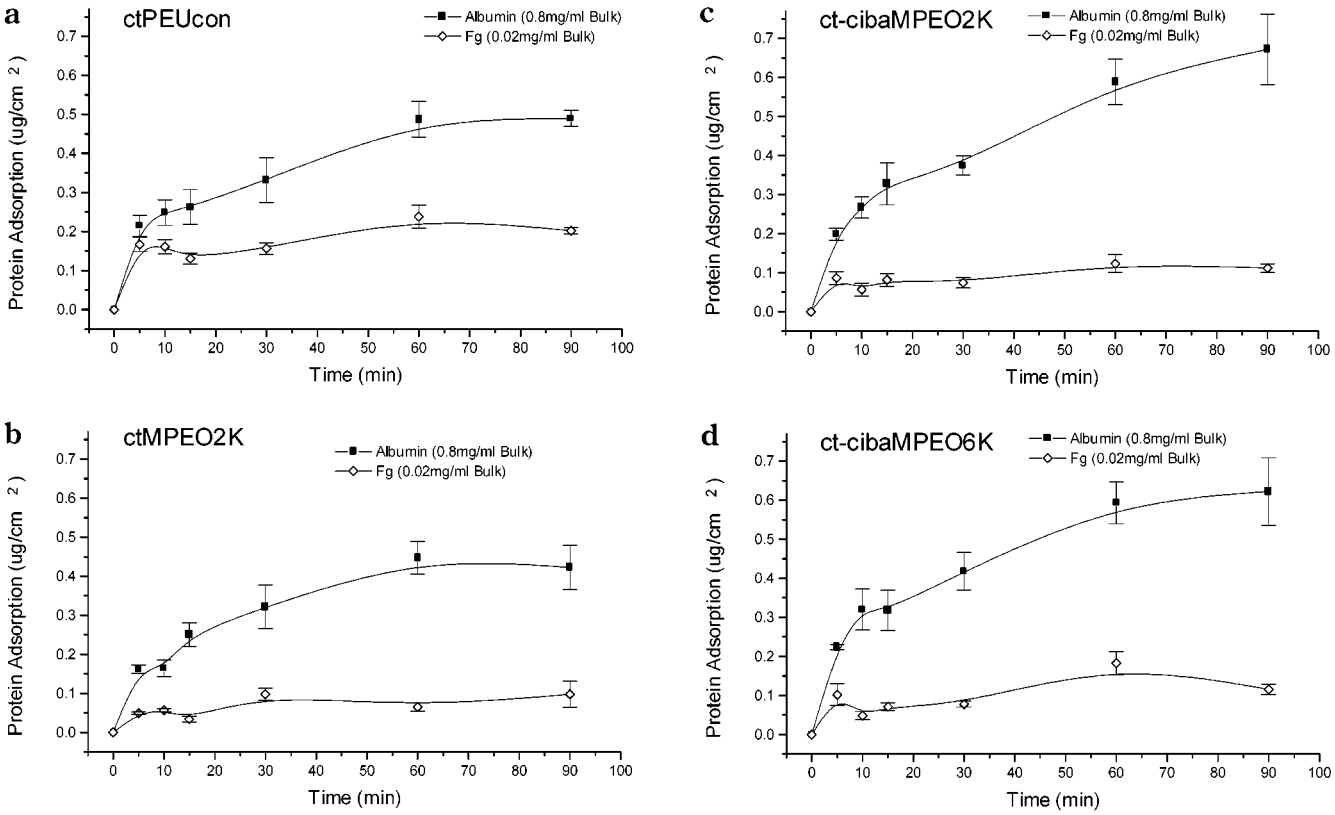

Figure 11. Static BSA−Fg (BSA: 0.8 mg/mL, Fg: 0.02 mg/mL) binary competitive adsorbing kinetics: (a) PEU-control, (b) ctMPEO2k, (c) ct-cibaMPEO2k, and (d) ct-cibaMPEO6k, characterized by radioactive ^{125}I-probe.

bulk-concentration (0.4 mg/ml, shown in Figure 9) demonstrate a similar kinetic adsorbing behavior to that in the high concentration solutions characterized by ATR-FTIR, whereas the difference of BSA-binding capacity between the various samples exhibited under low bulk concentration is not so dramatic as that under high bulk concentration.

The desired effective protein-adsorption is a dynamic equilibrium of adsorption and desorption. Thus, adsorbed proteins with activity can be displaced by the proteins in the bulk solution by probability. Proteins that remain adherent to the polymeric surface permanently are considered irreversibly bound (*22*). Figures 9a and 9b indicate that approximately 41% and 19% of previously bound BSA (radioiodine-labeled) respectively on PEU-control and ctMPEO2k could be displaced in 60 min. From Figures 9c and 9d, it is indicated that approximately 83% and 80% of previously bound BSA (radioiodine-labeled) respectively on ct-cibaMPEO2k and ct-cibaMPEO6k could be displaced within 60 min. Therefore, BSA was reversibly bound to ct-cibaMPEOs, and for ctMPEO2k, despite the high repulsion of PEO, the bound BSA was mostly unrenewable.

Adsorption of ^{125}I-Labeled Fg. Fg was used as a competitive protein because it is known to readily adsorb to implant surfaces and because surfaces that avidly adsorb fibrinogen may be highly thrombogenic (*22*). The amount of adsorbed Fg (bulk-concentration 0.04 mg/mL) on each sample is shown in Figure 10. Within 90 min, the ctMPEO2k and ct-cibaMPEOs bound approximately from 30% to 70% as much ^{125}I-labeled Fg as did PEU-control. The weakest Fg adsorption took place on ct-cibaMPEO6k, and the amounts of the adsorbed Fg on ctMPEO2k and ct-cibaMPEO2k were quite close to each other. All the results listed above indicate that ciba has little special capacity for Fg-binding, while the PEO chains' repulsion to Fg-adsorption has been largely exhibited, and as the dominant factor, the longer the PEO chain length, the higher the repulsion.

Selectivity and Homogeneity of Surface BSA Binding. The direct determination of the extent of preferential binding of BSA to the modified surfaces in the presence of Fg-competition was also performed. The results from the binary BSA−Fg solution with the concentration of 0.8−0.02 (mg mL^{-1}, 40:1 w/w, Bi−Sys I) are shown in Figures 11 and 12, and the results from the 0.8−0.06 system (mg mL^{-1}/mg mL^{-1}, 40:3 w/w, Bi−Sys II) are shown in Figures 13 and 14. The bulk-concentration ratio of BSA to Fg in Bi−Sys II agrees with that ratio in plasma (*23*). From Figures 12b and 14b, it is observed that in the presence of competing Fg, the BSA-adsorbing kinetics on all the surfaces, including PEU-control, ctMPEO2k, and ct-cibaMPEOs, was similar to that in the BSA−one-protein system. As for Bi−Sys I, the curves of competitive adsorbing kinetics (shown in Figure 11) and the ratios of adsorbed-BSA amount to adsorbed-Fg amount (shown in Figure 12a) already can exhibit preferential binding of BSA to the ct-cibaMPEOs. Yet as for Bi−Sys II, the case of more Fg binding than SMA binding on PEU-control was even completely reversed on the ct-cibaMPEOs (shown in Figures 13 and 14a), which can indicate a further dramatic predominance of the homogeneous albumin binding brought by SMA-cibaMPEO.

Plasma Recalcification Time Tests. The results of the PRT tests are shown in Figure 15. Compared with the case of glass and PEU-control, the anticoagulative performance of the modified surfaces was improved, in which the best performance was exhibited on the surfaces modified by cibaMPEO2k-6k. The antithrombogenicity

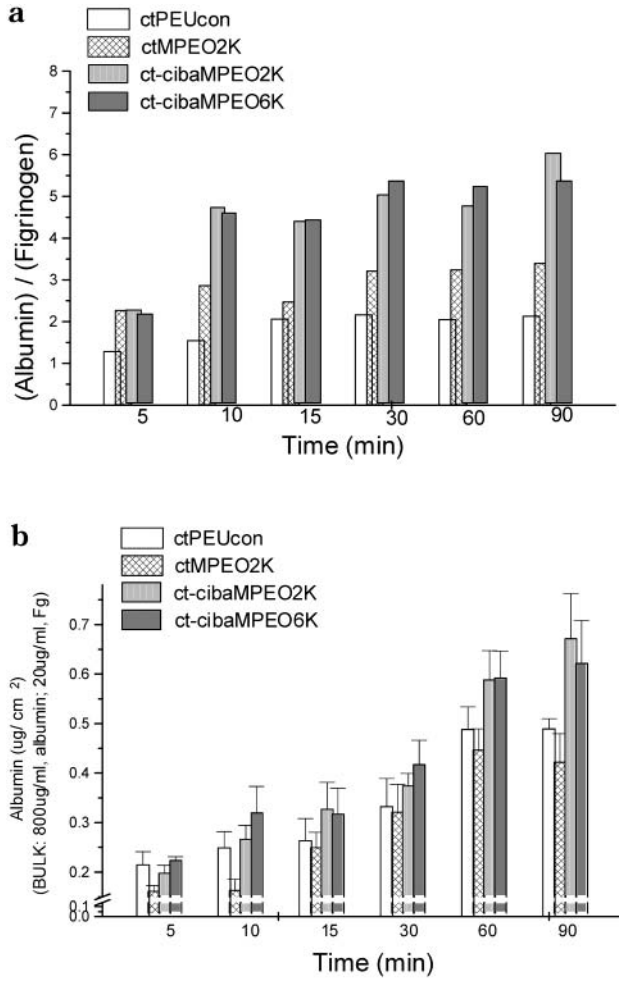

Figure 12. Static BSA−Fg (BSA: 0.8 mg/mL, Fg: 0.02 mg/mL) binary competitive adsorption data of PEU-control, ctMPEO2k, ct-cibaMPEO2k and -6k: (a) ratio of adsorbed BSA amount to adsorbed Fg amount, (b) amount of adsorbed BSA, characterized by radioactive ^{125}I-probe.

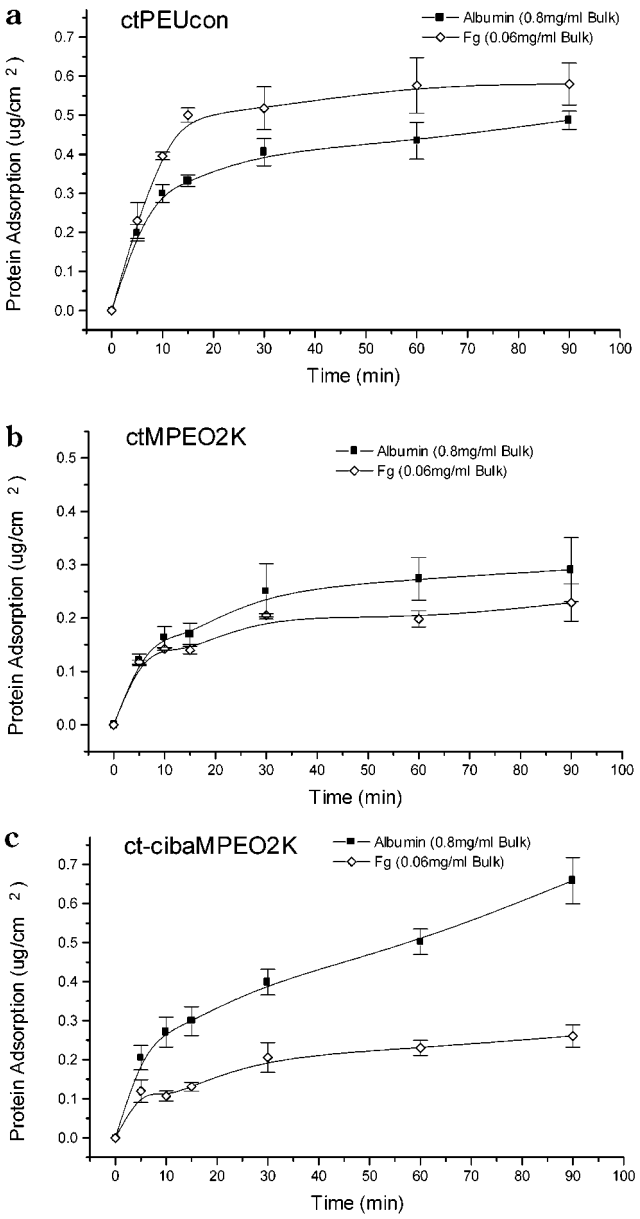

Figure 13. Static BSA−Fg (BSA: 0.8 mg/mL, Fg: 0.06 mg/mL) binary competitive adsorbing kinetics: (a) PEU-control, (b) ctMPEO(2k), and (c) ct-cibaMPEO(2k), characterized by radioactive ^{125}I-probe.

of ct-cibaMPEO1k was similar to that of ctMPEO2k. Along with enlargement of the PEO-chain size from 6k to 10k, the capacity of anti-coagulation decreased. Up to ct-cibaMPEO10k, the anti-coagulative performance was also down to the level of ctMPEO2k. The PRT of the samples is related to the corresponding demonstration of protein adsorption under the competition of albumin−fibrinogen binding. The antithrombogenicity of the cibaMPEOs is originated from the cooperation between ciba endgroups and the PEO spacer, which is due to the coeffect of the exclusion of the thrombogenic proteins and cells plus the selective binding of the inert and biocompatible albumin. While for MPEO2k, it is only from the nonspecifically repulsive function of PEO. On one hand, too long a PEO spacer would make the surface ciba-content limited and the albumin binding would be limited, but on the other hand too short a PEO spacer would immobilize the ciba endgroups and make them less active. Therefore, the cooperative effect between ciba and PEO would finally act on the antithrombogenicity of the modified surfaces.

CONCLUSIONS

In this study, the SMA−cibaMPEOs were synthesized, and the cibaMPEO-modified PEU surfaces were prepared by dip-coating. The surface analysis by XPS revealed the surface enrichment of both ciba and PEO. On the modified surfaces, the quantitative analysis of serum proteins' adsorption was performed. The BSA-adsorption respectively in the low and high BSA bulk-concentration solutions was correspondingly characterized by the methods of radioactive ^{125}I-probe and ATR-FTIR. The Fg-adsorption in the Fg bulk solution and the BSA−Fg competitive adsorption in the BSA−Fg binary solutions were also characterized utilizing the radioactive ^{125}I-probe. Finally the blood compatibility of the modified surfaces was examined by PRT tests.

According to the results of the two independent methods, the BSA-adsorbing kinetics curves of the samples both in the low and high BSA-bulk-concentration solutions, as well as including that in the BSA−Fg binary solutions, were respectively exhibited to be similar to each other. The only difference observed was the higher BSA adsorption in the high BSA-bulk-concentration solution. The comparison between the protein-adsorbing results on PEU-control, ctMPEO2k, and the ct-cibaMPEOs indicates that ciba has a high capacity of selectively

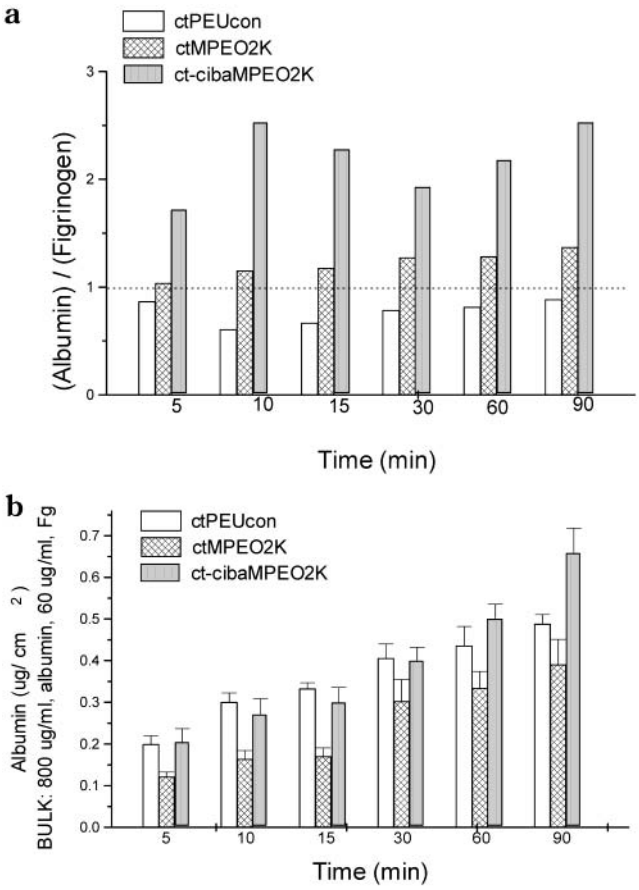

Figure 14. Static BSA-Fg (BSA: 0.8 mg/mL, Fg: 0.02 mg/mL) binary competitive adsorption data of PEU-control, ctMPEO-(2k), and ct-cibaMPEO(2k): (a) ratio of adsorbed BSA amount to adsorbed Fg amount, (b) amount of adsorbed BSA, characterized by radioactive ^{125}I-probe.

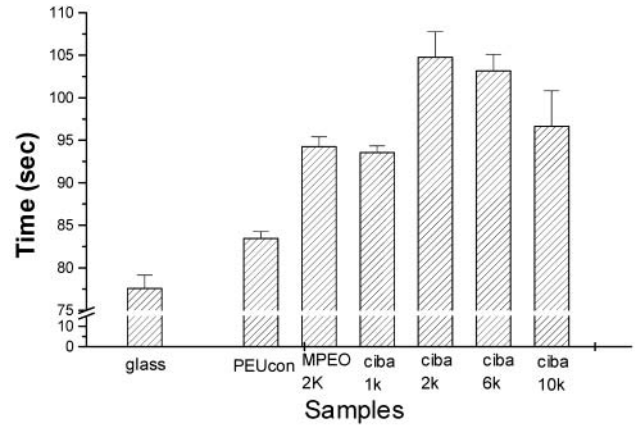

Figure 15. Plasma recalcification time data of glass, PEU-control, ctMPEO(2k), ct-cibaMPEOs.

binding albumin, while PEO can nonspecifically repulse both of the protein adsorption. Whether in a competitive binary protein system or in a one-protein system, the achievement of the albumin-coated surface depends on the demonstration of the cooperative effects between the functional endgroup ciba and the PEO spacer. If the hydrophilic and mobile PEO spacer is too short like PEO1k, it could not sufficiently support and activate the ciba endgroup in the aqueous environment. If the PEO spacer is too long like PEO10k, the surface content of ciba endgroups will inevitably be reduced and the folding of long-chain PEO will also decrease the chain mobility. The results indicate that the remarkable coeffect between the nonspecific repulsion by PEO spacer and the reversibly selective albumin-binding by ciba endgroups is achieved on cibaMPEO2k and -6k, and accordingly, good blood compatibility was also obtained.

Received January 24, 2002

Intraalveolar fibrin formation is a common histopathological finding in acute inflammatory and chronic interstitial lung diseases. Incorporation of hydrophobic surfactant components into polymerizing fibrin results in a severe loss of surface activity, altered mechanical and structural clot properties, and a reduced susceptibility toward fibrinolytic degradation. Such events have been implicated in atelectasis formation, impairment of gas exchange, and provocation of fibroproliferative changes. In an effort to address the unique features of alveolar fibrin, we designed a hybrid molecule consisting of a monoclonal antibody against surfactant protein SP-B (8B5E) and the catalytic domain of urokinase (B-chain), which was termed MABUC. The urokinase B-chain was prepared by limited reduction of human two-chain-urokinase and subsequent affinity purification and coupled to the antibody using a heterobifunctional cross-linker. Purification of the chimeric protein included gel filtration chromatography and affinity chromatography. An ELISA-like microtiter plate assay, based on the immunological detection of the SP-B moiety and the fibrinolytic activity of the u-PA domain, was developed for the detection of the hybrid molecule. Chromogenic substrate assays, ^{125}I-based fibrin plate assays, and active site titration were performed to analyze the specific fibrinolytic activity of the conjugate. MABUC was found to fully retain the ability of SP-B binding and the fibrinolytic activity of u-PA. In addition, MABUC was noted to be 1.5−2-fold more effective in the dissolution of surfactant embedding clots and to be ∼3-fold more resistant against PAI-1, the predominant fibrinolysis inhibitor in the alveolar compartment, as compared to the native u-PA. The superiority of MABUC was particularly prominent (>5-fold efficacy) when investigating clot material incorporating both PAI-1 and surfactant, as a mimicry of alveolar fibrin. We conclude that urokinase and 8B5E can be cross-linked chemically, thus yielding a fibrinolytic enzyme with enhanced substrate specificity for surfactant-containing clots and higher PAI-1 resistance as compared to native u-PA.

INTRODUCTION

Intraalveolar accumulation of fibrin-rich material ("hyaline membranes") is a hallmark of acute inflammatory lung diseases such as the adult respiratory distress syndrome (ARDS[1]), but also of chronic interstitial pulmonary diseases such as idiopathic lung fibrosis (IPF) (*1*−*6*). Under a variety of inflammatory conditions, the alveolar hemostatic balance is shifted toward a predominance of procoagulant activity, which is mainly attributable to the extrinsic pathway enzymes tissue factor and FVII (*7*−*15*). In contrast, the fibrinolytic activity in the alveolar space is often markedly reduced under these circumstances. Concentrations of urokinase, representing the predominant plasminogen activator within the alveolar compartment, were found to be decreased in lavage fluids from patients with ARDS and those suffering from IPF. In addition, highly elevated activities of plasminogen activator inhibitor 1 (PAI-1) and α_2-antiplasmin were consistently encountered in these patients (*8*−*10*, *12*, *15*, *16*). Under these conditions, fibrinogen leaking into the alveolar space due to an impaired capillary−endothelial and alveo−epithelial barrier function must be assumed to be rapidly converted into fibrin.

The role of alveolar fibrin formation is presently largely unsettled. Although probably helpful in limiting events of pulmonary hemorrhage, in reducing transepithelial fluid flux, and in promoting repair processes after lung tissue injury, it may also have major disadvantages:

First, in ARDS (*17*, *18*), severe pneumonia (*19*), and interstitial lung diseases (*20*), the ability of pulmonary surfactant to reduce the alveolar surface tension is markedly impaired. Changes in the surfactant composi-

tion including altered phospholipid and fatty acid profiles and reduced content of the surfactant proteins SP-A, SP-B, and SP-C serve as one explanation for this consistent finding (*19*−*21*). In addition, inhibition of surfactant properties by inflammatory mediators and plasma-derived proteins including albumin, C-reactive protein, hemoglobin, and fibrinogen has been reported (*22*−*25*). Furthermore, fibrin polymerization in vitro in the presence of pulmonary surfactant was shown to result in a nearly complete incorporation of all hydrophobic surfactant compounds, such as phospholipids and surfactant protein SP-B and SP-C (*26*). In this regard, polymerizing fibrin was found to represent the most effective surfactant inhibitory mechanism hitherto described.

Second, in vitro experiments revealed that fibrin clots embedding natural surfactant compounds display markedly altered mechanical properties (*27*) and are less susceptible to proteolytic attack by plasmin, trypsin, or elastase (*28*). This may be advantageous to meet lung physiological demands, but hinders the removal of alveolar fibrin once it is established.

Third, by inactivation of the pulmonary surfactant system, alveolar fibrin formation may seriously deteriorate gas exchange and lung compliance. This has recently been directly demonstrated in rabbit lungs, in which selective alveolar generation of fibrin by sequential aerosolization of fibrinogen and thrombin forwarded a marked increase in pulmonary shunt flow due to severe atelectasis formation (*29*).

Last, alveolar fibrin formation may provide a provisional matrix for subsequent invasion of fibroblasts and may thus promote the fibroproliferative response in late ARDS and in fibrotic lung diseases (*30*−*35*). It was, indeed, observed in morphological studies that atelectatic and fibrin-adherent alveoli may serve as nidus for the fibroblast activation (*3*).

Interestingly, complete lysis of such surfactant incorporating fibrin clots in vitro was recently noted to result in the liberation of intact surfactant material, alongside with a marked improvement in surface tension properties (*27*). In this regard, the plasminogen activators u-PA and t-PA were shown to be the more effective agents as compared to plasmin or activated anisoylated-streptokinase−plasminogen-activator complex (APSAC) (*36*). It is in line with these findings that the markedly increased shunt flow in the above-mentioned model of alveolar fibrin formation was reversed by subsequent nebulization of surfactant plus urokinase. Therapeutic dissolution of alveolar fibrin may thus represent an interesting approach to recruit alveolar units and to prevent lung fibrotic events in prolonged pulmonary inflammatory states. To this end, any tool would be welcomed that might enhance selectivity and potency of the fibrinolytic attack toward surfactant-containing fibrin, a structure unique to the alveolar space. Following this line, we presently constructed and characterized a monoclonal anti-SP-B-antibody−urokinase-conjugate (MABUC) that was obtained by chemical cross-linking of the B-chain of u-PA and a monoclonal antibody against SP-B (8B5E, (*37*)). We report that this hybrid molecule indeed shows an increased fibrinolytic activity toward surfactant-containing clots, as compared to native urokinase, and a clearly increased resistance against the predominant antagonist of fibrinolyis in the alveolar compartment, plasminogen-activator-inhibitor (PAI)-1. Moreover, due to the antibody-dependent targeting of the surfactant-specific protein SP-B, the volume of distribution of this new tool may be expected to be largely restricted to the alveolar space when aerosol is administered to this compartment.

MATERIALS AND METHODS

Bovine SP-B was purified by LH-60-chromatography as described previously (*38*); human high molecular weight two-chain urokinase (HMW-tc-u-PA) and purified human fibrinogen were kindly provided by Prof. N. Heimburger (Behringwerke, Marburg, Germany). Thrombin (30 IU/mL) was purchased from Behring (Marburg, Germany), and benzamidine, PEG 8000, 4-methylumbelliferyl-*p*-guanidinobenzoate hydrochloride (MUGB), methylumbelliferone, and Tween 20 were received from Sigma (Munich, Germany). Sulfosuccinimidyl 4-(*p*-maleidophenyl)butyrate (S-SMPB) was obtained from Pierce (via KMF Laborchemie, St. Augustin, Germany). The anti SP-B antibody (8B5E) was a kind gift from Y. Suzuki (*37*) (Chest Disease Research Institute, Kyoto University, Kyoto, Japan). HMW-tc-u-PA (activity standard with 2860U/mg protein) was a product from ADI (via Loxo, Dossenheim, Germany), and ^{125}I-labeled human fibrinogen was obtained from Amersham (Braunschweig, Germany). Immuno plates (Maxisorp, Polysorp) were purchased from Nunc (Wiesbaden, Germany). BSA was obtained from Paesel & Lorei (Frankfurt, Germany), and the chromogenic substrates (S2251, S2444) and plasminogen were products from Chromogenix (Mölndal, Sweden). Benzamidine-Sepharose-6B, Sephadex-G-100, HiTrap-Protein-G, and the HiPrep-desalting column were obtained from Amersham Pharmacia (Freiburg, Germany). AB-complex was from Dako (Hamburg, Germany). Mutant, recombinant PAI-1 was obtained from Calbiochem (Bad Soden, Germany). Alveofact was a kind gift from Thomae (Biberach, Germany). All other chemicals were obtained from Merck AG (Darmstadt, Germany).

Preparation and Isolation of B-Chain of Urokinase. HMW-tc-u-PA (98 mg) was reduced at room temperature for 60 min in 40 mL of 0.6 M sodium acetate, containing a 3000-fold molar excess of benzamidine (1 g) and a 350-fold molar excess of DTT (98 mg). The mixture was immediately desalted by gel filtration on a HiPrep desalting column (2.6 × 10 cm), equilibrated with 0.1 M sodium acetate/5 mM EDTA, pH 6.8. The protein fractions were pooled and applied to a benzamidine-sepharose column (1.6 × 7.5 cm). After the column was washed with pH 6.8 acetate/EDTA buffer to remove nonadsorbed A-chain, B-chain was eluted with 0.1 M sodium acetate/0.5 M sodium chloride/5 mM EDTA, pH 4.0. It was stored frozen at −80 °C until use.

Protein-G Affinity Chromatography for Isolation of Anti SP-B. For removal of non IgG components possibly interfering with the coupling reagent, 8B5E was further purified by means of affinity chromatography. The lyophilized antibody was dissolved in phosphate-buffered saline (PBS) containing 0.5M NaCl, pH 7.4, and applied to a HiTrap-Protein-G column (bed volume 1 mL). The column was washed with PBS containing 0.5 M NaCl, pH 7.4 until the baseline was stable. Desorption of bound IgG was achieved with 0.2 M acetic acid, pH 2.8. For buffer exchange, the eluted protein was passed through a HighPrep desalting column (2.6 × 10 cm), equilibrated with PBS, pH 8.2. It was stored frozen at −80 °C until use.

Coupling Protocol. 8B5E and the B-chain of urokinase were conjugated with the heterobifunctional cross-linker sulfosuccinimidyl 4-(*p*-maleidophenyl)butyrate (S-SMPB) (Figure 1): In the first step, 8B5E dissolved in

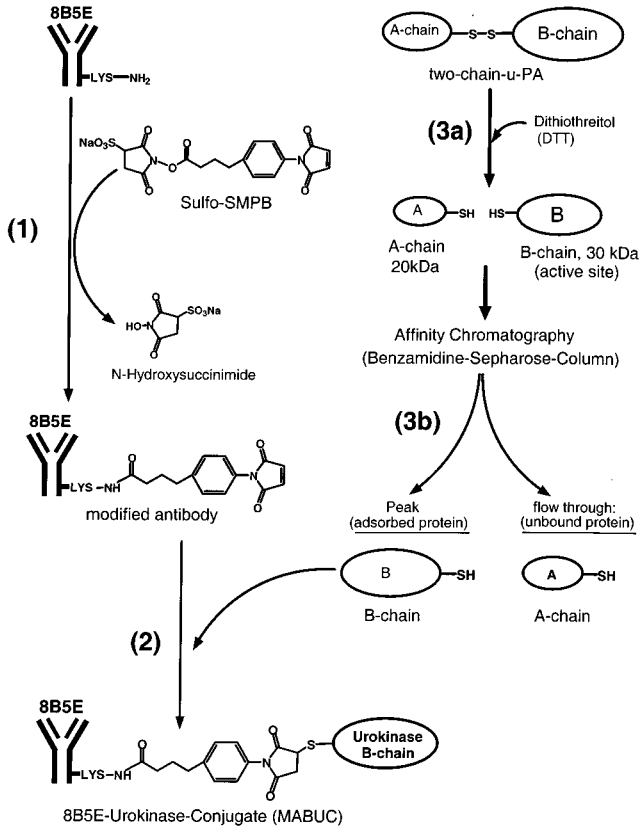

Figure 1. Scheme for the conjugation of monoclonal anti SP-B antibody (8B5E) with urokinase B-chain. In a first step, 8B5E was incubated with Sulfo-SMPB. The *N*-hydroxysuccinimide residues of the heterobifunctional cross-linkers react with lysine-amino groups of the antibody, forming a covalent amide bond (1). After removal of unbound linker molecules (gel filtration on HiTrap desalting column), the modified protein was reacted with urokinase B-chain. Free thiol groups (most likely CYS 279) of the B-chain react with maleimide groups of the activated antibodies, forming a stable thioether linkage (2). Urokinase B-chain was obtained by limited reduction of tc-u-PA in the presence of benzamidine (3a) and subsequent purification by affinity chromatography (3b).

PBS, pH 8.2, at a concentration of 1 mg/mL, was reacted with a 20-fold molar excess of S−SMPB for 45 min at 37 °C. The mixture was then applied to a HiPrep-desalting column (2.6 × 10 cm) for removal of excess uncoupled linker molecules and eluted with PBS/5 mM EDTA, pH 6.8. In the second step, the pooled protein fractions were mixed at a 1:1 molar ratio with the purified B-chain of urokinase preincubated with a 2000× molar excess of benzamidine for protection of the catalytic site, and the mixture was allowed to react for 3 h at room temperature. The reaction was terminated by the addition of iodoacetamide (1 μM final).

Detection of MABUC ("Hybrid-ELISA"). MABUC was identified employing an ELISA-like, microtiter plate-based assay by modification of a solid-phase adsorption-ELISA protocol for quantification of SP-B as previously described (*39*). For this purpose, Polysorp microtiter plates were coated with bovine SP-B dimer (400ng/well) and free binding sites were saturated with BSA (1% BSA/50 mM Tris, pH 7.4, 200 μL/well). Next, samples (150 μL/well) were applied and incubated overnight. Upon triple washing (50 mM Tris/0.5% Tween20, pH 7.4, 200 μL/well) conjugates were detected using S-2444 (2 mM, 200 μL/well), a chromogenic substrate for urokinase. Absorbance was read at 405 nm.

Purification of the Conjugate. The reaction mixture (3 mL aliquots) was first applied to a Sephadex-G100 gelfiltration column 2.6 × 16 cm) equilibrated with 0.1 M sodium acetate, pH 6.8, at a flow rate of 1.5 mL/min. Fractions from the eluted first peak, containing both the conjugate and uncoupled antibody, were loaded onto a benzamidine-Sepharose column (1.6 × 7.5 cm), equilibrated with 0.1 M sodium acetate, pH 6.8, and extensively washed with the same buffer. The adsorbed conjugate was eluted with 0.1 M sodium acetate/0.5 M sodium chloride, pH 4.0.

Fibrin Plate Assay. Proteolysis of fibrin clot was assayed by use of microtiter plates as previously reported (*40*). The final volume in each well was 150 μL. All concentrations refer the final clot volume of 50 mL, and all components were dissolved in 3 mM Ca^{2+} containing saline. First, unlabeled (4 mg/mL) and labeled (≈5 kBq/mL) fibrinogen and plasminogen (4 μg/mL) were introduced into the wells at a volume of 30 μL. Complete clotting was achieved by incubation with thrombin predissolved in 20 μL of buffer fluid (0.12 U/mL, 37 °C, 1.5 h). The plates were spun with 1485*g* for 10 min (Univapo 150H centrifuge) for further consolidation of the clot material in the wells. Next, 100 μL saline/Ca^{2+} without protease or containing u-PA or MABUC were carefully layered onto the surface of the clot and incubated for various time intervals at 37 °C.

To address lysis of fibrin strands embedding surfactant and/or PAI-1, respectively, Alveofact (10−30 mg/mL final volume) and/or PAI-1 (400 ng/mL) was admixed to the fibrinogen solution prior to induction of clotting. Control experiments ascertained complete conversion to fibrin by the protocol of thrombin incubation used. Moreover, this procedure was ascertained to cause >95% incorporation of the surfactant phospholipids into the insoluble fibrin matrix.

After incubation of the clot material with u-PA or MABUC, 75 μL of the supernatant was aspirated, and counts were measured in a Canberra Packard γ-counter. For each time point, the liberation of radiolabel in the presence of the fibrinolytic agent was corrected for baseline release of ^{125}I activity detected in the parallel control experiments with incubation of saline. This baseline release of tracer persistently ranged at <15% of total radioactivity. All data of protease-induced liberation of radiolabel from the insoluble clot are given in percent of total activity applied to each well.

Assay of Amidolytic Activity. The amidolytic activity of the conjugate and urokinase was measured using the chromogenic substrate S-2251. Samples or standards were diluted in 50 mM Tris/0.1 M NaCl, pH 7.4, to a final volume of 50 μL, to which 100 μL of a diluted plasminogen solution (50 mg/mL) was added. Finally, 100 μL S-2251 (2 mM) dissolved in 50 mM Tris/0.1 M NaCl, pH 7.4, was admixed. After incubation, the reaction was stopped by addition of 50 μL of acetic acid (50% aqueous solution), and the absorbance was measured at 405 nm. Sample activity was determined by interpolation from a calibration curve of human tc-u-PA. In some experiments, the amidolytic activity of urokinase was assayed using S-2444. Test samples (50 μL) were incubated with 100 μL buffer (50 mM Tris, pH 8.8) and 100 μL S-2444 (2 mM in distilled water). Reactions were terminated by adding 50 μL of acetic acid (50% solution), and the absorbance was determined at 405 nm against a blank.

To determine the influence of the serine protease inhibitor benzamidine on the enzymatic activity of urokinase during reduction, urokinase (20 μg) was incubated with excess amounts of DTT in the presence or absence

of bezamidine (2500× molar excess) for 1 h at 37 °C. Upon removal of reductant and benzamidine, the remaining activity was assessed by the chromogenic substrate S-2444 and related to the initially employed activity and is given in percent.

Active Site Titration. The active site titration of the conjugate and native urokinase was performed by titration with the fluorogenic substrate 4-methylumbelliferyl-*p*-guanidinobenzoate hydrochloride (MUGB) according to Geiger et al. (*41*). MUGB (1 μM final concentration) was added to urokinase or MABUC, respectively, in 0.1 M barbital-Na−HCl buffer, pH 8.3 (final volume 1 mL), at 25 °C in a spectrofluorometer (Perkin-Elmer). The change in fluorescence intensity was recorded in relative units over time and compared with that of a control containing no enzyme (excitation wavelength 363 nm, emission wavelength 450 nm). The reaction was continuously monitored until a linear increase of the cleavage product (4-methylumbelliferone) occurred. The linear portion of the curve was extrapolated to zero time, and the displacement of the nonlinear portion from the extrapolated linear region of the experimental curve was employed as a measure of the "initial burst" reaction. Active sites of MABUC and urokinase were calculated by interpolation from a calibration curve obtained by recording the relative fluorescence intensity of different known concentrations of 4-methylumbelliferone in the sample buffer.

PAI-1 Inhibition Assay. Inhibition of the plasminogen activators by PAI-1 was investigated using the chromogenic substrate assay as described above and a human recombinant PAI-1 mutant with higher stability as compared to natural PAI-1. In brief, a stock solution of PAI-1 was prepared in 5 mM MES, pH 6.0, containing 0.12 M NaCl, 1 mM EDTA, and 0.1% PEG 8000. The amidolytic activity of urokinase and MABUC was adjusted to 8U/mL, and the proteins were incubated with increasing concentrations of PAI-1 (31.25−500 ng/mL final concentration). After 30 min incubation, 100 μL plasminogen and 100 μL S-2251 were added, and the residual amidolytic activity was determined by reading the absorbance at 405 and by interpolation from a calibration curve of human tc-u-PA.

RESULTS

Preparation and Purification of Urokinase B-Chain. The B-chain of urokinase and thus the active moiety was obtained upon limited reduction of tc-u-PA in the presence of benzamidine. The presence of this low molecular weight serine protease inhibitor preserved the enzymatic activity of urokinase during reduction with DTT over a large dose range (up to 1000-fold molar excess), whereas in the absence of benzamidine the enzyme activity rapidly declined and was completely lost at DTT concentrations surpassing a 700-fold molar excess (Table 1). After application of the incubation mixture onto a HiPrep desalting column for removal of DTT and benzamidine, the resulting B-chain containing one free sulfhydryl moiety was easily isolated from other reduction products (A-chain) by application on a benzamidine-Sepharose column. The islolated B-chain ran as a single band on SDS−PAGE (data not shown). The yield of B-chain was 50.5 mg out of 98 mg HMW-u-PA applied, which corresponds to a 93% recovery.

Preparation and Detection of Anti-SP-B-Antibody-Urokinase Conjugates. First, the maleimide residues of the heterobifunctional linker S-SMPB were introduced into the antibody molecule (8B5E) by induction of an amide bond, resulting in a modified protein being activated for the following coupling reaction. In a second step, the B-chain of urokinase was linked to the maleimide residues via its free sulfhydryl group. Conjugates were detected by means of a "hybrid-ELISA" of the reaction mixture. This assay is based on the functional properties of both SP-B binding by the antibody and fibrinolytic activity of the urokinase B-chain, i.e., only enzymatically active 8B5E−u-PA conjugates are detected (Figure 2). The uncoupled proteins 8B5E and B-chain, lacking the respective complementary component, showed no color development at 405 nm.

Table 1. Influence of Benzamidine on u-PA Stability in Presence of DTT[a]

concentration of DTT [*x*-fold molar excess]	reduction in the absence of benzamidine [% amidolytic activity]	reduction in the presence of benzamidine [% amidolytic activity]
0	100	100
175	29.52 ± 0.8	83.9 ± 1.49
350	5.4 ± 0.08	80.29 ± 2.06
700	0.0 ± 0.0	68.31 ± 0.42
1000	0.0 ± 0.0	64.15 ± 0.25

[a] Enzymatic activity of u-PA was assessed in the presence of increasing concentrations of DTT (*x*-fold molar excess given), in the presence or absence of benzamidine, using the chromogenic substrate S-2444. Mean ± SE of four independent experiments each are given.

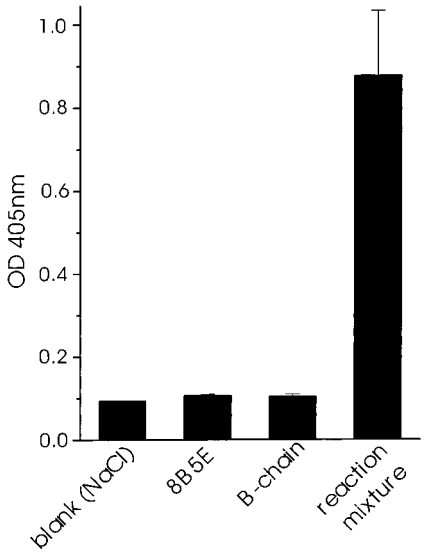

Figure 2. Identification of an anti-SP-B-antibody−u-PA hybrid molecule. Microtiterplate based "Hybrid-ELISA" of the reaction mixture and the uncoupled components B-chain and 8B5E. Samples were transferred to the wells of a microtiter plate coated with SP-B and allowed to bind. After removal of unbound proteins, conjugates were detected using S-2444, a chromogenic substrate for urokinase.

Purification of the Conjugates. Isolation of the conjugates from the reaction mixture required a two-step purification procedure consisting of a gel filtration and an affinity chromatography. To separate uncoupled B-chain from the residual reaction mixture, we chose a Sephadex G-100 column (fractionation range 4−100 kDa). Molecules > 100 kDa (uncoupled antibodies, conjugates) were eluted within the void volume (~15−22 mL), whereas the smaller B-chain appeared later in a second peak (~25−35 mL) (Figure 3a). In addition, the separation of uncoupled B-chain from the residual components was documented by means of SDS−PAGE (not given in detail). Using urokinase affinity chromatography, MABUC could be separated from the remaining uncoupled antibody (Figure 3b) by application of the

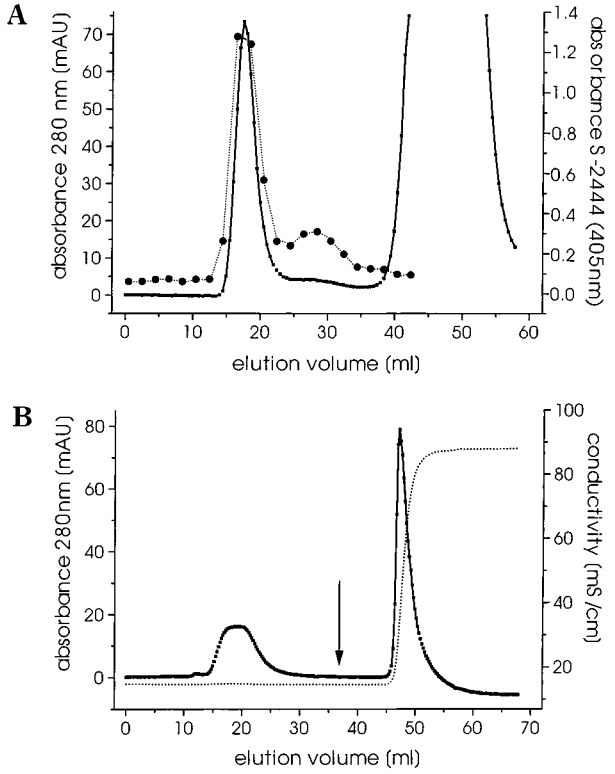

Figure 3. A/B: Chromatographic separation of MABUC from side products. A. 1 mL of the reaction mixture employed for synthesis of the SP-B-u-PA hybrid molecule was loaded onto a Sephadex-G-100 gelfiltration column (2.6 × 16 cm) equilibrated with 0.1 M sodium acetate, pH 6.8. The online recording of the absorbance at 280 nm (squares, solid line) is given. Furthermore, eluted fractions were analyzed for enzymatic activity by means of S-2444, a chromogenic substrate for u-PA (circles, dashed line). B. Pooled fractions of the first chromatographic step (first peak, 15−22 mL) were loaded onto a benzamidine-Sepharose column (1.6 × 7.5 cm), equilibrated with 0.1 M sodium acetate, pH 6.8, and washed with the same buffer to remove uncoupled antibody. The adsorbed conjugate was eluted with 0.1 M sodium acetate/0.5 M sodium chloride, pH 4.0. The online recordings of the absorbance at 280 nm and the conductivity (dashed line) are given. The switch to the elution buffer is indicated by an arrow.

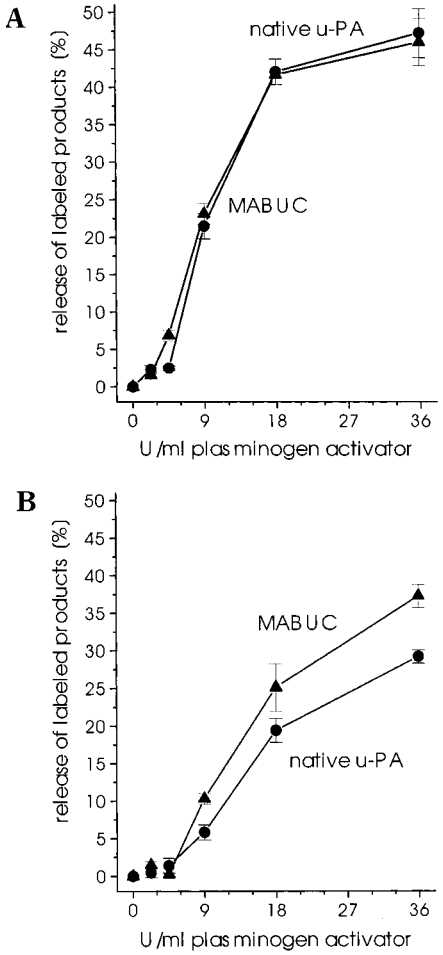

Figure 4. A/B: Fibrinolytic properties of native u-PA or MABUC in absence or presence of clot-embedded surfactant. ^{125}I-labeled fibrinogen was clotted in a microtiter plate in the presence (B, right panel) or absence (A, left panel) of surfactant (Alveofact, 20 mg/mL final). Fibrinolysis was induced by addition of increasing activities of native u-PA or MABUC, and the release of radiolabeled split products was measured after 4 h and is given in percent of the initially provided radioactivity. Mean ± SE of four independent experiments each are given.

pooled fractions of the first chromatographic step. Elution from the benzamidine-Sepharose-column resulted in a single peak. The yield of purified conjugate was 139 μg (13.6% of the originally employed protein).

Fibrinolytic Properties of the 8B5E−B-Chain Conjugate. Incubation of a preformed radiolabeled fibrin clot with increasing activities of native u-PA or MABUC resulted in a dose-dependent release of radioactivity into the soluble phase (Figure 4). Concentrations of the proteolytic enzymes were chosen to surpass baseline liberation of tracer manifold and to achieve release of labeled scisson products in the range of 30−50% of total radioactivity within 4 h. In the absence of surfactant, both native u-PA and MABUC displayed a similar, dose-dependent fibrinolytic activity (Figure 4a). In contrast, a marked retardation of the fibrinolysis kinetics was noted when a fixed dose of calf lung surfactant extract was admixed to fibrinogen prior to coagulation (Figure 4b). Concerning such surfactant-containing clots, MABUC turned out to be the more effective fibrinolytic agent as compared to native u-PA. This was true for both the overall extent of fibrinolyis in this assay (Figure 4b) and the initial kinetics of fibrin-split product release (not shown in detail).

Similarly, at a constant activity of MABUC or native u-PA, incubation of fibrin clots with increasing concentrations of the calf lung surfactant extract resulted in a dose-dependent inhibition of fibrinolysis (Figure 5); however, this effect was markedly less pronounced in case of MABUC-induced fibrinolysis as compared to native u-PA-induced lysis of the fibrin clot. In contrast to clots containing preembedded surfactant, fibrinolysis was not influenced by Alveofact when this natural surfactant was administered simultaneously with native u-PA or MABUC (not shown in detail).

PAI-1 Resistance. When tested using the synthetic substrate S-2444, incubation of native u-PA and MABUC with increasing concentrations of a mutant and thus a more stable form of recombinant human PAI-1 resulted in a dose-dependent inhibition of the enzymatic activity of both agents (Figure 6). MABUC was, however, shown to be markedly less susceptible toward inhibition by PAI-1 than by native u-PA. In addition, this increased PAI-1 resistance was demonstrated in clot lysis experiments employing preformed fibrin clots with embedded PAI-1 (Figure 7).

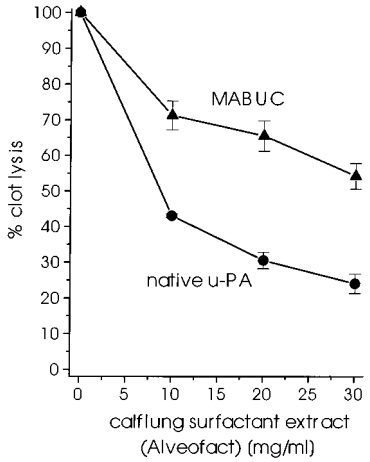

Figure 5. Influence of the concentration of clot-embedded surfactant on fibrinolysis by urokinase and MABUC. Alveofact (10−30 mg/mL, final) was admixed to the fibrinogen solution before performing clotting. The clot material was then incubated with native u-PA or MABUC (1 pmol active enzyme/mL each). After 4 h, the release of labeled products was measured and related to the relative amount of split products released in the absence of surfactant. Mean ± SE of eight independent experiments each are given.

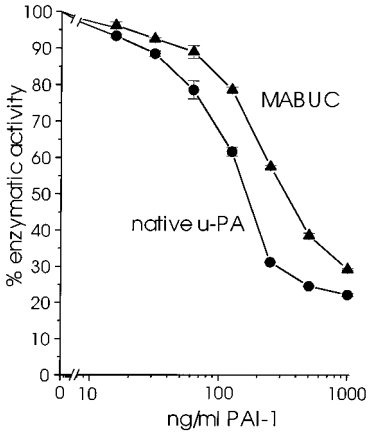

Figure 6. Influence of PAI-1 on the enzymatic activity of native u-PA or MABUC. Native u-PA and MABUC, at an activity of 20 U/mL, were incubated with increasing concentrations of PAI-1 (15.625−1000 ng/mL), and the enzymatic activity was assayed using a chromogenic substrate (related to the activity in the absence of PAI-1). Mean ± SE of three independent experiments each are given.

DISCUSSION

In the current study we have constructed and characterized a hybrid molecule consisting of the B-chain of urokinase and 8B5E, a monoclonal antisurfactant protein SP-B antibody. Using a chemical cross-linking technology as described similarly for conjugation of urokinase with an antibody directed against a fibrin neoantigen (*42*), we manufactured enzymatically active conjugates of 8B5E and urokinase B-chain (MABUC) by use of the heterobifunctional linker sulfosuccinimidyl-4-(*p*-maleidophenyl)butyrate (S-SMPB). Prerequisite for this coupling procedure was the limited reduction of HMW-tc-u-PA and isolation of the B-chain. Care had to be taken not to impair the catalytic property of u-PA during the limited reduction of urokinase necessary for generation and isolation of the B-chain. For this purpose, the enzyme was stabilized by the presence of benzamidine, a known competitive inhibitor targeting the active moiety of u-PA during the reduction process as recently suggested (*43*). Isolation of the B-chain was forwarded by affinity chromatography as also published previously (*43*, *44*) and yielded highly active B-chain at high purity (>93%).

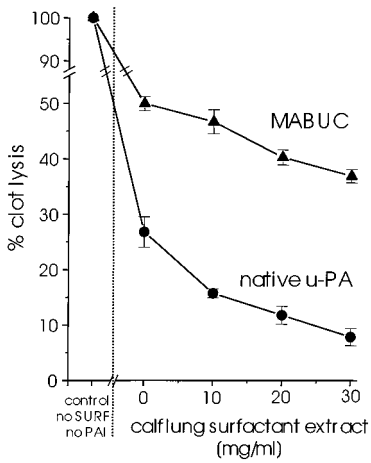

Figure 7. Influence of clot-embedded PAI-1 and various concentrations of surfactant on fibrinolysis by urokinase and MABUC. Alveofact (10−30 mg/mL, final) and PAI-1 (400 ng/mL) were admixed to the fibrinogen solution before performing clotting. The clot material was then incubated with native u-PA or MABUC (1 pmol active enzyme/mL each). After 4 h, the release of labeled products was measured and related to the relative amount of split products released in the absence of surfactant and PAI-1. Mean ± SE of eight independent experiments each are given.

The obtained 8B5E/u-PA-B chain conjugates, named "MABUC", were identified and characterized by a "hybrid-ELISA" based on the functional properties of both the antibody (binding to the solid-phase-adsorbed SP-B) and the B chain of u-PA (scission of the chromogenic substrate). A sequentially performed chromatographic procedure, consisting of gel filtration chromatography for removal of native B-chain followed by affinity chromatography for removal of native antibody, turned out to be suitable for the isolation of MABUC at high purity (>95% by SDS−PAGE).

The precise structure or amino acid sequence of the novel conjugate is not known, as the cross-linker reacts in a random fashion preferentially with the ϵ-amino group of lysine residues, which are present in large number in the antibody molecule. However, according to the coupling protocol the following speculations can be made: Concerning the coupling of the reduced B-chain to the maleimide group of the activated antibody, thioether-based bondage may be expected for Cys 279, and can be assumed to represent the only free thiol group of the B-chain. This view is based on the observation that absence of benzamidine during the reduction process would result in a loss of u-PA activity, suggesting reduction of some important disulfid bonds in close proximity to the catalytic triad. The results obtained with the "hybrid-ELISA" showed that MABUC fully retained the ability of antigen binding suggesting that coupling did not interfere with the antigen binding region of the antibody.

The presently employed coupling protocol was chosen because it greatly reduced the size of possible conjugates. Other protocols, in which native urokinase (HMW-tc-u-PA, 54 kDa) is first modified by the cross-linker and then connected to the antibody, would result in larger hybrid molecules and might affect the enzymatic activity, as the cross-linker could also be linked to lysine residues within or close to the active site of u-PA.

The purified hybrid molecule was shown to possess distinct advantages that could make it a preferable

plasminogen activator for induction of fibrinolysis in the alveolar compartment. First, the SP-B binding ability was fully maintained and might thus be operative to limit the action of this hybrid molecule to the alveolar space, preventing substantial leakage into the systemic circulation. The underlying reason is that SP-B is a unique protein of this compartment and due to its extreme hydrophobicity and intimate interaction with the alveolar phospholipid pool may not be expected to pass into the vascular space in substantial quantities, even under conditions of alveolo−epithelial barrier damage, as, for example, noted for the hydrophilic SP-A. This assumption was, however, not directly addressed in the present study, but will demand additional pharmacokinetic investigations in intact animals. Second, when adjusted to a similar activity as native u-PA using the fibrin plate and the chromogenic substrate assay in absence of surfactant, MABUC was shown to be ∼1.5−2 times more effective in fibrinolysis of surfactant embedding clots. These investigations were performed at concentrations of surfactant and fibrin realistically assumed to exist in vivo under conditions of extensive alveolar clotting (*26*). Third, when analyzing the sensitivity toward inhibition by PAI-1, the predominant fibrinolysis inhibitor of the alveolar compartment, MABUC turned out to be more resistant as compared to the native molecule, with approximately 2-fold concentrations of PAI-1 being necessary to gain the same degree of inhibition. Last, the difference between u-PA and MABUC became particularly apparent when analyzing their efficacy toward fibrin clots incorporating both natural surfactant and PAI-1, a condition representing the most realistic mimicry of alveolar fibrin arising in inflamed lung tissue. Under these circumstances, the lytic capacity of u-PA was largely lost, but that of MABUC was still maintained on a lower yet appreciable level (when probing clots containing 30 mg/mL surfactant and 400 ng/mL PAI-1, the lytic effect of MABUC surpassed that of u-PA > 5-fold).

The following drawbacks of the hybrid molecule of urokinase B-chain and the monoclonal SP-B antibody are imaginable when targeting fibrinolysis in the alveolar comparment. (i) The antibody might interfere with surfactant function, as previously described upon delivery of high concentrations of 8B5E into the alveolar space (*45*). However, such an anti-SP-B effect is clearly dose-dependent, and calculations taking into consideration the lytic capacity of MABUC and the dose-inhibition curves of anti-SP-B on surfactant function do suggest that such an effect might not be relevant. However, this aspect has to be addressed in a detailed fashion when delivering MABUC to the alveolar space of intact lungs. (ii) The antibody binding to the antigen (SP-B) in the alveolar compartment might provoke immunological sequelae that may not be foreseen from in vitro experiments. Even if the present body of knowledge on conjugates of u-PA with antibodies detecting a fibrin neoantigen does not suggest major relevance of such phenomena, the immunological responsiveness of the alveolar space might differ from that of the intravasular space, thus making detailed analysis of this aspect mandatory when delivering MABUC to intact lungs. (iii) The hybrid molecule migh be seriously damaged when undergoing aerosolization; however, pilot experiments addressing this issue rather suggest that this is not the case.

In view of the pathogenetic relevance of alveolar fibrin formation and accumulation of surfactant-rich fibrin clots in the lung for impairment of surfactant function, gas exchange properties and—still hypothetically—fibroproliferative changes in late ARDS and inflammatory lung disease, selective fibrinolysis in the alveolar compartment might offer as new therapeutic approach. Coaerosolation of native urokinase and natural surfactant material was, indeed, recently shown to improve gas exchange and to limit lung fibrosis in experimental models of acute and chronic inflammatory injury (*29*, *46*). A properly designed fibrinolytic agent, addressing the unique nature of alveolar fibrin, might be an interesting tool for such a purpose, and the data of the present study render the anti-SP-B−u-PA-B-chain conjugate an interesting candidate in this context.

Poly(ethylenimine-*co*-L-lactamide-*co*-succinamide): A Biodegradable Polyethylenimine Derivative with an Advantageous pH-Dependent Hydrolytic Degradation for Gene Delivery

Holger Petersen, Thomas Merdan, Klaus Kunath, Dagmar Fischer, and Thomas Kissel*

Department of Pharmaceutics and Biopharmacy, Philipps-University of Marburg, Ketzerbach 63, D-35032 Marburg, Germany. Received February 7, 2002; Revised Manuscript Received April 24, 2002

A biodegradable gene transfer vector has been synthesized by linking several low molecular weight (MW) polyethylenimine (PEI, 1200 Da) blocks using an oligo(L-lactic acid-*co*-succinic acid) (OLSA, 1000 Da). The resulting copolymer P(EI-*co*-LSA) (8 kDa) is soluble in water and degrades via base-catalyzed hydrolytic cleavage of amide bonds. With regard to its application as a gene transfer agent, the polymer showed an interesting pH dependency of degradation. At pH 5, when DNases are highly active, the degradation proceeds at a slower rate than at a physiological pH of 7.4. PEI and P(EI-*co*-LSA) spontaneously formed complexes with plasmid DNA. Whereas the complexes formed with PEI were not stable and aggregated, forming particles of up to 1 μm hydrodynamic diameter, P(EI-*co*-LSA) formed complexes, which were about 150 nm in size and of narrow size distribution. The latter complexes were stable, due to their high surface charge (ζ-potential + 18 mV). Similar to low MW PEI, the copolymer exhibited a low toxicity profile. At the same time, the copolymer showed a significant enhancement of transfection activity in comparison to the low MW PEI. This makes P(EI-*co*-LSA) a promising candidate for long-term gene therapy where biocompatibility and biodegradability become increasingly important.

INTRODUCTION

Over the past decade, charged macromolecules have found considerable interest as drug carrier systems. Whereas anionic polymers have often been reported to adsorb proteins (*1*), polycations (*2*) have shown promise as interpolyelectrolyte complexes containing nucleic acids in the field of nonviral gene transfer. Nevertheless, several requirements have to be fulfilled by these polymers used for in vivo gene delivery. One of the most important demands on macromolecular drug carriers is that they must not accumulate in the human body. The elimination of the polycation as a function of time is very important. Almost all types of polycations have already been studied as gene delivery vehicles (for a review see ref *3*). It is has been reported that cationic macromolecules and their drug complexes accumulate mostly in the liver or kidney (*4*). Furthermore, it is well-known that hydrophilic low molecular weight (MW[1]) substances can be eliminated by the kidney, when their MW is lower than 30 kDa. Therefore, high MW polymers must be degraded or metabolized before they can be eliminated. In the case of natural polymers this metabolic process can be performed by enzymes. However, synthetic polymers are often resistant to enzymatic degradation. Thus, their application as a component of a drug delivery system is limited, especially in the case of chronic or multiple administrations. Whereas in specific indications, such as a terminal cancer, a higher dose of polycations might be tolerable, special care must be taken when treating young patients with inherited genetic disorders. In this case, accumulation of polycations over years might cause severe organ damage.

Therefore, one aim of further development in the field of polymeric gene delivery should be the development of biodegradable polycations. Surprisingly, only scant information about water-soluble, biodegradable polymers for gene transfer is available in the literature. For example, Lim et al. (*5*) reported a biodegradable aliphatic polyester poly[α-(4-aminobutyl)-L-glycolic acid)] (PAGA), which initially degraded very rapidly within the first 100 min and then gradually degraded to its monomers within 6 months. The polymer showed approximately a 2-fold higher transfection efficiency than its structural amide analogue poly(L-lysine). Putnam et al. (*6*) synthesized another amino group bearing aliphatic polyester poly(4-hydroxy-L-proline ester), which were of low toxicity. However, results of degradation studies or transfection experiments have not been reported as of yet. Apart from their biodegradability, these polymers need to be optimized with respect to transfection efficiency.

Our strategy was to use polycations well-known for their high transfection activity and render this polymer degradable. We selected polyethylenimine (PEI) since it has already been widely and successfully used for gene delivery both under in vitro (*7*, *8*) and in vivo (*9*, *10*) conditions.

It has been reported (*11*, *12*) that PEI with high MW (≥25 kDa) is characterized by a high transfection activity, but unfortunately by a high cytotoxicity, as well. In contrast, low MW PEI (≤2 kDa) shows almost no transfection, but seems to be less toxic (*13*). Our concept was to combine the good transfection efficiency of high MW PEI and the low toxicity of low MW PEI by linking several low MW PEIs with an appropriate spacer to form a biodegradable, high MW polycation.

All of the published biodegradable polycationic gene transfer systems exhibited ester bonds as degradable linkages. Here, we report the first synthesis of a biodegradable PEI derivative and its degradation mechanism based on the hydrolytic cleavage of amide bonds. This novel polycation exhibited a degradation profile with a favorable pH dependency.

Finally, it should be noted that Gosselin et al. (*14*) very recently published a concept, which is similar to ours. They coupled several PEIs with a MW of 800 Da together. In contrast to our work, they used a linker chemistry involving disulfide bonds so that the resulting polymer is expected to be degraded via intracellular reduction and not by hydrolysis.

MATERIALS AND METHODS

Polymer Synthesis. *Synthesis of the Oligo(*L*-lactic acid-co-succinic acid) (OLSA)* **3**. The oligomer was prepared by polycondensation of 40.51 g of L-(+) lactic acid **1** (Fluka, 90% in water, 0.405 mol, 20 equiv) in the presence of 2.39 g of succinic acid **2** (Fluka, ≥99.5%, 20 mmol, 1 equiv). The reaction was carried out in vacuo (20 mbar) at 160 °C for 4 h and resulted in a clear, colorless, and highly viscous material. The amount of condensed water (11 g, 0.386 mol condensation product, 19 equiv) corresponds to a conversion of the polycondensation of 90%, which is related to the formation of decamers. Thus, the MW of OLSA is approximately 1000 Da. Determination of the MW by end group analysis from ^{1}H NMR spectra is not possible due to very similar chemical shifts of the methyl protons and the methine protons adjacent to an acid or ester group. ^{1}H NMR ($CDCl_3$): δ = 5.11 (m, OC*H*, 1H), 4.33 (m, HOC*H*, terminal, 0.2 H), 2.64 (m, C(O)CH_2CH_2C(O), 0.2 H), 1.51 (m, CH_3, 3 H), 1.41 (m, CH_3, terminal, 0.6 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 174.9 (*C*═O, lactic acid (LA) terminal), 171.5 (*C*═O, succinic acid (SA)), 169.5 (*C*═O, LA), 68.9 (*C*H, LA), 66.6 (*C*H, LA terminal), 28.5 (*C*H_2*C*H_2, SA), 20.2 (*C*H_3, LA terminal), 16.5 (*C*H_3, LA) ppm.

*Synthesis of Poly(ethylenimine-co-*L*-lactamide-co-succinamide) [P(EI-co-LSA)]* **6**. Amounts of 2.34 g of PEI **4** (1200 Da, Polyscience, 99%, 1.95 mmol, 1.2 equiv) and 1.66 g of OLSA **3** (1000 Da, 1.66 mmol, 1 equiv) were dissolved in 25 mL of absolute ethanol. After 1 h, the solvent was removed under reduced pressure at 40 °C, and the product was isolated as a clear, colorless, and highly viscous material in quantitative yield. This isolated product is referred to as intermediate **5** in this report and was treated at 160 °C for 2 h in vacuo (1 mbar). The resulting polymer was dissolved in ethanol and precipitated in diethyl ether. Solvent residues were removed in vacuo. The orange-red-colored polymer was isolated with a yield of 81%.

Polymer Characterization. *Nuclear Magnetic Resonance Spectroscopy (NMR).* ^{1}H NMR and ^{13}C NMR spectra were recorded in d_6-DMSO (Merck) at 35 °C or $CDCl_3$ (Merck) at an ambient temperature on a Eclipse+ 500 spectrometer from JEOL, Tokyo, Japan, at 500 MHz for ^{1}H NMR and 125 MHz for ^{13}C NMR spectra, respectively. Spectra were evaluated with the NMR data processing program MestRe-C Version 2.2.

Fourier Transform Infrared Spectroscopy (FTIR). FTIR spectroscopy was conducted with a FT-IR 510P spectrometer from Nicolet with PC/IR v. 3.20 software using KBr (for IR spectroscopy, Uvasol, Merck) disks. The waxy and oily samples were smeared on the KBr disk.

Capillary Viscosimetry. The polymers were characterized by capillary viscosimetry (Ubbelohde, Schott, type No. 50101/0a) at 25.0 °C in filtered water (0.22 μm, 0,-055 μS/cm). The polymer concentration was 0.5 g/dL. Inherent viscosity (η_{inh}) was calculated using the equation: $\eta_{inh} = \ln(t/t_0)/c$, where t is the flow time of the polymer solution, t_0 the flow time of the solvent, and c the polymer concentration. The η_{inh} listed in Table 1 and Figure 4A is the mean of five measurements.

Degradation Study. Degradation was studied with the polymer solution used for viscosimetry, incubated for several days in a slowly rotating heating block (Rotatherm, Liebisch, Bielefeld, Germany) at 37.2 °C. Solutions of P(EI-*co*-LSA) at a concentration of 0.5 g/dL exhibited a pH of 9. Solutions with a pH of 7 and 5 were prepared by adding the appropriate amount of HCl. To compare the degradation process at different pH values, relative η_{inh} values were plotted in Figure 8A. Absolute MW determination of these samples were carried out using SEC-MALLS.

Size Exclusion Chromatography in Combination with Multiple Angle Laser Light Scattering (SEC-MALLS). The SEC setup consisted of a HPLC Pump L-6000 from Merck-Hitachi, Darmstadt, Germany, a Merck-Hitachi autosampler AS-200A, and a Merck column thermostat T-6300. Polymers were detected by a differential refractive index (RI) detector RI-71 from Merck and an 18 angle laser light scattering detector from Wyatt Technologies, Santa Barbara, CA (DAWN EOS, GaAs Laser 690 nm, 30 mW, K5 cell). SEC column Novema 3000 was from Polymer Standard Service, Mainz, Germany. As an eluent, 1% formic acid (Riedel-de Haen, 98−100%) was used. The eluent was prepared with pure reagent water (0.22 μm, 0.055 μS/cm, USF Seral, Seradest BETA 25 and Serapur DELTA UV/UF), filtered through 0.2 μm sterile filter, and degassed with a four-channel online vacuum degasser DDG-75 from Duratec, Reilingen, Germany. Additionally, an inline filter (0.45 μm, stainless steel, Rheodyne, Cotati, CA) was set between the columns and MALLS detector. A flow rate of 1 mL/min was applied. Polymer concentration was 5 g/L and 20 μL were injected for each run. MWs were calculated by Astra for Windows Software, version 4.73.04, using Zimm plots. We have evaluated our SEC-MALLS with an commercially available PEI 25 kDa (Aldrich) and found following standard deviations (n = 5). dn/dc: 0.64%. M_n: 4.16%. M_w: 1.67%. M_w/M_n: 3.48%. Similar errors can be expected for the PEI and the PEI derivatives used in this study.

Formation of the Polymer−DNA Complexes. All complexes of DNA and polymer were prepared freshly before use. Plasmid DNA pGL3 control (luciferase reporter vector, 3.5 MDa, 5256 bp) was from Promega, Heidelberg, Germany, and was amplified with a competent *E. coli* strain JM 109 (Promega) according to a protocol from QIAGEN, Hilden, Germany (*15*). Plasmid DNA was used for all experiments except for the MTT

assay, in which DNA from herring testes (Type XIV, Sigma, Steinheim, Germany, 0.3−6.6 MDa, 400−10000 bp) was used.

The polymer solutions were added to DNA solutions in equal volumes, mixed by vortexing, and incubated for 1 min (physicochemical experiments) or 10 min (biological experiments) before use. DNA stock solutions were diluted to a concentration of 40 μg/mL with 150 mM NaCl at pH 7.4. The polymer stock solutions were also diluted with 150 mM NaCl (pH 7.4) to the appropriate concentration depending on the required polycation-nitrogen/polyanion-phosphorus ratio (N/P ratio) and filtered through 0.22 μm pore sized filters. DNA stock solutions were composed of 1 mg/mL pGL3 plasmid in 10 mM tris(hydroxymethyl)aminomethane hydrochloride (Tris HCl) (pH 8) and 1 mM ethylenediaminetetraacetic acid (EDTA). Polymer stock solutions exhibited a concentration of 0.9 mg/mL. Polymer concentration was based on the PEI content in the copolymer only; the lactic acid and succinic acid is ignored in this calculation. Thus, all polymer stock solutions contain the same polycation concentration for a better comparability of the results.

Physicochemical Characterization of Copolymer−DNA Complexes. *Dynamic Light Scattering (DLS).* Complex size measurements were carried out with a Zetasizer 3000 HS from Malvern Instruments, Worcs., UK, at 25 °C (10 mW HeNe laser, 633 nm). Scattered light was detected at a 90° angle through a 400 μm pinhole. Measurements yielding hydrodynamic diameters (*Z* average mean) and polydispersity indices (PDI) were performed with count rates of about 100−400 kCps in form of 10 runs of 60 min duration each and analyzed in the CONTIN mode. The viscosity (0.8905 mPas) and refractive index (1.333) of pure water at 25 °C were used for data analysis. The instrument was calibrated with Nanosphere Size Standards (polymer microspheres in water, 220 nm ± 6 nm) from Duke Scientific, Palo Alto, CA.

Laser Doppler Anemometry. ζ-Potential (zeta-potential) measurements of the complexes were carried out in the standard capillary electrophoresis cell of the Zetasizer 3000 HS from Malvern Instruments at position 17.0 and at 25 °C. Measurement duration was set to automatic. Average values of the ζ-potential were calculated with the data from eight runs. The instrument was calibrated with DTS5050 Electrophoresis Standards from Malvern Instruments.

Biological Characterization of the Polymers and the Polymer−DNA Complexes. *MTT Cytotoxicity Assay.* In vitro cytotoxicity was studied on L929 mouse fibroblasts by MTT assay according to the method of Mosmann (*16*). The cells were incubated with the polymers for 3, 12, and 24 h (8000 cells/well, 96-well microtiter plates) as described in detail earlier (*17*). Each point in Figure 10 represents the mean ± SD of seven determinations.

Transfection Experiments. Transfection activity of the polymers was also studied on L929 mouse fibroblasts using a Luciferase Kit from Promega. Measurements of relative light units (RLU) were conducted on a Sirius Luminometer from Berthold, Pforzheim, Germany. Protein quantification was performed with freshly prepared bicinchoninic acid (BCA) reagent (Pierce, Rockford, IL) and was carried out with an ELISA plate reader from Dynatech MR 5000, Denkendorf, Germany, at 570 nm. Experiments were performed in triplicates as described in more detail in a previous report (*18*).

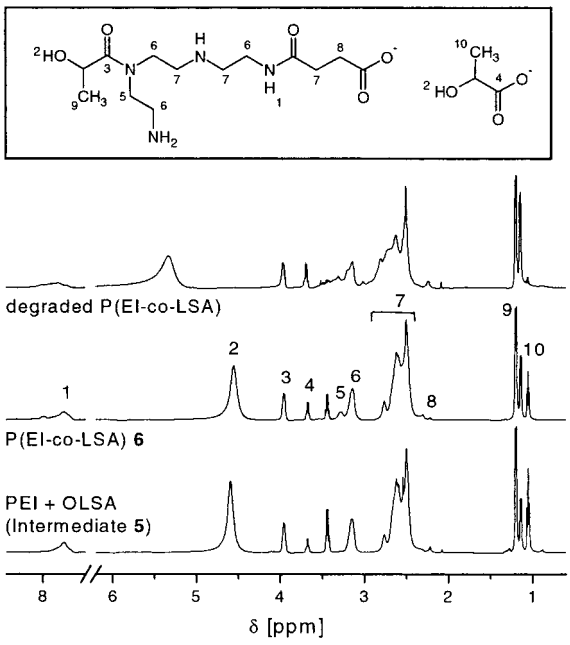

Figure 1. ^{1}H NMR spectra (500 MHz, d_6-DMSO) of polymers **5**, **6**, and the degraded P(EI-*co*-LSA) **6′** after 500 days. The structure shown in this figure is only a part of the macromolecules. Signals at δ = 1.05 and 3.45 ppm are derived from residues of ethanol in the product.

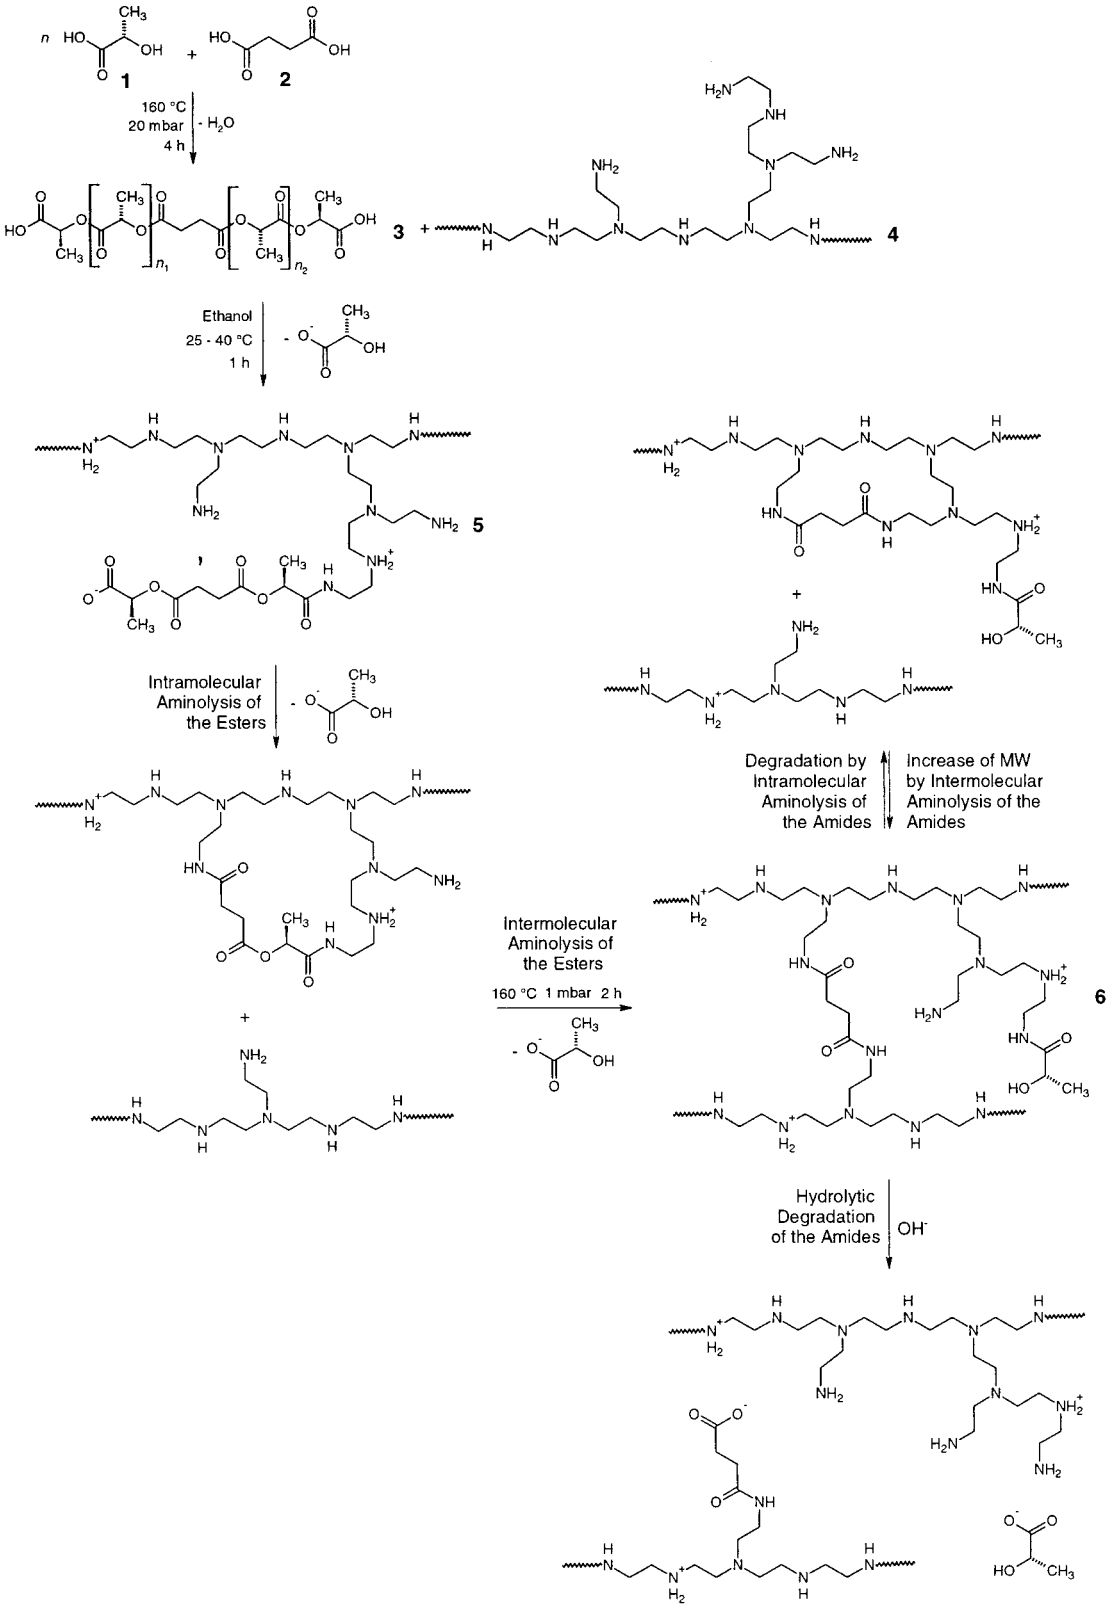

RESULTS AND DISCUSSION

Synthesis and Characterization of P(EI-*co*-LSA). To link several macromolecular PEI units together, we chose the simple bifunctional succinic acid, which had to be activated for the reaction with the amino groups of PEI. It is well-known that primary amines react with many esters just upon mixing and sometimes even at room temperature to yield amides (*19*). Therefore, an easy way to activate succinic acid for the reaction with PEI was to transform the acid into an ester. We used the α-hydroxy acid L-lactic acid as an alcohol. The use of this alcohol for esterification had at least two advantages: On one hand, this alcohol allows the formation of a polyester, which incorporates the succinic unit. As a consequence, there are not only two ester bonds per linker which can react with PEI, but a large number of ester bonds instead. This should improve the conversion of the coupling reaction. On the other hand, it does not matter if not all of the ester bonds of this polyester react with PEI. In this case, the linker will contain amide and ester bonds, so that hydrolytic degradation is guaranteed in every case.

In a first step, we synthesized the polyester to activate the succinic acid (Scheme 1). Polycondensation of succinic acid and L-lactic acid were carried out in bulk. As a result, the conversion of this polycondensation reaction was 90%, which implied that a decamer (10mer) with a MW of about 1000 Da was formed. Because of the low degree of polymerization the polyester will be referred to as oligo(L-lactic acid-*co*-succinic acid) (OLSA) in this article. Due to the incorporated succinic unit, the oligomer did not crystallize, but remained in its glassy state.

PEI and OLSA are highly viscous substances and cannot be mixed easily in bulk. Therefore, in preparation for the next reaction step, a blend of these homopolymers was prepared by dissolving the two components in ethanol and removing the solvent again under reduced pressure. During this process the first reactions took place. The ^{13}C NMR (175 ppm, signal 2 in Figure 2) and

Scheme 1. Synthesis Route and Degradation Mechanism of P(EI-*co*-LSA) 6

the FTIR (1653 cm^{-1}, signal E in Figure 3) spectra verified the formation of amide bonds. Signals of the ester groups (169 ppm, 1761 cm^{-1}, signal D_1 in Figure 3) disappeared. Only in the FTIR spectrum did a weak signal of the ester bond remain. Due to H-bonding between N−H of PEI and the C═O of OLSA, the ester signal had shifted to 1733 cm^{-1} (signal D_2 in Figure 3). In the ^1H NMR spectrum a new signal (6 in Figure 1) at 3.05 ppm appeared and was assigned to methylene protons of the PEI, which are neighbored to an amide bond. Hence, aminolysis of the ester bonds yielded an intermediate of the structure **5** shown in Scheme 1. Only a slight MW increase occurred at this step. While viscosimetry does not indicate any increase of MW, SEC-MALLS revealed an MW (M_w) increase from 1116 to 2853 (Table 1). This suggests that OLSA most likely reacted

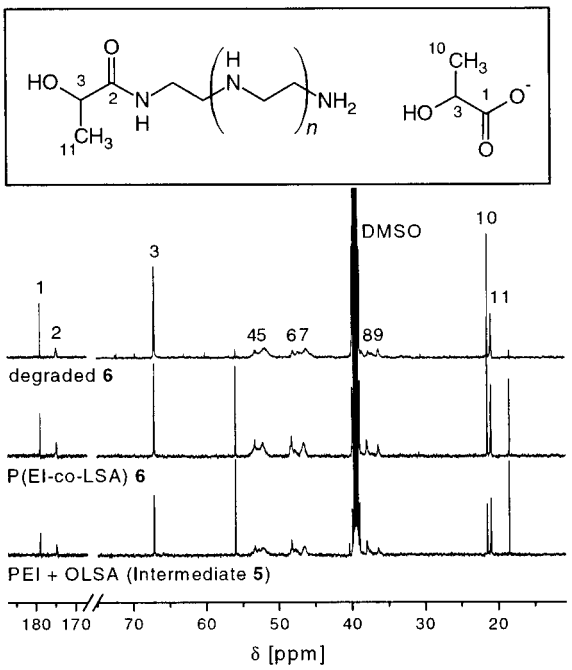

Figure 2. ^{13}C NMR spectra (125 MHz, d_6-DMSO) of polymers **5**, **6**, and the degraded P(EI-*co*-LSA) **6′** after 500 days. The structure shown in this figure is only a part of the macromolecules. Signals at δ = 18.9 and 56.5 ppm are derived from residues of ethanol in the product. Signals 4−9 are derived from the methylene carbons of PEI.

with PEI only to modify and graft the polycation, but did not link different PEI macromolecules together. In this case, a theoretical MW of about 2000 Da is expected for **5** which is in good agreement with M_n = 1795 Da found by SEC-MALLS. Since the reactants were in diluted solution the aminolysis will most likely occur *intra*molecularly. This also explains why the inherent viscosity did not increase, but instead slightly decreased (from 0.050 to 0.042 dL/g, Table 1). Despite the grafting of new blocks onto PEI, the density of the macromolecule remained constant or was even enlarged by the intramolecular linkages. Since density and viscosity are antiproportional to each other (Einstein's viscosity law: $\eta_{sp}/c = 2.5/\rho$, where η_{sp} is the specific viscosimetry [$\eta_{sp} = (t - t_0)/t_0$]) and ρ is the equivalent coil density), the viscosity of the polymer solution is expected to decrease in this case even if MW increases.

In a second reaction step the intermediate **5** was allowed to react at high temperatures (160 °C) and at maximum concentration (in bulk). Under these conditions, the aminolysis of the ester bonds was completed (no remaining ester absorptions in FTIR for **6**) and two additional processes began: Aminolysis of amides (amine−amide interchange reaction) and transamidification (amide−amide interchange reaction) (*20*). The latter reaction most likely played only a minor role, while the predominant reaction was the aminolysis of the amides (*21*). Aliphatic primary amines and, under forced reaction conditions secondary amines as well, can react with the amides (*22*−*24*). Hence, a new signal (signal 5 in Figure 1) appears in the ^1H NMR spectrum at 3.3 ppm. This signal was attributed to methylene protons of PEI adjacent to an *N*,*N*-disubstituted amide, which was formed by the reaction of a secondary amine with an N-monosubstituted amide. The formation of *N*,*N*-disubstituted amides was also verified by the decreased intensity of the N−H amide II absorption in the FTIR spectrum (signal G in Figure 3) from **5** to **6**. While during the first step most reactions probably occurred *intra*molecularly, due to the relatively high dilution, this step favors *inter*molecular reactions, because of the extremely high polymer concentration in bulk. These rearrangements toward intermolecular linkages are responsible for the large MW increase up to 8000 observed by SEC-MALLS. At the same time, inherent viscosity increased from 0.05 dL/g to almost 0.1 dL/g by a factor of 2.

Finally, the solubility behavior of oligomers and polymers are compatible with the proposed reaction scheme. OLSA is soluble in organic solvents, such as ethanol, chloroform, and dimethyl sulfoxide (DMSO), but insoluble in water. In contrast, the intermediate **5** and the resulting polymer **6** are insoluble in chloroform, but soluble in water, ethanol, and DMSO. This also is a measure for the progress of the reaction between PEI and OLSA at ambient temperature after as little as 1 h.

We are aware that copolymer synthesis can be further optimized. Especially, the optimum ratio between lactic acid and succinic acid in the oligomer OLSA has still to be determined. With less lactic acid in OLSA, more amino groups of the PEI will remain unsubstituted, which will probably affect the toxicity of the polymer and the DNA complexation. Copolymers with higher MW can be achieved when the ratio OLSA to PEI is increased. However, this ratio is probably limited. A larger amount of succinic acid linker could lead to cross-linking and would result in loss of solubility of the polymeric network. This optimization process is currently being carried out in our laboratories.

Polymer−DNA Complexes. PEI 1200 Da **4** and copolymer P(EI-*co*-LSA) **6** spontaneously formed complexes with plasmid DNA upon mixture of the solutions. These complexes were studied by DLS, which determined the hydrodynamic diameters and the polydispersity indices (PDI). The results are shown in Figures 4 and 5. The low MW PEI generated complexes of 350 nm in size with a PDI of 0.15, indicating a narrow complex size distribution. However, within 10 min the complexes aggregated to particle diameters of more than 700 nm. Furthermore, the PDI also increased significantly up to 0.5, implying an extreme broad size distribution. Thus, DNA complexes formed with low MW PEI were prone to aggregation. Surprisingly, a decisive enhancement of DNA condensation was observed in the case of copolymer P(EI-*co*-LSA), where the tendency toward aggregation was significantly reduced. In this case, size and stability of the complexes were strongly dependent on the N/P ratio. At N/P 10 complexes were not stable and aggregated from 320 to 570 nm within 10 min. Even at N/P 20 complexes were not quite stable, although the aggregation process (from 220 to 380 nm) was reduced significantly. However, stable complexes were obtained with N/P 50. In this case, no aggregation was observed at all. Complexes were found to be very small in size (150 nm). Also, the size distribution of the P(EI-*co*-LSA) complexes was considerably narrower (PDI < 0.1) in comparison to the PEI 1200 Da complexes. The large difference in complex size distribution between the homopolymer (PDI = 0.601) and copolymer (PDI = 0.077) is exemplarily presented in Figure 8 for N/P 20 after 10 min incubation.

These results could be explained by the differences in ζ-potential of the complexes (Figure 6). Complexes formed with PEI 1200 Da were only of moderate ζ-potential (4−13 mV), which apparently was not sufficient to electrostatically stabilize the complexes against aggregation. In

contrast, the stable complexes of P(EI-*co*-LSA) exhibited highly positive ζ-potentials of about 18 mV for N/P 20 and 50.

Transfection Experiments. Transfection experiments were performed with L929 mouse fibroblasts, as opposed to 3T3 cells, which are more widely used in

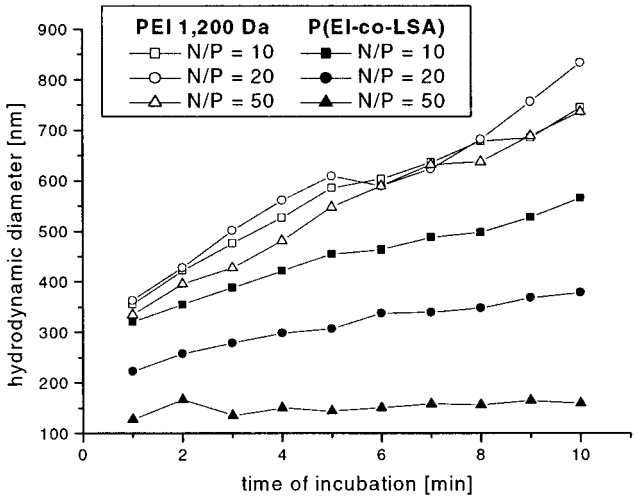

Figure 4. Hydrodynamic diameter of the polymer−DNA complexes as determined by dynamic light scattering at different N/P ratios in 150 mM NaCl at 25 °C.

transfection studies. However, we used the L929 cells in order to provide results which could be correlated with the cytotoxicity data raised from the MTT assay for which this cell line is recommended (see below). In previous experiments using PEI and its derivatives, we found that the transfection activities with L929 cells are similar to the results with 3T3 fibroblasts (data not shown). Results of the transfection experiments are shown in Figure 7. At N/P ratios 10 and 20 no significant differences in transfection activity could be observed between the homopolymer **4** and the copolymer **6**. However, at N/P ratio 50 a 10-fold higher reporter gene expression was found for copolymer P(EI-*co*-LSA) as compared to the homopolymer PEI. This high transfection activity can be attributed to the highly positive surface charge of the complexes (ζ-potential +18 mV) which favors a strong interaction with the negatively charge cell membrane, as well as to the small complex size (150 nm) which allows an easier cellular uptake by endocytosis.

For an efficient gene delivery with polymeric transfer agents it seems to be important that the polycation has

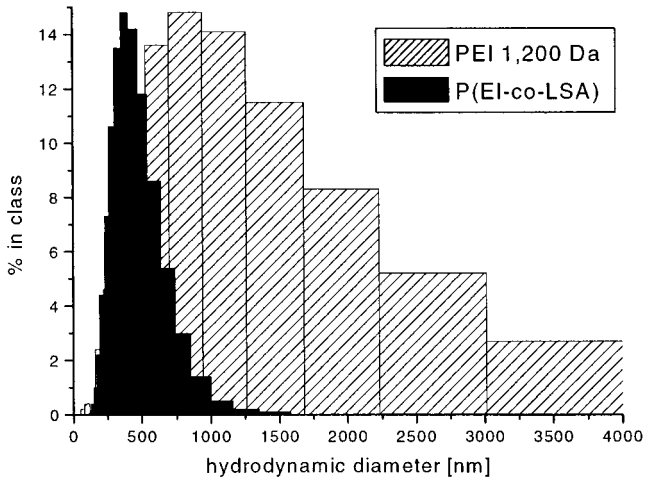

Figure 5. Size distributions of polymer−DNA complexes at N/P = 20 and after 10 min incubation as determined by dynamic light scattering in 150 mM NaCl at 25 °C.

a MW > 2000 Da. It has already been reported that low MW PEIs (≤2000 Da) do not transfect efficiently and sometimes not at all (*11*, *12*). Herein, we give an explanation for this poor transfection activity: The instability of the complexes, due to the relatively low ζ-potential, resulted in the formation of aggregates, which might be too large (>800 nm) for a nonspecific uptake into the cells. Apart from increasing the MW of the polycation by optimized polymerization methods, we demonstrate that improved transfection activity can also be achieved by linking low MW polycation units together. These conjugates of higher MW form stable and small complexes with DNA and, therefore, exhibit higher transfection efficiencies.

Degradation of P(EI-*co*-LSA). Biodegradable polymers, especially those for implants or other medical devices, have, in the past, been based on aliphatic polyesters, such as poly(lactic acid), poly(glycolic acid), or poly(ϵ-caprolactone). Creating a degradable polycation with cleavable ester bonds is difficult, since almost all polycations are based on amines, which can easily react with esters. This also is the reason the amino group bearing polyester, PAGA, reported by Lim et al. (*5*) degraded very quickly. The initial MW is reduced to 1/3 after only 100 min. The authors explained the rapid degradation as being a result of self-degradation of the polymer's own ester linkages by the ϵ-amino groups. Generally, ester bonds are easily cleaved if the polymer and the degradation products are water-soluble. Thus, a polycation linked with ester bonds would possibly degrade too fast and is not able to delivery the therapeutic gene efficiently before degradation. A very rapid degradation might be just tolerable in the case of cell culture experiments since only a few hours are required to yield a maximum transfection of the cells. In the case of in vivo gene delivery, however, the gene has to be protected for several hours or more, due to longer circulation times of the complexes in the blood system. A degradable polymeric network based on amides might be more appropriate for an in vivo gene delivery since it shows a higher stability as compared to a system with ester bonds, however, is still degradable, as we will show here.

The degradation pattern of our copolymer was studied in aqueous solutions at pH 5, 7, and 9 at 37 °C. The results of the viscosity measurements (Figure 8A) and MW determination by SEC-MALLS (Figure 8B and 9, Table 1) demonstrated that P(EI-*co*-LSA) had degraded within months and that degradation was accelerated with increasing pH. This finding is compatible with a degradation process which is base-catalyzed by the amino-groups of PEI. Table 1 displays the absolute MW during the degradation process. At pH 9 the copolymer **6** is degraded from M_w 8000 to the MW of the starting material **5** (M_w 3000) within 2 month. At the same time, the MWD is reduced to the original distribution of the PEI homopolymer. This is reasonable because the degradable copolymer P(EI-*co*-LSA) is cleaved into parts of the nondegradable PEI macromolecules with their narrower distribution. While the copolymer **6** is degraded after 1.5 month to a M_w of 3449 Da at pH 9, it is degraded to M_w = 4181 Da at pH 7 and M_w = 6360 Da at pH 5, respectively. Hence, at neutral and physiological pH the copolymer still degrades relatively fast, whereas under acidic conditions (pH 5) the degradation process is remarkably inhibited. We think that this pH dependency is quite favorable for a biodegradable gene delivery system, since it should protect the DNA against enzymatic degradation, especially at the pH at which DNAses are extremely active, as is true for the acidic conditions found in lysosomes (pH 5).

Two possible degradation mechanisms have to be discussed (see Scheme 1). On one hand, since the degradation process is performed in diluted solution, *intra*molecular aminolysis might cleave the *inter*molecular linkages, which would results in a decrease of MW.

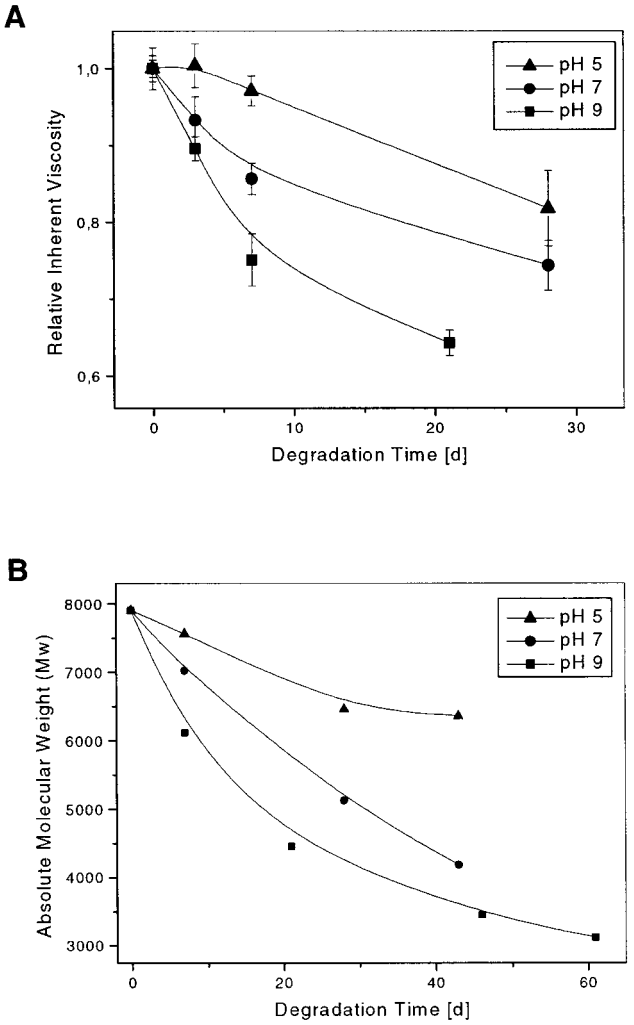

Figure 8. Degradation experiments with P(EI-*co*-LSA) **6** in aqueous solution at 37.2 °C and pH 5, 7, and 9. (A) Change of inherent viscosity during the degradation process as determined by an Ubbelohde viscosimeter. Relative values are presented in this plot. (B) Absolute MW (M_w) during degradation process as determined by SEC-MALLS.

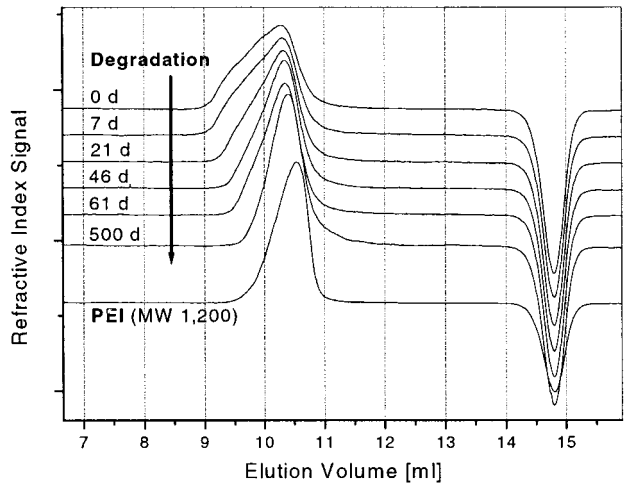

Figure 9. Degradation of P(EI-*co*-LSA):SEC eluograms of PEI 1200 Da **4** and its biodegradable derivative P(EI-*co*-LSA) **6** as detected by a refractive index detector. The degradation study was performed at pH 9 and 37.2 °C.

Still, it remains questionable if the aminolysis of amides really occurs under these mild conditions. On the other hand, the large number of primary amino groups in the vicinity of the amide bonds might facilitate this reaction. The second possible degradation process is the hydrolytic cleavage of the amides. It is generally assumed that the amide bond is rather stable against hydrolysis under mild conditions and that hydrolysis of amides only occurs at extreme pH and temperatures. Nevertheless, three points should be taken into account. First, to significantly decrease the MW of polyamides only a few amide bonds have to be cleaved. Second, the basic environment of the amides in our copolymer caused by the amino groups of PEI probably accelerates the hydrolytic cleavage. Third, several authors (e.g., *25*, *26*) reported the hydrolysis of polyamides under mild conditions and demonstrated that polyamide degradation can be observed after a few days. For instance, it has been reported that even water-*in*soluble aliphatic polyamides made from D- and L-tartaric acids and 1,6-hexamethylenediamine showed a weight loss between 10 and 30% and decays in the MW of nearly 50% after 2 months upon incubation in water under physiological conditions (pH 7.3, 37 °C) (*25*). In contrast, our P(EI-*co*-LSA) and all its degradation products are water-soluble. Thus, in our case the contact of the polymer with water is optimized which favors the amide hydrolysis.

The spectroscopic data support the theory of hydrolytic cleavage of amide bonds. A comparison of the NMR spectra of intermediate **5**, the copolymer **6** and the degraded copolymer **6′** (see Figures 1 and 2) showed an increase in the intensities of free lactic acid (^{1}H: signals 4 and 10, ^{13}C: signals 1 and 10) and a decrease in the intensities of polymer bound lactamide (^{1}H: signals 3 and 9, ^{13}C: signals 2 and 11) is clearly observed. During the reaction from **5** to **6**, aminolysis of the remaining ester bonds led to the release of additional lactic acid. The degradation process from **6** to **6′** released even more lactic acid, which is only possible by hydrolytic cleavage. A decrease of amide bonds by hydrolysis was also detectable by FTIR (Figure 3). Compared to the spectrum of **6**, the intensity of the carbonyl amide I absorption (signal E) was decreased in the spectrum of **6′**, while the intensity of the amino N−H bending absorption (signal G) had increased, thus, indicating an increasing number of free amino groups.

Consequently, if our copolymer is degradable two other polycations known for their application as gene delivery vehicles should also degrade via hydrolytic cleavage of its amide bonds since they also exhibit neighboring amido bonds and amino groups: poly(L-lysine) (PLL) (*27*) and polyamidoamine dendrimers (PAMAM) (*28*). In the case of polylysine, Oppermann et al. (*26*) states that almost nothing is known about the degradation behavior of this poly(amino acid). However, Kunioka et al. (*29*) reported that the similar polyamide poly(ϵ-lysine) had slightly degraded at its amide bonds (2% weight loss after 17 h at 40 °C) in water. In the case of PAMAM dendrimers, it was found that a short heat treatment of aqueous polymer solutions caused hydrolysis of some of the amide bonds, which surprisingly resulted in an even better transfection activity (*30*). Ranucci et al. (*31*) studied the hydrolysis of PAMAMs under physiological conditions and found that, after incubation for 24 h, polymer intrinsic viscosity was decreased by approximately 50%. Interestingly, they also pointed out that hydrolytic degradation progressed much more slowly at pH 5.5 which is in good agreement with our pH−rate profile for polyamide hydrolysis.

Cytotoxicity of the Polymers. The cytotoxicity of the copolymer **6** was studied using the same cell line as in the transfection experiments. As recommended by many

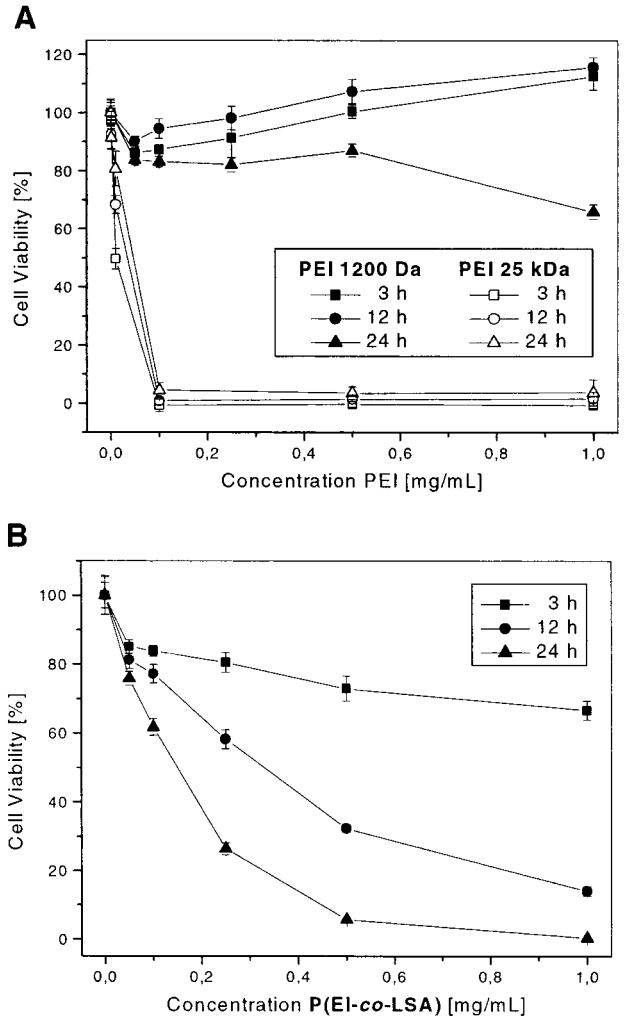

Figure 10. Dose- and time-dependent effects of PEI **4** 1200 Da in comparison to PEI 25 kDa (A) and copolymer **6** P(EI-*co*-LSA) (B) on L929 mouse fibroblasts determined by MTT-assay. Each point represents the mean ± SD of seven determinations.

standard institutions, L929 mouse fibroblasts were used as cell line to test the cytotoxicity of the polymers (*32*, *33*). PEI **4** was also studied as a reference (Figure 10A) and was found to be nontoxic up to a concentration of 0.5 mg/mL for 24 h. Only a slight decrease of cell viability (70%) was found at 1 mg/mL after a 24 h incubation time. IC_{50} values (>1.0 mg/mL) could not be determined in this case. The copolymer **6** (Figure 10B) also showed only a slight decrease in cell viability (67%) after 3 h incubation (IC_{50} > 1.0 mg/mL). At 12 and 24 h incubation time, an increase in toxicity with increasing polymer concentrations was observed (IC_{50}: 0.34 and 0.16 mg/mL, respectively). However, in comparison to commercially available high MW PEI, such as PEI 800 kDa from Fluka or PEI 25 kDa from Aldrich [IC_{50} approximately 0.01 mg/mL, see Figure 10A and (*13*)], the copolymer **6** was still of relative low toxicity. Its toxicity is comparable with the low MW PEI that is described in the literature as a highly effective gene transfer reagent with a low toxicity profile (*17*). Thus, the results of this cytotoxicity assay indicate a good biocompatibility of the biodegradable copolymer. A positive contribution toward the low toxicity profile of the copolymer might have the lactamide units with their terminal hydroxy groups which are generally assumed to have a positive influence on the biocompatibility of drug carrier systems (*34*). Furthermore, biocompatibility should even increase when degradation proceeds. With progressive degradation, copolymer **6** is expected to show a decrease in cytotoxicity, since the degradation products are nontoxic low MW PEI and lactic acid, whose acidity is neutralized by the basic PEI. Finally, it should be emphasized that we measured cytotoxicity of the free polymers. When applied as a gene transfer vehicle, the polymer is complexed with DNA. These complexes are generally less toxic compared to the free polymer (*35*, *36*). Therefore, the results of our cytotoxicity study represent the maximum toxic effect of the polymers.

CONCLUSIONS

A new type of copolymer has been prepared by linking several low MW PEI macromolecules using an oligomer of lactic acid and succinic acid. The resulting copolymer of high MW spontaneously formed complexes with plasmid DNA. Compared to low MW PEI the complexes were much smaller in size and more stable against aggregation which resulted in a 10-fold higher transfection activity of the copolymer. However, the decisive advantage is the biodegradability of this new copolymer which is based on hydrolytic cleavage of amide bonds. It was found that degradation was strongly dependent on pH. Keeping in mind the fact that DNAses are highly active under acidic conditions, as seen in lysosomes (pH 5), biodegradable gene transfer agents should be stable under acidic conditions in order to sufficiently protect the therapeutic gene. On the other hand, the polycation should be degradable under physiological conditions (pH 7.4) where the DNA should be released from the system. Our copolymer fulfils these demands and degrades within a reasonable time period that is long enough to secure gene transfer, but as short as necessary to prevent accumulation in the human body. Additionally, a low toxicity profile was observed for the new copolymer, which indicates its good biocompatibility.

These results demonstrate that the copolymer, P(EI-*co*-LSA), formed by a new synthesis method is a promising candidate for in vivo gene therapy applications. Further development will focus on the modification of the synthesis to improve the MW of the copolymer. It is expected that the transfection efficiency can be even enhanced by this process.

Received February 16, 2002; Revised Manuscript Received April 23, 2002

2′-Deoxyoligonucleotides and 2′-*O*-methyloligoribonucleotides carrying one or more 2′-aldehyde groups were synthesized and coupled to peptides containing an N-terminal cysteine, aminooxy, or hydrazide group to give peptide−oligonucleotide conjugates incorporating single or multiple peptides in good yield. The facile conjugation method allows specific coupling in aqueous solution of unprotected oligonucleotides containing aldehyde groups to unprotected N-terminally modified peptides and other small molecules. A 12-mer 2′-*O*-methyloligoribonucleotide complementary to the HIV-1 TAR RNA stem-loop and containing two conjugated copies of an 8-mer model laminin peptide was hardly affected in TAR RNA binding and showed a similar level of inhibition of HIV-1 Tat-dependent in vitro transcription compared to the unconjugated 2′-*O*-methyloligoribonucleotide. Advantages of this conjugation method include (1) the ability to attach more than one peptide or other small molecule to oligonucleotide at defined nucleoside residue locations; (2) a conjugation route that does not affect significantly oligonucleotide binding to RNA structures; and (3) three alternative, facile, and mild conjugation reaction types that do not require use of a large excess of peptide reagent.

INTRODUCTION

Oligonucleotides and their analogues have been studied for more than two decades as specific inhibitors of gene expression. Oligonucleotides can be used to target mRNA by antisense (*1*) or RNAi (*2*) mechanisms, double-stranded DNA by triplex formation (*3*), or proteins by aptamer selection (*4*). Oligonucleotides conjugated to certain peptides have been found to possess improved cell-specific targeting, cellular uptake efficiency, or stability to degradation in comparison to unmodified oligonucleotides (*5*−*7*). In some cases improved binding strength to RNA and target specificity has been achieved (*8*).

Several methods of chemical synthesis of peptide−oligonucleotide conjugates have been developed to date (*5*). The two most popular synthetic approaches are total stepwise solid-phase synthesis and coupling in solution of separately prepared peptide and oligonucleotide fragments. In total synthesis, the same solid support is used for both peptide and oligonucleotide assemblies. Peptide synthesis may be followed by oligonucleotide synthesis (*9*), or vice versa (*10*), or a branched linker is attached to the support permitting independent growth of both peptide and oligonucleotide chains (*11*). Unfortunately, the chemistries of peptide and oligonucleotide synthesis have been poorly compatible up to now. Attempts to solve these problems include modification of the solid support (*12*), base protecting groups of nucleoside components (*13*), side-chain amino acid building blocks (*14*), or deprotection conditions (*15*). Some recent advances in total solid-phase synthesis look promising (*16*), but so far no routine procedure has emerged.

Fragment coupling of peptides to oligonucleotides has found particular utility in the case of longer peptides. One method involves coupling of a protected peptide segment to a support-bound, protected, or partially unprotected oligonucleotide (*17*). A particular advantage of this method is that, as for regular solid-phase synthesis, the excess of reagents is removed easily by filtration. However, coupling yields have been found to be poor in the case of long or "difficult" peptides. A more general approach is the separate solid-phase assembly of oligonucleotide and peptide fragments, deprotection (and purification if necessary) followed by a solution-phase chemoselective ligation mediated by mutually reactive groups introduced into each component during solid-phase assembly or postsynthetically. These methods include formation of disulfide (*18*), thioether (*19*), amide (*20*), oxime (*21*, *22*), thiazolidine (*22*), or imine (*23*) linkages.

An alternative route to synthesis of peptide−oligonucleotide conjugates is by an addition−elimination reaction of a nucleophile to an electrophilic aldehyde group. Here, weakly basic nucleophiles attached to the N-terminus of a peptide should be suitable because they would be expected to have a pK_a lower than that of peptide side chain amino groups (such as of Lys and Arg) and thus should react with aldehydes at pH near or below 7, where aliphatic amino groups of peptide should be

largely protonated. The use of unprotected peptide fragments has several advantages. First, unprotected peptides are usually water-soluble or can be solubilized by addition of organic cosolvents, such as DMF, or denaturing agents, such as urea or guanidinium chloride. Second, products of conjugation reactions may be readily purified by PAGE or HPLC, do not require additional deprotection steps, and thus may be used directly for biological assays. Appropriate nucleophiles which may react with aldehyde groups include *O*-alkyl hydroxylamines, arylhydrazines, acyl- and sulfonylhydrazides, and carbazates. The linkages thus formed are correspondingly oxime and hydrazone, which are sufficiently stable, yet are prone to cleavage by hydrolysis under forcing conditions. Further, 1,2-aminothiols react with carbonyl groups to form thiazolidines, which are also stable over a wide pH range (*24*). Normally, such conjugation reactions are conducted at a slightly acidic pH.

The advantages of an aldehyde group include the possibility of a reversible additive-free conjugation with a range of nucleophiles without an additional preactivation step that is required for other carboxylic groups. There are two well-known ways to introduce an aldehyde group into oligonucleotides through use of solid-phase phosphoramidite chemistry. One route involves use of a masked aldehyde moiety (*25*) such as an acetal. A second approach involves use of a precursor incorporating a suitably protected 1,2-diol group (*26*). Here an aldehyde can be generated under the more convenient and mild conditions of periodate oxidation (*26*), whereas demasking conditions of an aldehyde group can sometimes be harsh (*25*). 1,2-Diols can be obtained by OsO_4-catalyzed hydroxylation of alkenes (*27*). We described recently a new phosphoramidite reagent for incorporation of 1,2-diol groups into oligonucleotides using 2′-modification (*28*). Conjugation of the subsequently generated 2′-aldehydes may be effected through use of any of three alternative chemistries and thus provides the possibility of introducing multiple peptides into defined positions within an oligonucleotide sequence.

The formation of thiazolidines using N-terminal cysteinyl peptides has been used widely for protein ligation and peptide dendrimer formation (*29*). Cysteine residues can also be introduced at the N-terminus of oligonucleotides by use of phosphoramidite reagents developed recently (*30, 31*). A cysteinyl group has been used frequently for peptide–oligonucleotide conjugation through disulfide or thioether formation (*5*), or more recently for native ligation of peptide (*30*) or oligonucleotide thioesters (*32*). Use of organic cosolvents and elevated temperature leads to consistently better results than aqueous buffer alone (*33*). However, the most common polar aprotic solvents DMF and DMSO are not suitable in the case of thiazolidine formation. DMF use results in side reactions, e.g., formylation of peptide amino groups, and DMSO is a mild oxidizing agent that can cause disulfide formation of cysteine peptides (*29*). Use of NMP or acetonitrile as cosolvents usually gives better results.

An *O*-alkyl hydroxylamino group, more specifically an aminooxyacetyl group, has been widely used for peptide ligation (*29, 34, 35*). Recently aminooxy groups have been incorporated into oligonucleotides (*21*) and used in conjugation reactions with reporter groups (*36, 37*) or modified peptides (*21, 22*). Not only is an oxime linkage stable over a wide pH range (*33*), but aminooxyacetic acid per se or Boc-protected is commercially available. The latter can be used directly in the final coupling step in solid-phase peptide synthesis.

Hydrazone formation seems to be a favorite method for coupling of various groups in carbohydrate and protein chemistry (*38*). Sometimes, a reduction by $NaBH_3CN$ is needed to increase the stability of such conjugates to acidic or basic treatment. Peptide hydrazides can be easily generated from esters by hydrazinolysis. An alternative approach that is better suited for solid-phase synthesis is to introduce Fmoc-4-hydrazinobenzoic acid on to the N-terminus of a peptide (*29*). However, since this method seemed not to be altogether successful, we have used our previously developed thiosuccinate reagent, pentafluorophenyl *S*-benzylthiosuccinate (*30*), to generate a succinic acid monohydrazide on the N-terminus of a peptide after a mild hydrazine treatment.

A few papers describe the synthesis of peptide–oligonucleotide conjugates where a peptide is attached to the 2′-position via a 2′-aminonucleoside (*39–41*), but this route can suffer from low yields (*40, 41*). Further, the incorporation of 2′-aminonucleosides and their acyl derivatives strongly decreases duplex stability (*42*).

2′-*O*-Alkyloligonucleotides are widely used in antisense research. As described in a recent review (*43*), 2′-*O*-alkyloligonucleotides in general show improved binding affinity to target mRNA, a large increase in nuclease resistance, and added stability against depurination compared to unmodified oligodeoxyribonucleotides. Incorporation of multiple 2′-*O*-alkylnucleotides is known to preserve an A-type duplex structure when bound to an RNA strand, since, in contrast to 2′-aminonucleosides, 2′-*O*-alkyl-modified nucleosides adopt a sugar conformation similar to that of ribonucleotides. Pendant peptides conjugated through a 2′-*O*-alkyl modification would be expected to be positioned on the minor groove side of an oligonucleotide–RNA duplex. Considering these potential benefits for peptide–oligonucleotide conjugates, we now report the highly efficient conjugation of peptides, either singly or multiply through 2′-aldehydes, to oligodeoxynucleotides and to 2′-*O*-methyloligoribonucleotides. Further, we show that such conjugates are not impaired significantly in their ability to bind to complementary RNA, and in some cases binding is enhanced. We also report that a 12-mer 2′-*O*-methyloligoribonucleotide complementary to the HIV-1 TAR RNA stem-loop and containing two conjugated copies of an 8-mer model laminin peptide was able to inhibit HIV-1 Tat-dependent in vitro transcription as well as the umodified 2′-*O*-methyloligoribonucleotide, suggesting that such conjugation routes should be suitable in principle for attachment of single or multiple cell-penetrating or cell-targeting peptides.

EXPERIMENTAL SECTION

General. Materials were obtained from commercial suppliers and used without further purification unless otherwise noted. Polystyrylmethyl trimethylammonium metaperiodate (loading 2.17 mmol/g) and polystyrylmethyl trimethylammonium borohydride (loading 3.65 mmol/g) were purchased from Novabiochem, creatine phosphate, creatine kinase, poly[d(I-C)] (Boehringer Mannheim), RNAsin, transcription plasmid phRL-CMV (Promega). Analytical HPLC of peptides was carried out with dual wavelength (215 and 230 nm) UV detection using a Vydac RP-C8 column (4.6 × 250 mm). Preparative peptide HPLC was carried out using a Vydac RP-C8 column (25 × 300 mm) and 215 nm UV detection. A gradient of acetonitrile in 0.1% aq TFA from 10 to 90%

in 30 min was used for the HPLC analysis and purification of peptides. HPLC analysis and purification of 5′-O-Dmt-protected oligonucleotides and conjugates were carried out on a Tracor instrument using 4 × 250 mm DIAKS-130-CETYL column; buffer A: 0.1 M ammonium acetate (pH 7); buffer B: 0.1 M ammonium acetate, 40% MeCN, (pH 7); gradient of B from 0 to 100% in 60 min; flow rate 1 mL/min; temperature 45 °C. Oligonucleotides and conjugates were analyzed by a reversed phase HPLC (ion-pair mode) (Waters) on a DIAKS-130-CETYL column (4 × 250 mm) using a logarithmic gradient: 0−45.9% B (1 min); 45.9−49.2% B (1 min); 49.2−53.6% B (3 min); 53.6−56.9% B (5 min); 56.9−60.2 B (10 min); 60.2−62.1% B (10 min); 62.1−63.5% B (10 min). Separation of oligomers with a retention time step of 1 min/unit was carried out; mobile phase A: H_2O-MeCN (95:5 v/v), 2 mM tetrabutylammonium dihydrogen phosphate, 48 mM KH_2PO_4, pH 7; mobile phase B: H_2O-MeCN (60:40 v/v), 2 mM tetrabutylammonium dihydrogen phosphate, 48 mM KH_2PO_4, pH 7; flow rate 1 mL/min, and temperature 45 °C. MALDI-TOF mass spectra were run on a Voyager DE workstation (PE Biosystems) in a freshly prepared 1:1 v/v mixture of 2,6-dihydroxyacetophenone (40 mg/mL in MeOH), and aq diammonium hydrogen citrate (80 mg/mL) as a matrix. Denaturing gel electrophoresis of oligonucleotides was performed in 15% PAGE containing 2 M urea in Tris-borate buffer (50 mM Tris HCl, 50 mM boric acid, 1 mM EDTA, pH 7.5).

Peptide Synthesis and Characterization. Peptides **6** and **7** were purchased from Bachem. Solid-phase peptide synthesis of peptides **8** and **9** was carried out by the solid-phase Fmoc/*tert*-butyl procedure (*44*) on a PE Biosystems Pioneer peptide synthesizer on a 0.05 mmol scale using HATU/DIEA in situ activation protocol (*45*) and Rink amide NovaGel HL support (Novabiochem). Boc-Aminooxyacetic acid for **8** and *S*-benzyl thiosuccinic acid (*30*) for **9** were placed at the last amino acid position and incorporated at the end of normal Fmoc-on solid-phase synthesis protocol by a standard coupling cycle. In the case of **9**, the resin was removed from a column, treated with 0.5 M hydrazine hydrate solution in dioxane for 2 h at room temperature, filtered, washed by DMF, MeOH, and diethyl ether, and finally dried in vacuo. Both peptides **8** and **9** were subjected to normal acidolytic cleavage and deprotection procedure by TFA−phenol−1,2-ethanedithiol−triisopropylsilane−water (900:25:25:25:25 v/v/v/v/v). Resulting peptides were analyzed by RP-HPLC, their respective molecular masses confirmed by a MALDI-TOF analysis; matrix: 10 mg/mL α-cyano-4-hydroxycinnamic acid, 3% (v/v) TFA in H_2O/MeCN (1:2 v/v).

Oligonucleotide Synthesis and Characterization. Oligodeoxyribonucleotides and 2′-*O*-methyloligonucleotides were assembled on a ABI 380B DNA synthesizer by the cyanoethyl phosphoramidite method (*46*) following manufacturer's recommendations. Protected 2′-deoxy- and 2′-*O*-methylnucleoside phosphoramidites were purchased from Glen Research. Prepacked 0.4 μmol columns were used throughout. For couplings with modified phosphoramidite (*28*), 0.15 M concentration in anhydrous acetonitrile was used, and the coupling time was increased to 15 min. Oligonucleotides were cleaved from the support and deprotected using concentrated aq ammonia overnight at 55 °C.

Synthesis of 2′-Aldehyde Oligonucleotides. *Method A (for subsequent thiazolidine conjugation).* To a solution of 2′-diol oligonucleotide (5 A_{260} units, 43 nmol) in 50 mL of 0.2 M acetate buffer, pH 4.5, were added a few granules of polystyrylmethyl trimethylammonium metaperiodate. After 1 h of shaking, the solution was decanted and polymer washed by H_2O (2 × 20 mL). The solution was evaporated in vacuo to remove volatiles.

Method B (other cases). To a solution of 2′-diol oligonucleotide (5 A_{260} units, 43 nmol) in 50 mL of 0.2 M acetate buffer, pH 4.5, was added 5 mL of 0.1 M $NaIO_4$. After 30 min, the reaction mixture was evaporated in vacuo.

Coupling of N-Terminal Cysteine Peptides to 2′-Aldehyde Oligonucleotide. A solution of peptide **6** or **7** (50−70 nmol) in a mixture of 0.4 M acetate buffer, pH 4.5, and acetonitrile (3:7−7:3 v/v, 50 mL) was added to the oligonucleotide **I**. The reaction mixture was incubated at 37 °C for 0.3−18 h and then evaporated in vacuo and purified by PAGE.

Coupling of *O*-Alkylhydroxylamine Derivatives to 2′-Aldehyde Oligonucleotides. A solution of *O*-alkylhydroxylamine derivative (100 nmol of **2** and **5** or 60−70 nmol of **8**) in 50 mL of the mixture of 0.4 M acetate buffer, pH 4.7, and DMSO (3:7−7:3 v/v) was added to an oligonucleotide. The reaction mixture was incubated at 37 °C for 0.3−5 h, depending on the molecular weight of the conjugated molecule and purified by PAGE in the case of peptide conjugates. Other conjugates were precipitated by addition of 0.1 mL of 2 M $LiClO_4$ and 1 mL of acetone and purified by RP-HPLC.

Coupling of Hydrazines and Hydrazides to 2′-Aldehyde Oligonucleotides. A solution of hydrazine or hydrazide (100 nmol of **3** or 60−70 nmol of **9**) in 50 mL of the mixture of 0.4 M acetate buffer, pH 4.7, and DMSO (3:7−7:3 v/v) was added to an oligonucleotide. The reaction mixture was incubated at 37 °C for 0.3−5 h, and then a few granules of polystyrylmethyl trimethylammonium borohydride were added. The reaction mixture was incubated for 30 min more and purified by PAGE in the case of **9**. In the case of **3**, the conjugate was precipitated by addition of 0.1 mL of 2 M $LiClO_4$ and 1 mL of acetone and purified by RP-HPLC.

Analysis of Hydrolytical Stability of Thiazolidine and Oxime Conjugates. Conjugates (0.2 A_{260} units) were dissolved in 20 mL of 0.2 M acetate buffer, pH 2.0, 3.0, or 4.0, or 0.2 M phosphate buffer, pH 8.0, 9.0, or 10.0. After 24 h, conjugates were precipitated by addition of 0.1 mL of 2 M $LiClO_4$ and 1 mL of acetone.

Analysis and Characterization of Peptide−Oligonucleotide Conjugates. Product elution from gel was performed with 0.5 M aq sodium acetate for 12 h at 4 °C. Conjugates were precipitated by addition of 1 mL of EtOH followed by cooling at −70 °C for 1 h. RP-HPLC (ion-pair mode) analyses were carried out as described previously (*28*). Purified conjugates were then analyzed by MALDI-TOF mass spectrometry.

Thermal Melting Experiments. Absorbance vs temperature profiles were measured on a Varian Cary 50 spectrophotometer in a buffer containing 100 mM NaCl, 10 mM Na_2HPO_4, 1 mM EDTA, pH 7.0. Oligonucleotides, conjugates, and their complementary templates were combined at 4 μM of each strand, heated at 90 °C, and cooled at a rate of 0.5 °C/min in a 1 cm path length cell and then heated back to confirm reversibility and lack of evaporation.

In Vitro Transcription Inhibition. Cell-free transcription reactions with DNA template derived from plasmid p10SLT carrying the wild-type HIV-1 LTR (strain NL4-3) were carried out as described previously (*47*, *54*). Briefly, the reaction mixtures (40 μL) containing 15 μL of HeLa cell nuclear extract (*48*), 10 nM −345 to +524 fragment (*Eco*RV-Xba I) of plasmid p10SLT, 80 mM KCl, 3.5 mM $MgCl_2$, 20 mM HEPES (pH 7.9), 2 mM DTT,

10 μM $ZnSO_4$, 10 mM creatine phosphate, 100 μg mL^{-1} creatine kinase, 1 μg of poly[d(I-C)], 50 μM ATP, GTP, and CTP, 5 μM UTP, [α-^{32}P]-UTP (10 μCi), 1 unit mL^{-1} RNAsin, 200 ng of recombinant Tat protein (*48*), and increasing concentrations of inhibitor oligonucleotide were incubated at 30 °C for 20 min and then stopped by addition of 50 μL of 150 mM sodium acetate solution, 0.5% SDS, 10 mM EDTA, and 20 μg mL^{-1} tRNA. After phenol/chloroform extraction and ethanol precipitation, the reaction products were analyzed by 6% PAGE containing 7 M urea followed by autoradiography. The autoradiographs were scanned densitometrically using a Personal SI (Molecular Dynamics, Inc.), and the resulting digitized images were analyzed by Geltrak software (*49*).

For HIV Tat-independent in vitro transcription plasmid phRL-CMV was linearized using Nhe I. Transcription reactions were carried out essentially as in Tat-dependent transcription with minor differencies. The amount of DNA template was 200 ng, the concentration of KCl was decreased to 50 mM and the HIV Tat protein was not added to the reaction mixture. Tat-independent transcription inhibition was assessed at 0.5 and 2 μM concentrations of the inhibitor.

RESULTS AND DISCUSSION

We have described recently the introduction into oligonucleotides of 2′-*O*-(2,3-dihydroxypropyl)uridine as a suitable precursor of an aldehyde group (*28, 50*). The hydroxyl functions of the 1,2-diol in the modified residue were protected by benzoyl groups, which are removable during standard oligonucleotide deprotection with ammonia solution (Scheme 1). For peptide conjugation studies, we chose to introduce 2′-diol-modified uridine in place of thymidine or uridine residues within oligonucleotides complementary to the HIV-1 TAR RNA apical stem-loop, the target sequence for the HIV-1 trans-activator protein Tat (*51*). We have already shown that such oligonucleotides inhibit Tat binding to TAR RNA in vitro (*52, 53*) and that a 12-mer 2′-*O*-methyloligoribonucleotide inhibits Tat-dependent in vitro transcription (*54*). Both oligodeoxynucleotides (**I**, **II**, **III**, and **VII**) and 2′-*O*-methyloligoribonucleotides (**IV**, **V**, and **VI**) were synthesized containing diol modifications.

GCU̲CCCAGGCTCAAA **(VII)**

where U̲ is 2′-*O*-(2,3-dihydroxypropyl)uridine, 2′-deoxynucleotides are capitalized, and 2′-*O*-methyl nucleotidesare in lower case

Oxidation of the 1,2-diol group was carried out under mild conditions, namely a 2-fold excess of $NaIO_4$ in acetate buffer, pH 4.5, 30 min. Polymer-supported periodate may also be used, in which case the reaction time was extended to 1 h (Scheme 1). The latter method is especially suitable for a subsequent thiazolidine conjugation, since it requires just a simple filtration step to remove the excess of periodate. The reaction is not very sensitive to pH, thus allowing a variety of buffers to be used. Subsequent conjugations can be carried out without purification of the aldehyde, except for thiol-containing compounds, which may be oxidized to disulfides by an excess of periodate.

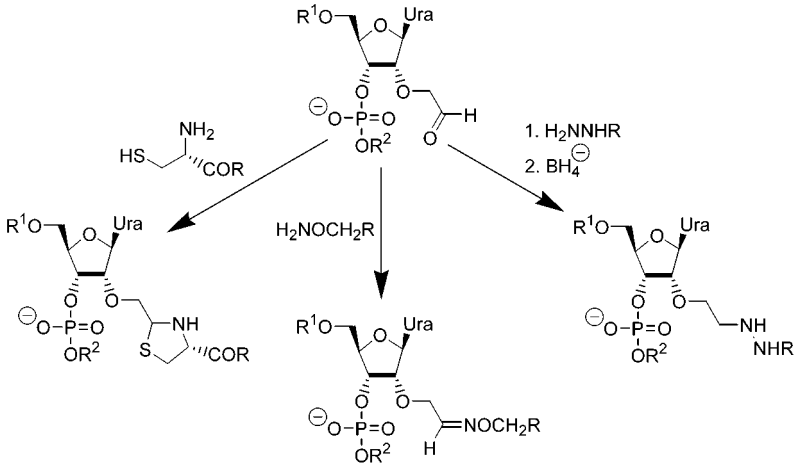
Scheme 1[a]

[a] R^1, R^2 = protected oligonucleotide chain; R^3, R^4 = unprotected oligonucleotide chain; P_1 = controlled pore glass, P_2 = macroporous polystyrene.

For initial conjugation experiments (Scheme 2), we have chosen several model compounds and short peptides (Table 1). Peptide **6** is a glycoprotein hormone α (32−46) receptor binding domain (*55*). Peptide **7** incorporates SV-40 large T antigen NLS sequence (*56*). N-Terminally functionalized peptides **8** and **9** include residues 926−933 of laminin B1 chain. This sequence is known to bind laminin receptors and inhibits angiogenesis and tumor growth (*57*). We have studied the effects of pH, stoichiometry, organic solvent addition, and temperature on the reaction efficiency.

When the pH was increased from 3.5 to 6.0, the time of complete reaction (>95%) was also increased, in the case of L-cysteine ethyl ester from less than 5 min to 20 min. In the case of *O*-benzylhydroxylamine and 4-hydrazinobenzoic acid better results were obtained at pH 4.5−5.0, since after 3 h at pH 3.0 traces of degraded oligonucleotide were observed (data not shown). Therefore, thiazolidine formation was carried out at the safer pH 4.5. The effect of stoichiometry was less significant. Use of a 10-fold excess of nucleophile resulted in reaction proceeding twice as fast as when a nearly equimolar ratio was used. The reaction was therefore routinely carried out in the presence of 1.2−1.8 equiv of nucleophilic peptide.

As previously mentioned, DMF and DMSO are unsuitable for use during thiazolidine formation. Acetonitrile, which can be removed easily by evaporation, and NMP provided the best results, while formamide strongly decreased the efficiency of the reaction (data not shown). The best cosolvent for oxime and hydrazone conjugation was DMSO. At elevated temperature (37 °C) the efficacy of all reactions was increased also. In the case of hydrazinobenzoic acid, the resultant hydrazone was reduced to the corresponding hydrazine linkage by use of polystyryl trimethylammonium borohydride.



Conjugates of 2′-aldehyde-containing oligonucleotides with *O*-benzylhydroxylamine showed two peaks (Figure 1b, peaks *2* and 3) with close retention times on reversed-phase HPLC in ion-pair mode. After reduction by $NaBH_3CN$, only one peak (Figure 1c, peak 4) on the HPLC trace was observed. We therefore conclude that the two peaks represent oxime syn- and anti-isomers.

[a] Type of linkage between oligonucleotide and conjugated moiety: **T** = thiazolidine, **O** = oxime, **H** = hydrazine.

Scheme 2[a]

[a] R^1, R^2 = unprotected oligonucleotide chain; R = conjugated moiety (Table 1).

The hydrolytic stabilities of thiazolidine and oxime conjugates were studied as a function of pH. Purified conjugates were incubated in a suitable buffer for 24 h and then analyzed by RP-HPLC in ion-pair mode (Table 2). Conjugates proved to be stable over a wide pH range, thiazolidine being more stable than oxime.

Initially, we chose to use 4-hydrazinobenzoic acid as a model compound and N-terminal hydrazine modification of peptides (*24*, *29*). However, use of 4-Fmoc-hydrazinobenzoic acid, which is commercially available, may give rise to side-products involving acylation of unprotected nitrogen atoms during solid-phase peptide synthesis under forcing conditions. Therefore, we decided to use our recently developed *S*-benzyl thiosuccinate reagent originally proposed for Fmoc-based solid-supported peptide N-terminal thioester synthesis (*30*). *S*-Benzyl thiosuccinic acid was coupled at the end of normal Fmoc-on solid-phase synthesis by the same HATU-mediated coupling cycle as used for a standard Fmoc amino acid. Then, the resin was treated manually with 0.5 M hydrazine hydrate solution in dioxane for 2 h at room temperature, and, after washing and drying, subjected to normal TFA cleavage. The resulting peptide N-terminal succinyl monohydrazide **9** was analyzed by RP-HPLC and found to be >95% pure and had the correct mass as judged by MALDI-TOF mass spectrometry.

Peptides were conjugated to oligonucleotides under the conditions reported above that were optimized for conjugation of small molecules. The main problem during conjugate synthesis was found to be product isolation and purification, especially in the case of cationic peptides **6** and **7**. Various methods were tried, such as NAP-5 desalting, precipitation by acetone, ethanol, or *n*-butanol, and dialysis, but all of these methods led often to considerable losses of final product. Also we were unable to purify conjugates of peptides **6** and **7** by direct RP-HPLC. In general, the best results were obtained by use of denaturing PAGE, and therefore this method of initial purification was adopted routinely for all conjugates. Analyses of PAGE-purified conjugates by RP-HPLC (ion-pair mode) and by MALDI-TOF MS are presented in Table 3, and a typical HPLC trace is shown in Figure 2.

Table 2. % Hydrolysis of Thiazolidine and Oxime Conjugates at Various pH

	pH					
conjugate[a]	2.0	3.0	4.0	8.0	9.0	10.0
I.1	100	5	<5	<5	10	55
I.2	100	10	<5	<5	30	>90

[a] Oligonucleotides are designated by roman numbers, conjugated molecules by arabic (Table 1).

In the case of the doubly modified 2′-deoxyoligonucleotide III, we were unable to isolate conjugates with cationic peptides (conjugates **III.6** and **III.7)** since during the reaction a white precipitate was formed. This precipitate was insoluble in 4 M NaCl or 2 M $LiClO_4$ and only marginally soluble in DMSO. Further studies will be required to identify more suitable solvent conditions for conjugation of these more demanding peptides. However, conjugates of the singly modified 2′-deoxyoligonucleotide **I** with cationic peptides **6** and **7** were isolated in reasonable yield. Further, good yields were obtained for both singly and doubly modified oligonucleotides **II** and **III** and for singly and doubly modified 2′-*O*-methyloligoribonucleotides **IV**, **V**, and **VI** in conjugation with a model laminin peptides through either oxime or hydrazine linkages (peptides **8** and **9**).

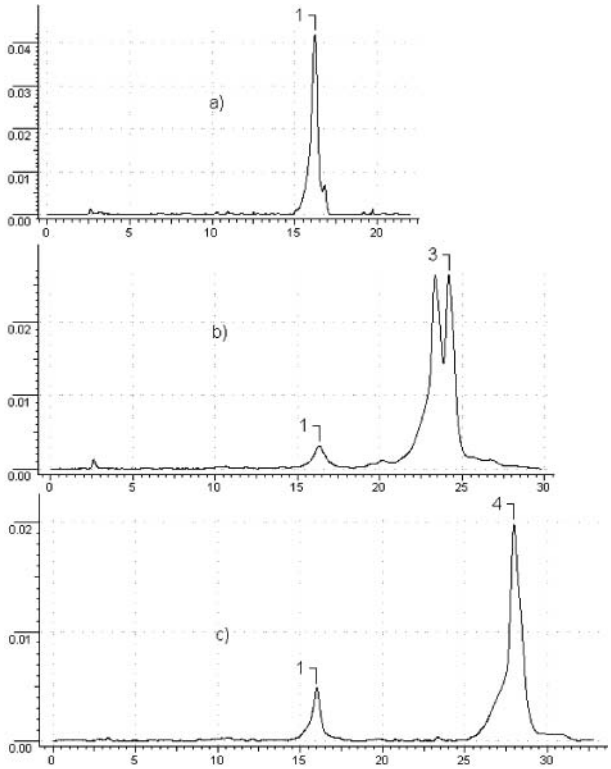

Figure 1. (a) Starting oligonucleotide **VII** (1); (b) reaction mixture of **VII** with *O*-benzylhydroxylamine **2**, peaks 2 and 3 are likely *E*,*Z*-isomers of the conjugate **VII.2**; (c) $NaBH_3CN$ reduction of **VII.2**, peak 4 is the reduced conjugate.

[a] Oligonucleotides are designated by roman numbers, conjugated molecules by arabic (Table 1). [b] RP-HPLC in ion-pair mode (for details, see Experimental Section).

A number of conjugates with various hydrazides, hydrazines, and carbazates were synthesized (Table 4), including reporter group (biotin), marker groups (acridine, pyrene), terephthalic dihydrazide that can be used for oligonucleotide cross-linking, and several lipophilic groups.

We have also studied the influence of 2′-modification and 2′-peptide conjugation on the stability of duplexes formed with complementary DNA and RNA targets. It has been shown previously that incorporation of a similarly modified 2′-*O*-(2,3-dihydroxypropyl)thymidine (*58*,*59*) decreased duplex stability with complementary

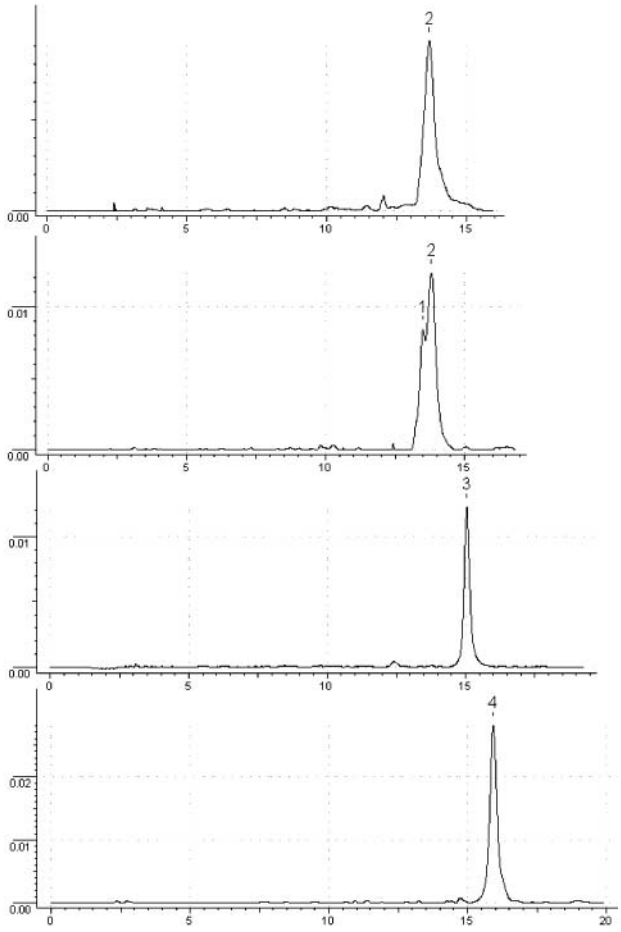

Figure 2. (a) 2′-Aldehyde **III** (2); (b) coinjection of 2′-aldehyde **III** (2) with parent 1,2-diol (1); (c) purified conjugate **II.9** (3); (d) purified conjugate **III.9** (4).

DNA (ΔT_m/mod = −2.2 °C) but increased stability with complementary RNA (ΔT_m/mod = +0.8−1.5 °C). It should be noted that here we have used the corresponding modified U derivative and that replacement of thymidine by uridine of itself would be expected to lead to a duplex T_m decrease of about 0.5 °C (*59*). With this in mind, the thermal melting results of duplexes formed with complementary DNA and RNA targets are summarized in Table 5. In general, the results are in accordance with published data (*5*, *8*). Thus in the case of a DNA target, diol (lines 2−4) or aldehyde modification (lines 5−7) resulted in moderate destabilization of about 3 to 4 °C per residue modified. Very similar destabilizations were found for conjugates with a dipeptide Cys-Gly (lines 8−10), aminooxyacetic acid (lines 11−13) and with a model laminin peptide conjugated through either oxime (lines 14 and 15) or hydrazine linkages (lines 16 and 17). Conjugation of two peptides (**III.8**, **III.9**) decreased duplex stability by about twice the amount seen for conjugation with a single peptide (**II.8**, **II.9**). By contrast in the case of the RNA target, diol modifications were slightly stabilizing (lines 2−4), whereas aldehyde modifications were broadly neutral (lines 5−7, taking into consideration the U for T substitution). Slight stabilization was seen for dipeptide (lines 8−10) and acetic acid conjugates (lines 11−13). Single laminin peptide conjugation (lines 14 and 16) resulted in duplexes melting some 2.8 to 3.1 °C higher, but slightly less stabilization per modification was seen for the double laminin peptide conjugates (lines 15 and 17). The nature of the linkage between peptide and oligonucleotide fragments had little or no influence on

Table 4. Examples of Oligonucleotide II Hydrazine Conjugates with Small Molecules

[a] $\Delta T_m/\text{mod} = [T_m(n) - T_m(1)]/m$, where m is the number of modifications in a duplex. [b] Modified oligonucleotide containing 2′-*O*-(2,3-dihydroxypropyl)uridine.

duplex stability (compare lines 14 with 16 and 15 with 17).

Finally, we have studied the influence of 2′-peptide conjugation on binding of a 12-mer 2′-*O*-methyloligoribonucleotide to its complementary sequence in the apical stem-loop of the HIV-1 TAR RNA (*53, 54*). Under the buffer conditions of transcription (see Experimental Section), single laminin conjugates **IV.8** and **V.8** were insignificantly affected in K_d of binding to the structured TAR RNA target (3.1 ± 0.2 and 4.3 ± 0.9 nM, respectively) compared to the unmodified 2′-*O*-methyloligoribonucleotide (3.2 ± 0.7 nM) (*54*). The double laminin conjugate was only about 2-fold increased in K_d (6.5 ± 0.7 nM). Single and double laminin conjugates of 12-mer 2′-*O*-methyloligoribonucleotides (**IV.8**, **V.8**, and **VI.8**) were tested also for their ability to inhibit Tat-dependent in vitro transcription on an HIV-1 DNA template in the presence of HeLa cell nuclear extract (*54*). The results showed (Figure 3) that the two single laminin conjugates were almost identical in their ability to inhibit Tat-dependent transcription compared to the unconjugated 2′-*O*-methyloligoribonucleotide. For the double laminin conjugate, the inhibition was a little less pronounced at the lower concentrations, but at higher concentrations above 600 nM there was an increased inhibitory power. Control in vitro transcription using a CMV promoter showed that this double laminin conjugate also had significant nonspecific inhibition of constitutive transcriptional activity, particularly above 600 nM, but single laminin conjugates showed only a small nonspecific inhibitory activity (data not shown). It should be borne in mind that the laminin peptide sequence was chosen only as a model and not for any other property. Thus, the nonspecific transcriptional inhibition activity is likely to be inadvertent.

In conclusion, we have shown that oligonucleotides containing 2′-aldehydes generated from 2′-*O*-(2,3-dihydroxypropyl)uridine residues may be conjugated singly or multiply with unprotected peptides by nucleophilic addition−elimination reactions to form thiazolidine, oxime, or hydrazone linkages. Reactions are carried out at pH 4.0−4.5 for thiazolidine and 4.5−5.0 for oxime and hydrazone. The peptide excess can be reduced to 1.2 to 1.8 equiv, and reaction is best carried out at 37 °C in the presence of an organic cosolvent. Similar oxime and thiazolidine conjugation chemistry has been reported recently for the attachment of peptides to 5′-aldehyde-substituted oligonucleotides (*22*). The advantage of our 2′-aldehyde conjugation route is the ability in principle to conjugate more than one peptide at specific locations along the oligonucleotide chain. Further, the 5′- and 3′-termini of the oligonucleotide remain free for attachment of other labels, such as fluorescent or radioactive, or enzyme-catalyzed transformations. In addition, we have

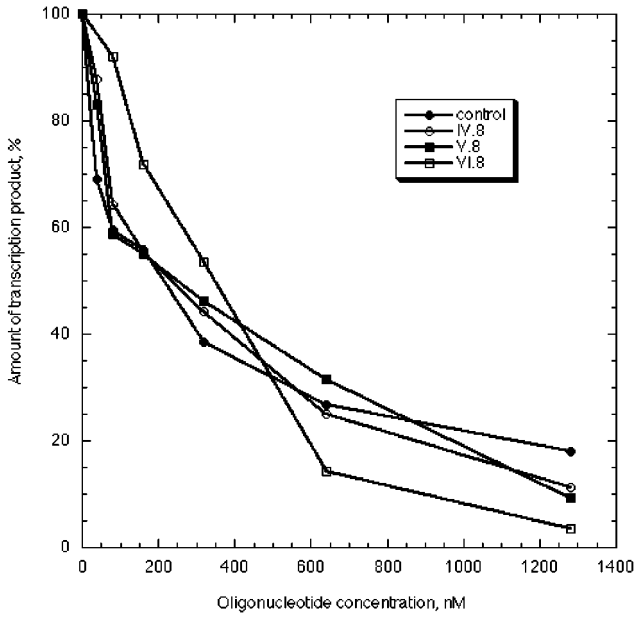

Figure 3. 2′-*O*-Methyloligonucleotide–peptide conjugate inhibition od Tat-dependent in vitro transcription in HeLa cell nuclear extract. Amount of full-length transcript is depicted as a function of oligomer concentration (see inset for key). Control is 2′-*O*-methyldodecamer CUCCCAGGCUCA.

explored a third conjugation procedure by formation of hydrazone linkages, which may be conveniently reduced to hydrazine linkages by use of a solid-supported borohydride reagent.

We have found that for the peptide and small molecule models studied, the resultant peptide–oligonucleotide conjugates generally bind to complementary RNA targets with equally high or better affinity than the corresponding unmodified, unconjugated oligonucleotides. Further, single and double model laminin peptide conjugates of 2′-*O*-methyloligoribonucleotides retained their ability to bind to a structured TAR RNA target and to inhibit HIV-1 Tat-dependent in vitro transcription. Therefore, this 2′-aldehyde conjugation route should be suitable for general use in the design of conjugates of oligonucleotide analogues antisense to RNA targets. We are now exploring these conjugation routes for the attachment of cell-penetrating and cell-targeting peptides in single or multiple copies for cell delivery studies.

ACKNOWLEDGMENT

Intracellular Delivery of Nanometric DNA Particles via the Folate Receptor

Emmanuel Dauty, Jean-Serge Remy, Guy Zuber, and Jean-Paul Behr*

Laboratoire de Chimie Génétique associé CNRS/Université Louis Pasteur de Strasbourg, Faculté de Pharmacie BP 24, 67401 Illkirch, France. Received February 22, 2002

The size of condensed DNA particles is a key determinant for both diffusion to target cells in vivo and intracellular trafficking. The smallest complexes are obtained when each DNA molecule collapses individually. This was achieved using a designed cationic thiol-detergent, tetradecyl-cysteinyl-ornithine (C_{14}COrn). The resulting particles were subsequently stabilized by air-induced dimerization of the detergent into a disulfide lipid on the DNA template. Particles are anionic (zeta potential = −45 mV), and their size (30 nm) corresponds to the volume of a single plasmid DNA molecule. The electrophoretic mobility of the condensed DNA, though quasi-neutralized, was found higher than that of the extended DNA. Moreover, the dimerized $(C_{14}COrn)_2$ lipid was found to be an efficient transfection reagent for various cell lines. In an attempt to achieve extended circulation times and to target tumors by systemic delivery, we have coated the particles with PEG−folate residues. Plasmid DNA was condensed into monomolecular particles as described above and coated by simple mixing with DPPE−PEG−folate. Physicochemical measurements showed particles coated with 2% of DPPE−PEG_{3400}−folate remain monomolecular and are stable in the cell-culture medium. Caveolae-mediated cell entry was demonstrated by ligand-dependence, by competition with excess folic acid as well as by confocal microscopy.

INTRODUCTION

Gene delivery with synthetic DNA vehicles remains an attractive approach to gene therapy. Nonviral systems are essentially based on gene compaction by cooperative electrostatic interaction between DNA phosphates and cationic lipids or polymers (*1*−*4*). Their efficacy depends on their ability to overcome several extra- and intracellular barriers the particles encounter between the site of delivery and the nucleus of the target cells. An ideal synthetic vector should (i) condense DNA into neutral or negatively charged complexes, thus avoiding interaction with anionic plasma and extracellular matrix proteins, (ii) form the smallest possible particles to facilitate diffusion, (iii) mediate cell-specific internalization, and (iv) provide vectorial intracellular trafficking to the nucleus.

A small particle size is considered to be a critical parameter for delivery because of known physiological barriers, such as extravasation through blood vessels (*5*), diffusion through mucus (*6*, *7*) or a tumor mass (*8*). Ligand-mediated cellular uptake may be size-dependent as well (*9*, *10*). It was for instance shown that glycolipid-containing liposomes with a size of 30−70 nm were effectively taken up by the asialoglycoprotein receptor of hepatocytes in vitro and in vivo, whereas 90 nm particles were not (*11*). The next step, intracellular trafficking, is also a size-restricted process. Cytoplasmic diffusion of microinjected fluorescent DNA was measured by fluorescence recovery after photobleaching (*12*). It was found that DNA molecules with size > 1 kbp are essentially immobile. Finally, active nuclear pore crossing of nucleoplasmin-coated gold particles was reported to be restricted to particles with size < 25 nm (*13*). These multiple observations highlight the prime importance of controlling the size of the DNA complexes.

Unfortunately, DNA condensation by cationic lipids or polymers generally leads to large polydisperse aggregates containing many DNA molecules. We therefore developed an alternative two-step technique where plasmid DNA molecules were individually condensed with a designed cationic thiol-detergent. The nanometric particles were then stabilized by air oxidation of the detergent into a disulfide lipid on the DNA template (Figure 1) (*14*, *15*). Clean monomolecular DNA collapse was shown to occur for detergent concentrations below the detergent critical micelle concentration (cmc). Recently, we investigated the properties of a series of novel dimerizable cationic detergents made of various combinations of aliphatic chains and headgroups. The tetradecyl-ornithinyl-cysteine (C_{14}COrn) derivative was found capable of both monomolecular DNA condensation and efficient 3T3 cells transfection (*16*). Here, we present additional physical and biological properties of C_{14}COrn, and we explore surface modification of monomolecular DNA particles as a means to increase both intravenous half-life and cell targeting. It is well-known that grafting of flexible water-soluble poly(ethylene glycol) (PEG) chains to the surface of liposomes increases their intravenous circulation time (*17*, *18*). This is thought to be mainly a consequence of the conformational flexibility of PEG chains. Rather than derivatizing our detergent directly with a cell-specific ligand, we attached the ligand to the distal end of a lipid-conjugated PEG molecule. In this way, surface modification of the particle is simply achieved by mixing with the lipid, and so the ligand extends flexibly away from the particle where it can randomly probe the cell surface (*19*). We chose folic acid as the targeting moiety (Figure 1),

(b) Monomolecular DNA complexes are subsequently coated with PEG−folate residues by means of hydrophobic anchoring.

because certain cancer cells express large amounts of the folic acid receptor.

MATERIALS AND METHODS

Materials. *N*-Hydroxysuccinimidyl-poly(ethyleneglycol)-maleimide (NHS−PEG$_{3400}$−Mal) was purchased from Shearwater Polymers (Huntsville, USA). Dipalmitoylphosphatidylethanolamine (DPPE) and triethylamine (TEA) were from Fluka (St Quentin Fallavier, France). Acetonitrile (ACN), dichloromethane (DCM), *N*,*N*-dimethylformamide (DMF), ethanol (EtOH), methanol (MeOH), and chloroform ($CHCl_3$) were from Carlo Erba (Val de Reuil, France). YOYO-1 and Lissamine rhodamine B-DPPE (DPPE−rhodamine) were from Molecular Probes (Eugene, USA). Transfectam was from Promega (Madison, USA), and JetPEI was from Polyplus (Illkirch, France). The pCMV−Luc plasmid (5.5 kbp) was propagated and purified as described (*20*, *21*). Three additional purification steps were carried out by ultrafiltration (Centricon-100 filter devices, Millipore). Matrix-assisted, laser desorption/ionization time-of-flight spectroscopy (MALDI-TOF-MS) was performed in the positive ion mode using α-cyano-4-hydroxycinnamic acid matrix.

SYNTHESIS

DPPE−PEG$_{3400}$−Mal. DPPE (11.4 mg, 17 μmol) was added to a solution of NHS−PEG$_{3400}$−Mal (50 mg, 14 μmol) in $CHCl_3$ (500 μL), followed by TEA (11 μL, 85 μmol). The resulting suspension was vigorously stirred and maintained at 40 °C for 1 h. The solvent was rotatory evaporated, and the residue was taken up in ACN (2 mL). After being kept for 1 h at −20 °C, the solution was centrifuged to remove traces of insoluble unreacted DPPE and evaporated. The ACN precipitation step was repeated once, and the product was dried in vacuo. Yield: 55.5 mg (96%). TLC ($CHCl_3$/MeOH 85:15) R_f: 0.55. ^{1}H NMR ($CDCl_3$) ∂ 0.88 (t, J = 6 Hz, CH_3, 6H); 1.21−1.35 (s, 48H); 1.57−1.59 (m, CH_2CH_2C=O, 4H); 2.26−2.32 (m, CH_2CH_2C=O, 4H); 3.39−3.48 (m, CH_2NH, 4H); 3.64 (s, PEG, ≈ 300H); 3.82−3.99 (overlapping m, CH_2O−P, $CHCH_2OP$, CH_2−NMal, 6H); 4.13−4.4 (dd, CH_2OC=O, 2H); 5.22 (m, CH, 1H); 6.7 (s, CH_{Mal}, 2H); mass spectrum (MALDI-TOF-MS) The spectrum exhibited a distribution of 44 Da-spaced lines centered at 4345 Da (calculated molecular mass of 4375 Da).

DPPE−PEG$_{3400}$−Folate. Cysteamine-folate (*22*) (2.6 mg, 5.5 μmol) was added to a solution of DPPE−PEG$_{3400}$−Mal (11 mg, 2.5 μmol) in DMF (100 μL), followed by TEA (3.8 μL, 27.5 μmol). The resulting suspension was stirred and maintained at 40 °C for 24 h. The solvent was rotary evaporated, and the residue was taken up in $CHCl_3$ (1 mL). Mass spectrum (MALDI-TOF-MS) The spectrum exhibited a distribution of 44 Da-spaced lines centered at 4825 Da (calculated molecular mass of 4875 Da).

Particle Formation. C_{14}COrn/DNA complexes were prepared by adding the desired amount of detergent (from a 5 mM EtOH stock solution) to 20 μg of pCMV−Luc plasmid DNA in 1 mL of Hepes buffer (15 mM, pH 7.4) under constant stirring. C_{14}COrn/DNA/DPPE−rhodamine complexes were prepared by mixing 36 nmol of C_{14}COrn (N/P = 1.2) and 0.72 nmol (2%) of DPPE−rhodamine in EtOH prior to addition to 20 μg of pCMV−Luc plasmid DNA (60 nmol of phosphates) in 1 mL of Hepes buffer (15 mM, pH 7.4). The DNA concentration was checked by measuring the absorbance at 260 nm before addition of the detergent. The complexes were kept at room temperature to allow cross-linking to occur prior to further characterization. Complexes that were subsequently PEGylated were prepared in advance. Twenty-four hours after mixing plasmid DNA and C_{14}COrn (N/P = 1.2), the desired amount of DPPE−PEG$_{3400}$−folate (from a 0.18 mM solution in EtOH) was added to the complexes. For flow cytometry experiments, plasmid DNA was labeled with YOYO (1 molecule/150 base pairs) before condensation with C_{14}COrn and PEGylation.

Monitoring Complex Formation by Gel Electrophoresis. Twenty microliter samples containing 0.4 μg of pCMV−Luc plasmid DNA in Hepes buffer (15 mM, pH 7.4) were loaded onto a 0.8% agarose gel. The gel was run for 90 min at 8 V/cm in Tris-acetate buffer (40 mM, pH 8). The location of DPPE−rhodamine was assessed by fluorescence spectroscopy (λ_{ex} = 532 nm, λ_{em} = 580 nm) with a Typhoon 8600 apparatus (Amersham Pharmacia Biotech, Orsay, France), and the gel was stained with ethidium bromide to reveal DNA.

Light Scattering Measurements. After overnight oxidation, the particle size and zeta potential were determined by dynamic light scattering using a Zetamaster 3000 (Malvern instruments, Paris, France) with the following specifications: sampling time, 30 s; medium viscosity, 1.054 cP; refractive index, 1.45 (typical liposome RI); scattering angle, 90°; temperature, 25 °C. Data were

analyzed using the multimodal number distribution software included with the instrument. Zeta potentials were measured with the following specifications: sampling time, 30 s; 10 measurements per sample; medium viscosity, 1.054 cP; medium dielectric constant, 80; temperature, 25 °C; beam mode F(Ka) = 1.5 (Smoluchowsky).

Transmission Electron Microscopy. Samples were prepared by adding 36 nmol of C_{14}COrn (N/P = 1.2) to 20 μg of pCMV−Luc plasmid DNA (60 nmol of phosphates) in Hepes buffer (15 mM pH 7.4) and leaving the solution in aerobic condition during 24 h. Carbon films were prepared by sublimation on freshly cleaved mica and recovered by flotation on Cu/Rh grids (300 mesh, Touzard & Matignon, Courtaboeuf, France). After overnight drying, grids were kept on blotting paper in a Petri dish. Immediately before sample addition, grids were glow-discharged (110 mV, 25 s, 25 μA). A drop (5 μL) of sample was left on the grid for 1 min. Complexes were stained with 30 μL of aqueous uranyl acetate (2 % wt/wt) for 20 s, and excess liquid was removed with blotting paper. Observations were performed at 80 kV with a Philips EM 410 transmission electron microscope. Size was determined taking into account the length (L) and the width (l) of each particle (($L + l$)/2).

Cell Culture and Transfection. 3T3 murine fibroblast were grown in Dulbecco's modified Eagles medium (DMEM) (Gibco BRL, Paris, France), BNL CL2 murine hepatocytes in DMEM high glucose (4.5 g/L), HeLa human cervix epitheloid carcinoma in modified Eagles medium (MEM) with Earle's salt (PolyLabo, Strasbourg, France), CHO hamster ovary cells in Ham F-12 (Gibco BRL, Paris, France), and BHK-21 hamster kidney in BHK-21 medium (Gibco BRL). All cell culture media were supplemented with 10% heat-inactivated fetal calf serum (FCS, D. Dutcher, Brumath, France), 2 mM glutamine (Gibco BRL), 100 units/mL penicillin (Gibco BRL), and 100 μg/mL streptomycin (Gibco BRL). Cells were maintained at 37 °C in a 5% CO_2 humidified atmosphere. Complexes were formed by adding at once the desired amount of detergent from the concentrated ethanolic stock solution to the plasmid solution (60 μM phosphate) in Hepes buffer (15 mM, pH 7.4). The solution was kept for 24 h to ensure cross-linking to be completed. Complexes (100 μL of solution corresponding to 2 μg of plasmid per well) were added to the cells maintained in serum-free medium. FCS was added to a final concentration of 10% v/v 3 h later. Transfectam and JetPEI were used as positive controls (*23*, *24*). Cells were lysed 24 h post-transfection, and luciferase gene expression was quantified using a commercial kit (Promega, Cergy Pontoise, France) and a luminometer (Mediators PhL, Wien, Austria). Results were expressed as relative light units (RLU) integrated over 10 s per milligram of cell protein lysate (RLU/mg of protein) using the bicinchoninic acid assay (Pierce, Paris, France). The errors bars represent standard deviation derived from triplicate transfection experiments (± S.D., $n = 3$).

Flow Cytometry. KB cells, a human nasopharyngeal cancer cell line that expresses elevated levels of folate receptors, were cultured in MEM containing 10% heat-inactivated fetal calf serum, 2 mM glutamine, 100 units/mL penicillin, and 100 μg/mL streptomycin, at 37 °C in a 5% CO_2 humidified atmosphere. As described by others (*25*), before each experiment, the cells were grown for two passages in folate-deficient modified Eagle's medium (FDMEM) containing the above-mentioned supplements. Cells were seeded in 24-well plates 24 h before incubation. Immediately prior to incubation with the fluorescent complexes (see "particle formation" paragraph), cells were washed with 1 mL of serum-free FDMEM and incubated for 4 h at 37 °C with particles in 300 μL of serum-free FDMEM (20 μg of plasmid DNA/mL). For the inhibition experiment, incubation was carried out in the presence of 1 mM of free folic acid. After incubation, cells were washed with 1 mL of serum-free FDMEM and incubated 15 min with 100 μg of calf thymus DNA in 0.5 mL of serum-free DMEM to account for any nonspecific electrostatic binding (I. Kopatz, unpublished result). After incubation, the cells were harvested by trypsinization, washed with phosphate-buffer saline (PBS) (centrifugation, 5 min, 500*g*) and suspended in PBS 1% BSA.

Flow cytometric analysis was performed with a FACStar^{Plus} (Becton Dickinson, San Jose, USA) using an argon laser (400 molecular mass power at a wavelength of 488 nm). Sorting windows were used on forward and side scatter to eliminate debris. Granulation, size, and fluorescence (λ_{em} 515 nm) intensity were recorded at a rate of 300 cells/s. Data were analyzed using CellQuest software (Becton Dickinson) and were expressed as mean fluorescence.

Confocal Microscopy. For the confocal microscopy experiments, the cells were cultured on 4-well-chambered cover glass dishes (Lab-Tek, Merck, France) at room temperature. Transfections were done as described above, and the images were taken 24 h post-transfection from living cells on a A MRC-1024ES (Bio-Rad/Elexience, Verrières-le-Buisson, France) confocal laser scanning imaging system equipped with an Eclipse TE 300 (Nikon) inverted microscope, using a 60× water immersion objective. YOYO-labeled DNA was imaged using the 488 nm excitation line of an argon/krypton laser. Confocal sections were taken every 0.8 μm. Digital image recording was performed using the LaserSharp 2.3 software (Bio-Rad).

RESULTS AND DISCUSSION

Synthesis of the Amphiphiles. C_{14}COrn was synthesized as previously described (*16*). To equip the DNA particles with a targeting ligand, we first synthesized a lipid−PEG conjugate capable of inserting within the particle and bearing a maleimide group at its distal end. DPPE−PEG_{3400}−Mal was synthesized from DPPE and the commercially available bifunctional reagent *N*-hydroxysuccinimidyl-poly(ethylene glycol)-maleimide with average molecular mass of 3400 Da. The cysteamine-folate ligand (*22*) was covalently attached to the maleimide group to give DPPE−PEG_{3400}−folate. At the end of the reaction, the desired product was solubilized in $CHCl_3$ and the unreacted cysteamine-folate was simply removed by centrifugation. Sample purity was checked by TLC, and MALDI-TOF analysis of DPPE−PEG_{3400}−folate showed a broad peak centered at $m/z = 4825$ that was consistent with formation of the conjugate (Figure 2).

Monomolecular DNA Condensation. As schematically depicted in Figure 1 path a), anionic DNA molecules were individually condensed with the cationic detergent. Detergents are water-soluble and upon addition of the complexes to cells, their fast exchange with the medium or cell membranes would lead to DNA unfolding (*26*), hence their poor transfection properties (*27*). The particles were therefore stabilized by chemically converting the thiol detergent to a gemini lipid on the template DNA (*14*). In practice, complexes were prepared by adding the desired amount of dimerizable cationic detergent to plasmid DNA, under constant stirring. For each condition, the DNA concentration was determined by measur-

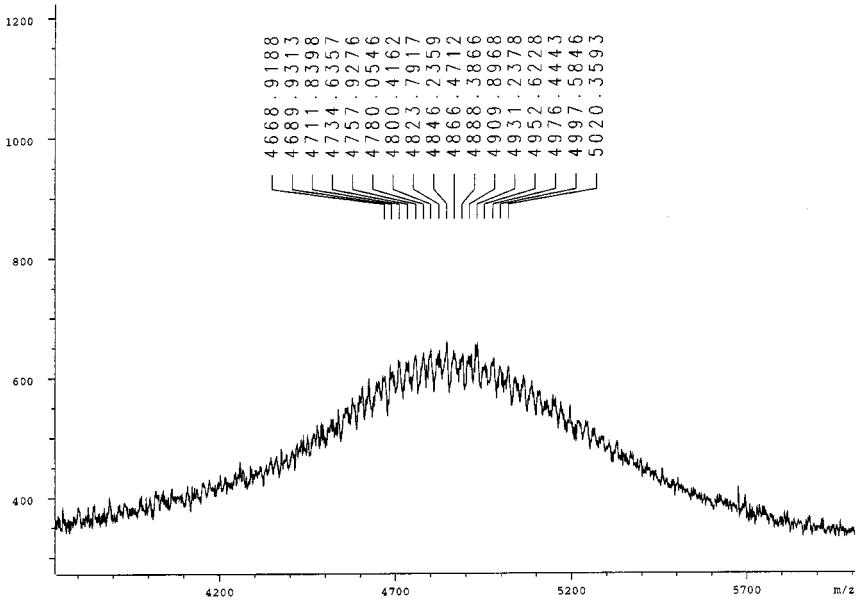

Figure 2. MALDI-TOF spectrum of DPPE−PEG_{3400}−folate.

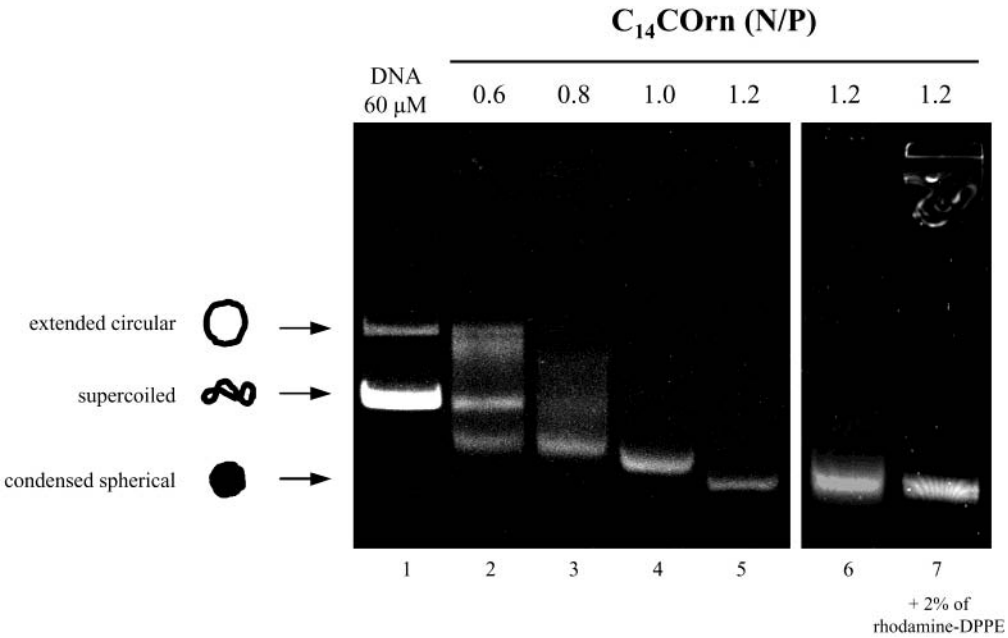

Figure 3. Complex formation as visualized by gel electrophoresis. Free DNA (lane 1) and its complexes with C_{14}COrn for various N/P ratios (lanes 2−5). The gel was stained with ethidium bromide to visualize DNA. The presence of lipid in the particles (N/P 1.2, lane 6) was revealed by addition of 2% of rhodamine-labeled DPPE to the initial mixture (lane 7; fluorescence $\lambda_{ex/em}$: 538/580 nm). Twenty microliter samples containing 0.4 μg of pCMV−Luc plasmid DNA in Hepes buffer (15 mM, pH 7.4), and concentrations of C_{14}COrn detergent as indicated were loaded onto the gel after 6 h incubation.

ing the absorbance at 260 nm before addition of the detergent and complexes were kept at room temperature for at least 4 h to allow cross-linking to occur prior gel electrophoretic analysis. Figure 3 shows the electrophoretic migration pattern observed for plasmid DNA mixed with increasing initial concentrations of C_{14}COrn. For cationic lipids, it is well-known that DNA complexes are too large to migrate into the gel. Here, we found lipid/DNA particles to be fully mobile when formed by oxidation of the detergent in the presence of DNA. At low charge ratios (N/P < 1), the coexistence of free DNA with the complexes showed dimerizable cationic detergent-mediated DNA condensation to be an all-or-nothing process. For a stoichiometric ratio (N/P = 1.0), condensation was completed and particles moved in the gel faster than free plasmid DNA, albeit most DNA phosphate residues were neutralized by the cationic amphiphile. To fully characterize the nature of this surprisingly fast-moving band, its lipidic component was revealed by addition of a 2% rhodamine-labeled DPPE to the initial mixture. The position of rhodamine-labeled DPPE was examined under fluorescence illumination ($\lambda_{ex/em}$: 538/580 nm) before the gel was stained with ethidium bromide to visualize DNA. As shown in Figure 3, the fluorescence of rhodamine colocalized with that of ethidium bromide-intercalated DNA. Stokes diffusion of condensed DNA particles through the agarose gel thus appears to be easier than reptation of the extended micrometric DNA polymer. As already discussed in the introduction, favorable in vivo diffusion and intracellular trafficking properties may thus be expected from the fast migration of the complexes.

The size and surface charge of the $(C_{14}COrn)_2$/DNA particles (N/P = 1.2) were measured by laser light

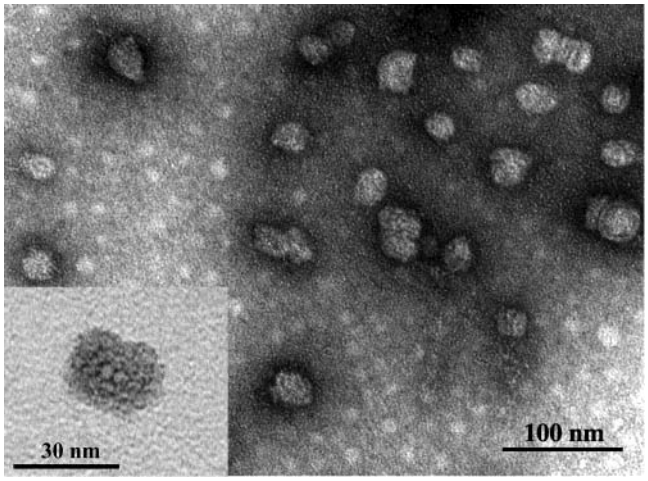

Figure 4. Transmission electron microscopy of $(C_{14}COrn)_2$/DNA particles at N/P = 1.2 in Hepes buffer (15 mM, pH 7.4).

scattering. The average size of the particles and their zeta potential were found to be 39 ± 4 nm and −45 ± 5 mV, respectively. To visualize their morphology and to confirm their size and dispersity, the particles were observed by transmission electron microscopy. A single population of particles with size of 28 ± 4 nm (n = 20) was found (Figure 4). The significantly smaller size found by transmission electronic microscopy may be due to the dehydration process which occurs during sample preparation. According to typical plasmid DNA and amphiphile molecular dimensions, the volume of a monomolecular DNA particle should correspond to a 31 nm sphere. The actual size of the particles thus provides strong evidence for monomolecular collapse of plasmid DNA. Uranyl acetate staining also suggested an internal supramolecular organization consistent with a compacted tubular or micellar phase (Figure 4, inset). This type of packing was previously observed with complexes prepared with Transfectam, a potent cationic lipid transfection reagent (*28*). The similarity of both structures was a good sign that $C_{14}COrn$ would be able to transfect cells.

Cell Transfection Properties of $(C_{14}COrn)_2$. The gene delivery properties of $(C_{14}COrn)_2$/DNA particles were tested on cells of various origins. The transfection

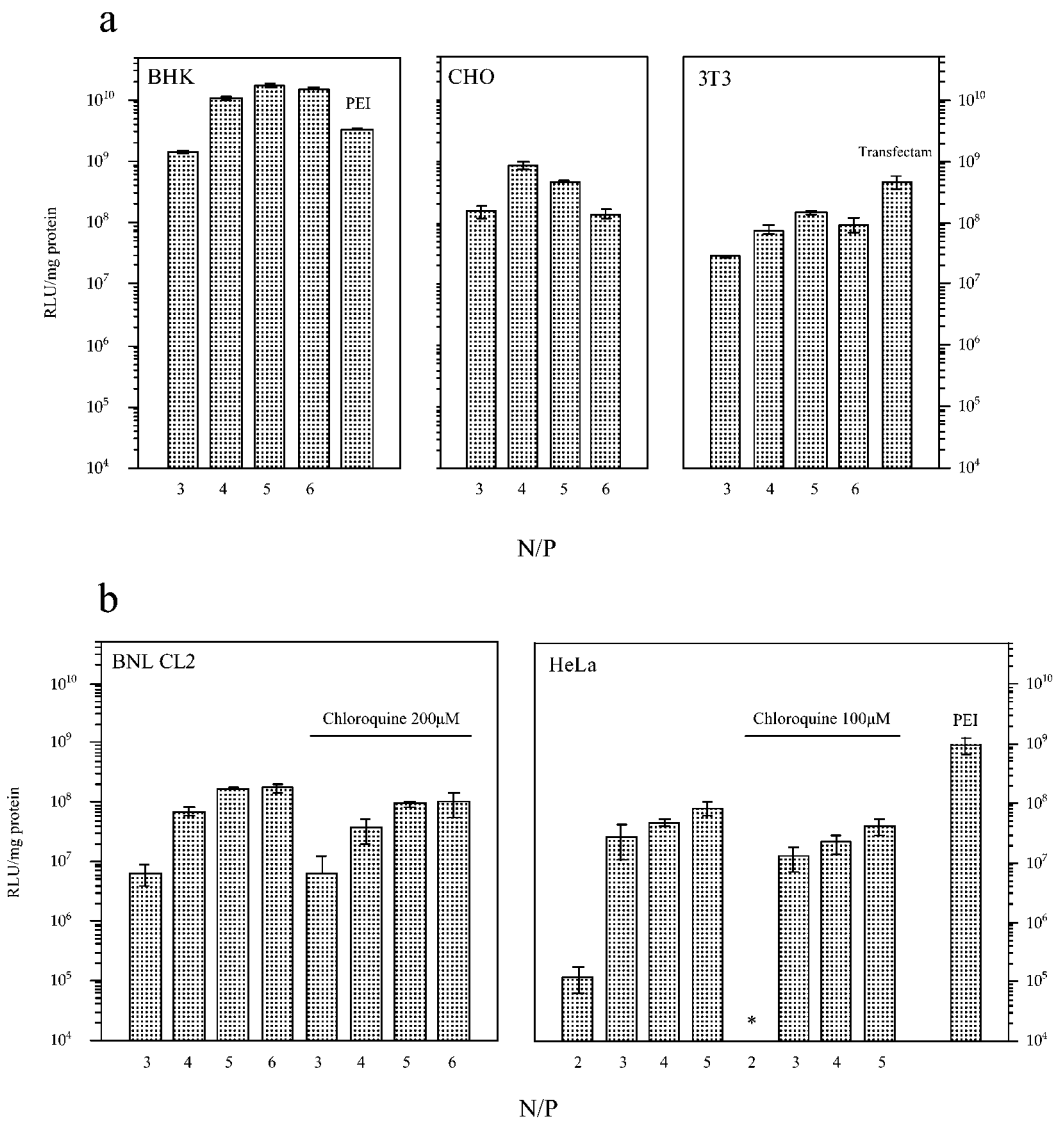

Figure 5. Transfection of BHK, CHO, 3T3, BNL CL2, and HeLa cells. (a) BHK, CHO and 3T3 cells were transfected with pCMV−Luc (2 μg/well) complexed with increasing amounts of $C_{14}COrn$. After 3 h, the transfection medium was completed with 10% FCS, and cells were cultured for an additional 21 h (b) BNL CL-2 and HeLa cells were transfected with pCMV−Luc (2 μg/well) complexed with increasing amounts of $C_{14}COrn$ in the presence or absence of chloroquine. After 3 h, the transfection medium was replaced with fresh culture medium, and cells were cultured for an additional 21 h. Luciferase activity was measured as described in Experimental Procedures. Transfections were carried out in triplicate; error bars indicate standard deviations.

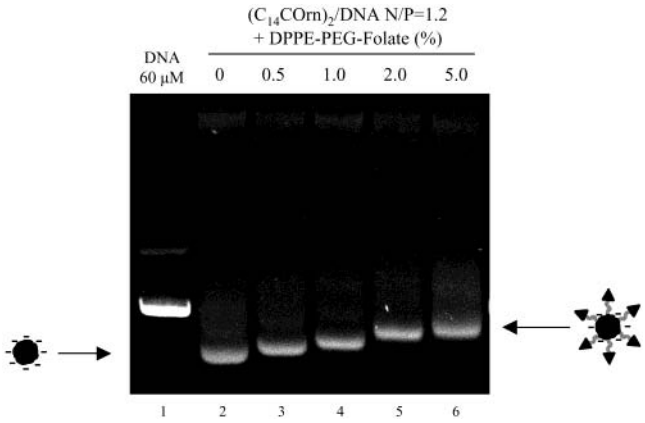

Figure 6. Characterization of $(C_{14}COrn)_2$/DNA/DPPE−PEG_{3400}−folate complexes by agarose gel electrophoresis. The minigel shows plasmid DNA (lane 1) and its complexes with $C_{14}COrn$ 1.2 eq (N/P) with various amounts of DPPE−PEG_{3400}−folate (%): 0, 0.5, 1.0, 2.0, and 5.0 (lanes 2−6). Twenty microliter samples containing 0.4 μg of pCMV−Luc and amphiphile(s) in Hepes buffer (15 mM, pH 7.4) were loaded onto the gel after 24 h incubation.

efficiency of the monomolecular complexes was only slightly above that of naked DNA. Indeed, being devoid of a cationic surface charge (zeta potential of −45 mV), these particles are unable to bind their internalizing receptors, namely, heparan sulfate polyanions (*28*, *29*). Larger cationic particles were therefore prepared with higher N/P ratios, i.e., standard conditions for cationic lipids, and tested in vitro using the luciferase reporter gene. The magnitude of gene expression varied with cell type (Figure 5). However, $(C_{14}COrn)_2$ was always found close to potent transfection reagents such as Transfectam and JetPEI (*23*, *24*). Optimal transfection was observed for N/P = 4−5, which corresponds to the formation of cationic particles. Beyond this optimum, luciferase activity eventually decreased as the N/P ratio was further raised, a possible sign of toxicity. Taken together, these results show that, provided the cationic $(C_{14}COrn)_2$/DNA complexes are able to bind to the cell membrane, they follow the typical intracellular fate of synthetic gene delivery vectors.

Gene expression was not enhanced in the presence of 100 μM (HeLa) or 200 μM (BNL CL2) chloroquine. The $(C_{14}COrn)_2$/DNA complexes must therefore be released from the endosomal compartment by an intrinsic membrane disrupting activity. Treatment of the complexes with a biologically relevant concentration of glutathione (5−20 mM) (*30*, *31*) caused a partial DNA release as seen by electrophoresis (data not shown). Although the cellular compartments in which glutathione is present are not clearly identified, there is some evidence for the presence of glutathione within endosomes (*32*). The cationic disulfide lipid $(C_{14}COrn)_2$ may thus be reduced back into a cationic detergent that causes endosome disruption (*33*, *34*).

PEG-Coated Monomolecular DNA Particles. Systemic delivery through the blood circulation is the most attractive route for transferring genes to nonlocalized tumor metastases. Poly(ethylene glycol) is being extensively used to enhance the stability and the life span of liposomes in the bloodstream, via the so-called "steric-stabilization" mechanism (*17*). Several publications have also described the synthesis of PEG-containing polymers designed to create an inert hydrophilic layer at the surface of DNA condensates, with the aim of improving their solubility and in vivo performances (*35*−*38*). As PEG will also inhibit the ionic interaction between the

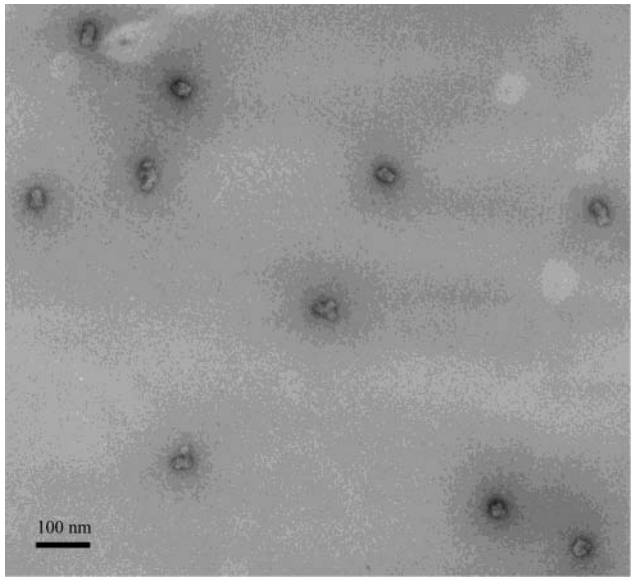

Figure 7. Transmission electron microscopy of $(C_{14}COrn)_2$/DNA/2% DPPE−PEG_{3400}−folate particles at N/P = 1.2 in Hepes buffer (15 mM, pH 7.4).

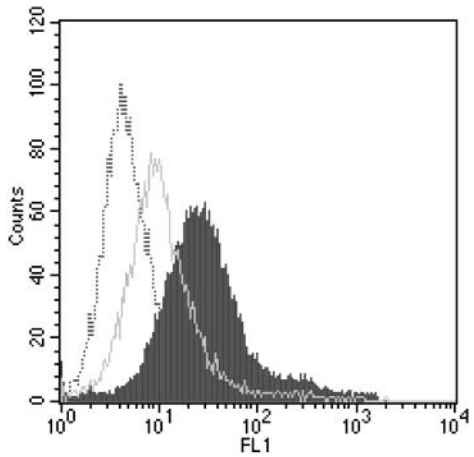

Figure 8. Folate-coated particles adhere to KB cells. Flow cytometry of KB cells exposed for 4 h to 2%-coated DPPE−PEG_{3400}−folate monomolecular YOYO-DNA particles (grey peak). Continuous line: plus 1 mM folic acid. Dotted line: autofluorescence of the cells. *X* axis, fluorescence intensity; *Y* axis, number of cells.

DNA complexes and the cell membrane that leads to cell entry, we coupled folic acid to the remote end of the PEG chain. This vitamin interacts with nanomolar affinity with the folate receptor overexpressed on tumor cells, and is able to trigger receptor-mediated endocytosis of the complexes (*39*). Accordingly, we synthesized a DPPE−PEG_{3400}−folate derivative that may anchor itself into the hydrophobic core particle (Figure 1). Since it was shown that grafting PEG molecules on the condensing agent may interfere with DNA compaction (*40*), we chose a postgrafting strategy. Plasmid DNA was first condensed by the cationic detergent. The monomolecular particles were subsequently coated with the lipid−PEG derivative by simple addition to the aqueous dispersion. The insertion equilibrium was reached within minutes as previously reported by Sou and co-workers in the case of liposomes (*41*). Incorporation was monitored by electrophoresis as a function of the DPPE−PEG_{3400}−folate/C_{14}-COrn ratio (Figure 6). Particles containing 0.5−5% DPPE−PEG_{3400}−folate were stable and able to migrate through the gel. However, their mobility decreased as the

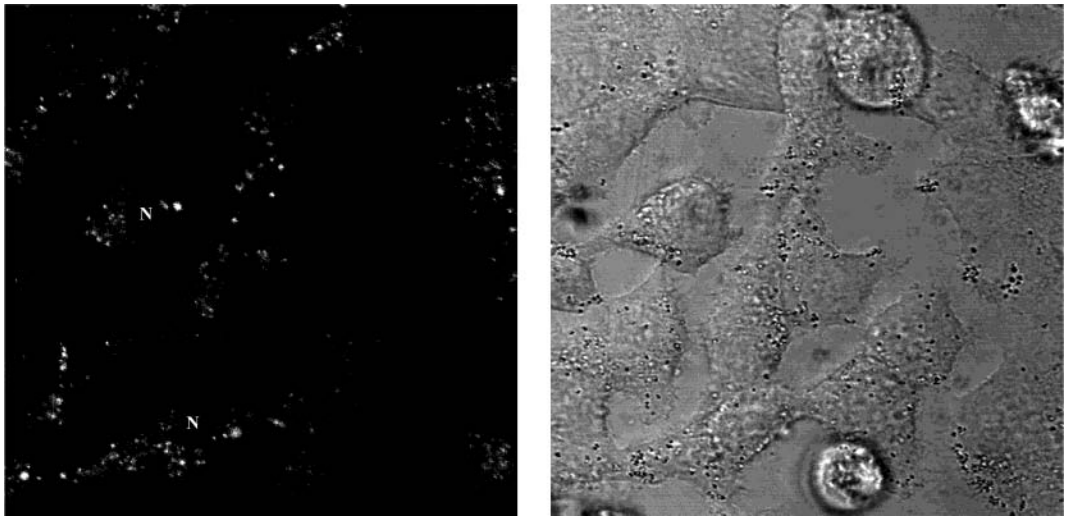

Figure 9. Folate-coated particles are taken up by KB cells. Cells were exposed to 2%-coated DPPE−PEG_{3400}−folate monomolecular YOYO-labeled complexes for 4 h. The medium was subsequently replaced by cell culture medium and cells incubated for an additional 20 h before analysis. Images were taken from living cells. The picture in the left panel corresponds to the fluorescence overlay of z-sections between 2 and 8 μm from the bottom of the cell. The corresponding transmission image is presented in the right panel. N indicates nucleus.

amount of DPPE−PEG_{3400}−folate increased, possibly due to diffusional hindrance brought about by the poly(ethylene glycol) calix (Figure 6).

The optimal in vivo formulation of PEG-grafted liposomes was shown to be reached using 3−7% of DSPE−PEG_{2000} in the lipid mixture (*42*). Since the lipid−PEG was distributed among the two bilayer leaflets, half this percentage should in principle be sufficient to cover a solid particle. The surface of a spherical 35 nm $(C_{14}COrn)_2$/DNA particle is approximately 4000 nm^2. Assuming a PEG_{3400} residue covers roughly 80 nm^2 (*43*), the insertion of ca. 50 molecules DPPE−PEG_{3400}−folate in the particule (i.e., 1%) should be sufficient for effective protection, in rough agreement with the liposome data. Experimentally, particle migration profiles became identical above 2% DPPE−PEG_{3400}−folate. Electron microscopy confirmed that the PEG-coated particles remained compact (Figure 7). Importantly, electrophoresis also showed that coated monomolecular particles did not aggregate in cell-culture medium (data not shown).

Entry into Folate Receptor-Expressing Cells. We finally examined the ability of the particles to carry genes into carcinoma cells overexpressing the folate receptor. The $(C_{14}COrn)_2$/DNA/2%DPPE−PEG_{3400}−folate particles were labeled with the fluorescent DNA-intercalating dye YOYO-1. Particles binding and entry into KB cells was studied by flow cytometry following a 4 h incubation period in folate-free cell culture medium. As shown in Figure 8, virtually all cells took up similar, yet moderate, amounts of the fluorescent complexes. This is to be compared to cationic lipid/DNA complexes, where cellular uptake was shown to be both higher and more heterogeneous (*44*, *45*). Control experiments performed with anionic $(C_{14}COrn)_2$/DNA as well as with $(C_{14}COrn)_2$/DNA/2%DPPE−PEG particles, both lacking the folic acid ligand, confirmed this shift to be significant. Competition experiments in the presence of 1 mM folic acid decreased the amount of particle binding (Figure 8). Effective competition required a large excess of ligand, as a single particle may form multiple tethers with a cluster of receptors on the cell surface. Taken together, these results clearly show that cell binding occurred via the folate receptor.

Unfortunately, transfection results were very disappointing: luciferase activity was found ca. 5 orders of magnitude lower than using JetPEI as a vector. We thus followed the fate of the particles by confocal microscopy (Figure 9). Tiny fluorescent spots were found beneath the cell surface or spread throughout the cytoplasm at 4 h. At 24 h, they were somewhat larger and spread ramdomly. The cytometry (see above) and microscopic observations contrast with typical cationic lipid-mediated transfection, where large clumps of DNA complexes sediment onto the cells, are taken up by heparan sulfate proteoglycan ligation (*46*) and accumulate in a perinuclear compartment (*44*, *45*).

Unsuccessful transfection may thus arise from either (or from a combination) of several factors: (i) 35 nm particles do not sediment well onto the cells; (ii) the number of folate receptors is certainly well below that of ubiquitous anionic proteoglycans; (iii) caveolae are thought to be folic acid-storing organelles and vehicles for transcytosis (*47*). All functions may be nonproductive for gene delivery.

CONCLUSION

This work was meant to be an extension of encouraging results described in the literature that showed that grafting of poly(ethylene glycol)−folic acid residues to DNA complexes led to selective expression of foreign genes in folate-expressing cells in vitro (*35*, *39*, *48*). To our knowledge, these results have had no in vivo developments so far. The size of DNA complexes being a key factor for successful delivery in vivo, we applied our recently developed technique of monomolecular DNA condensation to this goal. The reason we failed up to now is not clear, yet it precludes in vivo experiments. Additional in vitro experiments are being performed.

ACKNOWLEDGMENT

This work was supported by grants and a fellowship (to E.D.) from Vaincre la Mucoviscidose. We warmly thank Dr. Przemyslaw Godzina for help with the mass spectrometer and Liliane Italiano for her skillful technical help.

Differential Conjugation of Tat Peptide to Superparamagnetic Nanoparticles and Its Effect on Cellular Uptake

Ming Zhao,*,† Moritz F. Kircher,† Lee Josephson, and Ralph Weissleder

Center for Molecular Imaging Research, Harvard Medical School, Room 5404, Building 149, 13th Street, Charlestown, Massachusetts 02169. Received February 27, 2002; Revised Manuscript Received April 19, 2002

Surface modification of superparamagnetic contrast agents with HIV-1 tat peptide has emerged as a promising means for intracellular magnetic labeling and noninvasive tracking of a large number of cell types with MRI. To achieve efficient intracellular delivery of the nanoparticles, we investigated the effect on cellular uptake of superparamagnetic iron oxide particles by varying the number of attached tat peptides. First, we report here a modified P2T method in measuring the numbers of surface attachments per particle through disulfide linkage. The method was shown to have desirable simplicity and reproducibility. With the P2T method as a tool, conjugates with progressively higher ratios of peptide-to-particle were synthesized. We were able to demonstrate that higher numbers of tat peptide facilitate the cellular uptake of iron oxide nanoparticles in a nonlinear fashion. Cells labeled with these optimized preparations were readily detectable by MR imaging. The increase in sensitivity could allow in vivo tracking of 100-fold lower cell concentration than currently described.

INTRODUCTION

Magnetic resonance imaging (MRI) has emerged as a potentially powerful tool in the investigation of cell migration in vivo (*1*). With a growing array of cell labeling techniques, cells tagged with various monocrystalline MR probes have been evaluated in the past in their detection both in vitro and in vivo (*1*−*4*).

Among these, HIV-1 tat peptide, which carries a transmembrane and a nuclear localization signal within its sequence (*5*), is capable of translocating exogenous molecules into cells (*6*−*10*). Due to its membrane translocation function, tat peptide has been used to derivatize the surface of magnetic pharmaceuticals and substantially facilitated their uptake into target cells. For instance, using tat conjugated 1,4,7,10-tetraazacyclododecane-*N*,*N*′*N*″*N*‴-tetraacetic acid (DOTA), paramagnetic chelates were delivered to intracellular compartments (*2*). In addition, tat-derivatized CLIO (cross-linked superparamagnetic iron oxide), which consists of dextran-coated superparamagnetic iron oxide nanoparticles and is a potent T_2 shortening agent, has been shown to achieve high loading and allowed ex vivo tracking of progenitor cells to bone marrow (*1*).

In a continuous effort to further improve cell labeling conditions and to achieve maximum detectability of labeled cells, it has become necessary to understand how the number of tat peptide per CLIO particle may influence cellular uptake of the complex. To do so, it is imperative to have a method which can accurately and conveniently determine the peptide-to-CLIO ratio. Here we report such a protocol adapted to measure the degree of conjugation on CLIO through disulfide linkage with simplicity, reliability, and reproducibility. Subsequently, a series of CLIO−tat conjugates with progressively higher numbers of tat peptide per CLIO particle were synthesized based on the assumption that higher numbers of peptides would facilitate cellular targeting with greater density of affinity ligands and/or multivalency effects. We observed that high (above 10 per CLIO) numbers of tat peptide increased the intracellular accumulation of CLIO−tat (up to 100-fold) compared to prior preparations, and that this greatly enhanced the detection threshold of labeled cells.

† These authors made an equal contribution to the study.

MATERIALS AND METHODS

General. A modified tat peptide was synthesized and purified as previously described (*3*), with a sequence GRKKRRQRRRGYK(FITC)C-NH_2. The inclusion of FITC in the peptide sequence is essential for measuring peptide-to-CLIO ratios using the fluorescent absorption method, which is to be compared with the new P2T method (see below). The iodination site (tyrosine), FITC modified lysine, and site of attachment to the nanoparticle (cysteine) are at the C terminal end and separated from the residues involved in membrane translocation by a spacer glycine. The synthesis of amino-CLIO and reaction with *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP) have been described elsewhere (*3*).

Measuring the Degree of Conjugation Using the P2T Method. Tat peptide of appropriate amount was dissolved in DMSO (Fisher) to make a concentrated stock. 37.5 μL of tat solution was mixed with 500 μL of CLIO−P2T (1.5 mg/mL Fe). The mixture was allowed to stand for 2 h at room temperature. At the end of the incubation, 70 μL of the reaction mixture was withdrawn for the measurement of pyridine-2-thione (P2T). A microconcentrator (50 kDa molecular weight cut off, Amicon, Beverly, MA) was used to remove CLIO, and the fraction containing P2T was collected as flow-through. A 50 μL amount of the P2T fraction was diluted to 400 μL using 1 × PBS, pH 7.4. The absorbance of P2T was determined at 343 nm on a spectrophotometer, and its concentration was calculated using an extinction coefficient of 8100 $M^{-1}cm^{-1}$. Tat-to-CLIO ratio was subsequently deduced with known iron concentration in the reaction mixture.

To validate the P2T method, the degree of conjugation was also quantified using fluorescent absorption from

Published on Web 06/08/2002

FITC. Briefly, for a suspension of CLIO−tat, the absorbance was determined at 494 nm and the concentration of FITC was calculated using an extinction coefficient of 73000 M^{-1} cm^{-1}.

Synthesis of CLIO−tat Series with Progressively Higher Ratios. A calibration curve was constructed by setting up a series of reactions in smaller scale with a range of peptide concentrations, while keeping all other conditions constant. In detail, 7.5 μL of each peptide stock solution was mixed with 100 μL aliquots of CLIO−P2T (1.5 mg/mL Fe). The reactions were allowed to proceed as above. In due course, tat-to-CLIO ratios were determined to establish a relationship between the amount of peptide used and the resulting ratios. According to the calibration curve, CLIO−tat conjugates of expected ratios were synthesized and characterized. The products were cleaned of unreacted free peptide and low molecular weight impurities using 1.5 × 5 cm gel filtration column (Sephadex G-50) equilibrated with 1 × PBS, pH 7.4.

Control conjugates were synthesized using a peptide (Gly-Arg-Arg-Lys(FITC)-Cys-NH_2) that lacks the transmembrane and nuclear localization sequence of tat. Two control conjugates were synthesized with 9.7 and 12.9 peptides per CLIO particle, respectively. The products were treated with Bolton−Hunter reagent, SHPP (Pierce) to introduce a phenolic group for iodination (see below). In detail, 50 μL of 8 mg/mL of SHPP was mixed with 500 μL of conjugates at pH 8.0. The reaction was allowed to proceed for 2 h at room temperature. The modified product was purified with 1.5 × 5 cm gel filtration column (Sephadex G-50) equilibrated with 1 × PBS, pH 7.4.

Isolation of Lymphocytes. Lymphocytes were obtained from the spleen of C57 Bl/6 mice (National Cancer Institute, Bethesda, MA). Donor animals were sacrificed by inhalation of an overdose of Halothane, and their spleens were removed using aseptic procedures. The spleens were disrupted between frosted histology slides and dispersed in RPMI 1640 medium (Cellgro; Mediatech, Washington, DC) supplemented with 10% fetal bovine serum (FBS; Cellgro; Mediatech). Cells were filtered through a cell-strainer with 30 μm mesh size (Miltenyi Biotech, Auburn, CA) and washed. Erythrocytes were lysed by resuspending the cell pellet in 0.83% ammonium chloride in distilled water. After being washed further, the cells were incubated in RPMI 1640 supplemented with 10% FBS in 175 cm^2 tissue culture flasks (Falcon; Becton Dickinson Labware, Bedford, MA). To remove the majority of the monocyte/macrophage population, the nonadherent cell population was transferred into a new flask after 1 h. This method yielded a cell population containing about 95% lymphocytes, as described (*11*).

Preparation of ^{125}I-Labeled CLIO−tat. Radioactive labeling of CLIO−tat was performed according to the Chizzonite indirect method using IODO-GEN precoated tubes (Pierce, Rockford, IL) following closely the protocol of the manufacturer (Pierce). Briefly, for each sample of CLIO−tat with different tat-to-CLIO ratios 1 mCi ^{125}I was activated for 7 min at RT in IODO-GEN tubes in 100 μL of Tris iodination buffer. The activated ^{125}I was added to 100 μg of CLIO−tat and reacted for 10 min, followed by a reaction with scavenging buffer (50 μL/sample) for 5 min. The samples were added to 1.5 × 5 cm gel filtration columns (Sephadex G-50) and centrifuged at 400*g* for 5 min and the eluates collected. Immediately before performing cell uptake assays, the labeled samples were again purified and equilibrated to the culture conditions with 1.5 × 5 cm gel filtration columns (Sephadex G-50) equilibrated with RPMI-1640 supplemented with 10% FBS.

Cell Uptake Assay. To quantify the cellular uptake of the different CLIO−tat conjugates, 20 μg ^{125}I−CLIO−tat was added to lymphocytes in RPMI-1640 supplemented with 10% FBS at a final concentration of 10^6 cells/ml. Cells were incubated for 2 h in coated (1% BSA in Hanks' balanced salt solution (HBSS; Cellgro; Mediatech)) 5 mL polystyrene culture tubes (Fisher Scientific, Pittsburgh, PA) and incubated at 37 °C, 5% CO_2 in a humidified atmosphere. After an initial washing step with 4 mL HBSS cells were washed 3 times by centrifugation through a step gradient of 40% Histopaque-1077 (Sigma; St. Louis, MO) in HBSS. The cell-pellets were then transferred to a new set of culture tubes and washed again in HBSS. Cell numbers per tube and numbers of viable lymphocytes were determined by trypan blue stain exclusion in a hemocytometer (Fisher Scientific). After aspiration of the supernatant, cell pellets were counted in a gamma counter (Model 1282 Compugamma CS; LKB Wallac, Turku, Finland). Background counts were subtracted, and cell uptake was calculated by scaling cpm/tube to the number of cells/tube. All experiments were performed in triplicate.

Conjugates with thioether (SC) linkage were synthesized using a heterobifunctional cross linker *N*-succinimidyl iodoacetate (SIA). Briefly, CLIO-NH_2 was treated with SIA to introduce iodoacetyl groups, which then reacted with free SH on tat peptides to form SC bonds. The conjugates were purified, radiolabeled, and tested for cellular uptake as described above.

MR Imaging. Phantoms were prepared by immobilizing 10 million cells in 0.8% low-melting agarose (Bio-Rad, Hercules, CA) in small plastic tubes in a final volume of 100 μL per sample. The tubes were embedded in 1% agarose (Bio-Rad) and imaged with a 1.5 T superconducting magnet (Signa 5.0; GE Medical Systems, Milwaukee, WI) using a 3-in. surface coil. A T_2-weighted spin−echo sequence with the timing parameters 3000/60 (TR/TE) was used. Slice thickness was 1 mm, field of view (FOV) 7 × 7 cm, imaging matrix 256 × 256, and number of excitations (NEX) 2.

RESULTS AND DISCUSSION

Noninvasive cell tracking using MRI is being established as a powerful tool in monitoring cell migration in real time in vivo and native environments. Surface modification with HIV-1 tat peptide on a number of MR probes has resulted in substantially enhanced uptake and hence improved MR detection of labeled cells in tissue. In the current study, we set out to optimize CLIO−tat preparations by systematically altering the degree of tat attachment on the surface of CLIO, a potent nanometer T_2/T_2* contrast agent.

To meet this goal, a P2T method was adapted and evaluated in measuring the degree of conjugation on CLIO through disulfide linkage. Instead of directly assaying for the amount of attached peptide, the method determines the average number of pyridine-2-thione (P2T) groups released during conjugation reaction (Figure 1) (*12*). The number of displaced P2T is strictly equal to that of disulfide bonds formed, which in turn reflects the amount of peptide covalently attached on the surface of CLIO.

The usefulness of the P2T method can be summarized as follows. First, P2T is relatively stable, and the absorbance of P2T at 343 nm varied less than 5% within a 24-hour period in aqueous solution, at room temperature

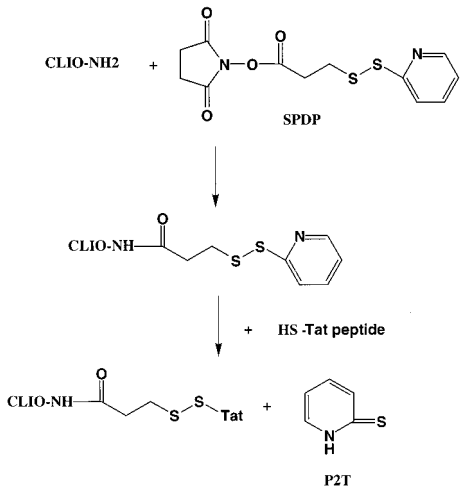

Figure 1. Synthesis of CLIO−tat with disulfide linkage, with P2T as a measurable byproduct.

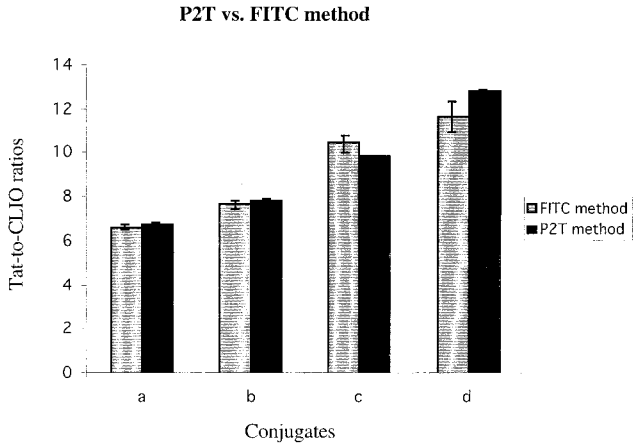

Figure 2. Direct comparison between fluorescent absorption and 2 PY method. Tat-to-CLIO ratios were determined for four conjugates, a, b, c, and d, using the fluorescent absorption method (gray) and P2T method (black), respectively. Error bars indicate the SD ($n = 3$).

(data not shown), whereas the conjugation reaction approaches completion in minutes. Thus uncertainties arisen from P2T degradation are negligible. Second, a distinct absorbance of P2T at 343 nm is well resolved from other chemical components in the reaction. The absorbance of peptides occurs over wavelength below 300 nm, creating little or no interference with P2T measurement. In the same sense, the P2T method could be applied equally well in the conjugation of proteins and nucleic acids, where both are commonly known to have absorbance at below 300 nm. In addition, the method measures the degree of conjugation by determining the number of disulfide bond formation, therefore eliminating the need to tag the peptide or protein solely for quantification purposes.

To evaluate the effectiveness of the P2T method, the degree of conjugation determined using this method was compared with that quantified from FITC absorbance at 494 nm. Figure 2 illustrates the comparison from two preparations. The average numbers of tat peptide per CLIO particle as determined by the two methods have good agreement and are within ±10% variation of each other. Quantification using FITC absorbance directly measures the number of peptide carried on CLIO and thus serves as an authentic standard in the evaluation

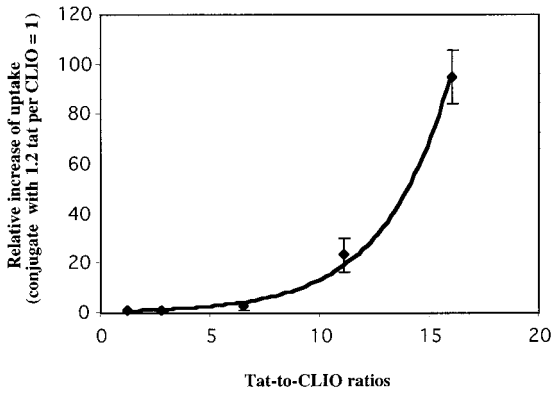

Figure 3. Cellular uptake of radio-labeled CLIO−tat as a function of tat-to-CLIO ratio. The uptake levels of different conjugates are expressed in relative to the conjugate with the lowest tat-to-CLIO ratio. Error bars indicate the SD ($n = 3$).

of the P2T method. By doing so, the latter was shown to have excellent accuracy, reliability, and reproducibility.

With a reliable method to determine the degree of conjugation, a series of CLIO−tat conjugates were designed for cell uptake studies, carrying a progressively increasing number of tat per particle. A calibration curve was constructed between the amount of tat peptide used in the reaction mixture and the resultant tat-to-CLIO ratios. On the basis of the calibration curve, conjugates were synthesized with progressively higher tat/CLIO ratios. The maximum number of peptide which can be attached to CLIO is ultimately limited by the reactive sites on the surface of CLIO particles, where CLIO−NH_2 carries 20−30 amine groups in average per particle. In addition, the degree of conjugation is influenced by the size and hydrophobicity of the peptide. We have observed that the solubility of CLIO can be severely lowered when attached with high number of larger, more hydrophobic peptides.

With a series of CLIO−tat conjugates, the effect of increasing numbers of tat per CLIO particle on cellular uptake could be demonstrated with radiolabeled ^{125}I-CLIO−tat using mouse lymphocytes. As expected, a substantial increase in radioactivity uptake is associated with progressively higher tat-to-CLIO ratios (Figure 3). This effect was clearly not linear, and the observed exponential pattern suggested a role of multivalency. Overall, an increase of 15 tat per CLIO resulted in an elevation of radioactivity uptake of roughly 100 folds. While the current studies used a SS linkage between tat and CLIO, it could be argued that this instability would offset cellular uptake by degradation in serum, our results indicated that this was not the case during the relatively short incubation periods. In addition, comparative studies using similar CLIO−tat preparations containing SC linkage resulted in similar cellular uptake curves. These observations suggested a less important role of the linker type in cellular uptake. In control experiments, where CLIO was attached to similar degrees with a short peptide lacking the transmembrane and nuclear localization sequences, the uptake was near background level. This result indicated that neither the disulfide linker nor FITC contributes to the internalization of CLIO−tat complex.

A dramatically elevated cellular uptake at high tat-to-CLIO ratios is further demonstrated using T_2 weighted MRI (Figure 4). After a 2-h incubation in 20 ng/mL Fe with each of the conjugates, the cells were washed thoroughly and fixed in a phantom, and T_2-weighted MR images were acquired. Changes in signal intensity from

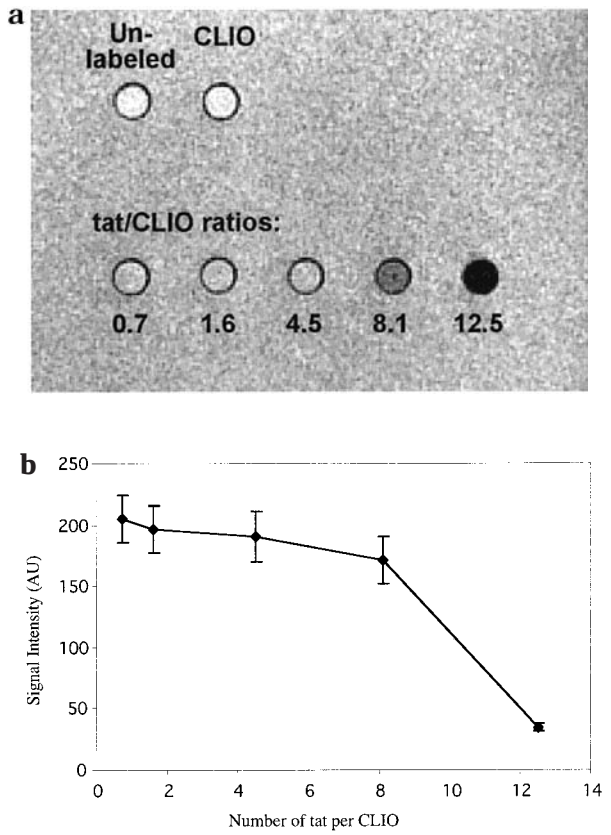

Figure 4. T_2 weighted spin–echo images of cells incubated with a series of CLIO–tat conjugates of progressively increasing tat-to-CLIO ratios. A, 10 million cells were immobilized in 0.8% agar in 100 μL volume. The top row includes images of unlabeled cells (left) and plain CLIO (right). Images in the bottom row were from cells incubated with identical iron concentration of CLIO–tat with increasing tat-to-CLIO ratios. B, relative signal intensities were averaged and plotted as a function of tat-to-CLIO ratios.

cells labeled with plain CLIO were barely detectable compared with unlabeled cells. Magnetic effects from the low tat-to-CLIO conjugates produced little detectable effect. In particular, one to three tat peptides per CLIO generated little difference upon visual inspection of the images. With increasing numbers of tat, the magnetic effect becomes significantly more prominent. At the highest ratio, there were no signs of toxic effects observed with trypan blue exclusion staining.

Finally, the MRI data is consistent with the result from radioactivity uptake experiments in that the loss in signal intensity is clearly associated with progressively increasing tat-to-CLIO ratios. A cluster of basic amino acids in tat peptide is thought to be crucial for membrane translocation (*13*). In addition, the GRKKR nuclear localization signal within its sequence may play a role in the rapid accumulation in the nuclear regions (*13*). Indeed, using a monoclonal antibody against dextran, which is the polysaccharide coating of CLIO, it has been demonstrated that CLIO–tat particles are internalized and localized in and through the nucleus (*3*). These reports confirmed that the observed elevation in radioactivity uptake and the loss of MR signal intensity are caused by the intracellular accumulation of CLIO–tat particles, and that the number of tat peptide on the surface of CLIO dramatically influences uptake of the contrast agent. Once internalized, CLIO–tat is distributed to daughter cells during cell divisions. This can be seen in flow cytometric studies of CLIO–tat labeled cells where cell proliferation is accompanied by a decrease of mean signal intensity and increase in signal heterogeneity (Weissleder, unpublished observations). In addition, the material is clearly biodegradable as demonstrated in nondividing cells and by experiments in vivo (data not shown). We had previously shown that the iron from a CLIO precursor gradually enters global iron metabolism. This is evident from observed decrease in the apparent T_2 effect from injected iron oxide contrast agent over a period of days in vivo and that ^{59}Fe radio tracer became incorporated into hemoglobin of red blood cells (*14*).

In conclusion, we describe a P2T method adapted to determine the degree of conjugation in peptide/protein and CLIO complex with disulfide linkage. The method was shown with simplicity, accuracy, and reproducibility. Using a series of conjugates with progressively increasing numbers of tat peptide per CLIO particle, we demonstrated the multivalent effect of peptide conjugation on cellular uptake, which led to a vastly improved CLIO–tat preparation with 100-fold increase in cell labeling efficiency. This would translate directly into lower detection thresholds of labeled cells in vivo, where imaging of individual, magnetically labeled cells has been a long cherished goal, particularly in tracking immune cells and stem cells.

Polyethylenimine-*graft*-Poly(ethylene glycol) Copolymers: Influence of Copolymer Block Structure on DNA Complexation and Biological Activities as Gene Delivery System

Holger Petersen,[†] Petra M. Fechner,[†] Alison L. Martin,[‡] Klaus Kunath,[†] Snjezana Stolnik,[‡] Clive J. Roberts,[‡] Dagmar Fischer,[†] Martyn C. Davies,[‡] and Thomas Kissel*[,†]

Department of Pharmaceutics and Biopharmacy, Philipps University, Ketzerbach 63, D-35032 Marburg, Germany, and School of Pharmaceutical Sciences, University of Nottingham, University Park, Nottingham, NG7 2RD, United Kingdom . Received March 18, 2002; Revised Manuscript Received April 25, 2002

For two series of polyethylenimine-*graft*-poly(ethylene glycol) (PEI-*g*-PEG) block copolymers, the influence of copolymer structure on DNA complexation was investigated and physicochemical properties of these complexes were compared with the results of blood compatibility, cytotoxicity, and transfection activity assays. In the first series, PEI (25 kDa) was grafted to different degrees of substitution with PEG (5 kDa) and in the second series the molecular weight (MW) of PEG was varied (550 Da to 20 kDa). Using atomic force microscopy, we found that the copolymer block structure strongly influenced the DNA complex size and morphology: PEG 5 kDa significantly reduced the diameter of the spherical complexes from 142 ± 59 to 61 ± 28 nm. With increasing degree of PEG grafting, complexation of DNA was impeded and complexes lost their spherical shape. Copolymers with PEG 20 kDa yielded small, compact complexes with DNA (51 ± 23 nm) whereas copolymers with PEG 550 Da resulted in large and diffuse structures (130 ± 60 nm). The ζ-potential of complexes was reduced with increasing degree of PEG grafting if MW ≥ 5 kDa. PEG 550 Da did not shield positive charges of PEI sufficiently leading to hemolysis and erythrocyte aggregation. Cytotoxicity (lactate dehydrogenase assay) was independent of MW of PEG but affected by the degree of PEG substitution: all copolymers with more than six PEG blocks formed DNA complexes of low toxicity. Finally, transfection efficiency of the complexes was studied. The combination of large particles, low toxicity, and high positive surface charge as in the case of copolymers with many PEG 550 Da blocks proved to be most efficient for in vitro gene transfer. To conclude, the degree of PEGylation and the MW of PEG were found to strongly influence DNA condensation of PEI and therefore also affect the biological activity of the PEI-*g*-PEG/DNA complexes. These results provide a basis for the rational design of block copolymer gene delivery systems.

INTRODUCTION

Surface modification of drug delivery systems with PEG[1] has met with increasing interest to enhance biocompatibility (*1*), increase systemic circulation times (*2*), and alter their biodistribution (*3*). For instance, nanoparticles (*4*), liposomes (*5*), and also adenoviruses (*6*) have been "PEGylated" mainly to obtain long-circulating particulate delivery systems, based on the so-called "stealth" effect. Recently, PEGylation methodology has been reviewed (*7*). PEGylation of polycations for gene delivery has also been realized leading to block or graft copolymers as summarized in refs *8* and *9*. Among other polycations, PLL has been modified by PEGylation (*10*−*12*) most extensively with the result of reduced complement activation and an increase of DNA complex stability. However, PLL requires endosome disruptive reagents such as chloroquine (*13*) to attain sufficient transgene expression. As compared to PLL, PEI has successfully been used for gene delivery both under in vitro (*14*, *15*) and in vivo (*16*, *17*) conditions. PEI offers a high positive charge density and exhibits a strong proton buffer capacity over a broad pH range (*18*). The latter characteristic is advantageous for PEI since the proton-sponge effect (*19*) allows sufficient gene transfer without endosome disruptive reagents.

PEGylated PEIs have been studied by several authors as potential gene delivery systems. For instance, PEI 25 kDa was grafted with three and 10 PEG 3400 Da blocks carrying a terminal galactose ligand for hepatocyte targeting (*20*). Kabanov and co-workers modified PEI 25 kDa with 37 and 61 PEG 5 kDa blocks and PEI 2 kDa with two blocks of PEG 8 kDa and one block of PEG 10 kDa (*21*, *22*) to study the influence of PEG on oligonucleotide and plasmid DNA complexation. Instead, Choi et al. grafted PEI 25 kDa with 40 and 133 short blocks of PEG 550 Da (*23*) and applied this copolymer for in vitro gene transfer. While all of these groups grafted the PEG onto PEI first and formed the DNA complexes in a subsequent step, Wagner and co-workers first condensed

DNA with PEI 800 kDa and subsequently grafted the complex with more than 1600 blocks of PEG 5 kDa (*24*, *25*).

Nevertheless, PEGylation of PEI has not been studied varying both the degree of substitution and the MW of PEG under similar experimental conditions to our knowledge. A retrospective comparison of literature data obtained with PEI of different MW and different experimental conditions is notoriously difficult. Therefore, our investigations were aimed at providing a PEI-*g*-PEG block copolymer sample set in which PEI is kept constant but the extent of PEGylation and the MW of the PEG is varied. Here, we use two series of PEI-*g*-PEG block copolymers in an effort to elucidate the influence of copolymer block structure on DNA condensation (copolymer structure/complex property relationship) and in a second step to compare the physicochemical properties of the complexes with their biological activity revealed in cell culture experiments (complex property/biological activity relationship).

MATERIALS AND METHODS

Materials. bPEI with a MW of 25 kDa (Polymin water free, 99%) was a gift of BASF, Ludwigshafen, Germany. mPEG 550 Da and mPEG 5 kDa were obtained from Aldrich, Milwaukee, WI. Monoamino-mPEG (mPEG-NH_2) 20 kDa was purchased from Rapp Polymere, Tübingen, Germany. All polymers were thoroughly dried in vacuo before use. HMDI (≥99%) was from Fluka, Deisenhofen, Germany. Chloroform (Riedel-de Haën, Seelze, Germany, ≥99%) was treated with HMDI for 4 h at 60 °C and distilled to remove any traces of water and ethanol. Diethyl ether (≥99.5%) from Merck, Darmstadt, Germany, was distilled before use. Light petrol (≥99%, 40−60 °C) was from Riedel-de Haën.

Three different types of DNA were used in this work. DNA from herring testes (Type XIV, 0.3−6.6 MDa, 400−10 000 bp) and plasmid DNA pBR322 (2.9 MDa, 4363 bp) were from Sigma, Steinheim, Germany. Plasmid pGL3 control, luciferase reporter vector (3.5 MDa, 5256 bp) was from Promega, Heidelberg, Germany, and was amplified with a competent *Escherichia coli* strain JM 109 (Promega) according to a protocol from QIAGEN, Hilden, Germany (*26*).

Block Copolymer Synthesis. Synthesis and characterization of the block copolymers has been described in detail elsewhere (*27*, *28*). Briefly, PEG dissolved in anhydrous chloroform ($c = 200$ g/L) was activated for the reaction with the amino groups of PEI with a 10−100-fold excess of HMDI at 60 °C for 8−72 h depending on the MW of PEG (higher MW required longer reaction times). Unreacted HMDI was carefully removed by repetitive extraction with light petrol. Activated PEGs were reacted with PEI at concentrations of 10 g/L in anhydrous chloroform at 60 °C for 8−72 h. The reaction solutions were concentrated to 100 g/L by evaporation of the solvent and dropped into a 20-fold larger volume of diethyl ether to obtain the copolymer by precipitation. Finally, the products were dried in vacuo. Polymers were characterized by ^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectroscopy, which verified the structure of the copolymers and allowed calculation of the composition of ethylenimine and ethylene glycol units in the copolymer. Size exclusion chromatography demonstrated the absence of unreacted PEG and PEI homopolymers. Thus, no further purification steps were necessary.

Formation of the Copolymer−DNA Complexes. All complexes of DNA and polymer were prepared freshly before use. Polymer solutions were added to the DNA solutions in equal volumes, mixed by vortexing, and incubated for 10 min before use unless otherwise stated. DNA stock solutions were diluted to a concentration of 20 μg/mL with 10 mM NaCl at pH 7.4 (AFM experiments) or to 40 μg/mL (all other experiments) with 150 mM NaCl at pH 7.4. The polymer stock solutions were diluted with the same medium as above to the appropriate concentration depending on the required N/P ratio and filtered through 0.22 μm. DNA stock solutions were 2 mg/mL pGL3 plasmid in 10 mM TRIS HCl (pH 8) and 1 mM EDTA, 100 μg/mL pBR322 plasmid in pure reagent water, and 1.11 mg/mL herring testes DNA in 10 mM TRIS HCl (pH 7.4). Homopolymer and copolymer stock solutions were 0.5 mg PEI/mL (AFM experiments) and 0.9 mg PEI/mL (all other experiments) so that all polymer solutions contained the same PEI concentration.

Physicochemical Characterization of Copolymer−DNA Complexes. *AFM.* AFM images were conducted on a Dimension3000 Scanning Probe Microscope from Digital Instruments (Santa Barbara, CA) with a Nanoscope IIIa controller. The solution of polymer−DNA complex was prepared as described above and incubated for 5 min before it was deposited onto freshly cleaved mica and imaged under 10 mM NaCl solution. Immobilization was achieved using electrostatic forces between the opposite charges of the mica and polymer−DNA complexes. All imaging was carried out in the tapping mode at a scan speed of approximately 2 Hz with 512 × 512 pixel data acquisition. V-shaped cantilevers with a pyramidal tip of silicon nitride were used (Park Scientific, CA). The experiments were repeated twice, and the observed structures were found to be reproducible. To determine the mean complex size from these images, the diameter at about half-height of 30 complexes was measured.

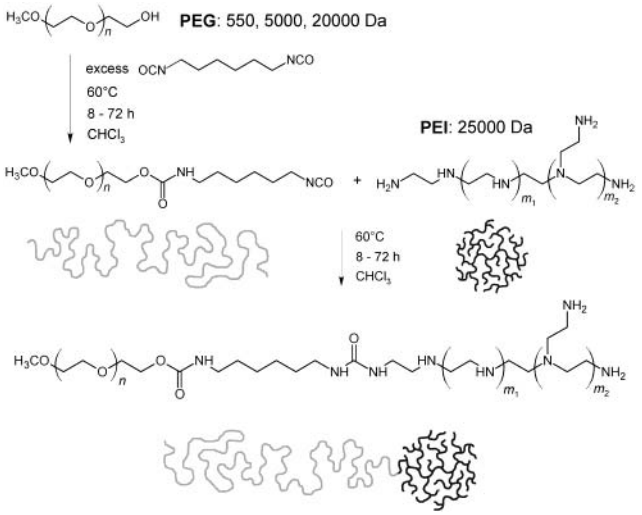
DLS. Complex size measurements were carried out with a Zetasizer 3000 HS from Malvern Instruments, Worcs., U.K. at 25 °C (10 mW HeNe laser, 633 nm). Scattering light was detected at 90° angle through a 400 μm pinhole. Measurements yielding hydrodynamic diameters (Z average mean) and PDI were performed with count rates of about 100−400 kCps in the form of 10 runs of 60 min duration each and analyzed in the CONTIN mode. For data analysis, the viscosity (0.8905 mPas) and refractive index (1.333) of pure water at 25 °C were used. The instrument was calibrated with Nanosphere Size Standards (polymer microspheres in water, 220 ± 6 nm) from Duke Scientific, Palo Alto, CA.

Laser Doppler Anemometry (LDA). The ζ-potential measurements of the complexes were carried out in the standard capillary electrophoresis cell of the Zetasizer 3000 HS from Malvern Instruments at position 17.0 and at 25 °C. Measurement duration was set to automatic. Average values of the ζ-potential were calculated with the data from eight runs. The instrument was calibrated with DTS5050 Electrophoresis Standards from Malvern Instruments.

Agarose Gel Retardation Assay. Amounts of 40 μL aliquots of the complex solution were mixed with 4 μL of loading buffer [glycerol (85%) and TAE (40 mM Tris/HCl, 1% acetic acid, 1 mM EDTA, pH 7.4) in equal parts] and loaded onto an EtBr containing 1% agarose gel. Electrophoresis (Blue Marine 200, Serva, Heidelberg, Germany) was carried out at a voltage of 80 V (LKB Bromma 2197 Power Supply, Pharmacia, Freiburg, Germany) for 2 h in TAE running buffer solution. UV light (254 nm) detection was conducted with a Video Copy Processor P67E from Mitsubishi, Japan.

Biological Characterization of PEI-PEG-Copolymer-DNA Complexes. *Hemolysis Assay*. For hemolysis, fresh blood (700 g) from 6 month old rats (Fischer 344 rats, Institute for Pharmacology and Toxicology, University of Marburg) collected in heparinized tubes was centrifuged at 4 °C for 10 min and washed several times with phosphate-buffered saline (PBS) until the supernatant was colorless. A 500 μL amoount of a 2.5% (v/v) suspension of erythrocytes was mixed with 500 μL of complex solution in Eppendorf cups. After it was incubated for 2 and 60 min at 37 °C in a shaking water bath, the blood cells were removed by centrifugation and the supernatant was investigated spectroscopically at 540 nm for the release of hemoglobin. Experiments were performed in triplicate. As controls, PBS (negative = 0%) and 0.2% Triton X-100 solution (positive = 100%) were used.

Aggregation of Erythrocytes. To study polymer/DNA complex-induced aggregation of erythrocytes, rat blood (see hemolysis test) was applied. Ringer's solution (with the addition of sodium citrate, pH 7.4) was used to prevent coagulation. The blood was washed several times with Ringer's solution until the supernatant was colorless as described above. Finally, the erythrocytes were diluted with Ringer's solution 1:50. A 200 μL amount of this cell suspension was treated with 100 μL of polymer solution in 24 well plates (Nunc). After it was incubated for 2 h at 37 °C, pictures were taken of the cells with a Contax RTS 2 camera from AGFA (ASA 100) fitted to a reverse phase contrast microscopy (Nikon TMS) at 40 times magnification. Experiments were performed in triplicate.



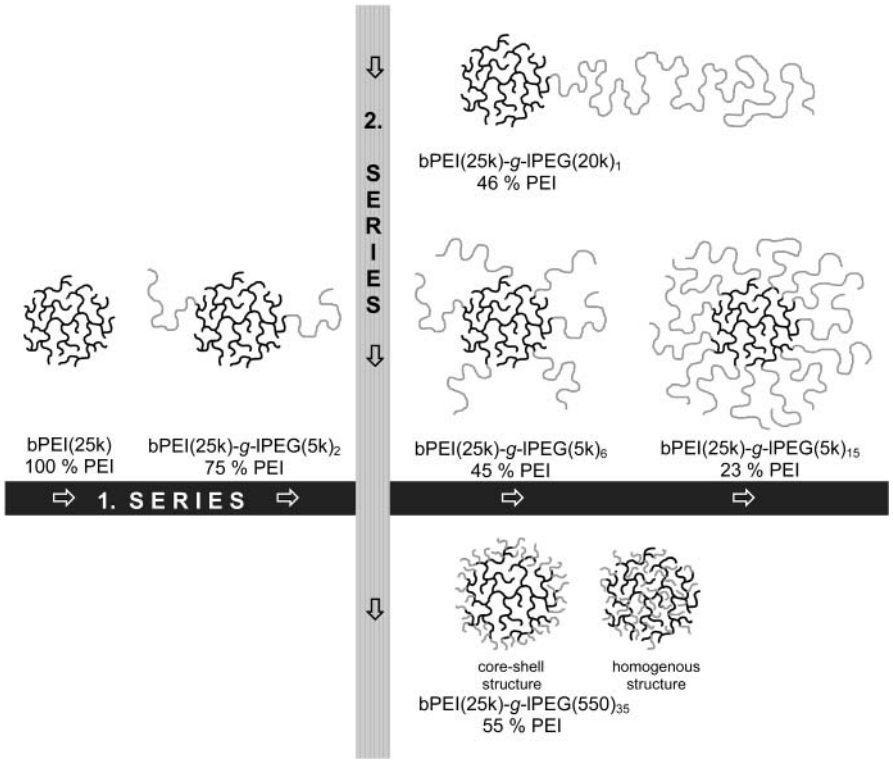
LDH Assay. In vitro cytotoxicity of the complexes with herring testes DNA was evaluated using an LDH assay with 3T3 mouse fibroblasts (500 000 cells/well, 4 h incubation). As reference, PBS (negative, 0%) and 0.1% (w/w) Triton X-100 solution (ICN, Eschwege, Germany) in PBS (positive, 100%) were applied. The LDH content was measured photometrically (340 nm) using a commercial test kit (DQ 1340-K, Sigma) as described in more detail earlier (*28*). Experiments were performed in triplicate.

Transfection Experiments. Transfection activity of the copolymer complexes was studied on 3T3 mouse fibroblasts (NIH 3T3, Swiss mouse embryo, ATCC, Rockville, Maryland) using a Luciferase assay kit from Promega. Measurements of relative light units (RLU) were conducted on a Sirius Luminometer from Berthold, Pforzheim, Germany. Protein quantification was performed with freshly prepared bicinchonic acid (BCA) reagent (Pierce, Rockford, IL) and was carried out with an enzyme-linked immunosorbent assay (ELISA) plate reader from Dynatech MR 5000, Denkendorf, Germany, at 570 nm. Experiments were performed in triplicate as described in more detail in ref *30*.

RESULTS AND DISCUSSION

Two series of block copolymers were prepared by grafting lPEG onto bPEI using a straightforward synthesis route (Scheme 1). Diisocyanate HMDI was used as a linker generating hydrolytically stable urethane bonds between PEG and linker and urea bonds between PEI and linker. In the first series (Scheme 2, horizontal), the PEI (25 kDa) was grafted with different degrees of substitution using PEG blocks all of MW 5 kDa in order to study the quantitative effect of PEG blocks. As a result, the polycationic domain of the copolymers was increasingly surrounded by PEG blocks in this series. The second series (Scheme 2, vertical) was arranged with copolymers all containing an equal weight percent of PEG and PEI (about 50:50%) but with PEGs of different molecular weights (MW 550−20 000 Da). Thus, we varied the copolymer structure in such a way that on one extreme PEG is homogeneously distributed in short blocks within the PEI domain, whereas in the other extreme a clear separation of the PEG and the PEI domain is realized. In other words, the copolymer structure is varied from multiarm grafting to a diblock structure.

Scheme 1. Synthesis of bPEI(25*k*)-*g*-lPEG Copolymers[a]



[a] The PEG has a linear structure, and the PEI has a hyperbranched structure.

For these graft (*g*) copolymers, we chose following nomenclature: bPEI(25*k*)-*g*-lPEG(*x*)$_n$ where b and l denote a branched or linear structure. The numbers in brackets (25*k* or *x*, where *x* = 550, 5*k*, or 20*k*) represent the MW of the PEI or the PEG block and the index *n* is the average number of PEG blocks per one PEI macromolecule. The index *n* was calculated from integration of the ^{1}H NMR signals with the MW values of the homopolymers given by the suppliers.

Size and Morphology of the Complexes. To study the influence of copolymer structure on size and shape of the complexes formed with plasmid DNA, we performed AFM experiments in aqueous solution. While transmission electron microscopy (TEM) has been frequently used to characterize DNA/polycation complexes (*20*−*22*), the advantage of AFM stems from the direct observation of these complexes in aqueous solution. Samples for TEM are visualized in vacuo and need to be pretreated and stained, e.g., with zinc uranyl acetate. Therefore, dimensions and structure of DNA/polycation complexes determined in aqueous media using AFM and by TEM could be different. In this study, physiological salt concentrations (150 mM NaCl) as used for the biological experiments were not feasible technically due to formation of salt crystals during the AFM imaging process. Therefore, a low salt concentration of 10 mM NaCl and pH 7.4 was selected. Because immobilization was based on electrostatic forces between the negative charge of mica substrate and the complex, the latter had to exhibit a distinct positive net charge. Therefore, we chose the N/P ratio 9 for this study (compare with ζ-potential measurements below).

The homopolymer PEI showed images of spherical and compact complexes of 142 ± 59 nm diameter (Figure 1A and Figure 2). The first copolymer series (images A−D)

Scheme 2. Schematic of the bPEI(25*k*)-*g*-lPEG Copolymer Sample Set[a]

[a] The black part of the structure represents the cationic branched PEI, and the gray part represents the nonionic linear PEG blocks. It should be remarked that the structures are reduced to two dimensions. Thus, the density of the PEG shield in (3D) reality is smaller than it appears in this scheme. The copolymer bPEI(25*k*)-*g*-lPEG(550)$_{35}$ has two possible structures; however, PEG is more likely homogenously distributed within the PEI than concentrated at the outer sphere of the PEI (core−shell structure).

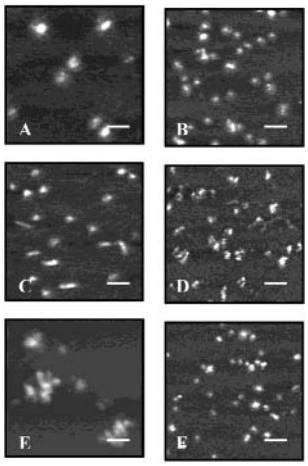


Figure 1. AFM images of polymer/plasmid DNA complexes at N/P ratio 9. Image A shows PEI 25 kDa homopolymer DNA condensates. Images B−D show DNA−polymer condensates produced with plasmid DNA and bPEI(25*k*)-*g*-lPEG(5*k*)$_n$ where n = 2, 6, and 15, respectively. Images E and F show DNA condensates produced with bPEI(25*k*)-*g*-lPEG(550)$_{35}$ and PEI-(25*k*)-*g*-PEG(20*k*)$_1$, respectively. Scale bars are equivalent to 250 nm. The color-encoded height scale extends 15 nm.

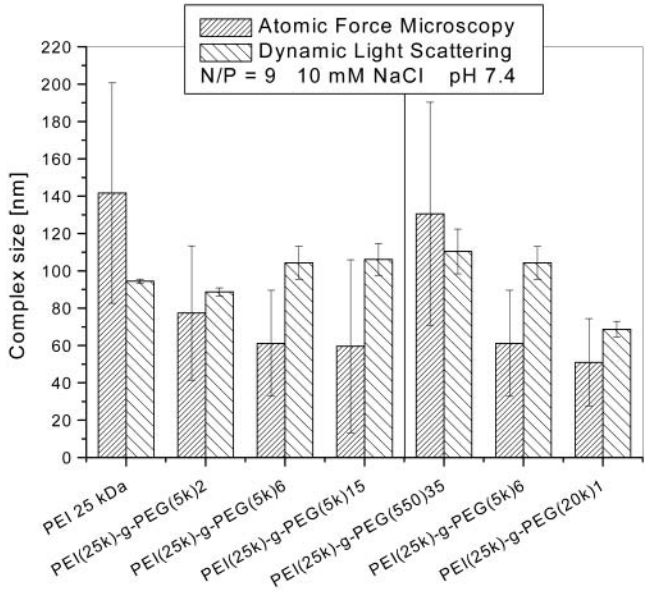

Figure 2. DNA−polymer complex size as determined by AFM (n = 30) and DLS (n = 10) at N/P ratio 9 in 10 mM NaCl. The error bars indicate the standard deviation (SD). In the case of the AFM results, the SD reflects the size distribution.

demonstrated that PEG 5 kDa significantly reduced the diameter of the complexes from 142 nm to about 60 nm, but with an increasing number of PEG blocks, DNA condensation was affected and complexes lost their spherical shape. Whereas the copolymer containing 2 PEG blocks gave spherical complexes with diameters of 77 ± 36 nm, bPEI(25*k*)-*g*-lPEG(5*k*)$_6$ showed a mixture of spherical and rodlike particles (diameter 61 ± 28 nm). When PEI was grafted with 15 PEG blocks, complexes of ill-defined shape were found (diameter 60 ± 46 nm). Furthermore, some of the complexes exhibited stringy structures, which can be attributed to poorly condensed DNA.

Complex size was also determined by DLS in the same medium as used for AFM (10 mM NaCl, pH 7.4). Hydrodynamic diameters are shown in Figure 2 in comparison with the results of the AFM experiments. Differences in complex size were much smaller as compared to the AFM results, and no specific trend could be

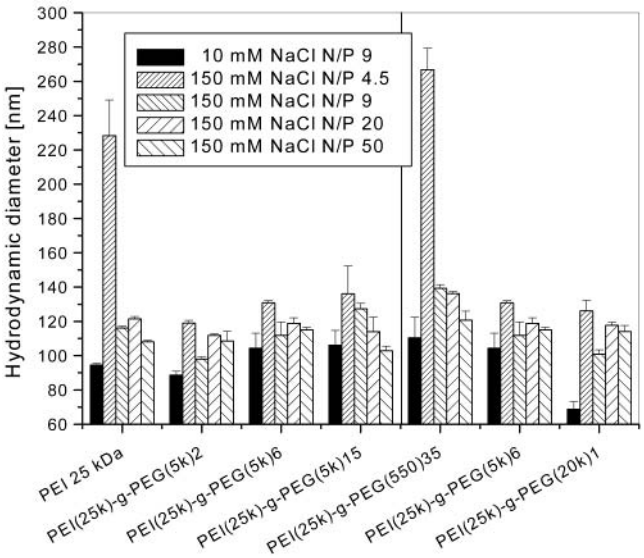

Figure 3. Hydrodynamic diameters of complexes assembled by plasmid DNA with bPEI 25 kDa and bPEI-*g*-lPEG copolymers at different ionic strength and different N/P ratios as determined by DLS.

observed for the first series. The trend found by AFM that PEG 5 kDa reduces the size of the complex was observed by DLS only for bPEI(25*k*)-*g*-lPEG(5*k*)$_2$. Their complexes (88.7 ± 2.2 nm) were on average slightly smaller than complexes formed by the homopolymer PEI (94.5 ± 1.1 nm). However, copolymers with 6 and 15 PEG blocks formed complexes with slightly larger average diameters of about 105 nm probably due to the rodlike shape of some of the complexes as observed in AFM.

In the second series, another trend is observed in AFM (Figure 1C,E,F): Complexes gradually lose their compact and spherical shape with decreasing MW of PEG. Copolymers with one long PEG 20 kDa formed small (51 ± 23 nm) and clearly spherical complexes, whereas copolymers with many short PEG 550 Da gave rather large complexes (131 ± 60 nm), which were fluffy or diffuse and almost shapeless. For this series, DLS measurements revealed the same trend: For bPEI(25*k*)-*g*-lPEG(20*k*)$_1$, a small complex diameter of 68.7 ± 4.3 nm was found, whereas in the case of bPEI(25*k*)-*g*-lPEG(550)$_{35}$ larger diameters (110.4 ± 12.0 nm) were determined.

The results of both the AFM experiments and the DLS measurements demonstrated that DNA complexation with PEI-*g*-PEG is strongly dependent on the block copolymer structure. In the case of PLL-*g*-PEG copolymers, a negative influence of PEG and other hydrophilic polymers on the condensation of DNA was observed (*11*, *31*). Similar disadvantageous effects were anticipated for PEI; therefore PEGylation of the PEI/DNA complex was carried out as a second step after condensation (*25*). This procedure may, however, be impractical in a clinical setting. Here, we demonstrated that PEG does not necessarily interfere with the condensation process of DNA. Attaching only one or two PEG blocks to PEI can even enhance DNA condensation forming compact and spherical complexes with smaller sizes as compared to homopolymer PEI complexes.

Using DLS, complexes were also studied at high ionic strength (150 mM NaCl, pH 7.4) and at different N/P ratios (Figure 3). Under these (more physiological) conditions, all polymers formed larger complexes as compared to low salt concentration. However, with an increasing N/P ratio, the complex size was reduced again. Two exceptional polymers were found. At a low N/P ratio (4.5),

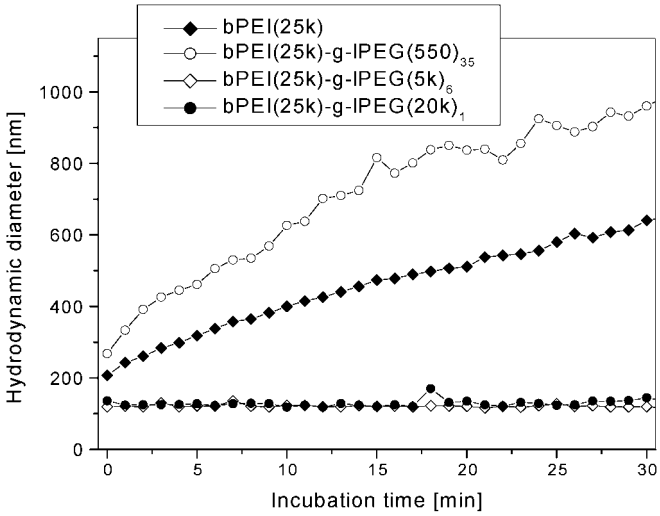

Figure 4. Stabilization study of the complexes assembled by plasmid DNA with bPEI 25 kDa and bPEI-*g*-lPEG at N/P 4.5 and 150 mM NaCl. Complex size (diameter) is as a function of incubation time as determined by DLS.

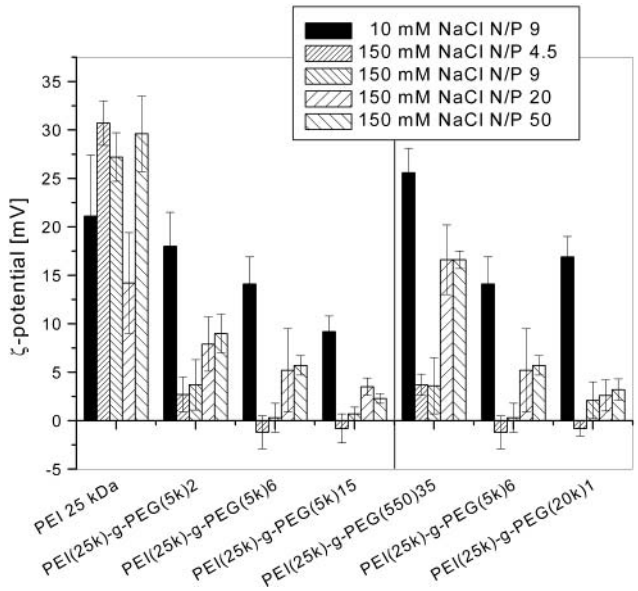

Figure 5. ζ-Potential of plasmid DNA complexes with PEI 25 kDa and bPEI-*g*-lPEG block copolymers at different ionic strength and at different N/P ratios as determined by laser Doppler anemometry.

PEI and bPEI(25*k*)-*g*-lPEG(550)$_{35}$ did not give stable complexes. Over a period of 30 min, complex size increased from 200 to 600 nm and from 270 to 900 nm, respectively (Figure 4). In contrast, all copolymers with PEG of 5 and 20 kDa formed stable complexes at N/P 4.5 (copolymers bPEI(25*k*)-*g*-lPEG(5*k*)$_n$ where *n* is 2 or 15 are not shown in Figure 4). A stabilizing effect of PEG against aggregation of PEI/DNA complexes has been noted previously (*21*, *25*). Short PEG blocks seem to provide little stabilization, and a MW of PEG ≥ 5 KDa is necessary to obtain this effect. At higher N/P ratios (≥9), all homo- and copolymers formed stable complexes, which are probably stabilized electrostatically under these conditions by a larger excess of polycations present.

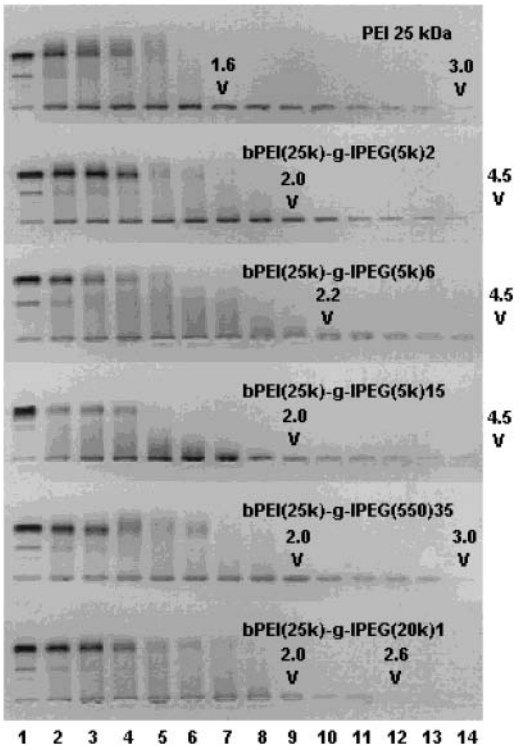
Surface Charge of the Complexes. To estimate the surface charge of the complexes, we measured the ζ-potential of the complexes by LDA. The results are shown in Figure 5. In the first series of bPEI(25*k*)-*g*-lPEG(5*k*)$_n$ copolymers, the ζ-potential is reduced with an

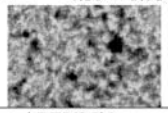
increasing number *n* of PEG blocks. This is true for different salt concentrations and different N/P ratios. Thus, PEG 5 kDa blocks seem to orientate toward the surface of the complex and shield its core with the cationic net charge. In the case of the copolymers, the ζ-potential increases with increasing N/P ratios. The ζ-potential did not increase further from N/P 20 to 50 since free copolymer was present at N/P 50. In the case of homopolymer PEI, even at low N/P ratio 4.5, ζ-potential is highly positive and is found in the range of +25 to +35 mV. Similar values have been reported by others (*24*, *25*, *32*). A ζ-potential of +35 mV seems to be the maximum surface charge of the PEI−DNA complexes. PEI was reported to possess a ζ-potential of +37 mV (*33*).

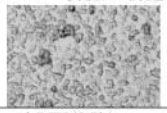
In the second series with the copolymers containing about 50% PEG, the ζ-potential is reduced with increasing MW of PEG. Therefore, PEG 5 kDa and especially PEG 20 kDa are able to shield the charged core of the complex. The high ζ-potential of complexes formed with bPEI(25*k*)-*g*-lPEG(550)$_{35}$ points to the poor shielding properties. As we have previously shown using differential scanning calorimetry (*28*), bPEI(25*k*)-*g*-lPEG-(550)$_{35}$ probably did not form a simple core−shell structure in which the PEG blocks surrounded the positively charged PEI core. During the synthesis, the short PEG blocks might penetrate into the branched PEI structure and react also with the inner amino groups. This would yield a copolymer where PEG is more homogeneously distributed over the PEI macromolecule as schematically shown in Scheme 2. This structure could explain the high ζ-potential of the complex.

DNA Complexation and Condensation. Finally, to study DNA complexation and condensation as a function of N/P ratio, agarose gel retardation assays were performed. The gels are shown in Figure 6. No difference was found for the copolymers from the first series with PEG 5kDa: Complete retardation of DNA (indicating complete DNA complexation) was achieved at N/P = 2.0−2.2 whereas for complete exclusion of EtBr (indicating complete DNA condensation) a further excess of the polycation was needed (N/P = 4.5, data not shown). In the case of homopolymer PEI, DNA was complexed completely at N/P = 1.6 and condensed at 3.0. Thus, grafting PEI with PEG 5 kDa slightly hindered the interaction with DNA. When PEI was grafted with short PEG blocks as in the case of copolymer bPEI(25*k*)-*g*-lPEG(550)$_{35}$, the complexation was hindered slightly (N/P = 2.0) but condensation was realized at the same N/P ratio (N/P = 3.0). Here again, we found that short PEG blocks behaved differently than longer PEG chains: PEG 550 Da did not stabilize the complex against aggregation, it did not reduce the positive surface charge, and here, it did not affect DNA condensation. However, the most interesting result from the agarose gel retardation assay is the enhanced DNA condensation observed for copolymer bPEI(25*k*)-*g*-lPEG(20*k*)$_1$ already at N/P = 2.6. This is in line with the results from AFM images where small and compact particles were found. The excellent DNA condensation might be attributed to the special copolymer structure. With only one PEG block on average, this is a diblocklike copolymer and there might be a PEI domain and a PEG domain clearly separated from each other. Thus, the DNA seems to interact with the PEI domain without interference from PEG. Furthermore, some authors reported the DNA condensation ability of PEG (*34*, *35*). Therefore, PEG might additionally participate in the condensation process in a synergistic manner.

Hemocompatibility of the Complexes. The blood compatibility of PEI-*g*-PEG/DNA complexes was screened







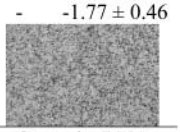


Figure 6. Agarose gel electrophoresis of the complexes of plasmid DNA with bPEI 25 kDa and bPEI-*g*-lPEG block copolymers. Lane 1, N/P = 0 (plasmid only); lanes 2−14, N/P 0.6−3.0 with increments of 0.2. N/P ratio 4.5 was determined with another gel experiment (data not shown).

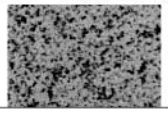

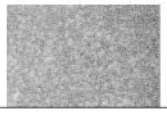

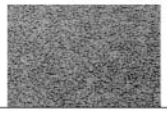

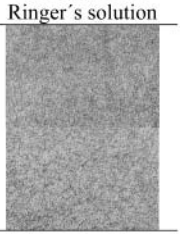

using a hemolysis and an aggregation of erythrocytes under in vitro conditions. These assays are a prerequisite for the intravenous administration of PEI-*g*-PEG/DNA complexes in animals or humans.

The results of the hemolysis assay are presented in Table 1. In a short term experiment (incubation time with erythrocytes, 2 min; data not shown), the acute phase of an intravenous administration is reflected. No hemolysis was observed after short incubation time for any of the PEI-*g*-PEG preparations. Complexes with PEI 25 kDa showed a slight hemolytic activity (1−2%). The long term experiment (60 min incubation) still showed only negligible hemolysis for the complexes of PEI and most copolymers. PEI, bPEI(25*k*)-*g*-lPEG(5*k*)$_2$, and bPEI(25*k*)-*g*-lPEG(550)$_{35}$ caused more hemolysis (up to 5%) after 60 min in comparison with the results after 2 min of incubation. Only bPEI(25*k*)-*g*-lPEG(550)$_{35}$ exhibited a remarkable value of 12% at very high N/P ratios, which is still tolerable since substances are classified as non-hemolytic when hemolysis remains <15% (*36*).

The erythrocyte aggregation assay allowed only semiquantitative estimations about the hemocompatibility of the complexes. Results of this study are given in Table 1. Exemplarily, microscopic images of the erythrocytes are shown in this table for N/P ratio 20. Ringer's solution and free DNA did not show any aggregation (control experiment). In the case of the complexes, aggregation tendency was found as a function of N/P ratio: the larger the excess of polycation in the complex, the stronger the aggregation. Complexes of PEI, bPEI(25*k*)-*g*-lPEG(5*k*)$_2$, and bPEI(25*k*)-*g*-lPEG(550)$_{35}$ showed strong to very strong aggregation of the red blood cells. Because aggregation is often caused by electrostatic interactions between the anionic cell membranes and a cationic object,

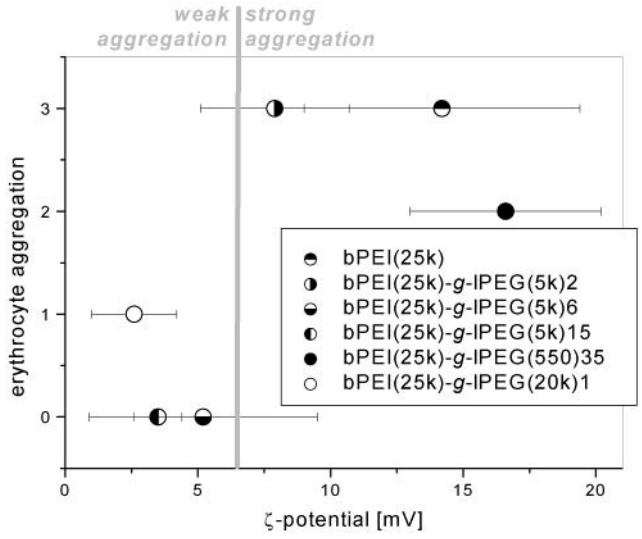

Figure 7. Plot of polymer/DNA complex-induced erythrocyte aggregation (N/P 20) against ζ-potential of the complexes (N/P 20, 150 mM NaCl). Erythrocyte aggregation is given semiquantitatively as follows: 0, no aggregation; 1, weak aggregation; 2, strong aggregation; 3, very strong aggregation.

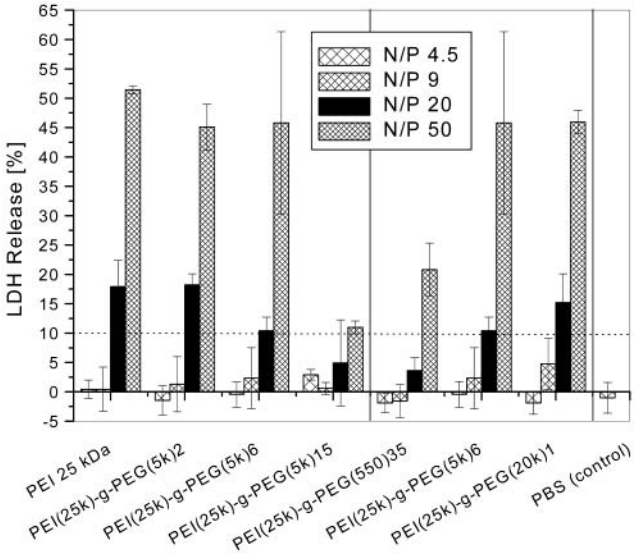

Figure 8. LDH assay of bPEI 25 kDa and bPEI-*g*-lPEG copolymer complexes with herring testes DNA at different N/P ratios after an incubation of 4 h. The experiment was performed with 3T3 mouse fibroblast cell line. A release of less than 10% can be understand as nontoxic.

the surface charge of the complexes was an important key to interpret these results. When the extent of aggregation is plotted against the ζ-potential (Figure 7), a threshold at a ζ-potential of about 6 mV is observed. Below this value, no or only weak aggregation was observed, whereas above this ζ-potential strong aggregation occurred. In all cases where PEGylation reduced ζ-potential of the complexes below 6 mV, no erythrocyte aggregation was observed. This was achieved by grafting six PEG 5 kDa blocks or one 20 kDa block. Because the three polymers showing strong aggregation also induced a relatively strong hemolytic activity, it is likely that high ζ-potentials also affect hemolysis.

Cytotoxicity of the Complexes. The cytotoxicity of the complexes was studied using the LDH assay, which provides information on the destructive interaction of the complexes with cell membranes. It was found that with increasing N/P ratio, the cytotoxicity of the complexes increased (Figure 8). In the first series with the bPEI-(25*k*)-*g*-lPEG(5*k*)$_n$ copolymers, toxicity is reduced with an increasing number *n* of PEG blocks. Another trend is observed for the second copolymer series: Toxicity is reduced with decreasing MW of PEG. Consequently, there are two copolymers that formed complexes with a low toxicity profile: bPEI(25*k*)-*g*-lPEG(550)$_{35}$ and bPEI-(25*k*)-*g*-lPEG(5*k*)$_{15}$. Because their LDH release is <10%, DNA complexes with these copolymers can be regarded as relatively nontoxic (*37*). These two copolymers have two features: First, they both form complexes of ill-defined and more diffuse complex shape. Severe cell membrane damage is often observed when many charges are locally concentrated on the cell membrane (*37*). In contrast, the charges of a diffuse complex are more distributed over a wider area of the cell membrane in comparison with compact complexes. Second, both copolymers are characterized by a high degree of PEG substitution ($n = 15$ and 35, respectively). The toxic sites

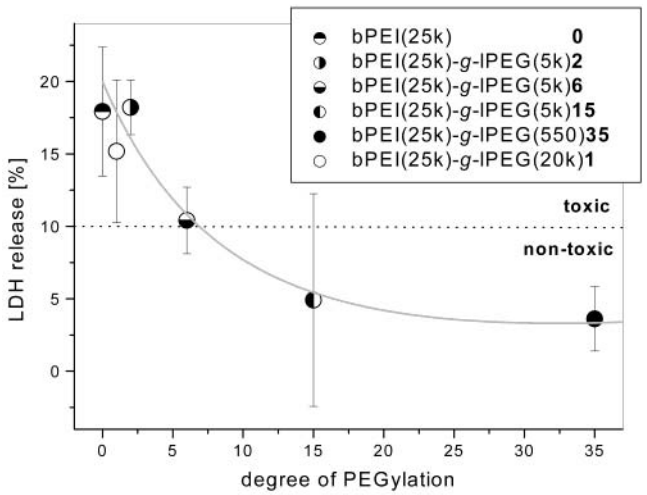

Figure 9. Correlation of degree of PEG grafting (average number of PEG blocks per one PEI molecule) with cytotoxicity of the polymer/DNA complexes as determined by LDH assay (LDH release at N/P = 20).

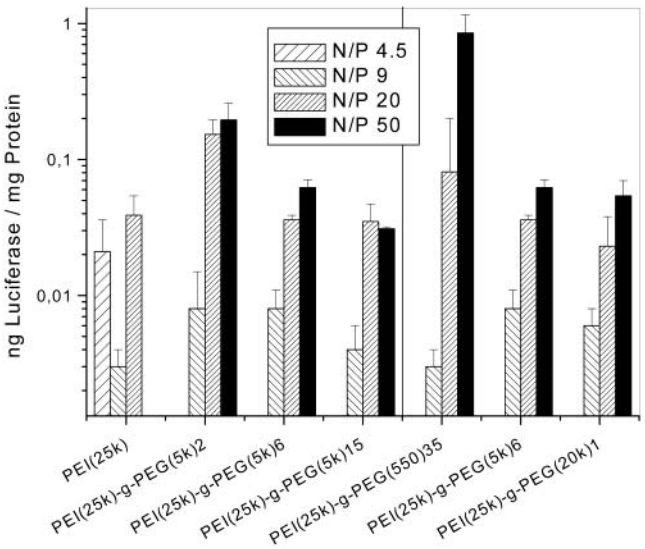

Figure 10. Transfection efficiency of polymer/plasmid DNA complexes with bPEI 25 kDa and bPEI-*g*-lPEG block copolymers at different N/P ratios. The experiment was performed with 3T3 mouse fibroblast cell line.

of the copolymers are the amino groups of PEI. If they are substituted with PEG, the basic amino groups are transformed into neutral urea bonds (according to our synthesis route). Thus, the reduction of the toxicity of PEI is expected to be a function of degree of PEG substitution. Indeed, a plot of percent LDH release against the degree of PEGylation (Figure 9) clearly shows this function, which seems to be independent of the MW of the PEG.

Transfection Efficiency of the Complexes. Finally, the transfection activity of the complexes was studied using the same cell line as in the cytotoxicity assay. The transfection efficiency expressed by amount of luciferase per amount protein was measured at three different N/P ratios for each polymer. As a consequence of the results from preliminary experiments, not every N/P ratio was repeatedly measured for all polymers. Because of the high toxicity of the homopolymer PEI, all cells died at N/P = 50 and a transfection experiment was not feasible. No perceptible transfection could be observed at N/P = 4.5. Therefore, the experiments were run only at higher N/P ratios. The results are presented in Figure 10.

Despite PEGylation, all copolymers showed transfection activity at least as high as homopolymer PEI. Furthermore, at higher N/P ratios, the copolymers turned out to be even more efficient than PEI. This is quite remarkable since most other groups found a significant decrease in transfection activity for the PEG-modified PEIs (*20*, *21*, *23*). All polymers showed higher transfection activities with increasing N/P ratios. In the first series with bPEI(25*k*)-*g*-lPEG(5*k*)$_n$ copolymers, transfection efficiency decreases with increasing number of PEG blocks. Complexes of copolymer with $n = 2$ were even more efficient in gene transfer than complexes of homopolymer PEI. In the case of the second series, copolymer bPEI(25*k*)-*g*-lPEG(20*k*)$_1$ gave similar results as the other 50% PEG copolymer bPEI(25*k*)-*g*-lPEG(5*k*)$_6$. Remarkable results were found for bPEI(25*k*)-*g*-lPEG(550)$_{35}$ even with a high N/P ratio of 50.

The complexity of the gene transfer process prevents the correlation of transfection data with a single physicochemical or biological parameter. For instance, ζ-potential or complex size alone cannot explain why the two polymers with high ζ-potential and large complex size (PEI and bPEI(25*k*)-*g*-lPEG(550)$_{35}$) transfected differently, the first very poorly and the latter very strongly. Also, the cytotoxicity alone did not give a reasonable relationship with transfection activity. Here again, the two polymers with high LDH release (PEI and bPEI(25*k*)-*g*-lPEG(5*k*)$_2$) transfected differently, the first poorly and the latter strongly. Furthermore, the two copolymers of low cytotoxicity (bPEI(25*k*)-*g*-lPEG(5*k*)$_{15}$ and bPEI(25*k*)-*g*-lPEG(550)$_{35}$) also showed quite different transfection activities. Therefore, the results of the transfection experiments could be explained only by a combination of physicochemical and biological parameters. Cytotoxicity and ζ-potential turned out to be the key factors for the explanation of the results of the gene transfer experiments. Whereas a strong cytotoxicity was unwanted, a high ζ-potential is generally assumed to be advantageous for in vitro gene delivery since it enhances the adhesion of the cationic complex with the negatively charged cell membrane (*38*). In Figure 11, the cytotoxicity in means of LDH release is plotted against ζ-potential and the transfection efficiency is represented semiquantitatively by the size of the polymer symbols. The six polymer/DNA complexes could be divided into four groups of different transfection activities. First, in the case of low toxicity and of low ζ-potential, the complexes showed only poor gene expression. These complexes are probably too inert due to the thoroughly shielding PEG blocks and do not interact with the cells. Second, when the ζ-potential was relatively low but the LDH release was high, medium transfection activities were observed for the appropriate complexes. Because of the low ζ-potential, the concentration of cell-adherent complexes might remain low; therefore, the cells survived the treatment of these toxic complexes. Third, the combination of high ζ-potential and high LDH release yielded poor transfection possibly due to a strong interaction of the highly toxic complexes with the cells that did not survive. Fourth and finally, complexes with high ζ-potential but with low cytotoxicity showed high transfection activities and seemed to be most efficient as in vitro gene transfer vectors. Here, highly positive surface charge is not accompanied by toxic side effects. The representative copolymer of this group is bPEI(25*k*)-*g*-lPEG(550)$_{35}$. Also another explanation for the good transfection activity of this copolymer can be put forward. It has been reported for in vitro gene delivery that large complexes more easily reach the cells

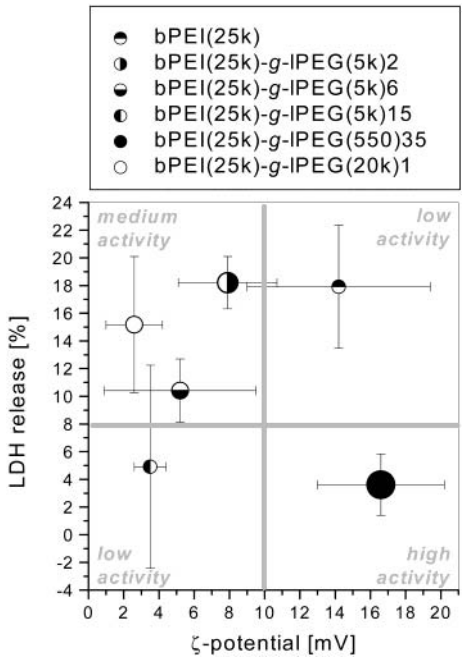

Figure 11. Transfection efficiency in correlation to ζ-potential (N/P 20, 150 mM NaCl) and cytotoxicity as determined by LDH assay (N/P 20) on 3T3 fibroblast. The size of the dot indicates semiquantitatively the transfection efficiency (the larger the symbol, the higher transfection activity).

due to sedimentation (*39*). Thus, the large complexes formed by bPEI(25*k*)-*g*-lPEG(550)$_{35}$ could show higher sedimentation.

CONCLUSIONS

By variation of the degree of substitution and the MW of PEG, we have obtained a set of PEI-*g*-PEG copolymers, which represent a broad range of different block copolymer structures. We have demonstrated that copolymer structure has a strong influence on the shape of the polycation/DNA complex and its surface charge. Copolymers with many short PEG blocks formed large and diffuse complexes of high positive surface charge. Copolymers with only a few but long PEG blocks self-assembled to small and compact condensates of low surface charge. Copolymers with many long PEG blocks generated complexes of ill-defined shape and of almost no surface charge. Furthermore, the physicochemical parameters have a decisive impact on the interaction of the complexes with cells. A high positive ζ-potential of the complexes resulted in a strong erythrocyte aggregation and hemolysis. However, cytotoxicity monitored with fibroblasts was a function of the degree of PEGylation independent of the MW of the PEG. Sufficient in vitro gene expression was realized with the copolymer that formed large complexes with a high positive surface charge and a low toxicity profile, as it was found for the copolymer with many short PEG 550 Da blocks.

Cathepsin B-Labile Dipeptide Linkers for Lysosomal Release of Doxorubicin from Internalizing Immunoconjugates: Model Studies of Enzymatic Drug Release and Antigen-Specific In Vitro Anticancer Activity

Gene M. Dubowchik,* Raymond A. Firestone,*,† Linda Padilla, David Willner, Sandra J. Hofstead, Kathleen Mosure, Jay O. Knipe, Shirley J. Lasch,§ and Pamela A. Trail§

Bristol-Myers Squibb Pharmaceutical Research Institute, P.O. Box 5100, Wallingford, Connecticut 06492. Received April 2, 2002; Revised Manuscript Received April 30, 2002

The anticancer drug doxorubicin (DOX) has been linked to chimeric BR96, an internalizing monoclonal antibody that binds to a Lewis^y-related, tumor-associated antigen, through two lysosomally cleavable dipeptides, Phe-Lys and Val-Cit, giving immunoconjugates **72** and **73**. A self-immolative *p*-aminobenzyloxycarbonyl (PABC) spacer between the dipeptides and the DOX was required for rapid and quantitative generation of free drug. DOX release from model substrate Z-Phe-Lys-PABC-DOX **49** was 30-fold faster than from Z-Val-Cit-PABC-DOX **42** with the cysteine protease cathepsin B alone, but rates were identical in a rat liver lysosomal preparation suggesting the participation of more than one enzyme. Conjugates **72** and **73** showed rapid and near quantitative drug release with cathepsin B and in a lysosomal preparation, while demonstrating excellent stability in human plasma. Against tumor cell lines with varying levels of BR96 expression, both conjugates showed potent, antigen-specific cytotoxic activity, suggesting that they will be effective in delivering DOX selectively to antigen-expressing carcinomas.

INTRODUCTION

Effective cancer treatment using macromolecular or small molecule prodrugs of cytotoxic agents requires systemic stability as well as selective drug release at the target tissue (*1*, *2*). The chimeric MAb[1] BR96 binds specifically to a Lewis^y-related, tumor-associated antigen expressed on the cell surface of many human carcinomas, and the resulting complex is internalized through the endosome/lysosome pathway (*3*). The DOX-containing immunoconjugate BR96−DOX depends on a hydrazone link for selective hydrolysis inside tumor cell lysosomes (pH ca. 5, $t_{1/2} = 4$ h) and a thioether linker to the MAb to achieve relative stability in circulation (pH ca. 7, $t_{1/2} =$ 120 h) (*4*). Besides its limited hydrolytic stability, the hydrazone can be used to carry only ketone-containing drugs such as DOX or its close analogues (*5*). We sought to replace the hydrazone with cathepsin B-sensitive peptides as they can be used to deliver a greater variety of drugs, they should release those drugs quickly upon internalization into lysosomes, and they do not spontaneously hydrolyze. Cathepsin B (*6*, *7*) is a ubiquitous cysteine protease whose properties do not differ very much from species to species. It is never found extracellularly, except in pathological conditions such as metastatic tumors (*8*) or in areas of tissue destruction in rheumatoid arthritis (*9*). Therefore, conjugates produced with cathepsin B-cleavable linkers are likely to be stable in circulation.

Lysosomally cleavable peptides such as Gly-Phe-Leu-Gly (*10*) and Ala-Leu-Ala-Leu (*11*, *12*) that have been used by others as drug carrier linkers were considered to have significant potential liabilities for our particular targeting vehicle for two reasons: (i) drug release is relatively slow and (ii) the hydrophobic nature of those tetrapeptides would probably cause precipitation or aggregation of a BR96 immunoconjugate carrying a maximal load of eight drug molecules. Because Z-Phe-Arg-X (where X is a fluorogenic moiety) is a general substrate for the assay of cathepsins B and L (*13*), we decided to use this simple sequence as a starting point for substrate design. We first prepared a series of model compounds to determine structural requirements for efficient enzyme-mediated drug release and plasma stability (*14*). In these,

Scheme 1

Arg was replaced by Lys and modified Arg at P_1 for synthetic ease as well as potential systemic stability (*15*). We also investigated Cit, which is isosteric and isoelectronic with Arg but much less basic (*16*). Concern that sterically demanding drugs such as DOX would be excluded from the active site of cathepsin B or would otherwise interfere with dipeptide binding led us to incorporate a self-immolative PABC spacer (*17*), which hydrolytically decomposes upon deacylation, spontaneously releasing free drug (Scheme 1). Elaboration of two exemplary dipeptide substrates into linker compounds followed by conjugation with chimeric BR96 gave immunoconjugates that demonstrated excellent in vitro stability and potent cytotoxic activity against antigen-expressing tumor cells.

EXPERIMENTAL SECTION

Chemistry. Protected AAs were purchased from Bachem (Torrance, CA). Cathepsin B, DTT, and EDTA were purchased from Sigma (St. Louis, MO). Tributyltin hydride, trichloromethyl chloroformate (diphosgene), diallyl dicarbonate, and PABOH were purchased from Fluka (St. Louis, MO). All other reagents were purchased from Aldrich Chemical Co. (Milwaukee, WI). Dry solvents were Aldrich Sure Seal grade except for methylene chloride, which was distilled from calcium hydride. All other solvents were reagent grade and were used as received. Sodium sulfate was used as the drying agent for extractive workup unless otherwise indicated. HPLC was carried out on a Varian Star System using a model 9010 solvent delivery system, a 9050 variable wavelength UV−vis detector, and a Micropak C-18 column. Preparative flash chromatography was carried out using Merck grade 9385, 230−400 mesh silica gel. All NMR spectra were run on a Varian Gemini 300 spectrometer (300 MHz). Centrifugation was done with a Tomy Capsule microcentrifuge model HF-120 (Peninsula Laboratories, Belmont, CA).

Boc-Lys(alloc) (1). A stirred solution of Boc-Lys (5.22 g, 21.2 mmol) and $NaHCO_3$ (1.87 g, 1.05 equiv) in water (30 mL) at room temperature was treated with diallyl dicarbonate (3.52 mL, 1.05 equiv) in DME (30 mL). After 16 h, the mixture was poured into a 15% aqueous citric acid solution and the resulting suspension was extracted with ethyl acetate (3 × 150 mL). The combined organic phases were washed with water and brine, dried, and evaporated to give a white solid, which was carried on without further purification (6.99 g, 99%). ^{1}H NMR ($CDCl_3/CD_3OD$): δ 1.41 (9H, s), 1.49 and 1.70 (6H, m), 3.13 (2H, m), 4.25 (1H, m), 4.52 (2H, d), 5.24 (2H, q), 5.87 (1H, m). MS (DCI): *m/e* 331 $(MH)^+$, 275 $(MH - C_4H_8)^+$.

Lys(alloc)·CF_3CO_2H (2). Boc-Lys(alloc) **1** (9.94 g, 30 mmol) in CH_2Cl_2 (50 mL) at room temperature was treated with TFA (19 mL). The mixture was sonicated for several minutes and then left to stand at room temperature for 1 h. The solvents were evaporated at 40 °C, and the gummy solid residue was triturated with ether (75 mL), giving a white solid that was collected by filtration, washed with ether, and dried in vacuo (8.58 g, 83%). ^{1}H NMR (D_2O): δ 1.46 and 1.87 (4H and 2H, m), 3.11 (2H, m), 3.80 (1H, t), 4.51 (2H, br s), 5.22 (2H, q), 5.90 (1H, m). MS (DCI): *m/e* 231 $(MH)^+$. Anal. Calcd for $C_{12}H_{19}N_2O_6F_3$: C, 41.86; H, 5.56; N, 8.14. Found: C, 42.30; H, 5.52; N, 8.29.

Preparation of HOSu-Activated Esters 3−8. A stirred solution of the Z-protected AA (40 mmol) and HOSu (1.1 equiv) in THF (100 mL) at 0 °C was treated with DCC (1.05 equiv). After 15 min, the mixture was allowed to warm to room temperature and was stirred for 16 h. The solid DCU byproduct was filtered off, and the filtrate was evaporated. The thick, colorless oil was dissolved in CH_2Cl_2 (80 mL). The mixture was allowed to stand for 1 h and then was filtered to remove more DCU. The filtrate was evaporated, and the resulting colorless glass was dried in vacuo for 3 h, giving a solid foam that was carried on without further purification. Representative ^{1}H NMR of **3**: ($CDCl_3/CD_3OD$): δ 2.88 (4H, s), 3.27 (2H, m), 4.70 (1H, m), 5.13 (2H, s), 7.27 (10H, m).

Z-Phe-Lys(alloc) (9). A vigorously stirred solution of Z-Phe-OSu **3** (2.783 g, 7.021 mmol) in DME (30 mL) at room temperature was treated with a solution of Lys(alloc)·CF_3CO_2H **2** (2.54 g, 1.05 equiv) and $NaHCO_3$ (1.24 g, 2.1 equiv) in water (30 mL). The temperature was maintained below 25 °C with a cold water bath for the first 30 min. The mixture was stirred at room temperature for 14 h. A small amount of DCU was removed by filtration, and the filtrate was diluted with water (50 mL) and then acidified to pH 3 with 15% aqueous citric acid. The resulting suspension was extracted with ethyl acetate (3 × 80 mL), and the combined organic layers were washed with water and brine, dried, and evaporated to give a glassy solid. This was treated with ether (150 mL), sonicated, and heated in a water bath (50 °C). After it was cooled, the white solid product was collected by filtration and washed with ether (2.79 g, 78%). ^{1}H NMR ($CDCl_3/CD_3OD$): δ 1.25, 1.43, 1.74 and 1.81 (6H, m), 3.00 (2H, m), 3.08 (2H, m), 4.43 (2H, m), 4.48 (2H, d), 5.02 (2H, m), 5.20 (2H, q), 5.84 (1H, m), 7.22 (10H, m). MS (FAB): *m/e* 512 $(MH)^+$, 534 $(M + Na)^+$, 550 $(M + K)^+$. Anal. Calcd for $C_{27}H_{33}N_3O_7$: C, 63.39; H, 6.50; N, 8.21. Found: C, 62.98; H, 6.48; N, 8.21.

Z-Val-Lys(alloc) (10). Compound **10** was prepared as described above for **9** in 82% yield. ^{1}H NMR ($CDCl_3/CD_3OD$): δ 0.89 (6H, 2 x d), 1.30, 1.42, 1.62 and 1.81 (6H, m), 2.03 (1H, m), 3.07 (2H, m), 3.92 (1H, AB q), 4.42 (1H, m), 4.49 (2H, d), 5.06 (2H, s), 5.19 (2H, q), 5.82 (1H, m), 7.28 (5H, m). MS (FAB): *m/e* 949 $(MH)^+$, 971 $(M + Na)^+$,

987 $(M + K)^+$. Anal. Calcd for $C_{23}H_{33}N_3O_7$: C, 59.60; H, 7.18; N, 9.07. Found: C, 59.84; H, 7.31; N, 8.90.

Z-Ala-Lys(alloc) (11). Compound **11** was prepared as described above for **9** in 76% yield. ^{1}H NMR ($CDCl_3/CD_3OD$): δ 1.09 (3H, 2 x d), 1.25, 1.40, 1.67 and 1.80 (6H, m), 3.04 (2H, m), 4.26 (1H, m), 4.40 (1H, m), 4.46 (2H, d), 4.95 (2H, s), 5.13 (2H, q), 5.79 (1H, m), 7.21 (5H, brs). MS (FAB): *m/e* 436 $(MH)^+$, 459 $(M + Na)^+$, 475 $(M + K)^+$. Anal. Calcd for $C_{21}H_{29}N_3O_7$: C, 53.15; H, 6.16; N, 8.85. Found: C, 52.99; H, 6.12; N, 8.78.

Z-Val-Cit (12). To a solution of Z-Val-OSu **4** (2.98 g, 8.566 mmol) in DME (25 mL) at room temperature was added a solution of Cit (2.25 g, 1.5 equiv) and $NaHCO_3$ (1.08 g, 1.5 equiv) in water (25 mL). The temperature was maintained below 25 °C with a cold water bath for the first 30 min. The mixture was stirred vigorously for 16 h. Water (20 mL) containing 2 mL of saturated $NaHCO_3$ was added, and the mixture was washed with ethyl acetate and then acidified to pH 3 with 10% HCl. The resulting suspension was extracted with 10% *n*-butanol/ethyl acetate (3×). The combined organic layers were dried and concentrated in vacuo to give a white solid (3.39 g, 97%). ^{1}H NMR ($CDCl_3/CD_3OD$): δ 0.73 (6H, q), 1.31, 1.46 and 1.63 (4H, m), 1.87 (1H, m), 2.88 (2H, m), 3.72 (1H, AB q), 4.17 (1H, m), 4.86 (2H, s), 7.10 (5H, m). MS (FAB): *m/e* 409 $(MH)^+$, 431 $(M + Na)^+$, 447 $(M + K)^+$. HRMS calcd for $C_{19}H_{29}N_4O_6$, *m/e* 409.2087; found, *m/e* 409.2086. Anal. Calcd for $C_{19}H_{28}N_4O_6 \cdot 0.5H_2O$: C, 54.66; H, 7.00; N, 13.42. Found: C, 54.50; H, 6.86; N, 13.55.

Z-Phe-Cit (13). Compound **13** was prepared as described above for **12** in 78% yield. ^{1}H NMR ($CDCl_3/CD_3OD$): δ 1.39 (2H, m), 1.59 and 1.86 (each 1H, m), 2.81 (1H, q), 3.01 (3H, m), 4.34 (2H, m), 4.92 (2H, ABq), 6.20 (1H, d), 7.15 (10H, m), 7.61 (1H, d). MS (FAB): *m/e* 455.2 $(M - H)^-$. Anal. Calcd for $C_{23}H_{28}N_4O_6 \cdot 0.5H_2O$: C, 59.35; H, 6.28; N, 12.04. Found: C, 59.40; H, 5.99; N, 12.05.

Z-Leu-Cit (14). Compound **14** was prepared as described above for **12** in 75% yield. ^{1}H NMR ($CDCl_3/CD_3OD$): δ 0.91 (6H, ABq), 1.15 (1H, m), 1.45 (2H, m), 1.79 and 1.97 (each 1H, m), 3.04 (2H, t), 4.15 and 4.37 (each 1H, m), 5.08 (2H, s), 7.30 (5H, m), 8.21 (1H, d). MS (FAB): *m/e* 421.2 $(M - H)^-$. Anal. Calcd for $C_{20}H_{30}N_4O_6 \cdot 0.5H_2O$: C, 55.67; H, 7.24; N, 12.98. Found: C, 55.32; H, 6.87; N, 12.82.

Z-Ile-Cit (15). Compound **15** was prepared as described above for **12** in 78% yield. ^{1}H NMR ($CDCl_3/CD_3OD$): δ 0.80 (3H, t), 0.89 (5H, d and m), 1.11 (1H, m), 1.46 (2H, m), 1.77 (2H, m), 3.05 (2H, m), 3.98 and 4.33 (each 1H, m), 5.02 (2H, s), 6.53 (1H, d), 7.27 (5H, m), 7.97 (1H, d). MS (FAB): *m/e* 421.3 $(M - H)^-$. Anal. Calcd for $C_{20}H_{30}N_4O_6 \cdot 0.5H_2O$: C, 55.67; H, 7.24; N, 12.98. Found: C, 55.50; H, 6.92; N, 12.89.

Z-Trp-Cit (16). Compound **16** was prepared as described above for **12** in 87% yield. ^{1}H NMR ($CDCl_3/CD_3OD$): δ 1.37 (2H, m), 1.60 and 1.81 (each 1H, m), 3.02 (2H, t), 3.15 (2H, ABq), 4.33 (1H, m), 4.46 (1H, ABq), 4.97 (2H, s), 6.96 (1H, t), 7.04 (4H, m), 7.22 (5H, m), 7.53 (1H, d). MS (FAB): *m/e* 494.3 $(M - H)^-$. Anal. Calcd for $C_{25}H_{29}N_5O_6 \cdot 0.5H_2O$: C, 59.51; H, 5.99; N, 13.88. Found: C, 59.70; H, 5.78; N, 13.85.

Z-Phe-Arg(NO_2) (17). Compound **17** was prepared as described above for **12** in 88% yield. ^{1}H NMR ($CDCl_3/CD_3OD$): δ 1.51 (2H, m), 1.63 and 1.80 (each 1H, m), 2.87 (1H, m), 3.09 (3H, m), 4.43 (1H, m), 4.66 (1H, m), 4.97 (2H, ABq), 6.00 (1H, brd), 7.05−7.30 (10H, m), 7.51 (1H, brd). MS (FAB): *m/e* 499.2 $(M - H)^-$. Anal. Calcd for $C_{23}H_{27}N_6O_7 \cdot 0.5H_2O$: C, 54.33; H, 5.55; N, 16.53. Found: C, 54.22; H, 5.48; N, 16.61.

Z-Phe-Arg(Ts) (18). Compound **18** was prepared as described above for **12** in 82% yield. ^{1}H NMR ($CDCl_3/CD_3OD$): δ 1.42 (2H, m), 1.62 and 1.77 (each 1H, m), 2.23 (3H, s), 2.84 (1H, m), 3.05 (3H, m), 4.42 and 5.53 (each 1H, m), 4.83 (2H, ABq), 5.99 (1H, br), 7.07 (10H, brs), 7.13 (2H, brs), 7.52 (1H, br), 7.63 (2H, d). MS (FAB): *m/e* 608.3 $(M - H)^-$. Anal. Calcd for $C_{30}H_{34}N_5O_7S \cdot 0.5H_2O$: C, 64.15; H, 6.28; N, 12.47. Found: C, 64.22; H, 6.24; N, 12.53.

Z-Phe-Lys(alloc)-PABOH (19). A stirred solution of Z-Phe-Lys(alloc) **9** (524.7 mg, 1.026 mmol) and PABOH (133 mg, 1.05 equiv) in THF (10 mL) at room temperature was treated with EEDQ (266.3 mg, 1.05 equiv). After 16 h, the mixture was evaporated to dryness at 30 °C, and the residue was triturated with ether (15 mL). The resulting white solid product was collected by filtration, washed with ether, and dried in vacuo (591.6 mg, 94%). ^{1}H NMR ($CDCl_3/CD_3OD$): δ 1.25, 1.42, 1.59 and 1.77 (6H, m), 2.97 (2H, m), 3.06 (2H, m), 4.37 (2H, m), 4.46 (2H, d), 4.55 (2H, s), 4.98 (2H, m), 5.18 (2H, q), 5.81 (1H, m), 7.08 and 7.43 (4H, 2 × d), 7.11 and 7.23 (10H, m). MS (FAB): *m/e* 617 $(MH)^+$, 639 $(M + Na)^+$, 655 $(M + K)^+$. Anal. Calcd for $C_{34}H_{40}N_4O_7$: C, 66.22; H, 6.54; N, 9.08. Found: C, 65.72; H, 6.43; N, 8.92.

Z-Val-Lys(alloc)-PABOH (20). Compound **20** was prepared as described above for **19** in 82% yield. ^{1}H NMR ($CDCl_3/CD_3OD$): δ 0.86 (6H, m), 1.24−1.67 (6H, m), 2.03 (1H, m), 3.08 (2H, m), 4.00 (1H, m), 4.47 (3H, m), 4.57 (2H, s), 5.05 (2H, s), 5.19 (2H, q), 5.81 (1H, m), 7.26 and 7.43 (4H, m), 7.30 (5H, s). MS (FAB): *m/e* 569 $(MH)^+$, 591 $(M + Na)^+$, 607 $(M + K)^+$. Anal. Calcd for $C_{30}H_{40}N_4O_7 \cdot 0.5H_2O$: C, 62.38; H, 7.15; N, 9.70. Found: C, 62.40; H, 7.22; N, 9.79.

Z-Ala-Lys(alloc)-PABOH (21). Compound **21** was prepared as described above for **19** in 88% yield. ^{1}H NMR ($CDCl_3/CD_3OD$): δ 1.18 (3H, 2 x d), 1.28, 1.45, 1.73 and 1.84 (6H, m), 3.08 (2H, m), 4.06 (1H, m), 4.49 (3H, m), 4.56 (2H, s), 5.05 (2H, s), 5.17 (2H, q), 5.81 (1H, m), 7.28 (7H, m), 7.45 (2H, m). MS (FAB): *m/e* 542 $(MH)^+$, 564 $(M + Na)^+$, 580 $(M + K)^+$. Anal. Calcd for $C_{28}H_{36}N_4O_7 \cdot 0.5H_2O$: C, 61.19; H, 6.78; N, 10.19. Found: C, 61.04; H, 6.64; N, 10.27.

Z-Val-Cit-PABOH (22). Z-Val-Cit **12** (1.0397 g, 2.545 mmol) and PABOH (470.2 mg, 1.5 equiv) in THF (10 mL) at room temperature were treated with EEDQ (944.2 mg, 1.5 equiv) with stirring. After 16 h, the mixture was diluted with 10% 2-propanol/ethyl acetate (100 mL) and the solution washed with 10% aqueous citric acid, water, and brine, dried, and evaporated in vacuo. The residue was sonicated in ether for 15 min, and the crude solid product was collected by filtration and dried in vacuo (954.2 mg, 73%). ^{1}H NMR ($CDCl_3/CD_3OD$): δ 0.79 (6H, q), 1.37, 1.53 and 1.72 (4H, m), 1.92 (1H, m), 3.00 (2H, m), 3.85 (1H, m), 4.41 (1H, m), 4.45 (2H, s), 4.95 (2H, m), 7.08−7.40 (9H, m). MS (FAB): *m/e* 514 $(MH)^+$, 536 $(M + Na)^+$, 552 $(M + K)^+$. Anal. Calcd for $C_{26}H_{35}N_5O_6 - H_2O$: C, 58.74; H, 7.01; N, 13.17. Found: C, 59.01; H, 6.62; N, 13.06.

Z-Phe-Cit-PABOH (23). A stirred solution of Z-Phe-Cit **13** (1.2005 g, 2.630 mmol) and PABOH (356.1 mg, 1.1 equiv) in THF (25 mL) at room temperature was treated with EEDQ (715.1 mg, 1.1 equiv). A heavy precipitate was formed overnight. Ether (50 mL) was added, and the suspension was sonicated at room temperature for several minutes. The solid was collected by filtration, washed with ether, and air-dried overnight (1.2665 g, 86%). ^{1}H NMR ($CDCl_3/CD_3OD$): δ 1.18 (2H, m), 1.39 (1H, m), 1.56 (1H, m), 2.60 (1H, q), 2.84 (3H, m), 4.16 (1H, m), 4.46 (3H, m and s), 4.79 (2H, ABq), 6.01

(1H, d), 7.11 (12H, m), 7.38 (2H, d). MS (FAB): *m/e* 561.3 $(MH)^+$. Anal. Calcd for $C_{30}H_{35}N_6O_6 \cdot 0.5H_2O$: C, 63.14; H, 6.36; N, 12.27. Found: C, 62.85; H, 6.26; N, 12.35.

Z-Leu-Cit-PABOH (24). Compound **24** was prepared as described above for **23** in 81% yield. ^{1}H NMR ($CDCl_3$/CD_3OD): δ 0.74 (6H, m), 1.36 (5H, m), 1.51 (2H, m), 1.71 (1H, m), 2.94 (2H, m), 4.02 (1H, q), 4.37 (1H, q), 4.41 (2H, s), 4.91 (2H, s), 7.13 (7H, m), 7.36 (2H, d). MS (FAB): *m/e* 528.4 $(MH)^+$, 550.3 $(M + Na)^+$. Anal. Calcd for $C_{27}H_{37}N_5O_6$-$0.5H_2O$: C, 60.43; H, 7.14; N, 13.05. Found: C, 60.50; H, 6.91; N, 13.02.

Z-Ile-Cit-PABOH (25). Compound **25** was prepared as described above for **23** in 76% yield. ^{1}H NMR ($CDCl_3$/CD_3OD): δ 0.72 (6H, m), 0.98 (2H, m), 1.32 (2H, m), 1.50 (1H, m), 1.63 (2H, m), 2.96 (2H, m), 3.82 (1H, m), 4.40 (3H, m and s), 4.90 (2H, s), 7.13 (7H, m), 7.45 (2H, d). MS (FAB): 526.4 $(M - H)^-$. Anal. Calcd for $C_{27}H_{37}N_5O_6 \cdot 0.5H_2O$: C, 60.43; H, 7.14; N, 13.05. Found: C, 59.94; H, 6.95; N, 13.05.

Z-Trp-Cit-PABOH (26). Compound **26** was prepared as described above for **23** in 98% yield. ^{1}H NMR ($CDCl_3$/CD_3OD): δ 1.12 (2H, m), 1.39 (1H, m), 1.62 (1H, m), 2.91 (2H, m), 3.11 (2H, m), 4.27 (1H, m), 4.48 (1H, m), 4.45 (2H, s), 4.91 (2H, ABq), 6.89 (1H, t), 6.98 (1H, t), 7.16 (9H, m), 7.31 (2H, d), 7.44 (1H, d), 9.42 (1H, br). MS (FAB): *m/e* 599.3 $(M - H)^-$. Anal. Calcd for $C_{32}H_{36}N_6O_6 \cdot 0.5H_2O$: C, 63.04; H, 6.12; N, 13.78. Found: C, 63.24; H, 6.19; N, 13.55.

Z-Phe-Arg(NO_2)-PABOH (27). Compound **27** was prepared as described above for **23** in 65% yield. ^{1}H NMR ($CDCl_3$/CD_3OD): δ 1.46 (2H, m), 1.58 and 1.74 (each 1H, m), 2.86 (m, 1H), 3.08 (3H, m), 4.32 (1H, q), 4.41 (1H, m), 4.51 (2H, s), 4.92 (2H, ABq), 5.99 (1H, d), 7.00−7.28 (12H, m), 7.38 (2H, d), 7.67 (1H, d), 9.14 (1H, br). MS (FAB): *m/e* 606.4 $(MH)^+$. Anal. Calcd for $C_{30}H_{35}N_7O_7 \cdot 0.5H_2O$: C, 58.62; H, 5.90; N, 15.95. Found: C, 58.29; H, 5.70; N, 15.81.

Z-Phe-Arg(Ts)-PABOH (28). Compound **28** was prepared as described above for **23** in 74% yield. ^{1}H NMR ($CDCl_3$/CD_3OD): δ 1.36 (2H, m), 1.52 and 1.71 (each 1H, m), 2.22 (3H, s), 2.86 (1H, m), 3.03 (3H, m), 4.50 (4H, m and s), 4.87 (2H, ABq), 5.97 (1H, br), 6.39 (1H, br), 6.95−7.25 (14H, m), 7.39 (2H, brs), 7.64 (2H, brs), 9.13 (1H, brs). MS (FAB): *m/e* 715.4 $(MH)^+$, 737.5 $(M + Na)^+$. Anal. Calcd for $C_{37}H_{42}N_6O_7S \cdot 0.5H_2O$: C, 61.40; H, 5.99; N, 11.61. Found: C, 61.28; H, 5.84; N, 11.40.

Z-Phe-Lys(alloc)-PABC-PNP (29). A stirred solution of Z-Phe-Lys(alloc)-PABOH **19** (269.6 mg, 0.4372 mmol) in dry THF (8 mL) at room temperature was treated with PNP chloroformate (106.0 mg, 1.2 equiv) and dry pyridine (0.0425 mL, 1.2 equiv). After 6 h, TLC (silica, 25:1 CH_2Cl_2/CH_3OH) indicated completion. Ethyl acetate (25 mL) and 10% aqueous citric acid (25 mL) were added. The organic layer was washed with water and brine, dried, and evaporated to give a yellow solid, which was purified by flash chromatography on silica gel, eluting with 30:1 CH_2Cl_2/CH_3OH, to give the product as an off-white solid (297.4 mg, 87%). ^{1}H NMR ($CDCl_3$/CD_3OD): δ 1.24, 1.42, 1.59 and 1.78 (6H, m), 2.97 (2H, m), 3.04 (2H, m), 4.38 (2H, m), 4.46 (2H, d), 5.01 (2H, s), 5.17 (2H, q), 5.21 (2H, s), 5.37 and 5.80 (each 1H, m), 5.83 (1H, m), 7.11 and 7.56 (4H, 2 × d), 7.13 and 7.25 (10H, m), 7.35 and 8.10 (each 2H, d), 9.23 (1H, br s). MS (FAB): *m/e* 782 $(MH)^+$, 804 $(M + Na)^+$, 820 $(M + K)^+$. Anal. Calcd for $C_{41}H_{43}N_5O_{11}$: C, 62.99; H, 5.54; N, 8.96. Found: C, 62.75; H, 5.49; N, 8.86.

Z-Val-Lys(alloc)-PABC-PNP (30). Compound **30** was prepared as described above for **29** in 71% yield. ^{1}H NMR ($CDCl_3$/CD_3OD): δ 0.91 (6H, m), 1.33−1.87 (6H, m), 2.02 (1H, m), 3.08 (2H, m), 3.95 (1H, m), 4.41 (1H, m), 4.48 (2H, d), 5.06 (2H, s), 5.17 (2H, q), 5.20 (2H, s), 5.82 (1H, m), 7.23 and 7.58 (4H, m), 7.30 (5H, m), 7.38 and 8.31 (4H, m). MS (FAB): *m/e* 734 $(MH)^+$, 756 $(M + Na)^+$, 772 $(M + K)^+$. HRMS calcd for $C_{37}H_{44}N_5O_{11}$, *m/e* 734.3037; found, *m/e* 734.3036.

Z-Ala-Lys(alloc)-PABC-PNP (31). Compound **31** was prepared as described above for **29** in 74% yield except that the eluting solvent for chromatographic purification was 20:1 CH_2Cl_2/CH_3OH. ^{1}H NMR ($CDCl_3$/CD_3OD): δ 1.09 (3H, 2 x d), 1.28, 1.40, 1.66 and 1.79 (6H, m), 3.08 (2H, m), 4.06 (1H, m), 4.38 (1H, m), 4.47 (2H, d), 5.02 (2H, s), 5.13 (2H, q), 5.23 (2H, s), 5.80 (1H, m), 7.25 and 7.60 (4H, m), 7.33 (5H, m), 7.42 and 8.35 (4H, m). MS (FAB): *m/e* 707 $(MH)^+$, 729 $(M + Na)^+$, 745 $(M + K)^+$. HRMS calcd for $C_{35}H_{40}N_5O_{11}$, *m/e* 706.2724; found, *m/e* 706.2722.

Z-Val-Cit-PABC-PNP (32). A stirred solution of Z-Val-Cit-PABOH **32** (383.0 mg, 0.7457 mmol) and PNP chloroformate (225.5 mg, 1.5 equiv) in THF (10 mL) in CH_2Cl_2 (5 mL) was treated at room temperature with pyridine (0.091 mL, 1.5 equiv). Workup as described above for **29** gave a crude, pale yellow solid, which was purified by flash chromatography on silica gel, eluting with (i) 30:1 and (ii) 12:1 CH_2Cl_2/CH_3OH, to give the product as an off-white solid (440.3 mg, 87%). ^{1}H NMR ($CDCl_3$/CD_3OD): δ 0.88 (6H, m), 1.42, 1.61 and 1.80 (4H, m), 2.02 (1H, m), 3.08 (2H, m), 3.99 (1H, m), 4.51 (1H, m), 5.00 (2H, m), 7.20−7.57 (9H, m), 7.30 and 8.20 (each 2H, m). MS (FAB): *m/e* 679 $(MH)^+$, 701 $(M + Na)^+$, 717 $(M + K)^+$. HRMS calcd for $C_{33}H_{39}N_6O_{10}$, *m/e* 679.2728; found, *m/e* 679.2720.

Z-Phe-Cit-PABC-PNP (33). Compound **33** was prepared as described above for **32** in 86% yield. ^{1}H NMR ($CDCl_3$/CD_3OD): δ 1.40 (2H, m), 1.59 and 1.78 (each 1H, m), 2.89 (1H, m), 3.03 (3H, m), 4.39 and 4.46 (each 1H, m), 4.95 (2H, brs), 5.19 (2H, s), 7.00−7.37 (14H, m), 7.55 (2H, d), 8.18 (2H, d). MS (FAB): *m/e* 727 $(MH)^+$, 765 $(M + K)^+$. HRMS calcd for $C_{37}H_{39}N_6O_{10}$, *m/e* 715.2728; found, *m/e* 715.2718.

Z-Leu-Cit-PABC-PNP (34). Compound **34** was prepared as described above for **32** in 83% yield. ^{1}H NMR ($CDCl_3$/CD_3OD): δ 0.73 (6H, m), 1.38 (4H, m), 1.52 (2H, m), 1.73 (1H, m), 2.91 (2H, m), 4.01 (1H, m), 4.38 (1H, m), 4.90 (2H, s), 5.09 (2H, s), 7.05−7.30 (9H, m), 7.44 (2H, d), 7.84 (1H, br), 8.11 (2H, d), 9.52 (1H, br). MS (FAB): *m/e* 693 $(MH)^+$, 715 $(M + Na)^+$, 731 $(M + K)^+$. HRMS calcd for $C_{34}H_{41}N_6O_{10}$, *m/e* 693.2884; found, *m/e* 693.2876.

Z-Ile-Cit-PABC-PNP (35). Compound **35** was prepared as described above for **32** in 83% yield. ^{1}H NMR ($CDCl_3$/CD_3OD): δ 0.72 (6H, m), 0.85 (2H, m), 1.20−1.90 (5H, m), 2.95 (2H, m), 3.94 (1H, m), 4.32 (1H, m), 4.89 (2H, s), 5.03 (2H, s), 7.05−7.30 (9H, m), 7.44 (2H, d), 8.05 (2H, d), 9.39 (1H, br). MS (FAB): *m/e* 715 $(M + Na)^+$, 731 $(M + K)^+$. HRMS calcd for $C_{34}H_{40}N_6O_{10}Na$, *m/e* 715.2704; found, *m/e* 715.2695.

Z-Trp-Cit-PABC-PNP (36). Compound **36** was prepared as described above for **32** in 72% yield. ^{1}H NMR ($CDCl_3$/CD_3OD): δ 1.11 (2H, m), 1.40 (1H, m), 1.63 (1H, m), 2.89 (2H, m), 3.05 (2H, m), 4.06 (1H, m), 4.40 (1H, m), 4.92 (2H, s), 5.09 (2H, s), 6.88 (1H, t), 6.94 (1H, t), 7.05−7.25 (10H, m), 7.34 (2H, d), 7.46 (1H, d), 8.04 (2H, d), 9.52 (1H, br). MS (FAB): *m/e* 766 $(MH)^+$, 788 $(M + Na)^+$, 804 $(M + K)^+$. HRMS calcd for $C_{39}H_{40}N_7O_{10}$, *m/e* 766.2837; found, *m/e* 766.2825.

Z-Phe-Arg(NO_2)-PABC-PNP (37). Compound **37** was prepared as described above for **32** in 84% yield. ^{1}H NMR ($CDCl_3$/CD_3OD): δ 1.35−1.85 (4H, m), 2.99 (2H, m), 3.17

(2H, m), 4.50 (1H, brt), 4.66 (1H, m), 4.92 (2H, ABq), 5.16 (2H, s), 7.00−7.32 (14H, m), 7.51 (2H, d), 8.18 (2H, d), 9.30 (1H, brs). MS (FAB): *m/e* 771 $(MH)^+$, 793 $(M + Na)^+$, 809 $(M + K)^+$. Anal. Calcd for $C_{37}H_{38}N_8O_{11}$: C, 57.66; H, 4.97; N, 14.54. Found: C, 57.53; H, 4.61; N, 14.77.

Z-Phe-Arg(Ts)-PABC-PNP (38). Compound **38** was prepared as described above for **32** in 99% yield. ^{1}H NMR ($CDCl_3$): δ 1.54 (3H, m), 1.82 (1H, m), 2.31 (3H, s), 2.91 (1H, q), 3.13 (3H, m), 4.55 (2H, m), 4.91 (2H, ABq), 5.18 (2H, s), 6.39 (1H, br), 7.02−7.35 (16H, m), 7.60 (2H, d), 7.69 (2H, d), 8.20 (2H, d). MS (FAB): *m/e* 880 $(MH)^+$, 918 $(M + K)^+$. Anal. Calcd for $C_{44}H_{45}N_7O_{11}S$: C, 60.06; H, 5.15; N, 11.14. Found: C, 59.89; H, 5.12; N, 11.31.

Z-Phe-Lys(alloc)-PABC-DOX (39). Z-Phe-Lys(alloc)-PABC-PNP **29** (337.2 mg, 0.4313 mmol) and DOX·HCl (275.2 mg, 1.1 equiv) in NMP (8 mL) at room temperature were treated with Et_3N (0.066 mL, 1.1 equiv). The mixture was allowed to stand in the dark for 2 d. The mixture was then diluted with 10% 2-propanol/ethyl acetate (100 mL) and washed with water (3 × 100 mL) and brine, dried, and evaporated to give an orange solid. This was purified by flash chromatography on silica gel, eluting with (i) 25:1 and (ii) 15:1 CH_2Cl_2/CH_3OH, to give the product as an orange solid (496.3 mg, 77%). ^{1}H NMR ($CDCl_3/CD_3OD$): δ 1.18 (3H, d), 1.22, 1.38, 1.56 and 1.77 (6H, m), 1.74 (2H, m), 2.23 (2H, m), 2.95 (2H, m), 3.02 (2H, m), 3.53 (1H, s), 3.80 (1H, m), 3.99 (3H, s), 4.06 (1H, m), 4.39 (2H, m), 4.43 (2H, d), 4.70 (2H, s), 4.89 (2H, m), 4.92 (1H, m), 4.96 (2H, d), 5.15 (2H, q), 5.11 and 5.39 (each 1H, s), 5.41 (1H, br), 5.60 and 5.92 (each 1H, m), 5.79 (1H, m), 7.08 and 7.23 (10H, m), 7.13 and 7.40 (4H, 2 x d), 7.50, 7.68 and 7.90 (each 1H, m), 9.15 (1H, brs). MS (FAB): *m/e* 1209 $(M + Na)^+$, 1224 $(M + K)^+$. HRMS calcd for $C_{62}H_{67}N_5O_{19}$, *m/e* 1186.4509; found, *m/e* 1186.4463.

Z-Val-Lys(alloc)-PABC-DOX (40). Compound **40** was prepared as described above for **39** in 69% yield. ^{1}H NMR ($CDCl_3/CD_3OD$): δ 0.83 (6H, m), 1.18 (3H, d), 1.29, 1.41, 1.63 and 1.79 (6H, m), 1.72 (2H, m), 1.98 (1H, m), 2.14 (2H, brs), 3.03 (2H, q), 3.02 (2H, m), 3.52 (1H, m), 3.76 (1H, m), 3.94 (1H, m), 3.99 (3H, s), 4.39 (1H, m), 4.42 (2H, d), 4.69 (2H, s), 4.88 (2H, m), 5.01 (2H, d), 5.14 (2H, q), 5.18 (1H, m), 5.41 (1H, br), 5.80 (1H, m), 7.13 and 7.40 (4H, 2 x d), 7.26 (5H, s), 7.32, 7.70 and 7.93 (each 1H, m), 9.25 (1H, br). MS (FAB): *m/e* 1160 $(M + Na)^+$, 1176 $(M + K)^+$. HRMS calcd for $C_{58}H_{67}N_5O_{19}$, *m/e* 1160.4328; found, *m/e* 1160.4358.

Z-Ala-Lys(alloc)-PABC-DOX (41). Compound **41** was prepared as described above for **39** in 67% yield. ^{1}H NMR ($CDCl_3/CD_3OD$): δ 1.08 (3H, m), 1.20 (3H, d), 1.28, 1.40, 1.60 and 1.81 (6H, m), 1.74 (2H, m), 2.19 (2H, brs), 3.02 (4H, m), 3.53 (1H, m), 3.79 (1H, m), 3.92 (1H, m), 3.97 (3H, s), 4.41 (1H, m), 4.45 (2H, d), 4.72 (2H, s), 4.89 (2H, m), 4.99 (2H, d), 5.08 (2H, q), 5.17 (1H, m), 5.39 (1H, br), 5.78 (1H, brs), 7.15 and 7.44 (4H, m), 7.27 (5H, s), 7.35, 7.73 and 7.94 (each 1H, m), 9.19 (1H, br). MS (FAB): *m/e* 1111 $(MH)^+$, 1133 $(M + Na)^+$, 1149 $(M + K)^+$. HRMS calcd for $C_{56}H_{64}N_5O_{19}$, *m/e* 1110.4196; found, *m/e* 1110.4178.

Z-Val-Cit-PABC-DOX (42). Z-Val-Cit-PABC−PNP **32** (126.9 mg, 0.187 mmol) and DOX·HCl (119.3 mg, 1.1 equiv) in NMP (5 mL) at room temperature were treated with Et_3N (0.029 mL, 1.1 equiv). The mixture was stirred in the dark at room temperature for 2 d. Workup as described above for **39** gave a crude orange solid. This was purified by flash chromatography on silica gel, eluting with (i) 12:1, (ii) 8:1, and (iii) 5:1 CH_2Cl_2/CH_3OH, to give the product as a red-orange solid (158.0 mg, 45%). HPLC (15 cm C-18 column, 4:1 CH_3OH /50 mM Et_3N/HCO_2H buffer (pH 2.8), flow rate: 1 mL/min, λ = 495 nm): retention time 3.70 min. ^{1}H NMR ($CDCl_3/CD_3OD$): δ 0.74 (6H, m), 1.07 (3H, d), 1.28−1.88 (4H, m), 1.64 and 2.08 (each 2H, m), 1.88 (1H, m), 2.87 (2H, m), 3.42 (1H, brs), 3.95 (1H, m), 4.11 (3H, s), 4.38 (2H, m), 4.58 (2H, s), 4.78 (2H, s), 4.90 (2H, s), 5.04 (1H, brs), 5.30 (1H, brs), 7.00−7.86 (12H), 9.31 (1H, brs). MS (FAB): *m/e* 1083 $(MH)^+$, 1105 $(M + Na)^+$, 1121 $(M + K)^+$. HRMS calcd for $C_{54}H_{63}N_6O_{18}$, *m/e* 1083.4199; found, *m/e* 1083.4161. Anal. Calcd for $C_{54}H_{62}N_6O_{18}\cdot 3.5H_2O$: C, 56.59; H, 6.07; N, 7.33. Found: C, 56.59; H, 5.79; N, 7.54.

Z-Phe-Cit-PABC-DOX (43). Compound **43** was prepared as described above for **42** in 35% yield. HPLC (15 cm C-18 column, 4:1 CH_3OH /50 mM Et_3N/HCO_2H buffer (pH 2.8), flow rate: 1 mL/min, λ = 495 nm): retention time 4.55 min. ^{1}H NMR ($CDCl_3/CD_3OD$): δ 1.19 (3H, d), 1.40 (3H, m), 1.59 (1H, m), 1.75 (3H, m), 2.18 (2H, ABq), 2.76−3.20 (6H, m), 3.51 (1H, s), 3.80 (1H, m), 3.97 (4H, m and s), 4.10 (1H, q), 4.38 (2H, m), 4.69 (2H, s), 4.92 (4H, m), 5.12 (1H, brs), 5.39 (1H, brs), 6.10 (1H, d), 6.98−7.25 (12H, m), 7.40 (3H, m), 7.71 (1H, t), 7.89 (1H, t). MS (FAB): *m/e* 1169 $(M + K)^+$. HRMS calcd for $C_{58}H_{62}N_6O_{18}K$, *m/e* 1169.3758; found, *m/e* 1169.3740.

Z-Leu-Cit-PABC-DOX (44). Compound **44** was prepared as described above for **42** in 38% yield. HPLC (15 cm C-18 column, 4:1 CH_3OH /50 mM Et_3N/HCO_2H buffer (pH 2.8), flow rate: 1 mL/min, λ = 495 nm): retention time 4.90 min. ^{1}H NMR ($CDCl_3/CD_3OD$): δ 0.72 (6H, m), 1.10 (6H, m), 1.35−1.60 (4H, m), 1.72 (3H, m), 2.09 (2H, m), 2.83 (2H, m), 3.05 (2H, m), 3.46 (1H, brs), 3.73 (1H, m), 3.95 (1H, m), 4.01 (3H, s), 4.41 (1H, m), 4.64 (2H, s), 4.78 (2H, m), 4.93 (2H, s), 5.06 (1H, brs), 5.36 (1H, brs), 6.98−7.90 (12H). MS (FAB): *m/e* 1119 $(M + Na)^+$, 1135 $(M + K)^+$. HRMS calcd for $C_{55}H_{61}N_6O_{18}Na$, *m/e* 1116.3940; found, *m/e* 1116.3911.

Z-Ile-Cit-PABC-DOX (45). Compound **45** was prepared as described above for **42** in 44% yield. HPLC (15 cm C-18 column, 4:1 CH_3OH /50 mM Et_3N/HCO_2H buffer (pH 2.8), flow rate: 1 mL/min, λ = 495 nm): retention time 4.62 min. ^{1}H NMR ($CDCl_3/CD_3OD$): δ 0.74 (6H, m), 0.98 (1H, m), 1.11 (2H, m), 1.20 (3H, d), 1.38 (3H, m), 1.71 (2H, m), 2.13 (2H, m), 2.82 (2H, m), 3.02 (2H, m), 3.48 (1H, brs), 3.75 (1H, m), 3.97 (3H, s), 4.01 (1H, m), 4.39 (1H, m), 4.64 (2H, s), 4.79 (2H, m), 4.93 (2H, s), 5.07 (1H, brs), 5.37 (1H, brs), 6.95−7.95 (12H). MS (FAB): *m/e* 1095 $(MH)^+$, 1133 $(M + K)^+$. HRMS calcd for $C_{55}H_{62}N_6O_{18}$, *m/e* 1094.4121; found, *m/e* 1094.4105.

Z-Trp-Cit-PABC-DOX (46). Compound **46** was prepared as described above for **42** in 48% yield. HPLC (15 cm C-18 column, 4:1 CH_3OH /50 mM Et_3N/HCO_2H buffer (pH 2.8), flow rate: 1 mL/min, λ = 495 nm): retention time 3.80 min. ^{1}H NMR ($CDCl_3/CD_3OD$): δ 1.22 (6H, m and d), 1.48 (1H, m), 1.75 (3H, m), 2.13 (2H, ABq), 2.70−3.17 (6H, m), 3.51 (1H, s), 3.79 (1H, m), 3.91 (3H, s), 4.10 (1H, q), 4.32 (1H, m), 4.38 (1H, m), 4.69 (2H, s), 4.91 (2H, m), 4.93 (2H, s), 5.04 (1H, brs), 5.37 (1H, brs), 5.91 (1H, br), 6.23 (1H, d), 6.89 (1H, t), 6.98 (1H, t), 7.16 (9H, m), 7.31 (1H, d), 7.36 (2H, d), 7.43 (1H, d), 7.64 (1H, t), 7.78 (1H, d). MS (FAB): *m/e* 1192 $(M + Na)^+$, 1208 $(M + K)^+$. Anal. Calcd for $C_{60}H_{63}N_7O_{18}\cdot 3.5H_2O$: C, 58.43; H, 5.72; N, 7.95. Found: C, 58.17; H, 5.57; N, 8.08.

Z-Phe-Arg(NO_2)-PABC-DOX (47). Compound **47** was prepared as described above for **42** in 65% yield. HPLC (15 cm C-18 column, 4:1 CH_3OH /50 mM Et_3N/HCO_2H buffer (pH 2.8), flow rate: 1 mL/min, λ = 495 nm): retention time 4.45 min. ^{1}H NMR ($CDCl_3/CD_3OD$): δ 1.18 (3H, d), 1.49 (3H, m), 1.72 (3H, m), 2.02 (1H, m), 2.21 (1H, m), 2.61 (1H, m), 2.87 (2H, m), 3.06 (4H, m), 3.52 (1H, brs), 3.74 (1H, m), 3.93 (3H, s), 4.03 (1H, m), 4.42

(2H, m), 4.68 (2H, s), 4.87 (2H, m), 5.11 (1H, br), 5.39 (1H, brs), 5.66 (1H, brd), 6.97−7.78 (15H, m), 7.65 (1H, brt), 7.87 (1H, m)9.13 (1H, brs). MS (FAB): *m/e* 1173.7 $(M-H)^-$. Anal. Calcd for $C_{58}H_{62}N_8O_{19}$-$3H_2O$: C, 56.67; H, 5.57; N, 9.11. Found: C, 56.75; H, 5.28; N, 8.92.

Z-Phe-Arg(Ts)-PABC-DOX (48). Compound **48** was prepared as described above for **42** (74%). HPLC (15 cm C-18 column, 4:1 CH_3OH /50 mM Et_3N/HCO_2H buffer (pH 2.8), flow rate: 1 mL/min, λ = 495 nm): retention time 5.96 min. ^1H NMR ($CDCl_3/CD_3OD$): δ 1.16 (3H, d), 1.39 (3H, m), 1.53 (1H, m), 1.71 (3H, m), 2.01 (1H, d), 2.24 (3H, s), 2.82 (3H, m), 3.02 (5H, m), 3.52 (1H, s), 3.76 (1H, q), 3.92 (3H, s), 4.02 (1H, m), 4.40 (1H, m), 4.48 (1H, m), 4.68 (2H, s), 4.84 (2H, m), 5.08 (1H, brs), 5.38 (1H, brs), 5.61 (1H, brd), 5.98 (1H, brd), 6.37 (1H, br), 6.96−7.20 (14H, m), 7.25 (1H, d), 7.32 (2H, d), 7.64 (3H, m), 7.88 (1H, d), 9.11 (1H, brs). MS (FAB): *m/e* 1306 $(M + Na)^+$, 1322 $(M + K)^+$. HRMS calcd for $C_{65}H_{69}N_7O_{19}SNa$, *m/e* 1306.4269; found, *m/e* 1306.4251.

Z-Phe-Lys-PABC-DOX•HCl (49). Z-Phe-Lys(alloc)-PABC-DOX **39** (34.9 mg, 29.4 mmol) and $(PPh_3)_2PdCl_2$ (0.6 mg, 3 mol %) in dry THF (1 mL) under argon at room temperature were treated with acetic acid (0.0035 mL, 2 equiv) and then with Bu_3SnH (0.01 mL, 1.2 equiv). The reaction was stirred at room temperature for 1.5 h and then treated with 1 M HCl in ether (0.06 mL, 2 equiv). The mixture was stored in the freezer for 1 h, and then, the crude orange solid was collected by filtration and washed repeatedly with ether. The solid was washed through the glass frit with 5:1 CH_2Cl_2/CH_3OH, and then, the filtrate was evaporated. The residue was sonicated in CH_3OH (5 mL) to dissolve as much as possible and then filtered to remove an insoluble red byproduct. The filtrate was evaporated to give an orange-red solid (25.1 mg, 75%). HPLC (15 cm C-18 column, 4:1 CH_3OH /50 mM Et_3N/HCO_2H buffer (pH 2.8), flow rate: 1 mL/min, λ = 495 nm): retention time 7.09 min. ^1H NMR ($CDCl_3/CD_3OD$): δ 1.18 (2H, d), 1.34, 1.65 and 1.73 (6H, m), 2.14 (2H, m), 2.81 (2H, m), 3.76 (1H, m), 3.98 (3H, s), 4.05 (1H, m), 4.38 and 4.45 (each 1H, m), 4.67 (2H, s), 4.85 (1H, m), 7.04 and 7.20 (10H, m), 7.14 and 7.43 (4H, m), 7.30, 7.69 and 7.92 (each 1H, m). MS (FAB): *m/e* 1102 $(MH)^+$, 1124 $(M + Na)^+$. HRMS calcd for $C_{58}H_{64}N_5O_{17}$, *m/e* 1102.4297; found, *m/e* 1102.4290. Anal. Calcd for $C_{58}H_{64}N_5O_{17}$·$0.5H_2O$: C, 60.70; H, 5.71; N, 6.10. Found: C, 60.66; H, 5.93; N, 6.02.

Z-Val-Lys-PABC-DOX·HCl (50). Z-Val-Lys(alloc)-PABC-DOX **40** (84.3 mg, 0.0741 mmol) in THF (2 mL) under argon at room temperature was treated with $Pd(PPh_3)_4$ (0.22 mL of a solution of Pd_2dba_3 (4.7 mg, 5.13 mmol) and PPh_3 (13.5 mg, 10 equiv) in THF (1 mL) under argon, acetic acid (0.011 mL, 2.5 equiv), and tributyltin hydride (0.030 mL, 1.5 equiv). The mixture was stirred at room temperature in the dark for 1 h during which time an orange solid began to form. The mixture was diluted with ether (25 mL) followed by 1 M HCl in ether (1 mL). The resulting suspension was sonicated briefly and then filtered. The orange solid was washed repeatedly with ether and then dissolved in 5:1 CH_2Cl_2/CH_3OH. To this was added Celite (2 g), and the solvents were evaporated. The resulting solid was dry-loaded on a Celite column (from a slurry in 100:1 CH_2Cl_2/CH_3OH). The column was eluted with (i) 100:1 and (ii) 10:1 CH_2Cl_2/CH_3OH, to give the product as an orange solid (58.5 mg, 72%). HPLC (15 cm C-18 column, 4:1 CH_3OH /50 mM Et_3N/HCO_2H buffer (pH 2.8), flow rate: 1 mL/min, λ = 495 nm): retention time 6.03 min. ^1H NMR ($CDCl_3/CD_3OD$): δ 0.83 (6H, m), 1.20 (3H, d), 1.41 (2H, m), 1.73 (1H, m), 1.79 (2H, m), 2.02 (1H, m), 2.12 (2H, m), 2.92 (3H, m), 3.17 (1H, d), 3.52 (1H, s), 3.73 (1H, m), 3.92 (1H, m), 4.01 (3H, s), 4.04 (1H, m), 4.44 (1H, m), 4.70 (2H, s), 4.88 (2H, m), 5.11 (3H, m), 5.42 (1H, s), 7.10−7.30 (7H, m), 7.41 (2H, d), 7.32, 7.72 and 7.91 (each 1H, m). MS (FAB): *m/e* 1054 $(MH)^+$. HRMS calcd for $C_{54}H_{64}N_5O_{17}$, *m/e* 1054.4297; found, *m/e* 1054.4283. Anal. Calcd for $C_{54}H_{56}N_5O_{17}$·H_2O: C, 58.51; H, 6.00; N, 6.32. Found: C, 58.74; H, 6.03; N, 6.29.

Z-Ala-Lys-PABC-DOX·HCl (51). Compound **51** was prepared as described above for **50** in 68% yield. HPLC (15 cm C-18 column, 4:1 CH_3OH /50 mM Et_3N/HCO_2H buffer (pH 2.8), flow rate: 1 mL/min, λ = 495 nm): retention time 4.52 min. ^1H NMR ($CDCl_3/CD_3OD$): δ 1.28 (5H, 2 x d and m), 1.49 (2H, m), 1.67 (1H, m), 1.85 (4H, m), 2.91 (2H, m), 3.00 (1H, d), 3.22 (1H, d), 3.61 (1H, s), 3.80 (1H, m), 4.03 (3H, s), 4.11 (1H, m), 4.39 (2H, m), 4.74 (2H, s), 4.92 (2H, m), 5.09 (2H, m), 5.22 (1H, brs), 5.49 (1H, brs), 7.05−7.35 (8H, m), 7.45 (12H, d), 7.77 (1H, t), 7.99 (1H, d), 9.02 (1H, br). MS (FAB): *m/e* 1027 $(MH)^+$, 1049 $(M + Na)^+$. HRMS calcd for $C_{52}H_{60}N_5O_{17}$, *m/e* 1026.3984; found, *m/e* 1026.3967. Anal. Calcd for $C_{52}H_{60}N_5O_{17}$·$2H_2O$: C, 56.85; H, 5.87; N, 6.38. Found: C, 56.51; H, 5.99; N, 6.35.

Z-Phe-Lys(alloc)-DOX (52). A stirred solution of Z-Phe-Lys(alloc) **9** (127.5 mg, 0.2492 mmol), DOX·HCl (159.0 mg, 1.1 equiv), and HOSu (34.4 mg, 1.2 equiv) in NMP (7.5 mL) at 0 °C was treated with DCC (61.7 mg, 1.2 equiv) and Et_3N (0.038 mL, 1.1 equiv). After 30 min, the mixture was allowed to gradually warm to room temperature. After a further 16 h, the mixture was filtered and the filtrate was diluted with ethyl acetate (100 mL). The solution was washed with water (3×) and brine, dried, and evaporated in vacuo. The residue was purified by flash chromatography on silica gel, eluting with 15:1 CH_2Cl_2/CH_3OH, to give an orange solid (196.1 mg, 76%). ^1H NMR ($CDCl_3/CD_3OD$): δ 1.20 (5H, m and d), 1.36 (2H, m), 1.47 (1H, m), 1.64 (2H, m), 1.82 (1H, brt), 2.14 (2H, ABq), 2.81 (1H, d), 3.01 (2H, m), 3.09 (1H, d), 3.54 (1H, s), 3.73 (1H, m), 3.93 (3H, s), 4.06 (1H, q), 4.21 (1H, q), 4.31 (1H, m), 4.43 (2H, d), 4.70 (2H, s), 4.89 (2H, s), 5.17 (3H, q and s), 5.40 (2H, m and s), 5.79 (1H, m), 6.90−7.40 (11H, m), 7.64 (1H, t), 7.87 (1H, d). MS (FAB): *m/e* 1036 $(M - H)^-$. HRMS calcd for $C_{54}H_{60}N_4O_{17}$-Na, 1059.3851; found, 1059.3856.

Z-Val-Cit-DOX (53). This was prepared as described above for **52** in 68% yield, except that 10% *n*-butanol/ethyl acetate was used in place of ethyl acetate, and the eluting solvents in the chromatographic purification were (i) 20:1, (ii) 10:1, and (iii) 5:1 CH_2Cl_2/CH_3OH. HPLC (15 cm C-18 column, 4:1 CH_3OH /50 mM Et_3N/HCO_2H buffer (pH 2.8), flow rate: 1 mL/min, λ = 495 nm): retention time 3.49 min. ^1H NMR ($CDCl_3/CD_3OD$): δ 0.72 (6H, 2 x d), 1.18 (3H, d), 1.32 (2H, m), 1.46 (1H, m), 1.71 (2H, m), 1.83 (2H, m), 2.13 (2H, ABq), 2.81 (1H, d), 2.98 (2H, m), 3.09 (1H, d), 3.50 (1H, s), 3.87 (1H, m), 3.92 (3H, s), 4.02 (1H, m), 4.27 (1H, q), 4.69 (2H, s), 4.92 (2H, m), 5.05 (1H, brs), 5.33 (1H, brs), 6.02 (1H, d), 7.17 (5H, brs), 7.28 (1H, t), 7.62 (2H, t and d), 7.83 (1H, d). MS (FAB): *m/e* 932.6 $(M - H)^-$. Anal. Calcd for $C_{46}H_{55}N_5O_{16}$·$1.5H_2O$: C, 57.49; H, 6.08; N, 7.29. Found: C, 57.36; H, 6.10; N, 7.27.

Z-Phe-Lys-DOX·HCl (54). Compound **54** was prepared as described above for **50** in 77% yield. HPLC (15 cm C-18 column, 4:1 CH_3OH /50 mM Et_3N/HCO_2H buffer (pH 2.8), flow rate: 1 mL/min, λ = 495 nm): retention time 5.88 min. ^1H NMR ($CDCl_3/CD_3OD$): δ 1.15 (3H, d), 1.33 (2H, m), 1.63 (2H, m), 1.74 (2H, m), 2.03 (2H, m), 2.91 (4H, m), 3.19 (1H, d), 3.51 (1H, s), 3.73 (1H, m), 3.98 (3H, s), 4.02 (1H, m), 4.37 (1H, m), 4.43 (1H, m), 4.68 (2H, s), 4.95 (2H, m), 5.18 (1H, brs), 5.40 (1H, brs), 7.00−

7.30 (10H, m), 7.32 (1H, d), 7.69 (1H, t), 7.92 (1H, m). MS (FAB): *m/e* 953 $(MH)^+$, 975 $(M + Na)^+$, 991 $(M + K)^+$. HRMS calcd for $C_{50}H_{57}N_4O_{15}$, *m/e* 953.3820; found, *m/e* 953.3802. Anal. Calcd for $C_{50}H_{57}N_4O_{15}\cdot H_2O$: C, 59.61; H, 5.90; N, 5.56. Found: C, 59.54; H, 5.87; N, 5.40.

Fmoc-Lys(MMT) (55). A stirred suspension of Fmoc-Lys·HCl (23.78 g, 56.42 mmol) in dry CH_2Cl_2 (250 mL) under argon at room temperature was treated with trimethylsilyl chloride (15 mL, 2.1 equiv) and DIEA (10.3 mL, 1.05 equiv). The mixture was heated at reflux for 1 h, during which time it became homogeneous, and then cooled to 0 °C. DIEA (31 mL, 3.1 equiv) was added, followed by *p*-anisyldiphenylmethyl chloride (18.29 g, 1.05 equiv). The reaction was stirred at room temperature for 14 h. The solvent was evaporated, and the residue was partitioned between ethyl acetate and pH 5 buffer (0.05 M biphthalate). The organic phase was washed with more pH 5 buffer, water, and brine, dried, and evaporated to give a pale yellow foam (34.71 g, 96%). ^{1}H NMR ($CDCl_3$): δ 1.26 and 1.68 (2H and 4H, m), 2.45 (2H, m), 3.71 (3H, s), 4.05−4.40 (4H, m), 6.81 (2H, d), 7.15−7.77 (20H, m). MS (FAB): *m/e* 641 $(MH)^+$, 663 $(M + Na)^+$, 679 $(M + K)^+$. HRMS calcd for $C_{41}H_{41}N_2O_5$, *m/e* 641.3015; found, *m/e* 641.3001.

Lys(MMT) (56). Fmoc-Lys(MMT) **55** (5.25 g, 8.19 mmol) in 1:1 CH_2Cl_2/CH_3CN (80 mL) at room temperature was treated with diethylamine (80 mL). After 1.5 h, the solvents were evaporated. The residue was flushed with CH_3CN (2 × 50 mL) at 60 °C and then triturated with ether (80 mL). The resulting solid was collected by filtration, washed with ether, and then dissolved as far as possible in 1:1 CH_2Cl_2/CH_3OH. Some solid byproduct was removed by filtration, and the filtrate was concentrated in vacuo. The resulting light tan solid was dried in vacuo for 4 h (3.2221 g, 94%). ^{1}H NMR (DMSO-d_6): δ 1.34, 1.57 and 1.72 (m, 6H), 2.05 (m, 2H), 3.38 (m, 1H), 3.68 (s, 3H), 3.71 (d, 2H), 7.03−7.40 (m, 12H). MS (FAB): *m/e* 419.2 $(MH)^+$, 441.4 $(M + Na)^+$, 457.4 $(M + K)^+$. Anal. Calcd for $C_{26}H_{30}N_2O_3\cdot 0.5H_2O$: C, 73.04; H, 7.31; N, 6.55. Found: C, 73.12; H, 7.39; N, 6.56.

Fmoc-Phe-OSu (57). Fmoc-Phe (5.1043 g, 13.17 mmol) and HOSu (1.592 g, 1.05 equiv) in CH_2Cl_2 (100 mL) at 0 °C were treated with DCC (2.854 g, 1.05 equiv). The ice bath was allowed to warm to room temperature, and the mixture was stirred for 14 h. DCU was removed by filtration, and the filtrate was evaporated in vacuo. The resulting material was used without further purification.

Fmoc-Val-OSu (58). Fmoc-Val (5.060 g, 14.91 mmol) and HOSu (1.72 g, 1 equiv) in THF (50 mL) at 0 °C were treated with DCC (3.080 g, 1 equiv). The mixture was stirred at room temperature for 16 h, and then, the solid DCU byproduct was filtered off and washed with THF. The solvent was removed on the rotovap, and the resulting glassy solid was used without purification in the next step.

Fmoc-Phe-Lys(MMT) (59). A stirred suspension of Lys(MMT) **56** (4.686 g, 11.20 mmol) and $NaHCO_3$ (941.0 mg, 1 equiv) in water (100 mL) and DME (50 mL) was treated with a solution of Fmoc-Phe-OSu 57 (11.20 mmol) in DME (50 mL). THF (25 mL) was added to aid solubility. The mixture was stirred at room temperature for 2 d and then as much DME as possible was removed in vacuo at 30 °C. The resulting gummy suspension was partitioned between ethyl acetate and pH 5 buffer. The organic phase was washed with water and brine, dried, and evaporated to give a pale yellow foam. This was flushed with CH_2Cl_2 (100 mL). TLC showed the product to be pure enough to carry on without further purification (8.559 g, 97%). ^{1}H NMR ($CDCl_3/CD_3OD$): δ 1.10−1.93 (6H, m), 2.31 (2H, t), 3.00 (2H, m), 3.71 (3H, s), 4.02−4.48 (5H, m), 6.79 (2H, d), 7.00−7.75 (25H, m). MS (FAB): *m/e* 788.2 $(MH)^+$, 810.4 $(M + Na)^+$, 826 $(M + K)^+$.

Fmoc-Val-Cit (60). Fmoc-Val-OSu **58** (14.91 mmol) in DME (40 mL) was added to a solution of Cit (2.743 g, 1.05 equiv) and $NaHCO_3$ (1.315 g, 1.05 equiv) in water (40 mL). THF (20 mL) was added to aid solubility, and the mixture was stirred at room temperature for 16 h. Aqueous citric acid (15%, 75 mL) was added, and the mixture was extracted with 10% 2-propanol/ethyl acetate (2 × 100 mL). The solid product began to precipitate but remained in the organic layer. The suspension was washed with water (2 × 150 mL), and the solvents were evaporated. The resulting white solid was dried in vacuo for 5 h and then treated with ether (80 mL). After brief sonication and trituration, the white solid product was collected by filtration (5.801 g, 78%). ^{1}H NMR (DMSO-d_6): δ 0.87 (6H, q), 1.40, 1.59 and 1.69 (4H, m), 1.97 (1H, m), 2.94 (2H, q), 3.92 (1H, t), 4.10−4.35 (2H, m), 4.23 (2H, t), 5.37 (2H, brs), 5.92 (1H, t), 7.28−7.90 (8H, m), 8.15 (1H, d). MS (FAB): *m/e* 497 $(MH)^+$, 519 $(M + Na)^+$, 535 $(M + K)^+$. HRMS calcd for $C_{26}H_{33}N_4O_6$, 497.2400; found, 497.2394. Anal. Calcd for $C_{26}H_{32}N_4O_6$: C, 62.89; H, 6.50; N, 11.28. Found: C, 62.92; H, 6.67; N, 11.07.

Fmoc-Phe-Lys(MMT)-PABOH (61). Fmoc-Phe-Lys-(MMT) **59** (7.728 g, 9.808 mmol) and PABOH (1.450 g, 1.2 equiv) in CH_2Cl_2 (100 mL) at room temperature were treated with EEDQ (3.640 g, 1.5 equiv). The mixture was stirred at room temperature for 20 h, and then, the solvent was evaporated (water bath at 30 °C). The solid residue was triturated with ether (200 mL), and the resulting suspension was sonicated for 15 min and left to stand at room temperature for 2 h. The resulting solid was collected by filtration, washed well with ether, and dried in vacuo (7.6140 g, 87%). ^{1}H NMR ($CDCl_3/CD_3$-OD): δ 0.98−1.91 (6H, m), 2.06 (2H, t), 2.97 (2H, m), 3.71 (3H, s,), 4.12 (1H, t), 4.20−4.41 (4H, m), 4.59 (2H, s), 6.72 (2H, d), 7.00−7.73 (29H, m). MS (FAB): *m/e* 891.4 $(MH)^+$, 916.7 $(M + Na)^+$, 931 $(M + K)^+$. Anal. Calcd for $C_{57}H_{56}N_4O_6\cdot H_2O$: C, 75.14; H, 6.42; N, 6.15. Found: C, 75.25; H, 6.42; N, 6.19.

Fmoc-Val-Cit-PABOH (62). Fmoc-Val-Cit **60** (1.0443 g, 2.103 mmol) and PABOH (518.0 mg, 2 equiv) in 2:1 CH_2Cl_2/CH_3OH (35 mL) were treated with EEDQ (1.0402 g, 2 equiv). The mixture was stirred in the dark at room temperature for 1.5 d. The solvents were removed on the rotovap at 40 °C, and the white solid residue was triturated with ether (75 mL). The resulting suspension was sonicated for 5 min and then left to stand for 30 min. The solid was collected by filtration, washed with ether, and dried in vacuo (1.0070 g, 80%). ^{1}H NMR (DMSO-d_6): δ 0.88 (6H, t), 1.41 and 1.65 (4H, m), 2.00 (1H, m), 2.99 (2H, m), 3.92 (1H, t), 4.24 (2H, d), 4.19−4.50 (2H, m), 4.43 (2H, d), 5.11 (1H, t), 5.42 (2H, brs), 5.98 (1H, t), 7.15−7.92 (12H, m), 8.12 (1H, d), 9.99 (1H, brs). MS (FAB): *m/e* 602 $(MH)^+$, 624 $(M + Na)^+$, 640 $(M + K)^+$. HRMS calcd for $C_{33}H_{40}N_5O_6$, *m/e* 602.2979; found, *m/e* 602.2977. Anal. Calcd for $C_{33}H_{39}N_5O_6$: C, 65.87; H, 6.53; N, 11.64. Found: C, 65.61; H, 6.49; N, 11.73.

Phe-Lys(MMT)-PABOH (63). Fmoc-Phe-Lys(MMT)-PABOH **61** (4.286 g, 4.80 mmol) in CH_2Cl_2 (35 mL) at room temperature was treated with diethylamine (50 mL). The mixture was sonicated briefly and stirred at room temperature for 4 h after which time no starting material was observed by TLC (15:1 CH_2Cl_2/CH_3OH). The solvents were evaporated, and the residue was flushed with CH_2Cl_2 and purified by flash chromatography on silica gel, eluting with (i) 2%, (ii) 3%, and (iii) 4% CH_3-OH /CH_2Cl_2, to give the product as a colorless foam (2.230

g, 69%). ^{1}H NMR ($CDCl_3$): δ 1.26−2.00 (6H, m), 2.12 (2H, t), 2.75 and 3.21 (each 1H, ABq), 3.68 (1H, ABq), 3.76 (3H, s,), 4.42 (1H, q), 4.66 (2H, brs), 6.79 (2H, d), 7.10−7.42 (21H, m), 7.81 (1H, d), 8.71 (1H, s). MS (FAB): *m/e* 693.4 $(M + Na)^+$, 709 $(M + K)^+$. Anal. Calcd for $C_{42}H_{46}N_4O_4 \cdot 0.5H_2O$: C, 74.20; H, 6.97; N, 8.24. Found: C, 74.28; H, 7.00; N, 8.34.

Val-Cit-PABOH (64). Fmoc-Val-Cit-PABOH **62** (245.2 mg, 0.4075 mmol) in NMP (4 mL) at room temperature was treated with diethylamine (0.8 mL). The mixture was left to stand at room temperature for 16 h, and then, the solvents were removed on the rotovap at 40 °C. The thick, oily residue was treated with CH_2Cl_2 (15 mL), and the mixture was sonicated at room temperature. The resulting solid was collected by filtration, washed with CH_2Cl_2, and dried in vacuo (141.6 mg, 92%). ^{1}H NMR (DMSO-d_6): δ 0.82 (6H, 2 x d), 1.39, 1.59 and 1.66 (4H, m), 1.92 (1H, m), 2.98 (1H, m), 3.03 (2H, d), 4.45 (2H, d), 4.48 (1H, m), 5.10 (1H, brt), 5.41 (2H, brs), 5.99 (1H, brt), 7.21 and 7.52 (each 2H, d), 8.12 (1H, brd), 10.03 (1H, brs). MS (FAB): *m/e* 380 $(MH)^+$, 402 $(M + Na)^+$, 418 $(M + K)^+$. HRMS calcd for $C_{18}H_{30}N_5O_4$, *m/e* 380.2298; found, *m/e* 380.2290. Anal. Calcd for $C_{18}H_{29}N_5O_4$: C, 56.98; H, 7.70; N, 18.46. Found: C, 56.83; H, 7.63; N, 16.31.

MC-Phe-Lys(MMT)-PABOH (65). A stirred solution of Phe-Lys(MMT)-PABOH **63** (448.1 mg, 0.668 mmol) and DIEA (0.128 mL, 1.1 equiv) in CH_2Cl_2 (7 mL) at room temperature was treated with MC-OSu (230.4 mg, 1.12 equiv). The mixture was stirred at room temperature for 3 d. Ethyl acetate (60 mL) was added, and the mixture was washed with pH 5 buffer (2×), water, and brine, dried, and evaporated. The residue was triturated with ether (60 mL), and the resulting solid was collected by filtration and washed with ether (563.8 mg, 98%). ^{1}H NMR ($CDCl_3$): δ 1.05−1.96 (12H, m), 2.07 (2H, t), 2.18 (2H, t), 3.02 (2H, m), 3.39 (2H, t), 3.71 (3H, s), 4.64 (3H, s and m), 4.99 (1H, q), 6.61 (2H, s), 6.71 (2H, d), 6.89 (1H, m), 7.00−7.55 (21H, m), 8.97 (1H, brs). MS (FAB): *m/e* 864 $(MH)^+$, 886 $(M + Na)^+$, 902.4 $(M + K)^+$. Anal. Calcd for $C_{52}H_{57}N_5O_7 \cdot H_2O$: C, 70.81; H, 6.74; N, 7.94. Found: C, 71.15; H, 7.20; N, 8.27.

MC-Val-Cit-PABOH (66). A solution of Val-Cit-PABOH **64** (136.8 mg, 0.3605 mmol) and MC-OSu (122.3 mg, 1.1 equiv) in NMP (5 mL) was stirred at room temperature for 16 h. The NMP was removed under high vacuum on the rotovap (bath temperature, 40 °C), and the thick, oily residue was triturated with ether (20 mL). The solid product was collected by filtration and washed repeatedly with ether (205.7 mg, 99.6%). ^{1}H NMR (DMSO-d_6): δ 0.82 (6H, ABq), 1.10−1.90 (10H, m), 1.92 (1H, m), 2.16 (2H, t), 2.98 (2H, m), 3.33 (2H, t), 4.19 (1H, t), 4.38 (1H, m), 4.42 (2H, brd), 5.10 (1H, brt), 5.42 (2H, brs), 5.97 (1H, brt), 6.99 (2H, s), 7.21 and 7.52 (each 2H, d), 7.82 and 8.07 (each 1H, d), 9.90 (1H, brs). MS (FAB): *m/e* 573 $(MH)^+$, 595 $(M + Na)^+$, 611 $(M + K)^+$. HRMS calcd for $C_{28}H_{41}N_6O_7$, *m/e* 573.3037; found, *m/e* 573.3016. Anal. Calcd for $C_{28}H_{40}N_6O_7 \cdot 2H_2O$: C, 55.25; H, 7.28; N, 13.81. Found: C, 55.31; H, 6.98; N, 14.03.

MC-Phe-Lys(MMT)-PABC-PNP (67). MC-Phe-Lys-(MMT)-PABOH **65** (679.3 mg, 0.786 mmol) and bis-PNP carbonate (1.196 g, 5 equiv) under argon at room temperature were dissolved in CH_2Cl_2 (25 mL) and treated with DIEA (0.41 mL, 3 equiv). After 3 d, TLC indicated completion. The volume was reduced to ca. 5 mL on the rotovap, and the residue was diluted with ethyl acetate (80 mL) and washed with pH 5 buffer, water, and brine, dried, and evaporated. The resulting solid was triturated with ether (80 mL), and the solid was collected by filtration, washed with ether, and purified by flash chromatography on silica gel, eluting with (i) 1:1 and (ii) 8:1 ethyl acetate/hexane, to give the product as a pale yellow glass (670.7 mg, 83%). ^{1}H NMR ($CDCl_3$): δ 1.10−1.95 (12H, m), 2.04 (2H, t), 2.13 (2H, t), 3.04 (2H, m), 3.39 (2H, t), 3.72 (3H, s), 4.58 (1H, q), 4.86 (1H, q), 5.27 (2H, s), 6.58 (1H, d), 6.61 (2H, s), 6.72 (2H, d), 7.03−7.62 (27H, m), 8.22 (2H, d), 8.86 (1H, brs). MS (FAB): *m/e* 1029 $(MH)^+$, 1051.5 $(M + Na)^+$, 1069.4 $(M + K)^+$. HRMS calcd for $C_{59}H_{61}N_6O_{11}$, *m/e* 1029.4398; found, *m/e* 1029.4422. Anal. Calcd for $C_{59}H_{60}N_6O_{11}$: C, 68.86; H, 5.88; N, 8.17. Found: C, 68.68; H, 5.88; N, 8.04.

MC-Phe-Lys(MMT)-PABC-DOX (68). MC-Phe-Lys-(MMT)-PABC-PNP **67** (126.6 mg, 0.123 mmol) and DOX·HCl (71.3 mg, 1 equiv) in NMP (5 mL) at room temperature were treated with DIEA (0.021 mL, 1 equiv). After 2 d standing in the dark at room temperature, the mixture was diluted with ethyl acetate (60 mL) and washed with water (4×) and brine, dried, and evaporated. The residue was purified by flash chromatography on silica gel, eluting with (i) 25:1 and (ii) 20:1 CH_2Cl_2/CH_3OH, to give the product as an orange glass (149.0 mg, 85%). ^{1}H NMR ($CDCl_3$): δ 1.10−1.95 (14H, m), 1.27 (3H, d), 2.10 (4H, m), 2.23 (2H, m), 3.03 (2H, m), 3.20 (2H, m), 3.41 (2H, t), 3.67 (1H, brs), 3.77 (3H, s), 4.08 (3H, s), 4.13 (1H, m), 4.40 (1H, m), 4.56 (2H, m), 4.76 (2H, brs), 4.99 (2H, m), 5.29 (1H, brs), 5.51 (1H, brs), 5.18, 6.02 and 6.38 (each 1H, m), 6.62 (2H, s), 6.77 (2H, d), 7.00−7.60 (22H, m), 7.78 and 8.03 (each 1H, m), 8.22 (1H, brs). MS (FAB): *m/e* 1433.8 $(MH)^+$, 1456.0 $(M + Na)^+$, 1471.8 $(M + K)^+$. HRMS calcd for $C_{80}H_{85}N_6O_{19}$, *m/e* 1433.5870; found, *m/e* 1433.5813.

MC-Phe-Lys-PABC-DOX·Cl_2CHCO_2H (69). A stirred solution of MC-Phe-Lys(MMT)-PABC-DOX **68** (1.1520 g, 0.804 mmol) in CH_2Cl_2 (50 mL) and anisole (8.73 mL, 100 equiv) was treated with dichloroacetic acid (0.66 mL, 10 equiv). After 1 h, ethyl acetate (80 mL) was added and the resulting suspension was stored in the freezer for 1.5 h. The solid was collected by filtration, washed with ethyl acetate, and dried in vacuo (1.0092 g, 97%). HPLC (15 cm C-18 column, 4:1 CH_3OH /50 mM Et_3N/HCO_2H buffer (pH 2.8), flow rate: 1 mL/min, λ = 495 nm): retention time: 4.52 min. ^{1}H NMR ($CDCl_3/CD_3OD$): δ 1.10−1.90 (14H, m), 1.21 (3H, d), 2.10 (2H, t), 2.20 (2H, m), 2.88 (2H, m), 3.02 (2H, m), 3.12 (2H, m), 3.38 (2H, t), 3.52 (1H, brs), 3.79 (1H, m), 4.02 (3H, s), 4.10 (1H, m), 4.43 and 4.54 (each 1H, m), 4.72 (2H, s), 4.92 (2H, m), 5.24 (1H, br s), 5.44 (1H, br s), 5.84 (1H, s), 6.67 (2H, s), 7.10 (5H, brs), 7.21 and 7.48 (each 2H, d), 7.38, 7.77 and 7.99 (each 1H, d, t, and d). MS (FAB): *m/e* 1159 $(M - H)^-$. HRMS calcd for $C_{60}H_{68}N_6O_{18}Na$, *m/e* 1183.4488; found, *m/e* 1183.4457. Anal. Calcd for $C_{62}H_{70}N_6O_{20}Cl_2 \cdot 2H_2O$: C, 56.15; H, 5.62; N, 6.34. Found: C, 55.87; H, 5.68; N, 6.05.

MC-Val-Cit-PABC-PNP (70). MC-Val-Cit-PABOH **66** (112.4 mg, 0.1963 mmol) under argon at room temperature was dissolved in dry pyridine (3 mL). The solution was cooled to 0 °C, and PNP chloroformate (119 mg, 3 equiv) in CH_2Cl_2 (2 mL) was added all at once. After 10 min at 0 °C, the ice bath was removed and the mixture was stirred at room temperature for 2 h. Ethyl acetate (50 mL) and 15% aqueous citric acid (75 mL) were added. The organic phase was washed with more citric acid, water, and brine, dried, and evaporated to give a light yellow gum. This was purified by flash chromatography on silica gel, eluting with (i) 20:1 and (ii) 15:1 CH_2Cl_2/CH_3OH, to give the product as a white solid (21.5 mg, 15%). ^{1}H NMR ($CDCl_3/CD_3OD$): δ 0.90 (6H, d), 1.16−1.95 (10H, m), 2.12 (1H, m), 2.23 (2H, t), 3.17 (2H, m), 3.48 (2H, t), 4.20 (1H, m), 4.59 (1H, m), 5.22 (2H, s), 6.66

(2H, s), 6.91 and 7.79 (each 1H, d), 7.34 and 7.60 (each 2H, d), 7.34 and 8.23 (each 2H, d), 9.49 (1H, brs). MS (FAB): *m/e* 738 $(MH)^+$, 760 $(M + Na)^+$, 776 $(M + K)^+$. Anal. Calcd for $C_{35}H_{43}N_7O_{11}$: C, 56.98; H, 5.87; N, 13.29. Found: C, 56.68; H, 5.82; N, 12.93.

MC-Val-Cit-PABC-DOX (71). MC-Val-Cit-PABC-PNP **70** (21.2 mg, 0.0287 mmol) and DOX·HCl (18.3 mg, 1.1 equiv) in NMP (1.5 mL) at room temperature were treated with DIEA (0.055 mL, 1.1 equiv). The mixture was left to stand in the dark at room temperature for 2 d, and then, CH_2Cl_2 (25 mL) was added. The resulting suspension was stored in the freezer overnight, and then, the solid was collected by filtration and washed with CH_2Cl_2. The undissolved material was purified by flash chromatography on silica gel, eluting with (i) 15:1, (ii) 10:1, and (iii) 5:1 CH_2Cl_2/CH_3OH (the sample was loaded in a minimum amount of 2:1 CH_2Cl_2/CH_3OH), to give the product as an orange solid (22.4 mg, 68%). HPLC (15 cm C-18 column, 4:1 CH_3OH /50 mM Et_3N/HCO_2H buffer (pH 2.8), flow rate: 1 mL/min, $\lambda = 495$ nm): retention time 3.49 min. ^1H NMR ($CDCl_3/CD_3OD$): δ 0.83 (6H, d), 1.18 (3H, d), 1.20−1.86 (12H, m), 1.93 (1H, m), 2.12 (2H, m), 2.17 (2H, t), 2.90−3.20 (4H, q and m), 3.39 (2H, t), 3.50 (1H, brs), 3.98 (3H, s), 4.02 (1H, m), 4.05 (1H, m), 4.46 (1H, m), 4.68 (2H, s), 4.88 (2H, q), 5.16 (1H, brs), 5.39 (1H, brs), 6.62 (2H, s), 7.13 and 7.42 (each 2H, d), 7.32, 7.71 and 7.92 (each 1H; d, t and d). MS (FAB): *m/e* 1141 $(MH)^+$, 1164.6 $(M + Na)^+$, 1180 $(M + K)^+$. HRMS calcd for $C_{56}H_{67}N_7O_{19}Na$, *m/e* 1164.4389; found, *m/e* 1164.4363. Anal. Calcd for $C_{56}H_{67}N_7O_{19}\cdot H_2O$: C, 57.97; H, 5.99; N, 8.45. Found: C, 58.23; H, 5.97; N, 8.18.

Preparation of Immunoconjugates. *BR96-SC-Phe-Lys-PABC-DOX (72).* A solution of the MAb BR96 in 0.025 M citrate buffer (400 mL, 8.52 mg/mL, ca. 0.057 mM, concentration determined by UV absorption at 280 nm, 1 mg/mL of MAb equals 1.4 absorbance units) was diafiltered in two Amicon model 8400 stirred ultra filtration cells fitted with a YM30 ultrafilter (MW cutoff 30 000) to exchange the citrate buffer with 0.01 M phosphate-buffered 0.9% sodium chloride solution (PBS, pH 7.4). The solution was then incubated at 37 °C under nitrogen with gentle stirring and then treated with 10 mM DTT in 0.01 M PBS (16.6 mL, freshly prepared, 7.0 equiv), giving a final DTT concentration of 0.40 mM. After 3 h, the solution was transferred to two Amicon cells and diafiltration was carried out against 0.01 M PBS at pH 6 until the effluent was free of SH groups (as detected by Ellman reagent). The antibody solutions were transferred to a sterile container and kept at 0 °C under nitrogen. The concentration of protein was determined by the UV absorbance at 285 nm and that of thiol by the method of Ellman (*18*) (9.01 mg/mL, and 0.468 mM, respectively; MR (SH/protein) = 8.31). To the stirred antibody solution was added 1 mol of MC-Phe-Lys-PABC-DOX·Cl_2CHCO_2H **69** (57.6 mL of a 5 mg/mL solution in DMF) per mole of free thiol generated on the antibody. After it was stirred at 4 °C for 30 min, the mixture was left to stand for 16 h at 4 °C and then filtered through a 0.22 μm cellulose acetate membrane. The filtrate was chromatographed on a 10 cm × 30 cm gel filtration column (Cellufine GH25, Amicon), and the product-containing fractions were combined. The conjugate solution was filtered again through a 0.22 μm cellulose acetate membrane (final volume, 475 mL). The concentration of DOX was determined using the UV absorbance at 495 nm ($\epsilon_{495} = 8030$ cm^{-1} M^{-1}; 328 mM, 67.9 mg/mL) and that of the MAb at 280 nm with a correction for DOX absorbance at 280 nm according to the formula (*19*)

$$[\text{MAb}]\ (\text{mg/mL}) = (A_{280} - (0.724 \times A_{495}))/1.4$$

where *A* is the observed absorbance at noted wavelength.

The MR of DOX conjugated to the antibody was 8.2. Human IgG (Rockland Inc., Gilbertsville, PA) was used to prepare a nonbinding control IgG-SC-Phe-Lys-PABC-DOX conjugate **74** as described above.

BR96-SC-Val-Cit-PABC-DOX (73). This was prepared essentially as described above for **72** giving an immunoconjugate with MR = 4.4. Human IgG was used to prepare a nonbinding control IgG-SC-Val-Cit-PABC-DOX conjugate **75**.

Drug Release by Cathepsin B. Assay conditions were chosen to approximate the lysosomal medium as a model for intracellular drug release. A stock solution of bovine spleen cathepsin B (EC 3.4.22.1, M_W ca. 40 000) was prepared by dissolving the lyophilized solid (1.2 mg, ca. 36% protein) in 1 mL of a 25 mM sodium acetate/1 mM EDTA buffer (pH 5.0). The enzyme solution was found to be stable at 4 °C for at least 8 h and was stored overnight at −80 °C. Stock solutions were discarded within 2 weeks of preparation. For each assay, a portion of the enzyme solution (0.006 mL) was activated at room temperature with a solution of 30 mM DTT/15 mM EDTA (0.012 mL) for 15 min. The activated cathepsin B was then diluted with 2 mL of a 25 mM acetate/1 mM EDTA buffer (pH 5.0, preincubated at 37 °C) (*20*).

For dipeptide model compounds, 0.008 mL of a 10 mM solution of the substrate in CH_3OH was added to the enzyme solution, giving the following approximate initial concentrations: [cathepsin B] = 30 nM and [substrate] = 0.04 mM. The mixture was incubated at 37 °C, and aliquots were removed at various time points and injected into the HPLC (15 cm C-18 column, 4:1 CH_3OH /50 mM Et_3N-HCO_2H buffer (pH 2.8), flow rate: 1 mL/min, $\lambda =$ 495 nm). The time between injections was varied depending on the speed of drug release. The ratios of DOX/substrate peak areas were used to calculate half-lives ($t_{1/2}$) of release. At 495 nm, the appearance of DOX correlated precisely with the disappearance of substrate. When Z-Phe-Lys-PABC-DOX **49** was run at higher concentrations (≥5 mM), a small, transient peak was observed between the substrate and the DOX peaks that might have been the intermediate PABC-DOX (Figure 1 and Scheme 1). Substrate stabilities were also measured in the pH 5 buffer solution in the absence of cathepsin B. No measurable release of DOX was ever observed within 6−7 h.

For testing of immunoconjugates, 0.3 mL of a 10 mg/mL solution of the substrate in PBS (pH 7.0) was diluted to 1 mL with the pH 5.0 acetate/EDTA buffer at 37 °C (final pH, 5.3). This solution was added to the cathepsin B, activated as described above. The mixture was incubated at 37 °C. Periodically, 0.025 mL aliquots were removed and diluted with ice-cold CH_3OH (0.05 mL) to precipitate protein. The samples were centrifuged, and the supernatants were injected into the HPLC (configured as described above). Half-lives were calculated by calibration of DOX peak areas with a standard curve of known DOX concentrations. For each immunoconjugate, >90% of the theoretical release of DOX was observed.

Drug Release in Rat Liver Lysosomes. Rat liver lysosomes were isolated by differential centrifugation according to the method of Lardeux (*21*). The protein concentration in the lysosomal pellets was determined by the Bradford assay (Bio-Rad Protein Assay Kit II, Bio-Rad, Hercules, CA). For a typical incubation, a known concentration of linker was added to a pH 5.5 sucrose/phosphate buffer mixture containing 0.1% Triton-X and

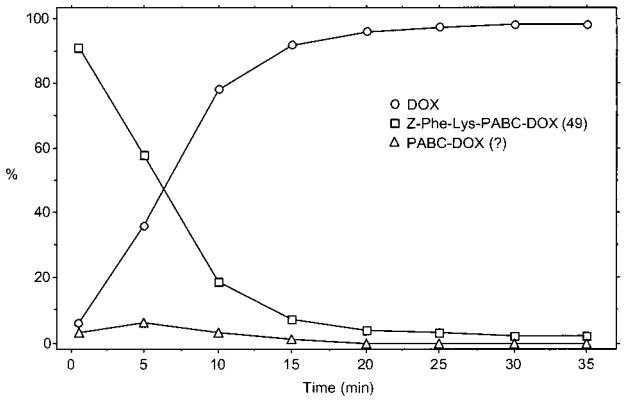

Figure 1. Cathepsin B-mediated release of free DOX from Z-Phe-Lys-PABC-DOX **49** at pH 5.0, 37 °C.

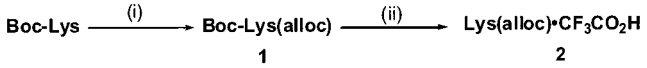
6 mg of lysosomal protein. The mixtures were incubated at 37 °C, and at specific time points, aliquots were removed and the protein was precipitated. The supernatant solution was then extracted and analyzed for free DOX by HPLC. In some experiments, the DOX-containing model substrates and immunoconjugates were incubated with the potent cathepsin B, H, and L inhibitor, E-64 (L-*trans*-epoxysuccinyl-L-leucylamido-(4-guanidino)-butane; final concentration, 0.010 mg/mL) (*22*).



Human Plasma Stability Assays. For each dipeptide model compound assay, a portion (0.004 mL) of a 10 mM solution of the substrate in CH_3OH was injected into freshly drawn human plasma (1 mL, preincubated at 37 °C). For the immunoconjugate, 0.3 mL of a 10 mg/mL solution in PBS (pH 7.0) was diluted to 1 mL with plasma. Each sample was incubated at 37 °C. Aliquots (0.05 mL) were periodically removed and diluted with ice-cold CH_3OH (0.1 mL) to precipitate proteins. The samples were centrifuged for 10 min, and the supernatants were injected into the HPLC (configured as described above). Half-lives were calculated as described above. Enough free DOX was added to a separate plasma sample to give a theoretical release of 1%. This was successfully detected using the same methods.

Human Tumor Cell Lines. L2987 is a lung adenocarcinoma line obtained from I. Hellstrom (Bristol-Myers Squibb, Seattle, WA), HCT116 is a colorectal tumor line obtained from M. Brattain (Baylor Institute, TX), and A2780 is an ovarian carcinoma line obtained from K. Scanlon (National Cancer Institute).

Binding Assays. Binding assays were performed by indirect immunofluorescence. Briefly, target cells were harvested in logarithmic phase using trypsin/EDTA (GIBCO, Grand Island, NY) in PBS. The cells were washed twice in PBS containing 1% BSA (Sigma Chemical Co.) and resuspended to 1×10^7/mL in PBS containing 1% BSA and 0.1% sodium azide. Cells (0.1 mL) were mixed with various antibodies (0.1 mL at 0.040 mg MAb/mL) and incubated for 45 min at 4 °C. The cells were washed twice and resuspended in 0.1 mL of an appropriate concentration of rabbit antihuman IgG (Cappel Laboratories, Cochranville, PA, Fab′2 fragment). Cells were incubated for 30 min at 4 °C, washed twice, and kept on ice until analyzed on a Coulter EPICS 753 fluorescence-activated cell sorter. Data are expressed as FI: the mean channel number of specific minus control antibody.

In Vitro Cytotoxicity. Antigen-specific cytotoxicity was evaluated as described previously (*2*). Briefly, monolayer cultures of various human carcinoma cells were harvested and the cells were counted and resuspended to 1×10^5/mL in RPMI-1640 containing heat-inactivated FCS (RPMI-10% FCS). Cells (0.1 mL/well) were added to each well of 96 well microtiter plates and incubated overnight at 37 °C in a humidified atmosphere of 5% CO_2. Media was removed from the plates, and serial dilutions of DOX or MAb-DOX conjugates were added to the wells. All dilutions were performed in quadruplicate. Cells were exposed to DOX or MAb-DOX conjugates for 2 h, at 37 °C, in a humidified atmosphere of 5% CO_2. Plates were then centrifuged (200*g*, 5 min), the drug or conjugate was removed, and the cells were washed three times and cultured in RPMI-10% FCS (37 °C, 5% CO_2). Approximately 48 h after the addition of conjugates or DOX, the cells were pulsed for 2 h with 1.0 mCi/well of ^{3}H-thymidine (New England Nuclear, Boston, MA). Cells were harvested onto glass fiber mats (Skatron Instruments Inc., Sterling, VA), and dried, and filter-bound ^{3}H radioactivity was determined (β-plate scintillation counter, Pharmacia LKB Biotechnology, Piscataway, NJ). Inhibition of ^{3}H-thymidine uptake was determined by comparing the mean CPM for treated samples with that of the untreated control.

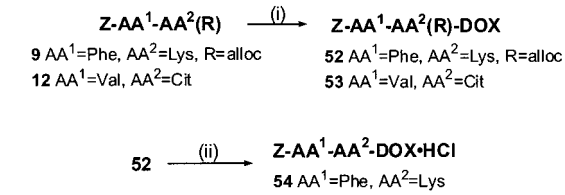
RESULTS AND DISCUSSION

Dipeptide Model Substrate Preparation. The Z-protected dipeptide model substrates were prepared as outlined in Schemes 2−4, for the most part using modifications of well-known methods in peptide chemistry. The self-immolative PABC spacer was introduced by coupling PABOH to the dipeptide using EEDQ (**19**−**28**) followed by reaction with PNP chloroformate to give the activated carbonates (**29**−**38**). Alloc was used for protection of the side chain amino group of Lys (Scheme 2). Deprotection of compounds **39**−**41** and **52** was effected by treatment with $Pd(PPh_3)_4$ or $(PPh_3)_2PdCl_2$ followed by quenching of the allyl−Pd complex with Bu_3SnH (*23*). Triethylsilane was also tried as a hydride source but was found to be too sluggish. Careful addition of either 1 M HCl/ether precipitated the crude ammonium salts (**49**−**51** and **54**). Satisfactory purification usually involved simply dissolving the solid as far as possible in methanol and filtering off insoluble byproducts but could also be carried out by chromatography on Celite, eluting with progressively more polar mixtures of CH_3OH/CH_2Cl_2.

Immunoconjugate Preparation. Chimeric BR96 is a human IgG_1 MAb directed against a Lewis^y-related, tumor-associated antigen. The MAb contains four interchain disulfides that can be opened under mild reducing conditions (i.e., titrated DTT at 37 °C) giving eight free thiol groups that can be functionalized with maleimides and other thiophiles and leaving 12 intrachain disulfides intact (*24*). DOX-peptide substrates **69** and **71** that possess a thiophilic maleimide ring for conjugation to BR96 were prepared as shown in Schemes 5−8. The Val-Cit dipeptide sequence was included because we did not want to rely solely on the in vivo stability of AA[1]-Lys-containing substrates. The six-carbon caproyl spacer used in BR96-DOX was retained to provide space between the dipeptide and the large antibody.



For the preparation of **69** and **71**, two major modifications had to be made to the syntheses shown for the model substrates. In both cases, an N-terminal protecting

group was required for the P_2 AA until the PABOH was installed (**65** and **66**) since we found that the presence of the maleimide caused nonproductive consumption of EEDQ. For MC-Phe-Lys-PABC-DOX **69**, a new side chain amino protecting group was needed for Lys as maleimides were found to be unstable under all conditions used to remove the alloc group. The selection of protecting groups is very restricted in this case because DOX is labile to all but very mild acids (including TFA) as well as reducing agents, while the maleimide is sensitive to

nucleophiles and reduction. We first used Boc and Fmoc as the N-terminal and Lys side chain protecting groups, respectively (synthesis not shown). In this sequence, Fmoc was removed in the final step by very brief (<1 min) treatment with 1% DBU in THF, followed by protonation with 1M HCl/ether. Yields of **69**, as the HCl salt, ranged from 30 to 50% and included large amounts of oligomeric byproducts probably resulting from addition of the Lys amino group to the maleimide. Purification on either LH-20 lipophilic Sephadex or Celite was cumbersome, and the whole procedure was not easily amenable to large-scale synthesis.

Substantial improvement resulted from the use of MMT as the Lys protecting group, with Fmoc blocking the N terminus of the P_2 AA (*25*). MMT was introduced through TMS activation/protection of Fmoc-Lys (Scheme 5) (*26*). Although MMT-protected amines are unreactive under normal conditions with the typical moderately activated carbonates and esters used in peptide-related synthesis, MC-Phe-Lys(MMT)-PABOH (**65**) overreaction with PNP chloroformate did occur at 0 °C, resulting in formation of the Lys-PNP carbamate with loss of MMT. However, we were able to replace the chloroformate with bis-PNP carbonate to provide the activated carbonate **67** in good yield. MMT was removed from the DOX-containing intermediate **68** by treatment with dichloroacetic acid/anisole in CH_2Cl_2 in nearly quantitative yield. The dichloroacetate salt **69** was precipitated out of solution by the addition of ether. Filtration, washing with ether, and thorough drying resulted in analytically pure product.

MC-Val-Cit-PABC-DOX **71** was prepared in a similar manner (Scheme 8). In subsequent work on other Cit-containing linkers, we found that the PNP carbonates (i.e., **70**) are also more efficiently made using bis-PNP carbonate as shown in Scheme 7.

DOX-peptide substrates **69** and **71** were conjugated with thiolated BR96 by a modification of the procedure used for BR96-DOX (*24*) as shown in Scheme 9, affording the immunoconjugates BR96-Phe-Lys-PABC-DOX **72** and BR96-Val-Cit-PABC-DOX **73**. The process involves the reduction of four interchain disulfide bonds in the hinge

region of the antibody to give eight free thiol groups. Protein yields for both immunoconjugates were nearly quantitative. The DOX/MAb MR of 8 for the Phe-Lys conjugate **72** represents maximal drug loading. The lower MR of 4.4 for the Val-Cit conjugate **73** probably resulted from the limited aqueous solubility of **71**. Subsequent experiments showed that even very hydrophobic linker compounds could be conjugated to give high MRs by careful manipulation of conditions (i.e., pH, rate of stirring, etc.) during addition. Nonbinding human IgG conjugates (**74** and **75**) were prepared or each dipeptide linker as a control.

Table 1. Half-Lives ($t_{1/2}$) of Cathepsin B-Mediated Release of DOX from Dipeptide Model Substrates at 37 °C, pH 5.0

substrate	no.	$t_{1/2}$ (min)
Z-Phe-Lys-PABC-DOX	**49**	8
Z-Phe-Lys-DOX	**54**	NH[a]

Z-Phe-Arg(Ts)-PABC-DOX	**48**	1980

[a] NH = not hydrolyzed (no observed change over 6−7 h).

Enzymatic DOX Release and Plasma Stability. Cathepsin B-mediated DOX release data for these substrates are shown in Table 1. Drug release from representative examples lacking the PABC spacer (**53** and **54**) was not observed over 6−7 h. Steric crowding around the P_1 amide carbonyl and/or the inability of the cathepsin B active site, which is located in a deep cleft in the protein (*6*), to include the bulky DOX moiety are the most probable explanations. Enhanced reactivity of the PABC anilide can be ruled out as the explanation even though aniline pK_a values are low (ca. 4), since cathepsin B released Gly-DOX from a substrate containing Val-Cit-Gly-DOX (synthesis not shown) with $t_{1/2}$ = 2 h, and the pK_a values of the DOX amino group (8.2) (*27*) and Gly-Ala-Ala (8.1) (*28*) are very similar. Therefore, Gly serves as an adequate steric, but not self-immolative, spacer for DOX.

Other trends are evident in the cathepsin B half-life data. At the P_1 site, the protonatable Lys is more readily attacked than Cit, whose side chain can only form hydrogen bonds. Substrates containing nitro- and tosyl-protected Arg (**47** and **48**) are very slowly cleaved. On the basis of the limited variety of side chains tested, the preference at the P_2 site is for a sizable hydrophobic residue. Cathepsin B also accepts basic AAs at P_2, but these sequences would probably be targets of other proteases in vivo (*6*). In the AA^1-Cit series (**42**−**46**), differences in release rates are seen when AA^1 is varied, with Val giving the best results. When P_1 = Lys, there

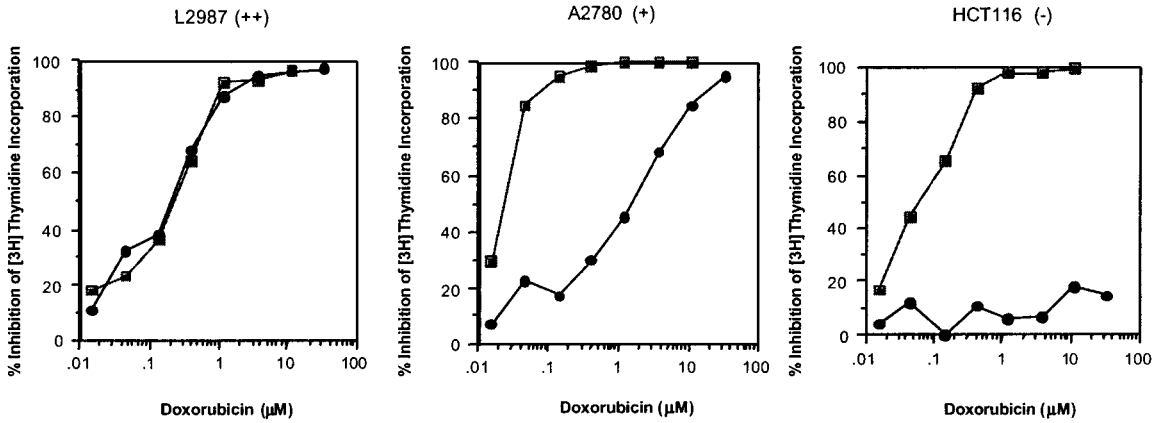

Figure 2. Cytotoxicities of BR96-SC-Phe-Lys-PABC-DOX **72** (●) and DOX (■) against human carcinoma lines L2987 (lung), A2780 (ovarian), and HCT116 (colon) that express different densities of the BR96-defined antigen.

Z-Val-Cit-PABC-DOX	**42**	240	29	NH
Z-Val-Cit-DOX	**53**	NH	NH	
BR96-SC-Phe-Lys-PABC-DOX	**72**	180	55	NH
BR96-SC-Val-Cit-PABC-DOX	**73**	285	159	NH

[a] NH = not hydrolyzed (no observed change over 6−7 h).

Table 3. Cytotoxicity of BR96-Phe-Lys-PABC-DOX 72, a Nonbinding IgG-SC-Phe-Lys-PABC-DOX Conjugate 74 and Unconjugated DOX Against Human Carcinoma Lines Expressing Varying Levels of the BR96 Antigen

		inhibition of proliferation (IC_{50} μM equivalent DOX)			specificity ratio[a]
cell line	BR96 antigen expression	**72**	**74**	DOX	IgG/BR96
L2987	+++	0.2	>33	0.2	>220
A2780	+	1.5	ND[b]	0.02	ND
HCT116	−	>33	>33	0.06	N/A[c]

[a] IC_{50} of **74**/**72**. [b] Not determined. [c] Not applicable.

is no measurable difference between Phe and Val at P_2. However, DOX release is so fast for these substrates that it is unlikely that a difference would have been seen. This P_2 selectivity in the Cit series may reflect different active site binding modes for Cit and Lys at P_1 resulting in somewhat different substrate orientations.

Representative model compounds were tested in a preparation of rat liver lysosomal enzymes (Table 2). Whereas Z-Phe-Lys-PABC-DOX **49** was cleaved much more quickly than Z-Val-Cit-PABC-DOX **42** by cathepsin B alone, in the lysosomal mixture the two showed no difference in their release rates. In addition, DOX release from both was completely inhibited by the cysteine protease inhibitor E-64 (*22*) (data not shown). These results suggest that other lysosomal cysteine proteases that are inhibited by E-64 (cathepsins L and H) may be involved in drug release from **42**. As was seen with cathepsin B, the two substrates that lack the self-immolative PABC spacer (**53** and **54**) are not hydrolyzed in the lysosomal mixture.

Importantly, the AA[1]-Lys substrates **49**−**51** and Z-Val-Cit-PABC-DOX **53** were found to be unchanged in freshly drawn human plasma at 37 °C over 6−7 h (Table 2), demonstrating the stability of these dipeptides to plasma proteases and the PABC spacer to plasma esterases and proteases.

Immunoconjugates **72** and **73** were tested for drug release with cathepsin B (Table 2) as described above for the model substrates. In both cases, DOX was released more slowly from the conjugate in comparison with the corresponding model substrate, perhaps reflecting the greater steric barrier that the antibody presents to the protease. However, the difference in rates between the two immunoconjugates was not of the same magnitude as was seen for the model compounds. DOX release was nearly quantitative (>90%) from both conjugates. In the rat liver lysosome preparation, both **72** and **73** released DOX more quickly than with cathepsin B alone, and release was completely inhibited by E-64, again implicating other lysosomal proteases acting along with cathepsin B, perhaps more effectively. No free DOX was detected from either conjugate upon incubation in freshly drawn human plasma over 7 h (Table 2).

Antigen-Specific Cytotoxicity of BR96-Phe-Lys-PABC-DOX and BR96-Val-Cit-PABC-DOX Conjugates. The L2987, A2780, and HCT116 human carcinoma cell lines were evaluated for their expression of the BR96 antigen using direct immunofluorescence. The L2987 lung tumor line expressed the greatest density of the BR96 antigen (FI = 172.8), the A2780 ovarian line expressed BR96 at a lower density (FI = 103.2), and the HCT116 colon line did not express the antigen (FI = 0). The in vitro potency of BR96-Phe-Lys-PABC-DOX **72** against these three lines was evaluated in comparison with a nonbinding IgG-Phe-Lys-PABC-DOX conjugate **74** and unconjugated DOX (Table 3 and Figure 2). The potency of **72** was directly related to the level of antigen expression on the various cell lines. The L2987 lung carcinoma line that expresses the highest level of BR96 antigen was the most sensitive to **72** (IC_{50} = 0.15 μM) whereas the conjugate was not active against the antigen negative HCT166 carcinoma line (IC_{50} > 33 μM). The antigen-specific activity of **72** was also shown by the lack of activity of the nonbinding conjugate **74**. Against L2987, the line expressing the highest level of the BR96 antigen, **72** was >220-fold more potent than **74** evaluated in parallel. The activity of **72** in comparison with DOX is shown for the three carcinoma lines in Figure 2. The potency of **72** was equivalent to that of unconjugated DOX against the high antigen-expressing line L2987, approximately 75-fold less potent than DOX against the low-expressing A2780 line, and >550-fold less potent than DOX against the antigen negative HCT116 line.

The activity of the BR96-Val-Cit-PABC-DOX conjugate

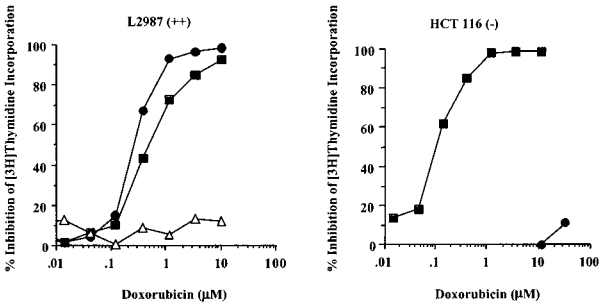

Figure 3. Cytotoxicities of BR96-SC-Val-Cit-PABC-DOX **73** (●), IgG-SC-Val-Cit-PABC-DOX **75** (△), and DOX (■) against human carcinoma lines L2987 (lung) and HCT116 (colon) that express different densities of the BR96-defined antigen.

73 (Figure 3) was also related to the density of BR96 antigen expressed by the L2987 and HCT116 carcinoma lines. The potency of **73** (IC_{50} = 0.4 μM) was similar to that of free DOX (IC_{50} = 0.2 μM) against the high-expressing L2987 line. In contrast, **73** was not active against the antigen negative HCT116 carcinoma line (IC_{50} > 33 μM), even though this line was quite sensitive to free DOX (IC_{50} = 0.1 μM). Both dipeptide-containing immunoconjugates showed superior potency to the hydrazone-linked BR96-DOX (IC_{50} (L2987) = 2.8 μM vs 0.15 μM for **72**) as well as greatly enhanced selectivity (specificity ratio = 8 vs >220 for **72**) (*29*).

In summary, the robust human plasma stability and the potent, antigen-specific cytotoxicity of **72** and **73** suggest that these dipeptide linkers may improve both the efficacy and the therapeutic index of MAb-directed delivery. Indeed, immunoconjugates **72** and **73** proved to be highly active in vivo. Those results will be the subject of a later paper.

NOTE ADDED AFTER ASAP POSTING

The units for a number of IC_{50} values in the text were corrected to micromolar (μM) from millimolar (mM). The corrected version was posted on June 27, 2002.

Introduction of Lanthanide(III) Chelates to Oligopeptides on Solid Phase

Jari Peuralahti, Harri Hakala, Veli-Matti Mukkala, Kristiina Loman, Pertti Hurskainen, Outi Mulari, and Jari Hovinen*

PerkinElmer Life Sciences, Wallac Oy, P.O. Box 10, FIN-20101 Turku, Finland. Received February 26, 2002.

The synthesis of oligopeptide building blocks for the introduction of nonluminescent and luminescent lanthanide(III) chelates to the oligopeptide structure on the solid phase is described. The oligopeptide conjugates synthesized were used in DELFIA-based receptor binding assay (motilin) as well as in LANCE time-resolved fluorescence quenching assay (caspase-3).

INTRODUCTION

Because of their unique luminescence properties, lanthanide(III) chelates are often used as nonradioactive markers in a wide variety of routine and research applications (*1*−*4*). Because lanthanide(III) chelates give strong, long decay-time luminescence, they are ideal labels for assays where high sensitivity is required. Time-resolved fluorometric assays based on lanthanide chelates have found increasing applications in diagnostics, research, and high throughput screening. The heterogeneous DELFIA technique is applied in assays requiring exceptional sensitivity, robustness, and a multilabel approach. Development of highly luminescent stable chelates extends the use of time resolution to homogeneous assays, based on fluorescence resonance energy transfer (TR-FRET), fluorescence quenching (TR-FQA), or changes in the luminescence properties of a chelate during a binding reaction.

Most commonly, the conjugation reaction is performed in solution between an amino or mercapto group of a bioactive molecule (such as a protein, a peptide, a nucleic acid, an oligonucleotide, or a hapten) and the isothiocyanato, haloacetyl, 3,5-dichloro-2,4,6-triazinyl derivatives of lanthanide(III) chelates (*5*), as well as other reporter groups. Because, in all of the cases, the labeling reaction is performed with an excess of an activated label, laborious purification procedures cannot be avoided. Especially, when attachment of several label molecules, or site-specific labeling in the presence of several functional groups of similar reactivities is required, the isolation and characterization of the desired biomolecule conjugate is extremely difficult and often practically impossible.

Quite recently, we reported our strategy for the introduction of lanthanide(III) chelates to an oligonucleotide structure on a solid phase (*6*). We extend here our approach of biomolecule derivatization to oligopeptides. We describe the synthesis of oligopeptide building blocks that allow for the introduction of nonluminescent and luminescent lanthanide(III) chelates to synthetic oligopeptides using standard machine-assisted chemistry. Also, the suitability of these blocks to oligopeptide derivatization as well as some application data is demonstrated.

EXPERIMENTAL PROCEDURES

General Methods. Adsorption column chromatography was performed on columns packed with silica gel 60 (Merck). Reagents for oligopeptide synthesis were purchased from Nova Biochem, Molecular Probes, and Applied Biosystems. The oligopeptides were assembled on an Applied Biosystems 433A instrument in 10 μmol scale using Fmoc chemistry and recommended protocols (Fmoc-Off synthesis). The time-resolved fluorometer (Victor^{2}V), DELFIA assay buffer, DELFIA wash solution, DELFIA enhancement solution, and the caspase buffer were from PerkinElmer Life Sciences. NMR spectra were recorded on a Brucker 250 or a JEOL GX-400 spectrometers operating at 250.13 MHz and 399.8 for ^{1}H, respectively. The signal of TMS was used as an internal reference. Coupling constants are given in hertz. Electrospray ionization time-of-flight mass spectra (ESI-TOF-MS) were recorded on an Applied Biosystems Mariner instrument. HPLC analyses were performed on a PerkinElmer LC 2000 instrument. The mobile phase used was the following: (Buffer A) 0.02 M TEAA (pH 7.5); (Buffer B) A in 50% (v/v) acetonitrile. IR spectra were recorded on a PerkinElmer Spectrum One spectrophotometer.

Tetra-*tert*-butyl-1-(4-nitrobenzyl)diethylenetriaminetetrakis(acetate), 2. 1-(4-Nitrobenzyl)diethylenetriamine (5.0 g, 21.0 mmol) was dissolved in dry dimethylformamide (DMF) (120 mL). DIPEA (34 mL), potassium iodide (3 g), and *tert*-butylbromoacetate (22 mL, 0.15 mol) were added, and the mixture was stirred for 2 h at ambient temperature and concentrated in vacuo. The residue was partitioned between water and diethyl ether. The organic phase was washed with water and brine and was dried. After concentration, the crude product was purified on silica gel column (eluent MeOH/CH_2Cl_2, 5:95, v/v). Yield was 17.2 g (95%) of compound **2**. ^{1}H NMR ($CDCl_3$, δ): 8.17 (2H, d, J = 8.5 Hz), 7.56 (2H, d, J = 8.5), 3.94 (2H, s), 3.75 (2H, s), 3.43 (4H, s), 3.32 (2H, br s), 2.79 (7H, br s), 1.46 (9H, s), 1.44 (18H, s), 1.43 (9H, s). IR (film): 1731, 1552, 1367, 1345, 1152 cm^{-1}. ESI-TOF-MS mass for $C_{35}H_{59}N_4O_{10}$ $(M + H)^+$: calcd, 695.42; found, 695.42.

Tetra-*tert*-butyl-1-(4-aminobenzyl)diethylenetriaminetetrakis(acetate), 3. Compound **2** (12.0 g, 17.2

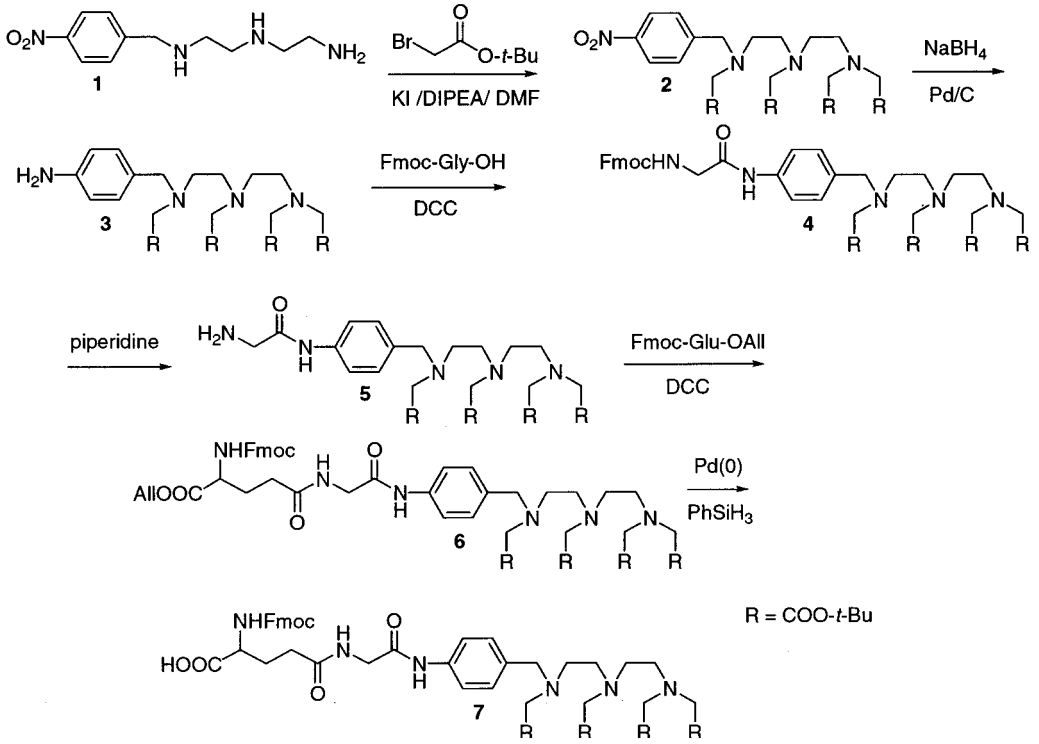
10.1021/bc025521l CCC: $22.00 © 2002 American Chemical Society
Published on Web 06/21/2002

mmol) was dissolved in dry methanol (240 mL) containing Pd/C (10%, 1.2 g). $NaBH_4$ (0.72 g, 19.0 mmol) was added portionwise (caution: exothermic reaction with foaming), and the reaction was allowed to proceed for 3 h at ambient temperature. The reaction mixture was filtered through Celite and neutralized with aq HCl. The filtrate was diluted with dichloromethane, washed with saturated $NaHCO_3$, and dried. Purification was performed on silica gel (eluent MeOH/CH_2Cl_2, 1:9, v/v) giving 10.0 g (87%) of compound **3**. ^{1}H NMR ($CDCl_3$, δ): 7.09 (2H, d, J = 8.5 Hz), 6.61 (2H, d, J = 8.5 Hz), 3.66 (2H, s), 3.45 (4H, s), 3.34 (2H, s), 3.20 (2H, s), 2.78 (8H, br s), 1.45 (36H, 2 s). ESI-TOF-MS mass for $C_{35}H_{61}N_4O_8$ $(M + H)^+$: calcd, 665.45; found, 665.44.

Tetra-*tert*-butyl-1-[4-(fluorenylmethyloxycarbonylaminoacetamido)benzyl]diethylenetriaminetetrakis(acetate), **4.** Compound **3** (9.8 g, 14.7 mmol) was dissolved in CH_2Cl_2 (100 mL) and deaerated with argon. Dicyclohexylcarbodiimide (DCC) (3.34 g, 16.2 mmol), DMAP (184 mg, 1.47 mmol), and Fmoc-Gly-OH (4.37 g, 14.7 mmol) were added, and the mixture was stirred at room temperature for 4 h. Precipitation formed was removed by filtration, and the filtrate was evaporated to dryness to give 11.4 g (81%) of the Fmoc derivative. Compound **4** was used in the next step without further purification. ^{1}H NMR ($CDCl_3$, δ): 7.97 (1H, s), 7.75 (4H, m), 7.59 (2H, m), 7.38 (3H, m), 7.30 (3H, m), 5.61 (1H, s), 4.48 (2H, d, J = 6.9 Hz), 4.24 (1H, t, J = 6.8 Hz), 4.00 (2H, d, J = 4.0 Hz), 3.75 (2H, s), 3.43 (4H, m), 3.33 (2H, m), 3.22 (2H, m), 2.76 (8H, s), 1.45 (36H, 3 s). ESI-TOF-MS mass for $C_{52}H_{74}N_5O_{11}$ $(M + H)^+$: calcd, 944.54; found, 944.56.

Tetra-*tert*-butyl-1-[4-(aminoacetamido)benzyl]diethylenetriaminetetrakis(acetate), **5.** Compound **4** (10 g, 10 mmol) was dissolved in the mixture of piperidine and DMF (300 mL; 20%, v/v), stirred at room temperature for 3 h, and evaporated to dryness. Purification was performed on silica gel (eluent initially petroleum ether/ethyl acetate/triethylamine, 5:2:1, v/v/v, and then MeOH/CH_2Cl_2, 1:4, v/v). Yield was 6.0 g (79%) of compound **5**. ^{1}H NMR ($CDCl_3$, δ): 9.43 (1H, br s), 7.55 (2H, d, J = 8.4 Hz), 7.29 (2H, d, J = 8.4 Hz), 3.75 (2H, s), 3.48 (4H, s), 3.44 (2H, s), 3.33 (2H, s), 3.21 (2H, s), 2.77 (8H, m), 1.70 (36H, s). ESI-TOF-MS mass for $C_{37}H_{64}N_{45}O_9$ $(M + H)^+$: calcd, 722.47; found, 722.47.

Tetra-*tert*-butyl-4′-{2-[4-allyloxycarbonyl-4-(fluorenylmethyloxycarbonylamino)-1-oxo-1-butylamino]-1-oxo-1-ethylamino}benzyldiethylenetriaminetetrakis(acetate), 6. Compound **5** (3.2 g, 4.38 mmol) was dissolved in dichloromethane (80 mL) and deaerated with argon. DCC (1.0 g, 4.67 mmol) and Fmoc-Glu-OAll (1.8 g, 4.25 mmol) were added, and the mixture was stirred at room temperature for 2 h. DCU formed was removed by filtration, and the filtrate was concentrated in vacuo. The allyl derivative was purified by flash chromatography using petroleum ether/ethyl acetate (2:5, v/v) as the eluent. Yield was 4.9 g (67%) of compound **6**. ^{1}H NMR ($CDCl_3$, δ): 8.39 (1H, s), 7.76 (2H, m), 7.56 (2H, m), 7.46 (2H, m), 7.40 (2H, m), 7.31 (2H, m), 7.24 (2H, m), 6.55 (1H, m), 5.89 (1H, m), 5.69 (1H, d, J = 7.9 Hz), 5.29 (2H, m), 4.64 (2H, d, J = 5.6 Hz), 4.41 (2H, m), 4.18 (1H, t, J = 6.8 Hz), 3.73 (2H, s), 3.43 (4H, m), 2.77 (8H, m), 2.32 (2H, m), 2.05 (4H, m), 1.91 (1H, m), 1.74 (4H, m), 1.44 (36 H, 2s). ESI-TOF-MS mass for $C_{60}H_{85}N_6O_{14}$ $(M + H)^+$: calcd, 1113.12; found, 1113.61.



Tetra-*tert*-butyl-4′-{2-[4-carboxy-4-(fluorenylmethyloxycarbonylamino)-1-oxo-1-butylamino]-1-oxo-1-ethylamino}benzyldiethylenetriaminetetrakis(acetate), 7. Compound **6** (2.0 g, 1.8 mmol) was dissolved in dichloromethane (120 mL) and deaerated for 10 min with argon. $Pd(PPh_3)_4$ (41.5 mg, 35.9 μmol) and $PhSiH_3$ (0.5 mL, 3.6 mmol) were added, and the mixture was stirred at room temperature for 1 h. The solution was washed with citric acid (100 mL, 10%, w/v), dried over 4 Å molecular sieves, and evaporated to dryness. Yield of compound **7** was quantitative. ESI-TOF-MS mass for $C_{57}H_{81}N_6O_{14}$ $(M + H)^+$: calcd, 1073.58; found, 1073.57.

Tetra-*tert*-butyl-2,2′,2″,2‴-{[4′-(4″-bromophenyl)-2,2′:6′,2″-terpyridine-6,6″-diyl]bis(methylenenitrilo)}tetrakis(acetate), 9. Compound **8** (3.3 g, 5.25 mmol, pentahydrochloride) was suspended in dry DMF (25 mL). Diisopropylethylamine (13.7 mL), *tert*-butylbromoacetate (7 mL, 47.4 mmol), and potassium iodide (1.0 g, 6.0 mmol) were added, and the mixture was stirred overnight at room temperature and concentrated. The residue was dissolved in dichloromethane (150 mL), washed with saturated $NaHCO_3$ (3 × 40 mL), and dried. Purification was performed on silica gel (eluent petroleum ether/ethyl acetate/triethylamine, 5:1:1, v/v/v). Yield of compound **9** was 3.8 g (80%). ^{1}H NMR ($CDCl_3$, δ): 8.70 (2H, s), 8.55 (2H, dd, J = 1.0 and 7.8 Hz), 7.86 (2H, t, J = 7.8 Hz), 7.77 (2H, d, J = 8.6 Hz), 7.70 (2H, dd, J = 1 and 7.6 Hz), 7.64 (2H, d, J = 8.6 Hz), 4.17 (4H, s), 3.56 (8H, s), 1.44 (36H, s). ESI-TOF-MS mass for $C_{47}H_{61}BrN_5O_8$ $(M + H)^+$: calcd, 902.38; found, 902.41.

Tetra-*tert*-butyl-2,2′,2″,2‴-{[4′-(4″-(3-amino-1-propyn-1-yl)phenyl)-2,2′:6′,2″-terpyridine-6,6″-diyl]bis(methylenenitrilo)}tetrakis(acetate), 10. A mixture of compound **9** (1.0 g, 1.1 mmol), bis(triphenylphosphine)-palladium(II) chloride (15 mg, 0.022 mmol), and CuI (9 mg, 0.16 mmol) in dry THF (6 mL) and triethylamine (4 mL) was deaerated with argon. 3-(Methoxytrityl)aminopropyne was added, and the mixture was stirred overnight at 55 °C. The cooled solution was filtered, and the filtrate was evaporated and redissolved in dichloromethane. The solution was washed with water, dried, and concentrated. It was then dissolved in dichloromethane containing 1% (v/v) of TFA, stirred for 30 min at room temperature, and concentrated. The residue was dissolved in dichloromethane, washed with saturated $NaHCO_3$, dried, and concentrated. Purification on silica gel (eluent petroleum ether/ethyl acetate/triethylamine, 3:5:1, v/v/v) gave the title compound (compound **10**) (45%) as an oil. ^{1}H NMR ($CDCl_3$, δ): 8.70 (2H, s), 8.55 (2H, d, J = 8 Hz), 7.87 (2H, t), 7.77 (2H, d, J = 7.5 Hz), 7.70 (2H, d, J = 7.5 Hz), 7.55 (2H, d, J = 7.5 Hz), 4.17 (4H, s), 3.71 (2H, s), 3.55 (8H, s), 1.46 (36H, s). ESI-TOF-MS mass for $C_{50}H_{64}N_6O_8Na$ $(M + Na)^+$: calcd, 899.47; found, 899.51.

Tetra-*tert*-butyl-4′-{3-[4-allyloxycarbonyl-4-(fluorenylmethyloxycarbonylamino)-1-oxo-1-butylamino]-1-propyn-1-yl}-2,2′:6′,2″-terpyridine-6,6″-diyl]bis(methylenenitrilo)}tetrakis(acetate), 11. Compound **10** (200 mg, 0.23 mmol) and Fmoc-Glu-OAll (104 mg, 0.25 mmol) were dissolved in dichloromethane (6 mL). DCC (52 mg, 0.25 mmol, predissolved in 1 mL of dichloromethane) was added, and the mixture was stirred overnight at room temperature. DCU formed was removed by filtration, and the filtrate was concentrated in vacuo. The residue was filtered through silica gel using diethyl ether as eluent and concentrated to give the allyl derivative (compound **11**) (yield 250 mg, 90%). ^{1}H NMR ($CDCl_3$, δ): 8.71 (2H, s), 8.54 (2H, d, J = 8 Hz), 7.87−7.30 (tot, 16H), 6.15 (1H, br s), 5.67 (1H, br s), 5.64 (1H, br s), 5.36 (1H, m), 5.30 (2H, m), 5.27 (1H, m), 4.65 (2H, m), 4.45 (2H, m), 4.32 (2H, m), 4.25 (1H, m), 4.17 (4H, s), 3.55 (8H, s), 2.33 (2H, m), 1.46 (36H, s). ESI-TOF-MS mass for $C_{73}H_{84}N_7O_{13}$ $(M - H)^-$: calcd, 1266.61; found, 1266.61.

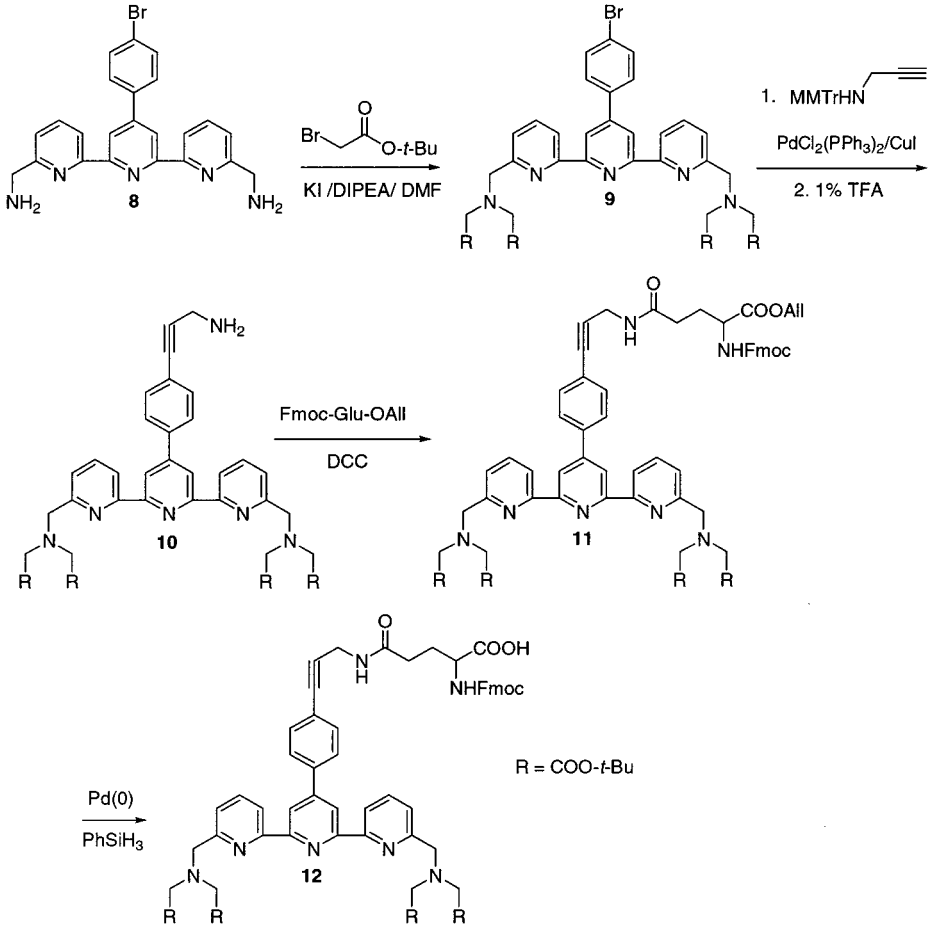
Tetra-*tert*-butyl-4′-{3-[4-carboxy-4-(fluorenylmethyloxycarbonylamino)-1-oxo-1-butylamino]-1-propyn-1-yl}-2,2′:6′,2″-terpyridine-6,6″-diyl]bis(methylenenitrilo)}tetrakis(acetate), 12. Cleavage of the allyl group from compound **11** and workup was performed as described for compound **7**. (Compound **12**) ESI-TOF-MS: mass for $C_{70}H_{80}N_7O_{13}$ $(M - H)^-$: calcd, 1226.58; found, 1226.61.

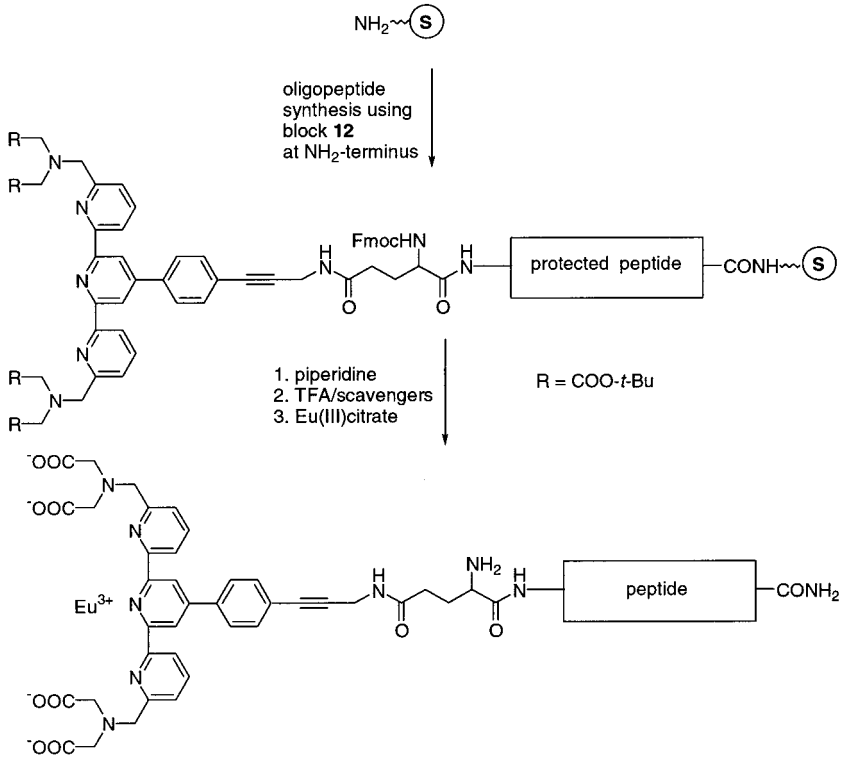
Synthesis of the Oligopeptide Conjugates. Oligopeptides were assembled on an Applied Biosystems 433A instrument in 10 μmol scale using Fmoc chemistry and recommended protocols (coupling time 30 min for natural amino acid analogues, and 2 h for blocks **7** and **12**). In the synthesis of the caspase-3 substrate, a commercial ϵ-dabsyl Fmoc-lysine block (Molecular Probes) was used to introduce the quencher and Fmoc-hexanoic acid (Fluka) as a spacer at the C-terminus. When the chain assembly was completed, the resin was treated with the mixture of crystalline phenol (75 mg), ethanedithiol (25 μL), thioanisole (50 μL), water (50 μL), and trifluoroacetic acid (1 mL) for 2−4 h. The resin was removed by filtration, and the solution was concentrated in vacuo. The crude oligopeptide was precipitated with diethyl ether. The precipitate was redissolved in water and treated with aqueous europium(III) citrate (5 equiv). Purification was performed on HPLC techniques (column, LiChrocart 125-3 Purospher RP-18e 5 μm; gradient, from 95% to 0% A in 30 min; flow rate was 0.6 mL min^{-1}).

Motilin Assay. Eu-motilin prepared using the ligand building block, **7**, was tested in saturation binding assay using human motilin receptor. All of the reagents were diluted in 50 mM Tris-HCl buffer (pH 7.5) containing 10 mM $MgCl_2$, 0.2% bovine serum albumin, and 25 μM EDTA. Human motilin receptor membrane preparate (0.5 μg/well; PerkinElmer Life Sciences) was incubated in the presence of Eu-motilin (0.25, 1, 4, and 16 nM) in an AcroWell filtration plate (Pall Life Sciences) in the total volume of 100 μL/well at room temperature for 90 min. To determine nonspecific binding, the assay was performed also in the presence of 800 nM motilin. Next, the wells were washed with 50 mM Tris-HCl and 10 mM $MgCl_2$ (pH 7.5) 4 times (300 μL/well) using a manifold (Millipore) and a vacuum pump. After washing, DELFIA enhancement solution was added (200 μL/well), and the plate was shaken for 15 min. Europium fluorescence was measured using a VICTOR^{2}V multilabel counter.



Caspase Assay. The performance of the caspase-3 substrate prepared using the building block **12** was tested in time-resolved fluorescence quenching assay (TR-FQA). The assay was performed in a Wallac 384-plate. Accordingly, caspase buffer (18 μL), substrate (2 μL, 200 pM−2 μM; final concentrations), and caspase-3 enzyme (1 μL, 5 pg/well) were pipetted to a well. In blank wells, there was buffer instead of enzyme. The plate was incubated at 37 °C. Europium fluorescence was measured with VICTOR^{2}V multilabel counter in 15 min time intervals.

RESULTS AND DISCUSSION



Synthesis of the Nonluminescent Oligopeptide Block. The synthesis of a nonluminescent oligopeptide building block for the introduction of lanthanide(III) chelates to the oligopeptide structure is shown in Scheme 1. Initially, 1-(4-nitrobenzyl)diethylenetriamine (**1**; *7*) was allowed to react with bromoacetic acid *tert*-butyl ester in the presence of potassium iodide as a catalyst to give the corresponding tetraester (**2**) in high yield. Reduction of the nitro group to the amino function gave **3**. It was then converted to the corresponding oligopeptide building block, **7**, by attachment of the spacer arm and the appropriately protected amino acid to the amine function. It is worth noting that elongation of the spacer arm with the glycine residue was essential to reach acceptable coupling efficiency. Transient protection of the glutamic acid residue, in turn, considerably simplified the purification procedures. Palladium-catalyzed allyl cleavage using phenylsilane as allyl scavenger (*8*) gave the final product quantitatively after washing with aq citric acid without need of further purification.

Synthesis of the Luminescent Block. The oligopeptide building block for the introduction of luminescent

Scheme 3. Introduction of a Luminescent Europium(III) Chelate to an Oligopeptide in the Aid of Block 12

lanthanide(III) chelates to the oligopeptide structure, **12**, was synthesized as shown in Scheme 2. In general, synthesis of the protected ligand was analogous to that published for the corresponding oligonucleotide building block (*6*). Accordingly, alkylation of the amine, **8**, with bromoacetic acid *tert*-butyl ester yielded **9**, the reaction of which with MMTr-protected propargylamine in the presence of Pd(II) and Cu(I) gave, after removal of the

X_2 is the position of the label. For chromatographic conditions, see Experimental Procedures.

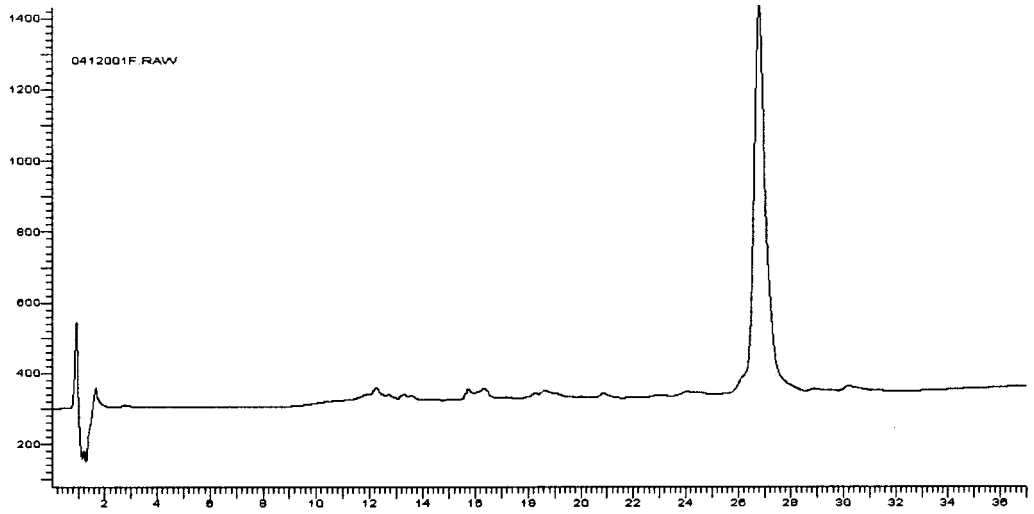

Figure 2. Reversed-phase HPLC trace of an oligopeptide conjugate Phe-Val-Pro-Ile-Phe-Thr-Tyr-Gly-Glu-Leu-Gln-Arg-Met-Gln-Glu-Lys-Glu-Arg-Asn-Lys-Gly-Gln-X_1-$CONH_2$ (motilin) labeled with a nonluminescent europium(III) chelate synthesized in the aid of block **7** (crude reaction mixture) detected at 220 nm. X_1 is the position of the label. For chromatographic conditions, see Experimental Procedures.

amine protection, the ligand **10**. It was then converted to the oligopeptide building block, **12**, as described previously for **7** but by omitting the now unnecessary glycine spacer unit from the linker arm.

Synthesis of the Oligopeptide Conjugates. To demonstrate the applicability of the building blocks **7** and **12** for oligopeptide derivatization, model sequences (e.g., motilin, substance-P, neurokinin-A, and caspase-3) were synthesized in 10 μmol scale using Fmoc chemistry. The blocks **7** and **12** were coupled either to the amino or carboxyl terminus or to the internal position of the coding sequence using prolonged coupling time (2 h instead of 30 min) but otherwise standard conditions (5 equiv of blocks; HBTU/HOBt as an activator). According to fulvene-piperidine assay, coupling efficiencies of **7** and **12** were comparable to natural amino acid analogues. After completion of the oligopeptide synthesis, the oligopeptides were released from the resin and deprotected followed by precipitation from ether. Treatment of the deblocked oligomers with europium(III) citrate converted the oligopeptide conjugates to the corresponding europium chelates (Scheme 3).

tures) are shown in Figures 1 and 2 as illustrative examples. In all of the cases, the observed molecular weights were in accordance with the proposed structures (Table 1).

Assays. Two of the oligopeptide conjugates synthesized were used in a DELFIA-based binding assay as well as in a LANCE fluorescence quenching assay. Accordingly, the motilin conjugate prepared using the ligand building block, **7**, was tested in saturation binding assay using human motilin receptor (Figure 3). Analysis of data gave a K_d value of 1.7 nM. The performance of the caspase-3 substrate prepared using the building block, **12**, in turn, was tested in TR-FQA. The substrate was cleaved by caspase-3 enzyme. The cleavage separates the quencher and the chelate and thus recovers the europium fluorescence. The results showed that the linear range of the assay is from 200 pM to 200 nM (Figure 4).

ACKNOWLEDGMENT

We thank Mrs. Mirja Koski, Ms. Jenni Degerholm, and Mr. Lassi Jaakkola for skillful technical assistance.

TECHNICAL NOTES

Synthesis of Nonluminescent Lanthanide(III) Chelates Tethered to an Aminooxy Group and Their Applicability to Biomolecule Derivatization

Jari Peuralahti, Katri Puukka, Harri Hakala, Veli-Matti Mukkala, Outi Mulari, Pertti Hurskainen, and Jari Hovinen*

PerkinElmer Life Sciences, Wallac Oy, P.O. Box 10, FIN-20101 Turku, Finland. Received January 3, 2002; Revised Manuscript Received May 2, 2002

Synthesis of nonluminescent lanthanide(III) chelates tethered to an aminooxy group (i.e., 1-[4-(6-aminooxyhexamido)benzyl]diethylenetriaminetetraacetic acid lanthanides(III), **6a**−**d**, where Ln^{3+} is Eu, Dy, Sm, and Tb) is described. Their applicability to biomolecule derivatization is demonstrated by allowing them to react with a synthetic oligopeptide, a protein, two synthetic drugs, and a steroid. The oligopeptide and protein were linked to **6** after preoxidation of their *N*-terminal serine residues, while the drugs and the steroid reacted via their ketone functionality. Also some application data is included.

INTRODUCTION

Ketones and aldehydes are known to react with hydroxylamines under mild conditions giving stabile oximes in high yield (*1*). This reaction has been exploited in biomolecule derivatization, e.g., for the introduction of tether arms and label molecules to ketosteroids (*2*, *3*) and for detection of abasic sites of DNA (*4*−*7*). Oligopeptides and proteins, in turn, react smoothly with hydroxylamines after periodate oxidation of their *N*-terminal serine and threonine residues (*8*−*10*). Aminooxy conjugation has also been applied to cell-surface ketone modification (*11*) as well as to the modification of native peptides (*11*) and nucleic acids and oligonucleotides (*12*, *13*).

The labeling reactants described in the literature are most commonly organic dyes. Although organic chromophores can be utilized for several applications, they suffer from many drawbacks, such as Raman scattering, low water solubility, and concentration quenching. Because of their unique fluorescence properties, lanthanide(III) chelates are often used as nonradioactive markers in a wide variety of routine and research applications (*14*, *15*). Since lanthanide(III) chelates give strong long-decay-time fluorescence, they are ideal labels for assays where high sensitivity is required. Time-resolved fluorometric assays based on lanthanide chelates have found increasing applications in diagnostics, research, and high-throughput screening. The heterogeneous DELFIA (dissociation-enhanced lanthanide fluorescence immunoassay) technique is applied in assays requiring exceptional sensitivity, robustness, and multilabel approach (*14*). Development of highly fluorescent stable chelates extends the use of time resolution to homogeneous assays, based on time-resolved energy transfer (TR−FRET), time-resolved fluorescence quenching (TR−FQ), or changes in the chelate's fluorescence properties during a binding reaction (*14*−*20*).

We describe here a simple method for the preparation of nonluminescent lanthanide(III) chelates tethered to an aminooxy group. Also their applicability for biomolecule labeling is demonstrated.

EXPERIMENTAL PROCEDURES

General. Adsorption column chromatography was performed on columns packed with silica gel 60 (Merck). Reagents for oligopeptide synthesis were purchased from Nova Biochem and Applied Biosystems. The oligopeptide was assembled on an Applied Biosystems 433A instrument in 10 μmol scale using Fmoc chemistry and recommended protocols. IL-8 (human) was purchased from PeproTech, and naltrexone, naloxone, and testosterone from Sigma. The time-resolved fluorometer (Victor^{2}V), DELFIA Assay Buffer, DELFIA Wash Solution, and DELFIA Enhancement Solution were obtained from PerkinElmer. NMR spectra were recorded on a Brucker 250 spectrometer operating at 250.13 MHz for ^{1}H. The signal of TMS was used as an internal reference. ESI-TOF mass spectra were recorded on an Applied Biosystems Mariner instrument. HPLC analyses were performed on a Merck-Hitachi Instrument consisting of L-7400 detector, 7100 gradient pump, and D-7500 integrator. Mobile phase used was the following: buffer A: 0.02 M TEAA (pH 7.5); buffer B: A in 50% (v/v) acetonitrile.

6-Aminooxyhexanoic Acid Hydrobromide (1). *N*-Hydroxyphthalimide (7.13 g, 43.7 mmol) and ethyl 6-bromohexanoate (12.28 g, 55 mmol) were dissolved in DMF (45 mL). Triethylamine (9.2 mL, 66 mmol) was added, and the mixture was stirred for 2 d at RT. The precipitate formed was filtered and washed with DMF (5 mL). The

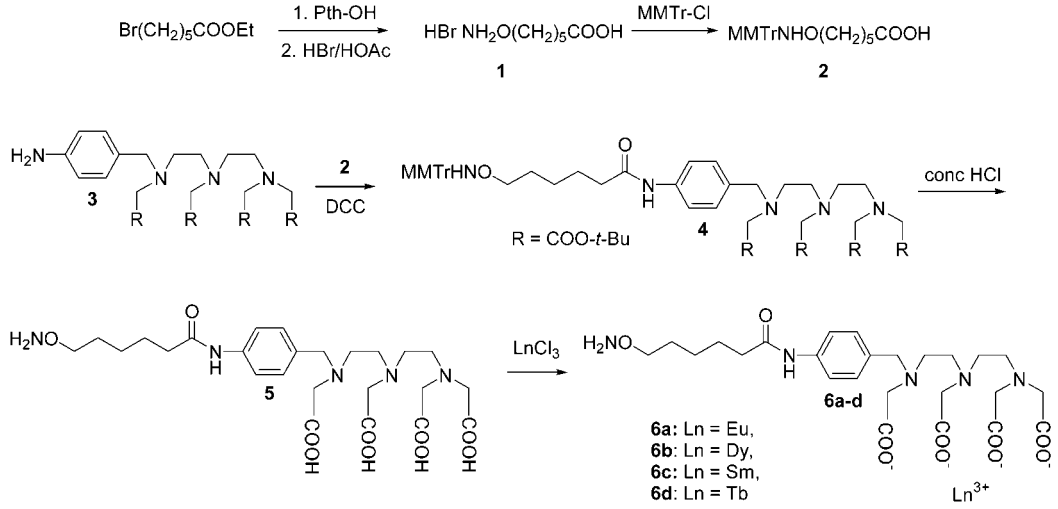
filtrate was poured slowly into ice−water (300 mL) and the product separated as an oil. The aqueous layer was decanted, and the remaining oil was washed with ice−water (100 mL). The remaining water was removed using a rotavapor. The residue was dissolved in the mixture of acetic acid (23 mL) and hydrobromic acid (48%, 38 mL) and refluxed for 2 h. The mixture was cooled on an ice bath, and the precipitate formed was removed by filtration. All volatile material was evaporated off in vacuo. The residue was coevaporated twice with water. The solid material was washed with ether and collected by filtration. The residue was suspended in ice−water (15 mL), and the remaining phthalic acid was removed by filtration. The filtrate was concentrated and treated with ether as above. Yield was 9.41 g (94%). It was used for the next step without further purification. ^{1}H NMR (D_2O): δ 3.88 (t, J = 6.4 Hz, 2H); 2.20 (t, J = 7.4 Hz, 2H); 1.50 (p, J = 6.8 Hz, 2H); 1.43 (p, J = 7.5 Hz, 2H); 1.23 (m, 2H). $[M + H]^+$ obsd 148.096, calcd for $C_6H_{14}NO_3^+$: 148.098.

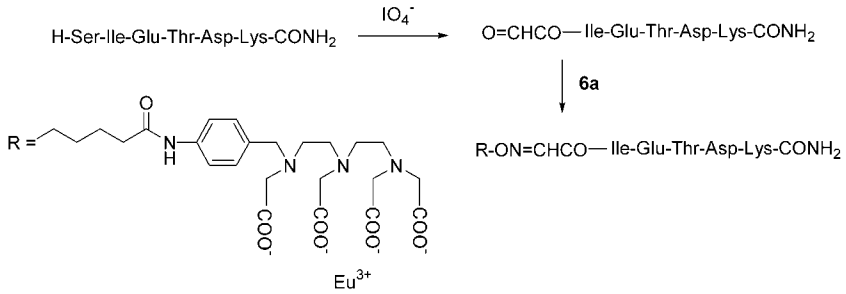
6-(4-Methoxytrityl)aminooxyhexanoic Acid (2). 6-Aminooxyhexanoic acid hydrobromide (**1**; 5.0 g, 21.9 mmol) was dried by coevaporations with dry pyridine and dissolved in the same solvent (50 mL). Triethylamine (5 mL) and 4-methoxytrityl chloride (7.44 g, 24 mmol) were added, and the reaction was allowed to proceed overnight at ambient temperature. All volatile materials were removed in vacuo. The residue was suspended in methylene chloride, washed with sat. $NaHCO_3$, dried over Na_2SO_4, and concentrated. Purification was performed on a silica gel column (eluent CH_2Cl_2:MeOH, 9:1, v/v). Yield was 6.0 g (65%). ^{1}H NMR ($CDCl_3$): δ 8.65 (br s, 1H); 7.30 (m, 12H); 6.81 (d, J = 9.0 Hz, 2H); 3.79 (s, 3H); 3.64 (t, J = 6.3 Hz, 2H); 2.25 (t, J = 7.3 Hz, 2H); 1.49 (m, 4H); 1.25 (m, 2H). $[M - H]^-$ obsd 418.21, calcd for $C_{26}H_{28}NO_4^-$: 418.20.

1-[4-(6-(4-Methoxytrityl)aminooxyhexamido)benzyl)]diethylenetriaminetetraacetic Acid Tetra-*tert*-butyl Ester (4). Compounds **2** (0.42 g, 1.0 mmol) and **3** (0.66 g; 1.0 mmol) were dissolved in methylene chloride (10 mL). DCC (227 mg; 1.10 mmol; predissolved in 2 mL of CH_2Cl_2) was added, and the mixture was stirred for 4 h at room temperature after which dicyclohexyl urea formed was filtered off. Purification was performed on a silica gel column (eluent CH_2Cl_2:MeOH, 9:1, v/v). Yield was 0.45 g (42%). ^{1}H NMR ($CDCl_3$): δ 10.13 (br s, 1H); 8.62 (br d, 1H); 7.44 (d, J = 8.2 Hz, 2H); 7.32−7.24 (m, 14H;) 6.81 (d, J = 8.6 Hz, 2H); 3.79 (s, 3H); 3.74 (s, 2H); 3.65 (t, J = 6.4 Hz, 2H); 3.43 (s, 4H); 3.34 (s, 2H); 3.21 (s, 2H); 2.77 (s, 8H); 2.22 (t, J = 6.4 Hz, 2H); 1.51 (m, 4H); 1.45 (s, 27 H); 1.43 (s, 9H); 1.26 (m, 2H). $[M - H]^-$ obsd 1066.64, calcd for $C_{61}H_{87}N_5O_{11}^-$: 1066.37.



1-[4-(6-Aminooxyhexamido)benzyl]diethylenetriaminetetraacetic Acid Tetrahydrochloride (5). Compound **4** (150 mg, 0.14 mmol) was dissolved in concd HCl (5 mL) and stirred for 2 h at room temperature. All volatile materials were removed in vacuo. Precipitation from diethyl ether yielded the title compound as a solid. It was used for the next step without further purification. ^{1}H NMR (DMSO-d_6): δ 11.08 (br s, 4H); 10.38 (s, 1H); 7.72 (d, J = 8.2 Hz, 2H); 7.47 (d, J = 8.2 Hz, 2H); 4.35 (s, 2H); 4.00 (2 s, 4H); 3.93 (s, 2H); 3.83 (s, 2H); 3.43 (m, 2H); 3.39 (m, 2H); 3.32 (m, 2H); 3.20 (m, 2H); 2.37 (t, J = 7.0 Hz, 2H); 2.22 (t, J = 7.1 Hz, 2H); 1.61 (m, 4H); 1.34 (m, 2H). $[M - H]^-$ obsd 568.26, calcd for $C_{25}H_{39}N_5O_{10}^-$: 568.26.

1-[4-(6-Aminooxyhexamido)benzyl]diethylenetriaminetetraacetic Acid Lanthanide(III) (6a−d). Compound **5** (56.5 mg, 0.079 mmol) was dissolved in water (1.5 mL), and the pH was adjusted to 6.5 with solid $NaHCO_3$. Lanthanide(III) chloride hexahydrate (ca. 35 mg, predissolved in 0.5 mL of water) was slowly added, and the mixture was stirred for 1 h at ambient temperature, after which pH was adjusted to 8.5 with 0.1 M NaOH. Lanthanide hydroxide precipitated was removed by centrifugation, and the solvent was evaporated off in vacuo. The residue was dissolved in water (1 mL) and extracted with phenol (0.5 g). The aqueous layer was removed, after which phenol and the product were partitioned between water (1 mL) and diethyl ether (8 mL). The organic phase was removed, and the aqueous phase was washed with diethyl ether (3•5 mL) and concentrated. Precipitation from THF yielded the title compounds as solids in ca. 70% yield. Their homogenities were judged on HPLC. Gradient 0−1 min 95% A, from 1 to 31 min from 95% A to 100% B, from 31 to 36 min 100% B. Flow rate was 0.6 mL min^{-1}, wavelength 270 nm. Column: LiChrocart 125−3 Purospher RP-18, 5 μm. t_R (**6a−d**) 15.3 min. ESI-TOF MS: The europium(III) chelate, **6a**: $[M - H]^-$ obsd 742.152 calcd for $C_{25}H_{35}N_5O_{10}Eu^-$: 742.157; The dysprosium(III) chelate, **6b**: $[M - H]^-$ obsd 728.08 calcd for $C_{25}H_{35}N_5O_{10}Dy^-$: 728.07; The samarium(III) chelate, **6c**: $[M - H]^-$ obsd 715.07 calcd for $C_{25}H_{35}N_5O_{10}Sm^-$: 715.07. The terbium(III) chelate, **6d**: $[M - H]^-$ obsd 724.09 calcd for $C_{25}H_{35}N_5O_{10}Tb^-$: 724.16.



Labeling of H-Ser-Ile-Glu-Thr-Asp-Lys-CONH$_2$ with the Nonluminescent Aminooxychelate (6a). The oligopeptide (3 μmol) predissolved in a phosphate buffer (0.02 M, pH 7.7; 1 mL) was added to a solution of $NaIO_4$ (2 mL, 17.5 mM) in the same buffer solution. The mixture was stirred at room temperature for 30 min, and the reaction was stopped by adding ethylene glycol (2 equiv over sodium periodate). The reaction mixture was applied to a C18 Sep-Pak cartridge. The cartridge was initially washed with 10% CH_3CN containing 0.1% TFA (5 mL). The product was eluted with 80% CH_3CN containing 0.1% TFA (8 mL). The fraction containing the oxidized product was concentrated and purified by HPLC. Column: LiChrocart 250-4 Purospher RP-18, 5 μm and buffer solutions were as above. Gradient: 0 to 10 min 98% A, from 10 to 30 min from 98% A to 100% B, from 30 to 35 min 100% B. Flow rate 1.0 mL min^{-1}. t_R (oxidized product) 22.68 min. The α-*N*-glyoxolyl derivative was dissolved in HEPES-buffer (0.5 M, pH 7.5; 100 μL). The chelate **6a** (ca. 2 equiv) was added, and the mixture was stirred overnight at room temperature. Purification was performed on a HPLC Column: LiChrocart 125-3 Purospher RP-18, 5 μm. Gradient 0−1 min 95% A, from 1 to 31 min from 95% A to 100% B, from 31 to 36 min 100% B. Flow rate was 0.6 mL min^{-1}, t_R (product) 20.23 min.

Labeling of IL-8 with the Nonluminescent Aminooxychelate (6a). IL-8 (0.1 mg) was dissolved in TEAA buffer (pH 7.5, 35 μL; 50 mM) containing methionine as a scavenger (50-fold excess). Sodium metaperiodate (2.4 μL; 50 mM in water; 10-fold excess) was added, and the pH of the solution was adjusted to pH 7.5 with NaOH. The solution was incubated at room temperature for 13 min, after which the reaction was stopped with ethylene glycol (60 μL; 10 M; 10000-fold excess). The oxidation product was purified on NAP-5 column equilibrated with sodium acetate (25 mM; pH 5). Then a 10-fold excess of compound **6a** predissolved in water was added to the oxidized IL-8 solution. The solution was concentrated in SpeedVac until the concentration of IL-8 was ca. 1.3 mg mL^{-1}. After concentration the pH was readjusted to pH 4.7 with aq HCl. The solution was incubated at +4 °C overnight. The pH of the solution was adjusted to 6.5 with

Scheme 1

Scheme 2

1 M Tris-HCl (pH 7.5) and was further incubated for 1 h at +4 °C. The product was purified by gel filtration (Column: Sephadex G-25, grade fine, diameter 0.7 cm, length 50 cm). The column was equilibrated with Tris-HCl buffer, pH 7.8, containing 0.9% NaCl and 0.05% NaN_3. Eu-concentration was 6.5 μM.

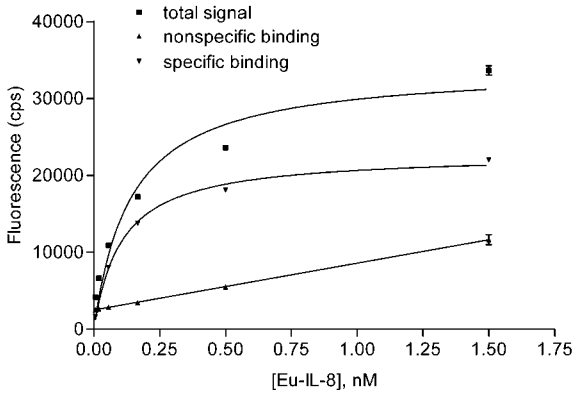
The Interaction between Receptor and Ligand. Eu-IL-8, prepared using the chelate **6a**, was tested in saturation binding assay using receptor membrane preparation (CXCR2). All the reagents were diluted in 50 mM Tris-HCl buffer, pH 7.5, containing 10 mM $MgCl_2$, 0.2% bovine serum albumin, and 25 μM EDTA. Receptor preparate (0.5 μg/well; PerkinElmer Life Sciences) was incubated in the presence Eu-IL-8 (0.25, 1, 4, and 16 nM) in an AcroWell filtration plate (Pall Life Sciences) in the total volume of 100 μL per well at room temperature for 90 min. To determine nonspecific binding, the assay was performed also in the presence of 100 nM unlabeled IL-8. Next the wells were washed with 50 mM Tris-HCl, 10 mM $MgCl_2$, pH 7.5, four times (300 μL/well) using a manifold (Millipore) and a vacuum pump. After the wells were washed, DELFIA Enhancement Solution was added (200 μL/well) and the plate was shaken for 15 min. Europium fluorescence was measured using VICTOR^{2}V multilabel counter.

Labeling of Ketones with the Nonluminescent Aminooxychelate, 6a. General Procedure. The ketone (i.e., naltrexone hydrochloride, naloxone hydrochloride, or testosterone; 9.9 μmol; testosterone predissolved in DMF) and compound **6a** (7.3 mg, 9.9 μmol) were dissolved in HEPES-buffer (0.5 M, pH 7.5; 200 μL), and the mixture was stirred overnight at room temperature and precipitated with acetone. The precipitate was dissolved in 0.05 M TEAA (pH 7.5; 0.5 mL) and purified on HPLC. Mobile phase: buffer A: 0.05 M TEAA; buffer B: A in 50% v/v acetonitrile. Gradient 0−1 min 95% A, from 1 to 31 min to 100% B, from 31 to 36 min 100% B, flow rate 0.6 mL min^{-1}, wavelength 270 nm. Column: XTerra MS C-8, 5 μm, 4.6 × 150 mm. Pure fraction was concentrated in vacuo and characterized on ESI-TOF MS. Naloxone conjugate (**7**) $[M - H]^-$ obsd 1027.3, calcd for $C_{44}H_{55}EuN_6O_{13}^-$: 1027.9. Naltrexone conjugate (**8**) $[M - H]^-$ obsd 1041.3, calcd for $C_{45}H_{56}EuN_6O_{13}^-$: 1040.9. Testosterone conjugate (**9**) $[M - H]^-$ obsd 988.3, calcd for $C_{44}H_{61}EuN_5O_{11}^-$: 988.4.

RESULTS AND DISCUSSION

Synthesis of nonluminescent lanthanide(III) chelates tethered to an aminooxy group is outlined in Scheme 1. Initially, 6-aminooxyhexanoic acid, **1**, was prepared by allowing ethyl 6-bromohexanoate to react with *N*-hydroxyphthalimide in the presence of triethylamine followed by acidic hydrolysis. It was then converted to the corresponding MMTr-protected derivative, **2**, reaction of which with 1-(4-aminobenzyl)diethylenetriaminetetraacetic acid tetra-*tert*-butyl ester (**3**; *21*) in the presence of DCC resulted in **4** in moderate yield. Deprotection of the aminooxy and carboxylic acid functions with concd HCl gave the free acid, **5**, which was finally converted to the corresponding europium, terbium, samarium, and dysprosium(III) chelates, **6a**−**d**, by treatment with the appropriate lanthanide(III) chloride at pH 6.5. The chelates were purified by phenol extraction. Their homogenities were judged on HPLC, and their structures were verified by mass spectrometry. It is worth noting that Eu^{3+}, Sm^{3+}, Dy^{3+}, and Tb^{3+} are those four lanthanides routinely used in assays based on DELFIA technology.

The DELFIA Principle (*14*). In dissociative fluorescence enhancement assays polycarboxylate-based non-



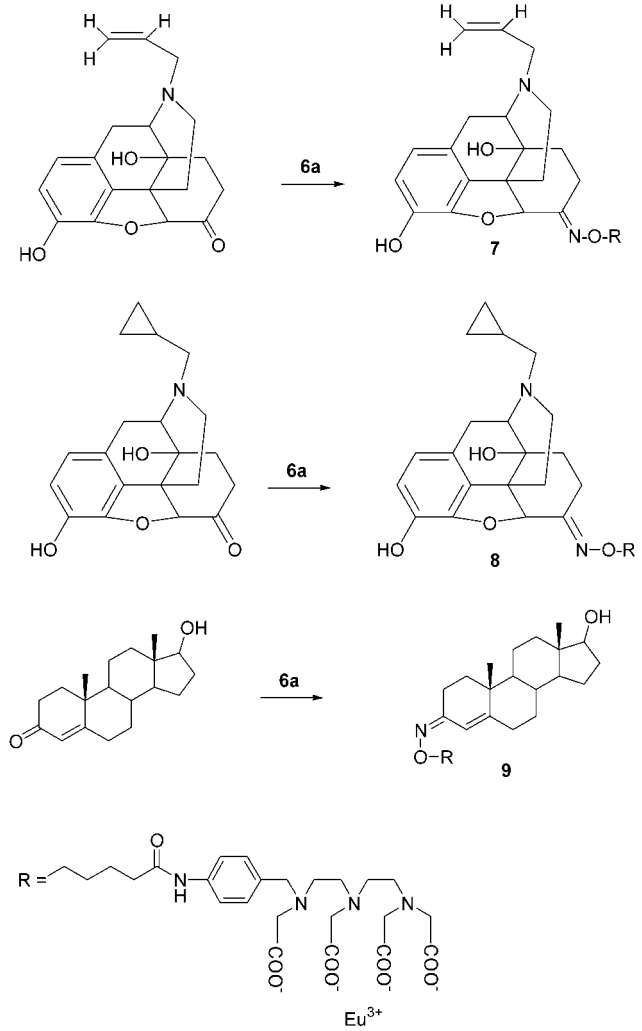


Figure 1. Saturation binding assay of IL-8 labeled with the chelate **6a**. Saturation binding experiments were performed with 0−1.5 nM Eu-interleukin-8 with 2 μg of membrane preparation (CXCR2). Nonspecific binding was determined in the presence of 100 nM unlabeled IL-8. Detection was performed by measuring europium fluorescence.

Scheme 3

fluorescent lanthanide(III) chelates are used as labels. These chelates are applied as carriers of the lanthanide ions through the assay. After perfoming the assay, fluorescence is developed by dissociation of chelated ions and creating new fluorescent chelates in solution. This is achieved by decreasing conditional stability of the complexones by reduction of pH to 3.2. Fluorinated β-diketones present in excess are able to form lanthanide complexes rapidly at the pH used. One lanthanide binds

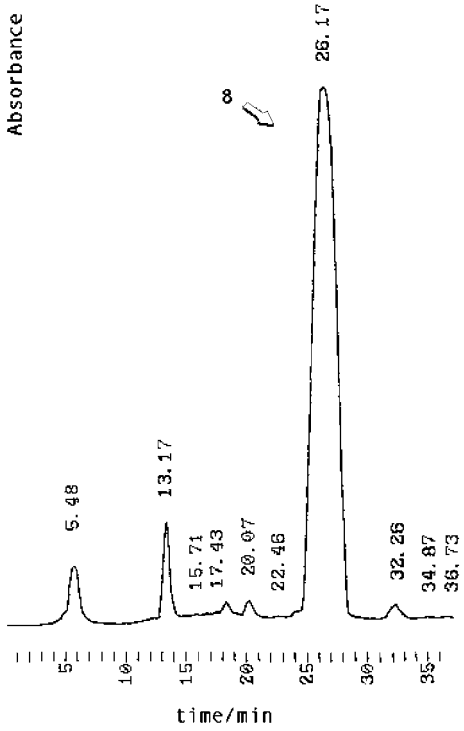

Figure 2. HPLC trace of the reaction of **6a** with naloxone (crude reaction mixture). The major peak (t_R 26.17 min) is the desired product **8** as judged on MS analysis. For chromatographic conditions, see Experimental Procedures.

three diketones to form the light-harvesting group in the chelate. The remaining water molecules are removed with a synergistic agent, TOPO, and the newly formed complex is solubilized with detergents. Finally, lanthanide content is measured fluorometrically. DELFIA is an ultrasensitive assay working well even in picomolar range. As a heterogeneous assay, DELFIA technology is used almost exclusively with solid-phase (microtitration plate) immobilized reagents. It has wide applications as a diagnostic test system, in DNA hybridizations, research immunoassays, receptor−ligand assays, end-point detection of enzymatic reactions, and cytotoxicity assays.

Conjugation to Bioactive Molecules. To demonstrate the applicability of the aminooxychelates synthesized for biomolecule derivatization, one of them, **6a**, was allowed to react with a model peptide, a protein, and two synthetic drugs having a ketone function in their structure, and a ketosteroid. The key steps are discussed below.

A synthetic oligopeptide H-Ser-Ile-Glu-Thr-Asp-Lys-$CONH_2$ was oxidized at its amino terminal serine to the corresponding aldehyde using a standard literature procedures (*8*−*10*), and the reaction was followed on HPLC-MS techniques (Scheme 2). The starting peptide gave a single peak on HPLC with an observed $[M - H]^-$ of 689.3 (calcd 689.3). Its reaction with periodate gave initially the expected α-*N*-glyoxolyl derivative with an observed $[M - H]^-$ of 658.3 (calcd 658.3). Prolonged reaction time gave an additional product with longer t_R on HPLC with an $[M - H]^-$ of 656.3. The undesired product can be attributed to result from oxidation of the threonine residue of the oligopeptide. Its existence could be suppressed by reducing the reaction time and performing the reaction at 0 °C. Finally, the desired α-*N*-glyoxolyl derivative was allowed to react with the europium(III) chelate, **6a**, and the desired site-specifically labeled oligopeptide derivative, with an observed [M −

H]$^-$ of 1359 (calcd 1359), was formed quantitatively. The same labeling strategy was also applied to attachment of **6a** to Interleukin-8 (IL-8).

Saturation Binding Assay. The IL-8 protein labeled with aminooxy-Eu chelate was tested in saturation binding assay based on DELFIA technology using receptor membrane preparation (CXCR2). Saturation binding experiments were performed with 0−1.5 nM Eu-interleukin-8 with 2 μg of membrane preparation. Nonspecific binding was determined in the presence of 100 nM unlabeled IL-8. The ligand binded to receptor specifically, which was detected by measuring europium fluorescence. The K_d-value of Eu−IL-8 for CXCR2 receptor was 0.10 nM (Figure 1).

The applicability of aminooxychelates for hapten labeling was demonstrated by allowing two synthetic drugs, naltrexone and naloxone, and one ketosteroid, testosterone, to react with **6a** at neutral pH (Scheme 3). In all the cases, the desired conjugates were formed quantitatively. The HPLC trace of the reaction of **6a** with naloxone is shown in Figure 2 as an illustrative example.

In summary, nonluminescent europium(III), terbium(III), dysprosium(III), and samarium(III) chelates tethered to an aminooxy group were synthesized, and their applicability to biomolecule derivatization was demonstrated.

^{99m}Tc-Labeling of a Hydrazinonicotinamide-Conjugated LTB_4 Receptor Antagonist Useful for Imaging Infection and Inflammation

Shuang Liu,* Anthony R. Harris, Neal E. Williams, and D. Scott Edwards

Bristol-Myers Squibb Medical Imaging,† 331 Treble Cove Road, North Billerica, Massachusetts 01862.
Received September 23, 2001; Revised Manuscript Received January 23, 2002

This report describes the ^{99m}Tc labeling of a hydrazinonicotinamide (HYNIC)-conjugated LTB_4 receptor antagonist (SG380). The ternary ligand technetium complex [^{99m}Tc(SG38)(tricine)(TPPTS)] (RP517) was prepared using a non-$SnCl_2$-containing formulation ((2001) *J. Pharm. Sci. 90*, 114−123). Unlike other HYNIC-conjugated small biomolecules, SG380 is lipophilic and has low solubility in the kit matrix. Using a combination of a solubilizing agent (Lysolecithin) and a cosolvent (ethanol), we have developed a new formulation for routine preparation of RP517. Using this formulation, RP517 can be prepared in high radiochemical purity (RCP > 90%) and remains stable in the kit matrix for at least 6 h. We also prepared the corresponding ^{99}Tc analogue, [^{99}Tc]RP517. An HPLC concordance experiment using RP517 and [^{99}Tc]RP517 showed that the same technetium complex was prepared at both the tracer and macroscopic levels. The LC-MS data are completely consistent with the 1:1:1:1 composition for Tc:SG380:tricine:TPPTS.

INTRODUCTION

Accurate and rapid detection of infectious and inflammatory foci is of great importance for elucidation of the cause of the disease, early prevention of the onset of complications, and rapid implementation of a tailored therapeutic regimen. While in some cases infections are diagnosed on the basis of clinical history, physical examination of the patient, in others it is more difficult because they are asymptomatic or cause nonspecific symptoms. Numerous imaging procedures have been developed for visualization of infectious and inflammatory lesions (*1*−*14*). These include ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), and nuclear medicine procedures. Ultrasonography, CT, and MRI provide details of morphological changes, variations in density, and differences in proton content in tissues (*13*). Nuclear medicine procedures can be used for in vivo characterization of cellular structure and function and for monitoring biological changes in the infectious tissues at the molecular level.

Various ^{99m}Tc-labeled small biomolecules that bind to receptors on inflammatory cells have been studied as potential new radiopharmaceuticals for scintigraphic imaging of infection and inflammation. These include include ^{99m}Tc-labeled chemotactic peptides (*15*−*23*), tuftsin receptor antagonists (*24*−*27*), antimicrobial peptides (*28*−*30*), and a fragment of human platelet factor 4 (*31*, *32*). Although animal studies show that the ^{99m}Tc-labeled chemotactic peptides bind to leukocytes and localize at sites of infection, the use of ^{99m}Tc-labeled agonists as radiopharmaceuticals suffers a major drawback, severe reduction of peripheral leukocyte count. This problem can be avoided by using antagonist peptides as targeting molecules. Unfortunately, the receptor binding affinity of the antagonists tested to date appear to be much lower than that of the agonists.

Leukotriene B_4 (LTB_4) is a proinflammatory mediator, which is derived from the action of 5-lipoxygenase on arachidonic acid and is synthesized primarily by PMNLs, monocytes, and macrophages. LTB_4 is known to stimulate degranulation, aggregation, chemotaxis, and chemokinesis of PMNLs, as well as promote superoxide generation. LTB_4 also promotes the adhesion of neutrophils to the vascular endothelium. LTB_4 receptors are highly expressed on a number of inflammatory cells such as neutrophils, monocytes, macrophages, and lymphocytes. Numerous LTB_4 receptor antagonists have been evaluated for their potential in the treatment of various infectious and inflammatory diseases.

In our previous communication (*33*), we reported a non-$SnCl_2$-containing formulation useful for the ^{99m}Tc-labeling of hydrazinonicotinamide-conjugated small biomolecules (HYNIC−BM[1]). In the non-$SnCl_2$ formulation, each lyophilized vial contains 20 μg of HYNIC−BM, 5 mg of TPPTS (trisodium triphenylphosphine-3,3′,3″-trisulfonate), 6.5 mg of tricine, 40 mg of mannitol, 38.5 mg of disodium succinate hexahydrate, 12.7 mg of succinic acid, and 0.1 mg of pluronic acid (Poloxamer-188, 0.1%). HYNIC is the bifunctional coupling agent for ^{99m}Tc-labeling. Tricine and TPPTS are used as coligands to stabilize the [^{99m}Tc]HYNIC core. The combination of HYNIC−BM, tricine, and TPPTS produces a versatile ternary ligand system which forms technetium complexes, [^{99m}Tc(HYNIC−BM)(tricine)(TPPTS)], with high solution stability. We have been able to use the non-$SnCl_2$ formulation for the ^{99m}Tc-labeling of many small biomolecules, including a GPIIb/IIIa receptor antagonist for thrombus imaging (*33*−*35*), a chemotactic peptide (*23*) for imaging infection and inflammation, and vitronectin receptor antagonists for tumor imaging (*36*).

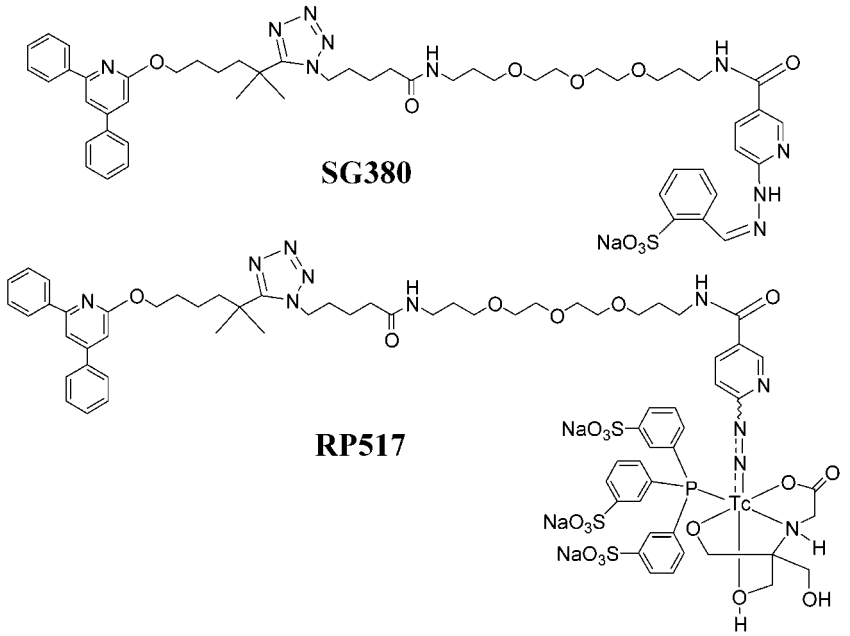

Figure 1. Structures of the HYNIC-conjugated LTB_4 receptor antagonist (SG380) and its ternary ligand technetium complex (RP517).

SG380 is an HYNIC-conjugated LTB_4 antagonist. Theoretically, we should be able to use the non-$SnCl_2$-containing formulation for the ^{99m}Tc-labeling of SG380. To our surprise, direct substitution of 20 μg of SG-380 for HYNIC−BM in the non-$SnCl_2$–containing formulation gave very low yields (60−70%) for RP517 even though the radiolabeling conditions are the same as those used for preparation of the ^{99m}Tc-labeled GPIIb/IIIa receptor antagonist (*33*) and vitronectin receptor antagonists (*36*). The goal of this study is to explore the factors influencing the yield of RP517 and to develop a formulation that provides RCP ≥ 90% for routine preparation of RP517.

EXPERIMENTAL SECTION

Materials. *N,N*-Dimethylacetamide (DMA), L-α-lysophosphatidylcholine (Lysolecithin), Tween-80, mannitol, pluronic acid (Poloxamer-188), succinic acid, TPPTS (trisodium triphenylphosphine-3,3′,3″-trisulfonate), and tricine were purchased from Aldrich or Sigma. Synthesis of SG380 will be published as a separate communication (*37*). $Na^{99m}TcO_4$ was obtained from a commercial DuPont Pharma ^{99}Mo/^{99m}Tc generator, N. Billerica, MA. The generator eluant was collected into a dry and clean 30 mL vial and diluted to the required concentration before use.

Analytical Methods. The HPLC method used a HP-1090 system, a homemade NaI radiometric detector, and a heated (50 °C) Cosmosil C_{18} column (4.6 mm × 250 mm) at a flow rate of 1 mL/min. The gradient mobile phase started from 100% solvent A (75:25 0.025 M succinate buffer, pH = 5.0/acetonitrile) to 30% solvent A and 70% solvent B (acetonitrile) at 35 min. The mobile phase was isocratic at 35−45 min using 30% solvent A and 70% solvent B. LC-MS spectral data were collected using a HP1100 LC/MSD system with an API-electrospray interface. The LC-MS method used a Zorbax C_{18} column (4.6 mm × 150 mm, 3.5 μm particle size) and a mobile phase gradient starting from 92% solvent A (10 mM ammonium acetate buffer, pH 7.0) and 8% solvent B (methanol) to 100% B at 23 min at a flow rate of 1 mL/min. The ITLC method used Gelman Sciences silica gel ITLC paper strips and a 1:1 mixture of acetone and saline as eluant. Using this ITLC method, RP517 and [^{99m}Tc]-pertechnetate migrate while the [^{99m}Tc]colloid remains at the origin.

A General Procedure for Radiolabeling. RP517 was prepared according to the published procedure (*33*) with a slight modification. Briefly, to a lyophilized vial containing 5 mg of TPPTS, 6.5 mg of tricine, 40 mg of mannitol, 38.5 mg of disodium succinate hexahydrate, 12.7 mg of succinic acid, and 0.1 mg of pluronic acid (0.1%); pH = 4.8) was added 1.0 mL of SG380 solution (20 μg/mL in an appropriate solvent or mixture of solvents). The vial was placed into a lead pig, and to the vial was added 0.5 mL of Na[$^{99m}TcO_4$] solution (100 mCi/mL) in saline. The reconstituted vial was heated at 100 °C for 10−40 min in a lead-shielded water bath. After being cooled to room temperature, the reaction mixture was analyzed by radio-HPLC and ITLC. The radiochemical purity (RCP) was calculated as the percentage of integrated area for the radiometric peak of RP517 versus the total area. Since the [^{99m}Tc]colloid formation is negligible (<0.5%), no correction is needed for the HPLC data.

[^{99}Tc]RP517. To a clean 10 mL vial was added 1.5 mg of SG380, 84 mg of tricine, 49 mg of TPPTS, 1.2 mg of NH_4[$^{99}TcO_4$] in 0.4 mL of H_2O, and 1.5 mL of 25 mM succinate buffer (pH = 5.0). The reaction mixture was heated in a 100 °C water bath for 30 min. After being cooled to room temperature, the product was separated by HPLC. The collections of the peak due to RP517 were combined, and volatiles were removed under reduced pressure. The product, [^{99}Tc]RP517, was then desalted using the same HPLC method using water as mobile phase A. The HPLC concordance experiment showed the same retention time for RP517 and [^{99}Tc]RP517. LC-MS: m/z = 1627.2 for $(M + 1)^+$ ($[C_{70}H_{86}N_{11}O_{20}PS_3Tc]^+$) and m/z = 813.7 for $(M + 2)^{2+}$.

RESULTS AND DISCUSSIONS

Recently, we reported a series of the ^{99m}Tc-labeled LTB_4 receptor antagonists for imaging infection and inflammation (*38*−*42*). RP517 (Figure 1) was evaluated in two animal (guinea pig and rabbit) models of focal infection. In the guinea pig peritonitis model (*38, 39*), RP517 showed uptake of 0.6 ± 0.05% ID/g at the site of infection

1 h postinjection. The radioactivity was retained with uptake of 0.5 ± 0.08% ID/g at 4 h postinjection. RP517 is excreted mainly via the hepatobiliary route (*42*). In the rabbit infection model, RP517 showed similar uptake at the infection site with the target-to-background (infected muscle/normal muscle) ratio of 16:1, 1 h postinjection. A primate dosimetry study indicates that the dose-limiting organ is the gall bladder. RP517 is under clinical investigation as a new imaging agent for acute infection and inflammation.

Discovery of a new radiolabeled biomolecule for the intended receptor is just the first step in a long process of the radiopharmaceutical development. In addition to its biological efficacy, the new radiopharmaceutical must have high radiochemical purity (RCP ≥ 90%) and solution stability (≥6 h). A kit formulation is also required due to the 6 h half-life of ^{99m}Tc. The kit components are often dissolved in a buffer system and then lyophilized to form a white powder in a "cake" form. A buffer is used to control the pH in the kit, which is extremely important during manufacturing and radiolabeling processes. A bulking agent is needed so that the kit components can crystallize on the well-formed crystal frameworks of the agent during the lyophilization process. Injection of the whole or part of the reconstituted kit should not cause any significant biological effect, such as neutropenia.

To support clinical studies, we have to develop a formulation for routine preparation of RP517. Recently, we reported a non-$SnCl_2$-containing formulation for the ^{99m}Tc-labeling of HYNIC−BM (*33*). The non-$SnCl_2$ formulation has been successfully used for the ^{99m}Tc-labeling of a HYNIC-conjugated GPIIb/IIIa receptor antagonist for imaging thrombi (*33*) and a HYNIC-conjugated vitronectin receptor antagonist for imaging tumors (*36*). Since SG380 is also an HYNIC-conjugated biomolecule, we decided to use the non-$SnCl_2$ formulation as the platform for the ^{99m}Tc-labeling of SG380. However, it was soon found out that the direct substitution of 20 μg of SG380 for HYNIC−BM in the non-$SnCl_2$ formulation gave fairly low yields (60−70%) of RP517 under the same radiolabeling conditions used for the preparation of other ^{99m}Tc-labeled biomolecules (*33*−*36*).

During our initial radiolabeling studies, we noticed that unlike other HYNIC-conjugated small biomolecules, SG380 is lipophilic and has low solubility in the kit matrix. Even though a surfactant (Poloxamer-188, 0.1%) is used in the non-$SnCl_2$ formulation, both SG380 and its ternary ligand ^{99m}Tc complex RP517 showed significant adsorption on the glass surface of reaction vials. When the solution containing RP517 was filtered through a 0.22 μm filter, only ∼70% of radioactivity was recovered. We hypothesized that the low yield of RP517 is caused by poor water solubility of SG380 in the kit matrix.

The glass surface adsorption of SG380 imposes a significant problem in the manufacturing process and during radiolabeling. In the manufacturing process, the formulation has to be filtered into individual vials to remove any particles. If SG380 shows a significant adsorption on glass surface or in the filter, it will be very difficult to maintain the reproducibility of the whole process. On the other hand, the glass-surface adsorption of SG380 means that there will not be sufficient SG380 available for reaction with ^{99m}Tc. Therefore, the first objective of our formulation efforts was to find an appropriate solubilizing agent or cosolvent to reduce glass-surface adsorption and to increase the solubility of SG380 in the kit matrix.

Table 1. Effect of the Solubilizing Agent or Cosolvent on RCP of RP517.

solubilizing agent or cosolvent concentration[a]	RCP (%)
13.3% EtOH (A)	91.3 ± 0.9/n = 4
0.07% Tween-80 (B)	65.6 ± 0.5/n = 4
0.07% Lysolecithin (D)	86.1 ± 0.9/n = 5
13.3% DMA (E)	91.9 ± 0.9/n = 5
13.3% EtOH + 0.07% Lysolecithin (F)	92.4 ± 0.3/n = 4
water only	81.2 ± 0.4/n = 4

[a] Each lyophilized vials contains 5 mg of TPPTS, 6.5 mg of tricine, 40 mg of mannitol, 38.5 mg of disodium succinate hexahydrate, 12.7 mg of succinic acid, and 0.1 mg of pluronic acid (0.1% Poloxamer-188). This is the concentration after addition of 0.5 mL of [^{99m}Tc]pertechnetate solution.

Screening of Solubilizing Agents and Cosolvents. There are several ways to improve solubility and to reduce the glass-surface adsorption of SG380. These include the use of a solubilizing agent such as Lysolecithin, Tween-80, or a cosolvent such as ethanol or *N*,*N*-dimethylacetamide (DMA). To study the effect of the solubilizing agent or cosolvent on the RCP of RP517, we performed a radiolabeling study using lyophilized vials containing 5 mg of TPPTS, 6.5 mg of tricine, 40 mg of mannitol, 38.5 mg of disodium succinate hexahydrate, 12.7 mg of succinic acid, and 0.1 mg of pluronic acid (Poloxamer-188, 0.1%). In this study, SG380 (∼20 μg) was dissolved in 1 mL of the following solutions: 20% EtOH (A), 0.1 wt % Tween-80 in water (B), 0.1 wt % Lysolecithin in water (C), 20% *N*,*N*-dimethylacetamide (D), 20% EtOH with 0.1 wt % Lysolecithin (E), and water (G). Lyophilized vials were reconsitituted by adding 1 mL of the SG-380 solution and 0.5 mL of Na[$^{99m}TcO_4$] solution (100 mCi/mL). The total volume for each vial was 1.5 mL. After addition of Na[$^{99m}TcO_4$], the actual concentration of the solubilizing agent or cosolvent becomes two-thirds of the original concentration. The reconstituted vials were heated at 100 °C for 30 min. After being cooled to room temperature, they were analyzed by HPLC. Four vials were tested for each condition, and the experiment was repeated using a different generator or the same generator on a different date. Table 1 summarizes the RCP data of RP517. Ethanol (13%) and *N*,*N*-dimethylacetamide (13%) alone or a combination 13% ethanol with 0.07% lysolecithin gave average RCP values ∼90% for RP517. Water by itself gave a RCP value of only 81%. Tween-80 did not give satisfactory yields for RP517.

Ethanol Concentration versus RCP. A radiolabeling study was performed using the same lyophilized vials as in the previous experiment. SG380 was dissolved in aqueous ethanol (0−30% EtOH) to give a concentration of 20 μg/mL. Reconstitution of the vials was achieved by adding 1 mL of the SG380 solution and 0.5 mL of Na[$^{99m}TcO_4$] solution (100 mCi/mL). The reconstituted vials were heated at 100 °C for 30 min, and samples of the reaction mixtures were characterized by HPLC and ITLC. Four vials were tested for each condition, and the experiment was repeated using a different generator or the same generator on a different date. Figure 2 shows the histogram of RCP versus EtOH concentration. The optimal ethanol concentration range is 5−15%.

Heating Time versus RCP. Heating time is another factor influencing the RCP of RP517. In SG380, the hydrazine moiety is protected as a hydrazone of 2-sulfonatobenzylaldehyde. For SG380 to bond to the Tc, hydrolysis of the hydrazone group has to occur. The yield of RP517 depends largely on the amount of hydrazine groups available for Tc-binding and the kinetics of in situ hydrolysis of the hydrazone functionality. The greater the

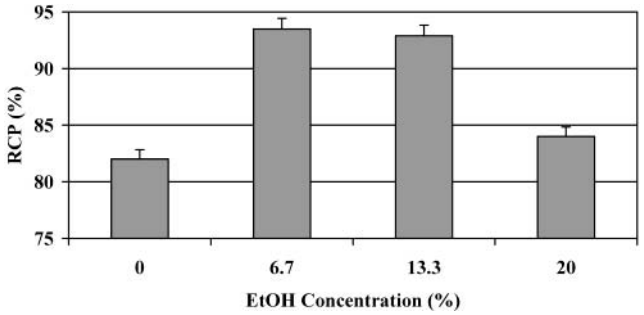

Figure 2. Effect of ethanol concentration on RCP of RP517. Four vials were tested for each condition, and the experiment was repeated using a different generator or the same generator on a different date.

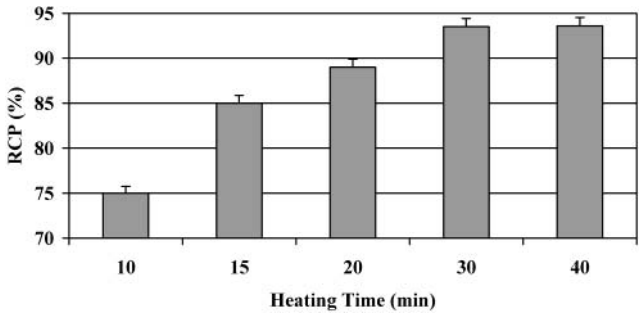

Figure 3. Heating time versus RCP. Four vials were tested for each condition, and the experiment was repeated using a different generator or the same generator on a different date.

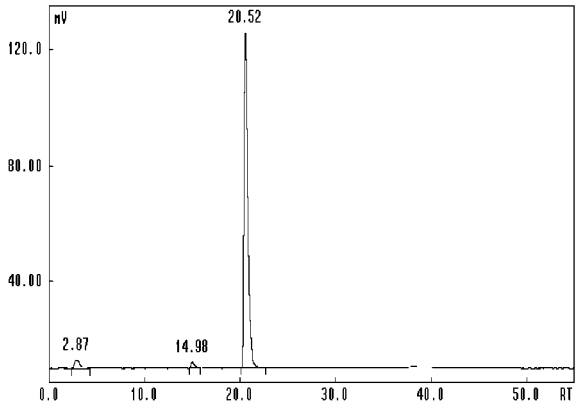

Figure 4. Radio-HPLC chromatogram of RP517.

hydrolysis of the hydrazone group, the more the free hydrazine groups available for Tc-binding; thereby the higher the radiolabeling yield of RP517.

To find an optimal heating time for the preparation of RP517, we performed a radiolabeling study using the same lyophilized vials as in the previous experiments. In this experiment, SG380 was dissolved in 1 mL of 10% EtOH to give a concentration of 20 μg/mL. To each lyophilized vial were added 1.0 mL of SG380 solution and 0.5 mL of Na[$^{99m}TcO_4$] solution (100 mCi/mL). The ethanol concentration was ~6.7%. Reconstituted vials were heated at 100 °C for 10, 15, 20, 30, and 40 min. Figure 3 shows the histogram of heating time versus RCP of RP517. Longer heating time gives better RCP for RP517; but there is no significant difference in RCP between the vials heated 100 °C for 30 min and vials heated 100 °C for 40 min.

HPLC Characterization. Figure 4 shows a typical radio-HPLC chromatogram of RP517. The small peak at ~3 min is due to a combination of several radioimpurities. Since most of radioimpurities in the RP517 kit are less than 1.0%, no further characterization was performed. The LTB_4 targeting moiety contains no chiral center. The technetium chelate is formed as an equal mixture of D and L enantiomers due to the tricine ligand being prochiral. These enantiomers are not separable using the chromatographic conditions described in this study. Thus, RP517 shows only one radiometric peak in its radio-HPLC chromatogram.

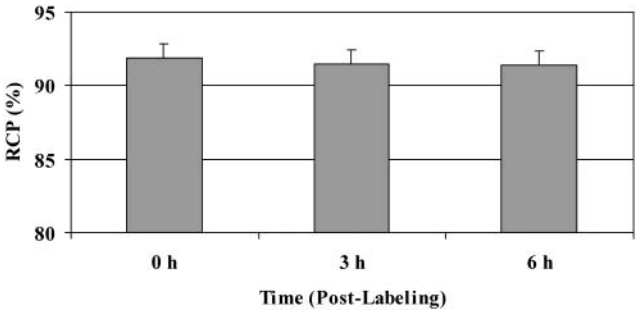

Figure 5. Solution stability of RP517 in the kit matrix.

Solution Stability Studies. We also examined the solution stability of RP517. Each lyophilized vial was reconstituted by adding 1.0 mL of SG380 solution (20 μg/mL in 18% EtOH) and 0.5 mL of Na[$^{99m}TcO_4$] solution (100 mCi/mL). The final ethanol concentration was 12%. Reconstituted vials were heated at 100 °C for 30 min. Samples of the resulting solutions were analyzed by radio-HPLC at $t = 0$, 3, and 6 h post-labeling. The results are shown in Figure 5. RP517 is stable for at least 6 h in the kit matrix.

Synthesis and Characterization of [^{99}Tc]RP517. [^{99}Tc]RP517 was prepared in one step by reacting [NH_4][$^{99}TcO_4$] with SG380 in the presence of excess tricine and TPPTS. The yield for [^{99}Tc]RP517 is relatively low (<30% by UV). After HPLC purification and desalting, [^{99}Tc]RP517 was obtained only in milligram quantities, which is sufficient for the HPLC concordance experiment and LC-MS characterization. The HPLC concordance experiment showed that the same complexes were prepared at the tracer (^{99m}Tc) and macroscopic (^{99}Tc) levels. The LC-MS spectrum of [^{99}Tc]RP517 showed both the monoprotonated molecular ion, $(M + 1)^+$, peak at $m/z = 1627.2$ for $[C_{70}H_{86}N_{11}O_{20}PS_3Tc]^+$ and the diprotonated molecular ion, $(M + 2)^{2+}$, peak at $m/z = 813.7$. The LC-MS data support the proposed structure (Figure 1) and is completely consistent with the 1:1:1:1 composition for Tc:SG380:tricine:TPPTS.

CONCLUSIONS

In this report, we described the synthesis and characterization of a ternary ligand complex [^{99m}Tc(SG380)(tricine)(TPPTS)] (RP517). RP517 was prepared using a non-$SnCl_2$-containing formulation. Unlike other HYNIC-conjugated small biomolecules, SG380 is lipophilic and has low solubility in the kit matrix. To reduce the glass-surface adsorption and to increase the solubility of TA138 in the kit formulation, we have to use a solution containing both Lysolecithin (solubilizing agent) and ethanol (cosolvent) for the radiolabeling. Using this formulation, RP517 can be prepared in high radiochemical purity (>90%) and remains stable in the kit matrix for at least 6 h. The chromatographic and spectroscopic data of the corresponding ^{99}Tc analogue, [^{99}Tc]RP517, are completely consistent with the 1:1:1:1 composition for Tc:SG380:tricine:TPPTS.

Acknowledgment is made to Dr. Thomas D. Harris for the synthesis of hydrazinonicotinamide-conjugated LTB_4 receptor antagonist (SG380).

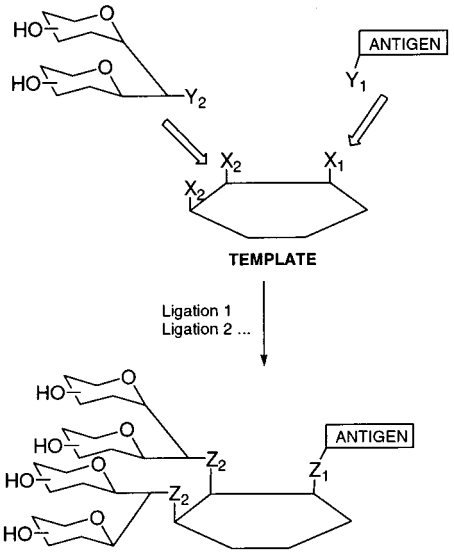
Combined Thioether/Hydrazone Chemoselective Ligation Reactions for the Synthesis of Glycocluster−Antigen Peptide Conjugates

Cyrille Grandjean,*,† Valérie Santraine,† Jean-Sébastien Fruchart,‡ Oleg Melnyk,‡ and Hélène Gras-Masse‡



SEDAC−Therapeutics, Parc Eurasanté - Le Galenis, Bâtiment B, 85, rue Nelson Mandela, 59120 Loos, France and UMR 8525 CNRS, Université de Lille II, Institut de Biologie et Institut Pasteur de Lille, 1, rue du Prof Calmette, BP447, 59021 Lille Cedex, France. Received January 16, 2002; Revised Manuscript Received March 21, 2002

Hydrazone/thioether ligation reactions show promise for the synthesis of clustered glycosides−antigen conjugates. Due to its propensity to aggregate, tetanus toxoid-derived epitopic peptide $TT^{830-846}$ was elected to further evaluate this three-component ligation process. This difficult sequence was supplemented by a hydrazine or a glyoxylyl group either at its C- or N-terminus. The peptide-hydrazines or peptide-aldehydes thus obtained were coupled with glyoxylyl- (or hydrazino-) *N*-chloroacetylated-L-lysinyl trees and 2-thioethyl-α-D-mannopyranoside. As anticipated the ligations were controlled by the nature of the peptide and proved difficult for the C-terminal aldehyde derivative. However, when the process was performed in absence of buffer and using mannitol as a dispersing agent, all combinations finally led to the expected glycoconjugates in 40−60% purified yields.

INTRODUCTION

The chemoselective ligation, which refers to the coupling of fully deprotected molecular fragments through two mutually and uniquely reactive functional groups in aqueous media, has become a powerful tool in the synthesis of peptides, proteins, bioconjugates, and even engineered cells (*1*−*5*). Iteration of a single ligation reaction has allowed the assembly of peptide conjugates from more than two segments, but this strategy is hampered by the need for additional steps to remove impurities, excess reagents, and temporary protective groups (*6*−*13*). Elegant solutions have been proposed by adapting the native and the expressed protein ligations on the solid phase which simplifies these processes (*14*−*16*). For solution-phase synthesis, *true orthogonal ligation reactions*, performed sequentially or in a one-pot procedure, are required and examples thereof remain exceedingly rare. One can cite the synthesis of an RNA−peptide conjugate (*17*), the preparation of a heterodimeric transcription factor (*18*), and more recently the synthesis of analogues of chemokines and somatostatins (*19*), by means of thioether/native chemical ligation, thioester/oxime, or pseudoproline/native chemical ligation reactions, respectively. Combination of thioether/oxime ligations has also been envisioned for the Template Assembled Synthetic Proteins approach (*20*), or the synthesis of glycoproteins (*21*, *22*), proof of principle of this strategy being demonstrated (*23*). Finally, our laboratory has proposed a thioether/hydrazone ligation strategy (Scheme 1) (*24*) for the preparation of antigen-clustered glycosides conjugates for the selective targeting of the human dendritic cells' mannose receptor (*25*).

Scheme 1. General Strategy for the Synthesis of Oligoglycosides−Antigen Peptides Conjugates[a]

[a] CTL epitopes, T helper epitopes and (oligo)glycosides or clusters thereof are assembled on a template through one pot or combination of orthogonal ligations. Present study: X_1 = CHO (or $NHNH_2$); Y_1 = $NHNH_2$ (or CHO); X_2 = $ClCH_2CO$; Y_2 = SH.

This approach seems to compete favorably with stepwise oligomannosides−antigen peptides conjugate synthesis, which, among others, requires finely devised protective group manipulations (*26*, *27*). However, our process was (a) dependent on the nature of the antigen and was somewhat troublesome for difficult sequences which tend to aggregate: A more generally applicable procedure would be highly desirable; (b) limited to the conjugation of antigen peptides via their *N*-terminus: The corresponding antigens modified at their C-terminus would be useful to document whether the conjugation site has an impact on the antigen processing by the dendritic

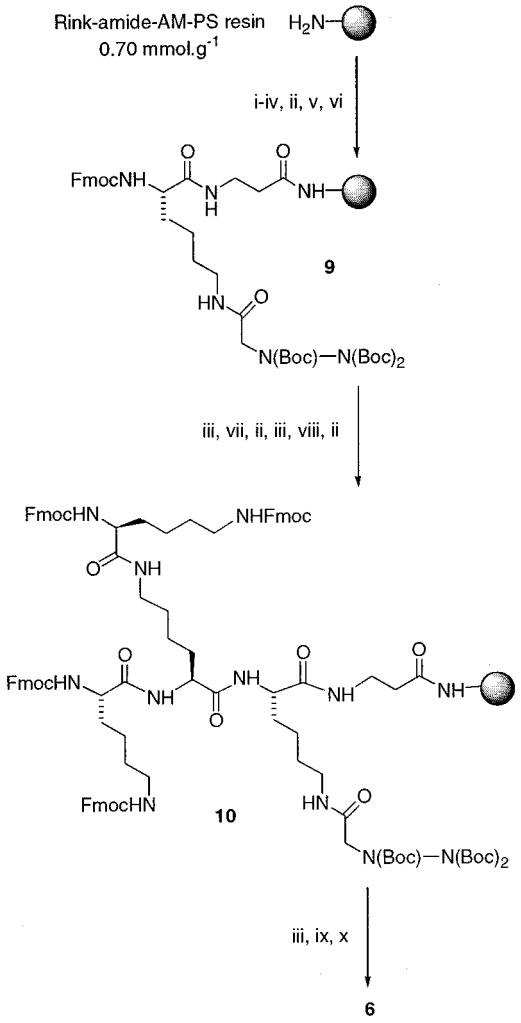
Chart 1. Glyoxylyl and Hydrazino Peptides Evaluated in This Study

cells; and (c) mainly successful using templates bearing the two types of electrophilic groups namely glyoxylyl-poly-*N*-chloroacetylated-L-lysinyl trees: Scope of the hydrazone ligation (and probably those of the ligation strategies) would be extended if one was able to prepare and use hydrazino chloroacetylated templates, i.e., templates bearing a priori uncompatible electrophile/nucleophile groups (*28*).

We now report methodologies and experimental conditions which alleviate most of the above-mentioned limitations. These achievements allow the convenient incorporation of hydrazine and glyoxylyl groups on both template and antigen peptide, either at its N- or C-terminus, and the successful couplings of the fragments thus obtained.

RESULTS AND DISCUSSION

To further examine the hydrazone/thioether ligation, we planned to synthesize and condense compounds **1**−**4**, derived from the tetanus toxin $TT^{830-846}$ epitope, representative of a difficult sequence, with pendant tetravalent-L-lysinyl trees **5** or **6** and 2-thioethyl α-D-mannopyranoside **7** (*29*), (Chart 1).



Compounds **1**−**6** were obtained by using the Fmoc[1]/*tert*-butyl solid-phase peptide synthesis strategy (*30*). Syntheses of compounds **1**−**5** were reported previously: Briefly, derivatives **4** and **5** were elaborated on a tartaric acid-derived linker which generates the glyoxylyl function upon cleavage from the solid support, in 15 and 31% yield, respectively (*31*). Glyoxylyl peptide **3** was attained after solution-phase periodic oxidation (*32*) of a $TT^{830-846}$ sequence, augmented with an *N*-terminal serine in 5% overall yield (*28*). Bromine displacement of an *N*-bromoacetylated $TT^{830-846}$-derived peptidyl resin by *tert*-butyl carbazate (*33*) led to the hydrazino peptide **1** in an actual 40% yield following acidic deprotection and cleavage from the resin (*24*). For compounds **2** and **6** (Scheme 2), a Fmoc-L-Lys(Mtt)-OH residue was introduced near the C-terminus. Following selective removal of the 4-methyltrityl group (*34*), the lysinyl side chain amine was coupled with [*N*,*N*′-tri(*tert*-butyloxycarbonyl)hydrazino]-acetic acid **8** using HOBt/HBTU/DIEA activation to install the hydrazine moiety. Full protection of the α-hydrazinoacetic acid was necessary to avoid self-condensation of the corresponding activated ester (*35*). Rest of the syntheses were then completed to give **2** and **6** in 17 and 25% yield, respectively.

Contrasting with our previous attempt to synthesize the hydrazino-tetra-*N*-chloroacetylated lysinyl tree (*28*), we did not detect the presence of any cyclic compound which arises from intramolecular substitution of one chlorine atom by the hydrazine. Hydrazino peptides **1**, **2**, and **6** proved to be stable during RP-HPLC purification (provided mixtures of CH_3CN/TFA were not used as solvent) (*35*) and upon storage at −30 °C. Glyoxylyl derivative **3** was stored as a hydrochloride salt to prevent it from noncovalent aggregation. Glyoxylyl peptide **4** exhibited even more propensity to aggregate. Noncovalent aggregation was partially avoided when the RP-HPLC purification was performed following the cleavage step, and the pure fractions were lyophilized without dilution; the noncovalent aggregation was totally suppressed by adding about a 10-fold excess of mannitol to the fractions, prior to the freeze-drying step (*31*).

When all the partners were available, the combined hydrazone/thioether ligation was next investigated. We decided to perform the hydrazone ligation, the most

[1]Abbreviations: Fmoc, 9-fluorenylmethoxycarbonyl; Mtt, 4-methyltrityl; HOBt, 1-hydroxybenzotriazole; HBTU, *N*-[1*H*-benzotriazol-1-yl)-(dimethylamino)methylene]-*N*-methylmethanaminium hexafluorophosphate; TNBS, 2,4,6-trinitrobenzenesulfonic acid; DIC, diisopropylcarbodiimide; TIS, triisopropylsilane; RP-HPLC, reverse phase-high-pressure liquid chromatography.

Scheme 2. Solid Phase Synthesis of Lysinyl Core 6[a]

[a] Reagents and conditions: i, 4 equiv of Fmoc-*β*-Ala-OH, HBTU−HOBt−DIEA (4:4:12 equiv), DMF,, 45 min; ii, Ac_2O−DIEA−CH_2Cl_2 (5:10:85), 10 min; iii, piperidine−DMF (20:80), 20 min; iv, 4 equiv Fmoc-L-Lys(Mtt)-OH, HBTU−HOBt−DIEA (4:4:12 equiv), DMF, 45 min; v, TFA−CH_2Cl_2 (1:99), seven times; vi, 4 equiv of **8**, HBTU−HOBt−DIEA (4:4:12 equiv), DMF, 45 min; vii, 4 equiv of Fmoc-L-Lys(Fmoc)-OH, HBTU−HOBt−DIEA (4:4:12 equiv), DMF, 45 min; viii, 8 equiv of Fmoc-L-Lys(Fmoc)-OH, HBTU−HOBt−DIEA (8:8:24 equiv), DMF, 45 min; ix, $ClCH_2COOH$ (32 equiv), DIC (16 equiv), DMF, 40 min; x, TFA−H_2O−TIS (95:2.5:2.5), 0 °C, 1 h 30 min.

challenging of the two reactions since involving sensitive material, at once. Moreover, in the reverse strategy, the hydrazine group of compound **5** would have competed with thiols for the chlorine substitution. Thus, L-lysinyl core **5** was reacted at room temperature with hydrazino peptides **1** and **2** in a 95:5 mixture of degassed 2-methyl-2-propanol/water. This solvent was selected for its ability to increase the reaction rate compared to other systems, based on mixtures of organic solvent and aqueous buffer (*36*), and to delay noncovalent aggregation (*28*). L-Lysinyl tree **6** was reacted similarly with glyoxylyl derivatives **3** and **4**. The latter compound was used dispersed in mannitol or partially aggregated in two distinct experiments. As expected, the reactions were almost driven to completion after 10 min (as monitored by RP-HPLC, see for examples Figures 1a and 1b), with the exception of the one conducted with "aggregated" **4** (Figure 1c).

The second ligation was performed after 5 h, a period over which any unreacted α-hydrazinoacetyl peptide tends to evolve with decomposition of the hydrazine group. 2-Thioethyl-α-D-mannopyranoside **7** in degassed 2-methyl-2-propanol/water (1:1) was introduced into each reaction vessel, the apparent pH being adjusted to 8−8.5 (pH paper) by addition of solid potassium carbonate. Formation of the conjugates **11**−**13** was readily observed by RP-HPLC monitoring (see, for example, Figure 1d). By contrast, compound **14** was only obtained cleanly in the presence of mannitol which acts like a dispersing reagent. In its absence, noncovalent aggregation prevailed resulting in incomplete ligations and complex crude mixture (compare Figures 1b, 1e and 1c, 1f). Conjugates **11**−**14**, which appeared very hydrophilic, were actually obtained in 48, 55, 41, and 40% purified yields, respectively (Charts 2 and 3).

In summary, we have shown that hydrazine or aldehyde could equally be introduced at the C- or N-terminus of a peptide. The mild experimental conditions developed were applied for the synthesis of a hydrazino-tetra-*N*-chloroacetylated tree otherwise difficult to obtain. These methodologies allowed study of four combinations of hydrazone chemoselective ligation for the preparation of glycocluster−peptide conjugates using $TT^{830-846}$ as a model. Solution behavior of this difficult sequence was either improved or impaired when modified by a hydrazine group or an aldehyde. However, all permutations were eventually successful and permitted its linkage to be at least four glycosides.[2] Altogether, these achievements confer further flexibility and robustness to the hydrazone/thioether ligation strategy.

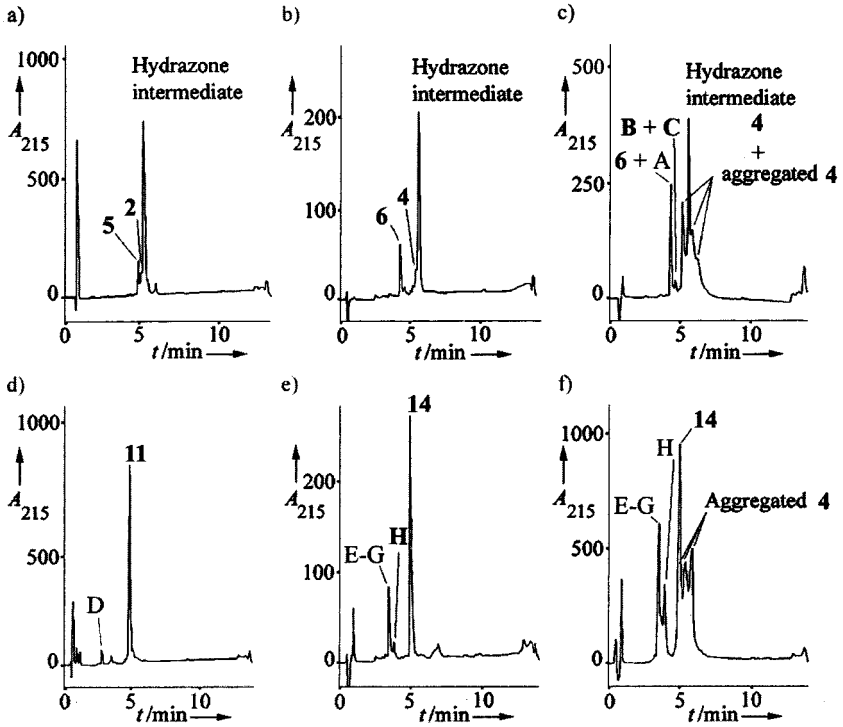
EXPERIMENTAL SECTION

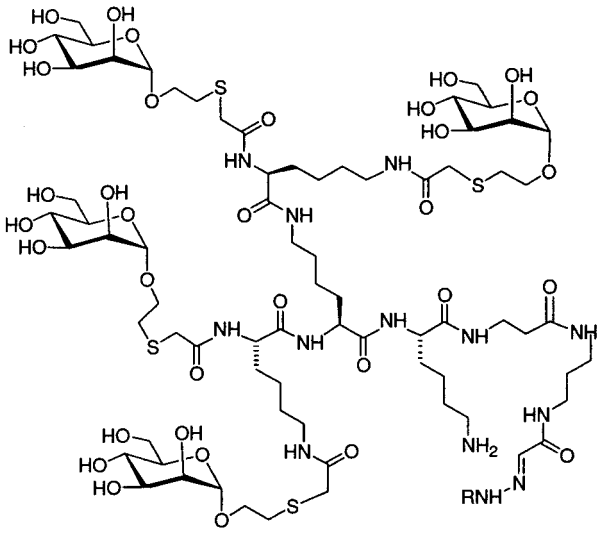
General. Analytical reverse-phase high performance liquid chromatography (RP-HPLC), separations were performed upon a Beckman system Gold system using a TSK gel super ODS (TosoHaas) (110 Å, 2 μm, 4.6 × 50 mm) column at a flow rate of 1.5 mL min^{-1} (monitoring and analysis), with detection at 215 nm at 50 °C. Gradient: 0% B for 5 min, 0−100% B over 10 min, 100% B for 1 min, 0% B for 2 min. Semipreparative RP-HPLC separations were performed on a Shimadzu LC-4A systems, on an Hypersil hyperprep C-18 (300 Å, 8 μm, 10 × 260 mm), column at a flow rate of 3 or 5 mL min^{-1}, with detection at either 215 or 230 nm at 50 °C. Solvent system A: 0.05% TFA in water; solvent system B: 0.05% TFA in 40% *i*PrOH-60% water. MALDI-TOF-MS spectra were recorded on a Finnigan Vision 2000 mass spectrometer.

Solid-Phase Peptide Synthesis. Syntheses of compounds **1**−**5** have been reported in references 28, 37, 28, 31, and 31, respectively.

Hydrazino-*N*-chloroacetylated-L-lysinyl Tree 6. This compound was synthesized manually on an rink amide-AM-PS resin (substitution, 0.70 mmol g^{-1}) (Senn Chemicals) using the Fmoc/*tert*-butyl strategy at a 0.1 mmol scale. The coupling steps were performed using a 4-fold excess of amino acid per amine to be reacted via HBTU−HOBt−DIEA activation in DMF and monitored by the TNBS test (*38*): typically, HBTU dissolved in DMF (4 equiv) was added to a mixture of the amino acid (4 equiv), HOBt (4 equiv), and DIEA (12 equiv) in DMF. After stirring for 1 min, the mixture was added to the peptidyl resin (1 equiv), swollen in DMF, and mechani-

[2]Tetravalency seems sufficient to confer specific dendritic cells' mannose receptor recognition, at least in vitro: see ref 25. It is indeed anticipated that the nature and the site of attachment of antigen peptides to the template will modify their behavior and reactivity and affect their processing by the dendritic cells.





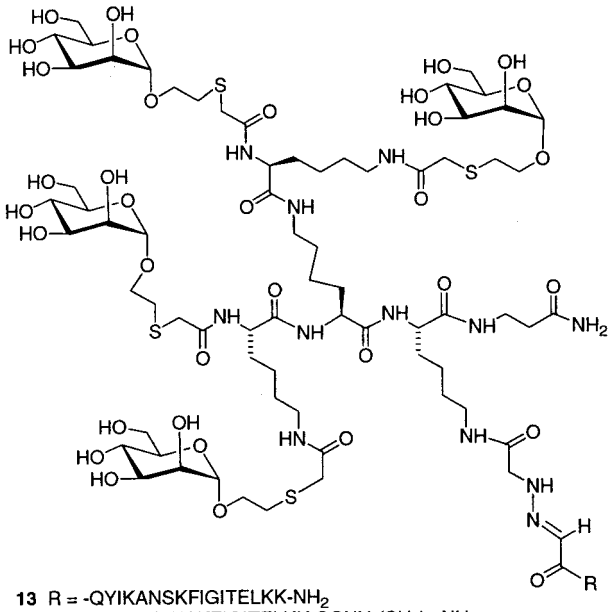


Figure 1. RP-HPLC chromatograms of crude mixtures from the hydrazone ligations after 10 min a) and b) or 5 h c), and following the second thioether ligations d)-f); a) and d) ligations between core **5** and hydrazinopeptide **2**; b) and e) ligations between core **6** and hydrazinopeptide **4** dispersed in mannitol; c) and f) ligations between core **6** and hydrazinopeptide **4** partially aggregated. We previously observed that an antigen and its corresponding tetra-mannosylated derivative usually possess close RP-HPLC retention time. Thus, excess L-lysinyl tree was used in every experiment to fully consume the antigen peptide and facilitate the purification step. The excess tree is transformed into hydrophilic side-products during the thioether ligation, easily separated from the desired conjugate. Side-products formed: Compound A: *m/z* 986.6 $(M + Na)^+$, 1002.4 $(M + K)^+$ (loss of amino group on **6**); Compound B: *m/z* 971.3 $(M + Na)^+$, 988.3 $(M + K)^+$ (loss of hydrazine on **6**); Compound C: *m/z* 1945.8 $(M + Na)^+$, 1961.7 $(M + K)^+$ (dimeric structure derived from **6**); Compound D: *m/z* 1859.3 $(M + Na)^+$ (tetra-mannosylated tree derived from **5**); Compound E: *m/z* 1794.1 $(M + H)^+$, 1817.8 $(M + Na)^+$, 1832.9 $(M + K)^+$ (tetra-mannosylated tree derived from **6**); Compound F: *m/z* 1801.8 $(M + Na)^+$, 1818.7 $(M + K)^+$ (loss of amino group on D); Compound G: *m/z* 1787.7 $(M + Na)^+$, 1802.7 $(M + K)^+$ (loss of hydrazine on D); Compound H: *m/z* 3576.6 $(M + Na)^+$, 3592.2 $(M + K)^+$ (dimeric structure derived from **6**). Chromatographic conditions, see Experimental Section.

cally shaken for 45 min. Following filtration, the peptidyl resin was washed with DMF (3 × 2 min) and CH_2Cl_2 (3 × 2 min). Each coupling was followed by a capping with Ac_2O−DIEA−CH_2Cl_2 10:5:85 for 10 min, followed by washing with CH_2Cl_2 (3 × 1 min). Cleavage of the Fmoc protecting groups was achieved by treatment with 20% piperidine in DMF (1 × 2 min, 1 × 20 min), followed by washing with DMF (2 × 2 min), and washing with CH_2Cl_2 (2 × 1 min). Fmoc-β-Ala-OH was first anchored to the resin. Chain protection of the first lysinyl residue

introduced was secured by 4-methyltrityl (Mtt). Following the coupling, the Mtt group of the ϵ-NH_2 of the first lysine residue was removed by treatment with a solution of 1% TFA in CH_2Cl_2 (seven times). Monitoring the deprotection was realized as described in reference 34. [*N*,*N*′-Tri(*tert*-butyloxycarbonyl)hydrazino]acetic acid **8** (4 equiv) was then introduced onto the peptidyl resin, swollen in DMF, via HBTU−HOBt−DIEA activation (4/4/12 equiv). The other lysinyl residues were added as their Fmoc-L-Lys-(Fmoc)-OH derivatives. After the second coupling step, the peptidyl resin was deprotected and acylated using an 4-fold excess of preformed chloroacetic anhydride, prepared via a DIC activation to provide the tetravalent core. The core was then cleaved from the resin and deprotected by TFA−H_2O−$^i Pr_3SiH$ 95:2.5:2.5 (10 mL per g of peptidyl resin), for 1.30 h at 0 °C, precipitated in cold diethyl ether−heptane 1:1, centrifugated, dissolved in H_2O−AcOH 95:5, and freeze-dried.

Compound **6** (27 mg, 25%) was obtained as a white powder after RP-HPLC purification [gradient: 90:10 to 50:50 (A/B), 35 min], followed by freeze-drying; *m*/*z* (positive MALDI-TOF-MS) 1003.5 $(M + Na)^+$, 979.4 $(M + H)^+$.

General Procedure for the Hydrazone/Thioether Ligation. All solvents were degassed by bubbling N_2 before use. *N*-Chloroacetylated core **5** or **6** (1 mg, 0.88 and 0.91 μmol, respectively) is reacted with the modified antigen **1**−**3** (0.9 equiv) or **4** [0.9 equiv, dispersed in mannitol, 6.6% (w/w) as determined by total acid hydrolysis (*31*)], in *tert*-BuOH−H_2O 95:5 (400 μL) for 5 h at room temperature under nitrogen.

In parallel, 2-thioethyl α-D-mannopyranoside disulfide (4 equiv), dissolved in *tert*-BuOH−H_2O 50:50 (200 μL), was reacted with tri-*n*-butylphosphine (1 equiv/disulfide) at room temperature under nitrogen, and the reduction was monitored by RP−HLPC. On completion, the reaction mixture is transferred to the crude lysinyl tree−antigen peptide conjugate and the apparent pH adjusted to 8−8.5 (paper) by addition of solid potassium carbonate. The reaction mixture was stirred at room temperature under nitrogen and monitored by RP-HPLC. After completion of the reaction, the crude mixture was diluted with H_2O, frozen, and freeze-dried. Compounds were obtained as white powders following semipreparative RP-HPLC purifications and freeze-drying.

Compound 11 (1.65 mg, 48%) was obtained as a white powder after RP-HPLC purification [gradient: 100:0 to 60:40 (A/B), 70 min], followed by freeze-drying; *m*/*z* (positive MALDI-TOF-MS) 3892.9 $(M + Na)^+$, 3870.8 $(M + H)^+$.

Compound 12 (2.42 mg, 55%) was obtained as a white powder after RP-HPLC purification [gradient: 100:0 to 80:20 (A/B), 10 min, then 80:20 to 70:30 (A/B), 25 min, then isocratic], followed by freeze-drying; *m*/*z* (positive MALDI-TOF-MS) 4077.9 $(M + K)^+$, 4061.9 $(M + Na)^+$, 4039.9 $(M + H)^+$.

Compound 13 (1.43 mg, 41%) was obtained as a white powder after RP-HPLC purification [gradient: 100:0 to 78:22 (A/B), 10 min, then 78:22 to 68:32 (A/B), 30 min, then isocratic], followed by freeze-drying; *m*/*z* (positive MALDI-TOF-MS) 3850.8 $(M + K)^+$, 3834.8 $(M + Na)^+$, 3812.9 $(M + H)^+$.

Compound 14 (1.43 mg, 40%) was obtained as a white powder after RP-HPLC purification [gradient: 100:0 to 80:20 (A/B), 10 min, then 80:20 to 65:35 (A/B), 30 min], followed by freeze-drying; *m*/*z* (positive MALDI-TOF-MS) 3934.0 $(M + Na)^+$, 3911.9 $(M + H)^+$.

Improving the Labeling of *S*-Acetyl NHS−MAG_3-Conjugated Morpholino Oligomers

Guozheng Liu,* Surong Zhang, Jiang He, Zhihong Zhu, Mary Rusckowski, and Donald J. Hnatowich*

Division of Nuclear Medicine, Department of Radiology, University of Massachusetts Medical School, Worcester, Massachusetts 01655. Received April 15, 2002

S-Acetyl MAG_3 (S-acetylmercaptoacetyltriglycine) has been used as a chelator for the ^{99m}Tc labeling of a variety of biomolecules. The objective of this study was to improve upon the labeling of morpholino (MORF), a DNA analogue, as a model biomolecule. A 15mer MORF with a primary amine was conjugated with NHS−MAG_3 in the usual manner, and the MORF−MAG_3 was purified over a P4 column as before. The conjugate was radiolabeled using stannous ion as usual, and the impurities were identified using size exclusion high-performance liquid chromatography (SE HPLC). Various methods were then investigated to remove the impurities. With tartrate as the transchelator, two impurities were identified as labeled MAG_3 and labeled tartrate. The labeled MAG_3 could not be removed by simply repurifying the conjugate using the usual pH 5.2 NH_4OAc buffer before labeling. However, this impurity could be completely removed if the conjugate was adjusted to pH 7.6 and heated before repurification. The labeled tartrate impurity was removed by heating during labeling. On the basis of these observations, the following procedure for purification of the conjugation mixture and subsequent labeling was adopted. After MORF was conjugated with NHS−MAG_3 and purified over P4 with pH 5.2 NH_4OAc eluant, the oligomer fractions were combined, adjusted to pH 7.6, and heated in a boiling water bath for 20 min. The conjugated oligomer was then repurified over P4 for storage at refrigerator temperatures. Labeling is achieved simply by adding fresh stannous ion to a solution of the MORF−MAG_3 in pH 7.6 containing tartrate followed by ^{99m}Tc−pertechnetate. After the mixture is heated for 20 min in boiling water, the labeling efficiency is always over 90% as determined by size exclusion HPLC and paper chromatography and the specific activities can exceed 7 mCi/μg. By making several relatively simple changes to the routine procedure used to conjugate and radiolabel biomolecules with ^{99m}Tc via MAG_3, a modified procedure was developed that results in labeling efficiency high enough to avoid postlabeling purification.

INTRODUCTION

Among other bifunctional chelators, this laboratory has used an activated NHS ester of S-acetyl MAG_3 (S-acetylmercaptoacetyltriglycine) for the radiolabeling of a variety of biomolecules (*1*−*15*). An acetyl group protecting the sulfur on MAG_3 was substituted for the benzoyl group to avoid the harsh conditions of alkaline pH and elevated temperatures required for the removal of this group (*14*). Labeling is successful at neutral pH (normal labeling efficiency 50−80%), but separation after labeling is always required to achieve acceptable radiochemical purities (*1*−*15*). Furthermore, because tartrate is used as a transchelator, the labeled biomolecule is often contaminated with labeled tartrate, which may then coelute with the biomolecule during postlabeling purification and subsequently become oxidized to ^{99m}Tc−pertechnetate. Heating can encourage transchelation of the labeled tartrate to the desired product. Heating can also accelerate the oxidation of stannous ion and, in the presence of low concentrations of this reducing agent, can result in oxidation of the labeled tartrate to ^{99m}Tc−pertechnetate. The pertechnetate will then be retained on the size exclusion column during postlabeling purification (*1*, *2*).

Recently, morpholino oligomers (MORF) and their complementary forms (cMORFs) have been under investigation as potentially useful agents for pretargeting applications after radiolabeling via MAG_3 (*1*, *2*). These oligomers were therefore selected as model biomolecules to search for methods leading to efficient labeling with no need for postlabeling purification.

MATERIAL AND METHODS

The 15mer MORF and its complement used herein were identical to those used by us earlier (*1*−*3*). The P4 separation gel (Bio-Gel Medium, Bio-Rad Laboratories, Hercules, CA) was purchased and used as received; S-acetyl NHS−MAG_3 was synthesized in house (*14*), and the structure was confirmed by elemental analysis, proton nuclear magnetic resonance (NMR), and mass spectroscopy. All other chemicals were reagent grade and were used without purification. The ^{99m}Tc−pertechnetate was eluted from a ^{99}Mo−^{99m}Tc generator (Dupont, Billerica, MA).

Size Exclusion High-Performance Liquid Chromatography (HPLC) and Paper Chromatography. Size exclusion HPLC analysis was performed on a Superdex Peptide column (optimal separation range: 1 × 10^2 to 7 × 10^3 Da; Amersham Pharmacia Biotech, Piscataway, NJ) with 0.10 M pH 7.2 phosphate buffer as eluant at a flow rate of 0.60 mL/min. ^{99m}Tc−pertechnetate is retained on this column. The HPLC was equipped with both an inline radioactive detector and an

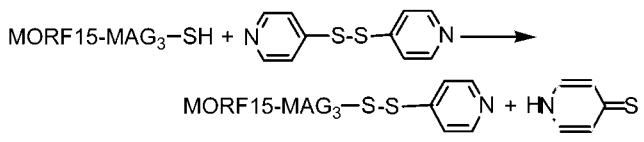
Published on Web 06/27/2002

inline Waters 2487 dual wavelength absorbance detector. Recovery was routinely measured. The presence of ^{99m}Tc−pertechnetate was confirmed by paper strip chromatography on Whatman No. 1 with acetone as the mobile phase. Only ^{99m}Tc−pertechnetate migrates with the solvent while labeled MORF and other labeled impurities remain at the origin.



Conjugating MORF with MAG_3 and Radiolabeling. MORF derivitized on the 3′ equivalent end with a primary amine was conjugated with S-acetyl NHS−MAG_3 as previously described (*1*−*3*). A solution of 1000 μg of MORF in 200 μL of 0.2 M, pH 8.0, *N*-(2-hydroxyethyl)piperazine-*N*′-ethanesulfonic acid (HEPES) buffer was added to a vial containing 1700 μg of S-acetyl NHS−MAG_3. The vial was immediately vortexed thoroughly, incubated for 1 h at room temperature, and purified on a 0.7 cm × 20 cm P4 column with 0.25 M, pH 5.2, NH_4OAc buffer as eluant.

MORF−MAG_3 was originally labeled by adding 5 μL (∼300 μCi) of ^{99m}Tc−pertechnetate generator eluate to a solution of 30 μL of MORF−MAG_3 in the pH 5.2 ammonium acetate buffer, 10 μL of 50 μg/μL Na_2·tartrate·$2H_2O$ in a pH 9.2 buffer (0.5 M Na_2HCO_3, 0.25 M NH_4OAc, and 0.175 M NH_3), and 4 μL of 1 μg/μL $SnCl_2$·$2H_2O$ in ascorbate−HCl solution (1 μg/μL sodium ascorbate in 10 mM HCl). The final pH was 7.6.

To better understand the original labeling method, several studies were performed as follows: (i) The pH 7.6 solution of labeled MORF was divided, one-half was stored at room temperature for 10 h while the other was heated in a boiling water bath for 20 min before storage at room temperature for 10 h. (ii) In addition, some of the heated half was purified again over P4. The three samples were then analyzed by HPLC.

As will be shown below, the radioimpurities after labeling by the original method are labeled tartrate and labeled MAG_3. If a 20 min heating step is introduced at the end of the labeling method, the only radioimpurity remaining is labeled MAG_3. Thus, if labeled MAG_3 can be prevented, postlabeling purification will be unnecessary. The labeled MAG_3 may arise from inefficient purification of the free MAG_3 remaining after the conjugation or it may be generated by cleavage during labeling of some relatively unstable MAG_3 conjugate. To better understand the origin of this impurity, (i) the purified MORF−MAG_3 in pH 5.2 was purified again on P4 before labeling and (ii) the purified MORF−MAG_3 in pH 5.2 was adjusted to pH 7.6, heated for 20 min, and then purified over P4 again using the same pH 5.2 NH_4OAc buffer as eluant.

MAG_3 Groups per MORF. After conjugation, the acetyl group on S-acetyl MAG_3 may no longer be necessary to protect the thiol group; nevertheless, its continued presence has been demonstrated following conjugation to one peptide (*10*). By introducing a 20 min heating step at boiling water temperature, especially at pH 7.6, it is possible that most of the acetyl groups are hydrolyzed (*16*, *17*). Because rapid kinetics of labeling may depend on the presence of the unprotected free sulfhydryl on MORF−MAG_3 (*18*, *19*), the number of unprotected MAG_3 groups on MORF−MAG_3 was determined. The assay employed 4,4′-dithiodipyridine (4-DTDP) according to the following reaction (*5*, *20*, *21*):

By measuring on a UV spectrophotometer (U-2000, Hitachi Instruments Inc., Danbury, CT), it was determined that MORF and cysteine show low to nonexistent absorption at the 323 nm absorption maximum of the indicator 4-thiopyridone (4-TP). Only 4-DTDP shows a small but measurable absorbance at this frequency. However, 4-DTDP was present at large excess such that its concentration was effectively unchanged by the reaction. Accordingly, free sulfhydryl groups could be quantitated in the presence of 4-DTDP.

A standard curve of absorbance vs free sulfhydryl concentration was obtained by adding 40 μL of 4-DTDP (80 pmol) in 0.1 M, pH 7.2, phosphate buffer to each of a series of cysteine solutions in the range of 5−45 μM in 100 μL of pH 5.2 acetate buffer and measuring the absorbance against a blank 4-DTDP solution. The concentration of free sulfhydryls in the MORF−MAG_3 sample was then determined by applying its absorbance to the standard curve. In this measurement, the concentration of MORF was obtained by its absorbance at 265 nm using the molar absorbance (1.583×10^5 M^{-1} cm^{-1}) provided by the manufacturer.

Optimization. Optimization of labeling conditions was accomplished by varying the amount of MORF−MAG_3, stannous ion, temperature, and time using a MORF solution with 0.13 unprotected MAG_3 per molecule, determined as described above. Thus, 5 μL (∼300 μCi) of ^{99m}Tc generator eluant was added to a mixture of 35 μL of 0.25 M, pH 5.2, NH_4OAc buffer containing various amounts of MORF−MAG_3, 10 μL of 50 μg/μL tartrate solution in a pH 9.2 buffer (0.5 M $NaHCO_3$, 0.25 M NH_4OAc, and 0.175 M NH_3 buffer), and 5 μL (4 μg/μL) of $SnCl_2$·$2H_2O$ solution in 10 mM HCl containing 1 μg/μL sodium ascorbate followed by heating in boiling water for 20 min. Thereafter, by holding the MORF−MAG_3 concentration constant, the influence of the tin, temperature, and time was evaluated. Finally, the influence of radioactivity levels was established by adding varying volumes of the pertechnetate generator eluant to the labeling solution. All samples were measured by HPLC, and in all cases, the recovery of radioactivity off the column was greater than 90% unless otherwise stated.

RESULTS

Removal of Labeled Tartrate. Figure 1A presents a HPLC radiochromatogram of labeled MORF−MAG_3 prepared from MORF−MAG_3 purified on P4 only once and incubated at room temperature for 1 h before analysis. The peak at 20.8 min is due to labeled MORF, that at 26 min is due to labeled tartrate, and that at 40.6 min is due to labeled MAG_3. Identification was made by comparison to radiochromatograms of labeled tartrate and commercial labeled MAG_3. The high molecular weight shoulder on the labeled MORF peak may be due to the 2:1 complex duplex ^{99m}TcO(MORF−MAG_3)$_2$ (*22*, *23*).

Despite a reasonable separation by HPLC, we were unable to remove labeled tartrate from the radiolabeled MORF using P4. However, increasing the room temperature incubation time from 1 to 5 h resulted in a decrease in labeled tartrate as shown in Figure 1A,B and an increase in HPLC recovery from 85 to 92%. Heating in boiling water for 20 min in place of longer room temperature incubations was more successful in decreasing this radiocontaminant as shown in Figure 1C. Because ^{99m}Tc−pertechnetate is retained on the HPLC column and because the recovery was quantitative, the decrease

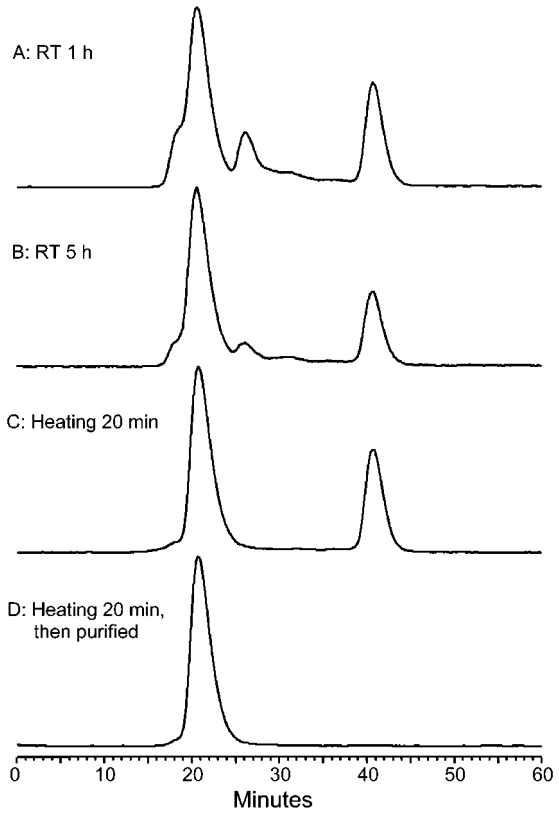


Figure 1. Size exclusion HPLC radiochromatograms of radiolabeled MORF−MAG_3 incubated at room temperature for 1 h (panel A) and 5 h (panel B) and after heating the radiolabeled MORF−MAG_3 for 20 min (panel C) followed by P4 purification (panel D).

in labeled tartrate must have been to the benefit of labeled MORF, presumably by increasing transchelation. Heating also removed the high molecular weight shoulder probably by its transformation from the 2:1 complex to a 1:1 complex (*22*, *23*). Figure 1D was obtained following postlabeling purification on P4 of the labeled MORF after heating for 20 min and shows that labeled MAG_3 can be removed by P4 purification of the heated labeled mixture.

Removal of Labeled MAG_3. Although heating during labeling of MORF−MAG_3 could remove the labeled tartrate radioimpurity, radiolabeled MAG_3 remained. Repurification on P4 before labeling lowered but did not eliminate this radiocontaminant. This indicated that the labeled MAG_3 was not solely due to insufficient purification of the conjugate. However, by adjusting the purified MORF conjugate to pH 7.6 from pH 5.2 and heating for 20 min followed by purification again on P4, the labeled MAG_3 radioimpurity was completely absent after labeling. This suggests that the labeled MAG_3 radioimpurity may be the result of some weak conjugation of MAG_3 to MORF that is susceptible to dissociation during heating in ammonium buffer at pH 7.6.

Therefore, the subsequent investigations were conducted using MORF−MAG_3 conjugates, which after conjugation and purification on P4 were adjusted to pH 7.6 and heated for 20 min before repurification on P4.

Determination of Deprotected MAG_3 Groups per MORF. Figure 2 presents the absorption spectra for cysteine, MORF, 4-DTDP, and the reaction mixture (i.e., 4-TP) in the range of 280−400 nm. Both the free cysteine and the MORF−MAG_3 therefore have no absorption at the 323 nm peak absorbance of the indicator product 4-TP. Only 4-DTDP has measurable absorbance at this

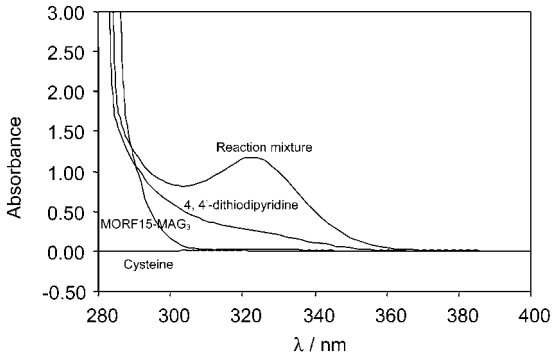

Figure 2. UV spectra of cysteine, MORF−MAG_3, 4,4′-dithiodipyridine, and the reaction mixture (i.e., 4-TP) in the determination of MAG_3 groups per MORF.

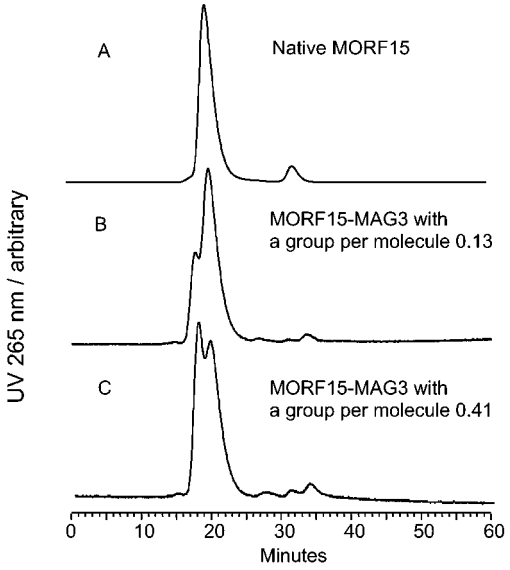

Figure 3. UV HPLC chromatograms of native MORF (panel A) and two MORF−MAG_3 preparations with an average of 0.13 (panel B) and 0.41 (panel C) groups per molecule.

frequency, but its concentration was unchanged during the measurement so that determination against the blank solution of 4-DTDP could eliminate its influence. The standard curve obtained provided a straight line over nine concentrations with a coefficient of regression of 0.998 (data not presented). In this manner, the average number of deprotected MAG_3 groups per MORF was determined for two preparations as 0.13 and 0.41.

These values are in qualitative agreement with the results of HPLC analysis of these samples. As shown in Figure 3, the UV chromatogram of native MORF shows a singlet at the retention time 20.8 min of the oligomer in panel A while those of MORF−MAG_3 conjugated at an average of 0.13 groups per molecule in panel B and MORF−MAG_3 conjugated at an average of 0.41 groups per molecule in panel C show a shoulder at 17.7 min whose intensity increases with increasing conjugation. The closely spaced doublet on HPLC could not be adequately separated for quantitating the relative amount of the new peak.

Optimization. The following studies were performed on the MORF−MAG_3 sample conjugated at an average of 0.13 groups per molecule. The results presented in Table 1 were obtained by HPLC analysis. The weight of MORF−MAG_3 with 300 μCi of ^{99m}Tc is clearly a determinent of labeling efficiency as shown in the table. The poor recovery at low weights of MORF−MAG_3 was

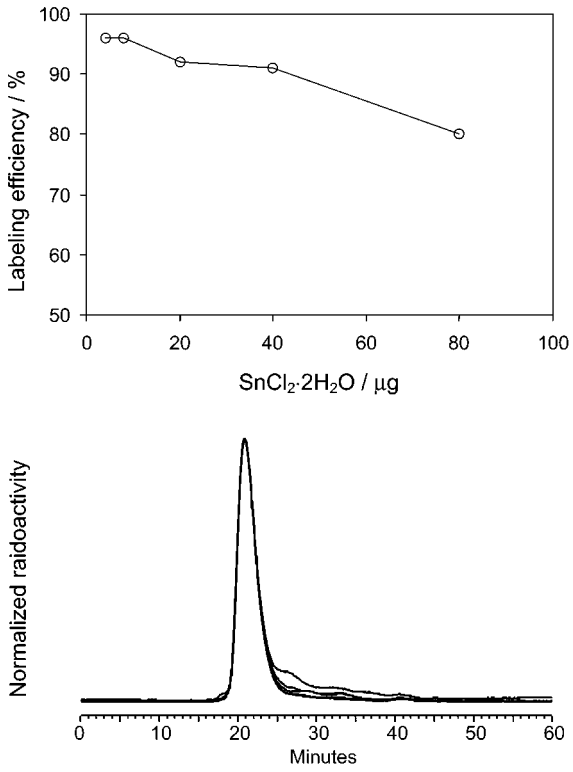

Figure 4. Influence of stannous ion on labeling efficiency.

Table 1. Influence of the Amount of MORF−MAG_3 on the Labeling

MORF−MAG_3 (μg)	0.02	0.04	0.08	0.20	0.78	3.90
recovery (%)	67	90	99	105	100	103
area of labeled MORF (%)	67	75	90	94	96	97
labeling efficiency (%)	45	68	89	94	96	97

assumed to be due to the presence of pertechnetate from oxidation of labeled tartrate, which is retained on the column. After the addition of 300 μCi of ^{99m}Tc to the labeling solution at pH 7.6 containing 0.2 μL of MORF−MAG_3 (i.e., 0.08 μg, 0.28 μM MORF, 0.036 μM MAG_3 as MORF−MAG_3) or more and a fixed amount of tin (20 μg of $SnCl_2{\cdot}2H_2O$), the labeling efficiency was greater than 90%.

Figure 4 presents the influence of stannous ion on labeling efficiency and shows that labeling efficiency drops with increasing tin. For 0.5 μL of MORF−MAG_3 (i.e., 0.20 μg of MORF, 0.026 μg of pure MORF−MAG_3), labeling efficiency drops below 90% when the amount of $SnCl_2{\cdot}2H_2O$ exceeds 40 μg, possibly by increasing the concentration of technetium in oxidation states lower than +5 that cannot be directly transchelated to MORF−MAG_3.

Heating is necessary for efficient labeling as shown in Figure 5. Panel A presents radiochromatograms obtained over time for the labeled MORF−MAG_3 prepared without heating (0.5 μL of 0.20 μg of MORF−MAG_3 and 20 μg of $SnCl_2{\cdot}2H_2O$). As shown, the radiolabeled tartrate peak at 26 min is still prominent even after 10 h postlabeling. In addition, recovery in this sample fell below 80% at 10 h presumably because of oxidation of labeled tartrate to pertechnetate. However, as shown in panel B, by introducing a 20 min heating step, the radiochemical purity is greater than 93% even after 8 h postlabeling.

Thus, at pH 7.6 with tartrate as the transchelator, if the amount of MORF−MAG_3 is greater than 0.08 μg and the amount of $SnCl_2{\cdot}2H_2O$ is between 4 and 20 μg, the

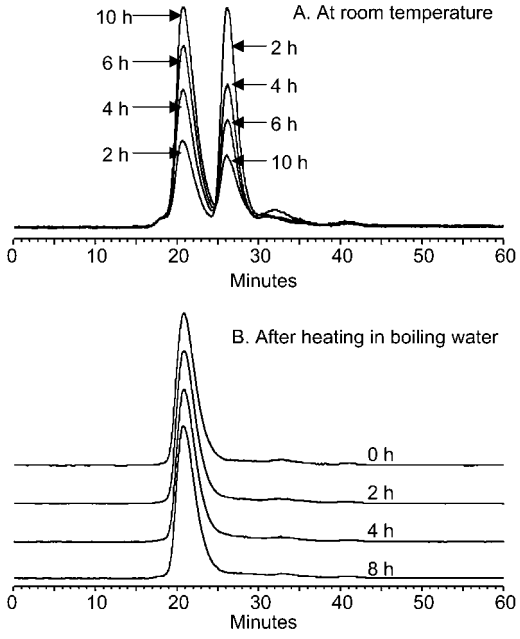

Figure 5. Size exclusion HPLC radiochromatograms of labeled MORF−MAG_3 vs time without heating during labeling (panel A) and with heating for 20 min (panel B).

labeling efficiency of MORF will be greater than 90% after the introduction of 5 μL (300 μCi) of pertechnetate followed by heating for 20 min. With 12 μg of $SnCl_2{\cdot}2H_2O$ and 0.39 μg of MORF−MAG_3, the labeling efficiencies were, respectively, 96, 91, 38, and 17% for 5, 20, 50, and 100 μL of ^{99m}Tc−pertechnetate (145 μCi/μL). The specific activity of at least 7400 μCi/μg (i.e., 38 Ci/μmol) can be achieved without postlabeling purification.

DISCUSSION

The object of this study was to optimize the labeling efficiency with ^{99m}Tc of a model oligomer conjugated with MAG_3. Our goal was to achieve 90% or greater radiochemical purity and thus avoid the need for postlabeling purification. Because in this investigation tartrate was selected as the transchelator, the possible radiochemical impurities are radiolabeled tartrate, radiolabeled MAG_3, and pertechnetate. In fact, using our original MORF−MAG_3 labeling method, both radiolabeled MAG_3 and tartrate were evident as shown in Figure 1A. Furthermore, because any labeled tartrate present will be susceptible to oxidation, it may be continually oxidized during HPLC analysis to explain the poor recoveries of about 85% that we have occasionally observed. If sufficient time is allowed, radiolabeled tartrate can continue its transchelation, in this case to MORF−MAG_3, as shown in Figure 1B. However, the process can be greatly accelerated by heating as shown in Figure 1C.

The removal of labeled MAG_3 is more difficult. All attempts to purify free MAG_3 from MORF−MAG_3 by P4 were unsuccessful in that radiolabeling of the repurified oligomer consistently provided a product contaminated with labeled MAG_3. This radiocontaminant could be removed, however, if the purified conjugated oligomer was placed in the pH 7.6 buffer and heated for 20 min or more before a second P4 purification and the subsequent labeling. We believe that the NHS−MAG_3 used in the conjugation of the amine derivitized MORF is capable of conjugating to the sulfhydryl on the deprotected MAG_3 group. The resulting thio ester bond is relatively unstable

against hydrolysis and aminolysis and may dissociate in neutral pH solution containing a large amount of ammonium (*16*, *17*). Originally (*1*−*3*), the labeled MORF−MAG_3 was placed in neutral pH only during labeling with the results that this dissociation introduced the observed radiolabeled MAG_3 impurity.

On the basis of these observations, the following procedure for purification of the conjugated biomolecule and subsequent labeling was adopted. After conjugation of MORF with NHS−MAG_3 (molar ratio 1:20) in pH 8.0 HEPES buffer and purification over P4 with pH 5.2 NH_4-OAc eluant, the oligomer fractions were combined, adjusted to pH 7.6, and heated for 20 min. The conjugated oligomer was then purified over P4 again for storage at refrigerator temperatures. Labeling is achieved simply by adding fresh stannous ion to a solution of MORF−MAG_3 and tartrate in pH 7.6 buffer followed by ^{99m}Tc−pertechnetate. After the solution is heated for 20 min in boiling water, the labeling efficiency is always over 90% as determined by HPLC and paper chromatography. With the proper selection of MORF−MAG_3, stannous ion, and pertechnetate concentration, specific activities more than 7000 μCi/μg have been achieved.

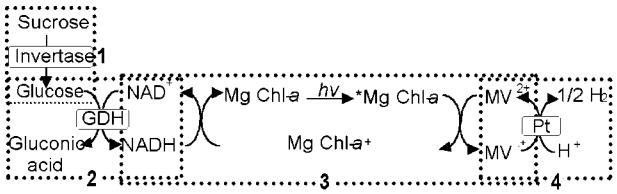
Visible Light Induced Biohydrogen Production from Sucrose Using the Photosensitization of Mg Chlorophyll-*a*

Yoshinobu Saiki and Yutaka Amao*

Department of Applied Chemistry, Oita University, Dannoharu 700, Oita 870-1192, Japan.
Received January 17, 2002; Revised Manuscript Received April 21, 2002



A photoinduced hydrogen production system, coupling sucrose degradation with invertase and glucose dehydrogenase (GDH) and hydrogen production with colloidal platinum as a catalyst using the visible light-induced photosensitization of Mg chlorophyll-*a* (Mg Chl-*a*), has been developed. Continuous hydrogen gas production was observed when the reaction mixture containing sucrose, invertase, GDH, nicotinamide adenine dinucleotide (NAD^+), Mg Chl-*a*, methyl viologen (MV^{2+}, an electron relay reagent), and colloidal platinum was irradiated by visible light.

INTRODUCTION

Hydrogen production from biomass resources is important in the environmental and alternative energy source fields (*1*−*5*). Some renewable biomass resources are starch, cellulose, sucrose, and lactose. These polysaccharides are hydrolyzed to form monosaccharides such as glucose. Thus, the conversion of glucose to hydrogen will be a useful new enzymatic pathway. Some studies on the hydrogen production from glucose using the enzymatic pathway have been reported (*6*−*10*). The hydrogen production from glucose with the combination of glucose dehydrogenase (GDH)[1] and hydrogenase has been reported (*11*, *12*). However, the enzymatic photoinduced hydrogen production from other monosaccharides, oligosaccharides, or polysaccharides has received little attention. Glucose was enzymatically obtained from sucrose by using invertase. Thus, hydrogen production from the oligosaccharide sucrose will be attained using the combination of invertase, GDH, and hydrogenase or some other hydrogen-producing catalyst.

On the other hand, some photoinduced hydrogen production systems consist of electron donor, photosensitizer, electron carrier, and catalyst (*13*−*19*). Regarding hydrogen-producing catalysts, colloidal platinum (*17*−*19*) and hydrogenase from *Desulfovibrio vulgaris* (Miyazaki) (*13*−*16*) are widely used in hydrogen production systems. Especially, colloidal platinum is stable against long-term irradiation. In photoinduced hydrogen production systems with visible light, water-soluble zinc porphyrins have an absorption band in the visible light region (380−600 nm), and these porphyrins have been widely used as effective photosensitizers (*13*, *14*). Especially, zinc tetraphenylporphyrin tetrasulfonate (ZnTPPS) is useful as a photosensitizer (*13*, *14*). However, the molar absorption coefficient of zinc porphyrins in the visible light region (500−600 nm) was lower than that in the near ultravisible light region (380−400 nm). On the other hand, Mg chlorophyll-*a* (Mg Chl-*a*), which acts as an effective photosensitizer in photosynthesis (*20*), has an absorption maximum at 670 nm. Thus, Mg Chl-*a* is attractive as a visible region photosensitizer. Photoinduced hydrogen production systems with chemically modified chlorophyll and hydrogenase (*21*, *22*), and chlorophyll derivatives (*23*−*25*), were reported previously. In photoinduced hydrogen production with a system consisting of an electron donor, photosensitizer, electron relay, and catalyst, the photoexcited photosensitizer reacts with an electron relay to form a reduced electron relay, hydrogen evolves by proton reduction with the catalyst, and then the oxidized photosensitizer is reduced by an electron-donating reagent such as reduced nicotinamide adenine dinucreotide (NADH). Thus, the electron donor, NADH, was a sacrificial reagent, and the oxidized electron donor, NAD^+, was consumed in the reaction system. If NADH is regenerated, the photoinduced hydrogen production system is accomplished without NAD^+ consumption. As GDH uses NAD^+ as a cofactor, photoinduced hydrogen production with GDH, electron donor, photosensitizer, electron relay reagent, and catalyst will be attained.

Scheme 1. Visible Light-Induced Hydrogen Production System Coupling the Sucrose Degradation with Invertase and GDH and Hydrogen Production with Colloidal Platinum Using the Photosensitization of Mg Chl-*a* in the Presence of MV^{2+}

In this work we describe the visible light-induced hydrogen production system that couples sucrose degradation with invertase and GDH, and hydrogen production with colloidal platinum using the photosensitization of Mg Chl-*a* in the presence of methyl viologen (MV^{2+}) as an electron relay reagent as shown in Scheme 1.

EXPERIMENTAL PROCEDURES

General. Mg Chl-*a* from *Spirulina*, invertase from yeast, and GDH from *Bacillus* sp. were purchased from Wako Pure Chemical Industries Ltd. (Osaka, Japan). NAD^+ and NADH were purchased from Oriental Yeast Co. Ltd. MV^{2+} dichloride and cetyltrimethylammonium bromide (CTAB) were purchased from Tokyo Kasei Co. Lid (Tokyo, Japan). Hydrogen hexachloroplatinate hexahydrate and sodium citrate dihydrate were obtained from Kanto Chemical Co. Ltd (Tokyo, Japan). The other chemicals were analytical grade or the highest grade available. One unit of GDH activity was defined as the amount of enzyme that reduced 1.0 μmol NAD^+ to NADH by glucose per minute. One unit of invertase activity was defined as the amount of enzyme that produced 1.0 μmol glucose by sucrose per minute. Mg Chl-*a* was solubilized with 10 mmol dm^{-3} of CTAB, since Mg Chl-*a* is insoluble in aqueous solution.

Preparation of Colloidal Platinum. Colloidal platinum was prepared by reduction of hexachloroplatinate solution with sodium citrate. The reduction procedure was similar to the previous reported method (*17*). A solution of 400 mL of water containing 30 mg of hydrogen hexachloroplatinate hexahydrate was brought to boiling temperature using a mantle heater with a magnetic stirrer for 1.5 h, and then a solution of 30 mL of water containing 600 mg of sodium citrate dihydrate was added and refluxed with a magnetic stirrer at 100 °C for 4 h. The particle size of colloidal platinum prepared was estimated to be 1.5 nm. In general, the colloidal platinum activity decreased with increase the particle size (more than 2.0 nm) (*17*). The prepared colloidal platinum has the ability to release 0.7 μmol of hydrogen in the reaction system of 10 μL of colloidal platinum, 1.2×10^{-5} mmol of methyl viologen, and 7.7×10^{-5} mmol of sodium dithionite in 4.0 mL of 50 mmol dm^{-3} Tris-HCl buffer (pH 7.4) at 30 °C for 10 min. One unit of colloidal platinum activity was defined as a release of 1.0 μmol of hydrogen per minute.

NADH Formation with Sucrose, Invertase, and GDH. The reaction was started by addition of NAD^+ (0.80 μmol) solution to the sample solution containing sucrose (16 μmol), invertase (4.0 units), and GDH (5.0 units) in 3.0 mL of 10 mmol dm^{-3} potassium phosphate buffer (pH 7.0). The reduction of NAD^+ to NADH by GDH was monitored using UV−vis spectrophotometer at 340 nm, with the molar extinction coefficient of 6.3×10^3 mol dm^3 cm^{-1}.

Photoreduction of MV^{2+}. Photoreduction of MV^{2+} was tested in the reaction mixture containing NAD^+, sucrose, Mg Chl-*a*, MV^{2+}, invertase, and GDH. The reaction system consisted of NAD^+ (15 μmol), sucrose (0.30 mmol), Mg Chl-*a* (3.0 nmol), MV^{2+} (1.2 μmol), invertase (4.0 units), and GDH (5.0 units) in 3.0 mL of 10 mmol dm^{-3} potassium phosphate buffer (pH 7.0). The sample solution was deaerated by repeated freeze−pump−thaw cycles and irradiated with a 200 W tungsten lamp at a distance of 3.0 cm, with a light intensity of 200 J m^{-2} s^{-1}, at 30 °C. The light of the wavelength less than 390 nm was removed by a Toshiba L-39 cutoff filter (Tokyo, Japan). The reduction of MV^{2+} was monitored using UV−vis spectrophotometer at 605 nm, with the molar extinction coefficient of 1.3×10^4 mol dm^3 cm^{-1} (*26*).

Visible Light-Induced Hydrogen Production. The photoinduced hydrogen production from sucrose was carried out as follows. The sample solution containing NAD^+ (15 μmol), sucrose (0.30 mmol), Mg Chl-*a* (3.0 nmol), MV^{2+} (1.2 μmol), colloidal platinum (0.5 unit), invertase (4.0 units), and GDH (5.0 units) in 3.0 mol of 10 mmol dm^{-3} potassium phosphate buffer (pH 7.0) was deaerated by freeze pump thaw cycle for six times and substituted by argon gas. The amount of hydrogen evolved was measured by Schimadzu GC-14B gas chromatography (detector: TCD, column temperature: 40 °C, column: active charcoal with the particle size 60∼80 mesh, carrier gas: nitrogen gas, carrier gas flow rate: 24 mL min^{-1}).

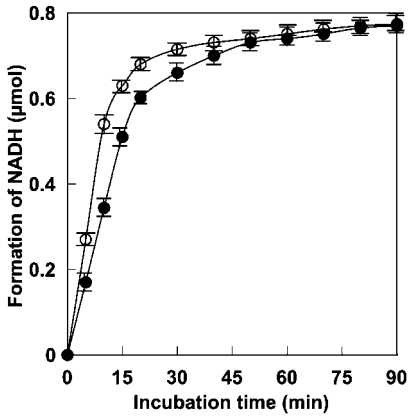

Figure 1. Time dependence of NADH formation with sucrose, invertase, NAD^+, and GDH. (Closed circles): Sucrose (16 μmol), invertase (4.0 units), NAD^+ (0.80 μmol), and GDH (5.0 units) in 3.0 mL of 10 mmol dm^{-3} potassium phosphate buffer (pH = 7.0). (Open circles): Glucose (16 μmol), NAD^+ (0.80 μmol), and GDH (5.0 units) in 3.0 mL of 10 mmol dm^{-3} potassium phosphate buffer (pH = 7.0). Each data point represents the mean of at least three separate experiments; bars are the standard error of the mean (SEM).

RESULTS AND DISCUSSION

NADH Formation with Sucrose, Invertase, and GDH System. When the sample solution containing sucrose, invertase, GDH, and NAD^+ was incubated, the of the NADH was formed in a time-dependent manner (Figure 1, closed circle). The initial rate of NADH formation, which was determined by the amount of NADH with incubation for 15 min, was estimated to be $(3.4 \pm 0.1) \times 10^{-8}$ mol min^{-1}. After 80 min incubation, 0.77 ± 0.03 μmol of NADH was formed. The yield of the conversion of NAD^+ to NADH in this system was ca. 100%. When the sample solution containing glucose (16 μmol), GDH, and NAD^+ (without sucrose and invertase) was incubated, NADH was formed in a time-dependent manner (Figure 1, open circle), and the initial rate of NADH formation was estimated to be $(4.2 \pm 0.1) \times 10^{-8}$ mol min^{-1}. After 80 min incubation, 0.77 ± 0.02 μmol of NADH was formed, and the yield of the conversion of NAD^+ to NADH in this system also was ca. 100%. These results show that glucose formation from sucrose (process 1 in Scheme 1) with invertase proceeded rapidly.

Stability of Mg Chl-*a* against Irradiation. The photostability of Mg Chl-*a* in the reaction mixture was investigated. The photostability was tested by irradiation with visible light using 200 W tungsten lamp (light intensity of 200 J m^{-2} s^{-1}). Figure 2 shows the absorbance change at 670 nm attributed to the absorption maximum of Mg Chl-*a* with irradiation time. CTAB solublized Mg Chl-*a* solution was rapidly bleached by irradiation (curve A). On the other hand, the absorbance decrease of Mg Chl-a in the presence of NAD^+ and NADH was slower as shown in curve B and C, indicating that the degradation of Mg Chl-*a* was suppressed by the addition of NAD^+

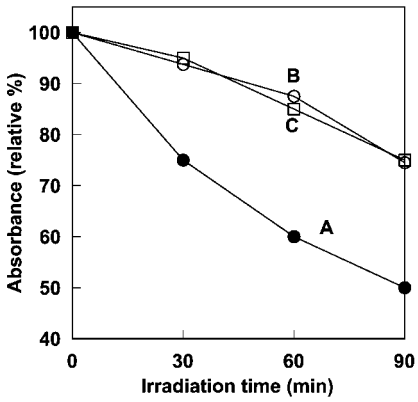

Figure 2. Photostability of Mg Chl-*a* solution under anaerobic condition. Curve A, CTAB solubilized Mg Chl-*a* aqueous solution. Curve B and C, CTAB solubilized Mg Chl-*a* aqueous solution in the presence of NAD^+ and NADH, respectively. Samples were irradiated with visible light using 200 W tungsten lamp at a distance of 3.0 cm (light intensity of 200 J m^{-2} s^{-1}).

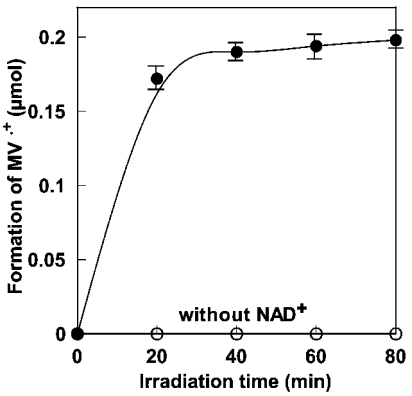

Figure 3. The time dependence of the $MV^{\bullet+}$ concentration under steady-state irradiation with visible light using 200 W tungsten lamp at a distance of 3.0 cm (light intensity of 200 J m^{-2} s^{-1}). The sample solution consisting of invertase (4.0 units), GDH (5.0 units), NAD^+ (15 μmol), sucrose (0.30 mmol), Mg Chl-*a* (3.0 nmol), and MV^{2+} (1.2 μmol) in 3.0 mol of 10 mmol dm^{-3} potassium phosphate buffer (pH = 7.0). (Open circles): In the absence of NAD^+. Each data point represents the mean of at least three separate experiments; bars are the SEM.

and NADH. The photoinduced degradation of Mg Chl-*a* proceeded by the reaction between photoexcited Mg Chl-*a* molecules. In the presence of the electron donor or acceptor reagent such as NAD^+ or NADH, on the other hand, the electron transfer from the photoexcited Mg Chl-*a* to the electron acceptor reagent or from the electron donor reagent to the photoexcited Mg Chl-*a* proceeded. These electron transfer processes rapidly proceeded compared with that of the reaction between photoexcited Mg Chl-*a* molecules. Thus, the reaction between photoexcited Mg Chl-*a* molecules was suppressed by the electron donor or acceptor reagent such as NAD^+ or NADH.

Photoreduction of MV^{2+}. Figure 3 shows the time dependence of the $MV^{\bullet+}$ concentration in the system containing NAD^+, sucrose, Mg Chl-*a*, MV^{2+}, invertase, and GDH with visible light irradiation. The absorbance at 605 nm, absorption band of $MV^{\bullet+}$, increased with irradiation time. After 80 min irradiation, (0.2 ± 0.01) μmol reduced MV^{2+} was produced and the yield of MV^{2+} to $MV^{\bullet+}$ was estimated to be ca. 33%. The photoreduction rate was independent of the concentrations of NAD^+, sucrose, invertase, and GDH. On the other hand, the reduction rate depends on the concentrations of Mg Chl-*a* and MV^{2+}. Thus, the rate-limiting step in the MV^{2+} reduction (processes 1, 2, and 3 in Scheme 1) is the photoinduced electron-transfer process from the photoexcited Mg Chl-*a* (*Mg Chl-*a*) to MV^{2+} (process 3 in Scheme 1). On the other hand, MV^{2+} was not reduced without NAD^+ in the above system (open circle). There is no direct electron transfer between sucrose or glucose formed with invertase and MV^{2+}, and between Mg Chl-*a* and MV^{2+}. Thus, the visible light-induced MV^{2+} reduction proceeded by coupling the sucrose degradation with invertase and GDH (processes 1 and 2 in Scheme 1) and MV^{2+} reduction using the photosensitization of Mg Chl-*a* (process 3 in Scheme 1).

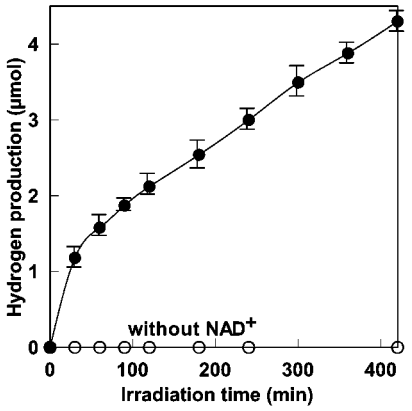

Figure 4. Time dependence of hydrogen production under steady-state irradiation with visible light using 200 W tungsten lamp at a distance of 3.0 cm (light intensity of 200 J m^{-2} s^{-1}). (Closed circles): The sample solution consisting of invertase (4.0 units), GDH (5.0 units) NAD^+ (15 μmol), sucrose (0.30 mmol), Mg Chl-*a* (3.0 nmol), MV^{2+} (1.2 μmol), and colloidal platinum (0.5 unit) in 3.0 mol of 10 mmol dm^{-3} potassium phosphate buffer (pH = 7.0). (Open circles): In the absence of NAD^+. Each data point represents the mean of at least three separate experiments; bars are the SEM.

Visible Light-Induced Hydrogen Production. As the MV^{2+} photoreduction system containing NAD^+, sucrose, Mg Chl-*a*, MV^{2+}, invertase, and GDH was achieved, the photoinduced hydrogen production system was investigated. Figure 4 shows the time dependence of the photoinduced hydrogen production in the system containing NAD^+, sucrose, Mg Chl-*a*, MV^{2+}, colloidal platinum, invertase, and GDH by the visible light. By irradiation, hydrogen evolved continuously for more than 420 min. The amount of hydrogen production was estimated to be 4.3 ± 0.1 μmol after 420 min irradiation. It indicated that 8.6 μmol of proton, that was 2867 times the amount of Mg Chl-*a* (3.0 nmol) in the sample solution, was reduced to hydrogen molecules. Therefore, the Mg Chl-*a* appeared to serve as the system for transferring electrons from NADH, which was formed from sucrose conversion to gluconic acid, to a more reductive molecule. It should be noted that hydrogen was not evolved in the absence of NAD^+ in the above system (open circles, Figure 4). There is no direct electron transfer between sucrose or glucose formed with invertase and colloidal platinum, and among Mg Chl-*a*, MV^{2+}, and colloidal platinum. These results suggest that the visible light-induced hydrogen production proceeded by coupling the sucrose degradation with invertase and GDH (processes 1 and 2 in Scheme 1) and the hydrogen production with colloidal platinum using the photosensitization of Mg Chl-*a* (processes 3 and 4 in Scheme 1).

In conclusion, a hydrogen production system coupling sucrose degradation with invertase and GDH, and hydrogen production with colloidal platinum using the

visible light-induced photosensitization of Mg Chl-*a*, was developed, and continuous generation of hydrogen gas was achieved. Renewable biomass resources are effectively used to produce an environmentally clean energy source, hydrogen gas. In the present system, fructose consumption occurred; glucose and fructose were formed from sucrose by invertase. The system involving fructose dehydrogenation is being studied in detail.

Comparison of Yttrium and Indium Complexes of DOTA-BA and DOTA-MBA: Models for ^{90}Y- and ^{111}In-Labeled DOTA−Biomolecule Conjugates

Shuang Liu,* John Pietryka, Charles E. Ellars, and D. Scott Edwards

Bristol-Myers Squibb Medical Imaging,† 331 Treble Cove Road, North Billerica, Massachusetts 01862.
Received October 8, 2001; Revised Manuscript Received January 18, 2002

Yttrium and indium complexes of 1,4,7,10-tetraaza-4,7,10-tris(carboxymethyl)-1-cyclododecylacetyl-benzylamine (DOTA-BA) and 1,4,7,10-tetraaza-4,7,10-tris(carboxymethyl)-1-cyclododecylacetyl-*R*-(+)-α-methylbenzylamine (DOTA-MBA) were prepared in order to study solution structures of ^{90}Y- and ^{111}In-labeled DOTA−biomolecule conjugates. ^{90}Y and ^{111}In complexes M(L) (M = ^{90}Y and ^{111}In; L = DOTA-BA and DOTA-MBA) were prepared from the reaction of MCl_3 with DOTA-BA and DOTA-MBA, respectively, in ammonium acetate buffer. A reverse phase HPLC method revealed that both ^{90}Y and ^{111}In complexes show only one radiometric peak in their radio-HPLC chromatograms. It was also found that ^{111}In(DOTA-BA) and ^{111}In(DOTA-MBA) are more hydrophilic than their corresponding ^{90}Y analogues, suggesting different coordination spheres in ^{111}In and ^{90}Y complexes of the same DOTA conjugate. Complexes M(L) (M = Y and In; L = DOTA-BA and DOTA-MBA) were prepared and characterized by HPLC, LC-MS, and NMR (^{1}H and ^{13}C) methods. The HPLC concordance experiments for ^{90}Y(DOTA-MBA)/Y(DOTA-MBA) and ^{111}In(DOTA-MBA)/In(DOTA-MBA) show that the same complex is prepared at both tracer and macroscopic levels. The NMR data (^{1}H and ^{13}C) clearly demonstrates that Y(DOTA-BA) and Y(DOTA-MBA) exist in solution as one predominant isomer. VT NMR data (^{1}H and ^{13}C) show that In(DOTA-BA) and In(DOTA-MBA) are fluxional at room temperature while Y(DOTA-BA) and Y(DOTA-MBA) become fluxional only at elevated temperatures. The fluxionality of these complexes is due to rapid rotation of acetate/acetamide chelating arms and inversion of ethylenic groups of the macrocyclic ring.

INTRODUCTION

There is great current interest in the development of target-specific therapeutic radiopharmaceuticals for the treatment of cancers. Several reviews have appeared recently covering a broad range of topics related to radiolabeled small biomolecules (BM) as target-specific therapeutic radiopharmaceuticals (*1*−*7*). Many acyclic and macrocyclic bifunctional chelators (BFCs) have been used for the radiolabeling of biomolecules, including antibodies and small peptides (*2, 6, 8*−*17*). While the ^{90}Y-labeled BFC−BM conjugate is used for tumor therapy, the ^{111}In-labeled BFC−BM conjugate is often used as an imageable surrogate for dosimetry determination and therapy monitoring (*17, 18*−*27*). The advantage of using ^{111}In as the imaging surrogate for ^{90}Y is that $^{111}InCl_3$ is commercially available and its half-life is almost identical to that of ^{90}Y. However, recent studies show biodistribution differences between ^{90}Y- and ^{111}In-labeled antibodies and small peptides (*17, 28*−*30*). The difference in biological properties raises some questions about structural differences between ^{90}Y and ^{111}In DOTA chelates.

To study solution structures of ^{90}Y- and ^{111}In-labeled DOTA−BM conjugates, we prepared yttrium and indium complexes (Figure 1) of two model compounds: 1,4,7,10-tetraaza-4,7,10-tris(carboxymethyl)-1-cyclododecylacetyl-benzylamine (DOTA-BA) and 1,4,7,10-tetraaza-4,7,10-tris(carboxymethyl)-1-cyclododecylacetyl-*R*-(+)-α-methylbenzylamine (DOTA-MBA). In this report, we present the synthesis and characterization of yttrium and indium complexes of DOTA-BA and DOTA-MBA at both tracer and macroscopic levels. The focus of this study is to compare yttrium complexes of DOTA-BA and DOTA-MBS with their corresponding indium analogues with respect to their structures in solution, hydrophilicity, and solution dynamics.

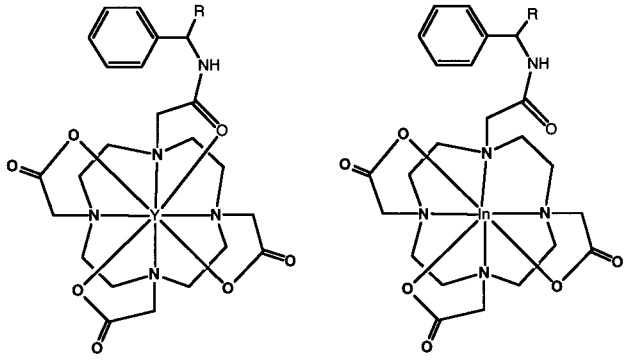

Figure 1. Structures for yttrium and indium complexes of DOTA-BA and DOTA-MBA.

Sigma Chemical Co. and were used as received. The tributyl ester of 1,4,7,10-tetraazacyclododecane-1,4,7-triacetic acid (DO3A(OBu-t)$_3$) was purchased from Macrocyclics Inc, Richardson, TX. $^{111}InCl_3$ and $^{90}YCl_3$ (in 0.05 N HCl) was purchased from NEN Life Sciences, N. Billerica, MA.

NMR (^1H, ^{13}C, $^1H-^1H$ COSY, and $^1H-^{13}C$ HMQC) data were obtained using a Bruker DRX 600 MHz FT NMR spectrometer, and chemical shifts as δ are reported in ppm relative to TMS. The LC-MS data were collected using a HP1100 LC/MSD system with an API-electrospray interface. The LC-MS method used a Zorbax C_{18} column (4.6 mm × 150 mm, 3.5 μm particle size) and a mobile phase gradient starting from 100% solvent A (95% water and 5% TFA) to 100% solvent B (95% acetonitrile and 5% water) at 16 min at a flow rate of 1 mL/min.

The HPLC method 1 used a HP-1050 HPLC system with a Rainin Dynamax UV/visible detector (model UV-C, λ = 230 nm) and a Zorbax C_{18} column (4.6 mm × 250 mm, 80 Å pore size). The flow rate was 1 mL/min with the mobile phase starting 10% of solvent A (0.1% TFA in water) and 90% solvent B (0.1% TFA in acetonitrile) to 20% solvent A and 80% of solvent B at 20 min, followed by an isocratic wash using 40% of solvent A and 60% solvent B from 21 to 26 min.

The HPLC method 2 used a HP-1050 HPLC system with a Rainin Dynamax UV/visible detector (model UV-C, λ = 230 nm) and a Zorbax C_{18} column (4.6 mm × 250 mm, 80 Å pore size). The flow rate was 1 mL/min with the mobile phase starting 30% of solvent A (0.1% TFA in water) and 70% solvent B (0.1% TFA in acetonitrile) to 40% solvent A and 60% of solvent B at 20 min, followed by an isocratic wash using 40% of solvent A and 60% solvent B from 21 to 26 min.

The HPLC method 3 used a HP-1100 HPLC system with a UV/visible detector (λ = 230 nm), an IN−US radiodetector, and a Zorbax C_{18} column (4.6 mm × 250 mm, 80 Å pore size). The flow rate was 1 mL/min with a gradient mobile phase starting 95% of solvent A (0.025 M ammonium acetate buffer, pH 6.8) and 5% solvent B (acetonitrile) to 8% solvent A and 92% of solvent B at 18 min, followed by an isocratic wash using 40% of solvent A and 60% solvent B from 19 to 25 min.

Synthesis of *N*-(Chloroacetyl)benzylamine. To solution of benzylamine (2.15 g, 0.02 mol) in chloroform (100 mL) was added chloroacetyl chloride (2.26 g, 0.02 mol) in an ice-bath, followed by slow addition of 3 mL of triethylamine. The resulting mixture was stirred at room-temperature overnight and was then heated to reflux for 2 h. Solvent and excess triethylamine were removed under reduced pressure. The residue was dissolved in 100 mL of chloroform and washed with water (2 × 50 mL). The organic layer was separated and dried over anhydrous sodium sulfate. Removal of chloroform gave a pale yellow waxy solid. Upon addition of a mixture of water and methanol (10:1 = water:methanol), it became a white solid. The solid was collected and dried under vacuum overnight. The yield was 2.5 g (69%). LC-MS: m/z = 184.0 for $[C_9H_{10}ClNO]^+$. ^1H NMR (600 MHz, in $CDCl_3$, chemical shift in ppm relative to TMS): 4.08 (s, 2H, CH_2); 4.54 (d, 2H, CH_2Ph); 6.97 (bs, 1H, NH); and 7.20−7.85 (m, 5H, benzene).

Synthesis of 1,4,7,10-Tetraaza-4,7,10-tris(carboxymethyl)-1-cyclododecyl-acetylbenzylamine (DOTA-BA). To a solution of DO3A(OBu-t)$_3$ (193 mg, 0.375 mmol) in anhydrous acetonitrile (45 mL) was added *N*-(chloroacetyl)benzylamine (195 mg, 1.06 mmol). The resulting mixture was stirred at room temperature for 3 days, and was then heated to reflux for 6 h. Solvents were removed under reduced pressure to give a gummy liquid, which was dissolved in chloroform (50 mL), washed with water, and dried over anhydrous sodium sulfate. Removal of chloroform gave a gummy liquid. To the residue were added dichloromethane (15 mL) and anhydrous TFA (15 mL). The mixture was stirred at room-temperature overnight. Solvents were removed under reduced pressure. The residue was dissolved in concentrated HCl (1.0 mL). Upon addition of acetone (100 mL), a white solid was formed. The solid was collected by filtration, washed with acetone and dried in air. The crude product (150 mg) was dissolved in 1.0 mL of water and was then purified by HPLC (method 1). The fraction at 10−12.5 min was collected. The collected fractions were combined and then lyophilized. The yield was 53 mg. The retention time was 12.5 min with the purity > 98% by HPLC (method 1). LC-MS: m/z = 494.2 for $[C_{23}H_{36}N_5O_7]^+$. ^1H NMR (600 MHz, in D_2O at 40 °C): 3.36−3.46 (m, 16H, CH_2, cyclen); 3.85−3.91 (m, 8H, CH_2Ph); and 7.46−7.56 (m, 5H, benzene).

Synthesis of *N*-(Bromoacetyl)-*R*-(+)-α-Methylbenzylamine. To solution of *R*-(+)-α-methylbenzylamine (2.4 g, 0.02 mol) in chloroform (150 mL) cooled in an ice-bath was added bromoacetyl bromide (4.1 g, 0.02 mol), followed by slow addition of 5 mL of triethylamine. The resulting mixture was stirred at room-temperature overnight. Solvent and excess triethylamine were removed under reduced pressure to give a white solid, which was washed with water and then a mixture of water and methanol (10:1 = water:methanol). The solid was collected and dried under vacuum overnight. The yield was 3.5 g (~73%). LC-MS: m/z = 242.0 for $[C_{10}H_{12}BrNO]^+$. ^1H NMR (600 MHz, in $CDCl_3$): 1.60 (d, 3H, CH_3); 3.85 (q, 2H, CH_2); 5.20 (q, 1H, CH); and 7.20−7.50 (m, 5H, benzene).

Synthesis of 1,4,7,10-Tetraaza-4,7,10-tris(carboxymethyl)-1-cyclododecyl-acetyl-(*R*-(+)-α-methylbenzylamine) (DOTA-MBA). To a solution of DO3A(OBu-t)$_3$ (193 mg, 0.375 mmol) in anhydrous acetonitrile (45 mL) was added *N*-(bromoacetyl)-*R*-(+)-α-methylbenzylamine (103 mg, 0.430 mmol). The resulting mixture was heated to reflux overnight. Solvents were removed under reduced pressure to give a gummy liquid, which was taken up with chloroform (50 mL), washed with water, and dried over anhydrous sodium sulfate. Removal of chloroform gave a liquid residue, to which were added dichloromethane (15 mL) and anhydrous TFA (15 mL). The mixture was stirred at room-temperature overnight. Solvents were removed under reduced pressure. The residue was dissolved in concentrated HCl (1.0 mL). Upon addition of acetone (100 mL), a white solid was formed. The solid was collected by filtration, washed with acetone, and dried in air. The crude product (185 mg) was dissolved in 1.0 mL of water and was then purified by HPLC (method 1). The fraction at 18−20 min was collected. The collected fractions were combined and then lyophilized. The yield was 65 mg. The retention time was 18.5 min with the purity > 98% by HPLC (method 1). LC-MS: m/z = 508.3 for $[C_{24}H_{38}N_5O_7]^+$. ^1H NMR (600 MHz, in D_2O at 40 °C): 1.38 (d, 3H, CH_3); 2.80−3.9 (m, 24H, CH_2, cyclen and acetate); 4.88 (q, H, CHPh); and 7.20−7.35 (m, 5H, benzene).

Synthesis of Y(DOTA-BA). To a 5 mL vial were added DOTA-BA (40 mg, 0.081 mmol) and $Y(NO_3)_3{\cdot}6H_2O$ (60 mg, 0.157 mmol), followed by addition of 0.5 mL of 0.5 N ammonium citrate buffer (pH = 4.8) and 0.5 mL of 0.5 N ammonium acetate buffer (pH = 7.5). The mixture was heated at 100 °C for 20 min. After being cooled to room temperature, the product was separated by HPLC

(method 2). The fraction at 10.0−13.0 min was collected. Lyophilization of collected fractions gave a white powder. The yield was 27 mg. The purity was > 98% by HPLC (method 3). LC-MS: m/z = 580.3 for $[M + H]^+$ ($[C_{23}H_{36}N_5O_7Y]^+$) and 290.7 for $[M + 2H]^{2+}$.

Synthesis of Y(DOTA-MBA). To a 5 mL vial were added DOTA-MBA (56 mg, 0.110 mmol) and $Y(NO_3)_3 \cdot 6H_2O$ (70 mg, 0.183 mmol). To the mixture were added 0.5 mL of 0.5 N ammonium citrate buffer (pH = 4.8) and 0.5 mL of 0.5 N ammonium acetate buffer (pH = 7.5). The resulting solution was heated at 100 °C for 20 min. After being cooled to room temperature, the product was purified by HPLC (method 2). The fraction at 12−15 min was collected, and the collected fractions were evaporated to dryness. The residue was dissolved in water (20 mL), and the resulting solution was lyophilized to give a white powder. The yield was ∼35 mg. The purity was > 98% by HPLC (method 3). LC-MS: m/z = 594.2 for $[M + H]^+$ ($[C_{24}H_{35}N_5O_7Y]^+$) and 297.7 for $[M + 2H]^{2+}$.

Synthesis of In(DOTA-BA). To a 5 mL vial were added DOTA-BA (50 mg, 0.081 mmol) and anhydrous $InCl_3$ (30 mg, 0.157 mmol), followed by addition of 0.5 mL of 0.5 N ammonium citrate buffer (pH = 4.8) and 0.5 mL of 0.5 N ammonium acetate buffer (pH = 7.5). The mixture was heated at 100 °C for 30 min. After being cooled to room temperature, the product was separated by HPLC (Method 2). The fraction at 10.0−13.0 min was collected. Lyophilization of collected fractions gave a white powder. The yield was 37 mg. The purity > 98% by HPLC (method 3). LC-MS: m/z = 606.3 for $[M + H]^+$ ($[C_{23}H_{36}N_5O_7In]^+$) and 303.7 for $[M + 2H]^{2+}$.

Synthesis of In(DOTA-MBA). To a 5 mL vial were added DOTA-MBA (56 mg, 0.110 mmol) and anhydrous $InCl_3$ (50 mg, 0.183 mmol). To the mixture were added 0.5 mL of 0.5 N ammonium citrate buffer (pH = 4.8) and 0.5 mL of 0.5 N ammonium acetate buffer (pH = 7.5). The resulting solution was heated at 100 °C for 30 min. After being cooled to room temperature, the product was purified by HPLC (method 2). The fraction at 12−15 min was collected, and the collected fractions were evaporated to dryness. The residue was dissolved in water (20 mL), and the resulting solution was lyophilized to give a white powder. The yield was ∼40 mg. The purity was > 99% by HPLC (method 3). LC-MS: m/z = 620.2 for $[M + H]^+$ ($[C_{24}H_{35}N_5O_7In]^+$) and 310.6 for $[M + 2H]^{2+}$.

Synthesis of ^{90}Y(DOTA-MBA) and ^{90}Y(DOTA-BA). To a clean sealed 5 mL glass vial were added 1.0 mL of the DOTA-BA or DOTA-MBA solution (50 μg/mL in 0.5 M ammonium acetate buffer, pH 6.0) and 20−30 μL of $^{90}YCl_3$ solution (20 mCi) in 0.05 N HCl. The resulting mixture was heated at 100 °C for 30 min. After being cooled to room temperature, a sample of the resulting solution was first diluted 20−40-fold with 2.0 mM DTPA solution (pH = 5.0) and was then analyzed by radio-HPLC (method 3; injection volume = 5 μL). For the ITLC, a sample of the resulting solution was used without further dilution. The ITLC method used Gelman silica gel paper strips and a 1:1 (v:v) mixture of acetone and saline as eluant. Using this method, both ^{90}Y(DOTA-MBA) and ^{90}Y(DOTA-BA) migrate to the solvent front while ^{90}Y-colloid and unchelated free ^{90}Y remain at the origin.

Synthesis of ^{111}In(DOTA-BA) and ^{111}In(DOTA-MBA). To a sealed 5 mL vial were added 1.0 mL of the DOTA-BA or DOTA-MBA solution (200 μg/mL in 0.5 M ammonium acetate buffer, pH 6.0) and 100 μL of $^{111}InCl_3$ solution (5 mCi) in 0.05 N HCl. The resulting mixture was heated at 100 °C for 30 min. After being cooled to room temperature, a sample of the resulting solution was analyzed by radio-HPLC (method 3) and ITLC. The ITLC method for ^{111}In(DOTA-BA) and ^{111}In(DOTA-MBA) is the same as that for ^{90}Y(DOTA-BA) and ^{90}Y(DOTA-MBA). Using this method, ^{111}In(DOTA-BA) and ^{111}In(DOTA-MBA) migrate to the solvent front while ^{111}In-colloid and unchelated free ^{111}In remain at the origin.

RESULTS

Synthesis of DOTA-BA and DOTA-MBA. The tributyl ester of DOTA-BA was prepared from the reaction of *N*-(2-chloroacetyl)benzylamine with DO3A(OBu-t)$_3$ in the presence of excess triethylamine. Hydrolysis of the tributyl ester of DOTA-BA in a mixture of anhydrous TFA and dichloromethane produced DOTA-BA as its TFA salt. The crude product was purified by HPLC. Lyophilization of collected fractions afforded DOTA-BA in high purity (>98%). DOTA-MBA was prepared in a similar fashion from the reaction of *N*-(bromoacetyl)-α-methylbenzylamine with DO3A(OBu-t)$_3$. Purification by HPLC and lyophilization of collected fractions gave DOTA-MBA with purity > 98%. Both DOTA-BA and DOTA-MBA have been characterized by HPLC, NMR, and LC-MS methods. It is important to note that DOTA-BA and DOTA-MBA have to be extremely pure for the preparation of their ^{90}Y and ^{111}In complexes. Otherwise, it would be very difficult to distinguish radioimpurities from possible isomers of ^{90}Y and ^{111}In complexes of DOTA-BA and DOTA-MBA in their radio-HPLC chromatograms.

Synthesis of M(L) (M = Y and In; L = DOTA-BA and DOTA-MBA). We prepared yttrium and indium complexes M(L) (M = Y and In; L = DOTA-BA and DOTA-MBA) by reacting DOTA-BA and DOTA-MBA, respectively, with excess yttrium(III) nitrate hexahydrate or indium(III) chloride in ammonium acetate buffer (0.5 M, pH ∼ 6) in the presence of ammonium citrate, which was used to prevent metal hydroxide formation. The product was separated from the reaction mixture by HPLC purification. Many attempts were made to grow crystals for these complexes using various solvents or solvent combinations, but were unsuccessful. In(DOTA-MBA) tends to give long needlelike microcrystals, which are unsuitable for X-ray diffraction studies. All four complexes, M(L) (M = Y and In; L = DOTA-BA and DOTA-MBA), have been characterized by HPLC, LC-MS, and NMR (^{1}H and ^{13}C).

Synthesis of M(L) (M = ^{90}Y and ^{111}In; L = DOTA-BA and DOTA-MBA). ^{90}Y and ^{111}In complexes of DOTA-MBA and DOTA-BA were prepared by reacting DOTA-BA and DOTA-MBA, respectively, with MCl_3 (M = ^{90}Y and ^{111}In) and in ammonium acetate buffer (pH = 6.0) at 100 °C for 30 min. We typically used 50 μg of DOTA-BA or DOTA-MBA for 20 mCi of $^{90}YCl_3$ and 100 μg of DOTA-BA or DOTA-MBA for 5.0 mCi of $^{111}InCl_3$. The use of excess DOTA-conjugate is to compensate for the presence of other trace metal contaminants in the reaction mixture and to achieve the high-yield radiolabeling. ^{90}Y(DOTA-BA), ^{90}Y(DOTA-MBA), and ^{111}In(DOTA-MBA) can be prepared in high yield with the radiochemical purity of > 98% while ^{111}In(DOTA-BA) was prepared with the RCP of ∼90% under similar radiolabeling conditions. [^{90}Y]- and [^{111}In]-colloid were usually minimal (<1%).

HPLC Characterization. We used a reverse phase HPLC method to analyze complexes M(L) (M = ^{90}Y/Y and ^{111}In/In; L = DOTA-BA and DOTA-MBA). The HPLC data for M(L) (M = ^{90}Y/Y and ^{111}In/In; L = DOTA-BA and DOTA-MBA) are listed in Table 1. Figures 2 shows typical radio-HPLC chromatograms for ^{90}Y(DOTA-MBA) and ^{111}In(DOTA-MBA). In general, all four complexes,

Table 1. HPLC Data for M(L) (M = ^{90}Y/Y and ^{111}In/Y; L = DOTA-BA and DOTA-MBA)

compound	RCP (%)[a]	retention time (min)
^{90}Y(DOTA-BA)	>99.0	11.2
Y(DOTA-BA)	>99.0	10.5
^{90}Y(DOTA-MBA)	>99.5	17.3
Y(DOTA-MBA)	>99.0	16.5
^{111}In(DOTA-BA)	~90	7.5
In(DOTA-BA)	>99.0	6.7
^{111}In(DOTA-MBA)	>98.5	11.4
In(DOTA-MBA)	>98.5	10.5

[a] Radiochemical purity in percentage.

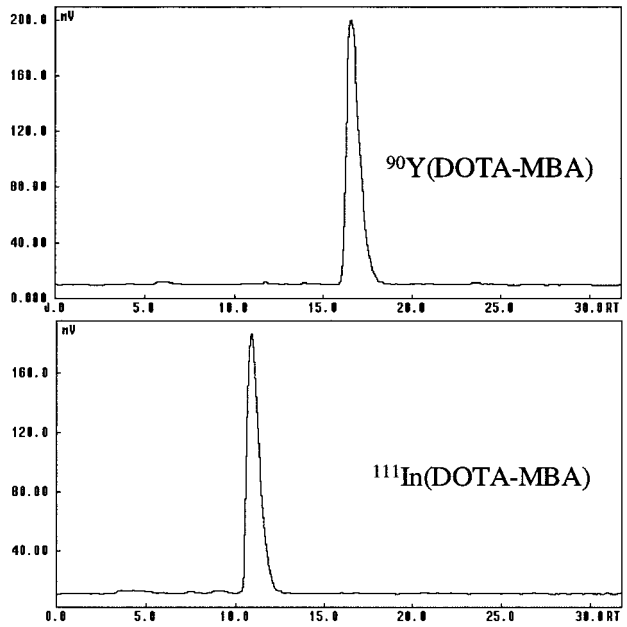

Figure 2. Typical radio-HPLC chromatograms (method 3) of ^{90}Y(DOTA-MBA) (top) and ^{90}Y(DOTA-BA) (bottom).

M(L) (M = ^{90}Y and ^{111}In; L = DOTA-BA and DOTA-MBA), show only one radiometric peak in the region of interest. There are some small peaks due to radioimpurities in their HPLC chromatograms (Figure 2). Since each radioimpurity is less than 0.5%, no further characterization was performed. HPLC retention times of M(DOTA-BA) (M = ^{90}Y and ^{111}In) are ~5 min shorter that those of M(DOTA-MBA) (M = ^{90}Y and ^{111}In) under the same chromatographic conditions, indicating their difference in lipophilicity due to the presence of the extra methyl group. HPLC retention times of M(L) (M = ^{111}In and In; L = DOTA-BA and DOTA-MBA) are 4−6 min shorter than those of M(L) (M = ^{90}Y and Y; L = DOTA-BA and DOTA-MBA). The HPLC concordance experiments for M(DOTA-MBA) (M = ^{90}Y/Y and ^{111}In/In; L = DOTA-BA and DOTA-MBA) showed that the same complex was prepared at both tracer and macroscopic levels.

^{1}H NMR Spectra of M(L) (M = Y and In; L = DOTA-BA and DOTA-MBA). Figure 3 shows the room temperature ^{1}H NMR spectra of Y(DOTA-MBA) (top) and Y(DOTA-BA) (bottom) in a mixture of 90% D_2O and 10% H_2O. In the ^{1}H NMR spectrum of Y(DOTA-MBA), there is only one doublet at ~1.5 ppm from hydrogens of the methyl group and one multiplet at 4.9 ppm from methylene hydrogen of the benzyl group. In the spectrum of Y(DOTA-BA), the two methylene hydrogens of the benzyl group are inequivalent and give an AB quartet at ~4.5 ppm. The hydrogens of the methylene group of each acetate or acetamide chelating arm are also inequivalent and give four sets of AB quartets in the region of 2.0−4.0 ppm. Each hydrogen atom in Y(DOTA-MBA) has its distinctive resonance signal. For both Y(DOTA-MBA) and Y(DOTA-BA), there are several superimposed AA′BB′ resonance signals from ethylenic hydrogens of the macrocyclic ring. NMR signals at ~9.40 ppm are from the amide-hydrogen. The coupling between the amide-hydrogen and methylene hydrogen(s) of the benzyl group is obvious. A close look at the ^{1}H NMR spectrum of Y(DOTA-MBA) shows that there are some small satellite peaks on the right or left side of each resonance, but these peaks are so small that they are barely detectable.

At temperatures <25 °C, all the aliphatic resonance signals from Y(DOTA-BA) become sharper; but no extra signals are seen. For Y(DOTA-MBA), however, the small satellite peaks are more visible, integration of which remains difficult due to partial overlapping. At elevated temperatures (30−85 °C), a general broadening of resonance signals was observed. For Y(DOTA-BA), all the resonance signals in the aliphatic region start to collapse almost simultaneously at temperatures above 35 °C (Figure 4). For Y(DOTA-MBA), however, the AB quartets from methylene hydrogens of the benzyl group and of the acetate or acetamide chelating arm start to collapse at temperatures above 50 °C while resonance signals from hydrogens of the cyclen backbone remain relatively unchanged (Figure 5).

Figures 6 and 7 show variable temperature ^{1}H NMR spectra of In(DOTA-BA) and In(DOTA-MBA), respectively, in a mixture of 90% D_2O and 10% H_2O. At room temperature, all resonance signals from In(DOTA-BA) and In(DOTA-MBA) are broad. As the temperature increases, these resonance signals become sharper until the high-temperature limiting spectrum is reached. At 85 °C, the spectrum of In(DOTA-BA) shows a singlet at 4.47 ppm from the methylene hydrogens of the benzyl group, and two singlets at 3.37 and 3.64 ppm (Figure 6) from methylene hydrogens of the acetamide and those of the acetate chelating arm, respectively. The methylene hydrogens of the remaining two acetate chelating arms, however, are inequivalent and give two doublets at 3.06 and 3.31 ppm, respectively. The ethylenic hydrogens in In(DOTA-BA) show only two pairs of overlapped AA′BB′ NMR patterns (Figure 6). Unlike In(DOTA-BA), In(DOTA-MBA) is not symmetrical due to the presence of the extra methyl group. Each hydrogen in In(DOTA-MBA) has its distinctive signal (Figure 7). For example, there is a doublet at 1.51 ppm due to hydrogens of the methyl group and a quartet at 5.02 ppm from the benzyl group. The methylene hydrogens of the acetamide group and three acetate chelating arms are inequivalent and appear as four distinctive sets of quartets. The coupling between the amide-hydrogen and methylene hydrogen(s) of the benzyl group remains obvious even though the NMR signals at ~9.40 ppm from the amide-hydrogen almost disappear at ~85 °C.

^{13}C NMR Spectra of M(L) (M = Y and In; L = DOTA-BA and DOTA-MBA). Figures 8 and 9 show the room temperature ^{13}C NMR spectra of Y(DOTA-BA) and Y(DOTA-MBA), respectively. For Y(DOTA-BA), ^{13}C NMR signals from benzyl, acetamide, or acetate groups are clearly distinguishable from one another while those from the cyclen backbone are partially superimposed. For Y(DOTA-MBA), however, most aliphatic carbon atoms are distinctive, giving a total of 13 resonance signals from 14 different aliphatic carbons. In all the cases, detailed assignments are difficult for ^{13}C NMR signals from the macrocyclic cyclen backbone. Figures 10 and 11 show VT ^{13}C NMR spectra of In(DOTA-BA) and In(DOTA-MBA), respectively. Most ^{13}C resonance signals from In(DOTA-

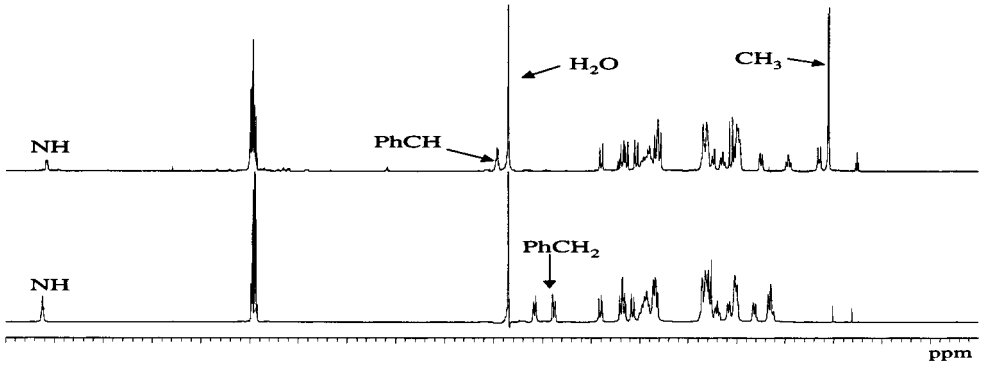

Figure 3. Room temperature ^{1}H NMR (600 MHz) spectra of Y(DOTA-MBA) (top) and Y(DOTA-BA) (bottom) in D_2O/H_2O (90%/10%).

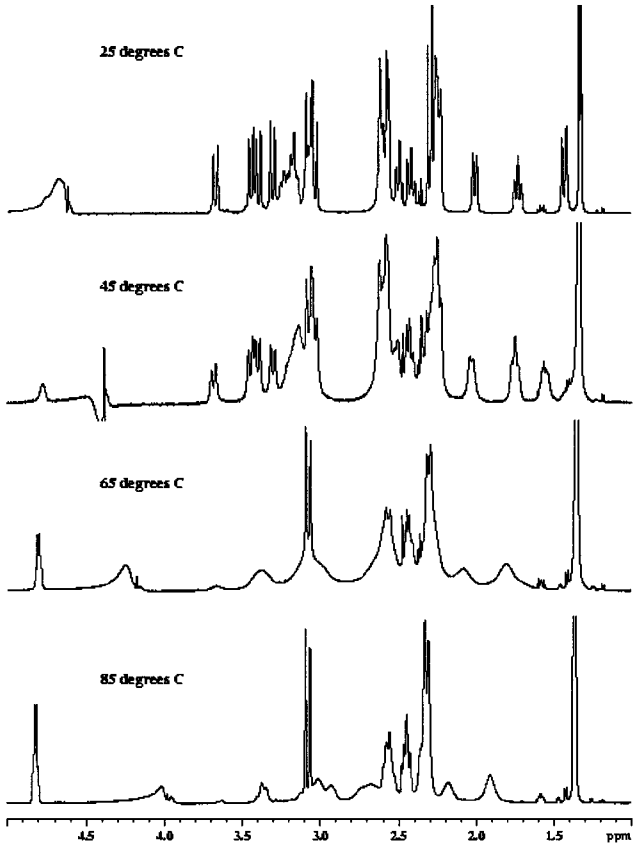

Figure 5. VT ^{1}H NMR (600 MHz) spectrum of Y(DOTA-MBA) in the aliphatic region.

BA) and In(DOTA-MBA) are not seen until the temperature is higher than 65 °C. As the temperature increases, all ^{13}C signals become sharper.

DISCUSSION

We are interested in radiolabeled vitronectin receptor antagonists as potential diagnostic or therapeutic radiopharmaceuticals by targeting tumor angiogenesis (*31*−*35*). Recently, we reported the ^{90}Y-labeling of a DOTA-conjugated vitronectin receptor antagonist. In a separate communication (*36*), we also described the anaerobic ^{90}Y-labeling of a DOTA-conjugated nonpeptide vitronectin receptor antagonist. In both cases, the ^{90}Y-labeled DOTA-conjugates show only one radiometric peak in their radio-HPLC chromatograms (*34, 36*). During these radiolabeling studies, we also noticed that the ^{90}Y-labeled DOTA-conjugates often have different HPLC retention times from those of the corresponding ^{111}In analogues.

Structural Differences between Yttrium and Indium Complexes M(L) (M = Y and In; L = DOTA-BA and DOTA-MBA) in Solution. Yttrium has an ionic radius of 0.87 Å (*37*) and is often treated as a "pseudo-lanthanide" metal due to its similarity to lanthanide metals with respect to the cationic charge, ionic radii, and coordination chemistry. Because of its large size, the coordination number for Y(III) is normally 8 or 9 (*6, 38*). The solution structure of yttrium and lanthanide complexes of DOTA derivatives has been studied by NMR methods (*39*−*50*). Indium is a group 13 element and has an ionic radius of 0.75 Å (*37*). The coordination number of indium is typically 6 or 7 (*51*−*55*). Only a few eight-coordinate indium complexes are known (*56*−*58*).

Recently, Mäcke and co-workers (*17, 58*) described the crystal structures of complexes M(DOTA-D-Phe-NH_2) (M = Y and In) and found that both In and Y in these M(DOTA-D-Phe-NH_2) are eight-coordinated with four

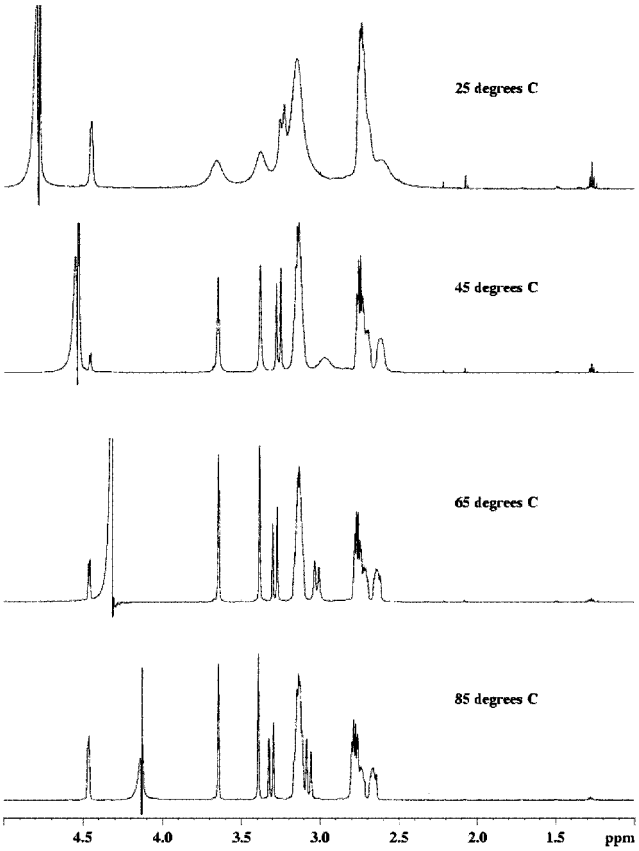

Figure 6. VT ^{1}H NMR (600 MHz) spectrum of In(DOTA-BA) in the aliphatic region.

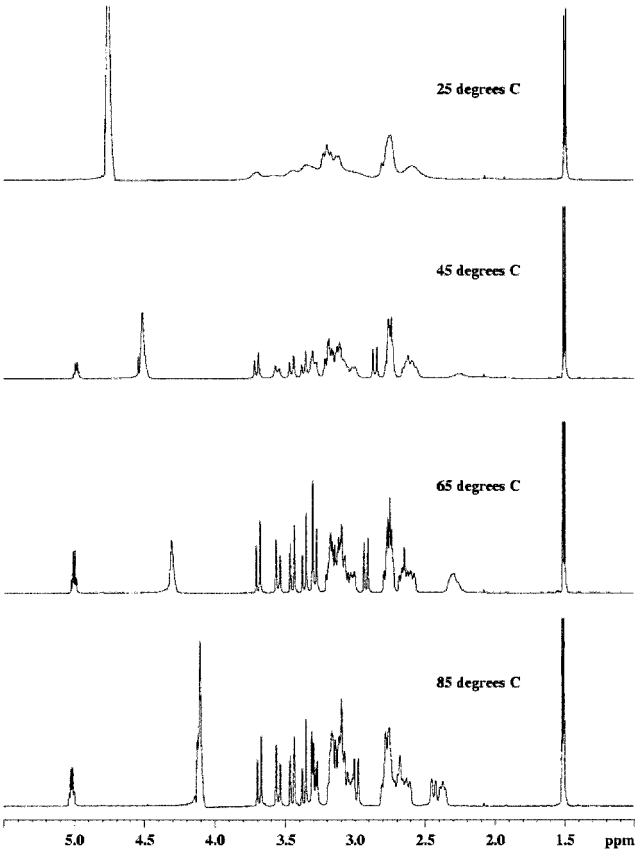

Figure 7. VT ^{1}H NMR (600 MHz) spectrum of In(DOTA-BA) in the aliphatic region.

amine-nitrogen, one carbonyl-oxygen, and three carboxylate-oxygen atoms bonding to the metal center (*17*). The major difference between the two structures arises from a different conformation of the ethylenic bridges and the different orientation of sidearms, leading to two pairs of isomers. The complex Y(DOTA-D-Phe-NH_2) exists in solid state as the m isomer (traditionally designated as the minor isomer) while the complex In(DOTA-D-Phe-NH_2) is observed as the M (major isomer) isomer.

It should be noted that the solution structure of a metal chelate might be different from that in the solid state because of possible dissociation of certain donor atom(s). In some cases, the isomers observed in the solid state may not be seen in solution due to rapid interconversion of different isomers or fluxionality of the ligand framework. On other occasions, only one isomeric form is found in the solid state while more isomers are observed in solution. Thus, it is imperative to study the solution structure of the metal chelate in order to understand the impact of structural differences in metal chelates on biological properties of ^{90}Y- and ^{111}In-labeled DOTA−BM conjugates.

To study the structural differences between ^{90}Y- and ^{111}In-labeled DOTA−BM conjugates in solution, we prepared yttrium and indium complexes of two model compounds: DOTA-BA and DOTA-MBA. We use the same HPLC method to characterize these complexes at both tracer (^{90}Y and ^{111}In) and macroscopic (Y and In) levels. Table 1 list the HPLC retention times of M(L) (M = ^{90}Y/Y and ^{111}In/In; L = DOTA-BA and DOTA-MBA). Since the only difference in In(DOTA-BA) and In(DOTA-MBA) and their yttrium analogues is the metal ion, the difference in HPLC retention times strongly suggests that indium and yttrium do not share the same coordination sphere even though they are coordinated by the same

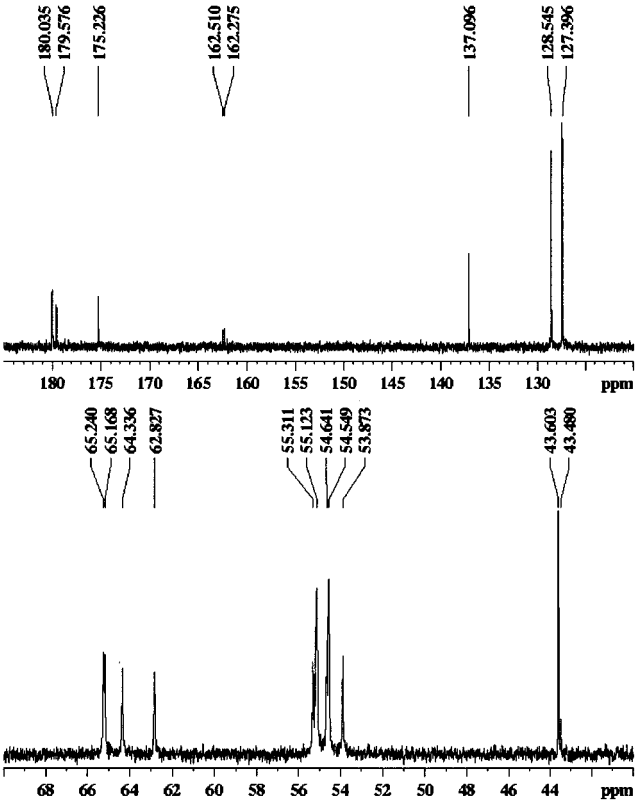

Figure 8. Proton-decoupled ^{13}C NMR spectra of Y(DOTA-BA) in D_2O/H_2O (90%/10%). The signals at 162 ppm are from residual TFA in the sample.

DOTA-conjugate. Since indium is smaller than yttrium, it is possible for the carbonyl-oxygen in complexes M(L)

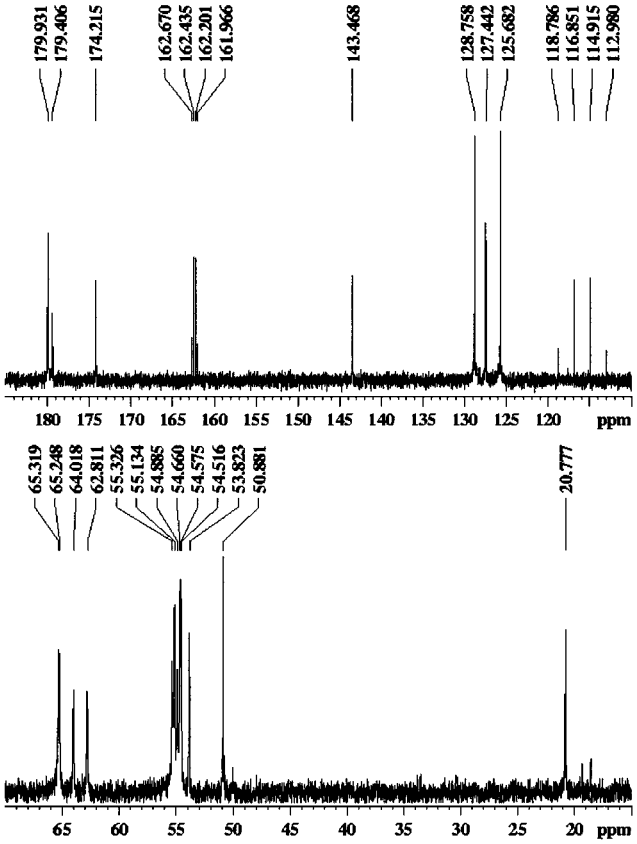

Figure 9. Proton-decoupled ^{13}C NMR spectra of Y(DOTA-MBA) in D_2O/H_2O (90%/10%). The signals at 162 ppm are from residual TFA in the sample.

(M = ^{111}In/In; L = DOTA-BA and DOTA-MBA) to become dissociated (Figure 12) due to the poor fit between the chelator cavity and metal ion size, even though both In and Y in M(DOTA-D-Phe-NH_2) are eight-coordinated in

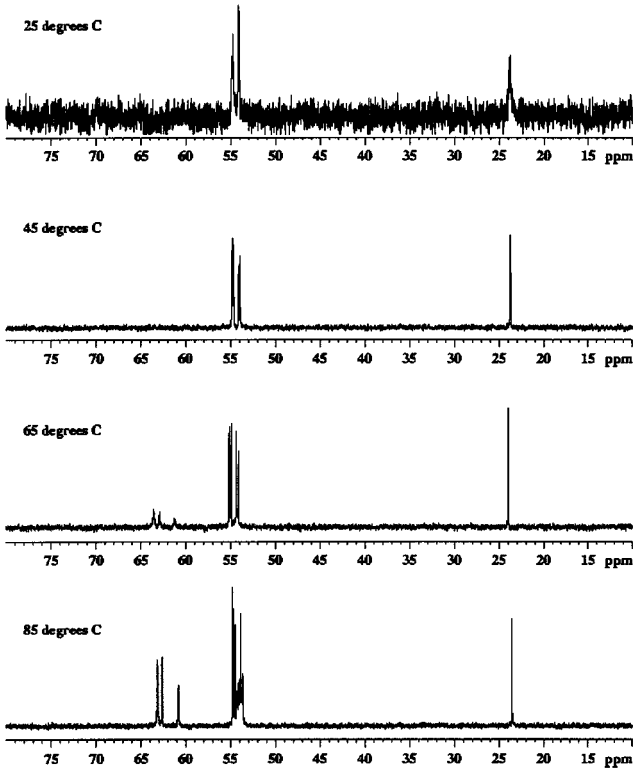

Figure 11. VT ^{13}C NMR spectra of In(DOTA-MBA) in D_2O/H_2O (90%/10%). The signals at 116 and 162 ppm are from residual TFA in the sample.

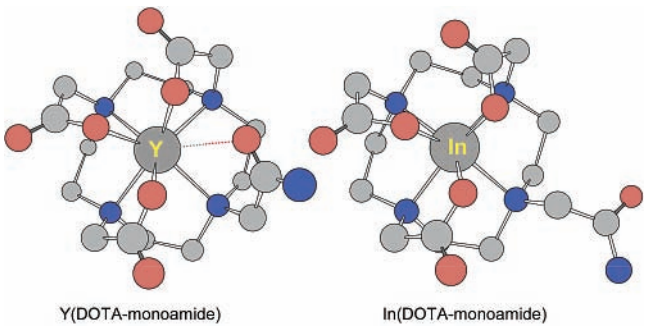

Figure 12. Possible solution structures of Y(DOTA-monoamide) and In(DOTA-monoamide).

the solid state (*58*). The presence of the uncoordinated carbonyl-oxygen in In(DOTA-BA) and In(DOTA-MBA) makes them more hydrophilic with shorter retention times than those of Y(DOTA-BA) and Y(DOTA-MBA). If indium and yttrium were to share the same coordination sphere, In(DOTA-BA) and In(DOTA-MBA) should have had the same retention times as those of Y(DOTA-BA) and Y(DOTA-MBA) under identical chromatographic conditions.

The structural difference between indium and yttrium complexes of DOTA-BA and DOTA-MBA is also reflected by their different solution dynamics. For example, the coordinated DOTA-BA in Y(DOTA-BA) (Figure 12) is rigid at room temperature. The rotation of the acetamide and acetate chelating arms and inversion of ethylenic groups are relatively slow at the NMR time-scale. The ^1H NMR data of Y(DOTA-BA) show four sets of AB quartets in the region of 2.0−4.0 ppm (Figure 3), corresponding to four pairs of hydrogens from the benzyl group, the acetamide group, and three acetate chelating arms. Y(DOTA-BA) becomes fluxional only at elevated temperatures (>45 °C). For In(DOTA-BA) (Figure 12),

however, the presence of the free carbonyl-oxygen makes DOTA-BA much more flexible. Rotation of the acetamide group and acetate chelating arms and inversion of ethylenic groups are relatively fast at the NMR time-scale. Therefore, ^{1}H NMR spectra of both In(DOTA-BA) and In(DOTA-MBA) show broad resonance signals at the room temperature (Figures 6 and 7). This also explains why most ^{13}C resonance signals of In(DOTA-BA) and In(DOTA-MBA) are not seen until the temperature is higher than 65 °C (Figures 10 and 11). If indium and yttrium were to share the same coordination geometry, In(DOTA-BA) and In(DOTA-MBA) should have had a much tighter coordination sphere and should have been more rigid than their yttrium analogues, Y(DOTA-BA) and Y(DOTA-MBA), due to the smaller size of indium.

The rotation of the acetamide and acetate chelating arms and inversion of ethylenic groups make In(DOTA-BA) to become symmetrical. As a result, methylene hydrogens from the acetamide group and those from the opposite acetate chelating arm become equivalent and show two singlets at 3.37 and 3.64 ppm, respectively, in the ^{1}H NMR spectrum of In(DOTA-BA) (Figure 6). However, methylene hydrogens of the remaining two acetate chelating arms remain inequivalent and give two doublets at 3.06 and 3.31 ppm. For In(DOTA-MBA), rotation of the acetamide group and acetate chelating arms and inversion of ethylenic groups do not change the symmetry of the molecule due to the presence of the extra methyl group. All aliphatic hydrogens are distinctive from each other, resulting in four sets of AB quartets for hydrogens from the acetamide group and those from three acetate chelating arms (Figure 6).

Isomerism in M(L) (M = ^{90}Y and Y; L = DOTA-BA and DOTA-MBA). Radio-HPLC is a powerful tool for separation of different diastereomers of radiolabeled compounds. In this study, we used a reverse phase radio-HPLC method to analyze ^{90}Y(DOTA-BA) and ^{90}Y(DOTA-MBA). The advantage of radio-HPLC is its capability to determine the radiochemical purity of the ^{90}Y-labeled DOTA-conjugate and to separate different ^{90}Y species in the reaction mixture. A slow gradient mobile phase was used to maximize the separation of different ^{90}Y-containing species. We also tried several other reverse phase radio-HPLC methods using various reverse phase columns or different solvent combinations. In all the cases, ^{90}Y(DOTA-BA) and ^{90}Y(DOTA-MBA) show only one radiometric peak in their radio-HPLC chromatogram.

DOTA-BA is a DOTA-monoamide with no chiral center. In principle four isomers (**A**−**D** in Figure 13) are possible for Y(DOTA-BA). The interconversion within each enantiomeric pair (**A** ⇔ **B** or **C** ⇔ **D**) occurs through inversion of the ethylenic groups and concerted or stepwise rotation of the acetate arms (*6*, *17*, *38*). On the other hand, the exchange between diastereomers (**A** ⇔ **C** or **B** ⇔ **D**) takes place either by rotation of the acetate/acetamide chelating arms while maintaining the same conformation of the macrocyclic ring or by inversion of the ethylenic groups without changing the orientation of the acetate/acetamide chelating arms. If the interconversion between diastereomers (M and m isomers) is sufficiently slow, they should be readily separable by HPLC, particularly using a slow gradient mobile phase.

There are two possible explanations for the presence of only one radiometric peak in the HPLC chromatogram of ^{90}Y(DOTA-BA). The lipophilicity of two diastereomers is so similar that they could not be separated by the HPLC method used in this study. Alternatively, the interconversion between two diastereomers is so fast at the HPLC time-scale that the observed single peak is an averaged signal from two diastereomers. To eliminate the first possibility, we prepared DOTA-MBA and introduced a chiral center into the DOTA−monoamide conjugate. Unlike those in Y(DOTA-BA), isomers **A** and **B** or **C** and **D** in Y(DOTA-MBA) are no longer enantiomers but diastereomers, if the exchange between isomers is sufficiently slow at room temperature. We hoped that the conjugation of a chiral amine would make these diastereomers more separable by HPLC. To our surprise, ^{90}Y-(DOTA-MBA) shows only one radiometric peak in its radio-HPLC chromatogram, suggesting that it exists in solution as one predominant isomer.

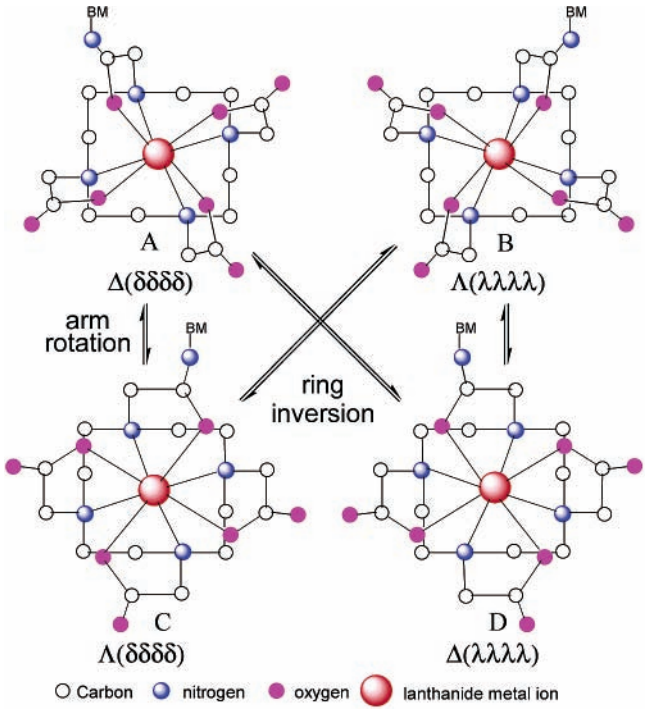

Figure 13. Four possible isomeric forms of the complex Y(DOTA-monoamide).

It should be noted that one radiometric peak in the radio-HPLC-chromatogram does not necessarily mean only one isomer for any radiolabeled small biomolecule. It needs further confirmation using other analytical methods. Therefore, we prepared Y(DOTA-BA) and Y(DOTA-MBA) and used NMR methods (^{1}H and ^{13}C) to study the solution structure of Y(DOTA-BA) and Y(DOTA-MBA). At the NMR time-scale, the rate of exchange between different isomers is relatively slow so that the presence of different isomers in solution is readily detectable.

In the ^{1}H NMR spectrum of Y(DOTA-BA), the two methylene hydrogens of benzyl group are inequivalent and give an AB quartet at ∼4.5 ppm (Figure 3). The methylene hydrogens from each acetate/acetamide chelating arm are also inequivalent, and four sets of AB quartets are seen in the region of 2.0−5.0 ppm. These observations suggest that Y(DOTA-BA) is chiral with DOTA-BA being prochiral and that the coordinated DOTA-BA is rigid and nonfluxional at room temperature. Thus, there should be no *rapid* interconversion within each enantiomeric pair (**A** ⇔ **B** or **C** ⇔ **D**) or between diastereomers (**A** ⇔ **C**, **B** ⇔ **D**, **A** ⇔ **D**, or **B** ⇔ **C**). For Y(DOTA-BA), isomers **A** and **B** or **C** and **D** are enantiomers and indistinguishable by NMR. For Y(DOTA-MBA), however, all isomers (**A**, **B**, **C**, and **D**) are diastereomers and should be distinguishable by NMR. The presence of only one doublet from the methyl group

strongly suggests that Y(DOTA-MBA) exist in solution as one predominant isomer. This conclusion supported by observations of only one ^{1}H NMR signal from the amide group and 13 aliphatic ^{13}C signals from 14 different aliphatic carbon atoms in Y(DOTA-MBA) (Figure 9) and is also consistent with the presence of only m-isomer of Y(DOTA-D-Phe-NH_2) in the solid state (*17*). If all four diastereomers were to exist in solution, a total of 56 aliphatic ^{13}C signals would have been detected in the ^{13}C NMR spectrum of Y(DOTA-MBA).

It should be noted that there are some small satellite peaks on both sides of each main peak of the ^{1}H NMR spectrum of Y(DOTA-MBA). This is particularly true in the ^{1}H NMR spectra of Y(DOTA-MBA) at lower temperatures (<25 °C). These observations suggest that there might be some other isomers in solution for Y(DOTA-MBA). However, the percentage of these minor isomers at the room temperature is so small that they are barely detectable by ^{1}H and ^{13}C NMR methods. For Y(DOTA-BA), there were no extra resonance signals observed except aliphatic resonance signals become sharper at temperatures <25 °C. On the basis of literature data and results from this study, we believe that Y(DOTA-BA) and Y(DOTA-MBA) exist in solution as only one predominant isomer. The exact structure of the predominant isomer observed in Y(DOTA-BA) and Y(DOTA-MBA) is not quite clear. However, it is reasonable to believe that the predominant isomer observed in Y(DOTA-BA) and Y(DOTA-MBA) is the m-isomer as observed in Y(DOTA-D-Phe-NH_2) (*17*).

Similar results have been reported for Na[La(DOTA)-La(HDOTA)]·$10H_2O$ (*59*) and the lanthanum complex of DOTA-pNB, in which the *p*-nitrophenyl group is attached to one of the four acetate chelating arms (*45*). The m-isomer is also present in the X-ray crystal structures of La(DOTPAM) (DOTPAM = 1,4,7,10-tetrakis(2-carbamoylethyl)-1,4,7,10-tetraazacyclododecane) (*60*), Eu(THP) (THP = 1,4,7,10-tetrakis(2-hydroxypropyl)-1,4,7,-10-tetraazacyclododecane) (*61*), Gd(DO3MA) (DO3MA = (1*R*,4*R*,7*R*)-α,α′α″-trimethyl-1,4,7,10-tetraazacyclododecane-1,4,7-triacetic acid) (*40*), and Yb(DOTPBz_4) (DOTPBz_4 = 1,4,7,10-tetraazacyclododecanetetrakis(methylbenzylphosphinic acid)) (*62*) even though the geometries were described as distorted antiprismatic. Apparently, the incorporation of substituents either on the acetate chelating arm or on the macrocyclic ring makes the regular antiprismatic structure (M isomer) much less common than originally expected.

As the temperature increases, all the resonance signals in the aliphatic region start to collapse at temperatures above 35 °C for Y(DOTA-BA) (Figure 4), suggesting that the coordinated DOTA-BA becomes fluxional at higher temperatures. The coalescence of resonance signals in the aliphatic region is most likely caused by the rotation of the acetate/acetamide chelating arms and the inversion of the ethylenic groups. When the sample was cooled to room temperature, the ^{1}H NMR spectrum returned to its original form. Thus, the coalescence process is reversible. The fact that no free DOTA-BA signals were detected over the temperature range (25−85 °C) suggests that the DOTA-BA remains bound to the Y center. For Y(DOTA-MBA), the AB quartets from methylene hydrogens of the acetate or acetamide chelating arm started to collapse at temperatures above 50 °C. It suggests that the presence of the methyl group provide certain steric hindrance for the rotation of acetate/acetamide chelating arms and the inversion of ethylenic groups. Similar inhibition effects on arm rotation have previously been noted for lanthanide complexes of DOTA derivative containing substituents at the acetate chelating arms (*63*) and of the chiral tetraamide (*64*). For Y(DOTA-BA) and Y(DOTA-MBA), the high-temperature limiting spectra could not be reached using D_2O/H_2O as the solvent.

The VT ^{1}H NMR spectra of Y(DOTA-MBA) revealed two interconversion processes: rotation of acetate chelating arms and inversion of ethylenic groups of the macrocyclic ring. At 50 °C, the acetamide and acetate chelating arms undergo rapid rotation, resulting in the coalescence of proton signals from the acetamide and acetate chelating arms. At temperatures higher than 65 °C, the inversion of ethylenic groups occurs and the ^{1}H NMR spectrum gives two overlapped NMR patterns. Similar results were observed for $[Lu(DOTA)(H_2O)]^-$, but the coalescence temperatures for the two process are much lower (*65*). However, the VT ^{1}H NMR spectra of Y(DOTA-BA) shows that both the rotation of acetate chelating arms and the inversion of ethylenic groups of the macrocyclic ring occur almost simultaneously at a lower temperature (35 °C).

CONCLUSIONS

In this study, yttrium and indium complexes of DOTA-BA and DOTA-MBA were prepared in order to study solution structures of ^{90}Y- and ^{111}In-labeled DOTA−BM conjugates. A reverse phase HPLC method revealed that both ^{90}Y and ^{111}In complexes show only one radiometric peak in their radio-HPLC chromatograms. The NMR data (^{1}H and ^{13}C) clearly demonstrates that Y(DOTA-BA) and Y(DOTA-MBA) exist in solution as one predominant isomer, and provide direct evidence for the presence of one radiometric peak in HPLC chromatograms of ^{90}Y-labeled DOTA−BM conjugates, in which the BM is attached to DOTA via one of four acetate chelating arms.

^{111}In(DOTA-BA) and ^{111}In(DOTA-MBA) are more hydrophilic than their corresponding ^{90}Y analogues, ^{90}Y-(DOTA-BA) and ^{90}Y(DOTA-MBA). Similar behavior was also seen for complexes In(DOTA-BA) and In(DOTA-MBA) as compared to their corresponding yttrium analogues, Y(DOTA-BA) and Y(DOTA-MBA). Since the only difference between In(DOTA-BA) and its Y(DOTA-BA) is the metal ion, the difference in their HPLC retention times strongly suggests that indium and yttrium do not share the same coordination sphere even though they are chelated by the same DOTA-conjugate.

The structural difference between indium and yttrium complexes of DOTA-BA and DOTA-MBA is also reflected by their different solution dynamics. Y(DOTA-BA) and Y(DOTA-MBA) are rigid while In(DOTA-BA) and In-(DOTA-MBA) are fluxional at the room temperature. Given the fact that In(DOTA-BA) and In(DOTA-MBA) are more hydrophilic and more fluxional than Y(DOTA-BA) and Y(DOTA-MBA), it is reasonable to believe that the coordinated DOTA-BA and DOTA-MBA are heptadentate with four amine-nitrogen and three carboxylate-oxygen donors binding to the indium center while the carbonyl-oxygen is uncoordinated.

It should be noted that the HPLC retention time is largely depends on the chromatographic conditions, and does not represent the "absolute" value of the hydrophilicity for a specific radiolabeled compound. As a matter of fact, the difference in hydrophilicity between ^{111}In-(DOTA-BA)/^{111}In(DOTA-MBA) and their ^{90}Y analogues is relatively small considering the chromatographic conditions used in this study. The hydrophilicity difference between the ^{111}In- and ^{90}Y-labeled DOTA−BM conjugate also depends on the relative size of the biomolecule. For large biomolecules such as antibodies, a

slight difference in the metal chelate may not cause any significant change in physical and biological properties of the ^{90}Y- and ^{111}In-labeled DOTA-conjugate. For small biomolecules, however, the slight difference in metal chelate may cause significant differences in biological properties of ^{90}Y- and ^{111}In-labeled DOTA−BM conjugates. Therefore, it is critical to prove that the ^{111}In-labeled DOTA−BM conjugate is *biologically* equivalent to the corresponding ^{90}Y analogue in various animal models in order to predict the radiation dosimetry of a specific ^{90}Y-labeled DOTA−BM conjugate more accurately.

Photoswitching of Ligand Association with a Photoresponsive Polymer−Protein Conjugate

Tsuyoshi Shimoboji, Zhongli L. Ding, Patrick S. Stayton,* and Allan S. Hoffman*

Department of Bioengineering, University of Washington, Seattle, Washington 98195. Received May 10, 2001; Revised Manuscript Received December 18, 2001

Light-regulated molecular switches that reversibly control biomolecular function could provide new opportunities for controlling activity in diagnostics, affinity separations, bioprocessing, therapeutics, and bioelectronics applications. Here we show that site-specific conjugation of light-responsive polymers near the biotin-binding pocket of streptavidin provides control of ligand binding affinity in response to UV and visible light irradiation. Two different light-responsive polymers were utilized that display opposite photoresponsive solubility changes under UV or visible (vis) light irradiation in aqueous solutions. At 40 °C, the *N*,*N*-dimethylacrylamide (DMA)-*co*-4-phenylazophenyl acrylate (AZAA) copolymer (DMAA) was soluble under UV irradiation and precipitated under visible light, while the DMA-*co*-*N*-4-phenylazophenyl acrylamide (AZAAm) copolymer (DMAAm) was soluble under visible irradiation and precipitated under UV light. Both polymers were synthesized with a vinyl sulfone terminus and conjugated to the Glu116Cys (E116C) streptavidin mutant via thiol coupling. The DMAA−streptavidin conjugate bound biotin efficiently when the polymer was in the soluble state under UV irradiation, but under visible irradiation, the polymer collapsed and blocked free biotin association. Furthermore, if biotin was allowed to bind when the polymer was in the soluble state under UV irradiation, then when the polymer was collapsed by visible light, the streptavidin released the bound biotin. The DMAAm−streptavidin conjugate showed the opposite response, with association of biotin allowed under visible light irradiation and blocked under UV irradiation. The photoresponses of the streptavidin conjugates thus correspond to the original photoresponsive phase transition properties of the polymer switches triggered by the cis−trans isomerization of the diazo chromophores.

INTRODUCTION

An important aspect of many technologies that utilize biomolecular components is the control of their recognition properties. For example, changes in solution conditions such as temperature or pH are commonly used to release target antigens from antibodies. These solution changes are often damaging to the biomolecules, and there is thus considerable interest in developing molecular switches that control recognition processes with mild signals. We have been developing molecular switches composed of stimuli-responsive polymers that control protein recognition processes in response to small changes in pH and temperature. Light represents another attrac-

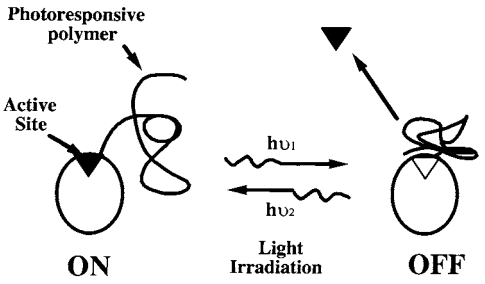

Figure 1. Schematic illustration showing the use of different wavelengths of light to switch the bioactivity of a protein "on" or "off", as provided by switching the conformation of a photoresponsive polymer that has been conjugated at a specific site near the active site of the protein.

tive signal because it would trigger these switches without requiring changes in solution conditions, and it is externally reversible; thus, it is amenable to device design and automation.

The control of enzymatic reactions and ligand affinity with light has been actively investigated by many researchers (*1*−*5*). In previous studies, chemical modification of biomolecules by direct conjugation of photochromomes such as azobenzene (*1*−*3*) or spiropyran (*3*−*5*) have been reported and have provided some photoregulation of catalytic activities and affinity binding processes. Although these bioconjugates of small molecule photochromes have demonstrated the potential of light regulation, their photoresponsiveness has been relatively weak. Intrinsic problems include (a) the thermally activated reversible isomerization of the photochromes that leads to the dyes existing as a mixture of two distinct physical states/conformations, (b) the limited size of the photochromes, and (c) their conjugation to the protein at random, nonideal positions for switching activity.

These results suggested that photoresponsive polymers might be conjugated to proteins at defined sites to control protein function more efficiently than single photochromes (Figure 1). We have described the site-specific conjugation of pH and temperature-sensitive polymers to control ligand association and dissociation in the model streptavidin−biotin system (*6*−*9*). These smart polymers change their size and physical properties reversibly between an extended hydrophilic random coil and a collapsed hydrophobic state over narrow changes of the defined stimulus. Here we report that photoresponsive polymers can serve as light-activated switches to reversibly control biotin-binding by site-specific conjugation to a critical site on streptavidin. The photoresponsive polymers rely on the cis−trans isomerization of diazobenzene chromophores to trigger the change in physical properties. The change in properties is reversible with distinct visible or far UV wavelengths of light, and these bioconjugates can thus be activated and deactivated by external light.

EXPERIMENTAL PROCEDURES

Materials. 4-Aminoazobenzene and 4-hydroxyazobenzene (Aldrich, Milwaukee, WI) were recrystallized from ethanol and water and dried in vacuo. *N*,*N*-Dimethylacrylamide (DMA) (Fluka, Milwaukee, WI), diethyl ether, acryloyl chloride, triethylamine, and 2-mercaptoethanol (MEO) (Aldrich, Milwaukee, WI) were purified by distillation under reduced pressure. 2,2′-Azobisbutyronitrile (AIBN) (J. T. Baker, Phillipsburg, NJ) was recrystallized from methanol. Ethanol, dimethylformamide (DMF), tetrahydrofuran (THF), methylene chloride, potassium ter-butoxide, divinyl sulfone (DVS), ethylenediaminetetraacetic acid (EDTA), 4-phenylazomaleinanil (PAM) (Aldrich, Milwaukee, WI), tris(2-carboxyethyl)phosphine hydrochloride (TCEP-HCl) (Pierce, Rockford, IL), Microcon-30 (Millipore, Bedford, MA), and [^{3}H]Biotin (d-[8,9-^{3}H(N)]-Biotin, Dupont, Wilmington, DE) were used as received. All other reagents were of analytical grade.

Azobenzene Monomer Synthesis. Two azobenzene-containing monomers, *N*-4-phenylazophenylacrylamide (AZAAm) and 4-phenylazophenyl acrylate (AZAA), were synthesized. 4-Aminoazobenzene or 4-hydroxyazobenzene (0.2 mol) and triethylamine (0.26 mol) were dissolved in diethyl ether (200 mL). Acryloyl chloride (0.24 mol) dissolved in 80 mL of diethyl ether was added dropwise at 0 °C under nitrogen atmosphere with stirring. The reaction mixture was allowed to come to room temperature and stirred for 4 h. The reaction solution was filtered to remove triethylammonium chloride, washed with water, and evaporated. The product was recrystallized from ethanol−water mixture and dried in vacuo. The structures were confirmed by ^{1}H NMR (*d*-DMSO).

Photoresponsive Polymer Synthesis. Two photoresponsive polymers with hydroxyl termini, DMAAm (DMA-*co*-AZAAm copolymer) and DMAA (DMA-*co*-AZAA copolymer), were synthesized by chain transfer initiated free-radical polymerization in DMF at 60 °C for 20 h, using MEO as a chain transfer regent and AIBN as an initiator (monomer concentration = 2 mol/L, monomer/MEO/AIBN = 100/1/0.2 molar ratio). The feed ratios of AZAAm and AZAA were 7.0 mol % and 4.0 mol %, respectively. The products were purified by precipitation into diethyl ether three times and dried in vacuo. The contents of AZAAm or AZAA incorporated in the copolymers were determined by ^{1}H NMR (Spectrospin & Bruker, dpx200), comparing the ratio of aromatic and aliphatic hydrogens. The molecular weights (MWs) of the polymers were determined by gel permeation chromatography (GPC, Water, Styragel HR3 and 4) in THF, using polystyrene as standards. The hydroxyl terminus of DMAA or DMAAm was converted to a vinyl sulfone group for conjugation to the protein thiol. DMAA and DMAAm were dissolved in 20 mL of methylene chloride with 0.03 g of potassium *tert*-butoxide and 100 μL of divinyl sulfone (DVS) (DVS/OH = 10/1 molar ratio). The solution was stirred for 12 h at room temperature under nitrogen atmosphere. The polymers were precipitated, washed in diethyl ether, and dried in vacuo.

Conjugation of Polymers to Streptavidin. The streptavidin mutant E116C was constructed by the same method as reported previously (*7*). Conjugation of streptavidin (E116C) and polymers (DMAA-VS, DMAAm−VS) were carried out in 100 mM sodium tetraborate buffer, pH 8.0, containing 50 mM sodium chloride and 5 mM EDTA. Cysteine residues in E116C form disulfide bonds during storage. To reduce disulfide bonds to sulfhydryl groups, TCEP at 50-fold molar excess to the mutants was added into the solution, which was then rotated at room temperature for 20 min. The DMAA-VS or DMAAm−VS was added in 50-fold molar excess to the mutants and reacted for 1 h at room temperature, followed by the reaction for 24 h at 4 °C. The conjugates were separated from the unconjugated mutants by thermally induced precipitation at 60 °C. The unconjugated protein was retained in the supernatant. The thermal-induced precipitation was repeated three times.

Conjugation of Azobenzene to Protein. PAM was reacted with cysteine in E116C in solution at pH 7.0 in phosphate-buffered saline, with TCEP as a disulfide reducing agent, mixing a 50:1 molar excess of 4-phenylazomaleinanil dissolved in DMF (10 vol % of protein

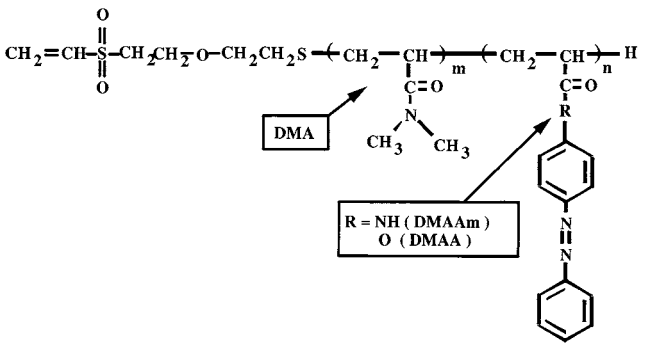

Figure 2. Photoresponsive polymers, DMAAm and DMAA, with vinyl sulfone end groups.

solution). The conjugate was purified from the unreacted PAM by ultrafiltration. The MW of the conjugate was determined as 13523 by electrospray ionization mass spectrometry (ESI-MS), which corresponds to one azobenzene conjugated to one monomer of E116C SA.

Photoirradiation. A UV Cure Lamp (Thorlabs, Newton, NJ) was used with a UG-1 band-pass filter (Edmund Scientific, Barrington, NJ) to select UV light between 300 and 400 nm, and a Fiber-Lite Illuminator (Edmund Scientific, Barrington, NJ) was used with a VG-1 band-pass filter to select for wavelengths greater than 420 nm.

Biotin-Binding Assay. [^{3}H]Biotin (d-[8,9-^{3}H(N)]-Biotin, Dupont, Wilmington, DE) was employed to quantitate biotin binding. A 10 μg amount of the conjugate was suspended in 1200 μL of 100 mM of sodium phosphate buffer, pH 7.4. A mixture of ^{3}H-biotin and unlabeled biotin (100 μL) was added into the conjugate solution (total volume was 1 mL) after incubation at 52 °C for 1 h. The ratio of total biotin/biotin binding sites was 1.5 (molar ratio). The solution temperature was reduced to 4 °C stepwise, incubating for 15 min at each temperature. A 50 μL aliquot was taken at the end of each incubation. The unbound biotin was separated from the bound biotin by ultrafiltration through a Microcon-30 (MW cutoff: 30 kDa) at the incubation temperature of the solution. A 30 μL aliquot of the filtrate, which contained unbound biotin, was measured in a β-counter (LS7000 Liquid scintillation system, Beckman Instruments, Inc. Fullerton, CA), to determine the unbound biotin. The biotin binding could be quantitated by the decrease of free biotin in the solution.

RESULTS AND DISCUSSION

Temperature- and Light-Dependent Polymer Properties. We have prepared two different copolymers that display both temperature- and light-sensitive properties. These copolymers differ mainly in the type of bond (ester vs amide) by which the azobenzene groups are attached to the main backbone chain. (Figure 2) These copolymers are similar to previously described photoresponsive polymers (*10*−*15*). The temperature- and light-responsive properties of copolymers of *N*-isopropylacrylamide (NIPAAm) and *N*-4-phenylazophenylacrylamide (AZAAm) have been characterized by Irie and co-workers (*10, 11*). Kröger et al. (*12, 13*) reported the largest differences in lower critical solution temperature (LCST) detected in aqueous solution using *N*,*N*-dimethylacrylamide (DMA)-*co*-4-phenylazophenyl acrylate (AZAA) copolymer. The photoresponsive properties of the copolymers described here depend on temperature, and conversely, the temperature-responsive properties depend on whether the diazo chromophore is in the cis or trans state. Previous work of Morishima and co-workers (*14, 15*) suggests that hydrophobic interactions of pendant groups such as pyrene and cholesterol will predominantly be intramolecular if the group is attached to the backbone via amide bonds, and intermolecular if it is attached via ester bonds. The trans configuration of azobenzene also permits stacking of the azobenzene moieties, which will enhance such hydrophobic interactions in the trans state. Thus, these very different hydrophobic interactions of the pendant azobenzene groups will depend on whether the groups are attached via ester or amide bonds, and this may explain the opposite visible vs UV photoresponses seen here for the DMAA and DMAAm copolymers. This is demonstrated for the free copolymers in Figure 3, which shows the temperature dependence under visible or UV irradiation of the phase separation. The UV light had a peak at 350 nm and a range from 300 to 400 nm, and the visible light had a peak at 520 nm while light less than 420 nm was filtered. When the LCST of the polymer was determined as the temperature of 10% of maximum biotin-binding, the DMAA and DMAAm exhibited LCST's under visible irradiation of 37 °C and 39 °C, respectively. Upon UV irradiation, the LCST of the DMAA increased to 43 °C, and that of the DMAAm decreased to 34 °C. The LCST transition of these polymers is relatively broad, and the polymers exhibited a maximal difference in the degree of phase separation under UV vs visible irradiation at around 40 °C. A significant feature of these diazo-chromophore-based polymers is that the thermal reconversion of the cis-state to the trans-state is not simultaneously accompanied by a conversion of the polymer from the collapsed state to extended state, or vice versa. This conformational con-

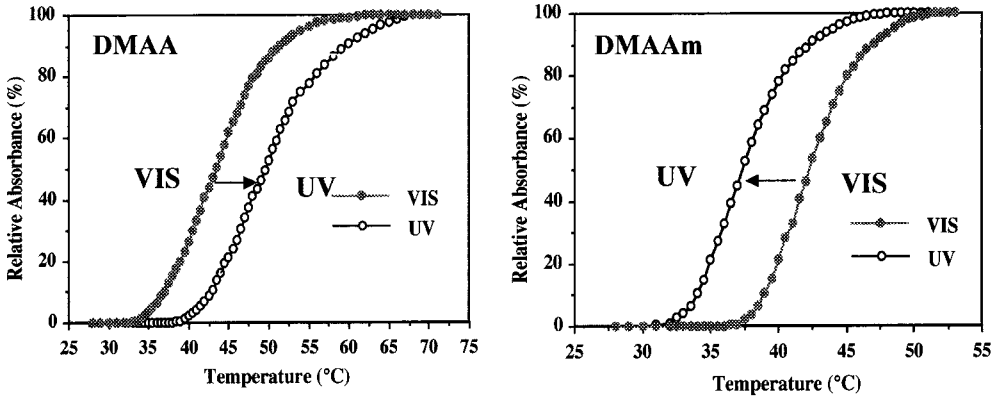

Figure 3. Effect of photoirradiation on the phase transition temperature of DMAA (AZAA: 5.9 mol %) and DMAAm (AZAAm: 9.6 mol %). The absorbance was measured at 600 nm. The polymer concentration was 2 mg/mL in 100 mM PB pH 7.2. The rate of heating was 0.5 °C/min. The UV and visible (vis) light irradiations were for 10 min and 3 h, respectively, before the measurement.

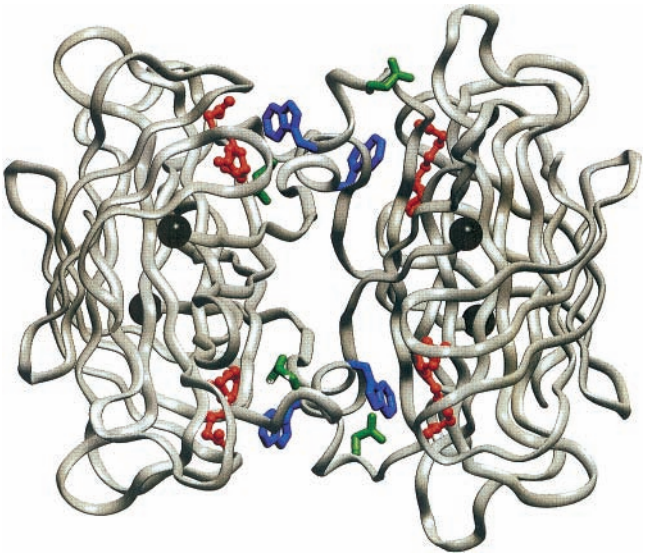

Figure 4. Three-dimensional model of streptavidin with a cysteine at amino acid position 116, showing the spacial relationship between the biotin-binding site and the cysteine-SH polymer conjugation site on E116C SA (*16*).

version of the polymer happens very slowly, on the time scale of days, unlike many diazo compounds where the cis−trans reconversion rate can often be fast, depending on the temperature.

Conjugation of Photoresponsive Polymers to Streptavidin. The general design of the streptavidin−polymer conjugate for light-responsive switching is schematically shown in Figure 1. We have found previously that the E116C SA mutant locates the unique thiol residue in an appropriate position to control both biotin binding and release (*7, 16*). This conjugation site is on the loop close to Trp120, which is critical for biotin-binding (*17*) (Figure 4). The polymers were specifically conjugated to E116C by the reaction of the vinyl sulfone group of the polymer with the thiol group of the protein under conditions that favored the vinyl group addition to the −SH over the $-NH_2$6. The conjugates were separated from the unconjugated E116C by thermally induced precipitation. The conjugation efficiency was estimated by the depletion of the mutant after thermally induced precipitation as 12−20%. For the E116C conjugates reported here, we have utilized two types of photoresponsive polymers (Figure 2) that exhibit phase transitions in aqueous solution in response to UV or visible light irradiation: (1) *N*,*N*-dimethylacrylamide (DMA)-*co*-4-phenylazophenyl acrylate ("AZAA") copolymer ("DMAA") (MW: 18 kDa, AZAA: 5.9 mol %) and (2) DMA-*co*-N-4-phenylazophenyl acrylamide ("AZAAm") copolymer ("DMAAm") (Mw: 10 kDa, AZAAm: 9.6 mol %) (Shimoboji et al., manuscript submitted). These polymers also exhibit thermoresponsive phase transitions in aqueous solutions (*16*). The DMAA polymer becomes soluble upon UV irradiation and insoluble upon visible irradiation, while the DMAAm polymer becomes soluble upon visible light and insoluble upon UV light. Thus, they

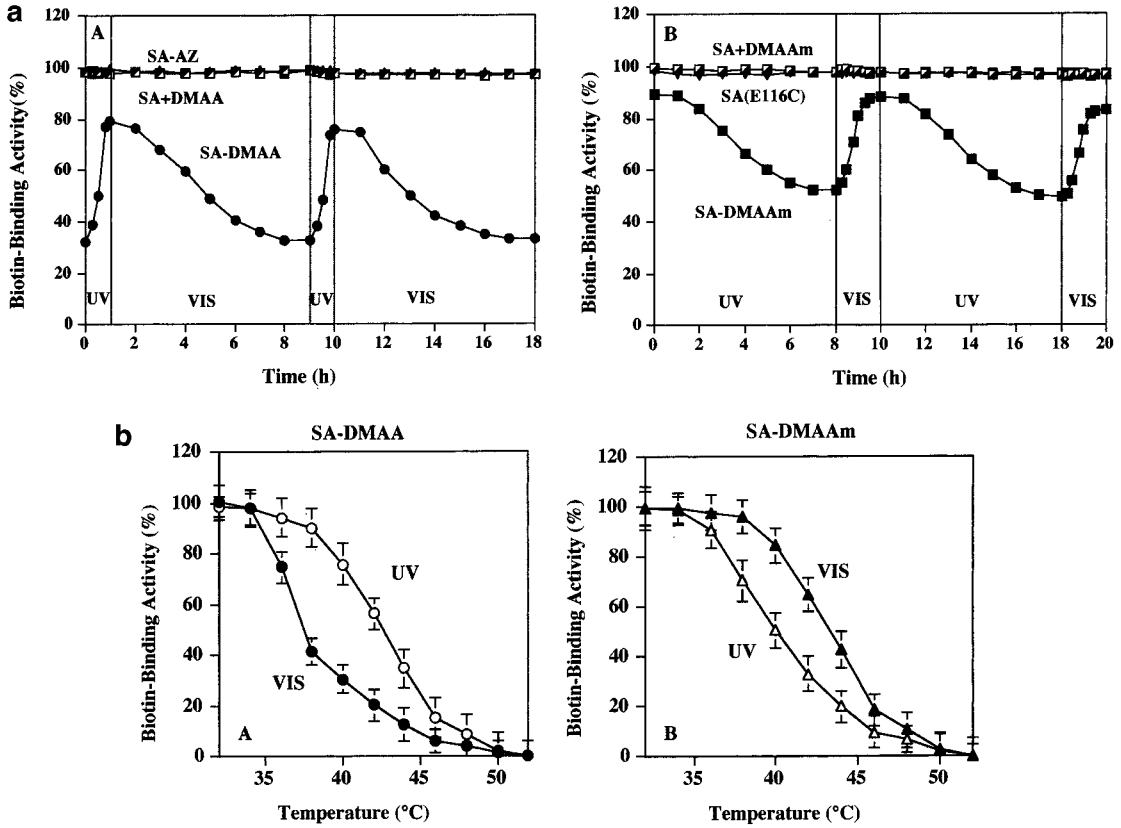

Figure 5. Photoresponsive switching of streptavidin biotin-binding activity. (A) The biotin binding activities for the SA−DMAA and SA−DMAAm conjugates were compared to controls of their physical mixtures, an SA−AZ conjugate, and SA (E116C), in response to UV/VIS cyclic irradiation under isothermal conditions at 40 °C. The biotin-binding activity represents the percentage change in the biotin-binding capacity of the conjugates from 4 °C to 52 °C, assuming 100% binding at 4 °C and 0% binding at 52 °C. (B) The normalized biotin-binding activities for SA−DMAA and SA−DMAAm as a function of temperature, under constant visible (>420 nm) or far-UV (360 nm) light irradiation. The biotin-binding activity represents the percentage change in the biotin-binding capacity of the conjugates with 100% normalized to maximal binding and 0% normalized to the minimal binding activity for each of the conjugates.

exhibited opposite photoresponses, as shown in Figure 3 and discussed above.

Photoresponsive Switching of Biotin Binding Activity. In order to characterize the time dependence of biotin association and release as a function of the photo-dependent polymer transition, biotin binding and release studies were carried out under isothermal conditions at 40 °C where the polymers displayed their maximum photoresponsiveness. As a control, azobenzene (AZ) was also conjugated site-specifically to E116C (SA−AZ conjugate). Figure 5a shows how UV/VIS photocycling alters the biotin binding and release properties of the SA−DMAA and SA−DMAAm conjugates. The unconjugated SA (E116C), a physical mixture of SA and the DMAA or DMAAm, and the SA−AZ conjugate did not exhibit any significant alteration in biotin binding affinity as a function of light irradiation. However, the SA−DMAA conjugate exhibited a 47% greater increase in biotin-blocking or release with VIS light than with UV light. Conversely, the SA−DMAAm conjugate displayed a 38% greater increase in the blocking of biotin association, and the release of bound biotin, with UV irradiation compared to VIS irradiation. These opposite photoresponsive phenomena agree with the photoresponsive phase transitions of the original polymers—i.e., DMAA collapses and becomes insoluble under VIS irradiation, while DMAAm collapses and becomes insoluble under UV irradiation. The temperature dependence of the photoswitch was also characterized and is shown in Figure 5b. The general trends follow the LCST behavior of the free polymers (Figure 3), but are shifted to slightly higher temperatures for the streptavidin conjugates.

Mechanism of Photoresponsive Switches. The time-dependence for the release of the bound biotin was measured, and the dissociation rate was determined to be 1.3×10^{-4} (s^{-1}) at 52 °C. This is within experimental error of the native streptavidin dissociation rate at this temperature. This result implies that biotin dissociates at the normal off-rate when the photoresponsive polymers are in the collapsed state near the binding pocket, but reassociation of biotin with streptavidin is blocked. The collapsed polymer does not interfere with dissociation or induce a faster off-rate through steric interactions at the binding pocket, but it does sterically retard access of free biotin to the binding pocket. The diazo monomers are not capable of modulating the access of biotin to the pocket when conjugated to E116C SA, consistent with the need for the larger polymer to achieve this steric blocking mechanism.

CONCLUSIONS

We have described the use of thermal and photoresponsive diazo-containing polymers that provide photoswitching of ligand-binding properties when conjugated near a protein's recognition binding site. This provides a general approach to the design and development of photoswitchable proteins, where function is controlled by external light signals of distinct wavelengths. In addition to the control of ligand capture and release, this approach should be applicable to a wide-range of technologies, such as photoswitching of enzyme−substrate catalytic reactions, and the optical blocking and de-blocking of recognition sites for light-based patterning of molecules and cells.

Biosurface Engineering Technologies, Inc., 387 Technology Drive, College Park, Maryland 20742-3371, and Medical Department, Brookhaven National Laboratory, Upton, New York 11973-5000. Received June 27, 2001; Revised Manuscript Received May 3, 2002

A growth factor delivery system was developed that is based on the use of silyl-heparin, a chemically modified analogue of heparin. The silyl-heparin was adsorbed onto surfaces by hydrophobic interaction via the prosthetic unit and can then be used as a solid-phase adsorbent for bFGF. All the coating steps were performed by adsorption, a process that allowed preparation of surfaces by immersion or "dip-coating". In this study a series of silyl-heparins were synthesized and each of the analogues found to function similar to unmodified heparin relative to their binding of antithrombin III and also the binding of bFGF. The silyl-heparins were found to be adsorbed onto a wide variety of substrates including polystyrene and lactide:glycolide copolymer. Enzyme-linked immumosorbant assay (ELISA) was used to establish that bFGF was readily bound to surface adsorbed silyl-heparin, and that the amount bound was directly related to amount offered for binding. Once adsorbed the silyl-heparin/FGF was able to induce capillary tube formation of endothelial cells and to increase the growth of endothelial cells. When coated onto suture material and implanted in muscle, the FGF/silyl-heparin coating caused an increased density of mesenchymal cells in the area of the implant. This coating method could prove to be useful in a number of tissue engineering applications for the local delivery of FGF and other growth factors.

INTRODUCTION

The objective of this research was to develop a growth factor delivery system for use in tissue repair that would provide a localized release of bFGF and related growth factors to enhance the tissue repair process.

Fibroblast growth factors comprise a large family of developmental and physiological signaling molecules (Szebenyi and Fallon, 1999). All FGFs have a high affinity for the glycosaminoglycan heparin and for cell surface heparan sulfate proteoglycans. The affinity of FGF for heparan sulfate limits its diffusion and restricts its release into the extracellular matrix. The binding of FGFs to heparin/HS results in the formation or stabilization of dimers and higher order oliomers along the proteoglycan chain (Herr et al., 1997; Mach et al., 1993; Moy et al., 1997). Heparin/heparan sulfate also play a role in the formation of an active FGF/FGF receptor signaling complex, and heparin/HS increases the affinity and half-life of the FGF/FGFR complex (Flaumenhaft et al., 1990; Szebenyi and Fallon, 1999). bFGF is mitogenic in many cell types including fibroblasts, endothelial cells, smooth muscle cells, and osteoblasts amoung others (Nugent and Iozzo, 2000). It is angiogenic and can protect cells from toxic insult.

Heparin-containing delivery systems for locoregional application of growth factors have been described by several investigators (Edelman et al., 1992; Gosselin et al., 1996; Nimni, 1997; Sakiyama-Elbert and Hubbell, 2000b; Wissink et al., 2000; Zarge et al., 1997). When heparin is covalently bound to a scaffolding, the release of growth factors has been suggested to be influenced by enzymatic factors such as heparinase or plasmin (Sakiyama-Elbert and Hubbell, 2000a), and by diffusion-based release. The current work presents a delivery system that is based on the use of heparin conjugated to silyl-type prosthetic units. The resulting conjugate, benzyl-bis-(dimethylsilylmethyl)oxycarbamoyl-heparin (silyl-heparin), is amphipathic and is readily adsorbed onto hydrophobic surfaces, including biodegradable polymers. The absorbed silyl-heparin can then be used as a solid-phase adsorbent for growth factors such as bFGF. A key advantage of the current method is that all the coating steps are performed by adsorption thereby allowing preparation of surfaces by "dip-coating".

METHODS

A schematic for the synthesis of silyl-heparins is provided in Figure 1, and the various steps are detailed below.

Synthesis of Benzyl(chloromethyl)dimethylsilane, 3 ($n = 1$). Under an atmosphere of nitrogen, chloro-(chloromethyl)dimethylsilane (100 g, 0.685 mol) was added by syringe to THF (500 mL) and solution cooled to 0 °C with an ice/acetone bath. Benzylmagnesium chloride (2.0 M solution, 400 mL, 0.8 mol) was added dropwise over 2 h. Care was taken to maintain the temperature below 10 °C until all the reagent was added. Thereafter, the ice bath was allowed to warm to room temperature and the reaction mixture stirred overnight. Hexane (300 mL) was added and saturated aqueous NH_4-Cl (300 mL) added dropwise. The reaction mixture was transferred to a 2 L separatory funnel with more hexane

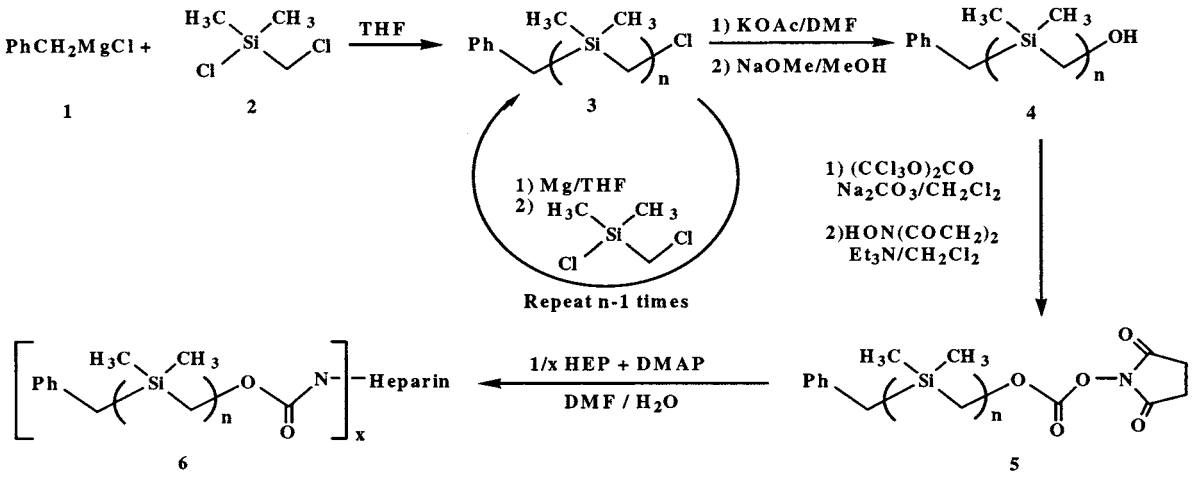

Figure 1. Experimental scheme of preparation of silyl-heparin. Treatment of benzylmagnesium chloride **1** with chloro(chloromethyl)-dimethysilane **2** gave benzyl(chloromethyl)dimethysilane **3** ($n = 1$). **3** then underwent a repetitive reaction resulting in chain elongation. For chain elongation, treatment of $\mathbf{3_n}$ with magnesium gave the Grignard Reagent which was, in turn, treated with chloro-(chloromethyl)dimethylsilane **2** to give the homologous silyl compound $\mathbf{3}_{n+1}$. This Grignard reaction was repeated as needed to obtain the desired chain-length for the silyl compound. At the desired chain length, **3** (or $\mathbf{3_n}$) was treated with potassium acetate, followed by trans-esterification of the corresponding acetate with basified methanol to give the alcohol **4**. The alcohol **4**, when treated with triphosgene, gave the corresponding chloroformate, which on treatment with *N*-hydroxysuccinimide gave the *N*-hydroxysuccinimidyl carbonate **5**. Heparin was conjugated to **5** in 1:1 DMF/H_2O containing 4-(dimethylamino)pyridine to give the silylated heparin **6**. Adjusting the molar ratios of the reactants controlled the number of prosthetic groups per heparin.

(300 mL). After partitioning, the organic layer was washed with saturated aqueous NH_4Cl (200 mL) and saturated aqueous NaCl (200 mL) successively. The combined aqueous layers were backwashed with hexane (2×500 mL), and the combined organic layers were dried over $MgSO_4$, evaporated on a rotory evaporator, and further concentrated under vacuum to give a colorless oil 162.0 g (109.5% yield). A quantitative yield was assumed with a purity of the crude product being 91.3%. The NMR spectrum for this and all other reaction products were recorded on a Varian XL300 300 MHz NMR spectrometer in a ~2% solution in $CDCl_3$ (~0.6 mL) unless otherwise indicated. The residual $CHCl_3$ signal at 7.24 ppm was used as reference line. ^{1}H NMR spectrum for $BnMe_2SiCH_2Cl$: δ 7.0−7.2 (m, 5H, arom Ph), 2.7 (s, 2H, $SiCH_2Cl$), 2.2 (s, 2H, $SiCH_2Ph$), 0.1 (s, 6H, $SiCH_3$). Quantitative organic microcombustion analysis for $BnMe_2SiCH_2Cl$: theoretical C 60.4%, found 60.8%; theoretical H 7.6%, found 7.4%. TLC in hexane, $R_f = 0.4$.

Grignard Reaction of $Bn(SiMe_2CH_2)_nCl$ 3_n and $ClSiMe_2CH_2Cl$ to give $Bn(SiMe_2CH_2)_{n+1}Cl$, 3_{n+1}. Magnesium powder (7.5 g, 0.31 mol), a catalytic amount of iodine, and THF (100 mL) were placed in a 500 mL three-necked flask equipped with a condenser-N_2 inlet, a septum, and a thermometer. The mixture was heated to reflux briefly until the brown color of iodine disappeared. $Bn(SiMe_2CH_2)_nCl$ (0.2 mol) was added by syringe and residual reagent washed into the reaction mixture with THF (2×25 mL). The reaction was initiated with a heat gun: an exothermic reaction was observed, and the reaction flask was placed in a water bath until the exothermic reaction subsided. The resulting gray mixture was heated to reflux for 24 h. The reagent was then cooled to room temperature and cannulated into a pressure filter funnel where it was added directly into another 500 mL round-bottom flask in which was placed a solution of $ClSiMe_2CH_2Cl$ (27.0 mL, 0.2 mol) in THF (50 mL) at room temperature. The magnesium residue was washed into the reaction mixture with THF (2×25 mL). The reaction mixture was heated to reflux overnight. To the resulting gray suspension was added saturated aqueous $NaHCO_3$ (50 mL), and the resulting solution was transferred to a 500 mL separatory funnel with hexane (200 mL). After partition, the organic layer was washed with saturated aqueous $NaHCO_3$ (50 mL) and saturated aqueous NaCl (50 mL). The combined aqueous layers were back-washed with hexane (2×100 mL). The combined organic layers were dried over $MgSO_4$ and extensively evaporated under vacuum to give an amber oil. The amber oil was purified by distillation to give a colorless oil. Yields were over 80%. ^{1}H NMR spectrum for $Bn(Me_2SiCH_2)_2Cl$: δ 7.0−7.2 (m, 5H, arom Ph), 2.7 (s, 2H, $SiCH_2Cl$), 2.0 (s, 2H, $SiCH_2Ph$), 0.0 and 0.1 (2 s, 2×6H, $SiCH_3$), −0.2 (s, 2H, $SiCH_2Si$). Quantitative organic microcombustion analysis for $Bn(Me_2SiCH_2)_2Cl$: theoretical C 57.6%, found 57.8%; theoretical H 8.6%, found 8.6%. TLC in hexane, $R_f = 0.3$.

Conversion of $Bn(SiMe_2CH_2)_nCl$ 3_n to $Bn(SiMe_2CH_2)_nOH$ 4_n. $Bn(SiMe_2CH_2)_nCl$ (0.16 mol) was dissolved in DMF (300 mL) in a 1-L three-necked flask. KOAc (50 g, 0.5 mol) was added followed by $^nBu_4NI$ (4.0 g, 0.01 mol), and the reaction mixture was stirred in a 135 °C oil bath for 24 h. The reaction mixture was worked up by cooling to room temperature and transferring to a 1-L separatory funnel with hexane (500 mL) and washed with saturated aqueous NaCl (3×100 mL). The combined aqueous layers were back-washed with hexane (3×300 mL) and the combined organic layers dried over $MgSO_4$ and vacuum-evaporated to an amber oil, which was dissolved in MeOH (400 mL). A generous amount of freshly prepared NaOMe was added to adjust the pH to >10 and the reaction mixture heated to reflux for 2 h. The reaction mixture was then neutralized with AcOH, evaporated to dryness, and chromatographed with silica gel in a 6.5×100 cm (height of silica 40 cm) flash column and eluted with 0−30% EtOAc/hexane to give the desired product, a slightly yellow oil. Yields were over 80%. ^{1}H NMR spectrum for $Bn(Me_2SiCH_2)_2OH$: δ 7.0−7.2 (multiplet, 5H, aromatic Ph protons); 3.3 (singlet, 2H, $SiCH_2OH$); 2.1 (singlet, 2H, $SiCH_2Ph$); 0.0 & 0.1 (2 singlets, 2×6H, $SiCH_3$); −0.2 (singlet, 2H, $SiCH_2Si$). Quantitative organic microcombustion analysis for $Bn(Me_2SiCH_2)_2OH$: theoretical C 61.8%, found 62.0%; theoretical H 9.6%, found 9.6%. TLC in 20% EtOAc/80%hexane, $R_f = 0.25$.

Conversion of $Bn(SiMe_2CH_2)_nOH$ 4_n to $Bn(SiMe_2CH_2)_nOCO_2N(COCH_2)_2$ 5_n. Triphosgene (60 g, 0.2 mol)

was dissolved in CH_2Cl_2 (200 mL) and stirred at 0 °C under N_2 in a 1-L three-necked flask equipped with thermometer, dropping funnel and N_2 inlet. Na_2CO_3 (65 g, 0.6 mol) was added followed by $Bn(SiMe_2CH_2)nOH$ (0.13 mol dissolved in 200 mL of CH_2Cl_2) dropwise over 30 min. Thereafter, the ice/acetone bath was allowed to come to room temperature. The reaction mixture was stirred overnight and filtered through a sintered glass funnel, and the reaction vessel was rinsed with $PhCH_3$ (200 mL). The solution was concentrated under vacuum to give a colorless oil. The oil was dissolved in CH_2Cl_2 and stirred in an ice bath under N_2. *N*-Hydroxysuccinimide (30 g, 0.26 mol) was added followed by Et_3N (40 mL, 0.28 mol) dropwise over 15 min and the resulting cloudy mixture stirred at room temperature for 1 h. The reaction mixture was diluted with hexane (600 m), washed with saturated aqueous NH_4Cl (3 × 100 mL), and the combined aqueous phases were backwashed with hexane (2 × 200 mL). The combined organic phases were dried over $MgSO_4$ and concentrated under vacuum to give an amber oil. The amber oil was chromatographed with silica gel in a 6.5 × 100 cm (height of silica 40 cm) flash column and eluted with 20−50% EtOAc/hexane to give an amber syrup. Yields are generally greater than 75%. ^{1}H NMR spectrum for $Bn(Me_2SiCH_2)_2OCO_2N(COCH_2)_2$: δ 7.0−7.2 (m, 5H, arom Ph); 4.0 (s, 2H, $SiCH_2OCO$), 2.7 (s, 4H, $N[COCH_2]_2$), 2.1 (s, 2H, $SiCH_2Ph$), 0.0 and 0.1 (2 s, 2 × 6H, $SiCH_3$), −0.2 (s, 2H, $SiCH_2Si$). Quantitative organic microcombustion analysis for $Bn(Me_2SiCH_2)_2$-$OCO_2N(COCH_2)_2$: theoretical C 54.9%, found 54.7%; theoretical H 6.9%, found 7.0%; theoretical N 3.6%, found 3.5%. TLC in 20% EtOAc/80%hexane, $R_f = 0.2$.

Conjugation of Heparin with $Bn(SiMe_2CH_2)_nOCO_2$-$N(COCH_2)_2$ 5_n To Give $6_{n,x}$. Heparin (ammonium ion-free, average molecular weight 10000; 100 g, 10 mmol) was dissolved in H_2O (500 mL) in a 2-L flask with stirring. DMF (400 mL) was added followed by DMAP (1.6× g, 13× mmol). $Bn(SiMe_2CH_2)_nOCO_2N(COCH_2)_2$, $\mathbf{5}_n$ (10× mmol), in DMF (100 mL) was added, and the resulting milky mixture was allowed to stir at room temperature for >24 h. The reaction mixture was concentrated by evaporating most of the water followed by trituration with acetone (1 L). The white suspension was filtered through a sintered glass funnel to give a white solid residue. This crude material was purified by Soxhlet extraction with acetone overnight to give a white powder. The yields were generally greater than 95%.

The average number of prosthetic units per molecule of heparin was estimated based on a comparison of the molar ratios of the hydrolyzed prosthetic unit benzyl-tri-(dimethylsilylmethyl)-OH and heparin as determined by use of dimethyl methylene blue (Groves et al., 1997). Heparin was detected using a commercially available enzyme-linked assay that measures the heparin-induced inhibition of antithrombin/factor Xa as measured with a factor Xa specific chromogenic substrate (Teien and Lie, 1977; Teien et al., 1976).

The silyl-heparin was used as a coating solution at 1% solution (w/v) in 60% aqueous ethanol. Materials were coated with silyl-heparins for 15 min at 37 °C. The coated materials were then rinsed extensively in water, air-dried, and stored until use.

Comparison of Silyl-heparins with Heparin. Comparisons were made using competitive binding to heparin-agarose (end-point attachment, Sigma Chemical Co.) generally following the methods of Ishihara (Ishihara et al., 2000). Heparin agarose was rinsed in phosphate-buffered saline and equilibrated in PBS containing 1% bovine serum albumin (PBS/BSA). Aliquots were added to microfuge tubes and the volume adjusted to 0.5 mL with 0.5 mL of PBS/BSA. An additional 0.5 mL of Dulbecco's modified Eagle's medium containing 10% fetal bovine serum (FBS) containing heparin or silyl-heparin-5135 was added. An aliquot of 5 μL of bFGF (50 ng/mL) was added and the solutions incubated for 30 min with mixing. The unbound bFGF was removed by multiple centrifugations and rinsing in PBS. Rabbit anti-bFGF (1:500) was added in 0.5 mL of PBS/BSA and the solution incubated with mixing for 1 h. After rinsing donkey anti-rabbit (1:500) in PBS/BSA was added and incubated 1 h. After rinsing and transfer to new vials, chromogen (ABTS One-Step, Pierce Chemical Co.) was added and the reaction developed and subsequently read at 595 nm.

Detection of Adsorbed Silyl-heparin. Adsorbed heparin was detected by staining with dimethyl methylene blue (Groves et al., 1997). Stains were filtered through 0.2 μm filters prior to use. The stain associated with the test materials was solublized by addition (1:1) of methanol and an aqueous solution of 0.5 M Tris, pH 6.8, containing 0.4% sodium dodecyl sulfate (SDS). Heparin was also detected by an enzyme-linked assay (Sigma Chemical Co., St. Louis) that measures the heparin-induced inhibition of antithrombin/factor Xa as measured with a factor Xa specific chromogenic substrate (Teien and Lie, 1977; Teien et al., 1976). The assay was performed following the directions of the manufacturer.

ELISA Detection of bFGF Bound to Silyl-heparins. Wells of polystyrene microtiter plates were coated with 30 μL of silyl-heparin for 15 min at 37 °C. The surface area of the well was 0.32 cm^2. The wells were rinsed extensively in water and air-dried. bFGF (Sigma Chemical Co.) in PBS/BSA was added in 150 μl aliquots and in doubling dilutions (final volume 150 μL). The plate was incubated at 37 °C for 1 h and rinsed 5× in PBS. A 150 μL aliquot of PBS/BSA containing 1:500 rabbit anti-FGF antibodies was added, incubated 1 h, and rinsed. In some cases an irrelevant rabbit antibody (rabbit anti-TGF-receptor II, Santa Cruz Biotechnology) was used at a similar concentration. An aliquot of PBS/BSA containing 1:500 HRPO-conjugated donkey anti-rabbit IgG was added, and after incubation and rinsing ABTS-chromogen was added. All antibody solutions were filtered through 0.2 μm filters prior to use. The absorbance was monitored at 405 nm.

Attachment Molecules. The following were used as heparin-complexing materials: murine type IV collagen, human fibrinogen, and bovine fibronectin isolated from plasma. The proteins were used at a concentration of 100 μg/mL in PBS/BSA. The wells were coated adding 100 μL followed by a 1 h incubation at 37 °C. Thereafter, the plates were washed extensively in water. To the wells was added bFGF in PBS/BSA in 150 μl aliquots. The plate was incubated at 37 °C for 1 h and processed as above using dilutions of 1:200 and 1:500 for the primary and secondary antibody, respectively.

Capillary Tube Formation. Bovine aorta endothelial cells were seeded into low-attachment 96-well plates. The wells had been pretreated with saline or silyl-heparin and/or fibrinogen and FGF. The silyl-heparin coating was applied as above, and the fibrinogen was applied as a 0.1% solution in PBS and uncomplexed material washed off with PBS. FGF (100 ng/mL) was allowed to attach for 30 min to the silyl-heparin in PBS containing 1% bovine serum albumin and the unbound material rinsed off with PBS. Endothelial cells (5×10^3 cells) were seeded into the wells in DMEM containing 10% FBS. The cells were allowed to grow for 4 days and the cultures examined by phase contrast microscopy.

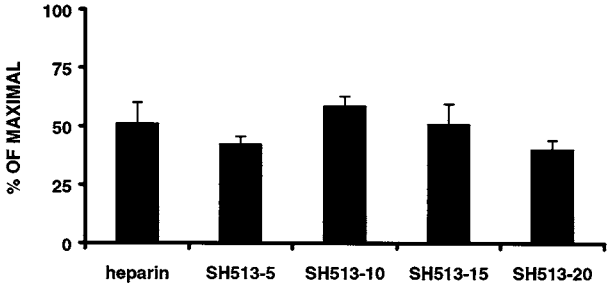

Figure 2. Comparison of the inhibition of bFGF binding to heparin-agarose by either heparin or silyl-heparin analogues as determined by immunochemical methods. The analogues nominally contained 5, 10, 15, and 20 prosthetic groups per heparin. A serial assay was used to establish the EC_{50} for heparin and then the comparison of the silyl-heparins made using identical concentrations. The data represents the average ± SD.

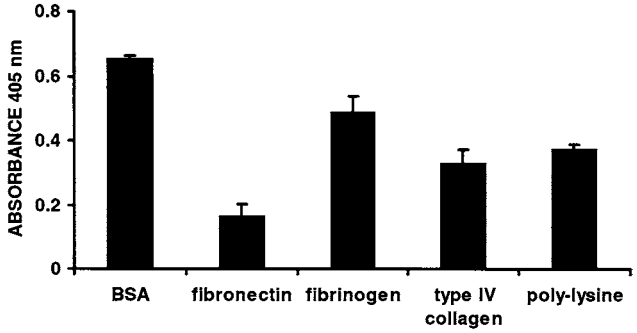

Figure 4. Effect of precomplexing adhesion molecules to silyl-heparin on the subsequent binding of bFGF. All adhesion molecules were complexed to silyl-heparin at a concentration of 100 μg/mL and unbound material rinsed out prior to use in experiments. The data represents the average ± SD. All treatments were statistically significant as indicated by $p < 0.05$ by Student's *t*-test relative to treatment with bovine serum albumin (BSA).

Stimulation of Endothelial Cell Growth. Six-well cluster plates were seeded with 5×10^4 bovine aorta endothelial cells. Cell culture inserts (25 mm diameter) with 3 μm pores in the bottom were placed in each well. Suture material (10 cm) with or without coatings was placed in the well and medium added sufficient to cover the suture (3 mL total). One set of inserts containing an uncoated suture was spiked with 50 ng of FGF by adding the FGF directly to the medium and was used as a positive control. The cells were allowed 4 days to grow, fixed, and stained with crystal violet. Thereafter, the stain was eluted in aqueous methanol and 0.4% SDS and monitored at 595 nm.

Implants. Vicryl suture material was immersed in water, silyl-heparin, or silyl-heparin followed by FGF for 15 min at 37 °C. Vicryl, a synthetic absorbable surgical suture composed of a copolymer made from 90% glycolide and 10% L-lactide. The suture material was then rinsed extensively, air-dried, mounted on 16-guage needles, and stored until use, typically overnight. The batch receiving FGF was immersed in PBS/BSA containing 100 ng/mL FGF (15 min, 37 °C). The sutures were passed through the thigh muscle of adult rats under anesthesia and secured with knots and surgical clips. After two weeks the animals were euthanized and the sutured area removed, fixed in formalin, and processed by standard histological methods.

RESULTS

FGF Binding by Silyl-heparins and Heparin. The inhibition of binding of bFGF to heparin-agarose was used to compare silyl-heparins with heparin. The heparin used in this assay was the same as was used in the synthesis of the silyl-heparins. In this assay silyl-heparin 5135 provided essentially the same EC_{50} as unmodified heparin (Figure 2) when used on equal weight basis. One of the silyl-heparins, SH513−5, was selected for further study, as the EC_{50} was similar for each of the silyl-heparin variants examined.

Adsorption of Silyl-heparin onto Polymeric Substrates. Heparin-specific assays and dimethylene blue dye uptake were used to establish that silyl-heparin could be adsorbed to a variety of materials including polystyrene, hydrogel-coated polystyrene, polycarbonate, polyurethane, polycaprolactone, poly(vinyl chloride), stainless steel, titanium, platinum wire, and glow discharge-deposited siloxane (over stainless steel). The loading efficiency of silyl-heparin was generally in the range of 10 mIU/cm^2, but did vary by type of substrate.

Silyl-heparin Coated onto Polystyrene. Staining with crystal violet and dimethyl methylene blue, stains known to react with heparin verified the presence of silyl-heparin-5135 on the polystyrene. The bound stain could be seen visually as a light coloration on the bottom of the wells. The stains were solubilized in 1:1 methanol/0.1% SDS; this slightly increased the stain intensity. Little if any stain was detected on plates to which 1 mg/mL heparin was added or which were uncoated. Wells coated with silyl-hepain-5135 were positive for bioactive heparin as determined by monitoring the heparin-induced inhibition of antithrombin/factor Xa. Wells simi-

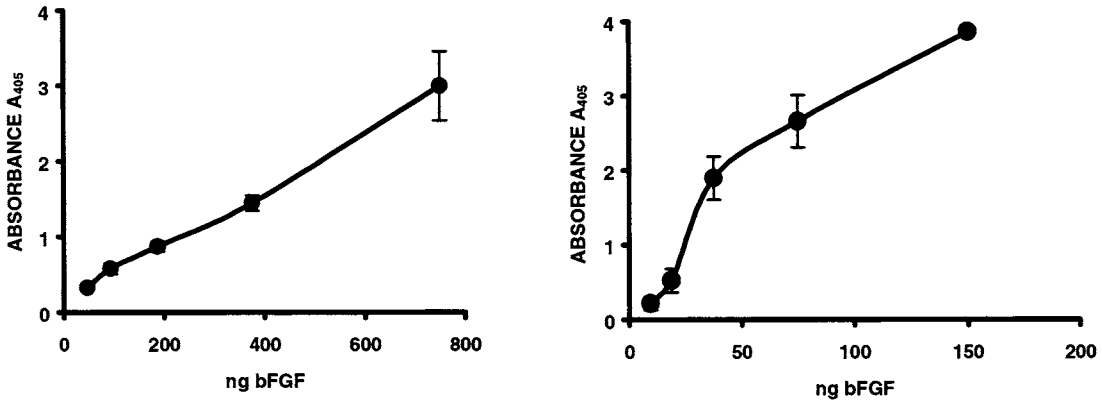

Figure 3. Effect of bFGF loading concentration the amount of bFGF bound to silyl-heparin. Left panel. The primary and secondary antibodies, as described in the Methods section were used at a dilution of 1:500. Right panel. The primary and secondary antibodies were used at a dilution of 1:250. The data represents the average ± SD.

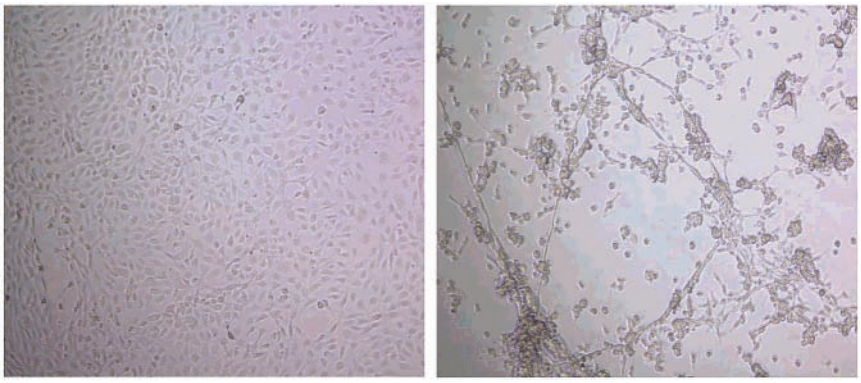

Figure 5. Capillary tube formation induced by growth of bovine aorta endothelial cells on FGF-silyl-heparin. The silyl-heparin was precomplexed to fibrinogen to increase the level of endothelial cell attachment. The panel on the left is a phase contrast micrograph of endothelial cells after 4 days on silyl-heparin/fibrinogen. The panel on the right illustrates endothelial cells grown on FGF-silyl-heparin/fibrinogen. Note the tubelike structures in the right panel and the typical endothelial cell morphology in the left panel.

larly coated with heparin or left untreated did not demonstrate such an inhibition.

bFGF Detection. bFGF was detected over a wide range of concentrations from as much as 750 ng to as low as 20 ng (Figure 3). The color development was linear at high concentrations indicating that under the conditions of the assay the upper saturation limit of the silyl-heparin had not been reached.

As controls, when anti-TGF-betaRII (irrelevant antibody directed against the transforming growth factor receptor) was used instead of FGF and at the same antidilutions, no bFGF was detected. When TGF-beta (40 ng) was used as an alternative to bFGF and with anti-bFGF antibodies, no activity was detected.

Effect of Adhesion Molecules on FGF Binding. Type IV collagen, fibronectin, and fibrinogen are known to complex to heparin, and therefore the effect of precomplexing these extracellular matrix molecules to silyl-heparin was evaluated (Figure 4). Fibronectin was found to considerably decrease the binding of bFGF to silyl-heparin, whereas type IV collagen and fibrinogen decreased the signal less. Immunochemical analysis of fibronectin indicated that it was bound to the silyl-heparin on the plate and had not undergone spurious sloughing.

Capillary Tube Formation. Bovine aorta endothelial cells underwent morphological changes consistent with the formation of capillary tube formation when cultured on a preformed coating of silyl-heparin plus fibrinogen and bFGF (Figure 5). Fibrinogen was used to help the endothelial cells attach to the silyl-heparin. It should be pointed out that the only source of bFGF was that which was bound to the silyl-heparin. Tubes did not form when the cells were cultured in wells coated with silyl-heparin, silyl-heparin and fibrinogen, fibrinogen, fibrinogen and FGF, or FGF. On silyl-heparin plus fibrinogen the cells formed essentially confluent monolayers.

Endothelial Cell Growth. FGF from the FGF/silyl-heparin coating was able to transit a separating membrane and act regionally to stimulate the growth of endothelial cells at the end of 4 days (Figure 6). In these experiments, FGF was complexed via silyl-heparin to suture material and separated from endothelial cells by a permeable membrane. The suture-derived FGF increased cell numbers to a similar extend as that observed in control cultures spiked with soluble FGF. Suture material coated with just silyl-heparin did not result in an increase in cell number.

Suture Implant. Coated sutures implant in rat muscle was selected as a simple model of an implant that could

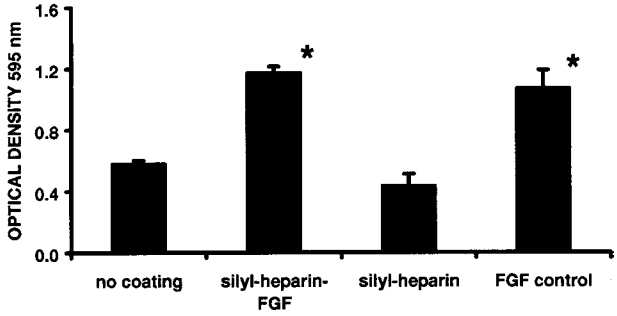

Figure 6. Trans-pore effect of FGF-silyl-heparin from coated sutures on the growth of bovine aorta endothelial cells after 4 days as determined by crystal violet staining. Cells were seeded into cluster plates and with 3 μm pores in the bottom placed in each well. Sutures with or without coatings were placed in the well and medium added sufficient to cover the suture. One set of inserts, containing an uncoated suture, was spiked by adding the FGF directly to the medium (positive control). The cells were allowed 4 days to grow, fixed, and stained with crystal violet. Thereafter, the stain was eluted in aqueous methanol and 0.4% SDS and monitored at 595 nm. The data are presented as the average absorbance ± SD. The asterisk indicates statistical significance greater than 0.05 as determined with Student's *t*-test.

be histologically monitored. At two weeks after implant, sutures coated with FGF/silyl-heparin had a marked increase in cell density in the area surrounding the implant compared to the uncoated suture or the suture coated with silyl-heparin (Figure 7). The diameter of the granulation tissue surrounding the implant coated with FGF/silyl-heparin was approximately 2 -fold larger than that of the uncoated material or silyl-heparin coated material (data not shown). The tissue surrounding the implant coated with FGF/silyl-heparin had numerous blood vessels (Figure 8) suggestive of angiogenesis.

DISCUSSION

FGFs have a well-characterized role in fibroblast and endothelial cell growth and are involved in angiogenesis, wound healing, tissue repair, and tissue regeneration (Powers et al., 2000). One of the defining features of the FGF family is a strong affinity for heparin and heparan sulfate proteoglycans. This affinity for heparin is shared by a number of other growth factors including VEGF, TGF-β, NGF, and PDGF, among others. The broad physiological impacts of growth factors on wound healing has led to efforts to deliver FGF, and other growth factors, from implant material or wound dressings (Nimni, 1997). A variety of approaches have been used for this

purpose including using conjugation of FGF (Sakiyama-Elbert and Hubbell, 2000b), FGF embedded in matrixes (Soparkar et al., 2000; Wang, 1996), FGF complexed to heparin-conjugates (Bos et al., 1999; Wissink et al., 2000), and the use of genetic engineering approaches to producing FGF-secreting cells (Sosnowski et al., 1999).

Because of the potential wide application of FGF to implants ranging from cardiovascular (Post et al., 2001) to osteocartilagenous applications and the variety of matrixes and surfaces that might be involved, our approach was to develop a simple coating approach that could apply FGF to a large number of substrates. To that end, we have synthesized heparins with prosthetic groups that promote heparin adsorption. The bound heparin can then be used to further complex FGF. The overall method is simple and requires a low level of technical skill, as all of the adsorption steps are performed by immersion.

FGF bound to adsorbed silyl-heparin as determined by ELISA, and the amount of FGF bound was directly related to the amount offered for binding. This correlation should allow for predictable loading of FGF on implant surfaces. And while the focus of this report is on FGF, similar approaches have been used for complexing vascular endothelial growth factor (VEGF) and transforming growth factor-beta (TGF-β).

Heparin is known to bind to a variety of extracellular matrix molecules including fibronectin, laminin, and type IV collagen (Kreis, 1993). Additionally, it can bind fibrinogen and fibrin (Mohri et al., 1994; Odrljin et al., 1996). All the aforementioned proteins have been used to support cell attachment on various experimental implants. We evaluated the binding of FGF to silyl-heparin following an initial complexation with silyl-heparin, as this might be a desirable format for certain applications where cell attachment is desired. At the concentration of extracellular matrix protein used, fibronectin was found to substantially reduce the subsequent binding of FGF. Fibrinogen had the least effect.

One interesting observation was that endothelial cells cultured directly on FGF-silyl-heparin that had been precomplexed to fibrinogen underwent capillary tube formation. This appears to be similar to those formed when endothelial cells are cultured on extracellular matrix (Matrigel) in the presence of FGF (Garrido et al., 1995; Zimrin et al., 1995). This clearly indicated that the FGF-silyl-heparin was having a local effect on the endothelial cells. In our studies, capillary tubes rarely developed in cultures grown on silyl-heparin-fibrinogen without FGF. On Matrigel, the formation of capillary tubes is widely used as an in vitro model of angiogenesis.

One prediction of the use of FGF-silyl-heparin was that the complex should elute from an implant surface and effect cells in the general region. The trans-pore studies support that hypothesis as endothelial cell growth was stimulated when implant material was coated with FGF/silyl-heparin and supplied to the cells across a membrane barrier.

The suture model was also used to evaluate the effect of the FGF-silyl-heparin coating on wound repair. Following implant, the granulation tissue surrounding the implant had a larger diameter and a higher cell density than uncoated suture material, clearly suggesting a locoregional effect of the FGF bound to the suture material. A fuller examination of the dose−response characteristics of this response is planned.

Collectively, the results of the current study suggest that silyl-heparin could be a useful vehicle for the local delivery of FGF and other growth factors.

NMR Characterization of the DNA Binding Properties of a Novel Hoechst 33258 Analogue Peptide Building Block

Jakob Bunkenborg,[†] Carsten Behrens,[‡,§] and Jens Peter Jacobsen*[,†]

Department of Chemistry, University of Southern Denmark, Odense University, Odense M, DK-5230 Denmark, and Department of Chemistry, University of Copenhagen, Universitetsparken 5, DK-2100 Copenhagen Ø, Denmark. Received January 5, 2002; Revised Manuscript Received May 14, 2002

A novel aryl-bis-benzimidazole amino acid analogue of the DNA-binding compound Hoechst 33258 has recently been designed for incorporation in peptide combinatorial libraries by replacing the *N*-methylpiperazine group with a carboxyl group and the hydroxy group with an amino-methyl group. The DNA-binding properties of the aryl-bis-benzimidazole monomer with the C-terminus derivatized with 3-(dimethylamino)-propylamine has been investigated in this paper by ^{1}H NMR studies of two different complexes with two different DNA sequences: A_5 d(5′-GCCA_5CG-3′):d(5′-CGT_5GGC-3′) and A_3T_3 d(5′-CGA_3T_3CG-3′)$_2$. Chemical shift footprinting shows that the ligand binds at the center of the A_3T_3 sequence but at the 3′-end of A_5. A large number of NOEs show a well-defined complex with the ligand situated at the center of the palindromic A_3T_3 but with the asymmetric A_5 the ligand binds with an orientational preference with the bis-benzimidazole moiety displaced toward the 3′-end from the center of the duplex. Two families of models of the complexes with A_5 and A_3T_3 were derived with restrained molecular dynamics based on a large set of 70 and 61, respectively, intermolecular ligand NOEs. Both models give a picture of a tightly fitting ligand with close van der Waals contacts with the walls of the minor groove and with the two benzimidazole and the amide hydrogens involved in bifurcated cross-strand hydrogen bonds to adenine N3 and thymine O2. The minor groove width of the models correlate well with the binding site of the ligand, and the orientational preference is argued to be a consequence of the minor groove width and hydrogen bonding.

INTRODUCTION

A large number of molecules bind noncovalently to the minor groove of DNA with a preference for AT regions. These minor groove binders, a few of which are illustrated in Figure 1, have some characteristics in common. They are generally aromatic crescent-shaped molecules that are complementary in shape to the minor groove walls giving optimum van der Waals contacts while hiding the hydrophobic surface away from the solvent. They have hydrogen-bonding capabilities and cationic groups suited for the negative electrostatic potential of the AT minor groove. Hoechst 33258 is a prominent member of the minor groove binder family that has been extensively derivatized and studied thoroughly by a number of biophysical methods: calorimetry (Haq et al., 1997), DNase I[1] footprinting (Abu-Daya et al., 1995; Abu-Daya and Fox, 1997), electric linear dichroism (Bailly et al., 1993), X-ray crystallography (Pjura et al., 1987; Teng et al., 1988; Quintana et al., 1991; Spink et al., 1994; Vega et al., 1994; Clark et al., 1996a; Clark et al., 1996b; Clark et al., 1997), and NMR (Searle and Embrey, 1990; Parkinson et al., 1990; Embrey et al., 1991; Fede et al., 1991; Fede et al., 1993; Fede et al., 1993; Embrey et al., 1993; Bostock-Smith et al., 1997; Bostock-Smith et al., 1998; Higgins and Searle, 1999; Gavathiotis et al., 2000).

Hoechst 33258 has been the object of a very large number of investigations (see Lown (Reddy et al., 1999) for a review) because it is a fluorescent DNA stain with easy access across the cell membrane and it has some biological activity (e.g., it has found use as an anthelmintic (Denham et al., 1976)). Hoechst 33258 binds preferentially in the minor groove of DNA sequences that have at least four consecutive AT base pairs and binds strongly with a binding constant of 3×10^8 M^{-1} (Bostock-Smith and Searle, 1999; Haq et al., 1997; Loontiens et al., 1990) but can also bind to GC-rich sequences in an intercalative mode with a smaller affinity constant (Bailly et al., 1993; Rao and Lown, 1991; Moon et al., 1996). NMR and X-ray crystallographic structural studies of Hoechst 33258−DNA complexes have mainly been of palindromic binding sites with four or six AT base pairs (e.g., AATT (Pjura et al., 1987; Teng et al., 1988; Quintana et al., 1991); AAATTT (Vega et al., 1994; Spink et al., 1994) and TAATTA (Embrey et al., 1993)) with the exception of a recent NMR solution structure of the 2:1 complex with d(5′-CTTTTGCAAAAG-3′)$_2$ (Searle and Embrey, 1990; Gavathiotis et al., 2000). These studies unanimously find that Hoechst 33258 penetrates deeply into the minor groove with a binding stoichiometry of only

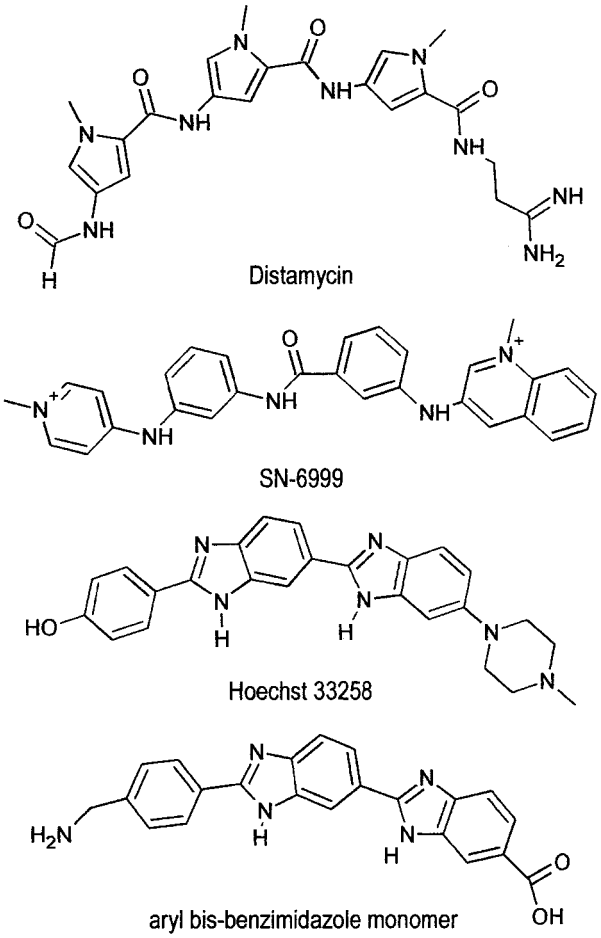

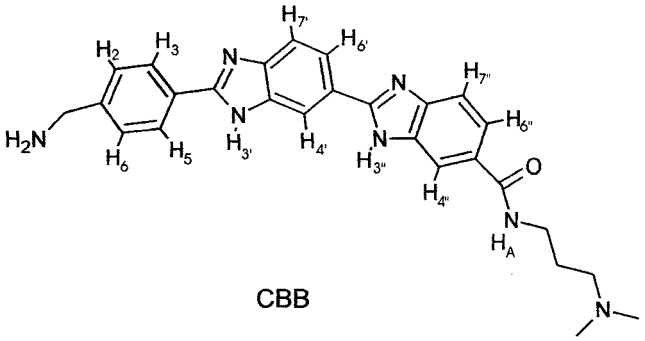

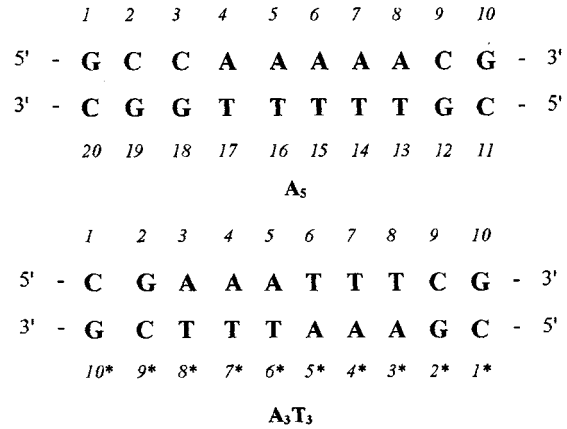

Figure 1. The minor groove binding ligands distamycin, SN-6999, and Hoechst 33258, and the novel Hoechst 33258 analogue bis-benzimidazole amino acid building block. These compounds are characterized by being composed of several planar aromatic moieties, by having a number of hydrogen bond donors, and by having a crescent shape that fits the minor groove.

one molecule bound per site. Each benzimidazole interacts with two A:T base pairs by means of a bifurcated cross strand hydrogen bond and spans approximately one and a half base pairs. The sequence selectivity and high binding affinity for AT regions have been attributed to the negative electrostatic potential within the minor groove of AT sequences (Lavery and Pullmann, 1981) and a narrowing of the walls of the minor groove for A-tracts.

A novel aryl-bis-benzimidazole amino acid analogue of the DNA-binding compound Hoechst 33258 has been designed as described in a preceding paper for incorporation in peptide combinatorial libraries by replacing the *N*-methylpiperazine group with a carboxyl group and the hydroxy group with an amino-methyl group (Behrens and Nielsen, 2001). To investigate the DNA binding properties of the aryl-bis-benzimidazole monomer a short minor groove binder 2′-(4-aminomethylphenyl)-3*H*,3′*H*-[2,5′]-bibenzimidazolyl-5-carboxylic acid (3-dimethylaminopropyl)amide (CBB, Scheme 1) where the C-terminal has been linked to 3-(dimethylamino)-propylamine was synthesized as described (Behrens and Nielsen, 2001). We have used ^{1}H NMR spectroscopy and molecular modeling to characterize the binding of CBB to the synthetic oligonucleotides d(5′-GCCAAAAACG-3′):d(5′-CGTTTTTG-GC-3′) and d(5′-CGAAATTTCG-3′)$_2$ (henceforth A_5 and A_3T_3). A large number of drug−DNA NOE connectivities (70 in all for the A_5−CBB complex and 61 for the A_3T_3−CBB complex) defines the binding site of CBB in the minor groove with some precision. CBB binds to the

Scheme 1. Chemical Structure of CBB and Numbering Scheme for the dsDNA Duplexes Used[a]

[a] Asterisks in the numbering scheme for A_3T_3 become relevant when the asymmetric CBB ligand binds to the DNA duplex and the two strands become distinguishable in the asymmetric complex

asymmetric oligonucleotide with an orientational preference with the NH_2-terminus of CBB situated at the beginning of the A-tract.

EXPERIMENTAL PROCEDURES

Materials. Purified DNA oligonucleotides were purchased from DNA Technology (Aarhus, Denmark) and desalted using a Sephadex G15 column. The non-self-complementary single-stranded DNA oligomers were added to an equivalent amount of the complementary strand, and both duplexes were formed by annealing from 80 °C to room temperature over 2 h. The numbering schemes for the duplexes are shown in Scheme 1 together with a numbering scheme for CBB that follows the conventional Hoechst 33258 naming.

A phosphate buffer containing ethylenediaminetetraacetic acid (EDTA) to complex paramagnetic ions, 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) as a chemical shift reference and NaN_3 as antibacterial agent was added, giving a final concentration in the NMR sample of 10 mM P_i (pD = 7.0), 0.025 mM EDTA, 0.1 mM DSS, and 0.01 mM NaN_3 in 500 μL of 99.96% D_2O (from Cambridge Isotope Laboratories). The concentrations of the single-stranded DNA were determined by UV absorption and the complementary stands were added to yield a concentration of 2 mM. For experiments in H_2O, a mixture of 90% H_2O/10% D_2O (500 μL) were used. A CBB stock solution was prepared in 99.96% D_2O and neutralized with 100 mM NaOD. CBB was titrated into the A_5 duplex DNA sample in approximately 0.4 mol of equiv/addition. The sample was slightly undertitrated (<5% free duplex) because a slight overtitration resulted in line broadening. The sample remained stable for months.

NMR Experiments. All NMR experiments on the DNA−CBB complex were performed on a Varian Unity 500 MHz NMR spectrometer and a Varian INOVA 800 MHz NMR spectrometer. NOESY spectra in D_2O were acquired with a mixing time of 100 and 200 ms using 2048 complex points in t_2 and a spectral width of 5000 Hz for a total of 512 t_1 experiments with 64 scans each at 298 K and at 308 K. An additional NOESY spectrum in D_2O was acquired at 800 MHz with a mixing time of 200 ms using 4096 complex points in t_2 and a spectral width of 8000 Hz for a total of 600 t_1 experiments with 48 scans each at 280 K. NOESY spectra in H_2O were acquired using 2048 complex points and a spectral width of 10000 Hz using a WATERGATE-NOESY (Piotto et al., 1992).

TOCSY experiments in D_2O were acquired with mixing time of 90 ms using 2048 complex points in t_2 and a spectral width of 5000 Hz with total of 512 t_1 experiments with 64 scans each. DQF−COSY experiments in D_2O were acquired using 2048 complex points in t_2 and a spectral width of 5000 Hz with total of 1024 t_1 experiments with 64 scans each. ^{1}H-^{13}C HSQC experiments were collected at natural abundance with 2048 complex points in t_2 using a spectral width of 5000 Hz; 660 t_1 experiments with 48 scans were recorded.

The acquired data were processed using FELIX (Version 97.2, Biosym/MSI, San Diego, CA). The free induction decays were apodized with skewed sine bell squared functions. The B-DNA resonances were assigned in the conventional way as described in the literature (Wijmenga and van Buuren, 1998). Assignment of the CBB resonances with the drug bound to DNA closely resembles the strategy described for Hoechst 33258 and an analogue (Fede et al., 1991; Bostock-Smith et al., 1998) for the aryl-bis-benzimidazole body and the flexible dimethylamino-propylamide linker was assigned nonstereospecifically using a combination of COSY, NOESY, and HSQC spectra.

Molecular Modeling. Molecular modeling was carried out on a Silicon Graphics O_2 with AMBER 6 (Case et al., 1999) software and employing the AMBER 94 force field. The starting canonical Arnott B-DNA models of the A_3T_3 and A_5 duplex were generated with the NUCGEN module. The CBB molecule was built in the XLEAP module, and missing force-field parameters were then estimated from the values of similar fragments and was then energy-minimized. The electrostatic potential was calculated with the HF/6-31G* basis set for the entire molecule using the Gaussian 94 program (Frisch et al., 1995), and the atomic centered charges were fitted to the electrostatic potential using the RESP module. CBB was then docked manually in the B-DNA minor groove using the XLEAP module of AMBER. A total of 70 intermolecular CBB−A_5 distance restraints and 61 CBB−A_3T_3 distance restraints were derived from NOESY data. NOE cross-peaks were classified semiquantitatively into three categories relative to the cytosine H5−H6 cross-peak volume: strong (1.8−2.5 Å), medium (2.5−3.7 Å), and weak (3.7−5.5 Å). A set of 30 structures was generated for each complex with the following protocol: An initial energy minimization was followed by 14 ps restrained molecular dynamics beginning at 400 K for a 4 ps period before cooling to 300 K in two 50 K steps. The outcome of this procedure was then energy minimized to a maximum derivative of 0.01 Å. As a further test, the experimental distance restraints were weighted with a force constant of 20 K cal Å^{-2} mol^{-1} and all of these restraints were fulfilled within 0.1 Å in the final models.

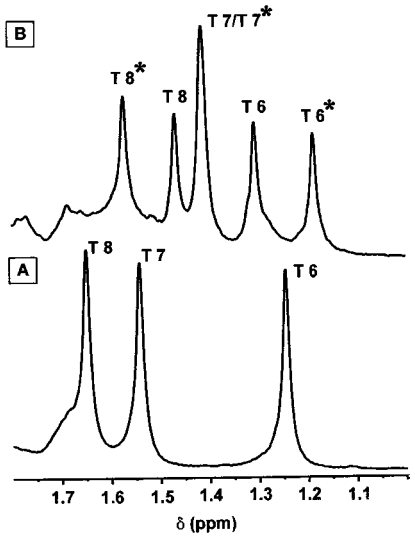

Figure 2. 1D ^{1}H NMR spectra of the thymine methyl region of (A) ligand-free A_3T_3 and (B) of the A_3T_3 complex with CBB. The thymine methyl proton resonances on the two strands are identical in the palindromic A_3T_3 duplex, but the symmetry is broken by the binding of CBB as evidenced by the appearance of a set of thymine methyl resonances for each strand (cf. Scheme 1).

The drug was docked in five different starting positions (∼1 bp apart) to ensure that the binding site was not an artifact of a local minimum energy starting structure and then submitted to the same RMD protocol and energy minimization, and all five ended in the same family of structures as the 30 others.

RESULTS

NMR Titration. One-dimensional ^{1}H NMR spectra were recorded at 298 K during the titration of the two duplexes with CBB, and they showed that the ligand forms a well-defined 1:1 CBB/duplex stoichiometry complex with fairly narrow lines (7 Hz) in both cases. Only a single form of complex was seen during the titration and CBB dissociates slowly on the NMR time scale from the duplex as evidenced by two distinct sets of DNA resonance lines from free and complexed DNA. In both cases, the asymmetric CBB binds to a single site which in the case of A_3T_3 breaks the dyad symmetry of the duplex leading to a doubling of the oligonucleotide resonances. The methyl region, shown in Figure 2, gives a very clear illustration of the symmetry breakage where the three thymine methyl resonances of the symmetric ligand-free A_3T_3 duplex are split into five distinct resonances in the final 1:1 complex. Only one set of resonances from CBB was observed during the titration to A_5 indicating that CBB binds with an orientational preference in the asymmetric AT-tract.

Characterization of the CBB−DNA Complexes. The assignment of resonances for the DNA and ligand followed the conventional approach using a combination of TOCSY and COSY for identifying deoxyribose and CBB spin systems and NOESY for establishing the sequential connectivity (the sequential $H1'_{(n-1)}$ − H6/H8$_{(n)}$ − $H1'_{(n)}$ connectivity pattern is shown in Figure 3). To resolve overlap and to obtain the largest possible number of unambiguous assignments, the spectra were acquired at several temperatures. A ^{1}H-^{13}C HSQC provided valuable information for resolving overlapping H2′/H2″ and dramatically upfield shifted H4′ resonances. The noncovalent binding of CBB to the duplex induces large changes in the DNA resonances and the perturbations

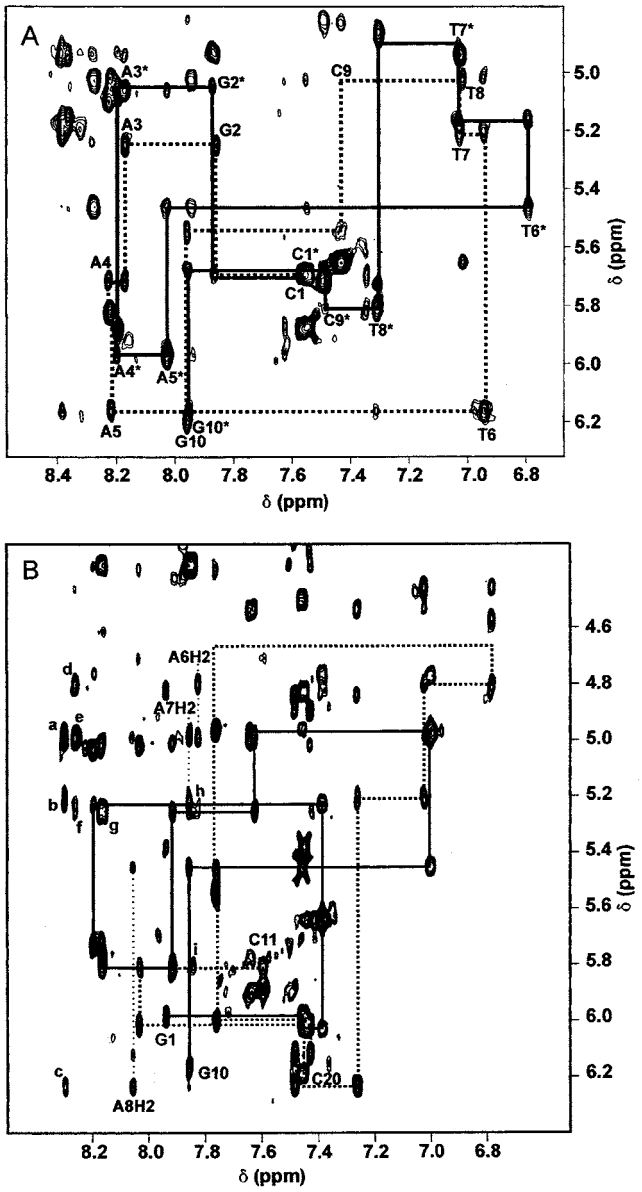

Figure 3. (A) The aromatic to H1′ region of an 800 MHz NOESY spectrum (mixing time of 200 ms) of the CBB−A_3T_3 complex at 280 K. The full sequential $H1'_{(n-1)}$ − $H6/H8_{(n)}$ − $H1'_{(n)}$ connectivity pattern is shown with solid lines for unprimed strand and with dashed lines for the other strand. (B) The aromatic to H1′ region of a 500 MHz NOESY spectrum (mixing time of 200 ms) of the CBB−A_5 complex at 308 K. The sequential $H1'_{(n-1)}$ − $H6/H8_{(n)}$ − $H1'_{(n)}$ connectivity pattern is sketched with solid lines for the A-strand and with dashed lines for the T-strand. The connectivity between T17−G18 is missing due to presaturation of water but is assignable at lower temperatures. A few NOE cross-peaks between CBB and the DNA are highlighted and assigned as follows: (a) H4″-A8H1′, (b) H4″-T15H1′, (c) H4″-T14H1′, (d) H4′−T17H1′, (e) H4′−A7H1′, (f) H4-A6H1′, (g) H3/H5-A6H1′, (f) H2/H6-A6H1′, and (i) H2/H6-A5H1′. Furthermore, NOE connectivities to A6H2, A7H2, and A8H2 are indicated with thin dotted lines.

to the proton chemical shifts ($\Delta\delta = \delta_{DNA-CBB} - \delta_{DNA}$) are shown in Figure 4. The greatest perturbations were observed for the deoxyribose H1′ and H4′, which are located in the minor groove, but significant (> 0.1 ppm) shifts were observed for other DNA protons as well. The chemical shift perturbations are quite similar for the two duplexes, and the pattern indicates that CBB spans 4−5 base pairs. The chemical shift changes for the A_3T_3 H6/H8 and H1′ protons are very much like those of an analogue complex with a Hoechst analogue (Bostock-Smith and Searle, 1999). For the palindromic A_3T_3, the perturbations seem to be particular pronounced for the thymine resonances, and the symmetric pattern suggests that the ligand binds centrally across the dyad axis of the duplex. For A_5, the perturbations are most pronounced for the residues on the A-strand toward the 3′-end of the A-tract, but 2−3 residues earlier the ligand causes the greatest perturbations for the thymines of the T-strand. A very similar chemical shift perturbation pattern is observed for the minor groove binding of SN-6999 to an A_5 binding site (Rydzewski et al., 1996). This strand crossing behavior is seen for a number of minor groove binders and simply reflects that these residues are close in space. The close proximity of the groove walls to CBB causing the dramatic ring current induced upfield shift of H4′ indicates that the ligand penetrates deeply into the minor groove and has close contacts with the walls. The chemical shift changes can be rationalized on the basis of the model where the aromatic rings of CBB are inserted edge-on into the minor groove as illustrated in Figure 8. The H1′ and H4′ resonances (situated at the walls of the minor groove) experience large upfield shifts because they are positioned perpendicular to the ring-plane of the ligand, while the H2 resonances (located at the floor of the minor groove) experience large downfield shifts because they are positioned parallel with the ring plane.

The NOESY data acquired in D_2O and H_2O contain a very large number of intermolecular NOE contacts between ligand protons and DNA sugar and adenine H2 protons, a few of which are shown in Figure 5. These connectivities show that the ligand is bound in the minor groove in agreement with the chemical shift perturbations. NOEs between adenine H2 protons and H1′ protons of the base pairing thymine indicate a narrow minor groove. The orientation of CBB within the A-tract is unambiguously defined by the pattern of NOEs to the floor of the minor groove as indicated in Figure 5: NOEs from the aryl H2/H6 to A4H2 places the NH_2-end of CBB at the 5′-end of the A-tract and the contacts to H2 can be followed along CBB to the A8H2 at the 3′-end of the A-tract. The ligand is situated with the bis-benzimidazole-carbonyl at the 3′-end of the A-tract and the flexible dimethylamino-propylamide extending into the GC region as indicated by a number of NOE connectivities (e.g., *N*-methyl to C9H1′ and G10H1′). No resonances were observed that could be attributed to a complex with the CBB-ligand binding in the opposite direction, and therefore the orientational preference is estimated to be larger than 20:1.

Molecular Modeling. Molecular models of the CBB complexes with the asymmetric A_5 and the symmetric A_3T_3 were generated by restrained molecular dynamics followed by restrained energy minimization using semi-quantitative NOE-derived distance restraints. The models indicate that CBB penetrates deeply into the A-tract with each of the aromatic rings almost parallel to the walls of the groove. Of the 30 models, the 15 with lowest energy were selected for further analysis. The DNA duplex retains an overall right-handed B-DNA conformation in both complexes in accordance with the cross-peak pattern of the DQF−COSY spectra that clearly indicate a B-type DNA-conformation [$J_{1'2'} > J_{1'2''}$] for all residues except the terminal ones.

Intermolecular hydrogen bonds were assigned using the CARNAL module of AMBER for the labile protons on the ligand on the basis of the models (only H3′, H3″, and H_A showed unambiguous bonding partners in all

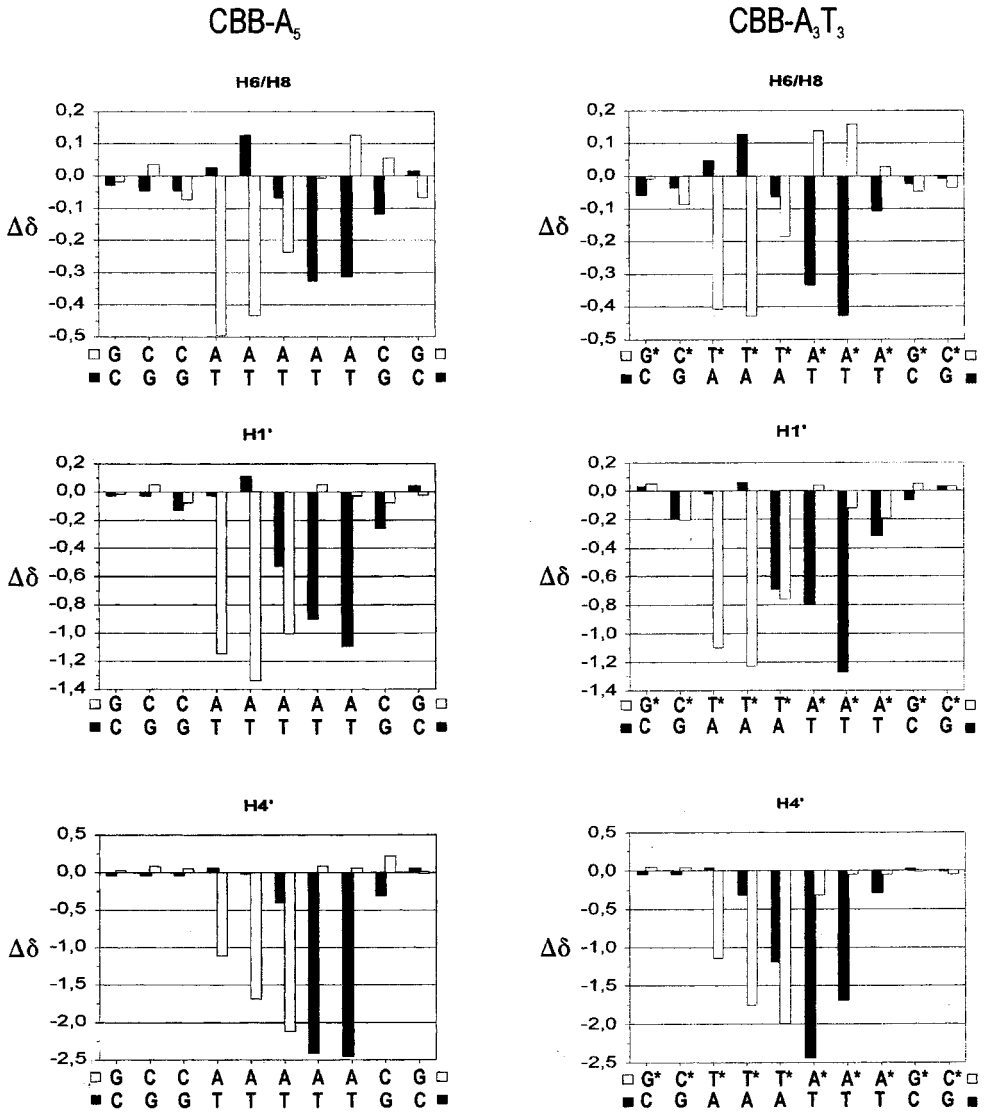

Figure 4. Chemical shift changes in ppm of the H6/H8 aromatic, H1′ and H4′ deoxyribose A_5 (A) and A_3T_3 (B) protons induced by the binding of CBB. The change in proton resonances for each residue is shown with the empty bars corresponding to the first sequence underneath the graph and the black bars to the lowest sequence. The two NOE-based models are consistent with the chemical shift perturbations as illustrated in Figure 8.

models). As indicated in Scheme 2 the protons are engaged in bifurcated cross-stand hydrogen bonds involving the adenine N3 and thymine O2 as hydrogen-bond acceptors.

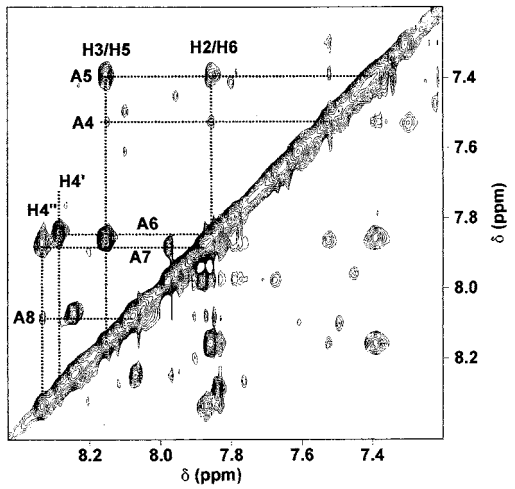
Both models exhibit a sequence-dependent minor groove width. The average phosphate−phosphate interstrand distance minus the van der Waals radius of phosphorus (5.8 Å) is shown in Figure 7. To assess the resulting models, the minor groove width for a number of related crystallographic structures containing the central 5′-A_3T_3-3′ sequence is shown in Figure 7 with a structure of the native DNA (Edwards et al., 1992), two Hoechst complexes (Spink et al., 1994; Vega et al., 1994) and a distamycin complex (Coll et al., 1987).

DISCUSSION

Extensive studies have made it increasingly clear that the minor groove width is very sequence dependent and that segments of DNA containing four or more consecutive A bases (A-tracts) exhibit a characteristic narrowing of the minor groove. NMR studies have shown that the minor groove becomes increasingly narrow in the 5′−3′ direction of an A-tract reaching a lower plateau after approximately four adenines (Chuprina et al., 1991; Katahira et al., 1990; Nadeau and Crothers, 1989). The minor groove is narrowest at the center of the symmetric sequence A_3T_3, while the A_5 has the smallest minor groove width at the 3′-end of the A-tract. These structural characteristics have been corroborated by a number of observations:

(i) The binding mode of distamycin has been shown to be very sensitive to the width of the minor groove (Pelton and Wemmer, 1989); depending on the sequence of the target duplex DNA distamycin can form either a 1:1 complex or a cooperative side-by-side binding 2:1 complex. For sequences with five or more consecutive AT bases that have narrow minor grooves (e.g., A_5) only 1:1 binding stoichiometry complexes are formed, while sequences with broad minor grooves (e.g., ATATA) only form 2:1 complexes.

(ii) Recent NMR studies by Feigon et al. (Hud et al., 1999) have shown that ammonium ion binding is most favored in the narrowest region of the A-tract minor groove, which turned out to be at the center for d(5′-GCA_4T_4GC-3′)$_2$ and at the 3′ end for the d(5′-GCA_5CG-3′):d(5′-CGT_5CG-3′) sequence.



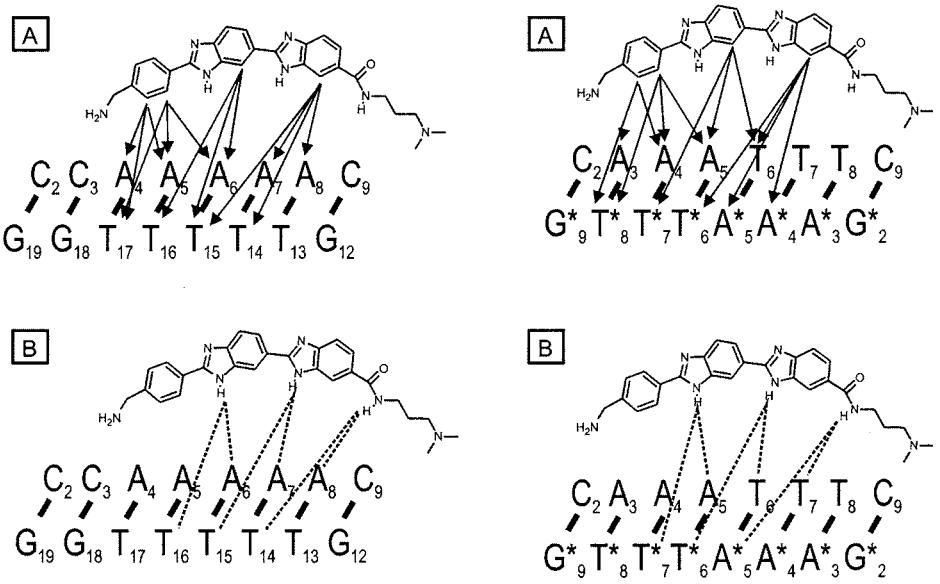


Figure 5. An excerpt of the 200 ms NOESY spectrum at 800 MHz and 280 K showing the aromatic region of the CBB-A_5 complex. The connectivities between the ligand and the adenines H2 protons at the floor of the minor groove can be followed along the A-tract beginning with connectivities between A4H2 and A5H2 to the H2/H6 and H3/H5 aryl protons, A6H2 to H4′ benzimidazole proton and then A7H2/A8H2 to H4″ benzimidazole proton. This unambiguously demonstrates that CBB binds with an orientational preference to the A-tract.

The minor groove width of the models conform very well with the above-mentioned sequence dependence. In the case of A_3T_3, a fairly large number of X-ray structures are available for the related dodecamer d(5′-CGCA_3T_3GCG-3′)$_2$, and there seems to be only fairly small variations in minor groove width from the native dodecamer (Edwards et al., 1992) to the three minor groove binding complexes of Hoechst 33258 (Vega et al., 1994; Spink et al., 1994) and distamycin (Coll et al., 1987). We have not found any obvious structures to compare A_5 with but the two A-tract X-ray structures (DiGabriele et al., 1989; DiGabriele and Steitz, 1993) have minor groove widths that lie within the error bars. Crystal packing forces are always a concern for X-ray structures, but the decrease in minor groove width also follows the pattern for the solution state duplexes found by NMR (Katahira et al., 1990; Nadeau and Crothers, 1989).

The features of the models are in accordance with other observations. Cross-peaks between an adenine H2 and the deoxyribose H1′ of the 3′-neighbor residue on the same strand and the 3′-neighbor of the base pairing residue on the complementary strand are indicative of a narrow minor groove (Chuprina et al., 1991; Katahira et al., 1988). For A_5, these cross-peaks become larger toward the 3′-end (A6H2, A7H2, and A8H2 have fairly large cross-peaks as can be seen in Figure 3) and for A_3T_3 it is especially large for A5H2 and A5*H2 at the center of the duplex. The propeller-twist angles are known to be fairly large at A-tracts and can be estimated from the NOEs between the thymine imino proton and the H2 of the base pairing and 3′-neighboring adenines (Katahira et al., 1988). The relative intensities had a value of around 1:0.4 in the H_2O−Watergate−NOESY spectra for the resolved pairs in CBB−A_5 and CBB−A_3T_3 complexes, which suggests a relatively large propeller-twist angle of about 17° according to Katahira (Katahira et al., 1990).

In the A_3T_3−CBB model, the ligand binds with the bis-benzimidazole moiety at the center of the binding site, which is where the minor groove is at its narrowest. This does not agree particularly well with the two X-ray structures of Hoechst 33258 in a A_3T_3-site: In one, the ligand is displaced somewhat off-center with the piperazine ring moving toward the broader part of the minor groove end of the dodecamer (Vega et al., 1994) and in the other Hoechst is further displaced and binds across the ATTTG sequence (Spink et al., 1994). The position of CBB is altered somewhat from that of Vega et al. (Vega et al., 1994) where the first benzimidazole after the phenyl group makes bifurcated hydrogen bonds to the two thymine O2 across the central ApT step. In the model of CBB, it is the second benzimidazole from the N-terminus that forms hydrogen bonds across the center as indicated in Scheme 2. In the X-ray structure of Spink et al. (Spink et al., 1994), the piperazine group is shifted even further down toward the 5′-end. However, these structures are a bit at variance with two NMR-studies: An analogue of Hoechst 33258 was found to bind at the center of a A_3T_3 binding site (Bostock-Smith and Searle, 1999) and Hoechst 33258 binds at the center of the longer A_4T_4 binding site (Higgins and Searle, 1999). The models

Scheme 2. (A) Schematic Representation of the CBB−A_5 and CBB−A_3T_3 Complexes with a Few of the Observed Intermolecular NOE Connectivities Observed between the Minor Groove Binding Ligand and the Duplexes. (B) On the Basis of the Models, the Bifurcated Hydrogen Bonds between CBB and the Thymine O2 or Adenine N3 at the Floor of the Minor Groove Are Indicated with Dashed Lines

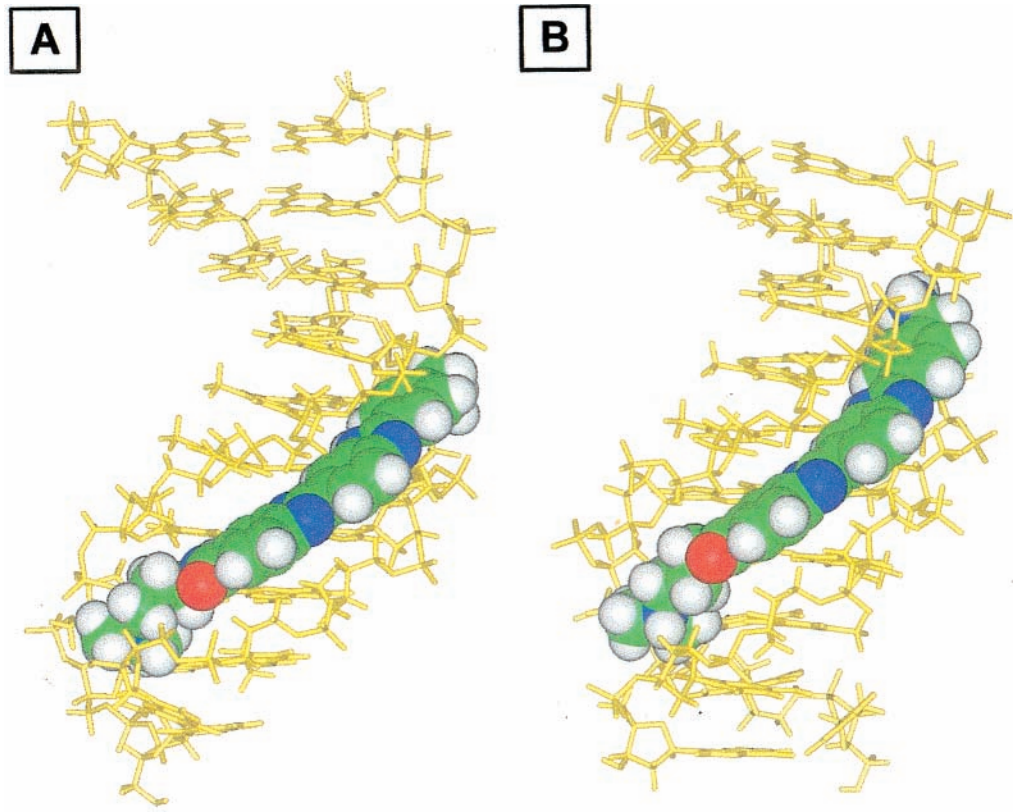

Figure 6. NOE-based models of the (A) CBB−A_5 and (B) CBB−A_3T_3 complexes obtained by restrained molecular modeling viewed into the minor groove. The CBB ligand, shown in a spacefilling CPK mode, fills the minor groove and binds at the center of the A_3T_3 decamer but is displaced toward the 3′-end of the A-tract for the A_5 decamer.

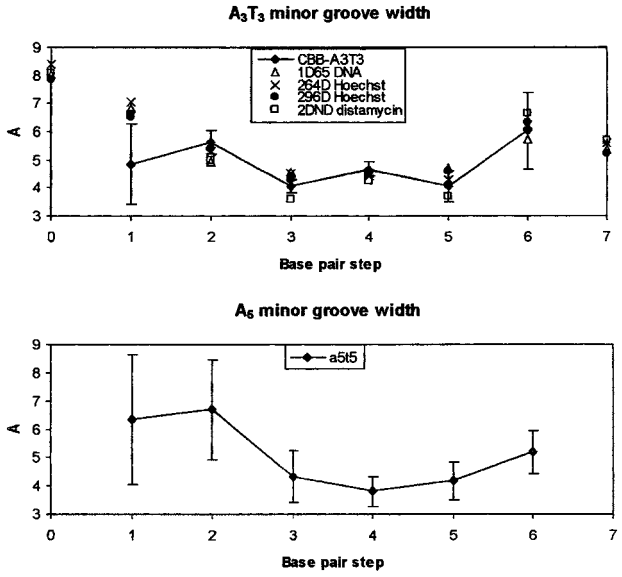

Figure 7. The average minor groove width of the (A) CBB−A_5 and (B) CBB−A_3T_3 complex for the model-ensemble shown together with that of a B-DNA dodecamer $(CGCA_3T_3GCG)_2$ a few analogous minor groove binder complexes (named by the PDB accession code) containing the A_3T_3 binding site. The error bars represent 1 standard deviation for the NOE-RMD derived ensemble.

of the CBB complexes may be sound enough despite this controversy, because the exact position of the Hoechst ligand depends strongly on the DNA conformation and in turn is dependent on the crystal packing as illustrated by a recent set of X-ray diffraction structures of *m*-iodo Hoechst analogue DNA complexes (Squire et al., 2000). On dehydrating the crystals the minor groove becomes increasingly narrow and in response to the changing DNA conformation the Hoechst analogues migrate about 3 Å along the groove—mainly to accommodate the bulky piperazine group in the wider part of the minor groove.

The minor groove width of the crystal structure of ligand free A_3T_3 is very similar to several drug−A_3T_3 complexes, and it seems that the binding of Hoechst 33258 does not perturb the structure greatly. This would suggest that the binding of Hoechst 33258 is more of a "lock-and-key" type of process than an "induced-fit". In both A_3T_3 and A_5, the drug molecule binds to the narrowest part of the AT-region of the ligand free DNA. However, an NMR study by Searle with a recent NMR solution structure has found the binding at the two sites of $d(5'\text{-CTTTTGCAAAAG-}3')_2$ (Searle and Embrey, 1990; Gavathiotis et al., 2000) is highly cooperative with only the 2:1 complex detected in equilibrium with the free duplex. No evidence was found of an intermediate 1:1 complex, and this was taken as conclusive evidence of cooperative binding. This cooperative binding is distinctly different from the side-by-side-binding of distamycin, and it is difficult to envision a mechanism by which the binding of one Hoechst molecule in one end of the DNA strand should facilitate the binding of yet another Hoechst molecule at the other end of the DNA strand.

The binding site placements of CBB seem fairly rationalizable in terms of binding site properties. A calorimetric study has shown that the major driving force for Hoechst 33258 is the hydrophobic transfer of the dye from solution into the binding site with a relatively minor contribution from hydrogen bonding and van der Waals contacts (Haq et al., 1997). How one can distinguish between hydrophobic interactions (dependent on changes in solvent-accessible surface area) and van der Waals interaction (depending on the number of close contacts) is not quite clear because the two contributions seem to be fairly

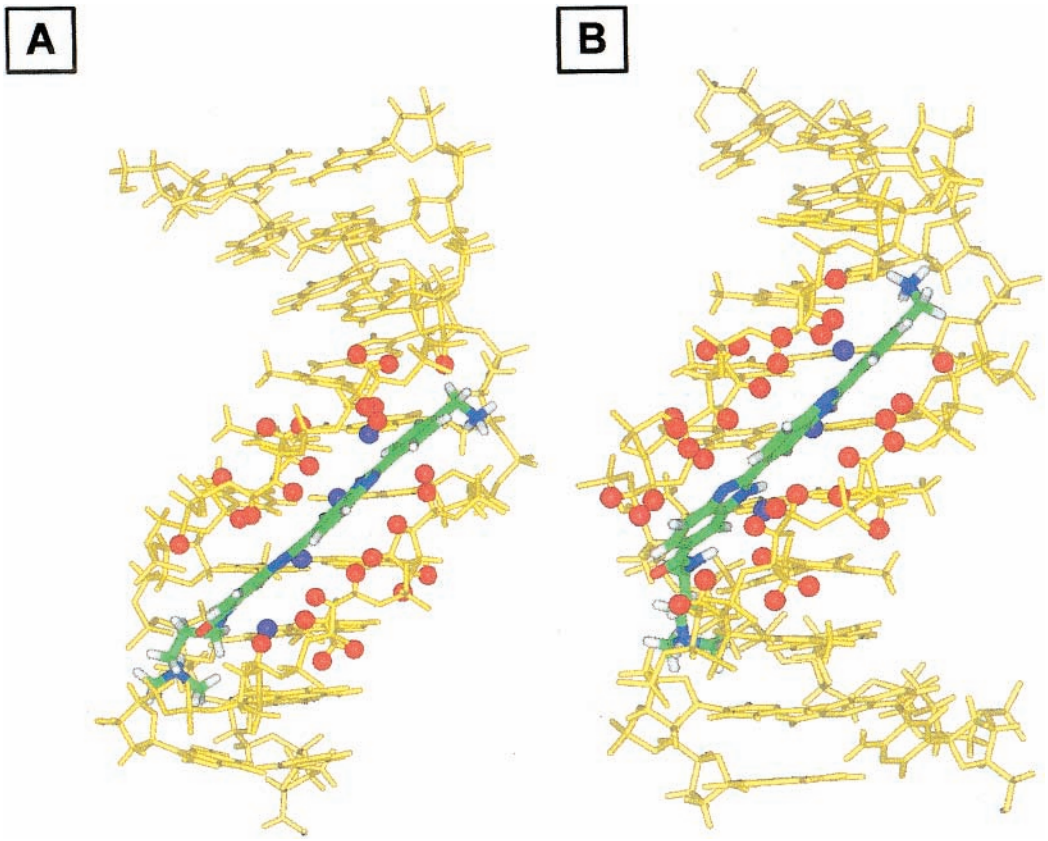

Figure 8. The NOE-based models of the (A) CBB−A_5 and (B) CBB−A_3T_3 complexes highlighting the nonexchangeable protons experiencing an upfield shift greater than −0.5 ppm (in red) or a downfield shift larger than 0.4 ppm (in purple).

correlated. Either way, the snug binding of CBB to the narrowest part of the minor groove can be rationalized either by invoking close van der Waals contacts between CBB and the minor groove walls or by pointing out that the narrower part of the minor groove offers the best possibility of reducing the solvent accessible surface.

The models do the dynamic features inherent in the NMR data less than justice. Resonance averaging is observed for the H2/H6 and H3/H5 aryl protons. A conservative guess on the chemical shift difference between the protons facing the minor groove and the protons facing the solvent would be about 2 ppm; because the chemical shift difference between the free and bound aryl resonances is in excess of 1 ppm for both proton pairs and assuming the solvent exposed protons to be too far away from the aromatic bases to experience significant deshielding means that the inner edge protons should experience a downfield shift of about 2 ppm. This chemical shift difference is averaged by ring rotation even at 280 K at 800 MHz, which suggests that the aryl-ring rotation rate is greater than 1500 s^{-1}. The rate of dissociation of CBB from the complex is estimated to be much slower than the ring-flipping motions. This has also been observed for Hoechst where an estimated ring flipping rate greater than 1000 s^{-1} (Embrey et al., 1993) is much faster than the rate of dissociation estimated to be 2.2 s^{-1} for GAATTC (Fede et al., 1991) and 1.3 s^{-1} for TAATTA (Embrey et al., 1993). It is difficult to reconcile the static model with the aryl-group fitting snugly in the minor groove and the rapid ring-flipping which must happen while CBB is bound to the DNA strand. The averaging of the aryl-group proton resonances suggests that the close van der Waal contacts indicated by the models do not constrain the rotation of the aryl-group, which, in effect, represents a quite bulky moiety.

The CBB binds to the A_5-tract with a larger than 20:1 orientational preference with the aryl-group pointing toward the 5′-end of the A-tract and the dimethylaminopropylamide group at the 3′-end. Hoechst 33258 is also known to bind to A-tracts with a considerable orientational preference with the piperazine group pointing toward the 3′-end (Searle and Embrey, 1990; Hawkins et al., 2000) i.e., with the opposite orientational preference compared to CBB. The orientational preference of Hoechst has been attributed to the sterically bulky *N*-methyl piperazine ring exerting a degree of orientational selectivity by preferring to bind in the wider minor groove of the 5′-end of an A-tract. In CBB, the bulky piperazine group has been replaced with the dimethylaminopropylamide group and still binds with an orientational preference, only that it is opposite that of Hoechst.

Distamycin was found to bind with a strong orientational specificity (>20:1) to an A-tract with the cationic amidine terminus directed toward the 3′-end of the A-tract (Hawkins et al., 2000). Replacement of the charged dimethylaminopropylamide tail group in a side-by-side binding lexitropsin polyamide with an uncharged ethoxyamide group lead to a decrease in orientational specificity (White et al., 1997). Thus, the altered orientational specificity of CBB from Hoechst could to some extent be attributed to the presence of the same cationic tail, but the arylamino group is most likely also protonized so charge cannot be the sole determinant. Another part of the explanation could be that the hydrogen bonding possibilities were better at the 3′-end of the A-tract. Associated with the very narrow minor groove is a high propeller twist for the bases, and a high propeller twist could be favorable for the formation of cross strand bifurcated hydrogen bonds because the

adjacent minor groove hydrogen bond acceptors (either adenine N3 or thymine O2) come into close proximity. Therefore, the hydrogen bond donors of the ligand are situated in the regions where the minor groove width is at its narrowest giving the orientational preference. Placing the cationic end group in the negative electrostatic potential of the A-tract will certainly also be energetically favorable (Gavathiotis et al., 2000).

A DNase I footprinting study (Abu-Daya et al., 1995a) has shown that while planar minor groove binding agents (e.g., distamycin, netropsin, berenil) all prefer AAAA over AATT binding sites, Hoechst 33258 prefers AATT; this could indicate that a broader minor groove is needed to accommodate the bulky piperazine and the narrowest part of the minor groove seems to interact with the benzimidazoles. A_4 offers the narrowest minor groove and thus the best van der Waals contacts but Hoechst 33258 cannot make hydrogen bonds with the bulky piperazine and phenol group at the 3′-end where the bifurcated hydrogen bonding opportunities are best. In AATT, the best bifurcated hydrogen bonding possibilities are at the center where the benzimidazoles have easy access.

The NOE connectivities for CBB-A_5 unambiguously orients the ligand with the aryl NH_2 -terminus at the broader 5′-end of the A-tract and the amide-end at the 3′-end, and it demonstrates the utility of NMR structural information. In the case of nearly symmetrical minor groove binders with narrow cross-sections, it is difficult to get the resolution of the X-ray data high enough to determine the orientation of the ligand from the electron density maps. The two NOE derived models do not have the structural resolution of an X-ray structure, but they do define a solution state binding site, unbiased by crystal packing forces, that seems to correlate well with the minor groove width.

ACKNOWLEDGMENT

We thank The Instrument Centre for NMR-Spectroscopy of Biological Macromolecules at The Carlsberg Laboratory, Copenhagen, granted by The Danish Natural Science Research Council for providing spectrometer time at the 800 MHz spectrometer. Finally, financial support from The Danish Natural Science Research Council and The Technical Research Council is acknowledged.

Design and Formulation of Polyplexes Based on Pluronic-Polyethyleneimine Conjugates for Gene Transfer

Catherine L. Gebhart,*,† Srikanth Sriadibhatla,† Sergey Vinogradov,† Pierre Lemieux,‡ Valery Alakhov,‡ and Alexander V. Kabanov*,†

Department of Pharmaceutical Sciences, College of Pharmacy, 986025 Nebraska Medical Center, Omaha, Nebraska 68198-6025, and Supratek Pharma Inc., c/o Armand-Frappier Institute, Laval, PQ, Canada. Received January 14, 2002; Revised Manuscript Received May 15, 2002

Previously, we reported the evaluation of several polyplex-based gene delivery systems with respect to their effectiveness, toxicity, and cell type dependence in vitro. One system, P123-g-PEI(2K), a cationic graft block copolymer, is of particular interest as it has been demonstrated to successfully deliver genetic material to murine liver following systemic delivery [Nguyen, H. K., Lemieux, P., Vinogradov, S. V., Gebhart, C. L., Guerin, N., Paradis, G., Bronich, T. K., Alakhov, V. Y., and Kabanov, A. V. (2000) Evaluation of Polyether-Polyethyleneimine Graft Copolymers as Gene Transfer Agents. *Gene Ther. 7,* 126−138 (*1*)]. The P123-g-PEI(2K) system requires nonmodified Pluronic P123 as an excipient to stabilize the dispersion. The purpose of the current work was to more closely characterize this system, to assess the role of each component of the system to the overall transfection process. We evaluated particle size, stability, and resistance to nuclease degradation. In addition, cellular uptake and localization of plasmid, as well as transgene expression, were evaluated following in vitro transfection of prostate cancer cells (PC-3) with various individual components of the system. Nonmodified Pluronic alone did not significantly enhance DNA uptake, transgene expression, or DNase protection. Therefore, we conclude that nonmodified Pluronic acted primarily by optimizing the size of the polyplex. Furthermore, though this system displays several characteristics thought desirable of a nonviral gene delivery system, these studies did discriminate a potential limitation of this system for in vivo applications, namely, the insufficient level of protection of plasmid DNA from nuclease degradation. This may limit the effective dose delivered, as well as limiting the effective circulation time. These studies provide vital information that will guide modification of this system to enhance the current in vivo profile.

INTRODUCTION

Nonviral vectors for gene delivery are rapidly gaining increased interest. Researchers are increasingly aware of the potential advantages of these nonviral systems over the currently investigated viral systems, in respect to their safety, production, and versatility (*2*). Complexes of DNA and polycation ('polyplexes') represent one such class of nonviral gene delivery systems that has recently generated significant interest for gene delivery applications (*3*−*5*). The first generation of polyplexes, based on homopolymers, that were developed as gene therapy vectors performed well in vitro, yet suffered from several drawbacks when tested in vivo, primarily due to the fact that they were often poorly soluble, resulting in aggregation in the lung and consequently in pulmonary embolism [reviewed in (*6*)]. Additionally, although a substantial portion of the dose accumulated in the liver, this was primarily the result of uptake by Kupffer cells and did not result in proportionately significant transgene expression. Therefore, several investigators in the area proposed a promising approach to overcome this problem, resulting in the creation of a second generation of polymeric systems. This approach involved the linkage of the polycation to a nonionic water-soluble polymer, resulting in a carrier with a block or graft copolymer architecture, which, upon mixing with DNA, formed soluble DNA delivery vectors. Several such systems have recently been described (*7*−*11*).

One promising type of system reported recently represents graft copolymers that employ Pluronics as the nonionic water-soluble segment, specifically P123-g-PEI(2K), which is a graft copolymer of a 2 kDa polyethyleneimine (PEI) and Pluronic P123 (*1*). Pluronics are poly(ethylene oxide)−poly(propylene oxide) block copolymers that possess the unique ability to incorporate into cell membranes as a result of the presence of the hydrophobic poly(propylene oxide) (PPO) chain (*12*). This is believed to enhance cell interactions, DNA transport, and transgene expression using such polyplexes (*1*). Initial studies determined that this system required the addition of nonmodified Pluronic P123 as an excipient in order to stabilize the dispersion (*1*). Once this was done, the system exhibited improved dispersion stability and improved in vivo biodistribution compared to unmodified PEI. In fact, this system was able to successfully deliver genetic material to the liver of mice following systemic administration (*1*).

The current work represents an expansion upon the initial characterization of the cationic graft copolymer system, P123-g-PEI(2K), with the goal to develop a better understanding of this multicomponent delivery system.

The obtained knowledge can then be applied both toward the improvement of the current system and toward the development of additional novel graft copolymer systems. Complete understanding of this P123-g-PEI(2K) system is particularly important in light of the fact that Pluronics are known to exhibit biological activity, including effects on cell membrane properties as well as effects on gene promoters (*13, 14*).

The P123-g-PEI(2K)-based gene delivery system is a self-assembling system, a characteristic that lends a large degree of freedom to the formulation of the polyplexes. This provides for 'built-in' versatility, specifically, the potential to replace or modify individual components of the system to enhance the system for a particular application. For example, there exists a wide array of Pluronic formulations, varying in their hydrophilic/lipophilic characteristics, that could potentially be utilized in place of the originally employed Pluronic P123. For the purposes of this study, we considered reformulation of the system with nonmodified Pluronic F127. This decision was made because: (1) though Pluronic F127 is more hydrophilic than Pluronic P123, the solubilization properties of the two Pluronics are relatively similar (*15*); and (2) Pluronic F127 is approved for use in current pharmaceutical preparations, and therefore the toxicological studies have been completed, a fact that could expedite further in vivo development.

We evaluated particle size and dispersion stability as well as the resistance of incorporated DNA to nuclease digestion in cell-free systems. In the prostate carcinoma cell line PC-3, we examined plasmid DNA (pDNA) uptake and cellular localization, as well as expression of a reporter construct following in vitro transfection with various polyplex formulations as well as with individual components of this delivery system. We determined that nonmodified Pluronic, when combined with naked plasmid DNA, did not significantly enhance the cellular uptake of the DNA, the expression of the encoded reporter gene, or the protection of DNA from nuclease digestion. We conclude that the addition of nonmodified Pluronic to the formulation of the graft copolymer-based polyplexes acted to improve the gene transfer profile of the system primarily by optimizing the size and stability of the polyplex, as well as delivery of the DNA within the cell. These studies provide valuable information regarding the design and formulation of stable and effective gene delivery particles.

EXPERIMENTAL PROCEDURES

Materials. P123-g-PEI(2K) was synthesized by grafting Pluronic P123 to the amino groups of PEI, as described previously (*1*). Briefly, 1,1′-carbonyl-diimidazole-activated Pluronic P123 was reacted with PEI, 2 kDa, to yield a copolymer with a molecular mass of 25 kDa and an average of 3.2 P123 chains per 1 PEI chain. Nonionic block copolymers Pluronic P123 and Pluronic F127 were kindly provided by BASF Corp. (Parispany, NJ). The commercial transfection reagent Exgen 500, a 22 kDa linear PEI, was purchased from MBI Fermentas Inc. (Hanover, MD). Luciferase encoding plasmid gWIZLuciferase was purchased from Gene Therapy Systems, Inc. (San Diego, CA). Green fluorescent protein encoding plasmid pIRES-EGFP was purchased from Clonetech (Palo Alto, CA). Both plasmids were expanded in DH5α *E. coli* and isolated using Qiagen endotoxin-free plasmid Giga-prep kits according to the supplier's protocol. The cyanine dimmer dye YOYO-1 was purchased from Molecular Probes.

Cell Culture. PC-3, a human prostrate carcinoma cell line, was kindly provided by Dr. Pi-Wan Cheng (UNMC). Cells were cultured in RPMI-1640 supplemented with 10% heat-inactivated fetal bovine serum (FBS), 10 mM HEPES, and 100 units/mL penicillin/100 μg/mL streptomycin (complete media). Cells were seeded into 12 well plates at a density of 70 000 cells per well, or at 50 000 cells per well in 24 well plates. For confocal microscopy studies, cells were seeded onto untreated glass coverslips at a density of 50 000 cells per coverslip. Cells were allowed to adhere to plates for 24−48 h prior to transfection.

Labeling of pDNA. YOYO-1 is an ultrasensitive high-affinity DNA labeling dye that exhibits a high fluorescence enhancement upon binding to double-stranded DNA. Therefore, it is a valuable tool to study the early phases of cellular transport during transfection. Briefly, 500 μL of gWIZLuciferase (0.1 mg/mL) was combined with 97.5 μL of 10× TAE buffer and 371 μL of 1.0 μM YOYO-1 dye and incubated at room temperature for 1 h in the dark.

Formation of Complexes and Transfection. The precise mixing order is a critical parameter, and was performed according to the following protocol. To a 1.5 mL eppendorf tube were added the following: (1) 45 μL of pDNA (0.1 mg/mL) or 90 μL of YOYO-1-labeled pDNA (0.05 mg/mL); (2) 9 μL of 50 mg/mL Pluronic P123 or 50 mg/mL Pluronic F127 (only to the appropriate samples); (3) 150 μL of DMEM with 1% Hepes; and, last, (4) 13.6 μL of polycation (10 μmol of NT/mL). The tube was vortexed for 30 s immediately following the addition of polycation. The mixture was incubated for 5 min at room temperature, and then 1270 μL of complete media was added. Immediately prior to transfection, culture medium was aspirated from the cells. Then the transfection mixtures were added to each well (250 μL per well for 24 well plates, 500 μL per well for 12 well plates or coverslips). Cells were exposed to transfection reagents for 2 h at 37 °C (5% CO_2) and then rinsed with PBS to remove polyplexes. For expression studies, cells were incubated an additional 20−22 h in complete media. In the case of luciferase expression, cells were then lysed, and luciferase assays were performed using a Promega Luciferase kit according to the manufacturer's protocol (Promega, Madison WI). Protein assays were also performed on lysates using the BCA Protein Assay (Pierce Scientific) to allow normalization of data. Cells on coverslips were rinsed 2 times with PBS, following the 2 h exposure to complexes, fixed for 10 min with 4% paraformaldehyde, and mounted on slides.

Particle Size Measurements. The effective hydrodynamic diameter was measured by photon correlation spectroscopy using a 'ZetaPlus' Zeta Potential Analyzer (Brookhaven Instrument) equipped with the Multi-Angle Option at 22 °C at an angle of 90°. Prior to particle formation, all reagents were passed through a Whatman 200 nm polysulfone filter. Polyplexes were formed exactly as they were for transfections, unless otherwise indicated. The data presented represent the average of five separate 3 min analyses, which allows for assessment of the stability of the system. Unless otherwise indicated, all systems exhibited stable effective diameters over the time course examined. If effective diameters increased during the 15 min period of measurement, these systems were considered 'unstable'.

Laser Scanning Microscopy. A Zeiss Confocal LSM410 (Goettinger, Germany) was used to obtain both DIC and fluorescent images of cells. When obtaining fluorescent images, all samples were excited at 488 nm,

and images were acquired with a brightness setting of 270 and a contrast setting of 9730. This standardization allowed for the quantitative analysis of uptake of YOYO-1 dye. Data were analyzed to quantitate uptake of pDNA by digital contrast enhancement and area measure using the LSM-PC software provided with the instrument.

Flow Cytometry Analysis. The mean fluorescence intensity of trypsinized, paraformaldehyde-fixed PC-3 cells, following a 2 h exposure plus 2 h additional culture, to polyplexes containing YOYO-1-labeled pDNA was obtained by flow cytometry analysis. In a second set of experiments, the percentage of PC-3 cells expressing green fluorescent protein (GFP) following transfection with pIRES-EGFP-containing polyplexes was also assessed by flow cytometry. The analysis for both sets of experiments was performed using a Becton Dickinson FACStarPlus flow cytometer operating under Lysis II (San Jose, CA), equipped with an argon ion laser (488 nm emission wavelength). The filter used for emission was a 530/30 nm band-pass. Data acquisition was performed in the linear mode, and data were visualized in the logarithmic mode. Dead cells were discriminated by a reduction in forward scatter and were excluded from the analysis.

DNase Protection Assay. Resistance to nuclease digestion was determined using a DNase I protection assay. Unlabeled gWIZLuciferase plasmid DNA (0.625 μg) or polyplexes were prepared in a final volume of 25 μL. Then 10 μL aliquots of each sample were placed into two separate tubes. Then 1 unit of DNase I (2 μL) (Promega, Madison, WI) or 2 μL of PBS was added. The samples were incubated for 15 min at 37 °C. Immediately following incubation, all samples were treated with 5 μL of 100 mM EDTA for 10 min to inactivate the DNase. Finally, 10 μL of 5 mg/mL heparin (Sigma, St. Louis, MO) was added to each tube, and tubes were incubated for 2 h at room temperature to allow complete dissociation of complexes. Samples were visualized using 0.2 μg of DNA/lane on an 0.8% agarose gel, stained with ethidium bromide. Images were acquired using an Alpha Imager (Alpha Innotech, San Leonardo, CA) and analyzed using ImageQuant software to obtain data in the form of volume per area.

RESULTS

Particle Size Analysis. The particle size analysis data presented in Table 1 demonstrate the impact of addition of nonmodified Pluronic P123 and the dependence on the order of mixing of the components of the P123-g-PEI(2K) system on the effective diameter of the resulting polyplex. In the absence of nonmodified Pluronic P123, the mixing of P123-g-PEI(2K) with plasmid DNA results in the formation of large, unstable aggregates (ca. 660+ nm). However, by combining plasmid DNA with 0.03% nonmodified Pluronic P123 prior to addition of the graft copolymer, stable particles with effective diameters of approximately 160 nm can be formed. It is important to note, though, that addition of Pluronic P123 after mixing of DNA and graft copolymer is not sufficient, and results in particles that are only slightly smaller than those formulated without the addition of Pluronic P123.

Table 1 is a summary table presenting the results of various assays performed to characterize this complex transfection system, in relation to the commercial transfection reagent Exgen 500. The particle size data introduced in this table present the effective diameters achieved for polyplexes based on Exgen 500, the graft copolymer alone, and the graft copolymer formulated with either 0.03% Pluronic P123 or 0.03% Pluronic F127. Polyplexes based on Exgen 500 and P123:P123-g-PEI(2K) are both within a relatively similar size range, while F127:P123-g-PEI(2K)-based polyplexes are approximately twice as large. Similar experiments were performed in which the concentration of free Pluronic was gradually increased, to determine the amount of Pluronic necessary to stabilize the dispersion. It was determined that 0.03% Pluronic was sufficient to stabilize the system at the pDNA concentrations used for all studies included in this paper (data not shown). It is noteworthy that by this method of analysis, the contribution of the micelles to the light scattering analysis is negligible as the scattering function is proportional to the sixth power of the particle size. The Pluronic P123 micelles are much smaller than the complex particles (20 nm vs 200 nm), and their volume fraction is low at 0.03%, since this is just slightly above the CMC. In fact, in the absence of polyplexes with Pluronic P123 at 0.03%, the micelles are not detected by the instrument (data not shown). However, particles of this size are clearly seen at copolymer concentration of at least 0.5% and above. Finally, it is important to note, that when preparing polyplexes at higher DNA concentrations, as would be needed for certain in vivo studies, additional free Pluronic must be added to the system to maintain the stability of the dispersion. The exact amount of excess required depends strongly on the exact concentration of the pDNA desired and the particular buffer employed. The maximum DNA solubility when formulated in these multicomponent polyplexes is in the range of 0.1−0.5 mg/mL (data not shown).

Resistance to DNase I Digestion. One primary responsibility of any gene delivery system is to protect DNA from degradation by nucleases. Therefore, the relative quantity remaining, as well as the integrity of the remaining quantity, of plasmid DNA was assessed

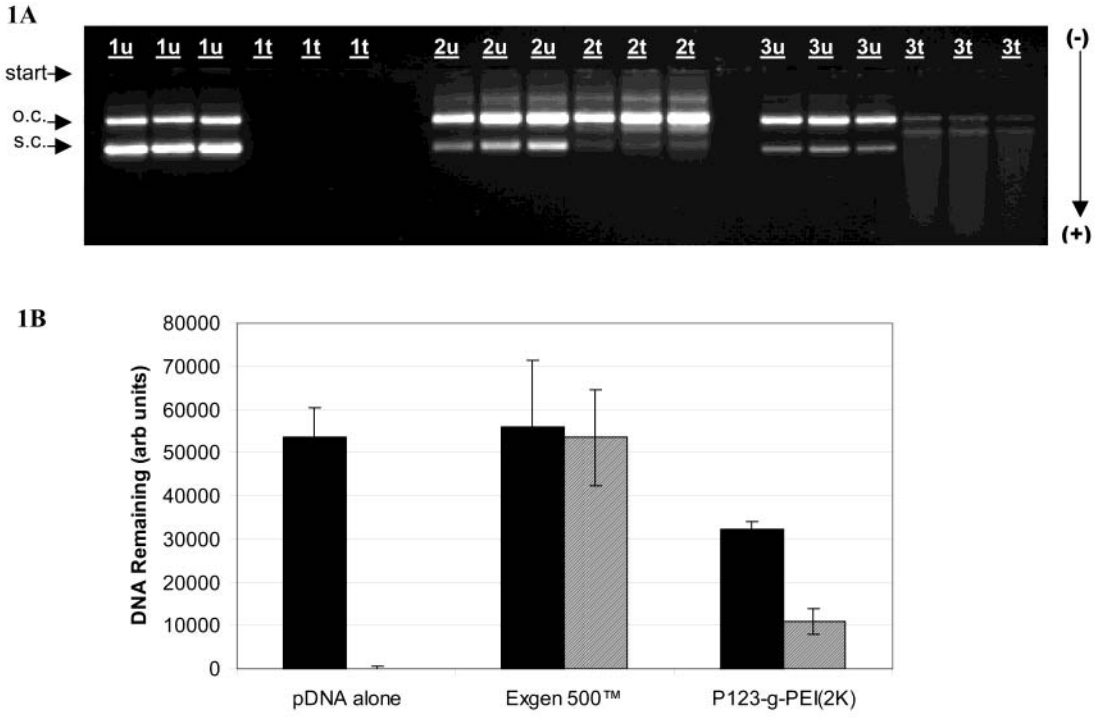

Figure 1. DNase protection assay. (A) Samples, in triplicate, containing (1) pDNA alone, (2) pDNA incorporated into Exgen 500 polyplexes, or (3) pDNA incorporated into P123-g-PEI(2K) complexes were treated with PBS (u) or DNase (t). All samples were subsequently treated with EDTA to inactivate DNase and then heparin to dissociate complexes. Samples were then subjected to agarose gel electrophoresis. (B) Densitometry analysis of the DNase assay presented in panel A. Values are represented as mean ± SD.

following incubation of various polyplexes with DNase I. Figure 1 presents typical results obtained during these experiments. By comparing the relative portions of open circular (o.c.) and supercoiled (s.c.) fractions in the pDNA alone lanes compared to those of the pDNA recovered from both Exgen 500 and P123-g-PEI(2K)-based polyplexes in Figure 1A, it is evident that the process of dissociation of DNA from polycation results in a conversion of a portion of the s.c. pDNA to o.c. pDNA. Furthermore, in the case of P123-g-PEI(2K), there appear to be additional changes in the topology of the pDNA (lanes labeled 3t), resulting in a band that migrates between the indicated o.c. and s.c. bands. The reasons for such changes in pDNA topology are unknown, and this phenomena is currently under investigation in our laboratory. Figure 1B reveals that the dissociation process for P123-g-PEI(2K)-based polyplexes was incomplete, allowing for dissociation of approximately 60% of the pDNA originally incorporated. Such incomplete dissociation was observed in several experiments, and the authors believe it occurs due to hindrance of access of heparin to the DNA as a result of the hydrophobic interactions of Pluronic. Figure 2 presents typical results obtained when comparing various formulations of the P123-g-PEI(2K) polyplex system. This figure shows that, while the positive control (lane 1) was completely degraded, a portion of the polyplex-protected pDNA remains in the case of all polyplexes presented in this figure. It is worthwhile to note the conversion of the supercoiled (s.c.) pDNA to the more relaxed forms, which migrate more slowly through the gel (lanes 3, 5, and 6). The densitometry data in Table 2 were obtained in a separate experiment employing sample replicates utilizing a different batch of pDNA. In this experiment, the pDNA was successfully completely dissociated from the P123-g-PEI(2K)-based polyplexes, allowing for a more accurate assessment of the integrity of the pDNA originally incorporated in the various P123-g-PEI(2K)-based polyplexes following exposure to DNase. These data show that Exgen 500-based polyplexes protected more total DNA than the others, although the integrity of the remaining DNA could be compromised, as demonstrated by the conversion of the majority of the s.c. fraction to a relaxed form. The densitometry data

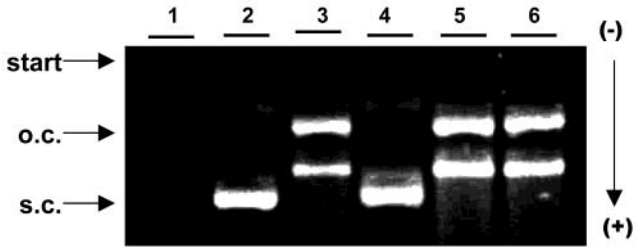

Figure 2. DNase protection assay. Plasmid DNA alone or pDNA incorporated into polyplexes was treated with DNase and subsequently treated with heparin to dissociate complexes; samples were then subjected to agarose gel electrophoresis. The samples were as follows: DNase-treated naked DNA (lane 1); untreated naked DNA (lane 2); DNase-treated P123-g-PEI(2K)-based complexes (lane 3); untreated P123-g-PEI(2K)-based complexes (lane 4); DNase-treated P123:P123-g-PEI(2K)-based complexes (lane 5); DNase-treated F127:P123-g-PEI(2K)-based complexes (lane 6).

Table 2. Plasmid DNA Remaining following DNase I Digestion

formulation	open circular	supercoiled	total (o.c. + s.c.)
Exgen 500	2267 ± 142[a]	64 ± 56[a]	2331 ± 156[a]
P123-g-PEI(2K)	805 ± 30[b]	552 ± 62	1357 ± 68[a]
P123 + P123-g-PEI(2K)	470 ± 46[b]	516 ± 19	986 ± 58
F127 + P123-g-PEI(2K)	649 ± 100	478 ± 8	1126 ± 107

[a] Results statistically different from the other three systems ($p < 0.05$). [b] Results statistically different from each other ($p < 0.05$).

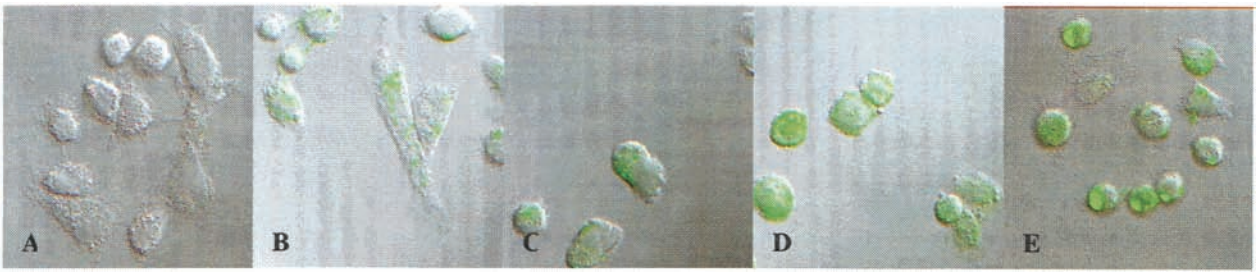

Figure 3. Intracellular distribution of YOYO-1-labeled pDNA. PC-3 cells were exposed for 2 h to YOYO-1-labeled pDNA alone or in combination with polymers: (A) no polymers; (B) Pluronic P123; (C) P123-g-PEI(2K); (D) P123:P123-g-PEI(2K); (E) Exgen 500. The images represent a Z-section through the middle of the cells.

show that the ratio of supercoiled to open circular forms is ca. 0.03. P123-g-PEI(2K) alone (lane 4) and P123-g-PEI(2K) formulated with either Pluronic P123 (lane 5) or Pluronic F127 (lane 6) protected less total DNA. However, it is important to note that the relative fraction of supercoiled versus relaxed DNA is much higher than what was observed with Exgen 500, with ratios ranging from 0.69 to 1.10. All DNase studies were performed in triplicate and are presented as the mean ± SD. Statistically, DNA formulated with P123-g-PEI(2K), without additional Pluronic, was better protected than DNA formulated with the graft copolymer plus either Pluronic, though those differences were small in comparison to the differences seen for Exgen 500 versus P123-g-PEI(2K)-based complexes ($p < 0.05$).

Imaging of Transport of pDNA. To examine internalization and intracellular localization of pDNA, this study conducted a similar set of experiments, transfecting PC-3 cells with YOYO-labeled DNA in polyplexes; in these experiments, the labeled pDNA within the cells was analyzed by confocal microscopy. The confocal microscopy images presented in Figure 3 illustrate the differences in the quantity and the localization of YOYO-1-labeled pDNA in PC-3 cells 2 h after a 2 h exposure to polyplexes. Consistent with the flow cytometry data presented above, both polyplex systems delivered a significant quantity of YOYO-1-labeled pDNA into the cytoplasm of the cells. More importantly, these images depict the apparent differences in the mechanisms of uptake and/or intracellular trafficking between the graft system and Exgen 500. Specifically, in Figure 3E, transfection with Exgen 500-based polyplexes results in localization of the fluorescence in discrete compartments within the cell, while transfection with P123:P123-g-PEI-based polyplexes results in a less localized, more diffuse appearance throughout the cytoplasm (Figure 3D).

Transfection of Complexes. Table 1 also presents the results of transfection of PC-3 cells with various formulations of polyplexes, containing expression plasmids for either luciferase or GFP. The level of transgene expression was examined following transfection with gWIZ-Luciferase, and the percent of cells successfully transfected was evaluated following transfection with pIRES-EGFP. The results quantifying the amount of transgene expressed were consistent with the results quantifying the number of cells successfully transfected. In brief, Exgen 500-based polyplexes were the most effective system, followed by the transfection systems composed of P123:P123-g-PEI(2K) and F127:P123-g-PEI-(2K), while the same graft block copolymer, in the absence of additional nonmodified Pluronic P123, produced little more luciferase than the naked DNA control. Interestingly, although F127:P123-g-PEI(2K)-based polyplexes were approximately twice as large and delivered about half as much pDNA into cells compared to P123:P123-g-PEI(2K)-based polyplexes, the difference in luciferase expression levels was less than 2-fold.

DISCUSSION

This work reports the critical evaluation of the design and formulation of a DNA−polycation polyplex based on a Pluronic-PEI conjugate. This delivery system was chosen for further evaluation because it demonstrated promising results as a systemically administered gene delivery system in vivo (*1*). Furthermore, because the delivery system contains multiple components, it was important to fully understand the function of each component to the overall transfection process.

The first objective of this work was to develop a more clear understanding of the process of particle formation, specifically as it occurs for the P123-g-PEI(2K)-based delivery system. As discussed earlier, when the graft copolymer itself is combined with DNA, it does not form a stable dispersion. In this situation, it is likely that the components are not combining in the appropriate manner to achieve the necessary structure possessing a tight core of DNA bound with PEI segments and a hydrophilic exterior shell stabilizing the system in dispersion. Such structures are, in fact, forming following the reaction of a plasmid DNA with a graft copolymer of PEI(2K) and PEO (*16*). It was demonstrated that PEO(8K) in this graft copolymer is essential for stabilizing the particle dispersion. P123-g-PEI(2K) has a similar structure as the PEO-(8K)-g-PEI that is a graft copolymer of a polycation with uncharged polyether. Furthermore, P123 has comparable length as the PEO(2K), and the architecture of the two graft copolymers is very similar, i.e., containing 1−2 polyether chains per PEI(2K) segment. The difference is that the Pluronic chain is more hydrophobic than the PEO chain since it contains PPO segments flanked by PEO chains (Figure 4). Therefore, the stabilizing ability of Pluronic is less than that of PEO, resulting in the formation of large aggregates. The improved dispersion stability observed following inclusion of nonmodified Pluronic to the formulation is most likely the result of incorporation of Pluronic chains into the polyplexes, driven by the interaction of PPO segments of Pluronic with PPO segments of P123-g-PEI conjugates. This process is very much like the self-assembly of Pluronic micelles, resulting in masking of the hydrophobic PPO sites from the aqueous environment by hydrophilic PEO chains. The final structure of the polyplex particles is complex, and it involves hydrophobic sites from electrostatically neutralized DNA and PEI chains, hydrophobic sites from the PPO chains of Pluronic and the conjugate, and a hydrophilic surface area formed by PEO chains of Pluronic and the conjugate. Therefore, the unconjugated Pluronic plays the role of a cosurfactant that forms mixed micelle-like structures with the complexes of DNA and

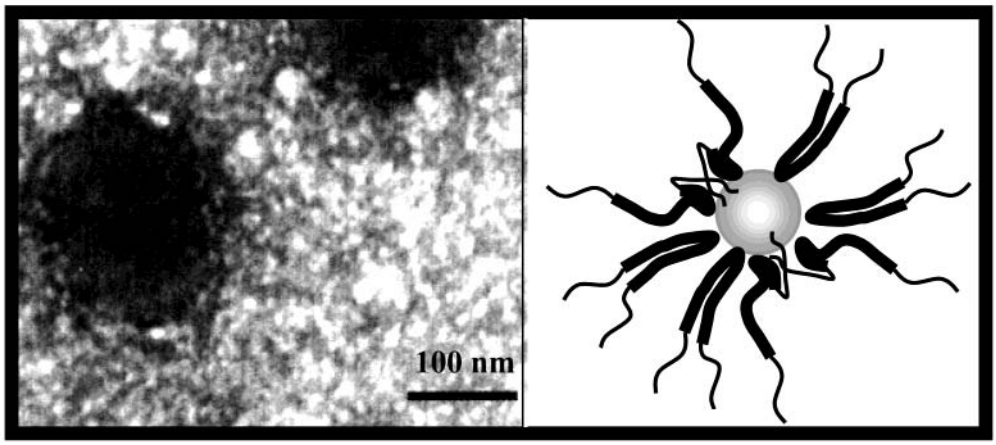

Figure 4. Polyplex structure. (Left) EM photo of complexes [taken from (*1*)] and (right) schematic representation of P123:P123-g-PEI(2K)-based complexes. The sphere represents the core of condensed DNA and polycation. The Pluronic P123 chains that are grafted to the PEI within the core are not incorporated into the core, but form a micelle-like structure around the core, orienting the lipophilic PPO segments (represented by heavy lines in the block copolymer) near the core and the hydrophilic PEO segments forming the exterior corona (represented by the thinner lines in the block copolymer). Additional nonmodified Pluronic P123 chains fill in to optimize the stability of the micelle-like structure.

Table 3. Pluronic Characteristics

copolymer	MW[a]	structure	CMC, M[b]	CMC, %	HLB[c]
P123	5750	$EO_{19}-PO_{69}-EO_{19}$	4.4×10^{-6}	0.0025	8
F127	12600	$EO_{100}-PO_{65}-EO_{100}$	2.8×10^{-6}	0.0035	22

P123-g-PEI(2K). Since the stable formulations of polyplexes contained up to 0.03 wt % of Pluronic P123, it was important to determine whether this component can be displaced with another Pluronic capable of fulfilling the same function. There are many Pluronics that could be tested for this role; an overview of their structure and relevant characteristics can be found elsewhere (*17*). This work examined reformulation with Pluronic F127, which was selected for this task for two primary reasons. One, the hydrophobic PPO chains of both Pluronics are nearly identical; therefore, only the size of the hydrophilic PEO chain would be significantly different from the original formulation (Table 3). Two, Pluronic F127 is already approved for use in pharmaceutical preparations; therefore, toxicological dat exists, which can speed the preclinical development of the formulation.

The first step toward understanding the process of particle formation was to establish the relevance of the order of mixing of the components in relation to the size and stability of the resulting polyplexes. By comparing particle size and stability following a variety of mixing protocols, the results of this work demonstrate that, due to the rapidity and nonreversibility of large aggregate formation, the graft copolymer must always be the last component introduced into the system, regardless of the nonmodified Pluronic employed. The next step to understanding the process was to determine the quantity of Pluronic necessary to stabilize the formulation. In the case of both Pluronic P123 and Pluronic F127, concentrations well above the CMC effectively stabilized the system (data not shown). At these concentrations, the dynamic equilibrium between unimers and micelles provides a favorable environment for the displacement of unimers from the solution and incorporation into the polyplexes (Figure 4). It is important to bear in mind that due to the measuring technique employed, the inclusion of Pluronic micelles, which exhibit effective diameters in the range of 20−30 nm, into the mixture could overexaggerate the differences in the effective diameters of polyplexes formulated either with or without the inclusion of nonmodified Pluronic. However, there are two important considerations that argue strongly against that possibility. First, the concentrations of Pluronic micelles used are relatively low when considering the relative concentration of polyplexes present in the solution. Second, although micelles of Pluronic P123 and Pluronic F127 are both within the range of 20−30 nm (data not shown), the effective diameters of P123:P123-g-PEI polyplexes versus F127:P123-g-PEI polyplexes formed with the same concentrations of either Pluronic are significantly higher than the diameters of the Pluronic micelles and significantly different from each other (Table 1). Therefore, the contribution of the small micelles in the overall scattering intensity is marginal compared to that of the large polyplexes.

The second objective of this work was to evaluate the ability of the P123-g-PEI(2K)-based delivery system to protect the incorporated pDNA from degradation by nucleases, specifically degradation by DNase I. This objective included assessment of the impact of each component of the system to the overall protection. The results presented indicate that the inclusion of nonmodified Pluronic had no significant impact on the protective capacity of the polyplexes. Therefore, it can be surmised that the polycationic component of the polyplex, PEI, is solely responsible for imparting the characteristic of nuclease resistance to the delivery system. When considering the total DNA remaining following digestion (open circular plus supercoiled), the 22 kDa linear PEI, Exgen 500, was twice as effective at protecting the DNA compared to the relatively short 2 kDa PEI contained in the graft copolymer. This likely indicates that the PEI segment used in the graft is too small to prevent access of the enzyme to the pDNA. The protective capacity is quite critical, because if even a very small piece of pDNA is accessible to such enzymes, any damage done to that segment of the DNA would likely result in a change in the conformation of the originally supercoiled DNA. A change in DNA conformation could result in changes in the dynamics of the polyplex, perhaps leading to overall destabilization of the polyplex and, further, more rapid degradation of the incorporated therapeutic pDNA. It is

important to realize that the data presented in Table 2 are open to broad interpretation. There are obvious differences in the fractions of open circular and supercoiled DNA recovered following digestion and subsequent dissociation of the complexes. Although Exgen 500 based polyplexes protected the largest quantity of DNA overall, the graft system retained the greatest portion of the supercoiled fraction, which many would argue should be the fraction of DNA retaining the greatest integrity. These questions regarding DNA topology are very important questions to be addressed in light of development of polyplex technology, but they go beyond the scope of this paper (*18*). The significant, undisputable conclusion of this experiment is that the level of protection observed with the current graft copolymer formulation is not nearly as high as the protection observed with Exgen 500 based polyplexes, and is a factor that may represent a significant limiting factor to the effectiveness of this system in vivo by limiting the effective circulatory time of these polyplexes.

The final objective of this work was to take the knowledge regarding the polyplexes obtained in the cell-free systems combined with evaluation of the polyplex systems in in vitro cellular systems in order to identify critical parameters for the successful application of the delivery systems. DNA uptake studies utilized the high affinity of DNA-binding dye YOYO-1, which has proven to be an excellent tool for monitoring this process (*19*−*21*). This dye is well suited for this task for multiple reasons. First, YOYO-1 alone emits negligible levels of fluorescence; however, its binding to DNA results in a persistent, high fluorescence enhancement. Second, the polycations that we have examined do not displace YOYO-1 when binding to labeled DNA, nor do the polycations quench the fluorescence of the DNA-bound dye (data not presented). This makes it possible to monitor the fate of the polyplex as well as the released DNA. Finally, YOYO-1 is membrane impermeable and is transported in the cells only when bound to DNA incorporated within a polyplex. The DNA uptake studies demonstrated that the relative quantity of pDNA taken into a cell by the various polyplex systems correlated inversely with the particle size of the polyplex. However, the differences in size may not be responsible for the differences in cellular uptake, as there are significant differences in the surface characteristics between some of the included polyplex systems. For example, it was previously demonstrated that polyplexes based on the graft copolymer exhibit a nearly neutral charge on their surface by zeta potential analysis (*1*), which is unlikely, due to the strong interactions between the polyplex and the cell surface, compared to the highly positively charged surface of the Exgen 500 based polyplexes, which allows for strong interaction of these complexes with the negatively charged proteoglycans present on cell surfaces (*22*). On the other hand, the data obtained for the graft copolymer based formulations formed with either P123 or F127 support the theory that smaller particle size correlates with higher transfection activity (*23*), as there should be no significant differences in the surface properties between these two systems; however, the smaller system [P123:P123-g-PEI(2K)] consistently transfects cells in vitro more efficiently than its F127 counterpart [F127:P123-g-PEI(2K)].

Finally, both the levels of transgene expression, as determined by luciferase expression, and the percentage of cells transfected, as determined by GFP expression, were as expected based on the particle size and pDNA internalization studies. Formulation of the graft copolymer with either Pluronic resulted in significantly improved pDNA uptake and transgene expression by PC-3 cells relative to the graft system alone; however, none of the formulations were able to perform as well as Exgen 500. There are likely several factors that prevent this graft copolymer based gene delivery system from performing as well, in vitro, as the linear PEI, Exgen 500. First, Exgen 500 protects the DNA from degradation more effectively, allowing more intact DNA to be delivered to the target cell. Second, as mentioned above, there are differences in the polyplex surface properties that likely result in stronger interactions between the Exgen 500 based polyplexes and cell surfaces. Third, there appear to be differences in the mechanism of internalization of the polyplexes formulated with P123-g-PEI(2K) versus complexes formulated with Exgen 500.

In summary, the nonmodified Pluronic component of this gene delivery system enhanced DNA uptake and expression primarily as a result of optimization of the size and morphology of the polyplex. It does not appear that the nonmodified Pluronic contributes significantly, alone, to either enhancement of DNA uptake, transgene expression, or protection from nuclease degradation. Although much of the preliminary work with this nonviral delivery system appears quite promising, the authors acknowledge the potential limitations of this system for in vivo application due to the low level of nuclease protection exhibited in the DNase protection assays. This may limit the effective dose delivered, as well as limiting the effective circulation time, upon systemic delivery of this formulation. The authors suggest that substitution of the relatively small 2K PEI used in this graft copolymer with a larger polycationic segment will enhance the 'tightness' of the polycation binding to the DNA and might significantly improve the nuclease protection characteristics. In addition, attachment of a receptor-specific ligand, such as transferrin, should improve complex cell membrane interactions, and perhaps improve the intracellular trafficking profile.

ACKNOWLEDGMENT

We thank the National Science Foundation (BES-9907281) and the Nebraska Research Initiative Gene Therapy program for supporting this research. We thank Dr. Pi-Wan Cheng of the UNMC Biochemistry Department for providing the PC-3 prostate cancer cell line and for useful discussion of this work, and Janice Taylor of the Confocal Laser Scanning Microscope Core Facility at the UNMC, which is supported by the Nebraska Research Initiative, for providing assistance with confocal microscopy. We also thank Charles Kuszynski, Ph.D., and Linda Wilkie of the UNMC Cell Analysis Core Facility for analyzing the flow cytometry samples. We thank Supratek Pharma Inc. for providing the sample of P123-g-PEI(2K), that was synthesized by Dr. Sergey Vinogradov. M-H-W Laboratories (Phoenix, AZ) did elemental analysis. We thank BASF for the gift of Pluronic P123 and Dr. Albert Descoteaux (Armand Frappier Institute, Montreal, PQ, Canada) for providing the pCMV-Luc plasmid.

Artificial Ribonucleases: Efficient and Specific in Vitro Cleavage of Human *c-raf-1* RNA

Laurence Canaple,[†] Dieter Hüsken,[‡] Jonathan Hall,[‡] and Robert Häner*[,†]

Universität Bern, Departement für Chemie und Biochemie, Bern, and Novartis Pharma AG, Functional Genomics, Basel. Received January 18, 2002; Revised Manuscript Received April 25, 2002

We report here the first successful sequence-specific cleavage of large RNA using artificial ribonucleases. A series of uniformly 2′-methoxyethoxy-modified oligonucleotides bearing a europium complex were investigated as artificial ribonucleases specific for the human *c-raf-1* mRNA. The efficiency and specificity of these oligonucleotide−metal conjugates to bind and to cleave 571 and 2977 nucleotides long *c-raf-1* RNA transcripts in vitro in a sequence-specific manner is demonstrated. Quantitative analysis reveals a cleavage efficiency of 60−70% within 4 h at 37 °C. Precise mapping of cleavage sites using primer extension analysis shows that cleavage generally occurs at two or three major sites adjacent to the 3′-end of the RNA target region. Cleavage is preferentially observed after purine nucleotides. This study demonstrates the potency of artificial ribonucleases targeting large, biologically relevant RNAs.

INTRODUCTION

Antisense oligonucleotides represent potent agents to modulate the expression of genes (Agrawal and Zhao, 1998; Baker et al., 2001). They act by inhibiting protein expression through the specific binding to complementary RNA targets, followed by the degradation of the targeted RNAs through a RNase H-mediated hydrolysis (Crooke, 1999). Before an antisense molecule can achieve its full potential, several biochemical and biological limitations of the oligonucleotides must be improved, including cellular uptake, nuclease stability, target selectivity, and intracellular localization (Jen and Gewirtz, 2000). The incorporation of chemical modifications at base, sugar or phosphate backbone of oligonucleotides leads to altered nuclease resistance as well as improved hybridization efficiency and pharmacokinetic parameters (Verma and Eckstein, 1998; Henry et al., 2000). Although they are not able to induce RNase H action, 2′-methoxyethoxy-modified oligonucleotides are considered as a promising class of antisense compounds since they combine both a significantly enhanced nuclease stability, an excellent binding affinity for the RNA target, and favorable pharmacokinetics (Geary et al., 2001a,b; Zellweger et al., 2001). The design of oligonucleotide-based artificial ribonucleases, which can selectively cleave targeted RNAs, independently of intracellular ribonuclease activity, could compensate for the loss of RNase H activity observed for almost all types of antisense oligonucleotides. In this approach, a catalytic group promoting the cleavage of the messenger is attached to an antisense oligonucleotide complementary to the targeted mRNA. Covalent attachment of stable macrocyclic lanthanide complexes to oligonucleotides leads to artificial ribonucleases acting without the requirement of cofactors or cellular enzymes for the sequence-specific cleavage of RNA. To date, lanthanide complexes are among the most potent transphosphorylation catalysts known (Magda et al., 1994; Matsumura et al., 1994; Hall et al., 1994, 1996) with a potential for cellular applications (Baker et al., 1999). However, examples of sequence-specific in vitro cleavage using lanthanide conjugates have been limited to short (i.e. < 40 nucleotides) RNA targets (Trawick et al., 1998; Häner and Hall, 1997). Insight into the cleavage of large RNA targets should considerably improve our understanding of the behavior and potency of such artificial ribonucleases.

The serine/threonine kinase Raf-1 functions as a central messenger of the mitogen-activated protein kinase signaling pathway, which is involved in the regulation of cell proliferation, differentiation and apoptosis. Raf-1 largely contributes to the control of the cell proliferation and plays a critical role in the development and the growth of tumors (Hagemann and Rapp, 1999; Robinson and Cobb, 1997). Studies have clearly demonstrated that Raf-1 is the immediate downstream-target of the well-described oncogenic Ras protein (Marshall, 1995), for which gene mutations have been reported in various solid tumors and leukemias (Bos, 1989). Raf-1 itself also presents an oncogenic potential, as *raf* gene mutations have been detected in human tumors and amino-terminal-deleted Raf-1 proteins displayed a transforming activity in a wide variety of cell types (Stanton and Cooper, 1987; Storm and Rapp, 1993). Since activation and aberrant expression of Raf-1 appear to be important mechanisms in malignant transformation, therapies allowing the down-regulation of Raf-1 expression could have a significant impact for the treatment of various human disorders (Cho-Chung, 1999).

In the present study, a series of uniformly 2′-methoxyethoxy-modified oligonucleotides bearing a europium complex were investigated as potential artificial ribonucleases specific for the human *c-raf-1* mRNA. We report the potency of these oligonucleotide-metal conjugates to bind and to cleave RNA transcripts of a length of 571 and 2977 nucleotides in vitro in a sequence-specific way.

Figure 1. Top: sequence of 2′-methoxyethoxy-modified oligonucleotide−metal conjugates used in the present study. Complementary positions of conjugates are indicated as nucleotide number on *c-raf-1*-mRNA. HO-554 is used as a control and is not complementary to *c-raf* messenger. Bottom: structure of the europium complex linked to the 2′-methoxyethoxy-modified oligonucleotides is shown. Possible secondary structure of the target RNA region of interest as predicted by RNA *mfold* (Zuker, 1989, http://bioinfo.math.rpi.edu/~mfold/rna). The AUG start codon used for initiation of translation is located at nucleotide 130. Eu-conjugates are drawn in solid, colored lines at complementary regions. The metal complex is symbolized by a point.

MATERIALS AND METHODS

Synthesis of Europium Complexes Conjugated to 2′-Methoxyethoxy-Modified Oligonucleotides. 2′-Methoxyethoxy-modified oligonucleotides were prepared by automated synthesis on a DNA synthesizer (Applied Biosystems Inc.) using commercially available reagents and following standard procedure. Europium complexes were synthesized in analogy to the previously published procedure (Hall et al., 1996). The europium complexes were covalently attached to the 5′-end of different 2′-methoxyethoxy-modified oligonucleotides via the intermediate isothiocyanate yielding the conjugates shown in Figure 1. All conjugates were purified by RP-HPLC and characterized by mass spectroscopy and UV spectroscopy.

Preparation of Target *c-raf* RNAs by in Vitro Transcription. *c-raf* RNAs were synthesized by in vitro runoff transcription with T7 RNA polymerase (RiboMAX Large Scale Production System, Promega) using Hind III or Pst I linearized plasmid which contains the human c-raf sequence (accession number XØ3484) inserted as a 2977 base pair part at the Eco RI site of pGEM-3Z vector (Promega). The transcription reactions were carried out in 20 μL of 80 mM Hepes-KOH (pH7.5) containing 24 mM magnesium chloride, 2 mM spermidine, 40 mM DTT,

each NTP (7.5 mM), 1−2 μg of linearized DNA template, and T7 RNA polymerase according to the manufacturer's instructions. Reaction mixtures were incubated overnight at 37 °C. The DNA template was removed by digestion with RQ1 RNase-free DNase (1−2 U/μg of DNA) for 30 min at 37 °C. After phenol/chloroform /isoamyl alcohol extraction and ethanol precipitation, the RNAs were washed with ethanol 70%. The dried pellet was resuspended in nuclease-free water and stored at −70 °C. The transcript concentration was estimated by UV-light absorbance and their integrity examined by gel electrophoresis. The labeled *Hind III c-raf* transcripts were made under the same experimental conditions with the four NTPs and in the presence of [α-^{32}P] ATP at a specific activity of 3000 Ci/mmol (Hartmann Analytic GmbH).

RNA Folding Prediction. Secondary structure predictions of *c-raf-1* RNAs were obtained using RNA *mfold* (Zuker, 1989; http://bioinfo.math.rpi.edu/~mfold/rna).

RNA Cleavage Assay. Cleavage of *c-raf* transcripts by europium complex conjugated to modified oligonucleotides were performed in 10 μL cleavage mixture containing at final concentration 20 mM Tris-HCl (pH 7.5), ~0.5 μM RNA, and 1 μM conjugate. The mixture was heated to 80 °C for 1 min and slowly cooled to 37 °C. The standard reaction time is 4 h. For the determination of the sequence-specificity, cleavage reactions were conducted with unlabeled *Hind III c-raf* transcript in the presence of HO-552, HO-553, HO-554, HO-560, or HO-563 conjugates under standard conditions as described above. Reactions were stopped by addition of formamide loading buffer and cleavage products were analyzed on an ethidium bromide-stained 2% agarose gel or on 5% polyacrylamide native gel. Results are representative of three independent experiments. Same protocol was carried out for the cleavage of *full length* transcripts. For the determination of the cleavage efficiency**,** cleavage reactions were performed with radiolabeled *Hind III c-raf* transcript in the presence of HO-552, HO-553, HO-560, or HO-563 conjugates under standard conditions. The cleavage products in formamide buffer were resolved on a 5% polyacrylamide native gel, visualized, and quantified using a Molecular Dynamics PhosphorImager. Results were normalized according to the length of the quantified products. Results are averages of three independent experiments.

Mapping of the Cleavage Site by Primer Extension Analysis. A synthetic oligodeoxynucleotide (5′-atcaaacacggcatc-3′) complementary to nucleotides 184−198 of the *c-raf-1* transcripts and 5′-end labeled with T4 polynucleotide kinase (USB protocol) and [γ-32 P] ATP (5000 Ci/mmol, Hartmann Analytic GmbH) was hybridized in a solution of 0.15 μM of conjugate-RNA (3 μL of cleavage mixture) in 20 μL of 50 mM Tris-HCl pH8.3, 75 mM KCl, 10 mM DTT, 3 mM $MgCl_2$, 1 mM dNTP each and extended with M-MLV reverse transcriptase (10 U/μL of reaction, Gibco BRL) at 37 °C for 90 min. Reverse transcripts were ethanol precipitated, resuspended in formamide loading buffer, and resolved on a 7 M urea/10% polyacrylamide gel. Gels were exposed to the PhosphorImager screen. RNA sequencing was carried out with the same oligonucleotide by a reverse transcription using dideoxy-chain termination. Sequencing reactions were coelectrophoresed with reverse transcripts. Results are representative of three independent experiments.

RESULTS

A series of 2′-methoxyethoxy-modified oligonucleotides targeted against the human *c-raf-1* mRNA were designed.

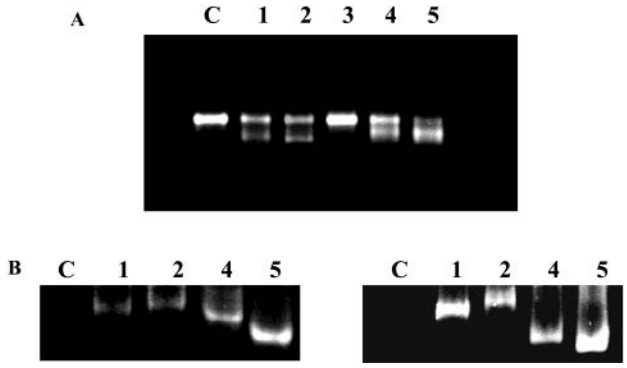

Figure 2. Sequence-specificity of *c-raf* transcript cleavage. A: Cleavage of *Hind III c-raf* transcript (571 nt) by Eu-conjugates as detected by 2% agarose gel stained with ethidium bromide. The upper bands correspond to the uncleaved *Hind III c-raf* transcript and the lower bands to the large cleaved RNA fragment (400−450 nt). B: Detection of the small cleavage products (100−150 nt) by 5% native polyacrylamide gel. Left, for *Hind III c-raf* transcript (571 nt). Right, for full length *c-raf* transcripts (2977 nt). Controls (lanes C) were carried out without addition of conjugate under identical experimental conditions. Cleavage reactions by HO-552, HO-553, HO-554, HO-560, and HO-563 are shown in lanes 1, 2, 3, 4, and 5, respectively.

All oligonucleotides were 12 or 14 bases in length and complementary to the region of nucleotides 112−156 of *c-raf-1* mRNA, which comprises the 5′-AUG translation start codon. The 2′-methoxyethoxy-modified oligonucleotides were covalently linked to a europium complex leading to the formation of the conjugates as detailed in Figure 1. *c-raf-1* RNAs were obtained by in vitro runoff transcription. The use of Hind III for linearization of the plasmid template prior to transcription reaction yielded a small transcript of 571 nucleotides (termed *Hind III c-raf* transcript) whereas Pst I linearization allowed the preparation of the *full length* transcript (2977 nucleotides). In a first series of pilot experiments, the reaction conditions for an in vitro cleavage of *c-raf* transcripts were established. We found that the extent of the RNA cleavage was time and temperature dependent. In addition, an additional step of denaturation of 1 min at 80 °C increased the efficiency of the cleavage, favoring the binding of the conjugate to the RNA target region before cooling to 37 °C. No cleavage was observed during this annealing step (data not shown). Efficient cleavage was obtained within 4 h at 37 °C using a 2-fold excess of the conjugate over the RNA target.

To prove that the action of Eu-conjugates is through an antisense mechanism, i.e., by binding to the complementary RNA sequence, we first tested the sequence requirements for cleaving *c-raf-1* RNAs by comparing the effects of complementary conjugates with a noncomplementary control conjugate (HO-554). As expected for a mechanism based on Watson−Crick recognition, no cleavage was observed when the noncomplementary conjugate HO-554 was incubated with the *Hind III c-raf-1* RNA target. In contrast, all other HO-compounds complementary to *c-raf-1* RNA displayed a potent cleavage, reflecting a high sequence specificity (Figure 2A). Further analyses of the cleavage reaction revealed that two cleavage products were generated over time (for *Hind III c-raf-1* transcript, one cleavage product of an approximate size of 400 nucleotides is shown in Figure 2A, the other small fragment of about 150 nucleotides is seen in Figure 2B, left panel). Treatment of the *full length* transcript with Eu-conjugates yielded the same small cleavage product (Figure 2B, right panel). In a further

Table 1. Cleavage Efficiency of Eu-Conjugates on *Hind III c-raf* Transcript[a]

europium-conjugate	percentage of cleavage
HO-552	68.6 ± 3.1
HO-553	56.3 ± 3.9
HO-560	63.3 ± 2.7
HO-563	70.9 ± 1.2

[a] Yield of the cleavage reaction of radiolabeled *Hind III c-raf* transcript by the different Eu-conjugates as described in Materials and Methods (1 μM conjugate, 0.5 μM RNA and a total reaction time of 4 h). Results are means ± SD of three independent experiments.

control experiment, no cleavage was detected if the conjugates were incubated with *luciferase* RNA instead of *c-raf-1* transcripts, again confirming high sequence specificity (data not shown).

An important aspect for an artificial ribonuclease is the efficiency of the cleavage process. Therefore, the extent of cleavage effected by each europium conjugate was quantified. Experiments were performed with radiolabeled *Hind III c-raf* transcript using a 2-fold excess of the conjugate for 4 h at 37 °C. The results of three independent experiments are given in Table 1. Experimental data showed 60−70% of cleavage of *Hind III c-raf* transcripts. The highest cleavage yield was obtained with the conjugate HO-563 (70,9% ± 1.2).

The precise location of the cleavage sites was mapped using primer extension analysis of the cleavage products. Reactions were carried out using a radiolabeled antisense primer complementary to nucleotides 184−198. As a control, *c-raf* RNAs incubated under the same conditions but without conjugate showed no cleavage bands in the targeted region (Figure 3, top, lanes C1), confirming that no decomposition of the targets occurred during the experiments. Furthermore, primer extension analysis was also performed in the presence of a large excess of a complementary 2′-methoxyethoxy-modified oligonucleotide without a metal complex (Figure 3, top, lanes C2). This control confirmed that the presence of an annealed oligonucleotide on the RNA did not block the reverse-transcriptase activity. As a general observation, several extension products were detected for each conjugate tested, reflecting a relative flexibility of the catalytic part (Figure 3, top). As expected, precise location of the cleavage sites was dependent on the hybridization site of the conjugate on the RNA and generally occurred at or near the 3′ end of the RNA adjacent to the europium complex (illustrated in Figure 3, bottom). Comparison of the cleavage patterns obtained with the *Hind III* (571 nt) and the *full length* (2977 nt) transcripts showed no significant difference (Figure 3, top, units A and B, respectively). Quantification of each cleavage product is shown in Figure 4. Overall, an excellent correlation between the cleavage sites of the two RNA targets differing in size was found. Generally, cleavage occurred at two or three major sites, along with several minor sites of cleavage at the flanking bases. RNA cleavage was predominantly observed after purine bases. An excep-

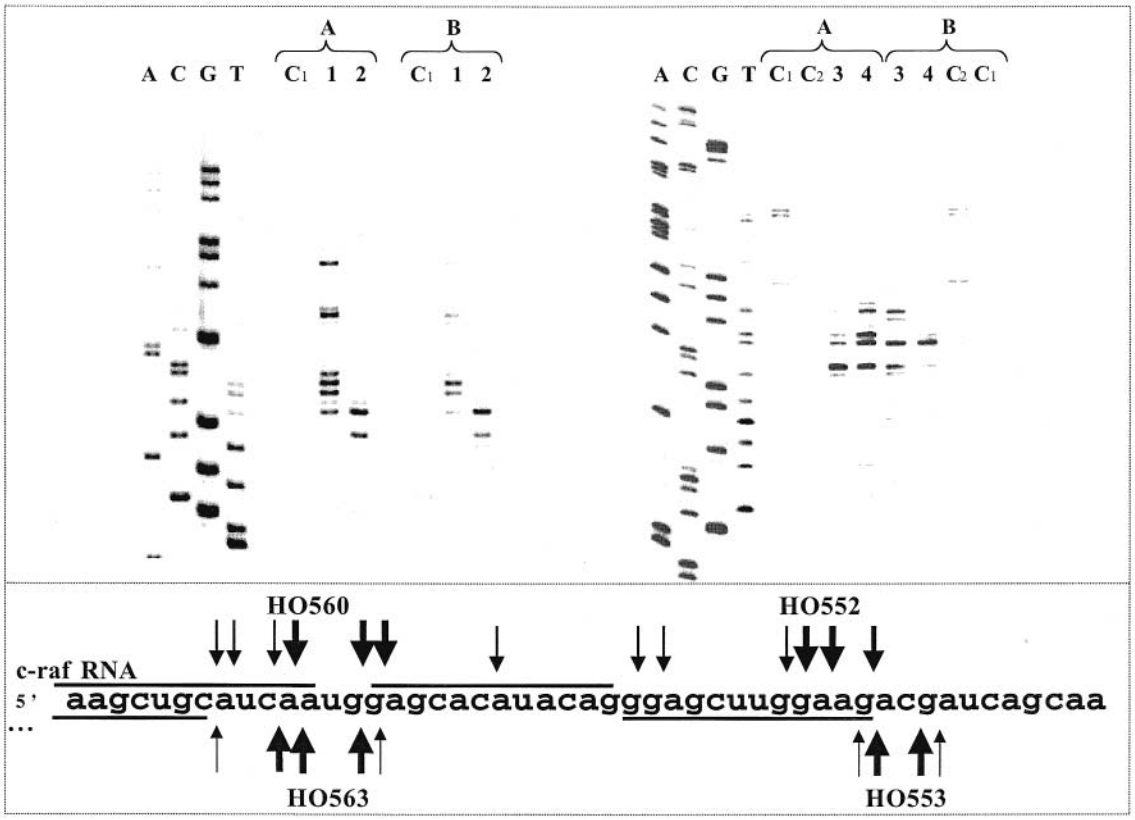

Figure 3. Mapping of the cleavage products. Top: primer extension analysis of cleavage products on a 10% denaturing polyacrylamide gel both for *Hind III* (A) and full length (B) *c-raf* transcripts for HO-552 (lanes 1), HO-553 (lanes 2), HO-560 (lanes 3), and HO-563 (lanes 4). Sequencing reactions (lanes A, C, G, T) of transcripts were coelectrophoresed to locate the cleavage sites. Lanes C1: primer extension products of corresponding RNA incubated in the reaction buffer without Eu-conjugate. Lanes C2: primer extension products of RNA incubated with a large excess of complementary 2′-methoxyethoxy-modified oligonucleotides bearing no metal complex. The data shown are representative of three independent experiments carried out in duplicate. Bottom: cleavage pattern obtained with *c-raf* RNAs and Eu-conjugates showing a preference for cleavage at purine sites. Cleavage sites are indicated by arrows with different size representing approximate cleavage intensities. Hybridization regions of HO-compounds on the *c-raf-1* RNA are displayed by horizontal lines.

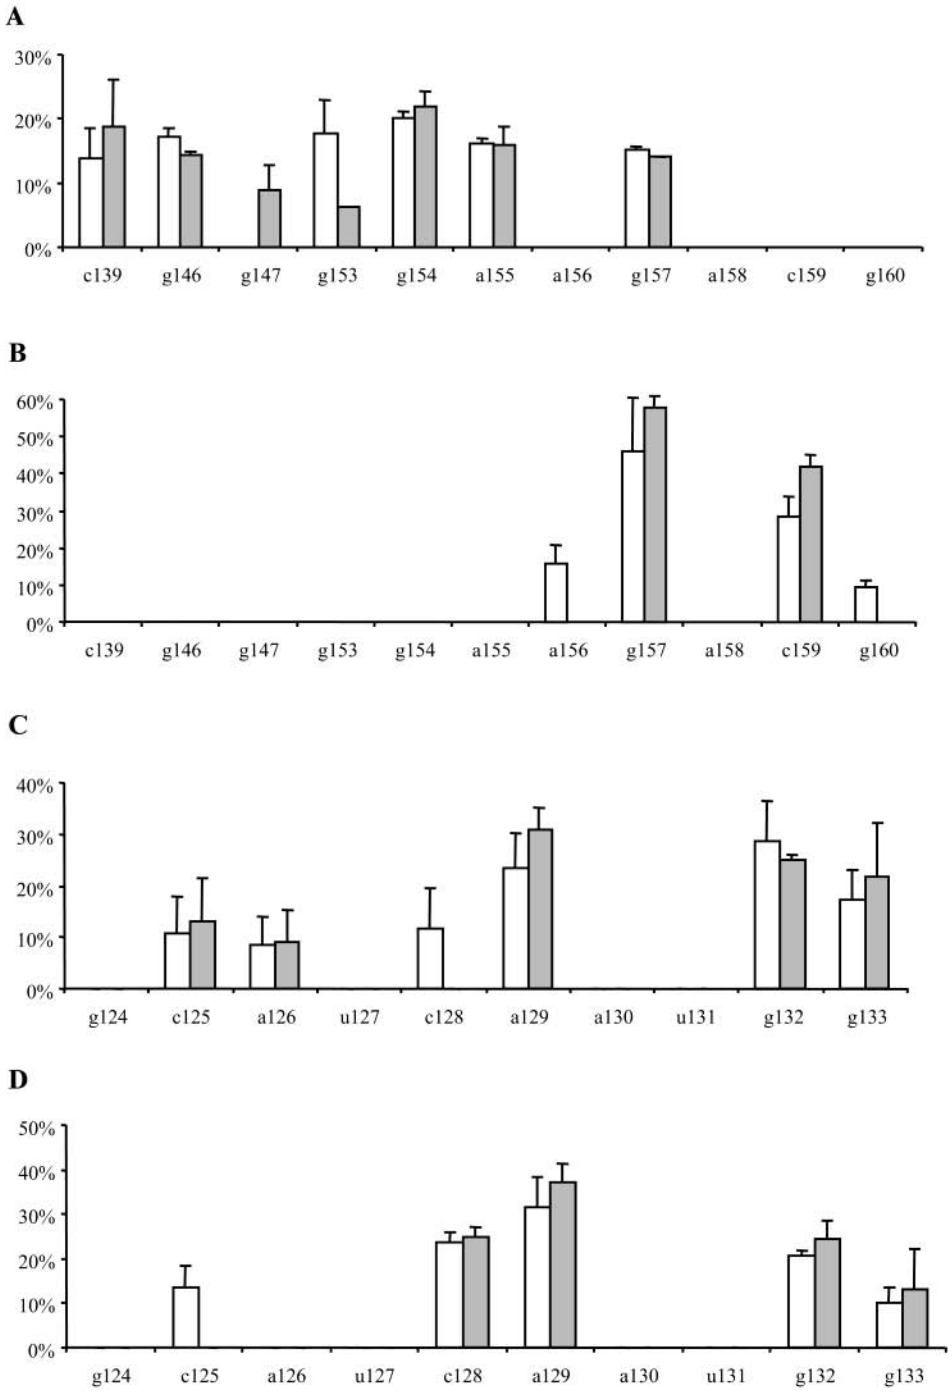

Figure 4. Quantification of cleavage sites for *Hind III* (in white) and full length (in gray) *c-raf-1* transcripts by HO-552 (A), HO-553 (B), HO-560 (C), and HO-563 (D). The values are means ± SD of three independent experiments in duplicate.

tional behavior was found using conjugate HO-552. This compound induced cleavage at sites relatively far downstream (9, 10, and 13 nucleotides) of the metal complex. In addition, one minor cleavage site was also located within the duplex formed by the RNA and this conjugate.

DISCUSSION

A current interest in the antisense field is directed to the development of novel mechanisms of oligonucleotide interference with gene expression. One promising approach in this direction consists of the sequence-specific hydrolytic cleavage of RNA using oligonucleotides bearing chemical moieties inducing phosphodiester transesterification (Trawick et al., 1998; Häner and Hall, 1997). In particular, metals are efficient catalysts for the cleavage of ribonucleic acids acting as *Lewis* acids, thus promoting the nucleophilic attack of the 2′-hydroxyl group on the adjacent phosphodiester group and leading to phosphodiester backbone cleavage. Promising results have been achieved using lanthanide metal complexes linked to oligonucleotides and several groups have reported the sequence-specific cleavage of short model oligoribonucleotides in the presence of at least 10-fold excess of conjugates during 16−24 h (Magda et al., 1994; Matsumura et al., 1994; Hall et al., 1994, 1996). Herein, we have tested the limits of the approach by targeting large RNAs (i.e. up to thousands of nucleotides long). Since the kinase Raf-1 plays an important role in the development of malignant tumors, we chose *c-raf-1* mRNA as a target of biological interest. Runoff transcripts of two different

sizes (571 and 2977 nucleotides) were prepared in vitro. As artificial ribonucleases, several 2′-methoxyethoxy-modified antisense oligonucleotides bearing a europium metal complex at the 5′-end were synthesized and tested against these two targets. 2′-Methoxyethoxy-modified oligonucleotides possess higher stability toward nucleases and exhibit higher hybridization affinity for complementary RNA than unmodified DNA. All oligonucleotides were designed to target the region between nucleotides 119−156 on *c-raf-1* mRNA. While the accessibility of the RNA target region may not be a limiting factor for the present in vitro studies, it will play a crucial role in vivo. Therefore, the choice of the target sites was based on RNA structure predictions obtained using Zuker's RNA folding program *(mfold,* Zuker, 1989). Calculations suggested this region to be folded into a stable structure composed of hairpins and loop structures (Figure 1), which should be ideal sites for hybridization of antisense oligonucleotides. We found that all four complementary conjugates were able to bind and cleave both the small *Hind III* and the *full length c-raf-1* transcripts. RNA cleavage was observed at a single region where the catalytic complex was expected to be located yielding two fragments of different size. No further product could be detected. The high specificity of the cleavage was furthermore confirmed by the absence of cleavage using a nontargeted RNA (luciferase) or a noncomplementary conjugate (HO-554).

We next determined the efficiency of the cleavage process. Quantitative analysis revealed that cleavage of *c-raf-1* transcripts amounts to 60−70% in 4 h at 37 °C using a 2-fold excess of conjugate. Precise location of individual cleavage sites for each conjugate was determined using the primer extension method. The region of cleavage is generally confined to the nucleotides flanking the end of the duplex formed by the target and the conjugate. With few exceptions, cleavage normally takes place after purine bases. The susceptibility of the different nucleotides toward the metal-catalyzed transesterification reaction is likely to be influenced by the particular folding of the targeted region. This may explain why the major cleavage sites induced by HO-552 are relatively distant from the hybridization region. Furthermore, the local RNA structure may also account for the accessibility and the slight but significant reactivity of several nucleotides located in the duplex formed by the RNA and HO-552 or HO-560 (see Figure 3). As previously reported (Hall et al., 1996; Hüsken et al., 1996), the extension of the cleavage into the duplex region can increase the potency of such artificial ribonucleases by facilitating the rapid dissociation of the cleaved RNA fragments from the nucleases and allowing, at the same time, the possibility of a catalytic turnover.

The conjugates tested induced efficient and specific RNA cleavage, which makes them promising reagents for targeting biologically relevant messenger RNAs. This type of conjugates might, therefore, present effective tools to investigate or artificially regulate processes involving RNA. Deregulated genes responsible for various human disorders, such as cancer and viral infectious diseases, represent attractive targets for artificial ribonucleases. The type of conjugates decribed in the present work should be stable and active in biological environment. We previously showed that no loss of metal occurs in the presence of EDTA and that the cleavage is not inhibited by the presence of phosphate or amines (Hall et al., 1994). Oligonucleotide−metal conjugates of this type may also find applications as tools in molecular biology. They can be useful as artificial restriction RNases, which are as yet unknown. Furthermore, they can be of interest to probe particular features of RNA structure. Structural motifs have been reported to affect oligonucleotide hybridization efficiency (Lima et al., 1992) and unpaired or bulged ribonucleotides are more susceptible to the cleavage than ribonucleotides within a duplex (Kolasa et al., 1993; Hüsken et al., 1996).

In conclusion, we have described the specific cleavage of human *c-raf-1* RNA in vitro by 2′-methoxyethoxy-modified oligonucleotides bearing a europium metal complex. The cleavage efficiency was found to be 60−70% within 4 h using 2-fold excess of conjugate. Precise mapping of cleavage sites revealed that cleavage occurred within the expected target region, and a strong preference for purine nucleotides was observed.

ACKNOWLEDGMENT

We thank Luzia Moesch and Andrea Deichert for their excellent technical assistance.

Biodegradable, Endosome Disruptive, and Cationic Network-type Polymer as a Highly Efficient and Nontoxic Gene Delivery Carrier

Yong-beom Lim, Seon-mi Kim, Hearan Suh, and Jong-sang Park*

School of Chemistry & Molecular Engineering, Seoul National University, Seoul 151-742, Korea. Received April 22, 2002; Revised Manuscript Received July 10, 2002

The success of gene therapy is largely dependent on the delivery vector system. Efficient transfection and nontoxicity are two of the most important requirements of an ideal gene delivery vector. To generate both an efficient and nontoxic vector, we rationally constructed polymeric vectors to have simultaneous multiple functions, i.e., controlled degradation, an endosome disruptive function, and positive charges. Remarkably, the transfection efficiency of network poly(amino ester) (n-PAE) synthesized in this manner was comparable to that of polyethylenimine (PEI), one of the most efficient polymeric gene delivery vectors reported to date. However, there was a marked difference in cytotoxicity between the polymers. The majority of PEI-transfected cells were granulated and dead, whereas most of the cells transfected with n-PAE were viable and healthy. Successive events of efficient endosome escape of n-PAE/DNA polyplex and n-PAE biodegradation should result in high transfection efficiency and favorable cell viability response. The n-PAE-mediated transfection was also very efficient in the presence of serum. These data show that the approach we applied is a very appropriate way of making an ideal gene delivery carrier.

INTRODUCTION

The vector for the delivery of therapeutic DNA has been considered as a major hurdle in achieving successful gene therapy. A number of delivery systems based on viral (*1*, *2*) or nonviral vectors (*3*−*5*) have been devised until now; however, none of these have proven to be satisfactory. Nonviral vectors have gained a great deal of interest by their advantages over viral vectors, such as low immunogenicity, limitless DNA incorporation capacity, the ease of large-scale production, and the possibility of fine-tuning the physicochemical and biological properties. However, those nonviral vectors efficient in transfection were toxic because of their nondegradable property (*6*). On the contrary, the transfection efficiencies of nontoxic nonviral vectors, e.g., biodegradable cationic polymers, were not satisfactory (*7*−*13*).

Here we demonstrate our approach for generating both a transfection-efficient and nontoxic gene carrier based on a nonviral polymeric vector. To meet these requirements, we rationally designed polymer structure to have simultaneous multiple functions, i.e., biodegradable property, endosome disruptive function, positive charge for DNA condensation, and three-dimensional network-type chain interconnected structure for controlled degradation. n-PAE synthesized in this manner showed very high transfection efficiencies and negligible cytotoxicity in various kinds of mammalian cells. The polymer combined with this type of approach should represent an important step toward the creation of an ideal gene delivery vector.

EXPERIMENTAL PROCEDURES

Materials. PEI (average molecular weight 25 kDa) was obtained from Aldrich. Fmoc-6-aminohexanoic acid (Fmoc-eAhx) was purchased from Novabiochem. pGL3-Control vector was purchase from Promega.

The pCN−LacZ vector encoding β-galactosidase gene was constructed by subcloning *E. coli* β-galactosidase cDNA to pCN, which contains the 600 bp HCMV IE promoter and its entire 5′ untranslated region consisted of 122 bp exon 1, 827 bp intron 1, and 16 bp exon 2 (*14*).

Synthesis of Network Poly(amino ester). Monomer **1**: To a stirred solution of methyl acrylate (150 mL, 1.67 mol) at 45 °C was added a solution of tris(hydroxymethyl)aminomethane (5 g, 41 mmol) in methanol (250 mL). The reaction mixture was stirred for 24 h at 45 °C. Methanol and excess methyl acrylate were evaporated to give 12 g (99%) of monomer **1** as a yellow oil. ^{1}H NMR (300 MHz, DMSO-d_6) δ 2.39 (t, 4H, CH_2CH_2COO), 2.75 (t, 4H, CH_2CH_2COO), 3.28 (s, 6H, $HOCH_2$), 3.57 (s, 6H, CH_3). ^{13}C NMR (75 MHz, DMSO-d_6) δ 35.41 (CH_2CH_2-COO), 36.93 (CH_2CH_2COO), 51.41 (CH_3), 59.98 (quaternary carbon), 61.05 ($HOCH_2$), 173.16 (ester carbonyl carbons). MS (MALDI) Calcd for $C_{12}H_{23}NO_7$ $(M + H)^+$ 294.325; found 294.323.

Polymer **1**: For the polycondensation reaction, monomer **1** (5 g) placed in a glass vial was immersed into a silicon bath. Polymerization was carried out in the bulk at 170 °C under constant argon flow. The temperature of the reaction was increased at a rate of 10 °C/min. After 5 h of reaction, the resulting network-type polymer, which was a solid at room temperature, was pulverized to yield a yellow powder. ^{1}H NMR (300 MHz, DMSO-d_6) δ 1.41−2.77 (br m, CH_2CH_2COO and CH_2CH_2COO), 3.24−3.42 (br m, $HOCH_2$), 3.50−3.57 (br m, CH_3), 4.01−4.10 (br m, $COOCH_2$). ^{13}C NMR (75 MHz, DMSO-d_6) δ 33.63−35.83 (CH_2CH_2COO), 36.61−37.79 (CH_2CH_2COO), 51.60 (*C*H3), 59.32, 62.62 (quaternary carbons), 60.86, 61.44, 64.27 ($HOCH_2$), 165.13−173.53 (ester carbonyl carbons).

n-PAE: A mixture polymer **1** (0.73 g) and Fmoc-eAhx (0.91 g, 2.58 mmol) in DMF (7 mL) at room temperature

was treated with 1,3-dicyclohexylcarbodiimide (DCC, 1.06 g, 5.15 mmol), 4-(dimethylamino)pyridine (DMAP, 0.16 g, 1.29 mmol), and *p*-toluenesulfonic acid monohydrate (PTSA, 0.23 g, 1.2 mmol). After 15 h at room temperature, the reaction mixture was filtered to remove DCU. The crude polymer was purified first by precipitating it into a large excess of water three times to remove DMAP and PTSA. The precipitates were collected, dissolved in $CHCl_3$, and precipitated into a large excess of EtOAc/ether (1:1) three times to remove residual DCC and Fmoc-eAhx. The resulting polymer obtained (0.6 g) was a viscous semisolid. ^{1}H NMR (300 MHz, DMSO-d_6) δ 1.21−1.47 (br m, $CH_2(CH_2)_3CH_2COO$), 2.26 (br, $CH_2(CH_2)_3CH_2$-COO), 2.93 (br, $CH_2(CH_2)_3CH_2COO$), 3.21−3.44 (br m, $HOCH_2$), 3.50−3.53 (br m, CH_3), 3.91−4.10 (br m, $COOCH_2$), 4.18 (br, CH), 4.26 (br, $CHCH_2$), 7.31−7.94 (br m, aromatic protons). Molecular weight by gel permeation chromatography (GPC): M_n = 3800, M_w = 4500, PDI = 1.18. GPC was carried out using a Waters model 600E Multi Solvent Delivery System, a model 410 refractive index detector, and Autochro-GPC software (Young-In Scientific, Korea) for data acquisition with Styragel 2 and Styragel 4E columns placed in series in order of increasing pore size. THF was used as the eluent at a flow rate of 1 mL/min. The molecular weights were determined relative to narrow molecular weight polystyrene standard.

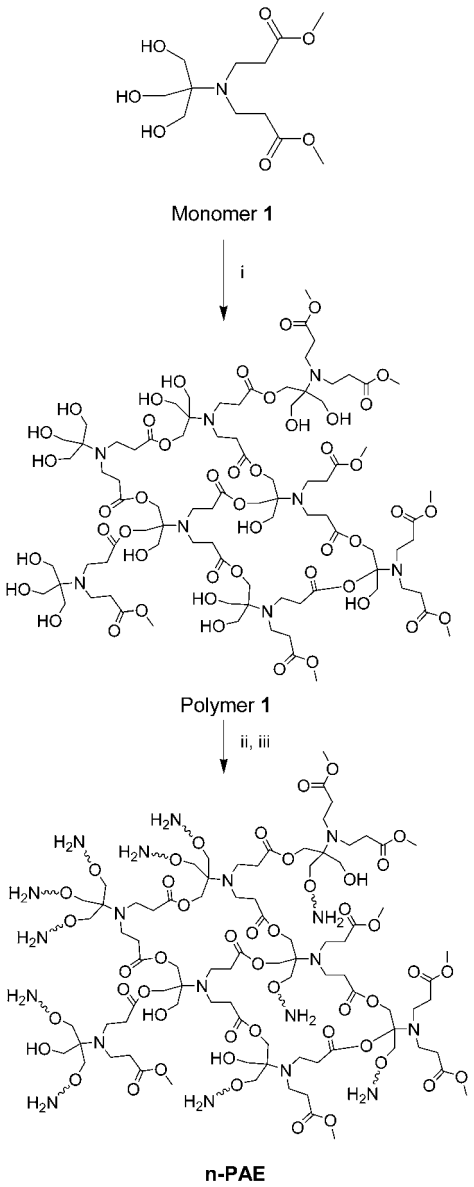
Fmoc protection groups from the Fmoc-eAhx-coupled polymer **1** (0.5 g) was removed by adding 20% piperidine in DMF (v/v). After 5 min of the deprotection reaction, the mixture was added dropwise into a large excess of EtOAc/ether (1:1) three times to give n-PAE (0.21 g) as a white solid. ^{1}H NMR (300 MHz, DMSO-d_6) δ 1.24−1.47 (br m, $CH_2(CH_2)_3CH_2COO$), 2.27 (br, $CH_2(CH_2)_3CH_2$-COO), 2.66 (br, $CH_2(CH_2)_3CH_2COO$), 3.21−3.40 (br m, $HOCH_2$), 3.51−3.55 (br m, CH_3), 3.85−4.15 (br m, $COOCH_2$).

Quantification of n-PAE Primary Amine Numbers by Using Fluorescamine. A series of known concentrations of *n*-butylamine (2 mL in 0.2 M sodium borate, pH 9.0) were placed in test tubes. While the tube was vigorously agitated on a Vortex mixer, 700 μL of fluorescamine solution (0.28 mg/mL in acetone) was added (*15*). Fluorescence measurements were carried out with an SFM 25 spectrofluorometer (Kontron Instruments). Excitation and emission wavelengths were set at 390 and 475 nm, respectively. A standard curve constructed in this way was used to find the amount of primary amines per mg n-PAE.

Atomic Force Microscopy (AFM). DNA (pGL3-control vector) was dissolved in Hepes-Mg (25 mM Hepes, 10 mM $MgCl_2$, pH 7.6) buffer at a concentration of 1 μg/mL to obtain a DNA image. Two microliters of the solution was deposited onto a freshly cleaved mica substrate. The solution was allowed to adsorb for 2 min, washed with 1 mL of distilled water, and rapidly dried in a stream of N_2 gas. For imaging the polyplex, the polyplex was made by mixing the plasmid solution in water (5 μg/mL) with an equal volume of polymer solution in water. Two microliters of the polyplex solution was deposited onto a freshly cleaved mica substrate. The solution was allowed to dry for 2 min, and then excess fluid was wicked off with filter paper. The solution was dried at room temperature before imaging.

AFM was performed using Nanoscope IIIa instrument equipped with an E scanner (Digital Instruments, Santa Barbara, CA). All AFM imaging was conventional ambient tapping mode AFM with scan speeds of about 5 Hz and data collection at 512 × 512 pixels.

Cytotoxicity Measurement. Cells were seeded at a density of 10000 cells/well in 96-well plate and grown in MEM supplemented with 10% fetal bovine serum (FBS), and 2 mM L-glutamine, 0.1 mM nonessential amino acids, and 1.0 mM sodium pyruvate to reach 60−70% confluence. Following exposure of the cells with polymer or polyplex solution for 4 h, cells were washed with phosphate-buffered saline (PBS), and 100 μL of the culture medium and 25 μL of 5 mg/mL stock solution of 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) were added to each well. After 2 h of incubation at 37 °C, 100 μL of extraction buffer (20% w/v of SDS in a solution of 50% of DMF, pH 4.7) were added. Absorbance was measured at 570 nm after an overnight incubation at 37 °C.



Transfection Protocol. Cells were seeded at a density of 10000 cells/well in 96-well plate and grown in MEM supplemented with 10% fetal bovine serum (FBS), 2 mM L-glutamine, 0.1 mM nonessential amino acids, and 1.0 mM sodium pyruvate to reach 60−70% confluence prior to transfection. Before transfection, cells were rinsed and serum-free or 10% FBS-containing medium was added to each well. The cells were treated with polyplex solution containing 1 μg of plasmid DNA for 4 h at 37 °C. The concentration of polymers varied depending on the polymer/DNA ratios. Then the transfection mixture was replaced with fresh medium. Cells were further incubated for 48 h at 37 °C.

Luciferase gene expression was measured by a luminescence assay. The growth medium was removed, and the cells were rinsed twice with PBS and lysed for 20 min at room temperature in 100 μL of Reporter Lysis Buffer (Promega). The lysate was cleared by centrifugation, and protein content was determined by using Micro BCA Protein Assay Reagent Kit (Pierce). Thirty microliters of the lysate was dispensed into a luminometer tube, and luciferase activity was integrated over 10 s with 2 s measurement delay in a Lumat LB 9507 luminometer (Berthold, Germany) with automatic injection of 100 μL of Luciferase Assay Reagent (Promega). Results were expressed as relative light units per mg of cellular protein.

RESULTS AND DISCUSSION

Synthesis and Characterization of n-PAE. The construction of n-PAE commences with the condensation polymerization of monomer **1**, which has three hydroxyls, two methyl esters, and one tertiary amine, affording polymer **1** (Scheme 1). Coupling of Fmoc-eAhx acid in the remaining hydroxyl groups of polymer **1** and successive deprotection of Fmoc groups yields n-PAE. Quantification of primary amine numbers by fluorescamine method showed that n-PAE had 1.3 μmol primary amines/mg. GPC analysis with linear polystyrene standard showed that M_n and M_w of Fmoc-eAhx-coupled polymer **1** (n-PAE precursor) were 3800 and 4500, respectively. The unusually low polydispersity index (1.18) as a condensation polymer is likely the result of fractionation during precipitation purification. It is well-known that GPC, based on the hydrodynamic radius (R_h) measurement of polymers, underestimate the true molecular weight distribution (MWD) of branched polymers several times (*16*). As a result, it is generally accepted that true MWD of branched polymers should be three to five times higher than the values obtained from GPC. In this respect, the true MWD of n-PAE should be much higher than the values obtained by GPC with linear polymer standard. We are currently investigating the absolute MWD of

Scheme 1. Synthesis of n-PAE[a]

n-PAE by using a multiangle laser light scattering technique in GPC. The structure of n-PAE was designed to be multifunctional by equipping it with biodegradable ester backbone linkages for nontoxicity, multiple primary amines for DNA condensation, multiple tertiary amines for selective protonation according to the pH of surrounding milieu, and network-type chain interconnected structure for controlled degradation.

Formation and Stability of n-PAE/DNA Polyplex. The formation and stability of n-PAE/DNA polyplex at pH 7.4, 37 °C were investigated by agarose gel electrophoresis as a function of time at various n-PAE nitrogen/DNA phosphate ratios (N/P ratios) (Figure 1). Partially formed polyplex was observed at a N/P ratio of 4. When the ratio reached 10, no DNA migrated through the gel, indicating the formation of the polyplex. n-PAE had 1.3 μmol primary amines/mg as describe above. This means that charge neutralization of the polyplex occurs at a N/P ratio of 4.9 on the assumption that only primary amines are protonated at pH 7.4. Therefore, the exact point of charge neutralization should be a N/P ratio of between 4 and 10. As time passed, DNA bands appeared and the polyplex bands at the wells of agarose gel disappeared, indicating that after degradation of n-PAE the condensed DNA was gradually released from the polyplex. The stability of the polyplex increased with increasing N/P ratio where the polyplex remained intact over 3 days at and above a N/P ratio above 20 (Figure 1C and 1D). The appearance of linear DNA, which was not observed in initial plasmid DNA bands, suggests that small parts of nicked circular DNA were cleaved during the incubation period. However, the majority of the released plasmid DNA maintained their initial conformations even after the complete degradation of the polyplex.

It has been reported that the linear polyesters having nucleophilic groups (primary amine, secondary amine, and carboxylic acid) in their structure were degraded very rapidly in aqueous solution through a self-destruction mechanism (*7*, *9*). For this reason, the stability of the polyplexes formed with the linear polyesters could not exceed 8 h at pH 7.4, 37 °C. However, there is a need to extend the degradation to a reasonable rate for the polymeric vector to protect DNA from the harsh extracellular and/or cytosolic environment until it enters the cell nucleus. It can be expected that the MWD of the linear polyesters would be halved by a single cleavage of the polymer chain, which explains the rapid degradation kinetics of the polymers. In a network-type chain interconnected structure, however, the MWD of the polymer is not likely to be changed by a single and/or several chain cleavages. For this reason, the stability of n-PAE/DNA polyplex was much extended over that of linear biodegradable cationic polymers.

AFM observations showed the formation of polyplex between n-PAE and DNA visually. Supercoiled or nicked circular DNA comprised the majority of the plasmid DNA population (Figure 2A). This result is consistent with the

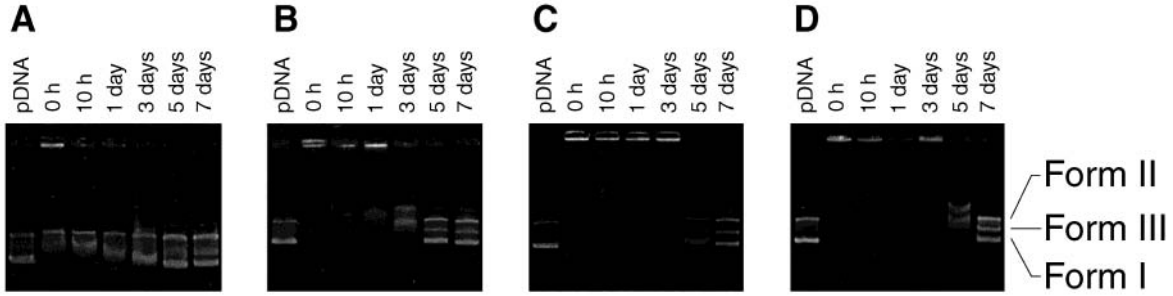

Figure 1. Formation and stability of n-PAE/DNA (pGL3-control) polyplex. The polyplex formed at n-PAE/DNA ratio (N/P) of (A) 4 and (B) 10 and (C) 20 and (D) 40 and incubated at 37 °C. Aliquots taken at the indicated times were electrophoresed through 0.7% agarose gel and stained with ethidium bromide to visualize DNA. Form I = supercoiled, form II = nicked circular, and form III = linear DNA.

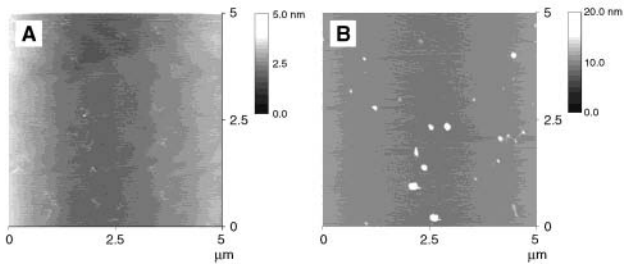

Figure 2. AFM images of (A) plasmid DNA (pGL3-control) and (B) n-PAE/DNA polyplex. The polyplex was formed at a N/P ratio of 10.

electrophoretic observation of the plasmid DNA conformation (vide ante). AFM image of n-PAE/DNA polyplex showed that all of the plasmid DNA was complexed with n-PAE to form a somewhat heterogeneous population of round-shaped particles (Figure 2B).

Cytotoxicity Measurement. The cytotoxicity profiles of n-PAE were investigated by using an MTT assay (Figure 3A and 3B). The results indicated that n-PAE was minimally toxic with 93% and 87% of cells remaining viable even at very high polymer concentration (200 μg/mL) for 293 and HepG2 cells, respectively. The order of cytotoxicity was PEI (branched) > poly[α-(4-aminobutyl)-L-glycolic acid] (PAGA) > n-PAE. PAGA is a biodegradable cationic polymer used for gene transfection as reported previously (*9*, *10*). The polyplexes showed similar cytotoxicity profiles (Figure 3C and 3D). The near nontoxic property of n-PAE should be the result of the biodegradable property of the polymer, which is in line with several biodegradable cationic polymers investigated in the previous reports (*7-13*).

Transfection Efficiency of n-PAE. The transfection efficiency (TE) evaluated by luciferase reporter gene assay revealed that n-PAE was very efficient in transfection (Figure 4A). Transfection was performed in the absence of chloroquine to show the polymers' own effect. Chloroquine is known to accumulate in endosomal compartment, buffer endosome acidification, and induce osmotic swelling of the endosome, which eventually results in endosome destabilization and release of internalized polyplex (*17*). Remarkably, the TE of n-PAE was not less than that of PEI 25 kDa. PEI has been one of the most efficient polymeric gene carriers reported until now. However, the high cytotoxicity of PEI, due to the nondegradable property of the polymer, poses a serious problem for its application in human gene therapy trials (*6*). In 293 cells, the TE of n-PAE was even about 7-fold higher than that of PEI. In comparison, the TE of PAGA was very low, with values 110 and 320-fold lower than those of n-PAE in 293 and HepG2 cells, respectively. PAGA is a linear biodegradable cationic polymer with multiple primary amines. Similarly, the high TE and low cytotoxicity profile of n-PAE were also observed in other mammalian cell lines (data not shown).

In situ X-gal staining of cells transfected with reporter gene expressing β-galactosidase highlighted the differences in cytotoxicity and transfection efficiencies among the polymers more demonstrably (Figure 4B). Far less than 1% of the cells were stained when PAGA was used

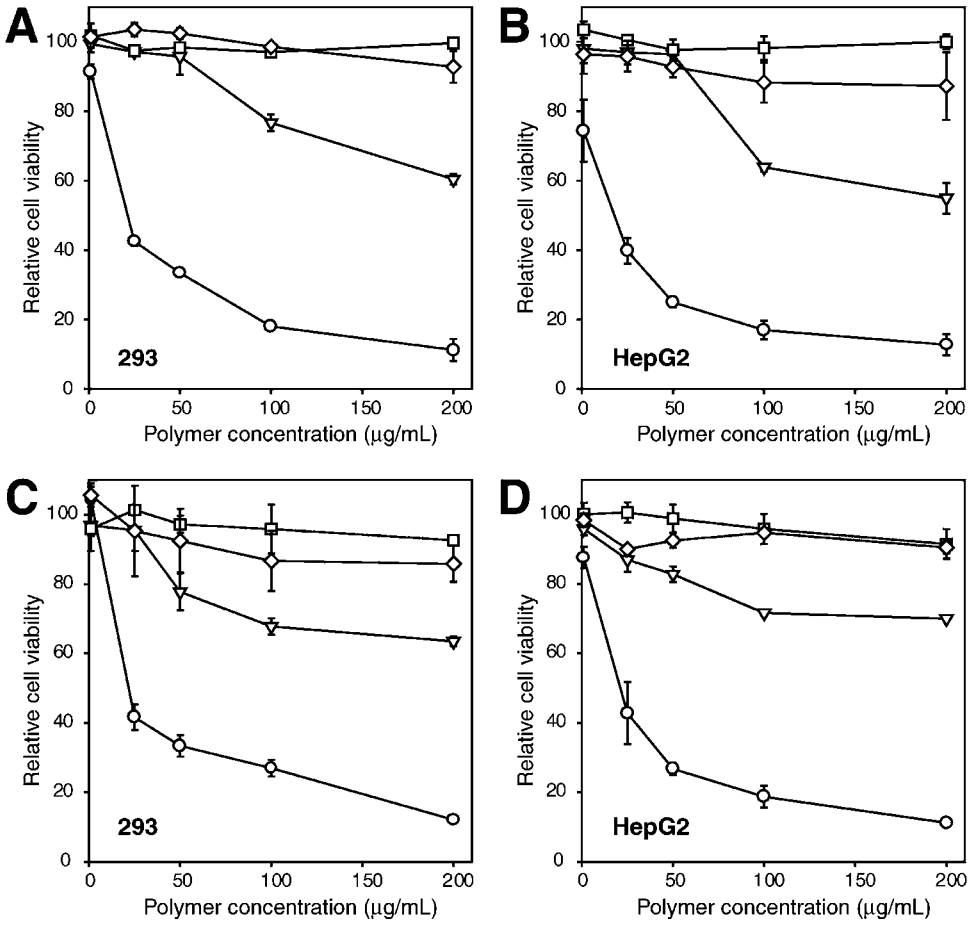

Figure 3. Cytotoxicity in 293 and HepG2 cells by MTT assay. (A, B) Cytotoxicity of polymers. (C, D) Cytotoxicity of polyplexes. All polyplexes were formed at polymer/DNA weight ratios of 5. PEI (○), PAGA (▽), n-PAE (◇), and polymer **1** (□). Relative cell viability was calculated as 100 × [(A_{570} of polymer treated cells − A_{570} of blank)/(A_{570} of control cells − A_{570} of blank)]. Mean ± SEM (n = 5).

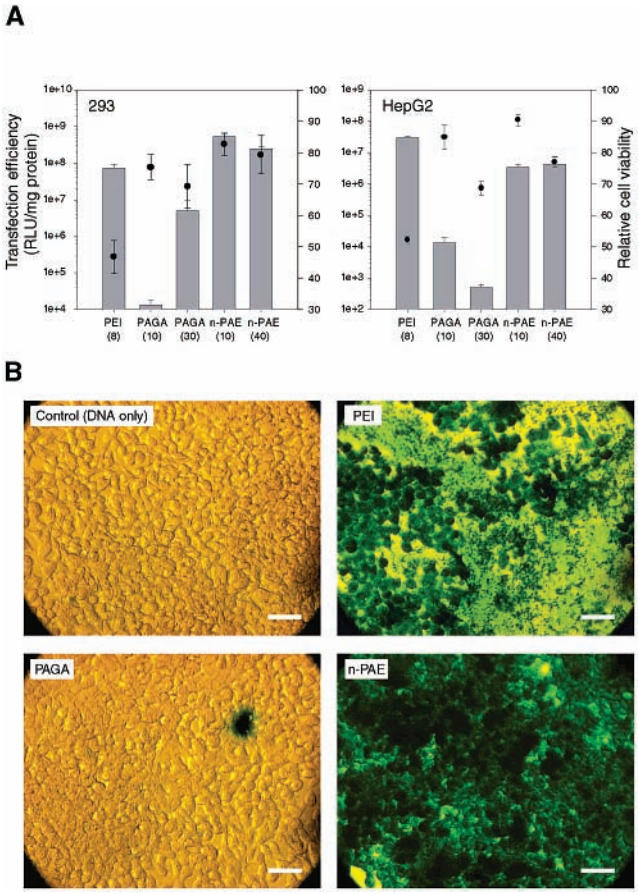

Figure 4. (A) Transfection efficiency (bar graph) and cytotoxicity (filled circle) in 293 and HepG2 cells. The cells were transfected with pGL3 control vector encoding firefly luciferase as a reporter gene. Numbers in parentheses indicate N/P ratios. RLU = relative light unit. Mean ± SEM ($n = 5$) (B) In situ X-gal staining of 293 cells transfected with pCN−LacZ vector encoding β-galactosidase gene. The scale bars represent 50 μm. Transfection experiments were performed without serum, chloroquine, and nigericin.

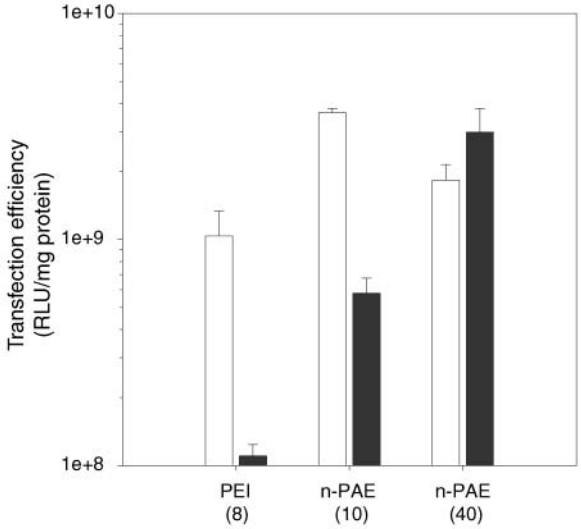

Figure 5. Transfection in the presence of serum. Transfection was performed in 293 cells in the absence (open bars) or the presence (filled bars) of 10% FBS. Numbers in parentheses indicate N/P ratios. Mean ± SEM ($n = 5$). Transfection experiments were performed without chloroquine and nigericin.

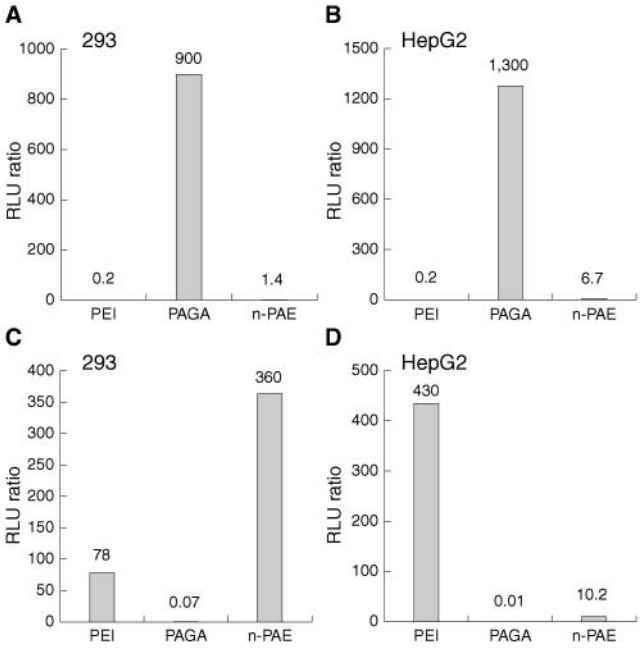

Figure 6. Effect of chloroquine or nigericin treatment on the TEs of PEI, PAGA, and n-PAE. (A, B) RLU in the presence of chloroquine (50 μm)/RLU in the absence of chloroquine. (C, D) RLU in the absence of nigericin/RLU in the presence of nigericin (5 μm). Values are indicated above each bar.

for transfection. In contrast, nearly all of the cells transfected with PEI and n-PAE were stained blue, which indicated the efficient transfection by both the polymers. However, the cells transfected with PEI are in striking contrast to the cells treated with PAGA and n-PAE. The majority of PEI-transfected cells were granulated and dead, whereas most of the cells transfected with PAGA and n-PAE were viable and looked healthy.

If gene delivery carriers are to be used in vivo, the transfection efficiencies of the carriers should be remain relatively unaffected by the presence of serum. As shown in Figure 5, the TE of n-PAE was decrease by 6.3-fold in the presence serum at a N/P ratio of 10. However, n-PAE-mediated transfection was even increased by 1.6-fold by the presence of serum at a N/P ratio of 40. The little or lack of serum inhibition on n-PAE transfection implies that n-PAE will be a promising candidate for in vivo gene therapy.

Transfection Mechanism of n-PAE/DNA Polyplex. The high TEs of n-PAE and PEI are likely to be the result of the "endosome buffering" or "proton sponge" effect of the polymers (*18*). Multiple tertiary amines in the polymers, mostly in the form of free bases at slightly basic physiological pH, become protonated at the acidic pH of endosome, which disrupt the endosomal vesicle either by mechanical swelling or osmotic effects. To verify that the high TE of n-PAE is a result of the endosome buffering effect, transfection experiments were performed in the presence or absence of chloroquine or nigericin (Figure 6). Nigericin is a carboxylic ionophore that mediates exchange of monovalent cations through the membrane and is known to be an inhibitor of endosomal acidification (*19*). Chloroquine treatment resulted in a decrease or a small increase in the TEs of PEI and n-PAE, respectively, but a large increase in the TE of PAGA in both cell lines tested (Figure 6A and 6B). For example, the TE of PAGA increased by 900-fold upon chloroquine treatment in 293 cells. In contrast, the TEs of PEI and n-PAE increased only by 0.2- and 1.4-fold, respectively. These findings suggest that polyplexes formed with PEI or n-PAE do not need chloroquine assistance for endosome escape, as they are already equipped with endosome buffering function

due to the presence of multiple tertiary amines in their structure. The effect of nigericin treatment on TEs further demonstrated the endosome buffering effect of PEI and n-PAE (Figure 6C and 6D). The efficiencies of PEI- and n-PAE-mediated gene delivery were significantly reduced when nigericin was added in the transfection medium, which are attributed to the inhibitory effect of nigericin on endosomal acidification. However, the TE of PAGA was even enhanced by nigericin treatment. Taken together, these results suggest that transfection of PEI and n-PAE is mediated by endosome acidification followed by release of the polyplex into cytosol, which would eventually increase the amount of DNA entering into the nucleus for the transcription.

We have described that through the rational design of polymer structure it was possible to make a nontoxic and efficient gene carrier, which represents a further step in mimicking the cell entry mechanism of viruses, yet maintaining safety profiles. Further elaboration of the structure of n-PAE and/or the analogous polymers based on our approach, such as the attachment of a targeting moiety, a nucleus localization signal, and a stealth function, are expected ultimately to lead to the development of a "safe artificial virus".

Received April 26, 2002; Revised Manuscript Received June 25, 2002

We have developed a solid-phase procedure for protein−protein conjugation that gives greater control over product size and composition than previous methods. Conjugates are assembled by sequential addition of activated proteins to the support under conditions suitable for maintaining the activity of the proteins. The total number of conjugate units to be prepared is fixed in the first step by the quantity of the first protein absorbed by the support. In each following step, the added protein links only to previously bound protein. The final conjugate is released to solution by cleaving the linker holding the first protein to the support. This stepwise assembly provides uniformly sized conjugates of the desired size and composition with placement of components at the desired positions within the structure. Using this approach, we have prepared a series of conjugates containing *R*-phycoerythrin as the central protein, with varying quantities of alkaline phosphatase and IgG with expected molecular masses ranging from 1.6 to 11.5 MDa. Size-exclusion chromatography and atomic force microscopy demonstrate homogeneity and control of the conjugate size. In an immunoassay for human thyroid stimulating hormone, the conjugates show signals consistent with their compositions.

INTRODUCTION

There are numerous occasions in life sciences in which it is desirable to link two or more proteins together to obtain a species that combines the properties of each. Most commonly, a protein with specific binding affinity to a target is linked to a second protein with a desired activity. In immunodiagnostic applications, the binding protein is typically an antibody directed against the desired analyte, and the second protein is usually a fluorescent protein or an enzyme that generates a signal detectable by eye or by instrumentation (*1*−*4*). In therapeutic applications, the binding protein may be an antibody or a ligand with specific binding to a cell surface receptor, and the second protein may be a toxin that kills the targeted cell (*5*). A variety of methods have been devised to link proteins together. Most commonly, the two proteins are chemically activated so that groups on one can form stable covalent links to groups on the other. They are then combined in a homogeneous solution and allowed to react under conditions suitable for both linking and maintenance of their activities. When a sufficient proportion of the proteins are linked, the reaction is stopped by adding reagents that deactivate one or both of the reactive groups. These conjugation reactions are difficult to control. The activating agents usually generate numerous active positions on each protein molecule, with the result that many points of attachment are possible. Linkage at one active group on a protein does not prevent linkage at a second or third point, and a broad distribution of aggregates consisting of many units of each of the proteins may result. While it is frequently desirable to produce multimeric conjugates, it is also desirable to control these so that a majority of the species produced contains the number of each protein unit most suitable for the intended purpose of the conjugate. We have developed a method for preparing protein−protein conjugates with highly predictable and controllable composition and size. A first protein, termed the "core", is bound to a solid support via a cleavable linker. Additional proteins are introduced sequentially as "layers" under conditions that allow their stable linkage only to the core or to the immediately previous layer of protein. After completion of the reaction sequence, the protein assembly is released by cleaving the linker holding the core protein to the support. Immobilization of the core protein on the support prevents interaction of the assembly with other immobilized assemblies during the reaction sequence. Therefore, at each step, the assembly can grow only by linking the added free protein. If the added proteins are not self-reactive, the growth at each step is limited to the quantity that can directly link to the previous layer. Excess can be added to saturate all available sites and unreacted material washed from the support before the next step is started. Each successive layer contains more protein than the previous layer, suggesting radial growth of the conjugates. Very large conjugates can be prepared with relatively few steps of protein addition.

This method of protein conjugation has several advantages over solution methods. The narrow distribution of sizes of the released conjugate allows it to be optimized with respect to intended properties. The sequence of addition allows placement of specific components at the most desirable position in the conjugate. Binding agents may be added in the final conjugation step, placing them at the periphery of the conjugate where they can most effectively interact with their target. Other proteins beyond the binding and reporter proteins may be included to confer additional properties. The ability to control the quantities and positions of proteins within the assemblies leads us to term them "defined conjugates".

In the present work, we use the solid-phase technique to prepare a number of defined conjugates containing

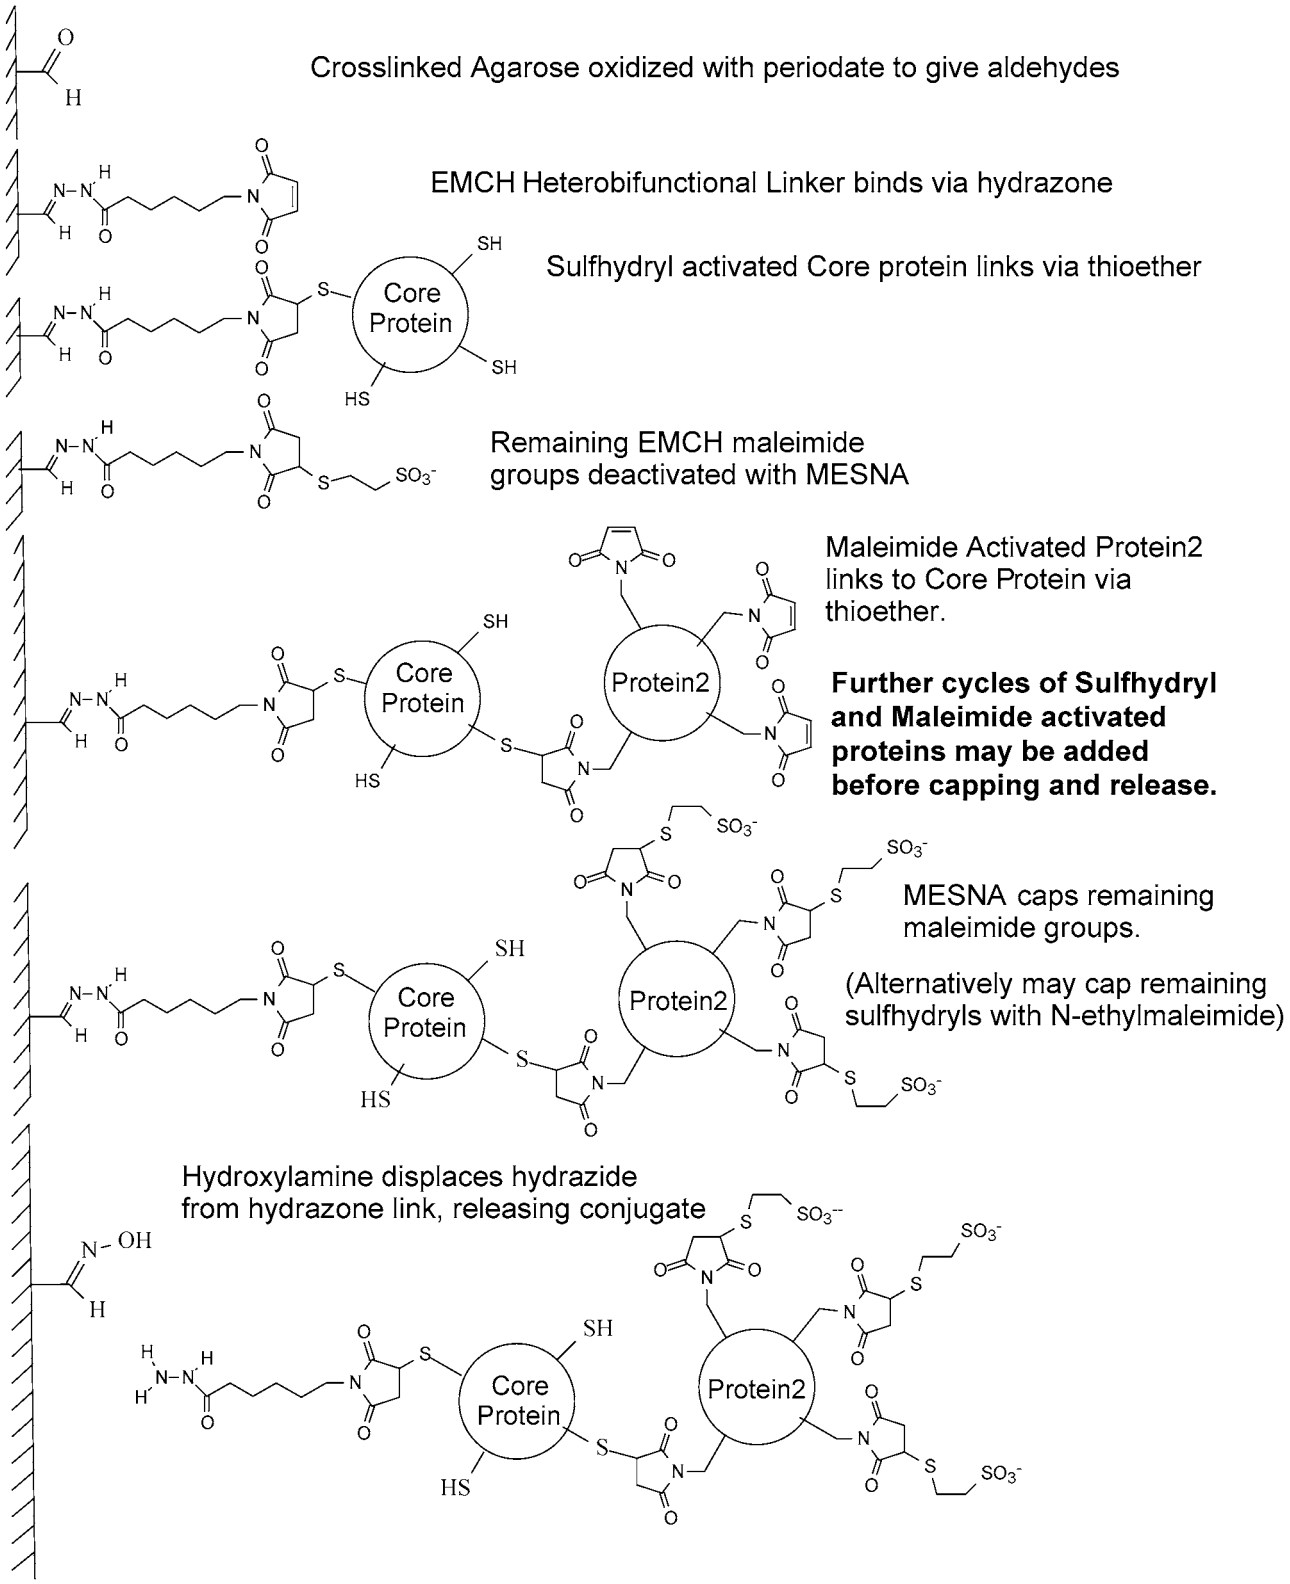
R-phycoerythrin (RPE)[1] as the core, several layers of alkaline phosphatase (AP), and a final layer consisting of antibody specific to the α subunit of thyroid stimulating hormone (Ab). We then compare these with conventionally prepared conjugates using HPLC and atomic force microscopy to compare size and dispersity. The defined conjugates are then tested in an immunoassay format to demonstrate the dependency of enzyme and antibody content on their ability to generate signal. Scheme 1 diagrams the process of controlled conjugation used in this report. An agarose support is oxidized with periodate to give immobilized aldehydes (*6*). The hydrazide function of the heterobifunctional linker *N*-(ϵ-maleimidocaproic acid)hydrazide (EMCH) reacts with the aldehydes to give a maleimide group linked to the support via the hydrazone. Proteins to be conjugated are activated with *N*-succinimidyl *S*-acetylthioacetate (SATA) to give sulfhydryl groups or with γ-maleimidobutyric acid *N*-hydroxysuccinimide ester (GMBS) to give maleimide groups. A sulfhydryl-activated protein reacts with the maleimide of the bound EMCH, forming a stable thioether linkage, still held to the agarose support. Remaining maleimide groups on the support are destroyed by adding mercaptoethanesulfonic acid sodium salt (MESNA). The support is then washed to remove excess MESNA, leaving sulfhydryl groups only on the bound protein. After washing the agarose to remove unbound reactive materials, a second protein, containing maleimide groups, is added. This reacts with remaining sulfhydryl groups on the first protein, again forming a thioether linkage. If an excess of the second protein is added, all the available binding locations on the first protein will be occupied. Remaining sulfhydryl groups on the first protein will be available for reaction only with small molecules. The exposed surface of the growing conjugate consists of the second protein with maleimide groups available for reaction with a third protein (or a repeat of the first) containing sulfhydryl groups. When all the desired layers of protein have been added, the remaining thiol groups are converted to unreactive thioethers with *N*-ethylmaleimide and the remaining maleimide groups likewise capped with MESNA. The conjugate is then released from the support by adding hydroxylamine. This reacts with the linkage holding the conjugate to the support and releases it, presumably as the hydrazide.

EXPERIMENTAL SECTION

Materials. *R*-Phycoerythrin was obtained from Prozyme (San Leandro, CA). Calf intestinal alkaline phosphatase was obtained from Boehringer Mannheim (Indianapolis, IN). AntiTSHalpha IgG (MIT 0414) was obtained from Genzyme (Framingham, MA). Sodium periodate, Sepharose CL2B, *N*-ethylmaleimide, mercaptoethanesulfonic acid sodium salt, 5,5′-dithiobis(2-nitrobenzoic acid), tris-(hydroxymethyl)aminomethane, 3-[(3-cholamidopropyl)-dimethylammonio]-1-propanesulfonate, triethanolamine hydrochloride, and γ-maleimidobutyric acid *N*-hydroxysuccinimide ester were obtained from Sigma (St. Louis, MO). *N*-Succinimidyl *S*-acetylthioacetate, *N*-(ϵ-maleimidocaproic acid)hydrazide, *p*-nitrophenyl phosphate substrate, Superblock blocking agent, and BCA protein assay kit were obtained from Pierce (Rockford, IL). Hydroxylamine 50% solution was obtained from Aldrich (Milwaukee, WI). The monoclonal antibody against the β subunit of human thyroid stimulating hormone (TSH) and standard solutions with known concentrations of TSH were obtained from Abbott Laboratories (North Chicago, IL).

Activation of Proteins. (A) RPE-SH. To 200 μL of *R*-phycoerythrin at 10 mg/mL in 100 mM triethanolamine hydrochloride at pH 7.6 was added 10 μL of 100 mM *N*-succinimidyl *S*-acetylthioacetate (SATA) (*7*) in dimethylformamide. After 1 h incubation at room temperature, 10 μL of 50% hydroxylamine was added. After 40 min at room temperature, the mixture was desalted on Sephadex G25 into PBS with 5 mM EDTA, collecting 550 μL. The concentration was determined by the absorbance at 565 nm to be 10.1 μM (*9*), and the number of SH groups per molecule was determined to be 22.5 using Ellman's reagent.

(B) AP-SH. To 500 μL of alkaline phosphatase at 10 mg/mL in triethanolamine HCl was added 50 μL of 1 M sodium phosphate, pH 7.5, and 25 μL of 100 mM SATA in dimethylformamide. After 1 h incubation at room temperature, 25 μL of 50% hydroxylamine was added. After 40 min at room temperature, the mixture was desalted on Sephadex G25 into PBS with 5 mM EDTA, collecting 1.2 mL. The concentration was determined by the absorbance at 280 nm to be 30.5 μM, and the number of SH groups per molecule was determined to be 15.3 using Ellman's reagent. According to the supplier, calf intestinal alkaline phosphatase contains 18 conjugatable amine groups.



(C) AP-Mal. To 500 μL of alkaline phosphatase at 10 mg/mL in triethanolamine HCl was added 50 μL of 1 M sodium phosphate, pH 7.5, and 25 μL of 100 mM GMBS (*8*) in dimethylformamide. After 100 min at room temperature, the mixture was desalted on Sephadex G25 into PBS with 5 mM EDTA, collecting 1.2 mL. The concentration was determined by the absorbance at 280 nm to be 29.8 μM, and the number of maleimide groups per molecule was determined to be 15.4 by the change in absorbance at 300 nm after addition of MESNA to destroy the maleimide chromophore.

(D) Ab-Mal. To 200 μL of Anti-TSHalpha IgG at 7.03 mg/mL in PBS was added 10 μL of 100 mM GMBS in dimethylformamide and 2 μL of 1 M sodium carbonate to give pH 7.7. After 100 min incubation at room temperature, the mixture was desalted into PBS with 5 mM EDTA, collecting 550 μL. The concentration was determined by the absorbance at 280 nm to be 15.9 μM, and the number of maleimide groups per molecule was determined to be 28.5 by the change in absorbance at 300 nm after addition of MESNA to destroy the maleimide chromophore.

(E) Ab-SH. To 100 μL of Anti-TSHalpha IgG at 7.03 mg/mL in 100 mM sodium phosphate 150 mM sodium chloride, pH 7.2, was added 5 μL of 100 mM SATA in DMF and 1 μL of 1 M sodium carbonate. After 1 h incubation at room temperature, 10 μL of 50% hydroxylamine was added. After 40 min at room temperature, the mixture was desalted into PBS with 5 mM EDTA, collecting 550 μL. The concentration was determined by the absorbance at 280 nm to be 11.7 μM, and the number

[1] Abbreviations: RPE, *R*-phycoerythrin; AP, calf intestinal alkaline phosphatase; Ab, antibody; EMCH, *N*-(ϵ-maleimidocaproic acid)hydrazide; MESNA, mercaptoethanesulfonic acid sodium salt; GMBS, γ-maleimidobutyric acid *N*-hydroxysuccinimide ester; SATA, *N*-succinimidyl *S*-acetylthioacetate; DTNB, 5,5′-dithiobis(2-nitrobenzoic acid); Tris, tris(hydroxymethyl)-aminomethane; CHAPS, 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate; PBS, 10 mM sodium phosphate, 150 mM sodium chloride, pH 7.2; EDTA, ethylenediaminetetraacetic acid; PCE, PBS containing 2 mg/mL CHAPS and 5 mM EDTA; TC75E, 100 mM Tris with 2 mg/mL CHAPS and 5 mM EDTA, pH 7.5; TC75E, 100 mM Tris with 2 mg/mL CHAPS and 5 mM EDTA, pH 7.5; TC8E, 100 mM Tris with 2 mg/mL CHAPS and 5 mM EDTA, pH 8.0.

Scheme 1. Reaction Sequence in Defined Conjugation

of SH groups per molecule was determined to be 25.4 using Ellman's reagent.

Preparation of Support. (A) Periodate Oxidation of Agarose. Approximately 20 mL of Sepharose CL2B was poured into a column fitted with a fritted disk, washed with water, and suspended in 20 mL of excess water. To this was added 200 μL of 100 mM sodium periodate and the mixture inverted several times to mix. After 75 min at room temperature, 1 mL of glycerol was added and the mixture inverted several times to mix. After 15 min, the column was drained and washed with several column volumes of water and then with PBS.

(B) Activation of Oxidized Agarose with EMCH. To a 20 mL column was added 6.0 mL of oxidized agarose. This was washed with 20 mL of PCE (see list of abbreviations). The washed support was vortexed with 3 mL of PCE and 90 μL of 100 mM EMCH in dimethylformamide. After 30 min incubation at room temperature,

the column was drained, washed with 15 mL of cold TC75E (100 mM Tris, 0.2% CHAPS, 5 mM EDTA, pH 7.5), and placed in ice.

Conjugation on Support. (A) Immobilization of RPE-SH. To each of eight 2 mL columns (reactions A−H of Table 1) was added 600 μL of the EMCH-treated resin, and the mixtures were washed with 2 mL of TC75E. The columns were cooled in ice; then 0.200 nmol (198 μL) of RPE-SH was added to each, and the resins were thoroughly dispersed by vortexing. After 20 min incubation in ice with occasional vortexing, 10 μL of 100 mM MESNA was added to each. After 5 min incubation in ice, the columns were drained and washed with 3.0 mL of cold TC8E. The absorbance of the first 1.5 mL of the effluent was measured at 565 nm to determine the quantity of RPE-SH in the effluent. This was subtracted from that originally added to determine the quantity bound to the support, shown in Table 1.

(B) Addition of AP-Mal and AP-SH to Immobilized RPE-SH. Except for time spent draining and washing, the columns were kept in an ice bath throughout the conjugation procedure. The quantity of activated protein indicated in Table 1 was added to each, along with 100 μL of 1 M magnesium chloride and sufficient TC8E for complete dispersal of the resin on vortexing. The columns were incubated in ice 30 min with occasional vortexing and then drained, and the effluent was recycled through the column for a total of approximately 1 column volume. The columns were then washed with TC8E, and the next addition of activated protein was performed. The absorbance at 280 nm of the effluents was measured to determine the quantity of remaining alkaline phosphatase [$\epsilon(280) = 140\,000$], shown in Table 1.

(C) Addition of Ab-Mal and Ab-SH to Immobilized Conjugate. After the final addition and incubation of activated alkaline phosphatase according to Table 1, the columns were washed with 1.5 mL of TC75E and cooled in ice. The indicated quantity of activated Ab was added, the mixtures were incubated 5 min to allow dispersal of the protein, then 100 μL of 1 M magnesium chloride was added, and the mixture was incubated 30 min in ice. The columns were then drained and washed with 1.5 mL of TC8E. The absorbance at 280 nm of the effluents was measured, and the quantity of Ab remaining in the effluent was calculated using $\epsilon(280) = 210\,000$. From this, the quantity of Ab bound to the resin was calculated, and is shown in Table 1.

(D) Release of Conjugates from Support. After washing off the unbound Ab, the resins were treated with 5 μL of 100 mM *N*-ethylmaleimide to deactivate residual SH groups. The columns were left in ice until protein addition and washing was complete for all of the preparations. To deactivate residual maleimide groups, 10 μL of 100 mM MESNA was added, the mixtures were vortexed, and the columns were returned to the ice bath. After 10 min, 20 μL of 50% hydroxylamine was added, and the mixtures were incubated 60 min at room temperature. The columns were then drained directly into desalting columns equilibrated with PBS and the products washed through with TC8E and PBS collecting 2.5 mL of product. Concentrations of product, shown in Table 2 , were calculated based on the absorbance at 565 nm, and yields were calculated based on recovery of RPE color. Protein concentrations of the conjugates were measured by the BCA protein assay using the enhanced protocol according to the manufacturers' instructions. Alkaline phosphatase was used as the protein standard.

Conjugation of Ab-SH and AP-Mal in Solution. To a solution of PBS with 5 mM EDTA was added 2 nmol of Ab-SH and 4 nmol of AP-Mal prepared as above to give a total 800 μL and the mixture incubated in an ice bath. Aliquots of 200 μL of the reaction mixture were mixed with 4 μL of 100 mM aqueous *N*-ethylmaleimide to stop the conjugations at times of 15, 60, 150, and 300 min.

Characterization of Conjugates. (A) HPLC. To 300 μL of each conjugate was added 30 μL of 10 mg/mL CHAPS in PBS. A sample of 20 μL was passed through a Whatman Macrosphere GPC 1000A 250 × 4.6 mm column with 1 mg/mL CHAPS in PBS as the mobile phase at 0.2 mL/min, monitoring at 280 nm and 566 nm with a diode array detector.

(B) Atomic Force Microscopy. Silicon wafers (International Wafer) were cleaned by immersion in 3% hydrogen peroxide in sulfuric acid at 100 °C for 10 min, then washed with distilled water and blown dry. Samples were prepared by exposing 8 mm squares of the silicon wafers to dilutions of the conjugates at 1:100 in 10 mM sodium phosphate, 150 mM sodium chloride, pH 7.2. After 30 min at room temperature, the wafers were washed with water, blown dry with air, and heated at 45 °C for 2 h. The wafers were imaged using a NanoScope IIIa (Digital Instruments) atomic force microscope. Images were collected in TappingMode at ambient temperature in air using silicon-etched tips with a resonance frequency of 275−395 kHz and a scan rate of 1 μm/s. Tips were changed between samples to eliminate cross-contamination.

(C) Comparison of Conjugates in TSH Assay. Wells of a 96-well microtiter plate were coated with a mAb directed against the β subunit of TSH at 20 μg/mL in PBS for 60 min at 37 °C and blocked with Superblock according to the manufacturers' instructions. To the wells was added 25 μL of TSH standards, and the plate was covered and incubated 3 h at 37 °C. The wells were drained and washed 5× with water, and 100 μL of conjugate in 50 mM bis-tris-propane, 150 mM NaCl, 10 mM $MgCl_2$, 1 mM $ZnCl_2$, pH 7.2, containing 10% Superblock was added. The conjugate concentration was 40 pM RPE for one test and 200 ng/mL protein for another test. After 3 h at 37 °C, the wells were drained and washed 5× with water. One hundred microliters of substrate (PNPP, Pierce) was added, the plate placed at 37 °C, and the absorbance read at 405 nm at 30 s intervals over 30 min. *V*max (mA/min) was reported for each well.

RESULTS

Yields of released conjugate, shown in Table 2, are based on recovery of bound RPE, measured by its absorbance at 565 nm. These range from 76% for conjugate A, with a single layer of AP, to 50% for conjugate H, with five layers. The remainder is visible as pink color remaining in the support. Very little additional conjugate was released from the supports even with prolonged exposure to hydroxylamine.

Table 2 shows the molar ratios of AP to RPE and Ab to RPE absorbed by the support in the defined conjugate preparations. In reactions A, B, C, D, and H, the AP absorbed ranges from 3.5 to 74.1 per RPE, and the Ab is nearly constant at 5.5−5.8. For reactions D, E, F, and G, the AP is nearly constant at 44.4−46.9, and the Ab varies from 2.2 to 25.8. The average molecular mass for each of the assemblies was calculated from the uptake of the activated proteins, assuming a single RPE core in each discrete unit of conjugate and using molecular masses of 240 kDa for RPE, 140 kDa for AP, and 150 kDa for Ab. The molecular masses range from about 1.6 MDa for A to about 11 MDa for H. Molar concentrations of product are used with the molecular masses to calculate the mass concentrations. These compare well with mass concentrations measured by protein assay.

HPLC traces of both defined and solution-phase conjugates on a size-exclusion column are shown in Figure 1. Peaks corresponding to the defined conjugates with more layers of AP elute earlier than those with fewer layers, consistent with the calculated molecular masses. Monitoring at 565 nm shows a decrease in peak intensity with larger conjugate size, reflecting the lower RPE concentrations, while monitoring at 280 nm shows an increase in peak intensity resulting from the higher levels

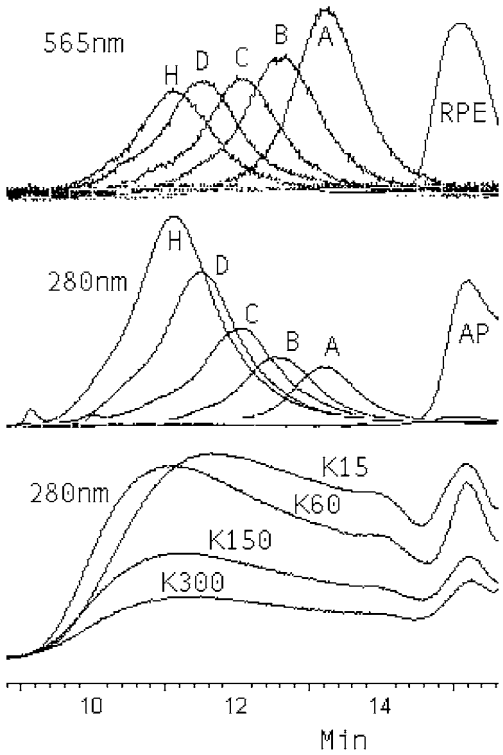

Figure 1. HPLC of conjugates Top: defined conjugates A−H, and native RPE and AP, monitoring at 565 and 280 nm. Bottom: solution-phase conjugates K15, K60, K150, and K300, monitoring at 280 nm.

of AP on the larger conjugates. In contrast, the conjugates prepared by solution-phase reaction (series K) show broad peaks reflecting a heterogeneous size distribution. Traces indicate large average conjugate size with 15 min reaction and some growth to larger size with 60 min reaction. With longer reaction times, the shape of the peak remains the same, but the signal intensity is decreased, suggesting that the conjugate has continued to grow to sizes that do not pass through the column prefilter.

Figure 2 shows representative atomic force microscopy images of defined and solution-phase conjugates. The defined conjugates are uniform in size and shape, with size increasing with the number of layers of AP, consistent with the calculated molecular masses and HPLC results. The solution-phase conjugates show extensive aggregation of the proteins increasing with reaction time, but a broad distribution of sizes for all reaction times.

Figure 3A shows results of an ELISA for TSH using the defined conjugates. When the molar concentration (based on absorbance at 565 nm of the RPE core) is held constant at 40 pM, and the antiTSH Ab is constant at about 5.7 per assembly, V_{max} for the hydrolysis of PNPP increases with AP content at each TSH level. Because the molecular masses of the conjugates vary over nearly an order of magnitude, the same experiment was performed with the weight-based conjugate concentration held constant at 200 ng/mL (results shown in Figure 3B). Here, the molar concentration of conjugate A is higher by a factor of 3 and that of H is lower by a factor of 2 than their respective concentrations in Figure 3A. Most of the conjugates give signals similar to those seen with molarity-based concentrations, supporting the interpretation that the signal depends more on the AP content of each conjugate unit than on the concentration of such units present in incubation. Conjugate H shows significantly less signal in the weight-based experiment. Most likely, the high molecular mass and low molar concentra-

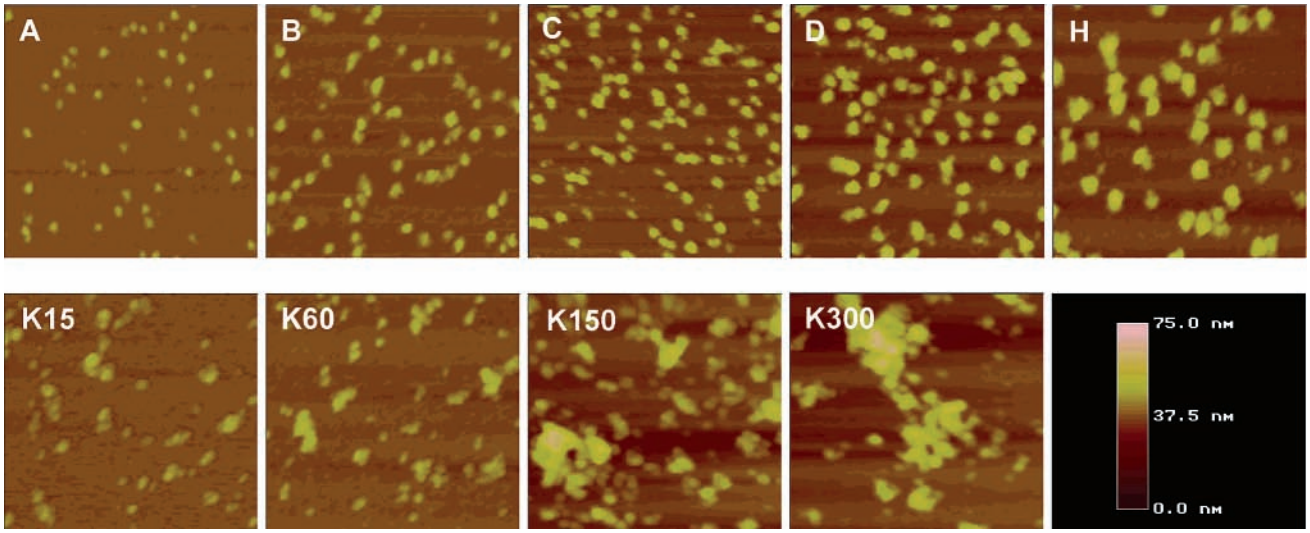

Figure 2. Atomic force microscopy height images of defined conjugates A, B, C, D, and H and solution conjugates K15, K60, K150, and K300 adsorbed to silicon surface. Each image is a 1 μm square. The height of features above the silicon surface is color-coded according to the scale shown.

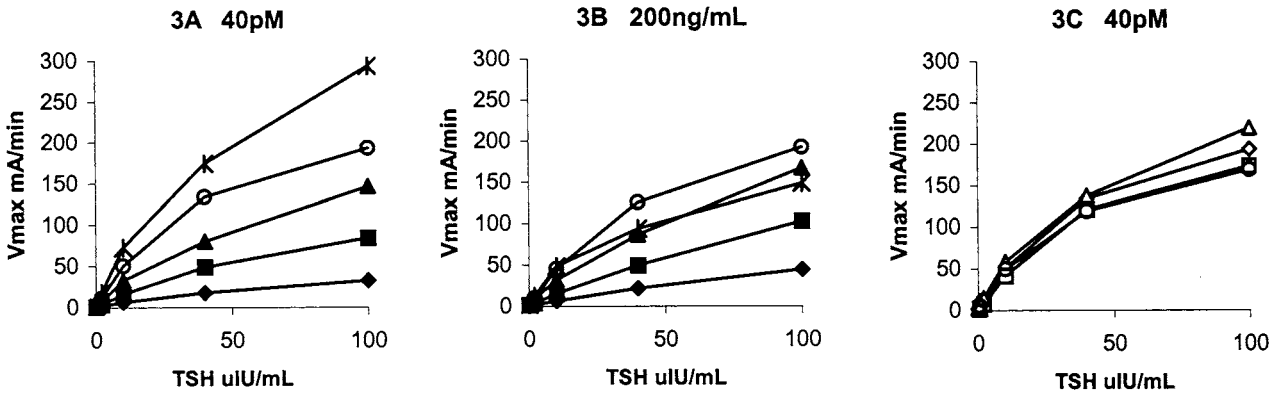

Figure 3. Comparison of defined conjugates varying AP and Ab contents in ELISA for TSH. (A) Conjugate at 40 pM shows that the signal-generating capacity of the conjugate is dependent primarily on its AP content, and (B) conjugate at 200 ng/mL shows that the AP content dependence holds even at constant mass of conjugate (see text for explanation of discrepancy for conjugate H). Conjugates with Ab content held constant at 5.5−5.8 with varying AP: ◆ A (AP = 3.5), ■ B (AP = 10.8), ▲ C (AP = 24.8), ○ D (AP = 46.9), ∗ (AP = 74.1). (C) Conjugate at 40 pM with AP held constant at 44.4−46.9; varying Ab shows that antibody content of conjugate has little effect on signal compared to AP content: □ E (Ab = 2.2), ○ D (Ab = 5.8), △ F (Ab = 16.0), ◇ G (Ab = 25.8).

tion result in slow diffusion of the conjugate to the surface containing the bound TSH.

Figure 3C shows the effect of varying Ab content of the defined conjugate while holding the AP content constant at about 45 per conjugate unit. With Ab content ranging from 2.2 to 26 per conjugate unit, the signal varies only by about 20%, pointing to the AP content of each conjugate unit as the primary determinant of its ability to generate signal.

DISCUSSION

In most applications, protein conjugation has been treated primarily as a combining of the desired functional properties of the proteins, for example, a specific binding property with a specific signaling property. Structural considerations are usually limited to those thought to affect these properties, such as the use of site-specific activation of the antibody to direct coupling away from the binding site. Typically, only two proteins are coupled, since a third protein would complicate the mixture. The intent of the present work is to control the physical construction of protein conjugates, placing arbitrarily chosen proteins in the desired numbers at the desired positions within the assembly.

Other subdisciplines of chemistry have achieved a high level of control of reactions by use of solid supports. Peptides (*10*), nucleic acids (*11*, *12*), and saccharides (*13*) with the desired sequence of subunits can be built up in discrete steps from specific starting points on the solid phase and finally released by chemical treatment. Intermediate reactions in the synthesis are driven to completion by use of excess reagents that are easily washed from the support before starting the next step. In the present work, immobilization of the starting material provides the same benefits, but even more importantly it prevents the uncontrolled polymerization that the plurality of reactive sites per molecule would lead to in a solution-phase reaction.

In peptide, nucleic acid, and saccharide synthesis, the target is a single chemical species, and precise control of the functional groups undergoing reaction is essential. For antibody−enzyme conjugates, linkage may occur at any of many different residues of either protein and still yield a product with the desired properties. Therefore, the target can be defined at a more macroscopic level to be a linkage of the desired protein species in the desired number and location in each independent unit. This relaxed requirement for control allows selection from a

wide range of linking agents, and permits the use of the aqueous reaction media needed to retain binding and enzymatic activity of the proteins.

Many of the same considerations for affinity chromatography hold in solid-phase conjugation. The support must allow free movement of proteins through its pores, but must also provide a high surface area for binding the desired proteins. The support must also be subject to modification to attach the chemical groups intended to interact with the proteins. Cross-linked agarose meets these criteria. The Sepharose CL-2B used in this work has an exclusion limit of 40 MDa, sufficient to allow conjugation and elution of the assemblies prepared here. Periodate oxidation produces aldehyde groups, which can be further modified as needed.

Several chemistries are available for linking proteins to the support and to other proteins. The linkage holding the assembly to the support must be stable throughout the reaction sequence, but must be cleavable by conditions that do not damage the desired properties of the conjugate. The hydrazone linkage we chose for this work is cleaved under mild conditions expected to have minimal effect on the protein. Other possible cleavable linking groups include disulfide (cleavable by reducing agents) and vicinal diol (cleavable by periodate). These would be less generally applicable than the hydrazone link used here, since the reagents used to cleave them would be expected also to react with disulfide and carbohydrate groups, respectively, in the protein conjugates.

The stepwise approach allows assembly of multiple proteins, with assurance that each conjugate unit will contain the desired quantity of each. Here, we have taken advantage of this to include a third protein, RPE, as the core. This adds a third property to the conjugate: a specific optical absorbance allowing accurate quantitation of the product. The high extinction coefficient of RPE at wavelengths at which most proteins have no absorbance makes it easy to measure its concentration even in dilute solutions containing components that would interfere with other protein measurements. Assuming that each conjugate unit contains a single core protein, the absorbance of the conjugate at 565 nm provides a direct measure of the molar concentration of the conjugate independent of the other proteins included.

As a practical note, the intense color of RPE also makes it easy to follow in the manipulations involved in solid-phase conjugation. Its uptake into the support gives visual confirmation that the activation steps to this point have been successful. After cleaving the linkage to the support, the elution of conjugate is easily observed, allowing collection of the product with minimal dilution by wash buffer.

For the purpose of composition and molecular mass calculations, we have assumed that reaction centers remain independent throughout the sequence and that each reaction center absorbs the same number of protein molecules in each step. Both of these assumptions must be considered ideals that are approached but may not be fully achieved in the present work. A small shoulder is present on the left side of the HPLC traces in Figure 1 for all the defined conjugates except the smallest, and is most visible for conjugates B, C, and D. While no molecular mass standards are available for proteins in the desired range, the elution times of these shoulders, each near the peak of the next larger conjugate, suggest the presence of a small proportion of dimeric forms of the conjugates. Most likely, this dimerization occurs during the assembly process when two neighboring reaction centers are bridged by the linking of an added protein to active sites on both. While it may not be possible to completely eliminate the formation of dimers, it may be possible to minimize it by decreasing the density of reaction centers on the support, or by decreasing the number of reactive groups on the proteins.

The assumption that each reaction center absorbs the same number of protein molecules in each step is also an approximation. In the first addition of AP-Mal, the mean uptake is 3.6 AP-Mal per RPE-SH, suggesting that some reaction centers have absorbed 4 enzyme molecules in this step and others only 3. These discrepancies are likely to be propagated through the remaining steps, and can be expected to result in some heterogeneity of size of the final conjugates.

The atomic force microscope was invented in 1986 (*14*) as a microscopic technique to probe surface topography at molecular resolution. Since its invention, AFM has been used to image a variety of materials including polymers (*15*) and biological-modified surfaces (*16*−*18*). In TappingMode AFM, a cantilever holds a tip above the surface of a material, oscillating it at its resonant frequency as it is rastered across the surface. During scanning, the resonant frequency is affected by attractive or repulsive interactions with features on the surface. The motion is measured by reflecting a laser off the back of the cantilever onto a photodiode detector, and the resulting signal is converted into a 3D image by the microscope's electronics. In this work, we imaged a selection of conjugates prepared by both solid-phase and solution methods adsorbed to silicon surfaces. The images are consistent with the HPLC results, showing average size increasing with number of layers of protein addition for the solid-phase preparations and increasing with reaction time for the solution-phase preparations. In solid-phase conjugates A−H, the protein assemblies appear approximately spherical with most at or near a maximum size characteristic of the preparation. A few appear close enough together that they may represent dimeric forms. In contrast, the solution conjugates K15−K300 show much more heterogeneity of size and shape at all reaction times. While the average size increases with reaction time, the size distribution appears largely random, and there is no indication of a preferred shape.

The ability to control the composition and structure of conjugates makes possible detailed studies of the effects of these features on the functional properties of the conjugates. We demonstrated this with a limited study comparing conjugates with different enzyme and antibody contents with regard to the signal generated in an ELISA. Subject to the assumptions discussed above, the RPE chromophore allows direct measurement of the molar concentration of each conjugate independent of the presence of bound AP and antibody. When the molar concentration and Ab content of the conjugates are held constant, the assay signal at each analyte concentration increases with increasing AP content. Over the range tested, the increase in signal was somewhat less than would be expected for full participation of each additional layer of AP: conjugate H with approximately 20 times the AP content of conjugate A shows only about 10 times the signal. This may be due to decreased accessibility of substrate to AP in the interior of the assembly, either from electrostatic repulsion or because of local depletion of the substrate by AP at the surface.

We also showed that, under conditions of the ELISA, the signal shows little change when the AP is held constant and the Ab content is varied over a factor of 10. This suggests that the solid-phase process may be of particular benefit when the binding agent is in limited

supply. It should be noted, however, that these experiments do not address the kinetics of binding. The rate of diffusion of the conjugate and the rate at which it binds to immobilized analyte can be expected to show dependencies on the conjugate size and the content of binding sites. The ability to control these parameters as well as the molar concentration of the conjugate may find application in such investigations.

Hybridon, Inc., 345 Vassar Street, Cambridge, Massachusetts 02139. Received May 25, 2002; Revised Manuscript Received July 15, 2002

Bacterial DNA and synthetic oligonucleotides containing unmethylated CpG dinucleotides (CpG DNA) activate the vertebrate immune system and promote Th1-like immune responses. Several CpG DNAs are currently being tested in clinical trials as either alone or in combination with vaccines, antibodies, and allergens separately or as conjugates for a number of disease indications including cancers, allergies, and asthma. In this paper, we show that conjugation of an oligonucleotide and a CpG DNA through their 5′-ends (5′-5′-linked DNA) significantly reduces the immunostimulatory activity of the CpG DNA. In addition, we found that the reduction in immunostimulatory activity of 5′-5′-linked CpG DNA depends on the size of the oligonucleotide conjugated to CpG DNA. Conjugation of a smaller group or molecule, such as a phosphorothioate group, at the 5′-end of CpG DNA has an insignificant effect on immunostimulatory activity. However, conjugation of a mononucleotide, tetra- or longer oligonucleotide or a fluorescein molecule to the 5′-end of a CpG DNA (5′-5′-linked DNA) significantly suppresses the immunostimulatory activity of CpG DNA. Surprisingly, conjugation of an oligonucleotide or a ligand through the 3′-end of CpG DNA (3′-3′-linked DNA) has an insignificant effect on immunostimulatory activity. Studies of cellular uptake and activation of transcription factor NF-κB in J774 cells using fluorescein-conjugated CpG DNAs suggest that the differences in the immune stimulation of 5′- and 3′-end-conjugated CpG DNAs is not as a result of differences in their cellular uptake properties. These results suggest that for optimal immunostimulatory activity, ligands should not be attached at the 5′-end of the CpG DNA.

INTRODUCTION

The immune system of vertebrates recognizes unmethylated CpG dinucleotides present in bacterial DNA and synthetic oligonucleotides (CpG DNA) in a sequence-selective manner. As a result of activation by CpG DNA, immune system cells secrete a myriad of cytokines, including IL-12, IL-6, TNF-α, and INF-γ, and up-regulate several costimulatory molecules (*1*−*4*). The cytokines and costimulatory molecules secreted provide nonspecific protection against infectious pathogens and strongly enhance the generation of antigen-specific B-cell responses (*5*−*7*). A number of CpG DNAs are at various stages of preclinical and clinical evaluation as antitumor, antiviral, antibacterial, and antiinflammatory agents and as adjuvants in immunotherapy (*5*−*7*).

A receptor, TLR9, recognizes CpG dinucleotides present in certain specific sequence contexts in CpG DNA and initiates signaling pathways that lead to the activation of NF-κB and the subsequent up-regulation of cytokines and costimulatory molecules (*8*). Alternately, CpG DNA activates DNA protein kinase, which phosphorylates IκB-kinaseB, leading to the activation of NF-κB, which leads to the production of cytokines (*9*). It is not clear whether the two pathways are activated sequentially or in parallel leading to a common function of activating the NF-κB pathway. The growing evidence suggests that TLR9 exhibits considerable sequence selectivity for CpG DNA (*10*, *11*). In addition, the receptor recognizes CpG-dinucleotides with a strict bias for the chemical and conformational nature of the unmethylated d(CpG) dinucleotide. However, it can accommodate a range of flanking sequences (*3*, *12*) that may vary from species to species (*13*, *14*).

Our laboratory has been studying the effects of sequence and structural changes in the flanking sequences that potentiate or neutralize the immunostimulatory activity of CpG DNA in an attempt to understand the molecular recognition events between the receptors and CpG DNA. Our studies suggest that incorporation of certain modified bases in place of C or G in a CpG dinucleotide does not affect immunostimulatory activity (*15*). However, the receptor recognizes only 2′-deoxyribonucleotides with a negatively charged internucleotide linkage between C and G of the CpG-dinucleotide (*16*). Further, a number of different modifications at the 2′-position of the sugar and phosphate backbone are tolerated about three or more nucleotides away from the CpG-dinucleotide in both the 5′- and 3′-flanking sequences (*17*−*19*). In fact, the incorporation of modifications in the 5′-flanking sequence usually potentiates the immunostimulatory activity of CpG DNA, while the incorporation of the same in the 3′-flanking sequence has minimal effect on the immunostimulatory activity. We have also shown that the presence of a nucleobase on nucleosides is not required for the immunostimulatory activity in certain positions in the 5′- or the 3′-flanking sequence to the CpG-dinucleotide (*20*). Although the incorporation of 2′-5′-deoxyribonucleosides within or adjacent to CpG dinucleotide is detrimental for immunostimulatory activity, the incorporation of the same in the flanking sequences is well tolerated and in certain positions they even potentiate the immunostimulatory activity (*21*).

In recent years, the conjugation of antigens and vaccines to CpG DNA has been reported (*22*−*26*). The use of such CpG DNA conjugates induces more efficient antigen/vaccine-specific immune responses than does CpG DNA and antigen/vaccine combination treatments (*25*, *26*). Our recent studies suggest that an accessible 5′-end of the CpG DNA is critical for the immunostimulatory activity (*27*). To confirm this observation, establish the size of the ligand conjugated at the 5′-end that could block immunostimulatory activity, and examine if cellular uptake is effected by 3′- or 5′-conjugation that could lead to different immunostimulatory activity, we carried out the study described herein. In this study, CpG-DNA was conjugated to different lengths or sizes of nucleotides or ligands through their 5′- or 3′-ends, and the impact on immunostimulatory activity was studied. These studies define the most appropriate site for conjugation on CpG DNA with large molecules such as antigens/vaccines for optimal therapeutic uses.

EXPERIMENTAL PROCEDURES

CpG DNA Synthesis and Purification. CpG DNA and their conjugates were synthesized using β-cyanoethyl phosphoramidite chemistry on a PerSeptive Biosystem's 8909 Expedite DNA synthesizer on 1 to 2 μmol scale as described earlier (*27*−*30*). The phosphoramidites of dA, dG, dC, and T were obtained from PE Biosystems. The 5′-phosphoramidites of dA, dG, dC, and T were obtained from Glen Research Corporation. The DMT-protected fluorescein phosphoramidite and DMT-protected CPG-bound fluorescein were obtained from Glen Research. Beaucage's reagent was used as an oxidant to obtain phosphorothioate backbone modification (*31*). After the synthesis, CpG DNAs were deprotected using standard protocols, purified by HPLC, and dialyzed against USP quality sterile water for irrigation (Braun). The CpG DNA conjugates were lyophilized and dissolved again in distilled water, and the concentrations were determined by measuring the UV absorbance at 260 nm. All the CpG DNAs synthesized were characterized by CGE and MALDI-TOF mass spectrometry (Brucker Proflex III MALDI-TOF mass spectrometer with 337 nm N_2 laser) for purity and molecular mass, respectively. The purity of full-length CpG DNA conjugates ranged from 89 to 95% and the rest being n-1 and n-2 as determined by CGE and/or denaturing PAGE.

Cell Culture Conditions and Reagents. BALB/c mouse (4−8 weeks) spleen cells were cultured in RPMI complete medium as described earlier (*16*, *32*). Murine macrophage-like cells, J774 (American Type Culture Collection, Rockville, MD) were culured in Dulbecco's modified Eagle's medium supplemented with 10% (v/v) FCS and antibiotics (100 IU/mL of penicillin G/streptomycin). All other culture reagents were purchased from Mediatech (Gaithersburg, MD).

ELISAs for IL-12 and IL-6. BALB/c mouse spleen or J774 cells were plated in 24-well dishes at a density of 5×10^6 or 1×10^6 cells/mL, respectively. The CpG DNA dissolved in TE buffer (10 mM Tris-HCl, pH 7.5, 1 mM EDTA) was added to a final concentration of 0.03, 0.1, 0.3, 1.0, 3.0, or 10.0 μg/mL to mouse spleen cell cultures and 1.0, 3.0, or 10.0 μg/mL to J774 cell cultures. The cells were then incubated at 37 °C for 24 h, and the supernatants were collected for ELISA assays. The experiments were performed two or three times for each CpG DNA in triplicate for each concentration.

The secretion of IL-12 and IL-6 was measured by sandwich ELISA. The required reagents, including cytokine antibodies and standards, were purchased from PharMingen. ELISA plates (Costar) were incubated with appropriate antibodies at 5 μg/mL in PBSN buffer (PBS/0.05% sodium azide, pH 9.6) overnight at 4 °C and then blocked with PBS/1% BSA at 37 °C for 30 min. Cell culture supernatants and cytokine standards were appropriately diluted with PBS/1% BSA, added to the plates in triplicate and incubated at 25 °C for 2 h. Plates were washed, 1 μg/mL of appropriate biotinylated antibody was added, and the plates were incubated at 25 °C for 1.5 h. The plates were washed extensively with PBS/0.05% Tween 20 and then further incubated at 25 °C for 1.5 h after the addition of streptavidine-conjugated peroxidase (Sigma). The plates were developed with Sure Blue (Kirkegaard and Perry) chromogenic reagent, and the reaction was terminated by adding Stop Solution (Kirkegaard and Perry). The color change was measured on a Ceres 900 HDI Spectrophotometer (Bio-Tek Instruments) at 450 nm. The levels of IL-12 and IL-6 in the cell culture supernatants were calculated from the standard curve constructed under the same experimental conditions for IL-12 and IL-6, respectively.

Mouse Splenomegaly Assay. Female BALB/c mice (4−6 weeks, 19−21 gm) were divided into different groups with three or four mice in each group. CpG DNAs were dissolved in sterile PBS and administered subcutaneously to mice at a dose of 5 mg/kg. After 72 h, mice were sacrificed, and the spleens were harvested and weighed.

Cellular Uptake. J774 cells were plated at a density of 1×10^5 cells/well in an eight-well chamber slide the day before addition of CpG DNAs. The medium was changed 1 h before the experiment, fluorescein-labeled CpG DNAs were added to a concentration of 10 μg/mL, and the cells were incubated for 1 h at 37 °C. At the end of the incubation period, medium was aspirated. The cells were washed thoroughly with ice-cold phosphate-buffered saline (PBS), fixed with cold 95% ethanol and 5% acetic acid for 10 min, washed, and finally mounted in an antifade medium (Vector Laboratories, Burlingame, CA) with DAPI (for nuclear staining). The slides were then examined, and photomicrographs were taken under a Zeiss Axiophot microscope. The fluorescein and DAPI images were merged using the Spot Imaging software.

Preparation of J774 Cell Nuclear Extracts and EMSA. For NF-κB activation studies, J774 cells were plated at a density of 5×10^6 cells/well in six-well plates, and nuclear extracts were prepared as described earlier (*33*). Briefly, after stimulation of J774 cells for 1 h with CpG DNAs at a concentration of 10 μg/mL, cells were washed three times in ice-cold PBS, harvested, and suspended in 0.24 mL of buffer A (10 mM HEPES, pH 7.9, 10 mM KCl, 0.1 mM EDTA, 0.1 mM EGTA, 1 mM DTT, and protease inhibitor cocktail) (Boehringer-Mannheim) and allowed to swell on ice for 15 min. Then 16 μL of 10% Nonidet-P40 was added, and the tubes were vortexed vigorously for 10 s. Nuclei were separated from cytosol by centrifugation at 500 g for 5 min and were lysed in 60 μL of buffer B (20 mM HEPES, pH 7.9, 0.4 M NaCl, 1 mM EDTA, 1 mM EGTA and protease inhibitor cocktail). After 30 min at 4 °C, lysates were separated by centrifugation (14000*g*, 10 min) and supernatants containing nuclear proteins were transferred to new vials. Protein concentrations were determined (*34*), and the samples were either used immediately or stored frozen at −70 °C.

The oligonucleotide probe (5′-AGTTGAGGGGACTTTC-CCAGGC-3′) containing the κB binding motif was end-labeled with [γ-^{32}P]-ATP using T4 polynucleotide kinase

(Invitrogen) and purified over two successive G-50 mini columns (Amersham Pharmacia Biotech). Reaction mixtures (25 μL) containing 10 μg of nuclear protein, 5 mM Tris (pH 7.5), 100 mM NaCl, 1 mM DTT, 1 mM EDTA, 4% glycerol (v/v), and 0.08 mg/mL salmon sperm DNA were preincubated on ice for 15 min. After preincubation, 1×10^6 cpm of the probe was added and the binding reaction was allowed to proceed for 20 min at room temperature. DNA−protein complexes were then resolved in a 6% native polyacrylamide gel in TBE buffer (22.5 mM Tris, 22.5 mM boric acid and 0.5 mM EDTA, pH 8.3) at 140 V for 2−3 h. Gels were dried and exposed to Kodak Biomax MR film at −70 °C. Films were scanned, and the images were processed using Adobe imaging software.

RESULTS AND DISCUSSION

We chose an oligonucleotide sequence (Chart 1, Table 1) containing a CpG dinucleotide (**1**), which showed immunostimulatory activity in earlier studies (*27*). We synthesized a number of analogues of CpG DNA sequence **1** conjugating a phosphorothioate group (**b**), mono- (**c**, **g**), 4- (**d**, **h**), 8- (**e**, **i**), or 19-mer (**g**, **j**) oligonucleotide, or a fluorescein (**l** or **k**) either at the 5′- (R) or the 3′- end (R′) (see Chart 1 for structures and Table 1 for sequences). CpG DNA conjugates **2**−**6** and **12**, in which a ligand conjugated to CpG DNA **1** through its 3′-hydroxyl group, are shown in Table 1. The 3′-end of these molecules is blocked as a result of conjugation at the 3′-end and CpG DNAs **3**−**6** have two 5′-ends. We also synthesized CpG DNAs **7**−**11** and **13**, in which a ligand conjugated to parent CpG DNA **1** through its 5′-hydroxyl group (Table 1). The 5′-end of these molecules is blocked by conjugation and, therefore, CpG DNAs **8**−**11** have two 3′-ends.

Phosphorothioate and Nucleotide Conjugation at the 3′-End of CpG DNA. In BALB/c mouse spleen cell cultures, all CpG DNAs induced a concentration-dependent IL-12 and IL-6 secretion (Table 2). At a concentration of 1.0 μg/mL, parent CpG DNA **1** induced 2391 ± 175 and 13320 ± 960 pg/mL of IL-12 and IL-6 secretion, respectively (Figure 2A and B). The secretion of IL-12 and IL-6, compared with media (PBS) control, in mouse spleen cell cultures suggest that CpG DNA **1** induced immunostimulatory activity as has been reported earlier (*27*). At the same concentration of 1.0 μg/mL, CpG DNA **2**, which has a phosphorothioate group conjugated to the 3′-end of the parent CpG DNA **1**, induced lower levels of IL-12 and IL-6 (1499 ± 191 and 5420 ± 370 pg/mL, respectively) secretion compared with CpG DNA **1**. CpG DNAs **3**−**6**, which have a mono-, 4-, 8- or 19-mer oligo-

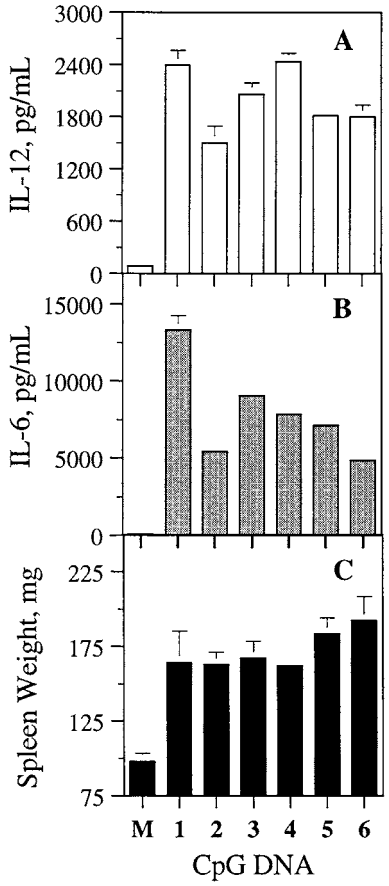

Figure 1. Secretion of IL-12 (A) and IL-6 (B) in BALB/c mouse spleen cell cultures in the presence of CpG DNAs **1**−**6** at a concentration of 1.0 μg/mL. Assays were carried out as described in Experimental Section. M stands for media/vehicle (PBS) control. (C) Spleen enlargement in BALB/c mice following subcutaneous administration of CpG DNAs **1**−**6** at a dose of 5 mg/kg. Control mice received vehicle (PBS). Three or four mice were used for each CpG DNA treatment, and the averages were calculated.

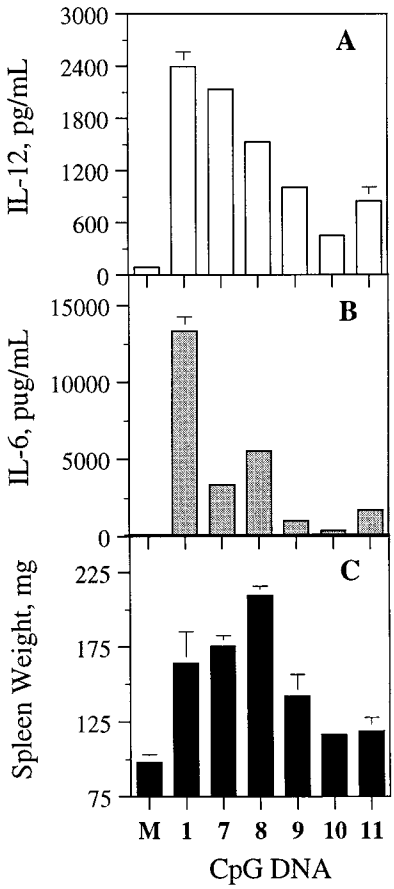

Figure 2. Induction of IL-12 (A) and IL-6 (B) secretion in BALB/c mouse spleen cell cultures in the presence of CpG DNA **1** and **7**−**11** at a concentration of 1.0 μg/mL. Assays were carried out as described in Experimental Section. M stands for media (PBS) control. (C) Spleen enlargement in BALB/c mice following subcutaneous administration of CpG DNA **1** and **8**−**11** at a dose of 5 mg/kg. See Figure 1 legend for other experimental details.

nucleotides conjugated through their 3′-ends to the 3′-end of parent CpG DNA **1**, induced 2060 ± 130, 2434 ± 100, 1812 ± 75, and 1797 ± 141 pg/mL of IL-12 (Figure 2A), and 9054 ± 120, 7841 ± 350, 7142 ± 467, and 4848 ± 288 pg/mL of IL-6 (Figure 2B), respectively, at the same concentration. These in vitro cytokine secretion studies suggest that the conjugation of a ligand at the 3′-end of a CpG DNA, in general, results in a similar or lower levels of IL-12 secretion and lower levels of IL-6 compared with parent CpG DNA. It is important to note that CpG DNA **6** contains two CpG dinucleotides as opposed to one in CpG DNAs **1**−**5**. In addition, the length of CpG DNA **6** is twice that of **1**, and **6** contains two 5′-ends compared with CpG DNA **1**, which has a 3′- and a 5′-end. The results presented here, however, suggest that the number of CpG dinucleotides and the length of CpG DNA do not affect immunostimulatory activity.

CpG DNAs **1** and **3**−**6** were studied for their ability to induce splenomegaly (increase in spleen weight) in BALB/c mice at a single dose of 5 mg/kg administered subcutaneously. The parent CpG DNA **1** caused a 67.5% increase in spleen weight compared with control mice injected with vehicle (PBS) (Figure 1C). At the same dose, CpG DNAs **3**−**6** caused 70.4, 64.3, 86.7, and 96.2% increase in spleen weight, respectively. These results

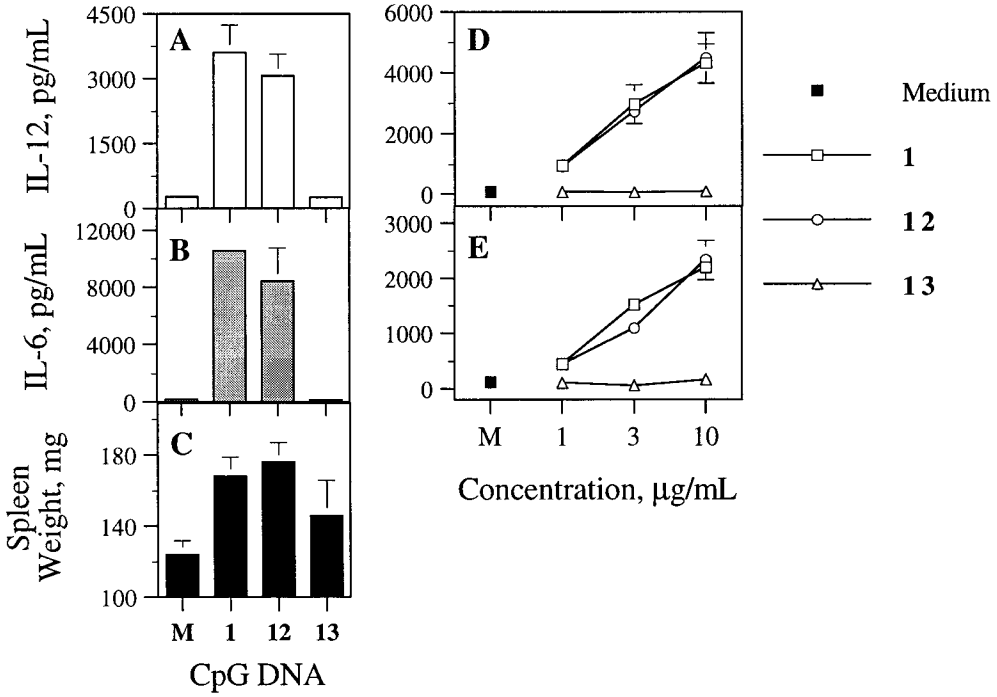

Figure 3. Induction of IL-12 (A) and IL-6 (B) secretion in BALB/c mouse spleen cell cultures in the presence of CpG DNAs **1**, **12**, and **13** at 1.0 μg/mL concentration. Assays were carried out as described in Experimental Section. M stands for media (PBS) control. (C) Spleen enlargement in BALB/c mice following subcutaneous administration of CpG DNAs **1**, **12**, **13** at a dose of 5 mg/kg. Control mice received vehicle (PBS). Three or four mice were used for each CpG DNA treatment, and the averages were calculated. Induction of IL-12 (D) and IL-6 (E) secretion in J774 cell cultures in the presence of CpG DNAs **1**, **12**, and **13** at different concentration. Assays were carried out as described in Experimental Section. M stands for media (PBS) control.

suggest that 3′-conjugation (CpG DNAs **3**−**6**) does not interfere with immunostimulatory activity compared with parent CpG DNA. In fact, CpG DNAs **5** and **6** showed a greater spleen weight increase than did parent CpG DNA **1** (Figure 1C).

Phosphate and Nucleotide Conjugation at the 5′-End of CpG DNA. CpG DNAs, **7**−**11**, which have either phosphate or nucleotide(s) conjugated at the 5′-end of the parent CpG DNA, were also tested for induction of cytokine secretion in BALB/c mouse spleen cell cultures. All CpG DNAs induced concentration-dependent IL-12 and IL-6 secretion (Table 2). The induction of IL-12 and IL-6 secretion by CpG DNAs **7**−**11** at a concentration of 1.0 μg/mL is shown in Figure 2A and 2B, respectively. CpG DNA **7**, which has a phosphorothioate group conjugated at its 5′-end, induced 2132 ± 58 and 3344 ± 0.5 pg/mL of IL-12 and IL-6 secretion, respectively, at 1.0 μg/mL concentration. At the same concentration, CpG DNA **8**, which has a mononucleotide conjugated through its 5′-end to the 5′-end of **1**, induced 1525 ± 45 and 5559 ± 415 pg/mL of IL-12 and IL-6 secretion, respectively. CpG DNAs **9**−**11**, which have a 4-, 8- or 19-mer oligonucleotide conjugated through their 5′-ends to CpG DNA **1**, induced 1007 ± 68, 452 ± 22, and 846 ± 165 pg/mL of IL-12, respectively, at 1.0 μg/mL concentration (Figure 2A). At the same concentration, CpG DNAs **9**−**11** induced 1000 ± 68, 383 ± 35, and 1697 ± 283 pg/mL of IL-6 secretion, respectively (Figure 2B). These in vitro results suggest that a phosphorothioate group conjugated at the 5′-end of CpG DNA has an insignificant effect on IL-12 secretion. However, the conjugation of nucleotides (1−19-mers) to CpG DNA through 5′-end (5′-5′-conjugation) resulted in significantly lower IL-12 and IL-6 secretion.

CpG DNAs **8**−**11** were further examined in vivo for their ability to increase spleen weight at a dose of 5 mg/kg as described above. CpG DNAs **8**−**11** showed 113.3, 44.8, 18.7, and 20.9% increase in spleen weight, respectively, compared with control mice injected with vehicle (PBS). CpG DNAs **9**−**11**, which have 5′-5′-conjugation produced a less spleen enlargement than did parent CpG DNA (67.5%) or the CpG DNA that contained 3′-3′-conjugations (**3**−**6**) (64.3−96.2%). Note that CpG DNA **11** contains two CpG dinucleotides as does CpG DNA **6**. Both CpG DNAs **6** and **11** are of the same length, but **6**, which has two free 5′-ends, caused a greater increase in spleen weight and slightly lower IL-12 secretion compared with that of CpG DNA **1**. In contrast, CpG DNA **11**, which has the 5′-ends blocked, caused a slight increase in spleen weight in BALB/c mice and induced significantly lower levels of IL-12 and IL-6 secretion in spleen cell cultures.

Fluorescein Conjugation at the 3′- or 5′-End of CpG DNA. To examine the effect of conjugation of a nonnucleoside ligand on the immunostimulatory activity of CpG DNA, we conjugated fluorescein (Chart 1, **k**/**l**) either at the 3′- (**12**) or the 5′-end (**13**) of CpG DNA **1**. Both conjugates (**12** and **13**) were studied in BALB/c mouse spleen cell cultures for IL-12 and IL-6 secretion and in BALB/c mice for splenomegaly. In addition, conjugates **12** and **13** were used to study the effect of 3′- and 5′-end conjugation on cellular uptake, activation of transcription factor NF-κB, and subsequent induction of cytokine production in the murine macrophage-like cell line J774 in comparison with parent CpG DNA.

In BALB/c mouse spleen cell cultures, both CpG DNA conjugates **12** and **13** induced a concentration-dependent IL-12 and IL-6 secretion. Figure 3A and B shows the levels of IL-12 and IL-6 secreted at 1.0 μg/mL concentration of **12** and **13** compared with **1**. CpG DNA **12**, which has a fluorescein moiety conjugated at its 3′-end, induced 3059 ± 512 pg/mL of IL-12 and 8422 ± 2327 pg/mL of IL-6 secretion at 1.0 μg/mL concentration. At the same concentration, the parent CpG DNA induced 3610 ± 637

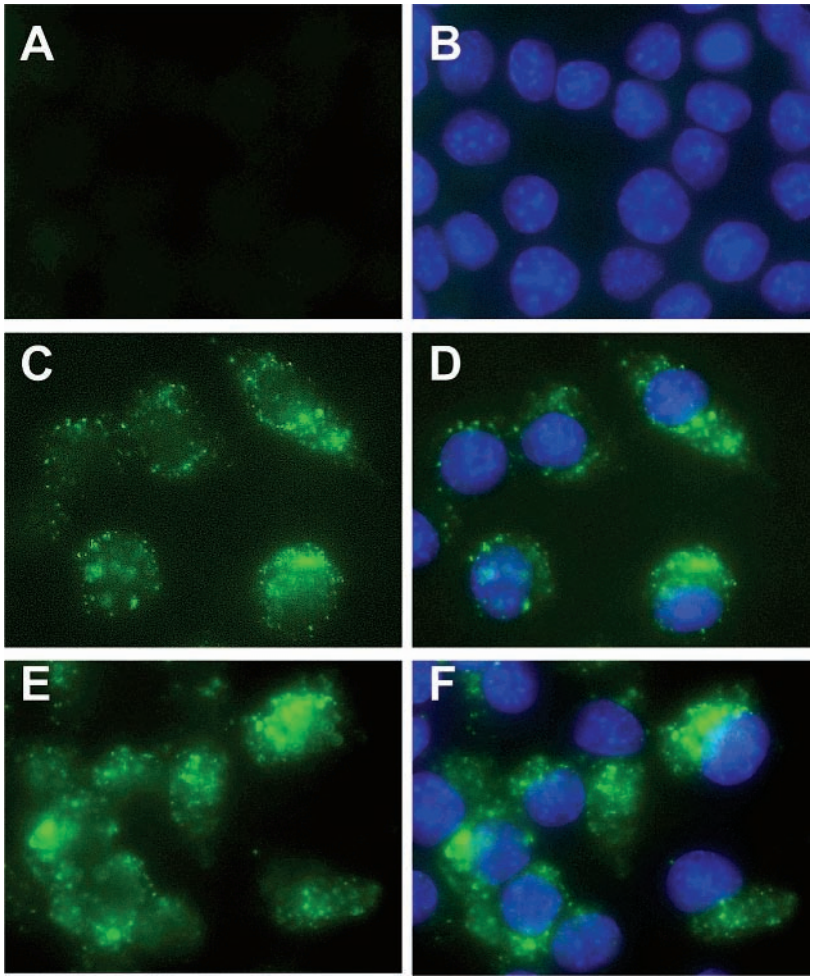

Figure 4. Cellular uptake of fluorescein-conjugated CpG DNAs **12** and **13** by J774 cells. J774 cells were incubated in medium alone (Panels A and B) or with CpG DNAs **12** (Panels C and D) and **13** (Panels E and F) and processed as described in Experimental Section. Panels A, C, and E are images taken in the fluorescein (green) channel. Panels B, D, and F are images A, C, and E superimposed with images taken in DAPI (blue, for nuclear staining) channel. Note the intense green fluorescein cytoplasmic staining in Panels C−F, indicating similar uptake of CpG DNAs **12** and **13**. Cells incubated in medium alone (A and B) are devoid of green color.

and 10540 ± 502 pg/mL of IL-12 and IL-6 secretion, respectively. In in vivo splenomegaly assay in BALB/c mice, CpG DNAs **1** and **12** caused spleen weight increases of 168 and 176 mg, respectively, compared with mice treated with vehicle (124 mg) (Figure 3C). These results suggest that conjugation of a fluorescein moiety at the 3′-end of CpG DNA does not affect (splenomegaly) or slightly reduces (cytokine secretion) immunostimulatory activity compared with the parent CpG DNA. In contrast, CpG DNA **13**, which has a fluorescein group conjugated at its 5′-end, induced 262 ± 20 pg/mL IL-12 secretion in BALB/c mice spleen cell cultures at a concentration of 1.0 μg/mL (Figure 3A). The same CpG DNA induced 168 ± 33 pg/mL of IL-6 secretion at the same concentration (Figure 3B). In BALB/c mice, CpG DNA **13** caused a spleen enlargement of 146 mg (Figure 3C). These results suggest that the conjugation of ligands at the 5′-end of a CpG DNA abrogates immunostimulatory activity significantly compared with the parent CpG DNA.

CpG DNA conjugates **12** and **13** were also examined for their ability to induce cytokine secretion in J774 cell cultures in comparison with parent CpG DNA **1**. Parent CpG DNA and its 3′-fluorescein conjugate **12** induced concentration-dependent IL-12 and IL-6 secretion (Figure 3D and E). The data presented in Figure 3D and 4E obtained from J774 cell cultures complement the results observed in murine spleen cells, which are predominantly B lymphocytes, and confirm the results obtained in BALB/c mouse spleen cell cultures.

Does Conjugation of Ligand at the 3′- or 5′-End of CpG DNA Affect Cellular Uptake? Conjugation of ligands to CpG DNA could also affect the cellular uptake and thereby immunostimulatory activity. Since CpG DNA conjugate **12** induced similar levels of cytokine secretion to that of parent CpG DNA and **13** did not, we examined whether these differences arise from different cellular uptake properties of the two conjugates in J774 cells. Figure 4 shows the uptake of CpG DNAs **12** and **13** after 1 h of incubation in J774 cell cultures. Both CpG DNAs are taken up by J774 cells and show a similar green (FITC) punctate cytoplasmic staining pattern (Figure 4, panels C−F). In some cells at this time, the nuclei also showed positive staining, as was observed with 5′-fluorescein-labeled CpG or antisense DNAs in other studies (*35*, *36*). Control cells that were treated with medium alone showed DAPI (blue) but no fluorescein staining (panels A and B). These results suggest that both 3′- and 5′-fluorescein conjugates are taken up by J774 cells to a similar extent and the differences observed in the immunostimulatory activities of CpG DNAs **12** and **13** are not as a result of differences in their cellular uptake but result from differential recognition of these molecules by receptors in the immunostimulatory pathway.

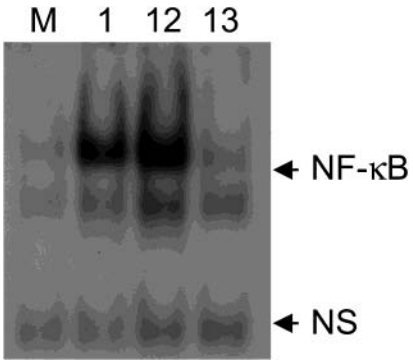

Figure 5. Effect of 3′- or 5′-fluorescein-conjugated CpG DNAs on NF-κB activatation in J774 cells. J774 cells were stimulated with CpG DNAs **1**, **12**, and **13**, nuclear extracts were prepared and analyzed on a native polyacrylamide gel as described in Experimental Section. M and NS stand for medium and nonspecific band, respectively. NF-κB band is shown with an arrow.

Effect of 5′- or 3′-Conjugation on Activation of Transcription Factor NF-κB in J774 Cells. CpG DNA stimulation has been shown to activate a number of signaling pathways, including the NF-κB pathway, which plays a critical role in up-regulation of cytokine gene expression (*37*). To study the effect of 3′- and 5′-conjugation of ligands to CpG DNA on the role of NF-κB activation, J774 cells were stimulated with CpG DNAs **1**, **12**, and **13** and the nuclear extracts were examined for NF-κB activation by EMSA. The results are presented in Figure 5. The presence of complexes that correspond to NF-κB in lanes labeled 1 and 12 suggest that parent CpG DNA **1** and its 3′-fluorescein conjugate, **12** activated transcription factor NF-κB. In contrast, the band intensities in the lane labled 13 were similar to that observed with control cells incubated with medium (lane M), suggesting that 5′-fluorescein-conjugated CpG DNA **13** failed to activate NF-κB. The results of NF-kB activation studies confirm and extend the results observed in cytokine secretion studies in J774 and BALB/c mouse spleen cell cultures.

Degradation of oligonucleotides occurs primarily by 3′-exonucleases present in vivo, which digest the oligonucleotides from their 3′-ends (*38*−*40*). Conjugation of a variety of chemical groups or ligands to the 3′-end of oligonucleotides was known to increase metabolic stability against nucleases (*41*−*44*). In the present study, the conjugation at the 3′-end could contribute to higher nuclease stability and thereby immunostimulatory activity. The splenomegaly data observed with CpG DNAs **3**−**6** and **12** especially support this hypothesis. It is surprising, however, to note that CpG DNAs that have a ligand conjugated at their 5′-ends (**8**−**11** and **13**) show lower immunostimulatory activity despite having equal, if not higher, nuclease stability compared with their parent CpG DNA **1**. In the present study, a phosphorothioate group conjugated at the 5′-end (**7**) failed to block the immunostimulatory activity (except lowering IL-6 secretion). Conjugation of a mononucleotide through 5′-5′-linkage (**8**) did not affect significantly immunostimulatory activity as determined by both in vitro and in vivo studies. Blocking the 5′-end of a CpG DNA with groups such as fluorescein or a tetranucleotide or larger oligonucleotides significantly reduced or blocked immunostimulatory activity compared with the parent CpG DNA. These results obtained with CpG DNAs **8**−**11** and **13** suggest that the differences in immunostimulatory activity of 3′-3′- and 5′-5′-linked DNAs do not arise from differences in nuclease stability or their cellular uptake but from the accessiblity to the 5′-end. In addition, the present results suggest that the size of ligand attached at the 5′-end determines the accessibility of the 5′-end of CpG DNA to the receptors in the immunostimulatory pathway and thereby the immunostimulatory activity. This study is focused on determining the size of ligand that blocks 5′-accessibility of CpG DNA but with insignificant affect on cellular uptake of conjugates. We are currently studying conjugation of other ligands with high lipophillic or cationic nature, including peptide ligands, that could influence physicochemical characteristics of the conjugates to understand the 5′-accessibility of CpG DNA for immunostimulatory activity.

In addition to conjugation of ligands, we also have shown in the past that the addition of guanine-rich sequences at the 5′- or 3′-end of a CpG DNA would effect its biological activity (*45*, *46*). The presence of G-rich sequences (four or more contiguous Gs) in oligonucleotides leads to the formation of secondary structures involving the G-rich sequences. The unusual tetrameric and other higher-order structures formed at the end of the oligonucleotide could also interfere with CpG DNA recognition and thereby pertinent activation of immunostimulatory pathways, as is the case with 5′-conjugated CpG DNAs in the present study. As has been reported earlier, now there is growing evidence that CpG DNAs containing G-rich sequences at their 3′-end are more immunostimulatory than those that contain the same sequences at their 5′-end (*47*). However, the difference in immunostimulatory activity has been presumed in terms of their differential cellular uptake only, the present results strongly suggest that it is not related to differences in cellular uptake but related to their ability to activate immune pathways through an accessible 5′-end of CpG DNA.

CpG DNA evokes host defense mechanisms such as the activation of macrophages/monocytes, B, and NK cells and induction of Th1 cell differentiation. A number of studies have shown improved responsiveness to antigens when the antigens are used together with CpG DNAs compared with antigen alone. Several studies have shown that the direct conjugation of CpG DNA with antigens increased the effectiveness of antigens severalfold compared with the use of antigen and CpG DNA mixtures because of the optimal presentation of antigen to APC by CpG DNA when used as conjugates. In general, ligands are routinely conjugated to oligonucleotides at their 5′-ends because of convenience of attaching required functional groups at the 5′-end in solid-phase synthesis (*48*). However, the present studies suggest that the immunostimulatory activity of CpG DNA conjugates is dependent on whether the ligand conjugated at the 5′-end or the 3′-end and the size of the ligand conjugated.

Taken together, the current results suggest that an accessible 5′-end of CpG DNA is required for its immunostimulatory activity and smaller groups such as a phosphorothioate or a mononucleotide do not effectively block the accessibility of the 5′-end of CpG DNA to receptors or factors involved in the immunostimulatory pathway. However, the conjugation of molecules as large as fluorescein or larger at the 5′-end of CpG DNA could abrogate immunostimulatory activity. These results have a direct impact on the studies of immunostimulatory activity of CpG DNA−antigen/vaccine/monoclonal antibody (mAb) conjugates. The conjugation of large molecules such as vaccines or mAbs at the 5′-end of a CpG DNA could lead to suboptimal immunostimulatory activity of CpG DNA. The conjugation of functional ligands at the 3′-end of CpG DNA not only contributes to

increased nuclease stability but also increased immunostimulatory potency of CpG DNA in vivo.

ACKNOWLEDGMENT

The authors thank Drs. Jin-Yan Tang and Qiuyan Zhao for their helpful suggestions.

Antisense Oligonucleotides Delivered to the Lysosome Escape and Actively Inhibit the Hepatitis B Virus

Keith D. Jensen,[†] Pavla Kopečková,[†,‡] and Jindřich Kopeček*[,†,‡]

Department of Pharmaceutics and Pharmaceutical Chemistry and Department of Bioengineering, University of Utah, Salt Lake City, Utah 84112. Received June 12, 2002; Revised Manuscript Received July 3, 2002

The subcellular fate and activity in inhibiting the hepatitis B virus of free and *N*-(2-hydroxypropyl)-methacrylamide (HPMA) copolymer-phosphorothioate oligonucleotides were studied. Their internalization and subcellular fate were monitored with confocal microscopy. A fraction of the internalized free oligonucleotides escaped into the cytoplasm and nucleus of Hep G2 cells but were not active antiviral agents. Covalently attaching the oligonucleotides to the HPMA copolymers via nondegradable dipeptide GG spacers resulted in sequestering the oligonucleotides in vesicles after internalization. Conjugation of the oligonucleotides to an HPMA copolymer via a lysosomally cleavable tetrapeptide GFLG spacer resulted in release of the oligonucleotide in the lysosome and subsequent translocation into the cytoplasm and nucleus of the cells. The HPMA copolymer-oligonucleotide conjugate possessed antiviral activity, indicating that phosphorothioate oligonucleotides released from the carrier in the lysosome were able to escape into the cytoplasm and nucleus and remain active. The Hep G2 cells appeared to actively internalize the phosphorothioate oligonucleotides as oligonucleotide-HPMA copolymer conjugates were internalized to a greater extent than unconjugated polymers.

INTRODUCTION

One of the most appealing aspects of antisense oligonucleotides is their inherent specificity. They are designed to inhibit the synthesis of a single unwanted protein (reviewed in ref *1*). Intense research has overcome many of the obstacles facing antisense therapy except delivery of the oligonucleotide to its target. In order for the antisense oligonucleotide to inhibit the synthesis of the target protein, the oligonucleotide must cross at least one cell membrane and hybridize with its target mRNA in the cytoplasm or nucleus of the diseased cell.

Endocytosis appears to be the major pathway by which oligonucleotides enter most cells, although much remains to be learned (*2*). Because phosphorothioate oligonucleotides are inherently large and charged molecules, it has been presumed that they cannot cross cell membranes without some type of help (e.g., permeation enhancers or microinjection), and degradation by lysosomal enzymes is the expected fate of the oligonucleotides. Yet the literature continues to accumulate positive evidence of antisense activity suggesting that at least a fraction of the oligonucleotides escape before being degraded (*3*).

More information on the subcellular fate of free oligonucleotides is needed as free antisense oligonucleotides approved by the FDA or in clinical trials are typically administered by intravenous injection (*4*, *5*). These oligonucleotides are presumed to be internalized by endocytosis and somehow cross the endosomal/lysosomal membrane before being degraded. It is not known at what stage of endocytosis the antisense oligonucleotides escape into the cytoplasm. In this research, we hypothesized that antisense oligonucleotides delivered in the lysosome would be able to escape into the cytoplasm before being degraded and actively inhibit synthesis of the target protein. To test this hypothesis, we conjugated the oligonucleotides to the HPMA copolymers via lysosomally cleavable spacers to ensure delivery of the oligonucleotides in the lysosome. Using confocal microscopy, we monitored the subcellular fate of the oligonucleotides and polymers, and demonstrated antisense activity by a biochemical assay.

EXPERIMENTAL PROCEDURES

Hep G2 (*6*) cells (human hepatocellular carcinoma) were from American Type Culture Collection (Manassas, VA). Minimum essential media alpha modification (MEM-α) and fetal bovine serum (FBS) were from HyClone (Logan, UT). *N*-Benzoyl-Phe-Val-Arg-*p*-nitroanilide was from Sigma (St. Louis, MO). A SlowFade Light Antifade Kit and Lissamine rhodamine B (LR) ethylenediamine were from Molecular Probes (Eugene, OR). Sephadex G-25 (PD-10) columns, a Superose 6 (10/30) column, a Superdex 75 (10/30) column, and a Sephadex LH-20 column were from Pharmacia (Piscataway, NJ). Deionized water was used for the preparation of all buffers. All other chemicals were of reagent grade or better.

The oligonucleotide was synthesized by the Emory Microchemical Facility (Atlanta, GA). The oligonucleotide was a 21-mer phosphorothioate oligonucleotide whose sequence was derived from work by Wu and Wu (*7*), 5′-TTTATAAGGGTCGATGTCCXX-3′. The oligonucleotide had a primary amine on the 5′-end [5′-amino-modifier C6 (Glen Research, Sterling, VA)] and a fluorescein on the 3′-end [6-Fluorescein CPG (Glen Research)]. The oligonucleotide was purified by reverse-phase HPLC [Brownlee ODS-300 (Perkin-Elmer, Wellesley, MA) C18, 250 × 10 mm column with 7 μm, 300 Å silica with a 50

mM triethylamine acetate (pH 6.9)/acetonitrile gradient buffer system], and the purity and identity were analyzed by capillary electrophoresis (1 predominate peak) and MALDI-TOF MS [molecular weight measured: 7523.29 (7517.40 calcd)].

Size exclusion chromatography (SEC) was used to estimate the molecular weight of the polymers, detect unbound oligonucleotide, and purify the oligonucleotide-HPMA copolymer conjugates. The molecular weight of the aminolysed (with aminopropanol) polymer precursors was determined on Superose 6 in PBS buffer using laser light scattering detector MiniDawn (Wyatt Inc., Santa Barbara, CA).

Synthesis. *Monomers.* HPMA (*8*), *N*-methacryloylglycylglycylgalactosamine (MA-Gly-Gly-GalN) (*9*), *N*-methacryloylglycylglycine *p*-nitrophenyl ester (MA-GG-ONp) (*10*), and *N*-methacryloylglycylphenylalanylleucylglycyl *p*-nitrophenyl ester (MA-GFLG-ONp) (*11*) were prepared according to previously described procedures.

N-Methacryloylglycylglycyl ethylenediamine Lissamine rhodamine B (MA-GG-LR) was prepared by slowly adding a solution of Lissamine rhodamine B ethylenediamine (20 mg, 33 μmol) in DMF (0.2 mL) to MA-GG-ONp (24 mg, 75 μmol) dissolved in DMF (0.3 mL). To this was added diisopropylethylamine (15 μL, 86 μmol) and allowed to stir for 3 h. The DMF was removed in vacuo, and the product was precipitated with acetone/ether. The product was separated on a Sephadex LH-20 column eluted with MeOH and the purity checked by TLC (methylene chloride/methanol/acetic acid 3:1:0.1, R_f = 0.68). The extinction coefficient of the product was ϵ_{561} = 120 000 M^{-1} cm^{-1} (methanol).

Polymer Conjugate P1 [P-GG-(Oligo-Fl)]. A polymer precursor was prepared by polymerization of the comonomers HPMA and MA-GG-ONp at a molar ratio of 92:8 (acetone, 50 °C, 24 h, AIBN). The polymer (0.47 mmol of ONp/g of polymer, 7.5 mol %, ϵ_{272} = 9500 M^{-1} cm^{-1} in DMSO, M_w = 25 kDa, M_w/M_n = 1.3) was purified by precipitation from methanol into acetone. The polymer precursor (34.3 mg, 16 μmol of ONp) and the oligonucleotide (3.05 mg, 0.41 μmol) were dissolved in anhydrous DMSO (0.2 mL). To this was added diisopropylethylamine (10 μmol) and allowed to stir overnight. The next day, an additional amount of diisopropylethylamine (10 μmol) was added and allowed to stir for 3 h. The reaction mixture was diluted with water, and the product was isolated on a PD-10 column followed by extensive dialysis (cutoff 12−14 kDa). The conjugate was analyzed by SEC (Superose 6 column, PBS, UV and RI detection), which found the oligonucleotide bound to the polymer with no detectable amounts of free oligonucleotide. The amount of bound oligonucleotide was 9.0 μmol/g of polymer [75% efficiency determined from the absorption of fluorescein (ϵ_{494} = 70 000 M^{-1} cm^{-1}, 0.1 M borate buffer, pH 9.1, chemical structure in Figure 1A)].

Polymer Conjugate P2 [P-(GG-LR)-(GFLG-(Oligo-Fl))]. Polymer P2 was similar to P1 except that the polymer backbone was labeled with LR and the oligonucleotide was conjugated via the tetrapeptide spacer, GFLG. Briefly, a precursor polymer was prepared by polymerization of the comonomers HPMA, MA-GFLG-ONp, and MA-GG-LR in the molar ratio 95:5:1 (acetone, 50 °C, 24 h, AIBN). The polymer [0.058 mmol of LR/g of polymer (0.90 mol %, $\epsilon_{563} = 1.2 \times 10^5$ M^{-1} cm^{-1}, methanol), 0.22 mmol of ONp/g of polymer (3.6 mol %, $\epsilon_{400} = 1.8 \times 10^4$ M^{-1} cm^{-1}, 0.1 N NaOH), M_w = 25 kDa, M_w/M_n = 1.4] was purified by reprecipitation from methanol into acetone. To conjugate the oligonucleotide, the precursor polymer (9.5 mg, 2.1 μmol of ONp) and the oligonucleotide (2.8 mg, 0.37 μmol) were dissolved in anhydrous DMSO (70 μL). To this was added diisopropylethylamine (3 μL) and allowed to stir overnight. The next day, an additional amount of diisopropylethylamine (5 μL) was added and allowed to stir for 3 additional hours. The reaction mixture was diluted with water and the product was isolated on a PD-10 column. The product was dialyzed (cutoff 12−14 kDa) extensively, but still contained free oligonucleotide. The conjugate was purified by SEC (Superdex 75 column, PBS), and fractions of the conjugate were collected and dialyzed to remove salts. The purified conjugate (chemical structure in Figure 1B) contained 21 μmol (70% binding efficiency) of fluorescein-labeled oligonucleotide per gram of conjugate and 35 μmol of LR per gram of conjugate.

Cell Culture. Hep G2 cells were cultured in MEM-α media supplemented with 10% FBS in a 37 °C incubator with 5% CO_2 (v/v) with humidified air without antibiotics. For all biological solutions, the pH was adjusted to 7.4 using cell culture grade HCl or NaOH as needed.

Confocal Fluorescent Microscopy. The preparation of the Hep G2 cells for microscopy was described previously (*12*). Briefly, after incubation, the cells were fixed with 3% paraformaldehyde for 20 min at room temperature and mounted with SlowFade Light antifade medium. Cells were analyzed on a Zeiss (Thornwood, NY) LSM 510 confocal imaging system with a Zeiss Axioplan 2 microscope (100 × plan-apo objective, NA = 1.4, oil) and an argon laser (for P1 fluorescein excitation: 488 nm emission, 505 nm long-pass filter; for P2 (LR present), excitation 488 and 543 nm, emission beam splitter 545 nm, green channel emission 500−550 nm, red channel emission 560 nm long-pass). The settings for all the confocal systems were adjusted so that control cells always yielded dark images (i.e., no background fluorescence was visible). To determine if the signals from the two dyes could be separated, two "control" HPMA copolymers labeled with either LR or fluorescein were utilized. Cells were incubated with each of the control polymers, and the microscope settings were adjusted to prevent "bleed-over" of green fluorescence into the red channel. The 8-bit fluorescent images were initially scaled to 256 Gy levels, and colored look-up tables were applied for both dyes.

Oligonucleotide Stability. Rat liver tritosomes (isolated lysosomal enzymes) were harvested as previously described (*13*). The activity of the enzymes was determined by measuring the cleavage of *N*-benzoyl-Phe-Val-Arg-*p*-nitroanilide. The tritosomes (100 μL) and 900 μL of a citrate−phosphate cocktail [citrate−phosphate buffer (pH 5.5), 5 mM glutathione, 0.2% Triton X-100, 0.65 mM EDTA, and 1 mM nitroanilide substrate (final concentrations)] were warmed to 37 °C and mixed, and the absorption at 410 nm (released *p*-nitroaniline) was recorded for 10 min. The change in absorption over 10 min was ΔA = 0.488.

The amount of degradation of the oligonucleotides was measured by HPLC [Dynamax, Varian Inc., Palo Alto, CA, C18 column (Varian), mobile phase: acetonitrile and 50 mM triethylamine acetate buffer (pH 7)] after digestion with the tritosomes. The oligonucleotide and oligonucleotide-HPMA copolymer conjugate, P1 (both at 1 μM final concentration of oligonucleotide), were digested in 250 μL of the citrate−phosphate cocktail (above) with 50 μL of tritosomes at 37 °C. The eluting oligonucleotide was assayed for fluorescence using a fluorescent detector [Waters (Milford, MA), excitation 495 nm, emission 520 nm], and the peak area of the respective peaks was used

to determine the amount of oligonucleotide degradation at various time points in a <15 h period.

Antisense Activity. The activity of the antisense oligonucleotides was determined by Dr. Brent Korba at Georgetown University as previously described (*14*). Briefly, chronically hepatitis B virus-producing human hepatoma cells, 2.2.15, were treated at confluence once daily for 9 days with the test compounds. The cell media were changed daily. HBV DNA levels in the culture medium were assessed by dot blot hybridization 24 h following the last treatment. Toxicity was assessed by uptake of neutral red dye at the time of analysis. As a positive control for the assay, the drug 3-thia-2′,3′-dideoxycytosine (3TC, commonly known as lamivudine) was also tested.

RESULTS

Delivery of the Oligonucleotide to the Lysosome. HPMA copolymers were used to deliver the oligonucleotide to the lysosome. As a small percentage of papers have found evidence of oligonucleotides entering cells by pathways other than endocytosis (reviewed in ref *15*), it was important to ensure lysosomal delivery of the oligonucleotides to test the hypothesis. A large body of evidence over several decades indicates that HPMA copolymers are internalized by endocytosis and are lysosomotropic (*16*−*20*). Conjugating drugs that normally enter cells by diffusion to these polymers result in their internalization by endocytosis (*19*, *20*); therefore, covalent attachment of the oligonucleotides to the HPMA copolymers should ensure that the oligonucleotides reach the lysosome.

Release of the oligonucleotides in the lysosome is accomplished by conjugating the oligonucleotides to HPMA copolymers via a lysosomally degradable spacer. The tetrapeptide spacer, Gly-Phe-Leu-Gly (GFLG), was designed to be stable outside the cell but degraded in the lysosome (reviewed in refs *21* and *22*). Covalent attachment by such a spacer prevents premature release of the oligonucleotide before reaching the lysosome.

To allow independent observation of the oligonucleotide from the polymeric carrier, the oligonucleotide was labeled with fluorescein and the polymer with Lissamine rhodamine B (Figure 1B). As a control, a fluorescein-labeled oligonucleotide was also conjugated to an HPMA copolymer via the nondegradable Gly-Gly spacer (*23*) (Figure 1A).

Subcellular Fate of Phosphorothioate Oligonucleotides. *Free Oligonucleotides.* The subcellular fate of the phosphorothioate oligonucleotides in Hep G2 cells was determined by confocal microscopy. The cellular distribution of the oligonucleotide was followed from 1 to 24 h. Initially the oligonucleotide was restricted to small vesicles distributed throughout the cytoplasm (Figure 2). The nuclei of many cells are visible as dark spheres in the fluorescent image (Figure 2A). From 2 to 4 h (Figure 3), fluorescence began to appear in the cytoplasm followed by nuclear staining and heightened fluorescence of nuclear structures (likely nucleoli). In Figure 3, one nucleus is marked with a ring in both the fluorescent and transmitted images for ease in identification. Dim staining of the nuclei with increased staining of nuclear structures was uniformly observed in all of the cells. In general, the fluorescence increased with longer incubation times, as expected.

A study of the effect of concentration on the distribution of the oligonucleotide did not reveal any qualitative difference between 0.6 and 3 μM (oligonucleotide concentration). The fluorescence was brightest in small vesicles distributed throughout the cytoplasm. In addition, there was considerable staining of the cytoplasm, nucleus, and nuclear structures at the concentrations studied (data not shown as images were similar to that in Figure 3). The fluorescence of the cells increased with a corresponding increase in the concentration.

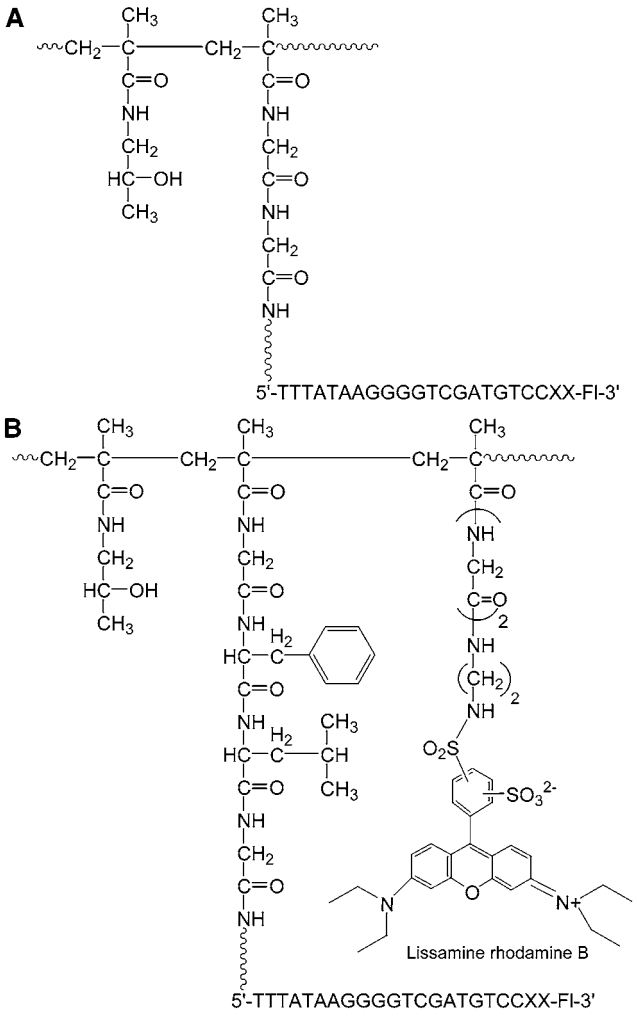

Figure 1. Chemical structures of oligonucleotide-polymer conjugates. (A) Polymer conjugate P1: the phosphorothioate oligonucleotide was covalently linked to the HPMA copolymer via a nondegradable GG linker. The oligonucleotide was labeled with fluorescein on the 3′ end. (B) Polymer conjugate P2: a phosphorothioate oligonucleotide was covalently linked to the HPMA copolymer via the degradable GFLG linker. The oligonucleotide was labeled with fluorescein on the 3′ end. The polymer backbone was labeled with Lissamine rhodamine B to allow independent visualization of the polymer and the oligonucleotide.

Polymer-Bound Oligonucleotides (Nondegradable Spacer). To determine the subcellular fate after conjugating the oligonucleotide to the HPMA copolymer via a nondegradable spacer, the fate of the polymer conjugate P1 was determined in Hep G2 cells from 0.5 to 24 h. For all of the samples, the vast majority of the fluorescence was located in small vesicles distributed throughout the cytoplasm (Figure 4). As expected, increasing the incubation time from 0.5 to 24 h resulted in increasingly bright samples (data not shown). A small amount of fluorescence, just above autofluorescence, was detected in the cytoplasm and nuclei, with less in the nuclei, when higher conjugate concentrations and very high microscope detector gain settings were employed (Supporting Information Figure 1). The amount of fluorescence in the cytoplasm

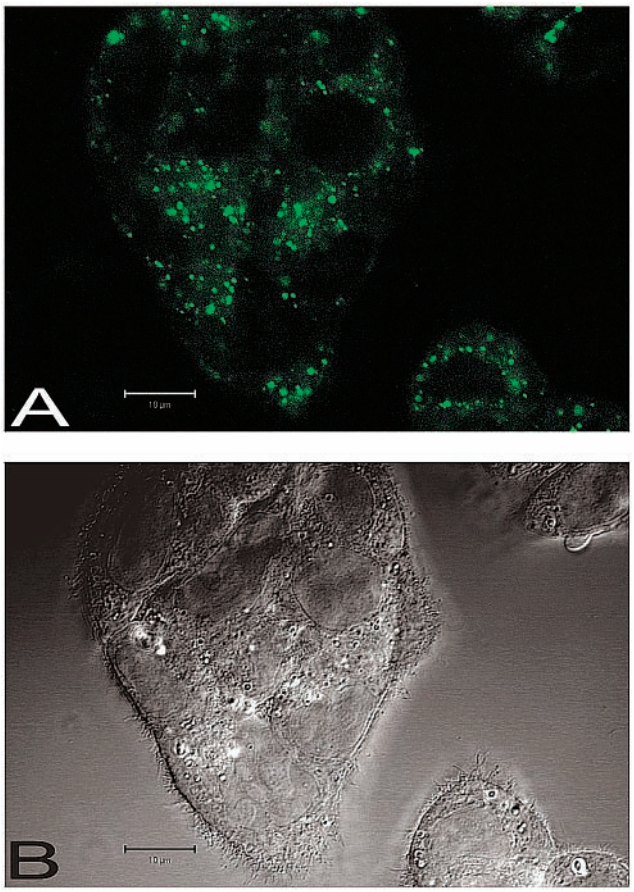

Figure 2. Hep G2 cells incubated with 1.5 μM free oligonucleotide for 2 h. (A) Fluorescent image: the oligonucleotide was predominantly located in small vesicles distributed throughout the cytoplasm. (B) Transmitted image. The scale bars are 10 μm.

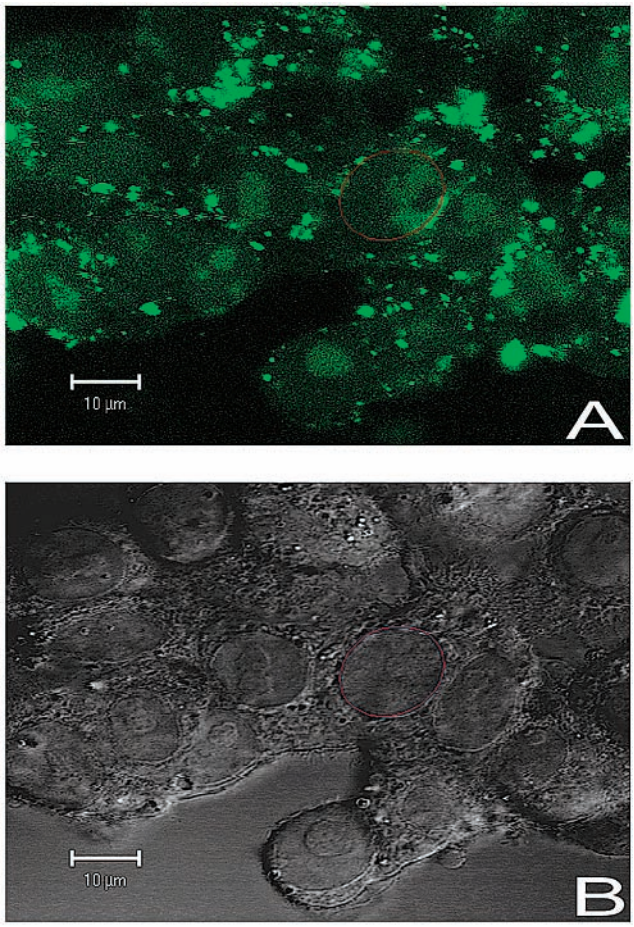

Figure 3. Hep G2 cells incubated with 3 μM free oligonucleotide for 3 h. (A) Fluorescent image: oligonucleotide was found in small vesicles as well as in the cytoplasm and nucleus of the Hep G2 cells. (B) Transmitted image. One nucleus is marked by a ring in both the fluorescent and transmitted images for ease in identification. The scale bars are 10 μm.

and nuclei of the cells was very small and only accounted for a minute fraction of the total fluorescence. Qualitatively, there was no change in the distribution of fluorescence in the cells with increasing incubation time up to 24 h—only an increase in brightness, which was expected (data not shown).

A study of the effect of concentration on the distribution of the conjugate with the nondegradable spacer (polymer conjugate P1) did not yield any unexpected results. Increasing the concentration (18 h incubation) from 0.4 to 3.6 μM (oligonucleotide concentration) resulted in a corresponding increase in the fluorescence of the cells. Qualitative evaluation of the polymer conjugate P1's fate did not reveal any significant difference in the distribution of the oligonucleotide at concentrations between 0.4 and 3.6 μM. The majority of the fluorescence was limited to small vesicles with a small fraction in the cytoplasm (data not shown as images were similar to those in Figure 4 and Supporting Information Figure 1).

Polymer-Bound Oligonucleotides (Degradable Spacer). Conjugating the oligonucleotide to the polymer via a lysosomally degradable bond allows the oligonucleotide to be liberated from the polymer in the lysosome, thus providing an opportunity to determine its ability to escape from the lysosome. To independently monitor the fate of both the polymer and the oligonucleotide, the polymer was labeled with Lissamine rhodamine B, and the oligonucleotide was labeled with fluorescein (Figure 1B).

The subcellular fate of the antisense oligonucleotide conjugated via the degradable spacer (polymer P2) was monitored from 0.5 to 24 h by confocal microscopy. At incubation times less than 2 h, most of the fluorescence was limited to small vesicles in the cytoplasm (Supporting Information Figure 2A,B). Between 2 and 4 h, the green (oligonucleotide) and red fluorescence (polymer) signals began to differ to an appreciable extent (Supporting Information Figure 2C). The green fluorescence increased in the cytoplasm and nucleus and green staining of the nucleolus appeared (Figure 5 and Supporting Information Figure 2C). For Figure 5, the microscope detector gain was increased (autofluorescence still not visible) to view the dim fluorescence in cytoplasm and nuclei—although this resulted in overexposure of the fluorescence in most of the vesicles. The oligonucleotide (green) was dim—but clearly visible—staining the cytoplasm, nucleus, and nuclear structures. The polymer (red) was found almost exclusively in small vesicles distributed throughout the cytosol. After 24 h, there was an increase in the separation of the green and red signals (Figure 6 and Supporting Information Figure 2C versus Figure 2D).

Significant changes in the subcellular distribution of each fluorophore could be observed between the 4 and 24 h time points utilizing higher detector gain settings. The image in Figure 6 contains cells incubated with the polymer conjugate P2 for 24 h. There was significant staining of the cytoplasm, nuclei, and nuclear structures for both sets of cell incubated for 4 (Figure 5) and 24 (Figure 6) h with the oligonucleotide (green), although

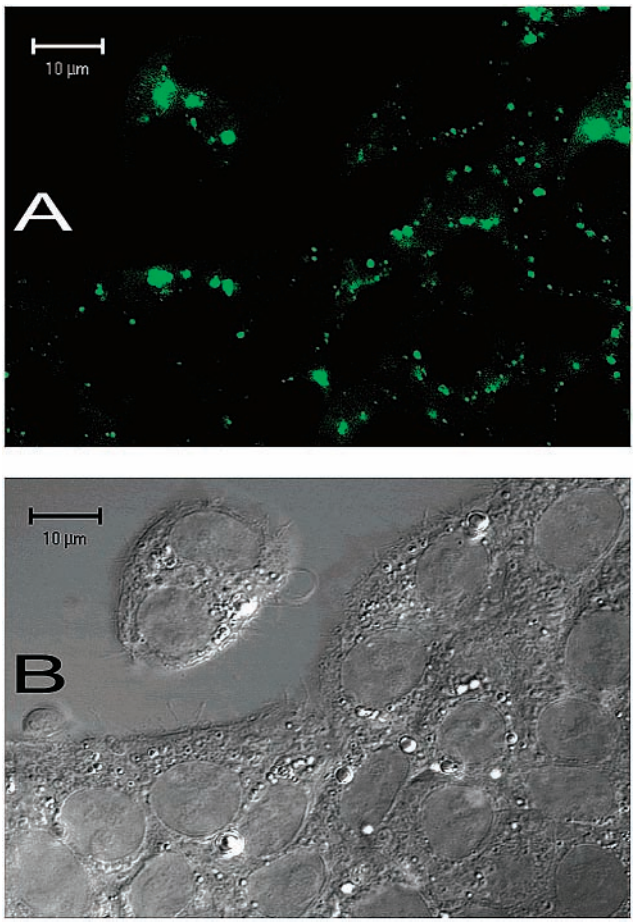

Figure 4. Hep G2 cells incubated with P1 (1.1 μM oligonucleotide) for 24 h. (A) Fluorescent image: the fluorescence was predominantly restricted to small vesicles. (B) Transmitted image. The scale bars are 10 μm.

those at 24 h were noticeably brighter (it should be noted that these two images were not taken at the same settings—the gain was higher for Figure 5 to allow ease in viewing fluorescence in the cytosol and nucleus). In contrast to the high staining by the oligonucleotide (green), the staining of the polymer (red) in the cytoplasm and nucleus was noticeably weaker, although varying the fluorescence of the two dyes only allowed a qualitative comparison. Also for the polymer, the nuclei of the cells were darker than the corresponding cytosol, and no staining of the nucleoli was observed.

Conjugating the oligonucleotide to the polymer resulted in increased uptake of the polymer. Hep G2 cells incubated with LR-labeled polymer were noticeably dimmer than cells incubated with the oligonucleotide-polymer conjugate P2 (Supporting Information Figure 3). The cells were incubated with each of the polymers such that similar amounts of dye were administered to the cells. Identical detector settings allowed a semiquantitative comparison of their respective intensities. The original black and white images acquired were double-checked to ensure that the settings used did not generate any signal in the control cells and to guarantee that the detectors had not been saturated. An equal-sized area inside the cells of each sample was then measured using the histogram feature of Photoshop (Adobe Systems Inc., version 6.0.1) The average pixel intensity was 15 times higher for the cells incubated with polymer conjugate P2 as compared to LR-labeled polymer, although the cells were incubated with about 6% more dye for the LR-labeled polymer compared to the polymer conjugate P2.

Stability. The stability of the phosphorothioate oligonucleotides in isolated rat liver lysosomal enzymes (tritosomes) was measured for +12 h. The stabilities of the free oligonucleotide and the oligonucleotide bound to the polymer via the nondegradable GG spacer (P1) were compared since the assay monitored the amount of oligonucleotide bound to the polymer and would not distinguish between cleavage of the degradable GFLG spacer from oligonucleotide degradation.

The polymer-bound oligonucleotide was approximately 3 times more stable than the free oligonucleotide (Table 1). The degradation of the free oligonucleotide was steady over the course of the experiment, decreasing from 100% to 42% of the intact oligo in 14.2 h. In contrast, for the polymer-bound oligonucleotide, there was an initial decrease to ~90% during the first 4 h; this was followed by a slow, steady decrease to 81% at 12.8 h. The biphasic degradation complicated calculation of the half-life of the polymer-bound oligonucleotide, and to err on the side of caution, we probably underestimated its true value. As such, the half-lives should only be used as relative comparisons to each other.

Activity. Although the free oligonucleotide and the oligonucleotide conjugated to the HPMA copolymer via the degradable spacer were observed in the nucleus using confocal microscopy, it was unknown whether they remained intact and active. The antisense antiviral activities of the free oligonucleotide, oligonucleotide-HPMA copolymer conjugate (P2), unconjugated HPMA copolymer, a physical mixture of free oligonucleotide and unconjugated HPMA copolymer, and 3TC (positive control) were determined (Table 2). The oligonucleotide conjugated to the polymer showed activity inhibiting 50% and 90% of the viral activity at oligonucleotide concentrations of 1.7 and 8.3 μM, respectively. The free oligonucleotide did not show any antiviral activity at the concentrations studied (0.01−10 μM). To ensure that the polymer was not contributing to the antiviral activity of the oligonucleotide-polymer conjugate P2, unconjugated polymer and a physical mixture of free oligonucleotide and unconjugated polymer were also tested and were not found to have any antiviral activity at the studied concentrations. As a positive control, the potent nucleoside analogue reverse transcriptase inhibitor 3TC was also examined to validate the assay.

DISCUSSION

Delivery of antisense oligonucleotides to their targets in the cytoplasm or nucleus is the current greatest challenge in antisense therapy. As most antisense oligonucleotides approved or in clinical trials are administered as free oligonucleotides (*4*, *5*) that are presumably internalized into cells by endocytosis, knowledge of their ability to escape from lysosomes before being degraded is paramount to developing more effective therapies.

Cationic polymers and liposomes are not ideal for determining the ability of the oligonucleotide to escape from the lysosome. Although endocytosis is likely to result using cationic polymers or liposomes to deliver oligonucleotides, such delivery systems present two major challenges for this internalization study: unreliable release of the oligonucleotide and unknown effects of the carrier. With these carriers, it is unclear where the oligonucleotides dissociate from the delivery system. Oligonucleotide release before internalization is even possible (*24*). These types of carriers may also play a role in the entry of the oligonucleotide into the cytoplasm (*25*).

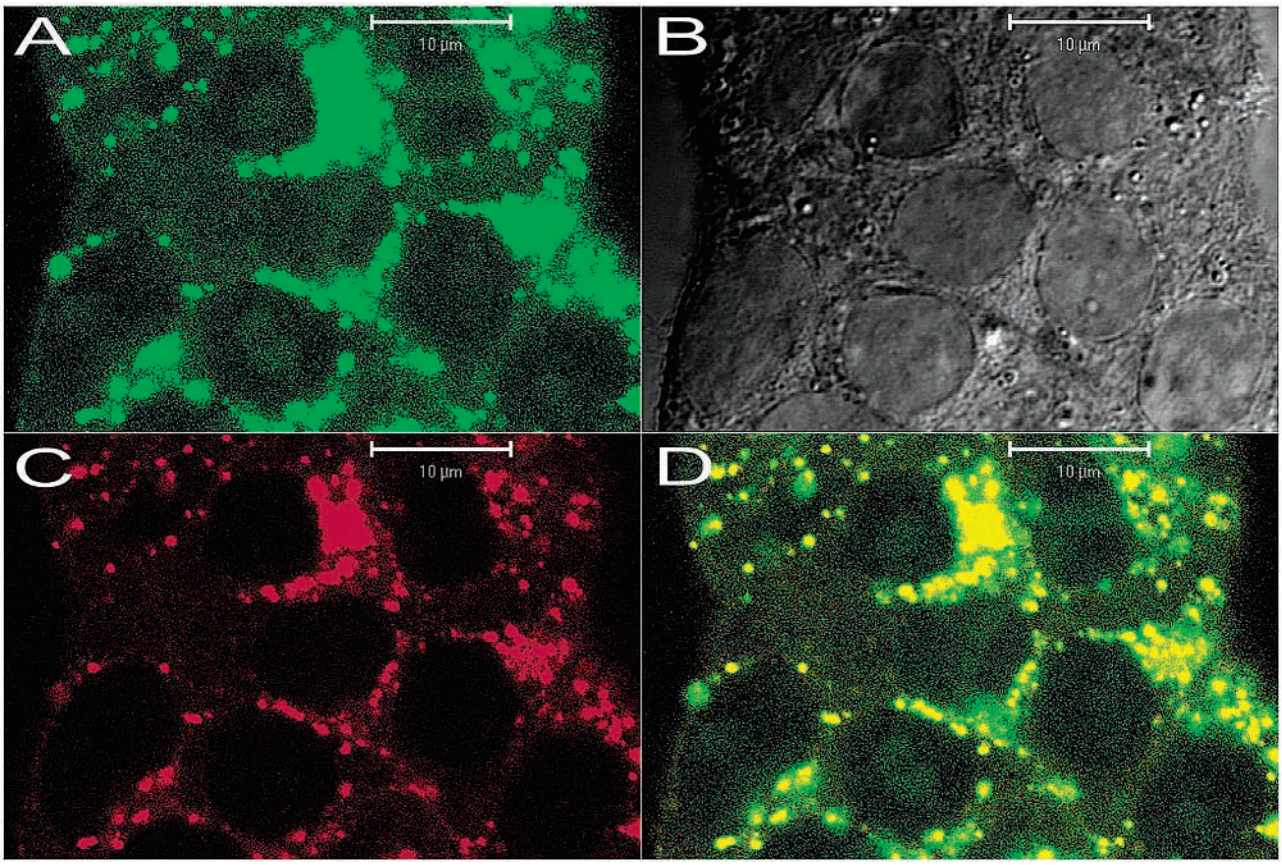

Figure 5. Hep G2 cells incubated with P2 (4.9 μM oligonucleotide, 8.12 μM LR) for 4 h. (A) Green fluorescence from the oligonucleotide was found predominantly in vesicles with minor amounts in the cytoplasm and nucleus. (B) Transmitted image. (C) Red fluorescence from the polymer was found almost exclusively in vesicles. (D) Combined green and red fluorescence; yellow color indicates colocalization. The scale bars are 10 μm.

A much more controlled delivery system was required to test the ability of the oligonucleotide to escape from the lysosome.

HPMA copolymers (reviewed in refs *21* and *26*) are well-suited for delivery of material to the lysosome. They are uncharged, hydrophilic polymers that are easily modified to incorporate various moieties. The polymers have been previously shown to be internalized by endocytosis (*12*, *16*−*20*). Conjugating the oligonucleotide to the polymers ensures their delivery to the lysosome. The covalent attachment of the oligonucleotides to the polymer via the lysosomally degradable GFLG spacer prevents premature release of the oligonucleotides before reaching the lysosome.

The subcellular fate of the free oligonucleotides was determined by confocal microscopy. The free oligonucleotides appeared to enter Hep G2 cells via endocytosis and accumulate in vesicles in the cytoplasm (Figure 2). Beginning at 2 h and continuing up to 24 h, increasing fluorescence was observed in the cytoplasm, nucleus, and nuclear structures of the Hep G2 cells (Figure 3). Fluorescence quenching, pH sensitivity of the fluorescein, and the large difference in fluorescent intensity of the vesicles and the other compartments prevented quantitative analysis. It is even difficult to make an estimate of the fraction of fluorescence which was able to escape from the endosomes/lysosomes. It is also unknown how much of the fluorescence in the cytoplasm and nucleus is due to degraded oligonucleotide. The stability study suggested that only a small fraction would have been degraded at short incubation times, but only a fraction of the fluorescence was found outside of the endosomes/lysosomes.

The subcellular fate of free oligonucleotides we observed in Hep G2 cells is consistent with most studies reported in the literature. Using cell fractionation, researchers have reported both nuclear accumulation and cytoplasmic accumulation of oligonucleotides (*3*, *27*, *28*). The subcellular distribution may be sequence-specific and is likely related to protein binding (*29*−*31*). Although we saw rapid entry of the oligonucleotides into the nucleus once they entered the cytosol, we did not see increased nuclear accumulation often reported after microinjection of phosphorothioate oligonucleotides into the cytoplasm (*32*−*35*).

Conjugating the oligonucleotide to the polymer via the nondegradable spacer (polymer conjugate P1) resulted in significant changes in the distribution of the conjugates. The vast majority of the fluorescence remained in the endosomes/lysosomes (Figure 4). There was a small amount of fluorescence just above the autofluorescence level of the cells found in the cytoplasm and to a lesser extent the nucleus (Supporting Information Figure 1). Contrary to the redistribution of the free oligonucleotide, time did not seem to have a significant effect on the subcellular distribution of the polymer-conjugate P1. Increasing the incubation time from 0.5 to 24 h only increased the intensity of the fluorescence without any distinct change in distribution. Changing the concentration from 0.4 to 3.6 μM (oligonucleotide concentration) did not also noticeably affect the subcellular distribution (data not shown).

There were some points of difference in cytoplasmic and nuclear staining of the oligonucleotide-polymer conjugate P1 from cells incubated or microinjected with

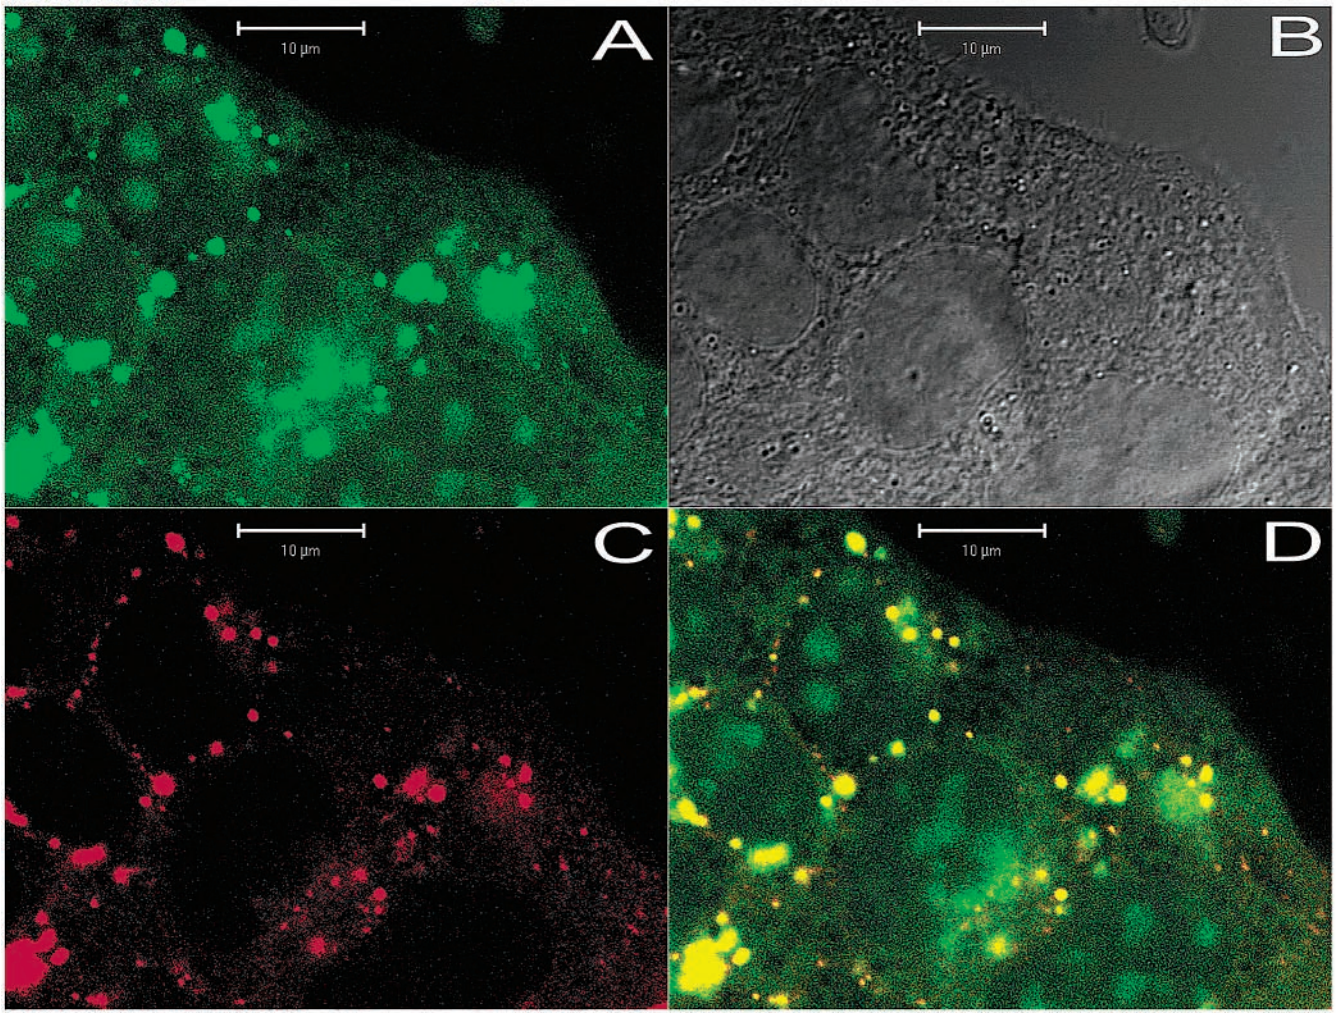

Figure 6. Hep G2 cells incubated with P2 (4.9 μM oligonucleotide, 8.12 μM LR) for 24 h. (A) Green fluorescence from the oligonucleotide. Increased amounts of oligonucleotide were found in the cytoplasm, nucleus, and accumulating in nuclear structures. (B) Transmitted image. (C) Red fluorescence from the polymer was found predominantly in vesicles. (D) Combined green and red fluorescence; yellow color indicates colocalization. The scale bars are 10 μm.

Table 1. Estimated Half-Life of the Free Oligonucleotide and Polymer-Bound Oligonucleotide (P1) after Digestion with Isolated Lysosomal Enzymes (Tritosomes) at 37 °C

compound tested	estimated half-life (h)
free oligonucleotide	14.8
oligonucleotide-polymer conjugate P1	43.3

Table 2. Antiviral Activity of the Antisense Oligonucleotides

compound tested	EC_{50}[a] (μM)	EC_{90}[b] (μM)
oligonucleotide-polymer conjugate P2	1.7	8.3
free oligonucleotide	–[c]	–
polymer without oligonucleotide	–	–
free oligonucleotide + unconjugated polymer	–	–
3TC (positive control)	0.059	0.175

[a] EC_{50}: effective concentration to achieve a 50% viral inhibition. [b] EC_{90}: effective concentration to achieve a 90% viral inhibition. [c] (–): no activity at the concentrations studied (0.01–10 μM for the oligonucleotide and 4.56 mg/mL for the polymer).

fluorescent HPMA copolymers in a previous study (*12*). We previously found (*12*) that HPMA copolymers incubated with Hep G2 cells were able to escape from endosomes/lysosomes, and that the polymer which entered the cytoplasm tended to accumulate in the nucleus. The lack of nuclear accumulation of polymer in this work may be due to a small number of sites with higher affinity for the polymer or oligonucleotide in the cytoplasm. At low polymer concentrations, these sites would be occupied first. More studies would be necessary to test such a hypothesis.

It is interesting to note that there was also a lack of heterogeneous staining previously observed with Hep G2 cells incubated with HPMA copolymers (*12*). In a previous study (*12*), we had found that HPMA copolymers were able to escape from lysosomes into the cytoplasm and nucleus of a fraction of the Hep G2 cells. The fraction of cells with nuclear and cytoplasmic staining increased with time, but it typically took >8 h of incubation to see staining for a majority of the cells. Such variability was not observed in this work as all cells that were incubated with oligonucleotides (free or conjugated) exhibited similar amounts and distribution of staining. The difference is likely due to the presence of the oligonucleotides on the polymers, but more studies are needed to determine the effect of conjugated moieties on the polymer's subcellular fate.

The subcellular distribution of the oligonucleotide conjugated to the polymer by the lysosomally degradable GFLG spacer (P2) differed significantly from that attached by the nondegradable spacer. Labeling the polymer backbone with LR and the oligonucleotide with

fluorescein allowed separate tracking of each component. At incubation times shorter than 2 h, the fluorescence from both dyes was predominantly found together in small vesicles in the cytoplasm (Supporting Information Figure 2). The green (oligonucleotide) and red (polymer) signals began to separate between 2 and 4 h and increase slightly after 24 h of incubation (Supporting Information Figure 2).

The staining of the cytosol, nuclei, and nuclear structures by the oligonucleotide conjugated via the cleavable spacer (polymer P2) appeared to be a combination of the staining of the free oligonucleotide and the oligonucleotide-HPMA copolymer conjugate P1. At incubation times of 4 h or greater, the oligonucleotide of polymer P2 was observed in the cytoplasm and nucleus (Figures 5A and 6A) similar to that of the free oligonucleotide (Figure 3A). There was only minimal staining of the cytoplasm by the polymer (Figures 5C and 6C) similar to that observed for the oligonucleotide-HPMA copolymer P1 with the nondegradable spacer (Figure 4A). There was increased staining of nuclear structures by the oligonucleotide in polymer P2 (Figure 6A) similar to that seen when incubating with the free oligonucleotide (Figure 3A). These results suggest that the oligonucleotide conjugated to the polymer by the degradable spacer was released from the polymer and escaped from lysosomes in a fashion similar to the free oligonucleotide. The oligonucleotide appeared to be able to escape from lysosomes faster than the polymer as more (qualitatively) of the oligonucleotide entered the cytoplasm and nucleus than the polymer (compare Figures 5A vs 5C and 6A vs 6C).

The increased uptake of the oligonucleotide-HPMA copolymer conjugate compared to the LR-labeled polymer (Supporting Information Figure 3) supported previous findings (*36*) that Hep G2 cells actively internalize phosphorothioate oligonucleotides.

The antiviral assay was needed to determine if the antisense oligonucleotide was still active after passing through the lysosome. The confocal microscopy supplied evidence that oligonucleotide delivered to the lysosome escaped into the cytoplasm and nucleus. The positive antiviral activity of the polymer-oligonucleotide conjugate P2 (Table 2) demonstrated that a fraction of the antisense oligonucleotide had not been degraded and was still active.

The relatively high concentration of the oligonucleotide-HPMA copolymer conjugate P2 required for antiviral activity was likely due to a combination of three causes: inefficient delivery of the oligonucleotide to its target, inactivation of the antisense oligonucleotide, and a reduced potency antisense oligonucleotide (fluorescein bound to the oligonucleotide and an unoptimized sequence). A significant amount of the fluorescence from the oligonucleotide appeared to remain in vesicles, indicating that only a fraction of oligonucleotide escaped into the cytoplasm and nucleus of the cells. The inactivity of the free oligonucleotide, at the concentrations studied, suggested that some of the fluorescence observed outside of the lysosomes was due to inactivated oligonucleotide. Degradation was the likely cause—as supported by the stability assay and by the fact that protein binding or modification should have been similar for free and polymer-liberated oligonucleotides.

After observing the free oligonucleotide in the cytoplasm and nuclei of the cells, we expected it to have antiviral activity also. This inactivity was most likely due to degradation of the oligonucleotide in the cell media or endosome/lysosome as some stability was afforded to the oligonucleotide by conjugation to the polymer (Table 1). Using a similar antisense oligonucleotide, Wu and Wu (*7*) also found that the free oligonucleotide had lower activity than the oligonucleotide complexed to a targeted poly-lysine carrier. They attributed the difference in activity to the increased amount of oligonucleotide delivered with the targeted polymeric carrier, increased stability due to the carrier, and potential help from the carrier in escaping the lysosome. In this work, the polymeric carrier likely increased the activity of the oligonucleotide by increasing its stability as the HPMA copolymer was not targeted nor was it likely to help the oligonucleotide escape the lysosome—it was uncharged, had no useful buffering capacity, and was less able to escape the lysosome than the oligonucleotide (Figure 6). The initial rapid degradation of a small fraction of the conjugated oligonucleotide followed by the slow degradation phase suggested that some of the oligonucleotide was easily accessible for degradation, but that the majority of the conjugated oligonucleotide was not. The slow degradation phase of the polymer-conjugated oligonucleotide was probably not due to inactivation of the lysosomal enzymes as the free oligonucleotide was continuously degraded over the course of the experiment. It is unlikely that the uncharged, hydrophilic polymer inactivated the enzymes as it was present from the beginning of the experiment.

Cleavage of the degradable tetrapeptide bond and protection of the oligonucleotide, both on the polymer, may appear an apparent contradiction. Both are likely afforded limited protection from degradation. Cleavage of the tetrapeptide is particularly efficient as its sequence was chosen as a good substrate for lysosomal thiol proteinases, especially cathepsin B (*37*, *38*), whereas the phosphorothioate oligonucleotide is designed to be resistant to nucleases.

CONCLUSIONS

- Phosphorothioate oligonucleotides internalized by endocytosis were able to escape into the cytoplasm and nucleus of Hep G2 cells.
- Binding the oligonucleotides to the HPMA copolymers via nondegradable spacers restricted the oligonucleotides from entering the cytoplasm and nucleus of the cells.
- Conjugation of the oligonucleotides to the HPMA copolymers via degradable spacers afforded them with increased stability and prevented their inactivation before escaping the lysosome and actively inhibiting the hepatitis B virus.

To better deliver antisense oligonucleotides to their targets in the cytoplasm and nucleus, knowledge of their subcellular distribution and ability to escape lysosomes is needed. The many positive examples of antisense oligonucleotides in the literature suggests that despite their large size and multiple negative charges, oligonucleotides are able to escape from lysosomes and actively inhibit synthesis of the target protein (*1*). To study this hypothesis, we delivered phosphorothioate oligonucleotides to the lysosome using HPMA copolymers. Conjugation via lysosomally cleavable spacers assured release of the oligonucleotide only in the lysosome. Confocal microscopy and an antiviral assay provided evidence that the oligonucleotide delivered to the lysosome was able to escape into the cytoplasm and nucleus of Hep G2 cells and actively inhibit its target. The high concentration of antisense oligonucleotides required for antiviral activity, the short half-life of the oligonucleotide, and the high fluorescence of vesicles suggest directions for improving antisense therapies. Increasing the activity and stability of the antisense oligonucleotides, while

maintaining high specificity, will provide potent drugs. Better delivery methods are also needed to ensure interaction of the antisense oligonucleotide with its intended target.

ACKNOWLEDGMENT

The antiviral activities of the antisense oligonucleotides were determined by Dr. Brent Korba (Georgetown University, Rockville, MD) under NIAID Contract N01 AI85349. This research was supported in part by National Institutes of Health Grants CA51578 and CA88047 from the National Cancer Institute. Partial support of K.D.J. was provided by NIH Training Grant GM08537 and by a fellowship from the American Foundation of Pharmaceutical Education.

Arano and co-workers (Arano et al. (1999) *Cancer Res. 59*, 128−134) have synthesized peptides with an N-terminal radioiodinated hippuric acid and a C-terminal lysine linked to antibody fragments via the ϵ-amino group of lysine that show reduced kidney uptake compared to antibody fragments directly radioiodinated. This approach takes advantage of the lysine specific carboxypeptidase activity of the kidney brush border enzymes that cleave off the radiolabeled peptide linker from the antibody fragment prior to uptake by proximal tubule cells. On the basis of their approach, we have synthesized a tetrapeptide with an N-terminal DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) and a C-terminal (N^{ϵ}-maleoyl)lysine that was site-specifically conjugated to an anti-CEA diabody (Yazaki et al. (2001) *Bioconjugate Chem. 12*, 220−228) that was engineered to contain a C-terminal cysteine (Cys-diabody). Biodistributions of the In-111-radiolabeled conjugate in nude mice show significantly reduced kidney uptake (a maximum of 82%ID/g at 6 h) compared to In-111 radiolabeled DOTA-diabody (184%ID/g at 6 h) in which DOTA was conjugated to endogenous lysine residues using DOTA-active ester chemistry. To further reduce kidney uptake, a homologous compound with a C-terminal (N^{ϵ}-amino-1,6-hexane-bis-vinyl sulfone)lysine was synthesized and site-specifically conjugated to the Cys-diabody. Biodistributions of this In-111-labeled conjugate reduced kidney uptake to 54%ID/g at 6 h. To explore the effect of the relative positions of the chelate vs the cys-diabody on kidney uptake, we also synthesized a tetrapeptide with an N-terminal bromoacetate for conjugation to Cys-diabody and a C-terminal (N^{ϵ}-amidino-propyl-3-thio-vinylsulfonyl-DO3A)lysine. This peptide essentially reverses the positions of the chelate and Cys-diabody attachment points on the peptide, while retaining the linker length on the ϵ-amino group of the lysine. In this case, biodistributions of the In-111-radiolabeled conjugate in nude mice showed high kidney uptake (189%ID/g at 6 h), comparable to that obtained with the In-111-radiolabeled active ester conjugated DOTA-diabody (184%ID/g at 6 h). We conclude that the peptide linker strategy of Arano and co-workers to reduce kidney uptake can be successfully applied to chelate/radiometal complexes and requires that the chelate/radiometal be located at the N-terminus of the peptide and the antibody fragment attachment site on the ϵ-amino group of the lysine. Furthermore, we demonstrated a role for the attachment chemistry to the ϵ-amino group of the lysine on the magnitude of kidney uptake.

INTRODUCTION

While bifunctional chelating agents (BCAs[1]) are routinely conjugated to recombinant antibodies for radiolabeling with radiometals such as ^{111}In for radioimmunoimaging and ^{90}Y for radioimmunotherapy (*1*−*4*), they suffer from high kidney uptake when conjugated to antibody fragments (*5*−*9*). Although intact antibodies have high clinical utility, their relatively long circulation times and poor tumor penetration (*10*) have prompted many studies on antibody fragments, including proteolytic Fab and F(ab′)$_2$ fragments made from intact antibodies (*6*, *11*−*15*), or recombinant fragments, including scFv (*16*−*18*), diabodies (*9*, *18*, *19*), and novel constructs such as ΔC_H2 (*20*), scFvFc (*21*−*23*), or the minibody scFvC_H3 (*24*). In almost all cases, the antibody fragments have shown unacceptably high kidney uptake when conjugated to chelates and radiometal labeled. Thus, their clinical use has been limited to radioiodinated fragments where the high kidney uptake is offset by rapid dehalogenation (*25*). Unfortunately, dehalogenation also

occurs in the tumor, and especially in the cases of internalizing antibodies, tumor dehalogenation further limits the clinical utlility of radiolabeled antibody fragments.

Several groups have studied the metabolism of chelate/radiometal-labeled antibody fragments in the kidney. Rogers et al. (*26*) identified ^{111}In-DTPA-ϵ-amino lysine as the major metabolite of ^{111}In-labeled DTPA-conjugated F(ab′)$_2$ fragments, and Tsai et al. (*27*) identified ^{111}In-DOTA-ϵ-amino lysine as the major metabolite of ^{111}In-labeled DOTA-conjugated Fab fragments. In both studies the BCA was attached to surface lysine residues, suggesting that that uptake of antibody by the kidney leads to complete degradation of the protein leaving the non-metabolizable chelate-lysine derivative as the ultimate product. In similar studies with ^{18}F-labeled disulfide stabilized Fv (dsFv) fragments, Lang et al. (*28*) identified [^{18}F]fluoromethylbenzoyl-ϵ-amino-lysine as the ultimate metabolite in the urine. Kidney uptake depends on both the rate of blood clearance and the molecular size of the fragment. For example, ^{177}Lu-DTPA-sFv (M_r = 27 kDa) of CC49 (anti-B72.3) has a $T_{1/2\beta}$ of 2h and 219% ID/g in the kidney at 6 h (*29*). ^{111}In-DOTA-diabody (M_r = 50 kDa) of T84.66 (anti-CEA) has a $T_{1/2\beta}$ of 3 h and 183% ID/g in kidney at 6 h (*27*). In contrast, ^{111}In-DOTA-scFvC$_H$3 (M_r = 75 kDa) of T84.66 has a $T_{1/2\beta}$ of 4.5h and 12.5% ID/g in kidney at 6 h (*9*). A discussion of the optimum size of antibody fragments as matched to radiolabel half-life is given by Williams et al. (*30*). In general, scFv fragments clear too rapidly and have low antigen binding (monovalent), precluding their use in imaging or therapy, while the larger fragments, such as scFvC$_H$3 (divalent), are attractive due to their rapid clearance and lack of kidney uptake. Although intermediate-sized fragments such as the diabody (also divalent) are highly attractive due to their more rapid blood clearance, their high kidney uptake has limited their clinical utility.

Several possible approaches to the kidney uptake problem have been investigated. The first is the co-administration of L- or D-lysine as originally described by Solling and Morgenson (*31*) and more recently reviewed (*32*, *33*). In one study, the high kidney uptake of ^{99m}Tc-labeled Fab′ (>100%ID/g at 4 h) was reduced to 40%ID/g at 4 h by adminstration of 1 mg/g × 4/h ip of L-lysine in balb/c mice (*34*). In a second study, ^{111}In-DOTA-diabody kidney uptake was reduced from 180%ID/g to 65%ID/g at 6 h by the administration of 100 mg of D-lysine, oral, 30 min prior to injection of antibody (9). In a third study, ^{88}Y-DOTA-Fab′ kidney uptake was reduced from 104%ID/g to 20%ID/g at 4 h by the administration of 4 × 2 mg/g/h ip of D-lysine (*6*). This approach has been applied to human studies in which patients receiving ^{99m}Tc-labeled anti-CEA Fab′ fragments were infused with 2 L of 2.25 g/L of L-lysine-L-glutamate and 2.5 g/L of L-arginine (*35*). The results were minor (11%ID vs 18%ID) compared to the animal studies, perhaps because the amount of lysine administered was less on a per weight basis.

A second approach to the problem is the use of BCAs with organ specific cleavable linkers. Arano and co-workers (*33*, *36*−*38*) have synthesized C-terminal Lys linkers for a radioiodinated hippuric acid−Fab conjugate that lowered kidney uptake by up to 50%. The BCA was hippuric acid-glycyl-N^{ϵ}-maleoyl-lysine which allowed linkage of antibody fragments to the maleimide moiety via thiol-specific Michael addition (*39*). In this study they demonstrated the critical importance of the α-carboxyl group of the C-terminal lysine residue, presumably confirming the role of brush border carboxypeptidase activity in the kidney. They have hypothesized that cleavage of the antibody fragment from the radiolabel prior to uptake by the proximal tubule cells allows excretion of the residualized radiolabel. When the peptide linker-radiolabeled fragment was compared to fragment radioiodinated by standard chemistry in a tumor bearing nude mouse model, no difference was observed in tumor uptake, but kidney uptake was reduced by 25% at 3 h. Thus, the peptide linker played a critical role in reducing kidney uptake while preserving tumor uptake.

In this work, we extend the model of Arano and co-workers to the use of C-terminal lysine peptide linkers with the chelate DOTA at the N-terminus. The Michael addition reagents maleimide (similar to Arano and co-workers) or hexanevinyl sulfone were attached to the ϵ-amino group of the C-terminal lysine residue in order to allow site-specific conjugation to a thiol group in an antibody fragment. We engineered a C-terminal cysteine residue into an anti-CEA diabody to provide the site-specific thiol group. The diabody quantitatively formed covalently linked dimers that had to be reduced prior to conjugation with BCA. We also synthesized a peptide linker in which the positions of DOTA and Cys-Diabody were exchanged, with Cys-diabody at the N-terminus and DOTA attached to the ϵ-amino group of the C-terminal lysine. When the conjugates were radioabeled with ^{111}In and biodistributed in nude mice, kidney uptake was significantly lowered in the first, but not the second conjugate. The results demonstrate that the C-terminal lysine peptide linker approach can be generalized to chelate/radiometal conjugates, and that the relative positions of the chelate and antibody fragment attachment points are critically important.

EXPERIMENTAL PROCEDURES

General. DOTA trisodium salt and the free acid were purchased from Parish Chemical Co. (Orem, UT) and Macrocyclics, Inc. (Richardson, TX), respectively. The tris-*tert*-butyl ester of DO3A was also obtained from Macrocyclics, Inc. DTPA was obtained from Fluka (Milwaukee, WI), 1,6-hexane-bis-vinyl sulfone from Molecular Biosciences (Boulder, CO), 2-iminothiolane HCl from Aldrich (Milwaukee, WI), and Chelex 100 from BioRad (Hercules, CA), Ultrapure water (18 MΩ-cm) was used to make all buffers which were passed over Chelex 100 and pH adjusted if necessary. $^{111}InCl_3$ (1.0 mCi/0.15 mL in 0.04 M HCl) was obtained from Mallinckrodt Medical Inc. (St. Louis, MO). $^{64}CuCl_2$ (2 mCi/0.05 mL in 0.01 M HCl) was obtained from Dr. Michael Welch, Mallinckrodt Radiological Institute, Washington University, St. Louis, MO. The anti-CEA diabody has been previously described (*40*). ITLC were performed as previously described (*41*). Mass spectra were recorded on a Finnigan LCQ ion trap mass spectrometer using a custom nanospray interface or on a Voyager DESTR MALDI-TOF mass spectrometer (Applied Biosystems). NMR spectra were recorded on a Varian Unity Plus 500 MHz spectrometer. Proton chemical shifts are reported relative to HOD (4.80 ppm). Antibody concentrations were calculated at 280 nm (A_{280}, 1 mg/mL = 1.42). UV spectrophometry was performed on a Shimadzu UV160 instrument using a 1 cm cell. Melting points were recorded on a Thomas-Hoover unimelt apparatus and are uncorrected. SDS and IEF gel electrophoresis was performed on a Pharmacia PhastGel apparatus according to the manufacturer's instructions.

Cloning and Expression of Cys-Diabody. The C-terminal sequence of the previously published T84.66/GS8 anti-CEA diabody (...VSS) (*40*) was converted to

(...VSLGGC) by PCR mutagenesis using the QuickChange protocol (Stratagene). Protein was expressed using the pEE12/glutamine synthetase expression system (Lonza Biologics) in NS0 murine myeloma cells. CEA-binding activity was assessed by ELISA using microtiter plates coated with recombinant CEA NA-3 and alkaline phosphatase-conjugated goat anti-mouse Fab as described (Yazaki et al., 2001). Cys-diabody was purified by sequential chromatography using anion exchange (Source 15Q, Amersham Biosciences) followed by ceramic hydroxyapatite chromatography (Bio-Rad Laboratories) using a BioCad 700E perfusion chromatography system (Applied Biosystems) (*42*).

DOTA-glycylleucylglycyl-N^{ϵ}-maleoyllysine, 2a. α-NH_2-GLGK−PS (**1**) was synthesized on α-Fmoc-Lys-(ϵ-Boc)-Wang resin (Bachem). Briefly, 1 g of α-Fmoc(ϵ-Boc)-Lys-resin (0.83 mmol/g) was vortexed 15 min with 5.5 mL of DMF/piperidine (10:1, v/v) at RT, filtered, and washed with ethanol (5 mL × 3), DMF (5 mL × 3), and DCM (5 mL × 3). The procedure was repeated until all traces of cleaved FMOC were removed (A_{300nm}). α-FMOC-Gly (1 mmol) was activated with DCC (2 mL of 1 M DCC in 2 mL of DCM; 2 mmol) and HOBt (2 mL of 0.5 M in NMP, 1 mmol) for 5 min at RT, the precipitate removed, and the filtrate vortexed with the Lys(ϵ-Boc resin) for 30 min at RT. The resin was washed with saturated NaHCO3 12× (or until $A_{300\ nm}$ of the washes were zero), water 3×, and DCM 3×. The α-Fmoc group was removed with DMF/piperidine as described above. The coupling procedure was repeated with α-Fmoc Leu and α-Fmoc Gly. After each step, a small amount of resin was removed, treated with TFA/H_2O (98/2), and analyzed by ESI/MS to determine if the correct mass was obtained. For intermediate **1**, the α-Fmoc group was removed after coupling. The TFA-cleaved peptide, α-Fmoc-GLGK−CO_2H, had the correct mass (MH^+ expected, 596.30, MH^+, observed, 596.47). For intermediate **3**, the Fmoc group was not removed and the TFA-cleaved peptide had the correct mass (MH^+ expected, 374.30, MH^+ observed, 374.34). **1** (129 mg, 110 μmol) was treated with the isobutyl formate ester of DOTA prepared according to Li et al. (*43*). Briefly, the trisodium salt of DOTA (440 μmol) was suspended in 16.8 mL of DMF/TEA (4:1, v/v), stirred overnight until clear, and reacted with isobutyl chloroformate (29 μL, 220 μmol) added dropwise over 15 min at 0 °C. The active ester was added to the resin and vortexed for 6 h at RT. The resin was filtered, washed with ethanol 5 mL ×5 and DCM 5 mL ×5, and cleaved with TFA/H_2O (6 mL, 98/2, v/v). The peptide was purified by RP-HPLC on oligo-R3 (Perseptive Biosciences) using a linear gradient of 100% A (0.1% TFA) to 100% B (0.1/9.9/90, TFA/H_2O/MeCN, v/v/v) at a flow rate of 5 mL/min over 15 min. The purified peptide gave a single peak on analytical RP-HPLC and the correct mass by ESI-MS (MH^+ expected, 760.41, MH^+ observed, 760.74). The yield of lyophilized product was 12.3 mg (14.7% overall). DOTA-GLGK−CO_2H (5.2 mg, 6.9 μmol) was mixed with 3 aliquots of *N*-(methoxycarbonyl)maleimide (18.6 mg, 120 μmol) added over 1 h in 0.5 mL of saturated $NaHCO_3$ at 4 °C. The reaction was stirred for 24 h and neutralized to pH 1 with 10% TFA, and the product was purified by RP-HPLC on an Oligo-R3 column. The approximate yield was 2.8 mg (48.4%) of purified product (MH^+ expected, 840.67, MH^+ observed, 840.41by ESI-MS). The synthesis of *N*-(methoxycarbonyl)maleimide was adapted from that of Arano and co-workers (*39*). Maleimide (2.14 g, 22 mmol) and *N*-methylmorpholine (1.38 mL, 20 mmol) were mixed in 50 mL of ethyl acetate at 4 °C. *N*-Methyl chloroformate (1.41 mL, 20 mmol) was added dropwise and stirred for 2 h. The white precipitate was filtered and washed with ethyl acetate twice (5 mL). The filtrate and washes were combined, concentrated, and redissolved in a minimum volume (3 mL) of ethyl acetate. White crystals were obtained (2.1 g, 67.7% yield).

DOTA-glycylleucylglycyl-(N^{ϵ}-1,6-hexane-bis-vinyl sulfone)lysine, 2b. DOTA-GLGK−CO_2H (2 mg, 2.6 μmol) was mixed with 1,6-hexane-bis-vinyl sulfone (26 μmol) in DMF/H_2O (0.6 mL, 1:1, v/v), the pH was adjusted to 8.5 with 1 M NaOH, and the reaction was run for 24 h at RT. The solution was extracted with ethyl acetate (2 mL, 3×) and the product purified by RP-HPLC as above. The product (**2b**, 2.47 mg, 73.5% yield) had the correct mass by ESI-MS (MH^+ expected, 1292.59, MH^+ observed, 1292.54).

DOTA-glycylleucylglycyllysine-(N^{ϵ}-bromoacetamido), 2c. DOTA-GLGK−CO_2H (2 mg, 2.6 μmol) was reacted with bromoacetyl bromide (4 μL, 45 μmol) in 0.5 mL of 0.1 M $NaHCO_3$ for 1 h at RT. The product was purified by RP-HPLC on an oligo R3 column. The product (1.63 mg, 71.2% yield) eluted as a single peak and had the correct mass (MH^+ expected, 880.46, MH^+ observed, 880.56, first peak of Br isotopic doublet).

N^{α}-Bromoacetamido-glycylleucylglycllysine-(N^{ϵ}-amidino-propyl-3-thio-vinylsulfonyl-DO3A), 4. α-Fmoc-GLGK−CO_2H (**3**, 20 mg, 34 μmol) in 1.0 mL of DMF was mixed with 8.13 mg (59 μmol) of 2-iminothiolane in 2.0 mL of H_2O, and the pH was adjusted to 8.0 with 1 M NaOH and allowed to react for 2 h at RT. The reaction was monitored by ESI-MS for the correct mass of the expected product (MH^+ = 697.4). DO3A-VS (**5**, 17.4 mg, 37 μmol) was then added to the reaction mixture, the pH adjusted to 8.0 and the reaction continued for 2 h at RT. Again the reaction was monitored for the correct mass of the expected product (MH^+ = 1161.5). The product was lyophilized, purified by RP-HPLC, and treated with 0.20 mL of piperidine−DMF (1:10, v/v) for 20 min at RT. The product (MH^+ expected, 939.50, MH^+ observed, 939.60) was repurified by RP-HPLC (yield, 4.1 mg, 12.8% yield). The product (2.8 mg, 3.0 μmol) was dissolved in 0.2 mL of TEA/DMF (1/200, v/v) at 4 °C and reacted with 0.3 μL × 3 additions (3.3 μmol) of bromoacetyl bromide every 2 h for a total of 8 h. The product was lyophilized and purified by RP-HPLC on an oligo R3 column. Two peaks were obtained, a small early eluting peak corresponding to starting material and a large late eluting peak corresponding to the expected product (**4**). The yield was 1.0 mg (31.5%) with the correct mass by ESI-MS (MH^+ expected, 1059.65, MH^+ observed, 1059.70, first peak of Br isotopic doublet).

Vinylsulfonyl-DO3A (5, DO3A-VS). DO3A (1,4,7-tris(carboxymethyl)-1,4,7,10-tetraazacyclododecane was prepared by TFA treatment of the commercially available tris-(*tert*-butyl) ester of DO3A. The tris-(*tert*-butyl) ester of DO3A (100 mg, 190 μmol) was treated with 3.0 mL of 95% TFA for 24h and lyophilized twice from water. DO3A (60 mg, 92% yield) had the correct mass by ESI-MS (MH^+ expected, 347.19, MH^+ observed, 347.21). Vinyl sulfone (55.8 μL, 500 μmol) was dissolved in 0.2 mL of H_2O/DMF (1:1, v/v), the pH was adjusted to 10.0 with 1 M NaOH, and DO3A (18 mg, 50 μmol) was added in 0.2 mL of water and reacted for 1.5h at RT. The reaction mixture was loaded onto a Dowex 1-X8 (formate) column (5 mL), washed with 30 mL of water, and eluted stepwise with 10 mL each of 0.05, 0.1, and 0.2 M formic acid (1 mL fractions). The correct product was found in fractions 7−11 (yield 10.4 mg, 45.0%). Later fractions which contained substantial amounts of the bis product were

discarded. The purified product (**5**) gave the correct mass by ES-MS (MH^+ expected, 465.19, MH^+ observed, 465.30).

Preparation of Cys-Diabody−BCA Conjugates. One example is given. Cys-diabody (FW = 50,000, 2.0 mg, 40 nmole, at 4 mg/mL, 80 μM) was dialyzed vs 20 mM, pH 7.0 PBS (3 changes, × 1L, 4 °C). The sample is treated with 20 μL of 20 mM TCEP (400 nmol) in PBS for 2 h at 37 °C under Ar and centrifuged through a Sephadex G25 spin column (1 mL, 1200 rpm, 2 min). DOTA-glycyl-leucylglycyllysine-(ϵ-amino-bis-1,6-hexanevinyl sulfone) (FW = 1292, 58 μL of 20 mM **2b** in PBS) was added and the solution rotated at 10 rpm for 4h at 25 °C. The conjugate was dialyzed vs 0.25 M NH_4OAc, pH 7.0 (3 changes, × 1L, 4 °C) and concentrated to 0.5 mL (Centricon 10).

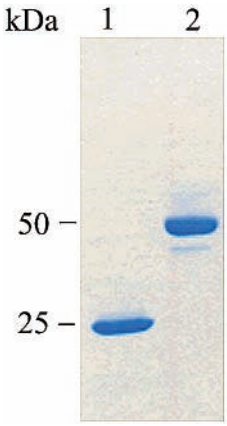
Radiolabeling of Conjugates. The conjugates were radiolabeled with $^{111}InCl_3$ as previously described (*44*). For the animal studies, the conjugates (0.1 mL of 5 mg/mL in 250 mM NH_4OAc, pH 5.7) were incubated with 1.0 mCi of ^{111}In (0.15 mL of 0.04 M HCl plus 0.05 mL of 1.0 M NH_4 OAc, pH 7.0) for 60 min at 43 °C. Excess ^{111}In was chelated with 1 mM DTPA and the radiolabeled product purified on a Pharmacia Superdex 75HR column (1.0 × 30 cm in saline, 0.5 mL/min, 0.5 mL fractions). The protein peak was mixed with 1 drop of 25% (w/v) of HSA. In other test labelings, 1.0 mCi of ^{111}In was added to 0.2 mg of conjugate and the specific activity determined by ITLC (kit 151−770, Biodex, Medical, New York). Determination of the number of chelates per conjugate and the immunoreactivity was performed as previously described (*45*).

Stability Studies. Aliquots (0.5 mL) of the radiolabeled conjugates in PBS-1% HSA were incubated at 37 °C and injected at various time points onto tandem Pharmacia Superose 6 columns to determine the amount of radiolabel in the conjugate and any released products. Separate aliquots were mixed with 0.05 mL of 10 mM DTPA and analyzed as above to determine the release of free ^{111}In.

Animal Biodistributions. Groups of five nude mice (Charles River) bearing LS174T human colon tumor xenografts (ave size = 1.5 mg ± 0.5 at t = 0 h) were injected with 2−4 μCi (2 μg) of radiolabeled conjugate via tail vein. Animals were sacrificed at various time points after injection, major organs, tumor, and blood were weighed, radioactivity was measured, and the results were expressed as mean %ID/g ± SD.

RESULTS

Design of Cys-Diabody. The diabody is the smallest bivalent recombinant antibody that retains many of the desirable properties of the scFv, namely fast pharmacokinetics and good tumor penetration, while overcoming many of its deficiencies such as too rapid blood clearance and poor tumor retention. In previous work we showed that an [^{111}In]labeled anti-CEA diabody gave high tumor uptake (12.5%ID/g at 2 h) and an excellent tumor-to-blood ratio of 4.6 at the same time point (*9*). However, this result was offset by high kidney uptake (135%ID/g and 184%ID/g at 2 h and 6 h, respectively), thus reducing the clinical utility of this agent. In that study we used the chelate DOTA which was attached by active ester chemistry to lysine residues in the diabody. In our present work we redesigned both the BCA and the diabody employing site-specific conjugation chemistry using a thiol-directed BCA with a cleavable peptide linker. To introduce a reactive thiol group in the diabody, the C-terminal Ser of the heavy chain was mutated to Leu and extended by three amino acids, Gly-Gly-Cys. Cys-diabody was expressed in high yield from NS/0) cells, purified by conventional chromatography (details to be presented elsewhere), and shown to exist as disulfide bonded dimers (Figure 1). To be used for site specific conjugation to BCAs, it was necessary to reduce the disulfide bond at the C-terminus prior to coupling. As expected, the radiolabeled BCA-Cys-diabody conjugates migrated as noncovalent dimers on gel filtration (data not shown).



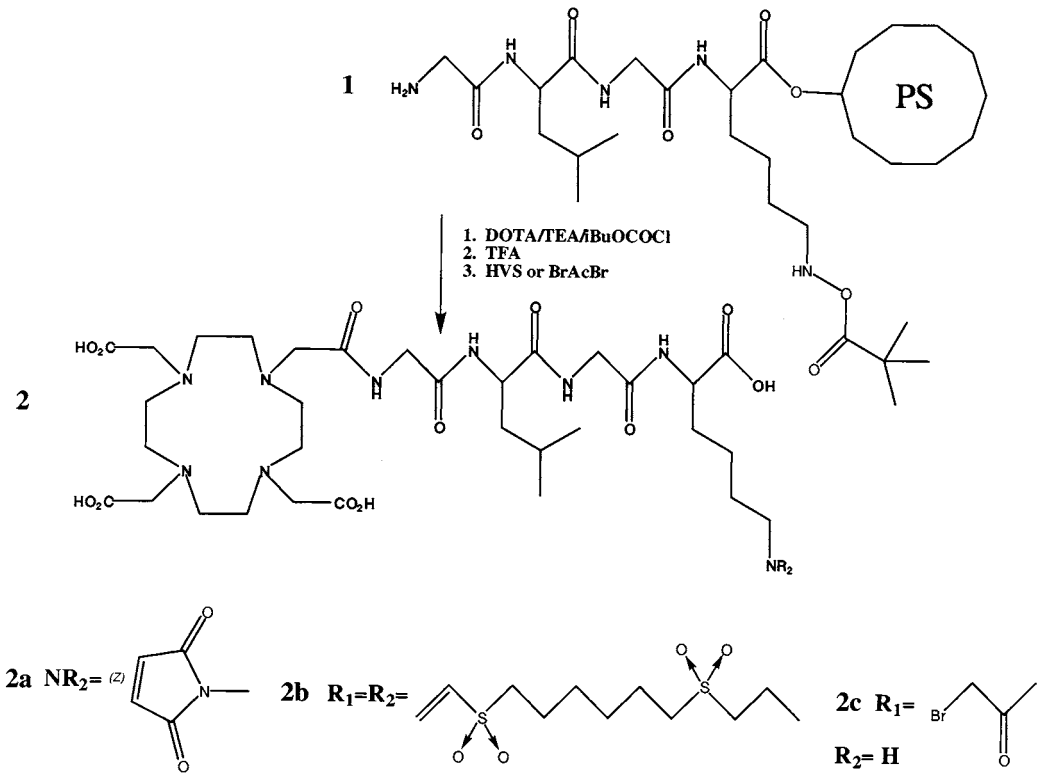


Figure 1. Analysis of Cys-diabody by SDS gel electrophoresis. Cys-diabody was run under either reducing (lane 1) or nonreducing (lane 2) conditions and stained with Coomassie Blue. The molecular weights were determined from the migration of authentic standards.

Synthesis of BCA and Antibody Conjugation. Our goal was to produce a BCA incorporating a peptide linker with DOTA at the N-terminus and lysine at the C-terminus with a thiol-reactive group attached to the ϵ-amino group of lysine. We chose NH_2-GLGK−CO_2H as the peptide because our experience with DOTA attached to Gly_3K peptides indicated that they did not bind to reversed phased resins making purification difficult. Two classes of thiol-reactive compounds were explored. The first was the use of two Michael addition reagents, maleimide and vinyl sulfone. The maleimide moiety, was introduced as N^{ϵ}-maleolyllysine according to Arano and co-workers (*39*). The synthesis of this BCA is shown in Scheme 1 (compound **2a**). The second Michael addition reagent was 1,6-hexane-bis-vinyl sulfone (HVS). The parent compound, vinyl sulfone, reacts with thiol groups specifically at pH 7 and also with amino groups at pH 9 (*46*). Although vinyl sulfone reacted smoothly with the ϵ-amino group of lysine, the product was the six-membered ring sulfone analogue of thiomorpholine, 4-sulfonylmorpholine (confirmed by NMR, data not shown). This product was obtained despite using a large excess of vinyl sulfone in the reaction. To avoid the entropically favorable six-membered ring formation, we used 1,6-hexane-bis-vinyl sulfone. The synthesis of the BCA is shown in Scheme 1 (compound **2b**). In both cases, the isobutyl formate active ester of DOTA was coupled to the free α-amino group of the peptide while still attached to the resin (compound **1**). This facilitated removal of excess DOTA from the reaction mixture and allowed protection of the ϵ-amino group of lysine. The peptide was then cleaved from the resin with TFA and purified by RP-HPLC. In this example, the presence of the leucine residue in the peptide linker promotes easy purification of the desired peptide product by RP-HPLC. The peptide was then reacted with either *N*-methoxycarbonyl-maleimide (compound **2a**) or excess HVS to

Scheme 1

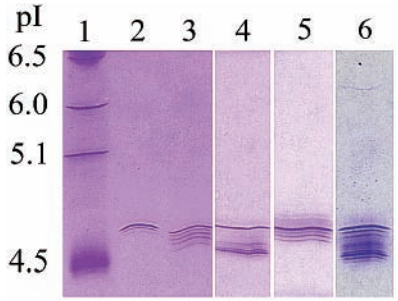
produce the bis-ϵ-amino-HVS derivative (compound **2b**). BFC **2a** was unstable at pH 7 at 37 °C similar to other maleimides (*41*), but was stable indefinitely when stored frozen as a powder. BFC **2b** was shown to be stable in PBS for 7d at 37 °C (data not shown).

The bromoacetamidyl group was the second class of thiol-reactive groups explored. This group was introduced by the reaction of DOTA-GLGK with bromoacetyl bromide in aqueous media to produce the desired product **2c**. In general, this group is thiol-specific if the conjugation conditions are mild (e.g., RT, pH 7, 1−2 h). The BCA **2c** was shown to be stable in PBS for 7d at 37 °C (data not shown).

We also considered reversal of the positions of the DOTA and the thiol-reactive group on the peptide linker. In this case, the starting peptide was α-Fmoc-GLGK (compound **3**). Although we considered the direct coupling of DOTA to the ϵ-amino group of lysine, we were concerned that the close presence of the acidic DOTA derivative would limit the action of the lysine-specific carboxypeptidase in the kidney. Therefore, we devised a strategy to lengthen the distance between the DOTA and the ϵ-amino group while preserving its positive charge (Scheme 2). α-Fmoc-GLGK was reacted with iminothiolane and then with DO3A-VS, which rapidly reacts with the exposed thiol. The peptide was purified by RP-HPLC, deprotected and reacted with bromoacetyl bromide to make the desired product (compound **4**). This synthesis relied on the use of the novel BCA DO3A-VS whose synthesis is shown in Scheme 3. DO3A is the tris-carboxymethyl derivative of cyclen and is readily synthesized from the commercially available tris-*tert*-butyl acetate ester derivative of cyclen. Treatment of DO3A with excess vinyl sulfone produces both the desired product (**5**) and the bis-derivative (DO3A-VS-DO3A). While we made no attempt to optimize the yield of DO3A-VS, sufficient quantities were obtained to proceed with Scheme 2.

All of the BCAs were conjugated to mildly reduced Cys-diabody at a molar ratio of 45 to 1 (BCA/Cys-diabody). The degree of conjugation was determined by IEF gel electrophoresis, wherein conjugation of the acidic BCA to antibody results in a dramatic shift of the Cys-diabody to a more acidic pI. The results of the conjugation reaction at pH 7 are shown in Figure 2. In all four cases there is evidence that the reaction is incomplete. Since all four BCAs react rapidly with thiols, their variable reaction with Cys-diabody may be due to reoxidation of the C-terminal exposed cysteines in the Cys-diabody.

The number of chelates per antibody as determined by trace labeling with ^{111}In in a standard solution of $InCl_3$ is shown in Table 1. Radiolabeling of these four conjugates with $^{111}InCl_3$ gave variable percent radiolabeling efficiencies, specific activities, and immunoreactivities (Table 1). In all cases the percent efficiency for radiolabeling was sufficient to proceed with animal biodistributions. When the radiolabeled conjugates were incubated in PBS-1% HSA plus or minus 1 mM DTPA for 1−4 d, negligible loss of radioactivity was seen for conjugates **2b**, **2c**, and **4**, while **2a** lost 34% of its ^{111}In to



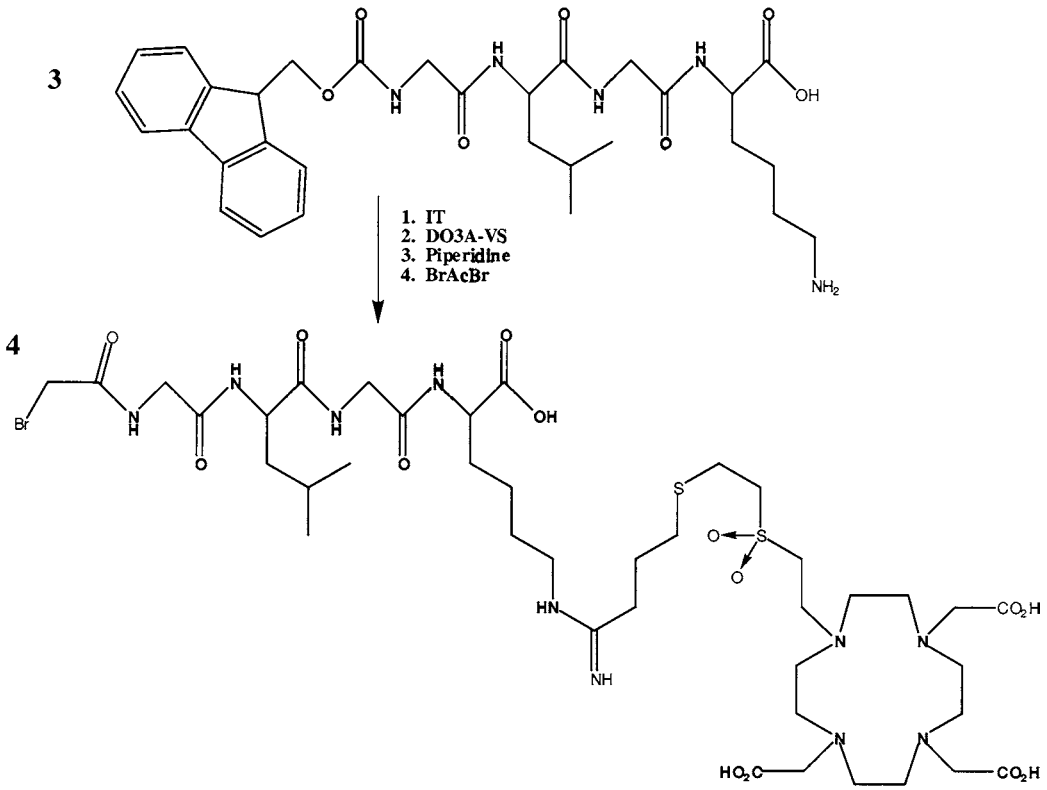


Figure 2. Analysis of BCA−Cys-diabody conjugates by IEF gel electrophoresis. A: Lane 1: IEF standards; Lane 2: Cys-diabody control; Lane 3: BCA = DOTA-GLGK[N^{ϵ}-$(HVS)_2$]; Lane 4: BCA = DOTA-GLGK(N^{ϵ}-AcBr); Lane 5: BCA = (N^{α}-AcBr)-GLGK(N^{ϵ}-IT-VS-DO3A); Lane 6: BCA = DOTA-GLGK(N^{ϵ}-mal).

Scheme 2

Scheme 3

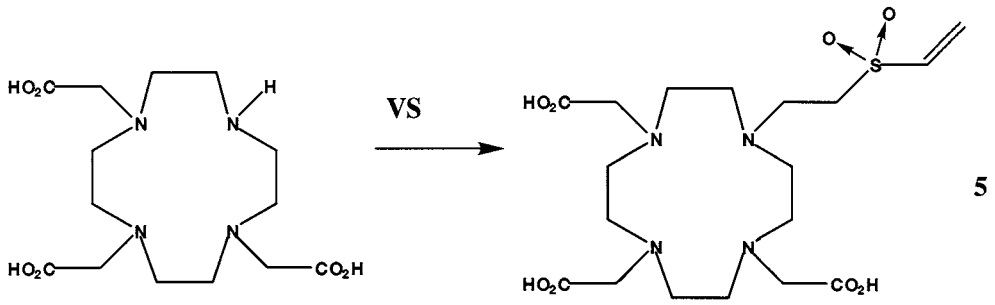

Table 1. Radiometal Labeling Efficiency and Immunoreactivity of BCA−Cys-Diabody Conjugates[a]

sample	chelates/ diab	% incorp	% immun
[^{111}In]DOTA-GLGK(N^{ϵ}-mal)	1.2	27	59
[^{111}In]DOTA-GLGK[N^{ϵ}-(HVS)$_2$]	0.8	8−55[b]	90
[^{64}Cu]DOTA-GLGK[N^{ϵ}-(HVS)$_2$]	0.8	56	24
[^{111}In]DOTA-GLGK(N^{ϵ}-AcBr)	1.3	85	100
(N^{α}-BrAc)-GLGK(N^{ϵ}-IT-VS-[^{111}In]DOTA)	0.6	99	100

[a] BCA was coupled to Cys-diabody as described in the text. The number of chelates per mAb was determined by trace labeling with ^{111}In in a standard solution of $InCl_3$. The labeling ratio was performed with 1.0 mCi of ^{111}In and 0.5 mg of conjugate in 0.3 mL of 0.25 mM ammonium acetate (pH 5.7). Immunoreactivity was performed as described in Methods. [b] This conjugate was test labeled two times at the 0.1 mg level giving labeling efficiencies of 45 and 55%. The labeling for the animal studies gave only 8% efficiency, but the low labeling was due to a rapid drop in pH caused by mixing the sample with the acidic $InCl_3$ and precipitating some of the conjugate. Despite this problem, sufficient sample was available for the HPLC purification of the radiolabeled conjugate and subsequent animal studies.

DTPA over 4 d (Table 1, Figure 3). The loss of radioactivity is found in a new slower migrating peak corresponding to ^{111}In-DOTA-peptide. Addition of DTPA causes no further loss in radioactivity, confirming that the radiolabel is still attached to DOTA. We conclude that the peptide is released due to the hydrolytic instability of the succinimide bonds at pH 7, a finding previously observed by us for other maleimide conjugates (*41*). Despite the instability of the BCA-conjugate, biodistributions were performed because <10% of the radioactivity was lost in 24 h, the critical time period for kidney uptake. In addition, the immunoreactivities of the **2b** and **2c** conjugates were >90% when radiolabled, bound to excess CEA, and analyzed by gel filtration chromatography (Table 1). The **2a** conjugate had lower immunoreactivity, suggesting that the conjugation reaction may have damaged the antibody.

Comparative Animal Biodistributions of BCA−Cys-Diabody Conjugates. [^{111}In]DOTA-GLGK(N^{ϵ}-mal)-Cys-diabody was injected into non-tumor-bearing nude mice, and the biodistribution determined over 24 h (Table 2). The kidney levels reached a maximum of 82%ID/g at 6 h, maintained that level through 15 h, and declined to 71%ID/g by 24 h. This is in contrast to diabody conjugated with the ^{111}In-labeled active ester of DOTA (DOTA-NHS), which reached an uptake in the kidneys of 135%ID/g at 2 h, increased to 184%ID/g at 6 h, and declined to 126%ID/g by 24 h (*9*). Although the reduction in kidney uptake for the **2a** conjugate was an improve-

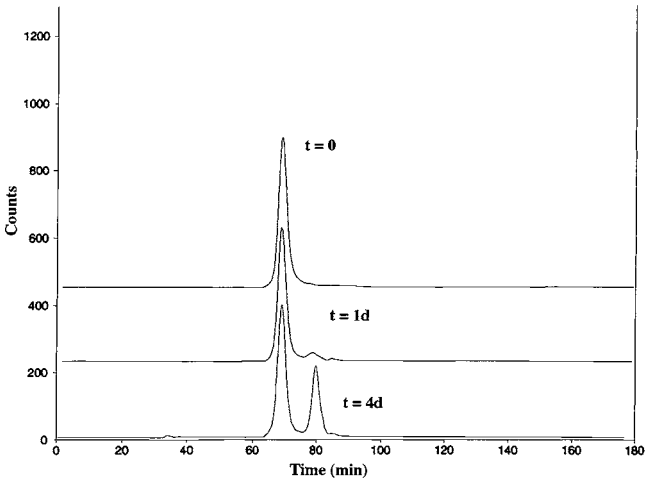

Figure 3. Stability study of [^{111}In] DOTA-GLGK(N^{ϵ}-mal). The sample was incubated at 37 °C in PBS/1% HSA and aliquots analyzed at indicated times by gel filtration on tandem Superose 6 columns as described in Methods. The %area of peak 1 (65 min) was 100% at $t = 0$, 91% at $t = 1$ d, and 66% at $t = 4$ d. The %area of peak 2 (80 min) was 34% at $t = 4$ d.

[a] Five animals per group were injected with ^{111}In-labeled conjugate as described in Methods. The results are reported as mean %ID/g (±SD).

ment over the active ester of DOTA conjugated to diabody, **2a** conjugate was not studied further due to its inherent chemical lability at pH 7 and the unexplained reduction in immunoreactivity of its Cys-diabody conjugate (unsuitable for use in tumor bearing animals).

[^{111}In]DOTA-GLGK[N^{ϵ}-$(HVS)_2$]-Cys-diabody was injected into nude mice bearing human colon tumor xenografts and the biodistribution determined over 24 h (Table 3). The kidney levels reached a maximum of 52%ID/g at 2 h, maintained that level through 15 h, and declined to 45%ID/g by 24 h. In contrast to diabody conjugated with the active ester of DOTA (DOTA-NHS) the reduction in kidney uptake at 24 h and 2 h was 64% and 61%, respectively (Table 7). In addition, [^{111}In]DOTA-GLGK[N^{ϵ}-$(HVS)_2$]-cys-diabody showed a tumor uptake of 8%ID/g at 1h and 11%ID/g at 6 h with a slow decline thereafter (Table 3). This is similar to the tumor uptake in [^{111}In]DOTA-NHS-diabody which reached 13%ID/g at 2 h and remained constant through 6 h. The tumor-to-blood ratios for the two BCA-conjugates were very different at all time points: at 2 h (0.8 vs 4.6), 6 h (2.6 vs 39.1), and 24 h (12 vs 193). The higher T/B ratios for [^{111}In]DOTA-NHS-diabody are due to its very high blood clearance rate, probably due to the higher kidney clearance. Although the blood levels are very different for the two BCAs, tumor uptake was comparable in the

two studies. Possible reasons for these differences are discussed later.

Since we are also interested in PET imaging radionuclides such as ^{64}Cu, we performed biodistribution studies on [^{64}Cu] DOTA-GLGK[N^{ϵ}-$(HVS)_2$]-Cys-diabody (Table 4). This study gave essentially identical results to [^{111}In]DOTA-GLGK[N^{ϵ}-$(HVS)_2$]-Cys-diabody (Table 3). The blood curves are nearly identical; the kidney uptake is identical except at the 24 h time point where the ^{64}Cu-labeled conjugate is lower; the liver uptake is slightly higher for the ^{64}Cu labeled conjugate, tumor uptake is slightly higher for the ^{64}Cu conjugate, and other tissues measured (spleen, lung, and carcass) are identical. Overall, the comparative biodistributions suggest that PET studies with the ^{64}Cu conjugate are feasible. The slightly higher liver levels have been reported for other ^{64}Cu conjugates and may be due to scavenging of ^{64}Cu from the lysosomal compartment in the liver (*1*).

[^{111}In]DOTA-GLGK(N^{ϵ}-AcBr)-Cys-diabody and Cys-diabody-N^{α}-BrAc-GLGK(N^{ϵ}-IT-VS-[^{111}In]DOTA) biodistributions were studied in nontumor bearing nude mice. The biodistributions of these BCA-conjugates (Tables 5 and 6) were similar to [^{111}In]DOTA-NHS-diabody, showing high kidney uptake at 2−6 h (e.g., 137−189%ID/g) and declining by 24h (e.g., 146%ID/g). Curiously, the blood levels of the Cys-diabody-N^{α}-BrAc-GLGK(N^{ϵ}-IT-VS-[^{111}In]DOTA were similar to [^{111}In]DOTA-GLGK[N^{ϵ}-$(HVS)_2$]-Cys-diabody. Thus, the high kidney levels did not

necessarily dictate low blood levels as in the case of [^{111}In]DOTA-NHS-diabody. A comparison of the three BCA-conjugates for kidney uptake at 2 and 24h is shown in Table 7. Overall, this comparison demonstrates that the BCA DOTA-GLGK[N^{ϵ}-(HVS)$_2$] has the most substantial impact on reducing kidney uptake of the diabody.

DISCUSSION

Radiometal-labeled antibodies and their fragments exhibit high retention of radiolabel in tumor sites because of their relative inertness to metabolic action and clearance from the lysosomal compartment. Thus, ^{111}In-labeled whole antibodies have superior tumor uptake compared to radioiodine labeled antibodies that are rapidly metabolized in both tumor and normal tissues. In the case of antibody fragments, where rapid blood clearance results in comparatively lower tumor uptake, the use of radiometals is beneficial in that higher tumor retention is obtained. However, this advantage is offset by high kidney uptake due to rapid filtration of the antibody fragment, reabsorption by the kidney tubule, and retention of the metabolic products in the lysosomal compartment (*26*, *27*, *47*). A second approach to increase tumor retention is the use of bivalent antibody fragments, since monovalent fragments such as the scFv have poor tumor retention (*16*, *17*, *19*).

In this study, we have engineered both the antibody fragment and the BCA to maximize tumor retention and minimize kidney uptake. First, we chose the diabody as the lowest molecular size fragment that retains bivalency. Second, we engineered a C-terminal cysteine residue to allow site-specific conjugation at the resultant thiol group. The introduction of a C-terminal cysteine residue into recombinant antibodies has been successfully used by other investigators. For example, Pastan and co-workers (*48*) introduced a C-terminal cysteine into a scFv anti-Tac antibody, but due to its low molecular weight (25 kDa) the antibody had high kidney uptake. In contrast, our Cys-diabody construct was expressed as covalently linked dimers which could be separated into monovalent fragments under reducing, denaturating conditions (Figure 1). Although this result necessitated the reduction of the covalent disulfide bond prior to BCA conjugation, it should be noted that the recombinant fragment is still a dimer held together by noncovalent bonds as shown by its migration at 50 kDa when run on gel filtration prior to injection into animals. Third, we synthesized a BCA that contained both a cleavable peptide linker and a thiol-reactive group for conjugation to the reduced Cys-diabody.

The design of the BCA incorporated the metal binding macrocycle DOTA at the N-terminus of the peptide and a thiol reactive group on the ϵ-amino group of lysine at the C-terminus of the peptide. The overall strategy is similar that of Arano and co-workers (*39*) who showed that carboxypeptidase activity in the kidney tubule brush border was able to cleave the peptide bond of the lysine, thus releasing the antibody fragment attached to the ϵ-amino group of the lysine, from the rest of the peptide which contains the radiolabel (in their case, a radioiodinated hippuric acid residue). In their study they showed that they could reduce kidney uptake by 50−60% and that the α-carboxyl-group of the lysine was essential for the result. Although our radiolabel and antibody fragment differs from that of Arano and co-workers, the result was essentially the same. Compared to the ^{111}In-labeled-DOTA-active ester version of the diabody (*9*), for the ^{111}In-labeled-BCA DOTA-GLGK(N^{ϵ}-mal) conjugated to Cys-diabody there was a 50−60% reduction in kidney uptake (Table 7). This result was further improved by using the BCA DOTA-GLGK[N^{ϵ}-(HVS)$_2$], demonstrating that the nature of the chemical linkage from the antibody to the lysine is important. In comparing the two BCAs, it is also worth noting that the maleimide linkage in DOTA-GLGK(N^{ϵ}-mal) is inherently unstable at pH 7.0 (*41*). In fact, it is possible that some of the reduction in kidney uptake may be due to the hydrolysis of the succinimido bonds between the linker and the antibody. However, in unpublished studies with the bis-maleimidehexane-Cys-DOTA conjugated to Fab′ fragments, we obtained high kidney uptakes, comparable to the NHS active ester conjugates of DOTA to the diabody. Thus, we believe that the C-terminal Lys residue in the linker plays an important role, just as Arano and co-workers suggest.

Overall, DOTA-GLGK[N^{ϵ}-(HVS)$_2$] lowered kidney uptake by up to 73% (Table 7) while retaining equivalent tumor uptake (ca. 12%ID/g at 2−6 h) compared to the

NHS active ester conjugates of DOTA to the diabody. One of the fascinating differences between the two studies is the difference in blood levels, where the blood levels are higher for the BCA DOTA-GLGK[N^{ϵ}-$(HVS)_2$] over the entire 24 h period. This difference is not easily explained, since one would predict the same rate of kidney filtration for both conjugates with the only difference due to the proteolysis of the one, but not the other, prior to reabsorption in the proximal tubule cells. This suggests that blood clearance is not the only factor of kidney clearance in these two studies. Further studies are required to determine the mechanism behind this interesting finding. Since the biodistributions of ^{64}Cu and ^{111}In were almost identical, we conclude that DOTA is a suitable chelate for both radionuclides and that the ^{64}Cu-labeled conjugate can be used in PET studies.

After demonstrating the reduction in kidney uptake with the carboxypeptidase-cleavable linker, we synthesized a related BCA in which the chelator DOTA and the thiol-reactive group positions were exchanged on the peptide. This BCA-Cys-diabody conjugate also labeled well with ^{111}In, but showed high kidney uptake, equivalent to that seen with the ^{111}In-labeled-DOTA-active ester version of the diabody. Thus, it appears that the relative positions of the chelator and antibody attachment site are important. Since this aspect was not tested in the radioiodine labeled compound developed by Arano and co-workers, we cannot compare our result to the literature.

With these results in hand, we decided to explore other conjugation chemistries on the BCA that lowered the kidney uptake the most. In the BCA DOTA-GLGK[N^{ϵ}-$(HVS)_2$], the conjugation chemistry relied on a Michael addition reaction of the free thiol on the mildly reduced Cys-diabody to one of the vinyl groups on the BCA. The conjugation efficiency of the BCA to cys-diabody was rather low as judged by IEF (Figure 2, lane 3), and radiolabeling efficiency (8−50%, Table 1). In the BCA DOTA-GLGK(N^{ϵ}-AcBr), the conjugation chemistry involved alkylation of the free thiol group of the cys-diabody. This conjugation reaction was more efficient as judged by IEF (Figure 2, lane 5) and radiolabeling efficiency (85%, Table 1). Thus, from the chemistry standpoint the alkylation reaction is more efficient, but the biodistribution results show high kidney uptake for the alkylated conjugate. Possible explanations for this biological difference are (a) lysine with an acylated amino group may be a poor substrate for carboxypeptidase in the brush border of the kidney, and (b) the close proximity of the antibody fragment to the lysine may sterically inhibit the carboxypeptidase. The latter explanation does not explain why the N^{ϵ}-maleimide conjugate has reduced kidney uptake, but it would explain why the N^{ϵ}-$(HVS)_2$ conjugate is superior to the N^{ϵ}-maleimide conjugate. Clearly, further derivatives need to be synthesized to further explore the effect of the chemical attachment on the degree of kidney clearance.

CONCLUSION

This study demonstrates that the use of cleavable peptide linkers between the radiolabel and an antibody fragment is a feasible approach to lower kidney uptake while preserving good tumor uptake. This approach incorporates the advantage of using radiometals which have higher tumor uptake compared to radioiodine, and the use of a diabody, that due to its bivalent binding, has higher tumor uptake than scFv fragments. Although the kidney uptake is significantly reduced by the use of an appropriate linker, the chemical linkage between the linker and the antibody fragment plays a large role, and if properly manipulated, has the potential to further reduce kidney uptake. The ultimate goal of this work is to reduce maximal kidney uptake below 10% ID/g, a level shown to be safe in work with radiometal labeled intact antibodies. The incorporation of additional strategies, such as administration of D-lysine or the lowering of the antibody fragment pI, may further lower kidney uptake, allowing the routine use of radiometal labeled antibody fragments in the clinic.

Revised Manuscript Received March 15, 2002

Poly(propylacrylic acid) (PPAAc) is a synthetic pH-responsive polymer that has been shown to disrupt cell membranes at low pH values typical of the endosome, but not at physiological pH, suggesting its use as an endosomal-releasing agent [Murthy et al. *J. Controlled Release 61*, 137−43]. We have constructed an antibody-targeted biotherapeutic model to investigate whether PPAAc can enhance intracellular trafficking of proteins to the cytoplasm. A ternary complex composed of a biotinylated anti-CD3 antibody, streptavidin, and biotinylated PPAAc was fluorescently labeled, and its intracellular fate was analyzed by confocal microscopy, flow cytometry, and quantitative western blotting of cell fractionates. The 64.1 anti-CD3 antibody was previously shown to direct receptor-mediated endocytosis in the Jurkat T-cell lymphoma cell line and was rapidly trafficked from the endosome to the lysosomal compartment. The antibody−streptavidin complex was also rapidly internalized to the endosomal/lysosomal compartment and retained there, as evidenced by punctate regions of fluorescence observed by confocal fluorescence microscopy. In samples containing the ternary complex of antibody, streptavidin, and PPAAc−biotin, diffuse fluorescence in the cytoplasm was observed, indicating that PPAAc enhanced translocation to the cytoplasm. This was confirmed by western blotting analysis of the isolated cytoplasm. Flow cytometry results demonstrated that neither streptavidin nor PPAAc caused nonspecific uptake of the complex, nor did they inhibit antibody-mediated endocytosis. The striking enhancement of protein delivery to the cytoplasm by complexed PPAAc suggests that this polymer could provide a new delivery agent for theapeutic, vaccine, and diagnostics development.

INTRODUCTION

The delivery of biotherapeutic agents such as DNA or proteins to a cell is often limited by intracellular trafficking barriers (*1*). Internalized biomolecular complexes are generally trafficked rapidly from early endosomes to late endosomes and finally to lysosomes where they are degraded (*2*). The processing of internalized complexes is tied to the increasingly acidic environment as they pass along the endocytic pathway, which is generated by ATP-dependent proton pumps in the membranes of the endocytic vesicles. The lowered pH and accompanying compartmental microenvironment changes are connected to alterations in protease activity, protein unfolding, and receptor−ligand interactions (*3*). Most internalized complexes are not released into the cytoplasm of the cell, including complexes that are readily endocytosed via specific receptor-mediated pathways such as the low-density lipoproteins (LDL) pathway (*2*).

For fragile biomolecular drugs such as DNA, RNA, peptides, and proteins, and particularly for targeted biotherapeutics, this barrier to cytoplasmic entry represents a significant drug delivery challenge. We have been investigating the use of pH-sensitive α-alkyl acrylic acid polymers that are capable of disrupting cell membranes at the lowered pH environment, similar to that in endosomes, while being nondisruptive at a physiologic pH of 7.4. These polymers interact with phospholipid bilayers in a pH-dependent manner (*4*). We have previously shown that poly(propylacrylic acid) (PPAAc), shown in Figure 1A, efficiently induces red blood cell hemolysis at pHs similar to those of the endosome, while being nondisruptive at physiological pH (*5*). We have shown that PPAAc also retains its ability to disrupt red blood cell membranes in a pH- and concentration-dependent manner when it is complexed to a protein (*6*).

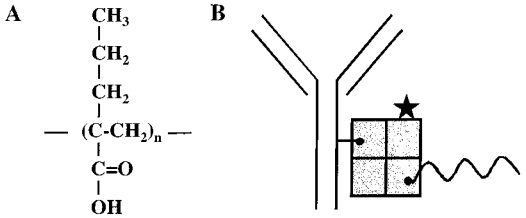

Figure 1. (A) Structure of poly(propylacrylic acid) (PPAAc). (B) Schematic of model biotinylated 64.1 antibody−streptavidin−biotinylated PPAAc complex.

Because red blood cell hemolysis has been correlated with endosomal release (*7*), these synthetic pH-responsive polymers may increase the intracellular efficacy of "fragile" therapeutics internalized via endocytosis. For example, the incorporation of pH-responsive polymers could enhance the endosomal translocation of immunotoxins to the cytosol, increasing access to target ribosomes. In this study, we have characterized the changes in intracellular trafficking elicited by PPAAc of a model antibody-

targeted protein complex. This model is a ternary complex composed of a biotinylated anti-CD3 antibody, streptavidin, and end-biotinylated PPAAc. The monoclonal anti-CD3 antibody 64.1 is a murine IgG2a which is internalized in large numbers by receptor-mediated endocytosis. It is rapidly trafficked to the lysosome for degradation, with minimal translocation from the endosome to the cytoplasm. The 64.1 antibody has been extensively studied for immunotherapy and immunotoxin development (*8*−*11*) and thus serves as an excellent model system for evaluating endosomal release strategies.

EXPERIMENTAL PROCEDURES

Antibody Conjugation. MoAb 64.1 is a murine IgG2a directed against the human CD3 ϵ chain T-cell antigen. MoAb 64.1 was purified from ascitic fluid by affinity chromatography on Sepharose-staphylococcal Protein A (*12*). Protein concentrations were determined using the BCA assay following the recommendations of the manufacturer (Pierce). The antibody was biotinylated using sulfosuccinimidyl 6-(biotinamido)-6-hexanoate (EZ-link Sulfo-NHS-LC−Biotin, Pierce). The NHS-LC-biotin was dissolved in water at a concentration of 20 mg/mL, and 6.4 μL was added to 2.5 mL of the antibody, in 0.1 M sodium phosphate, 0.15 M NaCl, pH 7.4, at a concentration of 2.3 mg/mL. The reaction was allowed to proceed for 30 min at room temperature, followed by purification using a PD-10 desalting column (Pharmacia) to remove unreacted biotin. Fractions containing protein were detected by absorbance at 280 nm and pooled. The protein concentration was determined using the BCA assay (Pierce), and the degree of biotinylation was determined using the avidin−HABA assay, as described previously (*6*). Briefly, avidin was dissolved in 3 mL of 0.1 M sodium phosphate, 0.15 M NaCl, pH 7.4. 4′-Hydroxyazobenzene-2-carboxylic acid (HABA) (Sigma) was dissolved in 10 mM NaOH at a concentration of 2.42 mg/mL (10 mM), and 75 μL was added to the protein. D-Biotin (Sigma) was dissolved in 0.1 M sodium phosphate, 0.15 M NaCl, pH 7.4, at a concentration of 0.5 mM. This solution was added in 10 μL aliquots to the protein−HABA complex, while the absorbance at 500 nm was measured after each addition. By plotting the absorbance at 500 nm versus the amount of biotin added, a calibration curve was constructed. In parallel, incremental amounts of MoAb 64.1-biotin were added to the protein and HABA solution, and the absorbance at 500 nm was measured. The slope of the curve was compared to the calibration curve to determine the biotin concentration, which in conjunction with the protein concentration obtained from the BCA assay yielded the degree of biotinylation.

Streptavidin Labeling. Wild-type streptavidin was expressed and purified as previously described (*13*). It was labeled using Oregon Green (Molecular Probes). The fluorophore was dissolved in DMSO at a concentration of 10 mg/mL, and 40 μL was added to 4 mg of streptavidin in 0.1 M sodium bicarbonate, pH 8.3. The reaction was performed for 1 h at room temperature, followed by purification using a PD-10 desalting column. Fractions containing protein were detected by the absorbance at 280 nm and pooled. Protein concentration and degree of labeling were determined spectrophotometrically. The protein concentration was determined by subtracting 0.12 $\times$ $A_{496\ nm}$ of the fluorophore from $A_{280\ nm}$ of the protein, and using an extinction coefficient of 136000. The degree of labeling was calculated by dividing the $A_{496\ nm}$ of the fluorophore by the molar concentration of the protein, and the extinction coefficient of 70000, according to manufacturer instructions.

Polymer Preparation. Amine-terminated PPAAc (PPAAc-NH_2) was synthesized and end-biotinylated as previously described (*5*, *6*). The propyl acrylic acid monomer (*5*) was mixed with 1 mol % initiator (azobis-(isobutyronitrile)) and 4 mol % chain transfer agent (cysteamine), and polymerized at 60 °C for 24 h to prepare amine-terminated polymers. Polymerization reactions were performed in bulk at 60 °C for 24 h. Polymer purification proceeded by dissolving the polymer in methanol and precipitating in diethyl ether three times.

The weight-averaged molecular weight of PPAA was 61 kD as determined by gel permeation chromatography with PEG standards using Ultrahydrogel 250 and 1000 columns connected in series (Waters Corporation, Milford, MA). A PI of 2.11 was calculated by manual integration of the GPC curve. PPAAc-NH_2 was end-biotinylated using sulfosuccinimidyl 6-(biotinamido)-6-hexanoate (EZ-Link Sulfo-NHS-LC−Biotin, Pierce). PPAAc-NH_2 was dissolved in 0.1 M sodium phosphate, 0.15 M NaC1, pH 7.4. The NHS-LC-biotin was dissolved in water at a concentration of 20 mg/mL and added to the polymer at a 20-fold molar excess. This was reacted for 2 h at room temperature. The biotinylation was repeated using a 15-fold molar excess of biotin to maximize the yield of biotinylated polymer molecules. The samples were purified using a PD-10 desalting column (Pharmacia) in order to ensure that all the free biotin was removed. Absorbance at 220 nm was used to detect fractions containing polymer, and these fractions were subsequently pooled. The quantity of biotinylated polymer was determined using the HABA assay (data not shown).

Preparation of Ternary Ab/SA/PPAAc Complex. The MoAb 64.1-biotin/streptavidin/PPAAc−biotin complex was assembled by mixing together the three components at a 1:1:1 molar ratios. SDS−PAGE was used to characterize the ternary complex, along with controls of the MoAb 64.1-biotin complexed to streptavidin, and physical mixtures of the proteins and PPAAc-NH_2. In addition, controls were run with nonbiotinylated MoAb 64.1, as well as without a targeting antibody.

Uptake of Biomolecule/Polymer Complex. A malignant T-(Jurkat) lymphoma cell line was maintained in log-phase growth in RPMI medium supplemented with 12% fetal calf serum, 2 mM glutamine, and 1 mM pyruvate at 37 °C in a 5% carbon dioxide atmosphere. Jurkat cells were plated at a density of 10^5 cells per well in 0.2 mL RPMI medium in a 96-well microtiter plate. Triplicate samples were prepared in 20 μL 0.1 M sodium phosphate, 0.15 M NaC1, pH 7.4, and incubated with the cells for 4 h at 37 °C in a 5% carbon dioxide atmosphere. The cells were washed twice with 0.2 mL of 0.1 M sodium phosphate, 0.15 M NaCl, pH 7.4, and then resuspended in 0.2 mL of 0.1 M sodium phosphate, 0.15 M NaCl, pH 7.4, with 10 μL of propidium iodide (50 μg/mL in 0.1 M sodium phosphate, 0.15 M NaCl, pH 7.4) for analysis on a Becton Dickinson FACScan analyzer, with excitation at 488 nm. The data collected included forward scatter (FSC), side scatter (SSC), fluorescence-1 (FL-1, Oregon Green), and fluorescence-3 (FL-3, propidium iodide). The instrument settings were E-1, 335V, 452V, and 443V, respectively. In all analyses, viable cells were gated based on their ability to exclude propidium iodide, and FL-1 results are reported for this population. In the first set of samples, the amount of antibody was held constant at 2 μg/10^5 cells, while varying the sample composition to study the effects of polymer incorporation and to compare

physical mixtures with molecular complexes. The number of cells that had taken up the labeled streptavidin was determined by gating cells with FL-1 greater than 9. Control wells with no labeled protein added showed negligible numbers of cells with fluorescence intensity above this level. In the second set of samples, the amount of targeting antibody was varied to verify that the uptake was specifically mediated. Samples containing 1 , 2, and 5 μg of antibody per 10^5 cells were studied both with and without complexed PPAAc−biotin. The mean fluorescence (FL-1) of the total cell population was reported in order to represent the degree of uptake of the labeled biomolecular complex.

Optical Microscopy. Confocal microscopy was used to visualize the intracellular distribution of fluorescently labeled streptavidin. Samples were incubated with Jurkat cells as described for the uptake study. The cells were washed twice and then resuspended in 20 μL of 0.1 M sodium phosphate, 0.15 M NaCl, pH 7.4, mounted on glass slides, and coverslipped for imaging using a BioRad MRC-1024 scanning confocal microscope. Images were acquired using a 63× objective and a 5 μM diameter iris, yielding images with an area of 501.3 μm^2. The fluorescently labeled streptavidin was detected by photomultiplier 2.

Western Blot Analysis of Antibody Compartmentalization. Jurkat cells were incubated with the molecular complexes at a ratio of 20 μg antibody/10^7 cells in 5 mL of RPMI medium. Cells were incubated with duplicate samples of MoAb 64.1-biotin/streptavidin, MoAb 64.1-biotin/streptavidin/PPAAc−biotin, and MoAb 64.1-biotin/streptavidin + PPAAc-NH_2 for 4 h at 37 °C in a 5% carbon dioxide atmosphere. The cells were washed twice with 1 mL 0.1 M sodium phosphate, 0.15 M NaCl, pH 7.4, suspended in 0.5 mL of TES buffer (10 mM triethanolamine, 1 mM EDTA, and 0.25 M sucrose, pH 7.5), homogenized with 30 strokes of a Dounce homogenizer (Kontes Inc.), and centrifuged for 10 min at 250*g* to sediment nuclei and unbroken cells. This crude homogenate was analyzed by western blotting for one set of samples. For the second set of samples, the homogenate was ultracentrifuged at 134000*g* for 1 h to sediment vesicular components. Western blotting was used to quantitate cytoplasmic delivery of the antibody upon incorporation of the polymer into the antibody/streptavidin complex. SDS−PAGE samples were prepared by mixing 20 μL of the homogenized cell samples with 20 μL of 2x SDS−PAGE sample buffer. Precast tris-glycine gels with a gradient of 4−20% (Novex) were run at 130 V for approximately 90 min, until the dye front had reached the end of the gel. The proteins were transferred to a PVDF membrane by running the blotting apparatus for 2 h at 70 V at 4 °C to prevent overheating. The membrane was suspended in blocking buffer (10 mM Tris-HCl pH 7.5, 100 mM NaCl, 0.1% Tween 20, 5% nonfat powdered milk), overnight at 4 °C with agitation. The membrane was stained with goat-anti-mouse horseradish peroxidase (Pierce) at a 1:20000 dilution in the blocking buffer for 1 h at room temperature with rocking. The PVDF was then washed 6 × 10 min with the blocking buffer with no milk. The blot was developed with Super-Signal West Dura Extended Duration Substrate (Pierce) for 5 min.

RESULTS

Characterization of Biomolecular Conjugates. The 64.1 antibody was biotinylated at a biotin/antibody ratio of 3.3, as determined by the avidin−HABA assay in conjunction with the BCA assay. The ability of the biotinylated antibody to bind streptavidin was verified using SDS−PAGE. In all cases, the molecules were mixed at equimolar ratios. This corresponded to 20 μg of antibody (MW 150 kDa), 7 μg of streptavidin (MW 52.8 kDA), and 8 μg of PPAAc (MW 60 kDa) per well. MoAb 64.1-biotin migrated equivalently to the unmodified antibody, yielding a band with a molecular weight of 150 kDa. The unmodified streptavidin and antibody ran at molecular weights of 60 kDa and l50 kDa, respectively. These individual bands disappeared after mixing streptavidin with biotinylated 64.1, and a corresponding band of approximately 200 kDa MW appears. This change in migration is not observed when the unmodified antibody is mixed with streptavidin, demonstrating that complexation is biotin-dependent. When PPAAc−biotin is mixed with streptavidin, the apparent molecular weight of the protein is shifter lower, due to the negative charge introduced by the polymer. The complexation is stoichiometric as the uncomplexed streptavidin band at approximately 60 kDa is no longer visible. There was also a shift to lower apparent molecular weight when the ternary complex consisting of biotinylated antibody, streptavidin, and PPAAc−biotin was electrophoresed. This is consistent with previous results showing that the negatively charged polymer increases migration of the complex toward the cathode, despite its large size.

Uptake of Biomolecule/Polymer Complex. Flow cytometry was used to quantitate the uptake of the antibody conjugates. Test samples included cells incubated with streptavidin alone, MoAb 64.1-biotin/streptavidin, MoAb 64.1-biotin/streptavidin/PPAAc−biotin, MoAb 64.1-biotin/streptavidin + PPAAc-NH_2, MoAb64.1 + streptavidin, MoAb64.1 + streptavidin/PPAAc−biotin, and streptavidin/PPAAc−biotin. These were compared to control samples containing only the cells. All samples contained equimolar amounts of the three components, with 2 μg of antibody per 10^5 cells. To verify that the uptake of the complex was mediated by antibody binding and unaffected by the complexation of streptavidin or PPAAc to the antibody, the fraction of fluorescent cells was measured for all samples. As seen in Figure 2, the percent of fluorescent cells remains constant in all samples in which the labeled streptavidin is targeted by the biotinylated antibody. No uptake of the labeled streptavidin is observed in samples without antibody, or with nonbiotinylated antibody, indicating that the complexation of the antibody is necessary to direct the internalization of the streptavidin moiety. The complexation or physical mixing of PPAAc does not inhibit the receptor-mediated endocytosis. Additionally, neither the streptavidin or the polymer cause any nonspecific uptake, as demonstrated by the fact that cell fluorescence is only seen in samples containing the MoAb 64.1-biotin. The dose dependence of the antibody-targeted internalization was also characterized. In Figure 3, the amount of antibody incubated with the cells was varied, while maintaining a MoAb 64.1-biotin/streptavidin/PPAAc−biotin complexation ratio of 1:1:1. All samples contained MoAb 64.1-biotin and streptavidin with either 1 , 2 , or 5 μg of antibody per 10^5 cells, and some contained PPAAc−biotin, as denoted in the figure legend. As shown by the mean fluorescence of the samples, the total uptake of the complex is controlled by the antibody and is unaffected by the presence of either complexed PPAAc−biotin or free PPAAc-NH_2.

Endosomal Release of Biomolecule/Polymer Complex. Visualization of the intracellular trafficking of the complex was achieved using confocal microscopy and

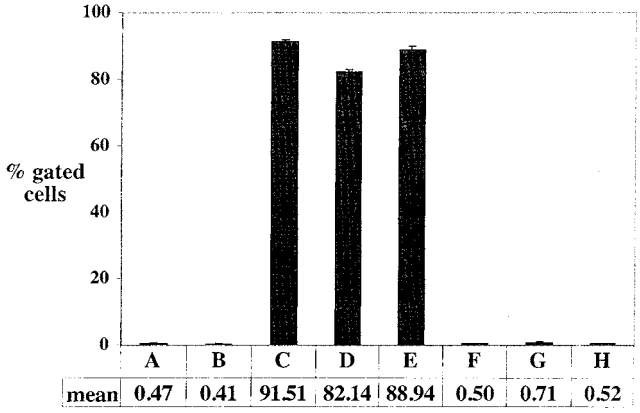

Figure 2. Efficiency of Jurkat cell uptake of antibody/streptavidin/polymer complexes after 4 h incubation in serum-containing medium at 37 °C. Streptavidin was labeled with Oregon Green as described in Materials and Methods. The following samples were characterized to test the specificity of antibody-mediated uptake and the effect of biotin-mediated complexation of streptavidin and PPAAc: (A) Jurkat cell control in culture medium, (B) streptavidin alone control, (C) MoAb 64 1-biotin/streptavidin, (D) MoAb 64.1- biotin/streptavidin/PPAAc−biotin, (E) MoAb 64.1-biotin/streptavidin + PPAAc-NH_2 control, (F) MoAb 64.1 + streptavidin control, (G) MoAb 64.1 + streptavidin/PPAAc−biotin control, and (H) streptavidin/PPAAc−biotin control. The results demonstrate that uptake is mediated by the MoAb 64.1 and not significantly affected by streptavidin or PPAAc complexation.

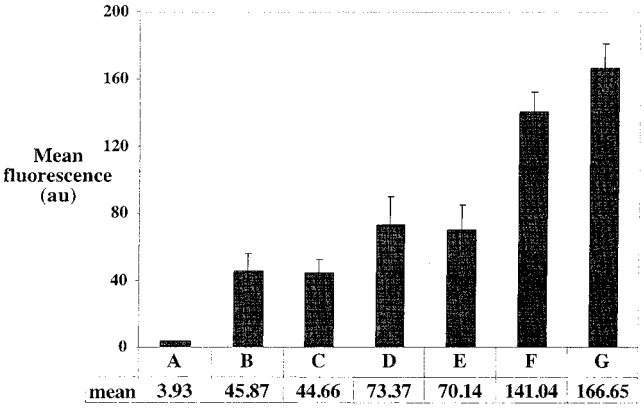

Figure 3. Fluorescence intensity dependence on the amount of antibody targeted to Jurkat cells, after 4 h incubation in serum-containing medium at 37 °C. All samples contained MoAb 64.1-biotin and Oregon Green labeled streptavidin (2.4 fluorophores per protein as determined by the absorbance and extinction coefficients for protein and label at 280 and 496 nm, respectively), with PPAAc−biotin added in the designated samples, all at a 1:1:1 molar ratio. The samples studied were cells incubated with (A) cell culture medium alone, (B) l μg of MoAb 64.1, (C) 1 μg of MoAb 64.1 with PPAAc−biotin, (D) 2 μg of MoAb 64.1, (E) 2 μg of MoAb 64.1 with PPAAc−biotin, (F) 5 μg of MoAb 64.1, and (G) 5 μg of MoAb 64.1 with PPAAc−biotin.

fluorescently labeled streptavidin. Representative images of single cells at roughly their midplane, 4 h after addition of the antibody complexes, are shown in Figure 4. In Figure 4A, the diffuse cytoplasmic staining is achieved upon incorporation of PPAAc−biotin into the biomolecular complex. In contrast, samples with no polymer show punctate fluorescence, indicating confinement of the complex within the endosomal/lysosomal vesicles of the cell, as shown in Figure 4B. Samples incubated with nonbiotinylated PPAAc also displayed punctate fluorescence (data not shown). Equivalent fluorescence localization was reproducibly observed in many fields of view, as well as by fluorescence microscopy on multiple days. In all samples without PPAAc, only punctate fluorescence was observed. In samples containing PPAAc−biotin, roughly half of the cells displayed diffuse cytoplasmic fluorescence after 4 h, comparable to that in Figure 4A. These results indicate that the complexation of PPAAc−biotin with the targeted biomolecule enables its release from the endosome to the cytoplasm.

Quantitation of Cytoplasmic Delivery. The total cell homogenate of the cells was compared to the isolated cytoplasm for the localization of the targeted molecular complexes with and without the polymer. The odd numbered lanes in the western blot of Figure 5 contain the total homogenate, while the even numbered lanes contain the isolated cytoplasmic contents.

In the first two lanes, which contain the MoAb 64.1-biotin/streptavidin complex, there is no detectable band in the isolated cytoplasm, indicating that this molecular complex is not released at significant levels into the cytoplasm at a 4 h timepoint, but is retained in the endosomal/lysosomal pathway as evidenced by the band in whole cell contents. In contrast, lanes 3 and 4 demonstrate that a large fraction of the MoAb 64.1-biotin/streptavidin/ PPAAc−biotin is released into the cytoplasm. The cytoplasmic band has 73% the intensity of the crude homogenate band, as determined by quantitative densitometry. Finally in lanes 5 and 6, the physical mixture of the polymer with the antibody/streptavidin complex does yield some release into the cytoplasm, but significantly less than that evidenced with the biotinylated polymer. The cytoplasmic band intensity is 29% of the whole cell band intensity for this sample.

DISCUSSION

The challenge of delivering proteins to the cytoplasmic compartment represents a significant barrier for the development of protein therapeutics and vaccines. Internalized proteins enter the intracellular trafficking pathway through endosomes and are generally subsequently localized to the lysosomal compartment where they are degraded. Several approaches have been taken to manipulate the intracellular trafficking pathways of biomolecular therapeutics, including the addition of compartment-targeting amino acid sequences (*14*−*16*) and peptides that aid transport either from the endosome (*17*, *18*, *7*) or across the cellular membrane (*19*−*21*).

We have been investigating the use of the polymer PPAAc as a pH-dependent, membrane-disrupting agent that can aid escape of biomolecular therapeutics from the endosome to the cytoplasm. Previous studies have demonstrated that PPAAc can enhance the transfection-efficiency of lipoplex/plasmid delivery systems (*22*). The PPAAc is designed to be inactive at physiological pH, while becoming membrane active in the lower pH environment of developing endosomes, thereby enhancing transport of biomolecules across the endosomal membrane. In this study, we tested whether PPAAc could enhance the cytoplasmic delivery of a model antibody therapeutic. The MoAb 64.1 is an anti-CD3 antibody that has been extensively characterized as a T-cell lymphoma targeting agent. This antibody was chosen because it is rapidly localized to the lysosome after receptor-mediated endocytosis (*8*) and can thus be used to evaluate whether PPAAc promotes cytoplasmic delivery.

Streptavidin has been exploited in this construct as a linker molecule. Because the antibody and the polymer are both easily biotinylated, the formation of the ternary complex is very efficient, as it is driven by biotin/streptavidin affinity. Previous studies have shown that

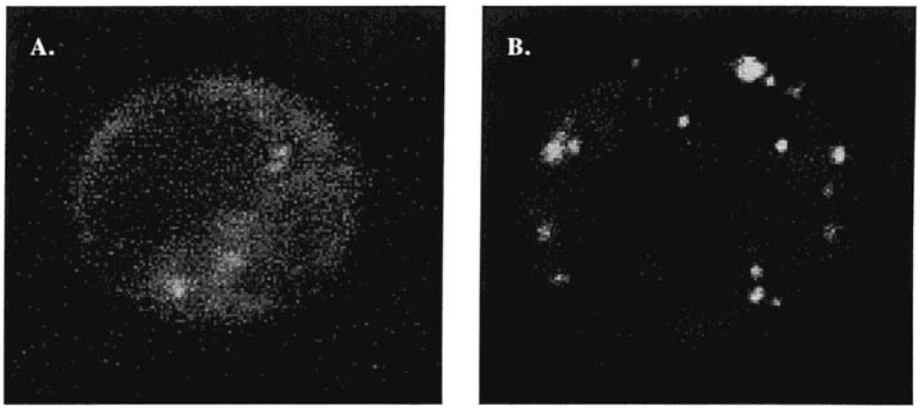

Figure 4. Confocal microscopy analysis of intracellular Oregon-Green-labeled streptavidin after receptor-mediated uptake of ternary antibody−streptavidin−PPAAc complexes. Confocal images of single Jurkat cell midplanes for (A) Jurkat cells incubated with ternary complexes composed of 2 μg MoAb/10^5 cells and equimolar MoAb 64.1-biotin/streptavidin/PPAAc−biotin ratios and (B) Jurkat cells incubated with 2 μg MoAb/10^5 cells and equimolar MoAb 64.1-biotin/streptavidin without PPAAc. Cells were incubated for 4 h in serum-containing medium at 37 °C and subsequently analyzed on a BioRad MRC-1024 scanning confocal microscope using a 63× objective.

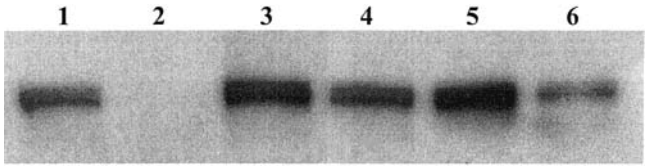

Figure 5. Quantitative western blot analysis of whole cell and isolated cytoplasmic homogenates. Jurkat cells were incubated with 20 μg antibody/10^7 cells and equimolar streptavidin, with and without equimolar biotinylated PPAAc. In addition, the MoAb−streptavidin complexes were physically mixed with PPAAc to quantitate intracellular localization after trans-uptake. The gel lanes were (1) MoAb 64.1-biotin/streptavidin whole cell homogenate, (2) MoAb 64.1-biotin/streptavidin isolated cytoplasmic homogenate, (3) MoAb 64.1-biotin/streptavidin/PPAAc−biotin whole cell homogenate, (4) MoAb 64.1-biotin/streptavidin/PPAAc−biotin isolated cytoplasmic homogenate, (5) MoAb 64.1-biotin/streptavidin + PPAAc-NH_2 whole cell homogenate, and (6) MoAb 64.1-biotin/streptavidin + PPAAc-NH_2 isolated cytoplasmic homogenate.

only one biotinylated macromolecule can bind per binding face of streptavidin (*23*), suggesting that the likely configuration of the complex is that diagrammed in Figure 1.

The trafficking routes of the antibody−streptavidin complexes were initially characterized by laser scanning confocal microscopy. The antibody−streptavidin complex without polymer remained in vesicular compartments, as evidenced by the punctate fluorescence emission that has been shown to be typical of endosomal/lysosomal localization (*24*−*26*). The addition of polymer does not significantly affect targeting and internalization, but the diffuse fluorescence emission within the cells after 4 h demonstrates the release of the complex to the cytoplasm. The nucleus is seen as a darkened region surrounded by the diffuse cytoplasmic fluorescence, indicating that the fluorophore is still attached to streptavidin. The fluorophore can diffuse into the nucleus if it is free to partition out of the vesicular compartment due to degradation of the linkage or of streptavidin.

This finding was confirmed by the western blotting analysis of the isolated cell cytoplasm. No detectable amount of the antibody is released into the cytoplasm in the absence of the polymer, whereas the complexed polymer significantly increases the release of the biomolecular complex into the cytoplasm. The physically mixed polymer also induces endosomal release, but at a much lower level than that of the complexed polymer. This is likely due to uptake of the polymer in trans to the antibody/streptavidin complex, due to their high local concentrations of the free PPAAc-NH_2 in the cell culture medium. The western blotting also verifies that the moiety detected in the cytoplasm has not been degraded, as the molecular weight of the cytoplasmic band is identical to that detected in the crude homogenate.

These results demonstrate that PPAAc can be a potent endosomal releasing agent for targeted antibody conjugates that are internalized through receptor-mediated endocytosis. No toxicity has been observed in samples containing PPAAc at concentrations of up to 2 μM. The MoAb 64.1 has served as a model antibody for immunotoxin therapy, and PPAAc could directly find application as an agent to enhance the cytoplasmic delivery of immunotoxins. The ability of PPAAc to enhance delivery to the cytoplasm could also potentially aid in the delivery of protein antigens for vaccines, where entry into the MHC1 pathway depends on cytoplasmic entry. The generality of PPAAc's ability to deliver a variety of biotherapeutics from the endosomes to the cytoplasm is currently being investigated to determine how broadly this polymer could serve with different cell types and different protein therapeutics.

Synthesis of Releasable Electrophore Tags for Applications in Mass Spectrometry

Xin Zhang, Linxiao Xu,† Poguan Wang, Zhixian Wang,‡ and Roger W. Giese*

Department of Pharmaceutical Sciences in the Bouve College of Health Sciences, Barnett Institute, and Chemistry Department, Northeastern University, Boston, Massachusetts 02115. Received July 25, 2001; Revised Manuscript Received November 23, 2001

Releasable electrophore mass tags (electrophore tags) are compounds for use as labels in ligand assays such as hybridization assays and immunoassays. In such assays, the electrophore-tagged reagent (e.g., DNA probe or antibody) is quantified at the conclusion of the assay by cleaving a bond in the attached tag so that the electrophore part can be brought into the gas phase (usually thermally) for detection by electron capture mass spectrometry (EC-MS) or a related technique. Interest in these tags is promoted mainly by their potential to provide highly sensitive and multiplexed assays. The high multiplexing arises from the opportunity to measure many such tags simultaneously in the mass spectrometer, where each tag has an electrophore part with a unique mass. In this study five precursors of electrophore mass tags are presented. Each precursor can lead to a large library of electrophore tags in a practical way, since each precursor can be converted to many different electrophore tags by reaction with commonly available phenols that provide a variation in mass. The phenol-reactive part of the tag is either a polyfluorobiphenyl or a benzyl chloride moiety. Representative library compounds are prepared and detected in an inert ester form by gas chromatography electron capture mass spectrometry (GC-EC-MS). Further, one tag is conjugated to DNA, and the resulting product is detected by laser-induced electron capture time-of-flight mass spectrometry on a silver surface. A calculation by the semiempirical method AM1 for an ion formed by one of the electrophores suggests that ring rotation promotes dissociative electron capture. The features of practical synthesis, simple composition, physicochemical stability, high multiplicity, high sensitivity, and potential for high throughput detection make releasable electrophore mass tags attractive for highly multiplexed assays. This includes their use in SNP assays or dideoxy DNA sequencing for detection of mutations in individuals, where the combination of high accuracy and speed is essential.

INTRODUCTION

A variety of substances such as radioisotopes and fluorescent dyes are employed as molecular tags in assays requiring high sensitivity. Examples of such assays are immunoassays, DNA sequencing, and SNP detection. One shortcoming of many current molecular tags is the limited number of them that can be detected simultaneously. For example, it is difficult to quantify more than four fluorescent tags with high sensitivity under ordinary and practical conditions when present as a mixture. This is because of the broadness of the emission bands along with differences, commonly, in their absorbance characteristics. One consequence of this is that automated DNA sequencing by means of capillary electrophoresis with fluorescence detection is done with only one sequence (or less) loaded into each capillary at a time (*1*). This barrier to high throughput is unfortunate since DNA sequencing is regarded as the gold standard for detecting mutations. Screening for DNA mutations in a population of people can be successful when some false positive and negative results are present, because the true positive and negative results are typically present in a larger abundance (*2*). However, as the practice of mutation detection turns to scoring individuals as part of routine diagnostics, high accuracy along with high speed will be essential. Increasing the multiplexing of dideoxy sequencing assays by employing molecular tags with high multiplicity is one way to accomplish this, for example, with releasable electrophore mass tags.

The concept and rationale for using releasable electrophore mass tags (electrophore tags) in chemical analysis is as follows. Each tag contains, effectively, three functional groups: electrophore, release, and reactivity. A tag is attached covalently to an analytical reagent of interest, such as a DNA oligomer or antibody, by means of the reactivity group. Once the assay employing the tagged reagent has reached the detection step, the electrophore part is released by a cleavage reaction at the release group and brought into the gas phase for ionization by electron capture (EC) with subsequent detection based on its mass. Since a mass spectrometer can detect many masses simultaneously, there is a potential for high multiplicity (e.g., 400 electrophore tags) in the assay. While mass spectrometry can detect a moderate number of unlabeled DNA molecules at the same time, large numbers of DNA molecules have never been detected in this way because of complications of fragmentation, adduct ions, isotopic peaks, and loss of signal at higher masses (*3*). Further, electrophores can be detected in general with much higher sensitivity than DNA molecules by mass spectrometry (*4*, *5*).

Previously, we reported the detection of a mixture of four electrophore-labeled DNA oligomers (*6*), and, in a separate study (*7*), of albumin labeled with six different

electrophores, by electron capture mass spectrometry (EC-MS). While these results were encouraging, the synthetic strategies that we used to prepare the electrophore tags did not open up a practical way to make a large number of them. Here we report our success in overcoming this limitation by designing and preparing five "branchpoint" electrophore tag precursors, each of which is easy to prepare, and reactive toward phenols as the moieties that provide the variation in mass.

EXPERIMENTAL SECTION

Materials and Software. 3-Bromo-2-butanone was purchased from Lancaster Inc, Windham, NH. 2,3,4,5,6-Pentafluorobenzyl alcohol, 2,3,5,6-tetrafluoro-4-(pentafluorophenyl)phenol, piperazine, pyridine, various acid chlorides, 2,3-*O*-isopropylidene-D-erythronolactone, ethyl and methyl isonipecotate, decafluorobiphenyl, phosphomolybdic acid, α-bromoacetic acid, thionyl chloride, dicyclohexylcarbodiimide (DCC), 2,2′-azobisisobutyronitrile, *N*-hydroxysuccinimide (NHS), *N*-bromosuccinimide, and all phenols were purchased from Aldrich Chemical Co. unless indicated otherwise. Acetonitrile was distilled over CaH_2 before use. All solvents were from Fisher Scientific Co. Most reactions were monitored by silica fluorescence-indicator thin-layer chromatography (TLC) with detection by UV (short wavelength) or phosphomolybdic acid. The ^1H, ^{19}F, and ^{13}C spectra were obtained on a Varian 300 MHz spectrometer with tetramethylsilane as internal reference for the proton spectra and $CFCl_3$ for the fluorine spectra. Cation exchange beads in NH_4^+ form (AG 50w−X8, 100−200 mesh 143−5441,) were from Bio-Rad. Hyperchem software was from Hypercube (Waterloo, Ontario). For flash chromatography, the ratio of compound to Si was 1:100 to 1:200.

Mass Spectrometry. GC-EC-MS was performed using a Hewlett-Packard (HP) 5973 mass spectrometer coupled to a HP 6890 gas chromatograph. The instrument was controlled by a HP 5973 MS Chemstation computer for data acquisition in the scan mode. An Ultra-1 HP capillary column (25 m, 0.20 mm i.d., 0.11 μm film thickness) from Hewlett-Packard was used. With helium as carrier gas, the column head pressure was set to 36 psi. The source pressure (methane) was set to 2.0 Torr at 250 °C. Inject (1 μL sample of 100 pg/μL in ethyl acetate) on-column at 50 °C; ramp column oven to 250 C at 30 °C/min after a 4 min solvent delay; then ramp to 300 °C at 50 °C/min and hold for 12 min.

MALDI-TOF-MS experiments were done using a Bruker Daltonics Proflex laser desorption TOF-MS instrument in the linear positive mode. A literature procedure (*8*) was followed with modifications. To 1 μL of oligonucleotide (0.5−1.0 μg/μL water) was added 2 μL of ammonium ion exchange bead suspension. After the suspension was mixed (rocking plate) for 3 min, 3 μL of 70 mg/mL, 3-hydroxypicolinic acid:picolinic acid (9:1 w/w) in 50% acetonitrile was added, and, after brief mixing and settling, 1 μL of the supernatant was placed onto the target and allowed to dry.

LI-EC(Ag)-TOF-MS experiments were carried out as described (*9*).

Synthesis. Ethyl *N*-(4-Hydroxy-2,3-*O*-isopropylidenebutyryl)isonipecotate (2). A 25 mL dry round-bottomed flask equipped with a N_2 inlet and a stir bar was charged with 1.0 g (6.3 mmol) of 2,3-*O*-isopropylidene-D-erythronolactone (**1**), followed by 2.0 mL of ethyl isonipecotate. The resulting mixture was allowed to stir at 70 °C (oil bath) until TLC analysis showed no lactone remained (about 12−16 h). The reaction mixture was then purified on a silica gel column (1:1 ethyl acetate: hexane, followed by 100% ethyl acetate), and 1.5 g (75%) of desired product was obtained. ^{13}C NMR ($CDCl_3$): 13.78, 24.97, 25.07, 26.78, 26.91, 27.18, 27.33, 27.86, 40.45, 40.41, 41.11, 41.21, 44.22, 44.37, 60.20, 61.33, 61.41, 74.31, 74.46, 77.35, 77.47, 109.10, 109.13, 166.11, 165.99, 173.49 ppm. ^1H NMR($CDCl_3$): 1.23−1.29 (m, 3H), 1.40 (s, 3H), 1.55 (s, 3H), 1.6−2.05 (m, 4H), 2.51−2.64 (m, 1H), 2.71−3.31 (m, 2H), 3.56−3.77 (m, 2H), 3.95−4.17 (m, 3H), 4.29−4.45 (m, 2H), 4.91 (dd, J = 3.5 Hz, 1H) ppm. TLC: R_f = 0.40 (100% ethyl acetate).

The methyl derivative (**2a**, 1.2 g, 60%) was prepared in a similar way. ^{13}C NMR ($CDCl_3$): 25.28, 25.36, 27.12, 27.26, 27.54, 27.65, 28.24, 28.31, 40.39, 40.70, 41.56, 41.67, 44.64, 44.79, 51.79, 61.93, 62.01, 75.01, 75.05, 77.98, 77.04, 109.532, 166.47, 166.60, 174.26 ppm. ^1H NMR ($CDCl_3$): 1.34 (s, 3H), 1.48 (s, 3H), 1.54−1.80 (m, 2H), 1.86−1.96 (m, 2H), 2.47−2.60 (m, 1H), 2.71−3.24 (m, 2H), 3.48−3.72 (m, 5H), 3.85−3.95 (m, 1H), 4.20−4.4 (m, 2H), 4.85 (m, 1H) ppm. TLC: R_f = 0.40 (100% ethyl acetate).

Ethyl *N*-[2,3-*O*-Isopropylidene-4-(4′-pentafluorophenyl-2′,3′,5′,6′-tetrafluorophenoxy)butyryl]isonipecotate (I). A 25 mL dry round-bottomed flask equipped with a N_2 inlet and a stir bar was charged with 0.67 g (2 mmol) of **2**, followed by 0.7 g (2.2 mmol) of decafluorobiphenyl, 0.5 g (3 mmol) of CsOH monohydrate, 10 mL of CH_3CN, and 1.5 g of powdered molecular sieves. The resulting mixture was allowed to stir at room temperature until TLC analysis showed no starting material remained (about 16−24 h). The solid was removed by filtration, and the filtrate was concentrated on rotary evaporator and further purified on a silica gel column (1:5 ethyl acetate:hexanes, 300 mL, followed by 1:2 ethyl acetate:hexanes) and 0.62 g (49%) of desired product was obtained. ^{13}C NMR ($CDCl_3$): 14.13, 14.17, 25.41, 25.57, 27.22, 27.45, 27.57, 27.79, 28.29, 40.44, 41.11, 41.49, 41.68, 44.46, 44.61, 60.69, 73.33, 73.40 (m), 73.80 (m), 74.32, 74.53, 75.74, 76.11, 110.46 (m), 136 (m), 139 (m), 143 (m), 146 (m), 165.20, 165.30, 173.84, 173.87 ppm. ^1H NMR ($CDCl_3$): 5.01 (d, J = 5.7 Hz, 1H), 4.60−4.71 (m, 1H), 3.98−4.56 (m, 6H), 2.48−3.32 (m, 3H), 1.60−2.00 (m, 4H), 1.54 (s, 3H), 1.42 (s, 3H), 1.15−1.28 (m, 3H) ppm. ^{19}F NMR ($CDCl_3$): −137.95 (m, 2F), −139.83 (m, 2F), −151.24 (m, 1F), −155.95 (m, 1F), −156.43 (m, 1F), −161.27 (m, 2F) ppm. TLC: R_f = 0.50 (1:1 ethyl acetate: hexanes).

Ethyl *N*-{{4-{4′-[4″-(*p*-Acetophenyl)-2″,3″,5″,6″-tetrafluorophenyl]-2′,3′,5′,6′-tetrafluorophenoxy}-2,3-*O*-isopropylidenebutyryl}}isonipecotate (I-447a). A 25 mL dry round-bottomed flask equipped with a N_2 inlet and a stir bar was charged with 0.40 g (0.64 mmol) of **I**, followed by 0.15 g (1 mmol) of 4-hydroxyacetophenone, 0.7 g K_2CO_3, and 10 mL of CH_3CN. The resulting mixture was allowed to stir at 60 °C oil bath overnight. The solid was removed by filtration and was washed with CH_3CN (3 × 10 mL). The combined organic solution was concentrated and purified on a silica gel column (1:5 ethyl acetate:hexanes, 500 mL, followed by 1:2 ethyl acetate: hexanes) to give 0.25 g (41%) product. ^{13}C NMR ($CDCl_3$): 14.12, 14.15, 25.39, 25.55, 26.50, 27.21, 27.43, 27.54, 27.76, 28.28, 29.67, 40.41, 41.08, 41.46, 41.66, 44.45, 44.60, 60.66, 73.40 (m), 73.84 (m), 74.30, 74.54, 75.74, 76.08, 110.37, 110.43, 115.37, 115.42, 130.68, 133.13, 136 (m), 139 (m), 143 (m), 146 (m), 160.01, 165.20, 165.29, 173.86, 173.81, 196.29 ppm. ^1H NMR ($CDCl_3$): 8.01 (dm, J = 8.9 Hz, 2H), 7.10 (dm, J = 8.8 Hz, 2H), 5.01 (d, J = 6.8 Hz, 1H), 4.68−4.77 (m, 1H), 4.00−4.59 (m, 6H), 2.52−3.32 (m, 3H), 2.60 (s, 3H), 1.60−2.03 (m, 4H), 1.56 (s,

3H), 1.44 (s, 3H), 1.26 (td, $J = 7.1$ Hz, $J = 3.1$ Hz, 3H) ppm. ^{19}F NMR ($CDCl_3$): −137.92 (m, 2F), −139.71 (m, 2F), −153.33 (m, 2F), −155.93 (m, 1F), −156.38 (m, 1F) ppm. TLC: $R_f = 0.45$ (1:1 ethyl acetate:hexanes).

Ethyl *N*-{{2,3-*O*-Isopropylidene-4{4′-[[4″-[*p*-(3‴-oxobutyl)phenoxy]-2″,3″,5″,6″-tetrafluorophenyl]]-2′,3′,5′,6′-tetrafluorophenoxy}butyryl}}isonipecotate (I-475a). Similarly, the reaction of **I** with 4-(hydroxyphenyl)-2-butanone gave 0.35 g (55%) of product. ^{1}H NMR ($CDCl_3$): 7.18 (d, $J = 8.5$ Hz, 2H), 6.97 (d, $J = 8.6$ Hz, 2H), 5.04 (d, $J = 6.1$ Hz, 1H), 4.69−4.77 (m, 1H), 4.02−4.59 (m, 4H), 3.69 (m, 3H), 2.52−3.32 (m, 7H), 2.15 (s, 3H), 1.61−2.14 (m, 4H), 1.56 (s, 3H), 1.40 (s, 3H) ppm. ^{19}F NMR ($CDCl_3$): −138.77 (m, 2F),-139.75 (m, 2F), −153.95 (m, 1F), −156.10 (m, 1F), −156.50 (m, 1F) ppm. TLC: $R_f = 0.25$ (1:1 ethyl acetate:hexanes).

Methyl *N*-(Bromoacetyl)isonipecotate (4). A 25 mL dry round-bottomed flask equipped with a N_2 inlet and a stir bar was charged with 1.30 g (10 mmol) of bromoacetic acid (**3**), followed by 1.38 g (12 mmol) of *N*-hydroxysuccinimide, and the flask was placed in an ice-bath. After 30 min of stirring, 15 mL of acetonitrile containing 3.68 g (12 mmol) of DCC was added dropwise, and the reaction mixture was allowed to stir overnight before addition of 1.43 g (10 mmol) of methyl isonipecotate. After the reaction mixture was stirred another 24 h, it was filtered and the filtrate was concentrated on an evaporator, yielding residue that was redissolved into 200 mL of ethyl acetate. The resulting solution was washed with 3 × 30 mL of H_2O and 30 mL of brine solution and dried over $MgSO_4$. The organic solvent was removed on a rotary evaporator, and the crude product **4** was dried further under vacuum (0.05 mmHg) for 16 h and used without further purification.

Methyl *N*-[α-(4-(Pentafluorophenyl)-2,3,5,6-tetrafluorophenoxy)acetyl]isonipecotate (II). A 25 mL dry round-bottomed flask equipped with a N_2 inlet and a stir bar was charged with 1.1 g of 4-pentafluorophenyl-2,3,5,6-tetrafluorophenol, 2.0 g of crude **4**, 1.5 g of potassium carbonate, and 20 mL of acetonitrile. The resulting mixture was allowed to stir at 60 °C (oil bath) until TLC analysis showed no phenol remained (about 12−16 h). The K_2CO_3 was removed by filtration and washed several times with 3 × 10 mL of acetonitrile. The combined organic solution was concentrated on rotary evaporator, and the residue was purified on a silica gel column (1:5 ethyl acetate:hexanes, followed by 1:2 ethyl acetate:hexanes), to give 1.1 g (65%) of product. ^{13}C NMR ($CDCl_3$): 28.05, 27.48, 40.39, 41.24, 43.85, 51.74, 70.38 (m), 136−146 (m), 164.63, 174.08 ppm. ^{1}H NMR ($CDCl_3$): 1.62−1.78 (m, 2H), 1.91−1.97 (m, 2H), 2.51−2.60 (m, 1H), 2.89 (td, $J = 10.3$ Hz, 1H), 3.16 (tm, $J = 11.3$ Hz, 1H), 3.63 (s, 3H), 3.63−3.71 (m, 1H), 4.25 (dt, $J = 13.5$ Hz, 1H), 5.01 (s, 2H) ppm. ^{19}F NMR ($CDCl_3$): −137.80 (m, 2F), −139.94 (m, 2F), −151.48 (m, 1F), −156.75 (m, 2F), −161.70 (m, 2F) ppm. TLC: $R_f = 0.40$ (1:1 hexanes: ethyl acetate).

Methyl *N*-{{{α-{{4-{4′-[*p*-(3″-Oxobutyl)phenoxy]-2′,3′,5′,6′-tetrafluorophenyl}-2,3,5,6-tetrafluorophenoxy}}acetyl}}}isonipecotate (II-475a). A 25 mL dry round-bottomed flask equipped with a N_2 inlet and a stir bar was charged with 0.12 g (0.23 mmol) of **II**, followed by 0.10 g of 4-(4-hydroxyphenyl)-2-butanone, 0.26 g K_2CO_3, and 3 mL of CH_3CN. The resulting mixture was allowed to stir at 60 °C overnight. The K_2CO_3 was removed by filtration and washed with CH_3CN. The combined organic solution was concentrated and purified on a silica gel column (1:5 ethyl acetate:hexanes, followed by 1:2 ethyl acetate:hexanes) to yield 0.15 g (96%) of desired product. ^{13}C NMR ($CDCl_3$): 27.60, 28.19, 28.83, 30.13, 40.51, 41.39, 44.05, 45.10, 51.96, 70.73 (t, $J = 4.1$ Hz), 115.83, 129.61, 136−146 (m), 155.30, 164.63, 174.15, 207.67 ppm. ^{1}H NMR ($CDCl_3$): 1.69−1.78 (m, 2H), 1.91−2.03 (m, 2H), 2.15 (s, 3H), 2.60 (m, 1H), 2.73−3.01 (m, 5H), 3.17−3.26 (m, 1H), 3.72−3.79 (m, 1H), 3.72 (s, 3H), 4.34 (dt, $J = 13.9$ Hz, 1H), 5.05 (s, 2H), 6.95 (dm, $J = 8.5$ Hz, 2H), 7.17 (dm, $J = 8.7$ Hz, 2H) ppm. ^{19}F NMR ($CDCl_3$): −138.60 (m, 2F), −139.70 (m, 2F), −154.00 (m, 2F), −156.9 (m, 2F) ppm. TLC: $R_f = 0.40$ (1:1 hexanes: ethyl acetate).

Electrophore II-861a was Synthesized in a Similar Way (0.1 g, 51% yield). ^{1}H NMR ($CDCl_3$): 7.55−7.58 (m, 2H), 7.29−7.32 (m, 2H), 7.15−7.18 (m, 2H), 6.93−6.96 (m, 2H), 6.04−6.08 (m, 1H), 4.98 (s, 2H), 4.25−4.30 (m, H), 3.60−3.71 (m, 6H), 3.49 (s, 2H), 3.11−3.18 (m, H), 2.84−2.93 (m, 3H), 2.51−2.58 (m, H), 2.25−2.30 (m, 4H), 1.90−1.98 (m, 2H), 1.61−1.70 (m, 2H), 1.17−1.53 (m, 32H), 0.80 (m, 6H). ^{19}F NMR ($CFCl_3$): −138.4 (m, 2F), −139.7 (m, 2F), −153.9 (m, 2F), −156.7 (m, 2F).

Electrophore II-981a was Synthesized in a Similar Way (0.11 g, 53%). ^{1}H NMR ($CDCl_3$): 7.72 (m, 2H), 7.48 (m, 2H), 7.31 (m, 2H), 7.24 (m, 2H), 7.01 (m, 2H), 6.93 (m, 2H), 6.21 (t, $J = 5.6$ Hz, 1H), 5.12 (s, 2H), 5.05 (s, 2H), 4.34 (m, 1H), 3.73 (m, 6H), 3.21−3.47 (m, 5H), 2.94 (t, $J = 7.0$ Hz, 2H), 2.96−3.00 (m, 1H), 2.59−2.62 (m, 1H), 2.03 (m, 2H), 1.25−1.81 (m, 34H), 0.87 (t, $J = 6.1$ Hz, 6H). ^{19}F NMR ($CFCl_3$): −138.42 (m, 2F), −139.67 (m, 2F), −153.82 (m, 2F), −156.66 (m, 2F).

Acid Form of II-475a. II-475a (145 mg) was dissolved in 3.5 mL of tBuOH/H_2O (2:1), and 35 mg of LiOH was added. The resulting solution was stirred at room temperature until no starting material remained by TLC analysis (usually about 10−20 min). The solution was then quenched in 20 mL of ice H_2O, acidified to pH 4−5 with 5% HCl and extracted with 5 × 10 mL of ethyl acetate. The combined organic solution was washed with 2 × 10 mL of H_2O and 10 mL brine and then dried over $MgSO_4$ or Na_2SO_4. The organic solvent was removed by the rotary evaporator, giving a residue was dried further at 0.05 mmHg for several hours (135 mg, 95%) before storing in a desiccator for further use.

***N*-Hydroxysuccinimide Ester of II-475a.** A 10 mL dry round-bottomed flask equipped with a N_2 inlet and a stir bar was charged with 50 mg of the above acid form of **II-475a**, followed by 15 mg of NHS, 3 mL of dry CH_3CN, and 23 mg of EDC. The resulting mixture was stirred at room-temperature overnight and then was quenched with 40 mL of ice−water. The resulting solution was extracted with 5 × 10 mL of ethyl acetate, and the combined organic solution was washed with 2 × 10 mL of ice-cold water and 10 mL of ice-cold brine and dried over $MgSO_4$. Rotary evaporation gave a residue that was dried at (0.05 mmHg) for several hours, giving 52 mg (95%) of product, $R_f = 0.5$ (100% ethyl acetate), that was stored in a desiccator.

3-(4′-(Pentafluorophenyl)-2′,3′,5′,6′-tetrafluorophenoxy)-2-butanone (III). A 25 mL dry round-bottomed flask equipped with a N_2 inlet and a stir bar was charged with 1.0 g (3 mmol) of 2,3,5,6-tetrafluoro-4-(pentafluorophenyl)phenol, 0.55 g of 3-bromo-2-butanone (**5**), 1.0 g of potassium carbonate, and 20 mL of acetonitrile. The resulting mixture was allowed to stir at 60 °C until TLC showed no phenol remained (about 12−16 h). The K_2CO_3 was moved via filtration and washed with 3 × 10 mL acetonitrile. The organic solvent was removed by rotary evaporation, and the residue was recrystallized from hexanes/diethyl ether to give 1.08 g (90%) of the desired product. ^{1}H NMR ($CDCl_3$): 4.94 (q, $J = 6.9$ Hz, 1H), 2.37

(s, 3H), 1.60 (d, $J = 7.0$ Hz, 3H) ppm. ^{19}F NMR ($CDCl_3$): −137.92 (m, 2F), −139.43 (m, 2F), −151.12 (m, 1F), −155.95 (m, 2F), −161.30 (m, 2F) ppm. $R_f = 0.50$ (ethyl acetate:hexanes, 1:9).

General Procedure for the Preparation of Phenol Derivatives of Compound (III). A 25 mL dry round-bottomed flask equipped with a N_2 inlet and a stir bar was charged with 0.41 g (1 mmol) of 3-[2′,3′,5′,6′-tetrafluoro-4′-(pentafluorophenyl)phenoxy]-2-butanone, 1.1 mmol of a selected phenol (see below), 0.5 g of potassium carbonate, and 20 mL of acetonitrile. The resulting mixture was allowed to stir at 60 °C until TLC analysis showed no starting material remained (about 12−16 h). The K_2CO_3 was removed via filtration and washed with 3 × 10 mL of acetonitrile. The combined organic solution was concentrated on a rotavapor giving a residue that was further purified on a silica gel column to give the product.

3-{4′-[4″-(*p*-Iodophenoxy)-2″,3″,5″,6″-tetrafluorophenyl]-2′,3′,5′,6′-tetrafluorophenoxy}-2-butanone (III-531a). By the above general procedure, the reaction of 4-iodophenol with **III** gave 0.51 g (85%) of product. ^{1}H NMR ($CDCl_3$): 7.66 (dm, $J = 9.2$ Hz, 2H), 6.84 (dm, $J = 9.3$ Hz, 2H), 4.90 (qm, $J = 6.8$ Hz, 1H), 2.37 (s, 3H), 1.60 (d, $J = 7.6$ Hz, 3H) ppm. ^{19}F NMR ($CDCl_3$): −138.19 (m, 2F), −139.25 (m, 2F), −153.5 (m, 2F), −155.9 (m, 2F) ppm.

3-{{4′-{4″-[*o*,*p*-Bis(α,α-dimethylbenzyl)phenoxy]-2″,3″,5″,6″-tetrafluorophenyl}-2′,3′,5′,6-tetrafluorophenoxy}}-2-butanone (III-641a). By the above general procedure, the reaction of 2,4-bis(α,α-dimethylbenzyl)phenol with **III** yielded 0.80 g (87%) product. ^{1}H NMR ($CDCl_3$): 7.03−7.36 (m, 11H), 4.47 (d, $J = 2.3$ Hz, 1H), 6.56 (d, $J = 8.3$ Hz, 1H), 4.88 (q, $J = 6.7$ Hz, 1H), 2.37 (s, 3H), 1.76 (s, 6H), 1.74 (s, 6H), 1.56 (d, $J = 7.0$ Hz, 3H) ppm. ^{19}F NMR ($CDCl_3$): −139.40 (m, 2F), −139.76 (m, 2F), −154.17 (m, 2F), −156.19 (m, 2F) ppm.

***N*,*N*-Didecyl 4-{4′-[4″-(α-Methyl-*β*-oxopropyloxy)-2″,3″,5″,6″-tetrafluorophenyl]-2′,3′,5′,6′-tetrafluorophenoxy}benzamide (III-728a).** By the above general procedure, the reaction of *N*,*N*-didecyl 4-hydroxybenzamide with **III** gave 0.28 g (49%) major product. ^{1}H NMR ($CDCl_3$): 7.39 (dm, $J = 8.4$ Hz, 2H), 7.06 (dm, $J = 8.5$ Hz, 2H), 4.94 (q, $J = 7.4$ Hz, 1H), 3.21−3.47 (m, 4H), 2.37 (s, 3H), 1.61−1.66 (m, 32H), 1.60 (d, $J = 6.9$ Hz, 3H), 0.87 (t, $J = 6.6$ Hz, 6H) ppm. ^{19}F NMR ($CDCl_3$): −138.27 (m, 2F), −139.29 (m, 2F), −153.39 (m, 2F), −156.02 (m, 2F) ppm. Also a minor product (**III-848a**) was obtained. ^{1}H NMR ($CDCl_3$): 8.25 (dm, $J = 9.3$ Hz, 2H), 7.44 (dm, $J = 8.5$ Hz, 2H), 7.25 (dm, $J = 8.8$ Hz, 2H), 7.15 (dm, $J = 8.5$ Hz, 2H), 4.93 (q, $J = 7.2$ Hz, 1H), 3.11−3.48 (m, 4H), 2.38 (s, 3H), 1.61 (d, $J = 6.5$ Hz, 3H), 1.16−1.66 (m, 32H), 0.88 (m, 6H) ppm ^{19}F NMR ($CDCl_3$): −137.68 (m, 2F), −139.15 (m, 2F), −153.10 (m, 2F), −155.82 (m, 2F) ppm.

4′-(Bromomethyl)acetophenone (7). A 50 mL dry round-bottomed flask equipped with a N_2 inlet and a stir bar was charged with 30 mL of CCl_4, 2.0 g of NBS, 1.34 g of 4-methylacetophenone (**6**), and a catalytic amount of 2,2′-azobisisobutyronitrile. The resulting solution was refluxed for 8 h and was monitored by TLC during reflux. After the solvent was removed by rotary evaporation, the residue was quenched with 30 mL of ice−water and extracted with 3 × 30 mL of diethyl ether. The combined organic solution was washed with 2 × 30 mL of water and dried over $MgSO_4$. After removal of solvent by rotary evaporation, the residue was purified further by silica column chromatography (methylene chloride:hexanes, 1:3) to give 1.06 g (50%) of product. ^{1}H NMR ($CDCl_3$): 7.93−7.96 (m, 2H), 7.48−7.5 (m, 2H), 4.51 (s, 2H), 2.61 (s, 3H) ppm.

***p*-(4′-(Pentafluorophenyl)-2′,3′,5′,6′-tetrafluorophenoxy)methylacetophenone (IV).** A 100 mL dry round-bottomed flask equipped with a N_2 inlet and a stir bar was charged with 2.73 g of 2,3,5,6-tetrafluoro-4-(pentafluorophenyl)phenol, 1.75 g of **7**, 2.0 g of potassium carbonate, 30 mL of THF: acetonitrile (1:1), and 0.1 g of potassium iodide. The resulting mixture was allowed to stir at 60 °C until TLC analysis showed no phenol remained (about 12−16 h). The K_2CO_3 was removed by filtration and washed with acetonitrile 3 × 10 mL. The combined organic solution was concentrated on a rotary evaporator, and the residue was recrystallized from hexanes/diethyl ether to give 2.93 g (77%) of product. (Further recrystallization could raise the combined yield to 90%.) ^{13}C NMR ($CDCl_3$): 197.53, 146.27 (m), 142.92 (m), 140.37, 140.36 (m), 138.60 (m), 137.32, 128.75, 127.80, 75.54 (t, $J = 4.0$ Hz), 26.51 ppm. ^{1}H NMR ($CDCl_3$): 8.00−8.03 (m, 2H), 7.56−7.59 (m, 2H), 5.42 (s, 2H), 2.63 (s, 3H) ppm. ^{19}F NMR ($CDCl_3$): −137.99 (m, 2F), −139.55 (m, 2F), −151.01 (m, 1F), −155.77 (m, 2F), −161.18 (m, 2F) ppm.

***p*-[4′-(4″-Piperidinyl-2″,3″,5″,6″-tetrafluorophenyl)-2′,3′,5′6′-tetrafluorophenoxy]methylacetophenone (IV-396a).** A 25 mL dry round-bottomed flask equipped with a N_2 inlet and a stir bar was charged with 0.93 g of **IV**, 0.30 g of piperidine, 1.0 g of potassium carbonate, and 15 mL of acetonitrile. The resulting mixture was allowed to stir at 60 °C until TLC analysis showed no starting material (about 24 to 48 h). The K_2CO_3 was removed filtrated and washed several times with 3 × 10 mL acetonitrile. The combined concentration on a rotary evaporation, and the residue was purified further on a silica gel column to give 0.53 g (50%) of product. ^{1}H NMR ($CDCl_3$): 7.99−8.02 (m, 2H), 7.56−7.59 (m, 2H), 5.39 (s, 2H), 3.27 (m, 4H), 2.63 (s, 3H), 1.68 (m, 6H) ppm. ^{19}F NMR ($CDCl_3$): −139.80 (m, 2F), −141.50 (m, 2F), −151.55 (m, 2F), −156.50 (m, 2F) ppm.

***p*-[4′-(4″-Piperazinyl-2″,3″,5″,6″-tetrafluorophenyl)-2′,3′,5′6′-tetrafluorophenoxy] methyl acetophenone (IV-397a).** A 25 mL dry round-bottomed flask equipped with a N_2 inlet and a stir bar was charged with 0.93 g of **IV**, 0.30 g of anhydrous piperazine,1.0 g of potassium carbonate, and 15 mL of acetonitrile. The resulting mixture was allowed to stir at 60 °C until TLC analysis showed no starting material left (about 24−48 h). After filtration, washing, and concentration, the residue was redissolved in 200 mL of ethyl acetate, and this solution was washed with 3 × 30 mL of water and 30 mL of brine and dried over $MgSO_4$. The solvent was removed by rotary evaporation, and the crude product was further dried under vacuum for several hours prior to the following reaction.

(Note: this key intermediate solution could be stored at 4 °C for 7 days without significant decomposition.)

***p*-{4′-[4″-(4‴-Acetyl-1‴-piperazinyl)-2″,3″,5″,6″-tetrafluorophenyl]-2′,3′,5′,6′-tetrafluorophenoxy}methylacetophenone (IV-439a).** A 25 mL dry round-bottomed flask equipped with a N_2 inlet and a stir bar was charged with 1.0 g of above crude material and 15 mL of dry THF. The solution was cooled to in an ice-bath for 0.5 h prior to addition of 1.0 mL of acetic chloride dropwise, followed by 1.0 mL of pyridine. The resulting mixture with stirring was allowed to warm to room-temperature overnight. The reaction mixture was quenched with 30 mL of ice−water and neutralized with 0.5% HCl. This mixture was extracted with ethyl acetate (5 × 20 mL). The combined organic solution was washed with 3

2,3,4,5,6-Pentafluorobenzyl Acetate (9). To a mixture of 1 g (5 mmol) of 2,3,4,5,6-pentafluorobenzyl alcohol (**8**) and 1 mL of pyridine in 50 mL of anhydrous methylene chloride was added 0.6 g (5.8 mmol) of acetic anhydride. After being refluxed for 3 h, the mixture was cooled to room temperature, and then 10 mL of water

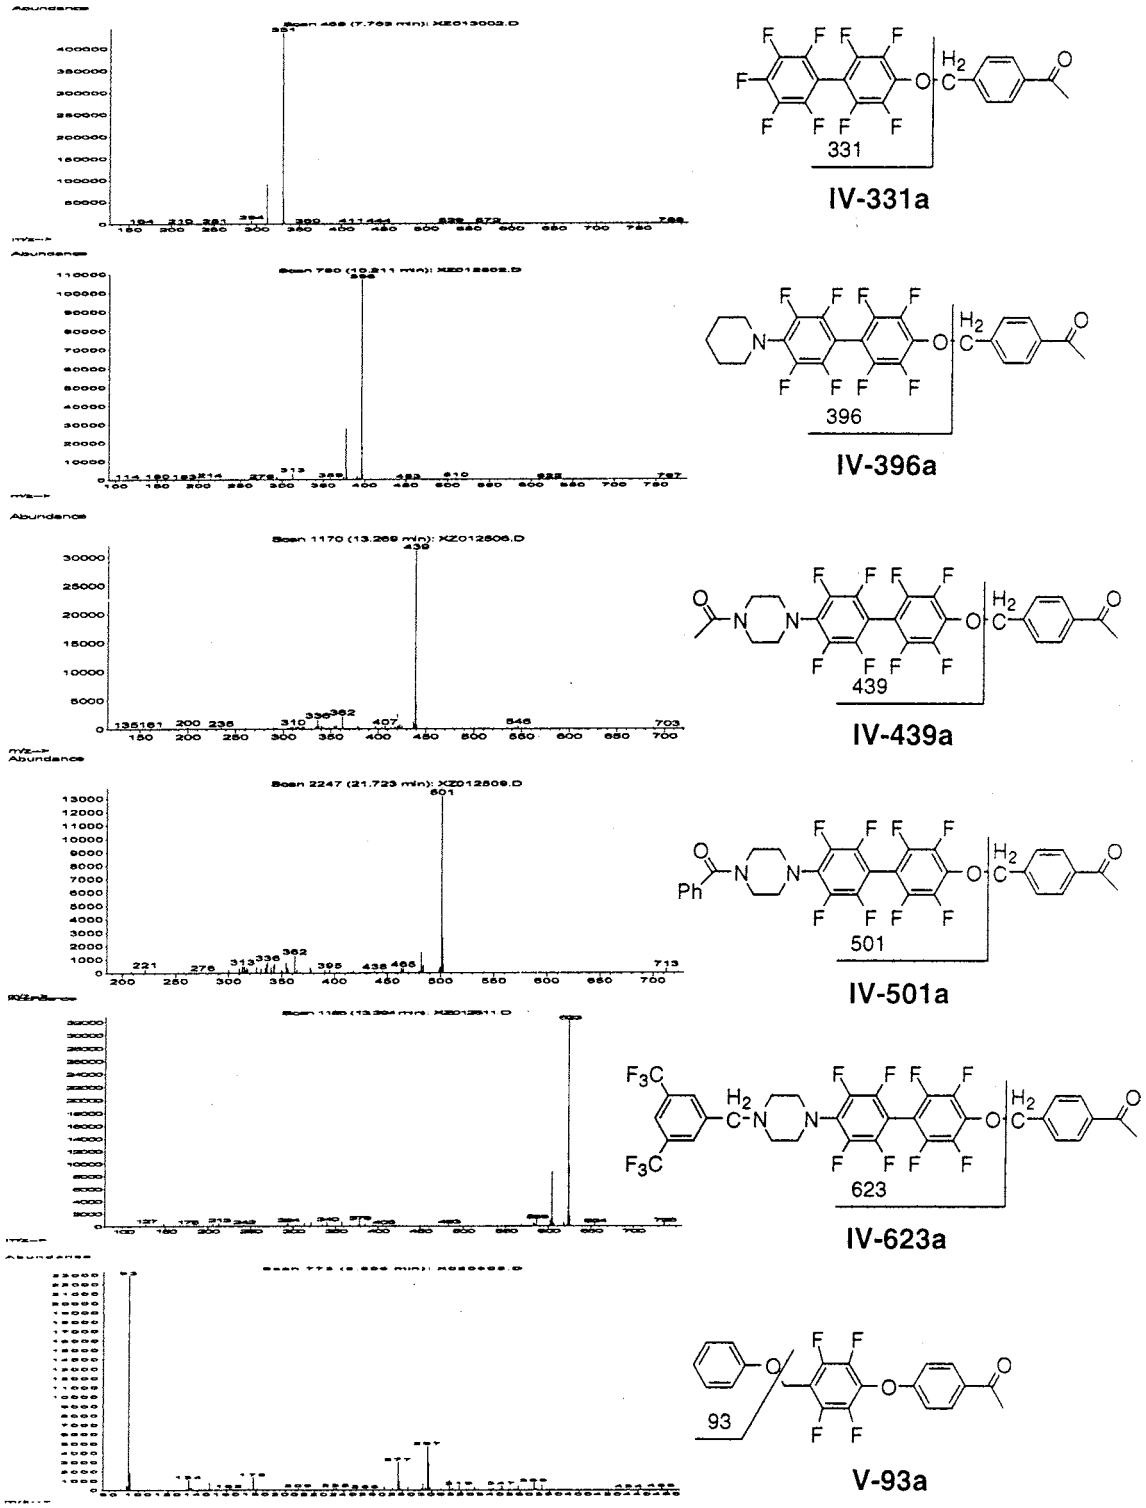

Figure 3. Mass spectra of electrophores by GC-EC-MS. Sample injection: 1 μL injection, 100 pg/μL in ethyl acetate.

was added. The aqueous phase was extracted with methylene chloride three times, and the combined organic solution was washed with 10 mL of brine and then dried over magnesium sulfate. After removal of the solvent on a rotavapor, 1.1 g (91%) of product was obtained as a colorless oil.

4′-(4″-Acetoxymethyl-2″,3″,5″,6″-tetrafluorophenoxy)acetophenone (10). A mixture of 1 g (4.16 mmol) of **9**, 0.57 g (4.18 mmol) of 4′-hydroxyacetophenone, 5 g of potassium carbonate, and 50 mg of 18-crown-ether in 50 mL of anhydrous toluene was refluxed for 16 h. After cooling to room temperature, the reaction mixture was filtered through a Celite bed. The filtrate was concentrated, and the residual solid was loaded on a silica gel column and eluted with 5:1 hexanes/ethyl acetate to afford 1.2 g (81%) of product as a white solid.

4′-(4″-Hydroxymethyl-2″,3″,5″,6″-tetrafluorophenoxy)acetophenone (11). To a solution of 1 g (2.8 mmol) of **10** in 50 mL of methanol was added dropwise 10 mL of 20% aqueous sodium hydroxide. The mixture was then stirred at room-temperature overnight, neutralized to pH 7, and concentrated to about 20 mL to remove most of methanol. The aqueous solution was extracted with ethyl acetate (3 × 50 mL). The combined organic solution was

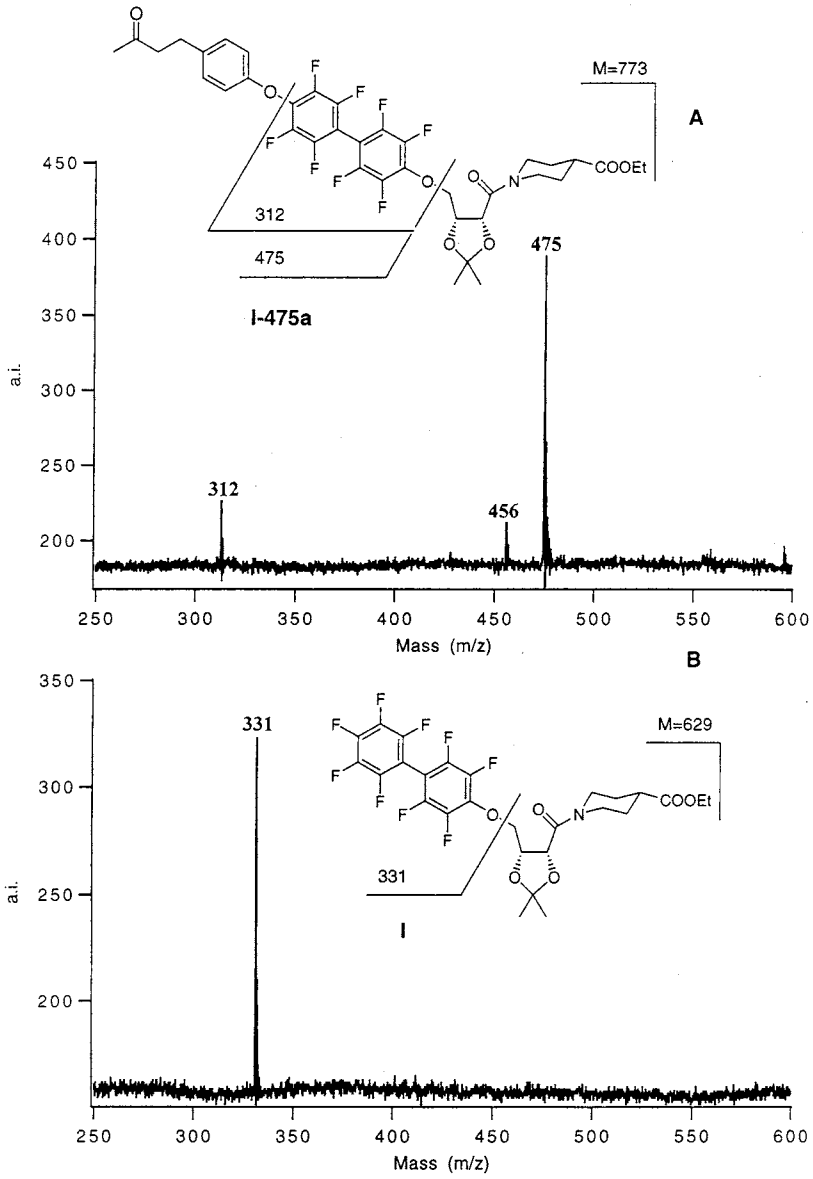

Figure 4. Detection of electrophores by LI-EC(Ag)-TOF-MS: 100 pmol on the target, 10 laser shots.

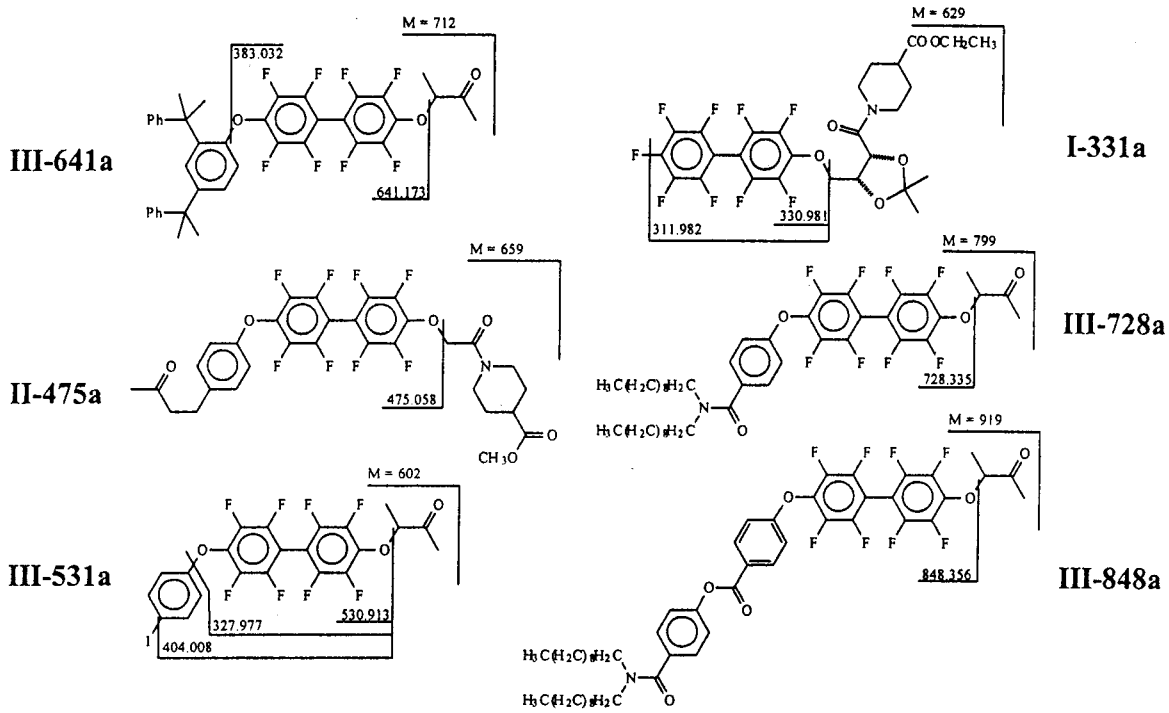
washed with water and brine and then dried over magnesium sulfate. After removal of the solvent, 0.84 (95%) of product was obtained as a white solid.

4′-(4″-Chloromethyl-2″,3″,5″,6″-tetrafluorophenoxy)acetophenone (V). A mixture of 0.85 g (2.7 mmol) of **11** and 5 mL of thionyl chloride in 30 mL of chloroform was refluxed for 6 h. The solvent was removed on a rotavapor, and the crude product was further purified by chromatography on silica gel to afford 0.83 g (92%) of product.



4′-(4″-Phenoxymethyl-2″,3″,5″,6″-tetrafluorophenoxy)acetophenone (V-93a). A mixture of 0.83 g (2.5 mmol) of **V**, 0.3 g (3.2 mmol) of phenol, and 2 g of potassium carbonate in 30 mL of acetone was stirred under reflux for 5 h. After being cooled to room temperature, the mixture was filtered through a Celite bed. The filtrate was concentrated and subjected to chromatography on silica gel with 6:1 hexanes/ethyl acetate to afford 0.95 g (97%) of product as a white solid. ^{1}H NMR ($CDCl_3$): 7.97−8.00 (m, 2H), 7.32−7.37 (m, 2H), 7.00−7.06 (m, 5H), 5.18 (s, 2H), 2.58 (s, 3H) ppm. ^{19}F NMR ($CDCl_3$): −142.66 (m, 2F), −154.10 (m, 2F) ppm.

RESULTS AND DISCUSSION

Shown in Figure 1 are five branchpoint precursors **(I−V)** of electrophore tags, along with their synthetic pathways. Each compound represents a point in a branching synthetic pathway that can lead to many releasable electrophore mass tags. Nucleophilic reactions with phenols can be employed at this branch point in all cases, involving substitution of a *p*-fluorine atom of **I**−**IV**, and of the chlorine atom of **V**, as summarized in Figure 2. Overall this can provide, as explained in more detail later, to two signal libraries, one shared in common by **I**−**IV**, and a second library from **V**.

As seen in Figure 1, precursor tag **I** is established by a synthetic pathway that consists of just two reactions, and all of the reactants are commercially available and inexpensive, including the starting compound, 2,3-O-isopropylidine D-erythronolactone. The isolated yield of **I** from compound **2** (reaction b) is 49%, and the overall yield of **I** from **1** is 37%.

Considerable effort went into the development of reaction conditions b (CsOH monohydrate, molecular sieves, acetonitrile). Many other conditions, involving a variety of bases, solvents, and temperatures, gave a lower

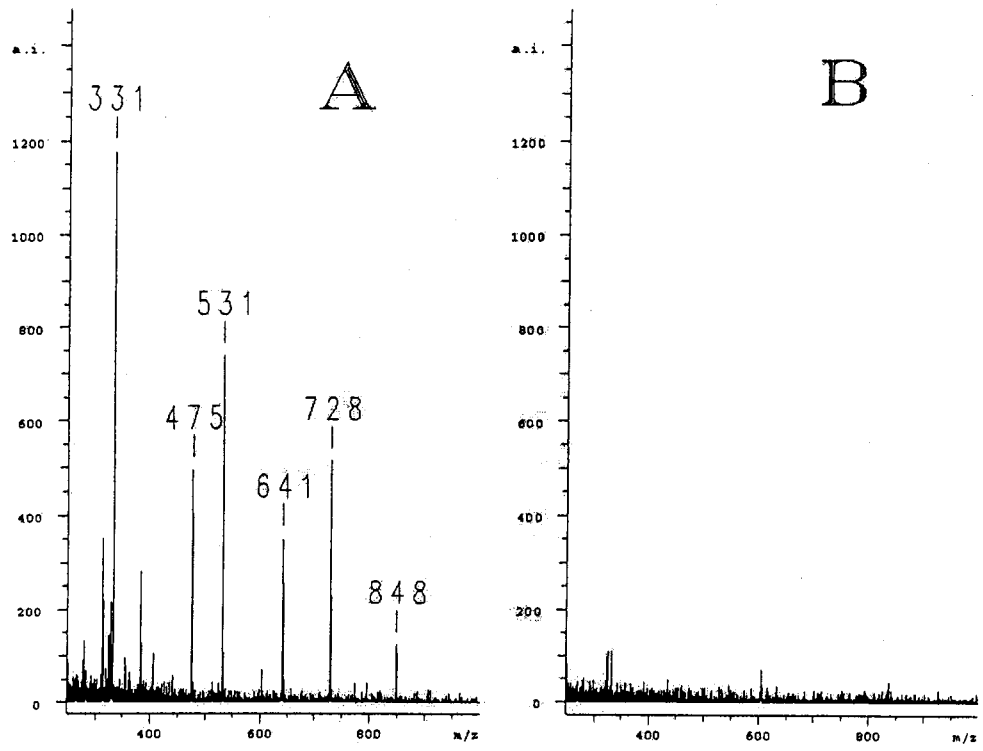


Figure 5. A: Detection of a mixture of six electrophores by LI-EC(Ag)-TOF-MS: 100 fmol of each on the target, 10 laser shots. B: LI-EC(Ag)-TOF-MS of blank silver surface under same condition as in A.

yield of **I**. Since the reactants in this sequence are commercially available and inexpensive, and **I** is easily purified from the side products, the synthetic procedure to form **I** is attractive.

Compound **I** can be converted into electrophore mass tags by a general reaction sequence consisting of the following series of steps: replace the para fluorine with a phenol; acid-hydrolyze the isopropylidine moiety to a corresponding glycol; base-hydrolyze the ester to a corresponding acid; and convert the latter to an *N*-hydroxysucccinimide (NHS) active ester (see Figure 2). Thus, the ensuing reactivity, release, and signal groups in the final release tags derived from **I** are NHS ester, β-hydroxy amide, and a para-substituted octafluorobiphenylate (signal ion form), respectively. The β-hydroxy amide moiety functions as a release group by undergoing a retro thermal-aldol type of reaction at an elevated temperature, as described before (*6*). Relative to our prior work (*6*) this pathway is more practical for the synthesis of many electrophore mass tags.

Analogous reaction pathways are employed to convert branchpoint compounds **II**−**V** into many releasable electrophore mass tags, as also summarized in Figure 2, where an example is shown (**II-475a NHS ester**). The latter tag, upon electron capture, furnishes an ion (RO^-) at *m*/*z* 475, due to dissociative cleavage of the $O-CH_2$ bond.

For the electrophore tags derived from **V**, the mass signals can begin at *m*/*z* 93, since this value corresponds to a phenolate anion, which ultimately forms when the chlorine atom of **V** is replaced by phenol in the synthetic pathway. In contrast, the signal libraries derived from **I**−**IV** begin at about *m*/*z* 343, due to replacing the *p*-fluorine atom of this compound with methoxy. This latter product eventually forms a 4-[(4′-methoxy)tetrafluorophenyl]tetrafluorophenolate ion (*m*/*z* 343). Thus, a main advantage of **V** over **I**−**IV** is that it extends the library of electrophore tags to much lower masses. For all five of the pathways, stable isotope phenols can be employed along with corresponding, ordinary phenols, as needed, to provide additional mass signals or to enhance quantitation by acting as an internal standard. While the use of stable isotopes would be necessary to fill in the mass range immediately above *m*/*z* 93, a large library of mass tags can be prepared without resorting to stable isotopes, because many phenols are readily available, a cost advantage.

In Figure 3 is shown a mass spectrum by GC-EC-MS of **IV** (designated as **IV-331a** in this figure), along with that of four corresponding electrophore mass tags derived from **IV**, and of a ketone electrophore derived from **V**. (Compound **IV** is designated as **IV-331a** here since it gives rise to a major ion at *m*/*z* 331, and is the first compound or "**a**", derived from **IV** that provides a signal at this mass.) It is meaningful to detect these ketones as synthetic intermediates since they are also the very signal compounds that are released for electron capture in the last step of our analytical technique.

Of special interest is the degree to which the compounds of Figure 3 form single ions in the EC-MS, as seen. This important property not only contributes to their sensitivity, but also helps to simplify the overall mass spectrum that a library of such compounds would yield. We consider that all of these derivatives are successful in this respect, since the electron capture mass spectrum of each one is dominated by a single ion (aside from M + 1). A minor, secondary ion arising from loss of a fluorine is seen in some of the spectra. While a 10-fold variation in response is observed for the major ion among these compounds, this result may have no meaning for our purposes. This is because the variation in response may be due to different recoveries of the compounds in the GC injection and separation steps, and these steps will be omitted in our ultimate detection scheme (which will involve laser desorption or laser-induced electron capture desorption).

Precursor tag **I** and the representative, corresponding derivative, **I-474a**, can be measured directly by laser-induced electron capture time-of-flight mass spectrometry on a silver surface (LI-EC[Ag]-TOF-MS), as shown in Figure 4, relying on the conditions that we introduced recently for the latter technique (*9*). We did not comparatively inject these compounds into the GC-EC-MS, because we would expect an irreproducible, low response for compounds of this type (high in mass and containing isopropylidine, amide, and ester groups). Whether the potentially labile isopropylidine moiety of **I** and **I-475a** remains intact throughout the electron capture process that leads to the observed ions is unknown.

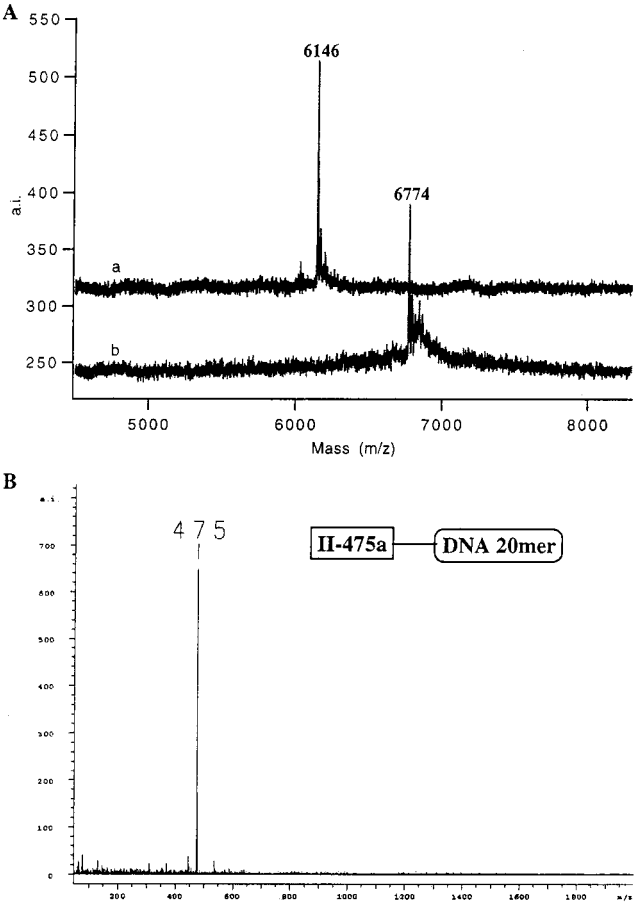

Figure 6. A: Detection by positive ion MALDI-MS of oligonucleotide P107 (5′-[aminoalkyl]-ACCGGCCATGCTCGCGACCA) in trace a; and of P107, after labeling with mass tag **II-475a**, in trace b. The oligomer was labeled with an NHS ester of **II-475a** in aqueous dimethyl sulfoxide containing 5% triethylamine using the conditions described previously (*10*). B: Detection by LI-EC(Ag)-TOF-MS of the latter, electrophore-labeled oligonucleotide, 500 fmol on the target, six laser shots.

Why does compound **I-475a**, but not compound **I**, lose fluorine in the LI-EC(Ag)-TOF-MS experiments of Figure 4? At least part of the reason is the variation in the experimental conditions. Arbitrarily, we used a lower power density for the laser in the detection of **I** (Figure 4B) vs **I-475a** (Figure 4A). Note the noisier baseline in Figure 4B both in terms of thickness and waviness, associated with a less abundant signal. This was confirmed by observing that fluorine loss from **I** could be increased by raising the laser intensity (data not shown).

In Figure 5 are shown the structures, fragmentation, and simultaneous detection by LC-EC(Ag)-TOF-MS, of a mixture of intermediates from the synthetic schemes presented in Figure 1. Importantly, all of the compounds are detected with high sensitivity: the amount of each compound applied to the silver target is 100 fmol, and only about 0.25% of each sample spot is in the laser beam. As seen, a relatively clean baseline is observed for a corresponding blank sample in Figure 5B. Also of note is the success of compound **II-475a** in this experiment. Compound **II-475a** possesses a new release group relative to prior literature. The preparation and testing of this latter compound was motivated by the behavior of **I-475a** (Figure 4A).

Extension of our detection strategy to a DNA oligomer labeled with an electrophore mass tag, for eventual use as a sequencing primer or hybridization probe, is shown in Figure 6. A 5′ amino linked DNA oligomer was labeled

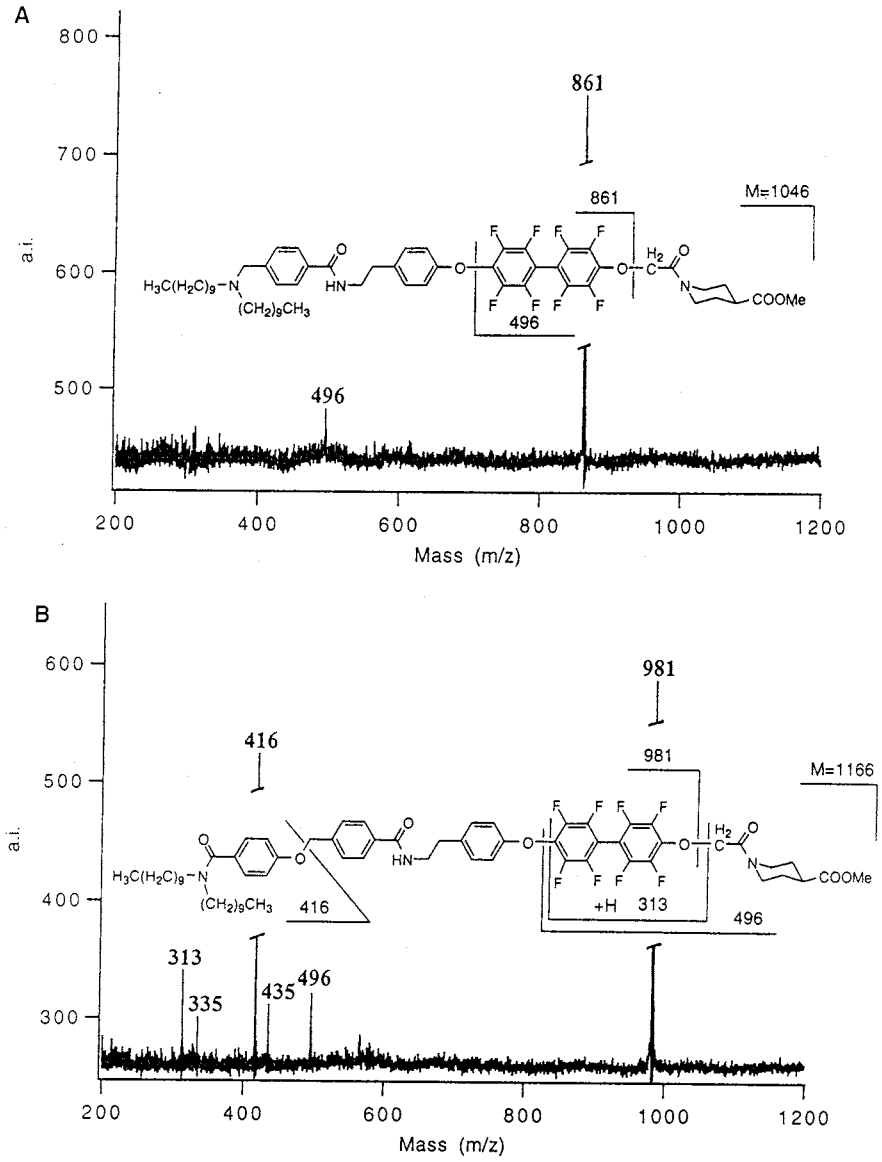

Figure 7. Detection of electrophores by LI-EC(Ag)-TOF-MS: A. 100 pmol of **II-861a** on the target, 17 laser shots. B. 1200 pmol of **II-981a** on the target, nine laser shots.

with a *N*-hydroxysuccinimide (NHS) ester of release tag **II-475a.** Analysis of the starting and electrophore-labeled product oligomers (**a** and **b**, respectively) by conventional MALDI-TOF-MS is shown in Figure 6A, and detection of the product oligomer (actually of the electrophore tag on this oligomer) by LI-EC(Ag)-TOF-MS is shown in Figure 6B. While we did not strive to demonstrate high sensitivity in this experiment, the observation that the simple conditions of LI-EC(Ag)-TOF-MS enable direct oligomer detection with a clean baseline (especially above 450 units of an electrophore-labeled DNA oligomer) is important in this technology.

Toward a goal of expanding the degree of multiplexing available from electrophore release tags, we have begun to explore higher-mass versions of these reagents. Initial success in this endeavor is shown by the data in Figure 7A, where compound **II-861a**, despite its more complicated structure, is detected by LI-EC(Ag)-TOF-MS as nearly a single ion (*m*/*z* 861). In work preceding this experiment, compound **II-981a** was prepared and found to yield six major ions (Figure 7B). The secondary cleavage at the benzyl ether site in **II-981a** is not surprising, since it forms a favorable amidophenolate species (the *m*/*z* 416 ion). The ion at *m*/*z* 496 in both spectra, assuming that we have assigned it correctly, would not be seen if the tag was attached to an oligomer, since the same cleavage would generate an oligomer ion. Our ability to avoid significant secondary cleavages in an ion having a mass as high as 861 units suggests that a considerable mass range can be anticipated for release tag electrophores, creating an opportunity for highly multiplexed assays that utilize them as tags.

Considering our need to design electrophores with favorable fragmentation properties upon electron capture (e.g., compound **II-861a** vs **II-981a** in Figure 7) we explored, in a preliminary way, whether the semiempirical method AM1 (using Hyperchem software) might be useful as a tool to understand some aspects of electron capture for our compounds. Arbitrarily, we selected a simple electrophore, **III**, and considered that the energy of the incoming electron was 0 eV for this calculation. For example, we wanted to find out whether the calculation could rationalize the emergence of ≥50 kcal/mol of excess, internal energy upon electron capture, to account for the observed cleavage of the C−O bond (bond energy 50−67 kcal/mol), aside from kinetic factors.

According to AM1, compound **III** prefers to exist with its two polyfluoro aromatic rings essentially perpendicu-

lar to each other, and this conformation provides a minimum value for the internal energy of −3789 kcal/mol. The corresponding anion radical of **III** in the same conformation is calculated to have an energy which is only 18 kcal/mol lower (−3807 kcal/mol), yielding an insufficient excess of internal energy to break the C−O bond. (What is being assumed is that the difference in energy between these two species is present as excess, internal energy in the incipient anion radical intermediate). Nevertheless, calculating the optimum geometry for the anion radical yields a structure in which the two polyfluoroaromatic rings have rotated to become more planar relative to each other. This furnishes another 35 kcal/mol of additional energy (to −3842 kcal/mol), sufficient in total (53 kcal/mol) to break the C−O bond. Much or most of the added electron density from electron capture, according to AM1, resides on the fluorine atoms of the outer perfluorphenyl ring in both the perpendicular and more planar conformers of the anion radical and then largely shifts to the adjacent polyfluorophenylate moiety that arises when the C−O bond breaks. Perhaps this shift in electron density is easier for the more planar conformer, having more conjugation between the rings.

The calculated energies for the observed anion and radical dissociation products in an optimum geometry from electron capture are −2704 and −1130 kcal/mol, respectively. The sum of these latter values is nearly the same (within 8 kcal/mol) of the energy calculated for the parent anion radical (the calculation assumes no excess internal energy is present) after aromatic ring twisting. From this argument it follows that the excess internal energy from ring rotation may not truly be needed for bond cleavage, since the emerging, extra stability of the favorable fragmentation products, due in part to resonance, could provide the energy necessary to drive (concurrently) the dissociation, assuming that this energy emerges early in the reaction pathway. Some of this resonance is due to the planarity of the polyfluorobiphenylate product, which creates a barrier for the parent, more perpendicular anion radical (−3789 kcal/mol) to access this alternative energy source. Thus, overall the postulated ring rotation may contribute to the observed dissociative electron capture both by increasing the amount of excess internal energy in the starting anion radical reactant and by enabling a shift in electron density from the outer to the inner polyfluorophenyl ring along the reaction pathway as a second source of excess internal energy, thereby breaking the bond.

CONCLUSION

Electrophore mass tags offer the advantages of low cost, physicochemical stability, high multiplicity, high sensitivity, and high throughput detection by mass spectrometry. Some of this promise has been demonstrated in this project. Practical synthetic strategies have been developed to make a large number of these tags which release under both gas phase and surface electron capture conditions, yielding gas phase signal groups that ionize with minimal secondary fragmentation to provide, in turn, nearly mono-ion spectra for high sensitivity. Representative tags with these properties furnishing ions from *m*/*z* 93 to 861 have been prepared, opening up a wide range of multiplicity to enhance multiplexing. This success guides and encourages the further development of these reagents.

Acridine Conjugates of 3-Clip-Phen: Influence of the Linker on the Synthesis and the DNA Cleavage Activity of Their Copper Complexes

Christophe Boldron, Steven A. Ross, Marguerite Pitié, and Bernard Meunier*

Laboratoire de Chimie de Coordination du CNRS, 205 route de Narbonne, 31077 Toulouse Cedex 4, France.
Received January 15, 2002

To increase the DNA cleavage activity and the cell delivery of the bis(phenanthroline) DNA cleaver "3-Clip-Phen", conjugates between 3-Clip-Phen and the intercalators acridine and 6-chloro-2-methoxyacridine, through amino acid linkers of various length, were prepared. After complexation with $CuCl_2$, the ability of these conjugates to cleave ΦX 174 DNA in the presence of a reductant and air was compared. The results indicated that (i) the coupling of 3-Clip-Phen to an acridine derivative increased the DNA cleavage efficiency of the copper complexes, (ii) the acridine derivatives were more active than 6-chloro-2-methoxyacridine derivatives, (iii) the linker length influenced cleavage efficiency, the highest DNA cleavage activity being obtained for an aminocaproic spacer.

INTRODUCTION

The redox activity of cuprous complexes of 1,10-phenanthroline (Phen) is well-known as an artificial nuclease (*1*, *2*). They are able to realize single-strand cleavages of DNA in the presence of H_2O_2 by oxidative degradation of deoxyribose units from the minor groove of DNA. Active species can also be generated from cupric complexes in the presence of oxygen and reductant. $Cu^I(Phen)_2$ is significantly more active than $Cu^I(Phen)$, but the association constant for the second phenanthroline ligand is only $10^{5.5}$ M^{-1} which is too low for biological use at submicromolar concentrations of these complexes.

We have recently prepared 2- and 3-Clip-Phen derivatives containing two Phen ligands linked at the 2′- or 3′-position by a serinol bridge in order to favor the 2/1 Phen/Cu stoichiometry (*3*, *4*). The oxidative nuclease activity of the copper complexes of these new ligands was found to be higher than with Phen itself, by a factor of 2 for 2-Clip-Phen, but by a factor of 60 for 3-Clip-Phen. The nuclease activity of (3-Clip-Phen)$CuCl_2$ complex has been associated to C1′-, C4′-, and C5′-deoxyribose oxidations resulting from a cleaver interaction within the DNA minor groove (*5*). (3-Clip-Phen)$CuCl_2$ appeared to be poorly sequence selective, but the preparation of a conjugate with an analogue of distamycin (a minor groove binder interacting selectively with five successive AT base pairs) allowed preparation of a sequence-selective DNA cleaver derivative of 3-Clip-Phen (*5*, *6*).

The high DNA cleavage activity of copper complexes of 3-Clip-Phen can be used for the preparation of new tools for molecular biology but also for the preparation of new chemotherapeutic agents based on the model of iron bleomycin (*7*, *8*), a well-known antitumor drug able to cleave the DNA of cancer cells. These new molecules must associate different properties of cell penetration and specificity for DNA associated to the nuclease activity of 3-Clip-Phen. The conjugation of 3-Clip-Phen to acridine derivatives appeared to be a good solution to increase cell penetration and DNA binding (*9*−*12*). These dyes are among the classical intercalators, and they are known to rapidly enter cells and accumulate in the nucleus which is an important consideration with regard to potential in vivo activity. In addition to their synthetic accessibility, derivatives of acridine are colored, stable, usually fluorescent, and exhibit a broad range of chemotherapeutic properties against prokaryotic and eucaryotic cells because of their facile interaction with DNA targets.

We chose to conjugate 3-Clip-Phen with acridine and 6-chloro-2-methoxyacridine, which are the intercalating moieties of the antitumor drug amsacrine and the antimalarial quinacrine, respectively. Previously, DNA minor groove binders, such as netropsine (*13*, *14*), alkylating mustards (*10*), photonucleases such as the nitrobenzamide derivatives (*15*, *16*), or oligonucleotides (*17*−*20*), have been conjugated to these types of acridine derivatives and shown an increased activity due to improved DNA interaction and/or cell delivery; but their activity was highly modulated by the arm of junction with the intercalator (this phenomenon being also described in the case of bis-intercalating agents (*21*, *22*)). To favor the interaction of 3-Clip-Phen with the minor groove (sugar C−H bonds accessible in the minor groove are attacked by copper complexes of Clip-Phen derivatives), the nuclease moiety of the conjugates has been linked through an amino function on the C9 of the acridine derivative which is known to be oriented in the DNA minor groove after intercalation (*10*). The choice of the amino junction has been justified by the good cell penetration capacities of C9-aminoacridine derivatives (*10*). Preliminary results with acridine conjugates of 2-Clip-Phen demonstrated that this strategy increased DNA cleavage activity and that the acridine part of the conjugate conserved DNA intercalation ability (*23*).

In this paper we describe the synthesis of 3-Clip-Phen/acridine conjugates. To obtain the most active compound, the length of spacer connecting the reactive center to the intercalator was modified. The preparation of all the conjugates for $n = 1$ to 7, where n is the number of methylene in the linker, allowed a strict analysis of the influence of the length of the arm of junction on the activity of the conjugates. Two methods of synthesis were

selected and optimized depending on the length of the tether in the conjugate. After complexation with $CuCl_2$, the DNA cleavage activity of the different conjugates was compared.

MATERIALS AND METHODS

General. Chemical syntheses were monitored by thin-layer chromatography on Merck silica gel 60 F_{254} plates eluted by CH_2Cl_2/CH_3OH (9/1) containing 1% of concentrated NH_4OH, and spots were visualized with UV light. Ligand metalation and DNA reactions were carried out in milli-Q water. DMF was dried over 4 Å molecular sieves. Other commercial reagents were used without purification.

Materials. 3-Clip-Phen (*4*), 9-phenoxyacridine (*23*), and 6-chloro-2-methoxy-9-phenoxyacridine (*23*) were synthesized as previously described in the literature. 2-(*tert*-Butoxycarbonylamino)-1-glycine (**2a**), 3-(*tert*-butoxycarbonylamino)-1-β-alanine (**2b**), 4-(*tert*-butoxycarbonylamino)-1-butyric acid (**2c**), 5-(*tert*-butoxycarbonylamino)-1-valeric acid (**2d**), and 6-(*tert*-butoxycarbonylamino)-1-caproic acid (**2e**) were prepared according to ref 24; see also ref 25 for additional characterizations of these compounds.

General Procedure for the Preparation of Carboxylic Derivatives of 6-Chloro-2-methoxyacridine (1c−g). The synthesis was optimized from ref 26.

6,9-Dichloro-2-methoxyacridine (1 equiv) and phenol (17 equiv) were stirred at 100 °C for 1 h before addition of amino acid (1.06 equiv). The reaction mixture was allowed to react at 100 °C for 3 h and then cooled at room temperature, and a large excess of diethyl ether (>50 volumes) was added. The resulting yellow solid obtained after filtration was dissolved in hot methanol (to about 15 mM of crude product) and precipitated with one volume of diethyl ether at −20 °C overnight. The precipitate was filtrated, washed with diethyl ether, and dried under vacuum.

In all cases, about 10% of 9-amino-6-dichloro-2-methoxyacridine was observed as an impurity. To remove it, the precipitate of compounds **1c** or **1d** was dissolved in a freshly prepared aqueous solution of 1 M NH_4OH/CH_3OH (10/1, v/v) and extracted with CH_2Cl_2 (2 × 50 mL), and then the aqueous layer was evaporated and dried under vacuum. Compounds **1e**, **1f**, and **1g** were purified by column chromatography on silica gel eluted with CH_2Cl_2/CH_3OH (85/15) containing 3% of concentrated NH_4OH.

***N*-[9-(6-Chloro-2-methoxy)acridinyl]-4-aminobutyric acid (1c)** was prepared from 300 mg (1.08 mmol) of 6,9-dichloro-2-methoxyacridine to give **1c** (279 mg, 0.81 mmol, yield = 75%) as a bright yellow powder. ^{1}H NMR (DMSO-d_6): δ 2.05 (m, 2H), 2.44 (t, 2H, J = 9.00 Hz), 3.89 (t, 2H, J = 9.00 Hz), 4.05 (s, 3H), 7.43 (dd, 1H, J = 2.75, 11.75 Hz), 7.53 (dd, 1H, J = 3.00, 11.75 Hz), 7.75 (d, 1H, J = 3.00 Hz), 7.93 (d, 1H, J = 11.75 Hz), 7.97 (d, 1H, J = 2.75 Hz), 8.46 (d, 1H, J = 11.75 Hz). MS m/z (ES > 0): 345 (MH^+, 100%).

***N*-[9-(6-Chloro-2-methoxy)acridinyl]-5-aminovaleric acid (1d)** was prepared from 600 mg (2.16 mmol) of 6,9-dichloro-2-methoxyacridine to give **1d** (619 mg, 1.73 mmol, yield = 80%) as a bright yellow powder. ^{1}H NMR (DMSO-d_6): δ 1.66 (m, 2H), 1.85 (m, 2H), 2.34 (t, 2H, J = 7.00 Hz), 3.87 (t, 2H, J = 7.00 Hz), 4.04 (s, 3H), 7.44 (dd, 1H, J = 2.25, 9.25 Hz), 7.53 (dd,1H, J = 2.50, 9.25 Hz), 7.75 (d, 1H, J = 2.50 Hz), 7.93 (d, 1H, J = 9.25 Hz), 7.97 (d, 1H, J = 2.25 Hz), 8.45 (d, 1H, J = 9.25 Hz). MS m/z (ES < 0): 357 (M−H, 100%).

***N*-[9-(6-Chloro-2-methoxy)acridinyl]-6-aminocaproic acid (1e)** was prepared from 1 g (3.60 mmol) of 6,9-dichloro-2-methoxyacridine to give **1e** (724 mg, 1.94 mmol, yield = 54%) as a bright yellow powder. ^{1}H NMR (DMSO-d_6): δ 1.42 (m, 2H), 1.62 (m, 2H), 1.85 (m, 2H), 2.29 (t, 2H, J = 7.00 Hz), 3.88 (t, 2H, J = 7.00 Hz), 4.04 (s, 3H), 7.45 (dd, 1H, J = 2.00, 9.25 Hz), 7.55 (dd, 1H, J = 2.50, 9.25 Hz), 7.76 (d, 1H, J = 2.50 Hz), 7.93 (d, 1H, J = 9.25 Hz), 7.97 (d, 1H, J = 2.00 Hz), 8.46 (d, 1H, J = 9.25 Hz). MS m/z (ES > 0): 373 (MH^+, 100%).

***N*-[9-(6-Chloro-2-methoxy)acridinyl]-7-aminoheptanoic acid (1f)** was prepared from 300 mg (1.08 mmol) of 6,9-dichloro-2-methoxyacridine to give **1f** (322 mg, 0.83 mmol, yield = 77%) as a bright yellow powder. ^{1}H NMR (DMSO-d_6): δ 1.46 (m, 4H), 1.61 (m, 2H), 2.00 (m, 2H), 2.30 (t, 2H, J = 7.25 Hz), 4.07 (s, 3H), 4.13 (m, 2 H), 7.62 (dd, 1H, J = 2.00, 9.25 Hz), 7.76 (dd, 1H, J = 2.50, 9.25 Hz), 7.98 (d, 1H, J = 9.25 Hz), 8.03 (m, 2H), 8.59 (d, 1H, J = 9.25 Hz). MS m/z (ES < 0): 385 (M − H, 100%).

***N*-[9-(6-Chloro-2-methoxy)acridinyl]-8-aminocaprylic acid (1g)** was prepared from 300 mg (1.08 mmol) of 6,9-dichloro-2-methoxyacridine to give **1g** (307 mg, 0.77 mmol, yield = 71%) as a bright yellow powder. ^{1}H NMR (DMSO-d_6): δ 1.35 (br m, 6H), 1.54 (m, 2H), 1.83 (m, 2H), 2.26 (t, 2H, J = 7.25 Hz), 3.87 (t, 2H, J = 7.00 Hz), 4.04 (s, 3H), 7.45 (dd, 1H, J = 2.00, 9.25 Hz), 7.54 (dd, 1H, J = 2.50, 9.25 Hz), 7.76 (d, 1H, J = 2.50 Hz), 7.93 (d, 1H, J = 9.25 Hz), 7.97 (d, 1H, J = 2.00 Hz), 8.45 (d, 1H, J = 9.25 Hz). MS m/z (ES > 0): 401 (MH^+, 100%).

General Procedure for the Preparation of 3-Clip-Phen-arm-Boc (3a−e). The synthesis was optimized from ref 23.

(Boc-amino)-carboxylic acid (0.28 mmol) was dissolved in 2 mL of CH_2Cl_2 (dried on basic alumina) at 0 °C, and then Et_3N (39 μL, 0.28 mmol) and ethyl chloroformate (26 μL, 0.28 mmol) were added. After the reaction was stirred for 1 h at room temperature, the solvent was evaporated. The residue was dissolved in CH_2Cl_2 (2 mL), Et_3N (39 μL, 0.28 mmol) and 3-Clip-Phen (50 mg, 0.11 mmol) were added, the solution was stirred at room temperature for 20 h, and then the solvent was evaporated. The residue was redissolved in CH_2Cl_2 (50 mL), the solution was washed with 1 M NaOH (2 × 50 mL), the solvent was evaporated, and the crude product was purified by column chromatography on silica gel eluted with CH_2Cl_2/CH_3OH (90/10) containing 1% of concentrated NH_4OH. The purity of products **3a−e** was analyzed by ^{1}H NMR before beginning the coupling reaction with 6-chloro-2-methoxy-9-phenoxyacridine.

3-Clip-Phen-ethyl-Boc (3a). Yield = 76% (51 mg, 84 μmol) as a pale brown powder. ^{1}H NMR (CD_2Cl_2): δ 1.21 (s, 9H), 4.22 (br, 6H), 4.87 (br, 1H), 7.18 (d, 2H, J = 2.75 Hz), 7.32 (t, 1H, J = 5.75 Hz), 7.47 and 7.67 (AB, 4H, J_{AB} = 8.75 Hz), 7.54 (dd, 2H, J = 4.25, 8.00 Hz), 8.17 (dd, 2H, J = 1.50, 8.00 Hz), 8.66 (d, 2H, J = 2.75 Hz), 9.03 (dd, 2H, J = 1.50, 4.25 Hz), 9.10 (d, 1H, J = 7.84 Hz).

3-Clip-Phen-propyl-Boc (3b). Yield = 79% (55 mg, 89 μmol) as a pale brown powder. ^{1}H NMR (CD_2Cl_2): δ 1.35 (s, 9H), 2.75 (t, 2H, J = 6.00 Hz), 3.51 (m, 2H), 4.32 (br, 4H), 4.87 (m, 1H), 5.77 (br, 1H), 7.34 (d, 2H, J = 2.75 Hz), 7.52 and 7.68 (AB, 4H, J_{AB} = 9.00 Hz), 7.53 (dd, 2H, J = 4.25, 8.00 Hz), 8.16 (dd, 2H, J = 1.50, 8.00 Hz), 8.69 (d, 2H, J = 2.75 Hz), 8.93 (d, 1H, J = 6.75 Hz), 9.03 (dd, 2H, J = 1.50, 4.25 Hz).

3-Clip-Phen-butyl-Boc (3c). Yield = 90% (64 mg, 101 μmol) as a pale brown powder. ^{1}H NMR (CD_2Cl_2): δ 1.27 (s, 9H), 1.91 (m, 2H), 2.50 (t, 2H, J = 6.75 Hz), 3.20 (m, 2H), 4.36 (br, 4H), 4.87 (br, 1H), 7.48 (d, 2H, J = 2.50 Hz), 7.55 (dd, 2H, J = 4.25, 8.00 Hz), 7.61 and 7.73 (AB, 4H, J_{AB} = 9.00 Hz), 8.20 (dd, 2H, J = 1.75, 8.00 Hz), 8.39

(d, 1H, $J = 7.50$ Hz), 8.75 (d, 2H, $J = 2.50$ Hz), 9.05 (dd, 2H, $J = 1.75, 4.25$ Hz).

3-Clip-Phen-pentyl-Boc (3d). Yield = 90% (65 mg, 100 μmol) as a pale brown powder. ^{1}H NMR (CD_2Cl_2): δ 1.34 (s, 9H), 1.50 (m, 2H), 1.77 (m, 2H), 2.49 (t, 2H, $J =$ 7.25 Hz), 3.09 (m, 2H), 4.35 (br, 4H), 4.87 (br, 1H), 7.42 (d, 2H, $J = 3.00$ Hz), 7.53 (dd, 2H, $J = 4.25, 8.00$ Hz), 7.57 and 7.70 (AB, 4H, $J_{AB} = 8.75$ Hz), 8.17 (dd, 2H, $J =$ 1.75, 8.00 Hz), 8.36 (d, 1H, $J = 7.25$ Hz), 8.73 (d, 2H, J = 3.00 Hz), 9.04 (dd, 2H, $J = 1.75, 4.25$ Hz).

3-Clip-Phen-hexyl-Boc (3e). Yield = 83% (61 mg, 93 μmol) as a pale brown powder. ^{1}H NMR (CD_2Cl_2): δ 1.36 (s, 9H,), 1.41 (br, 4H), 1.73 (m, 2H), 2.43 (t, 2H, $J = 7.50$ Hz), 3.02 (m, 2H), 4.39 (br, 4H), 4.80 (br, 1H), 4.87 (br, 1H), 7.47 (d, 2H, $J = 3.00$ Hz), 7.55 (dd, 2H, $J = 4.25$, 8.00 Hz), 7.60 and 7.72 (AB, 4H, $J_{AB} = 9.00$ Hz), 8.13 (d, 1H, $J = 7.75$ Hz), 8.19 (dd, 2H, $J = 1.75, 8.00$ Hz), 8.76 (d, 2H, $J = 3.00$ Hz), 9.04 (dd, 2H, $J = 1.75, 4.25$ Hz).

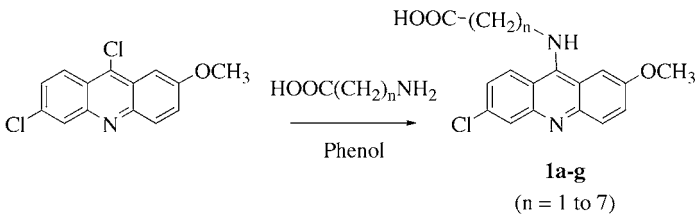
General Procedure for the Preparation of 3-Clip-Phen-acridine Conjugates (4a−h). Method A (for the preparation of 4e, 4f, and 4g). Chloroform was dried on basic alumina. The carboxylic derivative (0.28 mmol) of acridine (**1e**, **1f**, or **1g**) was dissolved in $CHCl_3$ (2 mL) at room temperature, and Et_3N (39 μL, 0.28 mmol) and ethyl chloroformate (26 μL, 0.28 mmol) were then added. After the reaction was stirred for 2 h at 70 °C, the solvent was evaporated. The residue was dissolved in $CHCl_3$ (2 mL), Et_3N (39 μL, 0.28 mmol) and 3-Clip-Phen (50 mg, 0.11 mmol) were added, the solution was stirred overnight at room temperature, and then the solvent was evaporated. The crude product was purified by column chromatography on silica gel eluted with CH_2Cl_2/CH_3OH (7/3). A second column, eluted with CH_2Cl_2/CH_3OH (95/5) containing 0.5% of concentrated NH_4OH, was used to remove the residual unreacted 3-Clip-Phen.

Method B (for the preparation of 4a, 4b, 4c, 4d). The syntheses were optimized from ref 23.

3-Clip-Phen-Boc derivative (1 equiv) was dissolved in 4 mL of CF_3COOH/CH_2Cl_2 (1/3, v/v), the solution was stirred for 1 h at room temperature, and then the solvent was evaporated. The residue was dissolved in acetonitrile (3 mL), 6-chloro-2-methoxy-9-phenoxyacridine (2 equiv) and acetic acid (5 equiv) were added, the solution was heated at reflux for 16 h, and then the solvent was evaporated. Crude product was triturated in diethyl ether, and solvent was evaporated (2×). It was then dissolved in CH_2Cl_2 and precipitated with diethyl ether before purification by chromatography on silica gel as follows: the acridine derivatives were eluted with CH_2Cl_2/CH_3OH (95/5), and then a gradient up to CH_2Cl_2/CH_3OH (80/20) was realized to elute 3-Clip-Phen-acridine conjugate. Concentrated NH_4OH (0.5%) was added to the gradient in the case of conjugates **4c** and **4d**. A supplementary step, consisting of a precipitation with acetone of conjugates **4a** and **4b** (eluted without NH_4OH) dissolved in CH_3OH alkalinized with few drops of concentrated NH_4OH, was necessary to obtain conjugates in nonprotonated form.

3-Clip-Phen-ethyl-chloromethoxyacridine (4a) was prepared from 51 mg (84 μmol) of **3a** to give **4a** (42 mg, 56 μmol, yield = 67%) as a yellow powder. ^{1}H NMR (CD_2Cl_2): δ 3.22 (s, 3H), 4.25 (br, 4H), 4.70 (d, 2H, $J = 4.75$ Hz), 4.95 (br, 1H), 6.76 (dd, 1H, $J = 2.00, 9.25$ Hz), 6.99 (dd, 1H, $J = 2.00, 9.50$ Hz), 7.13 (d, 1H, $J = 2.00$ Hz), 7.19 (d, 2H, $J = 2.50$ Hz), 7.41 and 7.59 (AB, 4H, $J_{AB} =$ 9.00 Hz), 7.45 (dd, 2H, $J = 4.25, 8.00$ Hz), 7.64 (d, 1H, J = 9.50 Hz), 7.73 (d, 1H, $J = 2.00$ Hz), 7.84 (d, 1H, $J =$ 9.25 Hz), 8.09 (dd, 2H, $J = 1.50, 8.00$ Hz), 8.40 (d, 2H, J = 2.50 Hz), 8.90 (dd, 2H, $J = 1.50, 4.25$ Hz), 10.01 (d, 1H, $J = 7.50$ Hz). MS m/z (DCI NH_3): 746 (MH^+, 6%), 550 (68), 259 (100).

3-Clip-Phen-propyl-chloromethoxyacridine (4b) was prepared from 55 mg (89 μmol) of **3b** to give **4b** (34 mg, 45 μmol, yield = 50%) as a yellow powder. ^{1}H NMR (CD_2Cl_2): δ 2.95 (m, 2H), 3.84 (s, 3H), 4.06 (m, 2H), 4.26 (br, 4H), 4.97 (m, 1H), 6.27 (br, 1H), 7.09 (dd, 1H, $J =$ 2.25, 9.50 Hz), 7.23 (d, 2H, $J = 2.75$ Hz), 7.25 (dd, 1H, J = 2.25, 9.50 Hz), 7.43 (d, 1H, $J = 2.25$ Hz), 7.47 and 7.65 (AB, 4H, $J_{AB} = 9.00$ Hz), 7.48 (dd, 2H, $J = 4.25, 8.00$ Hz), 7.82 (d, 1H, $J = 9.50$ Hz), 7.88 (d, 1H, $J = 2.25$ Hz), 8.08 (d, 1H, $J = 9.50$ Hz), 8.13 (dd, 2H, $J = 1.50, 8.00$ Hz), 8.45 (d, 2H, $J = 2.75$ Hz), 8.92 (dd, 2H, $J = 1.50$, 4.25 Hz) 9.68 (d, 1H, $J = 7.25$ Hz). MS m/z (DCI NH_3): 760 (MH^+, 14%), 564 (100).



3-Clip-Phen-butyl-chloromethoxyacridine (4c) was prepared from 64 mg (101 μmol) of **3c** to give **4c** (42 mg, 54 μmol, yield = 54%) as a yellow powder. ^{1}H NMR (CD_2Cl_2): δ 2.19 (m, 2H), 2.85 (t, 2H, $J = 6.00$ Hz), 3.85 (m, 5H), 4.22 (m, 4H), 4.90 (m, 1H), 6.97 (dd, 1H, $J = 2.50$, 9.25 Hz), 7.14 (d, 2H, $J = 2.75$ Hz), 7.17 (dd, 1H, $J =$ 2.00, 9.25 Hz), 7.43 and 7.65 (AB, 4H, $J_{AB} = 9.00$ Hz), 7.49 (dd, 2H, $J = 4.25, 8.00$ Hz), 7.75 (d, 1H, $J = 9.25$ Hz), 7.80 (d, 1H, $J = 2.00$ Hz), 8.06 (d, 1H, $J = 9.25$ Hz), 8.14 (dd, 2H, $J = 1.75, 8.00$ Hz), 8.53 (d, 2H, $J = 2.75$ Hz), 8.95 (dd, 2H, $J = 1.75, 4.25$ Hz), 9.46 (d, 1H, $J =$ 7.50 Hz). MS m/z (DCI NH_3): 774 (MH^+, 4%), 578 (100).

3-Clip-Phen-pentyl-chloromethoxyacridine (4d) was prepared from 65 mg (101 μmol) of **3d** to give **4d** (32 mg, 41 μmol, yield = 40%) as a yellow powder. ^{1}H NMR (CD_2Cl_2): δ 1.80 (m, 4H), 2.42 (t, 2H, $J = 6.00$ Hz), 3.68 (t, 2H, $J = 6.00$ Hz), 3.92 (s, 3H), 4.46 (m, 4H), 4.87 (m, 1H), 7.16 (dd, 1H, $J = 2.25, 9.25$ Hz), 7.32 (dd, 1H, $J =$ 2.50, 9.50 Hz), 7.35 (d, 1H, $J = 2.50$ Hz), 7.56 (dd, 2H, J = 4.25, 8.00 Hz), 7.59 (d, 2H, $J = 2.75$ Hz), 7.61 and 7.71 (AB, 4H, $J_{AB} = 9.00$ Hz), 7.82 (d, 1H, $J = 9.50$ Hz), 7.85 (d, 1H, $J = 2.25$ Hz), 8.04 (d, 1H, $J = 9.25$ Hz), 8.20 (dd, 2H, $J = 1.75, 8.00$ Hz), 8.80 (d, 2H, $J = 2.75$ Hz), 8.98 (dd, 2H, $J = 1.75, 4.25$ Hz). MS m/z (DCI NH_3): 788 (MH^+, 0.4%), 592 (100).

3-Clip-Phen-hexylchloromethoxyacridine (4e). Yield = 39% (34 mg, 43 μmol) as a yellow powder. ^{1}H NMR (CD_2Cl_2): δ 1.45 (m, 2H), 1.67 (m, 2H), 1.78 (m, 2H), 2.47 (t, 2H, $J = 7.25$ Hz), 3.54 (t, 2H, $J = 7.00$ Hz), 3.76 (s, 3H), 4.25 (m, 4H), 4.83 (m, 1H), 7.04 (dd, 1H, J = 2.00, 9.50 Hz), 7.14 (d, 1H, $J = 2.50$ Hz), 7.23 (dd, 1H, $J = 2.50, 9.50$ Hz), 7.26 (d, 2H, $J = 2.75$ Hz), 7.43 and 7.61 (AB, 4H, $J_{AB} = 9.00$ Hz), 7.48 (dd, 2H, $J = 4.25$, 8.00 Hz), 7.80 (d, 1H, $J = 9.50$ Hz), 7.85 (d, 1H, $J = 2.00$ Hz), 7.88 (d, 1H, $J = 9.50$ Hz), 8.11 (dd, 2H, $J = 1.50$, 8.00 Hz), 8.47 (d, 1H, $J = 7.25$ Hz), 8.65 (d, 2H, $J = 2.75$ Hz), 8.97 (dd, 2H, $J = 1.50, 4.25$ Hz). MS m/z (DCI NH_3): 802 (MH^+, 5%), 606 (100).

3-Clip-Phen-heptylchloromethoxyacridine (4f). Preparation of Cyclic Derivatives (5c and 5d). Chloroform was dried on basic alumina. Carboxylic derivative of acridine **1c** or **1d** (0.28 mmol) was dissolved in $CHCl_3$ (2 mL) at room temperature, and then Et_3N (39 μL, 0.28 mmol) and ethyl chloroformate (26 μL, 0.28 mmol) were added. After the reaction was stirred for 5 h at 70 °C, the solvent was removed under vacuum, and the residue was purified by column chromatography on silica gel eluted with CH_2Cl_2/CH_3OH (95/5) containing 0.5% of concentrated NH_4OH to afford the product.

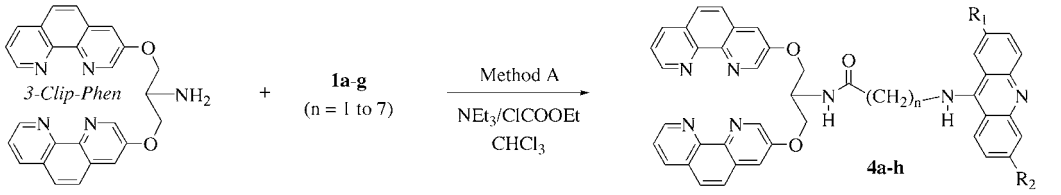
(Cyclopentyl-9-amido)-6-chloro-2-methoxyacridine (5c). Yield = 73% (68 mg, 0.20 mmol) as a yellow powder, 73%. ^{1}H NMR (CD_2Cl_2): δ 2.51 (m, 2H), 2.82 (t, 2H, J = 8.25 Hz), 3.95−4.06 (m, 2H), 3.98 (s, 3H), 6.97 (d, 1H, J = 2.75 Hz), 7.51 (dd, 1H, J = 2.75, 9.50 Hz), 7.53 (dd,1H, J = 2.00, 9.25 Hz), 7.80 (d, 1H, J = 9.25 Hz), 8.12 (d, 1H, J = 9.50 Hz), 8.22 (d, 1H, J = 2.00 Hz). MS *m/z* (DCI NH_3): 327 (MH^+, 100%).

(Cyclohexyl-9-amido)-6-chloro-2-methoxyacridine (5d). Yield = 33% (31 mg, 0.09 mmol) as a yellow powder. ^{1}H NMR (CD_2Cl_2): δ 2.17 (m, 4H), 2.78 (br, 2H), 3.66 (m, 2H), 3.98 (s, 3H), 6.99 (d, 1H, J = 2.75 Hz), 7.50 (dd, 1H, J = 2.75, 9.50 Hz), 7.52 (dd,1H, J = 2.00, 9.25 Hz), 7.83 (d, 1H, J = 9.25 Hz), 8.10 (d, 1H, J = 9.50 Hz), 8.21 (d, 1H, J = 2.00 Hz). MS *m/z* (DCI NH_3): 341 (MH^+, 100%).

DNA Cleavage Experiments. Metalations by $CuCl_2$ of the different ligands were performed by using 1 equiv of the desired ligand in a DMF/water mixture (2/3, v/v, the final copper concentration being 1 mM) during 2 h at room temperature. These stock solutions of complexes were diluted with water at the desired concentration just before use.



To 10 μL of ΦX174 DNA (7 nM, 40 μM in base pair) in 80 mM Tris-HCl buffer (pH 7.2), 100 mM NaCl, and 20 mM $MgCl_2$ was added 5 μL of the desired complex (0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, or 0.8 μM). After 30 min at room temperature, DNA cleavage was initiated by addition of a freshly prepared aqueous solution of sodium ascorbate (5 μL, 400 μM), and samples were incubated for 1 h at 37 °C. A 7.5 μL amount of a solution of 50% (v/v) glycerol/40 mM Tris-HCl buffer (pH 8.0) and 0.05% bromophenol blue (w/v) was then added, and samples were immediately loaded on agarose gel (0.8%) containing 1 μg/mL of ethidium bromide. Electrophoresis was run at constant current (25 mA for 15 h) in Tris/borate/EDTA (TBE) buffer. Bands were located by UV light (254 nm), photographed, and quantified by microdensity. The correction coefficient 1.47 was used for the decrease of stainability of form I DNA versus forms II and III (*27*).

RESULTS AND DISCUSSION

Synthesis. To enhance the cell delivery, the DNA affinity, and DNA cleavage activity of 3-Clip-Phen, we have prepared different conjugates with acridine and 6-chloro-2-methoxyacridine intercalators. The acridine derivative was fixed through an amino acid linker of different length on the primary amine of 3-Clip-Phen (*4*) in order to analyze the influence of this linker on the reactivity of the conjugates. We chose an aliphatic linker, and its length was modulated by incorporation of methylene units in order to facilitate the conformational flexibility between the acridine and 3-Clip-Phen entities of the molecule and thus the interaction of the two parts of the conjugate with the DNA target. Two synthetic routes were explored in order to optimize their preparation.

Method A was first used since it involved only two steps. In the first step 6,9-dichloro-2-methoxyacridine was activated as the phenoxyacridine derivative. Then, in a one-pot reaction, an aromatic nucleophilic substitution of the phenoxy group by the primary amine of the amino acid linker produced the acridine derivative **1a**−**g** functionalized by a carboxylic group (Figure 1). The second step consisted of activation of the carboxylic acid by ethyl chloroformate and coupling the resulting activated ester with the primary amine of 3-Clip-Phen through an amide function (Figure 2).

This method appeared to be efficient, with a yield of around 40%, for the preparation of 3-Clip-Phen-acridine conjugates **4e**−**g**, with 5 to 7 methylene groups between the acridine moiety and the 3-Clip-Phen entity of the conjugate. But several problems appeared during the preparation of conjugates with shorter arms of junction: (i) the acridine synthons with a long tether were generally obtained in good yields, but for a short linker (n = 1), the conversion of 6,9-dichloro-2-methoxyacridine into carboxylic derivative **1a** was poor and produced a mixture

Compound	R_1	R_2	n	Method A yield (%)	Method B yield (%)	Overall yield with respect to *3-Clip-Phen* (%)

Figure 2. Two methods for the synthesis of 3-Clip-Phen-acridine conjugates. a: Method A resulted in only a poor overall yield with respect to 3-Clip-Phen since **1a** was obtained in poor yield. b: **1c** and **1b** precursors were quantitatively converted to the corresponding cyclic derivatives. c: From method B. d: **4e** can be obtained in similar overall yield with respect to 3-Clip-Phen from method B.

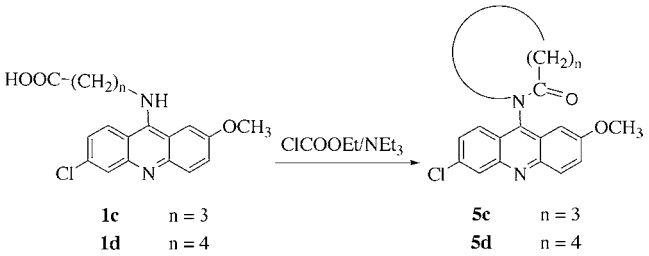

Figure 3. Formation of cyclic derivatives of 6-chloro-2-methoxyacridine.

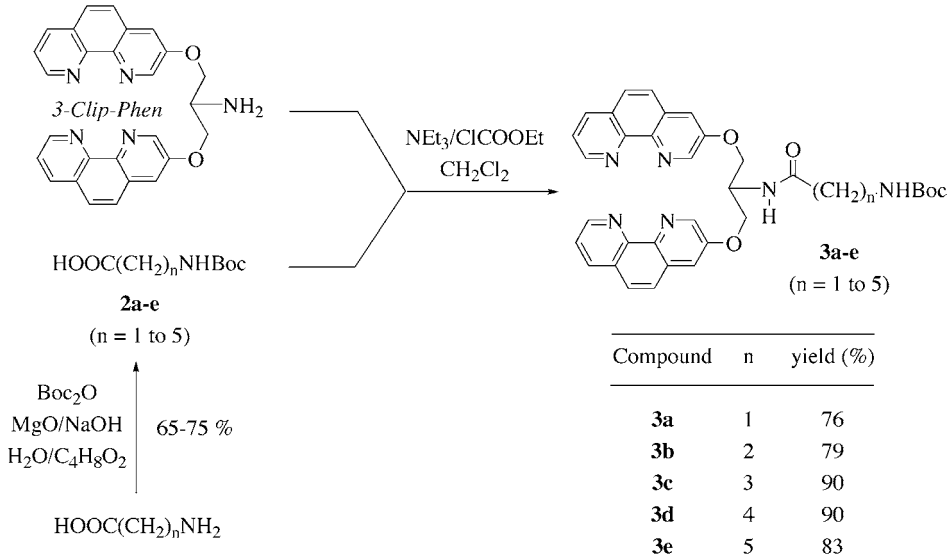
of acridine derivatives difficult to purify; (ii) the conjugation of the carboxylic derivatives **1c** and **1d** with 3-Clip-Phen was totally inefficient because the acridine derivatives were transformed into new products identified as being the cyclic derivatives **5c** and **5d**, respectively (Figure 3). To confirm this phenomenon, **1c** or **1d** was incubated with ethyl chloroformate: they were converted into cyclic derivatives **5c** and **5d** by intramolecular coupling between the activated carboxylic function and the amine of the acridine derivative. The formation of the five- or six-membered ring was sterically and thermodynamically favored in comparison to the intermolecular reaction with the primary amine of 3-Clip-Phen. Consequently the synthesis of **4c** or **4d** with the method A was totally inefficient. This last interpretation was confirmed by attempts to activate **1c** or **1d** by (benzotriazol-1-yloxy)tris(dimethylamino)phosphonium (BOP) directly in the presence of 3-Clip-Phen: **5c** or **5d** were again the major reaction products, and the conjugation was inefficient.



To overcome these difficulties, we considered another way of synthesis for the conjugates. Thus compounds **4a**−**e** were prepared with the more step-demanding method B (Figure 2). The primary amine function of the amino acid linker was first protected as a Boc-derivative to prevent the possibility of intramolecular amidification or its polymerization during the activation of the carboxylic acid. Then the amino acid linker was conjugated on 3-Clip-Phen to generate the protected 3-Clip-Phen derivatives **3a**−**e** in good yields (Figure 4). The Boc-protecting group was removed through acid hydrolysis. Then the free primary amine produced the aromatic nucleophilic substitution of the phenoxy group of 9-phenoxy-6-chloro-2-methoxyacridine derivative to generate the 3-Clip-Phen−acridine conjugates (Figure 2).

We compared the overall yield with respect to the starting 3-Clip-Phen in the preparation of conjugates **4a**−**g** (table of Figure 2). In all cases 50 mg of 3-Clip-Phen was used to facilitate this comparison. It appeared that methods A and B had roughly the same efficiency (around 40% overall yield). This result was confirmed in the case of conjugate **4e** which has been obtained by the two methods in similar yields. However, method B is more general and can be used for all arms of junction, but is more expensive and time-consuming than method A since this method requires five steps of synthesis. The 3-Clip-Phen-6-chloro-2-methoxyacridine conjugates were obtained from method A in only two steps.

The 3-Clip-Phen-acridine conjugate **4h** was also prepared in similar yield by method B (Figure 2) in order to study the influence of chloro and methoxy substituents on the DNA cleavage efficiency. An aminocaproic linker was used in **4h** since DNA cleavage experiments indicated that this tether led to higher DNA cleavage efficiency (see below).

DNA Cleavage. Ligands **4a**−**h** and 3-Clip-Phen have been metalated with 1 equiv of $CuCl_2$, and the DNA cleavage activity of the copper complexes obtained was evaluated. DNA cleavage was monitored by relaxation of supercoiled circular ΦX 174 DNA (form I) into nicked circular (form II) and linear (form III) conformations in 1 h at 37 °C. The redox activity of the Cu^{II} centers was initiated by addition of 100 μM ascorbate in the presence of air. Different concentrations of copper complexes have been tested.

Figure 5 shows a representative gel illustrating the relative reactivities of the different copper complexes at 100 nM concentration. In these experiments, the comparison of cleavage patterns of copper complexes of 6-chloro-2-methoxyacridine-3-Clip-Phen conjugates (compounds **4a**−**g**, lanes 6−12) allowed analysis of the influence of the length of the linker on the DNA cleavage efficiency. Since all the conjugates of this series were at the same concentration and differed only by the number *n* of methylene groups in the linker and since all values between $n = 1$ to 7 have been tested, a strict comparison

Figure 4. Synthesis of "3-Clip-Phen-arm-Boc" derivatives.

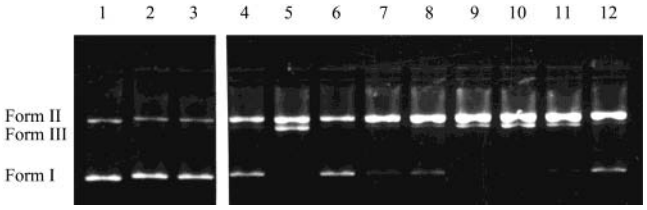

Figure 5. Comparison of DNA cleavage efficiency on ΦX 174 DNA (3.5 nM, 20 μM in bp) between copper complexes of 3-Clip-Phen and 3-Clip-Phen-acridine conjugates (**4a**−**h**) 100 nM. Reactions were done in the presence of ascorbate and air for 1 h in 40 mM Tris-HCl buffer (pH 7.2), 50 mM NaCl, 10 mM $MgCl_2$. Lane 1: Control $CuCl_2$. Lane 2: **4h** without ascorbate. Lane 3: **4e** without ascorbate. Lane 4: 3-Clip-Phen. Lane 5: **4h**. Lane 6: **4a**. Lane 7: **4b**. Lane 8: **4c**. Lane 9: **4d**. Lane 10: **4e**. Lane 11: **4f**. Lane 12: **4g**.

could be performed. Figure 5 shows that the residual percentage of DNA form I decreased (and thus that the quantity of cleaved DNA increased) when the length of the linker increased from $n = 1$ (**4a**−$CuCl_2$, lane 6) to $n = 5$ (**4e**−$CuCl_2$, lane 10). For the more active compounds, DNA form III could be also observed, its quantity being again higher in the case of DNA cleavage by **4e**−$CuCl_2$ ($n = 5$). It is reasonable to propose that conjugates with shortest linker ($n < 5$) are sterically constrained and therefore less efficient. But it is remarkable that copper complexes of conjugates with a larger arm of junction ($n > 5$) are also less efficient than **4e**−$CuCl_2$ since the residual percentage of form I increased again for $n = 6$ then 7 (conjugates **4f**−$CuCl_2$ and **4g**−$CuCl_2$, lanes 11 and 12, respectively), showing that the optimal linker was obtained for $n = 5$.

The influence of the chloro and methoxy substituents on the acridine part of the conjugates, with the same optimal linker with $n = 5$ and in the same cleavage conditions, was accessible (Figure 5) in comparing **4e**−$CuCl_2$ and **4h**−$CuCl_2$ (lanes 10 and 5, respectively). Both copper complexes cleaved all DNA form I which was transformed into form II and form III. However, the conjugate with the unsubstituted acridine was the more active since it produced more form III.

The cleavage pattern obtained for the same concentration of 3-Clip-Phen-$CuCl_2$ (lane 4, Figure 5) showed a residual form I, indicating that this parent ligand was less efficient than both **4e**−$CuCl_2$ and **4h**−$CuCl_2$ (Figure 5, lanes 10 and 5, respectively) and that the conjugation

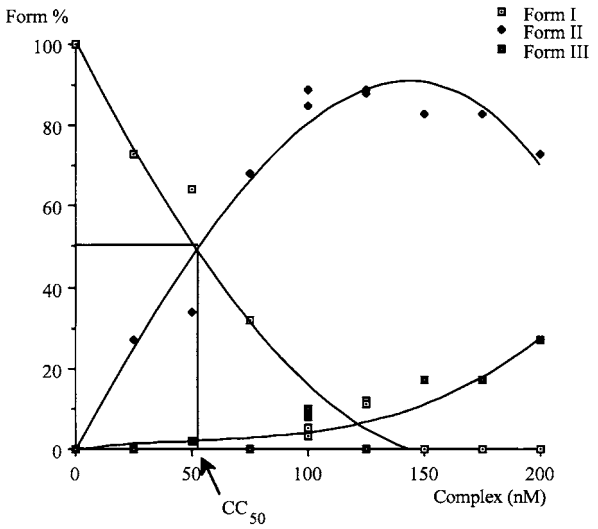

Figure 6. Example of determination of CC_{50} values: case of **4f**−$CuCl_2$.

of 3-Clip-Phen to an intercalator such as acridine had a positive effect on its DNA cleavage efficiency.

To quantify the nuclease activity of the different conjugates, DNA cleavage was also studied for different concentrations of all copper complexes. In all cases, the percentage of residual DNA form I decreased when the copper complex concentration increased, and form III appeared only when most of form I was transformed into form II. This result is in accordance to complexes producing single strand breaks on double stranded DNA, form III resulting from the accumulation of neighboring multi-single-strand breaks on form II. Figure 6 shows a typical example obtained for conjugate **4f**−$CuCl_2$.

Since the 3-Clip-Phen parent ligand has poor sequence selectivity (*5*), we tried to quantify the single-strand cleavage according to a random cleavage of the ΦX 174 DNA as in reference 28, but no linear relationship between the number of breaks and the concentration of copper complexes was observed in the case of the acridine conjugates. Other observations were also not in accordance to the fact that not all of these copper complexes cleaved DNA in a random fashion. For example, although low concentrations of copper complexes of **4a** and 3-Clip-Phen seemed to have roughly the same ability to cleave

Table 1. Comparative Efficiency of Copper Complexes of 3-Clip-Phen and 3-Clip-Phen−Acridine Conjugates (4a−f) on ΦX 174 DNA Cleavage. CC_{50} Values and Percentage of ΦX 174 DNA Forms I, II, and III Obtained after 1 h of Reaction of 45 nM of the Different Copper Complexes in the Presence of 100 μM Ascorbate

4e	CH_3O	Cl	5	45	50	50	0
4f	CH_3O	Cl	6	55	60	40	0
4g	CH_3O	Cl	7	75	75	25	0
4h	H	H	5	35	27	68	5
3-Clip-Phen	−	−	−	100	85	15	0
2-Clip-Phen conjugate	CH_3O	Cl	5	195	95	5	0

DNA form I, a higher percentage of form III was observed in the case of 3-Clip-Phen-$CuCl_2$ than in the case of **4a**-$CuCl_2$ at higher concentration (data not shown). This last result could reflect differences in the ability of the complexes to cleave supercoiled or relaxed DNA conformations, 3-Clip-Phen being perhaps more active than the acridine conjugates to cleave relaxed form II. Although there is little sequence selectivity for the intercalation of acridine derivatives (*24*), the presence and the position of the amide junction with 3-Clip-Phen could influence the interaction of the conjugates with DNA and consequently the cleavage pattern (*29*, *30*).

For these reasons, we chose to quantify the relative DNA cleavage efficiency of the different copper complexes through the classical determination of the concentration of chemical nuclease cleaving 50% of form I of ΦX174 DNA in 1 h at 37 °C (CC_{50} values, Table 1) (see references 31−35 for typical examples). Figure 6 illustrates the method of determination of the CC_{50} in the case of compound **4f**−$CuCl_2$. The advantage of using CC_{50} values is that they concern the same cleavage event and thus the comparison of the different copper complexes seemed easier. Data of Table 1 confirmed that (i) the conjugation of 3-Clip-phen-$CuCl_2$ (CC_{50} = 100 nM) to an acridine derivative generally increased the DNA cleavage efficiency, (ii) the optimized conjugate linker was obtained for $n = 5$ (CC_{50} = 45 nM for compound **4e**−$CuCl_2$ with five methylene groups in the arm of junction of the conjugate), (iii) conjugate with unsubtituted acridine **4h**−$CuCl_2$ (CC_{50} = 35 nM) was the more active DNA cleaver.

The determination of the CC_{50} has been also performed for the same acridine derivative and the same linker in the case of conjugates including 2-Clip-Phen, the less efficient isomer of 3-Clip-Phen (*23*). Table 1 shows that the conjugation to 3-Clip-Phen (compound **4e**−$CuCl_2$, CC_{50} = 45 nM) was more efficient than one with 2-Clip-phen (CC_{50} = 195 nM). This last result showed that the DNA cleavage efficiency of the copper complex was not only due to a better DNA affinity due to the presence of an acridine functionality in the conjugate but also to a higher nuclease activity of the 3-Clip-phen derivatives in comparison to 2-Clip-Phen derivatives.

However, it is remarkable to note that if the determination of CC_{50} values allowed easy comparison of the DNA cleavage efficiency between the different copper complexes, it cannot be used to quantify it. This problem is probably due to the fact that the overcleavage of DNA molecules is underestimated. This phenomenon appeared clearly in the comparison of the percentages of DNA form I, II, and III observed in the case of 45 nM of copper complexes (Table 1). This concentration was chosen since it is the CC_{50} of **4e**−$CuCl_2$, the more active 3-Clip-Phen-6-chloro-2-methoxyacridine conjugate observed in the optimization of the linker. Sometimes minor variation of the cleavage pattern, reflecting minor variation in the DNA cleavage activity, was observed for a small variation (10 nM) of the CC_{50} value, as is the case for the comparison of cleavage patterns of **4e**−$CuCl_2$ (CC_{50} = 45 nM) and **4d**−$CuCl_2$ or **4f**−$CuCl_2$ (CC_{50} = 55 nM). However, higher variations of the cleavage pattern, in particular the formation of DNA form III resulting from recleavage events, reflecting higher variation in the DNA cleavage activity, were observed during the comparison of the cleavage pattern of **4e**−$CuCl_2$ (CC_{50} = 45 nM) and **4h**−$CuCl_2$ (CC_{50} = 35 nM) although the difference of the CC_{50} values between these two compounds was again 10 nM.

CONCLUSION

Two methods of preparation of Clip-Phen−acridine conjugates have been described in the present report. These molecules incorporate in their structure different entities designed for specific functions: (i) an intercalator (acridine or 6-chloro-2-methoxyacridine) for cell penetration and DNA binding, (ii) a 2- or 3-Clip-Phen entity endowed with both binding and DNA cleavage functions, (iii) a flexible linker with an optimal length. The constitutive entities were modulated in these conjugates to get an insight to their mode of action and to prepare more active compounds. It appeared that the copper complex including 3-Clip-Phen, an aminocaproic linker, and acridine produced the most DNA cleavage. The next goal is to analyze the influence of acridine derivatives of the more active conjugates on the selective drug delivery of these potentially cytotoxic compounds within cells.

Received January 16, 2002; Revised Manuscript Received May 10, 2002

Among a variety of other factors, the clearance kinetics and routes of excretion of radiopharmaceuticals are of crucial importance for early and high tumor/background ratios and thus signal intensity in diagnostic imaging by single photon emission tomography (SPECT) or positron emission tomography (PET). To overcome the unfavorable pharmacokinetics of radiohalogenated octreotide analogues, we evaluated three carbohydrated conjugates of Tyr^3-octreotide (TOC). Glucose ([^{125}I]Gluc-TOC), maltose ([^{125}I]Malt-TOC), and maltotriose ([^{125}I]Mtr-TOC) derivatives of [^{125}I]TOC were synthesized via Maillard reaction and subsequent radioiodination. In cells transfected with sst1-sst5, I-Malt-TOC, and I-Mtr-TOC show sst-subtype binding profiles similar to I-TOC with high affinity for sst2. Comparative biodistribution studies 10, 30, and 60 min pi in nude mice bearing rat pancreatic tumor xenografts showed fast blood clearance for all glycosylated derivatives. Due to their markedly increased hydrophilicity, [^{125}I]Gluc-TOC and [^{125}I]Malt-TOC were mainly cleared via the kidneys, which led to a significant decrease in activity accumulation in liver and intestine (5.3 and 1.4 versus 10.6%ID/g for [^{125}I]TOC in the liver, 1.7 and 1.0 versus 3.8%ID/g for [^{125}I]TOC in the intestine 60 min pi). For all compounds, hydrophilicity and uptake in liver and intestines correlate. Uptake of the carbohydrate conjugates in the kidney was comparable. Compared to the parent compound, the accumulation of the carbohydrated compounds in sst-rich tissues (pancreas, adrenals) was increased by a factor of 1.5−3.5. While tumor uptake of [^{125}I]TOC (6.7 ± 2.6%ID/g), [^{125}I]Malt-TOC (5.3 ± 1.9%ID/g), and [^{125}I]-Mtr-TOC (4.9 ± 2.2%ID/g) at 30 min postinjection was comparable, accumulation of [^{125}I]Gluc-TOC was significantly increased (10.1 ± 2.8%ID/g at 30 min pi). Somatostatin receptor specificity of tumor uptake was confirmed by pretreatment, competition, and displacement experiments in vivo using 0.8 mg TOC/kg and γ-camera imaging. Glycosylation proved to be a powerful tool for the development of high affinity sst ligands with excellent excretion profiles and improved tumor accumulation.

INTRODUCTION

On the basis of the findings that many human tumors overexpress a variety of receptors for regulatory peptides and peptide hormones (*1*−*6*), neuropeptide receptor targeted diagnostic imaging and radiotherapy has become a major concept for the detection, localization, and therapeutic intervention of malignant neoplasms in Nuclear Medicine (*7*−*11*). For this purpose, a number of radiolabeled analogues of endogenous peptides are presently investigated and under preclinical evaluation: e.g., analogues of somatostatin (SS) (*9*, *12*, *13*), substance P (*14*), gastrin (*15*), bombesin (BB) (*16*), α-melanocyte stumulation hormone (α-MSH) (*17*, *18*), neurotensin (NT) (*19*), or vasoactive intestinal peptide (VIP) (*20*). The clinical potential of these tracers will rely, among a variety of other factors, such as high receptor affinity and selectivity, high metabolic stability, low nonspecific uptake, and high specific accumulation, upon two main factors with crucial importance for early and high tumor/background ratios, namely favorable blood clearance and excretion kinetics. New radiolabeling strategies mainly focus on improved in vivo stability against dehalogenation (e.g., *21*, *22*, *23*) or transchelation (e.g., *24*, *25*, *26*), fast and high yield radiolabeling, or basic aspects such as radiolabeling without affecting biological integrity (*27*, *28*) of the peptide investigated. However, peptide radiotracers often only suffer from disadvantages of less than optimal blood clearance, excretion pathways and nonspecific uptake (*29*, *30*).

Thus, to generate more adequate radioligands, the use and evaluation of suitable chemical tools with broad utility is recommended.

What are the demands for such a tool? To increase target-to-nontarget tissue ratio (tumor-to-nontumor ratio), the tracer should be rapidly cleared from the circulation. Furthermore, to reduce the whole body radiation exposure, the modification used should reduce hepatobiliary excretion. The tracer should be cleared via the kidneys. However, to avoid nephrotoxicity after application of therapeutic dosages, renal uptake should be minimized ([^{90}Y]DOTATOC) (*31*, *32*). Receptor affinity and selectivity should remain unchanged, and the modification used has to be compatible with the radiolabeling strategy, thus not affecting radiolabeling yield.

To influence receptor binding and enhance peptide delivery to the brain or spinal cord, attachment of carbohydrate groups to enkephalin peptides has been

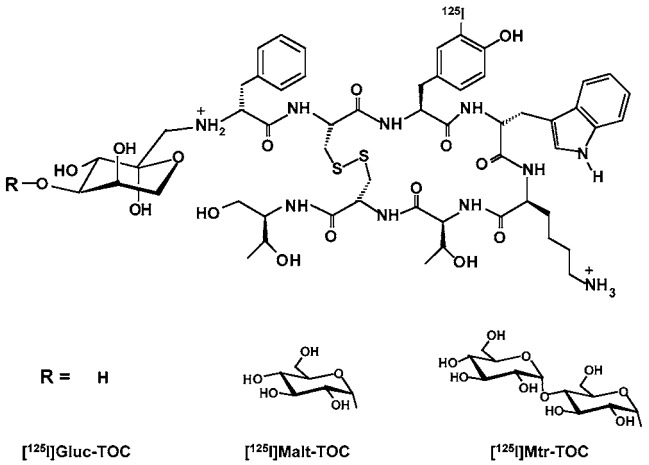

Figure 1. Structures of [125I]Gluc-TOC, [125I]Malt-TOC, and [125I]Mtr-TOC.

studied (*33*−*36*). It has been shown, that glycosyl groups, if properly placed, will preserve previously determined structure−activity relations (SAR) of the native peptides (*34*, *35*, *37*, *38*). Enkephalin analogues glycosylated in the near or at the C-terminus were shown to elicit prolonged and profound analgesia in mice (*34*, *35*). Furthermore it has been demonstrated, that the in vivo stability of an (N-linked) glycopeptide renin inhibitor is enhanced (*39*). Glucosyl, mannosyl, galactosyl, and 2-deoxy-glucosyl derivatives of Arg^8-vasopressin exhibited a sugar dependent renal uptake and intrarenal distribution (*40*). Glycosylated vasopressin analogues displayed an increased bioavailability resulting from absorption from the small intestine and most likely from an increased stability toward enzymatic degradation (*41*). Studies on the uptake of a glycosylated derivative of the tetrapeptide Gly-Gly-Tyr-Arg into brush border membrane vesicles and transport though the intestinal membrane has indicated increased resistance to aminopeptidases. Furthermore, the Na^+-dependent glucose transporter SGLT-1 played an important role in the intestinal absorption of both the α- and β-glucopyranoside derivative (*42*).

Recently, sugar-conjugated integrin antagonists have been investigated in our laboratory (*27*, *30*, *43*). It was shown that coupling of sugar amino acids significantly improves the pharmacokinetics of $\alpha_V\beta_3$-integrin antagonists (*27*, *43*). Furthermore we introduced radiolabeled carbohydrated octreotide analogues as a new series of somatostatin receptor (sst) binding radiotracers with excellent physicochemical characteristics (*44*−*48*).

The goal of the current study was to directly compare three carbohydrated conjugates of Tyr^3-octreotide (TOC), an agent previously evaluated for targeted imaging and radiotherapy of somatostatin receptor (sst) expressing tumors. The glucose ([125I]Gluc-TOC), maltose ([125I]Malt-TOC), and maltotriose ([125I]Mtr-TOC) derivatives of [125I]-TOC were synthesized via formation of an N-terminal N_α-glycosylamine with the respective aldose followed by Amadori rearrangement (*48*) and subsequent radioiodination (Figure 1).

The affinity profiles of I-Malt-TOC, I-Mtr-TOC and I-TOC were assessed in cells stably expressing sst1-sst5. We compared the effects of carbohydration on biodistribution in rat pancreatic tumor (AR42J) xenografted mice, particularly on hepatic uptake, biliary excretion, renal uptake, and tumor accumulation and demonstrate the suitablity of carbohydration to modify the physicochemical tracer characteristics in vivo by γ-camera imaging of tumor bearing mice. Specificity of tumor uptake was demonstrated in vivo by pretreatment, competition, and displacement experiments.

MATERIALS AND METHODS

Instrumentation. Analytic reversed phase high performance liquid chromatography (RP-HPLC) was performed using a Sykam gradient HPLC System (Sykam GmbH, Gilching, Germany) and a Nucleosil 100 C18 (5 mm, 250 × 4.0 mm) column. The peptides were eluted (if not stated otherwise in the text) applying a gradient of 10−60% B (solvent A: 0.1% TFA (trifluoro acetic acid) in H_2O, solvent B: 0.1% TFA in acetonitrile) in 30 min at a constant flow of 1 mL/min. UV-Detection was performed at 220 nm in a 206 PHD UV−Vis detector (Linear Instruments Corporation, Reno, NV).

Preparative RP-HPLC of all peptides was performed on the Sykam HPLC system using a Multospher 100 RP 18−5 (250 × 10 mm) column at a constant flow of 5 mL/min.

Mass spectra were recorded on the LC-MS system LCQ from Finnigan (Bremen, Germany) using the Hewlett-Packard series 1100 HPLC system.

Sample preparation for peptide sequence analysis was performed according to the following protocol:

For reduction of the disulfide bridge, 1 nmol of the synthetic peptide was dissolved in 5 μL of 10 mM NH_4HCO_3 containing 10 mM dithiothreitol and incubated at 56 °C for 30 min. The reduced peptide (10 pmol) was desalted over a POROS R2 microcolumn (Perseptive, Framingham, MA), packed in a GELoader Tip (Eppendorf, Hamburg, Germany), and eluted with 1 μL of 5% formic acid/60% methanol directly into the nanoelectrospray needle (MDS Proteomics, Odense, Denmark).

All experiments were performed on a QSTAR Pulsar quadrupole time-of-flight tandem mass spectrometer (AB/MDS Sciex, Toronto, Canada) equipped with a nanoelectrospray ion source (MDS Proteomics). The MS experiments were performed in the positive ion mode. Nitrogen was used as the collision gas at a pressure of 5.3×10^{-5} Torr. Peptide fragmentation data are listed according to the Roepstorff−Fohlmann−Biemann nomenclature (Figure 2).

Purification of all radioiodinated peptides was carried out on a J'Sphere R&D ODS−H80 (4 mm, 150 × 4.6 mm, 80A) column using a Sykam HPLC system connected to a UVIS 200 Photometer (Linear Instruments Corporation, Reno, NV) using a gradient of 10−60% B in 15 min. For radioactivity measurement, the outlet of the UV-photometer was connected to a NaI(Tl) well-type scintillation counter from EG&G (München, Germany).

Radioactivity measurements for the determination of lipophilicity and biodistribution assays were performed on a 1480 Wizard 3 gamma counter from Wallac (Turku, Finland).

Reagents. Fmoc-(9-fluorenylmethoxycarbonyl) amino acids as well as the DHP−HM (3,4-Dihydro-2*H*-pyran-2-ylmethoxymethylpolystyrene) resin were purchased from novabiochem (Bad Soden, Germany). IodoGen (1,3,4,6-tetrachloro-3α,6α-diphenylglycoluril) came from Pierce (Rockford, IL). N.c.a. [125I]NaI and [123I]NaI were supplied by Amersham (Buckinghamshire, UK). All other organic reagents were purchased from Merck Eurolab (Darmstadt, Germany), Alexis (Grünberg, Germany), Aldrich, or Fluka (Neu-Ulm, Germany).

Synthesis of the Glycosylated Derivatives of Tyr^3-Octreotide. *Reduction of Fmoc-Thr(tBu)-OH to the Corresponding Amino Alcohol (49).* A solution of Fmoc-Thr(tBu)-OH (1.391 g, 3.5 mmol) in 30 mL of THF

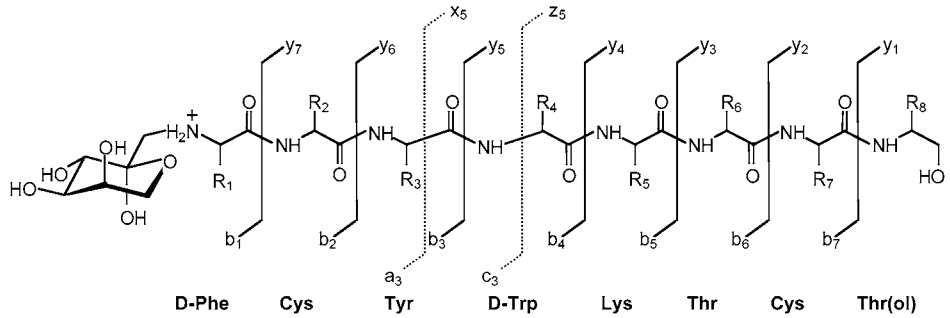

Figure 2. Fragmentation scheme and fragment nomenclature for Tyr³-octreotide and Gluc-Tyr³-octreotide in MS/MS-sequence analysis. Data are given in Tables 1 and 2.

(tetrahydrofuran) was cooled to −10 °C. *N*-Methylmorpholine (386 μL, 3.5 mmol) and ethyl chloroformate (333 μL, 3,5 mmol) were added successively. The reaction mixture was stirred at −10 °C for 30 min. Then $NaBH_4$ (396 mg,10.5 mmol) was added. Over a period of 30 min, 60 mL of MeOH (methanol) were slowly added to the reaction mixture, which was then stirred at 0 °C for 3 h.

After adding 50−70 mL of 1 N HCl (the cloudy reaction mixture has to become transparent), the organic solvents were evaporated and the remaining aequous phase was extracted twice with DCM (dichloromethane). The combined organic layers were dried over $MgSO_4$ and evaporated to dryness. The crude product, a yellowish oil, was purified by flash chromatography (ethyl acetate). Yield: 94%.

Calculated monoisotopic mass for $C_{23}H_{29}NO_4 = 383.21$; found: $m/z = 406.1$ $[M + Na]^+$ ^1H NMR ($CDCl_3$): δ(ppm) 1.16 (3H, d, $J = 6.2$ Hz, CH*CH₃*), 1.20 (9H, s, ^{t}Bu), 2.88 (1H, broad, OH), 3.61 (1H, broad, C*H*CH₂OH), 3.66 (2H, broad, CHC*H₂*OH), 3.94 (1H, m, C*H*CH₃), 4.22 (1H, t, $J = 6.8$ Hz, C*H*CH₂CO), 4.40 (2H, m, CHC*H₂*CO), 5.28 (1H, d, $J = 7.5$ Hz, N*H*), 7.30 (2H, d, $J = 7.4$ Hz, aromatics), 7.38 (2H, t, $J = 7.2$ Hz, aromatics), 7.59 (2H, d, $J = 7.4$ Hz, aromatics), 7.74 (2H, d, $J = 7.4$ Hz, aromatics).

SPPS of Tyr³-Octreotide (TOC) (50). DHP−HM-resin (1.000 g, load: 0.94 mmol linker/g) was allowed to preswell in 10 mL of dry DCE (1,2-dichloroethane) for 1 h. Then a solution of Fmoc-Thr(tBu)-ol (1.266 g, 3.3 mmol) and of pyridinium-*p*-toluenesulfonate (414 mg, 1.75 mmol) in 7 mL of abs. DCE was added, and the reaction mixture was stirred overnight at 80 °C under argon. To cap free functional groups on the resin, 5 mL of pyridine was added, and the suspension was stirred for another 15 min at RT. The loaded resin was then filtered off, washed twice with DMF (*N*,*N*-dimethylformamide) and DCM, respectively, and dried in vacuo. Synthesis of the peptide sequence Cys(Trt)−Thr(tBu)−Lys(Boc)−DTrp−Tyr−Cys(Trt)−DPhe−NH_2 on the resin-bound amino alcohol was performed according to Standard Fmoc-protocol using 1.5 equiv of HOBt (1-hydroxybenzotriazole) and TBTU (*O*-(1*H*-benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate) as coupling reagents.

After removal of the N-terminal Fmoc protection-group with 20% piperidine in DMF, the peptide was cleaved from the resin using a mixture of 95% TFA/2.5% TIBS (triisobutylsilane)/2.5% H_2O and DCM (1:1). After 90 min, the resin was filtered and washed twice with DCM. The combined filtrates were concentrated in vacuo, and the crude product was precipitated with Et_2O (diethyl ether).

Cyclization of TOC. The crude peptide was resuspended in 50 mL of THF (per 300 mg of peptide), and 5 mM NH_4OAc was added, until a clear solution was obtained. The pH was adjusted to 7 by dropwise addition of saturated $NaHCO_3$ solution. Then 100 μL (per 300 mg of peptide) of H_2O_2 (30%) were added. After 30 min of stirring at room temperature cyclization was complete (gradient HPLC control: 30→80% B in 30 min). The solvents were evaporated, and the cyclized product was lyophilized. Purification was performed using preparative gradient RP-HPLC.

Table 1. Fragmentation of Tyr³-Octreotide in MS/MS-sequence Analysis. Fragment Nomenclature and Fragmentation Schemes Are Given in Figure 2

b_7	$[C_{45}H_{58}N_9O_9S_2]^+$	932.38	932.36
$[M + 2H]^{2+}$	$[C_{49}H_{70}N_{10}O_{11}S_2]^+$	519.23	519.22

HPLC (10→60% in 30 min): t_R (linear peptide) = 14.1 min; $K' = 4.96$; t_R (cyclic peptide) = 12.9 min; $K' = 4.48$; Calculated monoisotopic mass for TOC ($C_{49}H_{66}N_{10}O_{11}S_2$) = 1034.49; found: $m/z = 1035.2$ $[M + H]^+$; the fragmentation of Tyr³-octreotide (linear) in MS/MS-sequence analysis is shown in Table 1.

Boc Protection of the Lys⁵-Side Chain. The peptide was redissolved in DMF (1 mL/100 mg). After the addition of 1.1 equiv (with respect to free Lys-N_ϵ-amino groups in the peptide) of Boc_2O (di-*tert*-butyl dicarbonate) in DMF, the solution was stirred at RT for 30 min. The protected peptide was precipitated by the addition of Et_2O, washed with Et_2O, and dried in vacuo.

HPLC (30→80% in 30 min): $t_R = 10.94$ min; $K' = 3.63$; calculated monoisotopic mass for $C_{54}H_{74}N_{10}O_{13}S_2$ = 1134.49; found: $m/z = 1135.3$ $[M + H]^+$.

Conjugation with Carbohydrates. On the basis of a method reported previously (*51*), 1 equiv of Lys⁵(Boc)-TOC and 10 equiv of the respective aldose (glucose, maltose, maltotriose) were dissolved in methanol/acetic acid (95/5 (v/v)), and the reaction mixture was stirred at 60°C for 24−48 h. The solvents were then evaporated, and the crude product was precipitated by the addition of Et_2O.

Boc Deprotection. A solution of protected peptide in TFA/H_2O/TIBS (95:2,5:2,5 (v/v/v); 1 mL/100 mg) was stirred at RT for 15−60 min. The deprotected peptide was precipitated by the addition of Et_2O, washed with Et_2O,

and dried in vacuo. Purification was carried out using preparative gradient RP-HPLC.

Gluc-TOC: HPLC (10→60% in 30 min): $t_R = 13.1$ min; $K' = 4.13$; calculated monoisotopic mass for $C_{55}H_{76}N_{10}O_{16}S_2 = 1196.5$, found: $m/z = 1197.1\ [M + H]^+$, 1219.7 $[M + Na]^+$.

Fragmentation of Gluc-TOC (linear) in MS/MS-sequence analysis is shown in Table 2.

Malt-TOC: HPLC (10→60% in 30 min): $t_R = 12.56$ min; $K' = 3.85$; calculated monoisotopic mass for $C_{61}H_{86}N_{10}O_{21}S_2 = 1358.54$, found: $m/z = 1359.1\ [M + H]^+$.

Mtr-TOC: HPLC (10→60% in 30 min): $t_R = 13.07$ min; $K' = 3.78$; calculated monoisotopic mass for $C_{67}H_{96}N_{10}O_{26}S_2 = 1520.59$, found: $m/z = 1521.1\ [M + H]^+$.

Radioiodination. TOC, Gluc-TOC, Malt-TOC, and Mtr-TOC were labeled with ^{125}I (or ^{123}I for γ-camera imaging) using the IodoGen method. A solution of 100−500 μg of peptide in 200 μL of PBS (phosphate-buffered saline, pH 7.4) was transferred to an Eppendorf cap coated with 150 μg of IodoGen. A 5−10 μL (18−37 MBq) amount of n.c.a. [^{125}I]NaI (specific activity > 2000 Ci/mmol) or c.a. [^{123}I]NaI (specific activity ∼5000 Ci/mmol) was added. The labeling reaction was allowed to proceed for 20 min at RT. The peptide solution was then removed from the insoluble oxidizing agent. Separation of the labeled products was achieved using gradient RP-HPLC. For biodistribution experiments, the collected fraction was evaporated to dryness, and the residue was redissolved in PBS to yield a solution of radiolabeled peptide with an activity concentration of about 370 kBq/100 μL.

Determination of Lipophilicity. To a solution of approximately 2 kBq of radiolabeled peptide in 500 μL of PBS (pH 7.4) was added 500 μL of octanol ($n = 6$). Vials were vortexed vigorously for 3 min. To achieve quantitative phase separation, the vials were centrifuged at 14600*g* for 6 min in a Biofuge 15 (Heraeus Sepatech, Osterode, Germany). The activity concentrations in 100 μL samples of both the aequous and the organic phase were measured in a γ-counter. Both the partition coefficient P_{ow}, which is defined as the molar concentration ratio of a single species A between octanol and water at equilibrium, and log P_{ow}, which is an important parameter used to characterize lipophilicity of a compound (*52*), were calculated.

Determination of the Affinity Profiles to hsst. Cells stably expressing human sst_1, sst_2, sst_3, sst_4, and sst_5 were grown as described previously (*53*). All culture reagents were supplied by GIBCO/BRL and Life Technologies (Grand Island, NY). Cell membrane pellets were prepared, and receptor autoradiography was performed on pellet sections (mounted on microscope slides), as described in detail previously (*53*). For each of the tested compounds, complete displacement experiments were performed with the universal somatostatin radioligand ^{125}I-[Leu^8,D-Trp^{22},Tyr^{25}]-somatostatin 28 using increasing concentrations of the unlabeled peptide ranging from 0.1 to 1000 nM. Somatostatin 28 was run in parallel as control using the same increasing concentrations. IC_{50} values were calculated after quantification of the data using a computer-assisted image processing system. Tissue standards (autoradiographic [^{125}I]microscales Amersham), containing known amounts of isotopes, cross-calibrated to tissue equivalent ligand concentrations, were used for quantification (*53*).

Tumor Xenografts. AR42J is a rat pancreatic acinar tumor cell line with high somatostatin receptor (sst_2) expression (*54*) and was obtained from ECACC (European Collection of Cell Cultures, Salisbury, UK). Cells were maintained in RPMI 1640 medium supplemented with 10% FCS (Biochrom Seromed (Berlin, Germany)) and 2 mM L-glutamine (Gibco BRL Life Technologies (Karlsruhe, Germany)) at 37 °C and 5% CO_2.

Animal Model. For all in vivo experiments, nude mice (CD1 nu/nu, male and female, 6−8 weeks) were used. To establish tumor growth, subconfluent monolayer cells were treated with 1 mM EDTA in PBS, suspended, centrifuged, and resuspended in serum free RPMI 1640. Mice were inoculated subcutaneously in the flank with 2.5−3 × 10E6 cells. Ten days postinoculation all mice showed solid palpable tumor masses (tumor weight 150−500 mg) and were used for the experiments.

Biodistribution Studies. About 370 kBq (10 μCi) of the ^{125}I-labeled peptides in 100 μL of PBS (pH 7.4) were injected intravenously (iv) into the tail vein of nude mice bearing an AR42J tumor. The animals were sacrificed 10, 30, and 60 min postinjection (pi) ($n = 5$), and the organs of interest were dissected. The radioactivity was measured in weighted tissue samples using a γ-counter. Data are expressed in %ID/g tissue (mean ± SD).

Pretreatment, Coinjection, and Displacement Studies. For pretreatment studies, 0.8 mg/kg Tyr³-octreotide (20 μg/mouse) was injected iv into the tail vein as a 100 μL bolus 10 min prior to the injection of 370 kBq (10 μCi) of radioligand in 100 μL of PBS. Coinjection was performed injecting a solution of radioligand and 0.8 mg/kg Tyr³-octreotide (20 μg/mouse) in 100 mL of PBS. For displacement studies, 0.8 mg/kg Tyr³-octreotide (20 μg/mouse) were administered 10 min after the injection of the radioiodinated tracer. All animals were sacrificed 30 min pi of the radioligand. Subsequent determination of the activity accumulation in all organs of interest was performed as described above (biodistribution studies).

γ-Camera Imaging. The ^{123}I-labeled peptides (3.7 MBq (100 μCi) in 100 mL of PBS (pH 7.4)) were injected iv into the tail vein of nude mice bearing an AR42J tumor. Mice were euthanized at 120 min pi of the radioligand. Acquisition of γ-camera images was performed on a Siemens Diacam γ-camera (20 min, medium energy general purpose collimator) by positioning the mice directly on the collimator. Region-of-interest (ROI) analysis was performed using the IconTM software, version 5.2.1 (1994), from Siemens Medical Systems, applying the RegionRatio protocol.

RESULTS

Peptide Synthesis. Solid-phase peptide synthesis yielded TOC in 82−86% yield, based on the amount of

Table 3. Lipophilicity of [^{125}I]TOC and Its Glycosylated Derivatives (n = 6, values are mean ± SD))

	[^{125}I]TOC	[^{125}I]Gluc-TOC	[^{125}I]Malt-TOC	[^{125}I]Mtr-TOC
P_{OW}	1.50 ± 0.09	0.26 ± 0.01	0.06 ± 0.01	0.10 ± 0.01
log P_{OW}	0.18 ± 0.03	−0.59 ± 0.02	−1.21 ± 0.03	−0.99 ± 0.03

Fmoc-Thr(tBu)ol initially coupled to the resin, and in UV-purities > 90%. Subsequent synthesis steps were performed without further purification of the peptide. Boc-protection of the Lys5-side chain usually led to quantitative transformation of the precursor. Final yields of the glycosylated octreotide derivatives generally ranged from 14 to 33% with respect to Boc-protected starting peptide. The glycosylation reaction itself usually proceeded smoothly within 16 h and yielded ratios of glycosylated product to precursor of 60/40 up to 90/10 (values are based on the results of the integration of RP-HPLC chromatograms (UV absorption at 220 nm); impurities were excluded from integration). Product-to-precursor ratios were higher for the maltose and maltotriose derivatives than for the glucose derivative.

The moderate overall yields of the sugar−octreotide conjugates can mainly be attributed to the preparative HPLC conditions. On the RP-18 column generally used, baseline-separation of the carbohydrate conjugate and the nonglycosylated precursor could hardly be achieved, even when a very slow gradient was used.

The structure of radioiodinated Gluc-TOC is shown in Figure 1. For the sugar moiety, only one of four possible conformations is shown. Beside the β-pyranoid structure (Figure 1), the α- and β-furanoid and the open-chain conformations of the deoxy-ketoses are possible and may be present in equilibrium mixtures (*55*).

Radiolabeling. Radioiodination efficiency generally exceeded 99%. Radiochemical yields ranged from 45 to 85% and were limited both by formation of radioiodinated sideproducts and by restrictions during [^{125}I]glycopeptide product-fractioning caused by tailing of the unreacted precursor.

After RP-HPLC isolation, all radioiodinated compounds were obtained in high radiochemical purity (>99.8%). Specific activities of all ^{123}I- and ^{125}I-labeled compounds were >1800 Ci/mmol.

Lipophilicity. The lipophilicity of the radioiodinated compounds is shown in Table 3. While log P_{ow} for the parent compound [^{125}I]TOC is > 0, all glycosylated derivatives exhibited log P_{ow} values below zero in the following order: log P_{ow} [^{125}I]Gluc-TOC > log P_{ow} [^{125}I]-Mtr-TOC > log P_{ow} [^{125}I]Malt-TOC.

Affinity Profiles to hsst. In vitro binding properties of the three compounds were evaluated in cells stably expressing sst1−sst5 in displacement experiments using [^{125}I]-]Leu^{8},D-Trp^{22},Trp^{25}]-somatostatin 28 as radioligand. Table 4 shows the IC_{50} of somatostatin-28, I-TOC, I-Malt-TOC, and I-Mtr-TOC to the five somatostatin receptor subtypes sst1−5.

Natural somatostatin 28, which binds with high affinity to all five subtypes, was used as control peptide. Both sugar conjugates of octreotide showed a binding profile to sst similar to I-TOC: no affinity to sst1, high affinity to sst2, and moderate or low affinity to sst3−5.

In Vivo Biodistribution. The tissue distributions of all radioiodonated tracers in AR42J tumor bearing nude mice 10, 30, and 60 min postinjection are shown in Table 5.

[a] Groups of five nude mice bearing AR42J tumors. Values are mean ± SD. %ID/g = percentage of injected dose per gram tissue

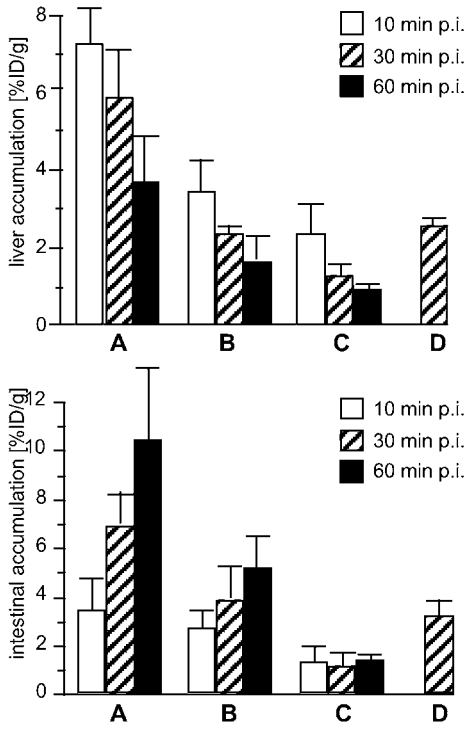

Figure 3. Activity accumulation of [^{125}I]TOC (**A**), [^{125}I]Gluc-TOC (**B**), [^{125}I]Malt-TOC (**C**) and [^{125}I]Mtr-TOC (**D**) in liver and intestine of AR42J tumor bearing nude mice 10, 30, and 60 min pi ($n = 5$, mean ± SD).

While [^{125}I]TOC was rapidly cleared from the blood via hepatobiliary excretion, resulting in high initial liver uptake (7.36 ± 0.92%ID/g 10 min pi), the glycosylated derivatives exhibited delayed initial blood clearance. Activity accumulation in the liver was decreased for all glycosylated analogues, in particular for [^{125}I]Malt-TOC. The maltose derivative exhibited only 25% of the liver uptake of the parent compound 60 min pi, while for [^{125}I]-TOC activity accumulation in the intestine reached 10.6 ± 2.8%ID/g at 60 min pi, intestinal uptake was reduced to 5.28 ± 1.27%ID/g for [^{125}I]Gluc-TOC and to 1.48 ± 0.18%ID/g for [^{125}I]Malt-TOC (Figure 3). Renal activity accumulation for [^{125}I]TOC, [^{125}I]Gluc-TOC, and [^{125}I]-Malt-TOC remained almost unchanged (6.95 ± 1.44%ID/g for [^{125}I]TOC, 6.25 ± 1.94 for [^{125}I]Gluc-TOC and 6.78 ± 1.52%ID/g for [^{125}I]Malt-TOC 60 min pi).

While for sst-rich tissues such as pancreas and adrenals activity accumulation was increased by a factor of 1.5−3.5 for all glycosylated derivatives compared to [^{125}I]TOC, tumor uptakes of [^{125}I]TOC and [^{125}I]Malt-TOC were comparable at all time points. In contrast, [^{125}I]Gluc-TOC exhibited an increase in tumor uptake of up to 160% compared to [^{125}I]TOC.

For [^{125}I]Mtr-TOC, highest activity concentrations 30 min pi could be detected in the kidneys (9.61 ± 1.69%ID/g), the tumor (4.87 ± 2.15%ID/g) and in the intestine (3.31 ± 0.58%ID/g).

Pretreatment, Competition, and Displacement Experiments. Both for [^{125}I]Gluc-TOC and for [^{125}I]Malt-TOC binding to sst-rich tissues in vivo was demonstrated to be specific. While tumor accumulation was significantly reduced in the pretreatment and co-injection experiments compared to the control experiment, resulting in tumor/sst-negative tissue ratios < 1 (Figure 4), displacement of the radioiodinated tracers by injection of 20 μg of Tyr^3-octreotide/mouse 10 min pi of the labeled compound was less effective, demonstrating fast internalization of the radiotracer.

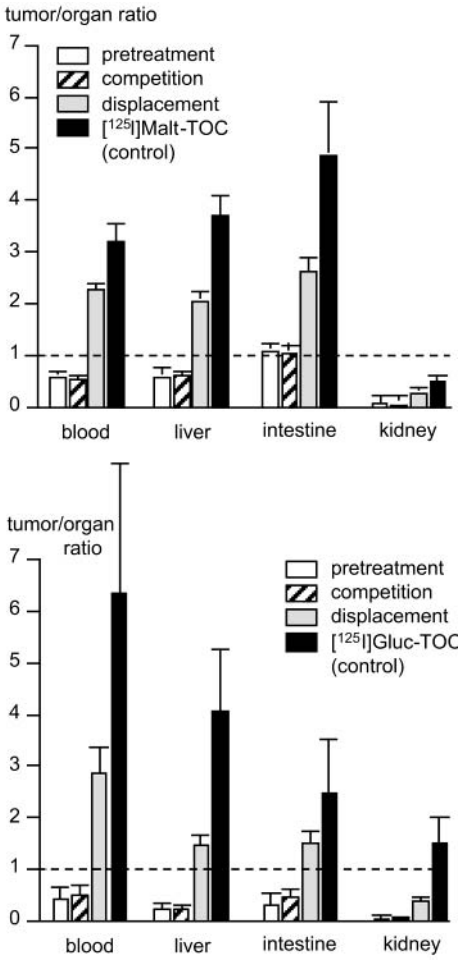

Figure 4. Tumor/organ ratios for [^{125}I]Malt-TOC and [^{125}I]Gluc-TOC under different experimental conditions in AR42J tumor bearing nude mice 30 min pi ($n = 3$, mean ± SD) *pretreatment*: injection of 0.8 mg/kg TOC (20 μg/mouse) 10 min prior to injection of the respective radioiodinated tracer, *competition*: injection of 0.8 mg/kg TOC (20 μg/mouse) with the respective radioiodinated tracer, *displacement*: injection of 0.8 mg/kg TOC (20 mg/mouse) 10 min after injection of the respective radioiodinated tracer.

γ-Camera Imaging. Images acquired 120 min pi of [^{123}I]TOC, [^{123}I]Gluc-TOC, and [^{123}I]Malt-TOC in AR42J tumor-bearing nude mice are shown in Figure 5. In the case of [^{123}I]TOC, the tumor is barely discernible from the high intestinal background. ROI analysis revealed a low tumor/intestine ratio of 0.62 (0.52 ± 0.17 in the biodistribution study 60 min pi). As expected from the biodistribution data, [^{123}I]Gluc-TOC still shows considerable nonspecific accumulation in the intestine, but also an increased tumor/intestine ratio due to its higher tumor accumulation (ROI analysis: 1.48; biodistribution study (60 min pi): 1.65 ± 0.48). This results in an improved contrast of the scintigraphic image. When [^{123}I]Malt-TOC was administered, only the kidneys and the tumor showed significant uptake of the radioligand, while abdominal activity accumulation was negligible. The tumor/kidney ratio determined via ROI analysis (0.81) is in accordance with the value found in the biodistribution study (0.77 ± 0.19 at 60 min pi). In all three scintigraphic images, the stomach is also visible. The intensity of activity accumulation in stomach shows some correlation with the tumor uptake of the respective radioligand. This observation is in accordance with the detection of somatostatin receptors in stomach in rats (*56*).

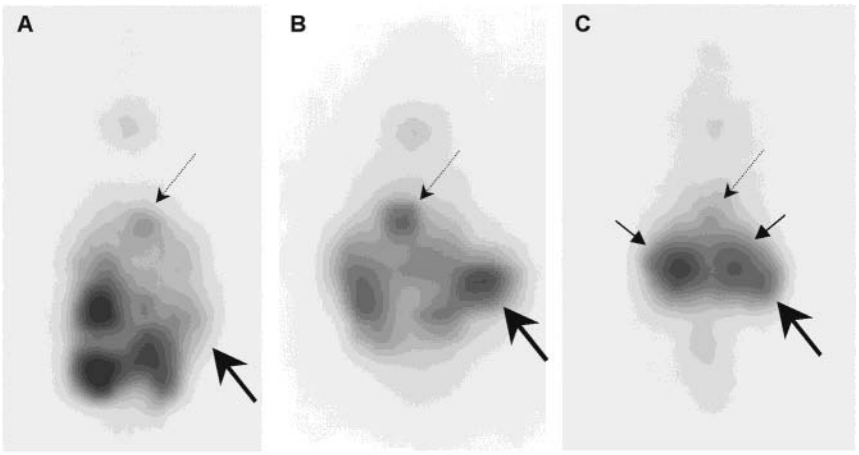

Figure 5. γ-Camera images of AR42J tumor-bearing nude mice 120 min pi of 100 μCi of [^{125}I]TOC (**A**), [^{125}I]Gluc-TOC (**B**), and [^{125}I]Malt-TOC (**C**). Large arrows indicate the tumor, small arrows indicate the kidneys, dashed arrows indicate the stomach.

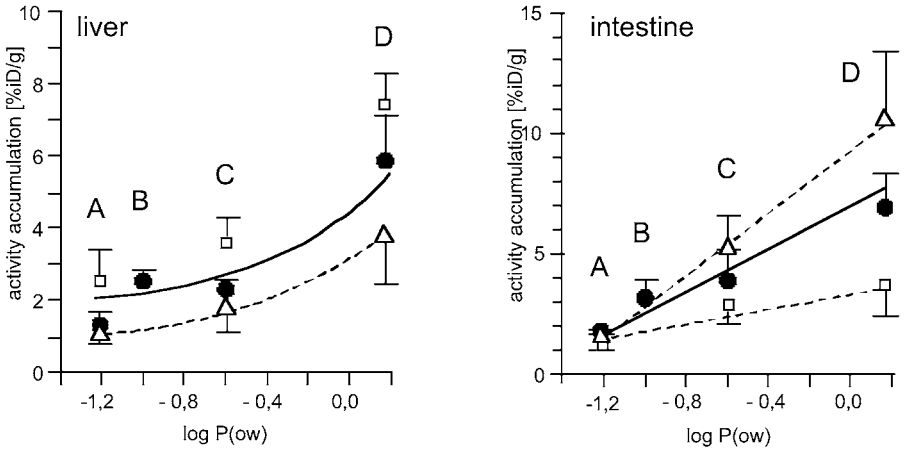

Figure 6. Correlation between the activity accumulation of [^{125}I]Malt-TOC (**A**), [^{125}I]Mtr-TOC (**B**), [^{125}I]Gluc-TOC (**C**), and [^{125}I]-TOC (**D**) in liver and intestine of AR42J tumor bearing nude mice ($n = 5$, mean $\pm$ SD) 10 (□) min, 30 (●) min, and 60 (△) min pi and the lipophilicity (log P_{OW}) of the respective compound.

DISCUSSION

[^{123}I]Tyr³-octreotide (TOC) (*57*) was the first radiolabeled SRIF analogue that was applied for scintigraphic in vivo localization of sst_2-expressing primary tumors and metastases. However, already in the first studies it was shown, that two major drawbacks restricted the applicability of this new tracer: its predominant hepatobiliary excretion and low tumor retention (*58*, *59*). Due to these disadvantages interpretation of planar as well as SPET images of the abdominal region are complicated considerably. In a pharmacokinetic study with patients with neuroendocrine tumors 55% of the administered activity was found in the feces 40 h pi (*29*). While average tumor doses were approximately 0.9−5 rad/mCi ([^{131}I]-TOC), doses calculated for the gallbladder wall and the lower colon were 2.37 rad/mCi and 16.4 rad/mCi, respectively. Therefore [^{131}I]TOC is not suited for PRRT, and there are certainly restrictions with respect to its suitability for tumor scintigraphy.

To make radioiodinated derivatives of TOC accessible for these applications, we evaluated the suitability of radiolabeled, carbohydrate-conjugated octreotide analogues and optimized the biokinetics in vivo (*44*−*47*). In previous studies we successfully applied sugar amino acid conjugation to improve the biokinetics of $\alpha v\beta 3$-antagonists (*27*, *43*). Furthermore, carbohydration was applied to increase peptide solubility (*60*), to enhance in vivo stability (*51*), to improve blood−brain barrier penetration (*33*, *34*) or intestinal absorption (*42*). In previous studies it has been demonstrated that derivatization of SMS 201−995 at D-Phe¹ with different aldoses via Maillard reaction yielded potent sst agonists with high receptor affinity (*51*). These compounds failed to misuse the transport system in hepatocyte sinusoidal plasma membranes (*61*) and thus showed significantly reduced hepatobiliary clearance and intestinal excretion. In a rat model, the maltose derivative of Phe³-octreotide ((*N*-α-(α-D-Glucosyl(1−4)-1-deoxy-D-fructosyl))Phe³-octreotide), SDZ CO-611, showed a cumulated biliary excretion of only 5% of the injected activity over a period of 120 min, while 65% were found for SMS 201−995.

The biodistribution studies in rat pancreatic tumor bearing mice demonstrate that carbohydrate conjugation of [^{125}I]TOC leads to significant changes in the pharmacokinetics of this tracer, too. The most lipophilic compound in our series, the reference [^{125}I]TOC, is mainly excreted via the liver and the intestine. The glucose derivative [^{125}I]Gluc-TOC already shows a 50% decrease in liver and intestinal uptake, while for the most hydrophilic derivative, [^{125}I]Malt-TOC, the activity accumulation in the liver and intestine is only 25% and 14%, respectively, of that of [^{125}I]TOC. These data indicate that the hydrophilicity of the tracers in this series has a major influence on the favored excretion pathway. For the mono- and disaccharide derivatives log P_{OW} decreased gradually with the size of the carbohydrate moiety, which correlated with decreasing hepatobiliary excretion (Figure 6).

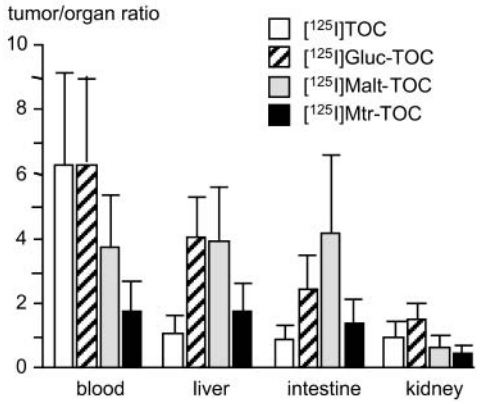

Figure 7. Tumor/organ ratios found for [^{125}I]TOC, [^{125}I]Gluc-TOC, [^{125}I]Malt-TOC, and [^{125}I]Mtr-TOC in AR42J tumor bearing nude mice 30 min pi ($n = 5$, mean ± SD).

Conjugation of [^{125}I]TOC with maltotriose (a trisaccharide) yielded a tracer with a log P_{OW} similar to that of [^{125}I]Gluc-TOC and therefore with a comparable degree of accumulation in liver and intestine. As previously suggested for non-carbohydrated radiometal labeled octreotide derivatives (*62*) and demonstrated in Figure 6 for the carbohydrated compounds, the correlation between the log P_{OW}'s of [^{125}I]TOC and its glycosylated derivatives and their accumulation in liver and intestine may be applied for predictions concerning the degree of hepatobiliary clearance of radiolabeled TOC-derivatives with N-terminal modifications.

Almost identical renal uptake was found for all compounds investigated. Whether these peptides are subject to renal tubular peptide-reabsorption by transport-mediated processes or charge dependent endocytosis (*31*) needs further investigations. In some studies, coadministration of lysine was reported to reduced renal accumulation of radiometalated octreotide derivatives (*63*, *64*). This effect was explained by competition of lysine at the charge dependent endocytosis of octreotide in the kidneys. Since the net charge of the four derivatives investigated are assumed to be nearly identical under physiological conditions (+1.7 to +2.0) no major differences in renal uptake were expected.

Concerning activity accumulation in tumor and other SSTR-positive tissues (pancreas, adrenals), we observed significant differences between [^{125}I]Gluc-TOC and the other derivatives. Tumor uptake of [^{125}I]Gluc-TOC ≫ [^{125}I]-TOC, [^{125}I]Malt-TOC, and [^{125}I]Mtr-TOC. However, due to the improved excretion profile of the carbohydrated compounds, improved tumor/nontumor ratios were found for [^{125}I]Gluc-TOC, [^{125}I]Malt-TOC, and [^{125}I]Mtr-TOC (Figure 7), especially for liver, kidney and intestine, well-known to be critical organs in [^{123}I]TOC-scintigraphy with tumor/nontumor ratios of about 1 or less. Interestingly, although the carbohydrated compounds are mainly cleared via the kidneys, tumor/kidney ratios of [^{125}I]TOC and its glycosylated analogues were comparable.

In cells transfected with sst1-sst5, I-Malt-TOC, and I-Mtr-TOC show high affinity for sst2- and sst-subtype binding profiles similar to I-TOC. Knowing that human tumors preferably express sst2 (*1*, *4*), a radiotracer with high selectivity and high binding affinity for sst2 such as the carbohydrated octreotide derivatives may be extremely valuable for clinical use.

As demonstrated by pretreatment, competition, and displacement experiments in tumor-bearing mice, activity uptake in AR42J tumors was sst_2 receptor specific. As expected, tumor/nontumor ratios decreased to 1 or less when 8 mg unlabeled TOC per kg was given prior to the tracer administration or when the cold compound was coadministered. Less effective displacement already 10 min postinjection of the tracer indicates fast internalization of the radioligand, a prerequisite for activity retention in the tumor.

CONCLUSION

Carbohydration fulfils the demands for a chemical tool suitable to modify the physicochemical behavior of TOC. Carbohydration leads to significantly improved general pharmacokinetics. The carbohydrated tracers were rapidly cleared from the circulation via the kidneys without increased renal uptake. Additionally, the reduced hepatic uptake and biliary excretion, the improved tumor uptake, and thus increased tumor-to-nontumor ratios minimize the effective whole body dose. Especially the glucose and the maltose analogue of Tyr^3-octreotide will be the basis for a new series of carbohydrated peptide receptor ligands with high potential for targeted imaging and radiotherapy of somatostatin receptor postive tumors. We assume that the concept of carbohydration is also a promising strategy for the development of tracers for other peptide receptor systems.

ACKNOWLEDGMENT

The authors are indebted to Jutta Grahneis for her excellent technical assistance. We also thank Dr. Hanno Steen from Odense University (Denmark) for carrying out the peptide sequence analyses. Furthermore, we appreciate the editorial help of Jodi Neverve in the preparation of the manuscript.

Pegylated Zinc Protoporphyrin: A Water-Soluble Heme Oxygenase Inhibitor with Tumor-Targeting Capacity

S. K. Sahoo, T. Sawa, J. Fang, S. Tanaka, Y. Miyamoto, T. Akaike, and H. Maeda*

Department of Microbiology, Kumamoto University School of Medicine, 2-2-1 Honjo, Kumamoto 860-0811, Japan. Received January 21, 2002; Revised Manuscript Received March 25, 2002

Heme oxygenase (HO) is a key enzyme in heme metabolism; it oxidatively degrades heme to biliverdin, accompanied by formation of free iron and carbon monoxide. Biliverdin is subsequently reduced by cytosolic biliverdin reductase to form bilirubin, a potent antioxidant. We recently found that tumor cells utilize HO to protect themselves from oxidative stress by producing the antioxidant bilirubin. This result suggested an important potential therapeutic strategy: suppression of bilirubin production with the use of HO inhibitors; hence, cancer cells become vulnerable to oxidative stress induced by anticancer drugs or leukocytes of the host. This concept was validated by using the intraarterial administration of an HO inhibitor, zinc protoporphyrin, in nonphysiological solution. In the present study, zinc protoporphyrin (ZnPP) was conjugated with poly(ethylene glycol) (PEG) with molecular weight of 5000, to make ZnPP, a water-soluble compound (PEG-ZnPP), and to improve its tumor-targeting efficiency. PEG was conjugated to ZnPP through newly introduced amino groups, where ethylenediamine residues were added at C6 and C7 of protoporphyrin. The divalent zinc cation was chelated into the protoporphyrin ring to obtain PEG-ZnPP. PEG-ZnPP did become highly water-soluble, and it formed multimolecular associations with molecules larger than 70 kDa in aqueous media. PEG-ZnPP inhibited splenic microsomal HO activity in vitro in a competitive manner in the presence of hemin, with an apparent inhibitory constant of 0.12 μM. Most important, PEG-ZnPP injected intravenously significantly suppressed intratumor HO activity in a murine solid tumor model, which suggests that tumor-targeted inhibition of HO is possible with the use of PEG-ZnPP.

INTRODUCTION

Heme oxygenase (HO)[1] is an enzyme of significant clinical importance because of its key role in heme degradation. HO oxidatively degrades the closed tetrapyrrole heme molecule to produce biliverdin; this process is accompanied by the release of free iron (Fe^{2+}) and carbon monoxide (CO) (*1*, *2*). To date, two isoforms of HO have been found: an inducible type HO-1, and a constitutive type HO-2. HO-1, a well-known heme oxygenase, is induced by a wide variety of oxidative stimuli including heme (*3*), ultraviolet irradiation (*4*), hydrogen peroxide (*4*), heavy metals (*4*, *5*), heat shock (*3*), hypoxia (*6*), and nitric oxide (NO) (*7*, *8*).

Biliverdin, one of the products of heme degradation, is immediately reduced by the cytosolic enzyme biliverdin reductase to form bilirubin (*1*, *2*). Although excessive increases in serum bilirubin concentrations cause hyperbilirubinemia or jaundice (*9*), recent findings suggest that adequate levels of bilirubin play an important role in protecting cells from oxidative stress because of bilirubin's potent antioxidant activity. It was reported that bilirubin can scavenge free radicals, especially peroxyl radicals (*10*); prevent protein oxidation by the potent reactive nitrogen species peroxynitrite (*11*); and protect neuronal cells from oxidative stress injury (*12*). We recently found that HO-1 production was enhanced in an experimental solid tumor model (*8*) and, more important, that HO-1 played a vital role in tumor growth by providing, at least in part, antioxidant bilirubin to protect tumor cells from host-derived oxidative stress. The evidence for this role was the marked antitumor effect of a specific HO inhibitor, zinc protoporphyrin (ZnPP) (*8*). These findings suggest a therapeutic potential of this HO inhibitor, which would act as a novel antitumor agent via disruption of the antioxidant defense system of cancer cells.

Metalloporphyrins represent a class of compounds in which the central iron of heme is replaced by various other metals such as cobalt, zinc, manganese, chromium, or tin (*13*). These metalloporphyrins function as competitive inhibitors of the HO reaction because of their inefficient binding to molecular oxygen, thus preventing HO from degrading metalloporphyrins (*1*, *13*). Inhibitory actions of these metalloporphyrins have been studied extensively, especially with respect to therapy for hyperbilirubinemia (*14*−*16*). As mentioned above, we also demonstrated antitumor activity of ZnPP in a solid tumor model (*8* and our unpublished data, S. Tanaka et al.). However, the very low solubility of these metalloporphyrins in aqueous media limits the use of these compounds in injectable formulations. In addition to the issue of solubility, targeted delivery of the HO inhibitor to tumor tissue is indispensable for antitumor treatment because nonspecific inhibition of HO may cause oxidative stress-related side effects by reducing the favorable antioxidant capacity of bilirubin in normal organs.

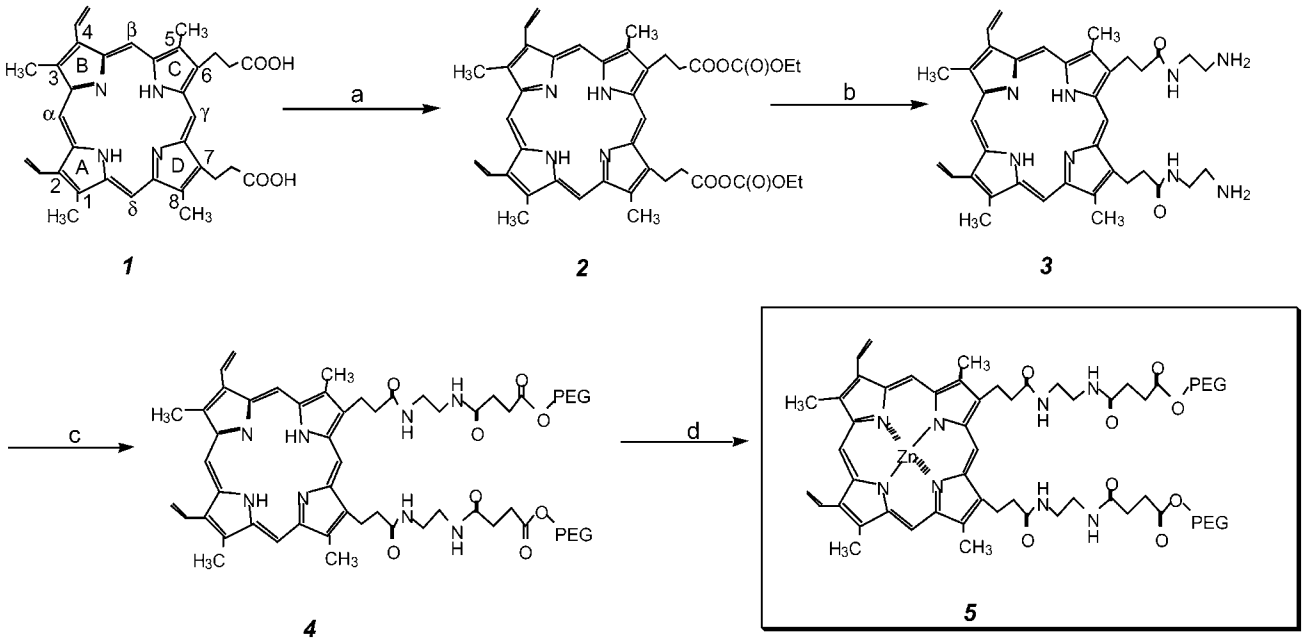

Figure 1. Synthesis of pegylated zinc protoporphyrin (PEG-ZnPP). Reagents and conditions: (a) ethylchloroformate, triethylamine, tetrahydrofuran, 0 °C, 2 h; (b) ethylenediamine, room temperature, 24 h; (c) succinimidyl PEG (M_r 5000), chloroform, room temperature, 24 h; (d) zinc acetate, room temperature, 1 h (See text for details).

Tumor-specific accumulation of biocompatible macromolecules and lipids, after intravenous and intraarterial administration, has been observed in many types of solid tumors of mice, rats, rabbits, and human patients. We called this phenomenon the "enhanced permeability and retention (EPR) effect" of macromolecules and lipids in solid tumor (*17*). The EPR effect is mainly mediated by four major factors: (i) hypervasculature of tumor tissues due to active angiogenesis, (ii) defective anatomical structure of tumor blood vessels (thus leaky), (iii) enhanced production of vascular mediators such as nitric oxide and bradykinin, and (iv) incomplete lymphatic drainage system (*17*−*20*). We hypothesized that if we could increase the molecular size as well as the water-solubility of an HO inhibitor such as ZnPP by conjugating it with water-soluble polymers, we will be able to achieve, based on the EPR effect, more effective and selective delivery of the HO inhibitor to tumor sites.

The present study describes the synthesis and characterization of a water-soluble derivative of ZnPP obtained by conjugation with PEG (PEG-ZnPP). The inhibitory constant (K_i) of PEG-ZnPP against HO was determined in vitro and compared with that of native ZnPP. The biological significance of PEG-ZnPP is further discussed in view of antitumor effect in vivo.

EXPERIMENTAL PROCEDURES

Materials. Protoporphyrin IX was purchased from Sigma Chemical Co. (St. Louis, MO). ZnPP was from Wako Pure Chemical Industries Ltd., Osaka, Japan. The succinimidyl derivative of PEG (MEC-50HS), with an average molecular weight of 5000, was kindly provided by NOF Co., Tokyo, Japan. PEGs used in this experiment have a molecular weight dispersity (Mw/Mn) of 1.025. Other reagents, of reagent grade, were from Wako Pure Chemical Industries and were used without further purification.

General Methods. Absorption spectra were determined by using a spectrophotometer (U-2000, Hitachi Ltd., Tokyo, Japan). Fluorescence spectra were recorded by a fluorescence spectrophotometer (F-4500, Hitachi). Mass spectra were obtained via a liquid chromatography spectrometer (LCMS QP8000α, Shimadzu Corp., Kyoto, Japan), with the electron spray ionization probe operating in the positive mode. Methanol was used as a solvent. Infrared spectra were recorded with a JIR-6500w spectrometer (JEOL, Tokyo, Japan). Thin-layer chromatography (TLC) was performed on 60 A silica with F254 aluminum-backed plates (Merck); UV−visualization was at 254 nm.

Animals and Tumor Implantation. Male ddY mice, 6 weeks of age and weighing 30−35 g (from SLC, Inc., Sizuoka, Japan), were used in this study. S-180 tumor cells (2×10^6 cells) were implanted subcutaneously in the dorsal skin of the ddY mice. The inhibitory activity of PEG-ZnPP in vivo was examined on days 10−14 after tumor inoculation, when the tumors were approximately 10 mm in diameter but contained no necrotic region. All experiments were carried out according to the guidelines of the Laboratory Protocol of Animal Handling, Kumamoto University School of Medicine.

Synthesis of PEG-ZnPP. The overall scheme of synthesis of PEG-ZnPP is shown in Figure 1. PEG-ZnPP synthesis proceeded by three major steps: (i) the introduction of amino groups into the protoporphyrin ring by reacting ethylenediamine with the intrinsic carboxyl groups of the ring; (ii) PEG conjugation to the amino groups; and (iii) chelation of Zn^{2+} into the PEG-porphyrin ring. Detailed procedures for each step are described in the following text.

Synthesis of the Aminated Derivative of Protoporphyrin IX (Compound 1; cf. Compound 3). Triethylamine (2.45 mL, 17.6 mmol) was added to a suspension of protoporphyrin IX (100 mg, 178 mmol) (**1**) in dry tetrahydrofuran (20 mL) to remove the hydrochloric acid formed. The suspension was then cooled to 0 °C; 1.7 mL (17.9 mmol) of ethylchloroformate was added in dropwise fashion, with stirring, and the reaction was continued at 0 °C for 2 h. The resultant suspension was then filtered to remove the triethylamine hydrochloride salt. By TLC (chloroform/methanol, 9:1 v/v), R_f was 0.9. To the solution obtained (**2**) was added an excess of

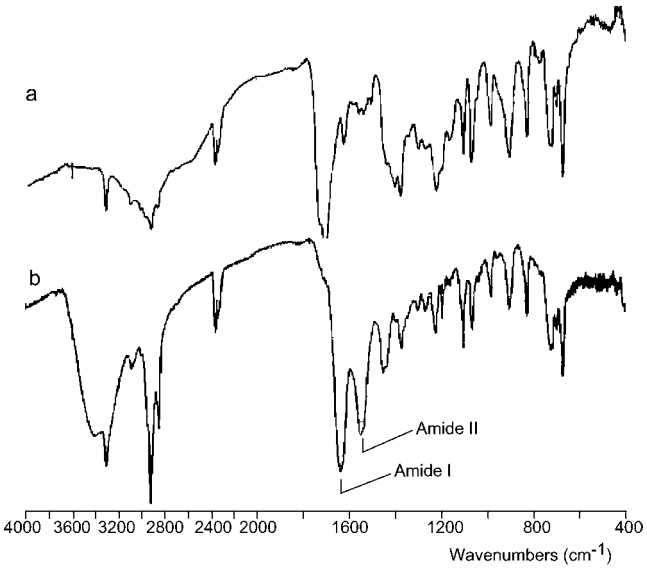

Figure 2. IR spectra of **1** (a) and **3** (b). Clear appearance of amide I (1641 cm^{-1}) and amide II (1552 cm^{-1}) was observed in **3** suggesting the conjugation of diaminoethylene to propionic acid residues of **1** through amide bond.

ethylenediamine (1.2 mL, 17.9 mmol) against mixed anhydride to introduce amino groups into the porphyrin ring (Figure 1). The reaction proceeded at room temperature for 24 h. The solvent was removed by evaporation in vacuo, and the solid material obtained (**3**) was washed several times with chilled distilled water. Finally, **3** was suspended in a small aliquot of distilled water and was then lyophilized, yielding 60 mg of product. By TLC (chloroform/methanol 9:1 v/v), $R_f = 0.3$. IR (KBr): 1641 cm^{-1} (amide I) and 1552 cm^{-1} (amide II) were distinct (Figure 2). The mass analysis (electron spray ionization, polarity positive) result, calculated for M+H, was 647.

Conjugation of PEG with Bis(ethylenediamino)-protoporphyrin. Bis(ethylenediamino)protoporphyrin (5 mg, 7.7 μmol, **3**) was dissolved in 20 mL of chloroform. To this solution, 860 mg (172 μmol) of succinimidyl PEG was added in stepwise fashion (five times, about 170 mg each time) at 30-min intervals, and the reaction proceeded at room temperature for 24 h with stirring. Pegylated protoporphyrin (PEG-PP) (**4**) thus obtained was subjected to dialysis (cutoff size of 50 000) against distilled water for 2 days with several changes of water to remove unreacted PEG. The resultant solution was then lyophilized to obtain a powder of **4**. The yield was 120 mg. The content of porphyrin moiety was determined spectroscopically, and the yield of **4** based on porphyrin moiety was 4 μmol (52%).

Chelation of Zinc into the Porphyrin Ring of PEG-PP. PEG-PP (100 mg, 0.16 mM porphyrin equivalent) was dissolved in 20 mL of chloroform, to which was added 20 mg (27 mM) of zinc acetate. The solution was stirred at room temperature for 1 h to complete chelation of Zn^{2+} into the porphyrin ring. After the reaction, chloroform was removed by evaporation, to yield the crude PEG-ZnPP (**5**). PEG-ZnPP was then purified by overnight dialysis against 1 L of distilled water, with a membrane filter having a cutoff size of 8000; the water was changed three times. The yield of PEG-ZnPP after lyophilization was 77 mg.

Size Exclusion Chromatography. The apparent molecular sizes of PEG-PP (**4**) and PEG-ZnPP were studied by means of size exclusion chromatography with the use of both polar (buffer) and nonpolar (chloroform) mobile phases. As molecular size standards for PEG, conjugates of nitrotyrosine and PEG were prepared in a manner similar to the procedure used for PEG-PP. Succinimidyl PEG, with a molecular size of 5 or 12 kDa, was incubated overnight with nitrotyrosine in 100 mM phosphate buffer (pH 7) at room temperature. During this incubation, the amino group of nitrotyrosine reacted with succinimidyl PEG, which was confirmed from the loss of free amino groups determined by fluorescamine assay (see below). The solution was then dialyzed to remove unreacted nitrotyrosine. PEG-nitrotyrosine thus obtained was easily detected by absorption at 390 nm during chromatographic separation.

Size exclusion chromatography was performed by using a Sephadex LH-60 column (13 mm inner diameter, 400 mm long), with chloroform as the mobile phase, at a flow rate of 60 mL/h. Absorption of each fraction (2 mL) was measured at 415 nm for porphyrin derivatives and at 390 nm for PEG-nitrotyrosine.

Also, a high-performance liquid chromatography (HPLC) system (LC-10DA and SPD-10A, Shimadzu) equipped with a YMC Diol-60 column was used for size exclusion chromatography of PEG-ZnPP in buffer. The mobile phase consisted of 20 mM sodium phosphate buffer (pH 7) containing 0.2 M sodium chloride. In this experiment, bovine serum albumin (M_r 67 000) was used as the molecular size standard.

Quantification of Free Amino Groups. To determine whether PEG reacted with the amino groups of **3**, loss of the primary amino group after the reaction was quantified by means of an amino group-reactive fluorescence agent, fluorescamine, according to the literature (*21*). In brief, 2 μM (protoporphyrin equivalent) PEG-PP was dissolved in distilled water and was then reacted with fluorescamine. The intensity of fluorescence at 475 nm (under excitation at 390 nm) was determined. The concentration of free amino groups in PEG-PP was estimated by using glycine as a standard.

Inhibitory Activity of PEG-ZnPP against HO in Vitro. A rat splenic microsomal fraction was prepared for measurement of splenic HO activity according to the literature (*15*). A liver cytosolic fraction was used as the source of bilirubin reductase (*15*). The HO reaction mixture was composed of the splenic microsomal fraction (1.0 mg of protein), the liver cytosolic fraction (3.0 mg of protein), and 333 μM nicotinamide adenine dinucleotide phosphate (NADPH), without or with inhibitors at a given concentration, in 1.0 mL of 90 mM potassium phosphate buffer (pH 7.4). The reaction was initiated by adding hemin (33 μM) to the mixture. In some experiments, the HO fraction and the inhibitors were incubated for 30 min before starting the reaction to permit interaction of the inhibitor to bind to HO before substrate ligand (hemin) binds to HO. The mixture was incubated for 15 min at 37 °C, and then the reaction was terminated by addition of 33 μL of 0.01 M HCl. The bilirubin formed in the reaction was extracted with 1.0 mL of chloroform, and the bilirubin concentration was determined spectroscopically by the difference in absorbance at 465 and 530 nm with a molar extinction coefficient of 40 mM^{-1} cm^{-1} as described previously (*15*). The K_i of PEG-ZnPP was determined by using double reciprocal Lineweaver−Burk plots and the slope of the plotted lines with added inhibitor (*15*).

Inhibitory Activity of PEG-ZnPP against HO in an in Vivo Solid Tumor Model. To examine whether PEG-ZnPP can be targeted to tumor tissue and can inhibit intratumor HO activity, PEG-ZnPP was administered intravenously to ddY mice bearing S-180 solid

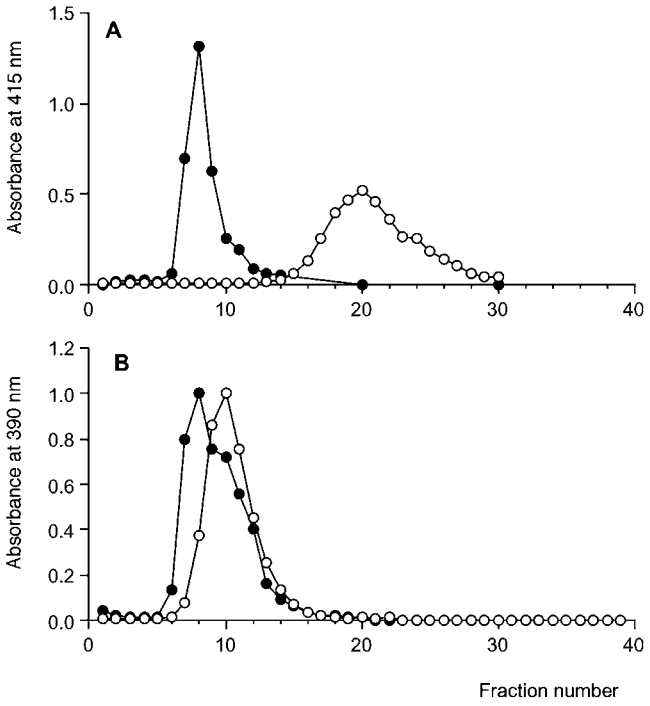

Figure 3. Size exclusion chromatography with chloroform. (A) bis(ethylenediamino)protoporphyrin before and after PEG conjugation. Symbols: open circle, aminated protoporphyrin; closed circle, pegylated protoporphyrin. (B) molecular weight standards of PEG-nitrotyrosine conjugates. Symbols: open circle, pegylated (5 kDa) nitrotyrosine; closed circle, pegylated (12 kDa) nitrotyrosine. tumor. In this study, 300 or 600 μM PEG-ZnPP dissolved in distilled water (0.1 mL) was injected via the tail vein (0.5 or 1 mg of ZnPP equiv/kg). At 24 h after injection, tumor tissue was collected, and intratumor HO activity was measured as described previously. Control animals received distilled water without PEG-ZnPP.

RESULTS

Synthesis of PEG-ZnPP. In the present study, amino groups were first introduced to protoporphyrin IX (**1**) as reactive nucleophils (*22*), because a variety of polymer conjugates can be targets for nucleophilic amino groups. PEG with a succinimidyl ester group at one end was utilized to introduce water-soluble moieties to the porphyrin structure (Figure 1).

LC-MS analysis indicated that **3** shows a single peak at a molecular weight of 647, which is identical to that of calculated mass (data not shown). Formation of an amide bond was demonstrated by infrared spectroscopy; **3** shows characteristic absorption at 1641 cm^{-1} (amide I) and 1552 cm^{-1} (amide II) (Figure 2).

Size exclusion chromatography with chloroform (Figure 3) clearly indicated that, under the present conditions, the reaction between **3** and succinimidyl PEG proceeded completely as that no **3** remained (Figure 3A). Comparison of the chromatographic profile of **4** with those of the molecular size markers nitrotyrosine conjugated with PEG, either 5 or 12 kDa (Figure 3B), indicated that **4** has an apparent molecular size similar to PEG 12 kDa-nitrotyrosine, and larger than PEG 5 kDa-nitrotyrosine. Thus, PEG conjugation might occur at both two amino groups of compound **3**. This notion was supported by the fact that **4** has no reactive free amino groups as determined by a fluorescamine-assisted amino group assay (data not shown).

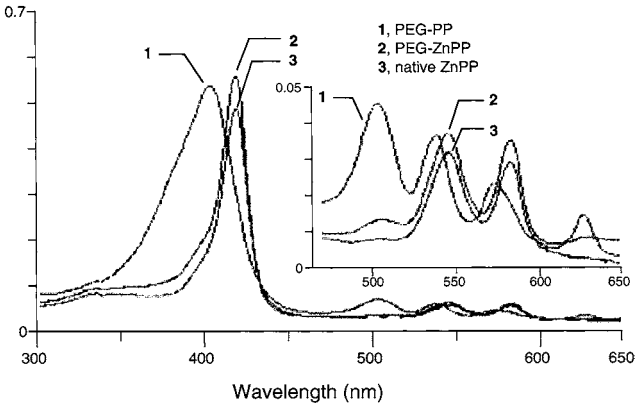

Figure 4. UV spectra of PEG−protoporphyrin conjugate (PEG-PP, 3.3 μM), PEG-ZnPP (4.0 μM), and native ZnPP (3.3 μM) in dimethyl sulfoxide. Inset shows the amplified spectra from 475 to 650 nm.

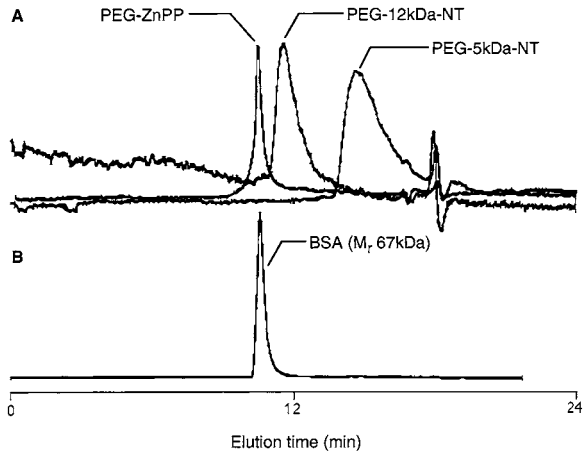

Figure 5. HPLC profiles of PEG in various conjugates (A) and the molecular size marker bovine serum albumin (BSA) (B) with the use of size exclusion column (Diol-60) eluted by sodium phosphate buffer (pH 7.0). Detection wavelengths of compounds were 415 nm (PEG-ZnPP), 390 nm (pegylated nitrotyrosine, PEG-12 kDa-NT and PEG-5 kDa-NT), and 280 nm (BSA), respectively.

Compound **4** shows intense absorption at 406 nm corresponding to the Soret band of protoporphyrin moiety (Figure 4). In addition, there are four bands, 505, 540, 575, 627 nm in the visible region, which correspond to the bands numbered I (627 nm), II (575 nm), III (540 nm), and IV (505 nm) for the porphyrin ring as reported previously (*23*). After the reaction with zinc acetate, the Soret band of **5** was found to red shift (422 nm) compared to that of **4**. A marked difference was also observed in the visible region, i.e., **5** shows two major bands at 548 and 584 nm, respectively (Figure 4). These observations are well consistent with the finding that divalent metal insertion into porphyrin ring induces a red shift of the Soret band and the formation of two major bands, alpha (584 nm) and beta (548 nm) (*23*). Furthermore, the spectrum of native ZnPP showed good agreement with that of **5**. Taken together, it was suggested that zinc was chelated into the porphyrin ring of **4**, and hence, the formation of **5** (PEG-ZnPP) as depicted in Figure 1.

Molecular Association of PEG-ZnPP in Aqueous Media. The PEG-ZnPP obtained here was highly water-soluble. The saturated concentration of PEG-ZnPP in water was determined to be 3.15 mM; in contrast, native ZnPP shows virtually no dissolution in water.

The apparent molecular size of PEG-ZnPP in an aqueous system was studied by using size exclusion

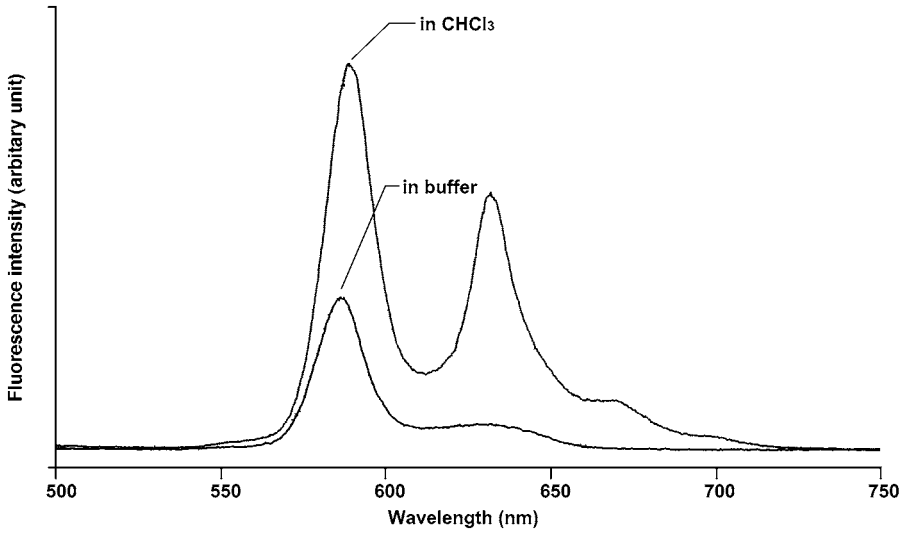

Figure 6. Fluorescence spectra of PEG-ZnPP in chloroform and in 200 mM phosphate buffer (pH 7.4). Excitation was at 370 nm.

chromatography. Interestingly, PEG-ZnPP was eluted much faster than PEG 12 kDa-nitrotyrosine (Figure 5). This result is different from the chromatographic data obtained by using chloroform as a mobile phase (Figure 3). These observations suggest that PEG-ZnPP behaves differently in solution as the tertiary and quaternary structure of macromolecules may differ depending on the type of solvents; PEG-ZnPP might form multimolecular association in aqueous media, resulting in increased apparent molecular size; whereas, it behaves as free monomolecular dispersion in chloroform.

It has been known that molecular size is an important factor for preferred tumor accumulation due to the EPR effect (*17*−*20*). Compounds smaller than 40 kDa will rapidly be cleared from circulation by urinary excretion mechanism, and hence, show no tumor accumulation. Elution time of PEG-ZnPP was comparable to that of bovine serum albumin (67 kDa), suggesting that PEG-ZnPP behaves as large as BSA in aqueous system. This increased molecular size of PEG-ZnPP would facilitate its tumor accumulation based on the EPR effect.

Fluorescence Spectroscopy of PEG-ZnPP. Porphyrins have intense fluorescence when they are well dispersed (monomeric form) in solution, whereas upon aggregation the fluorescence is strongly quenched (*24*). This different fluorescent property has been utilized to study the monomer−aggregate transition of porphyrins in solutions. As shown in Figure 6, we observed intense fluorescence of PEG-ZnPP dissolved in chloroform solution. The fluorescence of PEG-ZnPP was, however, strongly quenched when aqueous buffer is used as a solvent. These observations suggest that the porphyrin moiety of PEG-ZnPP may aggregate, but not disperse homogeneously, in buffer solution. Considering the size exclusion chromatographic data together, PEG-ZnPP might form multimolecular association facilitated in aqueous solution similar to the micelle system.

Inhibitory Activity of PEG-ZnPP against HO in Vitro. The inhibitory activity of PEG-ZnPP against HO was examined by using a rat splenic microsomal fraction as described earlier (*8*, *14*−*16*). The addition of PEG-ZnPP (1.0 μM) to a splenic HO incubation mixture drastically decreased the formation of bilirubin in a manner that depended on preincubation time (Figure 7A). This requirement for such a preincubation period was not observed for native ZnPP (Figure 7A). This result suggests a number of possibilities: (i) binding of PEG-ZnPP is a very weak and slow process, and it needs time to access or fit to the catalytic site; (ii) dissociation of monomeric PEG-ZnPP from associated molecules is required for inhibitory action, and/or (iii) hydrolytic cleavage between the PEG chain and the porphyrin ring results in the ZnPP moiety being more accessible to the catalytic site of HO, or a combination of these. Further investigation is needed to clarify this point. Neither PEG-

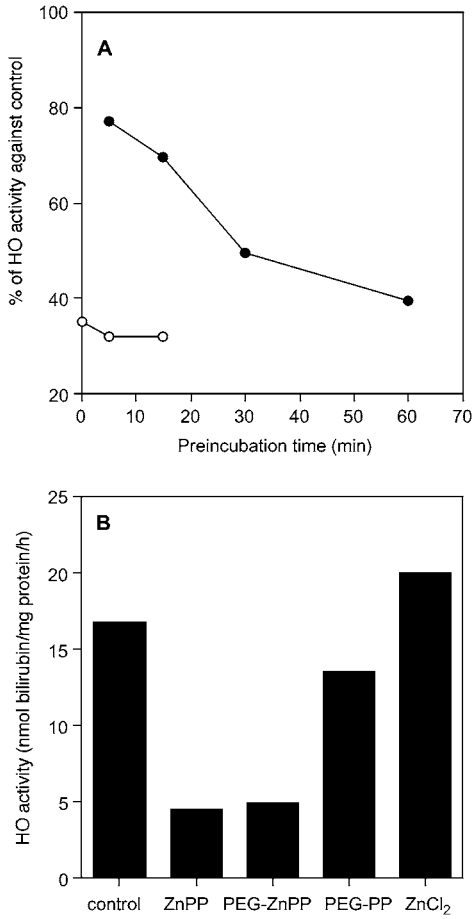

Figure 7. Inhibitory activity of PEG-ZnPP on splenic microsomal heme oxygenase (HO). (A) Effect of preincubation period. Symbols: open circle, native ZnPP (1 μM); closed circle, PEG-ZnPP (1 μM). (B) Effect of various compounds on HO activity. The concentration of each compound was 1.0 μM. Preincubation period was 30 min. Data were averages of two measurements.

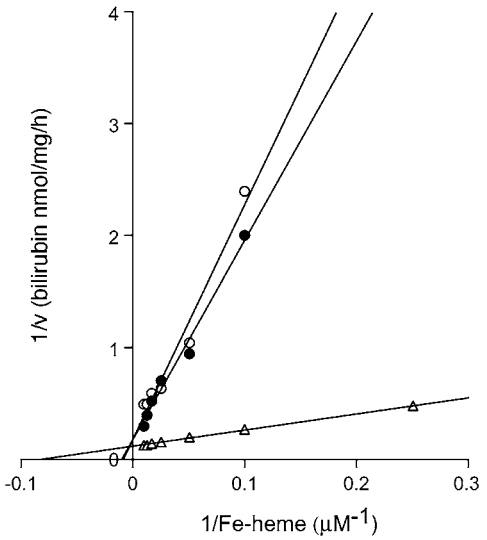

Figure 8. Lineweaver−Burk plot analysis of the effects of PEG-ZnPP and native ZnPP on the oxidation of Fe-heme in vitro by microsomal splenic HO. The concentration of both native ZnPP and PEG-ZnPP was 1.0 μM. Symbols: triangle (control without inhibitor), closed circle (native ZnPP), open circle (PEG-ZnPP). Data were averages of two measurements.

PP nor zinc alone showed any inhibitory activity against the splenic HO system, whereas PEG-ZnPP and ZnPP showed similar inhibitory activity (Figure 7B). This finding suggests that PEG-ZnPP inhibits HO activity in a manner similar to that of native ZnPP.

The apparent Michaelis−Menten constant (K_m) for heme in the splenic HO system was determined to be 12.2 μM (Figure 8), which is consistent with the previously reported value (*15*). Native ZnPP inhibited splenic HO activity in a competitive manner (Figure 8). The K_i of native ZnPP was determined to be 0.11 μM, which is also within the range of previously reported values (*15*). We found that PEG-ZnPP inhibited splenic HO activity in a competitive manner, similar to native ZnPP (Figure 8): the K_i of PEG-ZnPP was determined to be 0.12 μM, which is comparable to that of native ZnPP.

Inhibition of Intratumor HO Activity by PEG-ZnPP. As mentioned above, we recently found a high level of HO expression in the rat AH136B solid tumor model in vivo (*8*). This high level of HO expression in the solid tumor could be mediated by, at least in part, a high level of NO produced by monocyte-derived macrophages that infiltrated the tumor (*8*, *25*). In the murine S-180 solid tumor model, the model used in this study, we also previously demonstrated extensive production of NO in tumor tissue (*26*). We thus expected upregulation of HO-1 in the S-180 tumor in this study.

Here, at 15 days after tumor inoculation, S-180 tumor tissue excised from mice that had received no treatment was determined to contain HO activity of 4.17 ± 1.07 nmol of bilirubin (mg protein)$^{-1}$ h^{-1} (Table 1). This activity is comparable to that found in AH136B tumors reported previously (*8*) and is 3-fold higher than that in normal liver tissue (Table 1). Most important, PEG-ZnPP (30 or 60 nmol/mouse) administered intravenously significantly reduced HO activity in tumor tissue to almost 50% of the control level, i.e., tumor without treatment (Table 1). No acute lethal effect of PEG-ZnPP was observed at this dosage (n = 6, data not shown). These findings clearly demonstrate the potential of PEG-ZnPP to inhibit intratumor HO activity.

Table 1. Heme Oxygenase (HO) Activity in Tumor and Liver Tissues with or without PEG-ZnPP Administration[a]

tissue sample	dose of PEG-ZnPP (mg of ZnPP equiv/kg)	HO activity (nmol of bilirubin /mg of protein/h)
liver	0	1.32 ± 0.26
tumor	0	4.17 ± 1.07
	0.5	2.23 ± 0.54*
	1.0	2.46 ± 0.33*

[a] n = 6. *P < 0.05. ddY mice bearing S-180 solid tumor received 0.1 mL of distilled water (control) or an aqueous solution of PEG-ZnPP via the tail vein. After 24 h, tumor tissue was collected, and HO activity in the tissue was measured as described in Experimental Procedures.

DISCUSSION

The present study provides evidence that polymer-conjugated ZnPP possesses potent inhibitory activity against HO. PEG-ZnPP became highly water-soluble and showed potent inhibition of the splenic HO activity in vitro, inhibition that was equivalent to that of the well-known HO inhibitor ZnPP as its native form (Figure 8). Most important, PEG-ZnPP injected intravenously markedly suppressed intratumor HO activity (Table 1).

Chemical modifications of porphyrin structure have been found to affect the inhibitory potential of metalloporphyrin analogues. For example, reduction of vinyl groups at the C2 and C4 positions, to form mesoporphyrin, slightly increased the inhibitory potential of zinc porphyrin (*16*). Zinc deuterioporphyrin (ZnDP), which has no vinyl groups on C2 and C4, showed activity similar to that of ZnPP (*14*). Introduction of glycol moieties at positions C2 and C4 of ZnDP significantly increased the inhibitory potential, compared with the most potent HO inhibitor tin protoporphyrin, whereas introduction of sulfonic acid at these positions completely nullified the activity (*14*). In our study here with a zinc-modified porphyrin, although mechanisms of action of PEG-ZnPP remain unclear, the results obtained indicate a similarity to native ZnPP, in that PEG-ZnPP inhibited HO in a competitive manner to the substrate (hemin) concentration (Figure 8), with the zinc metal center playing an essential role (Figure 7B).

Crystal structure analysis of HO indicates that the heme substrate binds to the catalytic site of HO, called a heme pocket, by an α-methene bridge as a head, opposite a σ-methene bridge with both propionic acid residues exposed to the outer surface (*27*). This analysis may help understanding of the effect of PEG conjugation into the porphyrin ring. In this study, PEG chains were conjugated to propionic acid residues through an ethylenediamine linkage, which may not have a great effect on the binding affinity of the porphyrin portion of PEG-ZnPP to the heme pocket. The outer surface of the heme pocket is thought to play an important role in electron transfer from NADPH-cytochrome P450 reductase to the catalytic domain (*27*). Thus, binding of PEG-ZnPP to the heme pocket may disturb the interaction between HO and NADPH-cytochrome P450 reductase through steric hindrance caused by the PEG chains. Further investigation is needed to clarify these mechanistic points.

Several recent studies have demonstrated a high level of HO expression in tumor tissues: a human prostate malignant tumor (*28*), a human renal adenocarcinoma (*29*), and the AH136B rat hepatocyte solid tumor model (*8*). The remarkable inhibition of tumor growth after administration of ZnPP to AH136B-bearing rats supports a vital role for HO in tumor growth (*8*). Very recently,

we found that bilirubin could function as an antiapoptotic factor against oxidative stress-induced tumor cell apoptosis which is induced by caspase activation, and the caspase is induced by oxidative stress (S. Tanaka et al., unpublished data). In addition, expression of HO is reportedly involved in the resistance of tumor cells to oxygen radical-generating agents such as Adriamycin (*30*). Therefore, antitumor activity of PEG-ZnPP may exist as a function of decreasing the antioxidant defense capacity of tumor cells, which results in sensitizing tumor cells against host-derived oxidative stress as well as oxygen radicals generated by administration of antitumor agents.

Size exclusion chromatography analyses suggested that PEG-ZnPP spontaneously formed multimolecular associations in aqueous media, resulting in an increase in apparent molecular size, to that of bovine serum albumin (67 kDa) (Figure 5). Fluorescence spectroscopic analyses demonstrated a clear decrease in fluorescence intensity of PEG-ZnPP in buffer compared with that in chloroform (Figure 6). This phenomenon is explained by the different status of molecular associations of porphyrins in different media: porphyrin is well dispersed (monomeric dispersion) in chloroform and shows a high fluorescence intensity, whereas porphyrin has diminished fluorescence intensity in buffer because of molecular association, probably through $\pi-\pi$ stacking and hydrophobic interaction (*24*). These findings, together with size exclusion chromatography data, indicate that PEG-ZnPP forms a molecular association in neutral buffer in this way: a hydrophobic inner core consisting of porphyrin moieties covered with hydrophilic PEG chains.

Self-assembly association has been observed in a block copolymer system consisting of hydrophilic and hydrophobic polymeric chains, termed a "polymer micelle" (*31*). Core segregation in an aqueous milieu is the direct driving force for micellization and proceeds through hydrophobic interaction. Yokoyama and Kataoka and colleagues have extensively studied the physicochemical and biological importance of these polymer micellar systems and the application of these systems as anticancer drug carriers (*31*−*33*). These researchers found that polymer micelles with hydrophilic surfaces (i.e., polymers such as PEG) show an extremely prolonged circulation time in vivo because of the low excretion efficiency (renal clearance). Furthermore, these polymer conjugates and micelles preferentially accumulate in solid tumor after intravenous injection because of the unique vessel biology, the EPR effect, that operates in tumors (see recent reviews, refs *17*−*20*). Interestingly, both monoclonal antibody and normal immunoglobulin G accumulated similarly to solid tumor, indicating the EPR effect is the prime importance for tumor targeting of macromolecular drugs (*34*). In this context, the EPR effect is also relevant for PEG-ZnPP, with enhanced delivery of PEG-ZnPP to the tumor. Further studies of PEG-ZnPP targeting to tumors as well as its tissue distribution are now under way. A preliminary result shows almost complete suppression of S-180 tumor growth with PEG-ZnPP alone, by three times of iv injection (30 nmol/mouse for each time) (unpublished data).

In conclusion, we demonstrate here, for the first time, that a polymer conjugate of ZnPP effectively inhibits HO activity both in vitro and in vivo. The strategy of the synthesis described here (Figure 1) may allow us to produce functional water-soluble polymers as well as a series of metalloporphyrin analogues by alternating metal center (e.g., tin, manganese). The rational design of polymer chains may provide better organ-specific targeting capacity of HO inhibitors.

ACKNOWLEDGMENT

The authors thank Ms. Judith Gandy for editing and Ms. Chie Honda for typing the manuscript. This work was supported in part by a Grant-in-Aid for Research on Cancer from Ministry of Education, Culture, Sports and Science of Japan. Received January 29, 2002; Revised Manuscript Received May 25, 2002

Even for moderately sized proteins, the multiple occurrence of cysteine and lysine residues often prevents the specific labeling of polypeptides with a single probe. To increase specificity, a method was developed to convert the commonly available succinimidyl esters of fluorescent dyes into benzyl thioesters via trimethyl aluminum-activated benzyl mercaptan. The thioester can then be reacted very specifically with polypeptides containing an N-terminal cysteine residue, forming a stable amide bond, analogous to the native chemical ligation of peptide fragments. Both reaction steps are easy to perform and proceed to high yields. The practicability of the approach was demonstrated using the popular cyanine dye Cy5 and a soluble peptide, and it is expected to be applicable to a wide range of succinimidyl esters and both chemically and recombinantly synthesized proteins. The method should dramatically facilitate the preparation of proteins for experiments requiring exact positioning of labels, for instance, Förster resonance energy transfer studies.

INTRODUCTION

A general problem in the specific conjugation of chromophores or other molecules to polypeptides is the limitation to sulfhydryls and amines as suitable reactive groups. Therefore, most commercially available fluorophores can be obtained with functionalities that allow specific labeling of cysteine or lysine residues and the free amine at the N-terminus (Haugland, 2001). However, except for small peptides, the statistical and therefore often multiple occurrence of cysteine and lysine residues in one polypeptide prevents the specific attachment of just one label to a protein. For some applications, like in vivo imaging, the degree of labeling is only of secondary importance, although it is well-known for several fluorophores that severe fluorescence quenching can occur if multiple sites on one protein are modified (Hermanson, 1996; Gruber et al., 2000). For an increasing number of experimental approaches, specificity is strictly required, for instance the use of fluorophores for FRET[1] or polarization studies both in ensemble and single molecule experiments (Weiss, 1999). So far, the only solution to this problem has been solid-phase peptide synthesis followed by labeling of the polypeptide before side chain deprotection, sometimes in combination with native chemical ligation of peptide fragments (Deniz et al., 2000). A general approach for the specific attachment of single labels to recombinantly expressed proteins has not been available, which sometimes makes extensive sequence changes necessary to eliminate cysteine and lysine residues, thus potentially interfering with the stability and function of the protein. Here we present a simple protocol for the synthesis of thioester derivatives starting from succinimidyl esters, the function most commonly employed for the specific labeling of amino groups. These thioester derivatives can then be used to label polypeptides with an aminoterminal cysteine residue in a highly specific reaction analogous to the native chemical ligation of peptides (Dawson and Kent, 2000). In this case, the necessary sequence changes are limited to the introduction of a cysteine residue at the amino terminus.

EXPERIMENTAL PROCEDURES

Materials. The peptide Cys-(Ala-Gly-Gln)$_5$-Trp-CONH$_2$ (calculated average mass 1587.6 Da, ESI-MS, positive mode, observed average mass 1587.3 ± 0.3 Da) was obtained from California Peptide Research (Napa, CA). The carboxy terminal Trp residues was included to provide an intrinsic chromophore for accurate peptide concentration determination. The control peptide Ala-Gly-Gln-Lys-Cys-Lys-Ala-Gly-Gln-Trp was synthesized using standard FastMoc chemistry with a Model 433A peptide synthesizer (Applied Biosystems) on Fmoc-Trp-resin (Biosearch Research Chemicals). After cleavage, the raw material was purified by preparative reversed phase HPLC. Fractions containing the pure peptide as confirmed by electrospray ionization mass spectroscopy (calculated mass 1075.5 Da, ESI-MS, positive mode, observed mass 1075.5 ± 0.3 Da) were lyophilized and stored at −20 °C. Cy5-succinimidyl ester was obtained from Amersham Pharmacia Biotech, hydroxylamine from Pierce. All other chemicals and solvents were from Aldrich (Milwaukee, WI). All reactions were performed at room temperature. Exposure of dye solutions to bright light was avoided. A VirTis Benchtop 3.3 freeze-dryer with a condenser temperature of −105 °C was used for

lyophilization in order to minimize damage to the vacuum pump from uncondensed acetonitrile and other organic solvents.

Synthesis of Cy5-thioester. The following reactions were performed under a dry nitrogen atmosphere. It is advisable to use Hamilton syringes, ensure good ventilation, and avoid contact of the reaction mixture with water or oxygen. Benzyl mercaptan (117 μL, 1.0 mmol) was slowly added to a mixture of 0.5 mL of 2.0 M trimethylaluminum (1.0 mmol) in hexane and 2 mL of anhydrous dichloromethane cooled to 0 °C in a 4 mL glass reaction vessel while stirring. The reaction was allowed to warm to room temperature over a 20 to 30 min period. A 100 μL volume of this solution was added to 1 mg of Cy5-succinimidyl ester thoroughly dissolved in 50 μL of anhydrous DMF, yielding a clear colorless solution, and stirred for about 60 min. Solubilization of the dye in DMF at high concentration was slightly batch-dependent. Incomplete dissociation of the dye can be detected by a characteristic increase of the absorbance band at 600 nm. In this case, sonication should be continued until the absorbance spectrum of the monomeric dye is observed.

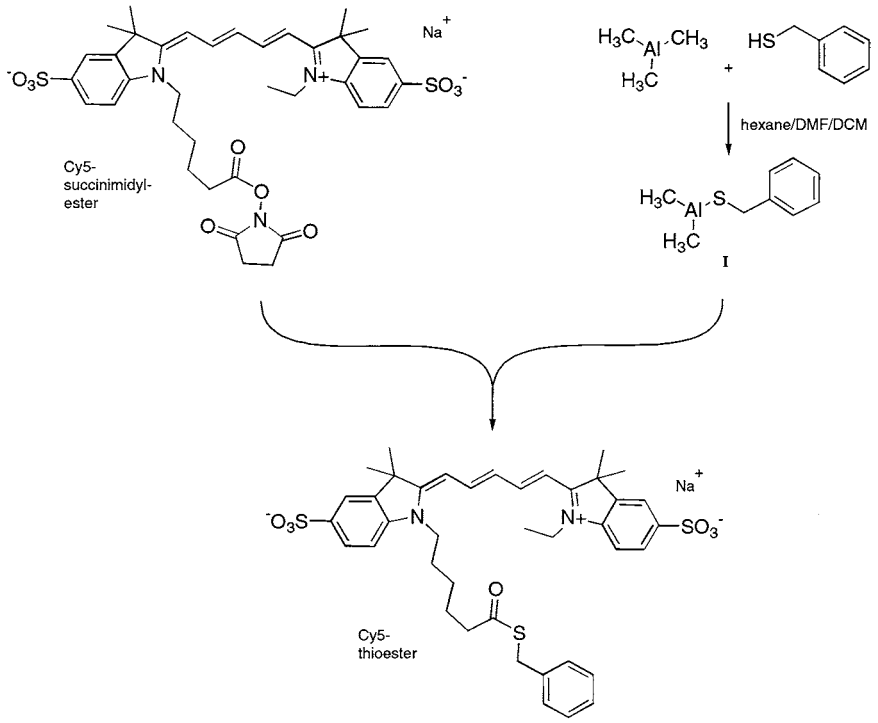
To avoid precipitation of the product under purification conditions, 20 μL portions of the reaction mixture were diluted 5-fold with DMF and added to 1 mL of a 10% acetonitrile/90% water mixture plus 0.1% TFA while stirring vigorously, centrifuged for 5 min at 10000*g* in a regular 1.5 mL polypropylene reaction vessel to clear the solution completely, and applied to a preparative reversed phase HPLC column. Fractions containing Cy5-thioester as detected by absorbance at 648 nm were combined, and the dye concentration was determined using the same molar extinction coefficient (ϵ = 250000 M^{-1} cm^{-1}) as published for the Cy5-monofunctional dye (Mujumdar et al., 1993). Portions corresponding to 10 to 100 nmol of Cy5-thioester were frozen in liquid nitrogen, lyophilized, and stored at −20 °C.

Reversed Phase HPLC. Analytical and preparative gradient HPLC were performed on a Waters 600E multisolvent delivery system equipped with a Waters 996 photodiode array absorbance detector. Preparative HPLC was run on a Vydac C4 column (214TP1022, 5 μm particle diameter, 22 × 250 mm) at a flow rate of 5 mL/min over 45 min. Analytical HPLC was performed on a Vydac C4 column (214TP54, 5 μm particle diameter, 4.6 × 250 mm) at a flow rate of 1 mL/min over 30 min. All runs used linear gradients of 0.1% TFA in 10% acetonitrile/90% water vs 0.1% TFA in 90% acetonitrile/10% water.

Peptide Labeling. The peptides were dissolved in buffer containing 6 M GdmCl, 100 mM sodium phosphate, pH 7.6, to a concentration of 1 to 2 mM, and 4% thiophenol was added. Peptide concentrations were determined using the absorbance of the single tryptophan residue present in the sequence (ϵ = 5690 M^{-1} cm^{-1} at 280 nm; Gill and von Hippel, 1989). Cy5-thioester was dissolved in DMF to a concentration of 20 mM, sonicated, and vortexed to completely dissolve the dye and then added to the peptide solution to give a final dye concentration equimolar with the peptide. The solution was vortexed to dissolve the thiol additive and then incubated at room temperature in the dark. The reactions were monitored by analytical reversed phase HPLC.

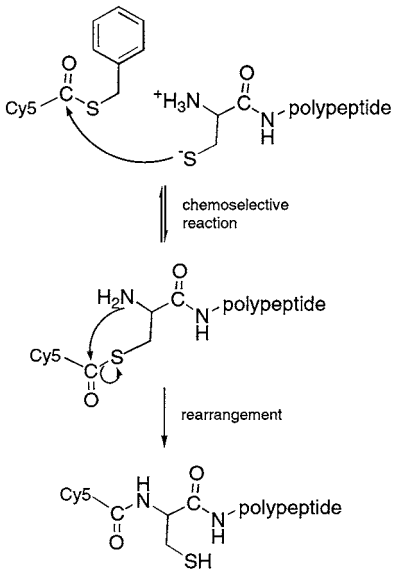
RESULTS AND DISCUSSION

The family of cyanine dyes (Mujumdar et al., 1993) has become one of the most frequently used groups of fluorophores in high sensitivity fluorescence detection and optical single molecule experiments due to their high extinction coefficients, high fluorescence quantum yields, and resistance to photobleaching. Especially Cy5 has attracted much attention due to its extremely long-wavelength fluorescence emission maximum at 667 nm, allowing excellent spectral separation in studies requiring multiccolor detection, e.g., single molecule fluorescence resonance energy transfer experiments (Ha, 2001). Currently, it is commercially available as a succinimidyl ester, which can be used for the modification of amines, and as a maleimide, which reacts with the sulfhydryl groups of cysteine residues. To increase the selectivity of protein labeling even further, we decided to devise a method that allows modification of a single position in a polypeptide chain. To this end, the succinimidyl ester of Cy5 was first converted to a benzyl thioester, which can then undergo a highly specific conjugation reaction with an N-terminal cysteine residue in a polypeptide chain.



Synthesis of Cy5-thioester. The direct formation of Cy5-thioester from the succinimidyl ester and an aromatic thiol like benzyl mercaptan proceeds to only very low yields (unpublished observation) and can thus not be used for an efficient synthesis. Therefore, a two-step reaction was used to synthesize Cy5-thioester starting from the Cy5-succinimidyl ester (or N-hydroxy succinimide/NHS ester) (Scheme 1). Initially, the aluminum reagent **I** was prepared from an equimolar mixture of trimethylaluminum and benzyl mercaptan in a protocol similar to the one described by Hatch and Weinreb in 1977. These aluminum compounds are known to react with a variety of esters at room temperature to produce the respective thioesters in good yield (Corey and Beames, 1973; Cohen and Gapinski, 1978) and can be used without further purification. It was therefore attempted to use this very simple procedure to generate the benzyl thioester of Cy5.

Surprisingly, incubation of Cy5-succinimidyl ester with the reaction mixture containing compound **I** resulted in a colorless solution, possibly via interaction of the chromophore with the aluminum compounds. It regained its deep blue color after dilution in aqueous solutions or acetonitrile/water mixtures, indicating a reversible association with some component of the reaction mixture. Analytical reversed phase HPLC indicated quantitative conversion of the succinimidyl ester after 60 min. The product eluted as a single peak with a clear shift to larger elution volume (Cy5-succinimidyl ester: 14.5 mL, Cy5-thioester: 16.5 mL), as would be expected from the presence of the more hydrophobic benzyl group instead of the *N*-hydroxysuccinimidyl group. The yield of thioester as calculated from the integrated absorbance signal at 648 nm was 95 ± 5%. The calculated molecular mass of the Cy5-benzyl thioester of 762.2 Da was confirmed by ESI-MS (positive mode, $[M - H]^+$ 763.3 ± 0.2 Da) and FABMS (negative mode, $[M - H]^-$ 761.2 ± 0.2 Da). Lyophilized product retained its reactivity for months if stored at −20 °C.



Spectroscopically, no significant differences of Cy5-thioester compared to the succinimidyl ester were detected. The absorbance maximum was at 648 nm for both derivatives, and the fluorescence quantum yield was unaltered in the thioester.

Peptide Labeling. The labeling approach described here makes use of the same chemistry as the method known as native chemical ligation (Scheme 2; Dawson et al., 1994; Dawson and Kent, 2000), which was developed for the synthesis of proteins from smaller, in particular chemically synthesized peptides. Exchange of a thioester with the thiol moiety of the N-terminal cysteine side chain gives a thioester-linked intermediate

Scheme 1. Conversion of Cy5-succinimidyl Ester to Cy5-thioester via Activation of Benzyl Mercaptan with Trimethylaluminum

Scheme 2. Probable Mechanism of the Peptide Labeling Reaction in Analogy to Native Chemical Ligation[a]

[a] Adapted from Dawson and Kent, 2000.

as the initial covalent product in a reversible reaction. Without change in the reaction conditions, a rapid intramolecular reaction occurs, forming the thermodynamically favored amide bond at the ligation site. This second step is irreversible under the conditions used, leading to the formation of the ligation product in high yield. Assuming that the mechanism of this reaction is not influenced significantly by the structure of the component containing the thioester, the reaction was adapted for the "ligation" of a polypeptide with the benzyl thioester of Cy5.

To test the reactivity of the Cy5-thioester in this type of reaction, a chemically synthesized model peptide with an N-terminal cysteine residue was used (see Experimental Procedures), and the reaction was carried out under essentially the same conditions as described for the native chemical ligation of peptides. The reaction is usually performed in 6 M GdmCl, under strongly denaturing conditions, which causes the reactivity of the N-terminal cysteine residue to be independent of the three-dimensional structures of the polypeptides in their native state. Additionally, 4% thiophenol were included in the reaction mixture. This has been shown to accelerate the reaction and increase reaction yields due to the formation of the more reactive phenyl thioester through in situ transesterification (Dawson et al., 1997). Additionally, excess thiol keeps cysteine side chains reduced and catalyzes the reversal of unproductive thioester formation. The advantage of using the less activated benzyl thioester as the primary component in the reaction mixture is its lower susceptibility to hydrolysis during storage and handling.

Analytical HPLC showed the emergence of two new components during the course of the labeling reaction eluting at volumes of 13.8 and 15.8 mL, which were identified by mass spectrometry as the labeled peptide (calculated average mass: 2226.5 Da, ESI-MS positive mode: observed average mass 2226.2 ± 0.3 Da) and Cy5-phenyl thioester (calculated mass: 748.2 Da, ESI-MS positive mode: $[M - H]^+$ 749.2 ± 0.2 Da), respectively. Figure 1 shows the kinetics of their formation at a peptide and Cy5-thioester concentration of 1.4 mM. The appearance of the signal corresponding to the labeled peptide exhibits a slight lag phase, during which a steady-state level of phenyl thioester builds up. This supports the concept of in situ transesterification of Cy5-benzyl thioester to the more reactive Cy5-phenyl thioester preceding the ligation reaction as described above. Under these conditions, a final Cy5-peptide yield of about 37% was reached after 24 h (Figure 1). At peptide and Cy5-thioester concentrations of about 2 mM, final yields of up to 68% labeled peptide were achieved. It would obviously be expected that the equilibrium can be shifted

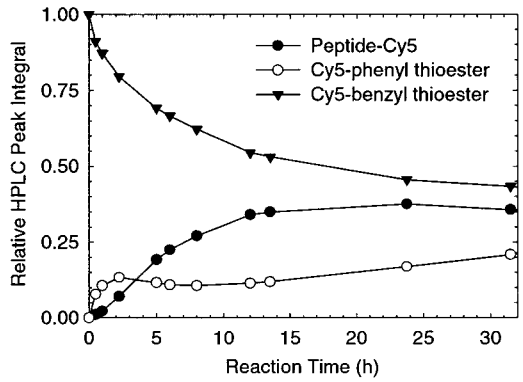


Figure 1. Kinetics of peptide labeling with Cy5-benzyl thioester at 20 °C in 6 M GdmCl, 100 mM sodium phosphate, pH 7.6, 4% thiophenol. Both peptide and Cy5-thioester concentration were 1.4 mM. Analytical HPLC runs were monitored by absorbance at 648 nm, all eluting peaks were integrated, and the relative fraction of the individual species was calculated, assuming equal extinction coefficients.

toward the products even further by increasing the concentrations of the reactants. Concentrated solutions of GdmCl (6 M) are very good solvents for unfolded proteins, allowing concentrations of up to 100 mg/mL (Rudolph et al., 1997). The solubility of the Cy5-thioester is more limited under these conditions. Even at 1 mM, it needs to be thoroughly predissolved in DMF, and a concentration of about 10% DMF must be present in the reaction mixture to avoid precipitation of the dye. At higher DMF concentrations, analytical HPLC indicated the accumulation of an unidentified side product heterogeneous in molecular mass at an elution volume of about 14.4 mL in analytical HPLC, which limits the concentration of DMF that can be used. Depending on the availability of the individual reaction components, increasing the protein concentration may thus be the more practicable approach.

After purification of the Cy5-peptide conjugate by preparative reversed phase HPLC, the lyophilized powder was redissolved in 6 M GdmCl, 100 mM sodium phosphate buffer, pH 7. The spectroscopic properties of the labeled peptide were very similar to those of the unreacted succinimidyl ester and the benzyl thioester of Cy5. The absorbance maximum was at 648 nm in 6 M GdmCl, and at 649 nm after dilution to 100 mM GdmCl. Cy5 fluorescence was quenched by 10 to 20% after attachment to the peptide (depending on GdmCl concentration), possibly due to the proximity of the tryptophan residue in the peptide. Similar effects are well-known for a variety of fluorescent dyes upon attachment to proteins and are apparently due to charge-transfer interactions with aromatic amino acid residues (Watt and Voss, 1977). Altogether, the peptide labeled by the protocol described here has the same spectroscopic properties expected from Cy5 conjugates using other commonly available chemistries such as maleimides or succinimidyl esters.

To determine the degree of specificity of the reaction for aminoterminal Cys residues, we used the peptide Ala-Gly-Gln-Lys-Cys-Lys-Ala-Gly-Gln as a control, which contains a central Cys flanked by two Lysine residues. In this case, the Cys would also be expected to form a thioester derivative with Cy5, which could then possibly be attacked by the ϵ-amino groups of the neighboring lysines, which have a p*K* value very similar to that of the α-amino group of cysteine. In a control reaction of this peptide with Cy5-benzyl thioester set up analogous to the one described above, 49% of the control peptide were found to be derivatized by the dye after 24 h, as determined by analytical HPLC and mass spectrometry (ESI-MS positive mode: observed average mass 1714.3 $\pm$ 0.3 Da). However, the mass of the thioester and a potential amide derivative are indistinguishable (calculated average mass:1714.0 Da), necessitating further characterization of the linkage. After incubation of samples of the reaction diluted 10-fold with 50 mM hydroxylamine in 6 M GdmCl, 100 mM sodium phosphate, pH 7.6 for 5 h, no labeled peptide was detectable by HPLC or mass spectrometry. This shows that no amide bonds had been formed between the ϵ-amino group of the lysine residues and Cy5. Instead, only Cy5-hydroxylamine was found as a product (calculated mass: 671.0 Da, ESI-MS positive mode: $[M - H]^+$ 671.1 $\pm$ 0.2 Da), resulting from the reaction of both the peptide-Cy5 thioester and unreacted Cy5-benzyl or Cy5-phenyl thioester with hydroxylamine. In the case of the peptide labeled at the aminoterminal Cys, on the other hand, hydroxylamine did not cause removal of the dye, as expected for an amide linkage. All the Cy5-hydroxylamine formed in this reaction originated from unreacted Cy5-benzyl and Cy5-phenyl thioester. This result demonstrates the extremely high specificity of the labeling reaction for aminoterminal Cys residues and illustrates the important role of the geometric arrangement of the α-NH_2 moiety with respect to the thioester formed in the first reaction step (Dawson et al., 1994). Additionally, it shows that dye molecules bound to internal Cys residues via thioester bonds can be removed efficiently by incubation with hydroxylamine, a step that should always be performed after labeling of proteins with the method presented here.

Applications and Limitations. In the case of native chemical ligation, the success of the reaction is largely independent of the amino acid residues neighboring the thioester moiety (Dawson and Kent, 2000). The preparation of thioesters using the activation of thiols with trimethylaluminum has been shown to work very efficiently with a wide variety of starting esters (Hatch and Weinreb, 1977). This indicates that the protocol described here will be applicable to succinimidyl esters of other fluorescent dyes and labels without major modifications. Here we focused on Cy5 because of its widespread use and its outstanding fluorescence properties.

The most important feature of the chemistry of native chemical ligation is that conjugation occurs at a unique N-terminal Cys residue. As shown above, it does not matter how many additional internal Cys residues are present in the polypeptide, and no protecting groups are necessary for any of the side-chain functional groups normally found in proteins, similar to what has been found for peptide−peptide ligation (Hackeng et al., 1997). This makes it an ideal approach for attaching a single label even to a large, recombinantly expressed protein containing many cysteine and lysine residues, a situation in which the usual labeling methods do not provide sufficient specificity.

The recombinant expression of proteins with an N-terminal cysteine residue is easily possible either by proteolytic cleavage next to a cysteine residue (Erlanson et al., 1996) or using an intein-based approach (Perler et al., 1997). The more straightforward method is usually the former. It involves constructing an expression vector in which a DNA sequence encoding a recognition site for a highly specific protease like FactorXa followed by cysteine is inserted between an upstream affinity-purification handle (e.g., maltose binding protein MBP, glutathione-S-transferase GST, or a polyhistidine tag) and the appropriate gene fragment of interest. Following

expression and affinity purification, the fusion protein is treated with the protease to give the desired Cys-polypeptide, which can be used directly in the labeling reaction described here and then purified, for instance by HPLC or size-exclusion chromatography.

One potentially limiting property of the method is that it requires refolding of the labeled protein to its native three-dimensional structure, because the reaction does not proceed efficiently in the absence of GdmCl, even for a highly soluble and unstructured peptide like the one used in this study (unpublished observation). The same requirement applies to proteins synthesized by native chemical ligation (Dawson and Kent, 2000) and to many recombinant proteins that aggregate and form inclusion bodies when expressed to high concentrations. For single domain proteins, refolding in vitro is usually simple and proceeds to very high yields, but even most larger multidomain proteins can be refolded very efficiently (Rudolph et al., 1997). Assuming that the N-terminus of the protein is surface-exposed, a serious effect of the additional cysteine or the attached dye on the folding of the protein is improbable, such that the refoldability of the protein under investigation can be investigated before any changes to the sequence are made.

An additional advantage of the dye conjugation to N-terminal cysteins using thioester derivatives is the high stability of the resulting chemical bond compared to many other labeling chemistries. As for the reaction of the commonly used succinimidyl esters with amines, an amide bond is formed, which allows storage and repeated use over an extended period of time. This is an important factor in many of the applications using bioconjugates. The conjugates are also stable in the presence of reducing agents such as dithiothreitol (unpublished observation), which can be important in the investigation of proteins or peptides with reduced cysteine residues.

In summary, the reaction of Cy5-benzyl thioester with N-terminal cysteine residues provides a reliable and uniquely specific method to label polypeptides. The synthesis of thioesters from the respective succinimidyl esters, which are available for most commonly used probes, is a simple and quantitative reaction. The protocol presented here is expected to be applicable to a wide range of labels and polypeptides, including large recombinantly expressed proteins. This will be an important tool for studies requiring the exact positioning of a label in a polypeptide containing multiple sulfhydryl or amino groups.

Incorporation of Reversibly Cross-Linked Polyplexes into LPDII Vectors for Gene Delivery

Michael A. Gosselin, Wenjin Guo, and Robert J. Lee*

Division of Pharmaceutics and Pharmaceutical Chemistry, College of Pharmacy, The Ohio State University, Columbus, Ohio 43210. Received February 5, 2002; Revised Manuscript Received June 12, 2002

LPDII vectors are synthetic vehicles for gene delivery composed of polycation-condensed DNA complexed with anionic liposomes. In this study, we evaluated the stability and transfection properties of polyethylenimine (PEI, 25 kDa)/DNA polyplexes before and after covalent cross-linking with dithiobis(succinimidylpropionate) (DSP) or dimethyl·3,3′-dithiobispropionimidate·2HCl (DTBP), either alone or as a component of LPDII vectors. We found that cross-linking PEI/DNA polyplexes at molar ratios ≥10:1 (DSP or DTBP:PEI) stabilized these complexes against polyanion disruption, and that this effect was reversible by reduction with 20 mM dithioerythritol (DTE). Transfection studies with polyplexes cross-linked at molar ratios of 10:1−100:1 in KB cells, a folate receptor-positive oral carcinoma cell line, showed decreasing luciferase gene expression with increasing cross-linking ratio. Subsequently, polyplexes, cross-linked with DSP at a molar ratio of 10:1, were combined with anionic liposomes composed of diolein/cholesteryl hemisuccinate (CHEMS) (6:4 mol/mol), diolein/CHEMS/poly(ethylene glycol)-distearoylphosphatidylethanolamine (PEG-DSPE) (6:4:0.05 mol/mol), or diolein/CHEMS/folate-PEG-cholesterol (folate-PEG-Chol) (6:4:0.05 mol/mol) for LPDII formation. Transfection studies in KB cells showed that LPDII vectors containing cross-linked polyplexes mediated ∼2−15-fold lower gene expression than LPDII prepared with un-cross-linked polyplexes, depending on the lipid:DNA ratio. Inclusion of PEG-DSPE at 0.5 mol % appeared to further decrease transfection levels ∼2−5-fold. Compared with LPDII formulated with PEG-DSPE, LPDII incorporating 0.5 mol % folate-PEG-Chol exibited higher luciferase activities at all lipid:DNA ratios tested, achieving an ∼10-fold increase at a lipid:DNA ratio of 5. Compared with cross-linked LPDII vectors without PEG-DSPE, inclusion of folate-PEG-Chol increased luciferase acitivities 3−4-fold between lipid:DNA ratios of 1 and 5. Interestingly, inclusion of 1 mM free folate in the growth media during transfection increased transfection activity ∼3−4-fold for cross-linked LPDII vectors and LPDII containing folate-PEG-Chol, but had no effect on the transfection activity of LPDII formulated with PEG-DSPE. However, in the presence of 5 mM free folate, the luciferase activity mediated by LPDII vectors containing folate-PEG-Chol was reduced ∼6-fold. Transmission electron micrographs were also obtained to provide evidence of LPDII complex formation. Results showed that cross-linked LPDII vectors appear as roughly spherical aggregated complexes with a rather broad size distribution ranging between 300 and 800 nm.

INTRODUCTION

Nonviral delivery of gene therapy is an emerging strategy for the treatment of genetic disease, but progress is currently limited by inadequacies in the vectors available for gene transfer (*1*). The main deficiency of nonviral vectors is their relatively low in vivo gene transfer efficiency, compared with viral vectors. Therefore, research efforts have been focused on the design of nonviral vectors capable of achieving high tissue-specific gene expression with low immunogenicity and minimal toxicity. One particular strategy being evaluated to achieve these goals involves the use of LPD (liposome-entrapped polycation-condensed DNA) vectors containing covalently cross-linked polyplexes for gene delivery.

LPD vectors are synthetic vehicles for gene delivery composed of polycation-condensed DNA (polyplex) complexed with cationic or anionic liposomes via electrostatic interactions. Early LPD formulations, coined LPDI, utilized poly-L-lysine (PLL)-condensed DNA in association with cationic liposomes composed of dioleoylphosphatidylethanolamine/1-*β*-[*N*-(*N*′,*N*′-dimethylaminoethane)carbamoyl]cholesterol (DOPE/DC-Chol; 6:4 mol/mol) (*2*). Subsequent alteration of the lipid component led to the development of LPDII transfection vectors. In contrast to LPDI, LPDII vectors are prepared with anionic pH-sensitive liposomes, such as dioleoylphosphatidylethanolamine/cholesteryl hemisuccinate (DOPE/CHEMS; 6:4 mol/mol) (*3*, *4*). Since LPDII can be prepared with a net negative charge, these vectors have greater potential for receptor targeting, due to reduced nonspecific electrostatic interactions with nontarget cells. Moreover, neutral or negatively charged transfection vectors should be more compatible with the physiological environment of the systemic circulation, due to reduced interactions with components of the blood and decreased activation of the complement system (*5*).

First-generation LPDII vectors, those formulated with DOPE/CHEMS liposomes, exhibit nearly a complete loss of transfection activity in the presence of serum. Recently, our lab has developed a method to circumvent this limitation through incorporation of a novel anionic pH-sensitive liposome formulation composed of diolein/

CHEMS (6:4 mol/mol) (*28*). Transfection studies with LPDII vectors containing diolein/CHEMS liposomes showed that transfection activity was sustained even when transfection was carried out in the presence of 50% fetal bovine serum (*28*). In addition, it has been shown that the DNA condensing agent can consist of polycations other than PLL, such as polyethylenimine (PEI) (*6*) or cationic dendrimers (*7*), without negatively affecting gene expression.

Recent efforts in our lab have been directed toward assessing the utility of homobifunctional cross-linking reagents for the development of reducibly cross-linked polyplexes for gene delivery (*8*). Two cross-linking reagents, dithiobis(succinimidylpropionate) (DSP) and dimethyl·3,3′-dithiobispropionimidate·2HCl (DTBP) (*9*), were utilized to create relatively high molecular weight polymers, composed of cross-linked low molecular weight PEI, for polyplex assembly. DSP is a homobifunctional *N*-hydroxysuccinimide (NHS) ester-based electrophilic cross-linking reagent containing an 8-atom spacer 12 Å in length. DTBP is similar to DSP in structure and length, but contains an imidoester reactive group for amidine bond formation. The significance of the amidine bond is that net molecular charge is retained after conjugation with DTBP, whereas amide bond formation mediated by DSP results in the elimination of two positive charges. Both cross-linking reagents react with primary amines to form stable covalent bonds, and are constructed around a centrally located disulfide linkage that is cleavable with common reducing agents after conjugation (Figure 1).

In the present study, we describe a novel LPDII transfection vector containing a covalently stabilized PEI-based polyplex core complexed with anionic pH-sensitive liposomes composed of diolein/CHEMS. We hypothesized that since LPDII formation is predicated on electrostatic interactions between a cationic polymer and plasmid DNA initially, and subsequently between cationic polyplexes and anionic liposomes, that covalent cross-linking of the polyplex core, after DNA condensation, would stabilize the polyplex against dissociation due to charge competition from the anionic lipid component. Therefore, studies were performed to assess the effects of cross-linking PEI/DNA polyplexes with DSP or DTBP on polyplex stability and transfection potential, and subsequently the transfection performance of LPDII vectors containing covalently cross-linked polyplexes in folate receptor-positive KB oral cancer cells in vitro. Furthermore, additional studies were perfomed to evaluate the effect of introducing a lipid-anchored folate receptor-targeting ligand or hydrophilic poly(ethylene glycol) (PEG) coating into the LPDII formulation. Covalent attachment of folate for receptor targeting has proven to be effective in vitro for targeting liposomes (*10*−*12*) and LPDII vectors (*3*) to cancer cells which overexpress the high-affinity folate receptor. In addition, incorporation of PEG into liposome formulations has been shown to enhance tumor accumulation in vivo by reducing clearance by the reticuloendothelial system (RES), thus extending the circulation half-life (*13, 14*).

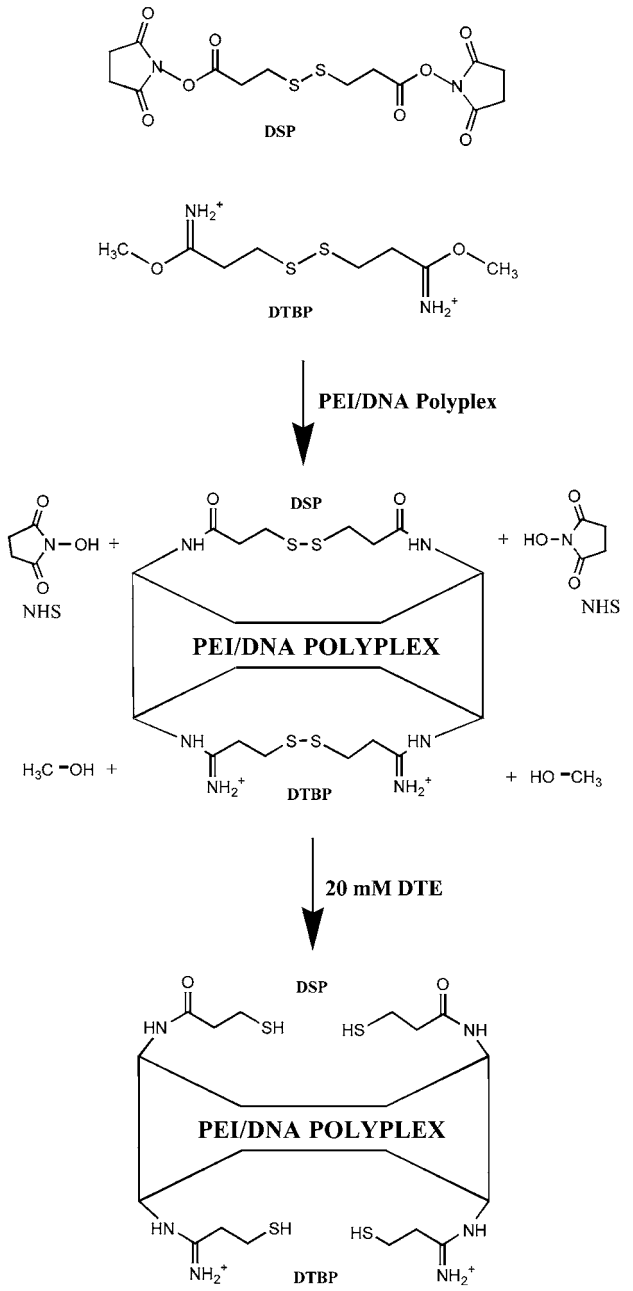

Figure 1. Proposed reaction scheme for covalent cross-linking of PEI/DNA polyplexes with cross-linking reagents DSP and DTBP. DSP cross-linking is illustrated above the schematic polyplex, while DTBP cross-linking is shown below. Also shown is the effect of disulfide bond reduction from 20 mM dithioerythritol (DTE).

MATERIALS AND METHODS

Materials. Cholesteryl hemisuccinate (CHEMS), di-9-octadecenoylglycerol (diolein, ∼85% 1,3- and 15% 1,2-isomer), dithioerythritol (DTE), bovine serum albumin (BSA) protein standards, ethidium bromide (EtBr), and other general use chemicals were purchased from Sigma Chemical Co. (St. Louis, MO). Dithiobis(succinimidylpropionate) (DSP), dimethyl·3,3′-dithiobispropionimidate·2HCl (DTBP), and bicinchoninic acid (BCA) protein assay reagents were purchased from Pierce (Rockford, IL). Anhydrous dimethyl sulfoxide (DMSO), polyethylenimine (PEI, branched, M_r ∼25 000), and poly(methacrylic acid) (PMAA, M_w ∼6500) were purchased from Aldrich Chemical Co. (Milwaukee, WI). Luciferase assay reagents and recombinant luciferase were obtained from Promega (Madison, WI). All tissue culture media and supplies were purchased from Gibco BRL (Rockville, MD).

Plasmid Preparation. pcDNA3-CMV-Luc (pLuc, 7.1 kb) plasmid DNA encoding the firefly luciferase gene under control of the cytomegalovirus enhancer/promoter was obtained as a gift from Dr. Leaf Huang at the University of Pittsburgh School of Pharmacy. Cloning and preparation of plasmid DNA were performed by propagating transformed DH5-α *E. coli* in LB media containing 50 μg/mL ampicillin, followed by isolation and

purification with a commercially available plasmid purification kit (Qiagen, Valencia, CA). Concentration and purity of DNA were assessed spectrophotometrically by measuring absorbance at 260 and 280 nm ($OD_{260}/OD_{280} \sim 1.7$). Plasmid size and integrity were confirmed using agarose gel electrophoresis (0.9% agarose gel containing 0.5 μg/mL ethidium bromide) and cleavage with the restriction endonuclease *Hin*dIII (Gibco BRL).

Cell Culture. KB cells, a folate receptor-positive human oral squamous cell carcinoma, were obtained as a gift from Dr. Philip Low at Purdue University. The cells were cultured in folate-free RPMI 1640 media supplemented with 10% fetal bovine serum (FBS), 100 units/mL penicillin, 100 μg/mL streptomycin, and 300 μg/mL L-glutamine at 37 °C in a 5% CO_2 humidified atmosphere. FBS provided the only source of folate in the growth media, which achieved physiologically relevant folate concentrations.

Liposome Preparation. Three pH-sensitive anionic liposome formulations were prepared: diolein/CHEMS (6:4 mol/mol); diolein/CHEMS/PEG ($M_r \sim 2000$)-distearoylphosphatidylethanolamine (DSPE) (6:4:0.05 mol/mol); and diolein/CHEMS/folate-PEG ($M_r \sim 3350$)-cholesterol (Chol) (6:4:0.05 mol/mol). PEG-DSPE was purchased from Avanti Polar Lipids, Inc., and folate-PEG-Chol was synthesized as described previously (*15*). Liposomes were prepared by mixing ~8−15 mg of total lipid (dissolved in chloroform as 20 mg/mL solutions) at the appropriate ratios in 13 × 100 mm glass test tubes. The chloroform was evaporated under a stream of nitrogen, and the lipids were further dried in a desiccator under vacuum for 30 min. The resulting lipid film was rehydrated with 20 mM HEPES buffer to a concentration of 3.33 mg/mL, and adjusted to pH 8.0−8.5. The suspensions were then vortexed and sonicated in a bath sonicator until the mean particle diameter was between 100 and 150 nm, as determined by dynamic light scattering using a NICOMP submicron particle sizer model 370. Lipid suspensions were stored at 4 °C until use.

Preparation of PEI/DNA Polyplexes and Stabilization by Cross-Linking. For polyplex preparation, 10 μg of pLuc DNA and the amount of PEI required to achieve the desired N/P (PEI nitrogen:DNA phosphate) ratios were each diluted in 250 μL of HEPES buffer (20 mM, pH 8.0). The PEI solution was quickly added to the DNA, and the resulting solution was then mixed and allowed to stand at room temperature (RT) for 15 min. For covalent cross-linking of polyplexes, DSP or DTBP, dissolved in anhydrous DMSO as a concentrated stock solution (1−10 mg/mL), was added to polyplexes at various concentrations depending on the desired cross-linking ratio. Cross-linking ratios are expressed as DSP:PEI molar ratios, and DMSO was kept below 5% of the total volume of polyplex solutions. After addition of the appropriate cross-linking reagent, samples were incubated at RT for 1 and 3 h for DSP and DTBP, respectively. Preparation of cross-linked and un-cross-linked polyplexes for transfection studies was performed similarly, with exceptions noted below.

Stability of Cross-Linked Polyplexes against Polyanion Disruption with PMAA. Polyplex stability against polyanion disruption was examined by measuring the ability of PMAA to restore DNA access to EtBr binding. Polyplexes with various N/P ratios containing 10 μg of pLuc DNA in 500 μL of HEPES buffer (20 mM, pH 8.0), either with or without DSP cross-linking, were diluted into 1.9 mL of 0.1× phosphate-buffered saline (PBS: 136.9 mM NaCl, 2.68 mM KCl, 8.1 mM Na_2HPO_4, 1.47 mM KH_2PO_4, pH 7.4). PMAA was added at various concentrations and incubated with polyplexes for 30 min at RT. To evaluate the reducibility of the disulfide bond present in the cross-linking reagent, 20 mM dithioerythritol (DTE) was added to some samples prior to the PMAA incubation. EtBr was present in the solution at a final concentration of 0.4 μg/mL, and EtBr fluorescence was measured on a Perkin-Elmer LS-50-B spectrometer, operated with a FTWinlab computer program (Morena Valley, CA). The excitation and emission wavelengths were set at 523 nm, with a 5 nm slit width, and 602 nm, with a 10 nm slit width, respectively.

Polyplex stability was further evaluated by agarose gel electrophoresis with EtBr staining. Polyplexes containing 1 μg of pLuc DNA prepared at a N/P ratio of 6, either with or without DSP cross-linking, were incubated with 100 μM PMAA for 30 min at RT. The reducibility of cross-linking was analyzed by including 20 mM DTE during the incubation. Half of each sample (0.5 μg of DNA) was then loaded on a 0.9% agarose gel containing 0.5 μg/mL EtBr, and run at 120 V for ~90 min.

Transfection of KB Cells with Cross-Linked Polyplexes or LPDII Vectors. For transfections, 10^5 KB cells/well were seeded in 24-well plates (Falcon) and allowed to incubate in folate-free RPMI 1640 growth media containing 10% FBS for approximately 20 h at 37 °C in a 5% CO_2 humidified atmosphere (~70−80% confluence). Immediately prior to transfection, cells were rinsed with warm PBS, and 0.5 mL of folate-free RPMI 1640 growth media was added to each well. LPDII transfections were carried out in the presence of 10% FBS, whereas polyplex transfections were performed under serum-free conditions. Transfection complexes were added to each well and incubated with KB cells for 2 or 4 h for LPDII vectors or polyplexes, respectively. After rinsing the cells with 300 μL of warm PBS, the transfection medium was replaced with 0.5 mL of fresh RPMI containing 10% FBS. A further 24 h incubation was imposed, followed by cell lysis and analysis of luciferase gene expression (see below).

PEI/pLuc polyplexes (N/P = 10) utilized for transfection were prepared as described above for EtBr fluorescence analysis, but with 1 μg of DNA and the desired amount of PEI, each dissolved in 30 μL of 20 mM HEPES buffer prior to mixing. Various concentrations of DSP or DTBP, dissolved in DMSO, were then added to polyplex solutions to achieve different cross-linking ratios, and incubated at RT for 1 or 3 h, respectively. DMSO comprised less than 5% of the solution volume.

LPDII vectors, containing PEI/pLuc polyplexes (N/P = 4) and diolein/CHEMS liposomes, were prepared as described above by diluting 3 μg of DNA and the desired amount of PEI, each in 50 μL of HEPES buffer (20 mM, pH 8.0) prior to mixing. For cross-linking, 2.5 μL of DSP in DMSO (0.1 mg/mL) was added to each sample, lightly vortexed, and incubated at RT for 1 h. Various concentratons of diolein/CHEMS liposomes in 50 μL of HEPES buffer were then added to each sample, depending on the desired lipid:DNA ratio, and allowed to stand at RT for 15 min. Finally, 50 μL (1 μg of DNA/well) of the resulting solution was added to each well of a 24-well plate to evaluate transfection potential.

To analyze luciferase expression, the growth medium was removed from each well, and the cells were rinsed twice with cold PBS. Next, 200 μL of ice-cold lysis buffer (0.5% Triton X-100, 100 mM Tris-HCl, 2 mM EDTA, pH 7.8) was added to each well, followed by incubation on ice for 30 min. The lysate was then removed and centrifuged for 1 min at 13 000 rpm. Finally, 10 μL of cellular lysate was mixed with 50 μL of luciferase substrate (Promega), and the luminescence was measured for 10 s on a Mini-Lum luminometer (Bioscan, Inc.,

Washington, DC). Relative light units were standardized for protein concentration as determined by the BCA protein determination assay using bovine serum albumin standards. Luciferase activity is also expressed as femtomoles of luciferase per milligram of protein, determined from a standard curve of luciferase activity using recombinant luciferase.

Negative Stain Transmission Electron Microscopy (TEM). DSP cross-linked polyplexes (10:1) and LPDII particles were prepared as described above at an N/P ratio of 6 and a lipid:DNA ratio of 5 (w/w), respectively, with each sample containing 10 μg of plasmid DNA. An aqueous solution of bacitracin was prepared at a concentration of 200 mg/mL, and diluted to a working strength of 10 mg/mL. An aqueous 1% uranyl acetate solution was also prepared, and was filtered and centrifuged to remove any particulate matter before use. Samples were prepared by placing a 200 mesh size Formvar-coated copper grid on a drop of bacitracin solution (10 mg/mL) for 1 min, before wicking away excess solution from the grid with filter paper. Next, each grid was placed in contact with the appropriate sample for 3 min, and the excess liquid was again wicked away with filter paper. The grid was then subjected to two brief sequential rinses by placing the grid on a drop of water and wicking away excess fluid. Finally, the grid was incubated in 1% uranyl acetate solution for 2.5 min, excess liquid was removed, and the grid was allowed to dry at RT for 5 min. Electron micrographs were obtained at 60 kV at 100000× magnification for polyplexes and diolein/CHEMS liposomes or 45000× magnification for LPDII particles.

RESULTS

To evaluate the effect of cross-linking on polyplex-mediated transfection of KB cells in vitro, 25 kDa PEI/pLuc DNA polyplexes were prepared at an N/P (PEI nitrogen:DNA phosphate) ratio of 10, followed by cross-linking with DSP or DTBP at various cross-linker:PEI molar ratios, as described under Materials and Methods. Specifically, cross-linking ratios of 0, 10, 20, 50, and 100:1 were evaluated. An N/P ratio of 10 was chosen based on previous studies showing efficient gene expression at this ratio (*16*). Figure 2 shows that as the cross-linking ratio with DSP or DTBP increases from 0 (control) to 100:1, luciferase gene expression decreases by approximately 3−4 orders of magnitude. The data further show that transfection is relatively independent of the reagent used for cross-linking, with nearly identical luciferase activity at a cross-linking ratio of 10. However, at higher cross-linking ratios (≥20), slightly better gene expression was observed with polyplexes cross-linked with DTBP.

Our next goal was to evaluate the stability of polyplexes, either with or without covalent stabilization by cross-linking, in the presence of a competing polyanion. Our initial stability analysis was performed on conventional PEI/DNA polyplexes prepared at a variety of N/P ratios, namely, 0 (DNA only), 2, 3, 5, and 10. These polyplexes were exposed to various concentrations of poly(methacrylic acid) (PMAA), an organic polyanion, ranging from 0 to 100 μM, followed by addition of ethidium bromide (EtBr) and quantitative fluorescence measurements. Detection of EtBr fluorescence is an indication of DNA being accessible for EtBr binding due to polyplex dissociation, or at least local decondensation of DNA. The EtBr fluorescence observed upon incubation with free plasmid DNA, in the absence of PEI and PMAA, was used as a reference control (i.e., 100% relative fluorescence). As seen in Figure 3, the addition of PMAA to free plasmid DNA, at concentrations up to 100 μM, had virtually no effect on fluorescence (N/P = 0). The results also show that in the absence of PMAA, EtBr fluorescence for all polyplexes decreases to ~10% of control, with the exception of polyplexes prepared at an N/P ratio of 2. Polyplexes prepared at this ratio are known to cause incomplete condensation of DNA due to inadequate charge neutralization, which led to an EtBr fluorescence reading of ~30%. As the concentration of PMAA was increased, progressively higher fluorescence readings were observed for all polyplexes, with values eventually approaching 100% of control at a PMAA concentration of 100 μM. Furthermore, polyplexes prepared at higher N/P ratios appeared more resistant to polyanion disruption, which can be seen in Figure 3 from the lower fluorescence readings obtained at high N/P ratios and low PMAA concentrations.

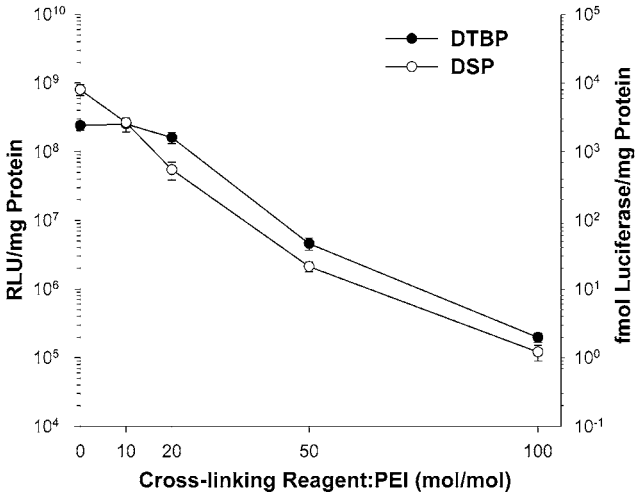

Figure 2. Effect of reducible cross-linking on the transfection activities of PEI/DNA polyplexes. Polyplexes were prepared at an N/P ratio of 10. Polyplexes were then cross-linked with DSP or DTBP at cross-linker:PEI molar ratios of 0, 10, 20, 50, and 100:1. The transfection activity of the covalently cross-linked polyplexes was then evaluated in KB cells in vitro. Cells were exposed to transfection vectors for 4 h in serum-free media, and luciferase activity was assayed 24 h later.

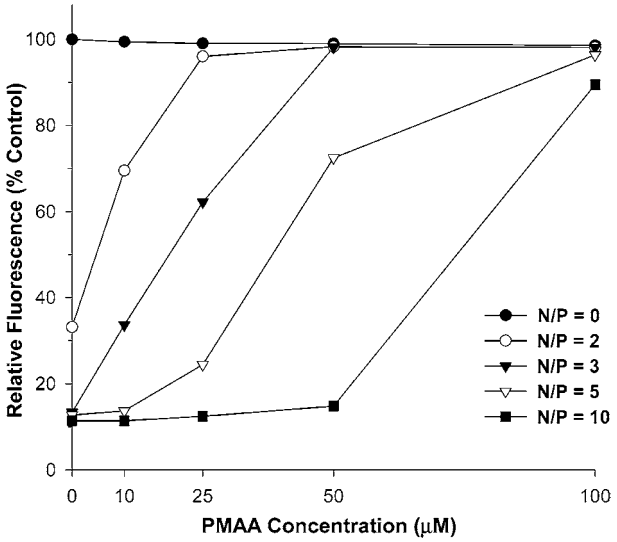

Figure 3. EtBr fluorescence from interactions with PEI/DNA polyplexes in the presence of a competing polyanion (PMAA). Polyplexes were prepared at N/P ratios of 0, 2, 3, 5, and 10, and exposed to various concentrations of PMAA up to 100 μM. EtBr was added to each sample at a concentration of 0.4 μg/mL, and fluorescence was measured at excitation and emission wavelengths of 523 and 602 nm, respectively.

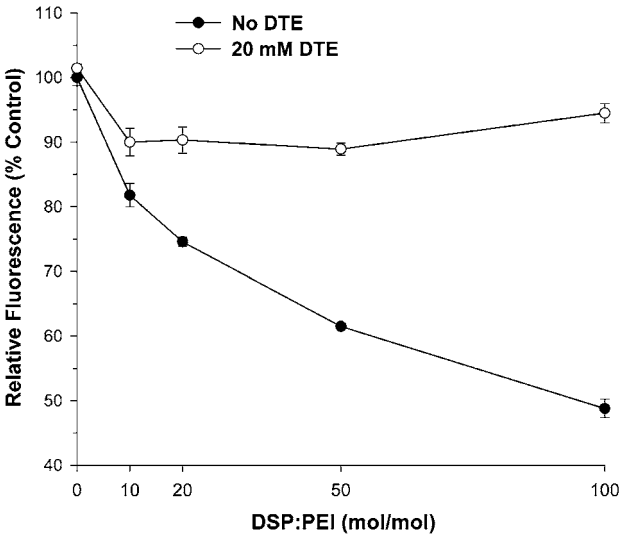

Figure 4. EtBr fluorescence from interactions with DSP cross-linked PEI/DNA polyplexes in the presence of 100 μM PMAA, with or without disulfide bond reduction with DTE. Polyplexes were prepared at a N/P ratio of 6, and cross-linked with DSP at DSP:PEI molar ratios of 0, 10, 20, 50, and 100:1. Cross-linked polyplexes were then exposed to 100 μM PMAA for 30 min, with or without 20 mM DTE. EtBr was added to each sample at a concentration of 0.4 μg/mL, and fluorescence was measured at excitation and emission wavelengths of 523 and 602 nm, respectively.

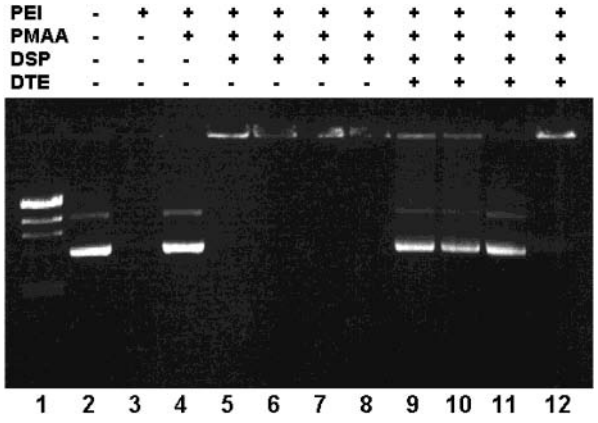

Figure 5. Stability of covalently cross-linked polyplexes analyzed by agarose gel electrophoresis. Polyplexes were prepared at a N/P ratio of 6, and cross-linked with DSP at DSP:PEI molar ratios of 10, 20, 50, and 100:1. Cross-linked polyplexes were then exposed to 100 μM PMAA for 30 min, with or without 20 mM DTE, and analyzed by agarose gel electrophoresis (0.5 μg of DNA/lane). Lane 1 is *Hin*dIII-digested phage λ DNA, used as a size marker; lane 2 is pLuc DNA only; lane 3 is PEI/pLuc polyplex (N/P = 6); lane 4 is PEI/pLuc polyplex with 100 μM PMAA; lanes 5−8 are PEI/pLuc polyplexes cross-linked with DSP at 10:1, 20:1, 50:1, and 100:1, respectively, with 100 μM PMAA; lanes 9−12 are identical to lanes 5−8, except for the addition of 20 mM DTE.

Since polyplex stability is apparently compromised by the presence of a competing polyanion, experiments were then performed to evaluate the consequence of cross-linking PEI/DNA polyplexes with DSP, at various DSP:PEI molar ratios, before exposure to PMAA. Polyplexes were prepared at an N/P ratio of 6, and were then cross-linked with DSP at molar ratios of 10, 20, 50, and 100:1. PMAA was included in all samples at a concentration of 100 μM, since that concentration restored nearly 100% EtBr fluorescence when incubated with un-cross-linked polyplexes. As seen in Figure 4, the results show that as the DSP:PEI cross-linking ratio is increased, PEI/DNA polyplexes become increasingly resistant to polyanion challenge, exhibited by the decrease in EtBr fluorescence. In fact, fluorescence readings for polyplexes cross-linked at a ratio of 100:1 decreased by more than 50%. However, when 20 mM dithioerythritol (DTE) was introduced to promote reduction of the intramolecular disulfide bond present in DSP, effectively reversing stabilization, EtBr fluorescence was restored to ~90% of control for all samples.

To obtain visual evidence, to supplement the quantitative fluorescence readings in Figure 4, agarose gel electrophoresis was performed. The underlying principle was the same as for fluorometric analysis (i.e., EtBr fluorescence is restored upon polyplex dissociation or local decondensation of DNA); however, visualization by electrophoresis provides a basis to discern between dissociation or local DNA decondensation. As seen in lane 4 of Figure 5, incubation of un-cross-linked polyplexes (N/P = 6) with 100 μM PMAA results in polyplex dissociation, as evidenced by the DNA migration through the gel. The results also show (lanes 5−8) that despite DSP cross-linking, some EtBr fluorescence can be seen in the loading wells, with the intensity slightly decreasing as the cross-linking ratio is increased. Lanes 9−12 illustrate the effect of DTE reduction of disulfide bonds on DNA migration and EtBr fluorescence. At cross-linking ratios of 10, 20, and 50:1 (lanes 9−11), pLuc DNA regained its fluorescence and was free to migrate through the gel. However, at 100:1 (lane 12), fluorescence was mainly visible in the loading well, with a faint band appearing where plasmid DNA would be expected, despite DTE reduction.

Transfection studies were performed to compare the transfection performance between LPDII vectors either with or without covalent cross-linking of polyplexes in KB cells in vitro. Polyplexes were prepared at an N/P ratio of 4, yielding condensed particles with a slight positive charge. Where DSP cross-linking was employed, polyplexes were cross-linked at a molar ratio of 10:1 (DSP:PEI). Figure 6 displays the transfection results from a series of four different LPDII formulations, along with results from a 1 mM free folate competition study for the folate receptor-targeted formulation. Specifically, the formulations tested included conventional diolein/CHEMS LPDII particles without DSP cross-linking, LPDII including covalently cross-linked polyplexes, LPDII prepared with PEG containing liposomes, and receptor-targeted LPDII particles containing a lipid-anchored folate moiety. As indicated, all polyplexes were PEI/DNA complexes, and the anionic liposome component was composed of diolein/CHEMS prepared at a molar ratio of 6:4. Inclusion of PEG-DSPE, for steric stabilization, or folate-PEG-Chol, for receptor targeting, was achieved by adding 0.5 mol % of the appropriate lipid-anchored molecule during preparation of the diolein/CHEMS liposomes.

Figure 6A,B depicts the luciferase gene expression achieved with each LPDII formulation as a function of lipid:DNA (w/w) ratio. Transfection levels mediated by all formulations increased initially, before achieving peak luciferase activities at a lipid:DNA ratio of 2.5. All formulations then exhibited a subsequent decrease in luciferase activity at a lipid:DNA ratio of 5. At ratios beyond 5, luciferase activities appeared to level off, with the exception of LPDII prepared without DSP cross-linking, which displayed steadily decreasing luciferase activities with increasing lipid:DNA ratio. From a comparison of conventional diolein/CHEMS LPDII vectors and LPDII that include DSP cross-linked polyplexes, it can be seen that cross-linking at a ratio of 10:1 led to an ~2−16-fold decrease in gene expression at lipid:DNA

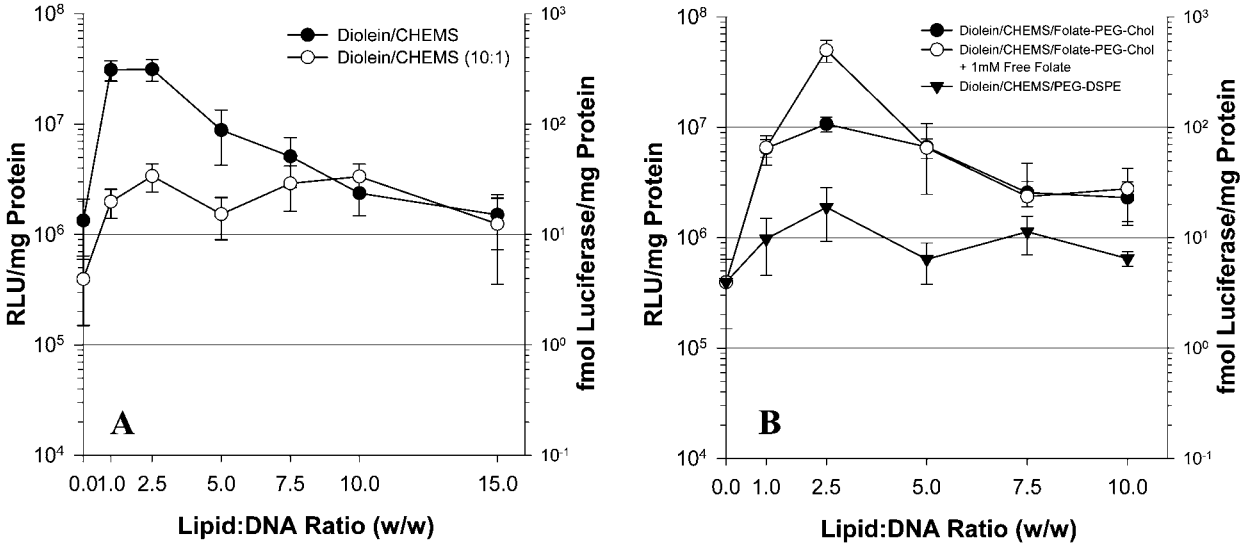

Figure 6. Transfection of KB cells with various LPDII formulations as a function of lipid:DNA ratio. The lipid:DNA ratios tested were 0 (cross-linked or un-cross-linked polyplex alone), 2.5, 5, 7.5, 10, and 15. All formulations contain PEI/pLuc DNA polyplexes prepared at a N/P ratio of 4. Except where noted in the figure, all polyplexes were cross-linked with DSP at a DSP:PEI molar ratio of 10:1. Diolein/CHEMS liposomes were prepared at a molar ratio of 6:4, and where indicated, 0.5 mol % PEG-DSPE or folate-PEG-Chol was included.

ratios ≤7.5, but that similar luciferase activities were achieved at ratios beyond 10. Inclusion of PEG-DSPE at 0.5 mol % appeared to consistently hinder transfection levels, reducing luciferase activities ∼2−5-fold, compared to LPDII containing cross-linked polyplexes prepared without PEG-DSPE. In contrast, LPDII containing folate-PEG-Chol exibited higher gene expression at all lipid:DNA ratios tested, compared with LPDII vectors containing PEG-DSPE. In fact, luciferase activities for LPDII containing folate-PEG-Chol were ∼5−10 times greater than the PEG-DSPE formulation at lipid:DNA ratios between 1 and 5, with decreasing differences at higher ratios. Compared with cross-linked LPDII without PEG-DSPE, inclusion of 0.5 mol % folate-PEG-Chol increased luciferase acitivities 3−4-fold between lipid:DNA ratios of 1 and 5, and, again, led to decreasing differences at high lipid:DNA ratios. Inclusion of 1 mM free folate in the growth media during transfection with LPDII vectors containing folate-PEG-Chol led to luciferase activities nearly identical to those achieved in the absence of free folate, with the exception of an ∼4.5-fold increase in activity at a lipid:DNA ratio of 2.5.

In contrast to the observed results, luciferase activities were expected to decrease for LPDII containing folate-PEG-Chol in the presence of 1 mM free folate, due to competition for the folate receptor. However, it has been shown previously that addition of free folate to the growth media during transfection increases transfection levels mediated by PEI/DNA polyplexes (*17*). Therefore, transfection studies to compare the effect of free folate on gene expression were repeated with conventional diolein/CHEMS LPDII vectors, LPDII formulated with PEG-DSPE, and LPDII containing folate-PEG-Chol, all containing DSP cross-linked polyplexes at a ratio of 10:1 (DSP:PEI). Free folate was included in the growth media at a concentration of 1 mM, as in earlier transfection studies, with additional concentrations of 2 and 5 mM included for the folate receptor-targeted formulation. Figure 7 shows that inclusion of 1 mM free folate in the growth media increased luciferase activities 3−4-fold for diolein/CHEMS LPDII and LPDII containing folate-PEG-Chol, but had little effect on LPDII containing PEG-DSPE. Furthermore, increasing the free folate concentration to 2 mM during transfection with folate receptor-targeted LPDII vectors decreased luciferase activity, in comparison to 1 mM free folate, and achieved similar transfection levels to those observed in the absence of free folate. Increasing the free folate concentration to 5 mM led to a further decrease in luciferase activity, which was ∼6-fold lower than transfection levels obtained without free folate present in the growth media.

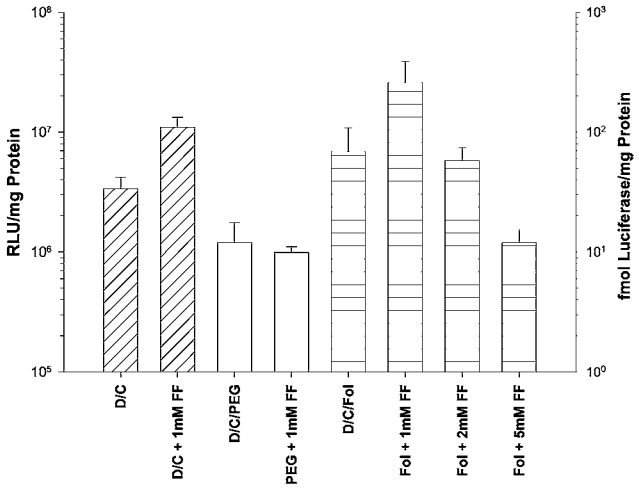

Figure 7. Effect of free folate on the transfection activity of the LPDII formulations containing DSP cross-linked polyplexes. Free folate (FF) was included at 1, 2, or 5 mM in the growth media during transfection. All polyplexes used in LPDII preparation were cross-linked with DSP at a DSP:PEI molar ratio of 10:1. The three LPDII formulations tested include diolein/CHEMS (D/C), diolein/CHEMS/PEG-DSPE (D/C/PEG or PEG), and diolein/CHEMS/folate-PEG-Chol (D/C/Fol or Fol). Diolein/CHEMS liposomes were prepared at a molar ratio of 6:4, and where indicated, 0.5 mol % PEG-DSPE or folate-PEG-Chol was included.

Finally, negative stain transmission electron microscopy was performed in order to obtain evidence confirming the association between diolein/CHEMS liposomes and cross-linked polyplexes. Samples were prepared as described under Materials and Methods, and the results are illustrated in Figure 8. Panel A shows PEI/DNA polyplexes cross-linked with DSP at a molar ratio of 10:1. Polyplexes appeared as small dark spherical particles

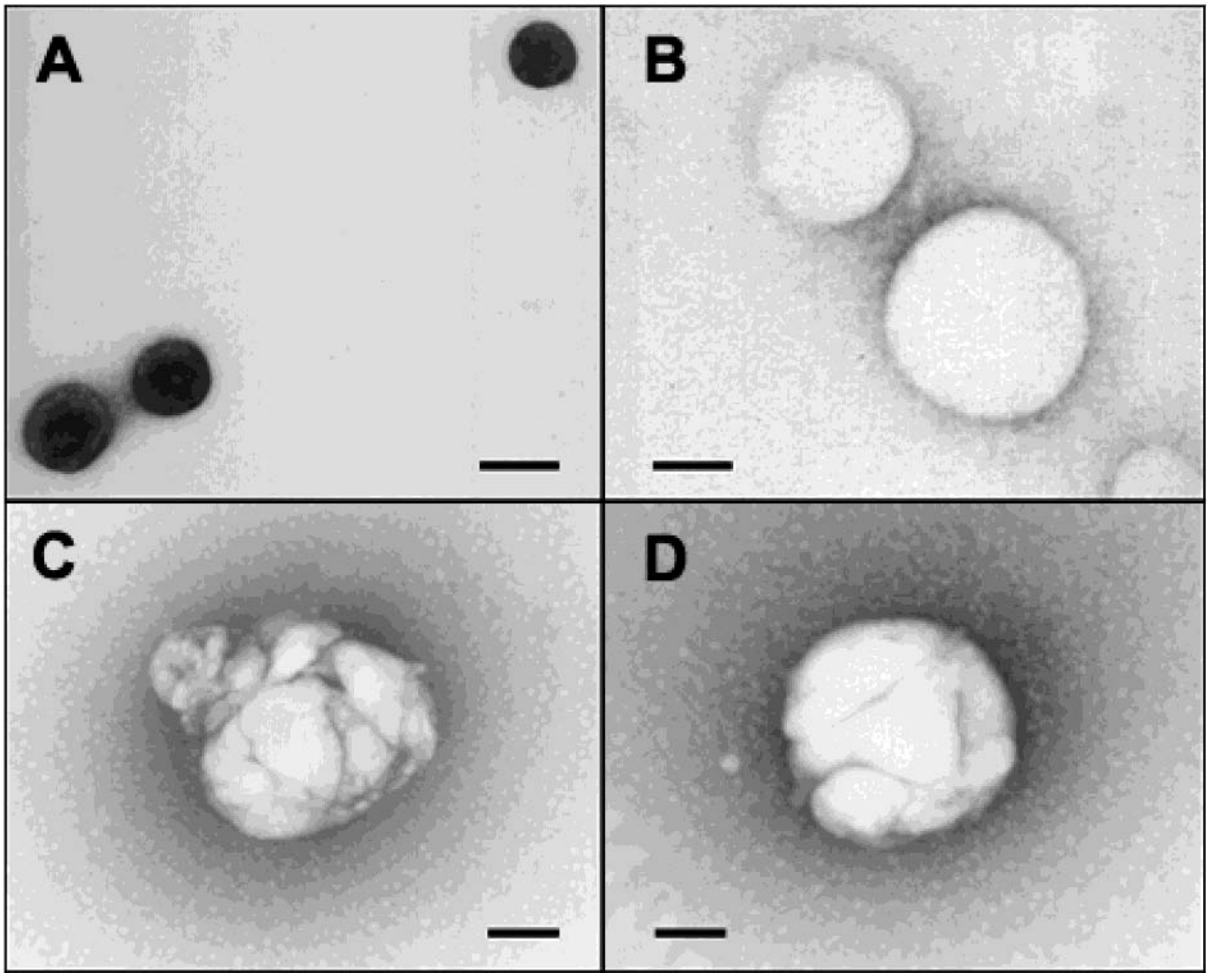

Figure 8. Negative stain transmission electron microscopy. DSP cross-linked polyplexes (10:1) and LPDII particles were prepared at an N/P ratio of 6 and a lipid:DNA ratio of 5 (w/w), respectively, with each sample containing 10 μg of plasmid DNA. Electron micrographs were obtained at 60 kV. (Panel A) DSP cross-linked PEI/DNA polyplexes at 100000× magnification. (Panel B) Diolein/CHEMS liposomes (6:4, mol/mol) at 100000× magnification. (Panels C and D) DSP cross-linked LPDII vectors at 45000× magnification. In panels A and B, the bar = 100 nm; in panels C and D, the bar = 200 nm.

ranging in diameter from ~70 to 100 nm. Panel B shows diolein/CHEMS liposomes prepared at a molar ratio of 6:4, which appeared as white spherical particles having a diameter between 100 and 250 nm. Finally, panels C and D depict LPDII particles formed at a lipid:DNA ratio of 5. These complexes were manifested as aggregated structures, roughly spherical in shape, with diameters ranging between 300 and 800 nm.

DISCUSSION

Currently, the primary limitation in the development of clinically useful nonviral gene therapy protocols is the lack of safe and efficient nonviral vectors for in vivo gene delivery. Here, we evaluate a novel approach to improve the stability and transfection potential of polyplex- and LPDII-mediated gene transfer. We have shown that cross-linking PEI/DNA polyplexes stabilizes these complexes against polyanion disruption, and that cross-linking is reversible upon reduction by DTE. We further demonstrated that LPDII transfection vectors mediate variable levels of transfection, depending on the presence of DSP cross-linking and the incorporation of PEG-DSPE or folate-PEG-Chol as a component of the diolein/CHEMS liposomes used for LPDII formation. It was also observed that the presence of 1 mM free folate in the transfection media has a surprisingly beneficial effect on transfection, but that this effect was dose-dependent for LPDII vectors containing folate-PEG-Chol. Finally, we provide evidence, by way of electron micrographs, that diolein/CHEMS liposomes and DSP cross-linked polyplexes form aggregated complexes under our experimental conditions.

Initial transfection studies with cross-linked polyplexes were performed to assess the effects of DSP or DTBP cross-linking of PEI/DNA polyplexes on luciferase reporter gene expression. Branched, 25 kDa PEI was used as the condensing agent because previous studies indicate that PEI is an effective transfection agent both in vitro (*16, 18*) and in vivo (*19*−*21*). Transfection results indicated that cross-linking polyplexes with DSP or DTBP, after DNA condensation, leads to a reduction in gene expression in KB cells, with significantly lower luciferase activities (3−4 orders of magnitude) observed at higher cross-linking ratios. These results were not surprising, since increasing the cross-linking ratio would be expected to increase polyplex stability. While increased stability may be beneficial prior to cellular uptake, ultimately the DNA has to be accessible by the nuclear transcription machinery, thus mandating polyplex dissociation and DNA decondensation preceding gene expression. High cross-linking ratios would require more extensive intracellular reduction of disulfide bonds present in the cross-linking reagents in order to reverse stabilization, which may ultimately limit gene expression.

Comparing the two cross-linking reagents, we found transfection activity to be slightly higher with DTBP cross-linked polyplexes, at cross-linking ratios ≥20.

However, in our experience, DTBP is less reactive toward PEI, compared with DSP, under the chosen reaction conditions. The slightly greater transfection levels mediated by DTBP cross-linked polyplexes at higher cross-linking ratios may be a reflection of less extensive cross-linking, and consequently a lower reduction in gene expression. Alternatively, the retention of positive charge after DTBP cross-linking may promote more efficient gene transfer. In the end, DSP was used to cross-link polyplexes for inclusion in LPDII vectors because cross-linking with DSP can be accomplished with a shorter reaction time, and it is possible to monitor the appearance of NHS from DSP spectrophotometrically to gauge reaction progress. In addition, there were relatively insignificant differences in transfection levels between DSP and DTBP cross-linked polyplexes, especially at a cross-linking ratio of 10:1.

While it was important to understand the effect of cross-linking on transfection levels, it was equally important to investigate the stability of cross-linked polyplexes, to justify covalent stabilization. Therefore, polyplex stability was evaluated in the presence of a competing polyanion, namely, PMAA, which should mimic the effect of polyanionic liposomes on polyplex integrity during LPDII formation. Anionic liposomes themselves were not used as the competing polyanion because lipid concentrations utilized for LPDII formulation interfered with EtBr fluorescence detection. Initially, we were interested in determining whether un-cross-linked polyplexes were susceptible to dissociation from polyanion disruption as a function of N/P ratio. Therefore, polyplexes were prepared at several N/P ratios, and incubated with various PMAA concentrations, followed by EtBr fluorescence analysis. This analysis is based on the concept that a large increase in fluorescence is observed upon intercalation of DNA by the phenanthridium moiety of EtBr (*22*). Condensed DNA, like the DNA present in polyplexes prepared with a net positive charge, will exclude EtBr from intercalating between base pairs, thus providing minimal fluorescence. In contrast, uncondensed DNA, resulting from local decondensation of DNA or polyplex dissociation, will permit EtBr intercalation to yield a sharp increase in EtBr fluorescence. The increase in fluorescence should be proportional to the amount of DNA available for intercalation. Our results showed that polyplexes exposed to PMAA exhibit an increase in EtBr fluorescence, and that fluorescence was directly related to PMAA concentration and inversely related to the N/P ratio. This result suggests that conventional polyplexes are susceptible to polyanion disruption, and that polyplexes prepared with large N/P ratios are more stable than those prepared with low ratios.

We anticipated that reversible cross-linking would stabilize polyplexes, and that reduction of the intramolecular disulfide bond present in DSP would restore polyplex susceptibility to polyanion disruption. Therefore, we cross-linked PEI/DNA polyplexes at various DSP:PEI molar ratios and evaluated EtBr fluorescence in the presence of 100 μM PMAA, either with or without 20 mM DTE. The results showed that increasing the cross-linking ratio leads to a decrease in EtBr fluorescence, suggesting more stable polyplexes at higher cross-linking ratios. Reduction with 20 mM DTE was found to restore fluorescence levels to ~90% of control. While these results are useful in demonstrating covalent stabilization with DSP, and we believe it is reasonable to infer that polyanionic liposomes would have a similar effect on polyplex integrity, we recognize that polymers such as PMAA may interact somewhat differently with polyplexes, and, therefore, these results do not provide actual evidence regarding the interaction between polyplexes and diolein/CHEMS liposomes. Nevertheless, although these results were considered positive in terms of demonstrating stabilization and cross-linking reversibility, they also introduced a dilemma in choosing the appropriate cross-linking ratio of polyplexes for incorporation into LPDII transfection particles. On one hand, earlier transfection results with cross-linked polyplexes showed a minimal reduction in gene expression if the cross-linking ratio was relatively low. However, the stability results showed that EtBr fluorescence was still ~75−80% of control for complexes cross-linked to the same extent. Therefore, the degree by which DSP might have contributed to cross-linking stability was unclear.

Consequently, polyanion disruption of cross-linked polyplexes was repeated as described above, but the samples were instead visualized by agarose gel electrophoresis. This assay provided a basis to distinguish between polyplex dissociation and local decondensation of DNA. With polyplex dissociation, free plasmid DNA would be expected to migrate through the gel at a rate proportional to its size, but with local decondensation of DNA, fluorescence would likely be observed in the loading well. This stems from the fact that DNA migration through the agarose gel is based on electrostatic attraction between polyanionic DNA and a positively charged anode. However, when DNA is present in the form of a polyplex, the negative charge is neutralized by the cationic polymer, consequently precluding its migration through the gel. In addition, the size increase resulting from the presence of the high molecular weight PEI in the polyplex would further hinder DNA migration. Ultimately, the electrophoresis results suggested that low cross-linking ratios are adequate to prevent dissociation, but will not completely prevent local DNA decondensation. This was shown in Figure 5 by DNA migration with un-cross-linked polyplexes in the presence of 100 μM PMAA (lane 4), but after cross-linking with DSP, fluorescence was only visible in the loading wells (lanes 5−9). These results provided a logical basis for cross-linking polyplexes at a DSP:PEI molar ratio of 10:1 for incorporation into LPDII vectors. Specifically, this ratio was chosen because preliminary transfection results using polyplexes cross-linked at 10:1 showed a minimal reduction in gene expression, compared with un-cross-linked polyplexes, and agarose gel analysis further showed that these complexes remained associated even with relatively strong polyanion challenge (100 μM PMAA).

To delineate the effects on gene expression, the transfection potential of four related LPDII vectors was evaluated in KB cells in vitro. PEI/DNA polyplexes were formed at an N/P ratio of 4, and, where indicated, cross-linked with DSP at a DSP:PEI molar ratio of 10:1. An N/P ratio of 4 was utilized because this ratio mediates complete condensation of plasmid DNA to form positively charged complexes, yet minimizes free PEI in solution not participating in polyplex formation (*19, 23*). If free PEI were present in the solution after polyplex formation, DSP could react preferentially with free PEI and reduce polyplex stabilization by consuming DSP. The anionic liposomes used for LPDII formation were composed of a novel serum-resistant formulation consisting of diolein/CHEMS (6:4 mol/mol). The four LPDII formulations tested for luciferase reporter gene expression included conventional LPDII vectors without DSP cross-linking, LPDII including covalently cross-linked polyplexes, LPDII prepared with PEG-containing liposomes, and receptor-targeted LPDII vectors containing a lipid-anchored folate moiety.

From the transfection results shown in Figure 6A, the first comparison can be made between LPDII vectors containing DSP cross-linked polyplexes and those without cross-linking. The transfection results show that LPDII vectors with covalent cross-linking mediated lower luciferase activities at lipid:DNA ratios ≤7.5, yet similar transfection levels at lipid:DNA ratios ≥10. Results from the transfection studies using cross-linked polyplexes for gene transfer, illustrated in Figure 2, showed that DSP cross-linking inhibited gene expression, and this effect may contribute to the observed decrease in transfection activity mediated by LPDII vectors containing cross-linked polyplexes. Alternatively, LPDII particle formation may be deleteriously altered by the presence of DSP, or more likely by the elimination of positive charges on PEI after reaction with DSP, since LPDII particles largely depend on electrostatic attraction for complex formation. LPDII vectors prepared in the absence of cross-linking achieve a peak luciferase activity at a lipid:DNA ratio of 2.5, and then display steadily decreasing transfection levels. In contrast, LPDII containing cross-linked polyplexes display a more level luciferase activity profile over the entire range of lipid:DNA ratios. This observation suggests that particle assembly may be saturable at low lipid:DNA ratios, again possibly due to the elimination of positive charge after DSP cross-linking. Despite the disparity in transfection activity between these two formulations, LPDII particles containing cross-linked polyplexes did mediate significant levels of transfection, and, therefore, may prove useful under in vivo conditions where complex stability could be a more dominant factor.

Inclusion of PEG-DSPE at 0.5 mol % into the LPDII formulation containing DSP cross-linking resulted in a further reduction in gene expression at all lipid:DNA ratios tested, compared with the cross-linked formulation in the absence of PEG-DSPE. This effect may be the result of reduced interaction between polyplexes and liposomes, or a reduction in cellular uptake. Since particle size is an important determinant for in vitro transfection, with smaller particles achieving lower transfection, it could also be postulated that incorporation of PEG-DSPE reduces any interactions between transfection complexes in solution that might cause an increase in particle size, thus reducing gene expression.

The contribution of folate receptor targeting, through incorporation of 0.5 mol % folate-PEG-Chol, can be seen in Figure 6B by comparing the transfection activity of folate receptor-targeted LPDII vectors with LPDII formulated with PEG-DSPE. Based on that comparison, the data suggest that attachment of folate to the distal end of a PEG linker does mediate an increase in luciferase activity at all lipid:DNA ratios, but especially at ratios ≤5. However, to confirm that folate receptor-mediated endocytosis contributes to increased gene expression, a folate receptor competition study was performed by introducing 1 mM free folate in the growth media during transfection. The results, also shown in Figure 6B, were inconsistent with our expectations that luciferase activity would decrease in the presence of competition by free folate. However, as indicated earlier, previous studies in our lab have shown that inclusion of free folate in the growth media during transfection increases the transfection activity of PEI-based polyplexes. In effect, transfection studies were performed to determine if free folate had a similar effect on LPDII particles prepared at a lipid:DNA ratio of 2.5. We found that inclusion of 1 mM free folate in the growth media during transfection increased the transfection activity of LPDII containing cross-linked polyplexes and LPDII containing folate-PEG-Chol, but had little effect on the transfection activity of LPDII formulated with PEG-DSPE. To determine if higher concentrations of free folate could inhibit the transfection activity of folate receptor-targeted LPDII vectors, similar transfection studies were performed in the presence of 2 and 5 mM free folate. The results showed that luciferase activity was inversely related to the concentration of free folate in the growth media. The mechanism responsible for the increased gene expression in the presence of 1 mM free folate has not been determined, and it is curious that LPDII containing PEG-DSPE were relatively unaffected. Regardless, we conclude that inclusion of folate-PEG-Chol in LPDII vectors mediates greater luciferase activities compared with LPDII formulated with PEG-DSPE. Furthermore, the presence of 1 mM free folate in the growth media during transfection apparently has a beneficial effect on transfection activity, and, therefore, does not offer conclusive evidence that increased gene expression from inclusion of folate-PEG-Chol is truly receptor-mediated. The fact that higher concentrations of folate do reduce observed transfection levels is consistent with expectations, but 5 mM free folate is orders of magnitude greater than the K_d for folic acid, $10^{-9}-10^{-10}$ M. Although the concentrations cited below are ∼10-times lower, similar observations have been reported previously that show the IC_{50} for folate receptor-targeted liposomes is 0.2−0.4 mM (*10*, *15*). The high binding strength of these liposomes has been attributed, in part, to the high binding affinity achieved by multivalent attachment of multiple targeting ligands.

Finally, negative stain transmission electron micrographs of DSP cross-linked polyplexes, diolein/CHEMS liposomes, and LPDII vectors containing covalently cross-linked polyplexes were obtained to gather size and structural information, and to provide evidence of LPDII complex assembly. The images shown in Figure 8A display cross-linked polyplexes that appear as dark spherical particles having a diameter between 70 and 100 nm. This micrograph is consistent with previously published observations of PEI-based polyplexes (*24*, *25*). Figure 8B displays images of diolein/CHEMS liposomes, which appear as white spherical particles smaller than 250 nm. To our knowledge, these are the first published images of diolein/CHEMS liposomes. Figure 8C,D portrays LPDII particles composed of diolein/CHEMS liposomes and cross-linked polyplexes. The diameter of these particles was somewhat variable, but was generally larger than either the polyplexes or the liposomes. The LPDII particles displayed in Figure 8 had diameters between 500 and 700 nm. This size information suggests that the increased transfection performance of LPDII particles may in part be a result of increased particle size, which would promote sedimentation of transfection particles in vitro. In addition, these images appear consistent with the hypothesis that LPDII complexes are composed of aggregated complexes of polyplex and anionic liposomes. However, since the polyplex would theoretically be located inside this complex, and the LPDII particles were not visualized in cross section, it cannot be ruled out that the particles observed in Figure 8C,D are simply aggregates of liposomes. The fact that these types of particles were not observed when viewing diolein/CHEMS liposomes, however, does provide some support to the notion that the complexes observed in Figure 8 are LPDII particles.

To our knowledge, this is the first report describing covalent stabilization of PEI/DNA polyplexes for subsequent inclusion in LPDII vectors. The concept of reversible cross-linking via reducible disulfide bonds has been investigated by other groups, but only in the context of

polyplex-mediated gene transfer (*26*, *27*). The underlying theory behind this approach is that reversible disulfide cross-linking will confer stability to transfection complexes until intracellular reduction of the disulfide bonds takes place. If the transfection vectors are in fact able to gain access to the reducing environment of the cytoplasm, it is plausible that reduction of these bonds will occur, possibly through interaction with reduced glutathione. Accordingly, the data presented here indicate that the effects of cross-linking are reversible upon disulfide bond reduction with DTE in vitro. Furthermore, our results show that polyplexes are more stable in terms of dissociation in the presence of a competing polyanion after DSP cross-linking, and that inclusion of cross-linked polyplexes into LPDII vectors mediates variable transfection, depending on the lipid:DNA ratio and the presence of PEG-DSPE or folate-PEG-Chol. The combination of serum resistance conferred by the diolein/CHEMS liposomes and the increased stability owed to cross-linking may make LPDII vectors incorporating these features more stable in the systemic circulation after intravenous delivery. This improved stability may ultimately translate into higher gene expression and improved therapeutic effects. Based on these results, further evaluation of the transfection properties of covalently cross-linked LPDII vectors in an animal model is warranted.

ACKNOWLEDGMENT

In addition to a grant (RPG-99-097-01-MGO) from the American Cancer Society National Division, this work was partly supported by a development grant from the Parenteral Drug Association (PDA).

The use of a divalent effector molecule improves bispecific antibody (bsMAb) pretargeting by enabling the cross-linking of monovalently bound bsMAb on the cell surface, thereby increasing the functional affinity of a bsMAb. In this work, it was determined if a bsMAb with divalency for the primary target antigen would improve bsMAb pretargeting of a divalent hapten. The pretargeting of a ^{99m}Tc-labeled divalent DTPA-peptide, IMP-192, using a bsMAb prepared by chemically coupling two Fab′ fragments, one with monovalent specificity to the primary target antigen, carcinoembryonic antigen (CEA), and to indium-loaded DTPA [DTPA(In)], was compared to two other bsMAbs, both with divalency to CEA. One conjugate used the whole anti-CEA IgG, while the other used the anti-CEA F(ab′)$_2$ fragment to make bsMAbs that had divalency to CEA, but with different molecular weights to affect their pharmacokinetic behavior. The rate of bsMAb blood clearance was a function of molecular weight (IgG × Fab′ < F(ab′)$_2$ × Fab′ < Fab′ × Fab′ conjugate). The IgG × Fab′ bsMAb conjugate had the highest uptake and longest retention in the tumor. However, when used for pretargeting, the F(ab′)$_2$ × Fab′ conjugate allowed for superior tumor accretion of the ^{99m}Tc-IMP-192 peptide, because its more rapid clearance from the blood enabled early intervention with the radiolabeled peptide when tumor uptake of the bsMAb was at its peak. Excellent peptide targeting was also seen with the Fab′ × Fab′ conjugate, albeit tumor uptake was lower than with the F(ab′)$_2$ × Fab′ conjugate. Because the IgG × Fab′ bsMAb cleared from the blood so slowly, when the peptide was given at the time of its maximum tumor accretion, the peptide was captured predominantly by the bsMAb in the blood. Several strategies were explored to reduce the IgG × Fab′ bsMAb remaining in the blood to take advantage of its 3−4-fold higher tumor accretion than the other bsMAb conjugates. A number of agents were tested, including those that could clear the bsMAb from the blood (e.g., galactosylated or nongalactosylated anti-id antibody) and those that could block the anti-DTPA(In) binding arm [e.g., DTPA(In), divalent-DTPA(In) peptide, and DTPA coupled to bovine serum albumin (BSA) or IgG]. When clearing agents were given 65 h after the IgG × Fab′ conjugate (time of maximum tumor accretion for this bsMAb), ^{99m}Tc-IMP-192 levels in the blood were significantly reduced, but a majority of the peptide localized in the liver. Increasing the interval between the clearing agent and the time the peptide was given to allow for further processing of the bsMAb-clearing agent complex did not improve targeting. At the dose and level of substitution tested, galacosylated BSA-DTPA(In) was cleared too quickly to be an effective blocking agent, but BSA- and IgG-DTPA(In) conjugates were able to reduce the uptake of the ^{99m}Tc-IMP-192 in the blood and liver. Tumor/nontumor ratios compared favorably for the radiolabeled peptide using the IgG × Fab′/blocking agent combination and the F(ab′)$_2$ × Fab′ (no clearing/blocking agent), and peptide uptake 3 h after the blocking agent even exceeded that of the F(ab′)$_2$ × Fab′. However, this higher level of peptide in the tumor was not sustained over 24 h, and actually decreased to levels lower than that seen with the F(ab′)$_2$ × Fab′ by this time. These results demonstrate that divalency of a bsMAb to its primary target antigen can lead to higher tumor accretion by a pretargeted divalent peptide, but that the pharmacokinetic behavior of the bsMAb also needs to be optimized to allow for its clearance from the blood. Otherwise, blocking agents will need to be developed to reduce unwanted peptide uptake in normal tissues.

INTRODUCTION

Pretargeting methods have become an important strategy for conveying targeting specificity to isotopes and drugs for a variety of applications, including tumor imaging and therapy (Chang et al., 2002; Goldenberg, 2002). Unlike direct targeting methods that rely on the association of the effector molecule directly with the antibody, a pretargeting method separates the effector molecule (e.g., isotope or drug) from the primary targeting agent (Goodwin and Meares, 1999). The primary targeting agent in a pretargeting method must have binding specificity for the target and bear a receptor capable of binding to the effector molecule. The vast majority of primary targeting agents used in pretargeting

have been antibodies directed to different tumor antigens. Many effector-binding systems employed by pretargeting methods have used the avidin/streptavidin−biotin recognition system, while others have used bispecific antibodies (bsMAbs)[1] and even oligonuclide binding systems (Bos et al., 1994; Cremonesi et al., 1999; Goodwin et al., 1992; Hnatowich et al., 1987; Paganelli et al., 1988; Rusckowski et al., 1997a; Stickney et al., 1991).

As initially evaluated by Hnatowich et al. (1987), the avidin−biotin pretargeting method can be configured according to several strategies, but two approaches have prevailed. One approach uses a streptavidin-conjugated antibody as the primary targeting agent, which is then followed by a derivatized biotin as the effector carrier. A third step is used to facilitate the clearance of the primary streptavidin-antibody conjugate from the blood prior to administering the biotin-effector molecule (Axworthy et al., 1994, 2000). The other strategy uses a biotin-conjugated antibody as the primary targeting agent (Cremonesi et al., 1999; Paganelli et al., 1988). After allowing sufficient time for the antibody-biotin conjugate to localize the tumor, avidin is given. Because it is highly glycosylated, avidin acts primarily as a clearing agent, binding to the biotin-antibody in the blood and removing it to the liver. Although some avidin could also localize to the tumor-bound biotin-conjugated antibody, streptavidin is also given. Streptavidin is not glycosylated, and therefore it has a longer residence time in the blood, which allows more time for it to localize to the biotin-conjugated antibody. Finally, the biotin-effector molecule is given, which then localizes to the biotin-conjugated antibody containing the streptavidin/avidin bridge. Both of these approaches have been used clinically and shown to produce high tumor/background ratios (Breitz et al., 2000; Magnani et al., 2000), and have even been used therapeutically (Breitz et al., 1999, 2000; Knox et al., 2000; Paganelli et al., 2001).

Another pretargeting approach relies on the use of bsMAb. The principal behind pretargeting was initially described by Reardon et al. (1985), who suggested that antibodies could be composed of dual binding specificity, one to a particular target and the other capable of binding a chelate. This group subsequently showed that the passive accumulation of an anti-chelate antibody in mice bearing the transplantable KHJJ tumor (Goodwin et al., 1988) could be used to target a radiolabeled chelate. A "chase" step using transferrin-conjugated chelate was introduced prior to administering the radiolabeled chelate as a means of reducing the anti-chelate antibody in the blood. More recently, this same passive targeting model was used to show the feasibility of pretargeting ^{90}Y-labeled chelate for therapy (Lubic et al., 2001). Subsequently, tumor-targeting specificity has been achieved with bispecific antibodies directed against tumor markers and, for the most part for the targeting of radionuclides by means of antibodies to metal chelators. Bispecific antibodies can be conveniently produced by chemically combining Fab′ fragments of one antibody with specificity to a tumor antigen with another antibody specific for the effector molecule. Effector molecules initially were monovalent metal-binding chelates (Goodwin et al., 1988), but then it was shown that a divalent effector molecule greatly enhances the residence time of the effector molecule at the site (Le Doussal et al., 1989). This method was called an affinity enhancement system (AES), since the bivalent effector molecule bridges two bispecific antibodies on the tumor cell surface, thereby increasing their functionally affinity [reviewed by Chang et al. (2002)]. Others have subsequently verified the advantage of a divalent effector molecule over a monovalent form (Goodwin et al., 1992; Boerman et al., 1999).

The bsMAb and avidin−biotin pretargeting approaches have their advantages and disadvantages. For example, the avidin−biotin system is subject to potential blockade by endogenous biotin. This is especially problematic when testing in mouse models, since mice have nearly 10 times the amount of biotin in their serum as humans (Rosebrough and Hartley, 1995; Rusckowski et al., 1997b). Using a biotin-deficient diet, the stores of biotin in their bodies can be minimized. Another potential problem with the avidin−biotin strategy is the immunogenic nature of avidin and streptavidin. Antibodies to avidin and streptavidin can develop, which could affect the subsequent use of these agents after an initial exposure. The greatest advantage of the avidin−biotin approach is the strength of the binding between avidin or streptavidin and biotin, such that once biotin is bound to avidin or streptavidin, these complexes are highly stable (Hnatowich et al., 1987). In contrast, the bispecific antibody approach combined with a monovalent effector molecule has a higher dissociation rate. Using a divalent effector molecule greatly enhances the cell binding but, still, antibody dissociation rates are typically several log units higher than that of the avidin−biotin complex (e.g., $K_D = 10^{-15}$ M for biotin with streptavidin/avidin vs 10^{-9} M most typically found for antigen−antibody complexes). In this regard, it is important to emphasize that the residence time in the tumor for both bsMAb and avidin/biotin pretargeting approaches is limited by the agent bound to the cell target, i.e., the affinity of an antibody.

Since many of the bispecific antibody-pretargeting studies have used bsMAbs with monovalent binding arms (i.e., chemically cross-linked Fab′ × Fab′ or hybrid IgG produced from a quadroma), the bridging of two bsMAbs by a divalent effector molecule was an important binding enhancement for these complexes at the primary target site. However, would a bispecific antibody with divalent binding to the primary target antigen increase tumor uptake of a radiolabeled peptide while maintaining excellent tumor/nontumor ratios typically associated with pretargeting methods? Increasing the amount of the peptide targeting to a tumor would be highly advantageous for use in radioimmunotherapy (RAIT). To test this hypothesis, a pretargeting system involving bispecific antibodies to carcinoembryonic antigen (CEA) and diethylenetriaminepentaacetic acid (DTPA), together with a divalent indium-loaded DTPA [(In)DTPA] peptide capable of binding ^{99m}Tc, was used (Karacay et al., 2000). Bispecific antibodies were prepared by chemically conjugating the IgG, F(ab′)$_2$, and Fab′ component of a humanized antibody to CEA to the Fab′ fragment of a chimeric anti-(In)DTPA antibody (c734). A ^{99m}Tc-labeled divalent (In)DTPA peptide (IMP-192) was used as the

effector molecule to assess each bsMAb conjugate's utility for pretargeting.

MATERIALS AND METHODS

Antibodies. hMN-14 IgG was prepared as described (Sharkey et al., 1995). The $F(ab')_2$ of hMN-14 was prepared by pepsin digestion, and purified using protein A and ion-exchange chromatography. A chimeric version of the murine 734 anti-(In)DTPA antibody originally described by Le Doussal et al. (1990) was prepared using the VH and Vλ sequences of murine 734, which were linked to human γ1 and κ constant domain sequences, respectively, using methods that have been described previously (Leung et al., 1994, 1995). The antigen-binding activity of c734 was determined with ELISA using (In)-DTPA-BSA-coated wells, and was found to be identical to murine 734.

The $F(ab')_2$ fragment of c734 was prepared by pepsin digestion. The fragment was purified by ammonium sulfate precipitation and then by size exclusion chromatography on a Superdex 200 (Amersham, Pharmacia Bio, Piscataway, NJ) column.

Bispecific Antibodies and Other Conjugates. The hMN-14 IgG × c734 Fab′ bsMAb was chemically prepared by cross-linking the Fab′-SH fragment of c734 to maleimide-derivatized hMN-14 IgG. The maleimide group was introduced by modification of the hMN-14 IgG lysine residues with 3×-molar excess of sulfosuccinimidyl 4-(*N*-maleimidomethyl)-cyclohexane-1-carboxylate (sulfo-SMCC, Molecular Biosciences, Boulder, CO) at pH 7.2 for 55 min at room temperature. The excess sulfo-SMCC was removed by centrifuged size exclusion chromatography (Penefsky, 1979; Meares et al., 1984) using Sephadex G-50−80 in 50 mM sodium acetate, 0.5 mM EDTA, pH 5.3. c734 Fab′-SH was produced by reduction of the $F(ab')_2$ fragment in 10 mM mercaptoethylamine, 20 mM HEPES, 150 mM NaCl, 10 mM EDTA, pH 7.2, at 37 °C for 1 h. Centrifuged size exclusion chromatography was used to isolate the Fab′-SH (c734) and IgG-mal (hMN-14) intermediates. The IgG × Fab′ conjugate was produced by reaction of a 1:1 mixture of the IgG-mal and Fab′-SH components at pH 5.3 for 1 h at room temperature. Sodium tetrathionate was added to the conjugation mixture to a final concentration of 6 mM. After 5 min at room temperature, excess sodium tetrathionate was removed by centrifuged size exclusion chromatography. The product was isolated following purification by affinity chromatography (Affigel-DTPA column) to isolate antibodies capable of binding DTPA, and then by size exclusion chromatography (Superdex 200, Amersham, Pharmacia Bio, Piscataway, NJ) to separate the anti-CEA × anti-DTPA bsMAb from anti-DTPA Fab′ or possibly $F(ab')_2$ that might have formed.

The hMN-14 $F(ab')_2$ × c734 Fab′ bsMAb preparation was similar to IgG × Fab′. $F(ab')_2$ fragment of hMN-14 was treated with 3.5-molar excess of sulfo-SMCC at pH 7.3 for 55 min to modify lysine residue(s) to introduce maleimide groups. Fab′-SH fragment of c734 was prepared as described above. The $F(ab')_2$-mal and Fab′-SH intermediates were purified on centrifuged size exclusion columns. The $F(ab')_2$ × Fab′ conjugate was formed by reaction of a 1:1 mixture of the two fragments at room temperature for 1.5 h at pH 5.3. The conjugation mixture was treated with 5 mM sodium tetrathionate, and the excess sodium tetrathionate was removed by centrifuged size exclusion chromatography. The reaction mixture was applied to Affigel-DTPA column to remove impurities containing hMN-14 only. To isolate the pure conjugate, the c734-containing portion from the Affigel-DTPA column was purified by size-exclusion chromatography (Superdex 200).

The hMN-14 Fab′ × c734 Fab′ bsMAb was prepared by the chemical coupling of the two reduced Fab′-SH fragments using *N*,*N*′-*o*-phenylenedimaleimide (PDM) by a standard literature method (Glennie et al., 1987). Briefly, MAbs were separately reduced to their Fab′-SH fragments by incubation with 10 mM 2-mercaptoethylamine at 37 °C for 1 h. The c734-Fab′-SH was converted to c734-Fab′-maleimide by reaction with 4 mM PDM at room temperature for 1 h. Centrifuged size exclusion chromatography was used to isolate the Fab′-SH (hMN-14) and Fab′-maleimide (c734) intermediates. Cross-linking of hMN-14-Fab′-SH to c734-Fab′-maleimide proceeded for 95 min at room temperature at a 1:1 molar ratio. The bsMAb was isolated after purification by DTPA affinity chromatography and by size exclusion chromatography (Superdex-200).

The purity and specificity of the bsMAbs were analyzed by SDS−PAGE (reducing and nonreducing conditions), as well as by SE-HPLC. SE-HPLC was used to examine the chromatographic properties of the bsMAbs alone and when mixed with an excess of CEA and after mixing with ^{111}In-labeled IMP-156, another divalent DTPA peptide (Karacay et al., 2000), or both CEA and the radiolabeled peptide. In both assays, the percentage of product failing to shift to a higher MW on SE-HPLC (shown by in-line monitoring of either UV or radioactivity) indicated the level of monospecific MAbs present in the preparations.

DTPA-conjugated bovine serum albumin (BSA) and DTPA-IgG, used as blocking/clearing agents, were prepared according to published procedures (Hnatowich et al., 1982). BSA and diethylenetriaminepentaacetic acid anhydride were obtained from Sigma (St. Louis, MO). The IgG was humanized LL2 anti-CD22 (Leung et al., 1995). MALDI-mass spectral analysis determined there were four DTPA conjugated to the BSA, and eight DTPA per IgG. The BSA- and IgG-DTPA conjugates were preloaded with indium on the day of their use by adding 20-times mole excess of indium to a prescribed amount of each conjugate.

Rat WI2 (rWI2) is an anti-idiotype antibody that is reactive with the hMN-14 IgG (Losman et al., 1994). It, along with a galactosylated conjugate of this antibody, has been used as a clearing agent to remove MN-14 IgG or MN-14 IgG-streptavidin conjugates from the blood (Karacay et al., 1997; Sharkey et al., 1997). BSA-DTPA and rWI2 were conjugated with galactose (43:1 and 49:1 mole substitution, respectively) using the methodology reported by others (Lee et al., 1976; Mattes, 1987). The ability of rWI2 and gal-rWI2 and BSA- and IgG-DTPA-(In) conjugates to bind to hMN-14 × 734 bsMAb was tested by SE-HPLC. A molar excess of each agent was mixed with ^{125}I-labeled bsMAb and after a brief incubation period the mixture was loaded on a Bio-Sil SE 250 size-exclusion HPLC column (BioRad, Richmond, CA). In each instance, the resulting product was shifted to a higher molecular weight than that of the ^{125}I-bsMAb alone.

Radiolabeling. IMP-192, a divalent DTPA peptide containing a thiosemicarbonylglyoxyl-cysteinyl group (TscGc) for radiolabeling with ^{99m}Tc, was prepared as previously reported by Karacay et al. (2000). For ^{99m}Tc-radiolabeling, IMP-192 was formulated in individually lyophilized vials that contained 50 μg of the peptide with Sn(II) for pertechnetate reduction and a 6-fold excess of nonradioactive indium to peptide for binding to DTPA. These vials were reconstituted with up to 77 mCi of

^{99m}Tc-pertechnetate (Mallinckrodt, Pine Brook, NJ) in 1.5 mL of saline. After 10 min at room temperature, the vials were heated in a water bath for 15 min. Quality assurance checks of the ^{99m}Tc-labeled IMP-192 included instant thin-layer chromatography (ITLC), which showed >95% of the radioactivity bound to the peptide, as well as an incubation with a mole excess of the bsMAb, which always showed >95% of the radioactivity shifted to a higher molecular weight peak by size-exclusion, high-pressure liquid chromatography (SE-HPLC).

The bsMAb was radiolabeled with Na^{125}I (Perkin-Elmer, Boston, MA) by the chloramine-T method (Greenwood and Hunter, 1963) to a specific activity of 10−14 mCi/mg. Quality assurance of the radiolabeled bsMAb included ITLC, SE-HPLC, and immunoreactive fraction. All radiolabeled bsMAb preparations had to have ≤ 5% unbound radioiodine by ITLC, ≥85% of the product migrating at the expected SE-HPLC elution volume for the bsMAb (i.e., no appreciable aggregation or other products), and an immunoreactive fraction when mixed with CEA >85%. The immunoreactive fraction of the bsMAb was tested against CEA by mixing 0.5 μCi of the radiolabeled bsMAb with 5 × the moles of CEA (Scripps Laboratories, San Diego, CA) for 5 min at room temperature. The dual specificity of the bsMAbs for CEA and DTPA was also spot-checked by incubating the ^{125}I-bsMAb with both CEA and another divalent DTPA-peptide, IMP-156, radiolabeled with ^{111}In (Karacay et al., 2000).

In Vitro Stability and Binding Studies. The in vitro stability of the bsMAbs in human serum was tested by incubating the ^{125}I-labeled bsMAb at 37 °C in fresh, sterile-filtered serum taken from a healthy donor. Samples were analyzed by SE-HPLC before and after mixing with CEA. The ability of the bsMAbs to retain binding ability to the peptide and CEA was analyzed using size-exclusion HPLC and radiolabeled bsMAbs and peptides. ^{99m}Tc-labeled peptide was diluted in 1.0% HSA and injected onto HPLC alone, and immediately after mixing with variable amounts of bsMAb. To demonstrate binding of the radiolabeled peptide to the antigen−bsMAb complex, bsMAb was mixed with CEA before addition of the radiolabeled peptide.

Animal Model. All animal studies were carried out with IACUC approved protocols. Female nude mice (Taconic, Germantown, NY) approximately 6−8 weeks old were inoculated subcutaneously (s.c.) with a 10% suspension of the serially transplanted GW-39 human colonic cancer cell line (Goldenberg et al., 1966; Goldenberg and Hansen, 1972). After allowing 2−3 weeks for tumor growth, the animals were given an intravenous injection of the bsMAb conjugate that contained a trace amount of ^{125}I-bsMAb so that its distribution properties could be evaluated. In all studies, a constant amount, 1.5 × 10^{-10} mol, of the bsMAb was administered (15, 22.5, and 30 μg of the Fab′ × Fab′, F(ab′)$_2$ × Fab′, and IgG × Fab′ conjugates, respectively). After waiting a defined period of time based on the conjugate used, the ^{99m}Tc-IMP-192 peptide was given at a constant bsMAb:peptide mole ratio of 10:1 based on the moles of bsMAb administered. Animals were then scheduled for necropsy at 3 and/or 24 h after the peptide was given. A number of studies were performed with the IgG × Fab′ bsMAb conjugate using a variety of clearing or blocking agents at a prescribed time after the bsMAb's injection. The timing of the administration of these agents after the bsMAb, the dose administered, and the time allotted before the ^{99m}Tc-IMP-192 peptide was given are provided for each study under Results. The dosage of these agents was based on a prescribed molar ratio in relation to the average amount of bsMAb in the blood as determined from samples taken by retroorbital bleeding of a minimum of three anesthetized animals, using the specific activity of the ^{125}I-bsMAb to estimate its concentration.

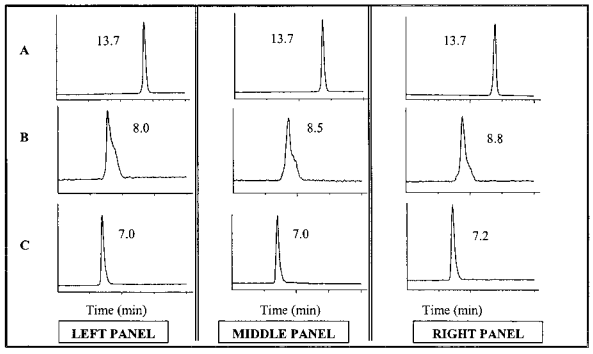

Figure 1. Size-exclusion HPLC chromatograms of the hMN-14 × c734 bsMAbs (IgG × Fab′ bsMAb, left panel; F(ab′)$_2$ × Fab′ bsMAb, middle panel; Fab′ × Fab′ bsMAb, right panel) showing the radioactivity traces for ^{111}In-IMP-156 alone (A), when mixed with the bsMAb (B), and mixed with the bsMAb after addition of CEA (C). The bsMAb was added in a 20-fold mole excess to the ^{111}In-IMP-156 (row B). A 5-fold mole excess of CEA was added to the bsMAb followed by the addition of the peptide (20:1, bsMAb/peptide ratio).

At the scheduled time of necropsy, groups of animals (n = 4−5) were anesthetized, approximately 0.2 mL of blood was removed by cardiac puncture, and then they were euthanized prior to dissection. Organs were removed, weighed, and placed in glass vials for counting ^{125}I- and ^{99m}Tc-activity. Windows were set to exclude ^{125}I from the ^{99m}Tc-window, and samples were first counted for their ^{99m}Tc content and then after allowing 2 days for decay, recounted for ^{125}I. For each counting session, standards were placed along with the tissues to calculate the total injected radioactivity. The amount of radioactivity in each tissue was first divided by the weight of the tissue and then by the total radioactivity injected to derive the percent injected dose per gram of tissue (% ID/g). Tumor to nontumor tissue ratios (T/NT) were derived by dividing the percent injected dose per gram of the tumor by the percentage in the respective tissue. A ratio of the % ID/g of ^{99m}Tc-IMP-192 peptide in each tissue compared to the % ID/g of ^{125}I-bsMAb (peptide/bsMAb ratio) was also calculated in a similar manner. Statistical analysis of these data was performed using an ANOVA with a two-tailed F-test.

RESULTS

In Vitro and in Vivo Properties of Chemically-Stabilized bsMAb Constructs. BsMAb composed of hMN-14 IgG, F(ab′)$_2$, or Fab′ chemically cross-linked to the Fab′ fragment of c734 were prepared, and according to SE-HPLC and SDS−PAGE, each conjugate contained the anti-CEA and anti-DTPA antibody at a 1:1 mole ratio. Figure 1 shows the SE-HPLC chromatograms of the bsMAb preparations when mixed in a molar excess with ^{111}In-IMP-156 divalent-DTPA peptide alone or with CEA and then the peptide. All of the peptide shifted to a higher molecular weight consistent primarily with the formation of complexes composed of 2 mol of bsMAb/peptide, and with a smaller fraction of bsMAb with 1 mol of peptide (Figure 1, row B). When added to the bsMAb after CEA addition, the complexes uniformly migrated as a higher molecular weight (Figure 1, row C). This shows that all of the antibody in each bsMAb preparation that is capable of binding the DTPA-peptide is also able to bind to CEA.

[a] Nude mice bearing GW-39 human colon cancer xenografts were injected i.v., with 1.5×10^{-10} mol of each bsMAb that contained a tracer amount (10 μCi) of the ^{125}I-bsMAb. Animals were necropsied at the times indicated, and the percentage of ^{125}I-bsMAb in the tissues shown was determined. Values represent the means ± SD ($n = 5$ per group).

Bispecific antibody conjugates placed in sterile-filtered mouse serum for 3 days were examined for stability by size-exclusion HPLC. After 3 days, 93%, 86%, and 76% of the IgG, F(ab′)$_2$, and Fab′ bsMAb conjugates shifted to a higher molecular weight fraction when mixed with CEA.

The distribution and clearance properties of the bsMAbs in tumor-bearing nude mice followed a predictable behavior based on the molecular size of the conjugates; e.g., the larger the construct, the slower it cleared from the blood (Table 1). Tumor uptake was highest for the IgG × Fab′ construct, but it took 2 days before it reached its maximum accretion level of 12.8 ± 2.7% ID/g. The maximum accretion in the tumor of the F(ab′)$_2$ × Fab′ and the Fab′ × Fab′ conjugates was observed at the earliest sampling time (4 h after the bsMAb injection). The F(ab′)$_2$ × Fab′ construct maintained this level for a period of 2 days, whereas the Fab′ × Fab′ conjugate steadily declined over the next 3 days, sustaining a loss of about 50% each day. The IgG × Fab′ conjugate stayed at its highest level for at least 2 days (days 2 and 3 after bsMAb injection), but by day 7 had decreased to 50% of its maximum level. The Fab′ × Fab′ fragment had somewhat higher renal uptake at 4 h than the other bsMAb constructs, but none of the constructs had sustained renal retention. This is most likely explained by the fact that all of these conjugates are a molecular size too large to be cleared directly by renal excretion, and because these were all radioiodinated by conventional means, any iodinated catabolic product would be rapidly filtered though the kidneys rather than retained in any major organ (e.g., liver).

Pretargeting ^{99m}Tc-IMP-192 with Each of the bsMAb Conjugates. Our earlier experience (Karacay et al., 2000) indicated that optimal pretargeting occurred when sufficient time was given for the bsMAb conjugate to clear from the blood prior to giving the radiolabeled peptide. Based on the data in Figure 1, a clearance time of 6 days, 49 h, and 19 h was selected for the initial testing of the IgG ×, F(ab′)$_2$ ×, and Fab′ × Fab′ conjugates, respectively. The protein dosage of the bsMAb was adjusted so that each conjugate was administered in equal mole amounts [1.5×10^{-10} mol; the molecular weights were assumed to be 200 000 for the IgG × Fab′, 150 000 for the F(ab′)$_2$ × Fab′, and 100 000 for the Fab′ × Fab′]. After allowing the allotted time for bsMAb clearance, ^{99m}Tc-IMP-192 was administered (1.5×10^{-11} mol; i.e., a bsMAb/peptide ratio of 10:1). Animals were then necropsied at 3 and 24 h after the peptide injection. As shown in Table 2, the ^{125}I-IgG × Fab′ bsMAb had the highest concentration in the tumor at 21.2 ± 9.7% ID/g 3 h after the peptide was injected, compared to the F(ab′)$_2$ × Fab′ conjugate, which was only 3.88 ± 0.66% ID/g, and the Fab′ × Fab′ at 1.45 ± 0.35% ID/g. At the time intervals selected, blood concentrations of the F(ab′)$_2$ × Fab′ and Fab′ × Fab′ conjugates were similar, but the blood concentration of the IgG × Fab′ was nearly 10-fold higher. Thus, despite having a higher concentration of bsMAb in the tumor, the peptide uptake was higher for the F(ab′)$_2$ × Fab′ and Fab′ × Fab′ conjugates than the IgG × Fab′. These results suggest that the peptide was more likely to bind to the IgG × Fab′ bsMAb in the blood, which could have reduced its availability for binding to the tumor. The ratio of the amount of peptide to the amount of bsMAb localized in the tumor (peptide/bsMAb ratio) was determined to illustrate the peptide's ability to localize with the bsMAb (see Table 2). For example, the peptide/bsMAb ratio was only 0.34 ± 0.15 for the IgG × Fab′ conjugate, which was 7 times lower than the peptide/bsMAb ratio for the F(ab′)$_2$ × Fab conjugate (2.38 ± 0.56) and 11 times lower than that observed for the Fab′ × Fab′ conjugate (3.79 ± 0.16). The IgG × Fab′ conjugate only had 1 mol of peptide for every 37 mol of bsMAb, whereas the F(ab′)$_2$ × Fab′ and Fab′ × Fab′ conjugate in the tumor had 1 mol of peptide for every 3−4 mol of bsMAb. Thus, the mole substitution level for the F(ab′)$_2$ × Fab′ and Fab′ × Fab′ conjugates was close to the theoretically ideal ratio for an affinity enhancement model, i.e., 1 mol of peptide for every 2 mol of bsMAb.

Although there were significant differences in the peptide/bsMAb ratios in the blood among the three groups, unlike the ratios seen in the tumor, the magnitude separating them was no greater than a factor of 2.0. It was estimated, using the radiotracers to determine the number of bsMAb for each mole of peptide in the blood at 3 h, that there was 4.4, 6.3, and 2.6 mol of the IgG ×, F(ab′)$_2$ ×, and Fab′ × Fab′ conjugates, respectively. The comparison of the peptide/bsMAb in the blood for these three conjugates may provide some insight into the

[a] Data include the percent injected dose per gram for ^{125}I-bsMAb and ^{99m}Tc-peptide, the tumor/nontumor ratio for ^{99m}Tc-peptide (T/NT pep), and the ratio of the % bsMAb and % peptide in the tissues (pep/bsMAb). 1.5×10^{-10} mol of bsMAb and 1.5×10^{-11} mol of ^{99m}Tc-IMP-192 were given for each conjugate. Values represent mean ± SD; $n = 5$ for each observation. The interval is the amount of time between the bsMAb and peptide injections. [b] Time after ^{99m}Tc-IMP-192 given.

relative efficiency of each conjugate for binding the peptide in vivo. For example, in the case of the F(ab′)$_2$ × Fab′ and the Fab′ × Fab conjugates, the concentration of bsMAb in the blood, as measured by the ^{125}I-bsMAb, was not significantly different ($p = 0.105$), yet the amount of peptide found in the blood at 3 h was significantly higher with the Fab′ ($p = 0.023$), and the difference between the peptide/bsMAb ratios for these two groups was significantly different at a level of $p = 0.007$. This assessment suggests that the Fab′ × Fab′ bsMAb conjugate was able to bind more avidly to the peptide than the F(ab′)$_2$ × Fab′ conjugate. This is not unexpected since the chemical coupling process of the hMN-14 Fab′ and the c734 Fab′ more effectively orients the twp molecules by binding each molecule at its hinge region. Because the Fab′ is coupled to lysine groups on the IgG and F(ab′)$_2$, it can be randomly positioned on the molecule, which could affect its ability to bind to the peptide. Although the IgG × Fab′ conjugate had higher peptide/bsMAb ratio in the blood compared to the F(ab′)$_2$ × Fab′, it is more likely that this occurred because the IgG × Fab′ conjugate had nearly 10 times the amount of bsMAb in the blood at the time the peptide was given, rather than an indication of it being more capable of avidly binding the peptide than the F(ab′)$_2$ × Fab′. Thus, this assessment can only apply to the F(ab′)$_2$ × Fab′ and Fab′ × Fab′ conjugates, since the blood concentration at the time of the injection was the same. It is also important to point out that Karacay et al. (2000) had previously shown ^{99m}Tc-IMP-192 was rapidly cleared from the blood, and since there is no detectable binding of the peptide to other serum proteins, such as albumin, as determined by SE-HPLC of ^{99m}Tc-IMP-192 incubated in plasma (not shown), it is reasonable to assume that any peptide remaining in the blood is most likely bound to the bsMAb.

There was also a substantial amount of ^{99m}Tc-IMP-192 in the liver with the IgG × Fab′ conjugate. This could have been a consequence of peptide binding directly to the bsMAb in the liver, but it is also possible that a portion of the liver uptake was a consequence of either mono- or dimeric complexes of the bsMAb formed with the peptide in the blood, which were then transported to the liver. Renal uptake of the ^{99m}Tc=IMP-192 alone (i.e., without pretargeting) was previously shown to be about 2.0% ID/g (Karacay et al., 2000). In a pretargeting setting, renal uptake is not much higher unless there is a substantial level of bsMAb in the blood. This suggests that a substantial portion of the bsMAb is not itself sequestered in the kidneys, leading to peptide localization.

Twenty-four hours after the peptide injection, the tumor uptake of the ^{99m}Tc-IMP-192 increased from 6.0 ± 0.9 to 10.0 ± 2.4% ID/g for the IgG × Fab′ conjugate, while it decreased for the other conjugates. Some of this increase could have been due to the subsequent tumor localization of the IgG × Fab′–^{99m}Tc-IMP-192 complexes that were formed in the blood. Indeed, the bsMAb–^{99m}Tc-IMP-192 complexes in the blood at 3 h after the peptide injection were more highly laden with peptide, having 1 mol of peptide for every 4.3 mol of bsMAb, than the bsMAb in the tumor, which had only 1 mol of peptide for every 37 ± 22 mol of bsMAb.

As a consequence of higher tumor accretion of the peptide with lower amounts in the blood, the ^{99m}Tc-IMP-192 tumor/blood ratios for the F(ab′)$_2$ × Fab′ and Fab′ × Fab′ bsMAb were higher than the IgG × Fab′ conjugate (Table 2). Although there was some improvement in the IgG × Fab′ conjugate by 24 h, the tumor/blood ratios never exceeded that seen with the other 2 conjugates. Thus, despite having the highest level of bsMAb uptake in the tumor, the higher concentration of IgG × Fab′ in the blood at the time of the peptide injection inhibited tumor accretion. Since the peptide was given to animals when the amount of the F(ab′)$_2$ × Fab′ and Fab′ × Fab′ conjugate in the blood were the same, the higher tumor uptake of the F(ab′)$_2$ × Fab′ resulted in this conjugate having the highest tumor/nontumor ratios for the peptide under these targeting conditions.

Examination of Clearing and Blocking Agents. Although the targeting results described above favored the F(ab′)$_2$ × Fab′ conjugate, the fact that the IgG × Fab′ conjugate had nearly 5 times the concentration of bsMAb in the tumor as the F(ab′)$_2$ × Fab′ conjugate meant that it might be possible to enhance peptide accretion in the tumor further if the blood concentration of the IgG × Fab′ could be reduced to a lower level at the time the peptide was given. A number of strategies were examined to determine a means of maintaining a high amount of IgG

× Fab′ bsMAb in the tumor while removing or blocking it in the blood.

Clearing Agents. We previously used galactosylated and nongalactosylated rat WI2 anti-MN-14 idiotype antibody as a clearing agent for an avidin−biotin pretargeting procedure (Karacay et al., 1997; Sharkey et al., 1997). Thus, these clearing agents were examined in combination with the hMN-14 IgG × c734 Fab′ in an attempt to improve pretargeting with the ^{99m}Tc-IMP-192 peptide. In the first studies, galactosylated rWI2 (gal-rWI2) was given 48 h after the bsMAb at a 5:1 mole ratio based on the concentration of bsMAb in the blood immediately prior to its administration. After waiting 3 h to allow for bsMAb clearance, ^{99m}Tc-IMP-192 was given, and then 3 h later, animals were necropsied to determine the distribution of the bsMAb and peptide. As shown in Table 3, gal-rWI2 was effective in clearing the bsMAb from the blood, reducing it from 9.5 ± 1.4% ID/g seen in the group that did not receive any clearing agent to 1.8 ± 0.50% ID/g in the group given gal-rWI2 clearing agent. With a lower amount of bsMAb in the blood, animals given the gal-rWI2 had only 0.9 ± 0.28% ID/g of the peptide in the blood, whereas the group that was not given the clearing agent had 11.3 ± 2.9% ID/g of the injected peptide in the blood. Despite the significant reduction of peptide binding in the blood, tumor uptake of the peptide for the animals given the gal-rWI2 was not any higher than that of the control animals. Liver accretion of the peptide, however, increased significantly in the animals given the gal-rWI2 (14.3 ± 2.1 vs 5.8 ± 0.6% ID/g for the control; $p < 0.001$), suggesting that bsMAb had been transported to the liver by the clearing agent, but had not been sufficiently processed to prevent its binding to the peptide, which in turn reduced the availability of the peptide for tumor localization. Therefore, despite improving tumor/blood ratios as compared to the control group (1.84 ± 0.87 vs 0.19 ± 0.05), the tumor/nontumor ratios and amount of peptide targeted to the tumor were not higher than those seen with the F(ab′)$_2$ × Fab′ or Fab′ × Fab′ bsMAbs.

It was also noted that the peptide/bsMAb ratio in the blood for the control group was 1.18 ± 0.15 (representing 1 peptide for every 8.4 mol of bsMAb). In contrast, the animals given the gal-rWI2 had a peptide/bsMAb ratio of 0.49 ± 0.08 (1 mol of peptide for every 20 mol of bsMAb in the blood). This substantially lower peptide/bsMAb ratio could be a result of less favorable kinetics for peptide binding to the lower amount of bsMAb in the blood of the gal-rWI2 group, or steric hindrance created by the binding of the gal-rWI2 to the bsMAb.

In the next study, galactosylated and nongalactosylated rWI2 were independently evaluated as clearing agents, and additional modifications were made in an attempt to reduce the amount of bsMAb that would be present at the time the ^{99m}Tc-IMP-192 was given. In this regard, the IgG × Fab′ bsMAb was allowed to clear for 65 h (rather than 48 h) before giving the clearing agents, and the radiolabeled peptide was not given until either 5 or 24 h after the clearing agents (rather than 3 h). Increasing the interval between the clearing agent and the peptide injection was intended to allow more time for the bsMAb−anti-id antibody complexes diverted to the liver to be processed, and therefore inaccessible at the time the peptide is given. Immune complexes cleared by the gal-rWI2 and nongalactosylated rWI2 would also be expected to localize to different cell types in the liver, which could also influence the processing of the bsMAb and peptide. The same amount of bsMAb and peptide were given as before (1.5 × 10^{-10} and 1.5 × 10^{-11} mol,

[a] hMN-14 IgG × c734 Fab′ (1.5 × 10^{-10} mol; 10 μCi) was given intravenously. Forty-eight hours later, the clearing/blocking agent was given, and after 3 h, the ^{99m}Tc-IMP-192 (1.5 × 10^{-11} mol) was given. Three hours later, the animals were necropsied, and the ^{125}I-bsMAb and ^{99m}Tc-IMP-192 radioactivity levels were determined. [b] gal-rWI2 was given at a 5:1 mole ratio, and In-DTPA was given at a 1:1 mole ratio based on the amount of bsMAb in blood at the time of their administration. The group that was not given a clearing/blocking agent received the ^{99m}Tc-IMP-192 51 h after the bsMAb and necropsied 3 h later. Values represent the means ± SD with 5 animals per group.

[a] Nude mice bearing GW-39 tumors were given an intravenous injection of hMN-14 IgG × c734 Fab′ bsMAb (1.5×10^{-10} mol) that contained a trace amount of ^{125}I-bsMAb. Sixty-five hours later, the clearing agent was given intravenously, and then after waiting either 5 or 24 h, ^{99m}Tc-IMP-192 (1.5×10^{-11} mol) was administered. Animals ($n = 5$, except where indicated) were necropsied 3 h later, and the amount of ^{125}I-bsMAb and ^{99m}Tc-IMP-192 was determined. Control animals not given any clearing agent received the ^{99m}Tc-IMP-192 at either 70 or 90 h after the bsMAb injection.

respectively), and animals were all necropsied 3 h after the peptide injection. The peptide was also given to animals that did not receive a clearing agent at either 70 or 90 h after the bsMAb injection so the time of necropsy would coincide closely with the animals given the clearing agents for comparison. Table 4 shows the % ID/g for the bsMAb and peptide, tumor/nontumor ratios for the peptide, and the peptide/bsMAb ratios obtained in these groups.

Delaying the ^{99m}Tc-IMP-192 injection until 70 and 90 h after the bsMAb was given reduced the blood concentration of the bsMAb to 7.21 ± 1.68 and 4.71 ± 1.82% ID/g, respectively, compared to 9.5 ± 1.40% ID/g seen in the previous study. However, the ^{99m}Tc-IMP-192 continued to show higher concentrations of the peptide in the blood and liver than the tumor. Both the rWI2 and gal-rWI2 effectively reduced the blood concentration of the IgG × Fab′ bsMAb, with the gal-rWI2 showing a greater ability to reduce the bsMAb level in the blood more quickly than the rWI2. For example, the bsMAb in blood was 2.31 ± 0.71% ID/g for the rWI2 group, which was about 4-fold lower than the group that was given no clearing agent (7.11 ± 1.68 at 70 h), but the blood concentration of the bsMAb in animals gal-WI2 was reduced to 0.88 ± 0.46% ID/g. When the period between the time the clearing agent and the peptide was extended to 24 h, then the level of bsMAb in the blood of galactosylated and nongalactosylated rWI2 was the same (0.55 ± 0.39 and 0.61 ± 0.30% ID/g, respectively), which was about 8-fold lower than if no clearing agent was given (4.71 ± 1.82% ID/g). It was also interesting to note that in the groups receiving the clearing agents, the ratio of peptide/bsMAb in the blood for the 5 h clearance group was 0.57 to 0.65, but with a 24 h clearance interval, this ratio increased to 1.48 to 2.87. This indicates that the bsMAb in the blood at the earlier time was not as receptive to binding the peptide as the bsMAb in the blood after 24 h, supporting the possibility of steric hindrance.

Tumor uptake of the bsMAb in the treated groups with a 5 h clearance time and control group (70 h) was the same, but despite having lower blood concentrations of the bsMAb, the animals given the clearing agents had the same amount of ^{99m}Tc-IMP-192 in the tumor as the control animals. In each of the treated groups, there was considerable peptide uptake in the liver with highly unfavorable tumor/liver ratios. Increasing the interval between the clearing agent and the time the peptide was given to 24 h reduced the bsMAb concentration in the blood to levels that were comparable to those seen with the F(ab′)$_2$ × Fab′ conjugate (0.61 ± 0.30, 0.55 ± 0.39, and 0.33 ± 0.15% ID/g for rWI2 and gal rWI2, and F(ab′)$_2$ × Fab′, respectively). Under these conditions, tumor uptake of the ^{99m}Tc-IMP-192 was 7.16 ± 1.68 and 7.27 ± 1.49% ID/g for the rWI2 and gal-rWI2, respectively, which was not significantly different ($p = 0.156$) to the peptide uptake seen with the F(ab′)$_2$ × Fab′ (9.0 ± 1.4% ID/g). Although tumor/blood ratios in animals given the clearing agents with a 24 h interval before administering the peptide were highly variable, the individual animal data revealed that when the blood concentration of the bsMAb was reduced to about 0.2−0.4% ID/g, tumor/blood ratios were between 13 and 26, thus being comparable to that achieved with the F(ab′)$_2$ × Fab′ conjugate. However, there continued to be considerable liver accretion of the peptide, most noticeably with the gal-WI2 clearing agent. In conclusion, tumor/liver ratios for the ^{99m}Tc-IMP-192 using IgG × Fab′ bsMAb with either clearing agent and a 24 h interval were much lower than that seen with the F(ab′)$_2$ × Fab′ bsMAb (i.e., <0.5 for the clearing agents compared to 27.3 ± 7.35 for the F(ab′)$_2$ × Fab′).

To see whether additional delays in the interval between the time the clearing agent and ^{99m}Tc-IMP-192 was given would yield any improvements, animals were again given 1.5×10^{-10} mol of the hMN-14 IgG × c734 Fab′ bsMAb, and after 65 h, rWI2 was given at a 5:1 mole ratio (anti-antibody to bsMAb) based on the blood con-

[a] Nude mice bearing GW-39 tumors were injected i.v. with 1.5×10^{-10} mol of the bsMAb that included a trace amount of ^{125}I-bsMAb. In one group, bsMAb blood concentration was monitored, and the peptide was given when it was <1.0% ID/g. The other groups of animals were given rWI2 65 h after the bsMAb injection (rWI2 given at a 5:1 mole ratio based on bsMAb concentration at 65 h). Following a delay of 24, 48, or 72 h, the peptide was given. In all groups, animals were necropsied 3 h after the peptide injection. Values represent means ± SD with 5 animals in each group.

centration of the ^{125}I-bsMAb at this time. The nongalactosylated rWI2 was selected because of the lower bsMAb and peptide accretion in the liver compared to the gal-WI2. After waiting 24, 48, or 72 h, ^{99m}Tc-IMP-192 was given (1.5×10^{-11} mol). In addition, another group of animals, without the aid of a clearing agent, was monitored until the concentration of ^{125}I-bsMAb in the blood was ≤1.0%/g, at which time the ^{99m}Tc-IMP-192 was given. In all instances, animals were then necropsied 3 h later.

In order for the IgG × Fab′ conjugate to be cleared from the blood to ≤1.0% ID/g, a period of 11 days was required. Three hours after the peptide was injected, the tumor contained 3.01 ± 0.49% ID/g of the bsMAb, which was able to capture 6.16 ± 1.03% ID/g of the ^{99m}Tc-IMP-192 (Table 5). However, the ^{99m}Tc-IMP-192 concentration in the blood was 3.01 ± 1.53% ID/g, which resulted in tumor/blood ratios of only 2.47 ± 1.21. Even though the concentration of the IgG × Fab′ bsMAb in the blood and liver was low, there was a high concentration of ^{99m}Tc-IMP-192 in the liver. Indeed, the concentration of the bsMAb in the liver was only 0.29 ± 0.13% ID/g, which was similar to that seen with the F(ab′)$_2$ × Fab′ conjugate (Table 2). This suggests that the IgG × Fab′ conjugate is more highly susceptible to forming complexes with the divalent IMP-192, which then subsequently localize in the liver.

Similar targeting results with the rWI2 clearing agent and a 24 h clearance period were obtained as seen previously (refer to data in Tables 4 and 5). Waiting for 48 h before administering the ^{99m}Tc-IMP-192 did not provide any significant improvements in the peptide targeting data (Table 5). By waiting 72 h, the amount of bsMAb in the tumor decreased while its concentration in the blood did not change significantly, which resulted in decreased tumor/blood ratios. Liver uptake of the peptide also remained a considerable obstacle, regardless of the interval. Thus, a 24 h clearance period for the rWI2 was considered to be the optimal clearing agent and condition for use with the IgG × Fab′ bsMAb, but even these conditions failed to meet the targeting results seen with the F(ab′)$_2$ × Fab′.

Blocking and Blocking/Clearing Agents. These data indicated that the primary problem with an agent that only clears the bsMAb from the blood is that a portion of the bsMAb remains in the system and is able to bind to the peptide, potentially redirecting it to the liver. Thus, additional agents were examined that had the ability to block the anti-DTPA-binding arm of the bsMAb to prevent it from subsequently binding the peptide.

Indium-loaded DTPA and indium-loaded IMP-156 (a divalent DTPA peptide; Karacay et al., 2000) represent agents that should only be able to block the bsMAb's anti-DTPA binding arm without necessarily altering its biodistribution (i.e., acting as a clearing agent). Because these compounds are similar to the peptide, and therefore could quickly penetrate into the tumor and block the subsequent binding to the radiolabeled peptide, the dosage of these agents was kept low. Indium-loaded DTPA was given to animals 48 h after the injection of the IgG × Fab′ clearance at a molar ratio of only 1:1, based on the amount of bsMAb in the blood at the time of the peptide injection. After waiting 3 h, ^{99m}Tc-IMP-192 was given. The data shown in Table 3 indicate that the indium-loaded DTPA had no impact on either the distribution of the bsMAb or the peptide, since the data for this group and the group that only received the ^{99m}Tc-IMP-192 were identical, with an identical peptide/bsMAb ratio in the blood. Indium-loaded IMP-156 was given at a slightly higher mole ratio of 1.5:1 and at 65 h after the bsMAb was given with the ^{99m}Tc-IMP-192, injected 30 min after the indium-loaded IMP-156. As shown in Table 6, a substantial portion of the ^{99m}Tc-IMP-192 was bound to the bsMAb in the blood. Although the percentage of the ^{99m}Tc-IMP-192 was significantly lower in the blood of the animals given the indium-loaded IMP-156 ($p = 0.019$), the peptide/bsMAb ratio for these 2 groups did not achieve statistical significance ($p = 0.087$). The data using the indium-loaded IMP-156 also indicated that the % ID/g of ^{99m}Tc-IMP-192 in the tumor was higher than in the control group [4.44 ± 2.0 and 8.45 ± 1.83% ID/g, control vs (In)IMP-156, respectively]. However, because the peptide/bsMAb ratio for the tumor in both groups was the same (0.47 ± 0.31 and 0.49 ± 0.17, control vs (In)IMP-156, respectively), this higher amount was likely a reflection of this group's higher concentration of bsMAb in the tumor than the control (e.g., 11.0 ± 4.1 vs 17.8 ± 3.8) as compared to a specific enhancement of peptide uptake. Thus, this dosing scheme did not produce the desired blocking effect. Since there was a concern that these small molecular weight blocking agents could also

[a] Animals were given 1.5×10^{-10} mol of the bsMAb (hMN-14 IgG × c734 Fab′), and then 65 h later, BSA-DTPA or indium-loaded IMP-156 was given. Two hours after the BSA-DTPA or 30 min after the IMP-156, the ^{99m}Tc-IMP-192 was given (1.5×10^{-11} mol), and then 3 h afterward, the animals were necropsied and tissues counted for ^{125}I-bsMAb and ^{99m}Tc-IMP-192. Groups A, B, C, and E used ^{125}I-bsMAb data from re-run groups as these were counted after decay of ^{99m}Tc. Values represent the means and SD of the percent injected dose per gram for the bsMAb and peptide, the tumor/nontumor ratio for the peptide, and the mole ratio of the concentration of the peptide and bsMAb in the tissues. $N = 5$ for each group, except where indicated.

quickly bind to bsMAb in the tumor, and therefore block the uptake of the radiolabeled peptide, additional escalation studies were not performed.

Efforts were then directed to an examination of indium-loaded DTPA bound to BSA. BSA-DTPA(In) conjugates could act as both a blocking agent and a clearing agent, since depending on the number of DTPA per BSA molecule, more than one bsMAb could be bound with the resulting complex being potentially cleared from the blood. To evaluate the role of DTPA substitution on the blocking and clearing ability of these agents, two BSA-DTPA conjugates were examined, one with an average of 4.4 mol of DTPA/BSA and another with 8.3 mol of DTPA/BSA. These 2 agents were given 65 h after the IgG × Fab′ bsMAb was injected, and 2 h later, the ^{99m}Tc-IMP-192 was given. The dosage of the blocking agent was also evaluated, with one group of animals receiving a 1.5:1 BSA-(4.4)DTPA(In):bsMAb ratio, while another was given a higher dose of the blocking agent, i.e., 5:1 BSA-(4.4)-DTPA(In):bsMAb ratio. BSA-(8.3)DTPA(In) was tested only at the 5:1 level. All animals were necropsied 3 h after the ^{99m}Tc-IMP-192 injection. A control group of animals were given the ^{99m}Tc-IMP-192 67 h after the bsMAb to coincide with the time the radiolabeled peptide was given to the animals receiving the BSA-DTPA conjugates.

Since the amount of ^{125}I-bsMAb in the blood of all animals given the BSA-DTPA(In) was the same as the control group, this indicates that they were not effective in removing the bsMAb from the blood under the conditions tested (Table 6). However, the BSA-DTPA(In) conjugates were effective in preventing the ^{99m}Tc-IMP-192 from binding to the bsMAb in the blood, reducing the amount from 20.8% ID/g seen in the control group to 5.8 ± 3.2% ID/g and 1.0 ± 0.5% ID/g in the animals given the 1.5:1 to 5:1 BSA-DTPA(In) dose, respectively. Increasing the mole substitution to 8.3 mol of DTPA did not significantly decrease the amount of ^{99m}Tc-IMP-192 bound to the bsMAb in the blood (0.90 ± 0.53 vs 0.61 ± 0.16% ID/g), but the variability among the various animals was considerably less with the higher level of DTPA substitution, suggesting that this conjugate may provide more reliable results. Regardless of the dose level given, the BSA-DTPA(In) conjugates significantly improved the tumor/nontumor ratios compared to the control group, with the 5:1 dose of BSA-(4.4)DTPA(In) and BSA-(8.3)DTPA(In) providing similar, but significantly higher ratios compared to the 1.5:1 dose of the BSA-(4.4)DTPA(In) ($p = 0.001$). In comparison to the peptide localization seen with the F(ab′)$_2$ × Fab′ bsMAb, tumor uptake was similar, regardless of the dose or DTPA substitution. However, peptide/bsMAb ratios were all substantially lower than that seen with the F(ab′)$_2$ × Fab′, indicating a diminished capacity of the bsMAb to bind the peptide. Tumor/blood ratios for the 1.5:1 dose of BSA-(4.4)DTPA(In) were lower than those achieved with the F(ab′)$_2$ × Fab′ conjugate, but by increasing the dose of the blocking agent to 5:1, the tumor/blood ratios were not significantly different from the F(ab′)$_2$ × Fab′ conjugate ($p = 0.197$). Tumor/liver ratios for the 5:1 dose of BSA-DTPA blocking agents were also not significantly different from the ratios for the F(ab′)$_2$ × Fab′ group ($p = 0.073$).

Peptide uptake in the kidneys of animals given the BSA-DTPA(In) conjugate was consistently about 2-fold lower than that seen in the control group or even in animals given the IMP-156 or (In)DTPA. This was most likely a consequence of the lower amount of peptide in the blood in these animals than a specific blockade of peptide uptake in the kidney, since this finding also was seen in the animals given the anti-id antibody as a clearing agent (i.e., no ability to block peptide binding).

Additional studies were performed with the BSA-(4.4)-DTPA(In) blocking agent to examine whether increasing the interval between the blocking agent from 2 to 24 h would improve the results, and a new conjugate, a galactosylated-BSA-(4.4)DTPA(In), was prepared and

[a] Animals were given an intravenous injection of hMN-14 IgG × Fab′ bsMAb (1.5×10^{-10} mol with a trace of ^{125}I-bsMAb), and 65 h later, BSA- or gal-BSA-(4.4)DTPA(In) was given using a 5:1 ratio of the blocking agent to blood concentration of the bsMAb at 65 h. After waiting the allotted time (2 or 24 h), ^{99m}Tc-IMP-192 was given (1.5×10^{-11} mol), and the animals were necropsied 3 h later. Values represent the means ± SD with 5 animals studied per group except where indicated.

tested using both a 2 and a 24 h clearance time prior to administering the ^{99m}Tc-IMP-192 (Table 7). In agreement with the previous study, nongalactosylated BSA-DTPA-(In) failed to clear the bsMAb from the blood, but it was effective in reducing the amount of peptide found in the blood at the time of necropsy (1.00 ± 0.41 and 1.17 ± 0.54% ID/g of the ^{99m}Tc-IMP-192 in the blood for the 2 and 24 h clearance groups, respectively, compared to 15.81 ± 2.48% ID/g seen in the control group at the 70 h necropsy time). However, not only did the gal-BSA-(4.4)-DTPA(In) fail to clear the bsMAb from the blood (7.09 ± 1.6% bsMAb/g blood for the gal-BSA(4.4)DTPA(In) group and 6.28 ± 2.25% bsMAb/g blood for the control), it also failed to block the peptide binding to the bsMAb in the blood (16.24 ± 2.67% ^{99m}Tc-IMP-192/g blood for the gal-BSA-DTPA blocking agent and 18.81 ± 2.48 for the control group). Regardless of the interval between the peptide and the time the gal-BSA-(4)DTPA(In) was given, peptide uptake in the blood as well as the other tissues was similar to that of control group. This suggests that the gal-BSA-DTPA was most likely cleared too quickly from the blood to allow for significant interaction with the bsMAb.

The 2 h clearance time for the BSA-(4.4)DTPA(In) yielded very good targeting results for the peptide, with 13.60 ± 6.09% ID/g in the tumor, and only 0.63 ± 0.22% ID/g in the liver and 1.0 ± 0.4% ID/g in the blood. Extending the clearance interval between the BSA-(4.4)-DTPA(In) and the peptide injection to 24 h showed a significant reduction in the amount of peptide in the tumor, reducing the uptake to 2.51 ± 1.15% ID/g, even though the percentage of bsMAb in the tumor had not decreased significantly (13.42 ± 5.56 vs 8.33 ± 4.47% ID/g for the 2 and 24 h clearance intervals, respectively). Extending the interval between the time the blocking agent was given to 24 h could have conceptually allowed the blocking agent time to bind to the bsMAb in the tumor, which could explain the lower peptide binding under this condition. Despite the fact that there was no statistical significance between the percentages of bsMAb in the tumor, the number of moles of bsMAb in the tumor was significantly 16.2 times more at the time the peptide was given with only a 2 h clearance compared to the 24 h clearance (p = 0.001). Another factor that could have contributed to the lower tumor uptake was the higher bsMAb in the blood capable of binding to the peptide (i.e., unblocked) at the 24 h interval. This can be seen by the peptide/bsMAb ratio in the blood at 24 h was higher than that observed with a 2 h spacing (0.46 ± 0.23 vs 0.18 ± 0.06). Thus, the lower percentage of peptide targeting to the tumor in the 24 h clearance group could have been due to a combination of both a higher proportion of unblocked bsMAb in the blood and a lower amount of bsMAb in the tumor, but a blockade effect cannot be ruled out.

Thus, the most promising of the agents tested for use with the IgG × Fab′ fragment was the nongalactosylated BSA-(4.4 or 8.3)DTPA(In), since the targeting results obtained in this study compared favorably with the F(ab′)$_2$ × Fab′. Overall, however, even this procedure failed to take full advantage of the higher amount of IgG × Fab′ bsMAb in the tumor and allow for even higher amounts of peptide targeting. For example, in this study, 13.4 ± 5.56% of the bsMAb was in the tumor of the BSA-(4.4)DTPA(In) group, but only 13.6 ± 6.09% ID/g of the peptide subsequently targeted to the tumor. In contrast with the F(ab′)$_2$ × Fab′, there was only 3.88 ± 0.66% of the bsMAb in the tumor, but 2.3-fold more peptide was able to localize to the tumor (i.e., 9.0 ± 1.40% ID/g). There could be 2 explanations for this finding. First, the amount of bsMAb in the blood had to be lowered to a level more comparable to that seen with the F(ab′)$_2$ × Fab′, which then might allow a higher portion of the ^{99m}Tc-IMP-192 peptide to gain access to the tumor. This could potentially be achieved by further adjusting the dose of the BSA-DTPA conjugate. Second, it was possible that even with a 2 h interval between the time the BSA-DTPA conjugate and the ^{99m}Tc-IMP-192 was given, this conjugate was able to also bind to the bsMAb in the tumor, thereby preventing the subsequent binding of the radiolabeled peptide.

[a] Animals were given an intravenous injection of hMN-14 IgG × Fab′ bsMAb (1.5×10^{-10} mol with a trace of ^{125}I-bsMAb), and 65 h later, a blocking agent was given using a 5:1 ratio of blocking agent to blood concentration of the bsMAb at 65 h. After waiting the allotted time, ^{99m}Tc-IMP-192 was given (1.5×10^{-11} mol), and the animals were necropsied 3 h later. Values represent the means ± SD with 5 animals studied per group, except where indicated.

To evaluate this second possibility, another study was performed where the length of time between the BSA-DTPA conjugate was shortened to 0.5 and 1.0 h. In addition, a larger molecular weight conjugate, namely, an IgG-(4)DTPA(In) conjugate, was prepared to determine if its larger size might delay its uptake in the tumor longer than that of the BSA-DTPA conjugate, and therefore further reduce the potential for blocking tumor uptake. With this latter conjugate, a period of 0.5 and 4.0 h was tested between the time the conjugate and peptide was given. This study showed that both the BSA- and the IgG-DTPA(In) conjugates effectively blocked peptide uptake in the blood, with 12.0 ± 4.6% ID/g of the ^{99m}Tc-IMP-192 in the blood for the control where the peptide was given without prior administration of a blocking agent, whereas the blocking groups averaged 0.6−1.4% ID/g (Table 8). There was no significant difference between the percentage of peptide bound in the blood in the group of animals where a 0.5 h or a 1.0 h interval was given, and this percentage was similar to that seen in the previous study with a 2 h interval between the time the BSA-DTPA(In) and ^{99m}Tc-IMP-192 was given. Thus, the BSA-DTPA(In) conjugate appeared to effectively block the bsMAb in the blood within 30 min. However, the peptide/bsMAb ratio in the tumor remained unchanged regardless of the interval given between the 2 injections. There were no significant differences between the % ID/g of peptide in the blood or tumor, nor were there significant differences in peptide/bsMAb ratios for the IgG-DTPA(In) at 0.5 or 4.0 h, and these targeting results were not significantly different from those obtained with the BSA-DTPA(In) blocking agent.

With the preliminary testing suggesting that the BSA- and IgG-DTPA(In) conjugates might provide the best ability to enhance the targeting results of the IgG × Fab′ bsMAb, a final study was performed where the biodistribution was monitored at 3 and 24 h after the peptide was injected, so that the results of these time periods could be compared to that of the F(ab′)$_2$ × Fab′. Animals were given the IgG × Fab′ bsMAb, and then 65 h later they received the BSA-(4.4)DTPA(In) or another IgG-DPTA(In) conjugate that had 8 mol of DTPA per IgG (IgG-(8)DTPA(In)). After waiting 2 h for clearance with the BSA-(4.4)DTPA(In) or 4 h for the IgG-(8)DTPA(In), the ^{99m}Tc-IMP-192 was given. Another control group received the IgG × Fab′ bsMAb and then the peptide 65 h later, without the intervention of a blocking agent.

The control group in which no blocking agent was given had the typical high concentration of peptide bound in the blood at 3 h, with only 50% of the bsMAb in the tumor having peptide bound (Table 9). Twenty-four hours after the peptide was given, tumor uptake had increased from 6.0 to 14.0% ID/g, which was most likely a consequence of the tumor localization of the bsMAb present in the blood that was radiolabeled in vivo with the ^{99m}Tc-IMP-192. Despite the higher tumor uptake, blood concentrations of the peptide remained elevated (9.5 ± 2.0% ID/g). Both the BSA- and IgG-DTPA(In) conjugates effectively blocked the uptake of the peptide by the bsMAb in the blood, reducing levels at 3 h from 19.5% ID/g in the control group to 0.7−1.2% in the animals receiving the blocking agents. Excellent uptake of the peptide was achieved at 3 h in both groups receiving the blocking agents, with the peptide uptake in the animals given the BSA-(4.4)DTPA(In) reaching an average of 19.8 ± 6.3% ID/g, significantly higher (p = 0.006) than the peptide uptake with the F(ab′)$_2$ × Fab′ (9.0 ± 1.4% ID/g). This result was directly related to a significantly higher tumor accretion of the IgG × Fab′ bsMAb in comparison to other studies reported herein. Tumor uptake of the ^{99m}Tc-IMP-192 for the group given the IgG-(8)DTPA(In) was not significantly higher than that seen with the F(ab′)$_2$ × Fab′ conjugate, but tumor to nontumor ratios were comparable to those obtained with the F(ab′)$_2$ × Fab′. However, the average peptide/bsMAb ratio did not exceed 1.0 (0.78 ± 0.25 and 0.83 ± 0.65, for the BSA- and IgG-DTPA(In) blocking agents, respectively), whereas a ratio 2.38 ± 0.56 was observed with the F(ab′)$_2$ × Fab′ at 3 h. Thus, the peptide targeting efficiency was not equal to that of the F(ab′)$_2$ × Fab′ conjugate. Of more concern was

[a] Sixty-five hours after the intravenous injection of 1.5×10^{-10} mol of IgG × Fab′ bsMAb, BSA-DTPA(In) or IgG-DTPA(In) was given. Two or four hours later (respectively), ^{99m}Tc-IMP192 (1.5×10^{-11} mol) was injected, and animals were then necropsied 3 and 24 h later. Control animals were given ^{99m}Tc-IMP-192 67 h after the bsMAb without the aid of a blocking agent, being necropsied 3 and 24 h thereafter.

the finding that 24 h after the peptide was given, the % ID/g of the peptide in the tumor decreased significantly in both groups of animals receiving the blocking agents. There was a concomitant significant decrease in the amount of bsMAb in the tumor at 24 h, but the loss in bsMAb from the tumor was not proportional to that of the peptide, with the peptide/bsMAb ratio decreasing about 3−4-fold. In contrast, the peptide/bsMAb ratio using the F(ab′)$_2$ × Fab′ bsMAb remained relatively constant over this same period (3.24 ± 1.19 at 24 h), and the percentage of peptide in the tumor decreased only 1.4-fold during this time.

DISCUSSION

Pretargeting methods are attractive alternatives to directly radiolabeled antibodies because the radioactivity is not associated with an antibody that has a long half-life in the blood. When the radioactivity is associated with a small, rapidly clearing compound, such as a peptide or biotin in a pretargeting approach, the residence time in the blood is greatly reduced and vastly improved tumor/blood ratios are possible very early after the peptide's injection. Excellent for imaging, but for therapy, rapid blood clearance decreases the proportion of the injected product that is available for tumor binding. Thus, the challenge for pretargeting is to provide sufficient surrogate targets within the tumor to facilitate the capture and retention of enough radioactivity for sufficient time so that the cumulative radiation exposure will result in tumor cell death.

In the early work with bsMAb pretargeting, bsMAbs were composed of F(ab′)$_2$ × Fab′ fragments (Le Doussal et al., 1989, 1990), but the major breakthrough in achieving optimum tumor loading came with the observation that divalent haptens greatly enhance the delivery and stability of the hapten in the tumor according to a mechanism termed "affinity enhancement". Using the AES concept, Le Doussal et al. (1990) ultimately selected the Fab′ × Fab′ bsMAb configuration for pretargeting because of its faster blood clearance provided higher tumor/nontumor ratios. Animal and clinical studies have shown the utility of this method for providing high-contrast images, and there have even been some investigations of this procedure for positron-emitters and PET imaging (Klivenyi et al., 1998; Schuhmacher et al., 2001). Excellent therapeutic responses in animal xenograft models and some promising clinical results have also been reported with a bsMAb pretargeting approach using a Fab′ × Fab′ bsMAb and an ^{131}I-labeled divalent hapten (Gautherot et al., 1998, 2000; Kraeber-Bodere et al., 1999;Vuillez et al., 1999). Although these studies clearly support the ability of the bsMAb pretargeting approach to have utility for both imaging and therapy, further optimization of the amount of radioactivity that can be delivered to a tumor without significant sacrifice of normal tissue exposure would be important. To this end, we hypothesized that one way to further optimize the amount of bsMAb delivered to the tumor with greater stability was to have a bsMAb constructed with more than one binding arm directed to the primary tumor antigen. To examine this, three bsMAb conjugates were prepared by chemically combining anti-CEA and anti-DTPA(In) antibodies so that they have different valencies to the primary target antigen, CEA. The conjugates were prepared using methods designed to produce stable thioether bonds between the two antibody molecules. The IgG × Fab′ and F(ab′)$_2$ × Fab′ conjugates are divalent to CEA, and therefore should have had similar dissociation rates, which is expected to be lower than that of the monovalent Fab′ × Fab′ conjugate. However, because the IgG and F(ab′)$_2$ bsMAb conjugates differ in their molecular weight, their clearance rate from the blood is slower than the Fab′ × Fab′ conjugates, with the IgG × Fab′ conjugate having the slowest rate of clearance. The pharmacokinetic behavior of the agent is also an important delivery property. The slower clearance rate may explain why, although both the F(ab′)$_2$ × Fab′ and the IgG × Fab′ conjugates are divalent to CEA, the IgG ×

Fab′ conjugate had the highest uptake in the tumor along with the longest retention time. The IgG × Fab′ conjugate's extended retention in the blood required an evaluation of agents capable of reducing the accessibility of the conjugate remaining in the blood for the radiolabeled peptide in order to optimize pretargeting. From this perspective, the $F(ab')_2$ × Fab′ conjugate's faster blood clearance was an advantage, and because it had a higher level in the tumor than the Fab′ × Fab′ conjugate, the peptide uptake was higher. Furthermore, the in vivo tumor targeting data for the ^{125}I-$F(ab')_2$ × Fab′ alone and together with the pretargeting data for the ^{99m}Tc-IMP-192 indicated that the $F(ab')_2$ × Fab′ had a longer retention in the tumor than the Fab′ × Fab′. This suggests that the avidity of this divalent construct to CEA might be higher than that of the monovalent conjugate. These data support the main concept explored by this work, namely, that increasing the valency of a bsMAb to the tumor antigen could improve pretargeting. However, the pharmacokinetic behavior of the bsMAb is also a critical factor. Overall, with tumor uptake of the radiolabeled peptide for the $F(ab')_2$ × Fab′ conjugate was significantly higher than that found for the Fab′ × Fab′ conjugate, and with tumor/nontumor ratios significantly better than that achieved with the IgG × Fab′ conjugate, the $F(ab')_2$ × Fab′ conjugate was considered to be the best of the 3 conjugates for pretargeting.

It is also noteworthy that the peptide/bsMAb ratio for the $F(ab')_2$ × Fab′ conjugate in the blood was significantly lower than that of the Fab′ × Fab′ conjugate, which suggested the possibility that a portion of the $F(ab')_2$ × Fab′ conjugate was not able to bind the peptide as avidly as rest of the preparation. This is not unexpected, since the chemical conjugation method used for the hMN-14 IgG or $F(ab')_2$ permits random placement of the c734 Fab′ on lysine residues, but the c734 Fab′ binding orientation to the lysine is directed toward its hinge region sulfhydryl groups. With Fab′ × Fab′ conjugates, the methodology is more site-selective, with each Fab′ coupling to their respective partner's hinge region to form conjugates with similar orientation as a $F(ab')_2$. The immunoreactivity testing of these conjugates showed that all of the bsMAbs were reactive with CEA, and when the peptide was mixed with a molar excess of the bsMAb, all of the peptide was associated with the bsMAb. However, this testing would be unable to detect subtle differences in bsMAb binding affinity to the peptide that might be more likely to occur with the IgG and $F(ab')_2$ bsMAb products. Thus, given the data supporting the concept that increasing the valency to the tumor antigen can improve bsMAb pretargeting and the need to develop a more uniform product with predictable orientation, efforts are already underway to construct a number of engineered bsMAbs with divalent specificity to the tumor target. Preliminary data with a recombinant bsMAb composed of single chain to CEA and a single chain to another effector molecule (monovalent × monovalent binding specificity) suggest that the engineered protein has an advantage over the chemically conjugated Fab′ × Fab′ fragment (Sharkey et al., 2001).

The IgG × Fab′ conjugate maximized the amount of bsMAb delivered to the tumor, but its slow clearance from the blood inhibited its use for pretargeting. Extending the amount of time between the bsMAb and the peptide injection only resulted in a decrease in the concentration of the IgG × Fab′ conjugate in the tumor to levels equal to that seen with the $F(ab')_2$ × Fab′ conjugate, with subsequently no ^{99m}Tc-IMP-192 pretargeting advantage. A number of strategies were examined to determine if the benefits of the higher tumor uptake of the IgG × Fab′ at an earlier time point could be realized if the bsMAb in the blood was either cleared or blocked prior to peptide administration. An agent capable of only clearing the bsMAb from the blood, namely, an anti-idiotype antibody, might not be suitable primarily because the bsMAb was only shifted to another compartment, the liver, and the peptide subsequently became sequestered there. Unexpectedly, neither extending the interval between when the clearing agent and peptide was given, nor did galacosylating the clearing agent so that it would be more rapidly cleared to the liver hepatocytes (Mattes, 1987) provide sufficient improvements in peptide targeting. This suggested that in this model system the bsMAb was not catabolized; and, therefore, it was accessible at the time the peptide was administered. Another important factor to consider when using a clearing agent is that once the antibody is cleared from the blood, its concentration in the tumor could decrease. Since it is not important whether the bsMAb is in the blood, but the fact that its peptide-binding arm is active, agents with an ability to block the bsMAb's peptide-recognition arm with or without the ability to clear the bsMAb from the blood would be expected to perform more successfully. The pretargeting results confirmed this, with BSA- or IgG-DTPA-(In) conjugates producing the most promising results.

Developing an appropriate blocking agent must also be approached carefully, since such an agent could also block the peptide-binding arm of the bsMAb in the tumor. At the doses tested, neither the prospective blocking agents DTPA(In) nor the divalent DTPA(In) peptide, IMP-156, inhibited the binding of the peptide to the bsMAb in the blood. We elected not to aggressively pursue further dose escalation of these agents, because their small size could allow them to easily penetrate the tumor vasculature and block tumor sites if the dose was not adjusted very carefully. In a similar bsMAb targeting system as used here, Gautherot et al. (1998) tested the use of monovalent peptide in conjunction with the targeting of preformed bsMAb × peptide complexes. Tumor uptake was decreased nearly 2-fold even with a 1:1 mole excess of peptide. Over time, tumor uptake of the preformed bsMAb × peptide complex in animals given the peptide chase decreased significantly compared to animals not receiving a chase. Again, this shows that once the concentration of the targeting agent is lowered, the level in the tumor will also decrease. The extent of this decrease will be dependent on the affinity of the agents, as well as other factors, such as the shedding of the targeting antigen or the potential for the processing of the agents in the tumor.

Coupling DTPA(In) to BSA or IgG provides a larger substrate that would decrease the rate of vascular leak, which in turn could limit the accessibility of the blocking component to the prelocalized bsMAb in the tumor. Both of these agents showed significant abilities to reduce the peptide binding to the bsMAb in the blood, even when the interval between the blocking agent and the peptide injection was just 0.5 h. Although increasing the interval between the blocking agent and peptide injections could allow the blocking agent more time to block sites in the tumor, there was not conclusive evidence of this occurring. Nevertheless, limiting the time the blocking agent is in the blood and potentially accessible to block the bsMAb in the tumor is important. Galactosylating a blocking agent's carrier has been the most widely used means of accomplishing this (Mattes, 1987; Karacay et al., 1997; Axworthy et al., 2000). In our studies, coupling galactose to BSA-DTPA(In) to encourage the clearance

of the BSA-DTPA(In) from the blood made this blocking agent completely ineffective, probably because it simply cleared too quickly to have sufficient time to interact with the bsMAb. In contrast, galactosylated rWI2 was very effective in clearing the bsMAb from the blood. We have previously shown that the rate of clearance of a galactosylated IgG was dependent on the galactose substitution level (Karacay et al., 1997), and both the BSA and IgG galactose conjugates were highly substituted to encourage rapid blood clearance. Thus, possible affinity differences between the rWI2 for hMN-14 and the c734 for BSA-DTPA(In) might explain the differences in the performance of these agents. Perhaps modifying the substitution level would have improved the performance of the gal-BSA-DTPA(In) and even the gal-rWI2 conjugate. Another parameter to consider is the level of DTPA substitution and even the spacer between the DTPA and the carrier molecule. Substituting either 4 or 8 DTPA's per BSA did not appear to have any significant impact on the utility of this blocking agent. With 4−8 DTPAs per BSA or IgG, these blocking agents could have bound several bsMAb molecules, which could have facilitated their clearance from the blood. However, based on the ^{125}I-bsMAb levels in the blood, there was no evidence of its enhanced clearance by any of the blocking agents. Studies to further elaborate the reason for this were not performed, because these agents were able to sufficiently block the bsMAb to enable peptide targeting to be equal, and in the case of the percent uptake of the peptide in the BSA-(4.4)DTPA(In) group, exceed that seen with the $F(ab')_2 \times Fab'$ bsMAb. This encouraging result was tempered by the finding that the tumor uptake of the radiolabeled peptide for animals given the IgG × Fab′ bsMAb and the blocking agents dropped 3− 4-fold by 24 h after the peptide injection. In contrast, the peptide concentration in the tumor of animals given the $F(ab')_2 \times Fab'$ conjugate only dropped 1.4-fold. These findings suggest that there may be an advantage for using the IgG × Fab′ conjugate combined with a blocking agent, especially when isotopes with a short physical half-life are considered. Indeed, it should be reemphasized that an exhaustive examination of each clearing and blocking agent was not performed, and therefore the possibility exists that further examination of any one of these methods could reveal significant targeting improvements. Significant improvements in pretargeting using clearing/blocking agents have been reported (Axworthy et al., 2000), but as the results described herein illustrate, these methods are not entirely trivial. Thus, if a primary targeting agent could be constructed that had sufficient tumor loading and retention time, along with adequate natural clearance from the blood, a clearing/blocking step would not be required. With the advances in molecular engineering, this might be realized.

In conclusion, these data support the view that increasing the valency of the primary targeting agent is one way to increase the stability of the bsMAb on the tumor. However, the molecular size of the bsMAb is also an important factor to consider, as this will have an impact on whether a clearing/blocking agent will be required. The results presented herein also demonstrate that should a clearing/blocking agent be required, a blocking agent has an advantage over a clearing agent. Given some of the inherent difficulties with preparing materials by chemical conjugation methods, our group is examining constructs prepared by recombinant technologies to determine if a bsMAb with ideal targeting properties can be made.

ACKNOWLEDGMENT

We thank Ms. L. Reed, H. Richel, and Mr. T. Jackson, P. Andrews, and G. Newsome for their technical support. Supported in part by USPHS Grants CA-81760 (W.J.M.), CA-37895 (R.M.S.), and CA-84379 (R.M.S.).

Synthesis of *N*-Acetyl-D-galactosamine and Folic Acid Conjugated Ribozymes

Jasenka Matulic-Adamic,* Vladimir Serebryany, Peter Haeberli, Victor R. Mokler, and Leonid Beigelman*

Department of Chemistry & Biochemistry, Ribozyme Pharmaceuticals, Inc., 2950 Wilderness Place, Boulder, Colorado 80301. Received March 7, 2002; Revised Manuscript Received April 8, 2002

To evaluate potential improvement in tissue specific targeting and cellular uptake of therapeutic ribozymes, we have developed three new phosphoramidite reagents. These reagents can be used in automated solid-phase synthesis to produce oligonucleotide conjugates containing *N*-acetyl-D-galactosamine (targeting hepatocytes) and folic acid (targeting tumor). *N*-Acetyl-D-galactosamine was attached through a linker to both 2′-amino-2′-deoxyuridine and D-threoninol scaffolds, and these conjugates were converted to phosphoramidite building blocks. Incorporation of a D-threoninol-based monomer into ribozymes provided multiply labeled ribozyme conjugates. Attachment of the fully protected pteroic acid to the D-threoninol-6-aminocaproyl-L-glutamic acid construct afforded the folic acid conjugate, which was converted into the phosphoramidite and incorporated onto the 5′-end of the ribozyme.

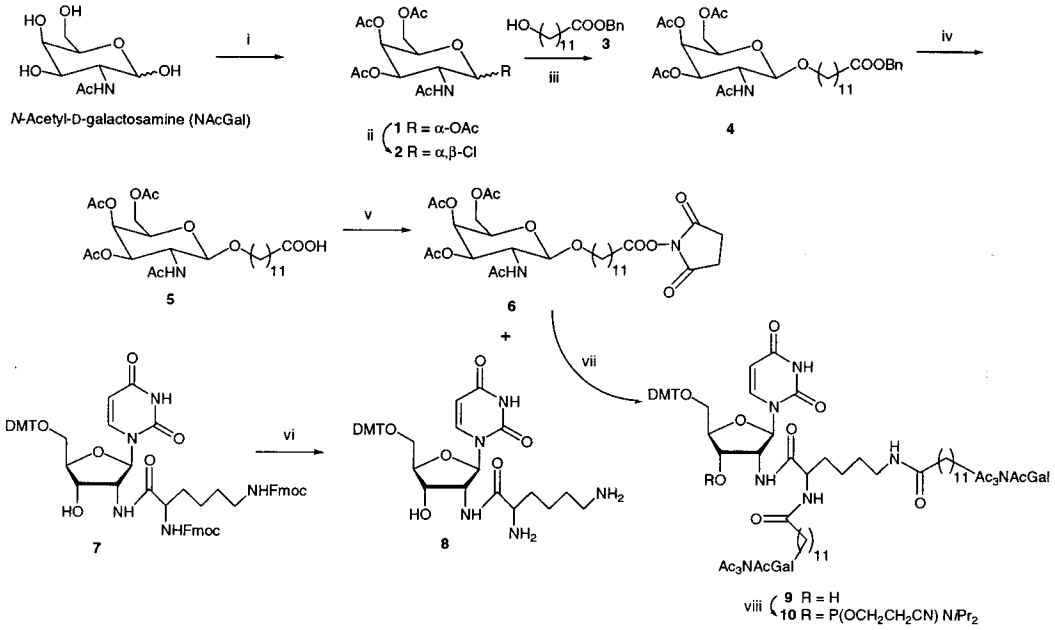
INTRODUCTION

The ability of catalytic RNA (*1*, *2*) to specifically bind and cleave other RNAs has been recognized as a method of controlling gene expression (*3*). The hammerhead ribozyme, being the smallest natural phosphodiesterase, has been chemically modified to function in a therapeutic setting (*4*, *5*). Several stabilized hammerhead ribozymes are currently being evaluated in human clinical trials.

To exert their activity, ribozymes (Rzs) must cross the cellular membrane(s), thereby gaining access to the cellular compartments containing their intended target. It is reasonable to expect that the potency of therapeutic Rzs will be directly dependent on the efficiency and specificity of cellular uptake. Therefore, improving tissue specific targeting and cellular uptake can potentially increase the efficacy and therapeutic index of intravenously or subcutaneously administered ribozymes.

A variety of methods to improve cellular uptake of oligonucleotides (ONs) have been described (*6*). Liposomes have been most extensively used to aid the cellular uptake of ONs in vivo. Most liposomes used for this purpose are cationic liposomes that can form stable complexes with the polyanionic ONs. Conjugation of ONs with lipophilic molecules such as cholesterol and phospholipids increases the cellular uptake by severalfold, and these ON conjugates are more potent antisense agents than their unmodified counterparts (*7*). Polymeric nanoparticles bind oligonucleotides and can protect them from degradation. Polylysine (PL) is another agent that has been shown to increase the uptake efficiency of ONs by nonspecific adsorptive endocytosis (*7*). Unfortunately, in the absence of targeting ligand, these approaches have limited promise for in vivo application.

Another approach explores receptor-mediated endocytosis to achieve drug targeting, as well as drug uptake enhancement.



One of the best characterized endocytic receptor systems is the asialoglycoprotein receptor (ASGPr) which is unique to hepatocytes. This receptor binds branched galactose-terminal glycoproteins, such as asialoorosomucoid (ASOR). Binding of such glycoproteins or synthetic glycoconjugates to the receptor takes place with an affinity that strongly depends on the degree of branching of the oligosaccharide chain: triatennary structures are bound with greater affinity than biatenarry or monoatennary chains (*9*, *10*). Lee and Lee (*11*) obtained this high specificity through the use of *N*-acetyl-D-galactosamine (NAcGal) as the carbohydrate moiety, which has higher affinity for the receptor, compared to galactose. The above "clustering effect" has also been described for the binding and uptake of mannose-terminated glycoproteins and other glycoconjugates (*12*, *13*).

Further practical advancements in this field resulted in development of synthetic ligand-based conjugates for targeted delivery of DNA to hepatocytes. It was shown that galactose-containing ligands smaller than proteins can achieve specific and potent ASGPr binding and internalization. In addition, association of these ligands with "cargo" in the form of condensed DNA resulted in targeted delivery of DNA to hepatocytes (*14*, *15*). In one such constructs the triatennary *N*-acetyl-D-galactosamine neoglycopeptide, YEE(ah-GalNAc)$_3$ (*11*), conjugated to human serum albumin which was in turn linked to poly-L-lysine, promoted efficient delivery of DNA into Hep G2 cells (*16*). Finally, it was demonstrated that a directly linked conjugate of the above-mentioned ligand and a model oligodeoxynucleoside methylphosphonate is efficiently taken up by mouse liver (*17*).

We decided to explore the ASGPr system to facilitate uptake of therapeutic ribozymes into hepatocytes with potential application for the treatment of hepatitis C, hepatitis B, and liver cancer. We designed both nucleoside− and nonnucleoside−*N*-acetyl-D-galactosamine conjugates **10** and **13**, respectively (Schemes 1 and 2). These monomers are suitable for incorporation at any desired position of the ribozyme using solid-phase phosphoramidite chemistry. Multiple incorporations of these monomers into the ribozyme construct (Figure 1) could result in the highly desired "glycoside cluster effect".

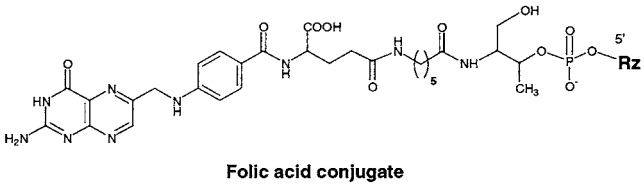

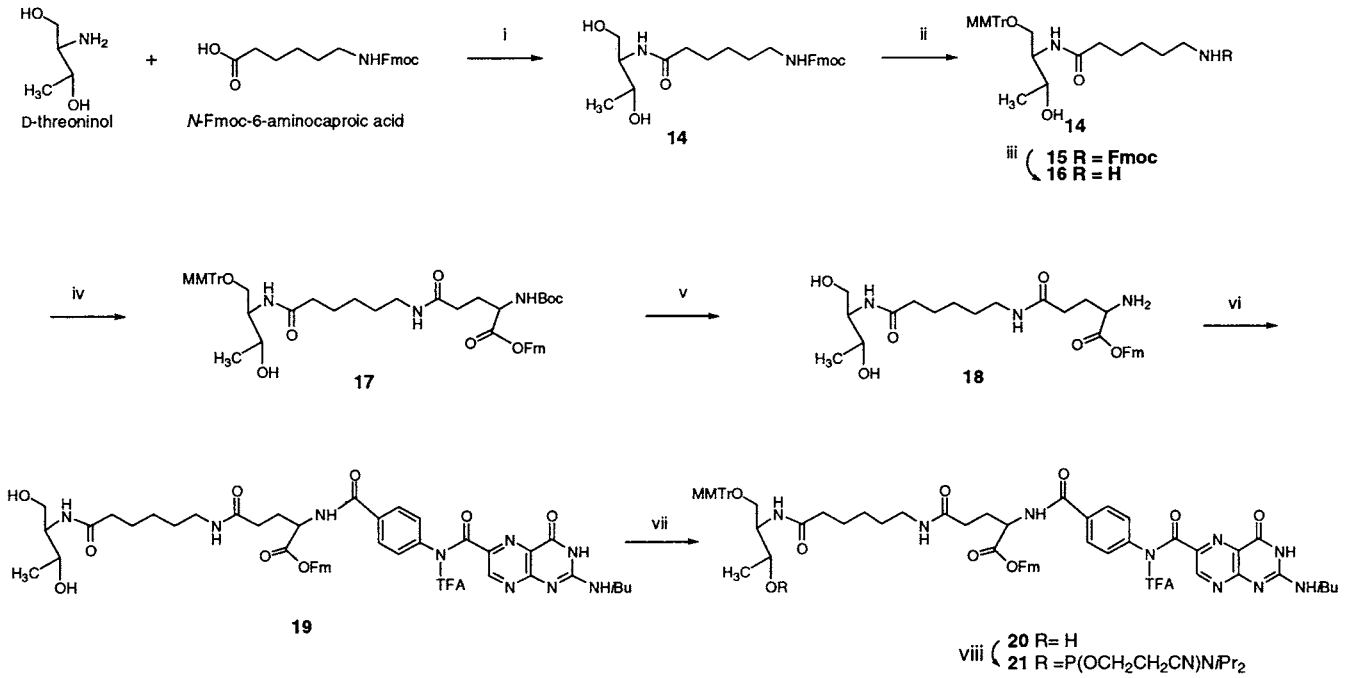

Figure 1. Conjugation of targeting ligands to the 5′-end of the ribozyme.

Among receptor-mediated endocytic systems with potential anticancer applications, the folate receptor attracted widespread attention. Indeed, several papers have described the facilitated intracellular delivery of proteins (*18*) and other macromolecules (*19*) as well as liposomes containing entrapped drugs (*20*) by folate complexation. Presumably, folic acid-receptor-mediated endocytosis is operative in these cases. Recently, a conceptually similar idea was explored in which antisense ONs were complexed with folic acid−polylysine conjugate (*21*). Importantly, it is claimed that macromolecular folate conjugates are internalized into cells by a nondestructive nonlysosomal pathway (*19*).

Several groups have recently conjugated folic acid to oligonucleotides, but most methods are difficult to scale up and lack regioselectivity. Conjugations are generally performed in a "postsynthetic" fashion. Habus et al. (*22*) coupled EDC-activated folic acid with the amino-linked antisense ON attached to the solid support, while Harrison and Balasubramanian (*23*) described a solution-phase coupling of 3′-thiol- or 3′-maleimide-derivatized oligonucleotides with cysteinyl folate to afford disulfide- and thioether-linked conjugates, respectively.

Recently, Bhat et al. (*24*) reported the synthesis of nucleoside−folic acid conjugate building blocks and their incorporation into oligonucleotides using solid-supported phosphoramidite chemistry. Their synthetic approach allowed for regioselective coupling of folic acid through the α- or γ-carboxylic group. It has been demonstrated that only those conjugates containing the adduct attached at the γ-carboxyl of folic acid retain the ability to bind to cell surface folate receptors with the same affinity as free folic acid (*25*).

Scheme 3. Synthesis of Folic Acid−D-Threoninol Conjugate[a]

[a] Reagents and conditions: (i) *N*-hydroxysuccinimide, DCC, DMF, (ii) MMTr-Cl, pyridine (iii) piperidine, DMF, (iv) *N*-Boc-α-OFm-glutamic acid, *N*-hydroxysuccinimide, DCC, DMF, (v) HCl, anisole, dioxane, (vi) N^2-*i*Bu-N^{10}-TFA-pteroic acid, 1-hydroxybenzotriazole, EDC, DMF, (vii) MMTr-Cl, pyridine, (viii) 2-cyanoethyl tetraisopropylphosphordiamidite, pyridinium trifluoroacetate, CH_2Cl_2.

In analogy with these studies, we hoped to achieve tissue-specific targeting and facilitated intracellular delivery of the ribozyme−folate conjugate (Figure 1) by a receptor-mediated endocytosis mechanism, since the receptors for certain growth factors, hormones, and vitamins (incliding folic acid) are overexpressed in rapidly dividing tumor cells (*26*−*29*).

Folic acid monomer **19** was assembled by stepwise peptide coupling of D-threoninol and 6-aminocaproic acid, followed by α-protected L-glutamic acid and N^2,N^{10}-bis-protected pteroic acid (Scheme 3). As in the case of NAcGal phosphoramidites **10** and **13**, folic acid phosphoramidite **21** can be incorporated at any desired position within the oligonucleotide.

EXPERIMENTAL PROCEDURES

All reactions were carried out under a positive pressure of argon in anhydrous solvents. Commercially available reagents and anhydrous solvents were used without further purification. ^{1}H (400.035 MHz) and ^{31}P (161.947 MHz) NMR spectra were recorded in $CDCl_3$, unless stated otherwise, and chemical shifts in ppm refer to TMS and H_3PO_4, respectively. Analytical thin-layer chromatography (TLC) was performed with Merck Art. 5554 Kieselgel 60 F_{254} plates and flash column chromatography using Merck 0.040−0.063 mm silica gel 60. The general procedures for RNA synthesis, deprotection, and purification have been described previously (*30*). MALDI-TOF mass spectra were determined on PerSeptive Biosystems Voyager spectrometer. Electrospray mass spectrometry was run on the PE/Sciex API365 instrument.

***N*-Acetyl-1,4,6-tri-*O*-acetyl-2-amino-2-deoxy-*β*-D-galactopyranose (1).** *N*-Acetyl-D-galactosamine (6.77 g, 30.60 mmol) was suspended in acetonitrile (200 mL), and triethylamine (50 mL, 359 mmol) was added. The mixture was cooled in an ice-bath, and acetic anhydride (50 mL, 530 mmol)) was added dropwise under cooling. The suspension slowly cleared and was then stirred at room temperature for 2 h. It was then cooled in an ice-bath, and methanol (60 mL) was added and the stirring continued for 15 min. The mixture was concentrated under reduced pressure and the residue partitioned between dichloromethane and 1 N HCl. Organic layer was washed twice with 5% $NaHC_3O_3$, followed by brine, dried (Na_2SO_4), and evaporated to dryness to afford 10 g (84%) of **1** as a colorless foam. ^{1}H NMR was in agreement with published data (*32*).

2-Acetamido-3,4,6-tetra-*O*-acetyl-1-chloro-D-galactopyranose (2). This compound was prepared from **1** as described by Findeis (*32*).

Benzyl 12-Hydroxydodecanoate (3). To a cooled (0 °C) and stirred solution of 12-hydroxydodecanoic acid (10.65 g, 49.2 mmol) in DMF (70 mL) was added DBU (8.2 mL, 54.1 mmol), followed by benzyl bromide (6.44 mL, 54.1 mmol). The mixture was left overnight at room temperature and then concentrated under reduced pressure and partitioned between 1 N HCl and ether. The organic phase was washed with saturated $NaHCO_3$, dried over Na_2SO_4, and evaporated. Flash chromatography using 20−30% gradient of ethyl acetate in hexanes afforded the benzyl ester as a white powder (14.1 g, 93.4%). ^{1}H NMR spectral data were in accordance with the published values (*33*).

1-(12-Benzyloxydodecanoyl)-2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-*β*-D-galactopyranose (4). 1-Chloro sugar **2** (4.26 g, 11.67 mmol) and benzyl 12-hydroxydodecanoate (**3**) (4.3 g, 13.03 mmol) were dissolved in nitromethane−toluene 1:1 (122 mL) under argon, and $Hg(CN)_2$ (3.51 g, 13.89 mmol) and powdered molecular sieves 4 Å (1.26 g) were added. The mixture was stirred at room temperature for 24 h and then filtered and the filtrate concentrated under reduced pressure. The residue was partitioned between dichloromethane and brine, and the organic layer was washed with brine, followed by 0.5 M KBr, dried (Na_2SO_4), and evaporated to a syrup. Flash silica gel column chromatography using 15−30% gradient of acetone in hexanes yielded product **4** as a colorless foam (6 g, 81%). ^{1}H NMR δ 7.43 (m, 5H, phenyl), 5.60 (d,

1H, $J_{NH,2}$ = 8.8, NH), 5.44 (d, $J_{4,3}$ = 3.2, 1H, H4), 5.40 (dd, $J_{3,4}$ = 3.2, $J_{3,2}$ = 10.8, 1H, H3), 5.19 (s, 2H, CH_2Ph), 4.80 (d, $J_{1,2}$ = 8.0, 1H, H1), 4.23 (m, 2H, CH_2), 3.99 (m, 3H, H2, H6), 3.56 (m, 1H, H5), 2.43 (t, J = 7.2, 2H,CH_2), 2.22 (s, 3H, Ac), 2.12 (s, 3H, Ac), 2.08 (s, 3H, Ac), 2.03 (s, 3H, Ac), 1.64 (m, 4H, 2 × CH_2), 1.33 (br m, 14H, 7 × CH_2). MS/ESI$^-$ m/z 634.5 $(M - H)^-$.

1-(12-Hydroxydodecanoyl)-2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-*β*-D-galactopyranose (5). Conjugate **4** (2 g, 3.14 mmol)) was dissolved in ethanol (50 mL), and 5% Pd−C (0.3 g) was added. The reaction mixture was hydrogenated overnight at 45 psi H_2, the catalyst was filtered off, and the filtrate was evaporated to dryness to afford pure **5** (1.7 g, quantitative) as a white foam. ^{1}H NMR δ 5.73 (d, 1H, $J_{NH,2}$ = 8.4, NH), 5.44 (d, $J_{4,3}$ = 3.0, 1H, H4), 5.40 (dd, $J_{3,4}$ = 3.0, $J_{3,2}$ = 11.2,1H, H3), 4.78 (d, $J_{1,2}$ = 8.8, 1H, H1), 4.21(m, 2H, CH_2), 4.02 (m, 3H, H2, H6), 3.55 (m, 1H, H5), 2.42 (m, 2H, CH_2), 2.23(s, 3H, Ac), 2.13 (s, 3H, Ac), 2.09 (s, 3H, Ac), 2.04 (s, 3H, Ac), 1.69 (m, 4H, 2 × CH_2), 1.36 (br m, 14H, 7 × CH_2). MS/ESI$^-$ m/z 544.0 $(M - H)^-$.

2′-(*N*-L-Lysylamino)-5′-*O*-4,4′-dimethoxytrityl-2′-deoxyuridine (8). 2′-(*N*-α,ϵ-bis-Fmoc-L-lysyl)amino-5′-*O*-4,4′-dimethoxytrityl-2′-deoxyuridine (**7**) (*31*) (4 g, 3.58 mmol) was dissolved in anhydrous DMF (30 mL), and diethylamine (4 mL) was added. The reaction mixture was stirred at room temperature for 5 h and then concentrated (oil pump) to a syrup. The residue was dissolved in ethanol, and ether was added to precipitate the product (1.8 g, 75%). ^{1}H NMR (DMSO-d_6-D_2O) δ 7.70 (d, $J_{6,5}$ = 8.4, 1H, H6), 7.48−6.95 (m, 13H, aromatic), 5.93 (d, $J_{1',2'}$ = 8.4, 1H, H1′), 5.41 (d, $J_{5,6}$ = 8.4, 1H, H5), 4,62 (m, 1H, H2′), 4.19 (d, 1H, $J_{3',2'}$ = 6.0, H3′), 3.81 (s, 6H, 2 × OMe), 3.30 (m, 4H, 2H5′, CH_2), 1.60−1.20 (m, 6H, 3 × CH_2). MS/ESI$^+$ m/z 674.0 $(M + H)^+$.

2′-(*N*-α,ϵ-Bis(12′-hydroxydodecanoyl-2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-*β*-D-galac-topyranose)-L-lysyl)amino-2′-deoxy-5′-*O*-4,4′-dimethoxytrityl uridine (9). 5 (1.05 g, 1.92 mmol) was dissolved in anhydrous THF and *N*-hydroxysuccinimide (0.27 g, 2.35 mmol), and 1,3-dicyclohexylcarbodiimide (0.55 g, 2.67 mmol) were added. The reaction mixture was stirred at room temperature overnight and then filtered through Celite pad and the filtrate concentrated under reduced pressure. The crude NHSu ester **6** was dissolved in dry DMF (13 mL) containing diisopropylethylamine (0.67 mL, 3.85 mmol) and to this solution was added nucleoside **2** (0.64 g, 0.95 mmol). The reaction mixture was stirred at room temperature overnight and then concentrated under reduced pressure. The residue was partitioned between water and dichloromethane, the aqueous layer was extracted with dichloromethane, and the organic layers were combined, dried (Na_2SO_4), and evaporated to a syrup. Flash silica gel column chromatography using 2−3% gradient of methanol in ethyl acetate yielded **9** as a colorless foam (1.04 g, 63%). ^{1}H NMR δ 7.42 (d, $J_{6,5}$ = 8.4, 1H, H6 Urd), 7.53−6.97 (m, 13H, aromatic), 6.12 (d, $J_{1',2'}$ = 8.0, 1H, H-1′), 5.41 (m, 3H, H5 Urd, H4 NAcGal), 5.15 (dd, $J_{3,4}$ = 3.6, $J_{3,2}$ = 11.2, 2H, H3 NAcGal), 4.87 (dd, $J_{2',3'}$ = 5.6, $J_{2',1'}$ = 8.0, 1H, H2′), 4.63 (d, $J_{1,2}$ = 8.0, 2H, H1 NAcGal), 4.42 (d, $J_{3',2'}$ = 5.6, 1H, H3′), 4.29−4.04 (m, 9H, H4′, H2 NAcGal, H5 NacGal, CH_2), 3.95−3.82 (m, 8H, H6 NAcGal, 2 × OMe), 3.62−3.42 (m, 4H, H5′, H6 NAcGal), 3.26 (m, 2H, CH_2), 2.40−1.97 (m, 28H, CH_2, Ac), 1.95−1.30 (m, 50H, CH_2). MS/ESI$^-$ m/z 1727.0 $(M - H)^-$.

2′-(*N*-α,ϵ-Bis(12′-hydroxydodecanoyl-2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-*β*-D-galactopyranose)-L-lysyl)amino-2′-deoxy-5′-*O*-4,4′-dimethoxytrityl uridine 3′-*O*-(2-Cyanoethyl *N,N*-Diisopropylphosphoramidite) (10). Conjugate **9** (0.87 g, 0.50 mmol) was dissolved in dry dichloromethane (10 mL) under argon, and diisopropylethylamine (0.36 mL, 2.07 mmol) and 1-methylimidazole (21 μL, 0.26 mmol) were added. The solution was cooled to 0 °C, and 2-cyanoethyl diisopropylchlorophosphoramidite (0.19 mL, 0.85 mmol) was added. The reaction mixture was stirred at room temperature for 1 h and then cooled to 0 °C and quenched with anhydrous ethanol (0.5 mL). After stirring for 10 min, the solution was concentrated under reduced pressure (40 °C) and the residue dissolved in dichloromethane and chromatographed on the column of silica gel using hexanes−ethyl acetate 1:1, followed by ethyl acetate and finally ethyl acetate−acetone 1:1 (1% triethylamine was added to solvents) to afford the phosphoramidite **10** (680 mg, 69%). ^{31}P NMR δ 152.0 (s), 149.3 (s). MS/ESI$^-$ m/z 1928.0 $(M - H)^-$.

***N*-(12′-Hydroxydodecanoyl-2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-*β*-D-galactopyranose)-D-threoninol (11).** 12′-Hydroxydodecanoyl-2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-*β*-D-galactopyranose **5** (850 mg, 1.56 mmol) was dissolved in DMF (5 mL), and to the solution were added *N*-hydroxysuccinimide (215 mg, 1.87 mmol) and 1,3-dicyclohexylcarbodimide (386 mg, 1.87 mmol). The reaction mixture was stirred at room temperature overnight, the precipitate was filtered off, and to the filtrate was added D-threoninol (197 mg, 1.87 mmol). The mixture was stirred at room temperature overnight and concentrated in vacuo. The residue was partitioned between dichloromethane and 5% $NaHCO_3$, and the organic layer was washed with brine, dried (Na_2SO_4), and evaporated to a syrup. Silica gel column chromatography using 1−10% gradient of methanol in dichloromethane afforded **11** as a colorless oil (0.7 g, 71%). ^{1}H NMR δ 6.35 (d, J = 7.6, 1H, NH), 5.77 (d, J = 8.0, 1H, NH), 5.44 (d, $J_{4,3}$ = 3.6, 1H, H4), 5.37 (dd, $J_{3,4}$ = 3.6, $J_{3,2}$ = 11.2, 1H, H3), 4.77 (d, $J_{1,2}$ = 8.0, 1H, H1), 4.28−4.18 (m, 3H, CH_2, CH), 4.07−3.87 (m, 6H), 3.55 (m, 1H, H5), 3.09 (d, J = 3.2, 1H, OH), 3.02 (t, J = 4.6, 1H, OH), 2.34 (t, J = 7.4, 2H, CH_2), 2.23 (s, 3H, Ac), 2.10 (s, 3H, Ac), 2.04 (s, 3H, Ac), 1.76−1.61 (m, 2 × CH_2), 1.35 (m, 14H, 7 × CH_2), 1.29 (d, J = 6.4, 3H, CH_3). MS/ESI$^-$ m/z 631.5 $(M - H)^-$.

1-*O*-(4-Monomethoxytrityl)-*N*-(12′-hydroxydodecanoyl-2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-*β*-D-galactopyranose)-D-threoninol (12). To the solution of **11** (680 mg, 1.1 mmol) in dry pyridine (10 mL) was added *p*-anisylchlorodiphenylmethane (430 mg, 1.39 mmol), and the rection mixture was stirred and protected from moisture overnight. Methanol (3 mL) was added and the solution stirred for 15 min and evaporated in vacuo. The residue was partitioned between dichloromethane and 5% $NaHCO_3$, and the organic layer was washed with brine, dried (Na_2SO_4), and evaporated to a syrup. Silica gel column chromatography using 1−3% gradient of methanol in dichloromethane afforded **12** as a white foam (0.75 g, 77%). ^{1}H NMR δ 7.48−6.92 (m, 14 H, aromatic), 6.15 (d, J = 8.8, 1H, NH), 5.56 (d, J = 8.0, 1H, NH), 5.45 (d, $J_{4,3}$ = 3.2, 1H, H4), 5.40 (dd, $J_{3,4}$ = 3.2, $J_{3,2}$ = 11.2, 1H, H3), 4.80 (d, $J_{1,2}$ = 8.0, 1H, H1), 4.3−4.13 (m, 3H, CH_2, CH), 4.25−3.92 (m, 4H, H6, H2, CH), 3.89 (s, 3H, OMe), 3.54 (m, 2H, H5, CH), 3.36 (dd, J = 3.4, J = 9.8, 1H, CH), 3.12 (d, J = 2.8, 1H, OH), 2.31 (t, J = 7.6, 2H, CH_2), 2.22 (s, 3H, Ac), 2.13 (s, 3H, Ac), 2.03 (s, 3H, Ac), 1.80−1.55 (m, 2 × CH_2), 1.37 (m, 14H, 7 × CH_2), 1.21 (d, J = 6.4, 3H, CH_3). ***N*-(6-(*N*-α-OFm-L-Glutamyl)aminocaproyl))-D-threoninol-N^2-*i*Bu-N^{10}-TFA-pteroic Acid Conjugate (19).** To the solution of N^2-*i*Bu-N^{10}-TFA-pteroic acid (*34*) (480 mg, 1 mmol) in DMF (5 mL) were added 1-hydroxybenzotriazole (203 mg, 1.50 mmol), EDC (288 mg, 1.50 mmol) and **18** (free base, 631 mg, 1.2 mmol, obtained by stirring methanolic solution of **18** with silver carbonate for 5 min). The reaction mixture was stirred at room temperature for 2 h and then concentrated to ca. 3 mL and loaded on the column of silica gel. Elution with dichloromethane, followed by 1−20% gradient of methanol in dichloromethane, afforded **19** (0.5 g, 51%). ^{1}H NMR (DMSO-d_6−D_2O) δ 9.09 (d, J = 6.8, 1H, NH) 8.96 (s, 1H, H7 pteroic acid), 8.02−7.19 (m, 13H, aromatic, NH), 5.30 (s, 2H, pteroic acid), 4.50 (m, 1H, Glu), 4.41 (d, J = 6.8, 2H, Fm), 4.29 (t, J = 6.8, 1H, Fm), 3.89 (dd, J = 6.2, J = 2.8, 1H, H3 Thr), 3.68 (m, 1H, H2 Thr), 3.48 (dd, J = 10.4, J = 7.0, 1H, H1 Thr), 3.36 (dd, J = 10.4, J = 6.2, 1H, H1′ Thr), 3.06 (m, 2H, CH_2CO Acp), 2.84 (m, 1H, *i*Bu), 2.25 (m, 2H, CH_2NH Acp), 2.16 (m, 3H, Glu), 1.99 (m, 1H,

Glu), 1.52 (m, 2H, Acp), 1.42 (m, 2H, Acp), 1.27 (m, 2H, Acp), 1.20 (s, 3H, *i*Bu), 1.19 (s, 3H, *i*Bu), 1.03 (d, $J = 6.2$, 3H, CH_3). MS/ESI$^-$ *m*/*z* 984.5 $(M - H)^-$.

1-*O*-(4-Monomethoxytrityl)-*N*-(6-(*N*-(α-OFm-L-glutamyl)aminocaproyl))-D-threoninol-N^2-*i*Bu-N^{10}-TFA-pteroic Acid Conjugate (20). To the solution of conjugate **19** (1 g, 1.01 mmol) in dry pyridine (15 mL) was added *p*-anisylchlorodiphenylmethane (405 mg, 1.31 mmol), and the reaction mixture was stirred and protected from moisture at room temperature overnight. Methanol (3 mL) was added and the reaction mixture concentrated to a syrup in vacuo. The residue was partitioned between dichloromethane and 5% $NaHCO_3$, and the organic layer washed with brine, dried (Na_2SO_4), and evaporated to dryness. Column chromatography using 0.5−10% gradient of methanol in dichloromethane afforded **20** as a colorless foam (0.5 g, 39%). ^{1}H NMR (DMSO-d_6−D_2O) δ 9.09 (d, $J = 6.8$, 1H, NH) 8.94 (s, 1H, H7 pteroic acid), 8.00−6.93 (m, 27H, aromatic, NH), 5.30 (s, 2H, pteroic acid), 4.50 (m, 1H, Glu), 4.40 (d, $J = 6.8$, 2H, Fm), 4.29 (t, $J = 6.8$, 1H, Fm), 3.94 (m, 2H, H3,H2 Thr), 3.79 (s, 3H, OCH_3) 3.11 (dd, $J = 8.6$, $J = 5.8$, 1H, H1 Thr), 3.04 (m, 2H, CH_2CO Acp), 2.91 (dd, $J = 8.6$, $J = 6.4$, 1H, H1′ Thr), 2.85 (m, 1H, *i*Bu), 2.25 (m, 2H, CH_2-NH Acp), 2.19 (m, 2H, Glu), 2.13 (m, 1H, Glu), 1.98 (m, 1H, Glu), 1.55 (m, 2H, Acp), 1.42 (m, 2H, Acp), 1.29(m, 2H, Acp), 1.20 (s, 3H, *i*Bu), 1.18 (s, 3H, *i*Bu), 1.00 (d, $J = 6.4$, 3H, CH_3). MS/ESI$^-$ *m*/*z* 1257.0 $(M - H)^-$.

1-*O*-(4-Monomethoxytrityl)-*N*-(6-(*N*-(α-OFm-L-glutamyl)aminocaproyl))-D-threoninol-N^2-*i*Bu-N^{10}-TFA-pteroic Acid Conjugate 3′-*O*-(2-Cyanoethyl *N*,*N*-Diisopropylphosphoramidite) (21). To a solution of **20** (500 mg, 0.40 mmol) in dichloromethane (2 mL) was added 2-cyanoethyl tetraisopropylphosphordiamidite (152 μL, 0.48 mmol), followed by pyridinium trifluoroacetate (93 mg, 0.48 mmol). The reaction mixture was stirred at room temperature for 1 h and then loaded on the column of silica gel in hexanes. Elution using ethyl acetate−hexanes 1:1, followed by ethyl acetate and ethyl acetate−acetone 1:1 in the presence of 1% pyridine, afforded **21** as a colorless foam (480 mg, 83%). ^{31}P NMR δ 149.4 (s), 149.0 (s).

Oligonucleotide Synthesis. Phosphoramidites **10**, **13**, and **21** were used along with standard 2′-*O*-TBDMS and 2′-*O*-methyl nucleoside phosphoramidites as previously described (*30*). Synthesis was conducted on a 394 (ABI) synthesizer using modified 2.5 μmol scale protocol with 2.5 min coupling step for monomers **13**, **21**, and 2′-*O*-methyl nucleotides. The coupling time was extended to 5 min for 2′-*O*-TBDMS protected nucleotides. Coupling efficiency for the phosphoramidite **10** (coupling time 15 min) was lower than 50%, while coupling efficiencies for phosphoramidites **13** and **21** were typically greater than 95% based on the measurement of released trityl cations. Removal of monomethoxytrityl groups was conducted using 3% trichloroacetic acid in four 30 s intervals. Once the synthesis was completed, the conjugated oligonucleotides in Tr-on form were deprotected as previously described (*30*) with the exception of using 20% piperidine in DMF for 15 min for the removal of Fm protection from the folic acid conjugated ribozyme, prior methylamine treatment. The 5′-tritylated oligomers were separated from shorter (trityl-off) failure sequences using a short column of SEP−PAK C-18 adsorbent. The bound, tritylated oligomers were detritylated on the column by treatment with 1% trifluoroacetic acid, neutralized with triethylammonium acetate buffer, and then eluted using 30% acetonitrile in water. Further purification was achieved by reverse-phase HPLC (column − C18 Trans-genomic, temp. 80 °C, buffer A: 100 mM TEAA, buffer B: 100 mM TEAA/50% ACN, gradient: 22% B to 40% B in 35 min).

Structures of the ribozyme conjugates were confirmed by MALDI-TOF MS. Conjugate A: calcd 13823.19, found 13822.05; conjugate B: calcd 12078.56, found 12077.56.

RESULTS AND DISCUSSION

***N*-Acetyl-D-galactosamine Conjugates.** We have designed, synthesized, and characterized a low molecular weight conjugates useful for targeting ribozymes to galactose receptor (Figure 1). The design of these conjugates was motivated by recent reports demonstrating viability of using synthetic galactose containing ligands smaller than proteins to achieve receptor binding and internalization of the ligand bound DNA (*14*−*17*). The triattenary cluster glycoside YEE(ah-GalNAc)$_3$ is the highest affinity synthetic ligand of the ASGPr reported to date. In binding assays using rat hepatocytes, this compound was reported to affect a 50% inhibition at a concentration of 0.2 nM of ASOR binding (*11*).

We reasoned that the attachment of two *N*-acetylgalactosamine residues through a linker to 2′-(*N*-lysylamino)-2′-deoxyuridine **8** (Scheme 1) will yield the monomer which can generate high density of carbohydrate ligands upon multiple incorporations into ribozyme. On the basis of the extensive ribozyme structure−activity studies (*4*, *35*), one can expect that incorporation of this conjugate into U4 and /or U7 positions of the catalytic core, as well as into the stem II loop, will not impair ribozyme catalytic activity.

Synthesis of desired amidite **10** consisted of the preparation of two key intermediates: *N*-Ac-galactosamine synthon **6** and 2′(*N*-lysylamino)-2′-deoxyuridine **8** to produce, following condensation, conjugate **9**. Synthesis of 2-acetamido-3,4,6-tetra-*O*-acetyl-1-chloro-D-galactopyranose **2** was accomplished according to the reported procedure (*31*) with minor modifications. Mercury salt-catalyzed glycosylation of 1-chloro sugar **2** with the benzyl ester of 12-hydroxydodecanoic acid **3** afforded β-glycoside **4** in 81% yield. An attempt to glycosylate **2** using the unprotected 12-hydroxydodecanoic acid resulted in a complex mixture, and no attempt was made to isolate the desired product. Hydrogenolysis of benzyl protecting group of **4** yielded carboxylate **5** which was activated as NHSu ester **6**.

On the other side, the bis-Fmoc protected lysine linker was attached to the 2′-amino group of 2′-amino-2′-deoxyuridine using the EEDQ-catalyzed peptide coupling as described by us earlier (*32*). The 5′-OH was protected with 4,4′-dimethoxytrityl group to give **7**, followed by the cleavage of *N*-Fmoc groups with diethylamine, to afford synthon **8** in the high overall yield.

Coupling of the sugar derivative **6** with the nucleoside synthon **8** yielded the final conjugate **9** which was phosphitylated under standard conditions to afford phosphoramidite **10** in 69% yield.

Unfortunately, phosphoramidite **10** coupled to the growing oligonucleotide chain with low efficiency and incorporation of only one monomer was possible. Utilization of "double coupling" technique, increasing coupling time, or extensive drying of the acetonitrile solution of amidite **10** over molecular sieves did not improve the coupling of **10**. The low efficiency of incorporation of **10** into the stem loop region or at the 5′-end of the stabilized ribozyme can be explained by steric crowding due to the bulky 2′-aminoacyl substituent.

To solve this problem, we redesigned the monomer by attaching *N*-acetyl-D-galactose to nonnucleosidic thre-

oninol moiety through the same $(CH_2)_{11}$ spacer as used for the nucleoside-based conjugate (Scheme 2). The three-carbon threoninol molecule, once incorporated into oligomer, closely mimics the spacing of a traditional ribose moiety. Using similar strategy as described for nucleoside-based conjugate, D-threoninol was coupled to NHSu ester **6** to afford conjugate **11** in a good yield. Monomethoxytritylation, followed by phosphitylation, yielded the desired phosphoramidite **13**.

Phosphoramidite **13** was incorporated into ribozymes with the efficiency comparable to unmodified phosphoramidites. Five consecutive couplings at the 5′-end of an anti-HCV ribozyme produced the desired conjugate in a good yield.

Folate Conjugate. We also designed, synthesized, and characterized phosphoramidite monomer **21** to target folate receptor. By incorporating this monomer into synthetic ribozymes, we hope to achieve tumor specific targeting and facilitated intracellular delivery of ribozyme−folate conjugates (Figure 1) by receptor-mediated endocytosis mechanism.

It is desirable to attach the targeting ligands to drug molecules through spacers in order to facilitate receptor−ligand recognition. Capitalizing on our experience in incorporation of *N*-Ac-galactosamine monomers **10** and **13** into oligonucleotides, we decided to pursue the synthesis of a nonnucleosidic folic acid monomer **21** (Scheme 3). 6-Aminocaproic acid was chosen as a spacer between folate and threoninol linker.

The choice of the protecting group for glutamic acid α-carboxylate is crucial for the successful phosphoramidite-based synthesis of the folate−ribozyme conjugate: it has to be stable to reagents used to assemble the oligonucleotide chain on the solid support and also has to generate carboxylic functionality under mild deprotection conditions. The fluorenylmethyl ester, which is cleaved by β-elimination with amine bases, fulfills these requirements.

D-Threoninol was condensed with NHSu ester of *N*-Fmoc-6-aminocaproic acid to yield conjugate **14** in 80% yield. Selective monomethoxytritylation, followed by Fmoc cleavage resulted in formation of 1-*O*-(4-monomethoxytrityl)-*N*-(6-aminocaproyl)-D-threoninol **16**. Coupling of **16** with *N*-Boc-α-OFm-L-glutamic acid NHSu ester afforded conjugate **17** in a high yield. Cleavage of both the monomethoxytrityl and *N*-Boc protecting groups with HCl in dioxane yielded the Fm-protected conjugate **18**. After conversion to the free base, this compound was conjugated to N^2-*i*Bu-N^{10}-TFA protected pteroic acid (*34*) in the presence of EDC and 1-hydroxybenzotriazole to afford conjugate **19** in a moderate yield. Primary hydroxyl of **19** was selectively protected with monomethoxytrityl group, and the resulting **20** was phosphitylated using 2-cyanoethyl tetraisopropylphosphordiamidite and pyridinium trifluoroacetate as a catalyst (*36*). It is worth noting that pyridine was successfully used during the chromatographic purification of the phosphoramidite **21**, instead of the commonly used triethylamine which is not compatible with the base-sensitive Fm protection.

The fully protected phosphoramidite **21** was attached to the 5′-end of the ribozyme using standard oligonucleotide synthesis protocol. The glutamic α-carboxylic acid function is unmasked using piperidine-catalyzed cleavage of the Fm-ester prior to methylamine removal of base protecting groups and cleavage from the solid support.

In conclusion, the new *N*-acetyl-D-galactosamine and folate monomers are synthesized and successfully incorporated into ribozymes using solid-phase phosphoramidite chemistry. Tissue localization studies using these ribozyme conjugates are under way and will be reported in due course.

ACKNOWLEDGMENT

We thank Kevin Johnson and Mark Sanseverino for recording mass spectra and David Eidenmueller for the oligonucleotide synthesis.

Trifunctional Conjugation Reagents. Reagents That Contain a Biotin and a Radiometal Chelation Moiety for Application to Extracorporeal Affinity Adsorption of Radiolabeled Antibodies

D. Scott Wilbur,*,† Ming-Kuan Chyan,† Donald K. Hamlin,† Brian B. Kegley,† Rune Nilsson,‡ Bengt E. B. Sandberg,‡ and Martin Brechbiel§

Department of Radiation Oncology, University of Washington, Seattle, Washington 98195, Mitra Medical Technology, Lund, Sweden, and National Cancer Institute, Bethesda, Maryland. Received April 1, 2002; Revised Manuscript Received May 21, 2002

A method of removing radiolabeled monoclonal antibodies (mAbs) from blood using a device external to the body, termed extracorporeal affinity-adsorption (EAA), is being evaluated as a means of decreasing irradiation of noncancerous tissues in therapy protocols. The EAA device uses an avidin column to capture biotinylated-radiolabeled mAbs from circulated blood. In this investigation, three trifunctional reagents have been developed to minimize the potential deleterious effect on antigen binding brought about by the combination of radiolabeling and biotinylation of mAbs required in the EAA approach. The studies focused on radiolabeling with ^{111}In and ^{90}Y, so the chelates CHX-A″-DTPA and DOTA, which form stable attachments to these radionuclides, were incorporated in the trifunctional reagents. The first trifunctional reagent prepared did not incorporate a group to block the biotin cleaving enzyme biotinidase, but the two subsequent reagents coupled aspartic acid to the biotin carboxylate for that purpose. All three reagents used 4,7,10-trioxa-1,13-tridecanediamine as water-soluble spacers between an aminoisophthalate core and the biotin or chelation group. The mAb conjugates were radioiodinated to evaluate cell binding as a function of substitution. Radioiodination was used so that a direct comparison with unmodified mAb could be made. Evaluation of the number of conjugates per antibody versus cell binding immunoreactivities indicated that minimizing the number of conjugates was best. Interestingly, a decrease of radioiodination yield as a function of the number of isothiocyanate containing conjugates per mAb was noted. The decreased yields were presumably due to the presence of thiourea functionality formed in the conjugation reaction. Radiolabeling with ^{111}In and ^{90}Y was facile at room temperature for conjugates containing the CHX-A″, but elevated temperature (e.g., 45 °C) was required to obtain good yields with the DOTA chelate. Stability of ^{90}Y labeled mAb in serum, and when challenged with 10 mM EDTA, was high. However, challenging the ^{90}Y labeled mAb with 10 mM DTPA demonstrated high stability for the DOTA containing conjugate, but low stability for the CHX-A″ containing conjugate. Thus, the choice between these two chelating moieties might be made on requirements for facile and gentle labeling versus very high in vivo stability. Application of the trifunctional biotinylation reagents to the blood clearance of labeled antibodies in EAA is under investigation. The new reagents may also be useful for other applications.

INTRODUCTION

The high-affinity binding pairs biotin/avidin (Av[1]) and biotin/streptavidin (SAv) have become important chemical tools in capture processes for a large number of diverse applications, both in vitro and in vivo. The most widely used in vitro detection systems employ biotinylated receptor binding biomolecules, particularly monoclonal antibodies (mAbs), in capture processes with avidin or streptavidin (*2*−*5*). An in vivo application of this capture process uses the biotin/streptavidin binding pair as conjugates of mAbs in an approach, termed "pretargeting", to selectively localize radionuclides on cancer cells for therapy (*6*−*8*). The pretargeting approach to "endoradiotherapy"[2] is being investigated due to the inherent problems associated with using directly radio-

[1] Abbreviations: Av, avidin; FAB$^+$, fast atom bombardment; BCA, bicinchoninic acid; BSA, bovine serum albumin; DOTA, 1,4,7,10-tetraazacyclododecane-N,N′,N″,N‴-tetraacetic acid; DTPA, diethylenetriaminepentaacetic acid; EAA, extracorporeal affinity adsorption; EDC, 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide; ES$^+$, electrospray; HABA, 4′-hydroxyazobenene-2-carboxylic acid; HRMS, high-resolution mass spectrometry; LRMS, low-resolution mass spectrometry; mAb, monoclonal antibody; IEF, isoelectric focusing electrophoresis; NHS-LC-biotin, N-hydroxysuccinimidyl biotinyl-6-aminocaproic acid; rt, room temperature; SAv, streptavidin; (strept)avidin, signifies either avidin or streptavidin; t-Boc, *tert*-butoxycarbonyl; TCDI, thiocarbonyldiimidazole; TFA, trifluoroacetic acid; TFP, tetrafluorophenyl; TFP−OH, tetrafluorophenol; TFP−OTFA, tetrafluorophenyl trifluoroacetate.

[2] "Endoradiotherapy" is a term used to describe an approach to radiotherapy in which a radiopharmaceutical, composed of a radionuclide coupled with a cancer cell targeting carrier molecule, is injected into a patient for cancer therapy. This approach is also termed "targeted radiotherapy".

labeled mAbs in this application (*9*). Those problems include long blood residence times, low concentrations of radioactivity in the tumor, and heterogeneous deposition of radioactivity in tumors. While encouraging results have been obtained using pretargeting protocols (*10*, *11*), that approach has problems as well, including complexity of protocols, immunogenicity of SAv, and interference by endogenous biotin (*12*, *13*). The difficulty of circumventing the problems associated with pretargeting protocols has led investigators to consider other approaches to improve the in vivo characteristics of directly radiolabeled mAbs. One approach being investigated, termed "extracorporeal affinity-adsorption" (EAA[3]), uses a device external to the body to remove radiolabeled mAbs from the patient's blood (*14*). If efficient removal of radiolabeled mAbs from blood is obtained, use of such a device may permit administration of higher doses of radiolabeled mAbs. This is important, as higher doses could increase the total amount of radioactivity in the tumor and decrease the heterogeneity of radiolabeled mAb deposition in the tumor.

The biotin/avidin capture system can be used in the EAA approach to remove directly labeled mAbs from blood (*15*−*17*). To achieve its removal in the EAA approach, the radiolabeled mAb must be biotinylated. Thus, the procedure involves administration of a biotinylated and radiolabeled mAb, which after sufficient time for tumor localization is removed from a patient's blood by passing it through a device that contains a high flow rate, high capacity avidin column. Using the EAA approach, complete removal of the radiolabeled antibodies will not be obtained unless every antibody has at least one biotin moiety conjugated. Unfortunately, biotinylation in combination with radiolabeling of mAbs can result in a heterogeneous mixture of products. This is particularly true when radionuclides other than radioiodine are used because radionuclide chelation moieties must also be conjugated to the mAb. While multiple conjugates of radiometal chelates and biotin can improve radiolabeling efficiency and capture by avidin columns, they can also result in a dramatic decrease in mAb binding to the target antigen. As a means of circumventing this problem and the issue of high conjugation heterogeneity, we have investigated the design and synthesis of trifunctional reagents that contain a biotin moiety, a radiometal chelation moiety, and a functional group for protein conjugation. By combining the biotin moiety and the radiolabeling moiety into a single molecule, every mAb that is radiolabeled will also have a biotin on it. Further, heterogeneity of radiolabeled mAb is diminished, as the same number of biotin molecules as chelates is always present, and a minimum number of conjugation reagents or moieties can be used. In the studies, three trifunctional reagents were synthesized, conjugated with mAbs, tested for radiolabeling with ^{111}In and ^{90}Y, and evaluated for efficiency for capture by an avidin column. The results of the investigation are described herein.

EXPERIMENTAL PROCEDURES

General. Solvents and chemicals obtained from commercial sources were analytical grade or better and were used without further purification. Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μm) prior to use. *d*-Biotin, 4,7,10-trioxa-1,13-tridecanediamine, 2,3,5,6-tetrafluorophenol, aminoisophthalate, di-*tert*-butyl dicarbonate, thiophosgene, 1,1′-thiocarbonyl-diimidazole, and most other chemicals were purchased from Aldrich Chemical Co. (Milwaukee, WI). L-Aspartic acid α-*tert*-butyl ester was obtained from Calbiochem-Novabiochem Corp. (San Diego, CA) or BACHEM California, Inc. (Torrance, CA). *p*-Isothiocyanatobenzyl-DOTA, **18**, was purchased from Macrocyclics (www.macrocyclics.com, Dallas, TX). N-Hydroxysuccinimidyl biotinyl-6-aminocaproic acid (NHS-LC-biotin) and immobilized Avidin were purchased from Pierce (Rockford, IL). 2,3,5,6-Tetrafluorophenyl trifluoroacetate was prepared as previously described (*18*). High-purity, low-metal HCl (Ultrex II) was obtained from J.T. Baker (Phillipsburg, NJ). High-purity NaOAc was obtained from Alfa Aesar (Ward Hill, MA). High-purity water was obtained from a Barnstead Easypure-Ultrapure water system. Microcon centrifugal filter devices, Microcon YM-30, were obtained from Amicon/Millipore Corporation (Bedford, MA). Size exclusion columns, PD-10, were obtained from Amersham Pharmacia Biotech AB (Lund, Sweden). Silica gel chromatography was conducted with 70−230 mesh 60 Å silica gel (Aldrich Chemical Co.). Melting points were obtained in open capillary tubes on a Mel-Temp II apparatus with a Fluke 51 K/J electronic thermometer and are uncorrected. ^{1}H NMR data, MS data, and HPLC chromatography were used to assess compound identity and purity (Data provided in the Supporting Information).

Radioactive Materials. All reactions involving radioactive materials were conducted in a charcoal filtered-Plexiglas enclosure within a fume hood. All radioactive materials were opened, handled, and stored in the Plexiglas enclosure until used in studies or removed as radiation waste. Standard radiation safety procedures were used. Radiation monitoring followed approved procedures.

^{111}In and ^{90}Y were obtained in 0.05 M HCl from NEN/Dupont (now-Perkin-Elmer Life Sciences, Inc, Billerica, MA) in high specific activity. Na[^{125}I]I was purchased from NEN/Dupont (Billerica, MA) as high-concentration/high-specific-activity radioiodide in 0.1 N NaOH. Measurement of radioactivity was accomplished in a Capintec CRC-15R or a Logic Model 111B gamma counter (Abbott Labs, Chicago, IL).

Spectral Analyses. All ^{1}H NMR were obtained on either a Bruker AC-200 (200 MHz) or Bruker AF-301 (300 MHz) instrument. Proton chemical shifts are expressed as ppm using tetramethylsilane or 3-(trimethylsilyl)propionic-2,2,3,3-d_4 acid, sodium salt as an internal standard (δ = 0.0 ppm). Mass spectral data were obtained on either (1) a VG Analytical (Manchester, England) VG-70SEQ mass spectrometer with associated 11250J Data System using fast atom bombardment (FAB$^+$) at 8 keV in a matrix of MeOH/DMIX (Thioglycerol/DMSO/TFAA: 90/9/1) or 3NBA (3-nitrobenzyl alcohol) or (2) a PerSeptive Biosystems Mariner Electrospray Time of Flight Mass Spectrometer (ESI-TOF). For ES$^+$ analysis, the samples were dissolved in 50/50 MeOH/H_2O and were introduced by an integral syringe infusion pump.

Analytical Chromatography. *Small Molecules.* Reaction progress and purity of compounds were evaluated by reversed-phase HPLC analysis. HPLC separations were obtained on Hewlett-Packard quaternary 1050 gradient pumping system with a variable-wavelength UV detector (254 nm) and a Varex ELSD MKIII evaporative light-scattering detector. Analyses of the HPLC data were conducted on Hewlett-Packard HPLC ChemStation soft-

[3] The terms extracorporeal immunoadsorption (ECIA) and whole blood immunoadsorption (WBIA) have also been used for this approach.

ware. Reversed-phase HPLC chromatography was carried out using an Alltech Altima C-18 column (5 μm, 250 mm × 4.6 mm) with a gradient solvent system at a flow rate of 1 mL/min. The gradient mixture was composed of MeOH (solvent A) and 0.1% aqueous HOAc (solvent B). Starting with 40% MeOH, the initial solvent mixture was held for 2 min, increased to 100% MeOH over the next 10 min, and then held at 100% MeOH for 8 min. Retention times (t_R) are provided with the compound experimental.

Proteins. All antibody conjugates were analyzed by size exclusion HPLC analysis. Size exclusion HPLC analyses were conducted on a system consisting of a Hewlett-Packard 1050 Multiple Wavelength Detector (280 nm), isocratic pump, and a Protein-Pak glass 300SW column (7.5 mm × 300 mm, 10 μm; Waters Corp., Milford, MA). The mobile phase was an aqueous solution containing 50 mM potassium phosphate (pH 6.8), 300 mM NaCl, 1 mM EDTA, and 1 mM NaN_3. A flow rate of 1.0 mL/min was used. Retention time for intact mAb is 8.4−8.6 min using this system.

Radio-HPLC. Radiolabeled antibodies were analyzed by size exclusion HPLC. HPLC separations of radiolabeled conjugated antibodies were conducted on a system consisting of a Waters 510 pump, a Waters Lambda Max model 481 UV detector (280 nm), and a Beckman model 170 radioisotope detector. The radiolabeled mAbs were separated by size exclusion chromatography on a Bioselect 250-5 column (8 mm × 300 mm; 10 μm; Bio-Rad, Hercules, CA). The mobile phase was an aqueous solution containing 50 mM potassium phosphate (pH 6.8), 300 mM NaCl, 1 mM EDTA, and 1 mM NaN_3. A flow rate of 1.0 mL/min was used. The retention time for the radiolabeled proteins (gamma trace) was approximately 10.8 min using this system.

5-N-*tert*-Boc-3-((15′-Biotinyl)-4′,7′,10′-Trioxapentadecanylamino)Isophthalamic Acid 2,3,5,6-Tetrafluorophenyl Ester, 5. N-(13-Amino-4,7,10-trioxatridecanyl)-biotinamide (*19*), **4**, (54 mg, 0.12 mmol) in anhydrous DMF (2.0 mL) was added over 20 min to a solution of N-*tert*-Boc-5-aminoisophthalate bis-tetrafluorophenyl ester (*20*), **3** (100 mg, 0.17 mmol), and Et_3N (0.048 mL, 0.34 mmol) in anhydrous DMF (8 mL) at room temperature. After the mixture was stirred at room temperature for 1 h, volatile materials were removed under vacuum. The residue was purified by silica gel column (60 g) eluting with 10% MeOH/EtOAc to afford 51 mg (49%) of **5** as a colorless solid, mp 180−183 °C. ^{1}H NMR (CD_3OD, 200 MHz): δ 1.43 (m, 1H), 1.54 (s, 9 H), 1.67 (m, 3H), 1.90 (m, 2H), 2.18 (m, 2H), 2.69 (d, 2H), 2.92 (m, 1H), 4.28 (dd, 1H), 4.47 (dd, 1H), 7.49 (m, 1H), 7.83 (t, 1H), 7.97 (s, 2H); LRMS (ES^+; M + H) 858.3. HRMS calcd for $C_{39}H_{52}F_4N_5O_{10}S$ $(M + H)^+$: 858.3371. Found: 858.3374. HPLC: t_R = 14.0 min.

13-(Benzylthiourea-CHX-A″)-4,7,10-Trioxatridecane-Diamine, 6. A quantity (10.4 mg, 0.018 mmol) of isothiocyanatobenzyl-CHX-A″ DTPA (*21*), **17**, in 2 mL of anhydrous DMF was added over 10 min to a solution of 4,7,10-trioxa-1,13-tridecanediamine (39 mg, 0.18 mmol) in 2 mL of anhydrous DMF at room temperature. After the addition was completed, the reaction mixture was stirred at room temperature for 30 min and then triturated with 40 mL of EtOAc. The product was filtered and washed with EtOAc/$CHCl_3$ to afford 9.6 mg (67%) of **6** as a tacky material. ^{1}H NMR (D_2O, 200 MHz): δ 1.26 (t, J = 7.3 Hz, 4H), 1.92 (m, 8H), 2.17 (m, 2H), 3.03 (t, 8H), 3.40 (m, 4H), 3.65 (m, 9H), 3.69 (s, 10H), 7.24 (d, J = 8.0 Hz, 2H), 7.39 (d, J = 8.0 Hz, 2H); LRMS (FAB^+; M + H) 815. HRMS calcd for $C_{36}H_{59}N_6O_{13}S$ $(M + H)^+$: 815.3861. Found: 815.3853. HPLC: t_R = 2.6 min.

5-N-*tert*-Boc-3-((15′-Biotinyl)-4′,7′,10′-Trioxapentadecanylamino)-1-((13-(Benzylthiourea-CHX-A″)-4,7,-10-Trioxatridecanediamino)Aminoisophthalic Acid, 7. A 15.3 mg quantity of **5** (0.018 mmol) in 1.0 mL of anhydrous DMF was added to a solution of **6** (9.6 mg, 0.012 mmol) and Et_3N (5.0 μL, 0.036 mmol) in 1.5 mL of anhydrous DMF at room temperature. The solution was stirred at room temperature for 4 h and then triturated with 40 mL of EtOAc/$CHCl_3$ to give 11.0 mg (62%) of **7** as an oil, which was used in the subsequent reaction without purification. ^{1}H NMR (CD_3OD, 200 MHz): δ 1.43 (s, 9H), 1.58 (m, 8H), 1.79 (m, 6H), 2.08 (t, 4H), 2.83 (m, 4H), 3.15 (t, 4H), 3.21 (m, 8H), 3.25 (m, 6H), 3.41 (m, 20H), 3.53 (m, 16H), 4.18 (dd, 1H), 4.38 (dd, 1H), 4.65 (m, 1H), 7.11 (m, 4H), 7.83 (m, 1H), 7.89 (m, 1H), 7.99 (m, 1H). LRMS (ES^+) mass calcd for $C_{69}H_{107}N_{11}O_{22}S_2$ $(M + Na)^+$: 1528. Found: 1528. HPLC: t_R = 10.9 min.

5-Isothiocyanato-3-((15′-Biotinyl)-4′,7′,10′-Trioxapentadecanylamino)-1-((13-(Benzylthiourea-CHX-A″)-4,7,10-Trioxatridecanediamino)Aminoisophthalic Acid, 8. A solution containing 11.0 mg, (0.0073 mmol) of **7** in 0.5 mL TFA was stirred at room temperature for 30 min; then the volatile materials were removed under vacuum. The residue was redissolved in 2.0 mL of H_2O; then thiophosgene (1.7 μL, 0.022 mmol) in 2.0 mL of $CHCl_3$ was added, and that mixture was stirred at room temperature for 1 h. The excess thiophosgene and $CHCl_3$ were evaporated in fume hood under a stream of argon. The remaining aqueous phase was evaporated to dryness under vacuum to afford the 9.2 mg (87%) of **8** as a colorless tacky material. ^{1}H NMR (DMSO-d_6, 200 MHz): δ 1.69 (m, 8H), 1.93 (m, 6H), 2.20 (m, 4H), 2.73 (t, 4H), 3.15 (t, 4H), 3.25 (m, 8H), 3.35 (m, 6H), 3.54 (m, 20H), 3.65 (m, 16H), 4.33 (m, 1H), 4.51 (m, 1H), 4.70 (m, 1H), 7.36 (m, 4H), 7.93 (m, 1H), 7.96 (m, 1H), 8.02 (m, 1H). LRMS (FAB^+) mass calcd for $C_{65}H_{98}N_{11}O_{20}S_3K$ $(M + K)^+$: 1487. Found: 1487. HPLC: t_R = 11.5 min.

1-((*N*-Biotinyl)-L-Aspartyl)-4,7,10-Trioxatridecane-1,13-Diamine TFA Salt, 9. This compound was synthesized as previously reported (*22*). In the final synthetic step, a 396 mg quantity (0.55 mmol) of 13-N-*tert*-Boc-1-((*N*-biotinyl)-L-aspartyl-α-*tert*-butyl ester)-4,7,10-trioxatridecane-1,13-diamine in 2 mL TFA was stirred at room temperature for 30 min, and then the volatile materials were removed under vacuum. The isolated **9** was used directly in the next reaction.

5-N-*tert*-Boc-3-((15′-((*N*-Biotinyl)-β-L-Aspartyl)-4′,7′,-10′-Trioxapentadecanylamino)-Isophthalamic Acid 2,3,5,6-Tetrafluorophenyl Ester, 10. A solution of **9** (310 mg, 0.55 mmol), Et_3N (0.23 mL, 1.65 mmol), and anhydrous DMF (5 mL) was dripped slowly into a solution of **3** (320 mg, 0.55 mmol) in anhydrous DMF (3 mL) at room temperature. The reaction mixture was stirred at room temperature for 30 min, and then volatile materials were removed under vacuum. The residue was purified by silica gel column (50 g) eluting with 10% MeOH/EtOAc to afford 190 mg (31%) of **10** as a colorless tacky material. ^{1}HNMR (CD_3OD, 200 MHz): δ 1.45 (m, 2H), 1.54 (s, 9 H), 1.70 (m, 8H), 1.91 (m, 2H), 2.25 (m, 2H), 2.59−3.01 (m, 2H), 3.11−3.33 (m, 6H), 3.45−3.70 (m, 11H), 4.32 (dd, J = 4.4, 7.7 Hz, 1H), 4.50 (dd, J = 4.4, 7.7 Hz, 1H), 4.65 (t, J = 6.2 Hz, 1H), 7.51 (m, 1H), 8.25 (m, 2H), 8.48 (t, J = 1.8 Hz, 1H); LRMS (ES^+; M + Na) 995.4. HRMS calcd for $C_{43}H_{56}F_4N_6O_{13}SNa$ $(M + Na)^+$: 995.3460. Found: 995.3393. HPLC: t_R = 13.8 min.

3-((15′-(*N*-Biotinyl)-β-L-Aspartyl)-4′,7′,10′-Trioxapentadecanylamino)-1-((13-(Benzylthiourea-CHX-A″)-4,7,10-Trioxatridecanediamine)-Aminoisophthalic Acid, 11. *Preparation A (Scheme 2*). A solution of **6** (64 mg, 78.7 μmol) and Et_3N (19 μL, 137 μmol) in anhydrous DMF (3 mL) was added dropwise to a solution of **10** (76 mg, 78.7 μmol) in anhydrous DMF (2 mL) at room temperature. The reaction mixture was stirred at room temperature for 1h; then DMF was removed under vacuum. The residue was redissolved in 2 mL of neat TFA and stirred at room temperature for 10 min. After that time, TFA was removed under vacuum, and the crude product was purified on a Sephadex G-15 column eluting with water. This provided 100 mg (83%) of **11** as a colorless tacky material. ^{1}H NMR (D_2O, 200 MHz): δ 0.86 (t, J = 6.6 Hz, 4H), 1.25 (m, 8H), 1.41−1.83 (m, 16H), 2.08 (m, 4H), 2.56 (m, 4H), 2.80 (m, 1H), 3.07 (m, 6H), 3.17−3.93 (m, 34H), 4.14 (m, 2H), 4.28 (m, 1H), 6.38 (m, 2H), 6.52 (m, 2H), 7.13 (s, 2H), 7.40 (m, 1H), 8.40 (m, 2H). LRMS (FAB^+) mass calcd for $C_{68}H_{105}N_{12}O_{23}S_2$ $(M + H)^+$: 1521. Found: 1521. HPLC: t_R = 7.9 min.

Preparation B (Scheme 3). A quantity (200 mg, 0.18 mmol) of **15** was dissolved in 2 mL of neat TFA, and the solution was stirred for 10 min at room temperature. The TFA was removed under vacuum, and the residue was dissolved in H_2O (4 mL). To that solution was added Na_2CO_3 (140 mg, 1.30 mmol), **17** (80 mg, 0.13 mmol), H_2O (4 mL), and DMF (4 mL). The reaction mixture was stirred at room temperature for 4 h and then neutralized with HOAc. The neutralized solution was placed on a gel filtration column (Sephadex G-15, 2.5 × 50 cm) and eluted with H_2O to provide 157 mg (77%) of **11** with physical and spectral properties identical to those reported above.

1-Isothiocyanato-3-((15′-(*N*-Biotinyl)-β-L-Aspartyl)-4′,7′,10′-Trioxapenta-Decanylamino)-1-((13-(Benzylthiourea-CHX-A″)-4,7,10-Trioxatridecanediamine)-Aminoisophthalic Acid, 12. Thiophosgene (25 μL, 0.33 mmol) in 3 mL of $CHCl_3$ was added to a 3 mL aqueous solution of **11** (100 mg, 66 μmol) at room temperature. The mixture was stirred at room temperature for 1 h; then excess thiophosgene and $CHCl_3$ were evaporated in fume hood under a stream of argon. The aqueous phase was evaporated to dryness under vacuum to afford the 84 mg (82%) of **12** as a light yellow tacky material. ^{1}H NMR (D_2O, 200 MHz): δ 0.86 (t, J = 6.6 Hz, 4H), 1.25 (m, 8H), 1.44−1.82 (m, 16H), 2.09 (m, 4H), 2.54 (m, 4H), 2.81 (2d, J = 5.1 Hz, 1H), 3.09 (m, 6H), 3.27−3.83 (m, 34H), 4.12 (m, 1H), 4.30 (m, 1H), 4.49 (m, 1H), 7.31 (d, 2H), 7.44 (d, 2H), 7.87 (t, 1H), 7.97 (s, 2H), 8.03 (d, J = 7.0 Hz, 1H), 8.30 (s, 1H), 8.72 (t, J = 5.5 Hz, 2H). LRMS (FAB^+) mass calcd for $C_{69}H_{103}N_{12}O_{23}S_3$ $(M + H)^+$: 1563. Found: 1563. HPLC: t_R = 11.7 min.

3-(13′-*N*-*tert*-Boc)-Trioxatridecanediamine-5-*N*-*tert*-Boc-Aminoisophthalate TFP Ester, 14. *N*-*tert*-Boc-trioxadiamine (*23*), **13** (0.44 g, 1.39 mmol), and Et_3N (0.29 mL, 2.08 mmol) in anhydrous DMF (5 mL) were added dropwise over 3 h to a solution of *N*-*tert*-Boc-aminoisophthalate di-TFP ester, **3** (0.80 g, 1.39 mmol), in anhydrous DMF (5 mL) at room temperature. After the addition was completed, the mixture was stirred at room temperature for another 30 min, and then the volatile materials were evaporated under vacuum. The product was purified by silica gel column (40 g) eluting with 50% EtOAc/Hexane to afford 0.74 g (73%) of **14** as a colorless oil. ^{1}H NMR ($CDCl_3$, 200 MHz): δ 1.42 (s, 9H), 1.54 (s, 9H), 1.69 (m, 2H), 1.77 (s, 1H), 1.91 (m, 2H), 2.92 (d, J = 14.7 Hz, 1H), 3.17 (m, 2H), 3.42−3.51 (m, 4H), 3.56−3.72 (m, 8H), 4.89 (t, J = 5.1 Hz, 1H), 6.97−7.14 (m, 1H), 7.51 (s, 1H), 7.57 (s, 1H), 8.01 (s, 1H), 8.28 (t, J = 1.5 Hz, 1H), 8.63 (s, 1H); LRMS (ES^+; M + Na) 754.3. HRMS calcd for $C_{34}H_{45}F_4N_3O_{10}Na$ $(M + Na)^+$: 754.2939. Found: 754.2941. HPLC: t_R = 14.8 min.

3-(13′-*N*-*tert*-Boc)Trioxatridecanediamine-1-(13″-Biotin-Asp-OH)Trioxadiamine-5-*N*-*tert*-Boc-Aminoisophthalate, 15. Biotin-Asp-OH-trioxadiamine TFA salt, **9** (0.32 g, 0.48 mmol), was added to a solution containing **14** (0.35 g, 0.48 mmol) and Et_3N (0.15 mL, 1.05 mmol) in anhydrous DMF (5 mL). The resultant mixture was stirred at room temperature for 1 h. Volatile materials were removed under vacuum and the residue was purified by silica gel column (40 g, 50% MeOH/EtOAc) to yield 0.45 g (83%) of **15** as a tacky oil. ^{1}H NMR (CD_3OD, 200 MHz): δ 1.41 (s, 9H), 1.53 (s, 9H), 1.63−1.74 (m, 6H), 1.86−1.92 (m, 4H), 2.18−2.29 (m, 2H), 2.58 (dd, J = 8.0, 14.8 Hz, 1H), 2.68 (d, J = 12.4 Hz, 1H), 2.74 (dd, J = 4.9, 14.8 Hz, 1H), 2.91 (dd, J = 4.9, 13.0 Hz, 1H), 3.09 (t, J = 6.8 Hz, 2H), 3.16−3.20 (m, 1H), 3.22 (t, J = 6.8 Hz, 2H), 3.30−3.31 (m, 4H), 3.44−3.54 (m, 12H), 3.59−3.66 (m, 16H), 4.30 (dd, J = 4.3, 8.0 Hz, 1H), 4.48 (dd, J = 4.3, 8.0 Hz, 1H), 4.55 (dd, J = 4.9, 7.4 Hz, 1H), 7.84 (t, J = 1.2 Hz, 1H), 7.99 (t, J = 1.9 Hz, 1H), 8.02 (t, J = 1.9 Hz, 1H). LRMS (ES^+) calcd for $C_{52}H_{87}N_8O_{17}S$ $(M + H)^+$: 1128. Found: 1128. HPLC: t_R = 11.4 min.

3-(13′-ThioureabenzylDOTA)Trioxadiamine-1-(13″-Biotin-Asp-OH)Trioxadiamine-5-Aminoisophthalate, 19. A 34 mg quantity (0.03 mmol) of **15** was dissolved in 1 mL of neat TFA and stirred at room temperature for 10 min. The TFA was removed under a stream of Ar, and the residue was redissolved in H_2O (1 mL). To that solution was added sodium carbonate (31.8 mg, 0.3 mmol) and DOTA-benzyl-NCS, **18** (20 mg, 0.036 mmol) in DMF (1 mL). The reaction mixture was stirred at room temperature for 4 h, neutralized with HOAc, and purified by gel filtration (Sephadex G-15) eluting with water to give 33 mg (74%) of **19**. ^{1}H NMR (D_2O): δ 1.24−1.45 (m, 3H), 1.47−1.99 (m, 14H), 2.26 (t, J = 7.1 Hz, 3H), 2.52 (dd, J = 10.0, 14.9 Hz, 1H), 2.69−2.82 (m, 1H), 2.95 (dd, J = 4.4, 13.2 Hz, 1H), 3.11−3.30 (m, 17H), 3.42−3.71 (m, 38H), 4.37 (dd, J = 4.0, 7.7 Hz, 1H), 4.48−4.60 (m, 2H), 7.18−7.31 (m, 5H), 7.38 (s, 1H), 7.45 (t, J = 1.5 Hz, 1H). LRMS (ES^+) calcd for $C_{66}H_{104}N_{13}O_{21}S_2$ $(M + H)^+$: 1479. Found: 1479. LRMS calcd for $C_{66}H_{103}N_{13}NaO_{21}S_2$ $(M + Na)^+$: 1501. Found: 1501. HPLC: t_R = 8.2 min.

3-(13′-ThioureabenzylDOTA)Trioxadiamine-1-(13″-Biotin-Asp-OH)Trioxadiamine-5-Isothiocyanato-Aminoisophthalate, 20. 1,1′-Thiocarbonyldiimidazole (3.6 mg, 0.02 mmol) was added to a solution of **19** (25 mg, 0.017 mmol) in anhydrous DMF (1 mL). The reaction mixture was stirred at room temperature for 1 h; then 30 mL of ether was added and stirred for another 20 min. Solvents were carefully decanted, and the residue was washed with ether (2 × 20 mL) to afford the 21 mg (82%) of **20** as light-yellow tacky solid. ^{1}H NMR (D_2O): δ 1.25−1.44 (m, 3H), 1.50−1.99 (m, 14H), 2.20−2.31 (m, 3H), 2.53 (dd, J = 9.9, 14.7 Hz, 1H), 2.66−2.83 (m, 1H), 2.91−3.00 (m, 4H), 3.13−3.34 (m, 14H), 3.46−3.71 (m, 38H), 4.39 (dd, J = 4.7, 8.1 Hz, 1H), 4.48−4.61 (m, 2H), 7.18−7.38 (m, 4H), 7.47 (s, 1H), 7.80 (s, 1H), 8.02 (s, 1H). LRMS calcd for $C_{67}H_{102}N_{13}O_{21}S_3$ $(M + H)^+$: 1521. Found: 1521. LRMS calcd for $C_{67}H_{101}N_{13}NaO_{21}S_3$ $(M + Na)^+$: 1543. Found: 1543. HPLC: t_R = 11.0 min.

Antibody Demetalation and Conjugation. The following procedure is an example; other quantities of the two antibodies (the antirenal cell antibody A6H (*24*) and the anti-PSMA antibody 107-1A4 (*25*)) and conjugation

reagents were also used in the studies. *(a) Reagent Preparation*. Preparation of low-metal reagents and buffers used was as previously described (*26*).

(b) Demetalation. A 5 mg quantity of a monoclonal antibody was placed in a Slide-A-Lyzer 10K dialysis cassette (Pierce) and dialyzed against 1L metal free HEPES with a minimum of 5 buffer changes over 3 days at 4 °C. To each buffer change solution was added 5 g of Chelex-100 resin. The antibody was then removed from the dialysis cassette and placed in an acid washed microcentrifuge tube. Care was taken to avoid the introduction of metals to the final solution. The demetalated mAb was stored at 4−8 °C until used in conjugation reactions.

(c) Conjugation with A6H. (1) A stock solution of **8** was prepared by dissolving 2 mg in 150 μL of 10% aqueous DMSO[4]. Aliquots of that solution were diluted with additional 10% aqueous DMSO to obtain 5, 10, 25, or 50 equiv in 15 μL. Then, 15 μL aliquot of the solutions containing the varying quantities of **8** were added to vials containing 150 μL of a 0.67 mg/mL (100 μg) of A6H in HEPES buffer at pH 8.5 for 16−18 h. After the reaction period, the A6H conjugates were purified by elution over a size exclusion column (Sephadex G-25, PD-10). The quantity of **8** conjugated with A6H was determined from the HABA and UV/BCA analyses as described in the following section. The analyses indicated that 0.4−11.5 conjugates of **8** were obtained per A6H molecule, depending on the amount reacted.

(2) A stock solution of **8** was prepared by dissolving 1.3 mg in 58 μL of DMSO. Then 30 μL of the DMSO solution of **8** (15 equiv) was added to a vial containing 1.2 mL of a 3.87 mg/mL solution of A6H in HEPES buffer at pH 8.5. The reaction mixture was stirred at room temperature overnight. After conjugation, the reaction mixture was placed in a dialysis cassette and was dialyzed against 3 × 1L of metal free citrate buffer (50 mM Na citrate, 150 mM NaCl, 0.05% NaN_3, pH 5.5) containing 5 g Chelex-100, followed by 2 × 1L metal free saline. The A6H conjugate had 2.9 conjugates of **8** per mAb.

107-1A4. Stock solutions of the trifunctional biotinylation reagents **12** and **20** were made in water. Aliquots of the stock solutions were diluted with additional water to obtain reagent solutions that contained 10, 25, or 50 equiv in 100 μL. Stock solutions of NHS-LC-biotin (1.15 mg in 38 μL), isothiocyanatobenzyl-CHX-A″, **17** (1.15 mg in 29 μL), and isothiocyanatobenzyl-DOTA, **18** (1.15 mg in 34 μL), were prepared in DMSO. The conjugation reactions were conducted as follows: To 303 μL of a 6.6 mg/mL solution of demetalated 107-1A4 (2 mg, 13.3 nmol) was added the appropriate volume (2 μL/10 equiv; 5 μL/25 equiv; 10 μL/50 equiv) of a DMSO solution containing NHS-LC-biotin, **12**, **17**, **18**, or **20**. After conjugation, the reaction mixtures were placed in dialysis cassettes and were dialyzed against 3 × 1L of metal free citrate buffer containing 5 g Chelex-100, followed by 2 × 1L metal free saline. The demetalated conjugated antibody (in saline) was stored at 4−8 °C until used in radiolabeling experiments.

[4] Due to their low water solubility, some of the reagents (i.e., **17**, **18**, and NHS-LC-biotin) were dissolved in DMSO prior to addition to the aqueous solutions. It should be noted that the trifunctional reagent **8** is soluble in water so the 10% aqueous DMSO does not have to be used. Addition of **8** in 10% aqueous DMSO solution for conjugation with A6H, and additions of **17**, **18** and NHS-LC-biotin in neat DMSO for conjugation with 107-1A4, resulted in conjugation solutions that had <3% DMSO by volume.

Antibody Conjugate Characterization. The conjugated antibodies were characterized by HPLC analysis, IEF, and SDS−PAGE electrophoresis, and the number of conjugates per antibody was determined. The methods used are described below.

Protein Concentration. Protein concentrations were estimated via UV absorption using the Beer's law equation, wherein the measured absorbance in water at 280 nm was divided by 1.5 L/g and by the BCA analysis method (*27*). The BCA analysis was conducted with a BCA Protein Assay Kit (Pierce, www.piercenet.com, Rockford, IL) following the procedure provided in the kit. The standard method was employed, but twice the concentration of copper in the working reagent was used to ensure that chelation of copper to the CHX-A″ or DOTA moieties did not give erroneous results.

Biotin Moieties per mAb. The spectrophotometric method of 4′-hydroxyazobenzene-2-carboxylic acid (HABA) displacement by biotin was used to evaluate the number of biotin moieties conjugated with the antibody (*28*). A modification of the original procedure by Green that was provided by Pierce (Rockford, IL) was used. A description of that procedure follows.

A HABA-avidin solution was prepared by adding 10 mg avidin and 600 μL of a 10 mM solution of HABA in 10 mM NaOH into 19.4 mL of PBS. A 900 μL aliquot of the HABA-avidin solution was placed in a cuvette, and the UV absorbance was measured at 500 nm. This measurement provides the A_{500} HABA and should be between 0.9 and 1.3. Following that measurement, 100 μL of the conjugated antibody is added to the cuvette and mixed well. The UV absorbance is again measured at 500 nm, and the value is taken after it stabilizes for at least 15 s. This value is the A_{500} biotin and should be 0.3 or higher. To determine the number of mmoles of biotin/mmole antibody, the following calculations were performed. First, the change in absorbance is calculated from $\Delta A_{500} = (0.9)(A_{500}{}^{HABA}) - (A_{500}{}^{biotin})$. Second, the mmol quantity of biotin/mL of the mixture is obtained from the equation $(\Delta A_{500}/34{,}000) \times 10$. Because the biotinylated antibody is diluted by a factor of 10 when it is put in the cuvette, the amount of biotin must be multiplied by that factor. Then, the calculated millimoles of biotin per milliliter are divided by the millimoles of antibody per milliliter obtained from the BCA or UV analysis to give the number of conjugates per antibody.

Electrophoresis. IEF analyses were conducted on a Novex PowerEase 500 instrument with the XCell II chamber using Invitrogen (Novex) precast gels, pH 3−10 or 3−7 (1.0 mm × 12 well) running under the standard IEF Program. The protein was stained with GelCode Blue Stain (Pierce). IEF standards were from Serva Electrophoresis GmbH: pH 10.7, cytochrome C; 9.5, ribonuclease A; 8.3, 8.0, and 7.8, lectin; 7.4 and 6.9, myoglobin; 6.0, carbonic anhydrase; 5.3 and 5.2, β-lactoglobulin; 4.5, trypsin inhibitor; 4.2, glucose oxidase; 3.5, amyloglucosidase. Examples of IEF gels are shown as Figure 1.

SDS−PAGE analyses were conducted on the Novex instrument described above using 8−16% Tris-Glycine precast gels (1.0 mm × 12 well) running under the tris−glycine gel program. The samples were prepared by addition of 5 μL of a 10% aqueous sodium dodecyl sulfate (SDS) solution to 20 μL of an aqueous 1 mg/mL solution of sample. For reducing gels, 1 μL of β-mercaptoethanol was added to each sample. After mixing, the samples were boiled for 5 min, and then a 10 μL aliquot of the sample to be run was added the gel. Molecular weight standards, MultiMark Multi-Colored Standard (5 μL, Novex), were used for reference. Those standards include

myosin (250 kDa), phosphorylase B (148 kDa), glutamic dehydrogenase (60 kDa), carbonic anhydrase (42 kDa), myoglobin (30 kDa; 22 kDa), lysozyme (17 kDa), Aprotinin (6 kDa), and insulin (4 kDa).

Radioiodination. Radioiodination of antibodies and their conjugates was conducted using the Chloramine-T method as previously described (*19*). For example, radioiodination of 107-1A4 and its conjugates was accomplished as follows. To 25 μL 0.5M sodium phosphate, pH 7.4, was added 1 μL (200 μCi) of $Na^{125}I$ in 0.1N NaOH. To that solution was added 133 μL of a 1.5 mg/mL solution of 107-1A4 derivative (200 μg) in PBS, followed by 22 μL of a 1 mg/mL solution of Chloramine-T in water. The reaction was allowed to proceed for 1 min at room temperature before quenching with 2.2 μL of a 10 mg/mL solution of sodium metabisulfite in water. The mixture was then passed over a G-25 Sephadex column (NAP-10, Pharmacia) eluting with 0.9% saline. Fractions were collected, and those containing protein were combined. Radiochemical yields ranged from 19% to 85% (Table 1).

^{111}In and ^{90}Y Labeling. *Labeling of A6H-**8**.* To a vial containing 100 μL of 50 mM NaOAc (high purity) was added 1−3 μL of [^{111}In]$InCl_3$ or [^{90}Y]YCl_3 in 0.05 M HCl. To that solution was added either 100 μL or 200 μL of a 1.47 mg/mL solution of the demetalated A6H (150 or 300 μg of mAb or mAb conjugate) in PBS. The radiolabeling was conducted at room temperature for 5 min; then the reaction was quenched by the addition of 10−20 μL of 10 mM DTPA. The radiolabeled antibody was eluted on a size exclusion column (either NAP-10 or PD-10) for purification. Labeling yields ranged from 74% to 97% (Table 1).

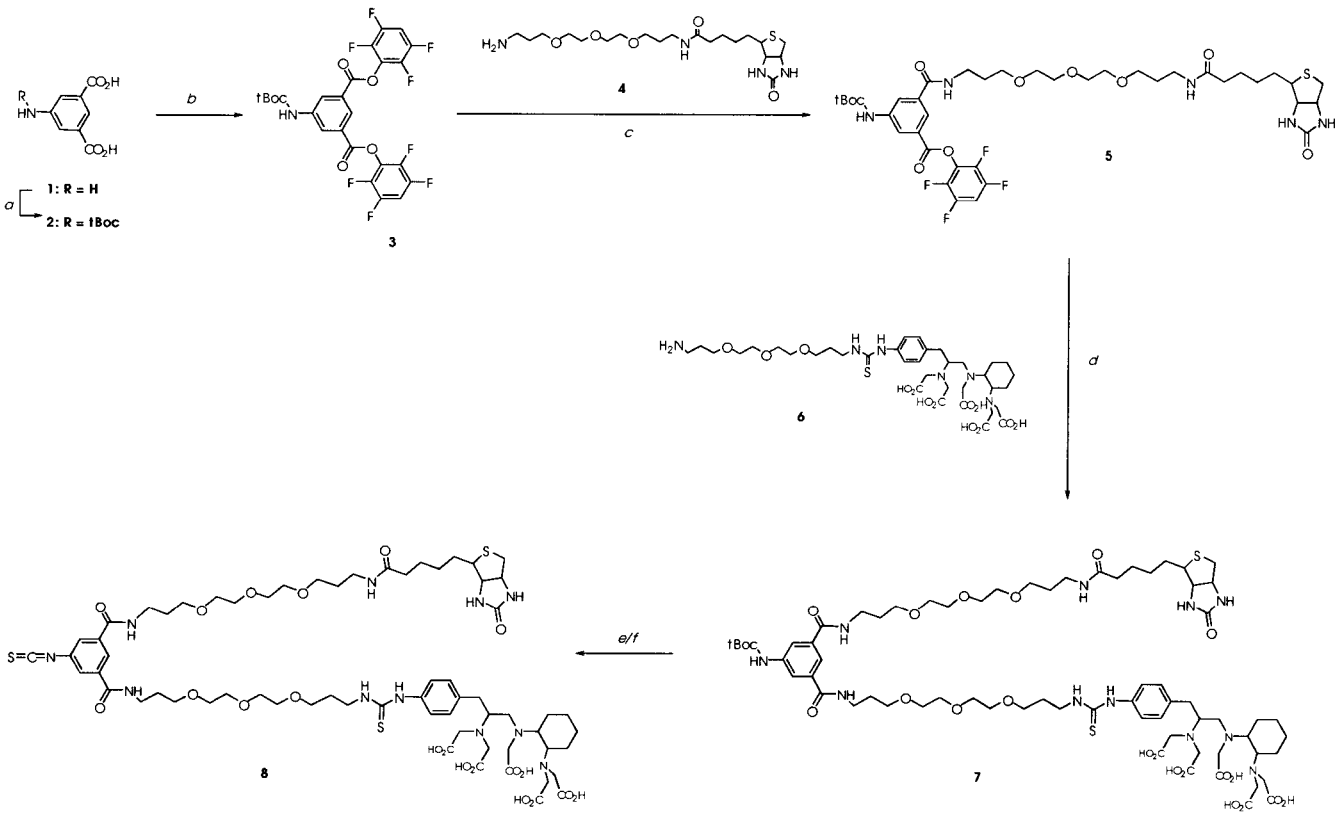
*Labeling of 107-1A4 Conjugated with **12**, **17**, **18**, or **20**.* To 200 μL of 0.05M NaOAc, pH 5.0, was added 200 μL of a 1.5 mg/mL solution of demetalated, conjugated 107-1A4 (300 μg) in PBS followed by 1 μL (160 μCi) of [^{111}In]-$InCl_3$ in 0.05N HCl or 0.5 μL (380 μCi) of [^{90}Y]YCl_3 in 0.05N HCl. The reaction solution was then heated to 45 °C for 1h. Following that, the radiolabeled antibody was passed over a G-25 Sephadex column (NAP-10, Pharmacia) eluting with 0.9% saline. Those fractions containing protein were combined. Radiochemical yields ranged from 36% to 100% (Table 1).

Stability of Y-90 Labeled Antibody. To 200 μL of either human serum, 10 mM EDTA, or 10 mM DTPA was added 2 μL of the radiolabeled mAb. The samples were vortexed lightly and incubated for 1h at room temperature, except for the serum sample, which was incubated at 37 °C. The stability was analyzed by placing a 100 μL aliquot in a centrifugal filter device (Microcon-30) and centrifuged at 4000 rpm for 5 min. The material remaining in the top portion of the Microcon-30 was rinsed with 3 × 100 μL PBS. The percent protein bound activity was determined by dividing the cpm remaining in the top portion of the Microcon by the total cpm in the Microcon device (top and bottom).

Avidin Column Binding. A series of 1 mL pipet tips were filled with approximately 750 μL of immobilized avidin (Pierce) to be used as columns. Half of the columns were washed with 3 mL of PBS/1% BSA (specific binding) and the other half with 3 mL of PBS/1% BSA/0.5 mg/mL biotin (nonspecific binding). Approximately 100,000 cpm (10 μL) of the labeled biotinylated mAb was placed on each column (duplicate), and they were eluted with either 2 × 1.5 mL PBS/1% BSA or PBS/1% BSA/0.5 mg/mL biotin as appropriate. The activity on the column and in the eluate was counted to determine % bound to the column.

Antibody Cell Binding Assay. The assay was conducted by addition of approximately 200,000 counts per min (cpm) of radiolabeled 107-1A4 or a conjugate in 0.1 mL PBS to 2 million trypsinized LNCaP prostate carcinoma cells suspended in 1.0 mL PBS containing 1% BSA. The actual cpm added to each tube was determined by quantification in a gamma counter. Cells were incubated at room temperature for 1 h with constant rotary inversion mixing, pelleted by centrifugation at 5000*g* for 3 min, decanted to remove supernatant, and resuspended in 1 mL PBS. The cell binding immunoreactivity estimation was taken as the counts remaining divided by initial total counts times 100. The cell binding values (average of 2) obtained are listed in Table 1.

RESULTS



Trifunctional Reagent Syntheses. Three trifunctional reagents, **8**, **12**, and **20**, were synthesized as shown in Schemes 1−3. All three syntheses used aminoisophthalic acid, **1**, as the core of the trifunctional reagent. In the first synthetic step, the amine in **1** was converted to the *tert*-butoxycarbonyl (t-Boc) derivative, **2**, using di-*tert*-butyl dicarbonate in a basic solution of H_2O and DMF. Subsequently, **2** was converted to the bis-tetrafluorophenyl (TFP) ester, **3**, using tetrafluorophenol (TFP−OH) and 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide (EDC) in DMF. The trifunctional reagent **3** has also been used to prepare radiolabeled bis-biotin compounds (*20*).

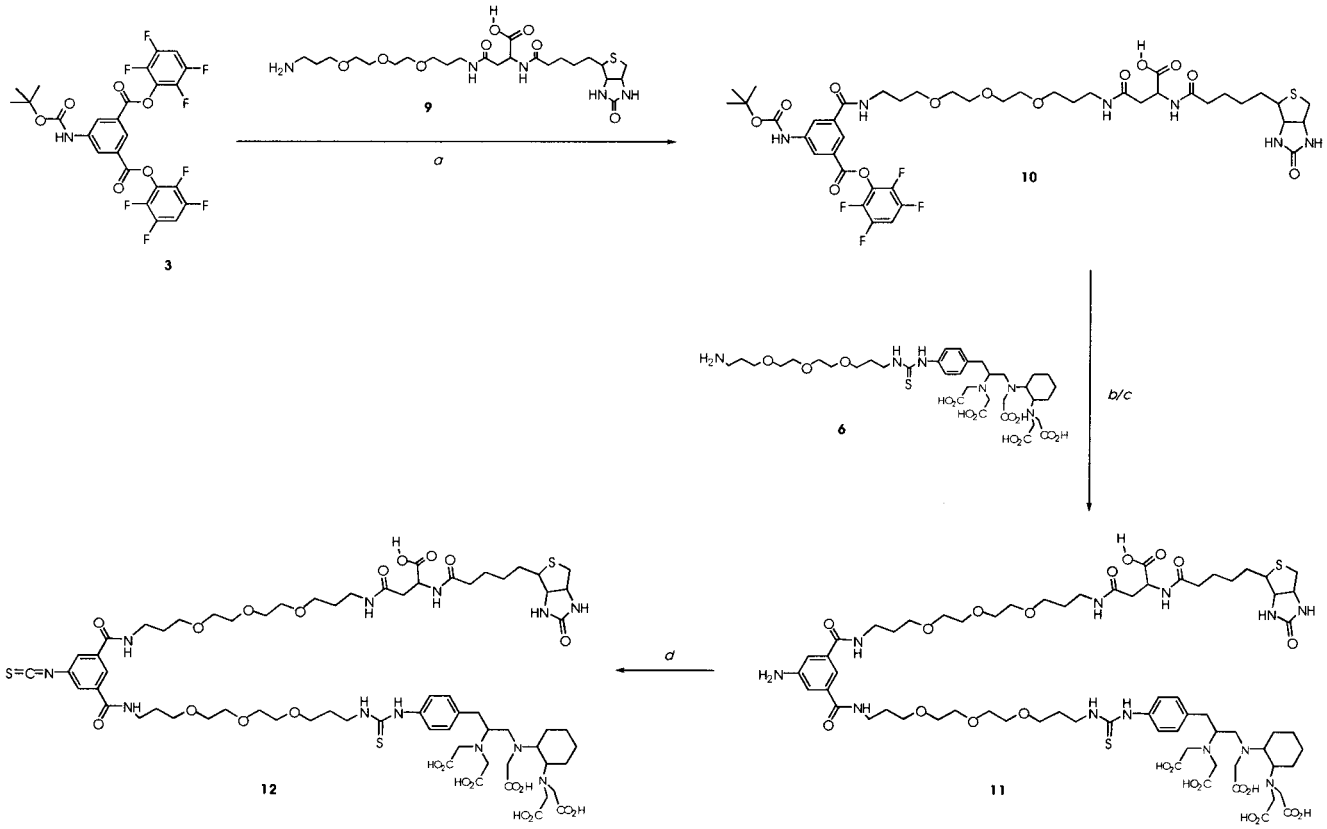
The trifunctional reagent **8** was synthesized as shown in Scheme 1. The bis-TFP ester, **3**, was reacted with 0.7 equiv of N-(13-amino-4,7,10-trioxatridecanyl)biotinamide, **4** (*19*), to provide the biotinyl-monoadduct **5**. Reaction of **5** with the adduct of 4,7,10-trioxatridecane-1,13-diamine and isothiocyanato-benzyl-CHX-A″, **17** (*21*), in the presence of triethylamine provided the N-*tert*-Boc-protected **7**. Conversion of **7** to the free amine was facile using trifluoroacetic acid (TFA), and the isolated amine was directly converted to the targeted isothiocyanate containing trifunctional reagent **8** by employing an aqueous biphasic reaction with thiophosgene in chloroform. Using this synthetic route, **8** was prepared in 13% overall chemical yield.

The synthetic route for preparing a second trifunctional reagent, **12**, is shown in Scheme 2. This synthesis is the same as that for reagent **8**, with the exception that 2-(N-biotinoyl)-4-(*N*′-(13′-*tert*-butoxycarbonylamino)-4′,7′,10′-trioxatridecaneamino)-L-aspartic acid, **9**, was reacted in the place of N-(13-amino-4,7,10-trioxatridecanyl)biotinamide, **4** (*22*). The incorporation of aspartic acid between the biotin carboxylate and the trioxadiamine linker introduces a carboxylate alpha to the biotinamide bond, which blocks the cleavage of that bond by the enzyme biotinidase (*29*,*30*). The overall chemical yield of **12** using this synthetic approach was 10%.

The synthetic steps for preparation of a third trifunctional reagent, **20**, is shown in Scheme 3. Due to difficulties encountered in purifying the trioxatridecanediamine adducts of the isothiocyanatobenzyl-CHX-A″, **6**, and the isothiocyanatobenzyl-DOTA (not reported), an alternate approach to that in Schemes 1 and 2 was taken. Reaction of one equivalent of the mono-*tert*-Boc protected trioxatridecanediamine, **13** with the aminoisophthalate bis-TFP ester, **3**, yielded the monoadduct, **14** in 73% yield. After conjugation of the biotin-aspartate derivative **9**, removal of two *tert*-Boc groups with TFA yielded a compound, **16**, which has a primary aliphatic amine and an aromatic amine. Preferential reaction of the aliphatic

Scheme 1. Synthesis of a Trifunctional Reagent Containing a Biotin Moiety, a Benzyl-CHX-A″ (DTPA) Chelation Moiety, and an Isothiocyanate for Protein Conjugation[a–f]

[a] $(tBuO)_2CO$, NaOH, H_2O, DMF, rt, 30 h, 73%. [b] TFP−OH, EDC, DMF, rt, 16 h, 67%. [c] Et_3N, DMF, rt, 1 h, 49%. [d] Et_3N, DMF, rt, 4 h, 62%. [e] TFA, rt, 30 min. [f] H_2O, $CHCl_3$, Cl_2CS, rt, 1 h, 87%.



amine in Na_2CO_3/H_2O with the isothiocyanatobenzyl-DOTA, **18**, yielded the anilino-derivative **19**, which was converted to the desired trifunctional reagent, **20**, by reaction with 1,1′-thiocarbonyldiimidazole. The overall yield of **20** was 23%. This route provided a convenient synthesis of **20**, but importantly, the diamino intermediate, **16**, can be used in the preparation of other trifunctional biotinylation reagents as well. Although trifunctional reagent **12** was prepared as shown in Scheme 2, the overall yield was nearly doubled (19%) when it was prepared from the reaction of **16** with **17** as depicted in Scheme 3.

Antibody Conjugation. Antibody conjugations were conducted with the trifunctional reagents **8**, **12**, and **20**. Two monoclonal antibodies, A6H and 107-1A4, were used in the studies. In the initial conjugation studies, the trifunctional reagent **8**, was conjugated with A6H. A6H is an murine IgG_1 monoclonal antibody that reacts with a 206 kDa cell surface antigen, which is present on renal cells, and is overexpressed on renal cell carcinoma cells (*24*, *31*). In later studies, the biotinidase-stabilized trifunctional reagents, containing the metal chelates CHX-A″ (**12**), and DOTA (**20**) were conjugated with 107-1A4 (*25*). 107-1A4 is a murine IgG_1 monoclonal antibody that reacts with the cell surface antigen, prostate-specific membrane antigen (PSMA), which is present on prostate cells and is overexpressed on prostate carcinoma cells (*32*, *33*). Due to a concern that metals associated with the antibodies could decrease radiolabeling yields, the antibodies were subjected to exhaustive demetalation prior to conjugation of the trifunctional reagents.

Conjugations with A6H and 107-1A4 were conducted with varying quantities of **8**, **12**, or **20** to determine the number of conjugates per mAb obtained per equivalent offered. Initial conjugations reacted 100 μg quantities of A6H with 5, 10, 25, and 50 M equiv of **8** in HEPES buffer at pH 8.5 for 16−18 h. The A6H conjugates were purified from the nonreacted/hydrolyzed **8** by passing them over small size exclusion columns (Pharmacia PD-10). The quantity of **8** conjugated per A6H molecule was obtained by determining the number of biotin moieties and amount of protein present in a known volume of the antibody conjugate. The number of biotin moieties present (in an aliquot) was determined by conducting a HABA assay, and the protein concentration was determined by conducting both UV and BCA protein concentration analyses. Both analyses were conducted as the protein concentrations obtained from the UV analyses when higher conjugation ratios were employed appeared to be erroneous (i.e., analyses indicated that there was more protein at the end of the conjugation than was used at the initiation). The analyses indicated that 0.4−11.5 conjugates of **8** were obtained per A6H molecule, depending on the amount reacted. The results are listed in columns 2 and 3 of Table 1. A larger quantity of A6H conjugated with **8** was prepared for radiolabeling studies. In that conjugation, 15 equiv of **8** was offered and 2.9 biotin conjugates per mAb was obtained. Due to concerns for introducing metals to the A6H-**8** conjugate, dialysis was used rather than size exclusion columns to rid it of unconjugated chelate and change the solvent to saline.

Conjugations of varying quantities (10, 25, and 50 equiv) of the trifunctional reagents **12** and **20** with 107-1A4 were conducted under conditions similar to those for A6H, except that **12** and **20** were dissolved in water rather than DMSO. In the conjugations, 2 mg quantities of mAb were used so that ample conjugate was available

[a] Dash signifies that it was not determined.

for radiolabeling, cell binding, and stability experiments. After reaction was complete, the conjugated 107-1A4 was dialyzed in a cassette against metal-free buffer. The number of conjugates per mAb was determined to be 2.1−5.1 by conducting HABA and BCA analyses. The quantities of **12** and **20** offered and the number of conjugates per mAb obtained are listed in columns 2 and 3 of Table 1.

Additional conjugations of 107-1A4 were conducted with the commercially available biotinylation reagent

N-hydroxysuccinimidyl biotinyl-6-aminocaproic acid (NHS-LC-biotin) and the bifunctional conjugation reagents, isothiocyantobenzyl-CHX-A″ (**17**) and isothiocyanatobenzyl-DOTA (**18**). These mAb conjugates were prepared to provide comparisons of radiolabeling and cell binding when only one functionality is present on the conjugate. The conjugations were conducted with the same number of equivalents offered (e.g., 10, 25, and 50) under the same reaction conditions as those described for **12** and **20**, except that the reagents were dissolved in DMSO due to their low solubility in water. The quantities of these reagents offered and the number of conjugates per mAb obtained, are also listed in columns 2 and 3 of Table 1. Conjugations with NHS-LC-biotin were efficient, resulting in 6−10 biotin moieties per mAb. Conjugations with the isothiocyanates were not as efficient, resulting in 2−5 conjugates of **12** and **20** per mAb. Since there were no biotins present when **17** and **18** were conjugated alone, the number of biotin moieties per antibody observed represent the error found in these analyses. The number of conjugated **17** or **18** per mAb was not assessed,[5] but IEF data comparing all the 107-1A4 conjugates (Figure 1) confirmed that the antibody was conjugated with these chelation moieties.

Analyses of Conjugates. The conjugates were analyzed by size exclusion HPLC, SDS−PAGE, and IEF. HPLC chromatograms for conjugates were essentially the same as those for the unmodified antibodies. This indicated that the conjugation process did not alter their structure significantly and did not cause aggregation. The SDS−PAGE analyses confirmed what was observed by HPLC. Interestingly, shifts to (an apparent) higher molecular weight could be seen on the SDS−PAGE gels (both reducing and nonreducing), but quantification was not possible (see Figures in Supporting Information). Analysis by IEF was most useful in that it provided evidence of the degree of substitution that occurred. Because the conjugations, with the exception of the NHS-LC-biotin, resulted in the elimination of a positive lysine amine and addition of four or five carboxylate functionalities, significant changes from the pI of the unmodified mAb was noted. When a broad pI gel was used (i.e., pH 3.0−10), only small differences in the pI of substituted mAbs was noted because they were all in the 4.5−6 range. Use of a short-range gel (i.e., pH 3.0−7) provided much better delineation of the changes in the protein pI. Digitized scans of short-range IEF gels for the conjugates **12**, **17**, **18**, and **20** are provided in Figure 1. Consistent with the HABA/BCA analyses (Table 1), the IEF indicate that about the same amount of substitution was obtained when 10 or 25 equiv of **12** or **20** was reacted with the mAb. In contrast with the HABA/BCA analyses, the IEF did not provide a measurable difference for reaction of 50 equiv **12** and **20** with the mAb. Conjugation of varying quantities of the isothiocyanatobenzyl-CHX-A″, **17**, and isothiocyanatobenzyl-DOTA, **18**, appears to have resulted in less substitution than for **12** or **20**. The reason for this is not certain but may be due to the fact that these reagents were stored for a length of time prior to their reaction, whereas freshly prepared **12** and **20** were used

[5] The spectrophotometric method of determining the number of chelates per antibody using Arsenzo III (*1*) was not employed to conserve the antibody conjugate for radiolabeling studies. Although the average number of chelates per mAb was not determined, IEF showed the extent of substitution from the conjugation reactions.

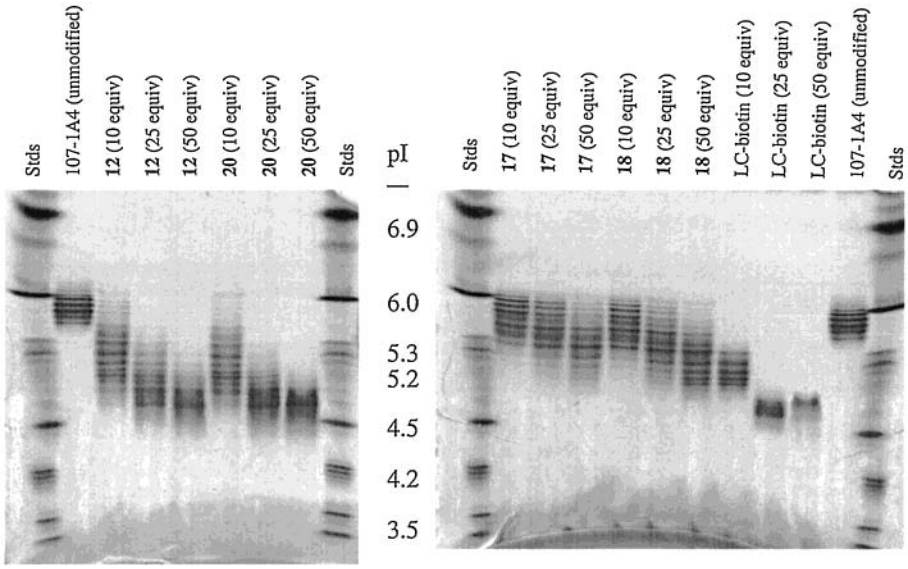

Figure 1. Digitized scans of to IEF gels that compare the pI of the anti-PSMA mAb and conjugates formed from reaction with 10, 25, or 50 equiv of (a) the trifunctional reagents **12** (CHX-A″) and **20** (DOTA), (b) the bifunctional chelating reagents **17** (CHX-A″) and **18** (DOTA), and (c) NHS-LC-biotin. The samples are identified above the lanes in the gel. IEF standards (stds) are identified in the Materials and Methods section.

in the conjugation reactions. Conjugation of the NHS-LC-biotin resulted in much higher substitution than that observed for the other reagents studied, presumably due to the higher reactivity of the N-hydroxysuccinimide ester.

Radiolabeling. The mAb conjugates were radiolabeled with ^{125}I, ^{111}In, and ^{90}Y. The purpose of radioiodination was to permit evaluation of the effect conjugation and radiolabeling had on the cell binding (immunoreactivity). In addition, the radioiodination yields were of interest in conjugates that are prepared from isothiocyanates. We have observed that radioiodination yields of compounds, including proteins, are dramatically decreased in compounds containing thiourea bonds (*34*). The standard Chloramine-T radioiodination method was used in the radioiodinations. The yields obtained for radioiodination reactions are shown in column 4 of Table 1. Radioiodination yields of 75−85% were obtained for unmodified A6H and 107-1A4. Radioiodination of the 107-1A4 that has up to 10 biotin per mAb were within the range of yields for unmodified mAb. However, there is a significant decrease in the radioiodination yields with increasing numbers of the conjugates **12**, **18**, and **20**. The decrease in radioiodination yield for conjugates prepared from reaction of 50 equiv of **18** is considerably larger than that observed for the conjugate formed from reaction of 50 equiv of **17** (32% vs 73%). Careful inspection of the IEF gel for these conjugates (Figure 1) shows that there is a higher degree of conjugation with **18** than with **17**, making the difference in radioiodination yields consistent with the other results. Importantly, the striking difference in radioiodination yields between those obtained with an active ester reaction and those obtained from an isothiocyanate reaction appear to further support the observation that thiourea bonds interfere with radioiodination reactions.

Several ^{111}In and ^{90}Y radiolabeling experiments were conducted using A6H conjugated with 2.9 conjugates of **8** per mAb. The labeling reactions were complete within 5 min at room temperature. Isolated purified radiolabeling yields of 74−90% were obtained with ^{111}In, and 84% and 97% were obtained with ^{90}Y. To ensure that the radiolabel was in the chelate and not associated with other functional groups on the protein, we added 10 mM DTPA to the reaction mixtures prior to purification by size exclusion chromatography. Additionally, labeling experiments with A6H that was not modified were conducted with ^{111}In and ^{90}Y, and only 2−8% of the radioactivity came out in the protein fraction when purified by size exclusion chromatography, indicating that the chelation groups were required for radiolabeling.

All ^{111}In and ^{90}Y labeling reactions of 107-1A4 conjugates were conducted at 45 °C rather than room temperature, as the higher temperature is required for efficient ^{90}Y labeling with the DOTA chelate. Although conjugates containing CHX-A″ will label at room temperature, the elevated temperature was used so that the mAb conjugates were treated in the same manner for comparison of immunoreactivities. The CHX-A″ conjugates (**12** and **17**) provided very good (91−100%) radiolabeling yields; however, the yields were significantly lower (36−79%) for the DOTA conjugates (**18** and **20**) under the reaction conditions employed. Importantly, attempts to radiolabel demetalated unmodified 107-1A4 with ^{111}In and ^{90}Y under the same reaction conditions proved that the labeling occurred specifically on the chelates as <3% of counts were found in fractions from size exclusion chromatography containing protein when no chelate was present. More recently, studies involving another mAb conjugated with **20** have provided radiochemical yields of >80% for both ^{111}In and ^{90}Y using 500 mM ammonium acetate as the radiolabeling buffer [unreported results].

Cell Binding Assessment. The effect of the number of conjugates per mAb on antigen binding was assessed in a radiolabeled mAb cell binding assay. In the assay, radiolabeled 107-1A4, or one of its conjugates, was incubated at room temperature with LNCaP human prostate carcinoma cells for 1h, and then the cells were separated from supernatant by centrifugation. The assay was run with excess antigen so that all antibody could bind. The percent cell binding for the radiolabeled conjugates is provided in columns 7−9 of Table 1. The data for radioiodinated 107-1A4 conjugates (column 7) clearly show that immunoreactivity decreases with increasing number of conjugates. As might be expected, the

highest level of substitution resulted in complete loss of cell binding. It is interesting to note that the mAb with six LC-biotin moieties had essentially the same cell binding properties as those that had 2−3 conjugates of **12** or **18**. Due to the differences observed in sensitivities of mAbs to radiolabeling and substitution, it should be emphasized that the results obtained with 107-1A4 shown in Table 1 may not be predictive of other antibodies. However, the trend of higher substitution causing diminished binding is consistent with all antibodies.

Stability of ^{90}Y label. An experiment was conducted to determine if ^{90}Y remained stably bound when 107-1A4 conjugated with **12** or **20** was incubated in serum or in the presence of chelates. In the experiment, the ^{90}Y-labeled 107-1A4 conjugates in 0.9% saline were incubated with serum (37 °C), 10 mM EDTA (rt), or 10 mM DTPA (rt) for 1 h. Approximately 10% of the activity dissociated from the labeled mAb when challenged with DTPA or EDTA. This is not surprising, as the concentration of these chelates was in large excess, and one might expect a transchelation process to occur to some extent. No dissociation was noted in normal saline, and only 3−5% dissociated in serum (at 37 °C) in the same time period. These data indicate that the label is very stably attached.

Avidin Column Binding. Specific binding of ^{111}In- or ^{90}Y-labeled A6H and 107-1A4 conjugates was determined by passing a solution of the radiolabeled antibody over a small avidin column. Nonspecific binding to the avidin column was determined in the same manner, except that the radiolabeled mAb solution contained a large excess of biotin. To diminish nonspecific binding to the column, BSA was added to the radiolabeled mAb solution. In an initial evaluation, avidin column binding of ^{111}In- and ^{90}Y-labeled A6H was assessed. Both labeled mAb preparations achieved 88−89% column binding. The nonspecific binding was high (9−10%), but that was attributed to the fact that only 0.1% BSA was used. The low BSA quantity was used, as there was a concern for the presence of biotin in the BSA. Higher percentages of avidin column binding was obtained for ^{111}In and ^{90}Y-labeled 107-1A4 conjugated with either **12** or **20.** In the later experiments, 1% BSA was used to diminish nonspecific binding. Although it may not have been the only influencing factor, the increased BSA concentration resulted in a much lower nonspecific binding (e.g., 1% or less). It is important to note that the avidin column binding experiments for the two different radiolabeled mAbs were conducted some time apart and agarose from different sources were used. We believe that this may have contributed to the differences observed in specific column binding.

DISCUSSION

Radiolabeled mAbs have not proven to be the "magic bullets" that they were once hoped to be. Although many clinical studies have been conducted with radiolabeled mAbs, problems associated with low tumor concentrations, heterogeneous deposition in tumors, and unacceptably high bone marrow and normal organ toxicity, have kept radiolabeled mAbs from being an effective treatment for cancer (*35*−*38*). A significant contributor to these problems is the long residence time of the radiolabeled antibody in blood. This fact has led investigators to evaluate other approaches for systemic delivery of radionuclides to cancer cells, such as those termed "pretargeting". Alternatively, development of a clinical method that can remove radiolabeled mAbs from blood after a period of sufficient time for tumor deposition could potentially result in an effective therapy for some types of cancers. This approach would allow administration of much higher quantities of radiolabeled antibodies, which in turn could result in higher tumor concentrations and a more homogeneous distribution of the radionuclide. Of course, it is important that the approach used to remove the radiolabeled mAbs from blood does not result in their deposition in organs or tissues of the body. Such an approach, termed extracorporeal affinity-adsorption (EAA), which removes radiolabeled mAbs from blood by passing it through a device external to the body, is under investigation (*14*, *39*, *40*).

As the EAA name implies, removal of the radiolabeled mAb from blood is achieved by conjugation of the antibody with a moiety that has an affinity for (binds with) a component in the device. While a number of affinity adsorbents could be used in such a device, the biotin/avidin binding pair was chosen because of their very high binding affinity and specificity (*41*). Thus, the EAA approach under investigation uses a high-capacity, high-flow-rate avidin column to capture biotinylated-radiolabeled mAbs as the blood is circulated through it. Although endogenous biotin can bind with the column, the amount present in blood of patients (e.g., 215−750 pg/mL; *42*), or released from liver stores during the procedure, can be offset by having a large excess of avidin on the column. The large quantity of avidin also helps to compensate for the requisite high flow rate. Preclinical studies have been conducted to determine the efficacy and safety of the EAA approach. In animal models, 80−95% of radioactivity in blood, and around about 50% of the radioactivity in the whole body, was removed from athymic rats bearing murine and human tumor xenografts (*15*, *39*, *43*, *44*). The removal of radiolabeled antibody from blood was accomplished with little effect on the radioactivity in the tumor, and no observable toxicity. Ex vivo studies have also shown good biocompatibility of avidin columns with perfused human whole blood (*45*).
