Conjugation of Various Acridines to DNA for Site-Selective RNA Scission by Lanthanide Ion

Akinori Kuzuya, Kenzo Machida, Ryo Mizoguchi, and Makoto Komiyama*

Research Center for Advanced Science and Technology, The University of Tokyo, 4-6-1 Komaba, Meguro, Tokyo, 153-8904 Japan. Received October 30, 2001; Revised Manuscript Received December 10, 2001

Three types of DNA conjugates having 9-acridinecarboxamide, 9-aminoacridine, and 9-amino-6-chloro-2-methoxyacridine at the 5′-ends were synthesized and used for site-selective RNA scission together with another unmodified DNA and Lu(III) ion. The target phosphodiester linkages in the substrate RNA were selectively and efficiently activated and were hydrolyzed by free Lu(III) ion. The conjugate bearing 9-amino-6-chloro-2-methoxyacridine was the most active. However, its duplex with the substrate RNA was almost as stable as that of the 9-aminoacridine-bearing conjugate, which was much less active for the RNA activation. The 9-acridinecarboxamide-bearing conjugate was only marginally active. The substituents on the acridine groups in these conjugates positively participate in the present RNA activation, probably by fixing the orientation of the acridine rings.

INTRODUCTION

To date, various conjugates of oligonucleotides with intercalating agents have been prepared mainly because of their attractive potentials for biological applications (e.g., antisense technology and antigene technology) (*1*). Acridine is one of the most popularly studied intercalating agents (*2*−*4*).

Recently, we have found a unique function of the DNA conjugates, which bear 9-amino-6-chloro-2-methoxyacridine, in RNA scission (*5*, *6*). When these conjugates form heteroduplex with RNA, specific phosphodiester linkages in the RNA are efficiently activated and thus are selectively hydrolyzed by lanthanide ions (see Figure 1). It is noteworthy that these metal ions are never covalently bound anywhere and are freely moving around in the solutions. The intercalation of the acridine (as well as the resulting conformational change of RNA) is the key for this RNA activation, although the mechanistic details have not yet been sufficiently clarified.

In this study, we have synthesized three acridine−DNA conjugates to understand the roles of the substituents on the acridine groups for the RNA activation. The DNAs in these conjugates are complementary with the 5′-side portion of the substrate RNA and have different acridine moieties (i.e., 9-acridinecarboxamide, 9-aminoacridine, and 9-amino-6-chloro-2-methoxyacridine) at the 5′-ends (**2a**−**c** in Scheme 1). For site-selective RNA scission, they are combined with another unmodified DNA **3**, which is complementary with the remaining portion of the RNA, and Lu(III) ion. The melting temperatures of the corresponding DNA/RNA heteroduplexes are presented.

EXPERIMENTAL PROCEDURES

^{1}H NMR spectra were obtained on a JEOL JNM-A500 spectrometer. MALDI- and LI-TOF mass spectra were measured on a KRATOS Kompact MALDI 2 TOF-MS spectrometer. For sonic spray ionization (SSI) mass spectroscopy, a HITACHI M-8000 LC/3DQMS mass spectrometer was used.

reaction, the solution was filtered and evaporated to dryness under reduced pressure. Washing with dilute HCl (50 mL) and ethyl acetate (50 mL) gave 0.92 g of **4** (67% yield) as white-yellow powder. TLC $R_f = 0.20$, 10:1 CH_2Cl_2/MeOH; ^{1}H NMR (DMSO-d_6) δ 9.00 (t, 1H, NH), 8.18 (d, 2H), 7.98 (d, 2H), 7.87 (t, 2H), 7.67 (t, 2H), 4.39 (t, 0.6H, OH), 3.49 (m, 0.5H), 3.44 (m, 1.5H), 3.33−3.25 (2H), 1.66 (m, 2H), 1.51−1.44 (m, 4H). MS (LI): *m*/*z* 309.1 (M + H).

Phosphoramidite Monomer 5. To a solution of **4** (0.30 g, 0.96 mmol) and 2-cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite (0.32 g, 1.1 mmol) in anhydrous DMF (6 mL) on ice was slowly added 1*H*-tetrazole (0.073 g, 1.1 mmol) in anhydrous DMF (6 mL) under nitrogen, and the mixture was stirred for 1 h at room temperature. After the solvent was removed, ethyl acetate (30 mL) was poured, and the organic layer was washed with saturated aqueous $NaHCO_3$ (10 mL × 2) and with brine (10 mL). This layer was dried over anhydrous Na_2SO_4 and concentrated under reduced pressure to afford 0.46 g of **5** (94% yield). This product was dissolved in anhydrous acetonitrile (0.5 M) and used for automated DNA synthesis without further purification. TLC $R_f = 0.71$, 10:1 CH_2Cl_2/MeOH. MS (SSI): *m*/*z* 509 (M + H), 531 (M + Na), 548 (M + K).

9-Phenoxyacridine (7). *N*-Phenylanthranilic acid (1.85 g, 8.7 mmol) and phosphoryl chloride (10 g, 65 mmol) were slowly heated to 90 °C (for 15 min) and then to 140 °C. After 2 h, excess phosphoryl chloride was evaporated, and chloroform (10 mL) was added to the residue. The mixture was poured into concentrated aqueous NH_3 (10 mL) containing crushed ice (25 g). When the solids disappeared, the aqueous layer was extracted twice with chloroform (20 mL), and the combined organic layer was dried over anhydrous Na_2SO_4, filtered, and evaporated to dryness. To the resultant 9-chloroacridine (**6** in Scheme 3), phenol (9.4 g) was added, and the mixture was stirred at 70 °C for 12 h (Scheme 4). Aqueous NaOH (2 N) was added dropwise to neutralize the solution, which was extracted with chloroform (50 mL × 3). The organic layer was dried with anhydrous Na_2SO_4 and concentrated under reduced pressure. The product was purified by silica gel column chromatography ($CHCl_3$) to afford 2.1 g of **7** (89% yield). TLC $R_f = 0.35$; ^{1}H NMR (DMSO-d_6) δ 8.23 (d, 2H), 8.04 (d, 2H), 7.88 (t, 2H), 7.59 (t, 2H), 7.32 (t, 2H), 7.08 (t, 1H), 6.88 (d, 2H). MS (LI): *m*/*z* 272.1 (M + H).

6-Chloro-9-(*p*-chlorophenoxy)-2-methoxyacridine (8). A mixture of 6,9-dichloro-2-methoxyacridine (1.39 g, 5.0 mmol) and *p*-chlorophenol (6.43 g, 50 mmol) was stirred at 100 °C for 12 h (Scheme 4). The solution was neutralized with aqueous NaOH (2 N). Resulting yellow precipitates were filtered, washed with large portions of water, and dried at 80 °C in vacuo (98% yield). ^{1}H NMR (DMSO-d_6) δ 8.31 (s, 1H), 8.19 (d, 1H), 8.03 (d, 1H), 7.66 (m, 2H), 7.43 (d, 2H), 7.22 (d, 2H), 7.21 (s, 1H), 7.01 (d, 2H), 6.82 (d, 2H), 3.86 (s, 3H, OMe). MS (LI): *m*/*z* 370.0 (M + H).

Preparation of Oligonucleotides. All the oligonucleotides were synthesized on an ABI 394 DNA synthesizer in 1 μmol scale. For the synthesis of **2b**, phenoxyacetyl (Pac)-protected dA, 4-isopropylphenoxyacetyl (^{i}Pr-Pac)-protected dG, and acetyl (Ac)-protected dC (from Glen Research Co.) were used. An extended coupling time of 10 min was adopted for the coupling of **5**. Unmodified DNA **2d** and **3** were synthesized with standard monomers.

Attachment of 9-Phenoxyacridine or 6-Chloro-9-(*p*-chlorophenoxy)-2-methoxyacridine to DNA. In the final coupling cycle for the synthesis of **2d**, an aminolinker C6, protected with a monomethoxytrityl (MMTr) group, was attached. The CPG column was removed from the synthesizer, and the MMTr group was taken off by passing 3% trichloroacetic acid in CH_2Cl_2 through the column with two glass syringes. The column was washed with CH_2Cl_2 (1 mL × 3) and filled with 1 M solution of **7** in DMF or **8** in THF (1 mL). After incubating the column at 60 °C for 4 h and at room-temperature overnight, it was washed with DMF (or THF: 1 mL × 3) and CH_2Cl_2 (1 mL × 3). The conjugates **2b** and **2c** were detached from the support and deprotected with 0.4 M methanolic NaOH (4:1 MeOH/H_2O) at room temperature for 16 h (*4*).

Purification and Characterization of the Acridine−DNA Conjugates. The oligonucleotides were purified by Poly-PaK II cartridges (Glen Research Co.) and then by a reversed-phase HPLC equipped with an RP−C18 column (Cica-Merck LiChroCART 125−4; a linear gradient of 5−25% acetonitrile in 50 mM ammonium formate over 20 min; flow rate 0.5 mL/min). They were characterized by mass spectroscopy in the negative ion mode (Table 1). Their base compositions were confirmed by the HPLC analyses on the digests with snake venom phosphodiesterase and alkaline phosphatase.

RNA Cleavage Assay. The substrate RNA **1** (5′-end ^{32}P-labeled with γ-^{32}P-ATP and T4 kinase, 1 μM), modified or unmodified DNA **2a**−**d** (10 μM), and another unmodified DNA **3** (10 μM) were dissolved in pH 8 Tris-HCl buffer (10 mM) containing 200 mM NaCl. The mixture was heated to 90 °C (for 1 min) and slowly cooled to room temperature. Then 1/10 volume of aqueous solution of $LuCl_3$ was added to the mixture (the final

concentration of Lu(III) was 100 μM). After 3 h at 37 °C, the reaction was quenched by 100 mM EDTA-2Na solution and analyzed on 20% denaturing PAGE. Imaging and quantification of RNA cleavage were carried out on a Fuji film FLA-3000G fluorescent imaging analyzer.

Measurement of Melting Temperature (T_m). The melting profiles of the duplexes were obtained on a JASCO V-530 spectrometer at 260 nm in a quartz cell of 1 cm path length. The specimens contained **2a**–**d** (1 μM), substrate RNA **1** (1 μM), and NaCl (200 mM) in pH 8 Tris-HCl buffer (10 mM). The heating rate was 1.0 °C/min.

RESULTS AND DISCUSSION

Syntheses of Acridine–DNA Conjugates (2a–c in Scheme 1). Three different types of DNA conjugates having an acridine at the 5′-end were synthesized in two strategies. The conjugate **2a** with 9-acridinecarboxamide was prepared using phosphoramidite chemistry, whereas 9-aminoacridine and 9-amino-6-chloro-2-methoxyacridine were directly attached to the end of DNA oligomer via an amino-linker (**2b** and **2c**).

The phosphoramidite monomer **5** bearing 9-acridinecarboxamide was synthesized as outlined in Scheme 2. 9-Acridinecarboxylic acid was condensed with 5-amino-1-pentanol, and the functionalized acridine **4** was then converted to **5** with 2-cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite. When this phosphoramidite monomer **5** was used for automated DNA synthesis together with the standard phosphoramidite monomers, however, the yield for the desired product **2a** was unexpectedly low. Probably the amide bond between the acridine and the linker arm was hydrolyzed under the deprotection conditions (concentrated aqueous NH_3, 55 °C, 6 h). In this study, this problem was successfully avoided by using Pac-dA, ^{i}Pr-Pac-dG, and Ac-dC, which can be deprotected under far milder conditions (room temperature, 2 h). Note that the linker length in **2a** is identical with that for other acridine–DNA conjugates **2b** and **2c**.

The HPLC chart of the purified product showed two peaks (**A** and **B** in Figure 2). The peak **A** was separated and analyzed by the HPLC. Interestingly, both the peaks **A** and **B** were observed again, and their relative intensities were the same as those in Figure 2. Similar results were obtained when the peak **B** was collected and analyzed. Furthermore, the mass spectroscopy on these two specimens gave the same molecular weights, which were in good agreement with the calculated mass of **2a** (*m*/*z* = 5801: Figure 3). Thus, we concluded that these peaks correspond to the two isomers of **2a**, which rapidly interconvert each other under ambient conditions. Probably, cis–trans isomerization of the amide bond is responsible for this isomerization.

The acridine–DNA conjugates bearing 9-aminoacridine or 9-amino-6-chloro-2-methoxyacridine (**2b** and **2c**) were prepared through 9-phenoxyacridine or 6-chloro-9-(*p*-chlorophenoxy)-2-methoxyacridine (**7** and **8**). *N*-Phenylanthranilic acid was reacted with phosphoryl chloride to afford 9-chloroacridine **6** (Scheme 3), which was converted to **7** with phenol (Scheme 4). From 6,9-dichloro-2-methoxyacridine as the starting material, **8** was synthesized in the same fashion. The DNA portion in **2b** and **2c** was prepared by using the synthesizer and an amino-linker was attached to its 5′-end. Then the CPG column was directly treated with **7** or **8**. With this simple method, the yield and purity of **2b** and **2c** were satisfactorily high. Both the observed molecular weights and the base compositions fairly agree with the calculated values (Table 1). Their structures have been concretely confirmed. The HPLC of the purified **2b** and **2c** showed a single peak (data not shown). In contrast with **2a**, these conjugates involve no amide linkages which can show cis–trans isomerization (vide ante).

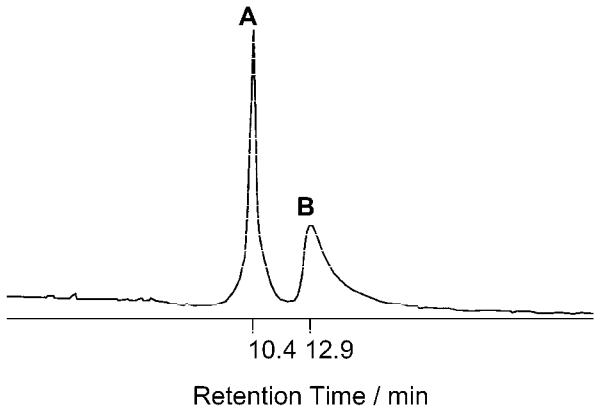

Figure 2. HPLC chart of purified **2a** monitored at λ = 260 nm.

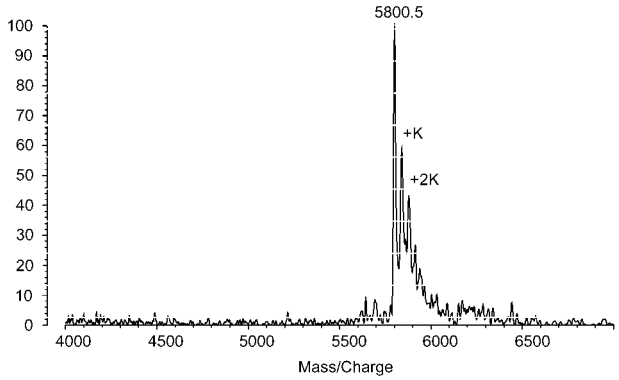

Figure 3. MALDI-TOF mass spectrum of the species for the peak A in Figure 1. Observed molecular weight of the species in the peak B was 5801.2.

Site-Selective RNA Scission Using the Acridine–DNA Conjugates. RNA cleavage assay was performed by combining **2a**–**d**, **3**, and the 36mer RNA **1** as the substrate in the presence of Lu(III) as cocatalyst (see Scheme 1). The results of PAGE analysis are presented in Figure 4. In the absence of the oligonucleotides (with only Lu(III)), RNA is cleaved randomly throughout the strand (lane 1). Lu(III) ion itself has no sequence-selectivity for RNA scission. When RNA is hybridized with the combination of the unmodified DNAs **2d** and **3**, RNA is cleaved at the 5′-sides of G-20, U-19, and C-18 (lane 2). However, the scission efficiencies are rather low. Here, all the nucleotides in the RNA, except for U-19, are forming base pairs with the DNAs.

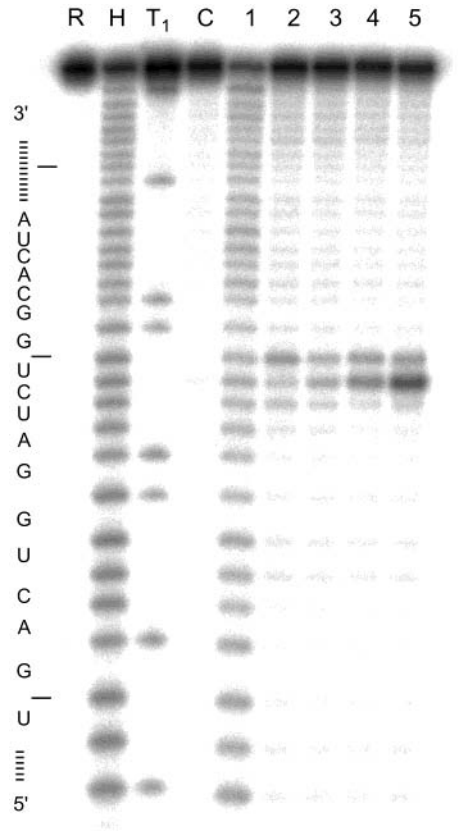

Figure 4. Site-selective scission of RNA **1** by the combinations of **2a**−**d**, **3**, and Lu(III) at 37 °C and pH 8 in 3 h. Lane 1, treatment with Lu(III) alone; lane 2, **2d** + **3** + Lu(III); lane 3, **2a** + **3** + Lu(III); lane 4, **2b** + **3** + Lu(III); lane 5, **2c** + **3** + Lu(III). In lane 1, the DNA, which has the same sequence as **1**, is added to make the phosphate concentration identical with that in lanes 2−5. R, no treatment of **1**; H, alkaline hydrolysis; T_1, RNase T_1 digestion; C, control (**1** was treated under the designated conditions, in the absence of Lu(III) and any DNA).

Quite significantly, the cleavage at U-19 is enormously accelerated when the acridine−DNA conjugate **2c** is used in place of **2d** (lane 5). Band intensity of the cleavage at U-19 in lane 5 (obtained with **2c)** is about 15 times as large as that in lane 2 (with **2d**), and 10 times as large as that of the random cleavage by Lu(III) in lane 1. The cleavage conversions for **2a**−**d** (together with **3** and Lu(III)), evaluated from Figure 4, are graphically presented in Figure 5. The target phosphodiester linkage in the RNA is greatly activated by the 9-amino-6-chloro-2-methoxyacridine in **2c** and is promptly hydrolyzed. Similarly, the 9-aminoacridine in **2b** also site-selectively activates the RNA (lane 4), although the effect is moderate. The scission rate by the **2b** + **3** + Lu(III) combination is about 40% of the value by the **2c** + **3** + Lu(III) combination. In contrast with the notable and site-specific RNA activation by these two conjugates, the DNA modified with 9-acridinecarboxamide (**2a**) scarcely activates the RNA (lane 3). The magnitude of the RNA activation is as follows: **2c** > **2b** ≫ **2d** ≈ **2a**.

When **1** is hybridized only with **2c** (in the absence of the second unmodified DNA **3**), the single-stranded portion of this RNA substrate is uniformly cleaved by Lu(III) ion (*5*). It is noteworthy that, without **3**, the scission at the target site is never accelerated by **2c**. Both **2c** and **3** are essential for the present RNA activation and its site-selective scission. In the ternary heteroduplex composed of **1**, **2c**, and **3**, the acridine is sandwiched between the neighboring two-base pairs (the CG and the GC pairs in this case). As the result, the RNA-base in front of the acridine (U-19) is partially pushed out, and the conformation of phosphate backbone is changed. The attacking 2′ OH is brought closer to the P-atom of scissile phosphate, and the intramolecular reaction is facilitated. The second DNA strand **3** is necessary for the acridine to interact efficiently with the RNA and to induce a sufficient conformational change. This argument is consistent with the finding that binding of two short DNAs to a long DNA is promoted by stacking interaction between the two base pairs which are located at the junction of these two short DNAs (*7*).

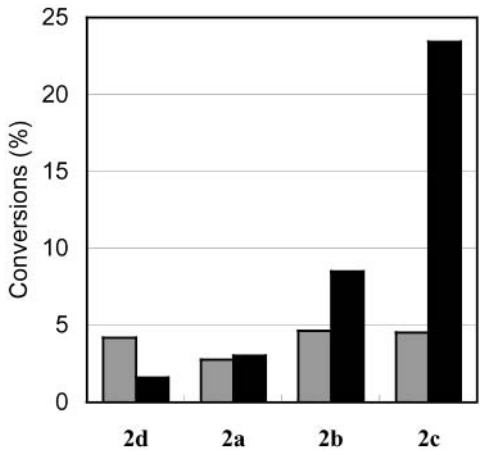

Figure 5. Conversions of the site-selective cleavages of **1** at G-20 and U-19 in 3 h. The hatched bars and the filled ones are for the cleavages at the 5′-sides of G-20 and U-19, respectively.

Thermodynamic Properties. To evaluate the strength of the interaction between the acridine and the RNA, T_m values of heteroduplexes of **1** with **2a**−**d** were measured (Table 1). All the acridines in the conjugates stabilize the duplex. The stabilizing effects of the 9-amino-6-chloro-2-methoxyacridine in **2c** and the 9-aminoacridine in **2b** are similar to each other ($\Delta T_m \approx 6$ °C). The 9-acridinecarboxamide in **2a** induces a smaller effect ($\Delta T_m = 2.9$ °C). In the reaction mixtures (pH 8), the major species of the 9-aminoacridine in **2b** and the 9-amino-6-chloro-2-methoxyacridine in **2c** are the corresponding cations (the pK_a value for 9-aminoacridine is 9.6 and that for 9-amino-6-chloro-2-methoxyacridine is 8.5 (*8*)). On the other hand, the 9-acridinecarboxamide in **2a** exists mostly as neutral species (the pK_a of methyl 9-acridinecarboxylate is 3.2 (*8*)). Relatively large duplex-stabilizing effects of the acridines in **2b** and **2c** are ascribed to their positive charges. Although the duplex-stabilizing effects of these acridines are similar, their RNA-activating capacities are significantly different from each other. Notable roles of both 6-chloro and 2-methoxy groups in **2c** are indicated. These bulky substituents orient the acridine on the intercalation, and probably this promotes the RNA activation. The positive charge on the acridine ring further assists this process. Interestingly, the order of the RNA activation (**2c** > **2b** ≫ **2d** ≈ **2a**) is the same as the order of antibacterial activities of these substituted acridines against some organisms (*8*). Importance of the acridine−RNA interaction for the present RNA activation is further supported.

In most of previously reported ribozyme-mimics, inorganic (*9*−*14*) or organic (*15*−*19*) catalysts were bound to oligonucleotides which are complementary with substrate RNA and localized near the target site. On the other hand, the present strategy utilizes site-selective RNA activation by noncovalent interactions with acridine−

DNA conjugates and has many advantages over these mimics. First, the fixation of catalysts to DNA oligomers, which often diminishes the catalytic abilities, is unnecessary. Second, various catalysts are easily applicable, since the systems are very simple.

Effects of Coligand Variation on the In Vivo Characteristics of Tc-99m-Labeled Interleukin-8 in Detection of Infection

Huub J. J. M. Rennen,* Julliëtte E. van Eerd, Wim J. G. Oyen, Frans H. M. Corstens, D. Scott Edwards,† and Otto C. Boerman

Department of Nuclear Medicine, University Medical Center Nijmegen, Nijmegen, The Netherlands. Received November 22, 2001

In our previous studies, interleukin-8 (IL-8) was labeled with ^{99m}Tc using hydrazinonicotinamide (HYNIC) as bifunctional coupling agent and tricine as coligand. This preparation showed excellent characteristics for imaging of infection in a rabbit model of soft-tissue infection. In the present study, the propylaldehyde hydrazone formulation of HYNIC was introduced to stabilize HYNIC−IL-8. ^{99m}Tc−HYNIC−IL-8 was prepared using 5 different coligand formulations. The effect of these coligand formulations on the in vitro characteristics and in vivo behavior of ^{99m}Tc−HYNIC−IL-8 was investigated. HYNIC-conjugated IL-8 was labeled with ^{99m}Tc in the presence of either (A) tricine, (B) ethylenediaminediacetic acid (EDDA), (C) tricine and trisodium triphenylphosphinetrisulfonate (TPPTS), (D) tricine and nicotinic acid (NIC), or (E) tricine and isonicotinic acid (ISONIC). These preparations were characterized in vitro by RP-HPLC, determination of the octanol/water partition coefficient, stability studies, and receptor binding assays. The in vivo biodistribution of the radiolabel in rabbits with *E. coli*-induced soft-tissue infection was determined both by γ-camera imaging as well as by tissue counting at 6 h pi. Specific activity (MBq/μg) was highest for (ISO)NIC (up to 80) > TPPTS (40) > tricine (15) > EDDA (7). RP-HPLC and octanol/water partition coefficients showed a shift toward higher lipophilicity for the TPPTS preparation. The leukocyte receptor binding fractions were around 40−55% for all preparations except for TPPTS, which showed predominantly nonspecific binding. All preparations were stabilized in serum, but the stability in PBS was highest for NIC and TPPTS > EDDA > ISONIC > tricine. The in vivo biodistribution showed highest abscess/muscle for NIC and ISONIC (>200) > EDDA and tricine (∼100) > TPPTS (<40). Gamma camera imaging rapidly visualized the abscess from 2 h pi onward for all formulations. The abscess/background (A/B) at 6 h pi for ISONIC was significantly higher ($P < 0.05$) than that of tricine and the A/B of TPPTS was significantly lower ($P < 0.05$). IL-8 can be rapidly and easily labeled with ^{99m}Tc using HYNIC as a chelator in combination with various coligands. The most optimal infection imaging characteristics were found for formulations using nicotinic acid/tricine as coligand system combining a high specific activity and high in vitro stability with high abscess/muscle ratios (>200) and high abscess/background ratios (>20). Protein doses to be administered were as low as 70 ng/kg bodyweight. At these low protein doses, side effects are not to be expected in the human system. This paves the way for infection imaging studies in patients.

INTRODUCTION

Scintigraphic imaging of infectious and noninfectious inflammation is a powerful diagnostic tool in the management of patients with inflammatory disorders. Most inflammatory foci can be visualized accurately with ex vivo radiolabeled autologous leukocytes. However, preparation of this radiopharmaceutical is laborious and requires the handling of potentially contaminated blood with inherent risks for both personnel and patients.

There is an ongoing search for radiolabeling small molecules that bind to circulating leukocytes (in vivo labeling of leukocytes) after the relatively poor results obtained with large size monoclonal antibodies directed against leukocytes. These small molecules include chemotactic peptides (analogues of formyl-Met-Leu-Phe) and cytokines (e.g., the interleukins, platelet factor 4 derivatives) (for a review, see ref 1). We have actively pursued a research program to explore the potential of radiolabeled formyl-Met-Leu-Phe-Lys, interleukin-1, interleukin-8, and other cytokines for imaging inflammation.

Radiolabeled interleukin-8 (IL-8) proved to be the most promising candidate so far. IL-8 is a member of the CXC subfamily of chemokines, or chemotactic cytokines, in which the first two cysteine residues are separated by one amino acid residue. This cytokine binds the CXC type I (= IL-8 type A) and CXC type II (= IL-8 type B) receptors expressed on neutrophils and monocytes with high affinity (0.3−4 nM) (*2*, *3*). Hay and colleagues (*4*) studied the in vivo behavior of radioiodinated IL-8 in a rat model with carrageenan-induced sterile inflammations and found only modest target-to-background ratios of 2.5. In a pilot study in eight patients these investigators showed that a ^{123}I−IL-8 could visualize inflammatory foci (*5*).

We investigated the in vivo behavior of radiolabeled IL-8 in various models of infection and sterile inflammation in rabbits (*6*−*10*). Studies with ^{123}I-labeled IL-8

in rabbits with focal *E. coli* infection showed rapid accumulation of the radiopharmaceutical in the abscess (*6*, *7*). Abscess-to-contralateral muscle ratios exceeded 100 in this model within 8 h postinjection. A drawback of this preparation was its relatively low specific activity; the imaging dose of ^{123}I−IL-8 (25 μg/kg) caused a transient drop of peripheral leukocyte counts to 45%, followed by a leukocytosis (170% of preinjection level) during several hours. Moreover, ^{123}I is not a very suitable radionuclide for clinical imaging: it is expensive and the Bolton−Hunter labeling method used for preparing ^{123}I-labeled IL-8 is rather laborious.

For clinical application, a simple and rapid labeling procedure of IL-8, using the radionuclide ^{99m}Tc, is preferable. ^{99m}Tc combines highly favorable physical characteristics ($t_{1/2}$ = 6 h, E_{max} = 140 keV) with easy availability and low cost. In a subsequent study, IL-8 was labeled with ^{99m}Tc using hydrazinonicotinamide (HYNIC) as bifunctional coupling agent (*8*). HYNIC has been introduced by Abrams and co-workers (*11*) for labeling polyclonal IgG with ^{99m}Tc to image infections. Since the HYNIC group can only occupy one or two coordination sites in the technetium coordination sphere, an additional coligand is required. For labeling HYNIC conjugated IL-8 with ^{99m}Tc tricine was chosen as coligand, because specific activities obtained with this coligand are much higher than with, for example, glucoheptonate (*12*). The specific activity of the ^{99m}Tc-labeled IL-8 preparation was found to be 25× higher than the specific activity of the ^{123}I-labeled IL-8 preparation. In rabbits with *E. coli*-induced softtissue infection abscess to contralateral muscle ratios and abscess-to-blood ratios obtained with the ^{99m}Tc- and the ^{123}I-labeled preparation were similar. Preparing ^{99m}Tc-labeled IL-8 is easy and fast, offering a major advantage over the radioiodination procedure.

The aim of the present study was to improve the characteristics for imaging infection of a ^{99m}Tc-labeled IL-8 preparation together with a further increase in specific activity of the preparation, thus reducing the required IL-8 protein dose. Two aspects of the labeling procedure were further optimized.

First, a modified form of HYNIC was synthesized. To improve long-term stability Schwartz and co-workers introduced the use of a propylaldehyde hydrazone formulation to stabilize HYNIC-modified proteins (*13*, *14*). This protection of the hydrazine moiety of HYNIC ensures greater stability in aqueous solutions, and the hydrazone retains the capacity to produce enough free hydrazine for successful labeling with ^{99m}Tc.

Second, different coligand formulations were adopted in labeling HYNIC conjugated IL-8 with ^{99m}Tc. Babich and Fischman (*15*) were the first to show that the nature of the coligand has a distinctive influence on the biologic properties of the radioconjugate. Liu and Edwards et al. have performed systematic studies on labeling a HYNIC-conjugated platelet glycoprotein receptor antagonist with ^{99m}Tc using various coligand formulations: tricine; ethylenediaminediacetic acid (EDDA) (*16*); tricine in combination with water soluble phosphines (*17*); tricine in combination with imine-N-containing heterocycles (*18*).

In the present study HYNIC conjugated IL-8 was labeled with ^{99m}Tc using five different coligand systems: (i) tricine; (ii) EDDA; (iii) tricine in combination with trisodium triphenylphosphine-3,3′,3″-trisulfonate (TPPTS); (iv) tricine in combination with nicotinic acid; and (v) tricine in combination with isonicotinic acid (see Figure 1). The proposed structures (*16*−*18*) of the resulting binary technetium complexes [^{99m}Tc(IL-8−HYNIC)(tricine)$_2$] and [^{99m}Tc(IL-8−HYNIC)(EDDA)] and ternary

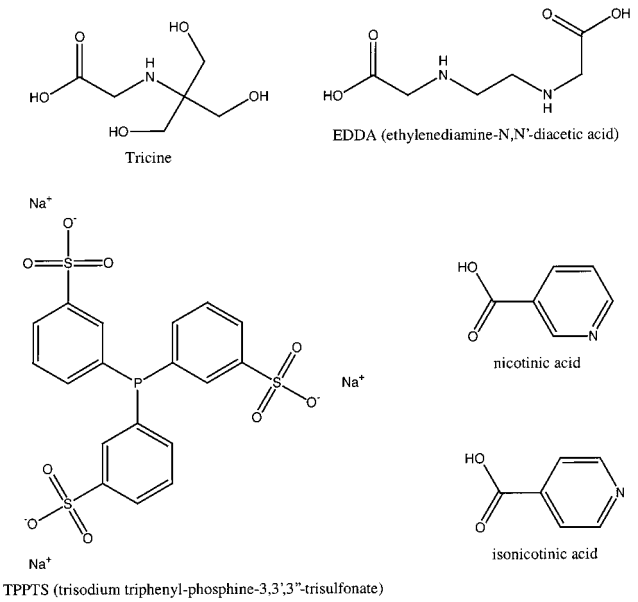

Figure 1. Structures of coligands used in this study.

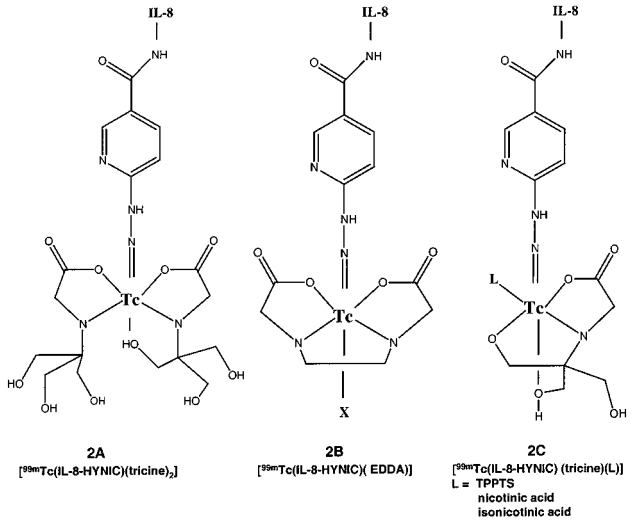

Figure 2. Binary technetium complexes (A) [^{99m}Tc(IL-8−HYNIC)(tricine)$_2$] and (B) [^{99m}Tc(IL-8−HYNIC)(EDDA)]. The exact nature of the bonding between the IL-8−HYNIC−^{99m}Tc core and EDDA is unclear. X is a supposed additional monodentate ligand, such as Cl^- (*16*). Ternary technetium complexes [^{99m}Tc(IL-8−HYNIC)(tricine)(L)] (L = TPPTS or nicotinic acid or isonicotinic acid) [Figure 2C].

technetium complexes [^{99m}Tc(IL-8−HYNIC)(tricine)(L)] (L = TPPTS or nicotinic acid or isonicotinic acid) are depicted in Figure 2. The effect of the coligand on the in vivo behavior of ^{99m}Tc-labeled IL-8 was investigated in a rabbit model of *E. coli*-induced soft tissue infection.

MATERIALS AND METHODS

Human recombinant IL-8 was kindly provided by Dr I. Lindley (Novartis, Vienna, Austria). Tricine (*N*-[tris-(hydroxymethyl)methyl]glycine) was purchased from Fluka, Buchs, Switzerland. EDDA (ethylenediaminediacetic acid), TPPTS (trisodium triphenylphosphine-3,3′,3″-trisulfonate), nicotinic acid, and isonicotinic acid were obtained from Sigma-Aldrich (St. Louis, MO).

Conjugation of HYNIC to IL-8. The propylaldehyde hydrazone of succinimidyl-hydrazinonicotinamide (HYNIC) was synthesized essentially as described by Abrams, Schwartz et al. (*11*, *13*). The IL-8−HYNIC conjugate was

prepared as described previously (*8*). Briefly, in a 1.5 mL vial, 4 μL of 1 M $NaHCO_3$, pH 8.2, was added to 35 μL of IL-8 (4.8 mg/mL). Subsequently, a 3-fold molar excess of HYNIC in 5 μL of dry DMSO was added dropwise to the mixture. After incubation for 5 min at room temperature, the reaction was stopped by adding an excess of 200 μL of 1 M glycine in phoshate-buffered saline (PBS). To remove excess unbound HYNIC, the mixture was extensively dialyzed against PBS (0.1−0.5 mL dialysis cell 3.5 MWCO, Pierce, Rockford, IL). Dialyzed samples of ca. 5 μg IL-8−HYNIC were stored at −20 °C.

Technetium-99m Labeling of HYNIC Conjugated IL-8. *(i) Tricine as Coligand.* Tricine−$SnSO_4$ kits (0.2 mL) were prepared containing 20 mg of tricine and 0.01 mg of $SnSO_4$ in 0.2 mL of PBS, pH 7.0. To prevent precipitation of tin colloid, $SnSO_4$ dissolved in 2 M HCl was added to a solution of tricine in PBS, and the pH was adjusted to 7.0 with 1.0 M NaOH. A 0.2 mL tricine−$SnSO_4$ kit and 100−350 MBq $^{99m}TcO_4^-$ in saline were added to 5 μg of thawed HYNIC−IL-8 and incubated at room temperature for 30 min.

(ii) EDDA as Coligand. A 10 μg amount of thawed HYNIC−IL-8 was incubated with 0.5 mL of solution of EDDA (10 mg/mL in PBS), 100−350 MBq $^{99m}TcO_4^-$ in saline, and 10 μL of tin(II) solution (1.0 mg/mL $SnSO_4$ in nitrogen-purged 0.1 N HCl) for 30 min at 70 °C.

(iii) TPPTS/Tricine as Coligands. A 5 μg amount of thawed HYNIC−IL-8 was incubated with 0.1 mL of solution of TPPTS (10 mg/mL in 25 mM benzoate buffer, pH 5.0), 0.3 mL of a tricine solution (100 mg/mL in 25 mM benzoate buffer, pH 5.0), 100−350 MBq $^{99m}TcO_4^-$ in saline, and 25 μL of tin(II) solution (1.0 mg/mL $SnSO_4$ in nitrogen-purged 0.1 N HCl) for 30 min at 70 °C.

(iv) Nicotinic Acid/Tricine as Coligands. A 5 μg amount of thawed HYNIC−IL-8 was incubated with 0.1 mL of solution of nicotinic acid (20 mg/mL in 25 mM benzoate buffer, pH 5.0), 0.4 mL of a tricine solution (100 mg/mL in 25 mM benzoate buffer, pH 5.0), 100−350 MBq $^{99m}TcO_4^-$ in saline, and 25 μL of tin(II)solution (1.0 mg/mL $SnSO_4$ in nitrogen purged 0.1 N HCl) for 30 min at 70 °C.

(v) Isonicotinic Acid/Tricine as Coligands. The labeling procedure was identical to the one above, using isonicotinic acid instead of nicotinic acid.

Chemical Characterization of ^{99m}Tc-Labeled IL-8 Preparations. *(i) Radiochemical Purity by ITLC.* The radiochemical purity was determined by instant thin-layer chromatography (ITLC) on ITLC−SG strips (Gelman Laboratories, Ann Arbor, MI) with 0.1 M citrate, pH 6.0, as the mobile phase.

(ii) Purification. Following the labeling reaction the reaction mixture was applied to a Sephadex G-25 column (PD-10; Pharmacia, Uppsala, Sweden) and eluted with PBS, 0.5% BSA, to purify the radiolabeled IL-8 conjugate.

(iii) Octanol/Water Partition Coefficient as a Measure of Lipophilicity. To determine the lipophilicity of the various ^{99m}Tc−HYNIC−IL-8 preparations, approximately 100 000 cpm of a purified preparation was diluted with PBS to a total volume of 3 mL. An equal volume of octanol was added, and the resulting biphasic system was mixed vigorously for 1 min and gently for another 10 min. The two phases were separated by centrifugation (10 min, 2000*g*), and 0.2 mL aliquots were taken from each layer. The partition coefficient was expressed as the ratio of cpm in the octanol phase to the cpm in the PBS phase.

(iv) Stability in PBS and in Serum. Following the labeling reactions, the five ^{99m}Tc-labeled IL-8 preparations were purified on a Sephadex G-25 column eluted with PBS without BSA. The stability of the purified preparations was monitored in PBS at room temperature and in human serum (1:5) at 37 °C for 6 h. At several time points postincubation (0, 2, 4, and 6 h), samples were analyzed for the amount of free radiolabel using ITLC. Samples of the serum incubated preparations were diluted 1:5 in PBS with 0.5% BSA before applying to the ITLC-strip in order to prevent protein overload of the strips by serum proteins.

(v) Analytical RP-HPLC. The radiochemical purity was determined by reversed phase high-performance liquid chromatography (RP-HPLC) (HP 1100 series, Hewlett-Packard, Palo Alto, CA) using an Agilent Zorbax Stable Bond Analytical 4.6 × 250 mm column (300SB−C8) at a flow rate of 1 mL/min. The radioactivity of the eluate was monitored using an in-line radiodetector (Flo-one Beta series A-100, Radiomatic, Meriden, CT).

Method 1. Solvents used: (A) 0.01% TFA in water; (B) 90% acetonitrile (ACN), 10% solution A. Gradient: from 70% A and 30% B to 45% A and 55% B in 30 min.

Method 2. Solvents used: (A) 10 mM phosphate buffer pH 6.0; (B) 100% ACN. Gradient: 0−3 min 0% B, 3−18 min 0%−30% B, 18−23 min 30% B, 23−33 min 30%−75% B, 33−34 min 70%−0% B.

Receptor Binding Assays. The receptor binding fraction (RBF) of the various ^{99m}Tc−HYNIC−IL-8 preparations was determined in receptor binding assays essentially as described by Lindmo et al. (*19*). The in vitro receptor binding assays were performed using Jurkat cells transfected with either IL-8 receptor 1 (CXCR1) or IL-8 receptor 2 (CXCR2), a kind gift of Drs. Loetscher and Baggiolini (Theodor Kocher Institute, University of Bern, Bern, Switzerland). The two cell lines were cultured at 37 °C in a humidified atmosphere of air/CO_2 (95:5) in RPMI 1640 medium (GIBCO, Gaithersburg, MD) containing 10% fetal calf serum and 1% glutamine, amino acids, and pyruvate. The medium also contained Pen/Strep, 5 × 10^{-5} M of β-mercaptoethanol, and 1.5 μg/mL puromycin for selection. Live Jurkat cells were centrifuged (5 min, 2000 g) and washed once with assay buffer (RPMI 1640, 0.5% BSA, 0.05% NaN_3). A series of serially diluted cell suspensions (0.125−2 × 10^8 cells/ml) of cells bearing CXCR1 and a second series bearing CXCR2 were incubated with 10000 cpm of a ^{99m}Tc-labeled IL-8 preparation in assay buffer. For each series, a duplicate of the lowest cell concentration was incubated in the presence of at least a 100-fold molar excess of unlabeled IL-8 to correct for nonspecific binding. After 30 min incubation at 37 °C, cells were centrifuged (5 min, 2000 g), and the radioactivity in the pellet (total bound radioactivity) was measured in a shielded well-type gamma counter (Wizard; Pharmacia, Uppsala, Sweden). The data were graphically analyzed in a modified Lineweaver−Burk plot: a double inverse plot of the conventional binding plot (specifically bound fraction versus cell concentration). The receptor-binding fraction at infinite cell excess was calculated by linear extrapolation to the ordinate.

Animal Studies. Abscesses were induced in the left thigh muscle of 25 female New Zealand rabbits (2.4−2.7 kg) with (1−2) × 10^{11} colony forming units (cfu) of *Escherichia coli* in 0.5 mL. During the procedure, rabbits were anaesthetized with a subcutaneous injection of a 0.6 mL mixture of fentanyl 0.315 mg/mL and fluanisone 10 mg/mL (Hypnorm, Janssens Pharmaceutical, Buckinghamshire, UK). The rabbits were divided into five groups of five animals (five animals per ^{99m}Tc−HYNIC−IL-8 coligand formulation). After 24 h, when swelling of the muscle was apparent, the rabbits were injected with 10−40 MBq ^{99m}Tc−HYNIC−IL-8 (protein dose 0.2−2 μg) via the ear vein. Three rabbits out of each group were

Table 1. In Vitro Characteristics of Five Different ^{99m}Tc-Labeled IL-8 Coligand Preparations[a]

coligand system	specific activity, MBq/μg	octanol/water partition	RBF: CXCR1, %	RBF: CXCR2, %	stability: PBS, %	stability: serum, %
tricine	15	0.017	50−55	40−45	15−20	>90
EDDA	7	0.0053	45−50	36−42	55−65	>90

[a] Specific activities (MBq/μg), octanol/water partition coefficients, receptor binding fractions (RBF) (%) to Jurkat cells transfected with either IL-8 receptor 1 (CXCR1) or IL-8 receptor 2 (CXCR2) and stabilities in PBS and in serum (labeling efficiencies after 6 h of incubation). [b] n.s. = predominantly nonspecific cell binding.

used for gamma camera imaging. These rabbits were immobilized, placed prone on the gamma camera and images were recorded at 0, 2, 4, and 6 h pi with a single-head gamma camera (Orbiter, Siemens Medical Systems Inc., Hoffman Estates, IL) equipped with a parallel-hole low-energy all purpose collimator. Images were obtained with a 15% symmetrical window over the 140 keV energy peak of ^{99m}Tc. After acquisition of 100000−300000 counts, the images were digitally stored in a 256 × 256 matrix.

Scintigraphic images were analyzed quantitatively by drawing regions of interest (ROI) over the abscess and the uninfected contralateral thigh muscle (background). Abscess-to-background ratios were calculated.

After completion of the final imaging (6 h pi), all rabbits were killed with a lethal dose of sodium phenobarbital. Samples of blood, infected thigh muscle, uninfected contralateral thigh muscle, lung, spleen, liver, kidneys, and intestines were collected. The dissected tissues were weighed and counted in a gamma counter. To correct for radioactive decay, injection standards were counted simultaneously. The measured activity in samples was expressed as a percentage of injected dose per gram tissue (%ID/g). Additionally, total uptake of the radiopharmaceutical (%ID) was determined for kidneys and abscesses. Abscess-to-contralateral muscle ratios and abscess-to-blood ratios were calculated.

Statistical Analysis. All mean values are given as %ID/g, %ID or ratios ± 1 standard error of the mean (sem). The data were analyzed statistically using the one-way ANOVA with Dunnett's posttest (GraphPad Instat 3.00 Win 95, San Diego, CA) comparing data for the EDDA, the TPPTS, the nicotinic, and the isonicotinic preparation with data for the tricine preparation.

RESULTS

Radiolabeling and Characterization of ^{99m}Tc-Labeled IL-8 Preparations. Table 1 shows the specific activities (MBq/μg), the octanol/water partition coefficients, the receptor binding fractions RBF for CXCR1 and CXCR2 receptors, and the stability of the preparations in PBS and in serum. The five preparations will be denoted here by their main discriminating component: tricine, EDDA, TPPTS, nicotinic acid, and isonicotinic acid.

Radiolabeling of each of the five HYNIC−IL-8 coligand formulations was rapid and straightforward, resulting in high specific activities of four out of five formulations. With EDDA only a modest specific activity could be obtained (7 MBq/μg) as compared to tricine (15 MBq/μg), TPPTS (40 MBq/μg), and nicotinic acid and isonicotinic acid (up to 80 MBq/μg). In our experience, the protection of the hydrazine moiety with propylaldehyde resulted in a HYNIC-conjugated IL-8 product with increased stability (at −20 °C): it could be labeled with high labeling efficiency over longer time periods (several months). Using the same tricine coligand formulation, the specific activity of ^{99m}Tc-labeled hydrazine protected HYNIC−IL-8 was found to be 15 MBq/μg as compared to 3 MBq/μg for ^{99m}Tc-labeled free hydrazine HYNIC−IL-8 previously reported (*8*). Both products started at similar labeling efficiencies but the free hydrazine HYNIC−IL-8 product showed a gradual decrease in labeling efficiency over 3 months even when stored at −20 °C.

The lipophilicity as reflected in the octanol/water partition coefficient was highest for the TPPTS preparation. This is in line with the HPLC analyses (Figure 3) and a significantly higher liver uptake of the TPPTS preparation as found in the biodistribution (Table 2) (see below).

All the formulations with the exception of TPPTS showed similar RBF values for both receptors: between 45% and 55% for CXCR1 and between 36% and 45% for CXCR2. The TPPTS preparation showed predominantly nonspecific binding to the cells.

All radiolabeled IL-8 preparations were stable in human serum: after 6 h of incubation at 37 °C the amount of free radiolabel was less than 10% as determined by ITLC. However, the same preparations diluted in PBS showed a large variation in stability: after 6 h of incubation at room temperature the amount of free radiolabel was less than 10% for TPPTS and nicotinic acid only. For EDDA between 35 and 45% of the radiolabel was released, for isonicotinic acid between 55 and 60% and for tricine around 80%.

The radio-HPLC chromatograms (method 1) of tricine and of TPPTS are presented in Figure 3A and 3B. The tricine chromatogram shows a pertechnetate peak with retention time of 3.5 min (<1.5%) and a doublet peak of [^{99m}Tc(IL-8−HYNIC)(tricine)$_2$] with retention times of 10.3 and 10.9 min. The radiochromatograms of the EDDA, nicotinic acid, and isonicotinic acid preparations showed essentially the same profile. Retention times of the doublet peak were found at 10.3 and 10.9 min for EDDA, at 10.3 and 11.0 min for nicotinic, and at 10.4 and 11.1 min for isonicotic. The radiochromatogram of TPPTS turned out to be completely different: the major peak eluted much later (16.3 min) indicating the higher lipophilicity of the preparation. It might be the case that TPPTS interacts with the protein outside the protein−HYNIC-core. For instance, triarylphosphines such as TPPTS can reduce disulfide linkages, whereas maintenance of the disulfide structure is critical for IL-8 activity. The possibility of interaction of TPPTS with IL-8 outside the protein−HYNIC-core was investigated in an additional experiment. The radiochromatograms of a iodinated IL-8 preparation and the same preparation incubated at 70 °C for 30 min in the presence of an excess of TPPTS were compared (not shown). The ^{125}I-IL-8 radiochromatogram showed a profile similar to that of [^{99m}Tc-(IL-8−HYNIC)(tricine)$_2$] with a doublet at 11.2 and 11.9 min. The radiochromatogram of ^{125}I-IL-8 incubated with TPPTS was similar, indicating that (chemical) interaction

of TPPTS with IL-8 is not the principal determinant for the aberrant in vitro behavior of [^{99m}Tc(IL-8−HYNIC)-(tricine)(TPPTS)]. The characteristics of the mobile phase itself may explain the chromatographic behavior of TPPTS. The acidic sulfonate groups of TPPTS are partly protonated/deprotonated using the acidic TFA/ACN mobile phase of method 1. A mix of protonation states might be responsible for the broad and multispecies chromatogram of TPPTS. To investigate this, the acidic mobile phase of HPLC method 1 (diluted TFA/ACN) was replaced by a more pH neutral mobile phase in HPLC method 2 (phosphate buffer pH 6.0/ACN) in an additional experiment. The radio-HPLC chromatograms (method 2) of nicotinic acid (representative for tricine, EDDA, and isonicotinic acid) and of TPPTS are presented in Figure 3C and 3D. The nicotinic acid chromatogram showed a pertechnetate peak with a retention time of 3.7 min and a single peak of [^{99m}Tc(IL-8−HYNIC)(tricine)(nicotinic acid)] with a retention time of 19.4 min. The chromatogram of TPPTS showed a pertechnetate peak with a retention time of 3.7 min and, again, a multispecies pattern with peaks at 19.0, 21.8, and 27.8 min, indicating a higher lipophilicity of the TPPTS preparation.

Animal Studies. The coligand system clearly affected the biodistribution of ^{99m}Tc-labeled IL-8−HYNIC as showed in Table 2. Figure 4 summarizes the main in vivo characteristics: abscess/muscle and abscess/blood ratios and the principal routes of clearance (renally and/or hepatobiliary) of the five preparations. As compared to tricine, the EDDA preparation cleared faster from the blood, resulting in a significantly lower percentage of residual activity in the blood ($P < 0.05$) and (in combination with a similar muscle uptake) in a significantly higher abscess/blood ratio ($P < 0.05$) (Figure 4b). The biodistribution pattern of TPPTS was very different from the other ones. This preparation had a significantly reduced uptake in the abscess as well as in muscles, lungs, and intestines ($P < 0.05$). Blood clearance was much faster ($P < 0.001$), presumably due to a more than 2-fold higher uptake by the liver ($P < 0.001$). Lower lung

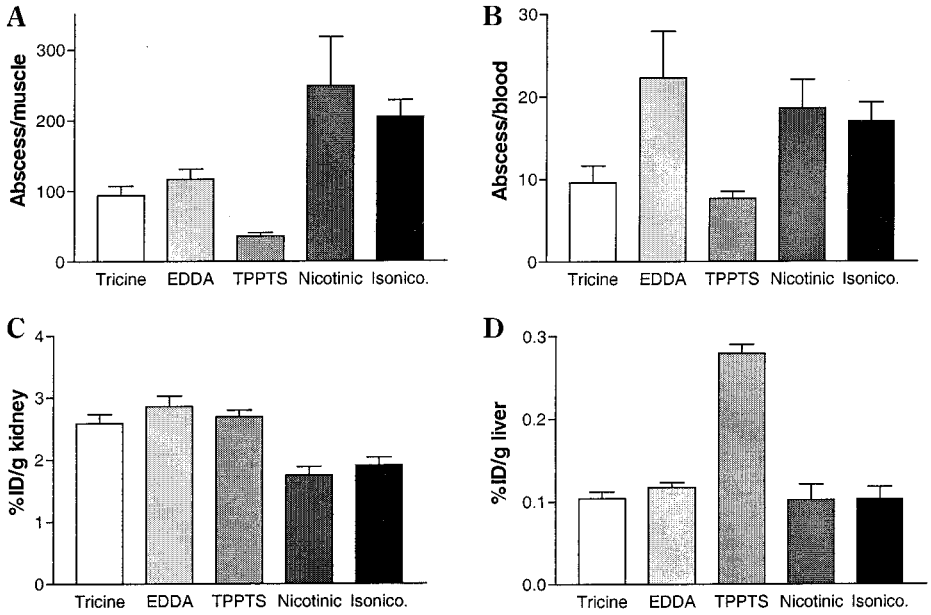

Figure 4. Biodistribution ratios: (A) abscess/muscle and (B) abscess/blood. Principal routes of clearance: (C) Renal and (D) hepatobiliar. The error bars indicate SEM.

uptake might suggest that there was less interaction of this preparation with leukocytes. The nicotinic acid and isonicotinic acid preparation had almost identical in vivo characteristics. In comparison to the tricine preparation, a significantly lower percentage residual activity in the muscles ($P < 0.001$ and $P < 0.05$, respectively) and intestines ($P < 0.001$) was found. Abscess/muscle ratio of the nicotinic acid preparation was significantly higher ($P < 0.05$) (Figure 4a). At 6 h pi, kidney uptake was significantly lower for nicotinic and isonicotinic acid ($P < 0.001$) (Figure 4c). All preparations were excreted renally except for the TPPTS preparation which partly cleared via the hepatobiliary route (Figure 4c and 4d).

The abscesses were clearly delineated on the images recorded from 2 h onward for all preparations with the exception of TPPTS (Figure 5). Quantitative analysis of the images indicated that the abscess/background ratios (A/B) improved with time for all preparations (Figure 6). The A/B at 6 h pi, of isonicotinic acid was significantly higher ($P < 0.05$) than that of tricine and the A/B of TPPTS was significantly lower ($P < 0.05$). Immediately after injection high kidney uptake was observed for all preparations, remaining prominent during the 6 h pi. In addition to this, high liver uptake was seen on all the TPPTS images.

DISCUSSION

In our previous study, IL-8 was conjugated with HYNIC and subsequently labeled with ^{99m}Tc using tricine as coligand (*8*). This preparation showed excellent characteristics as an infection imaging agent, approaching the characteristics of the ideal radiopharmaceutical for infection imaging: rapid and high accumulation in infectious foci together with rapid clearance from the blood and the nontarget tissues. The leukocyte receptor binding capacity was still largely preserved.

The primary concern in using IL-8 in vivo is that it is a highly potent activator of neutrophils. Administration doses of micrograms of IL-8 per kg of body-weight in healthy rabbits caused a serious but transient neutropenia followed by a leukocytosis lasting several hours (*6*). These side-effects are undesirable for a diagnostic utility in routine clinical practice. Our research program focused on increasing the specific activity of a radiolabeled IL-8 preparation in combination with preservation of the

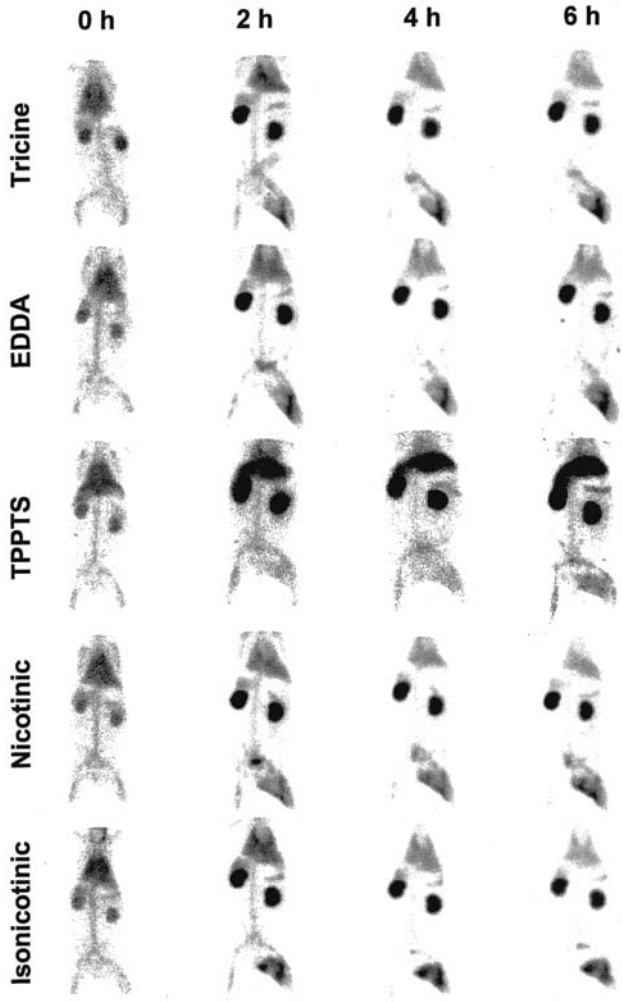

Figure 5. Images of rabbits with an *E. coli* abscess in the left thigh muscle at 1 min, 2, 4, and 6 h after injection of five different ^{99m}Tc−HYNIC−IL-8 coligand preparations.

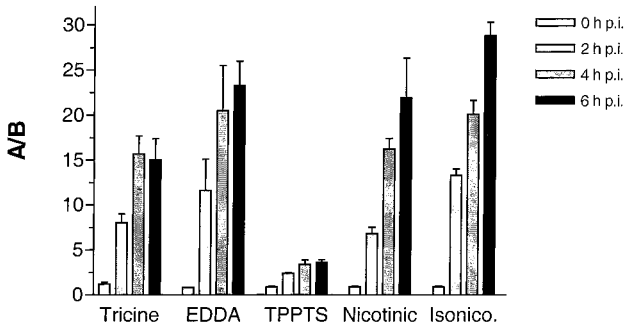

Figure 6. The abscess/background ratios as determined by quantitative analysis of the images of rabbits with *E. coli* infection injected with five different ^{99m}Tc−HYNIC−IL-8 coligand preparations. The coligand preparations are named by their discriminating component (nicotinic = nicotinic acid; isonico. = isonicotinic acid). The error bars indicate SEM.

leukocyte receptor binding capacity. A first and most important reduction of the amount of biologically active material to be injected was achieved with ^{99m}Tc−HYNIC−IL-8 (with coligand tricine) as compared to radioiodinated IL-8: 1 μg/kg ^{99m}Tc−HYNIC−IL-8 versus 25 μg/kg ^{123}I−IL-8 (*8*).

In the present study the bifunctional coupling agent HYNIC was adopted again for labeling IL-8 with technetium. A decisive improvement was obtained with a slightly modified HYNIC formulation: the propylaldehyde hydrazone formulation instead of the free hydrazine formulation (*13*). Protection of the hydrazine group of HYNIC in HYNIC-conjugated IL-8 resulted in a product with improved long-term stability resulting in an increased labeling efficiency using the same coligand tricine as in previous studies.

Further improvement was sought in the exploration of various coligands. Liu and Edwards et al. have performed systematic studies upon labeling a HYNIC-conjugated platelet glycoprotein receptor antagonist with ^{99m}Tc using various alternative coligand systems. The formulation with tricine was found to be unstable in solution, particularly under dilute conditions, and to exist in many isomeric forms (*16*). Increased stability of the complex and reduction of the number of isomers could be achieved by replacing tricine by other coligand systems such as EDDA (16), tricine/TPPTS (*17*), and tricine/(iso)-nicotinic acid (*18*). High specific activities were obtained with all these preparations, though the labeling efficiency using EDDA as coligand was not as high as that using the other coligand systems. Decristoforo and Mather described the preclinical evaluation of ^{99m}Tc-labeled HYNIC-conjugated somatostatin analogues using tricine, EDDA, and tricine in combination with nicotinic acid as coligands (*20*−*22*). These preparations showed preserved binding affinity for the somatostatin receptor. Again, reduced in vitro stability was found for the complex using tricine only as coligand, resulting in higher blood levels. The preparation using tricine/nicotinic acid produced significant levels of activity in the gastrointestinal tract. The preparation using EDDA showed the most promising overall biodistribution profile, though labeling efficiency was considerably lower. Consequently, a first clinical study was performed with this EDDA formulation (*23*).

Our findings concerning stability of the coligand complexes are in line with the above-reported results. The tricine formulation was found to be unstable in vitro under diluted conditions (PBS). Alternative coligand systems offered a solution toward more stable in vitro complexes, especially the TPPTS and the nicotinic acid preparations. In contrast, in serum all preparations proved to be equally stable. In a recent study Ono and co-workers have demonstrated that plasma proteins can stabilize ^{99m}Tc-labeled HYNIC-conjugated Fab fragments when tricine is used as coligand (*24*). The authors proposed that one of the tricine coligands is replaced by a plasma protein to generate higher molecular weight species that exhibit a slower blood clearance. This could explain not only the stability of the [^{99m}Tc(IL-8−HYNIC)-(tricine)$_2$] complex in serum, but also the relatively slow blood clearance of the [^{99m}Tc(IL-8−HYNIC)(tricine)$_2$] complex. In addition, Ono et al. found that replacement of one tricine molecule by a nicotinic acid molecule in the reported complexes resulted in a stabilized ternary ligand system which demonstrated a significantly faster blood clearance. We arrived at similar conclusions for [^{99m}Tc-(IL-8−HYNIC)(tricine)(nicotinic)].

It is rather surprising that the in vitro and in vivo properties of a 72 amino acid protein as IL-8 could be greatly affected by a coligand. Introduction of the bulky coligand TPPTS resulted in a severe reduction of in vitro receptor binding affinity, a shift in lipophilicity of the total complex, significant lower abscess uptake and lower blood levels, and a much higher liver uptake. Quality of the images was poor as compared to the other coligand systems. Several explanations can be given for the marked change in biodistribution pattern of TPPTS. First, TPPTS is considerably larger than the other coligands (Figure 1). TPPTS equals the size of approximately four amino acid residues, whereas the other coligands have the size of just one amino acid residue. Steric hindrance of the relatively bulky TPPTS group might, at least in part, explain the major impact on binding affinity toward the IL-8 receptors. Second, the charge of the complex is affected by the three TPPTS sulfonato groups. These sulfonato groups are expected to be deprotonated under physiologic conditions (*17*), which has a definite impact on the (local) electron distribution. We investigated the possibility of interaction of TPPTS with IL-8 outside the protein−HYNIC-core and compared the radiochromatograms of a iodinated IL-8 preparation with the same preparation incubated at 70 °C for 30 min in the presence of an excess of TPPTS. In this experiment the dramatic changes in RP-HPLC patterns were not seen as with the ^{99m}Tc-labeled IL-8 TPPTS preparation. Apparently, interaction of TPPTS with IL-8 outside the protein−HYNIC-core does not play a major role in explaining the aberrant in vitro and in vivo behavior of the TPPTS preparation.

The ^{99m}Tc−HYNIC−IL-8 EDDA preparation showed highly favorable characteristics for infection imaging. The preparation cleared relatively rapidly from the blood. EDDA is, however, not the coligand of choice for IL-8 for two reasons. First, the formulations using (iso)nicotinic acid generated higher abscess/muscle (and A/B) ratios. Second, the EDDA preparation had a relatively low specific activity. The specific activity of the tricine formulation was twice as high as that of EDDA, and with (iso)nicotinic acid, specific activities were up to 10 times higher (Table 1).

The most optimal characteristics for infection imaging were obtained with formulations using nicotinic acid or isonicotinic acid as coligands. With these coligands, specific activities 20-fold higher than those previously reported with the unprotected hydrazine and with tricine as coligand could be achieved, without compromising the receptor binding capacity. Administration of doses as low as 70 ng/kg ^{99m}Tc−HYNIC−IL-8 (versus 1 μg/kg previously reported) will suffice for imaging procedures.

Moreover, (iso)nicotinic acid showed the most favorable in vivo characteristics with abscess/muscle, abscess/blood, and ROI-derived abscess/background ratios being twice as high as those obtained with tricine. Its higher in vitro stability makes nicotinic acid the preferred coligand. Future experiments with ^{99m}Tc−HYNIC−IL-8 will exploit the advantages of the nicotinic acid/tricine coligand formulations. At low IL-8 protein doses of 70 ng/kg, side effects are not to be expected in the human system. This opens the way to infection imaging studies in patients.

CONCLUSION

IL-8 can be rapidly, easily, and efficiently labeled with ^{99m}Tc using (hydrazine protected) HYNIC as chelator and using various coligands. The most optimal infection imaging characteristics were found for formulations using nicotinic acid/tricine as coligands combining a high specific activity (up to 80 MBq/μg) and high in vitro stability with high abscess/muscle ratios (>200) and high abscess/background ratios (>20) in vivo. High quality images with clear delineation of infectious foci could be obtained within 2 h after injection of the radiopharmaceutical. The low administration doses of 70 ng/kg ^{99m}Tc−HYNIC−IL-8 paves the way for infection imaging studies in patients.

ACKNOWLEDGMENT

The authors thank G. Grutters (University of Nijmegen, Central Animal Laboratory) and C. Frielink (University Medical Center Nijmegen, Department of Nuclear Medicine) for their excellent technical assistance.

TECHNICAL NOTES

Advantage of the Ether Linkage between the Positive Charge and the Cholesteryl Skeleton in Cholesterol-Based Amphiphiles as Vectors for Gene Delivery

Yamuna Krishnan Ghosh,[†] Sandhya S. Visweswariah,[‡] and Santanu Bhattacharya*[,†]

Department of Organic Chemistry, Indian Institute of Science, Bangalore 560 012, India. Received June 15, 2001

Twelve novel cationic cholesterol derivatives with different linkage types between the cationic headgroup and the cholesteryl backbone have been developed. These have been tested for their efficacies as gene transfer agents as mixtures with dioleoyl phosphatidylethanolamine (DOPE). A pronounced improvement in transfection efficiency was observed when the cationic center was linked to the steroid backbone using an *ether* type bond. Among these, cholest-5-en-3b-oxyethane-*N*,*N*,*N*-trimethylammonium bromide (**2a**) and cholest-5-en-3b-oxyethane-*N*,*N*-dimethyl-*N*-2-hydroxyethylammonium bromide (**3d**) showed transfection efficiencies considerably greater than commercially available reagents such as Lipofectin or Lipofectamine. To achieve transfection, **3d** did not require DOPE. Increasing hydration at the headgroup level for both ester- and ether-linked amphiphiles resulted in progressive loss of transfection efficiency. Transfection efficiency was also greatly reduced when a 'disorder'-inducing chain like an oleyl (*cis*-9-octadecenyl) segment was added to these cholesteryl amphiphiles. Importantly, the transfection ability of **2a** with DOPE in the presence of serum was significantly greater than for a commercially available reagent, Lipofectamine. This suggests that these novel cholesterol-based amphiphiles might prove promising in applications involving liposome-mediated gene transfection. This investigation demonstrates the importance of structural features at the molecular level for the design of cholesterol-based gene delivery reagents that would aid the development of newer, more efficient formulations based on this class of molecules.

INTRODUCTION

Aqueous suspensions of cationic cholesterol derivatives have been shown to bring about DNA transfection in cells with greater efficiency than for many commercially available formulations composed of cationic lipids based on the pseudoglyceryl skeleton (*1*, *2*). Such an alternative class of cytofectins (*3*) based on synthetic cationic cholesterol derivatives are currently receiving much attention for use in gene therapy (*4*−*8*). In addition, they are being utilized in the studies involving enzyme inhibition (*9*) for the design of membrane-spanning conductors (*10*) or in medicinal applications (*11*).

The surge in the utilization of cationic cholesterol derivatives as cytofectin over traditional cationic glycerol-based amphiphiles stems from one practical fact that the 3β-OH of cholesterol is easily amenable to functionalization, and this facilitates the generation of a range of new cationic cholesteryl derivatives. The emergence of this class of molecules as efficient cytofectins has prompted structural studies such as the headgroup variation and location of the positive charge on the cholesterol monomer (*12*). However, little is known on the effect of the *linkage* region, which connects the positive charge to the steroid backbone. Our preliminary studies (*2*) using COS-7 cells suggested that use of an ether linkage over the more frequently used hydrolytically scissile ester- or urethane-based linkage offers significant advantage in effecting gene transfer. In the present investigation we undertake a detailed study using several cationic cholesterol derivatives (Figure 1) for their utilization in transfection through various cell lines. To derive a relationship between headgroup hydration and transfection efficiency (TE) involving this class of cytofectins, we prepared cationic cholesterol derivatives bearing varying lengths of oligooxyethylene glycol units. Earlier investigations with cationic fatty acid derivatives of glycerol-based transfection reagents have already indicated a crucial relationship that exists between the TE and the headgroup solvation (*13*−*15*). Herein we present the results where the transfection abilities of various cationic cholesterol derivatives having different linker regions and altered levels of headgroup hydration yield a correlation between molecular structure and gene transfection efficiency.

2. MATERIALS AND METHODS

2.1. Materials. All reagents, solvents, and starting materials were obtained from the best known commercial sources and were distilled, recrystallized, or used without further purification, as appropriate (*16*). Thin layer

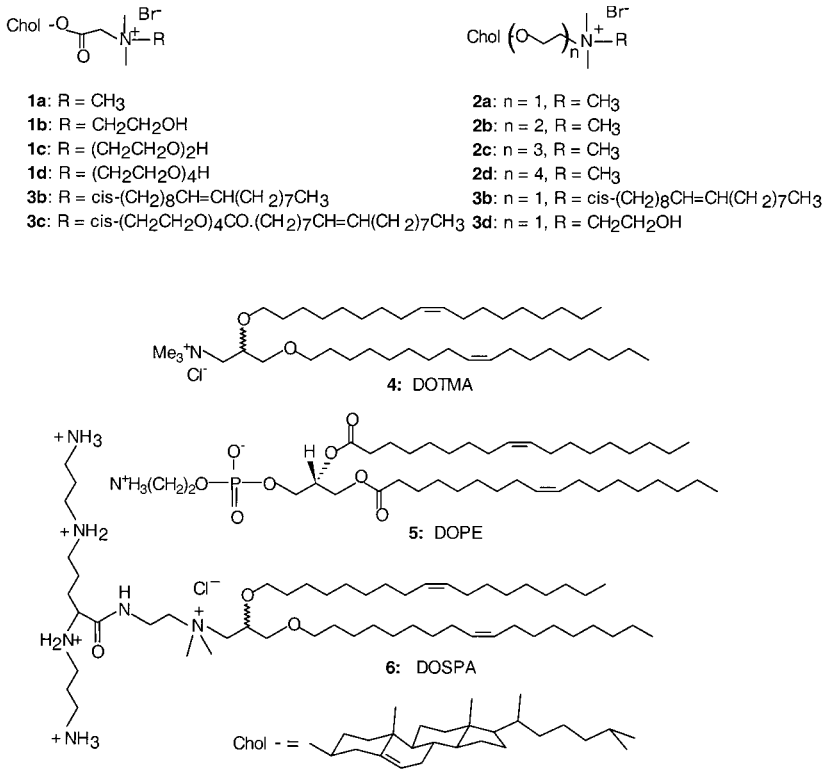

Figure 1. Molecular structures of the various Cytofectins and Helper Lipid (DOPE) employed in the present investigation.

chromatographic analyses were performed on silica gel-G (Merck) coated plates. Preparative chromatographic columns were packed with silica gel (60−120 mesh) obtained from Merck. 1,2-Dioleoyl-*sn*-glycero-3-phosphatidylethanolamine (DOPE) was purchased from Avanti Polar Lipids. Cholesterol was obtained Sigma (St. Louis, MO). *N,N*-Dimethylethanolamine was obtained from Aldrich and trimethylamine from Merck. Commercially available transfection reagents Lipofectin and Lipofectamine were obtained from GIBCO-BRL. Luciferase assay kit was obtained from Promega.

2.2 Synthesis. The syntheses of cationic cholesterol-based amphiphiles **1a**−**d** and **2a**−**d** have been reported elsewhere (*17*). Melting points were recorded in open capillaries and are uncorrected. ^{1}H NMR spectra were recorded on JEOL-JANL-LA-300 NMR spectrometers. Chemical shifts are reported in ppm downfield from the internal standard, tetramethylsilane. IR spectra were recorded on a Perkin-Elmer Model 781 spectrometer and are reported in wavenumbers (cm^{-1}). MALDI-TOF was recorded on a Kratos MALDI-TOF spectrometer.

General Procedure for the Synthesis of Cationic Cholesterol Derivatives. A solution of cholesteryl bromoacetate or 2-bromoethylcholesteryl ether (1 mmol) in dry acetone (20 mL) was refluxed for 12 h with the appropriate *N*-alkyl-*N,N*-dimethylamine. The white precipitate so formed was filtered off and washed with dry acetone. These were then recrystallized several times from dry acetone to give white solids, which were found to be pure by TLC, in yields of 88−95%. All compounds were found to be hygroscopic and existed as hydrates despite prolonged drying under vacuum and were characterized by IR, ^{1}H NMR, MALDI-TOF, and elemental analysis.

*Cholesteryl (2-N,N-dimethyl-N-oleylammonium bromide) acetate (**3a**).* Mp: 185−7 °C; IR ($CHCl_3$): 1735 cm^{-1}. ^{1}H NMR ($CDCl_3$, 300 MHz); δ: 0.65−2.45 (multiple peaks, 77 H), 3.48 (s, 8H), 4.623 (m, 3H), 5.34 (d, 1H). *Cholest-5-en-3β-oxyethane-N,N-dimethyl-N-2-hydroxyethylammonium bromide (**3d**).* White solid, 98 mg, 0.17 mmol, 83%. IR: 3240, 2930, 2865, 1465, 1350 cm^{-1}. ^{1}H NMR ($CDCl_3$, 300 MHz); δ: 0.67 (s, 3H), 0.85−2.35 (m, 41H), 3.20 (m, 1H), 3.67 (s, 6H), 3.82−3.92 (m, 6H), 4.15 (s, 2H), 5.36 (d, J = 4.5 Hz, 1H). MALDI-TOF: 503 (M^+ − Br). Anal. Calcd for $C_{33}H_{60}O_2$ NBr· 0.5 H_2O: C, 66.98; H, 10.39; N, 2.37. Found: C, 67.28; H, 10.45; N, 2.06.

2.3. Liposome Preparation. A mixture of cationic amphiphile and DOPE in the desired molar ratio was dissolved in $CHCl_3$ in autoclaved Wheaton glass vials, and then solvent was evaporated under vacuum from the solutions to form respective thin films. These were resuspended in freshly autoclaved Milli-Q water. The final cationic cholesterol lipid/DOPE concentration was

0.2 mg/mL for all formulations. The mixture was left to hydrate at room temperature for ~6 h and then vortexed for 5 min followed by bath sonication for 15 min. The solutions were filtered under sterile conditions through a 0.22 mm filter (Sartorius) and stored at 4 °C. The diameters of the cationic liposomes prepared by this method ranged generally between 80 and 400 nm as checked by transmission electron microscopy of individual aliquots of sterile vesicular suspensions from respective cationic cholesterol derivatives with DOPE suspensions.

2.4. Plasmid DNA. Plasmid PRL-SV40 vector containing the luciferase reporter gene was amplified in *Escherichia coli* (DH5a) and purified using the QIAGEN Midi Prep Plasmid Purification protocol.

2.5. Transfection Procedure. A general procedure for a typical transfection was as follows. Cells were seeded in 24 well tissue culture plates (Nunc) the day before transfection in order to be approximately 40% confluent the next day. All cell lines (COS-7, NIH3T3, T84, and HEK293) were cultured in Dulbecco's Modified Eagle Medium (DMEM) supplemented with 10% fetal calf serum (FCS). Cells were routinely maintained on plastic 24 well tissue culture dishes (Nunc) at 37 °C in a humidified 5% CO_2/95% air-containing atmosphere. Plasmid DNA (0.3 μg) and the desired cationic cholesteryl amphiphile (4 μg) were each diluted in 100 μL of DMEM without FCS. After ≈5 min, the two solutions were combined and gently mixed, and the resulting solution was allowed to incubate for 15 min at room temperature to allow complex formation. The transfection mixture was then added (0.2 mL/well) to the cells that had been washed with serum free medium. After 8 h incubation at 37 °C, the transfection mixture was removed and 0.4 mL of 10% FCS was added to each well. The cells were harvested at 2 days post-transfection for monitoring of the transient expression of the luciferase gene. Control transfections were performed by using commercially available transfection reagents. The lipopolyamine Lipofectamine was used at a concentration of 4 μg/well. For transfection with the commercial grade Lipofectin−DNA complexes were obtained using the standard conditions specified by the manufacturer.

2.6. Transfections in the Presence of Serum. Transfections in the presence of serum were carried out in an identical manner with the transfection mixture being overlaid on wells containing an equal volume of 10% FCS such that the wells contained the lipid−DNA complex in 5% FCS. All experiments were performed in duplicate.

2.7. Luciferase Assay. Luciferase activities were assayed 48 h post-transfection using a modified procedure of De Wet ET al. (*18*). This is briefly presented herein. After removal of the culture medium, the cells were washed with cold phosphate buffer−saline and lysed by incubation with 60 μL of cell lysis buffer (25 mM Tris-phosphate buffer, pH = 7.8, 2 mM DTT, 2 mM CGTA, 10% glycerol, 1% Triton × 100). The lysate was clarified from insoluble material by centrifugation (for 5 s at 12000 × g). The supernatant was transferred to a new tube, and the pelleted cell debris was discarded. An aliquot (2 μL) of the cell extract at room temperature was mixed with 20 μL of Luciferin also at room temperature. Samples were placed in a photon counting luminometer (Turner Designs Model, TD 20/20 Luminometer), and the integration value of light emission was measured for 10 s. Protein concentrations were measured by using Bradford's method with BSA as a standard. Data for luciferase activity are expressed as relative light units (RLU)/mg of cell protein.

3. RESULTS AND DISCUSSION

3.1. Molecular Structures of Cytofectins. Figure 1 shows the molecular structures of the three families of cationic cholesterol-based amphiphiles (*cholamphiphiles*) **1**−**3**. We first synthesized two families of cationic cholamphiphiles, one where the charge is linked to the cholesteryl skeleton either via an *ester* or an *ether* bond. In cholesteryl derivatives **1a**−**d**, the cationic headgroup is linked to the 3b-cholesterol via an *ester* connection. In the derivatives **2a**-**d**, the cationic headgroup was linked to the hydrophobic cholesteryl backbone via an *ether* linkage. In view of the fact that there is a relation between headgroup hydration and transfection efficiency we chose oligooxyethylene residues as elements of hydration modulation at the headgroup. Hence in series **1a**−**d**, the positive charge is located at a fixed distance from the cholesteryl backbone, and the headgroup hydration is continually modified with the progressive increase in the number of oxyethylene units on the NMe_2^+ center. In addition, due to lack of information on the optimum location of the positive charge with respect to the hydrophobic backbone, **2a**−**d** were synthesized where cholesterol derivatives are connected to the cationic NMe_3^+ groups via varying lengths of an oligo-oxyethylene spacer units. The cationic NMe_3^+ group is therefore placed at incrementally greater distance from the cholesteryl backbone with the insertion of increasing number of oxyethylene units.

Membranes formed from the aqueous suspensions of these amphiphiles were found to be highly rigid. For instance, these aggregates were found to be thermally insensitive (*17*), as no solid-to-fluid transition was observed under either temperature-dependent fluorescence depolarization studies or differential scanning calorimetry. To examine the role of such thermally insensitive, rigid hydrophobic segments toward transfection, a flexible, fatty acyl chain namely the oleyl chain, was appended to **1a**, **1d**, and **2a**, to give **3a**−**c**. In addition, the ether analogue of **1b**, i.e., **3d** was also synthesized.

3.2. DNA Transfection Studies in COS-7 Cells. The potency of a given cytofectin toward DNA transfection was checked as follows. The cytofectin of interest was mixed with DOPE (**5**) in mole percentages of 20, 33, 50, 66, and 100 in separate vials, and the corresponding mixed liposomes were prepared as given in the Materials and Methods. Transfections were carried out with five different liposomal formulations, and the luciferase assay was used to quantitatively assess the corresponding transfection efficiencies. Two control transfections, with commercially available liposomal transfection reagents, i.e., Lipofectin (which is a 1:1 mixture of 1,2-dioleyloxypropyl-3-trimethylammonium bromide (DOTMA) **4**/DOPE) and Lipofectamine (a mixture of 1:1 DOSPA **6**/DOPE) were carried out every time. It was ensured that the variation of light units obtained for control transfections was not greater than 5%. Transfection efficiency (TE) of a given formulation is expressed as relative light units (RLU)/g protein content normalized with respect to Lipofectamine. Thus a plot of mol % cytofectin in DOPE versus the TE gave the transfection profile of the cytofectin so investigated. The transfection profile of the cytofectin shows the amount of DOPE required by the cytofectin for optimal transfection efficiency (OTE).

The transfection profiles so obtained for the ester-based series **1a**−**d** are presented in Figure 2. **1a** showed the highest activity in the series, with the most effective formulation being 1:2 **1a**/DOPE (Figure 2A). This formulation was at least three times more active than that

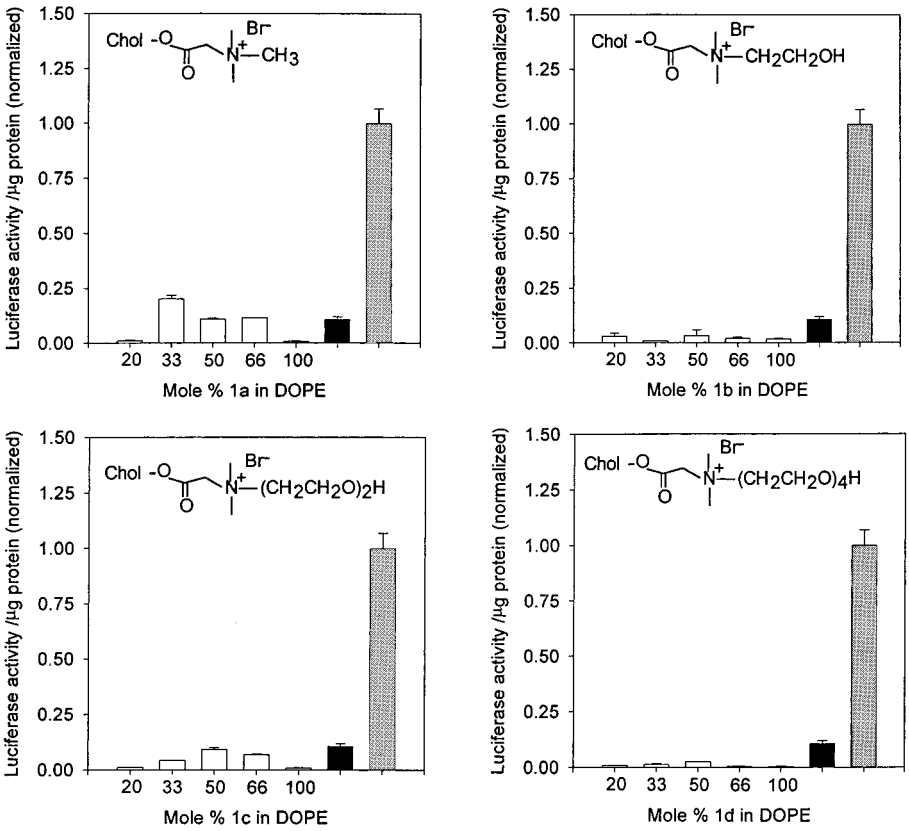

Figure 2. Comparison of transfection efficiencies of pGL3 control DNA using various compositions of **1a**−**d** in DOPE (open bar) with Lipfectamine (gray bar) and Lipofectin (black bar). DNA concentration was 0.3 μg/well and lipid concentration was 4.0 μg/well. Data are expressed as RLU/μg total protein content normalized to Lipofectamine.

of Lipofectin. The most active formulations for all the other compounds in this series were 1:1 formulations of cytofectin/DOPE (Figure 2B−D). OTE for a given cytofectin was found to decrease from **1a** to **1d**.

A similar study was carried out with the ether-based series of cytofectins **2a**−**d**. An appreciable improvement in transfection abilities was observed with the ether-linked cytofectins (Figure 3). **2a** was found to be the most active cytofectin in this series which showed an OTE as a 1:1 mixture with DOPE (Figure 3A). This mixture was found to transfect COS-7 cells at least 1.2 times as efficiently as Lipofectamine and over 1 order of magnitude as efficiently as Lipofectin. **2b** was most active as a 2:1 **2b**/DOPE mixture (Figure 3B) while 1:2 **2c**/DOPE and 1:2 **2d**/DOPE were the most active formulations for **2c** and **2d**, respectively (Figures 3C and 3D). OTE for a given cytofectin was again found to decrease from **2a** to **2d**. A close examination of the optimal transfection efficiencies of both the series revealed that without exception, all ether-based cytofectins in series **2a**−**d** showed TEs greater than 0.25, which is better than the OTE of the most efficient ester-based cytofectin formulation (1:2 **1a**/DOPE). This reflects the clear advantage the cytofectins with ether link possesses over their ester linked counterparts.

Appending **1a** and **2a** with oleyl chains to give **3a** and **3c** resulted in a decrease in transfection efficiencies for both compounds (not shown). This suggests that introduction of disorder-promoting elements reduce the activity of these cytofectins. Interestingly again in this series also, the ether-based analogue of **1b** i.e., **3d** was most active without DOPE and showed an OTE of 0.74 ± 0.03 at 100% of **3d**. Closer scrutiny of the molecular structures of **1a** and **2a**, **1b**, and **3d** as well as **3a** and **3b** reveal that these pairs are identical in all respects except for the fact that the ester link in the former is replaced by an ether link in the latter. A comparison of their OTEs normalized to Lipofectamine (Figure 4) shows that while **2d** transfects 600% as efficiently as **1d**, **3d** transfects ~15 times as efficiently as **1b** and **3b** transfects twice as well as **3a**. This reveals unambiguously that the ether-based lipids transfect DNA with much greater efficiency than their ester counterparts.

We then decided to study in detail two of the most efficient cytofectin formulations, i.e., 100% of **3d** and 1:1 **2a**/DOPE. Transfection efficiencies for the above formulations were optimized by varying DNA concentration from 0.76 mM to 30.3 mM while maintaining the lipid (liposomal formulation) concentration constant. Similarly the lipid concentration was varied from 3.85 mM to 77.04 mM (for 1:1 **2a**/DOPE) and up to 137 mM (for **3d**), keeping the DNA concentration constant. The 30 different assay conditions for each well for 1:1 **2a**/DOPE is shown in Figure 5. Figure 6 provides an overview of the reagent activity under all conditions elucidated in Figure 5. Transfection efficiencies for both cytofectin formulations increased with increasing concentrations of DNA till 1 μg/well. With a further increase in DNA concentration, transfection efficiencies decreased. This bell-shaped curve has been previously reported for other cationic lipid formulations and is most likely related to the oversaturation of the cationic charges by the excess DNA (*19*). The optimum DNA concentration of both 1:1 **2a**/DOPE and **3d** was 1.0 μg/well of DNA. However, the activity profiles of both formulations showed different characteristics. **2a** exhibited a bell-shaped dependence with lipid concentration (Figure 6A). For all DNA concentrations, the optimum [lipid]/[DNA] ratio was ~4. In contrast, **3d** showed a curve that saturated at an optimum [lipid]/[DNA] ratio of ~5 (Figure 6B).

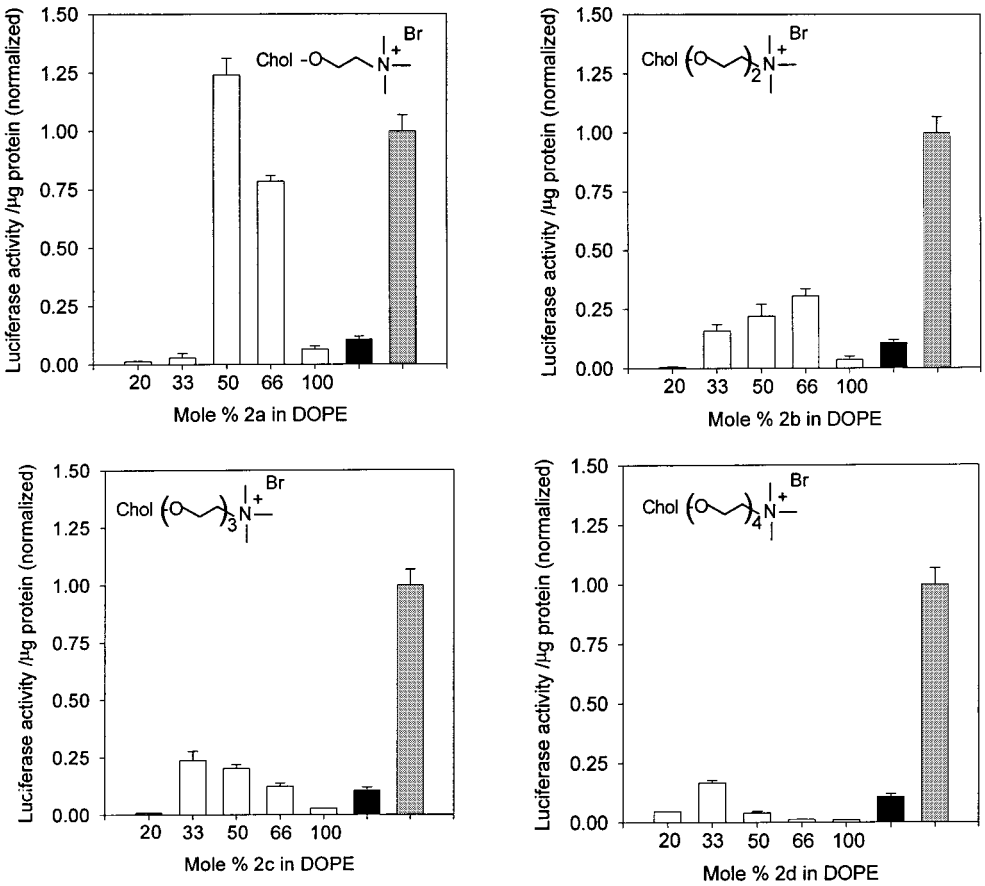

Figure 3. Comparison of transfection efficiencies of pGL3 control DNA using various compositions of **2a**−**d** in DOPE (open bar) with Lipfectamine (gray bar) and Lipofectin (black bar). DNA concentration was 0.3 μg/well and lipid concentration was 4.0 μg/well. Data are expressed as RLU/mg total protein content normalized to Lipofectamine.

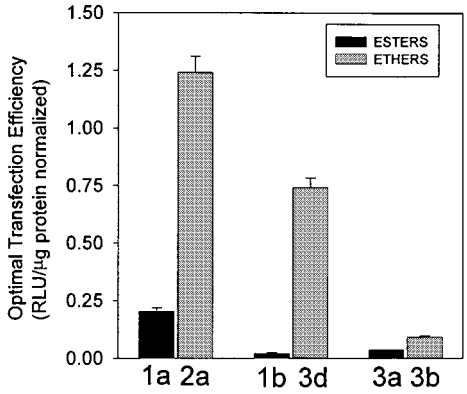

Figure 4. Comparison of transfection efficiencies of ether-based cationic cholesterol derivatives and the corresponding ester-based analogues.

3.3. Effect of Serum on Transfection Efficiency.

We then probed the efficiency of transfection of 1:1 **2a**/DOPE and **3d** in the presence of serum. Serum is known to inhibit the transfection due to the presence of negatively charged sulfate groups in certain constituents of serum which competes with the phosphodiester anions of the DNA backbone for the cationic liposome This presumably interferes with the formation of the cationic lipid−DNA complex and affects transfection efficiencies. To examine this aspect, transfections were carried out in the presence and absence of 10% fetal calf serum using the optimized conditions for the two formulations (Figure 7). A similar experiment was carried out with commercially available Lipofectamine as a comparison to evaluate the performance of these cationic cholesterol ether-based formulations. The conditions of Lipofectamine for transfection were maintained at those recommended

40,000 cells per well
0.2 mL volume

Figure 5. Concentration of cationic lipid **2a** and DNA in the transfection assay. Shown in the figure are the concentrations of cationic lipid and DNA that were present in the 30 wells of the transfection assay. Lipid concentration ranged from 3.8 to 77.0 μM (0.5 to 10 μg per well of the 1:1 **2a**/DOPE) and the DNA concentration from 0.8 to 30.3 μM (0.05−2 μg per well). DNA molarity was based on an average molecular weight of 330 per nucleotide monomer.

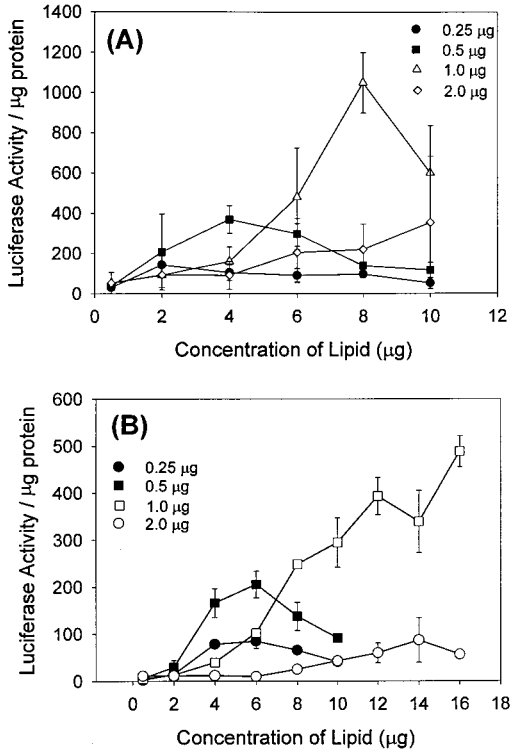

Figure 6. Optimization of Transfection Efficiency of 1:1 **2a**/DOPE (**A**) and **3d** (**B**) in DOPE. DNA concentrations were 0.05, 0.25, 1.0, and 2.0 μg/well. Data are expressed as RLU/μg of total cellular protein. Experiments were performed twice and in duplicate.

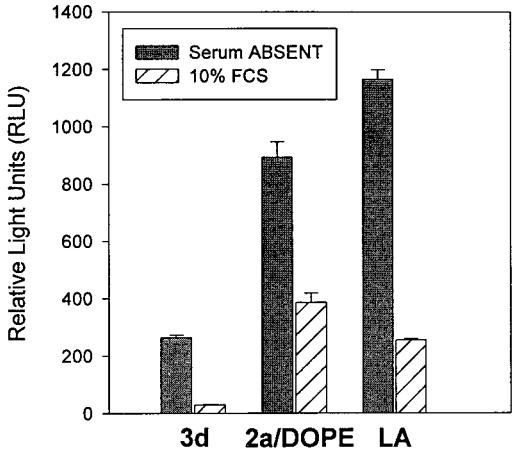

Figure 7. Transfection efficiencies in the presence of 10% FCS and absence of serum for **3d**, 1:1 **2a**/DOPE and LA (Lipofectamine). Concentration of DNA = 1.0 μg/well, concentration of **3** = 10 μg/well; LA = **2a**/DOPE = 4.0 μg/well. Data expressed as RLU for 10 μL of cell lysate.

by the manufacturers. In the presence of serum, the efficiency of **3d** was reduced to one-tenth of the activity in the absence of serum, showing that serum significantly hampers the ability of **3d** to transfect DNA. Lipofectamine activity in the presence of serum was suppressed to less than one-fourth of the transfection efficiency under serum-free conditions. In comparison, the efficiency of 1:1 **2a**/DOPE in the presence of serum was only reduced to ~50%. Thus, in the presence of serum, this formulation is about 1.4 times as efficient as Lipofectamine under these conditions.

These findings suggest that **2a** induces gene transfer by a mechanism that is probably different from the one mediated by Lipofectamine. Lipofectamine is composed of a lipid derivative of spermine (DOSPA) which at

Table 1. Optimal Transfection Efficiency of PGL3 DNA Using 1:1 2a/DOPE in Different Cell Lines

cell line	Luciferase activity (RLU/mg protein)	cell line	Luciferase activity (RLU/mg protein)
COS-7	1.1×10^6	NIH3T3	1.79×10^5
T84	3.36×10^4	HEK293	4.41×10^5

[a] Concentration of DNA = 1.0 μg/well; concentration of 1:1 **2a**/DOPE = 4.0 μg/well. Data expressed as RLU/mg of cellular protein content. Experiments were performed in duplicate.

physiological pH remains multiply protonated giving it a polycationic character. The large concentration of positive charges offered by this lipid on the membrane surface facilitates both DNA binding and fusion with the eukaryotic cell surface leading to efficient transfection. However, in the presence of serum the multicationic character of Lipofectamine makes it compete with serum against DNA, leading to significant suppression of transfection efficiency. On the other hand, **2a** possesses only one cationic center per molecule and is therefore not as drastically affected by serum.

The amount of extractable protein from treated cells was also determined (not shown) as an indication of the cytotoxicity of the treated cells. The total cellular protein for cells treated with 2 μg/well of DNA was about 80% of the untreated control. For DNA concentrations lower than 2 μg, the lowest protein content was observed for those conditions that showed the highest transfection efficiency, indicating that the lipid−DNA complex is slightly toxic. However, under optimized conditions, the toxicity of 1:1 **2a**/DOPE and **3d** were found to little lower than that of the Lipofectamine or Lipofectin−DNA complex.

Intrigued by the fact that **2a**/DOPE (1:1) induced excellent TE under various conditions in COS-7 cells, we proceeded to check its generality in conferring DNA transfection across other cell lines. Using the above determined optimized ratio of [lipid]/[DNA], 1:1 **2a**/DOPE was used to transfect cell lines such as HEK293, NIH3T3, and T84. Table 1 shows that the formulation 1:1 **2a**/DOPE is indeed able to transfect a number of cell lines. Even for a cell line such as T84, which is often not conducive to transfection, this formulation (1:1 **2a**/DOPE) shows reasonably high luciferase activity. Thus, as a liposomal transfection reagent, the cationic ether-based cholesterol derivative **2a** as a 1:1 formulation in DOPE is indeed quite versatile and efficient.

In summary, we have systematically investigated the transfection abilities of a number of new cytofectins based on cholesterol that vary in terms of linkage of the cationic charge to cholesterol. In addition, within a given series of identical linkages, the headgroup hydration was also progressively modified. In the ester-linked series **1a**−**d**, it was observed that the progressive introduction of oxyethylene units on a cationic center at a fixed location reduced the transfection efficiency. In addition, the introduction of oligooxyethylene units as a spacer in the linker region of the lipid monomer (Figure 4b) in the ether-linked series **2a**−**d** also resulted in a marked diminution of the transfection ability. Thus efficient transfection requires a rather "dry" positive charge located as close as possible to the steroid skeleton of the cytofectin. Introduction of a membrane 'disorder'-promoting element like an oleyl chain to **1a** and **2a** resulted in considerable loss of transfection efficiency. Thus, there seems to exist an optimum balance between rigidity and fluidity for this class of cytofectins. The effect of the nature of linkage was investigated in detail, and the

advantage of the ether linkage over the ester linkage was clearly evidenced.

Facile Synthesis of Thiol-Reactive Cy3 and Cy5 Derivatives with Enhanced Water Solubility

Alexei Toutchkine, Perihan Nalbant, and Klaus M. Hahn*

Department of Cell Biology, Scripps Research Institute, 10550, N. Torrey Pines Road, BCC162, La Jolla, California 92037. Received September 25, 2001

The cyanine dyes Cy3 and Cy5 have proven valuable in numerous applications involving conjugation with proteins. Practical syntheses of lysine-selective, succinimidyl ester derivatives of these dyes have been published, and succinimidyl esters are commercially available. However, the published syntheses of cysteine-selective derivatives produce relatively low yields from expensive starting materials, or produce molecules with marginal water solubility for protein labeling. We report here facile syntheses (four steps, >50% overall yield) of iodoacetamide, sulfhydryl-reactive derivatives of the Cy3 and Cy5 fluorophores. These novel derivatives have good water solubility (>2.5 mM) and bear only one reactive side chain, reducing possible protein cross-linking encountered with previous derivatives.

INTRODUCTION

The cyanine dyes Cy3 and Cy5, originally described by Waggoner and co-workers (*1*, *2*), have proven their utility in a wide range of applications. These dyes are bright and photostable, and are well suited to microscopy of living cells. Lysine-reactive succinimidyl ester derivatives of Cy3 and Cy5 for protein labeling can be readily made using published syntheses (*2*, *3*) and are commercially available. Because lysine is relatively abundant in most proteins, lysine-reactive dyes are valuable for introducing several dyes on the same protein (i.e. in antibody labeling for immunofluorescence staining). Lysine-reactive dyes, however, cannot readily be used for precise site-specific dye attachment. Site-specific labeling is usually accomplished through conjugation to cysteine, which is less abundant and can be introduced at the desired site using molecular biology approaches. Site-specific labeling is important in many potentially valuable applications of the cyanine dyes, including fluorescence resonance energy transfer (FRET) microscopy, where dyes must be placed to respond to protein activity without perturbing normal biological behavior (*4*−*6*).

This paper addresses the current inaccessibility of water soluble, cysteine-reactive Cy3 and Cy5 derivatives. Ernst et al. have described cysteine-reactive analogues of these dyes which are substantially less water soluble than the lysine-reactive derivatives and are therefore difficult to use for protein labeling. More recently, Gruber et al. produced water-soluble cysteine-reactive derivatives by linking the succinimidyl ester of the lysine-reactive dyes to chains bearing different thiol-reactive groups (*7*). The dyes used as starting materials for this approach are available only in small quantities and are very expensive. Moreover, Gruber et al. did not prepare any iodoacet-

amido derivatives, which may be advantageous in certain applications.

Here we describe straightforward, high-yielding syntheses of Cy3 and Cy5 derivatives bearing cysteine-selective iodoacetamide reactive groups. The new syntheses place two water-solubilizing sulfonate groups on the dyes, producing reagents with good water solubility for practical protein labeling. Only a single reactive side chain is introduced, minimizing problems with protein cross-linking. The new dyes are referred to as neo-Cy3 and neo-Cy5.

EXPERIMENTAL PROCEDURES

Materials. Analytical grade reagents were purchased from major suppliers.

5-Chloroacetamido-1,3,3-trimethyl-2-methyleneindoline (IV) and 5-chloroacetamidomethyl-1,3,3-trimethyl-2-methyleneindoline (VII) were prepared by the method of Gale (*8*, *9*). The potassium salt of 2,3,3-trimethylindolenine-5-sulfonate was prepared by the method of Waggoner (*2*).

Methods. UV−vis spectra were measured using a Hewlett-Packard 8453 diode array spectrophotometer. Emission and excitation spectra were obtained using a Spex Fluorolog 2 spectrofluorometer at 23 °C. Quantum yields were measured using merocyanine 540 (*10*) or indotricarbocyanine (*11*) as internal standards (*12*). Mass spectra were obtained by MALDI−FT MS techniques on an IonSpec FT MS spectrometer. ^{1}H NMR spectra of 0.5% solutions in CD_3SOCD_3 were recorded on Bruker DRX-400 or DRX-500 spectrometers. The peaks corresponding to the residual protons of CD_3SOCD_3 (2.49 ppm) were used as internal reference. All operations with dyes were performed under dim light. Flasks containing dyes were wrapped with aluminum foil.

2,3,3-Trimethyl-1-(3-sulfonatopropyl)-3*H*-indolinium-5-sulfonate (I). The potassium salt of 2,3,3-trimethylindolenine-5-sulfonate (*2*) (1.49 g, 0.006 mol, vacuum-dried) and 1,3-propane sultone (0.80 g, 0.0066mol) were mixed in 10 mL of dichlorobenzene and heated at 120 °C for 12 h with stirring under nitrogen. The mixture was cooled, 1,2-dichlorobenzene was decanted, and the solid was washed with ether to give practically pure quaternary salt. The yield was 2.20 g (90%).

^{1}H NMR (500 MHz, DMSO-d_6): δ 1.52 (s, 6H, 2 × CH_3), 2.13 (p, $^3J_{H-H}$ = 7.5 Hz, 2H, $CH_2CH_2CH_2$), 2.65 (t, $^3J_{H-H}$ = 7.5 Hz, 2H, CH_2SO_3), 2.82 (s, 3H, CH_3), 4.61(t, $^3J_{H-H}$ = 7.5 Hz, 2H, CH_2N), 7.70−8.00 (m, 3H, aromatic ring).

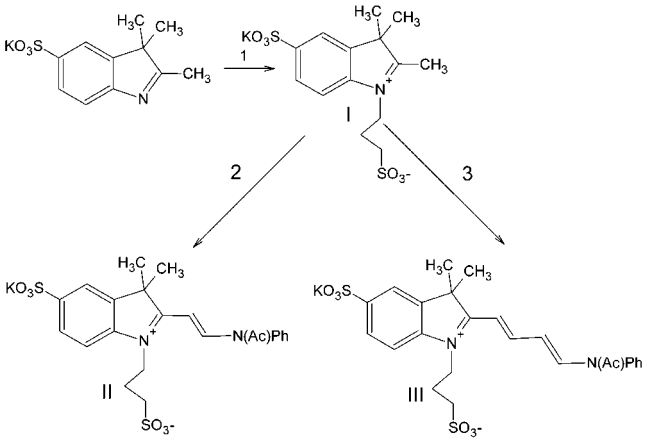
2-{(*E*)-2-[Acetyl(phenyl)amino]ethenyl}-3,3-dimethyl-1-(3-sulfonatopropyl)-3*H*-indolinium-5-sulfonate (II). A mixture of the quaternary salt I (2.00 g) and *N*,*N*′-diphenylformamidine (2.00 g) in 10 mL of acetic acid−acetic anhydride (1:2) was heated to reflux for 2 h. The solvent was removed on a rotary evaporator, and the product was washed with acetone until free yellow powder was obtained. The yield was 2.64 g (97%).

^{1}H NMR (500 MHz, DMSO-d_6): δ 1.71 (s, 6H, 2 × CH_3), 1.84 (p, $^3J_{H-H}$ = 7.5 Hz, 2H, $CH_2CH_2CH_2$), 2.15 (s, 3H, CH_3CO), 2.65 (t, $^3J_{H-H}$ = 7.5 Hz, 2H, CH_2SO_3), 4.21(t, $^3J_{H-H}$ = 7.5 Hz, 2H, CH_2N), 5.40 (d, $^3J_{H-H}$ = 14 Hz, C=C−H), 7.50−8.00 (m, 3H, aromatic ring) 9.05 (d, $^3J_{H-H}$ = 14 Hz, C=C−H).

2-{(1*E*,3*Z*)-3-[5-(Iodoacetylamino)-1,3,3-trimethyl-1,3-dihydro-2*H*-indol-2-ylidene]prop-1-enyl}-1-(3-sulfonatopropyl)-3*H*-indolium-5-sulfonate (Neo-Cy3, VI). A mixture of 1.35 g of anyl II and 0.65 g of 5-chloroacetamido-1,3,3-trimethyl-2-methyleneindoline IV was heated in 20 mL of acetic anhydride at 130 °C with stirring under nitrogen for 45 min. The mixture was cooled to room temperature, and the dye was separated by filtration. The crude dye was chromatographed over silica gel, eluting with acetone−methanol (3:1), to yield 1.15 g (71%) of pure chloroacetamido cyanine V. This dye was refluxed for 3 h in methanol (30 mL) containing 2.0 g of sodium iodide. The solution was cooled, filtered and concentrated in a vacuum to 10 mL. The dye was precipitated by the addition of 100 mL of acetone to give 1.2 g of dye VI (92%). The analytical sample of the dye was purified by HPLC on a Vydac C-18 column (no. 218TP152022, 22 × 250 mm, 15−20 μm), 3 mL/min water−acetonitrile gradient.

^{1}H NMR (500 MHz, DMSO-d_6): δ 1.74 (s, 6H, 2 × CH_3), 1.76 (s, 6H, 2 × CH_3), 2.08 (p, $^3J_{H-H}$ = 7.0 Hz, 2H, $CH_2CH_2CH_2$), 2.70 (t, $^3J_{H-H}$ = 7.0 Hz, 2H, CH_2SO_3), 3.71 (s, 3H, CH_3, N−CH_3), 3.91 (s, 2H, CH_2, CH_2I), 4.30 (t, $^3J_{H-H}$ = 7.0 Hz, 2H, CH_2N), 6.48 (d, $^3J_{H-H}$ = 13.6 Hz, 1H, C=C−H), 6.62 (d, $^3J_{H-H}$ = 13.6 Hz, 1H, C=C−H), 7.48−7.90 (m, 6H, aromatics), 8.38 (t, $^3J_{H-H}$ = 13.6 Hz, C=C−H), 10.59 (s, 1H, NH−CO). MALDI−FTMS: MH^+ found: 750.0746, calculated: 750.0775.

2-[(1*E*,3*E*)-4-Acetyl(phenyl)aminobuta-1,3-dienyl]-3,3-dimethyl-1-(3-sulfonatopropyl)-3*H*-indolium-5-sulfonate (III). A mixture of the quaternary salt I (2.00 g) and malonaldehyde dianilide hydrochloride (0.65 g) in 10 mL of acetic acid−acetic anhydride (1:2) was heated at reflux for 2 h. The solution of anyl was cooled to room temperature and used without further purification in the next step.



2-[(1*E*,3*E*,5*Z*)-5-(5-(Iodoacetylamino)-1,3,3-trimethyl-1,3-dihydro-2*H*-indol-2-ylidene)penta-1,3-dienyl]-1-(3-sulfonatopropyl)-3*H*-indolium-5-sulfonate (neo-Cy5, VIII). The solution of anyl III was mixed with 1.39 g of 5-chloroacetamidomethyl-1,3,3-trimethyl-2-methyleneindoline VII. The mixture was heated to 120 °C for 20 min and cooled to room temperature. The diethyl ether was added to the mixture to precipitate the dye. The crude dye was chromatographed over silica gel, eluting with acetone−methanol (3:1), to yield 2.14 g (61%) of pure chloroacetamido cyanine (VIII). This dye was refluxed in 30 mL of methanol containing 2.0 g of sodium iodide for 3 h. The solution was cooled, filtered, and concentrated in a vacuum to 10 mL. The dye was precipitated by the addition of 100 mL of acetone to give 2.30 g (95%) of dye IX. The analytical sample of the dye was purified by HPLC on a Vydac C-18 column (the same condition as for neo-Cy3 dye).

^{1}H NMR (400 MHz, DMSO-d_6): δ 1.67 (s, 12H, 4xCH_3), 1.98 (p, $^3J_{H-H}$ = 7.3 Hz, 2H, $CH_2CH_2CH_2$), 2.67 (t, $^3J_{H-H}$ = 7.3 Hz, 2H, CH_2SO_3), 3.60 (s, 3H, CH_3, N−CH_3), 3.71 (s, 2H, CH_2, CH_2I), 4.28 (t, $^3J_{H-H}$ = 7.3 Hz, 2H, CH_2N), 4.32 (d, $^3J_{H-H}$ = 5.6 Hz, 2H, CH_2−NH), 6.28 (d, $^3J_{H-H}$ = 14.1 Hz, 1H, C=C−H), 6.40−8.60 (m, 11H). MALDI−FTMS: MH^+found: 790.1078,calculated: 790.1088.

Preparation of Neo-Cy3−Cysteine Conjugate. A 30 mg amount of neo-Cy3 dye was added to 30 mg of cysteine in 2.0 mL of $NaHCO_3$−Na_2CO_3 buffer (pH = 8.0), and the mixture was stirred for 2 h at room temperature. Silica gel TLC (CH_3CN−H_2O: 90−10) showed complete consumption of starting dye. Several drops of hydrochloric acid were added to the mixture until pH = 5, and the conjugate was isolated by preparative HPLC on Vydac C18 column (same condition as for neo-Cy3 dye).

^{1}H NMR (500 MHz, DMSO-d_6): δ 1.74 (s, 6H, 2 × CH_3), 1.76 (s, 6H, 2 × CH_3), 2.08 (p, $^3J_{H-H}$ = 7.0 Hz, 2H, $CH_2CH_2CH_2$), 2.70 (t, $^3J_{H-H}$ = 7.0 Hz, 2H, CH_2SO_3), 3.71

(s, 3H, CH_3, $N-CH_3$), 3.91 (s, 2H, CH_2, CH_2I), 4.30 (t, $^3J_{H-H}$ = 7.0 Hz, 2H, CH_2N), 6.48 (d, $^3J_{H-H}$ = 13.6 Hz, 1H, C=C−H), 6.62 (d, $^3J_{H-H}$ = 13.6 Hz, 1H, C=C−H), 7.48−7.90(m, 6H, aromatics), 8.38 (t, $^3J_{H-H}$ = 13.6 Hz, C=C−H), 10.59 (s, 1H, NH−CO). MALDI−FTMS: MH^+ found:743.1868, calculated: 743.185.

Protein Labeling. A fragment of Wiskott Aldrich Syndrome Protein (WASP, residues 201−320), mutated to contain a single cysteine (F271C), was labeled with Cy3 and separately with Cy5 dye. A stock solution of the dye in DMSO (10−20 mM) was added to 200 μL of protein solution (200 μM in sodium phosphate buffer, pH = 7.5), to produce a final dye concentration of 1−2 mM. The reaction mixture was incubated for 4 h at room temperature and then quenched by addition of 1 μL mercaptoethanol. The reaction mixture was spun at 12000 rpm for 2 min to remove any precipitates, which might have formed during the reaction, and the supernatant was purified using G25 sepharose gel filtration. The dye−protein adduct was clearly separated from free dye during gel-filtration. Purity of the conjugates was confirmed by SDS−PAGE electrophoresis. No free dye was seen in purified protein conjugates. Control samples of free dye were clearly visible on the gel at lower MW than protein. Conjugates formed single, highly colored fluorescent

protein bands with molecular weights corresponding to the WASP fragment. The dye-to-protein ratio was calculated by measuring protein and dye concentrations using absorbance spectroscopy as previously described (*13*). In each case this ratio was between 0.9 and 1.0.

RESULTS AND DISCUSSION

The most widely used thiol-reactive groups for protein modification are maleimide and iodoacetamide. Maleimide adducts have disadvantages in that they can hydrolyze, thereby causing significant changes in the fluorescence of protein conjugates, and they can undergo a nucleophilic ring-opening reaction with amines to yield cross-linked protein products (*13*). We therefore chose the iodoacetamide group as the reactive side chain for the new dyes. They contain one reactive side chain rather than the two found in some earlier derivatives. This abrogates problems of protein cross-linking and inhomogeneous conjugation sometimes seen during labeling.

The synthesis of both new cyanine dyes was accomplished using the same general method (*14*), in which Fischer's bases IV and VII were condensed with acetanilidovinyl salts II and III (Scheme 2). These straightforward syntheses produced the dyes in four steps with overall yields of 57% (neo-Cy3) and 50% (neo-Cy5). The reactivity of these iodoacetamido dyes was verified by facile formation of conjugates with cysteine and with purified protein (see Materials and Methods).

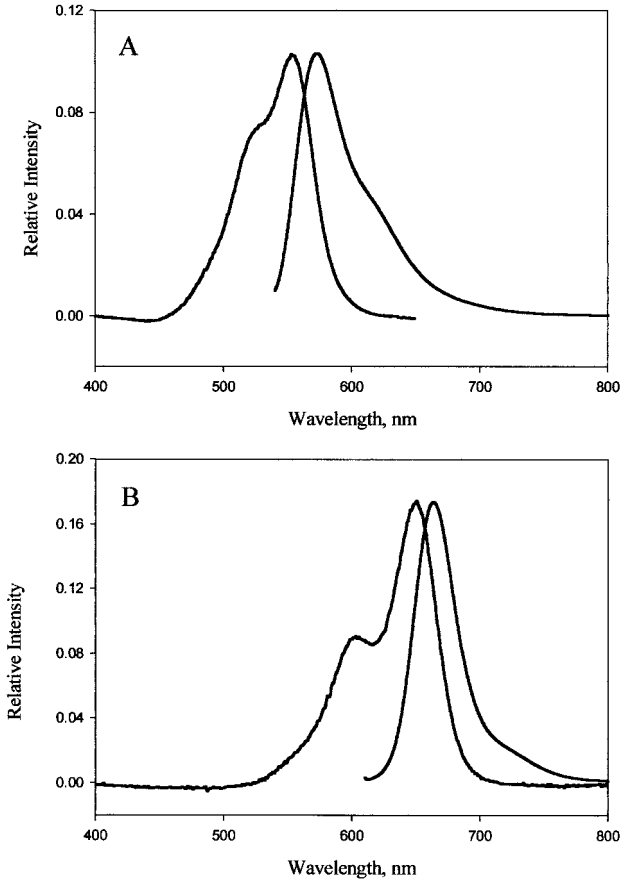

Figure 2. Normalized absorbance and fluorescence spectra of neo-Cy3-WASP (A) and neo-Cy5-WASP (B) conjugates in PBS (pH = 7.4), concentrations 1 μM.

Importantly, the neo-Cy dyes bear two sulfonate groups (Figure 1), and this leads to excellent water solubility (neo-Cy3, 3 mM; neo-Cy5, 2.5 mM), bringing accessible concentrations into the range typically used for protein labeling. The fluorescence properties of the neo-Cy dyes are given in Table 1. The quantum yields, extinction coefficients, and fluorescence maxima of the neo-Cy dyes deviate little from those reported for Cy3 and Cy5. As

with Cy3 and Cy5, the absorbance and emission maxima of the new dyes show little solvent sensitivity, while the quantum yields are greater in more hydrophobic (methanol) or more viscous (dimethyl sulfoxide) solvents (Table 1) as was previously reported for many polymethine dyes (*15*). The main nonfluorescent deactivation path for the exited state of cyanine dyes is photoisomerization around the central double bond, and the rate of this photoisomerization becomes smaller as hydrophobicity or viscosity of the solvent increases (*15*).

Attachment of the dyes to cysteine or to a protein (a fragment of WASP, see Materials and Methods) did not alter the dyes' favorable fluorescence properties (Table 1, Figure 2).

Both the absorbance and fluorescence spectra are similar to spectra of free dyes, indicating that there is no quenching of fluorescence after attachment of dyes to protein.

CONCLUSION

The many published applications of the original Cy3 and Cy5 dyes attest to their value. We hope that the straightforward syntheses presented here will make cysteine-reactive derivatives accessible to more researchers.

Low-Density Lipoprotein Reconstituted by Pyropheophorbide Cholesteryl Oleate as Target-Specific Photosensitizer

Gang Zheng,*,† Hui Li,† Min Zhang,†,§ Sissel Lund-Katz,‖ Britton Chance,‡ and Jerry D. Glickson†

Department of Radiology, Department of Biochemistry and Biophysics, University of Pennsylvania Medical School, Philadelphia, Pennsylvania 19104; and Department of Chemistry, Shanghai University, Shanghai 200436, China; and Department of Pediatric GI Nutrition, The Children's Hospital of Philadelphia, Philadelphia, PA 19104. Received December 14, 2001

To target tumors overexpressing low-density lipoprotein receptors (LDLr), a pyropheophorbide cholesterol oleate conjugate was synthesized and successfully reconstituted into the low-density lipoprotein (LDL) lipid core. Laser scanning confocal microscopy studies demonstrated that this photosensitizer-reconstituted LDL can be internalized via LDLr by human hepatoblastoma G_2 ($HepG_2$) tumor cells.

INTRODUCTION

Photodynamic therapy (PDT) is a promising cancer treatment that involves the combination of light and a photosensitizer, normally a porphyrin derivative. Each factor is harmless by itself, but when combined with oxygen they can produce lethal reactive oxygen species that kill tumor cells (*1*). Singlet oxygen ($^1O_2$) is a powerful, fairly indiscriminate oxidant that is generally recognized as the key agent of PDT-induced tumor necrosis. Because the diffusion range of $^1O_2$ is much smaller than the diameter of a single cell, the site of the primary generation of $^1O_2$ determines which subcellular structures may be attacked (*2*). Consequently, if a photosensitizer is preferentially localized in tumor cells, PDT-induced cellular damage will be highly tumor specific. Therefore, target-specific photosensitizers are desirable.

The LDL particle consists of a nonpolar core of neutral lipids (cholesterol esters, triglycerides) surrounded by a polar shell of phospholipid, unesterified cholesterol, and apolipoprotein B100 that is recognized by cell surface LDLr (*3*). A number of tumors overexpress LDLr to meet the high cholesterol demand for membrane synthesis. These include acute myelogenous leukemia (3- to 100-fold), colon cancer (6-fold), adrenal adenoma (8-fold), lung carcinoma, brain tumors, and metastatic prostate cancer (*4*−*6*). Therefore, numerous efforts have been made to use LDL as a vehicle for selective delivery of photosensitizers and other antitumor agents. Porphyrins are known for their ability to associate with LDL through direct incubation without inhibiting LDLr binding (*7*) or processing (*8*). Thus, many PDT agents were incorporated into LDL via this approach and showed improved activity (*9*). For example, a benzoporphyrin derivative (BPD) associated with LDL by simple mixing induced photodynamic cell killing 7-fold better than BPD alone (*10*). However, such a simple incubation method has a major drawback in that porphyrins can exchange between LDL, other phospholipids, and cell membranes, reducing the targeting specificity.

One of the most important methods for packaging and delivering LDL-targeting drugs is the LDL reconstitution approach. Kreiger et al. were the first to report that it is possible to reconstitute the core of LDL with exogenous neutral lipids or suitable hydrophobic compounds, and such reconstituted LDL (r-LDL) is essentially identical with native LDL in its ability to bind to LDLr, to be internalized by cells and to be hydrolyzed in lysosomes (*11*). Since r-LDL can be internalized exclusively by LDLr, many cytotoxic compounds were delivered to cancer cells using this method and showed good antitumor activity (*4*−*6*). However, competing with tumor for r-LDL are organs known to overexpress LDLr, particularly the liver and adrenals, leading to undesirable toxicity (*12*). In this regard, the PDT protocol utilizing photosensitizer based r-LDL will be more suitable because (1) organ selectivity of PDT will come from the ability to confine activation of the photosensitizer to the tumors by restricting the illumination to that specific region; (2) the photosensitizer itself should bear no dark toxicity; and (3) the photosensitizer phototoxicity can be postponed until after non-tumor-bound photosensitizer has been cleared from the body. Goldstein, Brown, and co-workers first introduced a pyrene-based r-LDL for targeted killing of cells by LDLr-mediated photosensitization (irradiation at 300−400 nm) (*13*). However, this pioneering approach has never been applied using porphyrins, the most useful PDT agents. We report here the design and synthesis of a novel chlorophyll-based photosensitizer containing anchors that render it compatible with LDL's phospholipid coat and lipophilic core. This new dye conjugate was successfully reconstituted into the LDL core, and such an r-LDL-based photosensitizer was internalized by tumor cells overexpressing LDLr and accumulated in intracellular compartments such as endosomes or lysosomes.

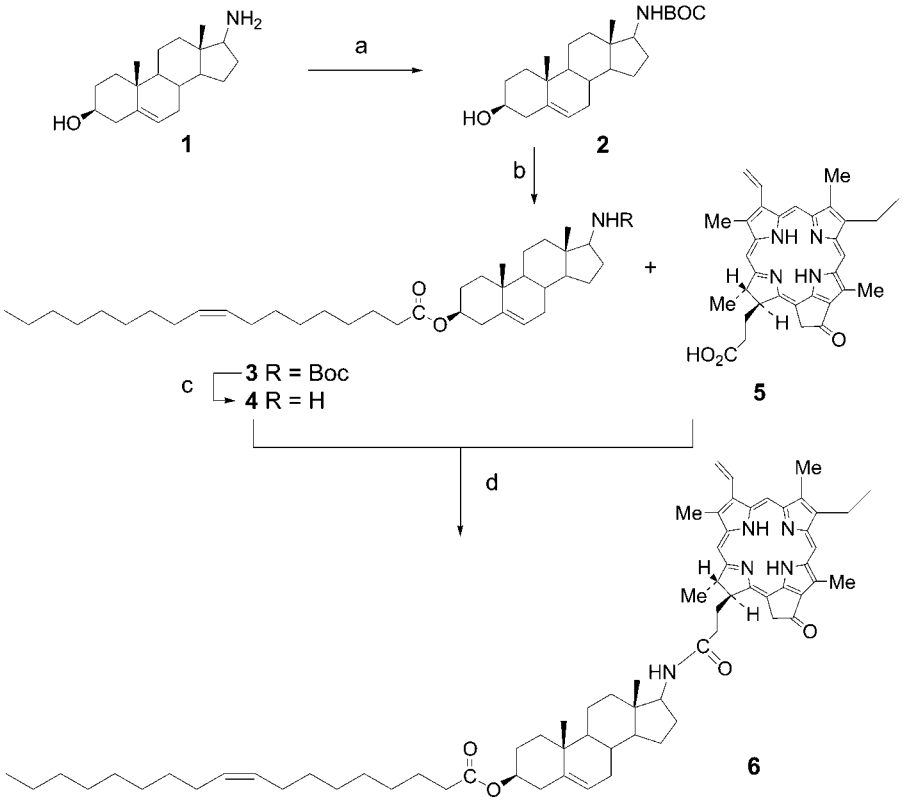
EXPERIMENTAL PROCEDURES

Materials and General Methods. Melting points (uncorrected) were measured with a Mel-Temp II apparatus. UV−vis spectra were recorded with a Beckman DU-600 spectrophotometer. ^{1}H NMR and ^{13}C NMR spectra were recorded with Bruker ASPECT 360 MHz instrument. Mass spectrometry analysis and elemental analysis were performed at the Mass Spectrometry Facility of the Department of Chemistry, University of Pennsylvania. 5-Androsten-17β-amino-3β-ol was purchased from Steraloid Inc., Newport, RI. Methyl pheophorbide *a* was obtained from *Spirulina pacifica* algae available from Cyanotech Corp., Hawaii. Other chemicals were purchased from Aldrich. Where necessary, solvents were dried before use. For TLC, EM Science TLC plates (silica gel 60 F_{254}) were used. Chlorophyll derivatives were visible without staining, and other compounds were stained with phosphomolybdic acid reagent. Reverse phase (RP) analytical HPLC was performed using a Zorbax RX-C8 (9.4 mm × 250 mm) column eluting at 1.0 mL/min with MeCN/phosphate buffer (25% to 95% MeCN gradient) with UV−vis detection at 414 nm.

5-Androsten-17β-Boc-amino-3β-ol (2). Di-*tert*-butyl dicarbonate (420 g, 1.90 mmol) was added to a solution containing 5-androsten-17β-amino-3β-ol (475 mg, 1.64 mmol) and triethylamine (0.27 mL, 1.94 mmol) in dichloromethane (50 mL). The reaction mixture was stirred at room temperature for 2 days. Evaporation of the solvent gave a white residue. This crude product was purified by silica gel column chromatography (30% ethyl acetate in hexanes) to give **2** as a white solid in 95% yield (610 mg, 1.57 mmol). Mp: 168−172 °C; exact mass calcd: 389.3; found by ESI-MS: 390.4 (MH^+). Anal. Calcd for $C_{24}H_{39}NO_3$: C, 73.99; H, 10.09; N, 3.60. Found: C, 73.52; H, 10.39; N, 3.19. ^{1}H NMR ($CDCl_3$): δ 5.34 (m, 1H, 6-H), 4.42 (brs, 1H, N−H), 3.53 (m, 2H, 3-H + 17-H), 2.27 (m, 2H), 2.17−1.92 (m, 2H), 1.90−1.70 (m, 3H), 1.69−1.49 (m, 6H), 1.48−1.32 (m, 3H), 1.44 (s, 9H for *tert*-butyl), 1.31−1.15 (m, 2H), 1.15−0.95 (m, 2H), 1.00 (s, 3H, 19-CH_3), 0.67 (s, 3H, 18-CH_3); ^{13}C NMR ($CDCl_3$): δ 156.2, 141.1, 121.5, 79.2, 71.9, 60.5, 53.0, 50.4, 42.8, 42.5, 37.5, 37.2, 36.8, 32.3, 31.8, 31.7, 29.0, 28.6, 28.6, 28.6, 23.7, 20.9, 19.6, 12.0.



5-Androsten-17β-Boc-amino-3β-yl Oleate (3). Oleoyl chloride (710 mg, 2.35 mmol) was slowly added into a 20 mL pyridine solution of **2** (610 mg, 1.57 mmol). After 2 h, the reaction mixture was poured into 40 mL of ice−water. It was filtered and washed with water three times to give a crude residue. This crude product was then chromatographed on silica column with 10% ethyl acetate in hexanes to afford the title compound as sticky solid in 60% yield (615 mg, 0.94 mmol). Exact mass calcd: 653.5; found by ESI-MS: 654.6 (MH^+). Anal. Calcd for $C_{42}H_{71}NO_4$: C, 77.13; H, 10.94; N, 2.14. Found: C, 77.35; H, 11.41; N, 1.76. ^{1}H NMR ($CDCl_3$): δ 5.32 (m, 3H, 6-H + 2 × vinyl-H of oleate), 4.58 (m, 1H, 3-H), 4.41 (brs, 1H, N−H), 3.52 (m, 1H, 17-H), 2.28 (m, 4H), 2.17−1.70 (m, 10H), 1.61 (m, 8H), 1.50−1.38 (m, 2H), 1.43 (s, 9H for *tert*-butyl), 1.37−0.95 (m, 23H), 1.00 (s, 3H, 19-CH_3), 0.85 (t, 3H, terminal CH_3 of oleate), 0.65 (s, 3H, 18-CH_3); ^{13}C NMR ($CDCl_3$): δ 173.3, 139.4, 130.1, 129.9, 122.4, 78.1, 73.7, 60.5, 52.8, 50.2, 42.7, 38.3, 37.1, 37.0, 36.8, 34.8, 32.2, 32.1, 31.7, 29.9, 29.8, 29.7, 29.5, 29.5, 29.3, 29.3, 29.2, 29.2, 28.9, 28.6, 28.6, 28.6, 27.9, 27.4, 27.3, 25.2, 23.7, 22.8, 20.7, 19.5, 14.3, 11.9.

5-Androsten-17β-amino-3β-yl Oleate (4). Compound **3** (340 mg, 0.52 mmol) was dissolved in trifluoroacetic acid (5 mL), and the mixture was stirred at room temperature under argon atmosphere for 2.5 h. The acid was removed by rotavapor. Saturated aqueous Na_2CO_3 (5 mL) was added to the residue and then extracted with CH_2Cl_2 (3 × 10 mL), and the combined extracts were dried with Na_2SO_4. After the solvent was removed, the residue was dried under high vacuum and used for the conjugation step without further purification (260 mg, 0.47 mmol). Mass calcd for $C_{37}H_{63}NO_2$: 553.5; found by ESI-MS: 554.8 (MH^+).

Pyropheophorbide *a* (5). Methyl pheophorbide *a* (500 mg, 0.82 mmol) isolated from *Spirulina* algae was heated under refluxed temperature in collidine (100 mL) for 3 h under nitrogen atmosphere. The solution was evaporated under high vacuum, and the residue so obtained was chromatographed over an alumina column (Grade III) and eluted with CH_2Cl_2. Pyropheophorbide *a* methyl ester was crystallized from CH_2Cl_2/hexanes in 91% yield (411 mg, 0.75 mmol). This intermediate (250 mg, 0.46 mmol) was dissolved in THF (65 mL) and mixed with a solution containing LiOH (500 mg), methanol (7 mL), and water (3 mL). The mixture was stirred under argon atmosphere for 24 h. After workup, the crude product was chromatographed on a silica column with 10% methanol in CH_2Cl_2 to give the title compound in 82% yield (200 mg, 0.37 mmol). The spectral and physical data of compound **5** are consistent with the literature (*14*). Mp: 220−223 °C. UV−vis in CH_2Cl_2: 411 nm (ϵ 1.1 × 10^5), 509 (1.1 × 10^4), 537 (9.6 × 10^3), 611 (8.2 × 10^3), and 669 (4.5 × 10^4). Mass calcd for $C_{33}H_{34}N_4O_3$: 534.5; found by ESI-MS: 535.6 (MH^+) and 557.6 ($M + Na^+$). ^{1}H NMR ($CDCl_3$): 9.47, 9.35, and 8.53 (each s, 1H, 5-H, 10-H, and 20-H); 8.00 (dd, J = 17.7, 11.4 Hz, 1H, 3^1-CH=CH_2); 6.27 (d, J = 17.7 Hz, 1H, *trans*-3^2-CH=CH_2); 6.15 (d, J = 11.4 Hz, 1H, *cis*-3^2-CH=CH_2); 5.18 (ABX, 2H, 13^2-CH_2); 4.47 (q, J = 7.1, 1.9 Hz, 1H for 18-H); 4.29 (m, J = 7.8 Hz, 1H for 17-H); 3.68 (q, J = 7.4 Hz, 2H, 8-CH_2-CH_3); 3.64, 3.39, and 3.22 (each s, 3H, 12-CH_3, 2-CH_3 and 7-CH_3); 2.65 and 2.32 (each m, 2H, for 2 × 17^1-H and 2 × 17^2-H); 1.81 (d, J = 7.2 Hz, 3H, 18-CH_3); 1.70 (t, J = 8.3 Hz, 3H, 8-CH_2CH_3), 0.87 and −1.35 (each brs, 1H, 2 × N−H).

Pyropheophorbide Cholesterol Oleate (6). Compound **5** (45 mg, 0.084 mmol) was activated with DCC (20 mg, 0.097 mmol) and 1-hydroxybenzotriazole (14 mg, 0.103 mmol) in CH_2Cl_2 (2 mL) and added to a solution of the cholesterol oleate amine **4** (50 mg, 0.090) in CH_2Cl_2 (3 mL). After being stirred for 24 h, solvent was removed, and the crude product was purified by silica gel plate chromatography (3% methanol in CH_2Cl_2) to afford the desired conjugate in 20% yield (18 mg, 0.017 mmol). Analytical RP HPLC: t_R 35.81 min, 99%. UV−vis in CH_2Cl_2: 414 nm (ϵ 9.8 × 10^4), 510 (1.1 × 10^4), 541 (1.1 × 10^4), 610 (5.4 × 10^3), and 667 (4.5 × 10^4). Mass calcd for $C_{70}H_{95}N_5O_4$: 1070.7462 (MH^+); found by HRMS: 1070.7412 (MH^+); ^{1}H NMR ($CDCl_3$): 9.37, 9.33, and 8.55 (each s, 1H, 5-H, 10-H, and 20-H of pyro); 8.00 (dd, J = 17.7, 11.4 Hz, 1H, 3^1-CH=CH_2 of pyro); 6.28 (d, J = 17.7 Hz, 1H, *trans*-3^2-CH=CH_2 of pyro); 6.17 (d, J = 11.4 Hz, 1H, *cis*-3^2-CH=CH_2 of pyro); 5.31 (m, 3H, 2 × vinyl-H and 6-H of oleate), 5.23 (ABX, 2H, 13^2-CH_2 of pyro); 5.02 (m, 1H, N−H of cholesterol), 4.55 (m, 2H, 18-H of pyro, 3-H of cholesterol); 4.35 (m, J = 7.8 Hz, 1H for 17-H of pyro); 3.75 (m, 1H, 17-H of cholesterol), 3.63 (q, J = 7.4 Hz, 2H, 8-CH_2CH_3 of pyro); 3.47, 3.46 and 3.23 (each s, 3H, 12-CH_3, 2-CH_3 and 7-CH_3 of pyro); 2.71 and 2.46 (each m, 2H, for 2 × 17^1-H and 2 × 17^2-H of pyro); 2.22 (m, 6H of cholesterol oleate), 2.10−1.75 (m, 11H of cholesterol oleate), 1.70−0.95 (m, 39H of cholesterol oleate), 1.82 (d, J = 7.2 Hz, 3H, 18-CH_3 of pyro); 1.65 (t, J = 8.3 Hz, 3H, 8-CH_2CH_3 of pyro), 0.88 (m, 6H, 19-CH_3

Scheme 1. Synthesis of Cholesteryl Oleate Amine 4 and Its Corresponding Pyropheophorbide Conjugate 6

[a] Reagents (yields in parentheses): (a) $(BOC)_2O$, Et_3N, CH_2Cl_2, 24 h (95%); (b) oleoyl chloride, pyridine, 2 h (60%); (c) TFA, 2.5 h (90%); (d) DCC, 1-hydroxybenzotriazole, CH_2Cl_2, 24 h (20%).

of cholesterol and terminal CH_3 of oleate), 0.32 (s, 3H, 18-CH_3 of cholesterol).

LDL Reconstitution. LDL (1.9 mg) was lyophilized with 25 mg starch and then extracted three times with 5 mL of heptane at −5 °C. Following aspiration of the last heptane extract, 6 mg of pyropheophorbide cholesteryl oleate (**6**) was added in 200 μL of benzene. After 90 min at 4 °C, benzene and any residual heptane were removed under a stream of N_2 in an ice−salt bath for about 45 min. The r-(Pyro-CE)−LDL was solubilized in 10 mM Tricine, pH 8.2, at 4 °C for 24 h. Starch was removed from the solution by low-speed centrifugation (500*g*) and followed by a 20 min centrifugation (6000*g*). The reconstituted LDL was stored under an inert gas at 4 °C. The protein content of the specimen was determined by the Lowry method (*15*), and the fluorescence was measured using an LS-50B Fluorometer.

Cell Preparations. $HepG_2$ tumor cells, which were obtained from Dr. Theo van Berkel's laboratory from the University of Leiden in The Netherlands, were cultured in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum (FBS), 100 U/mL penicillin−streptomycin. Cells were grown at 37 °C in an atmosphere of 5% CO_2 in a humidified incubator.

Confocal Microscopic Studies. For confocal microscopic studies, $HepG_2$ cells were grown for 5 days in four-well Lab-Tek chamber slides (Naperville, IL). Before the cell experiments, the culture medium was replaced by preincubation medium (medium with 1% (w/v) BSA instead of FBS). The cells were washed three times with preincubation medium (for 15, 15, and 30 min) and cultured in this medium for a further 20 h. Experiments were started, after two quick washes with preincubation medium, by the addition of preincubation medium containing the indicated amounts of r-(Pyro-CE)-LDL and/or unlabeled LDL. After 3 h incubation at 37 °C, the cells were washed five times with ice-cold PBS containing 0.8% BSA, two times with PBS alone, and fixed for 20 min with 2% formaldehyde in PBS at room temperature. Then the chamber slides were mounted and sealed for confocal microscopic analysis.

RESULTS AND DISCUSSION

Our choice of the photosensitizer, pyropheophorbide *a*, is a stable analogue of natural chlorophyll *a*. It has excellent photophysical properties with long wavelength absorption of 667 nm. One of its derivatives, the hexyl ether analogue of pyropheophorbide *a* (Photochlor) is currently in phase I/II clinical trial at the Roswell Park Cancer Institute (Buffalo, NY) (*16*). As for the anchor, a cholesteryl oleate containing a primary amine linker was designed for conjugation with a variety of PDT agents. The oleate moiety contains one cis-double bond leading to a bent form of the long hydrocarbon chain that may facilitate the reconstitution process, whereas the cholesterol moiety will serve to anchor lipids in the core, thus eliminating nonspecific leakage.

To synthesize the desired cholesteryl oleate amine, we developed a very short and efficient pathway. As shown in Scheme 1, a commercially available cholesterol amine (**1**), 5-androsten-17β-amino-3β-ol (Steraloid Inc., Newport, RI), was first Boc-protected and esterified with oleoyl chloride. Deprotection of the amine at C-17 gave the corresponding cholesteryl oleate amine **4** in 60% overall yield. Coupling of amine **4** to pyropheophorbide *a* **5** (Scheme 1), obtained from *Spirulina* algae in short steps (*14*), yielded the desired conjugate **6** in sufficient quantities for LDL reconstitution studies. All new compounds were characterized by mass and NMR spectro-

scopic studies, and the purity of these compounds was confirmed by either elemental analysis or HPLC studies.

The pyropheophorbide cholesteryl oleate (**6**) so obtained was then used for reconstituting LDL. Following a modified Krieger's procedure as reported by Craig et al. (*17*), we were able to extract the native cholesteryl esters from the LDL lipid core and successfully replace them with our newly synthesized conjugate. The success of reconstitution was determined by a protein recovery assay following Lowry's method. Our pyropheophorbide cholesteryl oleate reconstituted LDL, r-(Pyro-CE)-LDL, yielded a 45% protein recovery comparable to the published data of 48% protein recovery (*17*) for other hydrophobic molecules. This LDL-based photosensitizer has long wavelength absorption of 667 nm and produces a fluorescence signal in the near-infrared (NIR) range (720 nm). Therefore, this photosensitizer can also be used for NIR detection of early cancers by optical imaging techniques.

To visualize LDLr-mediated internalization into the tumor cells, we performed laser scanning confocal microscopy studies on our newly synthesized r-(Pyro-CE)-LDL in $HepG_2$ tumor cells. Four sets of experiments were performed on a Leica TCS SPII laser scanning confocal microscope (Heidelberg, Germany). Figure 1 shows the confocal microscopic images of $HepG_2$ cells incubated with/without fluorescent probe (B, D, F, H) as well as corresponding bright field images (A, C, E, G). In a control experiment, $HepG_2$ cells were incubated with native LDL but without the photosensitizer at 37 °C for 3 h to determine any possible background fluorescence. As expected, no fluorescence signal could be detected without the photosensitizer (Figure 1B). After the incubation with 20 μg/mL of r-(Pyro-CE)-LDL, an intense fluorescence signal was observed distributing throughout the whole cell except for the nucleus, presumably in intracellular compartments such as endosomes or lysosomes (Figure 1D). To determine the specificity of this LDL-based photosensitizer toward LDL receptors, $HepG_2$ cells were incubated with either a 25-fold excess of unlabeled LDL in addition to the 20 μg/mL r-(Pyro-CE)-LDL or the same amount of Pyro-CE (compound **6**) without reconstitution into LDL. No fluorescence could be observed in both experiments (Figure 1F, 1H), which clearly indicates specific binding of the reconstituted LDL to the LDL receptors.

In summary, we have demonstrated that pyropheophorbide, a stable photosensitizer derived from chlorophyll *a*, can be covalently linked to the primary amine functional group of the cholesteryl oleate, which serves as a double anchor for the LDL lipid core and can be synthesized in short steps. We were able to successfully incorporate this dye conjugate into the LDL lipid core via the LDL reconstitution approach. By using laser scanning confocal microscopy, we have demonstrated that photosensitizer-reconstituted LDL can be internalized by $HepG_2$ tumor cells and, therefore, can be used as a PDT agent directed at LDLr-overexpressing tumors.

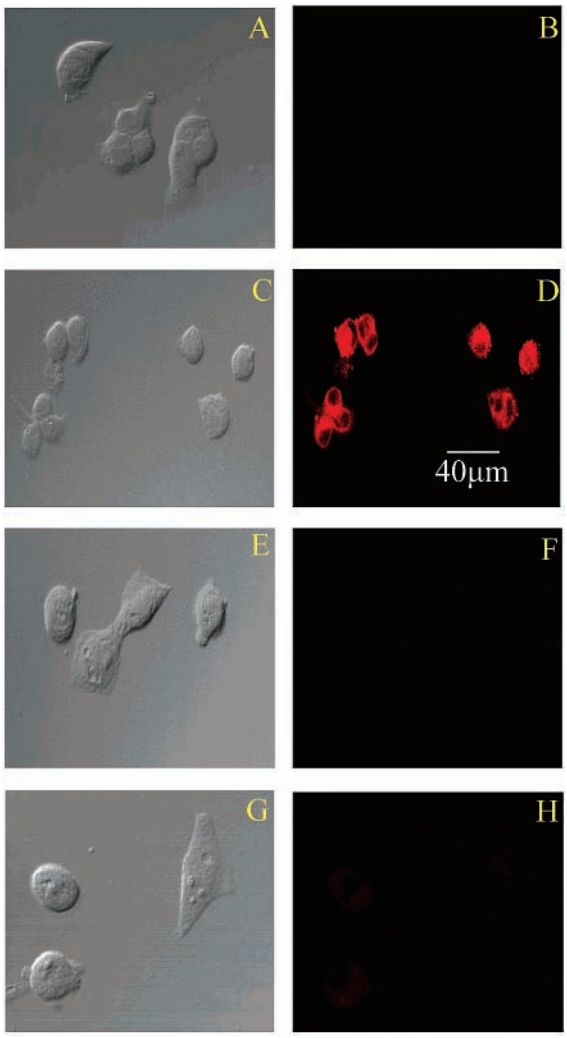


Figure 1. Fluorescence confocal microscopic images of $HepG_2$ tumor cells incubated with unlabeled LDL as control (B), 20 μg/mL of r-(Pyro-CE)-LDL for binding assay (D), 20 μg/mL of r-(Pyro-CE)-LDL with 25-fold excess of unlabeled LDL for competition assay (F), 20 μg/mL non-LDL-reconstituted Pyro-CE for comparison (H), as well as the corresponding bright field images (A, C, E, G).

ACKNOWLEDGMENT

We are grateful to Dr. Ponzy Lu of the Chemistry Department for accommodating our organic laboratory, to Ms. Jasmine X.-Y. Zhao of the Microscopy Core Facility of the Wistar Institute for taking confocal microscope images, to Mr. David Nelson and Mr. Dong Xin for technical assistance, and to Ms. Lida Gifford for critical reading of the manuscript. This research was supported by NIH contract BAA NO1-CM97065-02 and an Oncologic Foundation of Buffalo award. Partial support by NIH grants RO1 CA 83105-02, P20 CA86255-01, and HL 56083 are also acknowledged.

Effect of Heme Structure on O_2-Binding Properties of Human Serum Albumin−Heme Hybrids: Intramolecular Histidine Coordination Provides a Stable O_2−Adduct Complex

Teruyuki Komatsu, Yasuko Matsukawa, and Eishun Tsuchida*,†

Department of Polymer Chemistry, Advanced Research Institute for Science and Engineering, Waseda University, Tokyo 169-8555, Japan. Received July 3, 2001; Revised Manuscript Received October 8, 2001

5,10,15,20-Tetrakis[(α,α,α,α-*o*-pivaloylamino)phenyl]porphinatoiron(II) and 5,10,15,20-tetrakis-{[α,α,α,α-*o*-(1-methylcyclohexanoylamino)]phenyl}porphinatoiron(II) complexes bearing a covalently bound 8-(2-methyl-1-imidazolyl)octanoyloxymethyl or 4-(methyl-L-histidinamido)butanoyloxymethyl side-chain [**FeRP(B)** series: R = piv or cyc, B = Im or His] have been synthesized. The histidine-bound derivatives [**FepivP(His)**, **FecycP(His)**] formed five N-coordinated high-spin iron(II) complexes in organic solvents under an N_2 atmosphere and showed large O_2-binding affinities in comparison to those of the 2-methylimidazole-bound analogues [**FepivP(Im)**, **FecycP(Im)**] due to the low O_2-dissociation rate constants. On the contrary, the difference in the fence groups around the O_2-coordination site (pivaloyl or 1-methylhexanoyl) did not significantly influence to the O_2-binding parameters. These four porphinatoiron(II)s were efficiently incorporated into recombinant human serum albumin (rHSA), thus providing the synthetic hemoprotein, the albumin−heme hybrid [rHSA−**FeRP(B)**]. An rHSA host absorbs a maximum of eight **FeRP(B)** molecules in each case. The obtained rHSA−**FeRP(B)** can reversibly bind and release O_2 under physiological conditions (in aqueous media, pH 7.3, 37 °C) like hemoglobin and myoglobin. As in organic solutions, the difference in the fence groups did not affect their O_2-binding parameters, but the axial histidine coordination significantly increased the O_2-binding affinity, which is again ascribed to the low O_2-dissociation rates. The most remarkable effect of the heme structure appeared in the half-life ($\tau_{1/2}$) of the O_2−adduct complex. The dioxygenated rHSA−**FecycP(His)** showed an unusually long lifetime ($\tau_{1/2}$: 25 h at 37 °C) which is ca. 13-fold longer than that of rHSA−**FepivP(Im)**.

INTRODUCTION

A recombinant human serum albumin (rHSA) incorporating 2-[8-(2-methyl-1-imidazolyl)octanoyloxymethyl]-5,10,15,20-tetrakis[(α,α,α,α-*o*-pivaloylamino)phenyl]porphinatoiron(II) [**FepivP(Im)**[1]] [albumin−heme; rHSA−**FepivP(Im)**] is an entirely synthetic hemoprotein which can reversibly bind and release O_2 under physiological conditions like that of hemoglobin (Hb) and myoglobin (Mb) (Tsuchida et al., 1999). The exchange transfusion with this rHSA−**FepivP(Im)** solution into anesthetized rats has shown that it becomes an O_2-carrying fluid as a red blood cell substitute (Tsuchida et al., 2000). The albumin−heme hybrid is now recognized to be one of the most promising materials not only as a blood replacement composition, but also as an O_2-carrying medicine which will be adopted for use in several clinical applications, such as myocardial infraction, anemia, and tracheal blockade, etc. Only one limitation of this material is the relatively short lifetime of the O_2−adduct complex; the half-life of the dioxygenated rHSA−**FepivP(Im)** at 37 °C (pH 7.3 under 100% O_2 atmosphere) was 2 h. We believe that it should be improved by the optimizing of the chemical structure of the incorporated heme. Actually, the relationship between the heme structure and the O_2-binding parameters has been elucidated, but its effect to the O_2−adduct stability is still controversial (Collman et al., 1983; Traylor et al., 1985). We have employed **FepivP(Im)** as an active site of the albumin−heme, in which the sterically hindered 2-methylimidazole coordination plays a crucial role to realize the similar O_2-binding affinity with red blood cells. On the other hand, the low-binding constant of the 2-methylimidazolyl N atom to the central iron(II) has also been postulated to lead the short lifetime of the dioxygenated species. Other factors that regulate the O_2-binding ability of the heme are the basicity of the imidazole ligand and the hydrophobicity of the cavity around the coordinated O_2. The pK_a of the histidine, which is found in nature, is 6.0. This

value is significantly low compared to those of the *N*-alkylimidazole derivatives and may provide both a suitable O_2-binding affinity and a long lifetime. To increase the stability of the O_2−adduct complex of the albumin−heme hybrid, new porphinatoiron(II) derivatives with different substituents on the *distal* and *proximal* sides of the porphine planes [5,10,15,20-tetrakis[(α,α,α,α-*o*-pivaloylamino)phenyl]porphinatoiron(II) bearing a covalently bound 4-methyl-L-histidinamidobutanoyl-oxymethyl chains [**FepivP(His)**], and 5,10,15,20-tetrakis{[α,α,α,α-*o*-(1-methylcyclohexanoylamino)]-phenyl}porphinatoiron(II) with a 8-(2-methyl-1-imidazolyl)octanoyloxymethyl or the histidine side-chain [**FecycP(Im)** or **FecycP(His)**] have been synthesized. This paper describes the O_2-binding equilibria and kinetics of these newly synthesized **FeRP(B)** complexes in organic solvents and their rHSA hybrids in aqueous media. This is the first reported evaluation of the effect of the heme structure on the O_2-binding property of the albumin−heme hybrid.

EXPERIMENTAL PROCEDURES

Materials and Apparatus. Thin-layer chromatography was carried out on 0.2 mm precoated plates of silica gel 60 F_{254} (Merck). Purification was performed by silica gel 60 (Merck) column chromatography. Infrared spectra were measured with a JASCO FT/IR-410 spectrometer. ^{1}H NMR spectra were recorded using a JEOL Lambda 500 spectrometer. Chemical shifts were expressed in parts per million downfield from Me_4Si as an internal standard. FAB-MS spectra were obtained from a JEOL JMS−SX102A spectrometer. UV−vis absorption spectra were recorded on a JASCO V-570 spectrophotometer. 2-Hydroxymethyl-5,10,15,20-tetrakis[(α,α,α,α-*o*-pivaloylamino)phenyl]porphine (**3-piv**), 8-(2-methyl-1-imidazolyl)-octanoic acid, and 2-[8-(2-methyl-1-imidazolyl)octanoyloxymethyl]-5,10,15,20-tetrakis[(α,α,α,α-*o*-pivaloylamino)-phenyl]porphinatoiron(III) bromide [**FepivP(Im)Br**$^-$] were prepared according to our previously reported literature (Tsuchida et al., 1995). All solvents were purified by distillation before use. Other chemicals were commercial high-purity grades. The water used was deionized using a ADVANTEC GS-200 system. An rHSA (25 wt %) was provided from WelFide Corporation (Sumi et al., 1993).

Reduction of Ferric Complex to Ferrous Complex in Organic Solvent. Reduction to the porphinatoiron(II) complex was carried out using toluene (or benzene)−aq $Na_2S_2O_4$ in a heterogeneous two-phase system under aerobic conditions as previously reported (Tsuchida et a., 1995). After separation of the two phases, the organic layer containing the reduced compound was transferred into 1-cm quartz cuvette under an Ar atmosphre.

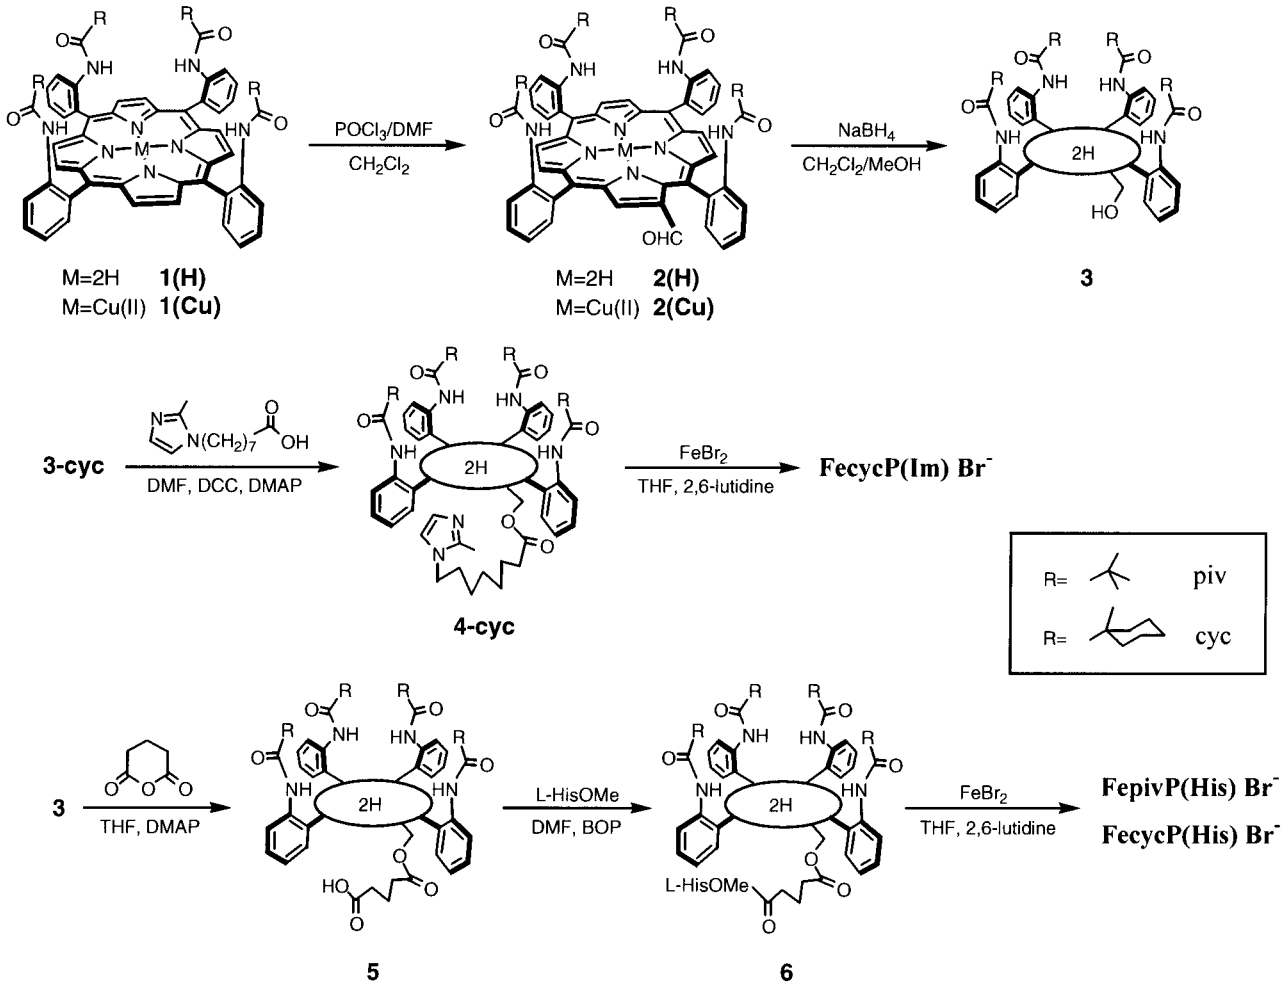
Resonance Raman Spectroscopy. RR spectra were obtained on a JASCO NRS-2000 laser Raman spectrometer equipped with a CCD multichannel detector. Excitation was carried out by the 457.9-nm line of an NEC GLG2162 Ar^+ ion laser at 25 °C. The details of the measurements were reported elsewhere (Komatsu et al., 1999; Wu et al., 1998).

Preparation of rHSA−FeRP(B) Hybrid. Aqueous ascorbic acid (15 mM, 20 μL) was added to an EtOH solution of **FeRP(B)** derivative (75 μM, 4 mL) under carbon monoxide (CO). After complete reduction of the central ferric ion, the UV−vis absorption spectrum showed a formation of the six-coordinated carbonyl complex. This EtOH solution was slowly injected into the phosphate buffer solution (33 mM, pH 7.3, 8 mL) of rHSA (4.69 μM) via the narrow tube under a CO atmosphere, and the mixture was dialyzed with cellulose membrane against phosphate buffer (pH 7.3) for 2 h and 15 h at 4 °C. We confirmed that the EtOH concentration in the solution reduced to less that 100 ppm. Finally, the total volume was adjusted to 15 mL, giving carbonyl rHSA−**FeRP(B)** solution (**FeRP(B)**/rHSA = 8 (mol/mol), [Fe] = 20 μM).

Binding Numbers of FeRP(B) into rHSA. Based on the absorbance intensity of the UV−vis absorption spectra of the rHSA−**FeRP(B)** hybrid with different **FeRP(B)**/rHSA mixing ratios, the binding numbers of **FeRP(B)** in the albumin host were assayed as previously reported (Komatsu et al., 1999). Furthermore, in the course of preparation of the hybrid, the remaining carbonyl **FeRP(B)** at the bottom of the round flask was extracted with $CHCl_3$ and its concentration was determined by the absorption spectra.

O_2-Coordination Equilibria and Kinetics. O_2-coordinations to **FeRP(B)** derivative are expressed by

$$\textbf{FeRP(B)} + O_2 \underset{k_{off}}{\overset{k_{on}}{\rightleftharpoons}} \textbf{FeRP(B)}{-}O_2 \qquad (1)$$



$$(K = k_{on}/k_{off})$$

The O_2-binding affinity ($P_{1/2} = 1/K$) of **FeRP(B)**s in organic solvents or their rHSA hybrids in aqueous media were determined by spectral changes at various partial pressure of O_2 as in previous literatures (Komatsu et al., 1999; Tsuchida et al., 1995). **FeRP(B)**s concentrations of 20 μM were normally used for UV−vis. absorption spectroscopy. The spectra were recorded within the range of 350−700 nm. The O_2-association and -dissociation rate constants (k_{on}, k_{off}) were measured by a competitive rebinding technique using a Unisoku TSP-600 laser flash photolysis apparatus (Collman et al., 1983; Tsuchida et al., 1995; Traylor et al., 1985). The absorption decays accompanied O_2-rebinding to **FeRP(B)**s in organic solvents obeyed single exponential, so that we applied a first-order kinetics to calculate the rates. On the other hand, rHSA−**FeRP(B)** in aqueous solution showed triphases. We used triple-exponential kinetics described elsewhere to analyze the absorption decays (Komatsu et al., 2000).

RESULTS AND DISCUSSION

Synthesis of FeRP(B) Complexes. We first report the synthesis of tetrakis[(α,α,α,α-*o*-amino)phenyl]porphinatoiron(II) derivatives with bulky fences around the

Scheme 1

O_2-coordination site (pivaloyl or 1-methylcyclohexanoyl) and a proximal base [2-methylimidazole or methyl-L-histidine (L-HisOMe)] at the β-pyrrolic position (Scheme 1, see Supporting Information). The parent porphines, namely 2-hydroxymethyl-5,10,15,20-tetrakis[(α,α,α,α-*o*-pivaloylamino)phenyl]porphine (**3-piv**) and 2-hydroxymethyl-5,10,15,20-tetrakis{[α,α,α,α-*o*-(1-methylcyclohexanoylamino)]phenyl}porphine (**3-cyc**) were prepared using the Vilsmeir reaction. The hydroxyl group was converted into a carboxylic acid chain by glutaric anhydride (**5**). Introduction of L-HisOMe into this carboxylic acid using DCC unfortunately failed. Several unknown products were detected. In contrast, the same coupling using benzotriazol-1-yloxytris(dimethylamine)phosphonium hexafluorophosphate (BOP) in a dry DMF solution yielded the target free-base compound (**6**) in high yield (~85%). Iron insertion was carried out using $FeBr_2$ in dry THF to afford the corresponding iron(III) complexes.

O_2-Binding Properties of FeRP(B)s in Organic Solvents. The UV−vis absorption spectrum of the toluene solution of **FecycP(Im)** with a 2-methyl-1-imidazolylalkyl arm under an N_2 atmosphere showed the formation of the five-N-coordinated complex (λ_{max}: 441, 539, 558 nm) as well as **FepivP(Im)** (not shown) (Tsuchida et al., 1995). The **FepivP(His)** and **FecycP(His)** with a proximal histidine also displayed the same spectral pattern (λ_{max}: 441, 544, 564 nm), which was constant in the range from 5 μM−1 mM at 10−70 °C. Resonance Raman (RR) spectroscopy of **Fepiv(His)** demonstrated a medium band at 219 cm^{-1}, which was assigned to the Fe(II)−N(imidazole) stretching mode,

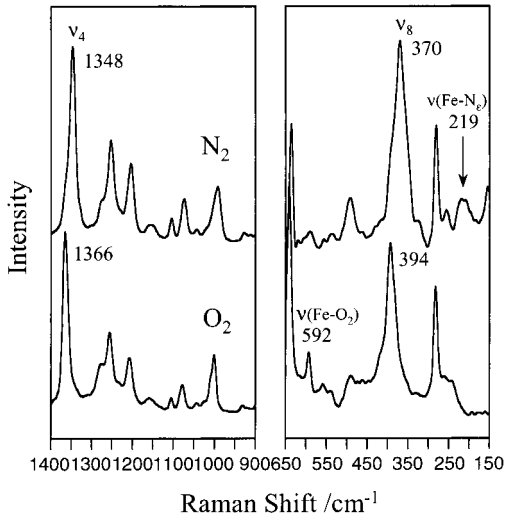


Figure 1. Resonance Raman spectra of **FepivP(His)** in benzene solution at 25 °C.

ν(Fe−N_ϵ) (Figure 1) (Hori et al., 1980; Wu et al., 1998). It can be concluded that the covalently linked histidine residue at the porphine periphery binds to the central iron(II) to give the five-coordinated high-spin iron(II) complex under an N_2 atmosphere in a fashion similar to the 2-methylimidazolated analogues [**FepivP(Im)** or **FecycP(Im)**].

Upon bubbling of O_2 or CO gas into the benzene solution of **FepivP(His)**, the UV−vis absorption spec-

trum immediately changed to those of the O_2−adduct complex (λ_{max}: 429, 551 nm) or CO−adduct complex (λ_{max}: 428, 546 nm) (Komatsu et al., 2001). The dioxygenation was sufficiently stable and reversible at 25 °C depending on the O_2-partial pressure. In the RR spectrum, the ν(Fe−O_2) vibration of the dioxygenated **FepivP(His)** appeared at 592 cm^{-1} after O_2 bubbling. This peak suggests a typical end-on type O_2-coordination to the porphinatoiron(II). The skeletal modes of the porphine ring (ν_8 and ν_4) were also upshifted from 370 and 1348 cm^{-1} to 394 and 1366 cm^{-1}, respectively. These observations indicate the formation of the six-coordinated low-spin iron(II) complex of **FepivP(His)** (Burke et al., 1978; Hori et al., 1980; Wu et al., 1998). All the shifts were reversibly observed depending on the O_2 concentration. The RR spectra of **FecycP(His)** showed the same results as well.

The O_2-binding affinities ($P_{1/2}$), and O_2-association and -dissociation rate constants (k_{on}, k_{off}) of the **FeRP(B)**s in organic solvents are summarized in Table 1. The difference in the fence structure around the O_2-coordination site (pivaloyl or 1-methylhexanoyl) did not significantly influence their O_2-binding equilibria and kinetics. On the basis of the important earlier studies, the distal steric encumbrance only reduces the association rate for O_2 (Collman et al., 1983; Traylor et al., 1985). According to the hypothesis, the inner volume of the cavities, which are constructed using the four pivaloyl or 1-methylcyclohexanoyl groups on the porphine plane, should be of similar size. On the other hand, the axial histidine coordination significantly increased the O_2-binding affinity compared to those of the 2-methylimidazole bound analogues by a factor of 11−24, that is kinetically due to the low O_2-dissociation rate constants. It is generally recognized that the steric hindrance of the 2-methyl group of the axially coordinated imdazole decreases the O_2-binding affinity, giving the "Tense state" model of Hb (Collman et al., 1978). Our results on the large O_2-binding affinities of **FepivP(His)** and **FecycP(His)** correlate well with the theory of the former study.

To clarify the geometry of the bulky cyclohexanoyl fences and axial histidine coordination, the stereostructure of the dioxygenated low-spin complex of **FecycP(His)** was simulated by molecular dynamics (Figure 2). It was found that (i) the repulsions between the cyclohexanoyl fences do not induce a ruffling of the porphine plane, and (ii) the dihedral angle of the imidazole ring with respect to the porphine was 89.3°, suggesting that the imidazole N-coordination to the central iron(II) is not distorted by the rigid amide spacer between the porphine and HisOMe. It is also remarkable that (iii) the H atom of the imidazole cannot form a hydrogen bond with the neighboring carbonyl O atom, which is known to partially influence the dioxygenation of the heme.

We concluded that covalently attaching the histidine group directly to the porphine periphery provides the five-N-coordinated high-spin iron(II) complex and a large equilibrium constant for the O_2 binding in comparison to that of the 2-methylimidazolated analogue due to the small dissociation rate, even though its O_2-binding affinity was 6-fold lower than that of the *N*-alkylimidazole-coordinated one, 2-[8-(1-imidazolyl)octanoyloxymethyl]-5,10,15,20-tetrakis[(α,α,α,α-*o*-pivaloylamino)phenyl]-porphinatoiron(II) ($P_{1/2}$: 0.29 Torr) (Tsuchida et al., 1995). This is probably caused by the low σ-basicity of the histidine.

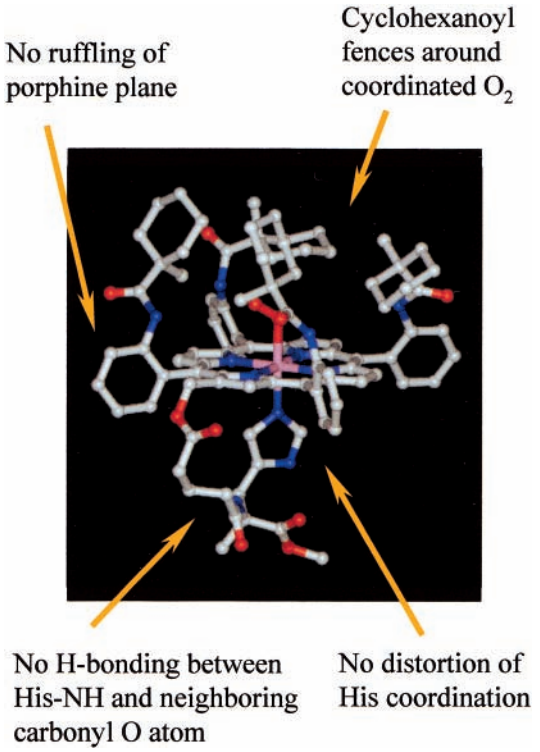

Figure 2. Simulated structure of the dioxygenated **FecycP(His)**. Molecular dynamics and minimization (force field: esff) were performed using an Insight II system (Molecular Simulations Inc.). The structure was generated by alternative minimizations and annealing dynamic calculations from 1000 to 100 K.

Anyway, these results are the first examples of the stable O_2−adduct complexes of the synthetic porphinatoiron(II)s with an intramolecularly coordinated proximal histidine and their O_2-binding equilibrium and kinetic parameters.

FeRP(B)s Incorporations into rHSA. A maximum of eight **FepivP(Im)** molecules were incorporated into certain domains of human serum albumin with binding constants from 10^6−10^4 M^{-1} (Komatsu et al., 1999). Other **FeRP(B)s** were also expected to bind to rHSA in a similar fashion, and the binding sites would also be identical. From the quantitative analyses of the absorption intensity for the Soret band of aqueous rHSA−**FecycP(His)**, the maximum binding numbers of **FecycP(His)** to an rHSA were determined to be eight by using molar extinction coefficient of the carbonyl heme complex. Actually, the unbound **FecycP(His)** remaining in the flask was less than 4% of the total amount of the heme in case of **FecycP(His)**/rHSA was eight (mol/mol). The other **FeRP(B)**s [**FepivP(His)**, **FecycP(Im)**] also showed the same results. The binding numbers are always eight and independent of the substituents and axial bases.

O_2-Coordination Properties of rHSA−FeRP(B). The UV−vis absorption spectrum of the aqueous rHSA hybrid including carbonyl **FepivP(His)** showed the formation of the typical CO-coordinated low-spin tetraphenylporphinatoiron(II) derivative (λ_{max}: 433, 548 nm) (Figure 3). Light irradiation using a 500-W halogen lamp

[a] From Antonini et al. (1971).

of this solution under an O_2 atmosphere led to CO dissociation, affording the O_2−adduct complex (λ_{max}: 433, 553 nm). Upon exposure of the dioxygenated rHSA−**FepivP(His)** to N_2, the UV−vis absorption spectrum changed to that of the five-N-coordinated iron(II) complex with an intramolecularly coordinated axial histidine (λ_{max}: 441, 548, 568 nm). This O_2-binidng was reversibly observed and kinetically stable under physiological conditions (pH 7.3, 37 °C). Similar dioxygenations were also observed in the rHSA hybrids with **FecycP(Im)** and **FecycP(His)** (Table 2).

The laser flash photolysis experiments provided the k_{on} and k_{off} values of the O_2 binding to rHSA−**FeRP(B)**s, and a detailed kinetic analysis gave the following results. (i) The absorption decays accompanying the O_2 recombination were composed of three-phases of the first-order kinetics, therefore, the curves were fit by a triple-exponential equation, which is similar to the previously reported rHSA− **FepivP(Im)** (Komatsu et al., 2000). The minor, almost 10% component, which has the fastest rate constant, was independent of the O_2 concentrations. It should be correlated with a base elimination reaction (Geibel et al., 1978). (ii) From the careful inspections of the other two phases, the association rate constants for the fast and slow rebindings [k_{on}(fast) and k_{on}(slow)] of O_2 were calculated (Table 3). The k_{on}(fast) values are 4−6-times larger than k_{on}(slow). (iii) The concentration ratios of the fast and slow reactions were 2−3. Consequently, the O_2 association to the **FeRP(B)**s in the hydrophobic domains of the serum albumin is influenced by the molecular microenvironments around each O_2-coordination site, e.g., steric hindrance of the amino acid residue and difference in polarity. These observations coincided with our previous results on rHSA−**FepivP(Im)** (Komatsu et al., 2000).

[a] At 37 °C in parentheses. [b] At 37 °C.

The $P_{1/2}$ of the rHSA−**FeRP(B)**s were determined on the basis of the UV−vis. spectral changes during the O_2 titration (Table 3). According to the kinetic experiments, the $P_{1/2}$ values were divided into two components using our previously reported equation (Komatsu et al., 2000). Nevertheless, the calculated $P_{1/2}$ for the fast and slow phases were all identical in each case. The rHSA−**FepivP(Im)** and rHSA−**FecycP(Im)** showed the same O_2-binding affinities (13 Torr), indicating that the fence structures on the porphine plane cause only negligibly small changes in their O_2-equilibria and -kinetics even in albumin. In contrast, the axial histidine coordination provided a 13-fold larger O_2-binding affinity compared to those of the 2-methylimidazole-linked analogues, which is again ascribed to the low O_2-dissociation rate constants.

Accompanying the autoxidation of the central iron(II), the absorption band (λ_{max}: 552−555 nm) slowly disappeared at 37 °C, leading to the formation of the inactive iron(III) porphinate (Momenteau et al., 1994). The effect of the heme structure on the half-life ($\tau_{1/2}$) of the O_2−adduct complex was rather remarkable. (i) The cyclohexanoyl fences gave ca. 5-fold longer $\tau_{1/2}$ values compared to those of the pivaloyl derivatives, and (ii) the proximal histidine coordination increased $\tau_{1/2}$ by a factor of 3. As a result, (iii) the dioxygenated rHSA−**FecycP(His)** showed an unusually long lifetime ($\tau_{1/2}$: 25 h at 37 °C) which is ca. 13-fold longer than that of rHSA−**FepivP(Im)**.

In conclusion, recombinant human serum albumin incorporating **FeRP(His)**s having an intramolecularly coordinated histidine residue formed stable O_2−adduct complexes under physiological conditions. In particular, dioxygenated rHSA−**FecycP(His)** showed a high stability against the proton-driven oxidation, and its half-lifetime reached a value similar to that of the native Hb A ($\tau_{1/2}$: 36 h at 37 °C) (Mansouri et al., 1973). Although the O_2-binding affinity of rHSA−**FecycP(His)** is too high to use as a blood replacement composition, it can be utilized as an O_2-carrying medicine for oxygenation of the hypoxia region in cancer tissue, the preservation or circulation liquid for organs, and culture medium for the regeneration of tissues, etc. As a red blood cell substitute, rHSA−**FecycP(Im)**, which has a similar $P_{1/2}$ value to red blood cells, is full of promise. In the bloodstream, the apparent lifetime of the O_2-coordinated albumin−heme is prolonged by a factor of 4 (Tsuchida et al., 2000), so that the rHSA−**FecycP(Im)** is expected to transport O_2 in the circulatory system for more than 36 h. The preclinical test of the administration of rHSA−**FecycP(Im)** into anesthetized rats is currently underway.

ACKNOWLEDGMENT

This work was partially supported by the Core Research for Evolutional Science and Technology, JST, by Health Science Research Grants (Artificial Blood Project) of the Ministry of Health, Labor and Welfare, Japan, and

by a Grant-in-Aid for Scientific Research (No. 13650938) from the Ministry of Education, Culture, Sports, Science and Technology, Japan.

Supporting Information Available: Experimental details of the synthesis procedures (^{1}H NMR, IR, MS, UV−vis) of the all compounds in Scheme 1. This material is available free of charge via the Internet at http://pubs.acs.org.

5,10,15,20-Tetrakis{[α,α,α,α-*o*-(1-methylcyclohexanoylamino)]phenyl}porphine [1(H)-cyc]. Oxalyl chloride (19 mL, 132.3 mmol) was added to 1-methylcyclohexane carboxylic acid (2.11 g, 14.8 mmol) and stirred for 1 h at room temperature. After excess oxalyl chloride was removed *in vacuo*, dry THF (55 mL) solution of 5,10,15,20-tetrakis(α,α,α,α-*o*-amino)phenylporphine (0.4 g, 0.59 mmol) and pyridine (1.7 mL, 20.7 mmol) was added dropwise to the acid chloride at 5 °C under the darkness. The reaction mixture was stirred for 2 hr at room temperature, and brought to dryness on a rotary evaporator. $CHCl_3$ extracted the residue and washed with 5% aqueous NH_3 and water. The organic layer was then dried over anhydrous Na_2SO_4, and chromatographed on silica gel column using $CHCl_3$/Ethylacetate (10/1 v/v) as the eluent. The main band was collected and dried at room temperature for several hours *in vacuo* to give the compound **1(H)-cyc** as a purple solid (0.56g, 82 %). Rf = 0.50 ($CHCl_3$/Ethylacetate, 10/1 v/v). IR (NaCl) ν = 1691 (C=O(amide)), 3428 (NH(amide)) cm^{-1}. UV-Vis. ($CHCl_3$) λ_{max} = 423, 516, 549, 590, 647 nm. ^{1}H-NMR ($CDCl_3$) δ = -2.6 (2H, s, innerH), 0.1 (12H, s, 1-Me), 0.3 – 1.0 (40H, m, cyclohexyl), 7.5 (4H, t, phenyl-4), 7.6 (4H, s, amide-H), 7.8 (4H, t, phenyl-5), 7.9 (4H, d, phenyl-3), 8.8 (4H, d, phenyl-6), 8.9 (8H, s, pyrrole-β) ppm. FAB-MS: *m/z* 1172 [M^+].

5,10,15,20-Tetrakis{[α,α,α,α-*o*-(1-methylcyclohexanoylamino)]phenyl}porphinatocopper(II) [1(Cu)-cyc]. Methanol solution (2 mL) of $CuCl_2 \cdot 2H_2O$ (0.18 g, 1.15 mmol) was added to a $CHCl_3$ solution (10 mL) of **1(H)-cyc** (0.54 g, 0.46 mmol) in the presence of TEA (0.23 mL), and the mixture was stirred for 1 h at 65 °C. After confirming the reaction complete by measuring the vis. absorption spectrum, the solvents were removed by an evaporator. $CHCl_3$ extracted the residue and dried over anhydrous Na_2SO_4. The obtained mixture was chromatographed on a silica gel column using $CHCl_3$/Ethylacetate (5/1 v/v) as eluent. The major band was collected and dried at room temperature for several hours in *vacuo* to give the compound **1(Cu)-cyc** as a purple solid

(0.45 mg, 79 %). Rf = 0.74 ($CHCl_3$/Ethylacetate, 5/1 v/v). IR (NaCl) ν = 1687 (C=O (amide)), 3434 (NH(amide)) cm^{-1}. UV-Vis. ($CHCl_3$) λ_{max} = 423, 541, 576 nm. FAB-MS: *m/z* 1233 [M^+].

2-Formyl-5,10,15,20-tetrakis{[α,α,α,α-*o*-(1-methylcyclohexanoylamino)] phenyl}porphinatocopper(II) [2(Cu)-cyc]. Phosphorus oxychloride (7.4 mL) was slowly dropped into DMF (6.3 mL) in an ice-water bath under an N_2 atmosphere and the mixture was stirred for 1 hr at room temperature, giving a pale orange Vilsmeir regent. A dry CH_2Cl_2 solution of **1(Cu)-cyc** (0.45 g, 0.36 mmol) was then added dropwise to this solution, and refluxed for 18 hr (the color of reactant changed to green). After cooling to the room temperature, saturated aqueous sodium acetate (300 mL) was carefully added to the mixture to neutralize the solution (the color of the organic layer was again turned to red). After additional stirring for 3 hr at 40°C, the mixture was extracted with $CHCl_3$. The organic phase was washed with water for several times, and dried over anhydrous Na_2SO_4. The evaporated residue was chromatographed on silica gel column using $CHCl_3$/Ethylacetate (6/1 v/v) as the eluent. The major band eluted was collected and dried at room temperature for several hours *in vacuo* to give the compound **2(Cu)-cyc** as a red-purple solid (0.22g, 50 %). Rf = 0.53 ($CHCl_3$/Ethylacetate, 5/1 v/v). IR (NaCl) ν = 1672 (C=O(formyl)), 1692 (C=O(amide)), 3428 (NH(amide)) cm^{-1}. UV-Vis. ($CHCl_3$) λ_{max} = 430, 552, 593 nm. FAB-MS: *m/z* 1262 [M^+ + H].

2-Formyl-5,10,15,20-tetrakis{[α,α,α,α-*o*-(1-methylcyclohexanoylamino)] phenyl}porphine [2(H)-cyc]. To a CH_2Cl_2 solution (8 mL) of **2(Cu)-cyc** (0.22 g, 0.174 mmol), conc. H_2SO_4 (2 mL) was added and vigously stirred for 10 min. The resulting green solution was added dropwise to CH_2Cl_2-ice-water (500 mL, 1:1 v/v) and slowly neutralized by $NaHCO_3$. The mixture was extracted by $CHCl_3$ and washed with water. After drying by Na_2SO_4, the organic layer was evaporated to dryness and the residue was chromatographed on silica gel column using $CHCl_3$/Ethylacetate (5/2 v/v) as

© 2002 American Chemical Society, Bioconjugate Chem., Komatsu bc010067r Supporting Info Page 3

the eluent. The main band was collected and dried at room temperature for several hours *in vacuo* to give compound **2(H)-cyc** as a purple solid (0.18 g, 84 %). Rf = 0.60 ($CHCl_3$/Ethylacetate 5/2 v/v). IR (NaCl) ν = 1672 (C=O(formyl)), 1691 (C=O(amide)), 3429 (NH(amide)) cm^{-1}. UV-Vis. ($CHCl_3$) λ_{max} = 432, 527, 555, 597, 662 nm. ^{1}H-NMR ($CDCl_3$) δ = -2.3 (2H, s, innerH), 0.1 – 0.2 (12H, d, 1-Me), 0.3 – 1.0 (40H, m, cyclohexyl), 7.4 – 7.6 (8H, m, amide-H, phenyl-4), 7.8 – 7.9 (8H, m, phenyl-3, 5), 8.7 – 8.9 (10H, m, pyrrole-βH, phenyl-6), 9.4 (1H, s, pyrrole-H), 9.6 (1H, s, formyl) ppm. FAB-MS: *m/z* 1200 [M^+].

2-Hydroxy-5,10,15,20-tetrakis{[α,α,α,α-*o*-(1-methylcyclohexanoylamino)] phenyl}porphine (3-cyc). $NaBH_4$ (53.6 mg, 1.47 mmol) was added to the CH_2Cl_2-MeOH solution (9.5 mL, 2.5/7 v/v) of **2(H)-cyc** (0.18 g, 0.15 mmol) under an Ar atmosphere under the ice-water bath, and stirred for 10 min. After adding water to stop the reaction, the mixture was extracted with $CHCl_3$. The organic phase was washed with water for several times, and dried over anhydrous Na_2SO_4. The evaporated residue was chromatographed on silica gel column using $CHCl_3$/MeOH (30/1 v/v) as the eluent. The major band eluted was collected and dried at room temperature for several hours *in vacuo* to give the compound **3-cyc** as a purple solid (144.2 mg, 80 %). Rf = 0.29 ($CHCl_3$/MeOH, 30/1 v/v). IR (NaCl) ν = 1690 (C=O(amide)), 3427 (NH(amide)) cm^{-1}. UV-Vis. ($CHCl_3$) λ_{max} = 423, 517, 548, 591, 645 nm. ^{1}H-NMR ($CDCl_3$) δ = -2.6 (2H, s, innerH), 0.1 (12H, m, 1-Me), 0.3 – 1.0 (40H, m, cyclohexyl), 4.9 (2H, q, -C<u>H</u>$_2$OH), 7.4 – 7.6 (8H, m, amide-H, phenyl-4), 7.7 – 7.8 (8H, m, phenyl-3, 5), 8.6 – 8.8 (10H, m, pyrrole-βH, phenyl-6), 9.0 (1H, s, pyrrole-H) ppm. FAB-MS: *m/z* 1202 [M^+].

2-[8-(2-Methyl-1-imidazolyl)octanoyloxymethyl]-5,10,15,20-tetrakis{[α,α,α,α -*o*-(1-methylcyclohexanoylamino)]phenyl}porphine (4-cyc). 8-(2-Methyl-1-imidazolyl)octanoic acid hydrochloride (74.0 mg, 0.287 mmol) and TEA (0.14 mL, 1.15 mmol) were dissolved in dry DMF (2 mL) and stirred for 10 min. After removing TEA

under reduced pressure, **3-cyc** (35 mg, 29.1 μmol), DMAP (3.5 mg, 28.7 μmol), and DCC (100.7 mg, 0.488 mmol) were added to the solution and stirred for 96 hr at room temperature in the darkness. The deposited DCU was filtered off and the mother liquid was evaporated to dryness. After the residue was redisolved in benzene, insoluble DCU was further removed by filtration. Then the $CHCl_3$ solution of the material was slowly dropped into ice-cooled hexane. The red precipitate was collected and chromatographed on silica gel column using $CHCl_3$/MeOH (10/1 v/v) as the eluent. The major band was collected and dried at room temperature for several hours *in vacuo* to give the compound **4-cyc** as a purple solid (31.1 mg, 76 %). Rf = 0.60 ($CHCl_3$/MeOH, 10/1 v/v). IR (NaCl) ν = 1734 (C=O(ester)), 1685 (C=O(amide)) cm^{-1}. UV-Vis. ($CHCl_3$) λ_{max} = 423, 517, 547, 591, 645 nm. ^{1}H-NMR ($CDCl_3$) δ = -2.6 (2H, s, innerH), 0.1 (12H, d, 1-Me), 0.3 – 1.2 (40H, m, cyclohexyl), 1.3 – 1.4 (10H, m, $-(CH_2)_5-$), 1.6 (2H, m, $-O(C=O)CH_2-$), 2.4 (3H, s, 2MeIm), 3.8 (2H, t, $-CH_2$Im), 5.3 (2H, s, Por-$CH_2O(C=O)-$), 6.8, 6.9 (1H, 2s, Im), 7.4 – 7.5 (8H, m, amide-H, phenyl-4), 7.6 – 7.8 (8H, m, phenyl-3, 5), 8.7 – 8.8 (11H, m, pyrrole-βH, phenyl-6) ppm. FAB-MS: *m/z* 1408 [M^+].

FecycP(Im) Br$^-$. A dry THF solution (5 mL) of **4-cyc** (23.5 mg, 16.7 μmol) and 2,6-lutidine (21.3 μL, 0.193 mmol) was added dropwise to anhydrous $FeBr_2$ (200 mg) under dry N_2 atmosphere. The mixture was refluxed for 4 hr under N_2. The obtained solution was brought to dryness, and the residue was extracted with $CHCl_3$ and washed with water. After drying over anhydrous Na_2SO_4, the organic layer was evaporated and chromatographed on a silica gel column using $CHCl_3$/MeOH (10/1 v/v) as eluent. The major band was collected and dried at room temperature for several hours in *vacuo* to give the compound **FecycP(Im) Br$^-$** as a purple solid (17.6 mg, 74 %). Rf = 0.34 ($CHCl_3$/MeOH, 10/1 v/v). IR (NaCl) ν = 1740 (C=O(ester)), 1685 (C=O(amide)) cm^{-1}. UV-Vis. ($CHCl_3$) λ_{max} = 361, 420, 504, 580, 648, 682 nm. FAB-MS: *m/z* 1462 [M^+ – Br].

2-(4-Carboxybutanoyloxymethyl)-5,10,15,20-tetrakis{[α,α,α,α-*o*-(1-methylcyclohexanoylamino)]phenyl}porphine (5-cyc). Gultaric acid anhydride (155 mg, 1.34 mmol) and DMAP (65.4 mg, 0.53 mmol) were added to a dry THF solution (15 mL) of **3-cyc** (0.54 g, 0.45 mmol), and the mixture was reacted for 18 hr at 60°C under an N_2 atmosphere. After evaporation of the solvent, the residue was extracted with $CHCl_3$ and washed with water. The organic layer was then dried with Na_2SO_4, and chromatographed on silica gel column using $CHCl_3$/MeOH (10/1 v/v) as the eluent. The major band was collected and reduced to a small volume on a rotary evaporator. The residue was dried at room temperature for several hours *in vacuo* to give the compound **5-cyc** as a purple solid (0.45g, 79 %). Rf = 0.49 ($CHCl_3$/MeOH, 5/1 v/v). IR (NaCl) ν = 1734 (C=O(ester)), 1688 (C=O(amide)) cm^{-1}. UV-Vis. ($CHCl_3$) λ_{max} = 423, 517, 547, 591, 645 nm. ^{1}H-NMR ($CDCl_3$) δ = -2.6 (2H, m, innerH), 0.1 (12H, s, 1-Me), 0.3 – 1.0 (40H, m, cyclohexyl), 2.0 (2H, t, -C$\underline{H_2}$COOH), 2.4 (4H, m, -O(C=O)C$\underline{H_2}$C$\underline{H_2}$-), 5.3 (2H, q, Por-CH_2O(C=O)-), 7.4 – 7.5 (8H, m, amide-H, phenyl-4), 7.7 – 7.8 (8H, m, phenyl-3, 5), 8.6 (1H, s, pyrrole-βH), 8.7 – 8.8 (10H, m, pyrrole-βH, phenyl-6) ppm. FAB-MS: *m/z* 1316 [M^+].

2-(4-Methyl-L-histidinamidobutanoyloxymethyl)-5,10,15,20-tetrakis{[α,α,α,α-*o*-(1-methylcyclohexanoylamino)]phenyl}porphine (6-cyc). **5-cyc** (46 mg, 35 μmol) and benzotriazol-1-yloxytris(dimethylamine)phosphonium hexafluorophosphate (BOP, 151 mg, 0.35 mmol) were mixed in a dry DMF including TEA (37.7 μL, 0.31 mmol) under an Ar atmosphere. After stirring for 10 min, the histidine methyl ester hydrochlolic acid (25.1 mg, 0.1 mmol) was added to the solution. The obtained mixture was reacted for 12 hr under an Ar atmosphere in the darkness. The reactant was slowly dropped into water, and the precipitation was collected by the glass filter. The obtained solid was dissolved in $CHCl_3$ and dried with Na_2SO_4. The organic layer was condensed and chromatographed on silica gel column using $CHCl_3$/MeOH (30/1 v/v) as the eluent.

The main band was collected and reduced to a small volume on a rotary evaporator. The residue was dried at room temperature for several hours *in vacuo* to give the compound **6-cyc** as a purple solid (43.6 mg, 85 %). Rf = 0.16 ($CHCl_3$/MeOH, 20/1 v/v). IR (NaCl) ν = 1740 (C=O(ester)), 1684 (C=O(amide)) cm^{-1}. UV-Vis. ($CHCl_3$) λ_{max} = 423, 517, 549, 591, 646 nm. ^{1}H-NMR ($CDCl_3$) δ = -2.6 (2H, s, innerH), 0.0 – 0.1 (12H, m, 1-Me), 0.3 – 1.0 (40H, m, cyclohexyl), 1.9 (2H, t, -C$\underline{H_2}$CONH), 2.3 – 2.5 (4H, m, -O(C=O)C$\underline{H_2}$C$\underline{H_2}$-), 3.2 (2H, s, Im-C$\underline{H_2}$-), 3.7 (3H, m, His-O$\underline{Me}$), 4.9 (1H, m, His-CH_2C$\underline{H}$-), 5.2 – 5.4 (2H, q, Por-CH_2O(C=O)-), 7.1 (1H, s, Im), 7.4 – 7.5 (8H, m, amide-H, phenyl-4), 7.7 (1H, s, Im), 7.8 (8H, m, phenyl-3, 5), 8.7 – 8.8 (11H, m, pyrrole-βH, phenyl-6) ppm. FAB-MS: *m/z* 1466 [M^+ – H].

FecycP(His) Br^-. Iron insertion to the compound **6-cyc** was carried out using the same procedure for FecycP(Im) Br^- as described above. Rf = 0.44 ($CHCl_3$/MeOH = 10/1 (v/v)). IR (NaCl) ν = 1740 (C=O(ester)), 1693 (C=O(amide)) cm^{-1}. UV-Vis. ($CHCl_3$) λ_{max} = 354, 420, 505, 581, 648, 683 nm. FAB-MS: *m/z* 1521 [M^+–Br].

2-(4-Carboxybutanoyloxymethyl)-5,10,15,20-tetrakis[(α,α,α,α-*o*-pivaloyl-amino)phenyl]porphine (5-piv). The synthetic procedure for preparation of compound **5-piv** was similar to that used for **5-cyc**. Yield: 85%. Rf = 0.60 ($CHCl_3$/Ethylacetate, 5/1 v/v). IR (NaCl) ν = 1739 (C=O(ester)), 1691 (C=O(amide)) cm^{-1}. UV-Vis. ($CHCl_3$) λ_{max} = 421, 515, 547, 589, 650 nm. ^{1}H-NMR ($CDCl_3$) δ = -2.6 (2H, s, innerH), 0.0 – 0.1 (36H, m, t-Bu), 1.8 (2H, m, -CH_2C(=O)O-), 2.3 – 2.4 (4H, m, -O(C=O)C$\underline{H_2}$C$\underline{H_2}$-), 5.2 (2H, s, Por-CH_2O(C=O)-), 7.1 – 7.2 (4H, m, amide-H), 7.4 – 7.5 (4H, m, phenyl-4), 7.7 – 7.9 (8H, m, phenyl-3,5), 8.6 – 8.8 (11H, m, pyrrole-βH, phenyl-6) ppm. FAB-MS: *m/z* 1155 [M^+].

2-(4-Methyl-L-histidinamidobutanoyloxymethyl)-5,10,15,20-tetrakis[(α,α,α,α -*o*-pivaloylamino)phenyl]porphine (6-piv). The preparation of compound **6-piv** was similar to that used for **6-cyc**. Yield: 87%. Rf = 0.53 ($CHCl_3$/MeOH, 10/1 v/v).

3-Methyladenine-DNA Glycosylase II: The Crystal Structure of an AlkA−Hypoxanthine Complex Suggests the Possibility of Product Inhibition

Michael Teale,*,‡ Jindrich Symersky,§ and Larry DeLucas§

Laboratory for Structural Biology, University of Alabama in Huntsville, Huntsville, Alabama 35899 and Center for Biophysical Sciences and Engineering, University of Alabama in Birmingham, Birmingham, Alabama 35294. Received July 12, 2001; Revised Manuscript Received October 31, 2001

Escherichia coli (*E. coli*) protein 3-methyladenine-DNA glycosylase II (AlkA) functions primarily by removing alkylation damage from duplex and single stranded DNA. A crystal structure of AlkA was refined to 2.0 Å resolution. This structure in turn was used to refine an AlkA−hypoxanthine (substrate) complex structure to 2.4 Å resolution. The complex structure shows hypoxanthine located in AlkA's active site stacked between residues W218 and Y239. The structural analysis of the AlkA and AlkA−hypoxanthine structures indicate that free hypoxanthine binding in the active site may inhibit glycosylase activity.

INTRODUCTION

AlkA[1] is one of two base excision repair (BER) enzymes produced by *E. coli* that remove the cytotoxic and mutagenic 3-methyladenine (3-mA); the other glycosylase is the Tag protein (Thomas et al., 1982). AlkA is produced constitutively in small amounts in *E. coli*. In the presence of an alkylating agent, the *adaptive response* is triggered (Evensen et al., 1982; Lindahl et al., 1988), and AlkA expression is increased 10 to 40-fold, resulting in cellular resistance to the alkylating agent (Karran et al., 1982; Nakabeppu et al., 1984). Alkylation of DNA from exposure to cellular (endogenous) alkylating agents or from those that are exogenous, results in a number of alkylation products targeted by AlkA for removal (Kaasen et al., 1986; Habarken et al., 1991; Saparbaev et al., 1994). Given the wide variety of AlkA substrates, it is reasonable to speculate that AlkA is present to remove alkylation damage that the Tag protein is unable to remove. It has been postulated that AlkA evolved to remove primarily 3-methylquanine (Bjelland et al., 1993). AlkA removes damaged bases from single-stranded DNA (Bjelland and Seeberg, 1996) and releases normal bases from duplex DNA (Berdal et al., 1998), indicating that AlkA on occasion orients undamaged bases in its active site such that they are susceptible to cleavage, which might be interpreted to mean that base movement into the active site is likely to result in cleavage.

As has been pointed out (Hollis et al., 2000), AlkA must search for substrate in a vast excess of DNA. It follows that cells would have developed an efficient mechanism to deal with the search for these substrates and thus the cytotoxic and mutagenic effects of alkylation damage. One search mechanism would require glycosylases to search indiscriminately by flipping every base encountered into its active site then cleaving (usually) only those bases that precisely fit the active site pocket (Hollis et al., 2000). Base flipping is believed to be the dominant mechanism for BER glycosylases (Mol et al., 1999). A more efficient search mechanism might be one in which the glycosylase searched the DNA by probing for substrate. Once the probe locates a target base, the base could be flipped out of the helix into the active site (occasionally flipping a normal base), and then the base could be cleaved. This supposition might be supported by the fact that AlkA's efficiency for removing normal bases is several orders of magnitude lower than that of 3-mA removal (Bjelland et al., 1996).

The cell must also deal efficiently with the resulting DNA base excision repair (BER) problem of toxicity resulting from apurinic and apyrimidinc sites (AP-sites). DNA glycosylases remove damaged DNA bases to protect cells from mutation and death. Yet, this relationship is vicarious at best, since removing damaged bases produces toxic AP-sites. The cell must balance its need to remove damaged bases with its need to repair the resulting AP-site. The cell may address this problem via the biochemical mechanism known as product inhibition. In product inhibition, one or more of the products of a given reaction may interact with the enzyme at the active site or a secondary site thereby inhibiting the enzyme's activity. The Tag DNA glycosylase from *E. coli* works in this manner (Bjelland et al., 1987). Tag has a much stricter substrate specificity than AlkA; Tag removes 3-mA and to a lesser extent 3-mG (Bjelland et al., 1987; Bjelland et al., 1993). Product inhibition could also be accomplished by rebinding to the AP-site (the other product of a base excision reaction), which would have the dual

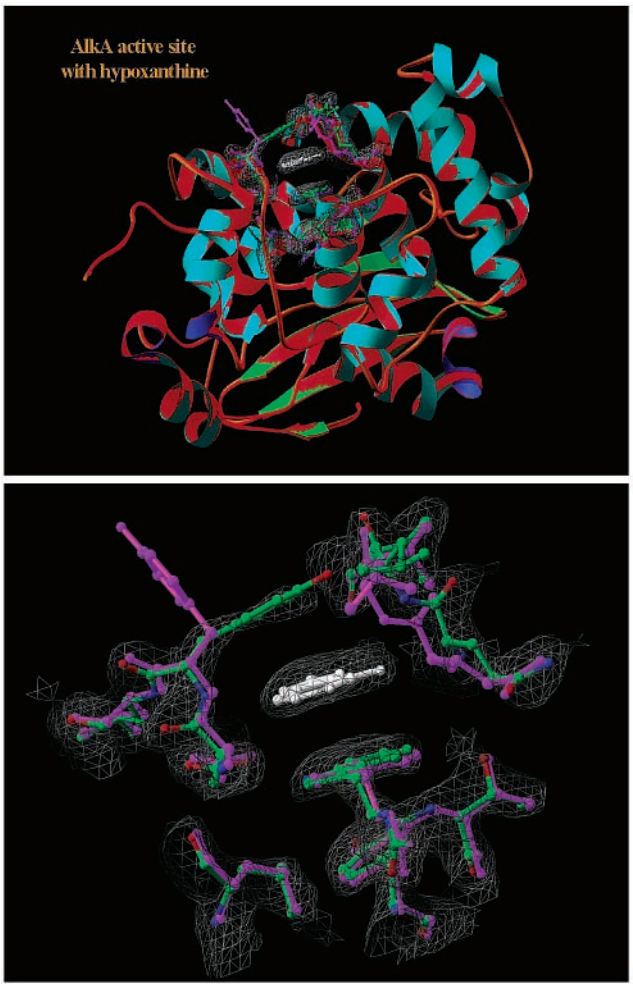

Figure 1. Upper panel: Ribbons diagram depicts two AlkA molecules superimposed red without hypoxanthine, cyan with hypoxanthine bound. White stick and ball model is hypoxanthine. Electron density outlines the hypoxanthine binding site and relevant residues (gray). Lower panel: Shows enlargement of hypoxanthine binding site. Purple stick and ball model shows side chain positions of residues with no hypoxanthine, green shows same residues with hypoxanthine.

purpose of removing AlkA from further activity and protecting the cell from the AP-site. Biochemical assays have shown that uracil-DNA glycosylase (UDG) actually binds to the AP-site more strongly than its target substrate (Bennet et al., 1993). In these reactions the AP-site acts as a competitive inhibitor at concentrations 2−3 orders of magnitude less than the noncompetitive product inhibitor, uracil. It was proposed that UDG cleaved its substrate, released the reaction products, and then rebound the AP-site (Parikh et al., 1998). This implies that some DNA glycosylases may have both reaction products (AP-sites and free damaged base) as inhibition substrates. Adenine in DNA molecules may under go oxidative deamination to form hypoxanthine, which is a substrate for AlkA albeit a weak substrate (Saparbaev, M. and Laval, J., 1994). Here we report the 2.4 Å resolution crystal structure of the E. coli AlkA protein complexed with reaction product free hypoxanthine. The hypoxanthine effectively blocks the active site by stacking between residues Y239 and W218 (Figure 1). The only other AlkA−ligand structure shows AlkA protein complexed to a duplex DNA molecule containing a ribose analogue, 1-azaribose (Hollis et al., 2000) in what might be called an AP-site analogue. Review of the AlkA−hypoxanthine complex structure shows that the hypoxanthine is not in the cleavage position as modeled by Hollis et al., but rather it is located in the general area of the 1-azaribose from the modified DNA. It is possible that the 1-azaribose bound an inhibition site similarly to that of the UDG AP-site inhibition model (Parikh et al., 1998). This putative orientation would probably be very similar to that of the base excision orientation.

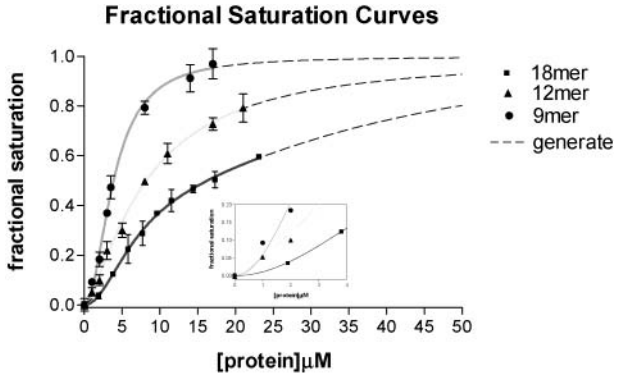

Figure 2. Binding isotherms of AlkA's interaction with normal DNA using 5 μM DNA were developed in an initial study using analytical ultra centrifugation techniques. The best-fit model was the Hill model when compared to a single noninteracting site model. Binding isotherms from 33mer DNA molecules were also obtained, using different DNA concentrations (data not shown), which also produced cooperative curves. The reduction in binding affinity with DNA length is due to nonspecific binding (McGhee et al., 1974). Experiments indicate that these binding isotherms are probably not due to end effects, and sedimentation equilibrium experiments gave binding stoichiometries of 2:1 for 9mers, 3:1 for 12mers, and 3:1 or 4:1 for 18mers.

A Hill analysis from an initial study of AlkA's interaction with undamaged DNA using analytical ultracentrifugation techniques (Figure 2) suggests that AlkA binds undamaged DNA as multiple monomers with a cooperative mechanism (Lebowitz et al., 1998; Teale, unpublished data). The positive cooperative nature of the binding curves suggests that the DNA and/or the protein change conformation upon binding. The structure reported by Hollis et al. shows the DNA separating at the point of AlkA binding. Yet, the DNA in the Hollis structure is not "normal" DNA. Given this, we point out that it is possible that AlkA binds this AP-site analogue as an inhibitor complex with K ∼ 100 pM (Hollis et al., 2000) with a putative AlkA function of protecting the cell from AP-site toxicity. A model where monomers combine on the DNA as the DNA strands and/or AlkA change conformation could explain the cooperative binding isotherms.

MATERIALS AND METHODS

AlkA Crystallization and X-ray Data Collection. AlkA was purified, concentrated, and stored with methods described (O'Connor et al 1993; Teale, unpublished results). The final storage concentration of AlkA was 158 mM (∼ 5 mg/mL) as measured by absorbance at 280 nm, extinction coefficient 2.16 (Pace et al., 1995). The storage buffer was 10 mM Tris-HCl pH 7.5 (KOH), 10 mM β-mercaptanoethanol, and 5% (w/v) glycerol, stored at −80 °C. The hanging drop vapor diffusion crystallization method was used with a 1:1 drop ratio (well/protein solution), and a well solution of 50 mM Hepes pH 6.9, 18% (w/v) poly(ethylene glycol) 8000, and 10 mM β-mercaptanoethanol at 22 °C. Crystals nucleated overnight and grew to a usable size in 4−6 days. The largest crystals were 0.3 × 0.3 × 0.15 mm; however, crystals that produced the best diffraction data were approximately 0.2 × 0.2 × 0.1 mm.

Table 1. Data Collection and Refinement Statistics

	AlkA-hypoxanthine	AlkA
unique reflections	19914	25541
completeness	96%	99%
resolution range (Å)	100−2.4	20−2.0
R_{merge} (%)[b]	3.8%	5.2%
R_{work}[c]	24.3%	18.8%
R_{free}[c]	25.7%	22.1%

[b] $R_{merge} = \sum|I_{obs} - <I>|/\sum I_{obs}$. [c] $R_{work} = ||F_o| - |F_c||/|F_o|$, R_{free} is the same parameter calculated with reserved reflections.

For data collection, crystals were transferred to droplets containing well buffer adjusted to 8%(w/v) glycerol as a cryoprotectant. Crystals were soaked for no more than 15 min. A single crystal was mounted from this droplet onto a Hampton 0.1 mm loop. The crystal was placed immediately into a nitrogen stream at approximately −180 °C. The loop size was selected to allow positioning of the crystal on the loop, minimizing the amount of trapped buffer around the crystal. X-ray diffraction data was collected using a Rigaku R-AXIS IV imaging-plate detector mounted on a Rigaku RU-200 rotating anode X-ray generator operated at 50 kV and 100 mA. A graphite monochromator yielded K radiation with the beam focused by Gobol mirrors. Data were indexed, integrated, and scaled using Denzo and ScalePack (Otwinowski et al., 1997). Completeness of data in the resolution range used for refinement was 96% (Table 1). The R_{sym} and average $I/\sigma(I)$ to 2.0 Å were 5.0 and 15, respectively. The space group was $P2_1$ with pseudo-C centering (seen as very weak reflections when $[h + k] = 2n + 1$), unit-cell parameters were $a = 58.17$, $b = 76.27$, $c = 61.69$, $\alpha = \gamma = 90°$, $\beta = 109.98°$. The Mathews (Mathews, 1968) coefficient was calculated to be 2.18 $Å^3$ Da^{-1}, which represents 44% solvent content for the unit cell with two AlkA monomers per asymmetric unit. The monomers are arranged head to tail in the asymmetric unit.

Cocrystallization of AlkA with hypoxanthine was carried out in hanging drops as described above in 7 mM hypoxanthine. A 0.32 M stock solution of hypoxanthine was made by dissolving hypoxanthine in concentrated well buffer (above), and then concentrated HCl was add until the solution cleared. The solution was then diluted to its final volume with distilled H_2O. The completed solution was filtered with a sterile 0.22 μm filter. A crystal was mounted and data collected as described above. The space group was $P2_1$ with unit cell parameters were $a = 58.17$, $b = 76.27$, $c = 61.87$, $\alpha = \gamma = 90°$, $\beta = 110.03°$.

Crystallographic Refinement and Model Building. The coordinates provided by Tom Ellenberger (see Acknowledgment) were used as the starting refinement model (water molecules not included) for AlkA. The initial R-factor was 30.7% and R-free 36.8% for the resolution range 20.0−2.0 with a 2-σ cutoff for the observed structure amplitudes (Table 1). Positional refinement of the model was performed using the programs X-PLOR (Brunger et al., 1992) and CNS. In alternating rounds of manual adjustments and positional refinement, the refined coordinates were compared with electron density maps with $2F_o - F_c$ and $F_o - F_c$ coefficients. Generally, no major adjustments were necessary other than for several side chain positions. After several rounds of positional refinement and manual adjustments the isotropic temperature factors (B-factors) of individual nonhydrogen atoms were refined. B-factor refinement produced a R-factor of 25.8% and R-free to 30.1%. At this stage of refinement, water molecules were added with regard to defined electron density, while maintaining acceptable intermolecular geometry. After several additional rounds of refinement, R-factors converged with final values: R-factor 18.8% and R-free 24.3%. The final model has 564 amino acid residues, and 379 water molecules with no significant residual electron density.

The coordinates refined above were used as the starting refinement model for the AlkA−hypoxanthine structure (water molecules not included). The initial R-factor was 28.65% and R-free 28.71% for the resolution range 100.0−2.4 with a 2.0 σ cutoff for the observed structure amplitudes. It was apparent in the initial $F_o - F_c$ maps that substantial electron density was present in the active site for hypoxanthine (Figure 1). The density was situated between residues W218 and Y239. Simulated annealing omit maps were generated using CNS scripts. The molecular structure of hypoxanthine was added to the electron density found in the active site. Positional refinement of the combined model was performed. After several rounds of refinement the R-factor values were: R-factor 25.77% and R-free 27.77%. At this point, automatic water selection from CNS was run, which chooses waters based on density maps and performs positional and B-factor refinement. Manual fitting of water positions was carried out using the computer program Chain (Sack, 1988). The final R-factor values were R-factor 22.1% and R-free 25.7%. The final model has 564 amino acid residues, 108 water molecules, and 2 hypoxanthine molecules.

RESULTS

The refined crystal structure of AlkA demonstrates that the monomer orientations in the unit cell are like those of the Labahn et al. (1996) structure. This orientation differs from the 2-fold noncrystallographic symmetry of an AlkA dimer observed in the AlkA structure determined by Yamagata et al. (1996).

A comparison between AlkA and AlkA-hypoxanthine structures shows residue Y239 positioned in the mouth of the active site with its side chain oriented away from the main body of the native AlkA structure (Figure 1, purple stick and ball model). In the AlkA−hypoxanthine structure, residue Y239 turned to block the active site (green stick and ball) with hypoxanthine situated at the opening to the active site (white stick and ball) stacked between residues Y239 and W218.

When residue Y239 rotates in toward the active site opening, its main chain atoms and those of the leucine loop directly across the active site opening are displaced laterally. The orientation of hypoxanthine at 2.4 Å resolution is based on the best fit to the electron density and the local chemistry.

DISCUSSION

AlkA exists as a three domain globular structure; domain 1 has strong structural homology to TATA box binding proteins (TBP), yet there is no sequence homology. There is probably a biological function of AlkA domain one, yet it remains unknown (Yagamata et al., 1996). Domains 2 and 3 define the glycosylase function and demonstrate that AlkA belongs to the helix−hairpin−helix (HhH) super family of DNA repair enzymes (Nash et al., 1996). This motif is found in domain 2 and consists of two α-helices connected by a four amino acid type II hairpin turn and plays a role in bending DNA (Hollis et al., 2000). The AlkA domain 3 helical-fold is similar to the domains containing iron−sulfur clusters in mismatch-adenine glycosylase (MutY)(Guan et al., 1998) and en-

donuclease III (EndoIII)(Kuo et al., 1994), which also have DNA glycosylase functions. AlkA has a leucine minor-groove-binding motif, possessed by DNA glycosylases in general (Mol et al., 1999), where a leucine (or glutamine) is positioned on a loop near the active site and probes the minor groove for substrate. Once a damaged base is located, this probe could take advantage of the possible base stack instabilities and altered minor groove structure due to alkylation (in AlkA's case) and cause the base to flip out of the helix. In this proposed flipping process the base must come in contact with residue Y239 (Figure 1).

Other glycosylase protein−DNA complex crystal structures show the glycosylase interacting with a base, and/or an AP site, or an AP-site analogue inhibitor (Lau et al., 1998; Barrett et al., 1998; Parikh et al., 1998; Hollis et al., 2000). The complex crystal structure of AlkA with an AP-site analogue inhibitor demonstrates inhibition ($K \sim 100$ pM) of AlkA's active site (Hollis et al., 2000). The inhibitor is in part a duplex DNA. The resulting structure is unusual in that it produces a pronounced bend (66°) in the DNA helix. This is unlike similar glycosylase structures as pointed out by Hollis et al. (Slupphaug et al., 1996; Vassylyev et al., 1995; Barrett et al., 1998; Lau et al., 1998). In an earlier study it was shown that a similarly modified DNA molecule designed to mimic a proposed reaction transition state also inhibited glycosylase activity (Schärer et al., 1995).

In the AlkA−hypoxanthine structure, the position of the hypoxanthine suggests a product inhibition mechanism, because the position of the hypoxanthine is similar to that of the 1-azaribose in the Hollis structure. If AlkA cleaved the hypoxanthine from DNA as modeled by Hollis et al., then the hypoxanthine bound as shown in Figure 1 is not in the cleavage position and thus it may have some other function. The AlkA−hypoxanthine complex crystallization conditions do not represent cellular reaction conditions; thus, the biological significance cannot be accessed from these results. However, the hypoxanthine binding at this position is unlikely to be merely a coincidence, given the positioning of the AP-site analogue inhibitor in the AlkA active site.

The complex structure reveals that the hypoxanthine locks up residues Y239 and W218. It's known that W218 is critical for binding substrate (Yamagata et al., 1996). This reaction product (free hypoxanthine) binding site might represent a product inhibitor site for reducing the enzyme activity of damaged base cleavage, thereby modulating the number of new AP-sites formed. By interacting with Y239 and W218, hypoxanthine effectively blocks the active site, which might give the cell time to repair existing AP-sites therefore preventing development of AP-site toxicity. This putative inhibition may very well be a weak interaction by design requiring large concentrations of product for inhibition. Product inhibition reactions could work in concert. Interaction between AlkA and the AP-site would inhibit development of toxicity, while the free damaged base, acting as an inhibitor, would limit new AP-site production.

Although it is still not completely understood, AlkA binding to undamaged DNA is an important aspect of DNA repair, and it has implications for glycosylase DNA interactions in general. The results described herein suggest the possibility of a mechanism for modulating AlkA−DNA interactions and perhaps this class of glycosylases in general.

ACKNOWLEDGMENT

We are very grateful to Tim O'Connor for an AlkA clone and purification protocol and to Tom Ellenberger of Harvard University for their AlkA coordinates. We are also grateful for the program Ribbons implemented by W. M. Carson carson@cmc.uab.edu, http://www.cmc.uab.edu/faculty_staff/carson/.

Monoclonal Antibodies That Recognize Minimal Differences in the Three-Dimensional Structures of Metal−Chelate Complexes

R. Mark Jones,[†] Haini Yu,[†] James B. Delehanty,[†] and Diane A. Blake*[,†,‡]

Department of Ophthalmology, Tulane University Health Sciences Center, New Orleans, Louisiana, 70112, and Tulane/Xavier Center for Bioenvironmental Research, New Orleans, Louisiana 70112. Received August 1, 2001; Revised Manuscript Received November 29, 2001

Immunization of BALB/c mice with a cadmium−chelate−protein conjugate resulted in the isolation of two hybridoma cell lines (A4 and E5) that synthesized antibodies with different variable regions, but similar metal−chelate affinity. The ability of these two monoclonal antibodies to interact with 12 different metal−chelate complexes was studied using the KinExA 3000 immunoassay instrument. The two antibodies showed the highest affinity for cadmium and mercury complexes of ethylenediamine *N*,*N*,*N*′,*N*′-tetraacetic acid (EDTA). The E5 antibody bound to EDTA complexes of cadmium and mercury with equilibrium dissociation constants (K_d) of 1.62×10^{-9} M and 3.64×10^{-9} M, respectively. The corresponding values for the A4 antibody were 14.7×10^{-9} M and 3.56×10^{-9} M. Addition of a cyclohexyl ring to the EDTA backbone increased the affinity of E5 for the metal−chelate haptens, while decreasing the binding of A4 to the same haptens. Based on available crystal structures, molecular models were constructed for five different divalent metal−chelate complexes. The models were compared to determine structural features of the haptens that may influence antibody recognition. Difference distance matrixes were used to identify areas of the metal−chelate haptens that differed in three-dimensional space. Antibody affinity correlated well with the extent of total structural difference for these metal−EDTA complexes.

INTRODUCTION

Half of the 20 amino acids have functional groups that can coordinate metal ions, and the resulting protein−metal complexes play a number of roles; they serve as electrophiles at active sites, redox centers, and foci for structural stabilization (*1*). Antibodies that bind metals and metal-containing antigens make up a special class of these metal-binding proteins. There are a number of reports of metal-binding antibodies. Myelomas producing Cu- and Ca-binding immunoglobulins were reported in the mid and late 1970s (*2*, *3*). More recently antibodies directed against glutathione− and chelate−metal complexes of Hg(II), In(III), Cd(II), and Pb(II) have been reported (*4*−*7*). These metal-specific monoclonal antibodies (mAbs)[1] have potential uses in both medicine and environmental analysis. Some metal-binding antibodies have had utility in tumor imaging and treatment (*8*). Immunoassays for specific metal ions have also been developed using metal-specific monoclonal antibodies as their primary reagent (*9*−*12*). These immunoassays, with sensitivities of sub-part per billion for some metal ions, will be useful adjuncts to more traditional analytical methods of metals analysis.

Metal-specific monoclonal antibodies also offer a unique opportunity to examine mechanisms of protein−metal interactions. The best studied metal-specific mAb is CHA255, which binds to In(III)−EDTA complexes (*13*). This antibody was studied in detail via X-ray crystallography and was shown to bind an In(III)−4-[*N*′-(2-hydroxyethyl)thioureido]-L-benzyl−EDTA (EOTUBE) complex through both direct metal coordination and ionic interactions with the chelate molecule. A histidine residue in the third complementarity determining region of the heavy chain (CDRH3) was shown to coordinate the In(III) ion. Contiguous to the histidine, an arginine appeared to ion-pair with one of the carboxylate arms of the In(III)−EOTUBE complex. When the In(III) was replaced with Fe(III), the affinity of CHA255 decreased 20-fold. The histidine in CDRH3 could no longer coordinate the Fe(III) due to changes in the conformation of the glycinate arms of the EDTA chelate. This study emphasized that the direct coordination of the metal by CHA255 was required for high affinity binding. The Cd(II)− and Hg(II)−EDTA specific antibody, 2A81G5, was homology modeled using CHA255 as a template (*6*). This model revealed a CDRH3 histidine residue in a similar metal-ion-coordinating orientation. Apart from this histidine, the two antibodies shared little CDR homology or binding similarities. The metal-ion selectivity of the CHA255 antibody could not be explained in terms of metal ion size or metal−chelate stability constants (*5*).

With the exception of Hg(II) and Mg(II), the metal-ion selectivity and affinity of the 2A81G5 antibody was found to correlate well with the atomic volume of the divalent metal ions (*6*). Both of these studies gave only cursory regard to the total metal−chelate structure, which is regulated by both ion size and coordination bond lability.

In the current study, we report the isolation and characterization of two monoclonal antibodies that showed similar metal−chelate affinities during initial screening studies. These two antibodies were subsequently found to have different N-terminal sequences in both their heavy and light chains. We have compared the ability of these two antibodies to bind to a variety of metal−chelate complexes and hypothesized about recognition mechanisms based on metal−chelate structure. The two antibodies were found to bind Cd(II)− and Hg(II)−chelate complexes with the highest affinity. Molecular modeling of five divalent metal−chelates with known crystal structures also allowed us to focus on differences in the metal−chelate hapten structures that may be important for antibody recognition.

EXPERIMENTAL PROCEDURES

Materials. Bovine serum albumin (BSA) (ultrapure) and an immunoglobulin G (IgG) isotyping kit were obtained from Boehringer Mannheim (Indianapolis, IN). Keyhole limpet hemocyanin (KLH) and 1-(4-isothiocyanobenzyl)ethylenediaminetetraacetic acid (ITCBE) were purchased from CalBiochem Corp. (La Jolla, CA). Centricon 30 microconcentrators were products of Amicon, Inc. (Beverly, MA). Metal ions were atomic absorption standards from Perkin-Elmer Corporation (Norwalk, CT). BALB/c AnNtacfBR inbred mice were purchased from Charles River Laboratories (Wilmington, MA). Ribi adjuvant was obtained from Ribi Immunochemicals (Hamilton, MT). HEPES, ethylenediamine-*N*,*N*,*N*′,*N*′-tetraacetic acid (EDTA), tissue culture medium, L-glutamine, HAT medium supplement, antibiotics, cyanogen bromide activated agarose, and goat anti-mouse IgG coupled to horseradish peroxidase were purchased from Sigma Chemical Co. (St. Louis, MO). Sodium dodecyl sulfate−polyacrylamide gel electrophesis (SDS−PAGE) reagents were obtained from Bio-Rad (Hercules, CA). Pyroglutmate amino peptidase was purchased from Panvera Corporation (Madison, WI). *trans*-1,2-Diaminocyclohexane-*N*,*N*,*N*′,*N*′-tetraacetic acid (CDTA) was purchased from Aldrich (Milwaukee, WI). 3,3′5,5′-Tetramethylbenzidine (TMB) microwell substrate was a product of Kirkegaard-Perry Laboratories (Gaithersburg, MD). Mini Problott membranes were obtained from Applied Biosystems (Foster City, CA). Immobilized protein G resin and BCA protein assay were purchased from Pierce Chemical Co. (Rockford, IL) and used according to the manufacturer's instructions.

Protein−Chelate Conjugates. Protein chelate conjugates were prepared as described in (*14*). A 20 mg/mL solution of protein (BSA or KLH) was prepared in phosphate-buffered saline (137 mM NaCl, 3 mM KCl, 10 mM sodium phosphate), pH 9.5. ITCBE and Cd(II) were added to the BSA solutions to achieve final concentrations of 1.36 mM and 1.4 mM, respectively. ITCBE and Cd(II) were added to KLH solutions in equimolar amounts to achieve a final concentration of 1.5 mM. The reactions were adjusted to pH 9.0 and stirred for 22 h at 25 °C. Unreacted low-molecular weight reagents were removed by buffer exchange using a Centricon 30 device that had been previously treated with EDTA and washed profusely with Hepes-buffered saline (HBS, 137 mM NaCl, 3 mM KCl, 10 mM Hepes), pH 7.4. The conjugates were washed five times with metal-free HEPES (0.1 M, pH 9.0) and twice with metal-free HEPES (0.1 M, pH 7.4). Protein conjugate concentration was determined using the Pierce BCA protein assay. The degree of conjugate substitution was quantified using the trinitrobenzenesulfonic acid method similar to that described in refs 15 and 16. The extent of substitution of free lysine residues was 15.8−17.0% for BSA conjugates and 15% for the KLH conjugate.

Mouse Immunization, Hybridoma Production, and Purification of Monoclonal Antibodies. Five 6-week old BALB/c AnNtacfBR mice were injected intraperitoneally with 50 μg of the Cd(II)−EDTA−KLH conjugate emulsified in Ribi adjuvant at days 0, 21, and then at 2-week intervals. Antibody response of each mouse was determined by indirect ELISA using both metal-free EDTA−BSA and cadmium-loaded conjugate (*6*). The mice showing highest antibody responses were given a final intraperitoneal boost of 50 μg of the KLH conjugate in phosphate-buffered saline (pH 7.4) 4 days prior to fusion. Mouse spleen cells were harvested, washed in RPMI 1640 medium, and fused with X63-Ag 8.653 myeloma cells. Supernatants from viable, replicating hybridoma clones were collected and screened for antibodies to a variety of metal−chelate complexes by competitive ELISA (described below). Hybridomas synthesizing and secreting metal-specific antibodies were subcloned twice by limiting dilution. Positive hybridoma clones were subcultured and frozen.

Ascites fluid was produced in BALB/c mice primed with Freund's incomplete adjuvant by intraperitoneal injection of 1.27×10^6 hybridoma cells. Ascites fluid was collected 10−15 days after the hybridoma injection. The clone E5 was difficult to grow as an ascites tumor, while clone A4 displayed no problems developing as ascites. The IgG fraction of ascites was isolated by affinity chromatography on immobilized protein G. A portion of the protein G purified antibody was further purified on a Cd(II)−EDTA−BSA affinity column. The Cd(II)−EDTA−BSA affinity-purified antibodies were separated under reducing conditions by SDS−PAGE and electroblotted to Mini Problott membranes. The heavy chain N-terminus of antibody E5 was blocked and required deblocking according to the method described in Mozdzanowski et. al prior to electrophoresis (*17*). The heavy and light chain proteins were excised, and N-terminal sequencing was performed at a commercial facility. The immunoglobulin subclass and light chain isotype of the antibodies were determined using an IsoStrip antibody isotyping kit according to the manufacture's instructions. Protein concentration was determined using the BCA protein assay kit.

Competitive ELISA. Competitive ELISAs were performed essentially as described in ref 11. Cd(II), Hg(II), Mn(II), Cu(II), Zn(II), Fe(III), Ni(II), In(III), Ag(I), Pb(II), Co(III), Mo(VI), and Ca(II) were tested for their ability to inhibit binding to the immobilized Cd(II)−EDTA−BSA conjugate in a HBS amended with 0.4 mM CDTA or 4.0 mM EDTA.

Determination of Equilibrium Dissociation Constants and Bimolecular Association Rate Constants. The KinExA 3000 (Sapidyne Instruments Inc., Boise, ID) is an automated flow fluorimeter used to determine the amount of antibody with unoccupied binding sites in a mixture of antibody and ligand (*18*). Binding experiments were performed by coating 200 mg of poly(methyl methacrylate) beads (63−103 μm) (Sapidyne Instruments, Inc.) with 1 mL Cd(II)−EDTA−BSA

conjugate (100 μg/mL). The conjugate and beads were rocked for 1 h at 37 °C. The beads were then pelleted and washed three times with 1 mL of HBS. The beads were blocked with 1 mL of 1% BSA in HBS at 37 °C for 1 h and stored in blocking buffer at 4 °C for up to six weeks. Detailed protocols for use of the KinExA instrument are available in ref 18.

Data acquisition and instrument control were accomplished using a PC interfaced with the KinExA and software distributed by Sapidyne, Inc. The resulting data was compiled using Microsoft Excel, and equilibrium dissociation constants were obtained from nonlinear regression analysis of the data using a one-site homogeneous binding model contained within SlideWrite Plus software (Version 5.0, Advanced Graphics, Inc, Encinitas, CA).

Modeling of Metal−Chelate Conjugates and Distance Matrixes. Crystal structures for Cd(II)−, Hg(II)−, Mn(II)−, In(III)−, Fe(III)−, Ni(II)−, and Zn(II)−EDTA complexes were obtained from the Cambridge Structural Database (*19*−*25*). Metal−EDTA structures were displayed on a Silicon Graphics Octane workstation with SYBYL 6.6 molecular modeling software (Tripos Associates, St. Louis, MO). The extended parameter set $TA_DEMOS/metals.tpd was used for metal recognition as provided by Tripos. The crystal structures were geometry-optimized using the standard Tripos molecular mechanics force field with 0.001 kcal/mol energy gradient convergence criterion. Interatomic distances were determined manually from the SYBYL menu using the ANALYSE>DISTANCE option. The atom numbering between the crystal structures varied, so the chelate−metal complexes were aligned and numbered according to ref 26. Distance Matrixes and Difference Distance Matrixes were built using the program Mathematica version 4.1 (Wolfram Research, Champaign, IL). The carbonyl oxygens (O2, O4, O6, and O8) (see Figure 3) were not included in the difference distance matrixes in order to reduce the size and complexity of Figure 4. Due to the planar nature of the carbonyl bond the distance information is mirrored by the metal-coordinating oxygens and thus would be repetitive.

RESULTS

Hybridoma Screen. Hybridoma cells were screened for antibodies that bound Cd(II)−EDTA−BSA and 49 positive clones were detected. The positive hybridomas were grouped based on the ability of their antibodies to be inhibited in competitive ELISA. Cells producing antibodies that showed little inhibition by soluble EDTA or Zn(II)−EDTA, but considerable inhibition by Cd(II)−EDTA, were selected for further analysis.

Cells in a single well showing activity were subcloned by limiting dilution and gave rise to two clones, A4 and E5. Supernatants from these two clones were again screened for their ability to be competitively inhibited by metal-free EDTA and Zn(II) or Cd(II) in a background of 5 mM EDTA. Both antibodies showed little inhibition by metal-free EDTA at concentrations as high as 5 mM (data not shown). As shown in Figure 1, addition of Zn(II) (765 μM)−EDTA inhibited A4 by 54% and E5 by 71%, while Cd(II) (445 μM)−EDTA inhibited 97% of the binding activities of the two antibodies. The initial interpretation of this screening data was that A4 and E5 were identical clones, and the differences in the competitive ELISA screen were due to variations of antibody concentration in the culture supernatants. Isotyping revealed that both mAbs were of the IgG1 subclass with κ light chains.

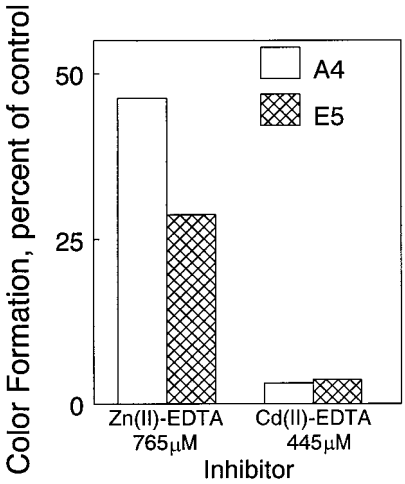

Figure 1. Hybridoma supernatant screen by competitive ELISA. The tissue culture supernatants from clones A4 and E5 were diluted in PBS containing 5 mM EDTA and tested by competitive ELISA for their ability to be inhibited by soluble Zn(II) (765 μM) or Cd(II) (445 μM) in a background of 5 mM EDTA.

Table 1. N-Terminal Amino Acid Sequence for A4 and E5 Variable Regions[a]

	heavy chain variable region sequence

E5	Q V Q L K E S G P G L V A P S Q S L S I T

	light chain variable region sequence
A4	D I V M S Q F P S S L A V S T G E R V T M
E5	D V V M T Q T P L S L P V S L G X Q A X I

[a] An X indicates amino acid residues that could not be accurately determined from the data.

N-Terminal sequencing subsequently revealed that the two antibodies differed in amino acid sequence in the first framework region of both their light chain and heavy chain variable regions as shown in Table 1. Although these framework sequences do not define the antigen-binding domains of the antibodies, these data, taken with the differences observed in binding affinities (see below), indicate that A4 and E5 are two different antibodies.

Binding Specificity. Binding comparisons of A4 and E5 were initially performed using competitive ELISA (data not shown). The ELISA data identified trends that could be more rigorously studied using the KinExA 3000. The KinExA instrument allows the separation and quantification of unbound antibody in an equilibrium mixture of antibody, ligand, and antibody−ligand complexes. Unbound antibody is removed from the equilibrium mixture by a brief passage through a column of immobilized ligand. The equilibrium mixture is exposed to the column for approximately 240 ms, and thus the immobilized ligand acts merely as a trapping reagent to remove a portion of uncomplexed antibody from the mixture (*18*).

The KinExA instrument generates fluorescence curves as shown in Figure 2A. A portion of the curve (for this study between 300 and 399 s) was integrated, and the concentration of free, unbound antibody in each equilibrium mixture was determined from the integrated fluorescence. The fraction of occupied binding sites on the antibody molecule was taken as:

$$\frac{I_0 - I_{exp}}{I_0 - I_\infty} \quad (1)$$

Table 2. Binding (K_d, M) of Chelators and Chelated Metals to Antibodies A4 and E5

	A4		E5	
chelator	EDTA	CDTA	EDTA	CDTA
metal free	$>10^{-3}$	$(5.27 \pm 1.60) \times 10^{-4}$	$>10^{-3}$	$(2.27 \pm 0.34) \times 10^{-8}$

Ca(II)	$>1 \times 10^{-6}$		$>2 \times 10^{-6}$	
Pb(II)	$>1 \times 10^{-5}$		$>3 \times 10^{-5}$	

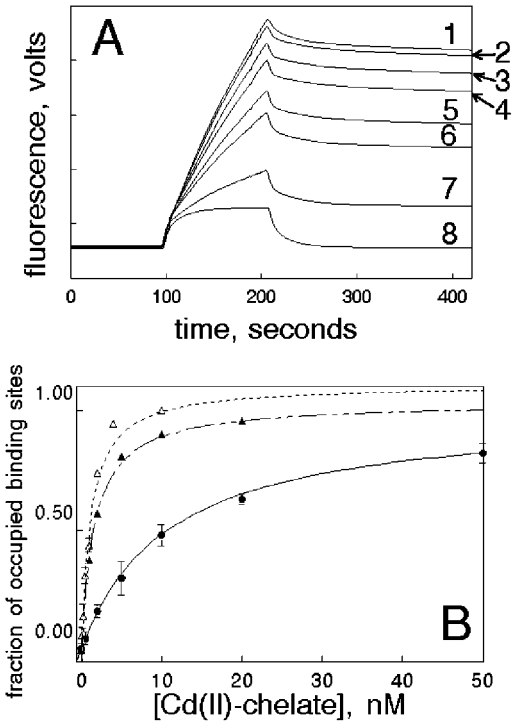

Figure 2. Determination of equilibrium dissociation constants for A4 and E5 to cadmium–chelate complexes. Panel A: Instrument response traces from the KinExA 3000. A4 inhibition by Cd(II) in a backgroud of 0.4 mM EDTA. Curve 1 corresponds to zero Cd(II) concentration, curve 8 corresponds to a saturating Cd(II) concentration (100 nM), and curves 2–7 correspond to Cd(II) concentrations of 0.5, 2,5, 10, 20, and 50 nM, respectively. Panel B: The fraction of occupied binding sites is determined by integrating a portion of the instrument response traces between 300 and 399 s, graphing against ligand concentration, and normalizing these integrated fluorescence curves. A4 binding to Cd(II)–EDTA is represented by closed circles (●). E5 binding to Cd(II)–EDTA is represented by closed triangles (▲), and E5 binding to Cd(II)-CDTA is represented by open triangles (△). Equilibrium dissociation constants are summarized in Table 1.

where I represents the integrated fluorescence and the subscripts 0, exp, and ∞ represent experimental traces corresponding to a ligand concentration of zero, an intermediate concentration, and a saturating ligand concentration, respectively. The fraction of occupied binding sites was plotted versus ligand concentration, and the equilibrium dissociation constant, K_d, was determined from a nonlinear regression fit of the data (example shown in Figure 2B) to the following rectangular hyperbola:

$$\text{fraction of occupied binding sites} = X/(X + K_d) \quad (2)$$

where X represents the free ligand concentration.

Both antibodies showed negligible affinity for metal-free EDTA as shown in Table 2. Antibody A4 bound most tightly to Hg(II)–EDTA complexes. Replacement of Hg(II) in the EDTA complex with Cd(II) decreased the affinity of A4 by 4-fold. Replacement with In(III) or Mn(II) lowered the K_d 2 orders of magnitude from that observed with the Hg(II)–EDTA complex. All other metal–EDTA complexes tested (Zn(II), Cu(II), Ni(II), Co(III), Fe(III), Ca(II), and Pb(II)) bound A4 more than 200-fold less tightly than Hg(II)–EDTA.

Of the EDTA complexes, E5 showed the highest affinity for Cd(II)–EDTA and only a 2-fold lower affinity for Hg(II)–EDTA (Table 2). Replacement of Cd(II) with In(III) or Mn(II) in the EDTA complex resulted in an approximate 100-fold decrease in affinity, while all other metals decreased the affinity of E5 for the metal–chelate complex by over 500-fold. The two antibodies bound EDTA complexes of Cd(II), Mn(II), and Ni(II) with differing affinities, but both antibodies bound the EDTA complexes of Hg(II), Zn(II), Co(III), Cu(II), Fe(III), and In(III) with very similar affinities.

When the structure of the chelator was changed by substituting CDTA for EDTA, antibody recognition of the metal-free CDTA was measurable (Table 2). A4 recognized metal-free CDTA with just under millimolar affinity, while E5 bound to metal-free CDTA with a surprisingly high affinity (22.7 nM). A4 bound less tightly to the metal–CDTA complexes than to the corresponding metal–EDTA complexes. Except for Mn(II)–CDTA, the average decrease in affinity of A4 for metal–CDTA complexes over metal–EDTA complexes was approximately 2-fold. The decrease for Mn(II)–CDTA versus Mn(II)–EDTA was just over 10-fold. In contrast, E5 bound more tightly to the metal–CDTA complexes than to the corresponding metal–EDTA complexes. E5 bound Cd(II)–CDTA slightly tighter than the Cd(II)–EDTA complex, but recognized Mn–CDTA with a 40-fold higher affinity than Mn(II)–EDTA. E5 also showed a 5-fold increase in affinity for In(III)–CDTA over the In(III)–EDTA complex.

Association and dissociation rate constant determinations were attempted for the Cd(II), Mn(II), In(III), and Hg(II) metal–chelate complexes and for the metal-free CDTA. The KinExA 3000 was used to determine bimolecular association rate constants in these procedures (*18*). The concentration of antigen was varied while maintaining a constant, but short reaction time. Antibody was injected into and mixed with a stream of antigen. This mixture was allowed to react for the 11 s it took the stream to flow from the injection point to the observation cell and interact with the bead column. The resulting fluorescent response curves were similar to those in Figure 2A, and a single-exponential function of

ligand	association rate constant, $M^{-1}\ s^{-1}$	dissociation rate constant, s^{-1}
	Antibody A4	
Hg(II)−EDTA	$(3.96 \pm 0.9) \times 10^6$	0.014
Mn(II)−EDTA	$(6.64 \pm 1.7) \times 10^4$	0.031
	Antibody E5	
Hg(II)−EDTA	$(2.26 \pm 0.2) \times 10^6$	0.008
Cd(II)−EDTA	$(1.73 \pm 0.2) \times 10^7$	0.028

[a] Association rate constants were determined as described in the text. Values for dissociation rate constants were obtained by calculation from the association rate constant and the K_d.

time was fit to each data set (see ref 18 for details). Unfortunately, association rate constants for metal-free CDTA and the In(III)−chelate complexes with both antibodies, Cd(II)−EDTA with A4, and Mn(II)−EDTA with E5 were not measurable by this method. The antibody and metal−chelates had reached equilibrium in the 11 s allowed for the mixing reaction, indicating that the antibody had an on-rate for these ligands that was faster than the operational deadtime of the instrument.

The on-rate for Hg(II)−EDTA with A4 was 59-fold higher than that determined for Mn(II)−EDTA as shown in Table 3. The off rate was determined by the identity $K_d = K_{off}/K_{on}$. A4 dissociated from Mn(II)−EDTA at a rate 2× faster than that determined for Hg(II)−EDTA. The on-rate for E5 was 7.5-fold faster with Cd(II)−EDTA than with Hg(II)−EDTA, but it also dissociated 3.5-fold faster. The bimolecular association rate constants of both antibodies with Hg(II)−EDTA were similar.

Difference Distance Matrixes. The ability of the A4 and E5 antibodies to discern subtle differences in the structures of metal−chelate complexes was further investigated by analyzing the available crystal data for several of these complexes. Figure 3 shows the energy-minimized crystal structures for EDTA complexes of Cd(II), Hg(II), Mn(II), Ni(II), and Zn(II). As can be seen from the 1 Å bar at the bottom of the figure, these complexes are structurally very similar. In Panels A and B, all five structures were superimposed and displayed from two different angles of view. A superimposition of the two most structurally similar complexes under study, Cd(II)−EDTA and Hg(II)−EDTA, is shown in Panel C, while the superimposed structures of the two most dissimilar complexes, the Cd(II) and Ni(II) complexes, are displayed in Panel D. While comparisons of such three-dimensional projections provided an overall appreciation of the similarities and differences in these metal−EDTA complexes, they were not sufficient to quantify structural differences between the complexes. Distance matrixes (DMs) were therefore developed to compare the molecular structures of the metal−chelate complexes. The DM for one individual complex was subsequently subtracted from that of another complex to yield difference distance matrixes (DDMs), which identified areas in two metal−chelate structures under comparison where differences in the three-dimensional structures occurred. This analysis required that the atoms compared be numbered identically. Metal−EDTA crystal structures obtained from the Cambridge Structural Database all had different numbering schemes; these crystal structures were therefore renumbered according to the scheme used by Nesterova and Porai-Koshits (*26*), and the numbering scheme used in this analysis is shown in Panel C of Figure 4. The glycinate arms are labeled A−D to aid in their identification. Two examples of the DDMs are shown in Panels A

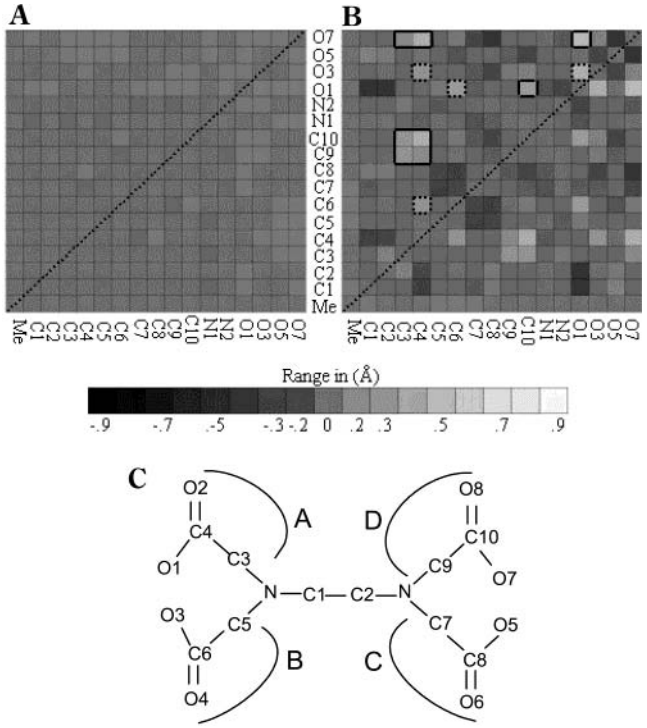

Figure 4. Difference distance matrixes. Panels A and B: The difference distance matrixes (DDM) were generated by subtracting the distance matrixes of two individual metal–chelate complexes (see Experimental Procedures), and the values were given a gray scale shade. Each square represents a value corresponding to the distance difference between the two atoms; therefore the lower right square represents the distance difference between the metal and oxygen 7. The entire bottom row of squares is distance differences from the metal atom. The dark dashed line separates the DDM into the two symmetric halves. This line runs through squares of zero value that can be used as a color reference with the range scale. Panel A: DDM for Cd(II)–EDTA minus Hg(II)–EDTA. The differences are all below 0.2 Å. Panel B: DDM for Cd(II)–EDTA minus Ni(II)–EDTA. The splotchy pattern reports atom distance differences up to 0.6 Å. Panel C: Distance matrixes require that the atoms compared be numbered identically. Metal–EDTA crystal structures obtained from the Cambridge Structural Database all had different numbering schemes; these crystal structures were renumbered according to the scheme used by Nesterova and Porai-Koshits (*26*). C1 was established by determining the ethylene carbon that was farthest from the metal ion. The glycinate arms are labeled A–D to aid in their identification.

and B of Figure 4 with the gray scale range (−0.9 Å to +0.9 Å) shown below. Figure 4A is the DDM for Cd(II)–EDTA minus Hg(II)–EDTA. The distance differences between atom positions in the Cd(II)–EDTA and Hg(II)–EDTA structures all fall below 0.2 Å, indicating that the three-dimensional structures of these two complexes are very similar (see also the superimposed structures in Figure 3C). In contrast, a number of differences are evident in the DDM for Cd(II)–EDTA minus Ni(II)–EDTA, shown in Figure 4B. Dark squares indicate distances in the Ni(II)–EDTA complex where the atoms are farther apart than corresponding atoms in the Cd(II)–EDTA structure; lighter squares indicate distances in the Ni(II)–EDTA complex where the atoms are closer together than atoms in the Cd(II)–EDTA structure. This analysis showed that the atoms of arm A (C3/C4/O1) (see Figure 4C) and the atoms of arm D (C9/C10/O7) were closer together in the Ni(II)–EDTA complex than in the Cd(II)–EDTA complex. When comparing the distance differences between the arms, compare the distance between the atoms C3 and C9, C4 and C10, and O1 and O7 (highlighted in Figure 4B by squares with bold edges). Lighter shading at the intersection of the atoms in arm A (C4/O1) with the atoms in arm B (C6/O3) (highlighted in Figure 4B by squares with dotted edges) indicates that these atoms are also closer together in the Ni(II)–EDTA complex than in the Cd(II)–EDTA complex. Worth noting is that O1 does not get closer to C5 or C9. This may indicate a rotation around the C–C bond in the glycinate arms. The dark shading at the intersection of C4 with C1/C2 and O1 with C1/C2 indicates that in the Ni(II)–EDTA complex these atoms were farther apart than in the Cd(II)–EDTA complex. This indicates arm A is further from the ethylene backbone in the Ni(II)–EDTA complex than the Cd(II) complex. This is counter-intuitive because Cd(II) has a larger ion size, but may be explained by crowding of the glycinate arms around the Ni(II) ion and forcing arm A to move away from the ion. The distances between the atoms in arm B (C5/C6/O3) with the atoms in arm C (C7/C8/O5) are farther apart from one another in the Ni(II)– compared to the Cd(II)–EDTA complex. These differences are mimicked by the Cd(II)–EDTA minus Zn(II)–EDTA difference matrix and similar differences are seen when either the Zn(II)– or Ni(II)–EDTA matrix is subtracted from the Mn(II)–EDTA matrix (data not shown).

In an effort to relate differences in the molecular shape of the metal–chelate complexes to their ability to be recognized by the A4 and E5 antibodies, the absolute values from one of the symmetric halves of the DDM were summed. This term is representative of the total differences between the two metal–chelate haptens being compared. The structures of five EDTA-chelated divalent metals (Cd, Hg, Ni, Mn, and Zn), available in the Cambridge Structural Database, were used in this comparison. As shown in Figure 5, when the total difference was related to the $-\log K_d$, an inverse relationship was observed. The metal–EDTA complex with the highest affinity for each antibody was used as the standard when the differences were calculated. The coefficient of determination (r^2) for the total difference related to the binding of A4 was very strong ($r^2 = 0.97$), while this relationship was only slightly weaker for E5 (r^2 of 0.84) (Figure 5).

DISCUSSION

Antigen specificity and antibody binding are believed to reside mainly in the CDRs found in the variable regions of the antibody molecule (*27*). The two antibodies examined in the present study differ in the N-terminal sequences of their light and heavy chain variable regions (Table 1). The differences in the N-terminal sequence data and the differences in affinity are compelling evidence that E5 and A4 are two different antibodies. Because of the differences in protein sequence and the similarities of activity in the initial screening, these two antibodies were chosen for a comparative binding study. Such a structure/function comparison requires the use of a number of structurally similar ligands to probe the antibody binding activity. The metal–chelate complexes offer a unique system whereby the hapten can be easily modified simply by changing the metal in the chelate complex. Larger hapten modifications can be made by replacing the chelate. For the metals examined in this study, the logarithms of the critical stability constants for EDTA range from 10.8 (Ca^{2+}) to 25.0 (Fe^{3+}), and those for CDTA from 17.5 (Mn^{2+}) to 28.7 (In^{3+}) (*28*). Under the conditions of our binding assays (400 μM chelator and 0.1 to 50 μM metal ion), it was reasonable to assume that all the metal ions in Table 2 existed as complexes with the chelator, and that the metal–chelate complex was the form that interacted with the antibody. The metal–

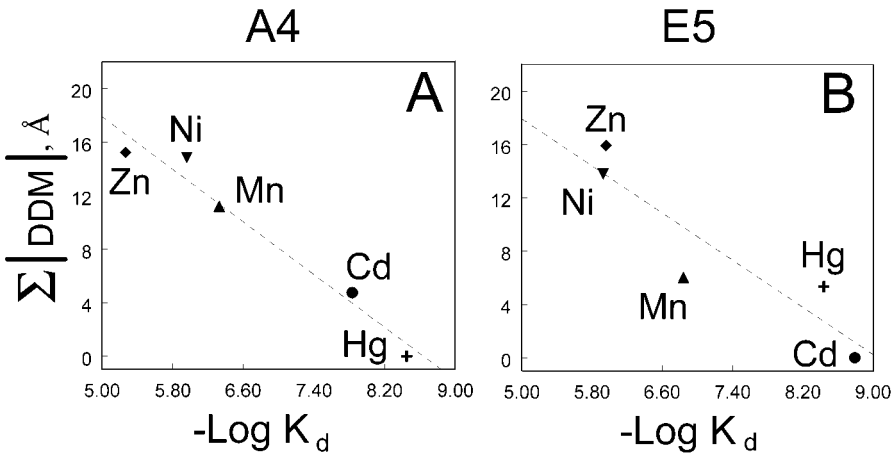

Figure 5. Changes in hapten shape correlate with antibody binding. One-half the sum of the absolute value of the DDM was plotted versus the negative logarithm of the equilibrium dissociation constant for the divalent metal ions modeled. Panel A: The relationship for A4 when the metal−EDTA DDMs are subtracted from the highest affinity ligand, Hg(II)−EDTA ($r^2 = 0.97$). Panel B: The relationship for E5 when the metal−EDTA DDMs are subtracted from the highest affinity ligand, Cd(II)−EDTA ($r^2 = 0.84$).

chelates used in this study exist in at least four distinct conformations. NMR studies have shown that these conformations arise primarily from the lability of the metal−ligand bonds and that the bond lability is dependent upon the identity of the metal ion (*29*, *30*). For example, the metal−oxygen bond of the Cd(II)−EDTA molecule is labile and rapidly rotates around the nitrogen−carbon bond, while the metal-nitrogen bond is longer lived and does not allow for complete dissociation between the chelate and metal (*29*). This may allow for rapid interconversion between different conformations of the Cd(II)−EDTA complex. In contrast, these NMR studies point out the longevity of both the metal−nitrogen and metal−oxygen coordination bonds in the Co(III)−EDTA complex, which may suppress rapid conformational conversion.

The crystal structures of Cd(II)−, Hg(II)−, In(III)−, and Mn(II)−EDTA were observed to be in the same stereoisomeric conformation as the In(III)−chelate complex in the CHA255 binding pocket (*13*, *20*−*22*, *24*). The crystal structures of Ni(II)−, Fe(III)−, and Zn(II)−EDTA, all recognized with lower affinity by both A4 and E5 antibodies, were in a second, different stereoisomeric conformation (*19*, *23*, *25*). Modeling and geometrical minimizing revealed that these original crystal structures were in the lowest energy conformation (data not shown). If the energy differences are indicative of conformer stability, then the metal−chelates' ability to exchange between conformations may play a role in how readily they adopt the proper conformation to fit into the antigen binding site of the antibodies.

The conformational changes of the chelate arms as they shift to accommodate various metal ions appear to be an important factor in antibody recognition. In our study, the DDM indicated that the major difference between the metal−EDTA haptens was the way in which the chelate arms encircled the metal ion. The strong correlation between the total difference in structure and binding activity for the divalent metal ions with A4 and E5 is striking, especially when the maximum, single distance difference between any of the atoms in the structures was 0.6 Å (Figure 4). The shifting of the chelate arms to accommodate metals was demonstrated when the separate crystal structures of the antibody CHA255 bound to In(III)− and Fe(III)−EDTA were solved (*13*); when Fe(III) replaced In(III) in the chelate complex, the conformation of the chelate arms around the metal changed and blocked the antibody coordination to the metal by the histidine, thus lowering the antibody's affinity. The crystallography data obtained with antibody CHA255 indicate that it is entirely plausible that the additive effects of these small differences can significantly alter antibody affinity.

Altering the chelate structure also played a major role in antibody affinity. The two antibodies showed opposite behavior when presented with CDTA-bound metals. In CDTA−metal complexes, the nitrogen becomes more basic due to the cyclohexyl ring; this serves to increase the strength of the nitrogen−metal bond and increase the metal−chelate stability. The stability constants for CDTA complexes are all higher than for their respective EDTA complexes (*28*). A4 bound less tightly to CDTA metal complexes than to the corresponding EDTA complexes, while E5 increased its affinity for the CDTA complexes. The increased affinity of E5 for the metal-free CDTA could be due to the positive hydrophobic interaction of the cyclohexyl ring with the antigen binding site. The same could be suggested for the affinity of A4 for the metal-free CDTA, but then we would expect an increase in affinity with metal-loaded CDTA. This is not what is observed. The increase in A4 affinity to metal-free CDTA may more likely be due to the preorganizing effect of the cyclohexyl group on the chelate; thus the normally nonstructured glycinate arms, as in EDTA, would now have a structured shape similar to the metal−chelated arms in metal-loaded EDTA (*31*). The decrease in A4's affinity for metal-loaded CDTA may be due to a negative hydrophobic interaction of the cyclohexyl portion of the chelate with the binding site.

The association rate constants may also yield information on how well the metal−chelates fit the binding site. Both antibodies have similar rate constants for Hg(II)−EDTA. The on-rate of A4 for Mn(II)−EDTA is almost 60-fold less than for Hg(II)−EDTA. The Mn(II) ion, like Co(III), Fe(III), and Ni(II), all have strong metal−oxygen bonds (*32*). If these smaller ions cannot convert rapidly to a conformation preferred by the antibody, it would most likely reduce the on-rate. Cd(II)−EDTA complexes were shown to have very labile metal−oxygen bonds (*29*). This fact, taken with the fast on-rate of Cd(II)−EDTA with E5, supports the idea of rapid interconversion assisting in binding to the protein.

Metal ion size has an effect on antibody affinity both through ionic radii and via the effect each metal has on the overall chelate complex conformation. This shape is directly related to the ion size and electronic properties

of the different metal ions. The information obtained from comparisons of the distance matrixes is superior to comparisons of ionic radii, because the DM compares the entire three-dimensional structure of the metal−chelate. We were able to demonstrate that Hg(II)− and Cd(II)−EDTA complexes appear very similar in three-dimensional shape, and these structural differences correlate well with antibody binding (Figure 5). Blake et al. used only the difference in ionic radii to correlate the affinity of mAb 2A81G5 to the metal ions, and the difference in ionic radii for Hg(II) from Cd(II) did not correlate well to antibody binding. Studies are in progress to further characterize the structure of the antibody binding sites of A4 and E5 and to develop models that may also correlate the effects of the electronic properties of the metal ions in antibody recognition.

ACKNOWLEDGMENT

The authors thank Drs. Thomas C. Bishop and Thomas E. Weise for advice and guidance on molecular modeling and for the use of the computing facilities in the Theoretical Molecular Biology Laboratory. Dr. Robert C. Blake II is acknowledged for his help in the binding studies and for his critical reading of this manuscript. This work was supported by a grant to D.A.B. from the Natural and Accelerated Bioremediation Research (NABIR) program, Biological and Environmental Research (BER), U.S. Department of Energy (grant #DE-FG02-98ER62704). The Theoretical Molecular Biology Laboratory at the Tulane/Xavier Center for Bioenvironmental Research was established under NSF Cooperative Agreement Number OSR-9550481/LEQSF (1996−1998)-SI-JFAP-04 and is also supported by the Office of Naval Research (NO-0014−99−1−0763).

Received August 9, 2001; Revised Manuscript Received November 7, 2001

Hongotoxin$_1$ (HgTX$_1$), a 39-residue peptide recently isolated from the venom of *Centruroides limbatus*, blocks the voltage-gated K^+ channels $K_v1.1$, $K_v1.2$, and $K_v1.3$ at picomolar toxin concentrations (Koschak, A., Bugianesi, R. M., Mitterdorfer, J., Kaczorowski, G. J., Garcia, M. L., and Knaus, H. G. (1998) *J. Biol. Chem. 273*, 2639−2644). In this report, we determine the three-dimensional structure of HgTX$_1$ using NMR spectroscopy (PDB-code: 1HLY). HgTX$_1$ was found to possess a structure similar to previously characterized K^+ channel toxins (e.g. margatoxin) consisting of a three-stranded antiparallel β-sheet (residues 2−4, 26−30, and 33−37) and a helical conformation (part 3_{10} helix and part α helix; residues 10−20). Due to the importance of residue Lys-28 for high-affinity interaction with the respective channels, lysine-reactive fluorescence dyes cannot be used to label wild-type HgTX$_1$. On the basis of previous studies (see above) and our NMR data, a HgTX$_1$ mutant (HgTX$_1$-A19C) was engineered, expressed, and purified. HgTX$_1$-A19C-SH was labeled using sulfhydryl-reactive Cy3-, Cy5-, and Alexa-dyes. Pharmacological characterization of fluorescently labeled HgTX$_1$-A19C in radioligand binding studies indicated that these hongotoxin$_1$ analogues retain high-affinity for voltage-gated K^+ channels and a respective pharmacological profile. Cy3- and Alexa-dye-labeled hongotoxin$_1$ analogues were used to investigate the localization of K^+ channels in brain sections. The distribution of toxin binding closely follows the distribution of $K_v1.2$ immunoreactivity with the highest expression levels in the cerebellar Purkinje cell layer. Taken together, these results demonstrate that fluorescently labeled HgTX$_1$ analogues comprise novel probes to characterize a subset of voltage-gated K^+ channels.

Current knowledge regarding the distribution and subunit composition of K^+ channels arises mainly from the use of antibodies directed against various ion channel subunits (Sheng et al., 1993; Knaus et al., 1996; Shamotienko et al., 1997; Koch et al., 1997; Knaus et al., 1996; Shamotienko et al., 1997; Koch et al., 1997). These antibodies are essential tools to enable high-resolution distribution studies clarifying the expression pattern of various K^+ channel subunits in various tissues or to establish their subunit composition (Shamotienko et al., 1997; Koch et al., 1997; Koschak et al., 1998; Koch et al., 1997; Koschak et al., 1998). However, production of selective antibodies is frequently hampered by a high degree of sequence conservation within several K^+ channel subfamilies (Chandy and Gutman, 1993). Moreover, these antibodies do not comprise a suitable tool to study native K^+ channels, as the tissues need to be fixed and permeabilized in order to allow antibody access to its intracellular binding site.

As an alternative, toxins have often been used to study native K^+ channels, mostly in functional assays (Miller, 1995; Tytgat et al., 1999; Tytgat et al., 1999). These K^+ channel toxins bind to the extracellular channel vestibule thereby physically occluding the ion conduction pathway (MacKinnon and Miller, 1988; MacKinnon and Miller, 1989; Gross and MacKinnon, 1996; Doyle et al., 1998; MacKinnon et al., 1998; MacKinnon and Miller, 1989; Gross and MacKinnon, 1996; Doyle et al., 1998; MacKinnon et al., 1998). Radioiodinated toxin analogues have extensively been used to map the distribution of toxin receptors through autoradiographic studies, to establish the pharmacological profile of various K^+ channels through radioligand binding studies, or to purify K^+ channels from native tissue thereby clarifying their subunit composition (Gehlert and Gackenheimer, 1993; Vazquez et al., 1990; Garcia-Calvo et al., 1994; Knaus et al., 1994; Vazquez et al., 1990; Garcia-Calvo et al., 1994; Knaus et al., 1994). However, use of these radioiodinated toxins for distribution studies is limited as the resolution of receptor autoradiography is notoriously low.

To overcome these limitations, several attempts were made to generate fluorescently labeled K^+ channel toxins. In most cases, direct fluorescence labeling procedures

were performed through incorporation via *N*-hydroxysuccinimidyl ester chemistry into ϵ-amino groups of lysine residues (Darbon and Angelides, 1984; Angelides, 1986; Angelides, 1989; Jones et al., 1989; Cohen et al., 1991; Angelides, 1986; Angelides, 1989; Jones et al., 1989; Cohen et al., 1991). However, lysine derivatization is often not desirable as they comprise crucial residues for high-affinity toxin interaction with the K^+ channel of interest (Park and Miller, 1992; Goldstein and Miller, 1993; Goldstein et al., 1994; Goldstein and Miller, 1993; Goldstein et al., 1994). Resulting toxin analogues often render a loss of affinity accompanied by an altered pharmacological profile.

In this paper, we report the three-dimensional structure of $HgTX_1$[1] determined through NMR experiments (PDB-code: 1HLY). On the basis of these NMR data and previous studies (Knaus et al., 1996; Koschak et al., 1998), we constructed, expressed, and purified a toxin analogue ($HgTX_1$-A19C) which carries a single free sulfhydryl group in the 'back' of the molecule, most opposite from the toxin's interaction surface with voltage-gated K^+ channels. This sulfhydryl group was used for derivatization with fluorescent dyes such as Cy3, Cy5, and the Alexa-dye-family. The resulting toxin analogues widely retain their pharmacological profile as shown in radioligand binding studies and fluorescence microscopy. Demonstrating one capability of these toxin analogues, $HgTX_1$-A19C−Cy3 was used to monitor the distribution of K_v1 channels in native brain tissue.

These toxin analogues will now allow 'real time' imaging of channels on living cells or heterogeneous tissues. In this respect they will overcome several limitations known to exist for radioligands or sequence specific antibodies. Additionally, they will enable quantification of ligand binding on the cellular level, even in heterologous tissues, or at the subcellular level.

EXPERIMENTAL PROCEDURES

Materials. *Escherichia coli* DH5a was used for plasmid propagation and strain BL21(DE3) for expression of the fusion protein. The plasmid pCI-neo was purchased from Promega (Mannheim, Germany), pcDNA3.1HisA from Invitrogen, and pUC from Boehringer-Mannheim (Mannheim, Germany). Restriction enzymes, Pfu-DNA-Polymerase, T4-DNA-Ligase, nucleotide triphosphates, and reagents for polymerase chain reaction were obtained from Boehringer Mannheim (Mannheim, Germany), tissue culture media and the LipofectAMINE reagent from GIBCO, Life Technology (Vienna, Austria), glass fiber filters (GF/C) from Whatman International (Maidstone, England), and polyethyleneimine and bovine serum albumin (BSA) from Sigma (Vienna, Austria). All other reagents were obtained from commercial sources and were of the highest purity grade commercially available. Cy3- and Cy5-NHS esters were purchased from Amersham-Pharmacia Biotech (Freiburg, Germany) while Cy5-PDP, Cy5-mal, and Cy3-mal were synthesized as described (Gruber et al., 2000). Alexa488-mal, Alexa546-mal, Alexa594-mal, Alexa660-mal, and Alexa680-mal were obtained from Molecular Probes Inc. (Eugene, OR; supplied as isomeric mixtures).

NMR Spectroscopy of Wild-Type $HgTX_1$. Recombinant wild-type $HgTX_1$ was produced as described previously (Koschak et al., 1998). Four milligrams of $HgTX_1$ was dissolved in a 0.5 mL mixture of H_2O and D_2O in a 9:1 ratio (v/v). The pH value of the $HgTX_1$ solution was 3.0 uncorrected for isotope effects. Amide proton exchange rate was determined after lyophilization and dissolution in 100% D_2O.

All 2D-^{1}H NMR measurements were obtained on a BRUKER DRX 500 spectrometer equipped with an HCN probe. Self-shielded triple axis gradients were used as previously described (Blanc et al., 1998). To solve assignment ambiguities, the experiments were performed at 283 and 300 K. All data were processed using the UXNMR Bruker's software running on a Silicon Graphics Indy R4400 workstation. Identification of amino acid spin systems and sequential assignment were done using the standard method described by Wuthrich (Wuthrich, 1986). Distance geometry calculations were performed with the variable target function program DIANA 2.8 (Guntert et al., 1991) following the well-established strategy for scorpion toxin structure determination (Blanc et al., 1998). The visual analysis of resulting structures was carried out with the TURBO−FRODO graphic software running on Silicon Graphics workstations. The quality of the structures was assessed using both PROCHECK 3.3 and PROCHECK−NMR software (Laskowski et al., 1993).

Plasmid Construction, Synthesis, and Purification of Recombinant $HgTX_1$-A19C. The plasmid pG9$HgTX_1$-A19C encodes a fusion protein of the T7 gene 9 product and $HgTX_1$, separated by six histidine residues and the factor Xa cleavage site. Polymerase chain reaction (PCR) was used to create cDNA mutations in the primary sequence of $HgTX_1$ described previously (Koschak et al., 1998). $HgTX_1$-A19C was generated by introducing cysteine at position 19 thereby replacing alanine. Mutations were introduced by the "gene SOEing" technique using mutagenic forward and reverse PCR primers (Horton et al., 1989). Desired mutations were verified by cDNA sequencing using the dideoxy chain termination method (Sanger et al., 1977). The fusion protein was expressed in *E. coli* and purified as described (Koschak et al., 1998). After purification of the fusion protein the toxin mutant was released by cleavage with trypsin. Purified fusion protein (20−40 mg) was incubated with 190 μL of trypsin solution (1 mg/100 μL H_2O) for 15 min at 22 °C. The cleavage mixture was applied to a cation-exchange column (MonoS HR5/5; Pharmacia) and $HgTX_1$-A19C was eluted with a linear gradient from 0 to 0.75 M NaCl in 20 mM borate pH 8.0 (over 40 min) at a flow rate of 0.6 mL/min. Cation exchange chromatography yielded two distinct peptide fractions (see Results). Each peptide fraction was applied separately to a C_{18} reversed-phase column (Vydac, 1 × 25 cm, 23 °C), and the respective toxin analogue was eluted with a linear gradient from 0 to 35% acetonitrile in 0.05% TFA (over 40 min) at a flow rate of 3 mL/min. Approximately equal amounts of two individual peptide isoforms, $HgTX_1$-A19C-βME and dimeric $HgTX_1$-A19C were obtained (see Results). Composition of the purified material was veri-

[1] Abbreviations: $AgTX_2$, agitoxin-2; βME, β-mercaptoethanol; BSA, bovine serum albumin; ChTX, charybdotoxin; Cy3, sodium 1-[5-(carboxyl)pent-1-yl]-2-[5-(3,3-dimethyl-1-ethyl-5-sulfonatoindolin-2-ylidene)-1-en-yl]-3,3-dimethyl-3*H*-indolium-5-sulfonate; Cy5, sodium 1-[5-(carboxyl)pent-1-yl]-2-[5-(3,3-dimethyl-1-ethyl-5-sulfonatoindolin-2-ylidene)-1,3-pentadien-1-yl]-3,3-dimethyl-3*H*-indolium-5-sulfonate; DTT, dithiothreitol; $HgTX_1$, hongotoxin-1; [^{125}I]$HgTX_1$-A19Y/Y37F, mono-[^{125}I]iodotyrosine-hongotoxin-1-A19Y/Y37F; IbTX, iberiotoxin; IC_{50}, concentration causing half-maximal inhibition; KTX, kaliotoxin; k_{+1}, association rate constant; k_{-1}, dissociation rate constant; K_d, dissociation constant; K_i, inhibition constant; mal, maleimide group; MgTX, margatoxin; n_H, pseudohill slope; NHS, *N*-hydroxysuccinimide; PDP, 3-(2-pyridyldithio)propionyl group; SDT, single dye tracing; TFA, trifluoroacetic acid.

fied by electrospray mass spectrometry. Aliquots were lyophilized and stored at −80 °C.

Reduction of Dimeric $HgTX_1$-A19C and $HgTX_1$-A19C-βME. For reduction of dimeric $HgTX_1$-A19C and $HgTX_1$-A19C-βME, aliquots of the respective peptides were dissolved in 0.1 M sodium phosphate buffer (pH 7.0) containing 10 mM DTT and incubated for 15 min at 22 °C. The reaction mixture was applied to a C_{18} reversed-phase column (Vydac, 0.45 × 25 cm, 23 °C). Reduced $HgTX_1$-A19C ($HgTX_1$-A19C-SH) was eluted with a linear gradient from 0 to 35% acetonitrile in 0.05% TFA (over 40 min) at a flow rate of 1 mL/min and stored as described above.

Synthesis of Fluorescently Labeled Hongotoxin$_1$ Analogues. *Conjugation of Cy5-PDP to $HgTX_1$-A19C−SH.* Cy5-PDP was synthesized as described for Cy5-mal (Gruber et al., 2000). Cy5-PDP was dissolved in 25% AcN and 0.05% TFA (in H_2O), an equimolar amount of $HgTX_1$-A19C-SH was added, and the reaction mixture was lyophilized. The reaction was started by addition of 100 μL aqueous buffer (100 mM NaCl, 50 mM NaH_2PO_4, pH 7.5 adjusted with NaOH, deoxygenated with N_2). The mixture was incubated under N_2 for 90 min at 37 °C (see Figure 3) and applied to a C_{18} reversed-phase column (Vydac, 0.45 × 25 cm, 23 °C). $HgTX_1$-A19C−Cy5 was eluted with a linear gradient from 0 to 35% acetonitrile in 0.05% TFA (over 40 min) at a flow rate of 1 mL/min.

Conjugation of Cy5-mal and Cy3-mal to $HgTX_1$-A19C−SH. Cy5-mal and Cy3-mal were synthesized as described for Cy5-mal (Gruber et al., 2000). A 3- or 5-fold molar excess of thiol-teactive Cy-dye was dissolved in 100 μL of aqueous buffer (150 mM NaCl, 50 mM NaH_2PO_4, pH 7.4 adjusted with NaOH) and applied to a vial containing lyophilized $HgTX_1$-A19C-SH. The reaction mixture was incubated for 90 min at 37 °C (see Figure 3) and applied to a C_{18} reversed-phase column (Vydac, 0.45 × 25 cm, 37 °C). $HgTX_1$-A19C−Cy5 and $HgTX_1$-A19C−Cy3 were eluted with a linear gradient from 0 to 35% acetonitrile in 0.05% TFA (over 40 min) at a flow rate of 1 mL/min. Due to the excess of dye no oxidation (dimerization) of the peptide could be detected.

Conjugation of Alexa488-mal, Alexa546-mal, Alexa594-mal, Alexa660-mal, and Alexa680-mal to $HgTX_1$-A19C−SH. A 25 μg or 50 μg amount of thiol-reactive Alexa-dye was dissolved in 200 μL of aqueous buffer (150 mM NaCl, 50 mM NaH_2PO_4, pH 7.4 adjusted with NaOH) and applied to a vial containing lyophilized $HgTX_1$-A19C-SH. The reaction mixture was incubated for 120 min at 37 °C (see Figure 3) and applied to a C_{18} reversed-phase column (Vydac, 0.45 × 25 cm, 23 °C). $HgTX_1$-A19C−Alexa488, $HgTX_1$-A19C−Alexa594, $HgTX_1$-A19C−Alexa660, and $HgTX_1$-A19C−Alexa680 were eluted with a linear gradient from 0 to 35% acetonitrile in 0.05% TFA (over 40 min) at a flow rate of 1 mL/min. $HgTX_1$-A19C−Alea546 was eluted with a linear gradient from 0 to 45% acetonitrile in 0.05% TFA (over 50 min) at a flow rate of 1 mL/min. Due to the excess of dye no oxidation (dimerization) of the peptide could be detected.

The structure of the compounds was verified by electrospray mass spectrometry. Aliquots of fluorescently labeled hongotoxin$_1$ analogues were lyophilized and stored at −80 °C.

Nano-Electrospray Mass Spectrometry. Nanoelectrospray mass spectrometry was performed with a Finnigan LCQ mass spectrometer equipped with a micromanipulator for the correct positioning of the nanospray needle. In short, capillaries (GC120F from Clark Instruments, Reading, United Kingdom) were pulled using the DMZ-universal puller (Zeitz-Instrumente GmbH, München, Germany). They were coated with gold using a Polaron SC7610 Sputter Coater (VG Microtech, Uckfield, United Kingdom) and a gold target. These needles were filled with 1−4 μL of aqueous solution and centrifuged for several seconds using a PicoFuge (Tomy Capsule, Tomy Tech Inc, Palo Alto, CA). The needles were mounted on the micromanipulator and were gently brought in contact with a surface near the inlet of the mass spectrometer. Air pressure was applied to the needle until a small droplet appeared on the tip. The needle was then adjusted 2.5 mm opposite the inlet of the heated cappillary. A potential of 900 V was applied to the needle. For measurements of aqueous solutions, the relative intensities of the corresponding peaks were maximized when the collision-induced decay at the inlet of the mass spectrometer was minimized. The tuning procedure of the mass spectrometer was applied for this purpose. The original data (i.e. abundance of the multiple charged peptide populations versus *m*/*z*) were deconvoluted into mass spectra (relative abundance versus mass) by means of the deconvolution software BioExplore. The error of the mass spectrometer was 100 ppm in the normal mass range (150−2000 *m*/*z*), which was used for all experiments.

Membrane Preparation and Binding Studies. Rat brain synaptic plasma membrane vesicles were prepared as previously described (Knaus et al., 1995). Membrane vesicles from HEK293 cells stably transfected with homotetrameric $K_v1.3$ channels were prepared as described (Helms et al., 1997). Binding experiments were carried out as previously described (Knaus et al., 1995). The incubation medium consisted of 20 mM Tris/HCl, pH 7.4, 0.1% BSA (rat brain membranes) or 20 mM TRIS/HCl, pH 7.4, 5 mM KCl, 0.1% BSA (HEK−$K_v1.3$ membranes). Nonspecific binding was defined in the presence of 1 nM recombinant $HgTX_1$ or MgTX, and incubation was carried out at 22−25 °C typically for 240 min.

Immunohistochemistry. Immunohistochemical distribution studies using an antibody directed against the voltage-gated K^+ channel $K_v1.2$ (anti-$K_v1.2_{(461-480)}$) were performed as previously published in detail (Koch et al., 1997).

Labeling of $K_v1.1$/$K_v1.2$ Channels with Fluorescent $HgTX_1$-A19C Analogues. Male Sprague−Dawley rats (250−300 g) were sacrificed by cervical dislocation, and their brains were rapidly removed and placed for 90 s in isopentane chilled to −40 °C. Thereafter, brains were transferred for 30 min at −30 °C and 10 μm horizontal sections were cut on a cryostat (Leitz, Germany) and thaw-mounted onto gelatin-coated glass slides. Sections were labeled in 20 mM Tris/HCl (pH 7.4), 10 mM NaCl, and 0.1% BSA for 12 h at 4 °C at a saturating concentration of $HgTX_1$-A19C−Alexa488, $HgTX_1$-A19C−Cy3, or $HgTX_1$-A19C−Alexa546 (2 nM). Nonspecific binding was determined in adjacent sections by inclusion of 100 nM $HgTX_1$. Sections were then rinsed four times 2 min each with in ice-cold 20 mM TRIS/HCl, pH 7.4, 10 mM NaCl. For fluorescence microscopy, the sections were embedded in pPD glycerol (30 mg of *p*-phenylendiamine dissolved in 10 mL of 10 mM Tris pH 8.0/90% glycerol (v/v), coverslipped, and sealed with nail polish.

Fluorescence images of the sections were obtained using a Zeiss Axiophot microscope (Carl Zeiss, Oberkochen, Germany) with a 40 × 1.3 NA oil immersion objective, a 20 × 0.5 NA objective, and a standard Rhodamine and FITC filter set. Images were captured by a Peltier cooled slow-scan CCD-camera system (Visitron Systems GmbH, Puchheim, Germany) at short exposure times (0.5−2 s)

and prepared for presentation with Metaview software (Metaview, Version 4.1, Universal Imaging Corp.).

Protein Determination. Protein concentration was determined as previously published (Bradford, 1976) using BSA as standard.

RESULTS

NMR Spectroscopy of Wild-Type $HgTX_1$. Approximately 10 mg of native $HgTX_1$ was purified from a 4 L of *E. coli* culture as described previously (Koschak et al., 1998) and a total of 4 mg of $HgTX_1$ subjected to NMR studies. Using this amount of toxin we were able to assign all spins unambiguously and to connect them in sequence. We collected a total of 380 NOEs which were then converted into distance constraints (144 intraresidue constraints, 109 sequential constraints, 41 medium range, and 59 long-range constraints). Study of the amide proton exchange rates led to the localization of 18 hydrogen bonds which were also converted into distance constraints. Finally, 27 measured coupling constants were converted into as many φ angle constraints.

The distance geometry calculations led to a single family of 25 structures. These structures, containing nonbonded bad contacts, were energy-minimized with the Powell algorithm of the XPLOR3.1 software (Brünger, 1992). The final set of 25 structures after energy minimization is of good quality as demonstrated by Procheck-NMR analysis. The negative van der Waals energy indicates the absence of nonbonded contacts. The correlation with the experimental restraints shows neither distance violation greater than 0.25 Å, nor angle violation greater than 5°. The low root-mean-square-deviation (RMSD) values of the bond lengths (0.012 Å) and the valence angles (2.9 Å) indicates that the covalent geometry is preserved for all 25 structures. The analysis of the Ramachandran plot shows (in PROCHECK software nomenclature) 80% of the residues in the most favored, 19% in the additional allowed regions, 1% in the generously allowed regions, and none in disallowed regions.

The final 25 calculated structures share the same fold and thus form a homologous family. The RMSD value of these 25 structures versus the calculated average structure is 0.57 Å for the backbone atoms and 1.10 Å for all heavy atoms. As shown in Figure 1, the backbone structure is well-defined all along the sequence. The results of structure analysis using TURBO−FRODO (Roussel and Cambillau, 1989) and PROCHECK−NMR (Laskowski et al., 1993) showed that residues G10 to C20 are in helical conformation with the first three residues in 3_{10} helix conformation and the seven following in pure α-helix. Further analysis of the distribution of φ/ψ angles and the location of hydrogen bonds indicated that three segments, 2 to 4, 26 to 30, and 33 to 37 form a three-stranded antiparallel β-sheet. This β-sheet is right-hand twisted and stabilized by standard hydrogen bonds. The two last strands of the β-sheet are connected by a well-defined type I′ β -turn centered between 31 and 32 (Margolskee et al., 1993). This β-sheet is connected to the α-helix through an $\alpha/\beta 5$ loop (Jones et al., 1989; Cohen et al., 1991; Park and Miller, 1992; Goldstein and Miller, 1993; Goldstein et al., 1994). On the basis of previous studies (Knaus et al., 1996; Koschak et al., 1998) and the NMR structure of $HgTX_1$, we were able to predict that mutations in position 19 will significantly alter neither the toxin's overall structure nor its interaction with the channel since this residue is located in the 'back' of the peptide, its side chain is oriented toward the solvent (see Figure 1) and it does not form part of the peptide's interaction surface with K^+ channels (Miller, 1995). Thus, we altered the synthetic $HgTX_1$ gene thereby substituting Ala19 for Cys19 (Koschak et al., 1998).

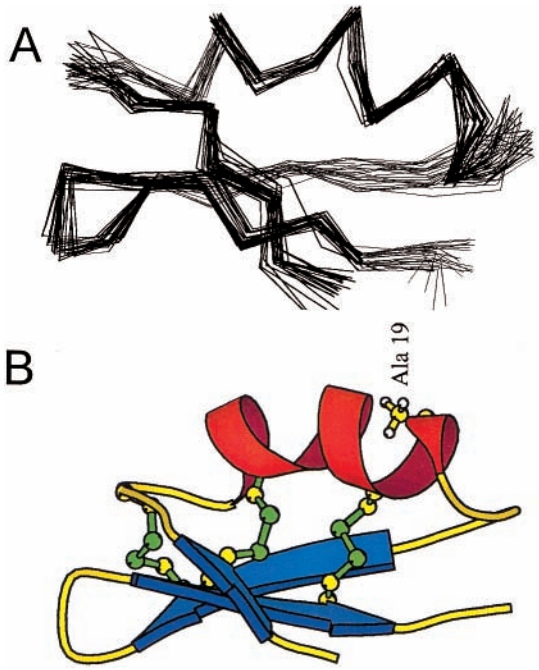

Figure 1. NMR spectroscopy of $HgTX_1$. Stereoview of the backbone (A) of the 25 best $HgTX_1$ structures superposed for best fit, and ribbon drawing of the averaged minimized $HgTX_1$ structure (B). The disulfide bridges are represented in balls and sticks, as well as A19 of $HgTX_1$.

Expression and Purification of $HgTX_1$-A19C. To obtain sufficient amounts of peptide for derivatization with fluorescence dyes, $HgTX_1$-A19C was recombinantly expressed in *E. coli* as part of a fusion protein (Figure 2A). Induction of the respective fusion protein was comparable to wild-type $HgTX_1$ (we determined an induction of 40−80 mg of protein/1500 mL of *E. coli* culture, data not shown). However, the final yield after cation exchange and reversed-phase chromatography was estimated to be only 11 ± 4% of the calculated theoretical yield (corresponding to 440−720 μg of $HgTX_1$-A19C/1500 mL of *E. coli* culture; $n = 4$). We currently favor the idea that the introduction of an additional Cys residue in position 19 impairs proper formation of the internal disulfide bonds of the toxins. Such an incompletely folded toxin analogue is expected to possess much lower resistance to trypsin and would therefore be degraded upon proteolytic release from the fusion protein (Koschak et al., 1998).

After partial purification of the fusion protein and cleavage with trypsin to release $HgTX_1$-A19C-SH, the peptide was purified to homogeneity by cation-exchange (Figure 2B) and C_{18} reversed-phase chromatography (Figure 2C). Cation-exchange chromatography yielded two distinct peptide fractions. Both peptides were subjected to electrospray mass spectrometry which yielded molecular weights of 4329.0 and 8506.0 Da, respectively (see Table 1). However, the calculated M_r for $HgTX_1$-A19C-SH is 4253 Da, a number which is significantly lower than that measured by mass spectrometry. The observed molecular weights are explainable by the formation of a disulfide bond between residue Cys19 (M_r 8506.0) or βME derivatization of this sulhydryl group of Cys19 (M_r 4329.0). Similar observations have been made for an IbTX mutant (which is preferentially isolated as a βME derivative (Knaus et al., 1996)) and for an $AgTX_2$

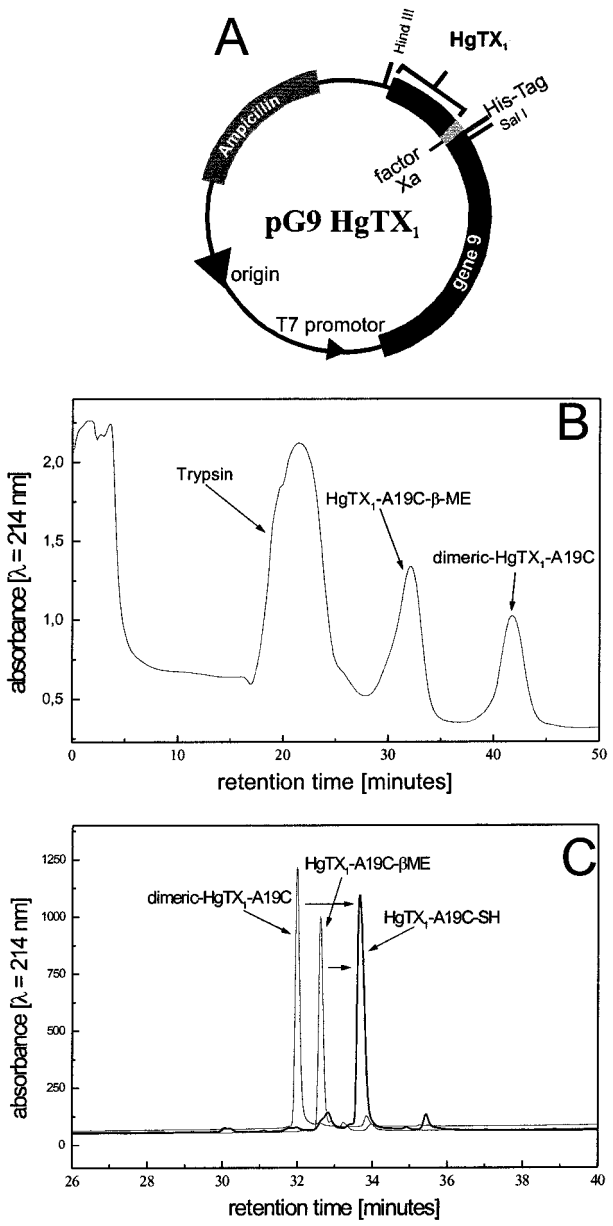

Figure 2. Design of the synthetic $HgTX_1$-A19C gene and purification of the recombinant toxin. (A) The plasmid map of pG9-$HgTX_1$-A19C shows the location of the $HgTX_1$-A19C gene, the factor Xa cleavage site and the T7 gene 9 fusion protein. (B) Cation exchange chromatography of ~ 1 mg trypsin-digested fusion protein loaded onto a MonoS HR5/5 column. Peaks 1, 2, and 3 correspond to trypsin, $HgTX_1$-A19C-βME, and dimeric $HgTX_1$-A19C. (C) Reversed-phase chromatography: Peak 2 and 3 were applied to a C_{18} reversed-phase HPLC. Aliquots of the $HgTX_1$-A19C dimer and $HgTX_1$-A19C-βME were incubated with 10 mM DTT to result in the free thiol form of $HgTX_1$-A19C. Elution of dimeric $HgTX_1$-A19C, $HgTX_1$-A19C-βME, and $HgTX_1$-A19C-SH is shown.

mutant (this toxin analogue quantitatively dimerizes during folding and isolation (Krezel et al., 1995)).

The individual fractions were tested for activity in [^{125}I]-$HgTX_1$-A19Y/Y37F binding to rat brain synaptosomal plasma membranes. Dimeric $HgTX_1$-A19C was a less potent inhibitor of [^{125}I]$HgTX_1$-A19Y/Y37F binding to rat brain synaptosomal plasma membranes compared to $HgTX_1$-A19C-βME and wild-type $HgTX_1$ (see Table 2).

Synthesis of Fluorescently Labeled Hongotoxin$_1$ Analogues. To selectively reduce the disulfide bond in the back of the toxin without disrupting the integrity of the internal disulfide bridges, both $HgTX_1$-A19C-βME and dimeric $HgTX_1$-A19C were incubated with DTT under carefully controlled conditions (see Methods). The peptide carrying a free sulfhydryl group ($HgTX_1$-A19C-SH) was easily identified by a change in retention time upon reversed-phase HPLC (Figure 2). The reduced toxin ($HgTX_1$-A19C-SH) was subjected to mass spectral analysis. A molecular weight of 4253 Da was determined which was identical to the calculated molecular weight. The reduction yield after reversed phase chromatography was estimated to be 90 ± 5% (n > 10). Equimolar amounts of $HgTX_1$-A19C-SH and the sulfhydryl-reactive Cy5-PDP were incubated in order to synthesize the respective fluorescently labeled toxin. For all other fluorescent dyes, a molar excess (see Experimental Procedures) over toxin was employed. The fluorescently labeled toxin mutants were isolated by reverse phase chromatography (see Figure 4) and the postulated structure (see Figure 3) was verified by electrospray mass spectrometry (see Table 1). The coupling yield after reversed-phase chromatography was estimated to be 95 ± 5% (n > 10). Noteworthy, coupling of $HgTX_1$-A19C-SH to maleimides will generate an asymmetric carbon and therefore lead to the formation of diastereomers (see Figure 3B).

Pharmacological Characterization of Fluorescently Labeled $HgTX_1$-A19C. To ascertain that wild-type $HgTX_1$ and the respective fluorescently labeled toxin analogue display similar affinities for native K_v1 channels, binding competition experiments using [^{125}I]$HgTX_1$-A19Y/Y37F were performed (Figure 7). As a tissue source, either rat brain synaptosomal membranes (which pre-

Table 1. Nano-Electrospray Mass Spectrometry[a]

$HgTX_1$-A19C-dye	mass (Da)
$HgTX_1$	4219
$HgTX_1$-A19C−βME	4329

$HgTX_1$-A19C−Alexa546	5263
$HgTX_1$-A19C−Alexa594	5138
$HgTX_1$-A19C−Alexa660	5153
$HgTX_1$-A19C−Alexa680	5233

[a] Nano-electrospray mass spectrometry was performed with a Finnigan LCQ mass spectrometer. The original data (i.e. abundance of the multiple charged peptide populations versus m/z) were deconvoluted into mass spectra (relative abundance versus mass) by means of the deconvolution software BioExplore. Experiments were performed as described in Experimental Procedures.

Table 2. Pharmacological Characterization of Fluorescently Labeled $HgTX_1$-A19C Analogues[a]

$HgTX_1$-A19C−dye	IC_{50} (pM)
$HgTX_1$	0.5
$HgTX_1$-A19C−βME	0.6
$(HgTX_1\text{-A19C})_2$	6.4
$HgTX_1$-A19C−Cy3	2
$HgTX_1$-A19C-Cy5 (Cy5−PDP)	11.6
$HgTX_1$-A19C-Cy5 (Cy5−mal)	11.6
$HgTX_1$–A19C−Alexa488	2.8
$HgTX_1$-A19C−Alexa546	6.7
$HgTX_1$-A19C−Alexa594	4.2
$HgTX_1$-A19C−Alexa660	2
$HgTX_1$-A19C−Alexa680	5

[a] To ascertain whether $HgTX_1$, $HgTX_1$-A19C-βME, $(HgTX_1\text{-A19C})_2$, and a variety of fluorescently labeled $HgTX_1$-A19C analogues display a similar affinity for heterotetrameric native K_v1 channels, binding competition experiments using [^{125}I]$HgTX_1$-A19Y/Y37F were performed. As a tissue source, rat brain synaptosomal membranes were used. IC_{50}, concentration causing half-maximal inhibition.

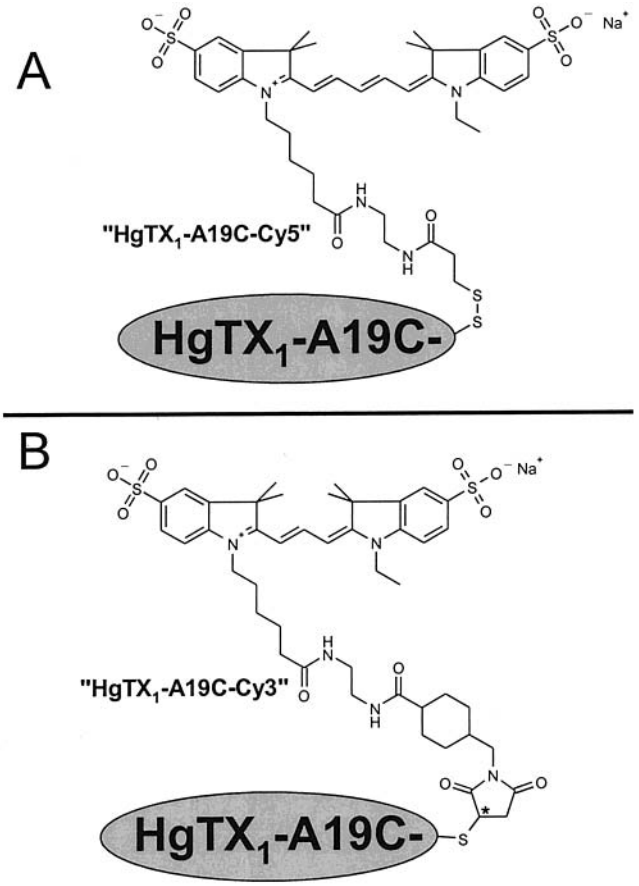

Figure 3. Coupling products of Cy5-PDP and Cy3-mal to the free thiol form of $HgTX_1$-A19C. Noteworthy, coupling of $HgTX_1$-A19C-SH to maleimides will generate an asymmetric carbon and therefore lead to the formation of diastereomers.

dominantly express heterotetrameric K_v1 channels formed by assembly of $K_v1.1$ and $K_v1.2$ (Koch et al., 1997)) or HEK-293 plasma membranes stably transfected with $K_v1.3$ were used (Figure 7). In both membrane preparations, [^{125}I]$HgTX_1$-A19Y/Y37F binds to a single class of sites that display a K_d of 0.15 pM (Koschak et al., 1998). The toxin analogue $HgTX_1$-A19C-βME retains this very high affinity for $K_v1.1/1.2$ channels as it displaces [^{125}I]-$HgTX_1$-A19Y/Y37F binding with an identical (compared to wild-type $HgTX_1$) IC_{50} value of 0.6 pM (see Table 2; $n = 6$). The respective dimeric toxin $(HgTX\text{-}A19C)_2$ suffers an approximately 10-fold loss in affinity (see Table 2; $n = 6$).

In good agreement with these data, $HgTX_1$-A19C−Cy5 displaces [^{125}I]$HgTX_1$A19Y/Y37F binding from native $K_v1.1/K_v1.2$ channels as well as from recombinant $K_v1.3$ channels with IC_{50} values of 11.6 pM ($n = 4$) and 1.3 pM ($n = 2$), respectively (Figure 7, open squares). By comparison, wild-type $HgTX_1$ inhibited [^{125}I]$HgTX_1$-A19Y/Y37F interactions with these membranes with IC_{50} values of 0.49 pM ($n = 3$) and 0.16 pM ($n = 2$), respectively (Figure 7, circles). These data indicate that $HgTX_1$-A19C−Cy5 binds to voltage-gated potassium channels with a slightly reduced binding potency (see Table 2).

To investigate the pharmacological profile of the other fluorescently labeled $HgTX_1$ analogues, they were screened in binding competition experiments using [^{125}I]$HgTX_1$-A19Y/Y37F and native $K_v1.1/1.2$ channels. All toxin analogues retain high affinity and a proper pharmacological profile (see Table 2; $n = 6$).

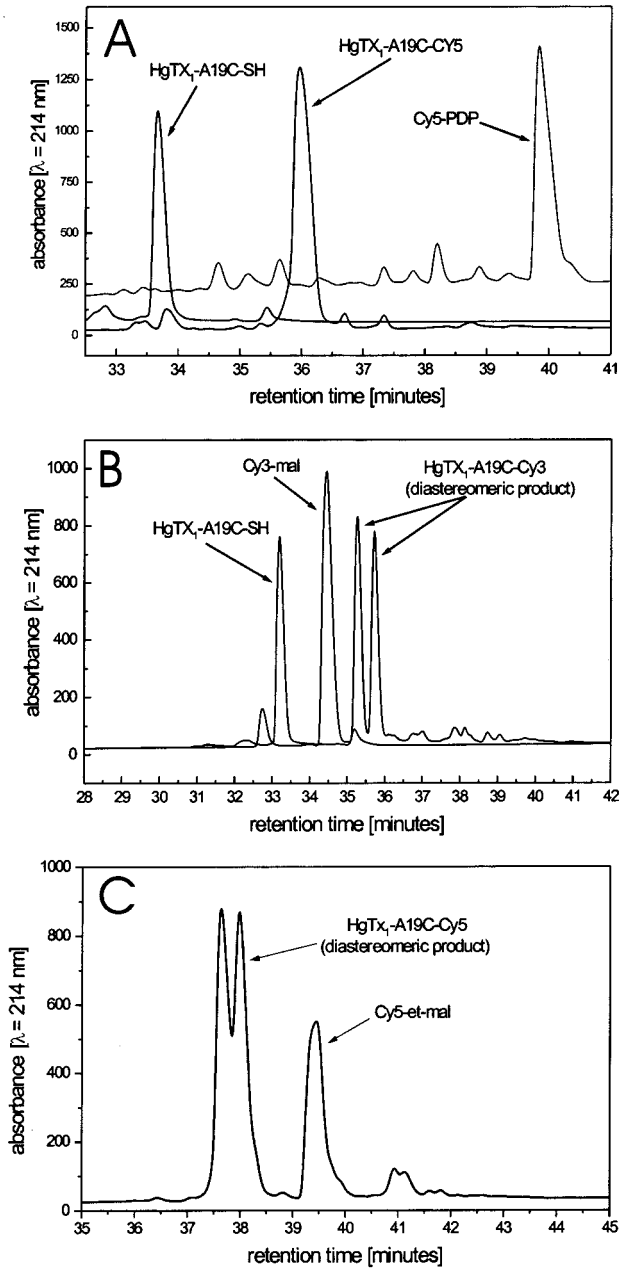

Figure 4. Coupling of thiol-reactive Cy5-PDP, Cy3-mal, and Cy5-mal to the free thiol form of $HgTX_1$-A19C. (A) $HgTX_1$-A19C-SH (peak 1) and Cy5-PDP (peak 3) were coupled, and the products were applied to a C_{18} reversed-phase HPLC. Elution of $HgTX_1$-A19C−Cy5 (Peak 2) is shown. (B) $HgTX_1$-A19C-SH (peak 1) and Cy3-mal (peak 2) were coupled as described in Experimental Procedures. Resulting products were applied to a C_{18} reversed-phase HPLC. Elution of the two diastereomers of $HgTX_1$-A19C−Cy3 (peaks 3 and 4) is shown. (C) The coupling mixture of $HgTX_1$-A19C-SH and Cy5-mal was applied to a C_{18} reversed-phase HPLC. Elution of the two diastereomers of $HgTX_1$-A19C−Cy5 (peaks 1 and 2) is shown.

We also monitored the effect of $HgTX_1$-A19C−Cy5 on recombinant $K_v1.3$ channels by means of electrophysiology. This toxin analogue completely supressed the K^+ current through these channels with a potency comparable to wild-type $HgTX_1$ (data not shown).

Localization of $HgTX_1$-Sensitive K^+ Channels in Native Rat Brain Sections. $HgTX_1$-A19C−Cy3, $HgTX_1$-A19C−Alexa488, and $HgTX_1$-A19C−Alexa546 were used to investigate the localization of native voltage-gated K_v1 channel in rat brain sections using fluorescence micros-

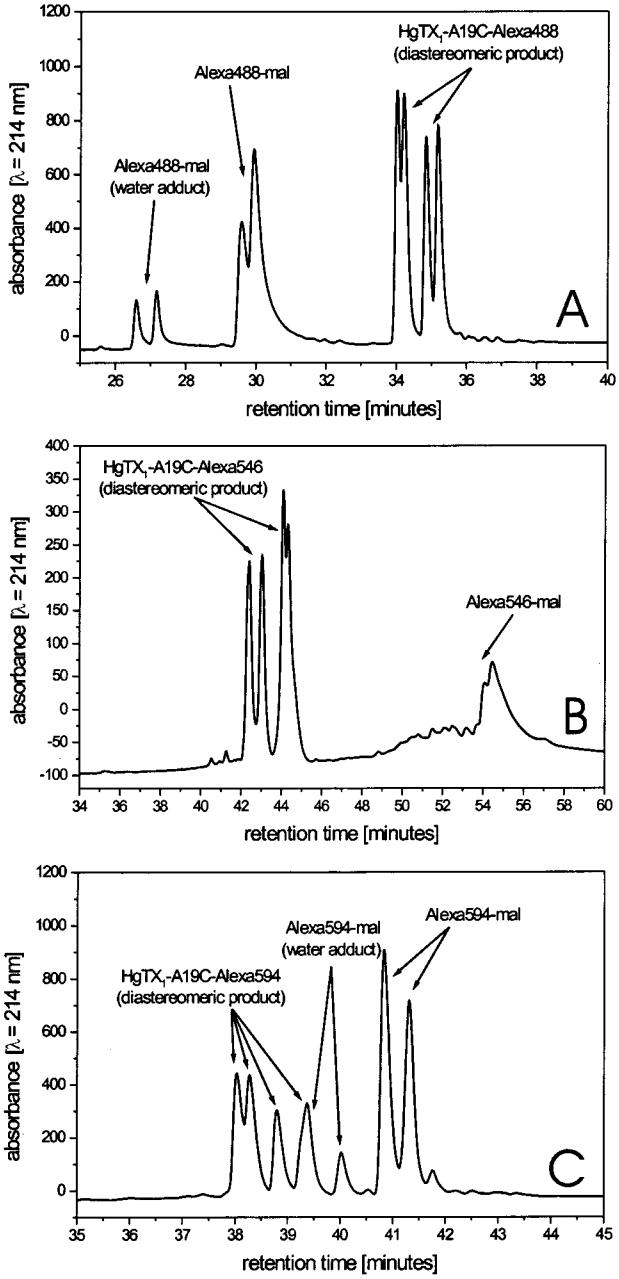

Figure 5. Coupling of thiol-reactive Alexa488-mal, Alexa546-mal, and Alexa594-mal to the free thiol form of $HgTX_1$-A19C. $HgTX_1$-A19C-SH and Alexa488-mal (A), Alexa 546-mal (B), or Alexa594-mal (C) were coupled as described in Experimental Procedures. Resulting products were applied to a C_{18} reversed-phase HPLC. Elution of the diastereomeric (one pair of diastereomers for each dye-isomer) coupling products is shown.

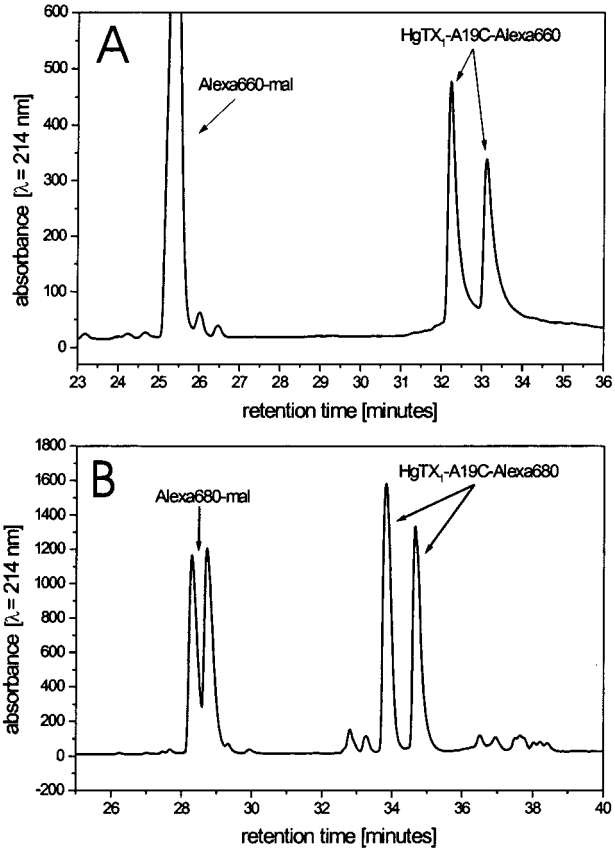

Figure 6. Coupling of thiol-reactive Alexa660-mal and Alexa680-mal to the free thiol form of $HgTX_1$-A19C. $HgTX_1$-A19C-SH and Alexa660-mal (A) or Alexa680-mal (B) were coupled as described in Experimental Procedures. Resulting products were applied to a C_{18} reversed-phase HPLC. Elution of the coupling products is shown.

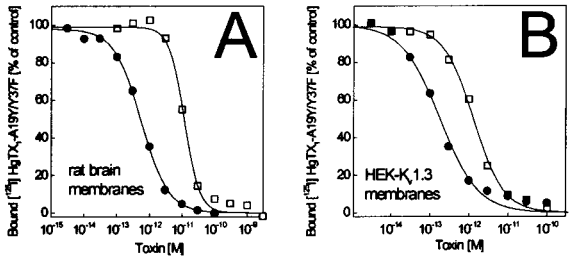

Figure 7. Functional characterization of $HgTX_1$-A19C−Cy5 − Radioligand Bindind Studies. (A) Rat brain membranes were incubated with 0.5 pM [^{125}I]$HgTX_1$-A19Y/Y37F in the absence or presence of increasing concentrations of $HgTX_1$ (circles, IC_{50} 0.5 pM; n_H 1.04) or $HgTX_1$-A19C−Cy5 (open squares, IC_{50} 11.6 pM; n_H 1.86) at room temperature for 2 h. (B) HEK−K_v1.3 membranes were incubated under the same conditions as described in (A). $HgTX_1$ (circles, IC_{50} 0.16 pM; n_H 0.89) and $HgTX_1$-A19C−Cy5 (squares, IC_{50} 1.3 pM; n_H 1.31). All displacement curves were computer fitted to the general dose−response curve as described in Experimental Procedures.

copy. Immunohistochemical studies using a sequence-directed antibody against K_v1.2 were performed.

High levels of $HgTX_1$-A19C−Cy3 binding were observed in the brainstem, cerebellum, and neocortex. The binding reaction was specific as no fluorescence signal was observed in the presence of 100 nM unlabeled $HgTX_1$ (data not shown). Under controlled conditions $HgTX_1$-A19C−Cy3 labeling resulted in specific staining of morphologically and anatomically well-defined neuronal structures which correspond to the immunohistochemical staining pattern using sequence-directed antibodies. The most prominent fluorescence signal was detected in the Purkinje cell layer of the rat cerebellum (Figure 8). This subregion of the cerebellum is known to harbor the highest density of K_v1.1/K_v1.2 channels of the entire rat CNS (Koch et al., 1997; Sheng et al., 1994; Wang et al., 1994; Wang et al., 1994; Koch et al., 1997). The channels are situated at pinceau terminals—giant basket cell synapses wrapping around the base of the Purkinje cell. Parallel experiments using a sequence-directed antibody against the voltage-gated K^+ channel K_v1.2 displayed a very similar distribution pattern (Figure 8B/D). Moreover, $HgTX_1$-A19C−Alexa488 and $HgTX_1$-A19C−Alexa546 show an identical distribution pattern compared to $HgTX_1$-A19C−Cy3 (Figure 9). In summary, the experiments confirm the suitability of this toxin for distribution

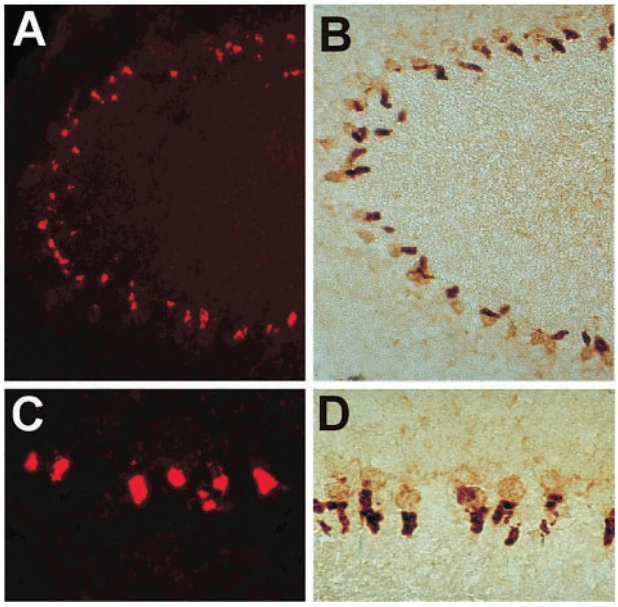

Figure 8. Application of HgTX1-A19C−Cy3 to fluorescence microscopy. Native 10 μm rat brain sections were incubated with 2 nM of $HgTX_1$-A19C−Cy3 overnight at 4 °C. Pinceau terminal staining in the cerebellum (A, B 20×, C, D 40×) is shown in comparison to K_v1.2 immunoreactivity.

studies of voltage-gated K^+ channel either in isolated cells (e.g. neurons in primary culture; recombinant channels in mammalian cell lines) or complex tissues (e.g. the brain).

DISCUSSION

Until now, fluorescently labeled K^+ channel toxins were synthesized by either covalent modification of lysine residues or toxin biotinylation (e.g. charybdotoxin (Robitaille et al., 1993) or apamin (Molecular Probes Inc., Eugene, OR)). However, in many instances, these procedures generate toxin analogues with reduced binding affinity and/or altered pharmacological profiles (H.G.K., unpublished observation). To circumvent these obstacles and to generate a fluorescently labeled $HgTX_1$ analogue which closely resembles wild-type $HgTX_1$ thereby preserving affinity and pharmacology, we adapted a recently developed strategy to radiolabel a structurally related toxin, namely IbTX, with [^{3}H] (Knaus et al., 1996). Our experiments were governed by studies in which ChTX (Goldstein et al., 1994), IbTX (Mullmann et al., 1999), KTX (Aiyar et al., 1996), and $AgTX_2$ (Gross and MacKinnon, 1996) were subjected to an extensive site-directed mutagenesis paradigm, coupled to functional screening of these mutant toxin analogues. These studies allowed the clear assignment of residues which are crucial for high affinity interaction with the respective channels. In addition, the NMR data presented in this paper enabled us to clearly assign residues which are known to be located opposite from the toxin's interaction surface with the voltage-gated K^+ channel K_v1.3 (Aiyar et al., 1995). As examplified for $HgTX_1$-A19C−Cy3, ion channel expression and distribution can be investigated in brain sections thereby complementing or even substituting antibody staining experiments. This approach offers the definite advantage that the respective tissue under investigation does not need to be fixed nor permeabilized before the staining reaction is performed. In contrast to all sequence-specific antibodies directed against individual ion channel subunits (which mostly recognize epitopes located on the intracellular side of the channel),

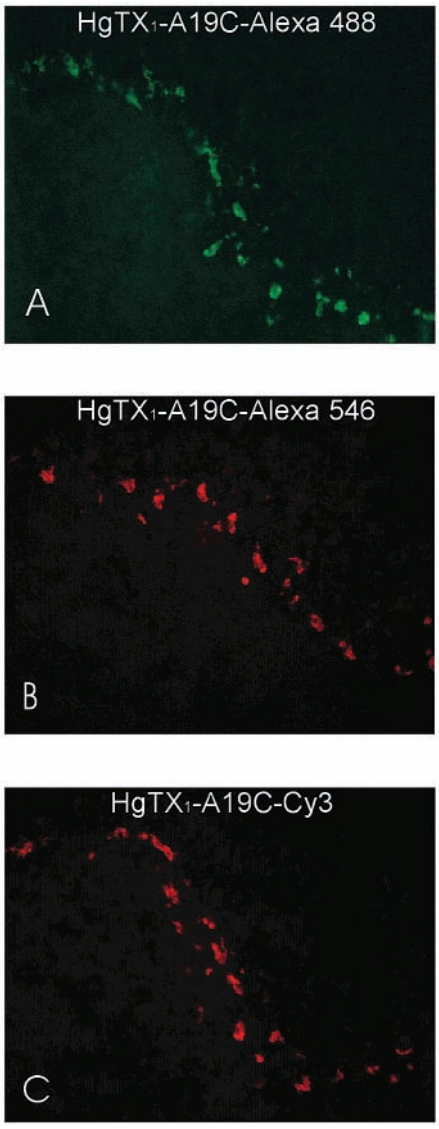

Figure 9. Comparison between $HgTX_1$-A19C−Alexa488, $HgTX_1$-A19C−Alexa546, and $HgTX_1$-A19C−Cy3 (fluorescence microscopy). Native 10 μm rat brain sections were incubated with 2 nM of $HgTX_1$-A19C−Alexa488 (A), $HgTX_1$-A19C−Alexa546 (B), and $HgTX_1$-A19C−Cy3 (C) overnight at 4 °C. Pinceau terminal staining in the cerebellum (A, B, C 20×) is shown.

most ion channel toxins bind to extracellular sites within the channel's vestibule (Gross and MacKinnon, 1996; Aiyar et al., 1995). In two very recent reports, we have shown that this toxin analogue can also be utilized to image individual ion channels in living cells by means of single dye tracing (SDT) experiments (Schütz et al., 2000a; Schütz et al., 2000b; Schütz et al., 2000a). For the first time, individual membrane proteins were visualized at a three-dimensional position of ~40 nm.

Besides studying individual ion channels at high spatial resolution through SDT experiments, a number of additional questions can now be addressed using fluorescently labeled K^+ channel toxins utilizing this general principle. Ion channel distribution studies could be extended to cultured neurons in order to address developmental changes in channel expression in distinct neuronal structures through fluorescence microscopy. An additional application is the monitoring of recombinant channel expression in, for example, mammalian cell lines. Individual cells could be screened based on the fluorescence signal, channel expression could be quantified, and

a single cell could be harvested and replated. Moreover, as only channels residing in the plasma membrane would be detected, precise information on the surface expression level could be obtained.

Soon this approach is going to be extended to produce and characterize additional ion channel-selective toxin analogues (e.g. iberiotoxin for BK channels or ω-conotoxin GVIA for a subset of voltage-gated Ca^{2+} channels). We aim to derivatize all these toxins by means of Förster donor−acceptor dye pairs (e.g. Cy3/Cy5 or Cy5/Cy5.5) and utilize them in fluorescence resonance energy transfer studies. Together with commercially available fluorescently labeled ion channel probes (e.g. dihydropyridines), these tools will help to address the issue of ion channel colocalization by means of two-photon laser miscroscopy and/or SDT experiments in native tissue.

ACKNOWLEDGMENT

We thank Drs. Hartmut Glossmann, Hans-Georg Schindler, and Bernhard Flucher for continuous support and discussion. This work is part of the Ph.D. diploma of B.P. This work was supported by research grants P12663-MED and P14594-PHA (Austrian Research Foundation) and European Community #BMH4-CT97-2118 and QLRT-1999-01356.

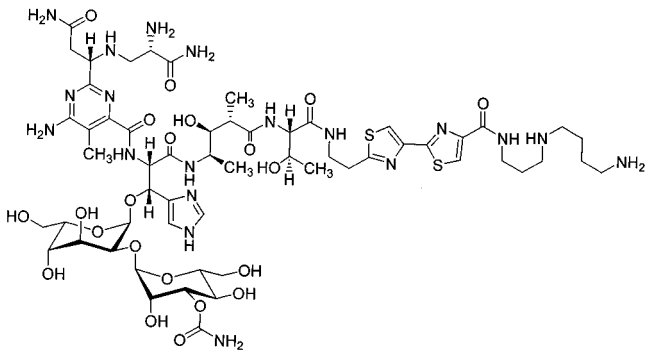
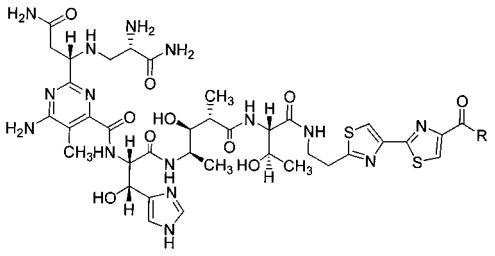
Solid-Phase Synthesis of Deglycobleomycins: A C-Terminal Tetraamine Linker That Permits Direct Evaluation of Resin-Bound Bleomycins



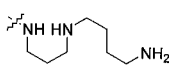
Zhi-Fu Tao, Christopher J. Leitheiser, Kenneth L. Smith, Shigeki Hashimoto, and Sidney M. Hecht*

Departments of Chemistry and Biology, University of Virginia, Charlottesville, Virginia 22901. Received September 8, 2001



Deglycobleomycin analogues having different length polyamine side chains at the C-terminus were synthesized using a novel solid-phase synthesis strategy that produces fully deprotected deglycobleomycin congeners attached to the resin. Detailed studies of DNA cleavage by these compounds and their resin-bound counterparts using supercoiled plasmid DNAs and DNA restriction fragments as substrates revealed that (i) the length of the polyamine side chain of free deglycoBLM had limited effect on its DNA cleavage potency or sequence selectivity, and (ii) the nature of the linker moiety between the resin and attached deglycobleomycin had a more substantial effect on the potency of DNA cleavage, but no effect on sequence selectivity of resin-bound deglycoBLMs. Resin-bound **4** exhibited efficient DNA cleavage, indicating that its tetraamine linker moiety could be used for the elaboration and direct evaluation of bleomycin congeners attached to resins.

The bleomycins (BLMs),[1] exemplified by bleomycin A_5, are naturally occurring, peptide-derived antitumor agents (*1, 2*) that are used clinically for the treatment of several cancers, notably squamous cell carcinomas and malignant lymphomas (*3*). The antitumor activity of these BLMs is believed to depend on their ability to effect the selective cleavage of DNA (*1, 2, 4*−*9*) and possibly also RNA (*10*−*12*). Deglycobleomycin lacks the carbohydrate moiety but nonetheless exhibits DNA cleavage properties quite similar to those of bleomycin itself as regards potency, sequence selectivity, and actual chemistry of DNA degradation (*13*−*15*).



Numerous analogues of bleomycin and deglycobleomycin have been synthesized and characterized for their properties in DNA degradation (*16*−*35*). However, with the exception of our discovery that the carbohydrate moiety of bleomycin is not essential for DNA cleavage (*13*−*15*), none of the analogues reported to date can be argued to have improved properties, simplified structures, or to be more readily accessible by synthesis such that improved antitumor agents might be realized. We have developed two solid-phase strategies for synthesis of BLM analogues (*36, 37*), one goal of which is the elaboration of BLM-like species having specific improved properties. It should be possible to realize this goal through the synthesis and survey of large numbers of BLM analogues.

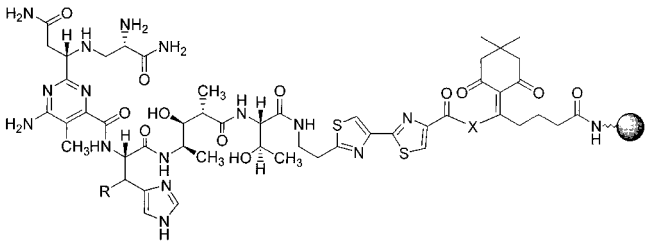
deglycobleomycin A_5 (**3**) R = 

Combinatorial chemistry has become a powerful tool for the organic and medicinal chemist. There are numerous ways in which libraries can be prepared and tested; solid-phase synthesis has been utilized widely for library construction (*38*−*43*). The assay of libraries on solid supports has been used successfully for the screening of medicinally important molecules and synthetic receptors (*44*−*50*).



A key parameter that defines the potential utility of resin-bound ligands for assaying ligand−receptor inter-

action is the accessibility of resin-bound library members to the receptors. The recent finding (*51, 52*) that conjugation of BLM A_5 to a solid support via its C-terminus had little effect on its ability to mediate DNA cleavage encouraged us to identify a C-terminal linker applicable to direct evaluation of resin-bound DNA-cleaving bleomycin analogues. Reported herein are (i) the solid-phase syntheses of deglycoBLM analogues in which the C-terminal polyamine substituent is varied in a systematic fashion, and (ii) a characterization of DNA cleavage by these resin-free and resin-bound analogues, resulting in the identification of a C-substituent that facilitates the direct evaluation of resin-bound bleomycin analogues.

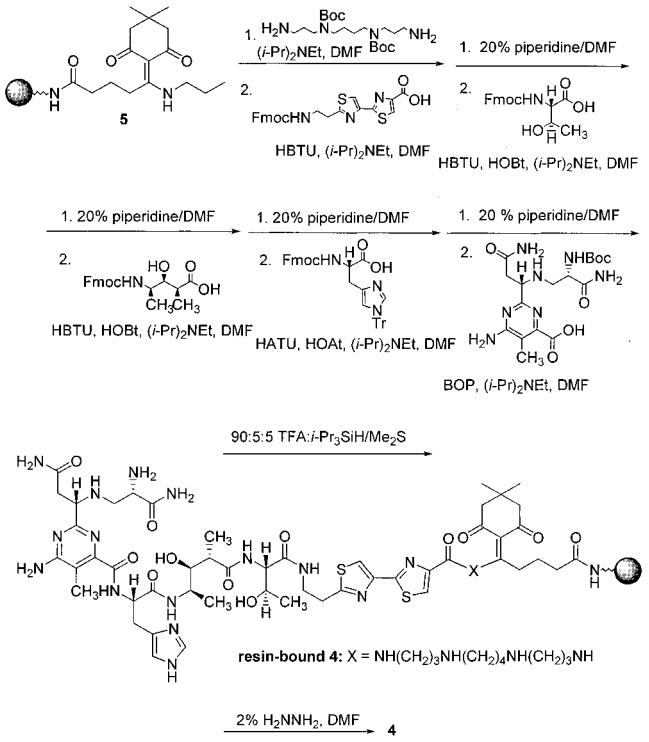
EXPERIMENTAL PROCEDURES

Materials and General Techniques. Calf intestinal phosphatase (one unit is the amount of enzyme that hydrolyzes 1 μmol of *p*-nitrophenyl phosphate to *p*-nitrophenol in 1 min at 37 °C in a total reaction volume of 1 mL), *Eco*RV, *Hin*dIII (one unit is the amount of enzyme required to digest 1 μg of λ DNA in 1 h at 37 °C in a total reaction volume of 50 μL), T4 polynucleotide kinase (one unit is the amount of enzyme catalyzing the production of 1 nmol of acid-insoluble ^{32}P in 30 min at 37 °C under the following conditions: 70 mM Tris-HCl, pH 7.6, 10 mM $MgCl_2$, 5 mM DTT, 66 μM [γ-^{32}P]ATP (5×10^6 cpm/mmol), 0.26 mM 5′-OH terminating salmon sperm DNA). Plasmid pSP64 was cultured in *E. coli* and isolated using a Qiagen resin. Plasmid pB*R*322 DNA was purchased from New England Biolabs. [γ-^{32}P]ATP (7000 Ci/mmol) was obtained from ICN Radiochemicals, Inc. $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$ (Aldrich) was used to prepare aqueous solutions for admixture with bleomycin; these were made immediately prior to use. Agarose gel electrophoresis was carried out in 90 mM Tris-borate buffer, pH 8.3, containing 5 mM EDTA. The agarose gel loading solution contained 30% glycerol and 0.05% (w/v) bromophenol blue. Polyacrylamide gel electrophoresis was carried out in 90 mM Tris-borate buffer, pH 8.3, containing 5 mM EDTA. The loading solution contained 80% formamide, 2 mM EDTA, 0.05% (w/v) xylene cyanol, and 0.05% (w/v) bromophenol blue. Chemical sequencing was carried out according to the method of Maxam and Gilbert (*53*). Distilled and deionized water from a Milli-Q system was autoclaved prior to use in all aqueous solutions in the DNA cleavage experiments. The 5′-^{32}P end labeled 158-bp DNA restriction fragment was prepared from pB*R*322 plasmid DNA according to reported procedures (*51, 52*).

Ultraviolet spectra were recorded on a Perkin-Elmer Lambda 20 UV−Vis spectrophotometer. ^1H NMR spectra were recorded on a General Electric QE-300 MHz NMR spectrophotometer using the residual HOD resonance at 4.80 ppm as an internal standard. HPLC purification was performed on a Varian 9012 HPLC gradient programmer system with a Perkin-Elmer LC-235 diode array detector. All synthetic reactions were carried out under nitrogen or argon. Anhydrous grade DMF, anhydrous grade piperidine, HATU, HOAt, trifluoroacetic acid, hydrazine monohydrate, and anhydrous grade Hunig's base were purchased from Aldrich chemicals. TentaGel resin, HBTU, HOBt, BOP, 9-fluorenylmethoxycarbonyl-β-alanine, and 9-fluorenylmethoxycarbamoylthreonine were purchased from NovaBiochem. Methylene chloride was distilled from calcium hydride. Fmoc cleavage was determined by UV measurement of the dibenzylfulvene−piperidine adduct formed upon treatment of the resin with piperidine (*54*). The optical density of 5540 M^{-1} at 290 nm and 7300 M^{-1} at 300 nm was used to calculate the loading from a known weight of dry resin.



Molecular beacon DNA oligodeoxynucleotide, labeled with 5′ FAM and 3′ BHQ dyes, was custom-synthesized by Integrated DNA Technology, Inc. BHQ is a trademark of Biosearch Technologies, Inc.; the chemical structure has not been disclosed. Fluorescence image analysis was performed at the W. M. Keck Center for Cellular Imaging, University of Virginia, using an Olympus Infinity corrected inverted microscope.

Synthesis of Resin-Bound DeglycoBLM 4. DeglycoBLM analogues **1**−**4** were prepared using closely related methods; these are exemplified by the synthesis of deglycoBLM **4**. To a suspension containing 200 mg (0.45 mmol/g) of TentaGel amino functionalized resin (**5**; Scheme 1) (*55*) was added a DMF solution containing 362 mg (0.90 mmol) of protected spermine and 313 μL (232 mg, 1.8 mmol) of Hunig's base. The reaction mixture was shaken for 24 h, and then the resin was filtered and washed successively for 30 s each with three 5-mL portions of DMF, three 5-mL portions of CH_2Cl_2, three 5-mL portions of methanol, and again with three 5-mL portions of DMF. A DMF solution containing 128 mg (0.27 mmol) of Fmoc-bithiazole, 102 mg (0.27 mmol) of HBTU, and 94 μL (70 mg, 0.54 mmol) of Hunig's base was added. After 30 min, the resin was filtered and washed successively for 30 s each with three 5-mL portions of DMF, three 5-mL portions of CH_2Cl_2, and again with three 5-mL portions of DMF. Quantitation of Fmoc cleavage indicated a loading of 0.17 mmol/g (57% yield for three steps). The resulting resin was treated for 5 min each with three 2-mL DMF solutions containing 20% piperidine in DMF. The resulting resin was washed for 30 s each with seven 5-mL portions of DMF, five 5-mL portions of CH_2Cl_2, and three 5-mL portions of DMF. A solution containing 35 mg (0.10 mmol) of Fmoc-threonine, 38 mg (0.10 mmol) of HBTU, 15 mg (0.10 mmol) of HOBt, and 36 μL (26 mg, 0.20 mmol) of Hunig's base in 0.5 mL of DMF was added. After 30 min the resin was filtered and washed with three 5-mL portions of DMF, three 5-mL portions of CH_2Cl_2, and again with three 5-mL

Scheme 1. Solid-Phase Synthesis of Resin-Bound and Free DeglycoBLM 4

portions of DMF. Quantitation of Fmoc cleavage indicated a loading of 0.17 mmol/g (>95%). The resin was treated for 5 min each with three 2-mL DMF solutions containing 20% piperidine in DMF. The resin was washed for 30 s each with seven 5-mL portions of DMF, five 5-mL portions of CH_2Cl_2, and three 5-mL portions of DMF. The resin was treated with a solution containing 37 mg (0.10 mmol) of Fmoc-methylvalerate, 38 mg (0.10 mmol) of HBTU, 15 mg (0.10 mmol) of HOBt, and 36 μL (26 mg, 0.20 mmol) of Hunig's base. After 30 min, the resin was filtered and washed for 30 s each with three 5-mL portions of DMF, three 5-mL portions of CH_2Cl_2, and again with three 5-mL portions of DMF. Quantitation of Fmoc cleavage indicated a loading of 0.15 mmol/g (94%). The resulting resin was treated for 5 min each with three 2-mL DMF solutions containing 20% piperidine in DMF and then washed for 30 s each with seven 5-mL portions of DMF, five 5-mL portions of CH_2Cl_2, and three 5-mL portions of DMF. The resin was treated with a solution containing 63 mg (0.10 mmol) of tritylated Fmoc histidine, 38 mg (0.10 mmol) of HATU, 16 mg (0.10 mmol) of HOAt, and 36 μL (26 mg, 0.20 mmol) of Hunig's base. After 30 min, the resin was filtered and washed for 30 s each with three 5-mL portions of DMF, three 5-mL portions of CH_2Cl_2, and with three 5-mL portions of methanol. The resulting resin was dried under diminished pressure over KOH pellets. A small sample (~20 mg) was treated for 5 min each with three 1-mL portions of 2% hydrazine in DMF (v/v). The resulting solution was concentrated under diminished pressure. The resulting oil was dissolved in 1 mL of an aq 0.1% TFA solution, frozen, and lyophilized to give an off-white solid: mass spectrum (electrospray) m/z 1249.4 $(M + H)^+$ and 1273.6 $(M + Na)^+$. A suspension containing 40 mg of the above resin swollen in 0.5 mL of DMF was treated for 5 min each with three 2-mL DMF solutions containing 20% piperidine in DMF. The resulting resin was washed for 30 s each with seven 5-mL portions of DMF, five 5-mL portions of CH_2Cl_2, and three 5-mL portions of DMF. The resin was treated with a cooled (0 °C) solution containing 5.0 mg (12 μmol) of Boc-pyrimidoblamic acid, 15 mg (35 μmol) of BOP, and 12 μL (9.0 mg, 70 μmol) of Hunig's base in 0.5 mL of DMF. After 16 h, the resin was filtered and washed for 30 s each with three 5-mL portions of DMF, three 5-mL portions of CH_2Cl_2, and three 5-mL portions of methanol. The resin was treated with a solution consisting of 100 μL of triisopropylsilane and 100 μL of dimethyl sulfide. The resin was shaken for 5 min and then 4 mL of trifluoroacetic acid was added to the suspension. After 4 h, the resin was filtered and washed with five 3-mL portions of CH_2Cl_2 and three 3-mL portions of methanol. The resulting resin was dried under diminished pressure over KOH pellets to give resin-bound deglycoBLM **4**.

Synthesis of DeglycoBLM 4. To a suspension containing 30 mg of resin-bound deglycoBLM **4** was added a 0.5 mL of DMF containing 2% hydrazine. The resin was filtered and then treated with three additional 0.5-mL portions of DMF containing 2% hydrazine. Each treatment was carried out for 5 min. The combined filtrate was concentrated under diminished pressure. The resulting oil was dissolved in 2 mL of CF_3COOH and added dropwise to cold (−20 °C) ether. The suspension was centrifuged and the ether decanted. The resulting solid was dissolved in water, frozen and lyophilized. HPLC of the crude material on an Alltech Alltima semipreparative C_{18} reversed-phase HPLC column (250 × 10 mm, 5 μm) was carried out using 0.1% aqueous CF_3COOH and CH_3CN as mobile phases. A linear gradient was employed starting from 88:12 0.1% aqueous $CF_3COOH-CH_3CN$ to 83:17 0.1% aqueous $CF_3COOH-CH_3CN$ over a period of 30 min at a flow rate of 4 mL/min. Fractions containing the desired product eluted after 12 min; these were collected and lyophilized. The yield was determined by ^1H NMR spectroscopy, by comparing the integration of the exocyclic methyl group on pyrimidoblamic acid vs the methyl signal resulting from a known concentration of *tert*-butyl alcohol, and then relating the calculated concentration to the amount of the di-*tert*-butoxycarbonyl spermine determined to have been attached to the resin initially. Yield 3.1 mg (66%); ^1H NMR (D_2O) δ 0.94 (d, 3H, J = 7.0 Hz), 0.99 (d, 3H, J = 7.0 Hz), 1.07 (d, 3 H, J = 7.0 Hz), 1.69 (m, 4H), 1.93 (s, 3H), 1.98 (m, 4H), 2.53 (t, 1H, J = 7.5 Hz), 2.63 (m, 2H), 3.03 (m, 12H), 3.21 (m, 4H), 3.44 (t, 2H, J = 7.0 Hz), 3.58 (t, 1H, J = 5.5 Hz), 3.64 (t, 1H, J = 5.0 Hz), 3.77 (t, 1H, J = 6.5 Hz), 3.97 (t, 2H, J = 6.0 Hz), 4.04 (t, 1H, J = 5.5 Hz), 4.12 (d, 1H, J = 5.5 Hz), 7.27 (s, 1H), 7.98 (s, 1H), 8.13 (s, 1H) and 8.59 (s, 1H); mass spectrum (electrospray), m/z 1114.6 $(M + H)^+$ (calculated 1114.4).

General Procedure for Relaxation of Plasmid DNA by DeglycoBLM Analogues. The reactions were performed in a 25 μL (total volume) reaction mixture containing 300 ng of pSP64 DNA, 10 mM sodium cacodylate, pH 7.0, and various concentrations of BLM (analogues) or Fe^{2+}. The concentrations of resin-bound deglycoBLM analogues are expressed as the concentration that would have been present in solution had the analogues not been attached to the resin. Each reaction mixture was incubated at 37 °C for 30 min, terminated by the addition of 5 μL of loading dye (30% glycerol containing 0.125% bromophenol blue) and applied to 1% agarose gel containing 0.5 μg/mL ethidium bromide. The gel was run in 90 mM Tris-borate buffer, pH 8.3, containing 5 mM EDTA at 138 V for 3−3.5 h; the DNA bands were visualized under UV light.

General Procedure for Degradation of 5′-^{32}P End Labeled DNA Duplexes by DeglycoBLM Analogues.

Reactions were carried out in 25 μL (total volume) of 10 mM sodium cacodylate, pH 7.0, containing ^{32}P-labeled DNA duplex (10^4 cpm) and the concentrations of reagents indicated in the figure legends. Each reaction mixture was incubated at 37 °C for 30 min, and then the reaction mixture was frozen in dry ice, lyophilized, and dissolved in gel loading solution (80% formamide, 2 mM EDTA, 0.05% (w/v) xylene cyanol, and 0.05% (w/v) bromophenol blue). The resulting solution was heated at 90 °C for 3 min, chilled on ice, and then applied to a 10% denaturing polyacrylamide gel. The gel was visualized by autoradiography or by use of a phosphorimager. The sites of cleavage mediated by (resin-bound) **1**−**4** were determined by comparison with Maxam−Gilbert DNA sequencing lanes (*53*).

Fluorescence Microscope Analysis of Beacon DNA Cleavage. A suspension of TentaGel-conjugated deglycoBLM **4** and agarose gel solution were prepared in 50 mM sodium cacodylate, pH 7.0, for the fluorescence microscopy studies. To a single well on a 96-well plate was added 35 μL of 2.4% agarose gel solution in 50 mM sodium cacodylate, pH 7.0; after solidification, this was followed by 20 μL of 500 μM TentaGel-conjugated deglycoBLM A_6 suspension in the same buffer, and an additional 35 μL of buffered 2.4% agarose gel solution. The resulting 55-μL suspension above the solidified gel was immediately mixed with a pipet tip. The plate was placed on ice for 20 min to facilitate solidification of the agarose mixture. A 30-μL solution of 1.5 μM beacon DNA solution was added to the agarose mixture containing the TentaGel beads. The plate was maintained on ice in the absence of light for 12 h to allow the beacon DNA to diffuse through the agarose gel. The final concentrations of deglycoBLM A_6 and beacon DNA were 0.11 mM and 0.37 μM, respectively. The supernatant on the agarose mixture was removed, and a gel piece containing the bleomycin bound resin was excised from the gel. The gel was sandwiched between two cover glass plates (22 × 22 mm), and the bleomycin was activated with 10 μL of 5 mM $Fe(NH_4)_2(SO_4)_2$ solution. Fluorescence images were taken every 5 min through an FITC filter (excitation at 480 ± 20 nm; fluorescence emission at 535 ± 25 nm).

RESULTS AND DISCUSSION

Solid-Phase Synthesis of DeglycoBLM Analogues. We have described a solid-phase synthesis of deglycoBLM A_5 (*36*), in which the final deprotection of acid-labile groups and detachment of the deglycoBLM from the solid support were accomplished simultaneously by treatment with CF_3COOH; therefore, fully deprotected resin-bound bleomycin analogues could not be obtained by this approach. Access to resin-bound, fully deprotected BLM analogues has been accomplished by the use of a solid-phase methodology (*37*) that employs a Dde-based linker (*54*). This linker has been shown to be stable to conditions used to remove both base and acid-labile protecting groups. As outlined in Scheme 1 starting from TentaGel-derived resin **5**, which was prepared according to reported procedures (*55*), Boc-protected spermine (*56*) was attached to the resin via a transamination procedure. The resulting primary amine was then condensed with the bithiazole moiety of bleomycin. For this purpose, Fmoc-protected bithiazole was activated with HBTU and Hunig's base in DMF; this solution was added to the resin containing a free primary amino group, and the mixture was shaken under N_2 at 25 °C for 30 min. The resin was then washed with DMF and CH_2Cl_2, and a small sample was utilized for qualitative verification of coupling by colorimetric assays using the Kaiser (*57*) and bromophenol blue (*58*) tests for amines. The extent of coupling was quantified by UV measurement following Fmoc cleavage with piperidine (*54*); this procedure indicated a loading of 0.17 mmol/g of resin, which represented a coupling efficiency of 57% for three steps. Successive treatments of the resin with 20% piperidine in DMF, followed by Fmoc threonine, resulted in successful synthesis of the tripeptide. The same procedure was used for attachment of Fmoc-methylvaleric acid, resulting in successive attachments of these two amino acids in yields of >95% (0.17 mmol/g) and 94% (0.15 mmol/g), respectively.

Lane 1: DNA alone; lane 2: 1.5 μM Fe^{2+}; lane 3: 3 μM **1**; lane 4: 1 μM **1** + 1.5 μM Fe^{2+}; lane 5: 3 μM **1** + 1.5 μM Fe^{2+}; lane 6: 3 μM **2**; lane 7: 1 μM **2** + 1.5 μM Fe^{2+}; lane 8: 3 μM **2** + 1.5 μM Fe^{2+}; lane 9: 3 μM **3**; lane 10: 1 μM **3** + 1.5 μM Fe^{2+}; lane 11: 3 μM **3** + 1.5 μM Fe^{2+}; lane 12: 3 μM **4**; lane 13: 1 μM **4** + 1.5 μM Fe^{2+}; lane 14: 3 μM **4** + 1.5 μM Fe^{2+}; lane 15: 3 μM deglycoBLM A_5; lane 16: 1 μM deglycoBLM A_5 + 1.5 μM Fe^{2+}; lane 17: 3 μM deglycoBLM A_5 + 1.5 μM Fe^{2+}.

The resin-bound oligopeptide was deblocked with piperidine in DMF and coupled with Fmoc histidine in the presence of the highly reactive coupling reagent HATU; the coupling efficiency was calculated as 95%, based on spectrophotometric assay of the dibenzylfulvene−piperidine adduct formed following treatment of a portion of the resin with piperidine (*54*). Boc pyrimidoblamic acid (*59*−*61*) was then coupled to the resin using BOP reagent and Hunig's base at 0 °C in the absence of light for 16 h. The resin was washed with DMF and methylene chloride, and the acid-sensitive trityl protecting group on histidine and Boc protecting group on pyrimidoblamic acid were removed simultaneously by treatment with 90:5:5 CF_3COOH−triisopropylsilane−Me_2S. This afforded fully deprotected resin-bound deglycoBLM **4**. A portion of resin-bound **4** was treated with 2% hydrazine in DMF to give deglycoBLM **4**; the structure was confirmed by ^{1}H NMR spectroscopy and electrospray ionization mass spectrometry. The yield of deglycoBLM **4** prepared by solid-phase synthesis was 66%. DeglycoBLMs **1**, **2**, and **3** were synthesized and characterized by following procedures analogous to those employed for analogue **4**.

DNA Cleavage Mediated by DeglycoBLM Analogues. The abilities of deglycoBLM analogues **1**−**4** to cleave DNA were investigated initially using supercoiled plasmid DNA as a substrate. As shown in Figure 1, deglycoBLM analogues **2**−**4** mediated DNA relaxation to roughly the same extent in the presence of Fe^{2+}; the cleavage mediated by Fe(II)·deglycoBLM A_5 was also determined for comparative purposes and shown to be quite similar. Thus the efficiency of DNA cleavage mediated by deglycoBLM analogue **4**, having three basic amino groups within the C-terminal substituent, was not significantly different in this assay than that of **2** or **3**, each of which contain two amino groups within the C-substituent. In comparison, analogue **1**, having a single amine within the C-substituent, was less efficient as a DNA cleaving agent. This finding was anticipated based on earlier studies of the effects of the number and spacing of positively charged groups in the C-substituent on the efficiency of DNA binding (*62*) and degradation (*63*).

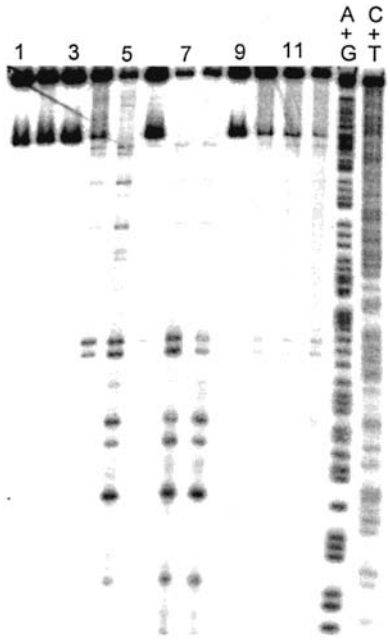

Figure 2. Cleavage of a 5′-^{32}P end-labeled 158-bp DNA restriction fragment by **1** and resin-bound **1**. Lane 1: DNA alone; lane 2: 15 μM Fe^{2+}; lane 3: 15 μM **1**; lane 4: 1.5 μM **1** + 15 μM Fe^{2+}; lane 5: 15 μM **1** + 15 μM Fe^{2+}; lane 6: 15 μM deglycoBLM A_2; lane 7: 1.5 μM deglycoBLM A_2 + 15 μM Fe^{2+}; lane 8: 15 μM deglycoBLM A_2 + 15 μM Fe^{2+}; lane 9: 200 μM resin-bound **1**; lane 10: 50 μM resin-bound **1** + 30 μM Fe^{2+}; lane 11: 100 μM resin-bound **1** + 30 μM Fe^{2+}; lane 12: 200 μM **1** + 30 μM Fe^{2+}.

DeglycoBLM analogues **2** and **3** have the same (spermidine) C-substituent, but differ in that analogue **2** contains a histidine moiety while **3** was synthesized using the amino acid analogue (*S*)-*erythro*-β-hydroxyhistidine; the OH group of the latter is the point of attachment of the disaccharide moiety in the BLMs (cf BLM A_5 and deglycoBLM A_5). The similar potencies of these two analogues in the experiment shown in Figure 1 argues that this OH group does not contribute to the efficiency of deglycoBLM-mediated DNA relaxation, a finding that is entirely consistent with a previous report from the Boger laboratory (*64*).

Also investigated was the sequence selectivity of DNA cleavage by these four deglycoBLMs. The substrate employed for this study was a 158-base pair DNA restriction fragment that has been employed previously as a substrate for Fe(II)·BLMs (*33,51,52*). As shown in Figures 2−4, and Figures 1 and 2 of the Supporting Information, each of the four analogues mediated sequence-selective cleavage of the DNA substrate in the same fashion as BLM itself. Thus the nature of the C-terminal substituent had little if any effect on sequence selectivity of DNA cleavage, as might have been anticipated based on earlier work (*28, 65*). The potency of DNA cleavage by **1**−**4** was investigated in direct comparison with a deglycoBLM congener obtained by HF-mediated cleavage of the sugar moiety (*66*). Thus deglycoBLM analogue **1** was compared directly with deglycoBLM A_2; both of these have a single positively charged group within the C-substituent, and the distance of these charged groups from the bleomycinic acid nucleus (*1*) is quite similar. As shown in Figure 2 and Supporting Information Figure 1, deglycoBLM analogue **1** and deglycoBLM A_2 were of comparable potency as DNA cleaving agents.

An analogous result was obtained for deglycoBLMs **2** and **3**, both of which contain spermidine C-substituents.

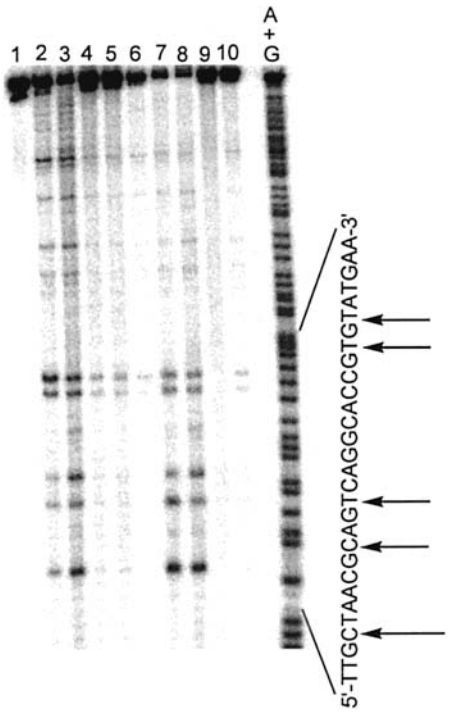

Figure 3. Cleavage of a 5′-^{32}P end-labeled 158-bp DNA fragment by **2**, **3**, resin-bound **2**, and resin-bound **3**. Lane 1: DNA alone; lane 2: 1 μM **2** + 10 μM Fe^{2+}; lane 3: 10 μM **2** + 10 μM Fe^{2+}; lane 4: 1 μM resin-bound **2** + 10 μM Fe^{2+}; lane 5: 10 μM resin-bound **2** + 10 μM Fe^{2+}; lane 6: 100 μM resin-bound **2** + 10 μM Fe^{2+}; lane 7: 1 μM **3** + 10 μM Fe^{2+}; lane 8: 10 μM **3** + 10 μM Fe^{2+}; lane 9: 1 μM resin-bound **3** + 10 μM Fe^{2+}; lane 10: 10 μM resin-bound **3** + 10 μM Fe^{2+}.

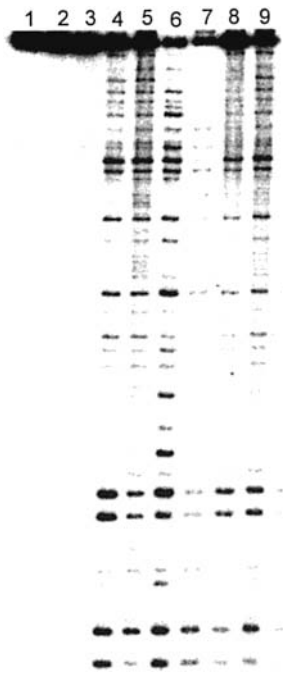

Figure 4. Cleavage of a 5′-^{32}P end-labeled 158-bp DNA fragment by **4** and resin-bound **4**. Lane 1: DNA alone; lane 2: 10 μM **4**; lane 3: 10 μM Fe^{2+}; lane 4: 1 μM **4** + 10 μM Fe^{2+}; lane 5: 10 μM **4** + 10 μM Fe^{2+}; lane 6: 0.1 μM BLM A_5 +10 μM Fe^{2+}; lane 7: 1 μM BLM A_5 +10 μM Fe^{2+}; lane 8: 10 μM resin-bound **4** + 10 μM Fe^{2+}; lane 9: 100 μM resin-bound **4** + 10 μM Fe^{2+}.

Their potencies of DNA cleavage assayed on a polyacrylamide gel (Figure 3) were the same, as had been noted in the supercoiled plasmid DNA relaxation assay (Figure 1). Further, assay of BLM **3** in direct comparison with

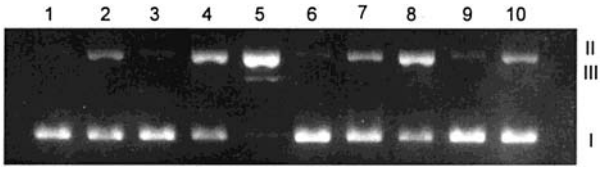

Figure 5. Relaxation of supercoiled pSP64 DNA by **1** and resin-bound **1**. Lane 1: DNA alone; lane 2: 1.5 μM Fe^{2+}; lane 3: 3 μM deglycoBLM A_2; lane 4: 1 μM deglycoBLM A_2 + 1.5 μM Fe^{2+}; lane 5: 3 μM deglycoBLM A_2 + 1.5 μM Fe^{2+}; lane 6: 3 μM **1**; lane 7: 1 μM **1** + 1.5 μM Fe^{2+}; lane 8: 3 μM **1** + 1.5 μM Fe^{2+}; lane 9: 10 μM resin-bound **1**; lane 10: 10 μM resin-bound **1** + 1.5 μM Fe^{2+}.

authentic deglycoBLM A_5, with which it was putatively identical, resulted in the same pattern and potency of cleavage of the 158-base pair DNA substrate when the BLMs were employed at each of two different concentrations (Supporting Information Figure 2).

Finally, comparison of deglycoBLM analogue **4** with BLM A_5 indicated good potency of cleavage by both (Figure 4), although the range of concentrations tested was not designed to permit a definitive assessment of the relative cleavage potencies of these two species.

DNA Cleavage Mediated by Resin-Bound DeglycoBLM Analogues. The successful synthesis of fully deprotected resin-bound deglycoBLM analogues has permitted an assessment of the ability to characterize these BLM analogue conjugates as DNA cleaving agents directly (*37*). It was anticipated that on-resin characterization might prove difficult for any of a few different reasons. These include simple lack of accessibility of the ligand to the target, as noted previously (*49*). Our earlier finding that BLMs tethered to each of two solid supports by linkers of three different lengths could all mediate DNA cleavage (*51, 52*) argued that the accessibility problem could be overcome by an appropriate choice of linkers. Potentially more serious was the observation that the attachment of BLM A_5 to a solid support resulted in a severalfold diminution in the potency of cleavage (*51, 52*). This effect was attributed to the attachment of BLMs to beads whose concentration in solution was (10^{12}−10^{13}-fold) lower than that usually employed for DNA cleavage by BLM, thus possibly diminishing the efficiency of encounter of BLMs by the DNA substrate. Since BLM A_5 was attached to the solid supports by utilizing a side chain amine to form an amide bond, it is also the case that the number of positively charged groups on the C-substituent would be reduced from 2 to 1; as illustrated in Figure 1, this could also potentially affect the efficiency of DNA binding and cleavage (*62, 63*). Accordingly, we sought to assess the DNA cleaving characteristics of deglycoBLM analogues having different numbers of positively charged functionalities within their C-substituents when the analogues were tested in resin-free or resin-bound form.

As shown in Figure 5, resin-bound deglycoBLM **1** gave only minimal cleavage of supercoiled plasmid DNA even when employed at high (i.e., 10 μM) concentration. An analogous effect was observed when resin-bound **1** was used in the presence of a ^{32}P-end labeled DNA duplex; no significant cleavage was observed in the presence of 200 μM resin-bound **1** + 30 μM Fe^{2+} (Figure 2). In comparison, the resin-free **1** gave detectable cleavage in the presence of 1.5 μM free **1** + 15 μM Fe^{2+}, and strong cleavage when 15 μM concentrations of free **1** and Fe^{2+} were present (Figure 2). Thus, attachment of this analogue to a solid support resulted in a much greater diminution in cleavage potency than had been observed previously for BLM A_5 (*51, 52*).

Lane 1: 100 μM resin-bound **3** + 1.5 μM Fe^{2+}; lane 2: 50 μM resin-bound **3** + 1.5 μM Fe^{2+}; lane 3: 10 μM resin-bound **3** + 1.5 μM Fe^{2+}; lane 4: 100 μM resin-bound **3**; lane 5: DNA alone; lane 6: 1.5 μM Fe^{2+}; lane 7: 5 μM **3**; lane 8: 1 μM **3** + 1.5 μM Fe^{2+}; lane 9: 3 μM **3** + 1.5 μM Fe^{2+}; lane 10: 5 μM **3** + 1.5 μM Fe^{2+}; lane 11: 50 μM resin-bound **4**; lane 12: 1 μM resin-bound **4** + 1.5 μM Fe^{2+}; lane 13: 5 μM resin-bound **4** + 1.5 μM Fe^{2+}; lane 14: 10 μM resin-bound **4** + 1.5 μM Fe^{2+}; lane 15: 25 μM resin-bound **4** + 1.5 μM Fe^{2+}; lane 16: 50 μM resin-bound **4** + 1.5 μM Fe^{2+}.

Although deglycoBLM analogues **2** and **3** exhibited greater potency than **1** in relaxing supercoiled plasmid DNA (Figure 1), these analogues also gave disappointing results when tested in their resin-bound forms. As shown in Figure 3, in the presence of 10 μM Fe^{2+}, analogues **2** and **3** gave readily detectable sequence selective DNA cleavage at 1 and 10 μM concentrations. In comparison, resin-bound **2** and **3** gave much weaker cleavage at all tested concentrations; the former species was utilized at concentrations up to 100 μM in the presence of 10 μM Fe^{2+}. Although **2** and **3** are formally analogues of BLM A_5, the conjugates of which do produce strong DNA cleavage in resin-bound form (*51, 52*), the (2−3-fold) diminution of DNA cleavage potency known to result from the absence of the BLM disaccharide moiety (*13*−*15*) was sufficient to compromise the ability of resin-bound **2** and **3** to produce a useful level of DNA damage.

In contrast, resin-bound **4** cleaved DNA very efficiently. A plasmid DNA relaxation assay (Figures 6 and 7) revealed that, in the presence of 1.5 μM Fe^{2+}, resin-bound **4** degraded the substrate significantly even at low micromolar concentrations (Figure 7, lanes 9−12) and completely degraded the DNA at 50 μM concentration. The potency of DNA cleavage by resin-bound **4** was further confirmed by high-resolution gel electrophoresis analysis of a 5′-^{32}P end labeled 158 base pair DNA fragment that had been treated with resin-bound **4**. As is clear from Figure 4, resin-bound **4** (lanes 8 and 9) cleaved the duplex with the same sequence selectivity and comparable potency as resin-free **4** (lanes 4 and 5) and natural BLM A_5 (lanes 6 and 7). The difference in potencies of DNA cleavage by resin-free and resin-bound analogue **4** was clearly less than 10-fold, demonstrating the ability of additional positively charged groups in the C-substituent to compensate for the absence of the BLM disaccharide moiety, as well as the attachment of the analogue to the TentaGel resin. It may be noted also that

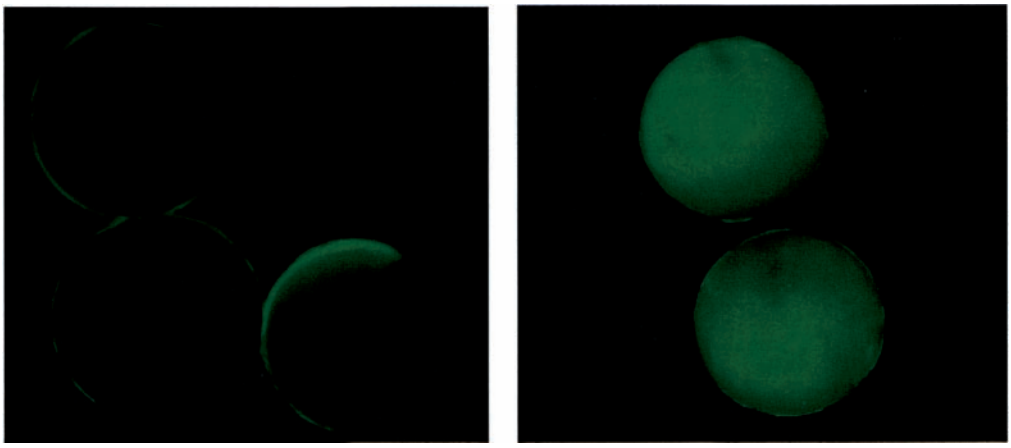

Figure 8. Fluorescence microscopy of TentaGel beads containing conjugated Fe(II)·deglycoBLM **4**. The images were recorded prior to Fe^{2+} addition (left) and 30 min after Fe^{2+} addition (right).

the sequence selectivity of DNA cleavage by resin-bound **4** was identical with that of resin-free **4** (Figure 4).

To evaluate the relative importance of the number of positive charges in the C-substituent vs conjugation to a resin on the efficiency of DNA cleavage, the ability of free **3** to effect plasmid DNA relaxation was compared to that of resin-bound **3** and resin-bound **4**. Resin-bound **3** has one fewer positively charged group than unbound **3** at physiological pH, while resin-bound **4** should have the same number as free **3**. As shown in Figure 7, neither resin-bound BLM analogue was nearly so potent as free **3** in effecting DNA relaxation, but resin-bound **4** was significantly more efficient than resin-bound **3**. Thus actual conjugation of a BLM to a solid support would seem to lower the efficiency of DNA cleavage primarily for reasons of localization of BLM to the (very small number of) resin beads, rather than by reducing the number of positively charged groups within the C-substituent. Nevertheless, it is clear from the foregoing results that the incorporation of additional positively charged groups can be effective in compensating for the loss of overall cleavage efficiency and can do so without altering the sequence selectivity of DNA cleavage. Resin-bound **4** exhibited strong DNA cleavage, indicating that the spermine-based linker in this analogue should be sufficient to permit the evaluation of many (deglyco)BLM analogues while they are still bound to the resin employed for their elaboration.

Molecular Beacon Assay Utilizing Fluorescence Microscopy. DNA cleavage by TentaGel-conjugated BLM **4** was also monitored by molecular beacon assay utilizing fluorescence microscopy (*37, 67*). A molecular beacon designed for bleomycin cleavage was shown to fluoresce following BLM-mediated DNA cleavage (*67*). The sequence of the molecular beacon used for the microscopy was 5′d($CGCT_3A_7GCG$); the beacon contained the fluorophore carboxyfluorescein (FAM) at the 5′-end and the "Black Hole Quencher" (BHQ) at the 3′-end. Though DABCYL has been used routinely as a quencher for commonly used fluorophores (*68*−*70*), the quenching efficiency is sometimes not high due to poor spectral overlap with the fluorescent dye (*71*). A new class of quencher, BHQ dye, has an absorption spectrum essentially superimposable with the emission maximum of FAM, and thus provided a significant increase in fluorescence resonance energy transfer (FRET). Therefore, a molecular beacon made with this quencher exhibited very low background fluorescence, enabling enhanced detection sensitivity. Beacon cleavage for visualization was carried out with the TentaGel embedded in an agarose gel medium to retard diffusion of the formed fluorescent cleavage products from the gel. Figure 8 shows the fluorescence images of beacon DNA cleavage by deglycoBLM A_6 without added Fe^{2+}, and 30 min after the addition of Fe^{2+}. As can be seen from the figure, fluorescence emission from each gel increased markedly after the addition of Fe^{2+}; the increase was also time dependent (not shown). The fluorescence intensity reached a maximum after about 40 min. No significant fluorescence increase was observed for beacon DNA treated with Fe^{2+} + TentaGel lacking a BLM A_6 moiety. These results demonstrate that beacon DNA cleavage by Fe(II)·BLM **4** can be monitored visually on individual beads, thus enabling the monitoring of BLM libraries elaborated on beads by split and mix synthesis.

ACKNOWLEDGMENT

We thank Michael Rishel for the β-hydroxyhistidine derivative employed in this study, and Dr. Ammasi Periasamy and Colten Noakes of the University of Virginia W. M. Keck Center for Cellular Imaging for technical assistance with the fluorescence microscopy. This work was supported by NIH Research Grants CA76297 and CA77284, awarded by the National Cancer Institute.

Boron-Containing Folate Receptor-Targeted Liposomes as Potential Delivery Agents for Neutron Capture Therapy

Xing Q. Pan,[#] Huaqing Wang,[#] Supriya Shukla,[#] Masaru Sekido,[#] Dianne M. Adams,[⊥] Werner Tjarks,[#] Rolf F. Barth,[⊥] and Robert J. Lee*[,#]

College of Pharmacy and Department of Pathology, The Ohio State University, Columbus, Ohio 43210. Received September 21, 2001; Revised Manuscript Received December 14, 2001

Boron neutron capture therapy (BNCT) depends on the selective delivery of a sufficient number of ^{10}B atoms to tumor cells to sustain a lethal $^{10}B(n,\alpha)^7Li$ reaction. Expression of FR frequently is amplified among human tumors. The goal of the present study was to investigate folate receptor (FR)-targeted liposomes as potential carriers for a series of boron-containing agents. Two highly ionized boron compounds, $Na_2[B_{12}H_{11}SH]$ and $Na_3(B_{20}H_{17}NH_3)$, were incorporated into liposomes by passive loading with encapsulation efficiencies of 6% and 15%, respectively. In addition, five weakly basic boronated polyamines were investigated. Two were the spermidine derivatives: N^5-(4-carboranylbutyl)spermidine·3HCl (SPD-5), N^5-[4-(2-aminoethyl-*o*-carboranyl)butyl]spermidine·4HCl (ASPD-5). Three were the spermine derivatives: N^5-(4-carboranylbutyl)spermine·4HCl (SPM-5), N^5-[4-(2-aminoethyl-*o*-carboranyl)-butyl]spermine·5HCl (ASPM-5), and N^5,N^{10}-bis(4-carboranylbutyl)spermine·4 HCl (SPM-5,10). These were incorporated into liposomes by a pH-gradient-driven remote-loading method with varying loading efficiencies, which were influenced by the specific trapping agent and the structure of the boron compound. Greater loading efficiencies were obtained with lower molecular weight boron derivatives, using ammonium sulfate as the trapping agent, compared to those obtained with sodium citrate. The in vitro uptake of folate-derivatized, boronated liposomes was investigated using human KB squamous epithelial cancer cells, which have amplified FR expression. Higher cellular boron uptake (up to 1584 μg per 10^9 cells) was observed with FR-targeted liposomes than with nontargeted control liposomes (up to 154 μg per 10^9 cells), irrespective of the chemical form of the boron and the method used for liposomal preparation. KB cell binding of the FR-targeted liposomes was saturable and could be blocked by 1 mM free folic acid. Our findings suggest that further evaluation of FR-targeted liposomes is warranted to assess their potential as boron carriers for neutron capture therapy.

INTRODUCTION

Boron neutron capture therapy (BNCT) currently is being evaluated as a modality for the treatment of primary and metastatic brain tumors and cutaneous and metastatic melanoma (Soloway et al., 1997; Barth et al., 1999; Hawthorne, 1998; Mishima et al., 2001). The effectiveness of BNCT depends on the selective accumulation of a sufficient concentration of the stable isotope, ^{10}B, in cancer cells, followed by neutron irradiation. The resulting nuclear reaction ($^{10}B[n,\alpha]^7Li$) yields tumoricidal high linear energy transfer (LET) α particles and recoiling ^7Li nuclei. Our efforts to improve the efficacy of BNCT have concentrated on (i) the development of novel boronated agents that have high boron content and exhibit selective uptake by tumor cells and favorable subcellular distribution (Soloway et al., 1997; Capala et al., 1996 and 1997) and (ii) methods to optimize the delivery of the two drugs that currently are being used clinically for BNCT: sodium borocaptate ($Na_2B_{12}H_{11}SH$ or BSH) and boronophenylalanine (BPA) (Barth et al., 1997 and 2000; Yang et al., 1997 and 2000). To maximize boron content, BNCT agents often consist of derivatives of one or more carborane cages, which contain 10 boron atoms. Boronated polyamines are potential delivery agents for BNCT due to their DNA-binding properties (Zhuo et al., 1999; Cai et al., 1997). The structures of a series of such derivatives, including two spermidine derivatives SPD-5 and ASPD-5, and three spermine derivatives SPM-5, ASPM-5, and SPM-5,10 (with two carborane cages), are shown in Figure 1. The polyamine moiety and, when present, the extra amino group provide hydrophilicity and aqueous solubility to these constructs. In contrast, the carboranyl moieties provide high molecular boron content, lipophilicity, and potential bilayer permeability upon deprotonation of the amino groups. Recently, a series of DNA-binding carborane-derivatized polyamines have been synthesized to facilitate the targeting of cellular DNA (Cai et al., 1997; Zhuo et al., 1999). Due to their superior boron-carrying capacity, Hawthrone and Shelly (1997) have carried out extensive studies on the incorporation of a variety of boronated agents into liposomes. The tumor-selective accumulation of boronated liposomes potentially can be further enhanced by introducing poly(ethylene glycol) (PEG)-derivatized lipids into the lipid bilayer to extend their systemic circulation time and a targeting ligand to increase selective tumor cell uptake (Yanagie et al., 2000).

FR, also known as the folate binding protein, is a glycosyl-phosphatidylinositol (GPI)-anchored membrane glycoprotein, which exhibits highly restricted normal

tissue distribution, and is amplified in a variety of human cancers (Antony, 1996). Folic acid has been shown to retain its high affinity ($K_a \sim 10^{10}$ M^{-1}) for FR upon derivatization via its γ-carboxyl (Leamon and Low, 1991). Folate-derivatized bioconjugates, including liposomal drug carriers, have been successfully selectively targeted to FR-α in ovarian and other cancers, in which FR is overexpressed (Sudimack and Lee, 2000; Reddy and Low, 1998). Folate can be incorporated into liposomes via conjugation to either a phospholipid or a cholesterol anchor (Lee and Low, 1994; Gabizon et al., 1999, Guo et al., 2000). Passive and remote loading (Muggia, 2001) have been used to incorporate hydrophilic molecules into liposomes. The former is based on producing the liposomes in an aqueous solution of the molecule of interest, thereby encapsulating it in the entrapped volume. Typically, this method has limited encapsulation efficiency. In contrast, the remote loading method relies on the establishment of a transbilayer pH gradient in preformed liposomes, which contain a "trapping" agent consisting of a counterion (Nichols and Deamer, 1976; Johnsson et al., 1999) and often yields near-quantitative drug loading. Remote loading, however, is only applicable to weakly basic molecules that exhibit membrane permeability at a slightly basic pH, e.g., anthracyclines doxorubicin and daunorubicin (Muggia, 2001).

In the present study a series of boron containing polyamine derivatives have been incorporated into liposomes targeted to the tumor cells via the folate receptor (FR). Following this, we have evaluated the liposomal loading efficiency and in vitro tumor cell binding properties of a series of boronated compounds, including the anionic agents BSH and $Na_3(B_{20}H_{17}NH_3)$ (Feakes et al., 1994; Shelly et al., 1992) and cationic boronated polyamines. Two were the spermidine derivatives N^5-(4-carboranylbutyl)spermidine·3HCl (SPD-5) and N^5-[4-(2-aminoethyl-*o*-carboranyl)butyl]spermidine·4HCl (ASPD-5). Three were the spermine derivatives N^5-(4-carboranylbutyl)spermine·4HCl (SPM-5), N^5-[4-(2-aminoethyl-*o*-carboranyl)butyl]spermine·5HCl (ASPM-5), and N^5,N^{10}-bis(4-carboranylbutyl)spermine·4HCl (SPM-5,10) (Zhuo et al., 1999; Cai et al., 1997). The anionic agents and cationic boronated polyamines were incorporated into liposomes by passive entrapment and remote loading, respectively. Higher cellular uptake was observed with FR-targeted liposomes than with nontargeted liposomes irrespective of the chemical form of the boron and the method used in liposomal preparation. A detailed description of these findings is presented in the following report.

EXPERIMENTAL PROCEDURES

Reagents. BSH was purchased from Centronic Ltd. (Croydon,U.K). Na_3 ($B_{20}H_{17}NH_3$) was kindly provided by Drs. M. Frederick Hawthorne and Kenneth Shelly in the Department of Chemistry at the University of California at Los Angeles; boronated polyamines, including the two spermidine derivatives N^5-(4-carboranylbutyl)spermidine·3HCl (SPD-5) and N^5-[4-(2-aminoethyl-*o*-carboranyl)-butyl]spermidine·4HCl (ASPD-5), and the three spermine derivatives N^5-(4-carboranylbutyl)spermine·4HCl (SPM-5), N^5-[4-(2-aminoethyl-*o*-carboranyl)butyl]spermine·5HCl (ASPM-5), and N^5,N^{10}-bis(4-carboranylbutyl)spermine·4HCl (SPM-5,10) were synthesized in our laboratories as reported previously (Zhuo et al., 1999; Cai et al., 1997). Egg phosphatidylcholine was purchased from Avanti Polar Lipids (Alabaster, AL). PEG900-Cholesterol (PEG-Chol) was purchased from Fluka Chemical Co. (Milwaukee, WI). Folic acid and cholesterol (Chol) were purchased from Sigma Chemical Co. (St. Louis, MO). Folate-free RPMI 1640 medium and other tissue culture reagents were purchased from Gibco-BRL (Grand Island, NY). BCA Protein Assay Kit was purchased from Pierce Chemical Co. (Rockford, IL). Folate−poly(ethylene glycol) (MW $\sim$ 3350)−distearoyl phosphatidylethanolamine (folate−PEG−DSPE) was synthesized as described previously (Lee and Low, 1995). The final folate−PEG−DSPE product was purified on a silica gel (70−200 mesh) using a solvent gradient of 15 to 80% methanol in CH_2Cl_2. Product purity was confirmed by thin-layer chromatography analysis on silica gel GF (75:36:6 chloroform/methanol/water), as described previously (Gabizon et al., 1999) and showed a single spot ($R_f = 0.61$).

Cell Culture. KB human cancer cells (American Type Culture Collection # CCL 17), derived from an epidermal carcinoma of the oral cavity, were obtained as a gift from Dr. Philip S. Low at Purdue University (West Lafayette, IN). The cells were maintained in folate-free RPMI 1640 medium supplemented with 100 units/mL penicillin, 100 μg/mL streptomycin, and 5% fetal bovine serum, which provides the only source of folate. The cells were cultured as a monolayer in a humidified atmosphere containing 5% CO_2 at 37 °C.

Liposome Preparation. Small unilamellar vesicles (SUVs) were prepared by high-pressure polycarbonate membrane extrusion, as previously described (Lee and Low, 1995). Briefly, a lipid mixture of the desired composition (including folate−PEG−DSPE for the FR-targeted formulation), containing 30 mg of total phospholipids, was dissolved in chloroform, dried into a thin film under a stream of nitrogen, and then desiccated under vacuum for another 30 min. Boronated agents then were loaded into liposomes by either passive entrapment (during liposome formation) or remote loading (after liposome formation), as described in the following sections.

Passive Entrapment. The dried lipids were hydrated in a 0.5 mL of aqueous solution containing the boronated compound (5 mg/mL BSH or 16.5 mg/mL Na_3 ($B_{20}H_{17}$-

NH_3)). To facilitate lipid hydration, the mixture was subjected to vortex mixing followed by brief sonication in a bath sonicator and six cycles of freezing and thawing, which resulted in the formation of a heterogeneous population of lipidic vesicles. These were manually extruded six times through a 100-nm pore-size polycarbonate membrane using a handheld LiposoFast extruder (Avestin Inc., Ottawa, Canada) attached to two 0.5-mL gastight syringes. The resulting SUVs were purified from nonentrapped molecules by size exclusion chromatography on a 10 mL Sepharose CL-4B column (Sigma Chemical Co., St. Louis, MO) preequilibrated in a buffer consisting of 10 mM sodium phosphate buffer and 150 mM NaCl (phosphate-buffered saline, PBS, pH 7.4). The liposomes were eluted in the void volume fractions whereas the free boronated compounds were eluted in later fractions. Boron concentrations in each of the fractions were quantified by means of direct current plasma-atomic emission spectroscopy (DCP-AES) using a Spectraspan VB spectrometer (Applied Research Laboratories, La Brea, CA), as previously described (Barth et al., 1991). Encapsulation efficiencies were determined by calculating the total boron content in the liposomal fractions and the total boron eluted from the column, including both the liposomal and the free boron fractions, as indicated in the following equation:

$$\% \text{ encapsulation} = \text{liposomal boron}/(\text{liposomal boron} + \text{free boron}) \times 100\%$$

The mean diameter and size distribution of the liposomes were determined by photon correlation spectroscopy on a NICOMP 370 submicron particle analyzer. Phospholipid concentration was measured by an ammonium ferrothiocyanate partitioning colorimetic assay, as previously described (Stewart, 1980). The mean particle diameters were between 100 and 150 nm for all liposome preparations. Liposome samples were stored at 4 °C and used within 2 weeks of preparation, during which time no significant leakage (<1%) of the entrapped contents was detected by gel-filtration fractionation on a Sepharose CL-4B column.

Remote Loading. Boronated polyamine derivatives (SPD-5, ASPD-5, SPM-5, ASPM-5, and SPM-5,10) were incorporated into preformed liposomes via a transmembrane pH gradient. Briefly, SUVs were prepared using the above-described method by hydrating them in either 300 mM citric acid (pH 4.0) or 250 mM ammonium sulfate. Boron loading was accomplished by incubating the liposomes with the boronated polyamines, which each contained 1.1 mg (or ~0.1 mmol) of boron dissolved in HEPES buffered saline (HBS, 150 mM NaCl, 20 mM HEPES, pH 7.4), for 60 min at 60 °C. Liposomes then were separated from the free drug by gel-filtration on a Sepharose CL-4B column and characterized as described above.

Uptake of Boronated Liposomes by Cultured KB Cells. Monolayer cultures of KB cells in a logarithmic growth phase were disaggregrated by a short exposure to 0.5% trypsin. The cells then were sedimented by centrifugation at 500*g*, resuspended in folate-free RPMI 1640 media, divided into aliquots of 1×10^6 cells, and incubated with folate-derivatized or nontargeted control boronated liposomes for 2 h at 37 °C with gentle shaking. The number of cells was determined by counting using a hemocytometer. The cells then were sedimented at 500*g* and washed 2× with PBS, and the boron concentration in the supernatant and the cell pellet was measured by DCP-AES, as previously described (Barth et al., 1991).

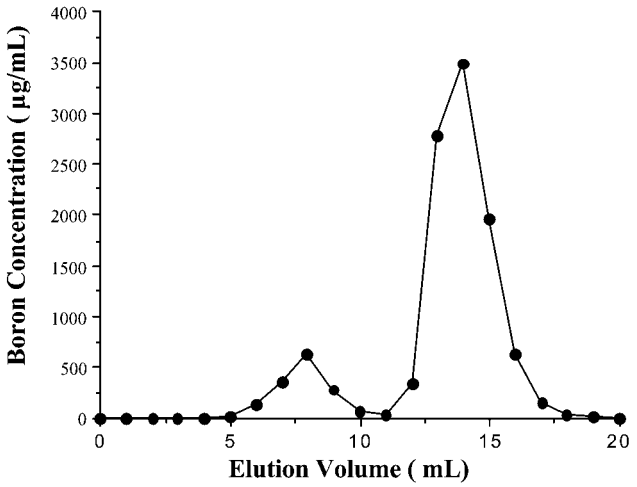

Figure 2. Size-exclusion chromatographic fractionation of L-[Na_3 ($B_{20}H_{17}NH_3$)] on a Sepharose CL-4B column. One milliliter of polycarbonate membrane extruded liposomes was loaded on to an 11-mL column, which had been prewashed with three volumes of PBS (pH7.4). Boron content in each elution fraction was determined by DCP-AES, as described in Experimental Procedures.

For FR blocking studies, the cells were incubated with boronated liposomes in the presence of 1 mM free folic acid. Cellular uptake was normalized to micrograms of boron per 10^9 cells by multiplying by the appropriate factor.

RESULTS

Liposomal Entrapment of BSH and $Na_3(B_{20}H_{17}NH_3)$. Boronated liposomes (SUVs), composed of egg PC/Chol/PEG-Chol (60:35:5, mole/mole), were prepared by lipid hydration in a solution of the anionic hydrophilic boron agent BSH or $Na_3(B_{20}H_{17}NH_3)$, followed by extrusion through a 100-nm pore-size polycarbonate membrane, as described in the Experimental Procedures. The 5 mol % PEG−Chol was incorporated in the liposome formulation to provide steric stabilization against plasma protein binding during systemic administration for future in vivo studies. Egg PC/Chol/PEG−Chol/folate−PEG−DSPE (60:35:4.5:0.5, mole/mole) was used in the preparation of FR-targeted liposomes. The liposome samples were fractionated on a Sepharose CL-4B column. As shown in a typical chromatogram (Figure 2), liposomal $Na_3(B_{20}H_{17}NH_3)$ (L-[$Na_3(B_{20}H_{17}NH_3)$]) could be efficiently separated from the unentrapped free drug using this method. The majority of the boron detected by DCP-AES was eluted in the low molecular weight fractions. Entrapment efficiencies, obtained for BSH and $Na_3(B_{20}H_{17}NH_3)$, were 6% and 15%, respectively. No significant differences were observed between the loading efficiency of FR-targeted and the nontargeted control liposomes (data not shown).

Liposomal Entrapment of Boronated Polyamines. Liposome loading was carried out by remote-loading methods based on the generation of a transmembrane pH gradient, as described in the Experimental Procedures. Either 300 mM sodium citrate (pH 4) or 250 mM ammonium sulfate was used as an intraliposomal trapping agent, which forms an insoluble complex with the boronated polyamines that have diffused across the lipid bilayer into the aqueous core of the liposomes. Identical lipid compositions, with or without the incorporation of folate−PEG−DSPE, were used, as described above for liposomes entrapping anionic boronated agents.

Table 1. The Entrapment Efficiency of Boronated Polyamines by Remote Loading (%)

boronated polyamine derivatives	trapping agent	
	sodium citrate	$(NH_4)_2SO_4$
SPD-5	30	93
ASPD-5	26	72
SPM-5	19	26
ASPM-5	13	45
SPM-5, 10	75	85

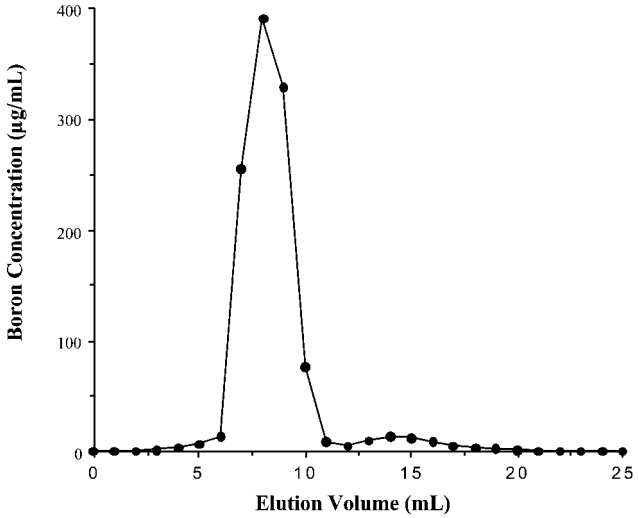

Figure 3. Size-exclusion chromatographic purification of L-[ASPD-5] on a Sepharose CL-4B column. One milliliter of polycarbonate membrane extruded liposomes was loaded on to an 11-mL column prewashed with three volumes of PBS (pH7.4). Boron content in each elution fraction was determined by DCP-AES, as described in Experimental Procedures.

The loading efficiencies were highly variable and ranged from 13% to 93%, as shown in Table 1. The boronated liposomes were easily separated from the free compound, as shown in a representative size-exclusion chromatogram of liposomes entrapping ASPD-5 (Figure 3). Comparing the various boronated polyamines with a single carborane moiety (SPD-5, ASPD-5, SPM-5, ASPM-5), the spermidine derivatives showed a higher entrapment efficiency compared to the spermine derivatives. Among the spermine derivatives, SPM-5,10, which has two attached carborane cages, showed a higher entrapment efficiency than SPM-5, which contains a single carborane moiety. Finally, liposome loading using ammonium sulfate as the trapping agent resulted in an overall higher efficiency of boron entrapment compared to procedures using sodium citrate as the trapping agent. Therefore, all liposomes containing the boronated polyamines used in subsequent tumor cell uptake studies were prepared using ammonium sulfate as the trapping agent. Incorporation of folate−PEG−DSPE did not significantly influence liposomal loading efficiency (data not shown).

Cellular Uptake of FR-Targeted Boronated Liposomes. To study the potential use of folate-derivatized liposomes as tumor cell selective delivery agents for BNCT, cellular binding of the liposomes was evaluated using cultured KB cells, which express amplified FR. A representative concentration dependent cellular uptake curve using liposome-entrapped BSH is shown in Figure 4. Greater cellular uptake of boron was obtained with folate-derivatized liposomal BSH (f-L-[BSH]) compared to the nontargeted control liposomes (L-[BSH]). Furthermore, the FR-targeted liposomes showed binding saturation at boron concentrations greater than 4 μM and this

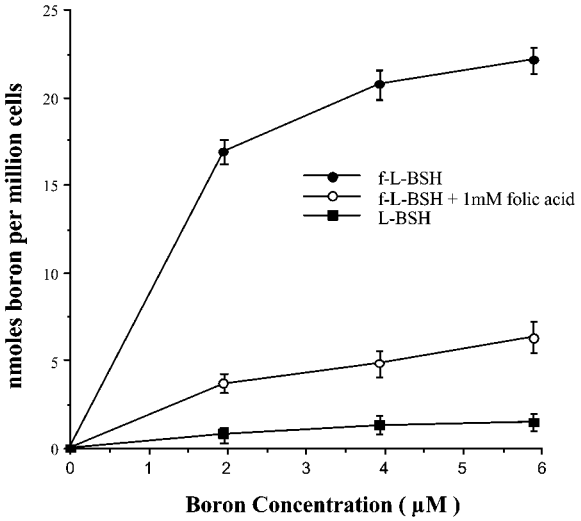

Figure 4. FR-mediated uptake of liposomal BSH in cultured KB cells. Tumor cells were suspended with trypsin and incubated with BSH-containing liposomes at the indicated boron concentrations for 2 h at 37 °C. Tumor cell associated boron was analyzed as described in Experimental Procedures.

was inhibited by 1 mM folic acid, suggesting that the uptake of f-L-BSH was dependent upon FR expression. The maximum boron uptake obtained with f-L-[BSH] was ~240 μg/10^9 cells.

Cellular uptake of boron, following a 2 h incubation at 37 °C with a variety of boronated agents, each containing 4 μM total boron, entrapped in either FR-targeted (f-L-[boron]) or nontargeted control liposomes (L-[boron]), are summarized in Table 2. There was a 2.3- to 49-fold higher boron uptake in cells treated with the f-L-[boron] compared to cells treated with L-[boron]. Furthermore, uptake of f-L-[boron] could be blocked by coincubation with 1 mM folic acid, indicating that cellular uptake was FR dependent. Boron delivery to KB cells generally was more efficient with f-L-[boron] containing the cationic polyamine derivatives compared to the liposomes containing the anionic boronated species. The maximum cellular uptake of f-L-[boron] was variable and was as high as 1584 μg per 10^9 cells with liposomes entrapping SPM-5,10.

DISCUSSION

In the present study, we have evaluated the incorporation of a series of carborane cage-containing derivatives into FR-targeted liposomes. Using either passive or remote loading techniques, the efficiency of loading and the cellular uptake of boron have been determined. Anionic carborane derivatives BSH and $Na_3(B_{20}H_{17}NH_3)$, which have very high boron content and are membrane impermeable due to their high degree of ionization (Hawthorne and Shelly, 1997), were loaded into SUVs by passive entrapment. In the absence of significant bilayer interactions, the liposomal entrapment efficiencies for water-soluble agents primarily will be determined by the percent entrapped volume, provided that solute concentrations reach equilibrium across the lipid bilayer during liposome preparation. Under these conditions, higher percentage entrapment can be achieved by (i) increasing the lipid concentration, (ii) adopting procedures to ensure equilibration of solute across the membrane, and (iii) increasing the mean vesicle diameter. A relatively small particle size is required for systemic liposomal drug delivery in order to enhance diffusion into the tumor. Therefore, we have selected a polycarbonate

Table 2. Uptake of Liposomal Boron Compounds by Cultured KB Cells

boron compounds	boron-to-lipid ratio × 10^3 (wt/wt)	f-L-[boron][a]	L-[boron][a]	f-L-[boron] + 1 mM folic acid
BSH	3.0	231 ± 40 [b]	14 ± 2	53 ± 10

[a] f-L-[boron] designates the FR-targeted boron containing liposomes; L-[boron] designates the nontargeted control liposomes. [b] Boron concentrations were determined by means of DCP-AES. The values indicated were micrograms of boron per 10^9 cells ± standard deviation, based on three replicate samples for each compound.

membrane extrusion-based procedure to generate SUVs with mean diameters in the range of 100−150 nm. The entrapment efficiencies obtained for BSH and Na_3 ($B_{20}H_{17}NH_3$) (6% and 15%) were substantially higher than those reported previously (Mehta et al., 1996; Feakes et al., 1994). The lower entrapment efficiencies observed by Feakes et al. possibly could have been due to the small size of the liposomes (~60 nm), although differences in lipid compositions and the procedure used to prepare these liposome preparation also may have played a role. The difference in encapsulation efficiency of BSH and $Na_3(B_{20}H_{17}NH_3)$ may be due to differences in their binding affinity for the lipid bilayer. The incorporation of folate−PEG−DSPE, a targeting ligand for the FR, did not significantly affect liposomal loading efficiency. Further enhancement in entrapment efficiency might be achieved by increasing the lipid concentration during lipid hydration. Although much greater incorporation efficiencies can be achieved using lipophilic derivatives of carboranes, their high lipophilicity would reduce subcellular localization to the nucleus. A combination of encapsulation of hydrophilic boron agents with the incorporation of lipophilic carborane derivatives into the bilayer would maximize liposomal boron content and simultaneously allow the targeting of multiple intracellular targets. Further evaluation of this approach is warranted.

Boronated polyamines have been designed to target DNA following cellular uptake (Cai et al., 1997). The amphiphilicity and weakly basic properties of these agents make them suitable candidates for remote loading into liposomes. In contrast to passive entrapment, remote loading is achieved based on the bilayer permeability of boronated polyamines at basic pH and the formation of insoluble complexes between these agents and a trapping agent, which consist of either sodium citrate or ammonium sulfate. Remote loading procedures have been applied to anthracyclines, resulting in close to 100% entrapment (Muggia, 2001). In the present study, we compared the effectiveness of 300 mM sodium citrate and ammonium sulfate as trapping agents during remote loading. The latter was found to be more effective, possibly due to its greater capacity to form stable complexes with the boronated polyamines. Remote loading of weakly basic compounds into liposomes is presumably mediated by precipitation of the agent inside the liposome, either with citrate or sulfate as the counterion. Neither citrate nor sulfate ions are expected to cross the lipid bilayer, either alone or as a polyamine complex. Therefore, the observed differences in loading efficiency were possibly due to differences in intraliposomal pH values and the solubility product (K_{sp}) values for the polyamines with each type of counterions.

The liposomal loading efficiency also appeared to be influenced by the chemical structure of the boron derivatives. When only one carborane cage was present, higher percentages of boron encapsulation were observed when the ionic component was spermidine (SPD-5, ASPD-5) compared to those obtained with spermine (SPM-5, ASPM-5). It is possible that at a weakly basic pH the additional ionizable amine component and the corresponding increase in overall size of the molecule impeded diffusion of spermine derivatives across the phospholipid bilayer. In addition, the presence of two carborane cages (in SPM-5,10), which increased the lipophilicity of the molecule, appeared to facilitate liposome loading, suggesting that lipophilicity might be an additional determining factor for optimizing remote loading.

Based on the premise that cholesterol formed a stable lipophilic anchor for PEG, PEG900-Chol was incorporated into the liposomes to enhance their colloidal stability. A previous report (Beugin et al., 1998) has shown that PEG-Chol derivatives have lower critical micelle concentration (CMC) values than the corresponding PEG-PE derivatives and were stably incorporated into liposomes with similar efficiency and stability. In addition, Ishiwata et al. (1995) reported that PEG−Chol derivatives could prolong systemic circulation time of liposomes. Furthermore, our previous studies have shown that folate−PEG−Chol effectively targeted liposomes to tumor cells expressing amplified level of folate receptor (Guo and Lee, 2000).

Receptor-mediated targeting of boronated liposomes potentially may improve the delivery of boron to tumor cells. FR-targeted liposomes can be easily prepared through the incorporation of folate−PEG−DSPE, a lipophilic derivative of FR ligand folic acid. A proposed mechanism of FR-mediated intracellular boron delivery is shown in Figure 5. Compared to polypeptide-based targeting ligands, folate is small in size, readily available, easily amenable to liposomal incorporation, highly specific for FR positive tumor cells, nonimmunogenic, and selective for a cellular marker that has very limited normal tissue distribution and is widely overexpressed in a wide variety of tumors, including over 90% ovarian carcinomas (Garin-Chesa et al., 1993; Ross et al., 1994; Weitman et al., 1992). Boron uptake by FR-positive KB cells was much greater with FR-targeted f-L-[boron] liposomes compared to the nontargeted control liposomes. The variability in the boron delivery efficiencies of f-L-[boron] partly may be attributable to differences in boron loading efficiencies and boron-to-lipid ratios of the various liposomal preparations. Uptake of f-L-[boron] by KB cell was only partially blocked by 1 mM folic acid, which may have been due to increased binding affinity resulting from multivalent interactions between liposomes and cellular FRs.

The ultimate purpose of developing FR-targeted boronated liposomes is to selectively deliver sufficient quantities of boron to FR-expressing tumor cells. Comparison

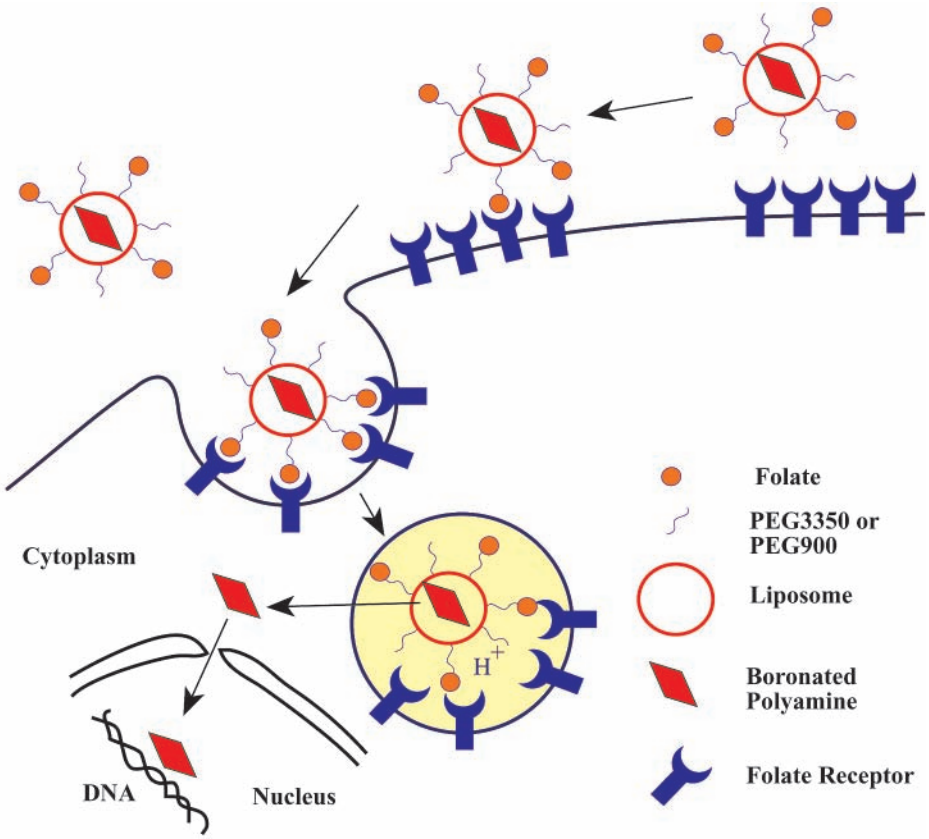

Figure 5. Proposed mechanism of intracellular boron delivery that involves both FR-mediated tumor cell targeting and intracellular DNA targeting. FR-targeted boronated polyamine containing liposomes are shown to be internalized by a cell via FR-mediated endocytosis. The encapsulated boron agent is then released into the cytosol via endosomal escape and bound to the DNA in the cellular nucleus.

of delivery efficiencies by different liposomal formulations, therefore, was based on exposing cells to the same concentrations of boron, rather than lipids. The FR targeting properties of folate-derivatized liposomes have been reported previously (Lee and Low, 1995) and, therefore, was not the main focus of the present study. The alternative would have been to keep the lipid concentration constant, which would result in variable amounts of boron. Results based on this strategy might be difficult to interpret since our data focused on measurements of cell-associated boron. The choice of 4 μM boron concentration in cellular binding studies was based on the finding that higher concentrations of boron and lipids resulted in significant nonspecific cellular uptake (data not shown).

The variability in cellular boron uptake and in FR-targeted-to-nontargeted enhancement ratios were influenced by a number of variables. These included (i) the lipid concentration used in the binding assay, (ii) the boron-to-lipid ratio of the liposomal formulation, and (iii) the ζ-potential of the liposomal surface, which was affected by binding of the cationic and lipophilic boronated polyamines. Data on cellular boron uptake indicated that boronated polyamine liposomal formulations with higher boron-to-lipid ratios generally had greater nonspecific cellular uptake. This suggests that uptake of FR-targeted liposomes may have been due to both receptor-mediated and nonspecific binding, which would increase with elevated ζ-potential due to greater liposome surface binding of the boronated polyamines.

In vivo tumor localization of boronated liposomes potentially can be affected by passive targeting due to increased endothelial permeability and limited lymphatic drainage frequently observed in solid tumors (Matsumura et al., 1986). Tumor-targeted immunoliposomes and FR-targeted liposomes have shown moderate enhancement in tumor accumulation compared to nontargeted liposomes, but the degree of enhancement was highly variable (Ishida et al., 2001; Park et al., 1997; Guo et al., 2000). For example, transferrin receptor-targeted immunoliposomes showed only a 2-fold increase in boron localization in a rat xenograft model (Maruyama et al., 1999; Ishida et al., 2001). Intratumoral and subcellular distribution of the boron are important determinants for the effectiveness of neutron capture therapy (Hartman et al., 1994). It is conceivable that FR-targeted liposomes may be more efficiently internalized by FR-bearing tumor cells following extravasation compared to nontargeted liposomes within the solid tumor.

In summary, we have shown that FR-targeted liposomes can deliver larger amounts of boron (up to 1584 μg/10^9 cells) to receptor positive tumor cells in vitro than any other delivery agent currently being investigated in our laboratories. This amount greatly exceeds the boron concentration (20−35 μg per gram of tumor) required to sustain a lethal $^{10}B(n,\alpha)^7Li$ capture reaction for BNCT. Boron delivery was selective to FR expressing cells since it can be blocked by excess free folate. Folate-derivatized liposomes containing boronated polyamines would be particularly attractive targeting agents since they also could deliver boron to cellular DNA. Further studies are warranted to evaluate the in vivo tumor localizing potential of these boron carriers in FR-positive tumor cells and their utility for BNCT.

Polyester Dendritic Systems for Drug Delivery Applications: Design, Synthesis, and Characterization

Henrik R. Ihre,[†] Omayra L. Padilla De Jesús,[†] Francis C. Szoka, Jr.,*[,‡] and Jean M. J. Fréchet*[,†]

Department of Chemistry, University of California, Berkeley, California 94720-1460 and School of Pharmacy, University of California, San Francisco, California 94143-0446. Received October 22, 2001

Attachment of drugs to high molecular weight polymers can significantly improve both tumor targeting and therapeutic efficacy due to the enhanced permeability and retention effect observed in tumor tissue. However, the commercial availability of well-defined water-soluble polymeric systems with narrow polydispersities that are biocompatible, nontoxic, and nonimmunogenic is rather limited. To address this need, we have investigated dendritic polymers as promising scaffolds for the preparation of new soluble polymeric drug carriers due to their well-defined molecular architecture and their multiplicity of surface sites. Herein we show the design and synthesis of dendritic polyester systems based on the monomer unit 2,2-bis(hydroxymethyl)propanoic acid as a possible versatile drug carrier. The potent anticancer drug doxorubicin was attached via a pH-sensitive linkage to one of the carriers presented, demonstrating the feasibility of using these polyester dendritic structures to prepare a viable polymer−drug conjugate.

INTRODUCTION

In the past few decades, there has been an increasing interest in the design and synthesis of polymeric systems with potential drug delivery applications, a concept initially introduced by Ringsdorf (*1*, *2*) and Kopeček (*3*−*5*). For certain medical treatments, such as chemotherapy, the use of high molecular weight (>20 000 Da) systems provide advantages compared to low molecular weight molecules (<1000 Da), that results in enhanced targeting of tumor tissue and efficiency of the treatment (*6*−*8*).

This effect is explained in part by the enhanced permeability and retention (EPR) phenomenon observed in tumor tissue (*9*−*11*). The EPR effect relies on the fact that the new blood capillaries formed by angiogenesis around tumor tissue, in contrast to normal tissue, are more loosely constructed with larger gaps between endothelial cells. This leaky character serves to supply oxygen and nutrients to the increasing number of neoplastic cells. However, this same physical characteristic also increases the possibilities of extravasation of larger molecules from the surrounding capillaries to the tumor tissue. Therefore, the less probable access of large molecules to normal healthy cells allows for the selectivity toward tumor tissue observed when using polymers as drug carriers. Furthermore, the access to lymphatic capillaries via the tumor is very limited, such that there is inadequate drainage of macromolecules from the tissue. Therefore, both the leaky capillaries that allow permeation of larger molecules and the absence of functional lymphatic drainage that causes accumulation provide an alternative means to passively target tumor tissue by using high molecular weight polymeric systems as drug carriers. The use of polymeric prodrugs also takes advantage of the endocytotic cell uptake mechanism, which contributes to bypass the multidrug resistance (MDR) effect observed in cancer cells (*12*, *13*). In addition, the coupling of an active drug to the appropriate polymeric backbone may overcome problems of water solubility, and lower the toxicity of the drug until it is delivered to the target tissue. The pharmacokinetics of the drug will also be affected, as the higher molecular weight of the conjugate increases its circulation time in the plasma. The combination of these factors makes the polymeric prodrug more accessible for accumulation in the target tissue, increasing the possibilities of improved delivery and efficacy (*7*, *8*).

Although there are many commercially available polymers, few of these polymeric systems possess properties that are suitable for drug delivery agents, such as water solubility, biocompatibility, nontoxicity, and nonimmunogenicity. One system that has been evaluated extensively in clinical trials is PK1, containing a polymeric backbone based on (2-hydroxypropyl)methacrylamide (HPMA) (*14*). Even though this system has shown very promising results in terms of its drug delivery capability, the reproducibility in the preparation of monodisperse poly(HPMA) remains a challenge (*15*, *16*). The broad polydispersity index (PDI) of most polymers may lead to irreproducible pharmacokinetic behavior due to the variation in the molecular weight distribution profile of the polymers from preparation to preparation. Therefore, the preparation of materials with low PDI (≤ 1.1) is essential for the development of systems with reproducible behavior.

Dendritic systems are excellent candidates for providing a well-defined molecular architecture, which is a result of a stepwise synthetic procedure consisting of coupling and activation steps (*17*−*19*). Dendrimers consist of branched, wedge-like structures called dendrons that are attached to a multivalent core, and emerge radially toward the periphery. The architecture and synthetic routes result in polymers with PDI near 1.00, as opposed to the much higher polydispersity of linear or hyperbranched structures (Figure 1). The flexibility to tailor both the core and surface of these systems make them very attractive, since different groups can be provided so as to optimize the properties of the drug carrier. For instance, the functional periphery can be

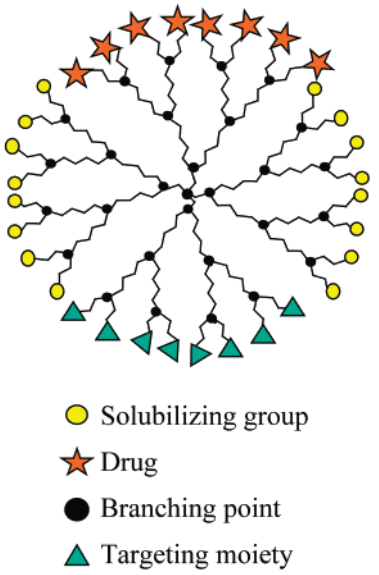

Figure 2. Schematic representation of a possible design for a dendritic drug carrier due to flexibility and versatility that dendritic systems provide.

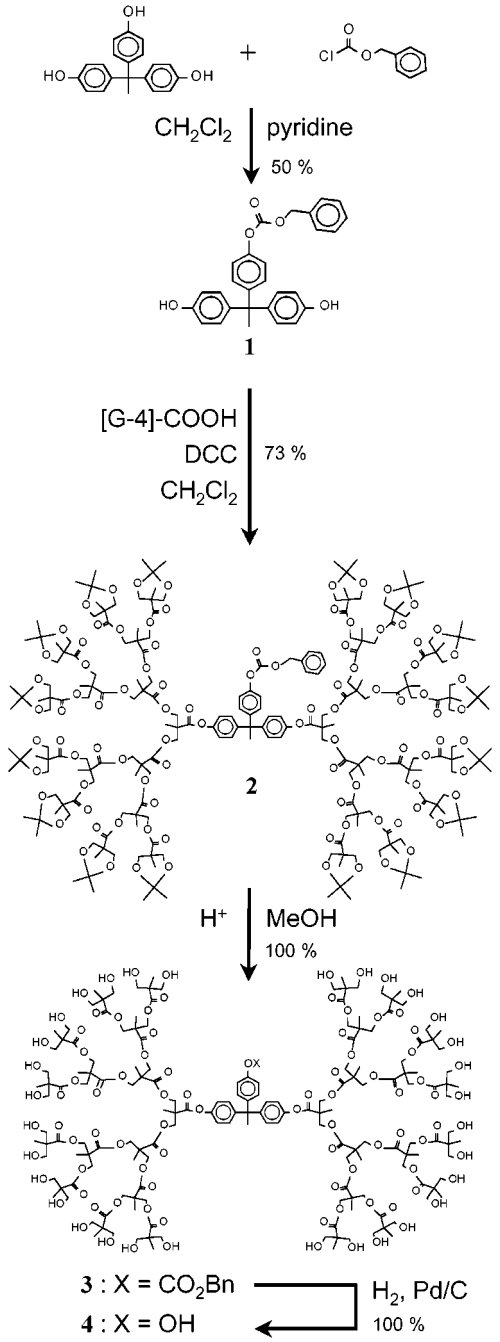
altered for improving water solubility properties. Orthogonal terminal groups can also be incorporated for nonstatistical attachment of drugs and targeting moieties (Figure 2). The covalent character of dendrimers is also advantageous, providing a stable system that is not dependent on an appropriate dynamic equilibrium or thermodynamic factors that rule large systems, such as micelles and liposomes, formed by aggregation of smaller parts (*20*−*22*). These intrinsic properties of dendrimers make them interesting multivalent molecules that can serve as scaffolds for the preparation of new polymeric systems for drug delivery purposes (*23*−*29*). Nevertheless, the commercial availability of dendritic systems is limited. Currently, the only "commercially" available dendrimers are poly(amidoamine) (PAMAM) and poly(propyleneimine) (PPI) dendrimers. These systems are toxic in cells and animals due to their polycationic character (*30*−*32*). As a result, the search for new dendritic systems for drug delivery purposes is of considerable interest. Less toxic but rather small convergent "Fréchet-type" dendrons (*18*) and related building blocks are commercialized by TCI (Tokyo Kasei Kogyo Co.).

We report the design and synthesis of a polyester dendritic scaffold based on 2,2-bis(hydroxymethyl)propanoic acid. Three different model compounds were prepared as possible scaffolds for the preparation of actual drug carriers. The potent anticancer drug doxorubicin was attached to model compound **11**, showing the feasibility of preparing a polymer-drug conjugate with these polyester dendritic structures. The biological evaluation of these systems is reported elsewhere (*33*).

RESULTS AND DISCUSSION



Design and Synthesis of Polymeric Carriers. The main advantages for the use of dendrimers as drug carriers reside in their multivalent design and their well-defined structure that results from the stepwise, iterative approach used in their preparation. This controlled synthesis allows the preparation of structures with specific, reproducible, and tunable characteristics. As previously stated, dendrimers would allow both control over the size of the drug−polymer conjugate, and over the functional groups used for drug and targeting moiety attachment. These groups may also be modified to improve the water solubility properties of the system. Furthermore, a well-defined system with low PDI also renders reproducible pharmacokinetic properties, which is important for the approval of new therapeutic agents by the FDA.

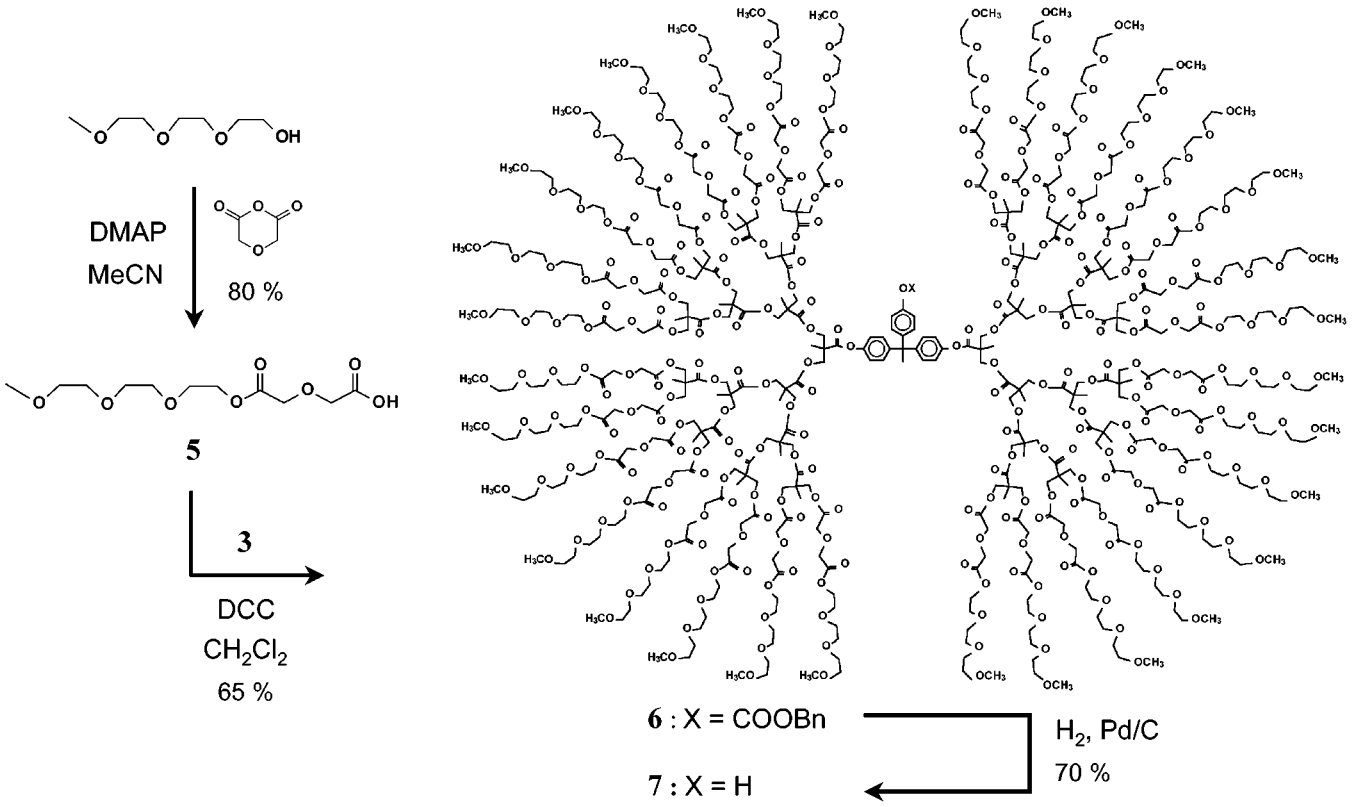
The monomer unit selected for the preparation of the dendritic scaffold, 2,2-bis(hydroxymethyl)propanoic acid, exhibits a set of unique advantages. This polyester system is water soluble in the uncharged state when the polyhydroxylated surface is exposed. This avoids the necessity of introducing functional groups that would contribute to water solubility by ionization, which can counteract the beneficial effect of the use of polymers. Generally, polycationic systems have shown to be toxic and quickly eliminated from circulation, while negatively charged systems often suffer from reduced uptake of molecules in cultured cells and rapid removal via the scavenger receptor in animals (*30*, *34*). In addition, even though polyester bonds are characterized by their susceptibility toward hydrolysis, an attractive feature for biodegradable systems (*35*, *36*), the sterically hindered ester bond of the monomer unit used makes this backbone more stable toward both nucleophilic attack and acid-catalyzed hydrolysis. However, if desired, the points of attachment of drugs to the dendrons and/or dendrons to the core can be designed for more rapid rates of hydrolysis. This feature is another advantage of the dendron architecture.

To perform preliminary biological evaluation of the dendritic scaffold proposed, three model compounds (**4**, **7**, **11**) of different molecular weights and architecture were prepared. The design and synthesis of the carriers are described below.

Model Compound ***4***. The monomer unit 2,2-bis(hydroxymethyl)propanoic acid was selected for the preparation of dendrimer **4**. The fourth generation dendrons [G-4] that compose **4** were synthesized using a double stage convergent approach as reported previously (*37*). In summary, two analogues of the monomer were prepared: the protected acid and the protected 1,3-diol. The protecting groups selected were a benzyl ester group and an isopropylidene ketal group, respectively, to provide access to an orthogonal selective deprotection. The carboxylic acid functionality of the focal point can be deprotected by hydrogenolysis, while the diol surface becomes exposed upon acid-catalyzed hydrolysis of the

Scheme 1

ketal groups. The peripheral hydroxyl groups were esterified by reacting one equivalent of the protected acid diol (HO_2-[G-1]-Bn) with two equivalents of the acid derivative of the monomer ([G-1]-COOH) in the presence of dicyclohexylcarbodiimide (DCC), forming the second generation dendron [G-2]. Following orthogonal deprotection of two samples of these [G-2] dendrons, the resulting [G-2]-OH_4 and [G-2]-COOH dendrons were coupled under DCC conditions to afford the [G-4] dendron in one step.



For the assembly of dendrimer **4** (Scheme 1), a monoprotected trisphenolic core was prepared (**1**) by reacting an excess of 1,1,1-tris(4-hydroxyphenyl)ethane with benzyl chloroformate, affording **1** in 50% yield after purification by column chromatography. Then, two equivalents of the [G-4]-COOH dendron were coupled to **1** in the presence of DCC. After coupling the dendrons to the bifunctional core, the isopropylidene ketal protecting groups were cleaved under mild acidic conditions, producing a highly water soluble system containing 32 free hydroxyl groups on the surface. Finally, the benzyl carbonate group was cleaved by hydrogenolysis to provide the free phenol for radiolabeling purposes in future biodistribution experiments, yielding dendrimer **4** with a molecular mass of 3790 Da (Scheme 1).

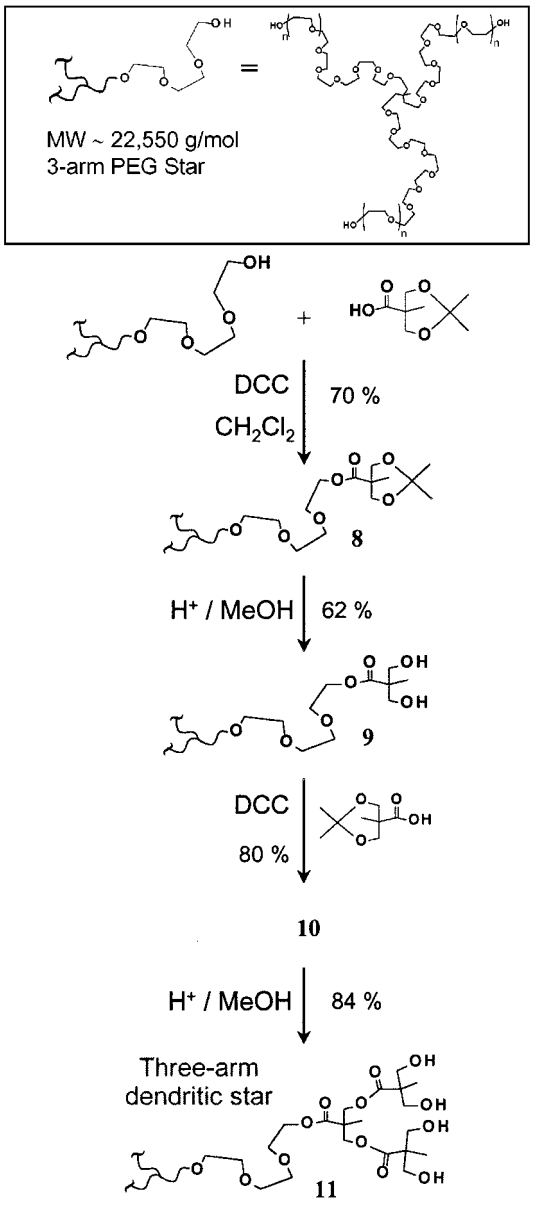
*Model Compound **7***. To evaluate the effect of increasing the mass of the dendritic system, a second dendritic model compound (**7**) was prepared. This system, consisting of dendrimer **4** with modified chain ends, has three times the molar mass of **4**. To increase the mass of dendrimer **4**, two different approaches were initially considered: (i) synthesizing higher generations of the dendrimer or (ii) simply coupling oligomeric groups to the chain ends of the preformed dendrimer. The former would require repetitive steps of activation, coupling, and purification for each generation as required by the protocols of dendrimer synthesis. Also, a potential difficulty would arise if steric hindrance at the focal point caused incomplete coupling for dendrimers of higher generations. The second approach, however, provides a significant increase in mass in a single step while still preserving the regular dendrimer structure. Thus, the second approach was followed.

For the preparation of **7** (Scheme 2) a capping agent consisting of monomethyl ether tri(ethylene glycol) was selected, since poly(ethylene glycol) and its derivatives are used extensively for biological applications due to their high water solubility and biocompatibility properties (*38*). To couple this moiety to the hydroxyl functionalized periphery of the dendrimer, an acid derivative of the monomethyl ether of tri(ethylene glycol) was prepared. Therefore, **5** was prepared by reaction of the monomethyl ether of tri(ethylene glycol) with diglycolic anhydride in the presence of (dimethylamino)pyridine (DMAP) as the catalyst. Compound **5** is more soluble in water than an analogous compound prepared from succinic anhydride we also prepared, and therefore was deemed to be better suited for our purposes. An excess of the capping agent **5** was reacted with the polyhydroxylated surface of **3** using DCC as the coupling agent to afford **6**. Although the surface of **6** with its methoxylated end groups is no longer reactive, our objective in preparing this dendritic molecule was to test the effect of increased mass and new building blocks on toxicity and biodistribution. If this system shows promising results after biological evaluation, an end-protected capping agent could be used instead of **5**. Finally, the phenolic protecting group located at the core of **6** was removed by hydrogenolysis to expose the free phenol for radio labeling purposes. The final product **7** has a theoretical mass of 12 182 Da; however, MALDI-TOF MS data suggest that coverage of the surface with **5** only occurred in a 90−95%, yielding a product with a mass of ca. 11 500 Da.

*Model Compound **11***. In contrast to the true dendrimer **4** and partly modified dendrimer **7**, model compound **11** is a hybrid macromolecule consisting of a commercially available 3-arm poly(ethylene oxide) (PEO) star and terminal dendritic polyester moieties (Scheme 3). The PEO star (MW = 22 550) used as a core for **11** contributes the majority of the molar mass of the hybrid. The linearity of the PEO arms also leads to a macromolecule with a larger hydrodynamic volume, which may contribute to an increase in plasma half-life without compromising either water solubility or biocompatibility (*38*). In addition, the star shape of the core provides a multivalency of three, as opposed to a valency of one for the more traditional monofunctionalized linear polymers.

Scheme 2

A divergent approach was followed for the synthesis of **11**. The same chemistry described above was used for the coupling steps and activation of the surface of the dendrons. To incorporate the dendritic moieties, the terminal hydroxyl groups of the PEO-star were coupled to the isopropylidene ketal derivative of the 2,2-bis-(hydroxymethyl)propanoic acid monomer unit in the presence of DCC. Activation of the chain ends of **8** was performed under mild acidic conditions to afford a star with six hydroxyl groups, each of which was further used for generation growth. Therefore, second generation dendrons were grown from the hexahydroxylated PEO core, eventually yielding product **11** with a total of 12 hydroxyl groups capable of further modifications (Scheme 3). Dendritic star **11** has a molar mass of ca. 23 500 Da and is highly water soluble (≥ 200 mg/mL). Unlike its dendrimer analogue **4**, the hybrid is not monodisperse but has a very low PDI reflecting that of its PEO core (PDI = 1.03). Due to their perfect structure, the incorporation of the dendritic moieties does not alter the polydispersity of the initial star affording a conjugate in which the periphery of the dendrons provides perfect multivalency with 12 hydroxyl groups available for both drug attachment and release. The PEO-star also contributes to the easy purification of **11** and its precursors by precipitation in diethyl ether affording a white solid, while the excess of reagents and byproducts remained in solution.

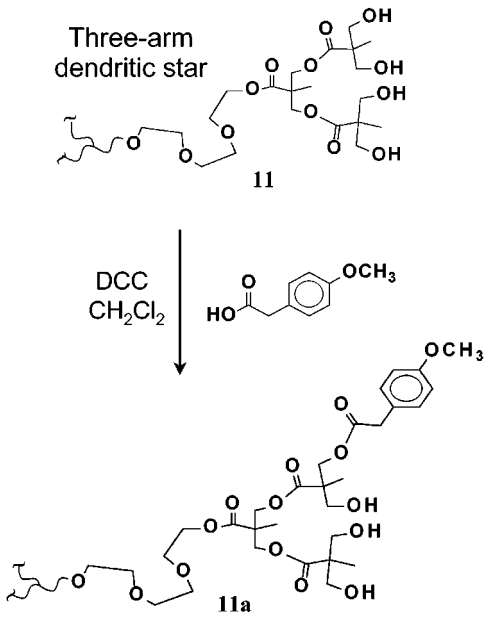


Model compound **11** does not contain a moiety that could be used as a handle for radiolabeling as was the case for **4** and **7**, each which contain a free phenolic group. Therefore, **11** was allowed to react with 2 equiv of 4-methoxyphenyl acetic acid per molecule of polymer under DCC coupling conditions, as shown in Scheme 4, to produce the statistically modified molecule **11a** that contains activated aromatic rings for radiolabeling and subsequent biodistribution studies.

Polymer−Drug Conjugate. Model compound **11** with its higher mass may exhibit the best properties of our three model compounds in terms of serum half-life (*7*). Therefore, a drug-conjugate was prepared from **11** to test the feasibility of the modification of the surface of these dendritic structures for attachment of a drug.

When preparing a polymer−drug conjugate, it is important to consider the mechanism of release and the location of the link used for drug attachment and release. A linkage that is stable under physiological conditions but sufficiently labile to be readily cleaved within the target tissue is the goal. The literature describes release mechanisms for covalently attached drugs that include acid-labile and enzyme-cleavable linkages (*39*−*43*). It has been difficult to specifically address enzyme cleavable linkages because enzymes levels vary at the target site and the rates of drug release from various systems can be appreciably influenced by the characteristics of the drug (*44*). On the other hand, the release rate of an acid labile linkage is often less affected by the type of drug after cellular uptake of the conjugate into the more acidic environment of the lysosomal cellular compartment. The environment around tumor tissue is also slightly more acidic than normal tissue. Therefore, an acid labile linkage might be suitable for drug release in the vicinity of a tumor even before the drug conjugate is internalized by the cancer cell.

The drug selected for the preparation of the drug−polymer conjugate was the anticancer drug doxorubicin (DOX). DOX contains several functional groups that could be utilized for polymer attachment. Typically, the sugar amino group has been used for the formation of hydrolyzable amide linkages. However, amide linkages may be too stable toward acid catalyzed hydrolysis. On the other hand, the keto group of DOX can be used to form an acid labile hydrazone linkage. An acid labile Schiff base could also be generated from this keto group,

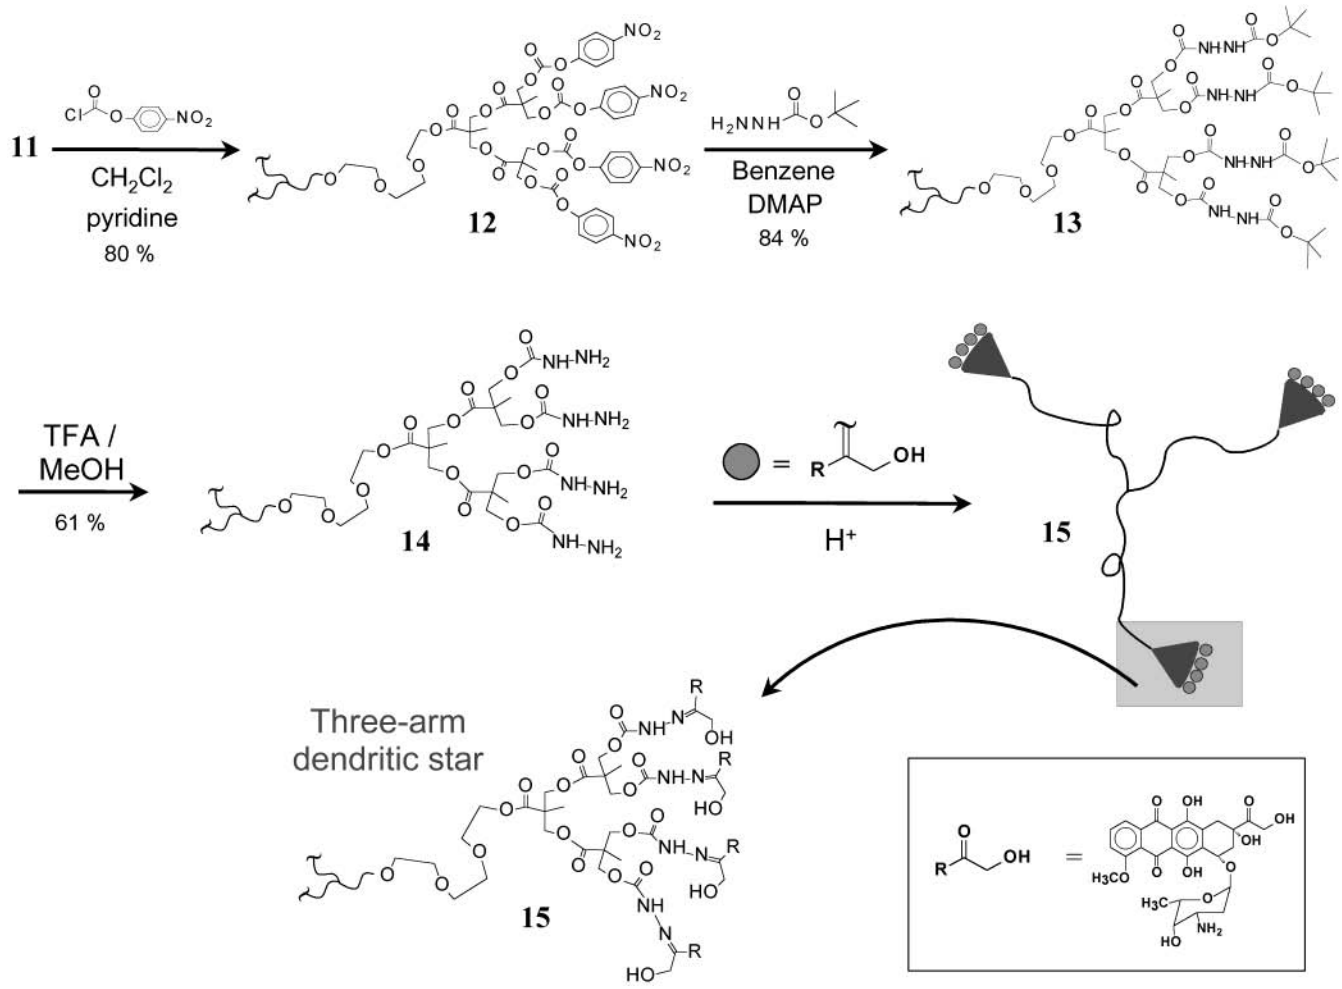


Scheme 3

but imines are thermodynamically less stable than hydrazones under physiological conditions (*45*). Therefore, the polyhydroxylated surface of the polyester dendrons on **11** was modified to produce hydrazides that could further be coupled to the ketone moiety of DOX, forming compound **15** that has the desired hydrazone linkage between the polymeric carrier and DOX.

For the surface modification of **11**, the hydroxyl groups were activated by reaction with an excess of 4-nitrochloroformate in the presence of pyridine, yielding **12** (Scheme 5). This activation step was followed by the displacement of 4-nitrophenol upon nucleophilic attack of *tert*-butyl carbazate in the presence of a catalytic amount of DMAP. It is noteworthy that this reaction could be driven to completion only when benzene was used as a solvent. The hydrazide groups of **13** were then deprotected using a (1:1) TFA/CH_2Cl_2 mixture to afford **14**. Finally, the polyhydrazide chain ends were coupled to an excess of DOX in acidic methanol, forming the hydrazone linkage between the polymeric carrier and the drug (Scheme 5). The product was isolated from the excess DOX by purification with Sephadex LH-20 resin. The coupling of DOX to the polyhydrazide surface proceeded to an extent

Scheme 4



of only approximately 50% (6 out of 12 sites), based on MALDI-TOF MS and UV absorbance measurements, affording a conjugate with a mass of ca. 27 200 Da (**15**). The incomplete coupling observed in this reaction may be due to the reversible character of hydrazone formation under acid-catalyzed conditions (*46*). Conjugate **15**, obtained as a red solid, exhibited very different solubility properties when compared to its precursors. It was not soluble in common organic solvents such as tetrahydrofuran (THF) and CH_2Cl_2. However, it was soluble in MeOH and water, a finding that further supports the covalent character of **15** as opposed to a mixture of two separate compounds.

General Characterization. The techniques used for characterization of the dendrimers and 3-arm star PEO-dendrimer hybrids include ^{1}H NMR, ^{13}C NMR, size exclusion chromatography (SEC), electrospray MS, and MALDI-TOF MS. MALDI signals for model compound **4** and its precursors were not detected. However, the molecular ions and multiply charged species of the corresponding molecules were observed by electrospray MS. Peaks corresponding to incompletely deprotected chain ends were not observed. Even though SEC cannot detect small imperfections, it was a valuable technique for monitoring coupling of the dendrons to the trisphenolic core and to assess the purity after purification from any remaining [G-4]-COOH. MALDI-TOF MS was also the preferred technique for the characterization of **6** and model compound **7**, due to the small but inherent polydispersity of the short PEO moieties attached to the surface of the dendrimer. These PEO derivatives, although mainly consisting of three repeat units of ethylene glycol, also contained ca. 5% of the oligomers with two or four repeat units. Therefore, it imparted a wider range of molecular weights to the resulting molecule. However, SEC indicated a low polydispersity (PDI = 1.03) for this modified dendrimer. MALDI−TOF MS was also helpful in confirming the high degree of coupling (~ 95%) of **5** to the surface of **4**.

For the 3-arm star PEO-dendrimer hybrids the most valuable characterization technique was ^{1}H NMR. The signals corresponding to the quaternary methyl of the monomer unit (1.1−1.3 ppm), and the set of two singlets corresponding to the methyl groups of the isopropylidene

Scheme 5

ketal protecting group (~1.4 ppm) are very sharp and highly differentiated. These signals integrate well with the triplet (~ 4.3 ppm) of the terminal methylene alcohol of the PEO star formed after esterification. The methylene protons of the monomer unit are also well resolved. If the coupling reaction had been incomplete, these peaks would have been observed as several sets of signals, whereas just one sharp set was observed when the desired product was obtained. For the modification of **11**, ^{1}H NMR was also the most helpful technique because it was not possible to observe the individual signals corresponding to the dendritic units by ^{13}C NMR after introduction of the *t*-Boc groups on the surface and their cleavage (**13**, **14**). Only the individual signal of the PEO core (~ 70.4 ppm) was observed even with a variety of solvents and concentration conditions with overnight scanning at 125 MHz. In contrast, all of the signals were clearly present and correlated with the integration in the ^{1}H NMR analysis. MALDI-TOF MS also showed the general trend corresponding to an increase in the mass of these hybrids. A discrepancy in mass for **12** and **13** may be due to partial cleavage of the surface groups upon reaction with the acidic matrix. However, after cleavage of these groups (**14**), the mass correlates well with expected values. The characterization of **15** was made more difficult by the lack of detailed information available in the ^{1}H NMR spectrum with its very broad signals. In this case, MALDI-TOF MS and comparison of UV absorbance spectrum of **15** (λ = 490 nm) against a doxorubicin calibration curve were used to determine the degree of drug coupling on the surface of the carrier. SEC studies proved inconclusive due to solubility issues or the existence of strong interactions between the anthracene ring of DOX and the solid support leading to extreme peak broadening. However, Figure 3 shows the HPLC trace of the conjugate, which suggests a highly regular system.

Further evidence for the low polydispersity of the various carriers is demonstrated in Figure 4 in which precursors of **4** and **14** were evaluated since their highly hydrophilic surface leads to strong interactions with the solid support. These SEC measurements confirm the low polydispersities for **2**, **7**, and **13**, 1.01, 1.03, and 1.05, respectively, as well as the progressive decrease in retention time as a result of the increase in size for the three carriers.

CONCLUSIONS

The necessity for the development of low polydispersities and structurally well-defined polymeric systems with potential use as drug carriers has motivated the design and preparation of dendritic polymeric scaffolds based on an aliphatic polyester backbone derived from 2,2-bis(hydroxymethyl)propanoic acid as the building block. These systems were designed to meet the needs of their intended use as drug carriers, including water solubility, nontoxicity, and stability of the polymeric backbone. The low polydispersity of the model systems has been demonstrated. In addition, model compounds **4**, **7,** and **11** all showed excellent water solubility properties (≥ 200 mg/mL) making them excellent candidates

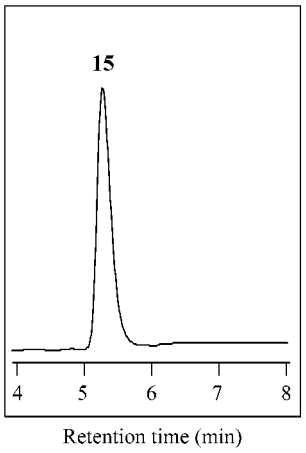


Figure 3. HPLC chromatogram of polymer−doxorubicin conjugate (**15**).

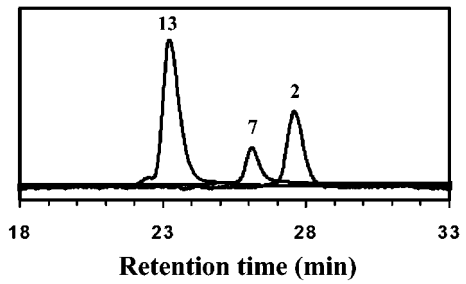

Figure 4. Size exclusion chromatography (SEC) traces of **2**, **7**, and **13** showing the low polydispersity of the systems prepared.

for further biological evaluation. In addition to the polymeric carriers, the feasibility for the modification of the surface of the polyester dendrimers and the preparation of a drug−polymer conjugate (**15**) have been demonstrated. The lack of quantitative coupling of DOX to the surface of the dendrons may be explained by thermodynamic factors due to the equilibrium conditions that prevail in the acid-catalyzed formation of the hydrazone linkage and perhaps some additional steric factors. These issues will be evaluated soon to optimize the coupling of the drug to the multifunctional carrier. Nevertheless, the carriers exemplified in this report show great promise due to their high degree of structure definition, polyvalency, and other desirable characteristics.

EXPERIMENTAL SECTION

General Procedures. All chemicals were purchased from Aldrich and used without any further purification. Solvents (Fischer) were reagent grade (99.9%). The 3-arm star poly(ethylene oxide) was purchased from Shearwater Polymers, Inc. (Huntsville, AL). ^{1}H and ^{13}C NMR spectra were recorded on Bruker AMX 300, AM 400 or DRX 500, as specified. The solvents used were $CDCl_3$ and DMSO-d_6. The solvent signals were used as internal standards for both ^{1}H NMR and ^{13}C NMR spectra. Size-exclusion chromatography (SEC) with double detection was performed at 45 °C on a chromatography line consisting of an M510 pump, a U6K universal injector, three 7-μm ultra-Styragel columns with pore sizes 100 Å, 500 Å, and a linear column, a differential refractive index (DRI) detector M410, and a photodiode array (PDA) detector M991 (Waters). THF was used as eluent at a nominal flow of 1 mL/min. The molecular weights and polydispersity were computed using a calibration curve constructed by polystyrene standards with narrow molecular weight distribution. Corrections for the flow rate fluctuation were made by using toluene as an internal standard. HPLC analysis was performed in a Model 2690 XE Alliance Separations module (Waters, USA) with built-in autoinjector and Photodiode Array detector (Waters 996). A Waters Symmetry C18 column (2.1 × 150 mm, 3.5 μm) was used with 40% phosphate buffer pH 7.0/60% methanol; 0.3 mL/min as mobile phase. MALDI-TOF MS data was collected on a PerSeptive Biosystems Voyager-DE instrument. The matrix used was α-cyano-4-hydroxycinnamic acid, and no silver trifluoroacetate was used. Electrospray and FAB mass spectrometry measurements were performed in the facilities of UC Berkeley. Elemental analyses were carried out by M-H-W Laboratories (Phoenix, AZ).

Preparation of Monoprotected Trisphenolic Core 1. The trisphenolic core (5.67 g, 18.51 mmol, 2 equiv) was dissolved in 150 mL of a 1:1 mixture of pyridine and CH_2Cl_2. The solution was placed in an ice bath and after stirring of the sample for 15 min, benzylchloroformate (1.58 g, 9.25 mmol, 1 equiv) was added dropwise. The reaction mixture was stirred for 1 h at 0 °C and warmed to room temperature. The solvent was evaporated and the residue was dissolved in CH_2Cl_2, followed by extraction with a 2 M HCl solution and H_2O. The organic layer was dried over $MgSO_4$, and the solvent was evaporated. The monoprotected product was separated from minor amounts of the diprotected product by column chromatography, using a gradient from CH_2Cl_2 to CH_2Cl_2/THF (1:1). A colorless solid product was obtained in a 50% yield (2.04 g, 4.63 mmol). IR (cm^{-1}, thin film from $CHCl_3$): 3359 (s), 1893, 1736. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 2.10 (s, 3), 4.69 (s, 2), 5.26 (s, 2), 6.72 (d, 4, J = 8.5), 6.94 (d, 4, J = 8.5), 7.07 (m, 4), 7.40 (m, 3), 7.45 (m, 2). ^{13}C NMR ($CDCl_3$, 100 MHz): δ 30.80, 50.92, 70.37, 110.48, 114.65, 120.17, 128.56, 128.68, 128.77, 129.66, 129.81, 134.73, 141.30, 147.42, 149.08, 153.61. Calcd.: $[M]^+$ m/z = 440.162374. Found: LRFAB-MS: $[M]^+$ = 440, HRFAB-MS: $[M]^+$ = 440.16108. Anal. Calcd. for $C_{28}O_5H_{24}$: C 76.35%, H 5.49%. Found: C 73.05%, H 5.87%.

Preparation of the Isopropylidene Ketal Protected Dendrimer 2. The [G-4]-COOH polyester dendron (3.0 g, 1.4 mmol, 2.2 equiv), prepared as previously reported (*37*) and 0.17 g (0.66 mmol, 1.0 equiv) of the monoprotected tris phenolic core were dissolved in 3 mL of CH_2Cl_2. Following addition of 0.34 g of DCC (1.64 mmol, 2.5 equiv) and a catalytic amount of DPTS (0.08 g, 0.26 mmol, 0.40 equiv), the reaction mixture was stirred overnight at room temperature. The product was purified by column chromatography using a mixture of hexanes and ethyl acetate (20:80) as eluent to afford 1.23 g (73%) of a white solid. IR (cm^{-1}, thin film from $CHCl_3$): 2990, 1740 (br). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 1.12 (s, 48), 1.26 (s, 24), 1.33 (s, 48), 1.39 (s, 48), 1.43 (s, 6), 2.16 (s, 3), 3.60 (d, 32, J = 11.7), 4.13 (d, 32, J = 11.7), 4.34 (m, 56), 5.25 (s, 2), 6.98 (d, 4, J = 8.7), 7.09 (bs,4), 7.11 (m, 8), 7.42 (m, 5). ^{13}C NMR ($CDCl_3$, 100 MHz): δ 17.51, 17.61, 18.42, 21.97, 25.13, 41.95, 46.67, 46.75, 46.99, 51.61, 64.74, 65.40, 65.83, 65.88, 70.28, 98.00, 120.44, 120.64, 128.47, 128.62, 128.71, 129.57, 129.74, 134.68, 146.02, 146.38, 148.49, 149.36, 153.51, 170.58, 171.38, 171.74, 173.39. Calcd: $[M]^+$ m/z = 4562.083502. Found: LRES-MS: $[MNa_2]^{+2}$ m/z = 2305.2, $[MNa_3]^{+3}$ m/z = 1544.7, $[MNa_4]^{+4}$ m/z = 1116.2. Anal. Calcd. for $C_{226}O_{95}H_{328}$: C 59.46%, H 7.24%. Found: C 59.60%, H 7.21%.

Preparation of Core-Monoprotected Dendrimer 3. For the deprotection of the hydroxyl groups of **2**, 1.12 g (0.22 mmol) of **2** was dissolved in 10 mL of methanol,

followed by the addition of 2 mL of 2 M H_2SO_4. The reaction mixture was stirred at room temperature for 2 days. The mixture was neutralized with a MeOH/NH_3 (1:1) solution. The ammonium sulfate salt was removed by filtration, and the solvent of the filtrate was evaporated to afford a quantitative yield (0.96 g) of a colorless solid product. IR (cm^{-1}, thin film from THF): 3369 (s), 2941, 1735 (s). ^{1}H NMR (DMSO-d_6, 500 MHz): δ 1.01 (s, 48), 1.14 (s, 24), 1.21 (s, 12), 1.36 (s, 6), 2.15 (s, 3), 3.45 (m, 64), 4.14 (bs, 32), 4.22 (bs, 16), 4.34 (d, 4, J = 9.5), 4.40 (d, 4, J = 9.5), 4.64 (bs, 32), 5.26 (s, 2), 7.12 (m, 12), 7.41 (m, 5). ^{13}C NMR (DMSO-d_6, 100 MHz): δ 16.73, 16.97, 17.17, 17.94, 30.45, 34.39, 46.30, 46.65, 50.27, 51.36, 63.72, 64.41, 65.37, 65.82, 69.83, 69.86, 120.75, 120.97, 124.94, 125.52, 128.41, 128.59, 129.46, 135.03, 146.18, 148.32, 148.97, 151.49, 152.96, 170.81, 171.49, 171.88, 174.07. Calcd: $[M]^+$ m/z = 3921.582700. Found: LRES-MS: $[MNa_2]^{+2}$ m/z = 1985.0, $[MNa_3]^{+3}$ m/z = 1330.9. Anal. Calcd for $C_{178}O_{95}H_{264}$: C 54.48%, H 6.78%. Found: C 54.23%, H 6.91%.

Preparation of Dendrimer 4. Dendrimer **3** (0.280 g, 0.071 mmol) was dissolved in 2 mL of ethyl acetate, and 0.04 g of Pd/C 10% was added. Following evacuation of the system, an atmosphere of H_2 under medium pressure was applied to the reaction mixture using a rubber balloon. After the sample was stirred vigorously for 6 h at room temperature, the catalyst was removed by filtration. A solid product was obtained in quantitative yield after evaporation of the solvent (0.27 g). IR (cm^{-1}, thin film from THF): 3367 (s), 2947, 1741 (s). ^{1}H NMR (DMSO-d_6, 500 MHz): δ 0.998 (s, 48), 1.136 (s, 24), 1.202 (s, 12), 1.348 (s, 6), 2.076 (s, 3), 3.363−3.505 (m, 64), 4.102 (bs, 32), 4.215 (bs, 16), 4.33 (d, 4, J = 9.5), 4.382 (d, 4, J = 9.5), 4.627 (bs, 32), 6.678 (d, 2, J = 8.0), 6.824 (d, 2, J = 8.0), 7.014 (m, 4), 7.102 (m, 4). ^{13}C NMR (DMSO-d_6, 125 MHz): δ 16.73, 16.95, 17.15, 17.94, 40.01, 46.28, 50.26, 63.69, 64.38, 65.03, 69.81, 120.72, 125.50, 128.08, 129.42, 137.64, 138.51, 147.01, 147.89, 170.83, 171.48, 171.86, 174.06. Calcd: $[M]^+$ m/z = 3789.86. Found: LRES-MS: $[MNa_2]^{+2}$ m/z = 1917.4, $[MNa_3]^{+3}$ m/z = 1286.0. Anal. Calcd for $C_{170}O_{93}H_{258}$: C 53.88%, H 6.86%. Found: C 51.96%, H 6.89%.

Preparation of 5. Tri(ethylene glycol) monomethyl ether (14.65 g, 89.20 mmol) was diluted with 60 mL of acetonitrile. DMAP (1.09 g, 8.92 mmol) used as a catalyst and diglycolic anhydride (10.87 g, 93.66 mmol) were added to the reaction mixture. After the reaction mixture was stirred for 24 h at room temperature, the solvent was evaporated and the crude product was diluted with 12 mL of acidified brine. The product was extracted with ethyl acetate. The combined organic layers were dried over $MgSO_4$. After removal of the drying agent by filtration, the solvent was evaporated to afford an 80% yield (20 g) of a colorless slightly viscous oil as a product. IR (cm^{-1}): 3400−2500 (br), 1753, 1140. ^{1}H NMR ($CDCl_3$, 400 MHz): δ 3.83 (s, 3), 3.56 (t, 2, J = 3.2), 3.66 (bs, 6), 3.72 (dt, 2, J = 3.2, 4.8), 4.25 (s, 2), 4.30 (s, 2), 4.35 (dt, 2, J = 3.2, 4.8). ^{13}C NMR (DMSO, 100 MHz): δ 58.72, 63.78, 63.98, 67.77, 68.13, 68.62, 70.19, 70.81, 71.62, 169.97, 171.88. Calcd: $[M]^+$ m/z = 280.115818. Found: LRES-MS $[M-H]^-$ m/z = 279.2. Anal. Calcd for $C_{11}O_8H_{20}$: C 47.14%, H 7.19%. Found: C 47.04%, H 6.96%.

Preparation of Surface Modified Dendrimer 6. The polyol **3** (0.94 g, 0.24 mmol, 1 equiv) was dissolved in 1 mL of pyridine and 15 mL of CH_2Cl_2. The acid derivative of tri(ethylene glycol) monomethyl ether (4.30 g, 15.36 mmol, 64 equiv) was added, followed by the addition of 3.17 g (15.36 mmol) of DCC and 1.02 g (3.48 mmol) of DPTS as a catalyst. The reaction mixture was stirred overnight at room temperature. The dicyclohexyl urea (DCU) formed as a byproduct was removed by filtration, and the solvent of the filtrate was evaporated. Trace amounts of DPTS present in the product were removed by filtration from a toluene solution and precipitation in diethyl ether. The colorless oily product was obtained in a 65% yield (1.91 g). IR (cm^{-1}, thin film from $CHCl_3$): 1737 (s), 1154 (s). ^{1}H NMR ($CDCl_3$, 400 MHz): δ 1.18 (bs, 72), 1.26 (s, 12), 1.41 (s, 6), 2.11 (s, 3), 3.32 (s, 96), 3.49 (m, 64), 3.59 (m, 224), 3.65 (m, 64), 4.19 (bs, 208), 4.24 (m, 64), 4.37 (m, 8), 5.21 (s, 2), 7.13 (m, 12), 7.30 (m, 5). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 17.42, 17.63, 46.21, 46.49, 58.87, 63.81, 64.98, 67.61, 67.79, 68.73, 70.39, 70.42, 71.77, 120.45, 120.62, 128.40, 128.57, 129.69, 132.29, 169.21, 169.58, 171.35, 171.52. Calcd: $[M]^+$ m/z = 12,316.63. Found: MALDI-TOF MS: $[M]^+$ = 11,930, $[M]^{+2}$ = 23,505. Anal. Calcd for $C_{530}O_{319}H_{840}$: C 51.69%, H 6.87%. Found: C 51.60%, H 6.73%.

Preparation of Dendrimer 7. The precursor **6** (1.7 g, 0.138 mmol) was dissolved in 6 mL of ethyl acetate. After the addition of 0.16 g of Pd/C 10%, the system was evacuated and the reaction mixture was stirred overnight at room temperature under H_2 atmosphere at 700 psi. The catalyst was removed by filtration, and the solvent was evaporated, affording 1.17 g of the product as an oil (70%). IR (cm^{-1}, thin film from $CHCl_3$): 3485, 2887, 1737 (s), 1145 (s). ^{1}H NMR ($CDCl_3$, 400 MHz): δ 1.10 (s, 12), 1.17 (bs, 48), 1.24 (s, 24), 1.40 (s. 6), 2.04 (s, 3), 3.34 (s, 96), 3.51 (bs, 64), 3.61 (bs, 224), 3.67 (bs, 64), 4.21 (bs, 272), 6.69 (d, 2, J = 7), 6.85 (d, 2, J = 7), 6.94 (d, 4, J = 7), 7.07 (d, 4, J = 7). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 17.02, 17.22, 17.48, 46.11, 46.41, 48.21, 51.04, 58.70, 61.30, 63.37, 63.72, 63.91, 64.99, 67.50, 67.70, 67.88, 68.04, 68.58, 69.99, 70.11, 70.17, 70.23, 70.28, 71.59, 72.16, 114.73, 120.33, 129.31, 129.56, 147.08, 148.10, 169.18, 169.56, 169.94, 171.18, 171.78, 172.89. Calcd: $[M]^+$ m/z = 12,182.17. Found: MALDI-TOF MS: $[M]^+$ = 11,458.

Preparation of 3-Arm Star PEO−Dendrimer Hybrid 8. The hydroxy terminated 3-arm PEO star of 22 550 Da (as measured by MALDI) (2.0 g, 0.1 mmol) and the propylidene ketal derivative of 2,2-bis(hydroxymethyl)propanoic acid were mixed and dissolved in 5 mL of CH_2Cl_2. DMAP was added as a catalyst (0.12 g, 1.0 mmol), followed by DCC (0.62 g, 3.0 mmol). The reaction mixture was stirred at room temperature under N_2 atmosphere for 3 h. After filtration of the DCU formed as a byproduct, the polymer was precipitated from CH_2Cl_2 solution into diethyl ether. The polymer was collected by filtration. Trace amounts of DMAP still present were removed by filtration after dissolving the polymer in benzene. The product was precipitated from the benzene solution directly into diethyl ether and filtered to yield 1.44 g (70%) of the product. IR (cm^{-1}, thin film from $CHCl_3$): 2874, 1730 (w), 1100 (s). ^{1}H NMR ($CDCl_3$, 400 MHz): δ 1.21 (s, 9), 1.38 (s, 9), 1.42 (s, 9), 3.46 (t, 16, J = 5.0), 3.64 (bs, 2140), 3.81 (t, 10, J = 5.0), 4.19 (d, 6, J = 10.8), 4.29 (t, 6, J = 4.8). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 18.60, 22.98, 24.13, 41.69, 56.79, 63.63, 63.78, 65.84, 68.91, 70.46, 97.94, 174.04. Calcd: $[M]^+$ m/z = 23,018. Found: MALDI-TOF MS: $[M]^+$ = 23,000. Anal. for **8**: Found: C 54.56%, H 8.46%.

Preparation of Hybrid 9. A mixture of 1.24 g (0.06 mmol) of **8** in 6 mL of MeOH and 2 mL of a 2 M H_2SO_4 solution was stirred overnight at room temperature. The crude reaction mixture was neutralized with a 7 N solution of ammonia in methanol and the ammonium sulfate salt was filtered off. The product was then precipitated from the filtrate in diethyl ether. The white solid product was recovered in a 62% yield (0.77 g). IR

(cm^{-1}, thin film from $CHCl_3$): 3484, 2885, 1727 (w), 1102 (s). ^1H NMR ($CDCl_3$, 300 MHz): δ 1.11 (s, 9), 3.64 (bs, 2288), 4.33 (t, 6, $J = 4.8$). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 17.06, 49.57, 56.75, 63.27, 63.59, 67.18, 68.70, 70.30, 84.09, 175.59. Calcd: $[M]^+$ $m/z = 22{,}895$. Found: MALDI-TOF MS: $[M]^+ = 22{,}890$. Anal. for **9**: Found: C 52.49%, H 8.40%.

Preparation of Hybrid 10. Polyol **9** (2.96 g, 0.15 mmol) was dissolved in 20 mL of CH_2Cl_2. DMAP (0.18 g, 1.45 mmol) and DCC (0.90 g, 4.34 mmol) were added and the reaction mixture was stirred overnight at room temperature under N_2 atmosphere. The DCU was filtered off and the product was precipitated from CH_2Cl_2 solution in diethyl ether affording a white powder in 80% yield. IR (cm^{-1}, thin film from $CHCl_3$): 2884, 1737, 1106 (s). ^1H NMR ($CDCl_3$, 300 MHz): δ 1.14 (s, 18), 1.20 (s, 9), 1.35 (s, 18), 1.40 (s, 18), 3.63 (bs, 2160), 4.14 (d, 12, $J =$ 11.7). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 17.67, 18.50, 22.21, 24.94, 41.98, 46.68, 63.70, 64.21, 65.20, 65.88, 65.93, 68.79, 70.53, 98.05, 172.47, 173.47. Calcd: $[M]^+$ $m/z =$ 23,831. Found: TOF-MALDI MS: $[M]^+ = 23{,}801$. Anal. for **10**. Found: C 54.26%, H 9.01%.

Preparation of Hybrid 11. A solution of 2.71 g (0.13 mmol) of **10** in 12 mL of MeOH was mixed with 4 mL of 2 M H_2SO_4, and the mixture was stirred overnight at room temperature, then neutralized with 7 N ammonia solution in methanol. The ammonium salt was removed by filtration and the product was purified by precipitation in diethyl ether. The product was recovered in 84% (2.25 g). IR (cm^{-1}, thin film from $CHCl_3$): 3459, 1736, 1105. ^1H NMR ($CDCl_3$, 400 MHz): δ 1.07 (s, 18), 1.31 (s, 9), 3.64 (bs, 2437), 4.31 (m, 12), 4.40 (d, 6, $J = 11.2$). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 17.11, 17.99, 46.44, 49.72, 63.68, 64.89, 67.56, 70.50, 173.01, 175.02. Calcd: $[M]^+$ $m/z = 23\,591$. Found: MALDI-TOF MS: $[M]^+ = 23\,583$. Anal. for **11**. Found: C 54.47%, H 9.04%.

Preparation of 11a. A solution of **11** (1.00 g, 0.042 mmol) in 5 mL of CH_2Cl_2 was treated with *p*-methoxyacetic acid (16 mg, 0.096 mmol), DMAP (58 mg, 0.474 mmol), and then DCC (20 mg, 0.097 mmol). The reaction mixture was stirred at room temperature for 5 h, and the product was precipitated from the reaction mixture into diethyl ether affording 0.86 g of product. IR (cm^{-1}, thin film from $CHCl_3$): 3449, 1731, 1135. ^1H NMR (DMSO-d_6, 300 MHz): δ 0.99 (s, 18), 1.16 (s, 9), 3.39 (bs, 3322), 4.09 (m, 20), 4.62 (t, 6, $J = 4.8$), 4.95 (t, 1, $J =$ 4.8), 6.85 (d, 6, $J = 9.0$), 7.11 (d, 6 $J = 9.0$). ^{13}C NMR ($CDCl_3$, 100 MHz): δ 17.10, 49.73, 70.49, 113.96, 130.22, 172.82, 176.10. Found: MALDI-TOF MS: $[M]^+ = 23\,897$. Anal. for **11a**. Found: C 54.89%, H 8.72%.

Preparation of Activated Hybrid 12. A solution of 1.07 g (0.05 mmol) of **11** in 4 mL of CH_2Cl_2 was treated with 0.25 mL of pyridine and 0.61 g (3.05 mmol) of 4-nitrophenyl chloroformate. The reaction mixture was stirred overnight at room temperature. The product was recovered in 80% yield after purification by precipitation from the reaction mixture into diethyl ether. IR (cm^{-1}, thin film from $CHCl_3$): 2883, 1774, 1737, 1626, 1593, 1527, 1107. ^1H NMR ($CDCl_3$, 400 MHz): δ 1.34 (s, 9), 1.36 (s, 18), 3.64 (bs, 2453), 4.27 (t, 6, $J = 4.8$ Hz), 4.39−4.53 (m, 36), 7.38 (d, 24, $J = 9.0$), 8.28 (d, 24, $J = 9.0$). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 17.62, 46.56, 5.39, 63.68, 69.10, 70.50, 121.71, 125.28, 145.54, 152.04, 155.14, 170.98. Calcd: $[M]^+$ $m/z = 25\,571$. Found: MALDI-TOF MS: $[M]^+ = 25{,}100$. Anal. for **12**. Found: C 56.39%, H 8.96, N 0.70%.

Preparation of *t*-Boc Terminated Hybrid 13. The protected hydrazide was coupled to **12** by dissolving 0.84 g (0.04 mmol) of **12** in 5 mL of benzene, followed by the addition of DMAP (0.02 g, 0.15 mmol) and *tert*-butyl carbazate (0.29 g, 2.19 mmol). The reaction mixture was stirred at room temperature under N_2 atmosphere for 3 h. The product was purified by precipitation in diethyl ether. The white solid product was recovered by filtration in 84% yield (0.69 g). IR (cm^{-1}, thin film from $CHCl_3$): 3300, 2885, 1736, 1104. ^1H NMR ($CDCl_3$, 300 MHz): δ 1.18 (s, 18), 1.31 (s, 9), 1.46 (s, 108), 3.64 (bs, 2300), 4.30 (m, 36). Calcd: $[M]^+$ $m/z = 25{,}487$. Found: MALDI-TOF MS: $[M]^+ = 24\,501$. Anal. for **13**. Found: C 53.96%, H 8.37, N 1.34%.

Preparation of Hydrazide Terminated Hybrid 14. The *t*-Boc groups of **13** were cleaved by dissolving 0.62 g (0.03 mmol) of **13** in 4 mL of a (1:1) trifluoroacetic acid (TFA) and CH_2Cl_2 solution. The reaction mixture was stirred for 5 h and the product was precipitated in diethyl ether from the reaction mixture solution, yielding a white powdery product in 61% yield (0.36 g). IR (cm^{-1}, thin film from $CHCl_3$): 3282, 2884, 1737, 1105. ^1H NMR ($CDCl_3$, 300 MHz): δ 1.23 (s, 18), 1.29 (s, 9), 3.64 (bs, 2688), 4.26 (m, 36). Calcd: $[M]^+$ $m/z = 24{,}287$. Found: TOF-MALDI MS: $[M]^+ = 24{,}210$. Anal. for **14**. Found: C 53.33%, H 8.71, N 1.43%.

Preparation of Polymer−DOX Conjugate (15). The polyhydrazide **14** (0.22 g, 0.01 mmol) and an excess of the HCl salt of doxorubicin (95 mg, 0.16 mmol) were dissolved in 3 mL of MeOH. A drop of TFA was added as a catalyst. The reaction mixture was stirred overnight at room temperature. The polymer was precipitated in diethyl ether from the reaction mixture. The solid was recovered by filtration and washed with diethyl ether. The conjugate was purified from free doxorubicin by size exclusion chromatography using Sephadex LH-20 resin and MeOH as the mobile phase. The conjugate fractions were combined, and the solvent was evaporated. The conjugate was redissolved in distilled water and lyophilized, recovering 0.21 g of a spongy red solid as the product (78% based on half coupling). IR (cm^{-1}): 3100−1900 (br), 1739. ^1H NMR (DMSO-d_6, 300 MHz): δ 1.16 (bs, 42), 1.62−1.95 (m, 9), 2.10−2.31 (m, 7), 3.50 (bs, 2200), 3.92 (bs, 18), 4.15 (bs, 38), 4.43 (s, 8), 4.89−5.18 (m, 5), 5.28 (s, 3), 5.44 (d, 3), 5.84 (s, 3), 7.50−8.00 (m, 36). Calcd (full coupling): $[M]^+$ $m/z = 30\,395$. Found: MALDI-TOF MS: $[M]^+ = 27{,}242$. Anal. for **15**. Found: C 54.21%, H 8.57, N 1.43%.

ACKNOWLEDGMENT

We thank the National Science Foundation (DMR-9816166), the Department of Energy (Basic Energy Sciences, and MDI II), the National Institutes of Health, Grant GM65361, and the UC Breast Cancer Research and Development Program (6JB-0137) for support of this research.

Polyester Dendritic Systems for Drug Delivery Applications: In Vitro and In Vivo Evaluation

Omayra L. Padilla De Jesús,[†] Henrik R. Ihre,[†] Lucie Gagne,[‡] Jean M. J. Fréchet,*[,†] and Francis C. Szoka, Jr.*[,‡]

Department of Chemistry, University of California, Berkeley, California 94720-1460 and School of Pharmacy, University of California, San Francisco, California 94143-0446. Received October 22, 2001

High molecular weight polymers (> 20 000 Da) have been widely used as soluble drug carriers to improve drug targeting and therapeutic efficacy. Dendritic polymers are exceptional candidates for the preparation of near monodisperse drug carriers due to their well-defined structure, multivalency, and flexibility for tailored functionalization. We evaluated various dendritic architectures composed of a polyester dendritic scaffold based on the monomer unit 2,2-bis(hydroxymethyl)propanoic acid for their suitability as drug carriers both in vitro and in vivo. These systems are both water soluble and nontoxic. In addition, the potent anticancer drug, doxorubicin, was covalently bound via a hydrazone linkage to a high molecular weight 3-arm poly(ethylene oxide)−dendrimer hybrid. Drug release was a function of pH, and the release rate was more rapid at pH < 6. The cytotoxicity of the DOX−polymer conjugate measured on multiple cancer lines in vitro was reduced but not eliminated, indicating that some active doxorubicin was released from the drug polymer conjugate under physiological conditions. Furthermore, biodistribution experiments show little accumulation of the DOX−polymer conjugate in vital organs, and the serum half-life of doxorubicin attached to an appropriate high molecular weight polymer has been significantly increased when compared to the free drug. Thus, this new macromolecular system exhibits promising characteristics for the development of new polymeric drug carriers.

INTRODUCTION

A variety of approaches have been implemented for the discovery of medicinal compounds, including the isolation of naturally occurring bioactive substances and the design and synthesis of new molecules with biological activity. Many compounds have been identified by these means, but the lack of selectivity of the majority of current highly toxic drugs used for chemotherapy has motivated the search for other means to improve their therapeutic efficacy and increase their selectivity (*1*).

In the past few decades, the use of polymers as carriers of both covalently bound (*2*−*5*) and physically entrapped drug molecules (*6*−*8*) has been widely explored. When a drug is linked to a polymer, it loses activity because it cannot interact with the drug target either due to steric constraints or the inability of the drug to reach the target site (*9*). Furthermore, the drug−polymer conjugate can no longer cross the cellular membrane by simple diffusion, but must do so by endocytosis. The resulting endosomal compartment containing the polymeric conjugate fuses with the more acidic lysosomal compartment (pH 4−5), whose hydrolytic enzymes then degrade the conjugate. This mechanism allows a more selective uptake of therapeutic agents, in contrast to small drugs that can easily diffuse into and out of the cell (*2, 10*). In certain cells, the endocytotic uptake enables drug−polymer conjugates to bypass multidrug resistance (MDR) mediated efflux mechanisms hence to overcome drug resistance in the cancer cells (*11, 12*). Furthermore, the anatomical differences between normal and tumor tissue allows for preferential accumulation of a polymeric drug in neoplastic tissue. High molecular weight polymers preferentially accumulate in solid tumor tissue due to a combination of the leaky character of tumor blood vessels formed during neo-angiogenesis and to limited lymphatic drainage. The combination of these two factors is responsible for the enhanced permeability and retention effect (EPR) observed with tumor tissue, which leads to a passive targeting of drugs to tumors (*13, 14*). In addition, the larger hydrodynamic volume of polymers contributes to the increased plasma half-life of the drug-polymer conjugates, increasing the probability of accumulation of the therapeutic agent in the tumor tissue by means of the EPR effect (*3, 15*). Drugs have also been conjugated to polymers to improve their water solubility properties, to decrease their toxicity due to local accumulation of the drug prior to reaching the target tissue, and to protect them from possible enzymatic degradation or hydrolysis.

Polymers previously evaluated for delivery of covalently attached drugs have primarily been random coil linear polymers such as poly(ethylene glycol) (PEG) (*16*), *N*-(2-hydroxypropyl)methacrylate (HPMA) (*17*), and styrene maleic anhydride (SMA) (*5*). However, the synthesis of some of these systems results in highly polydisperse materials with a wide range of molecular weights due to their mode of preparation (*18*). Molecules of different molecular weights found in a polydisperse sample will behave differently in the body. Therefore, either monodisperse or low-polydisperse (PDI < 1.1) polymers are required to achieve systems displaying homogeneous and reproducible pharmacokinetic properties. The intrinsic properties of dendrimers, with their well-defined structures and their flexibility for tailored functionalization, classify these molecules as good candidates for the assembly of multivalent drug carriers (*19*−*25*).

The well-designed step-by-step preparation of dendrimers results in a monodisperse system (*26*−*28*). Few dendritic systems have been evaluated previously, due to their lack of availability. At present, probably the best-known dendritic system is the polyamidoamine (PAMAM) Starburst family of dendrimers (*29*). These are

Published on Web 04/24/2002

commercially available, but their polycationic character must be pacified to reduce their in vivo toxicity (*30*−*33*). In addition, their polyamidoamine linkage is resistant to degradation in the body. Another well-known dendritic system is based on the polyaryl ether convergent dendrimers (*34*). Although promising preliminary studies were performed with the latter by coupling the drug methotrexate (MTX) (*21*), these dendrimers also have a backbone that is inherently resistant to degradation and thus were thought to be less suitable for drug delivery purposes than other structures incorporating hydrolyzable linkages.

Thus, it is of interest to develop and evaluate novel water-soluble, biocompatible, dendritic systems. A polyester dendritic scaffold based on 2,2-bis(hydroxymethyl)-propanoic acid has been investigated as a possible drug carrier. Herein, the biological evaluation of various polyester dendritic model compounds is described. The biodistribution of a doxorubicin−polymer conjugate is also reported, as well as drug release studies. The synthesis and chemical characterization of the systems evaluated are reported elsewhere (*35*).

MATERIALS AND METHODS

Cell Culture. The murine melanoma cell line B16F10 was obtained from the UCSF Cell Culture Facility. The cells were cultured in prewarmed medium (MEM Eagle's with EBSS medium containing 10% fetal bovine serum, 1% MEM nonessential amino acids, 110 mg/L sodium pyruvate, and 1% penicillin−streptomycin) at 37 °C in a humidified atmosphere composed of 5% CO_2. MDA-MB-231 and MDA-MB-435 breast cancer cell lines were cultured in a medium consisting of Dulbecco's Modified Earl's medium (DME) H-16, containing 10% FBS and 1% MEM nonessential amino acids. The medium for culturing the monkey kidney fibroblast CV-1 cells consisted of DME H-21 (high glucose 4.5 g/L) containing 10% fetal bovine serum, 1% MEM nonessential amino acids, 1% HEPES buffer, and 1% penicillin−streptomycin. For all of our experiments, cells were harvested from subconfluent cultures using trypsin-versene (0.05 and 0.02% respectively) and were suspended in medium. Cell viability was determined using the trypan blue exclusion method.

Cell Cytotoxicity Assay. The cytotoxicity of the polymeric carriers, and of the free or conjugated doxorubicin, was determined using a target cell line and the sulforhodamine B assay (SRB) (*36*). The target cells used were murine B16F10 melanoma cells and the human breast cancer cell lines MDA-MD-231 and MDA-MD-435. Cells were seeded into a 96-well plate at a density of 3×10^4 cells/mL with 100 μL per well for 19 h (37 °C and 5% CO_2) before the assay. The medium of each well was then replaced by 100 μL of antibiotic-free medium containing various concentrations of the polymer with no drug, drug, or conjugated doxorubicin. The tests were conducted in replicates of four to eight for each drug dose. The cells were incubated at 37 °C/5% CO_2. Following the incubation period, the cells were fixed for 1 h at 4 °C by adding 25 μL of ice-cold 50% trichloroacetic acid (TCA) to the growth medium of each well. The wells were washed 5 times with cold water to remove the excess TCA and then air-dried at room temperature for several minutes. Once dry, each well received 100 μL of 0.4% SRB in 1% acetic acid followed with a 30-min incubation at room temperature. The SRB solution was then aspirated off the cells and the wells were quickly washed with 1% acetic acid. The wells were air-dried at room temperature for several minutes until moisture was no longer detected visually. The dye bound to the cells was solubilized by adding 100 μL of 10 mM Tris base, unbuffered, per well and agitated for 5 min at room temperature. The optical densities were obtained using an OPTIMAX microplate reader (Molecular Devices, Sunnyvale, CA) at a wavelength of 564 nm. OD measured on wells containing cells that did not receive the drug were considered to represent 100% growth, and OD measured on wells containing no cells but that received drug are considered to represent 0% growth. The IC50 is evaluated by comparing the OD of wells containing cells that were exposed to at least five doses.

Maximum Tolerated Polymer Intravenous Bolus Dose. The polymers were dissolved at 162 mg/mL in HBS. CD-1 female mice, 6−8 week-old, were injected with increasing volumes of polymer solution via the tail vein and observed for 24 h postinjection. All mice were then anesthetized with an intraperitoneal injection of ketamine cocktail (44 mg Ketamine; 2.5 mg Xylazine; 0.75 mg acepromazine in PBS per kg of body mass) and their liver dissected and observed under a dissecting microscope for signs of toxicity.

Radiolabeling Methods. Compound **I** and **II** were iodinated using carrier-free ^{125}I and the chloramine T reaction as previously described (*37*). The radiolabeled polymer was separated from noncovalently attached iodine on a Sephadex G-25 column. Compound **III** containing the methoxyphenol group was not readily radiolabeled when using the chloramines T reaction described in ref *37* but was readily radioiodinated using noncarrier iodine and an electrophilic protocol based upon Krummeich et al (*38*). In brief, 3 mg of **III** was dissolved in 0.25 mL of trifluoroacetic acid (TFA), and 0.01 mL of an aqueous solution of ^{125}I was added containing 1 mCi ^{125}I. Chloramine T (0.54 mg) dissolved in 0.05 mL of TFA was added to the mixture, and the reaction was heated at 60 °C for 5 min. The reaction was stopped by the addition of sodium metabisulfite, 1 mg in 0.01 mL of water, and the TFA was evaporated under a stream of nitrogen that was vented through a trap containing activated carbon (Dupont-New England Nuclear, MA). The residue was dissolved in 0.1 mL of 0.1 N NaOH containing 100 mM sodium metabisulfite and chromatographed on a column containing 1.8 mL bed volume of Dowex 2 anion-exchange resin. The radiolabeled polymer was eluted in the first 4 mL using water as the mobile phase. There was about a 20% incorporation of radioiodine into the polymer under these conditions. The mixture was rechromatographed two additional times, and greater than 99% of the radioactivity eluted with the polymer fraction. The radiolabeled material eluted in the void volume from a Sephadex 25 size exclusion column.

A suitable quantity of radiolabeled polymer was mixed with the nonradiolabeled polymer in sterile HBS to create a 10 mg/mL polymer concentration with a specific activity of 4 μCi/mL for use in the biodistribution studies.

Biodistribution Assays for Compounds I, II, and III. A known amount of radiolabeled polymer was added to a stock solution of nonradiolabeled polymer prepared at a concentration of 10 mg/mL in sterile HBS, and 100 μL was injected intravenously into 6−8 week-old CD-1 female mice. Each mouse was housed separately to collect the urine and feces. At different times postinjection, either three or four mice per group were anesthetized with an intraperitoneal injection of a ketamine cocktail and sacrificed. The feces and urine were collected. Each mouse was bled by heart puncture, and the volume of blood measured and transferred to a scintillation vial. The circulation system was perfused with PBS via the

right ventricle to reduce blood in the organs. All the organs were collected separately and transferred to preweighed scintillation vials. The carcass was sectioned into three portions and placed into preweighted vials. The radioactivity contained in each organ was counted on a Beckman Gamma 8000 Spectrometer (Irvine, CA) and expressed as counts per minute/gram of tissue. Using this procedure we were able to account for 95 ± 5% of the injected radioactivity.

Blood Clearance Assay for Compounds I, II, and III. Female mice of 6−8 week-old (Charles River) were injected with 1 mg of radiolabeled polymer in 100 μL of HBS via the tail vein. At time 3, 10, 30, 60, and 90 min postinjection, each mouse was anesthetized with isoflurane, and 50 μL of blood was collected from the orbital sinus using a heparinized capillary. The level of radioactivity (cpm) found in the blood was determined using a Beckman Gamma 8000 gamma spectrometer (Irvine, CA) and the elimination rate computed using a log−linear regression of CPM/mL blood versus time after injection.

Biodistribution Assay for Compound IV. A known amount of the doxorubicin conjugate was dissolved in a 5 mM HEPES and 5% glucose solution. CD-1 females mice at 6−8 weeks old were injected i. v. via tail with 200 μL of the conjugate solution. Four mice per group were anesthetized with a ketamine cocktail by i. p. injection. All mice were bled by heart puncture, and the volume of blood was measured and transferred to a scintillation vial. An injection of 1 mL of PBS to the right ventricle of the heart was used to flush the circulation system. The whole organs were dissected and their weight was recorded. The organs were put into 2 mL tubes containing 1 mL of acidified alcohol (90% 2-propanol/0.075 HCl) and zirconia beads, followed by homogenization (Bead Beater, Biospec, Bartlesville, OK) for 20 s at 5000 rpm. The blood was allowed to coagulate at 4 °C and then centrifuged for 10 min at 1000 rpm. The serum (upper phase) was collected, and its volume was recorded. An aliquot of 100 μL of serum was transferred to a 2-mL tube containing 1 mL of acidified alcohol. The homogenized organ samples and the sera were placed in the refrigerator for 24 h to extract the drug. The cell debris in the organ homogenates was removed by centrifugation at 14 000 rpm for 5 min at 4 °C. An aliquot (400 μL) of the supernatants were transferred to tubes containing 1.6 mL of acidified alcohol. For the quantification of doxorubicin present in the organs, drug-free homogenates of organs and sera from untreated mice were spiked with free doxorubicin. Various organs had different background fluorescence levels, which required separate calibration curves for each organ. Fluorescence emission from the drug was measured in fluorescence intensity units (Ex 490 nm: Em 590 nm) in a Quantech Turner fluorometer (Barnstead/Thermolyne, Dubuque, IO). Calibration curves were linear over two orders and drug levels to 10 ng/g organ could be reliably measured.

Confocal Microscopy. GFP transfected and nontransfected MDA-MB-435 cells were plated on sterilized 4-well slides by the addition of 1 mL of a 1×10^5 cells/mL solution. After incubation for 24 h, the media was gently removed and the cells were washed once with 1 mL of PBS, followed by the addition of 0.5 mL of media containing free doxorubicin and conjugated doxorubicin. The control cells contained only media. The concentration of free and conjugated doxorubicin equals the IC50 of free doxorubicin for this cell line, as determined previously in vitro experiments (0.62 mg/mL). Cells were incubated at 37 °C and 5% CO_2 for 1 and 24 h. After incubation the cells were fixed for 1 h at 4 °C in 1.0 mL of 4% paraformaldehyde in PBS. The cells were mounted in Vector Vectrashield (Burlingame, CA) for confocal microscopy. Confocal images were obtained using LaserSharpe software installed on a Bio-Rad (Hercules, CA) krypton−argon laser scanning confocal microscope (MRC-1024) outfitted with a Nikon Diaphot 200 microscope using an ×60 objective lens. 512 × 512 pixel sections were taken every 2 μm using all laser lines, 10% laser power, slow scan, and Kalman averaging of three scans. For both GFP transfected and untransfected MDA-MB-5 cells, doxorubicin was imaged by PMT1 using low signal amplification, an iris of 2.5, a gain of 1500, and a black level of −6. For the GFP transfected MDA-MB-5, GFP was imaged on PMT2 using an iris of 2.5, a gain of 1500, and a black level of −3. Images were analyzed using Confocal Assistant 4.02 software.

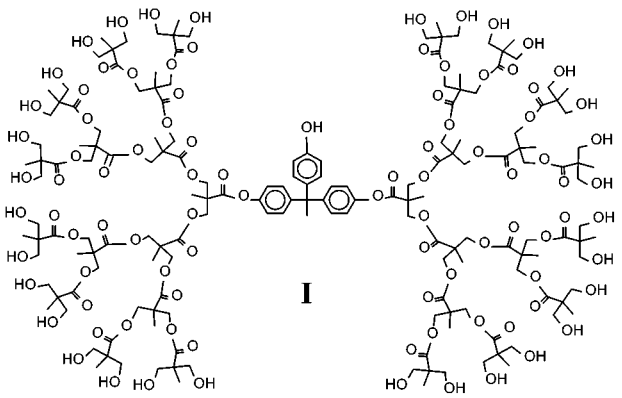

Figure 1. Dendritic polyester model compound **I** with molecular mass of 3790 Da.

Drug Release Studies as a Function of Buffer pH. A stock solution of conjugate was prepared using distilled water as a solvent. An aliquot of the stock solution was added to the respective prewarmed buffer solutions (37 °C), to initiate the reaction. The final concentration of the conjugate was of 3 mg/mL, 40 mM in buffer ion and 100 mM NaCl. Solutions at pH 2.4 (HCl), 4.5 (acetate), 5.5 (acetate), 6.5 (MES), and 7.0 (phosphate) were used to evaluate drug release as a function of pH. Quantification of drug released was performed by HPLC analysis on a model 2690 XE Alliance Separations module (Waters, USA) and a Photodiode Array detector (Waters 996). Aliquots of 10 μL were injected with built-in autoinjector at different times after the incubation started. The separation was carried out with a Waters Symmetry C18 column (2.1 × 150 mm, 3.5 μm) using a mobile phase consisting of 40% phosphate buffer pH 7.0 and 60% methanol at a flow rate of 0.3 mL/min. The data acquisition and processing were controlled by Millenium 32 software. In contrast to commonly used mobile phases for the separation of DOX conjugates from the free DOX, we used a neutral pH system, to minimize cleavage of DOX from the polymer during the analysis. A calibration curve was prepared with fresh doxorubicin and the extent of release was monitored by peak height based on the absorbance at 490 nm.

RESULTS AND DISCUSSION

Brief Description of Structure of Model Compounds Evaluated. Model compounds **I**, **II,** and **III** were evaluated as possible polymeric drug carriers (Figures 1−3). The common denominator of these systems is the polyester dendritic scaffold derived from the monomer unit 2,2-bis(hydroxymethyl)propanoic acid. These

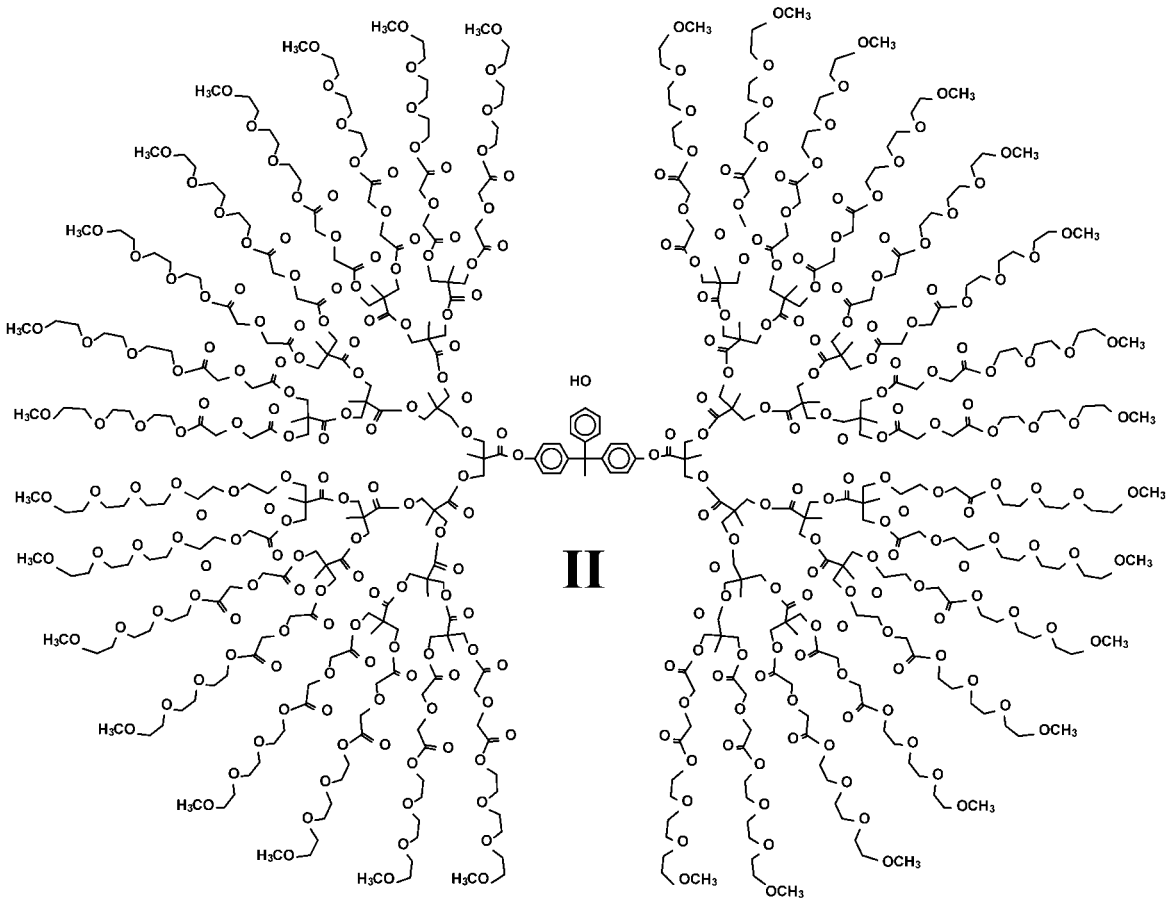

Figure 2. Modified dendritic polyester model compound **II** with molecular mass of 11 500 Da.

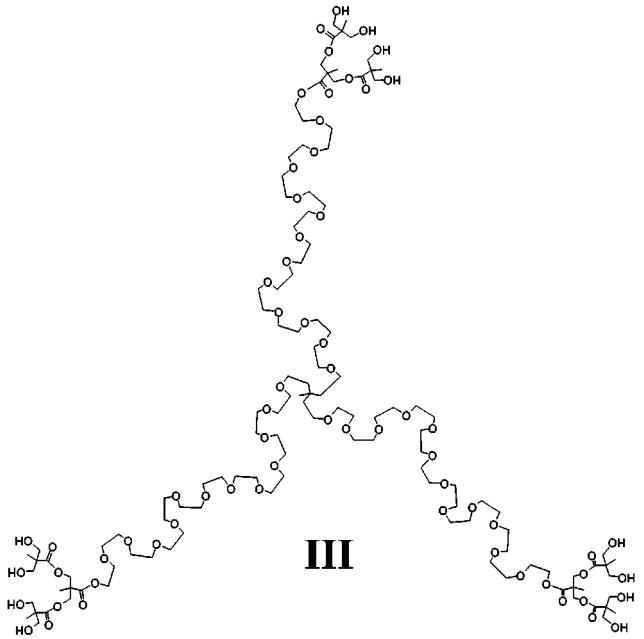

Figure 3. Model compound **III**, composed of 3-arm poly(ethylene oxide) star and [G-2] polyester dendrons (23 500 Da).

three polymers differ in molecular weight and architecture, so we could evaluate these factors on toxicity and biodistribution. Compounds **I** and **II** mainly consist of two fourth generation [G-4] polyester dendrons attached to a trisphenolic core. Carrier **I** has a molecular mass of 3790 Da and contains a fully activated surface with 32 hydroxyl groups, which can be further modified. The surface of **II** was modified with methoxy terminated tri(ethylene glycol) oligomeric units to increase the mass of the dendritic molecule by a factor of 3 in one single synthetic step, achieving a mass of 11 500 Da. An attractive feature of this polyester scaffold is that it is highly water soluble (at least 200 mg/mL) in an uncharged state, avoiding the necessity of introducing ionizable functional groups to achieve good solubility properties. This property decreases the possibilities for rapid elimination as is observed in the case for cationic systems, due to electrostatic interactions with the negatively charged cellular membranes and extracellular matrixes (*30*−*33*) or in the case of anionic systems due to their interaction with the scavenger receptor (*39*). Second, the sterically hindered ester bond of the monomer unit makes this backbone more stable toward both nucleophilic attack and acid-catalyzed hydrolysis avoiding its rapid and premature degradation.

In contrast to **I** and **II**, compound **III** consists of a hybrid between a 3-arm poly(ethylene oxide) (PEO) star and three [G-2] polyester dendritic units. This system has a molecular mass of ca. 23 500 Da, and its molecular architecture has a more linear character, as compared to the compact shape of the strictly dendritic systems **I** and **II**. In this instance, the trifunctional PEO core contributes most of the mass of the system. The advantages of using a star-PEO also include its contribution to biocompatibility and water solubility (*40*), without jeopardizing the polydispersity of the system, since star-PEO molecules with low polydispersity indices (PDI < 1.1) are commercially available. On the other hand, the [G-2] polyester dendrons of **III** provide the multivalency necessary for drug attachment. In contrast to linear polymers containing statistical amounts of reacting sites,

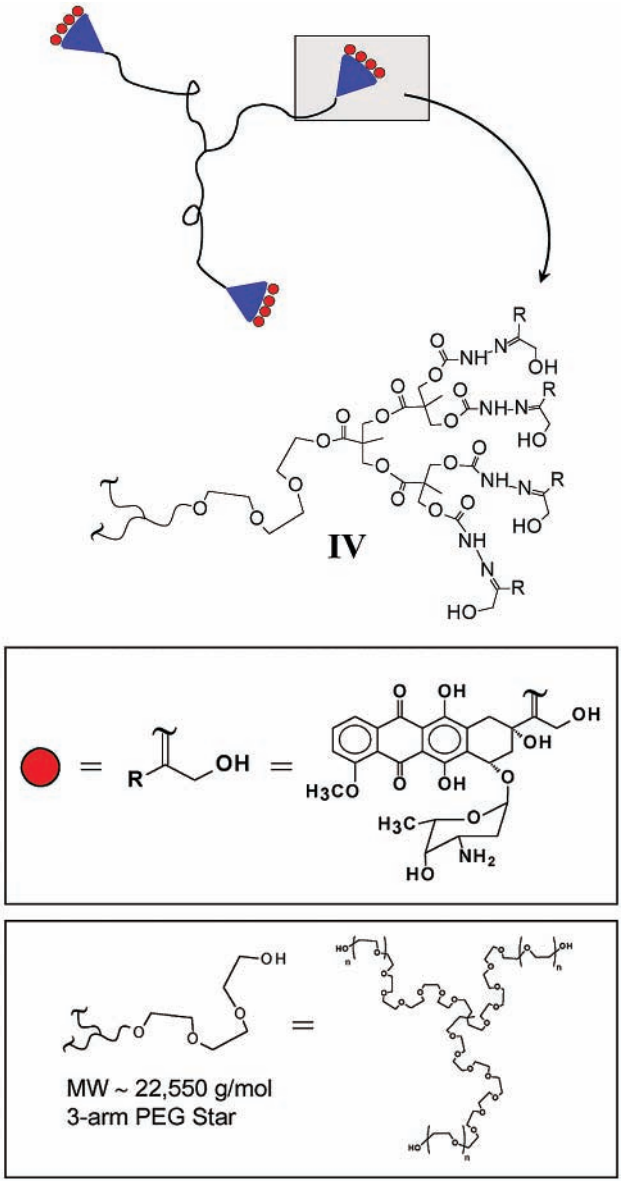

Figure 4. Model compound **IV**. Polymer drug conjugate consisting of modified **III** and doxorubicin using a hydrazone covalent bond as a linker.

this architecture provides a known and reproducible number of functional groups.

Finally, the drug−polymer conjugate **IV** (Figure 4) consists of the potent anticancer drug doxorubicin (DOX) and a derivative of the polymeric carrier **III**. DOX was covalently bound to the polymer by means of an acid-labile hydrazone linkage (*41*−*42*). An acid-labile linkage was selected because it can remain stable under physiological conditions, but once it is internalized in the cell by endocytosis, the more acidic environment of lysosomal compartments will trigger the release of the drug. An additional advantage of a pH-sensitive linker is that the release rate of the drug attached by an acid-labile linkage is often less affected by the type of drug than in the case of enzyme cleavable linkages, which have been difficult to address (*43*). Finally, the environment around tumor tissue is slightly more acidic than normal tissue; therefore, an acid labile linkage might be cleaved more rapidly in the vicinity of a tumor prior being internalized by the cancer cell.

Biological Evaluation of Model Compounds. *In Vitro Cytotoxicity of the Carriers.* In vitro studies were performed on the polymeric model compounds **I**, **II**, and **III** to evaluate the possible toxic effect of the polyester dendritic scaffold itself. The cell viability studies were performed on melanoma B16F10 cancer cells and cell proliferation was quantified by the sulforhodamine B assay (SRB), which measures the level of protein remaining on a cell culture dish. All of the polymers examined were well tolerated by cells in culture (Figure 5). For instance, after incubation for 48 h, cells exposed to **I** at a polymer concentration of 10 mg/mL retained 87% of the growth rate of the control cells. In the case of model compound **II**, cell proliferation was slightly suppressed to 81% of control at 5 mg/mL. Model compound **III**, the highest molecular weight carrier evaluated, also was very well tolerated with 87% of the growth rate of the control culture at 10 mg/mL of polymer (Figure 5).

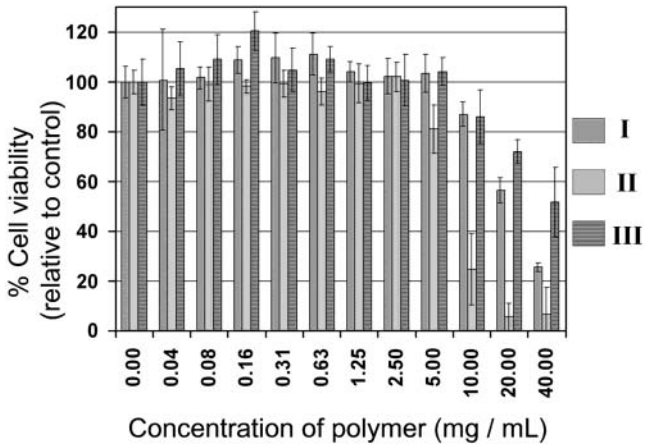

Figure 5. Cell viability results upon treatment of B16F10 cells with polymeric carriers **I**, **II**, and **III** after 48 h of incubation.

An interesting observation on this polymer is that even though there is an apparent growth inhibition at the highest concentrations, dead cells were not evident under microscopic observation even at 40 mg/mL, rather the cell density was decreased. This suggests a growth inhibition effect as a result of the very high polymer concentration. These results are very promising, considering that previously evaluated dendritic systems, such as PAMAM, polyethyleneimine and poly(ethylene oxide) grafted carbosilanes inhibit cell viability and induce hemolysis or cytolysis at concentrations much lower than 5 mg/mL (*31*).

In Vivo Tolerability of the Dendritic Polyesters. Nonionic polymers such as the poly(ethylene glycols) are very well tolerated upon injection into animals. Given the low toxicity of the polyester dendrimers in culture, we thought they would also be well tolerated upon injection into animals. However, we did not believe it warranted conducting a complete toxicity profile of the polymers at this stage of the investigation; rather, we undertook to learn if the polymers could be administered as an intravenous bolus at levels greater than 1 g/kg body weight in mice. If the polymers could be administered at this dose, a wide variety of drug delivery applications would be possible. Compound **I** was injected i.v. over a 10 s period into a number of animals at increasing doses. At the dose of 1.3 g/kg body weight, 1 of the 2 animals injected survived. In the animal that died, there was no evidence for blood hemolysis. The surviving animal was sacrificed at 24 h postinjection, the organs removed and visually examined. There was no gross evidence for toxicity in any organ examined.

Compound **III** was injected intravenous as a bolus into two mice at a dose of 1.3 g/kg body weight. Both mice

survived with no evidence for any adverse effect of the polymer. The animals were sacrificed at 24 h, the organs were removed and visually examined. There was no evidence for gross pathology in the liver, lungs, heart, kidney, or intestine.

These preliminary experiments confirmed that the polymers were very well tolerated in mice when administered by i.v. bolus. Upon the basis of this result, we decided to undertake biodistribution experiments at doses of 0.1 g/kg body weight. This is comparable to what has been used to study biodistribution of dextrans (*44*) and HPMA, polymers that have been used as drug carriers.

Biodistribution Studies. Dendrimer **I** was radiolabeled with ^{125}I, and the biodistribution of the radiolabeled polymer was monitored in CD-1 mice after intravenous administration. Polymer **I** was renally excreted and preferential accumulation in specific organs was not observed (Figure 6a). At 10 min postinjection, only 14% of the injected material remained in the serum, and the polymer was essentially completely excreted after 4 h. The low circulation time is most likely related to the compact shape of the branched dendritic structure and its modest molecular size.

Biodistribution of model compound **II** was evaluated and even though the mass of this system was 3 times larger than **I**, the polymer was also rapidly excreted in the urine. At 30 min postinjection, only 4% of the administered dose remained in serum, and after 5 h the material was essentially completely excreted from the body with no evidence for accumulation in any tissue (Figure 6b).

Model compound **III** was labeled with ^{125}I as well, but in contrast to **I** and **II** the radioactive label was attached to a *p*-methoxyphenyl acetic acid moiety that was statistically coupled to the surface of **III**. This compound exhibited a highly significant accumulation in the liver. At 10 min postinjection, 70% of injected dose is in the liver and 5% in serum. After 5 h, 53% of the injected dose was still found in the liver (Figure 6c).

This distribution behavior was not expected. One major difference between compound **III** and compounds **I** and **II** is that the labeled moiety was at the periphery of the PEO chains in **III**, as opposed to the well protected core in compounds **I** and **II**. This could possibly account for the liver uptake since it was previously observed that iodophenol containing PEGs would expose the methoxy iodophenol to the putative liver receptors whereas the iodophenol would be sterically hindered in compounds **I** and **II** (*37*). Another possibility is that the iodine-containing moiety was hydrolyzed from the polymer and incorporated into the liver rather than the model compound itself. Given the rapidity of uptake in the liver, this is unlikely. Moreover, iodinated polymer recovered from serum eluted in the high molecular weight fraction on a G-50 spin column. Thus, we attributed the biodistribution profile of compound **III** to the exposed iodinated phenol. Despite the uptake of **III** into the liver, we decided to prepare a polymer−doxorubicin conjugate with compound **III** for further biodistribution studies.

In addition to being a highly potent anticancer agent, doxorubicin is a fluorescent compound, providing a convenient analytical tool for monitoring distribution of the conjugate **IV**. In contrast to the radiolabeled **III**, the polymer−DOX conjugate **IV** showed no significant accumulation in any vital organ, including the liver, heart, and lungs (Figure 7). This is a significantly different distribution pattern than is observed for the free drug, which partitions into a variety of organs such as the liver

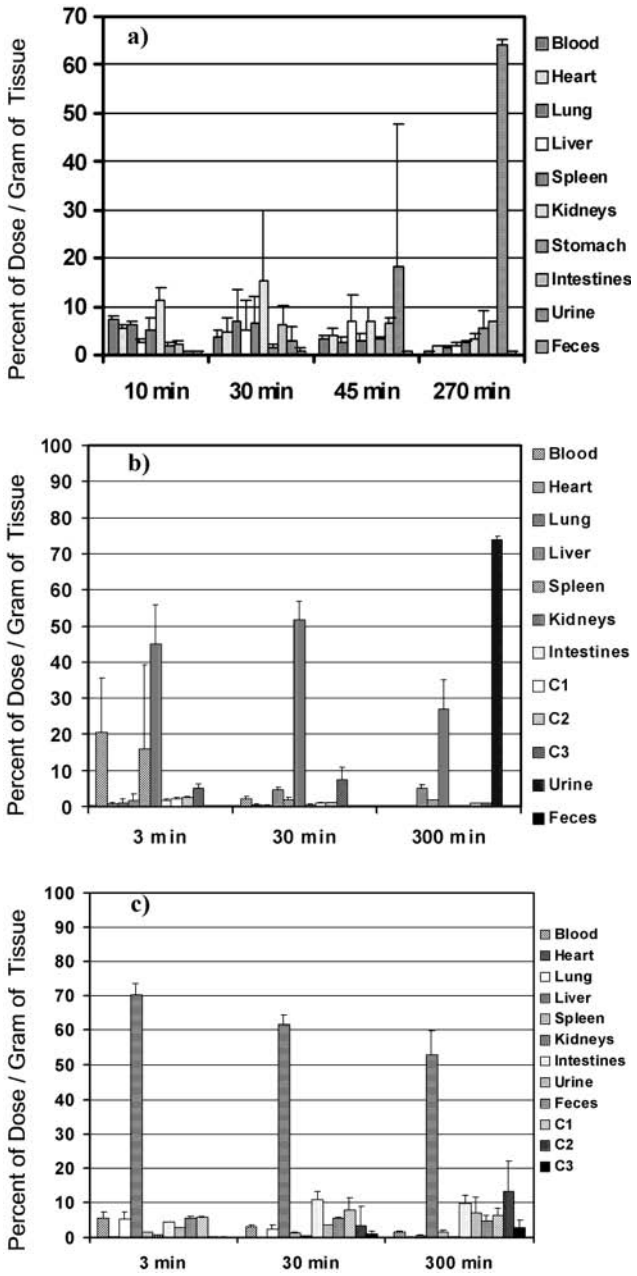

Figure 6. Biodistribution of model compounds (a) **I**, (b) **II**, and (c**) III**. The data are expressed in % of dose injected per gram of organ tissue. The blood is expressed in % of dose injected per mL, for ca. 2 mL of total blood volume in a CD-1 mouse.

and heart (*45*). Most importantly, conjugate **IV** had circulation half-life of 72 min, which is significantly longer than both the half-life of the free drug (ca. 8 min) and the carriers **I** and **II**. This demonstrates that the polymeric form of the carrier alters the pharmacokinetics and the distribution of the drug.

Drug Release Studies. One of the important features to take into consideration when designing polymeric carriers is the means of attachment of the molecule to be delivered. The nature of the attachment sites will determine whether selective release of the bioactive molecule can be attained. A hydrazone linkage was selected due to its known stability under neutral pH conditions and its ability to undergo hydrolysis under acidic conditions. The goal is to have a linkage that will be sufficiently labile at a pH range of 4−6 to provide a therapeutic level of the drug. This is the pH found in the endosomal and lysosomal environments, which are the

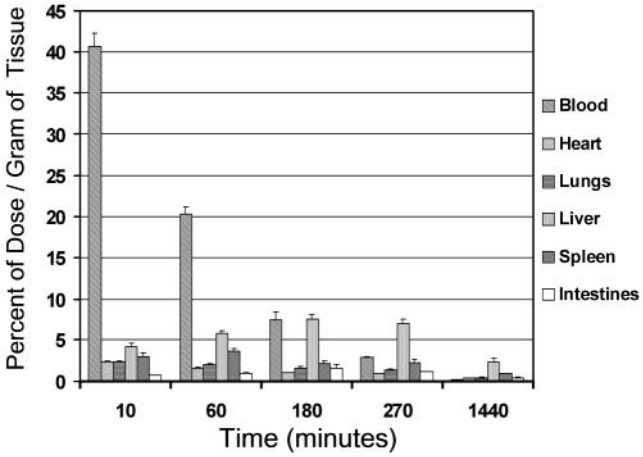

Figure 7. Biodistribution of **IV**.

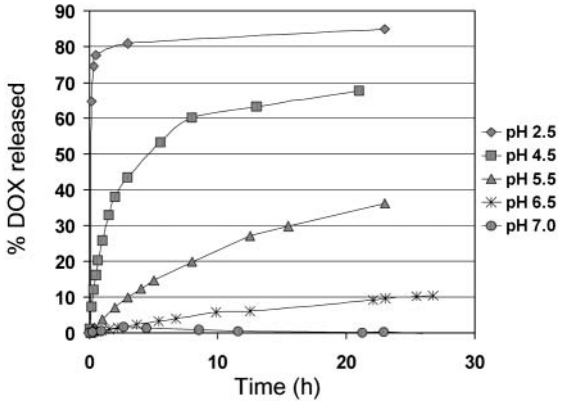

Figure 9. pH profile for release of doxorubicin from conjugate **IV**.

compartments where polymeric drugs are often internalized. The linkage we used and evaluated throughout this study is a hydrazone linkage.

Drug release was monitored by an HPLC method. Figure 8 shows the well-resolved peaks corresponding to the conjugate and free doxorubicin at retention times of 5.4 and 6.3 min, respectively. As shown in Figure 9, the hydrazone linkage is indeed very stable at neutral pH, while it is cleaved more rapidly under more acidic conditions. Due to the highly reversible character of the hydrolysis of hydrazone linkages, an apparent equilibrium is observed under the experimental nonsink conditions of the release assay. One can estimate the time for complete release of DOX from the conjugate based on the computed initial rates of release; a 100% release would

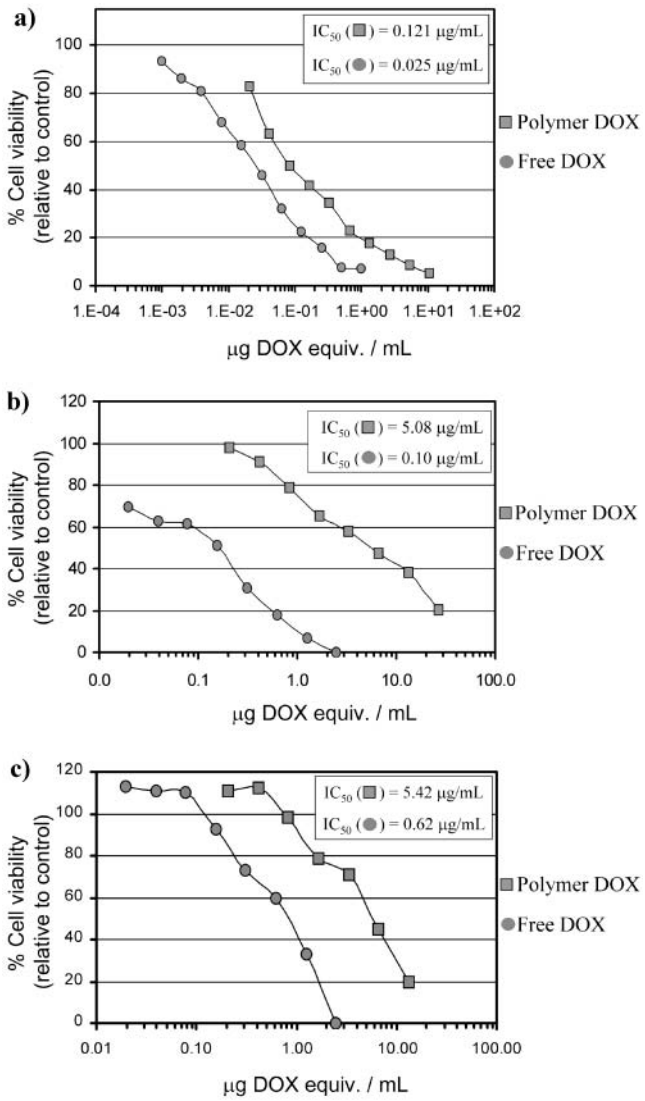

Figure 10. Comparative cell viability results upon treatment of (a) B16F10, (b) MDA-MB-231, and (c) MDA-MB-435 cell lines with bound DOX (**IV**) and free DOX. Results are compared in terms of DOX equivalents.

be achieved after 10 min, 3 h, 26.5 h, and 10 days for pH 2.5, 4.5, 5.5, and 6.5, respectively. Thus, the hydrazone linkage provides a suitable linker for a pH-dependent release that is compatible with conditions found in tumors.

Cytotoxicity of Drug−Polymer Conjugate in Vitro. The cell proliferation results suggest that these systems based on polyester dendrimers do not exhibit a significant toxic effect and the drug release rates from the hydrazone linker encouraged us to further evaluate model compound **IV** as a polymeric drug carrier. In vitro evaluation of the conjugate was performed in various cancer cell lines to compare the cytotoxic activity of the bound drug in relation to the free drug (Figure 10).

The three cell lines examined exhibited a range of sensitivity to the free doxorubicin, from 0.025 μg/mL for B16F10 to 0.62 μg/mL for the MDA-MB-435 cell lines. In all three cell lines examined, the free drug was considerably more potent than the drug−polymer conjugate (Figure 10); 6-fold in the B16F10 cells, 50-fold in the MDA-MB-231, and 9-fold in the MDA-MB-435 cells. In the experiments, the conjugated doxorubicin was chromatographed in a gel permeation column within 1 day of testing the material so that there was less than

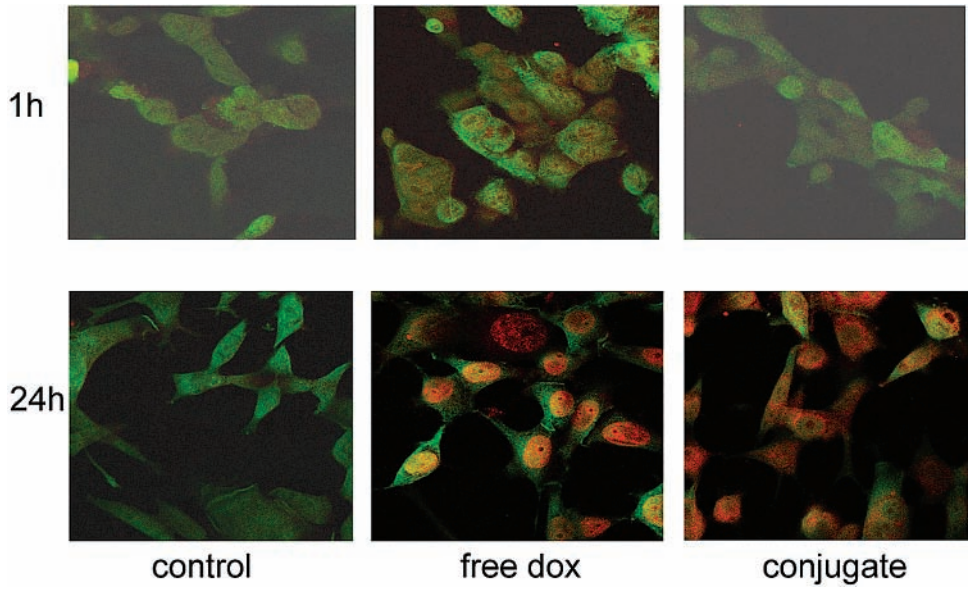

Figure 11. Fluorescence confocal microscopy images of localized DOX and DOX−polymer conjugate **IV** in MDA-MD-435 cells. MDA-MD-435 cells were grown to 40% confluence on sterilized coverslips and incubated for 1 and 24 h.

1% free doxorubicin in the conjugate preparation. Moreover, the amount of polymer at the highest dose tested (100 μg/mL) was substantially below the concentration where antiproliferation effects of the polymer were observed. Therefore, the antiproliferation effects of the conjugate were most likely due to the drug that had been released from the polymer in the course of the incubation.

These results are encouraging since the doxorubicin conjugate is less toxic than the free drug yet more toxic than the polymer alone. The question arises as to where the doxorubicin is being released from the polymer. At neutral pH in buffer, drug release is very slow. However, at low pH drug release is substantially faster. Therefore, we examined if the drug−polymer conjugate was internalized by cells.

MDA-MB-431 cells were treated for 1 h and 24 h with the drug−polymer conjugate (**IV**) or the free doxorubicin. The fluorescence of doxorubicin provides a means for monitoring cell uptake of the drug using fluorescence confocal microscopy. Both the cytoplasm and the nuclei were highly fluorescent both at 1 h and 24 h after exposition to free doxorubicin. When cells were exposed to polymeric drug, fluorescence is observed in the cytosol, confirming the cell uptake of the conjugate by endocytosis (Figure 11). However, as also observed with the HPMA derivative of doxorubicin (*46*), little fluorescence was observed in the cell nucleus with the drug−polymer conjugate. This may be due to the slow release of the drug from the carrier at the time of evaluation.

CONCLUSIONS

Various polyester dendritic carriers were evaluated as possible drug carriers. Each of the three drug carriers (**I**, **II**, **III**) are highly water soluble and nontoxic. Model compound **III** exhibited the longest circulatory half-life (72 min) as compared to the lower molecular weight systems **I** and **II** and was selected for further investigation. A doxorubicin−polymer conjugate was synthesized using **III** as the polymeric carrier (**IV**), and the drug was attached by means of an acid-labile hydrazone linkage. The cytotoxicity of the drug was significantly reduced (80−98%) after attaching it to the polymer. However, doxorubicin could be rapidly released from the polymer in an active form at pH values found in the lysosome. Uptake of **IV** by cells in culture was also observed by fluorescence confocal microscopy. In biodistribution experiments, none of these systems accumulated in any organ examined, including the liver, heart, and lungs. The results suggest that this polyester dendritic backbone is a highly water soluble, nontoxic, and biocompatible polymer. However, a higher molecular weight system must be prepared to further increase the circulation half-life to effectively exploit the EPR phenomenon. This new system is a promising polymeric backbone for use as scaffolds in the development of well-defined macromolecular drug carriers.

ACKNOWLEDGMENT

We thank Dr. Nikolay Vladimirov and Dr. Miroslav Janco (UCB) for their significant contribution in the development of the HPLC method for the performance of the drug release studies. We also thank John Andrew MacKay (UCSF) for his valuable assistance in the experiments involving confocal microscopy. Financial support of this research by UC Breast Cancer Research and Development Program (6JB-0137), the National Science Foundation (DMR-9816166), the Department of Energy (Basic Energy Sciences), and the National Institutes of Health (Grant GM 65361) is acknowledged with thanks.

Targeted drug delivery by cell-specific cytokines and antibodies promises greater drug efficacy and reduced side effects. We describe a novel strategy for assembly of drug delivery vehicles that does not require chemical modification of targeting proteins. The strategy relies on a noncovalent binding of standardized "payload" modules to targeting proteins expressed with a "docking" tag. The payload modules are constructed by linking drug carriers to an adapter protein capable of binding to a docking tag. Using fragments of bovine ribonuclease A as an adapter protein and a docking tag, we have constructed vascular endothelial growth factor (VEGF) based vehicles for gene delivery and for liposome delivery. Assembled vehicles displayed remarkable selectivity in drug delivery to cells overexpressing VEGF receptors. We expect that our strategy can be employed for targeted delivery of many therapeutic or imaging agents by different recombinant targeting proteins.

INTRODUCTION

The current revolution in drug discovery is driven by functional genomics, proteomics, high throughput screening, and in silico drug design. It is widely expected that these new technologies will yield numerous potent and highly selective drugs. Targeted drug delivery, as opposed to systemic delivery, can dramatically increase drug efficacy while decreasing side effects and the patient's treatment burden. Targeted delivery requires "loading" drugs onto cell-specific cytokines or antibodies. Although initially these targeting proteins were purified from natural sources, now most of them are available as recombinant proteins. Thus, effective technology for loading drugs onto recombinant targeting molecules is crucial for channeling the current revolution in drug discovery into targeted drug delivery.

Currently, several strategies are used for loading drugs onto targeting proteins (*1*). In one approach, drugs (e.g., radionuclides) are directly conjugated to targeting proteins. In another approach, drugs are loaded onto high capacity drug carriers (e.g., liposomes, synthetic polymers, etc.). These carriers are either directly conjugated to targeting proteins or derivatized for interactions with specific adapters that are conjugated to the targeting proteins. Streptavidin/biotin interaction is particularly widely explored for binding various carriers to targeting proteins (*2*). Since both strategies rely on chemical conjugation of drugs, carriers, or adapters directly to targeting proteins, they share common problems such as (i) potential for inactivation of cell binding domains by conjugation, (ii) the inevitable heterogeneity of final products, and (iii) development of custom conjugation procedures for every targeting protein. These problems are the major stumbling blocks in using cell-specific proteins for targeted drug delivery. Recently, heterobifunctional recombinant antibodies recognizing one epitope on the cell surface and another epitope on the drug carrier have been proposed for targeted drug delivery (*3*, *4*). This approach avoids chemical modification of targeting antibody but it requires custom development of heterobifunctional recombinant antibodies, and the prospects of efficient internalization of antibody are uncertain.

We have recently proposed a new strategy for converting targeting proteins into vehicles for drug delivery (*5*). The strategy relies on a modular assembly of drug delivery vehicles and therefore avoids random chemical modification of targeting proteins. We proposed to construct standardized "payload" modules by linking various drug carriers to a special adapter protein (Figure 1). The function of the adapter protein is to bind a payload module to a "docking" tag fused to a targeting protein. In this approach, the assembly of a drug delivery vehicle does not require chemical modification of targeting proteins and relies on standardized components. Here we describe vascular endothelial growth factor (VEGF) based vehicles for delivery of liposome-encapsulated doxorubicin and for gene delivery. To construct these vehicles we have used a 104-aa fragment of bovine ribonuclease A (known as S-protein), as an adapter protein and a 15-aa fragment of bovine ribonuclease A (known as S-peptide) as a docking tag. This tag is incorporated in various pET expression vectors from Novagen (Madison, WI) and is widely used for affinity purification and quantitation of recombinant proteins. Assembled vehicles displayed remarkable selectivity in drug delivery to cells overexpressing VEGF receptors. We expect that our strategy can be employed for targeted delivery of many therapeutic or imaging agents by different recombinant targeting protein.

MATERIALS AND METHODS

Cells. 293 human transformed embryonic kidney cells (CRL-1573) and HL-60 human promyelocytic cells (CCL-240) were from American Type Culture Collection (Rockville, MD). PAE/KDR porcine aortic endothelial cells expressing 2.5×10^5 VEGFR-2/cell and PAE/V control cells were kindly provided by Dr. B. Terman (Albert Einstein School of Medicine, Bronx, NY). 293/KDR cells expressing 2.5×10^6 VEGFR-2/cell and PAE/0.1-KDR

expressing 2.5×10^4 VEGFR-2/cell have been developed in SibTech, Inc. (*6*, *7*). HL-60 cells were grown in RPMI 1640 (Gibco Life Technologies, Carlsbad, CA) supplemented with 20% fetal bovine serum (FBS, Gemini, Newton, MA), 4 mM L-glutamine, and antibiotics at 37 °C, 5% CO_2. All other cells were grown in DMEM with 10% FBS, 2 mM L-glutamine, and antibiotics at 37 °C, 5% CO_2.

Plasmids. $VEGF_{121}$ was cloned into pET-32a(+) (Novagen, Madison, WI) containing a coding sequence for a 15-aa fragment of bovine ribonuclease A, known as S-tag, as described previously (*7*). DNA encoding *E. coli* thioredoxin was removed from pET-32/$VEGF_{121}$ plasmid by *Nde*I digestion. The resulting pET/$VEGF_{121}$ plasmid encoded human $VEGF_{121}$ with a 42-aa N-terminus containing S-tag. S-tagged VEGF was expressed in Origami-(DE3)pLysS (Novagen) and purified as described (*8*). The concentration of the purified protein was determined by the S-tag Rapid Assay kit (Novagen) and reflected the concentration of S-tagged VEGF monomers. Human procaspase 8b (Mch5-beta, GenBank accession: AF009620) was amplified by RT-PCR using total RNA of HL-60 cells (RNeasy RNA isolation kit, Qiagen, Valencia, CA) with primers 5′-ac*tctaga*ttggtcacttgaaccttggg and 5′-ac*tcta-ga*agcaccatcaatcagaaggg introducing *Xba*I sites (italic); and cloned into pcDNA3.1/Zeo(+) (Invitrogen, Carlsbad, CA). Cloned cDNAs were confirmed by sequencing. The pGL3 plasmid encoding firefly luciferase was from Promega (Madison, WI).

Liposomes Preparation and Loading. S-protein fragment of bovine ribonuclease A (SP, Sigma, St. Louis, MO) at a concentration of 0.93 mM was modified with 0.7 mM poly(ethylene glycol)-α-distearoyl phosphatidylethanolamine, ω-NHS ester (DSPE-PEG-NHS, average MW 3400, Shearwater Polymers, Huntsville, AL) in 0.1 M NaPi, 0.15 M NaCl, pH 7.2, under argon at 37 °C for 4 h. Dioleoyl phosphatidylcholine (Avanti, Alabaster, AL) and cholesterol (Sigma) were mixed at the molar percent ratio of 65:35, lyophilized from cyclohexane, and hydrated in a buffer containing 10 mM HEPES pH 7.2, 150 mM NaCl, 0.1 mM EDTA, 0.1 mM EGTA, and 0.34 mM doxorubicin (Dox, Sigma, St. Louis, MD), and 13 μM DSPE-SP. After four freeze−thaw cycles, the lipids were extruded for 15 cycles through two stacked 0.08 μm polycarbonate membranes using a miniextruder (Avanti). Free Dox and SP were removed by chromatography on Sepharose CL-4B (Sigma). Lipid content in purified liposomes, named Lip(Dox)−SP, was determined by phosphate assay (Pierce, Rockford, IL), Dox content was determined fluorometrically (excitation at 470 nm, emission at 590 nm), and SP content was determined by micro-BCA protein assay (Pierce). The liposome surface Zeta potential and size were measured by Delsa 440SX Zeta Potential Analyzer (Coulter-Beckman, Miami, FL). Complexes of Lip(Dox)−SP with VEGF had an average size of 139 nm (SD = 26) and a zeta-potential of 0.45 mV (SD = 2.25) indicating that our procedure yielded unilamellar liposomes.

The sensitivity of 293 and 293/KDR cells to free Dox was determined using MTT cell proliferation assay (Promega). Briefly, 293 and 293/KDR cells were seeded on 96-well plate, 10^3 cells/well. Twenty-four hours later cells in quadruplicate wells were treated with Dox at a concentration range of 0.1 pM to 10 μM. After 24 h of treatment, the Dox-containing medium was replaced with fresh culture medium. MTT cell proliferation assay was performed according to the manufacturer's instructions after additional 48 h of incubation under the normal culture conditions.

Preparation of Polyethylenimine/S-Protein Conjugates. Linear 25 kDa polyethylenimine (PEI, Polysciences Inc., Warrington, PA) at concentration of 5 mM was modified with 5 mM Traut's reagent (Pierce) in 50 mM triethanolamine, 0.15 M NaCl, 1 mM EDTA, pH 8.0,

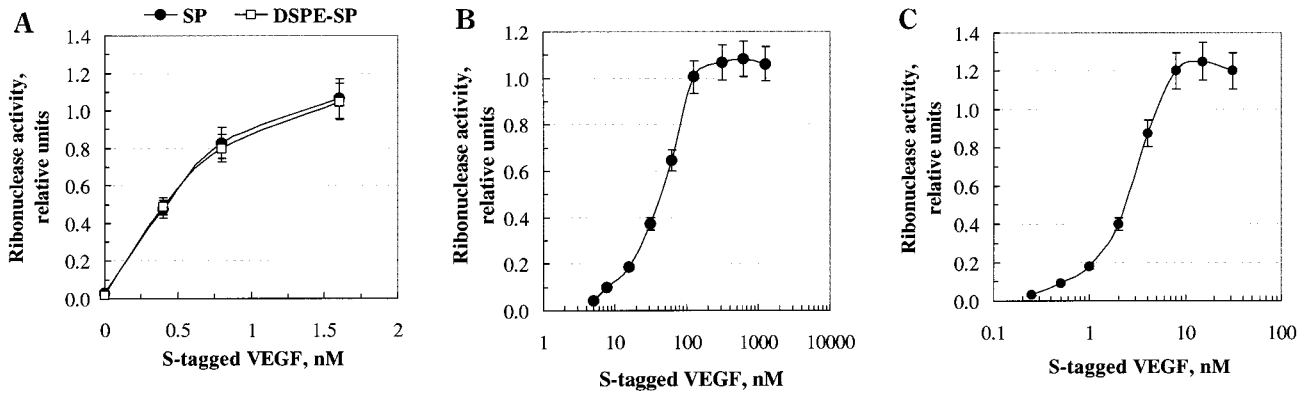

Figure 2. Derivatized S-protein (SP) binds to S-tagged VEGF. Derivatized SP was mixed with varying amounts of S-tagged VEGF. Ribonuclease activity was measured using S-tag Rapid Assay Kit (Novagen). A, DSPE-SP and control SP at concentrations of 4 nM, each. B, Lip(Dox)−SP, at SP concentration of 580 nM. C, PEI−SP, at SP concentration of 6 nM.

under argon at room temperature for 20 min. Concentration of SH groups in modified PEI was determined by Ellman's reagent (Pierce). SP at concentration of 0.66 mM was modified with 1.32 mM sulfo-MBS (Pierce) in conjugation buffer containing 0.1 M NaPi, 0.15 M NaCl, pH 7.2, at room temperature for 30 min. Modified SP and PEI were mixed at the molar ratio of 1:1 in conjugation buffer and incubated at room temperature for 4 h with constant agitation. PEI−SP conjugates were purified by gel-filtration on SE 100/40 (BioRad, Hercules, CA).

Preparation of DNA/PEI−SP−VEGF Complexes. DNA/PEI−SP−VEGF complexes were prepared as described (*5*). The surface zeta potential was measured by a Delsa 440SX Zeta Potential Analyzer (Coulter-Beckman). The ability of all cells to accept and express pGL3 DNA was determined using DNA/PEI complexes at N/P ratio from 5 to 13. The transfectability of VEGFR-2 expressing cells and control cells was found to be similar within 15% experimental error (data not shown).

Measurements of Ribonuclease Activity. Ribonuclease activity was measured with S-tag Rapid Assay Kit (Novagen). A relative unit of ribonuclease activity is 1 OU of acid-soluble material released from polyC incubated with various complexes of S-protein and S-tagged VEGF under the manufacturer's conditions.

RESULTS AND DISCUSSION

Construction of Molecular Drug Delivery Vehicles. The overall design of the modular drug delivery vehicle is shown in Figure 1. In our approach, conjugating the appropriate drug carriers to a universal adapter protein creates standardized payload modules. The role of the adapter protein is to bind with high affinity to a specific peptide fused to a targeting protein. This peptide serves as a "docking tag" for a payload module. In principle, any recombinant targeting protein expressed with such a docking tag can bind a premade adapter−carrier module, and the assembled vehicle can be used for targeted drug delivery.

A number of peptide tags recognized by specific proteins have already been developed for purification and detection of recombinant proteins. Among these, the so-called S-tag system based on interaction between S-peptide and S-protein fragments of bovine ribonuclease A appears to be the best choice for our purposes for the following reasons. First, the 15-aa S-peptide and 104-aa S-protein (SP) fragments form the smallest tag/adapter complex currently available with a K_d of 10^{-9} M^{-1} (*9*). Second, the S-peptide/SP complex is an active ribonuclease (known as RNase S), and therefore association of S-tagged recombinant proteins with SP-carrier modules can be readily detected by the reconstituted ribonuclease activity (*10*). Third, the bovine S-peptide/SP complex has been extensively studied for more than 40 years, detailed information about various aspects of this system is available, and bacterial expression plasmids for production of S-tagged proteins as well as S-protein are commercially available (*9*−*13*). Finally, the complex can be "humanized" by using appropriate fragments of human ribonuclease I (RNase I), thus improving chances for therapeutic success of the proposed strategy.

As a targeting protein we have chosen VEGF, the most specific cytokine for endothelial cells (*14*). The VEGF targeting ability is further narrowed by the evidence that its receptor, VEGFR-2 (KDR/Flk-1), is overexpressed at the sites of pathological angiogenesis (*15*−*17*). This exquisite specificity marks VEGFR-2 as a prominent target for anti-angiogenic therapy. Indeed, several recent reports indicated that VEGF-toxin fusion proteins and anti-VEGFR-2 neutralizing antibodies display highly selective activity in vivo and in vitro (*6*, *18*, *19*). Within VEGF family, $VEGF_{121}$ appears to be the most attractive candidate to be used as a targeting protein for two reasons. First, it has selective affinity to VEGFR-2 and second, it lacks a heparin-binding domain and, therefore, cannot be sequestered in the extracellular matrix. We have expressed $VEGF_{121}$ as a fusion protein containing bovine S-tag as a docking tag (S-tagged VEGF). Using SP as an adapter we have constructed payload modules for liposome delivery and for gene delivery.

Payload Module SP Binds to S-Tagged VEGF. To construct a payload module for liposome delivery, SP was conjugated to distearoyl phosphatidylethanolamine (DSPE) modified with poly(ethylene glycol). Derivatized SP (DSPE−SP) formed catalytically active complexes with S-tagged VEGF as effectively as unmodified SP ($K_d \sim 0.5$ nM), as judged by concentration dependence of ribonuclease activity of these complexes (Figure 2*A*). The fully assembled doxorubicin-loaded, DSPE−SP containing liposomes (Lip(Dox)−SP) also retained the ability to bind S-tagged VEGF (Figure 2B). The enzymatic activity of Lip(Dox)−SP−VEGF complexes was detectable at concentrations 50−100 fold higher than that of DSPE−SP−VEGF (compare Figure 2A and 2B), suggesting lower specific activity of liposome-associated reconstructed ribonuclease. In experiments with Lip(Dox)−SP−VEGF, the total concentration of SP was 580 nM and ribonuclease activity of the complexes reached a plateau at

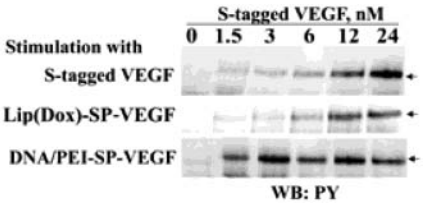

Figure 3. VEGF-based molecular delivery vehicles activate cellular VEGFR-2. Near confluent 293/KDR cells were incubated overnight in DMEM with 0.5% FBS, and then shifted to serum-free DMEM with 0.5 mM sodium vanadate for 5 min at 37 °C. Cells were stimulated with free S-tagged VEGF or VEGF-based delivery vehicles for 5 min at 37 °C, lysed, and analyzed by Western blotting using anti-phosphotyrosine RC20:HRPO conjugate (BD Transduction Labs, San Diego, CA). Arrows indicate positions of VEGFR-2.

~300 nM S-tagged VEGF as expected if SP is randomly distributed between the inner and the outer surfaces of liposomes.

To construct a payload module for gene delivery, SP was conjugated to polyethylenimine (PEI), a well-characterized DNA carrier (*20*−*22*). The conjugation protocol included (i) introduction of SH-group in PEI, (ii) introduction of a maleimide group in SP, and (iii) cross-linking of the modified PEI and SP via a reaction between SH and maleimide groups. We found that SP covalently bound to PEI (PEI−SP) binds S-tagged VEGF with nanomolar (K_d ~2 nM) affinity (Figure 2C).

VEGF Associated with Payload Modules Binds and Activates VEGFR-2. To test the functional activity of S-tagged VEGF in assembled delivery vehicles, we employed a VEGFR-2 tyrosine autophosphorylation assay. As a control we used free S-tagged VEGF. In this assay, assembled doxorubicin-loaded liposome delivery vehicles (Lip(Dox)−SP−VEGF) were as active as S-tagged VEGF alone, suggesting that binding of VEGF to the liposome surface did not affect its interaction with VEGFR-2 (Figure 3).

DNA delivery vehicles (DNA/PEI−SP−VEGF) containing pGL3 DNA at the N/P ratio of 8.4 (where N is the number of amino groups in PEI and P is the number of DNA phosphate groups) induced VEGFR-2 tyrosine autophosphorylation at VEGF concentrations as low as 1.5 nM (Figure 3). Importantly, DNA/PEI−SP−VEGF complexes were more efficient in this assay than free S-tagged VEGF. This effect can be explained by the higher avidity of DNA/PEI−SP−VEGF complexes to cells overexpressing VEGFR-2. Indeed, at the N/P ratio of 8.4 every pGL3 plasmid (5256 bp) is bound to several 25 kDa PEI (~600 monomers per molecule), and the complexes are packaged into highly condensed particles (*20*). Since every PEI−SP carries VEGF, assembled DNA/PEI−SP−VEGF will contain several VEGF molecules per a tightly packed complex and therefore can bind to cellular VEGFR-2 with higher avidity than individual VEGF.

VEGF-Based Targeted Delivery of Therapeutics. Lip(Dox)−SP−VEGF were tested on 293/KDR (2.5×10^6 VEGFR-2/cell) and 293 parental cells. To account for nonreceptor mediated toxicity, 293/KDR and 293 were treated with Lip(Dox)−SP and growth inhibition induced by Lip(Dox)−SP−VEGF was calculated relative to these controls. There were no difference in sensitivity of 293/KDR and 293 cells to Lip(Dox)−SP (data not shown). We found that Lip(Dox)−SP−VEGF did not affect 293, but inhibited growth of 293/KDR in a dose-dependent manner (Figure 4*A*) with IC_{50} of 0.8 nM for equivalent concentration of Dox. 293/KDR and 293 displayed similar sensitivity to free Dox with IC_{50} of 8 nM and 10 nM, respectively

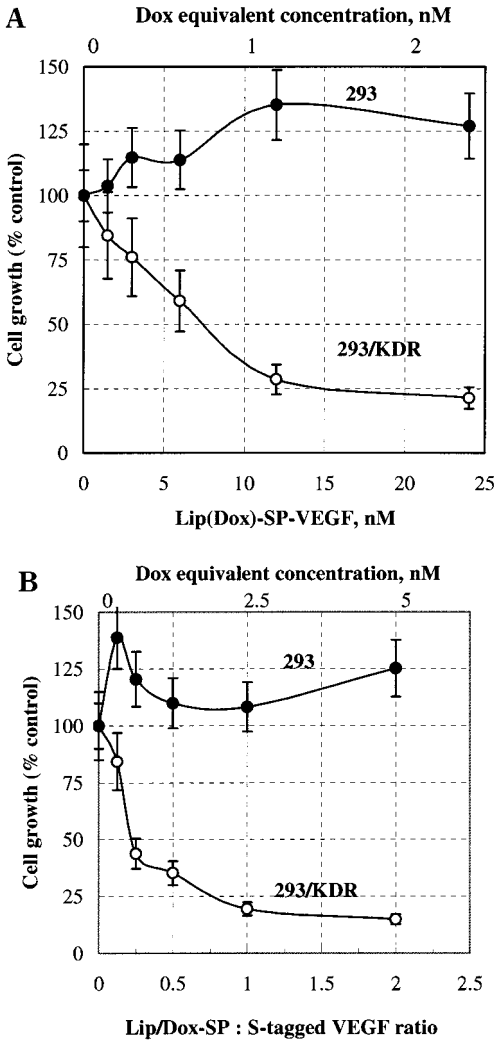

Figure 4. VEGF targets liposomes to cells overexpressing VEGFR-2. 293/KDR and 293 parental cells were plated on 24-well plates, 5×10^3 cells/well 20 h before the experiment. Lip(Dox)−SP were mixed with S-tagged VEGF at varying SP to VEGF molar ratios in serum-free DMEM, incubated on ice for 20 min, and then added to cells in complete culture medium in triplicate wells. After 20 h, cells were shifted to fresh culture medium. Cells were counted in a Coulter Counter (Coulter-Beckman) after 3-day incubations. Control cells were treated with equal amounts of Lip(Dox)−SP without VEGF and growth inhibition induced by Lip(Dox)−SP−VEGF was calculated relative to these controls. Liposome delivery experiments were repeated two times. A, Lip(Dox)−SP−VEGF at liposome SP to VEGF ratio of 1:1. Dox equivalent concentration is indicated. B, Varying amounts of Lip(Dox)−SP and constant 12 nM VEGF.

(data not shown). Thus, a 10-fold decrease in IC_{50} for 293/KDR can be attributed to VEGF-mediated delivery of liposome-encapsulated Dox. Similar decrease in IC_{50} was reported for human umbilical vein endothelial cells (HUVEC) treated with immunoliposome-encapsulated and free Dox (23). Interestingly, effect Lip(Dox)−SP−VEGF on 293/KDR was close to saturation at the liposome SP to S-tagged VEGF monomer ratio of 0.5:1 (Figure 4*B*). The latter result indicated that docking of Lip(Dox)−SP to both S-tags in the VEGF dimer does not significantly improve interaction of the resulting complex with cellular VEGFR-2.

VEGF-based DNA delivery vehicles were tested on three cell lines expressed varying number of VEGFR-2 per cell: PAE/0.1-KDR (2.5×10^4 VEGFR-2/cell), PAE/KDR (2.5×10^5 VEGFR-2/cell), and 293/KDR. PAE/V and 293/V cells transfected with empty vectors served as

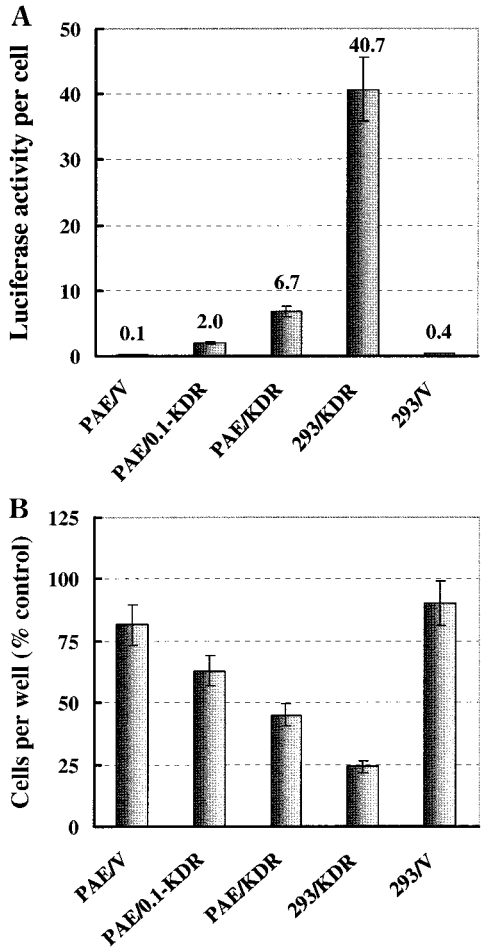

Figure 5. VEGF targets DNA delivery vehicles to cells overexpressing VEGFR-2. Cells were plated on 24-well plates at densities of 4×10^3 cells/well for PAE, PAE/KDR, PAE/0.1-KDR, and 2×10^4 cells/well for 293 and 293/KDR, 20 h before the experiment. PEI−SP was mixed with S-tagged VEGF (SP to VEGF ratio of 1:1.5) in 5% glucose, incubated on ice for 20 min, added dropwise to DNA in 5% glucose (N/P of 8.4), incubated on ice for an additional 20 min, and added to cells in complete culture medium to final concentrations of 12 nM VEGF, 36 nM PEI−SP, and 0.7 μg DNA per well. DNA delivery experiments were repeated three times. A, 40 h after luciferase DNA delivery, cells from triplicate wells were lyzed and assayed for luciferase activity, while cells from duplicate wells were washed with PBS, trypsinized, and counted in a Coulter Counter. B, 70 h after caspase DNA delivery, cells from triplicate wells were washed with PBS, trypsinized, and counted in a Coulter Counter.

controls. To reduce nonspecific DNA delivery, the DNA/PEI−SP−VEGF complexes were assembled with an N/P ratio of 8.4 giving a negative surface charge (zeta-potential of −25.4 mV, SD = 9.4). The efficiency of luciferase DNA delivery to cells depended on the cellular density of VEGFR-2, with the highest luciferase activity detected in 293/KDR cells expressing ~2.5×10^6 VEGFR-2/cell (Figure 5*A*). It should be noted that we have recently found that freshly isolated human circulating endothelial precursor cells express more VEGFR-2 than 293/KDR, indicating that VEGFR-2 may be overexpressed to very high density on certain cells in vivo (manuscript in preparation).

To test whether the VEGF-based vehicle can deliver therapeutically significant quantities of DNA to targeted cells, we have loaded the vehicle with the plasmid expressing human pro-caspase 8b, an apical protease of the apoptotic cascade (*24*). We found that VEGF-based caspase DNA delivery resulted in preferential death of cells expressing VEGFR-2 and that this effect also depended on the level of VEGFR-2 per cell (Figure 5B). Thus, we can expect that VEGF-based delivery vehicles in vivo will more efficiently target cells overexpressing VEGFR-2, such as endothelial cells at the sites of pathological angiogenesis or endothelial progenitor cells.

Our results provide evidence that VEGF-based molecular delivery vehicles can be constructed without random chemical modification of the targeting protein. We believe that molecular vehicles for delivery of therapeutic and imaging agents may be constructed using other targeting proteins, different drug carriers, and new payload modules. We expect that construction of a targeting protein, which can be combined with premade payload modules, would require significantly less effort than development of a customized chemical modification procedure for the same protein or development of a heterobifunctional antibody against the same target. Our recent experiments indicate that adapter/docking tag system can be based on human RNase I, and that random chemical modification of the adapter protein can be avoided by engineering an additional cysteine residue into S-protein fragment of RNase I (manuscript in preparation). Experiments are now in progress to develop novel payload modules based on humanized adapter/docking tag system.

ACKNOWLEDGMENT

Utility of Thiol-Cross-Linked Fluorescent Dye Labeled Terminators for DNA Sequencing

Satyam Nampalli, Mark G. McDougall, Katherine Lavrenov, Haiguang Xiao, and Shiv Kumar*

Amersham Biosciences, 800 Centennial Ave, Piscataway, New Jersey 08855-1327. Received December 11, 2001; Revised Manuscript Received March 13, 2002

Dipivaloyl-5-carboxyfluorescein *N*-hydroxysuccinimidyl ester **1** and 5-propargylamino-2′,3′-dideoxyuridine triphosphate **5** were modified with maleimide, haloacetamide, and sulfhydryl reactive functional groups to participate in cross-conjugation reactions via sulfide bonds to generate fluorescently labeled, thioether cross-conjugated terminators **10** and **11**. Their DNA sequencing potential was compared with an amide cross-conjugated terminator **13**, synthesized by directly coupling 5-carboxyfluorescein NHS ester with 18-ddUTP **9**. These terminators (**10**, **11**, and **13**) in combination with the Thermo Sequenase II DNA polymerase, in thermal cycle sequencing experiments, revealed that the thioether cross-conjugated terminator **10** and amide cross-conjugated terminator **13** served as good terminating substrates, generating satisfactory single-color gel images and electropherograms, while the other thioether cross-conjugated and maleimide derived one **11** underwent unexpected pH and temperature induced decomposition without showing fluorescent signatures for incorporation.

INTRODUCTION

The technique of using fluorescent dye-labeled terminators in Sanger (*1*) DNA sequencing has proven very cost-effective and safe over the radioactive isotope-labeled ones. Moreover, the FRET (fluorescence resonance energy transfer) dye-pair labeled terminators (*2*, *3*) or primers (*4*, *5*) are very widely used as part of the kit for high throughput DNA sequencing with a thermostable DNA polymerase. DNA polymerases are very sensitive to the unnatural, dye-labeled dideoxynucleotide terminators in that the rate of incorporation of the terminators and generation of an electropherogram with more evenly distributed peak heights, are highly dependent upon the spacer that serves as a bridge between the fluorescent dyes and nucleotide bases (*6*). To date, the spacers of these fluorescent terminators composed of alkynylamido (*2*, *3*), alkynylethoxyamido (*7*), and the rigidified alkynyl-aryl-alkynylethoxyamido (*8*) functional groups. None of these fluorescent terminators, so far utilized, for sequencing purposes, contained thioether cross-linked spacers interspersed with alkynyl-alkyl-amido functional groups. For achieving thioether cross-linking, between two molecules (e.g., nucleic acids/proteins and fluorescent dyes) of interest, one needs to modify one molecule with a thiol (sulfhydryl) in the disulfide form and the other with an alkyl halide or maleimide. Thiols can be generated in situ by reducing the disulfide-modified molecule with DTT (dithiothreitol, *9*) or TCEP (tris(2-carboxyethlyphosphine, *10*) to react with alkylhalides or maleimides forming thioether bonds. In our continued efforts to provide enzyme friendly fluorescent dye-labeled terminators for improved, high throughput DNA sequencing as well as protein and other nucleic acid detection studies, we have embarked on design and synthesis of the fluorescent dye terminators, involving thioether cross-linking in the ultimate step. These synthetic studies were aimed at investigating the substrate activity of these thiol cross-linked fluorescent ddNTPs with a DNA polymerase, stability to cycle sequencing conditions, and peak uniformity of the labeled amplicons in direct comparison with an amide bond cross-linked fluorescent terminator.

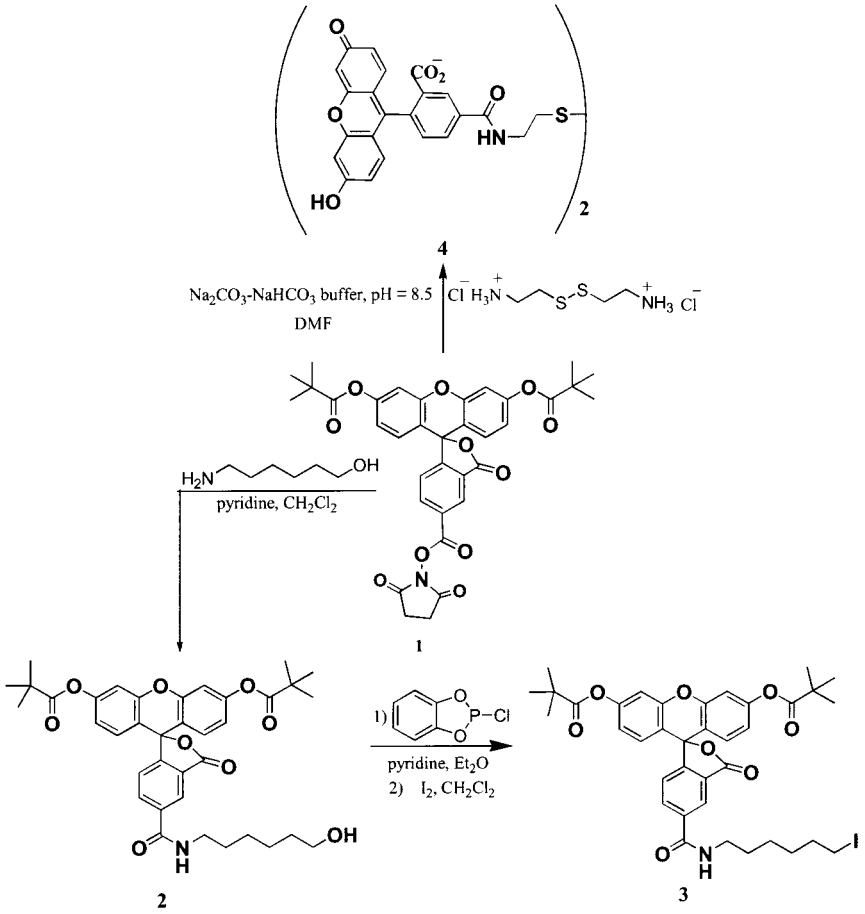
EXPERIMENTAL PROCEDURES



General Remarks. The chemical reagents such as SPDP, TCEP, and 5-FAM-NHS ester were purchased from Molecular Probes, Inc. The DNA polymerase, Thermo Sequenase II was obtained from Amersham Biosciences. NMR spectra were recorded on a Varian 300 MHz spectrometer and are reported in parts per million downfield from TMS. Mass spectra were obtained on a Micromass LC-MS instrument using TOF ES. DNA sequencing analysis and gel images were performed on ABI 377 sequencer. UV/vis spectra were recorded on a Perkin-Elmer Lambda20 spectrometer. The number in 11-ddUTP and 18-ddUTP denotes the number of atoms present in the spacer that connects the nucleotide base with the fluorescent dye or the pendant spacer moiety at the 5-position of the nucleotide base. For convenience, the abbreviation FAM is used for 5-carboxyfluorescein as mentioned in the Molecular Probes catalog.

5-(6-Hydroxyhexanamido)dipivaloylfluorescein (2). To a stirred solution of dipivaloyl-5-carboxyfluorescein *N*-hydroxysuccinimidyl ester **1** (0.5 g) in anhydrous CH_2Cl_2 (10 mL) were added anhydrous pyridine (250 μL) and 6-aminohexanol (100 mg). The reaction mixture was stirred overnight, diluted with 25 mL of CH_2Cl_2, and washed with 10% aqueous citric acid (2 × 15 mL) and brine (2 × 15 mL). The organic layer was dried over anhydrous Na_2SO_4 and evaporated under reduced pressure, and the residue was purified on silica gel column chromatography eluting with 2% MeOH−CH_2Cl_2 to give **2** (438 mg, 89%) as an amorphous solid.

5-(6-Iodohexanamido)dipivaloylfluorescein (3). To a stirred and cooled (0 °C) solution of **2** (322 mg, 0.5 mmol) in anhydrous ether (15 mL) were added anhydrous pyridine (41 μL, 0.5 mmol) and 1,2-phenylene phosphorochloridite (60 μL, 0.5 mmol) dropwise. The reaction

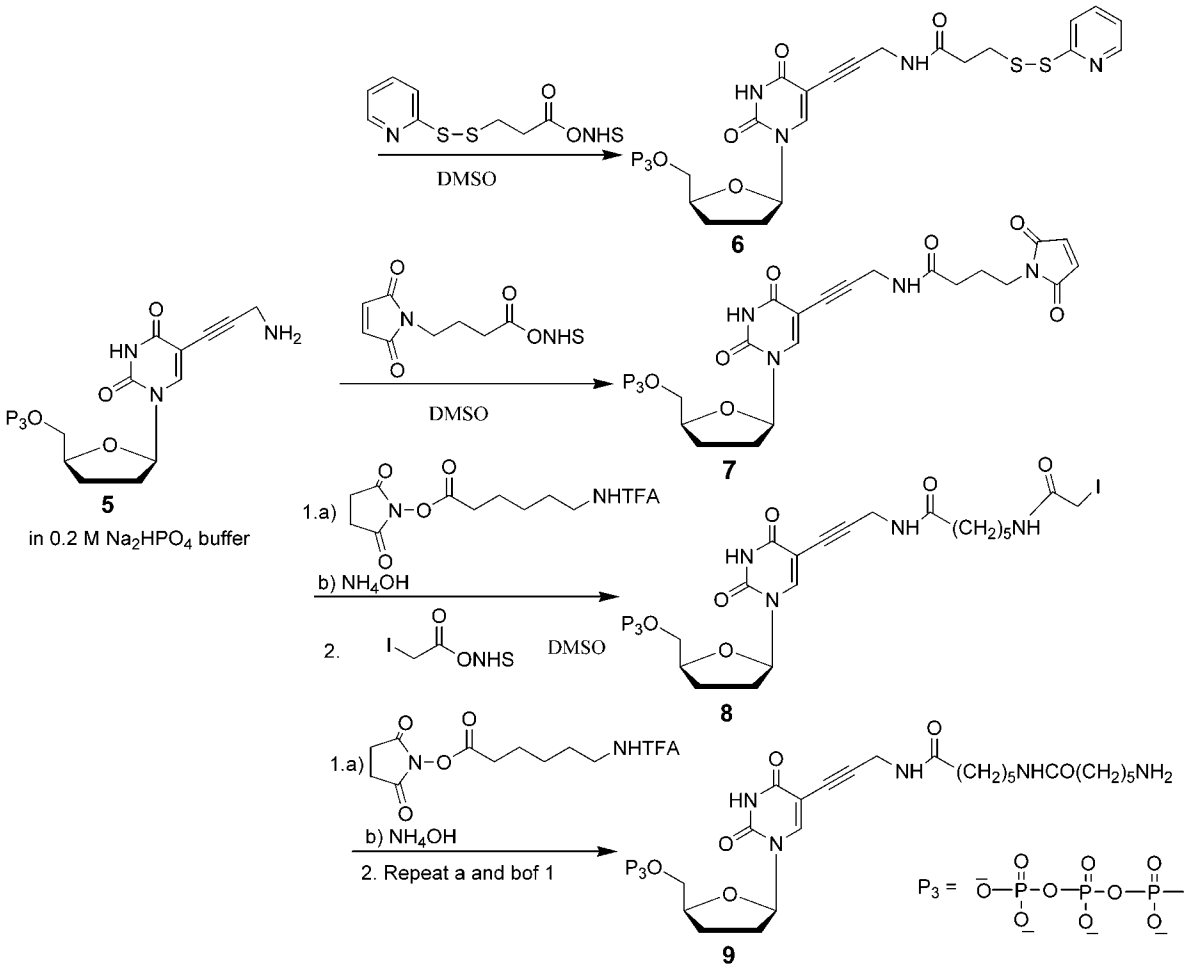
Scheme 1. Synthesis of Fluorescein Disulfide (4) and Alkyl Iodide (3)

mixture was allowed to come to room temperature and to continue stirring overnight. The salt formed was filtered and washed with ether and the filtrate evaporated under reduced pressure to provide the phosphorochloridite derivative, which without purification was treated with I_2 (127 mg, 0.5 mmol) in CH_2Cl_2 (10 mL) for 2 h to afford the crude alkyl iodide. Purification of the crude alkyl iodide on silica gel column, eluting with 1:1 hexanes−ethyl acetate, gave **3** (97%). ^{1}H NMR (300 MHz, $CDCl_3$) δ 8.34 (s, 1H, Ar-*H*), 8.16 (d, J = 8.5 Hz, 1H, Ar-*H*), 7.26 (d, J = 8.5, 1H, Ar-*H*), 7.25 (s, 1H, Ar-*H*), 7.06 (s, 1H, Ar-*H*), 6.77 (bs, 4H, Ar-*H*), 6.59 (bs, 1H, N*H*), 4.40 (m, 2H, CH_2NH), 3.18 (t, 2H, J = 17 Hz, CH_2I), 1.42−1.84 (m, 8H, (CH_2)$_4$), 1.35 (s, 18H, CH_3 × 3).

5-(Cystamido)fluorescein (4). To a stirred solution of **1** (270 mg, 0.42 mmol) in anhydrous DMF (10 mL) was added a 0.1 M Na_2CO_3−$NaHCO_3$ buffer (pH 8.5) solution of cystamine dihydrochloride (45 mg, 0.2 mmol) at room temperature. After stirring the reaction mixture overnight, it was evaporated under reduced pressure and the residue subjected to reversed-phase HPLC on a Delta-Pak C18 column (15 μm, 100 Å) eluting with a gradient of 0.1 M TEAB to 100% CH_3CN in 60 min at 5 mL/min gave compound **4** (27%). ^{1}H NMR (300 MHz, $CDCl_3$) δ 8.45(s, 2H, Ar-*H*), 8.07 (d, J = 8.5 Hz, 2H, Ar-*H*), 7.34 (d, J = 8.5, 2H, Ar-*H*), 7.00 (d, 4H, Ar-*H*), 7.05 (s, 1H, Ar-*H*), 6.66 (bs, 8H, Ar-*H*), 6.59 (bs, 2H, N*H*), 3.69 (t, 4H, J = 5.0 Hz, CH_2S), 3.31 (m, 4H, HNCH_2), 1.06 (s, 18H, CH_3).



Pyridyldithiopropionamidyl-PA-ddUTP (6). A 0.2 M sodium phosphate buffer (pH 7.2) solution (2.5 mL) of PA-ddUTP **5** (10 mg, 0.012 mmol) was treated with DMSO (0.5 mL) solution of SPDP (16 mg, 0.049 mmol) for 2 h at room temperature. The reaction mixture was subjected to reversed-phase HPLC on a Delta-Pak C18 semiprep column (15 mm, 100 Å, 300 × 19) eluting with 0.1 M TEAB (pH 7.5) to 100% CH_3CN in 60 min at 5 mL/min to provide **6** (8 mg, 60%) after evaporation and lyophilization.

Maleimidobutanamidyl-PA-ddUTP (7). Compound **5** (10 mg, 0.012 mmol) was reacted with SMB (succinimidyl 4-maleimidylbutanoate, 14 mg, 0.049 mmol) and product **7** (9.5 mg, 70%) purified using similar reaction and HPLC conditions as described for **6**. Observed 669.01 TOF MS ES− m/z for $C_{20}H_{24}N_4O_{16}P_3$, 669.00.

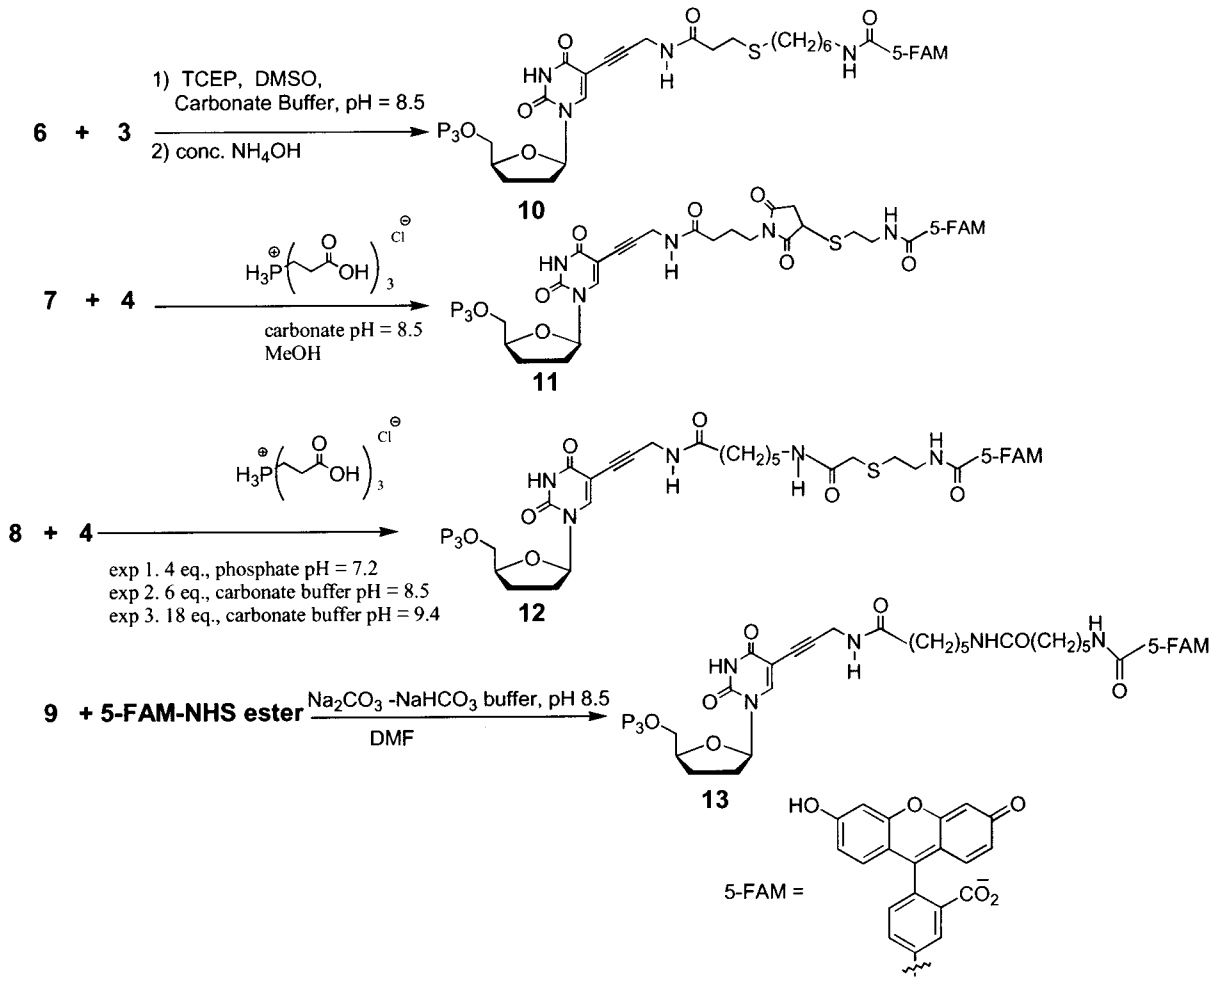
Iodoacetamidohexanamidyl-PA-ddUTP (8). In the first step, 11-ddUTP was synthesized from **5** and succinimidyl N-TFA-aminocaproate following the literature procedure. In the second step, 11-ddUTP (1.23 mL of 10 mM solution in phosphate buffer, pH 7.3, 0.012 mmol) was conjugated with succinimidyl iodoacetate (14 mg, 0.049 mmol) in DMSO (1.8 mL) by stirring at room temperature for 2 h. The reaction mixture was loaded onto a reversed-phase C18 HPLC column and purified as described for **6** to give **8** (86% yield based on the concentration determined using λ_{max} 291 nm, absorption (A) 1.33, and extinction coefficient (ϵ) 13000 M^{-1} cm^{-1} with 6.8 min retention time. Observed 784.55 TOF MS m/z ES− in water for $C_{20}H_{28}IN_4O_{15}P_3$, 784.98.

Amino-Terminated 18-ddUTP (9). To a stirred solution of **5** (200 mg, 0.25 mmol) in Na_2CO_3−$NaHCO_3$ buffer (pH 8.5, 7 mL) was added a DMF solution (3 mL) of

Scheme 2. Synthesis of Modified ddNTPs

succinimidyl N-TFA-aminocaproate (205 mg, 0.63 mmol). After 2 h, the reaction mixture was treated with 30% aqueous NH_4OH (2 mL) under sealed conditions for 2 h. After evaporation under reduced pressure, the residue was purified on a reversed-phase HPLC Delta Pak C18 semiprep column (15 μm, 100 Å, 300 × 19 mm), eluting with a gradient of 0.1 M TEAB to 100% CH_3CN 130 mL/min in 60 min to afford 11-ddUTP (165 mg, 71%). This extended 11-ddUTP (100 mg, 0.12 mmol) was further treated with succinimidyl N-TFA-caproate (53 mg, 0.16 mmol) in a mixture of Na_2CO_3−$NaHCO_3$ buffer (pH 8.5, 3 mL) and DMF(2 mL) for 2 h. After treatment with NH_4-OH, the product 18-ddUTP **9** (67 mg, 60%) was isolated using HPLC as described above.

Thioether-Cross-Linked Fluorescent Dye Terminator (10). To a stirred and cooled (5 °C) Na_2CO_3−$NaHCO_3$ solution (pH 8.5) of **6** (0.002 mmol) were sequentially added TCEP·HCl (4.3 mg, 0.015 mmol) and a DMSO solution (1.5 mL) of **3** (1.8 mg, 0.0023 mmol) under Ar gas. After 5 h, the reaction mixture was treated with 30% NH_4OH (200 μL) for 2 h and then loaded on a semiprep Q-Sepharose HPLC column (10 × 16). Elution with a gradient of buffer A (40% CH_3CN in 0.1 M TEAB; 10 min) to buffer B (40% CH_3CN in 1 M TEAB; 60 min) provided **10** (12%; concentration determined in water at 494 nm absorption/68000 extinction coefficient was 0.287 mM) with 70 min retention time. Observed 1049.25 TOF MS ES− *m/z* for $C_{42}H_{44}N_4O_{20}P_3S$, 1049.16.



Thioether-Cross-Linked Fluorescent Dye Terminator (11). Compound **4** (1.9 mg, 0.002 mmol) and TCEP·HCl (6.3 mg, 0.022 mmol) were dissolved in a mixture of 2 mM phosphate buffer (0.8 mL; pH 7.3) and MeOH (0.5 mL) and stirred at room temperature. The maleimide-modified-ddUTP **7** (200 μL, 0.002 mmol) was added, and monitoring by HPLC after 1 h indicated completion of the reaction. The reaction mixture was purified using Q-Sepharose HPLC column described for **10** to give **11** (10%, concentration determined in water at λ_{max} 494 nm, with ϵ = 68000). Observed 1171.72 TOF MS ES+ *m/z* for $C_{43}H_{39}N_5Na_3O_{22}P_3S$, 1171.75.

Amide-Cross-Linked FAM-18-ddUTP (13). A 0.1 M Na_2CO_3−$NaHCO_3$ buffer (pH 8.5) solution (1.5 mL) of **9** (10 mg, 0.01 mmol) was reacted with a DMF solution of 5-FAM-NHS ester (5.5 mg, 0.012 mmol) at room temperature for 3 h. Compound **13** (60%) was isolated following the procedure described for **10**.

RESULTS AND DISCUSSION

Synthesis. The electrophilic and nucleophilic fluorescent dyes **3** and **4** (Scheme 1) required for the intended study were synthesized starting from dipivaloyl-5-carboxyfluorescein succinimidyl ester (**1**). Reaction of 6-aminohexanol with **1** in the presence of pyridine in anhydrous CH_2Cl_2 provided **2** (87%), which was converted to the alkyl iodide **3** in 97% yield via the cyclic phosphite in a displacement reaction with I_2. Synthesis of the nucleophilic fluorescent dye, in the form of its disulfide (**4**), was achieved in 27% yield by reacting **1** with cystamine hydrochloride in a mixture of DMF and Na_2-CO_3−$NaHCO_3$ buffer (pH 8.5). On the other hand, the propargylamino functionality in 5-(3-aminopropynyl)-ddUTP **5** (*11*) was suitably modified to generate two each

Scheme 3. Synthesis of Thiol- and Amide-Crosslinked ddNTPs

of nucleo- and electrophilic partners to participate in the final conjugation reaction. Thus, **5** was indirectly thiolated by reacting with SPDP (succinimidyl 3-(2-pyridyldithio)propionate) in a mixture of DMSO and phosphate buffer (pH 7.2) to afford pyridyldithiopropionamidyl-PA-ddUTP (**6**) conjugate, which upon reduction would release the nucleophilic thiol of **6** and 2-pyridinethione (Scheme 2). The maleimidobutanamidyl-PA-ddUTP (**7**) was obtained by reacting **5** with succinimidyl 4-maleimidylbutanoate. Synthesis of the electrophilic terminator, iodoacetamidohexanamidyl-PA-ddUTP (**8**) was accomplished in three steps involving treatment with succinimidyl 6-N-TFA-aminocaproate, ammonolysis with 30% aqueous ammonia followed by iodide displacement reaction with succinimidyl iodoacetate. For preparation of the extended terminator, **9** containing 2-amide bonds and a terminal reactive amino functionality, compound **5** was reacted iteratively with succinimidyl 6-N-TFA-aminocaproate and NH_4OH.

In the ultimate cross-conjugation reactions, the thiol-reactive alkyl iodide **3** was employed to react with in situ generated thiol of **6** upon treatment with tris(2-carboxyethyl)phosphine (TCEP) in a mixture of DMSO and Na_2CO_3−$NaHCO_3$ buffer (pH 8.5) followed by removal of pivaloyl groups with aqueous ammonia provided the thioether-cross-conjugated terminator **10** (12%) (Scheme 3). Under the same reaction conditions (vide supra), the thiol-reactive maleimide **7** was allowed to cross-conjugate with in situ generated thiol of the disulfide **4** to give the fluorescent, thioether-cross-linked terminator **11** (10%). In sharp contrast, the iodoacetamide-modified-ddUTP (**8**) when reacted with thiol of **4** at three different pHs, 7.2, 8.5, and 9.4, produced disappointing yields of unstable, fluorescent thioether-cross-linked terminator **12**. This was due to faster hydrolysis of the iodoacetamide functionality in **8** than the nucleophilic displacement with **4**. HPLC (C18 Delta Pak) analysis of the reactions carried out under different pHs (vide supra) revealed dominant hydrolysis product formation showing 5.45 min retention time to that of **12** at 7.95 min. A small amount of **12** was isolated from the combined reaction mixtures and characterized by mass spectral analysis to show its mass at 1093.92 (TOF MS ES+, exact mass for $C_{43}H_{46}N_5O_{21}P_3S$ is 1093.16) The amino-terminated 18-ddUTP (**9**) was conjugated with 5-carboxyfluorescein succinimidyl ester to give FAM-18-ddUTP (**13**, 60%).

Cycle Sequencing. To test functional outcome of the synthesized thiol-cross-linked, fluorescein-ddUTPs (**10** and **11**) along with the FAM-18-ddUTP (**13**), under a DNA polymerase catalysis, individual cycle-sequencing reactions were performed. A typical cycle-sequencing reaction contained M13 mp18 DNA template, −40 universal primer, Thermo Sequenase II DNA polymerase, dNTPs (dATP, dCTP, dGTP, and dTTP), Tris buffer (50 mM, pH 8.5), $MgCl_2$ (5 mM), and the individual conjugates **10**, **11**, and **13**. For all three reactions, thermal cycling (95 °C, 20 s; 50 °C, 30 s; 60 °C, 2 min) program was used in 25 cycles. Following the PCR postreaction workup (ethanol precipitation), amplicons terminated with the fluorescent ddUTP conjugates were subjected to slab gel electrophoresis and detection on ABI 377 DNA sequencer. The slab gel images from the above three

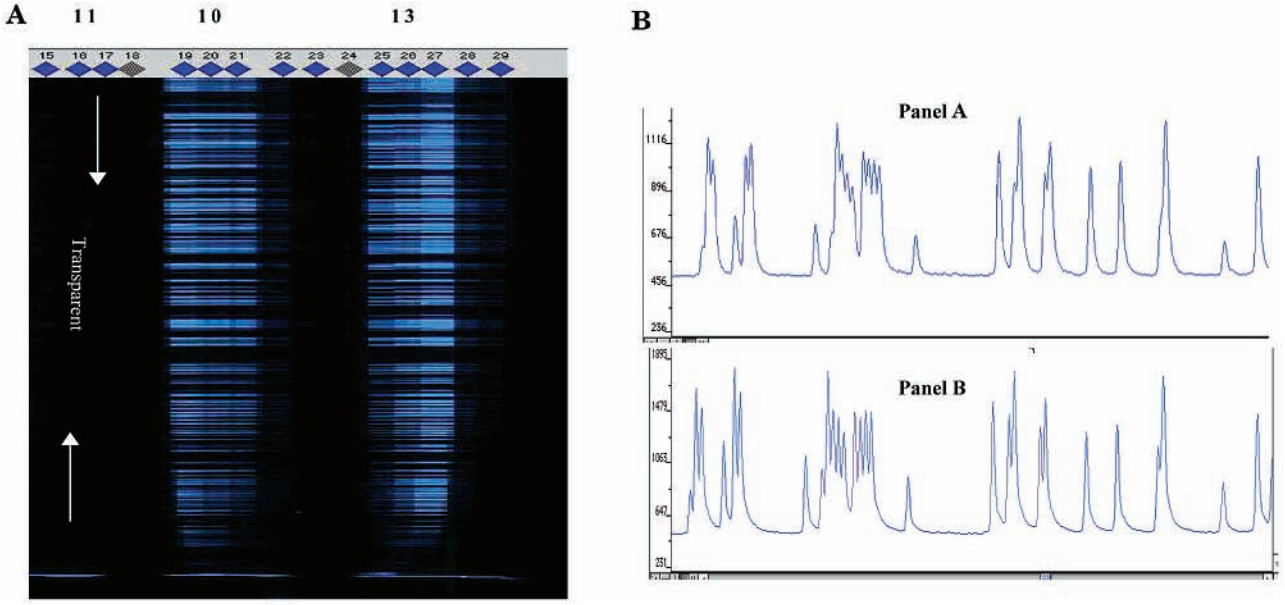


Figure 1. (A) DNA sequencing ladder images of amplicons terminated by thioether (**10**)- and triamide (**13**)-cross-linked terminators. Maleimide-derived, thioether-cross-linked fluorescent terminator (**11**) did not leave any fluorescent images due to cleavage. (B) Partial, one-color electropherogram generated by amplicons terminated by thioether (Panel A: **10**)- and amide (Panel B: **13**)-cross-linked fluorescent terminators.

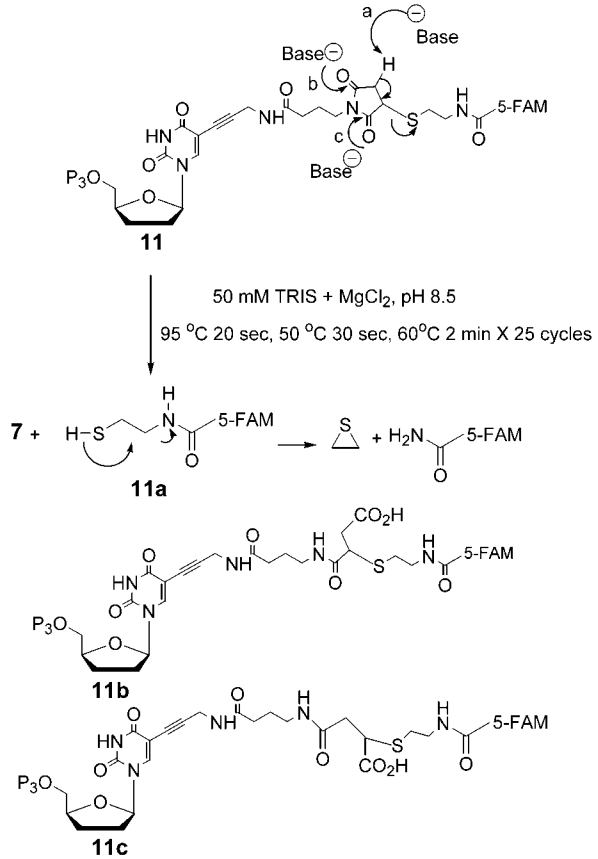
reactions indicated comparable ladders for **10** and **13** terminated amplicons, while that of **11** being transparent owing to have undergone reversed-Michael reaction under the cycle sequencing conditions (Figure 1).



As it was difficult to isolate the suspected, linker-specific cleavage products **7**, **11a**−**c** (Scheme 4), believed to have been formed via a, b, and c mechanistic pathways (*12*), from the PCR reaction mixture for characterization, compound **11** was subjected to mere PCR thermal cycling (vide supra) conditions in the same buffer and pH to see if it would generate cleavage products. Analysis by mass spectrometry of the reversed phase-HPLC-isolated compound revealed the structure for the cleavage product as **7**. Other cleavage products with a fluorescent tag could not be isolated and identified. Despite cleavage of the terminator **11** during thermal cycling, one cannot rule out the possibility of cleavage product **7** or its hydrolyzed version being incorporated into the amplicons, which lacked the ability to leave fluorescent signatures.

Comparative examination of the partial electropherograms, generated by the amplicons terminated by **10** and **13**, suggested that both terminators were equally good substrates for the Thermo Sequenase II DNA polymerase, showing almost the same level of peak intensity and uniformity with somewhat decreased peak resolution in case of **10**. On the other hand, comparison of **10** and **11** with commercial terminators (*3*) with shorter linkers between the nucleotide and the fluorescent dye generally show decreased peak uniformity and resolution.

CONCLUSIONS.

In this paper, we have reported the synthesis of two thiol-cross-linked fluorescent dye terminators (**10** and **11**) and their DNA sequencing potential compared to the amide-cross-linked fluorescent terminator (**13**). The single-color DNA sequencing experiments conducted, using these new terminators, revealed the structural importance of the chain-terminating nucleotides and their effect on the sequencing function. The DNA sequencing information derived from the amplicons of thiol-cross-linked fluorescent terminators serve as a new model and provide useful pointers for designing new terminators.

Total Chemical Synthesis of a 27 kDa TASP Protein Derived from the MscL Ion Channel of *M. tuberculosis* by Ketoxime-Forming Ligation

Gerd G. Kochendoerfer,* Janette M. Tack, and Sonya Cressman

Gryphon Sciences, 250 East Grand Avenue, Suite 90, South San Francisco, California 94080. Received December 19, 2001; Revised Manuscript Received February 19, 2002

A 27-kDa TASP protein, T_5Msc(103−151), that was derived from the cytoplasmic domain (amino acid residues 103−151) of the MscL ion channel of *M. tuberculosis* was synthesized by ketoxime-forming chemoselective ligation between a template molecule carrying five pyruvic acid groups, and linear channel peptides carrying one aminooxyacetic acid group. Ketoxime-forming ligation provided for highly efficient assembly of this large totally synthetic protein construct with yields >90% with modest excess (1.5×) of the aminooxy peptide. Formation of the desired TASP molecule was confirmed by SDS−PAGE analysis and MALDI mass spectrometry. The effect of template attachment on the structure of the peptides constituting the TASP was assessed by circular dichroism spectroscopy. Attachment of the peptides to the topological template induces predominantly helical secondary structure, whereas an analogous peptide that did not bear an aminooxy group, MscL(103−151), does not exhibit significant secondary structure at pH 7 and is found to be monomeric in concentrations up to 65 μM. This observation can be explained by entropic destabilization of the unfolded state of T_5Msc(103−151) due to the attachment to the template and the resulting loss of degrees of freedom. Pyruvic acid-based ketoxime-forming chemoselective ligation may thus prove to be a useful tool for the assembly of large, non-native protein constructs and their biophysical study.

INTRODUCTION

The molecular mechanisms underlying the folding and oligomeric assembly of membrane proteins are not fully understood (*1*, *2*). Membrane proteins are thought to be composed of distinct protein domains that fold independently prior to assembly of the full-length protein (*1*, *3*). For that reason, the study of folding and assembly of small membrane proteins, in particular small ion channels, is useful to understand membrane protein folding on an experimental and theoretical level. Recently, we introduced the application of chemical ligation to the total synthesis of membrane proteins. For instance, we showed that both the cytoplasmic and the membrane-spanning domains of totally synthetic influenza A M2 protein help to stabilize the tetrameric assembly of this protein (*4*). The MscL (mechanosensitive channel large)[1] of *M. tuberculosis* in conjunction with its known crystal structure (*5*) provides another interesting system to understand the assembly of membrane proteins. MscL is one of several channels constituting the stress response of the bacterium and allows the efflux of ions and small molecules in response to osmotic stress (*6*−*8*). The crystal structure of the 151-amino acid full-length channel reveals two membrane-spanning helices that are arranged as a homopentamer (*5*). In addition, this structure indicates that the cytoplasmic residues 103−115-fold into a homopentameric helical pore outside the putative membrane-spanning region (see Figure 1) (*5*). As pointed out by the authors, the crystals are disordered beyond residue 115 in the solved structure, and the crystals were obtained at pH 3.5 which casts doubt about the relevance of this structural motif at physiological pH.

When performing CD (circular dichroism) measurements on a peptide derived from the C-terminal domain (amino acid residues 103−151) of MscL, we observed that this peptide did not display any secondary structural feature in aqueous solution under neutral conditions, but rather displayed predominant random-coil structure (see below). We hypothesized that the folding of the C-terminal domain of MscL was partially driven by the attachment of the peptides to the topological template formed after the transmembrane domains assemble into the helical pore.

Design. In the TASP (template-assembled synthetic protein) approach pioneered by Mutter and co-workers (*9*−*11*), peptide building blocks are covalently linked to a topological template in order to direct folding toward a particular three-dimensional packing arrangement and thus mimicking some of the structural and functional properties of native proteins. To test our hypothesis, we designed a TASP that grafts five copies of the C-terminal peptide of MscL (amino acid residues 103−151) onto a peptidic template to mimic the situation in the full-length

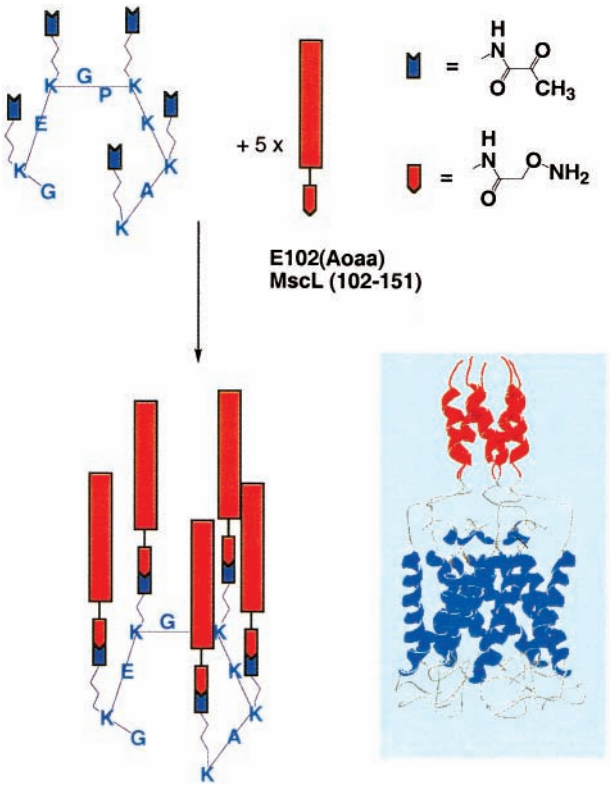

Figure 1. Total chemical synthesis of T_5Msc(103−151): The channel peptide E102(Aoaa) Msc(102−151) is attached to the linear template peptide by chemoselective oxime forming ligation. The inset shows the crystal structure of MscL of *M. tuberculosis* (PDB access code: 1MSL, graphics program: deep view). Amino acid residues 103−115 which comprise the N-terminus of the peptides making up T_5Msc(103−151) are coded in red.

protein (see Figure 1). The amino acid sequence of the template is identical to the sequence employed by Montal and co-workers (*12*) to build a pentameric ion channel TASP. The wild-type like activity of this construct demonstrated that nicotinic acetylcholine receptors assemble to form a pentamer, a finding borne out by electron microscopy and crystallographic analysis (*13*−*15*). We decided to construct a TASP that spans the entire C-terminal domain (starting in the helical region colored in red in Figure 1) beyond the region resolved in the crystal structure to enable future structural work on this protein domain. Our prediction was that attachment of the C-terminal MscL peptide to such a topological template would be sufficient to fold the peptides into a helical pore as observed in the crystal structure.

Synthetic Strategy. The TASP design target represents a formidable synthetic challenge due to its large size and complexity. Previously, TASPs have been synthesized either directly by SPPS (solid-phase peptide synthesis) (*16*, *17*) or by independent SPPS of the template and the peptide building blocks, followed by chemoselective ligation or segment condensation of the peptide building blocks to the template (*18*−*29*). The large size of the target protein precludes the direct assembly by SPPS due to the large expected number of side-products stemming from the assembly of 256 amino acids in one covalent construct. Therefore, chemoselective ligation is preferred because of the ease of synthesis and purification of unprotected synthetic peptides of ∼50 amino acid residue length, followed by the assembly of these segments into the full-length construct. The challenge was to identify a ligation chemistry that yields complete reaction due to the difficulty in chromatographically separating the very similar intermediate trimer and tetramer species from the desired pentameric species. Chemoselective linkage chemistries employed previously for TASP assembly included (a) thioether formation between a thio acid or thiol group and a haloalkyl group (*19*, *24*, *28*) or a thiol group and a maleimide group (*22*, *25*, *27*), (b) aldoxime formation between an aldehyde and an aminooxy group (*18*, *20*, *21*, *23*, *29*) and reductive amination (*26*). Initially, we attempted to form the TASP by reaction of a pentamaleimide or a pentaiodoacetyl template with a MscL(103−151) peptide containing an N-terminal cysteine. However, significant amounts (>30%) of dimer, trimer, and tetramer reaction intermediates remaining after completion of the reaction prevented the purification of large quantities of pure material, even in the presence of a 3-fold excess of peptide relative to template. We then considered ketoxime formation for the TASP (to avoid any additional template oxidation/deprotection steps prior to the oximation reaction which are necessary for aldoxime formation). In the literature, levulinic acid and its derivatives are the preferred ketones for chemoselective ligation of nucleophile-bearing groups to peptides and proteins (*30*−*34*). However, we and others (*33*) experienced incomplete reactions using a levulinic acid-based template for attachments of multiple peptides.

In this paper, we report a strategy for assembly of TASPs that involves the straightforward, efficient, and complete formation of a ketoxime bond between an aminooxy group on a linear peptide synthesized by Boc chemistry and a pentapyruvic acid bearing template synthesized by Fmoc chemistry. Oxime-forming ligation of these constructs not only provides for efficient assembly of the desired 27 kDa TASP protein, but may have general usefulness for the ligation of synthetic and recombinant peptides.

EXPERIMENTAL PROCEDURES

Boc-protected amino acids were obtained from Midwest Biotech (Fishers, IN) and Fmoc-protected amino acids were obtained from Novabiochem (San Diego, CA). Trifluoroacetic acid was obtained from Halocarbon (River Edge, NJ). DIEA (*N*,*N*-diisopropylethylamine) was obtained from Applied Biosystems (Foster City, CA). HBTU (2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate) was obtained from Spectrum (Gardena, CA). Carbonyl-free acetonitrile was obtained from Burdick & Jackson (Gardena, CA). Other chemicals were from Sigma (St. Louis, MO) or Aldrich (Milwaukee, WI) and were used as received.

Peptide Synthesis and Purification. The sequence of the E102(Aoaa) Msc (102−151) peptide in single-letter code is (Aoaa)-VEQPGDTQ VVLLTEIRDL LAQTNGDSPG RHGGRGTPSP TDGPRASTES Q. The peptide was synthesized at a 0.2 mmol scale on a custom-modified Applied Biosystems 433A peptide synthesizer. The peptide was synthesized on an S−DVB (stryrene−divinylbenzene) resin carrying a $-OCH_2-$PAM linker (Applied Biosystem, Foster City, CA) using an in situ neutralization protocol for machine-assisted Boc (*tert*-butoxycarbonyl) chemistry (*35*). Side-chain protecting groups were: Arg(Tos), Asp(OChx), Asn(Xan), Glu(OChx), His(DNP), Lys-(2ClZ), Ser(Bzl), Thr(Bzl), and Tyr(2BrZ). DMF (*N*,*N*-dimethylformamide) and DCM (dichloromethane) were HPLC grade and used as received. After the final amino acid coupling, the terminal Boc protecting group was removed by treatment with 100% TFA, followed by neutralization with 10% DIEA in DMF for 1 min. A 2 mmol amount of Boc-aminooxyacetic acid was added to

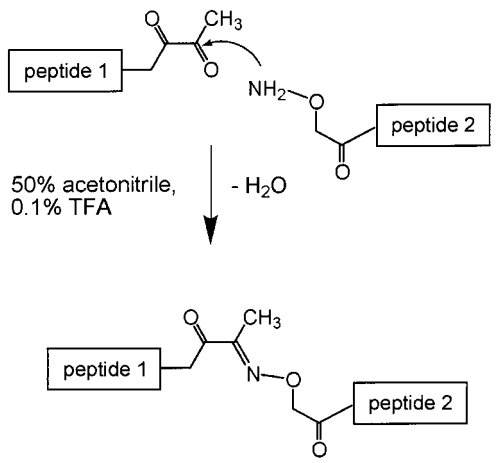
the resin after activation with 2 mmol of DIC (diisopropylcarbodiimide) and 2 mmol NHS (*N*-hydroxysuccinimide) in 3 mL DMF for 30 min. The terminal Boc protecting group was then removed by treatment with 100% TFA for 2 × 1 min. The peptide was deprotected and simultaneously cleaved from the resin support using HF/*p*-cresol according to standard Boc-chemistry procedures (*35*). The peptide was purified by preparative C-4 RP-HPLC with a linear gradient of 20 to 40% Buffer B (acetonitrile containing 0.08% TFA) versus 0.1% aqueous TFA in 80 min.

The sequence of the Msc (103−151) peptide in single-letter code is VEQPGDTQ VVLLTEIRDL LAQTNGD-SPG RHGGRGTPSP TDGPRASTES Q. It was prepared analogously except for the addition of aminooxyacetic acid. The sequence of the linear template is K(Mtt)AK-(Mtt)K(Boc)K(Mtt)PGK(Mtt)E(OtBu)K(Mtt)G. The template was synthesized manually using Fmoc chemistry (*36*) on an S−DVB resin carrying a Rink linker (Novabiochem, San Diego, CA). For a synthesis on a 0.2 mmol scale, 2.1 mmol of amino acid was dissolved in 3.8 mL of DMF containing 1.9 mmol of HBTU and 1 mL of DIEA and activated for 3 min. Coupling was performed for 20 min per cycle, and deprotection was performed with 2 × 3 min batch washes with 20% piperidine in DMF. After the last amino acid coupling step, the Fmoc protecting group was not removed. The Mtt side-chain protecting group was removed by multiple treatments with 2% TFA in DCM. After neutralization with 10% DIEA in DMF, 1 mmol of pyruvic acid was coupled to the resin after activation with 1 mmol of DIC and 1 mmol of NHS in DCM for 45 min. The template was purified by C-4 RP-HPLC with a linear gradient of 15−35% Buffer B versus 0.1% aqueous TFA in 60 min. Fractions containing the desired material were identified by ESI/MS, frozen, and lyophilized.

Analytical RP-HPLC. Analytical RP-HPLC was performed on a Vydac C-4 analytical column (5 μm particle size, 0.46 cm × 15 cm), using a Hewlett-Packard Model 1100 quaternary pump high-pressure mixing system with 214 and 280 nm UV detection.

Oxime-Forming Chemoselective Ligation. A 1.5-fold molar excess (aminooxy acetyl) peptide to pyruvic acid group on the template) of E102(Aoaa) Msc (102−151) was added to a solution of the template in 50% aqueous acetonitrile containing 0.09% TFA. After 15 min reaction time, solvents were evaporated to dryness on a speedvac to drive the reaction to completion, and the dry mix was redissolved in 50% aqueous acetonitrile containing 0.09% TFA. The N-terminal Fmoc-protecting group on the template was removed by addition of a 3-fold excess of 6 M guanidinium chloride, 100 mM acetate, pH 4 buffer, and an equivalent volume of piperidine (final concentration 20%) for 20 min. The solution was acidified with glacial acetic acid, and reactants and products were separated by preparative reverse-phase HPLC with a linear gradient of 20 to 48% Buffer B (acetonitrile containing 0.08% TFA) versus 0.1% aqueous TFA in 80 min. Fractions containing the desired material were identified by SDS−PAGE, frozen, and lyophilized.

Mass Spectrometry. T_5Msc(103−151) was dissolved in a saturated solution of α-cyano-4-hydroxycinnamic acid in 50% aqueous acetonitrile/0.09% TFA acid. A 1 μL aliquot was deposited directly on the sample slide and allowed to air-dry. The sample preparations were analyzed using a Ciphergen Biosystems Massphoresis System time-of-flight mass spectrometer. The spectra were externally calibrated using horseradish peroxidase (MW = 43240 Da) and represent an average of 50 shots.



Protein Folding. To induce folding, T_5Msc(103−151) and the Msc (103−151) peptide were dissolved at a concentration of 1 mg/mL in 6 M guanidinium hydrochloride buffer containing 200 mM $H_2PO_4^-$ (counterion sodium), pH 7, respectively. The peptides were dialyzed stepwise O/N against 100× volume into 20 mM $H_2PO_4^-$ (counterion sodium), pH 7, containing 100 mM NaCl, and finally 20 mM $H_2PO_4^-$ ((counterion sodium), pH 7. For folding at low pH, the final buffer was 20 mM glycine (counterion chloride), pH 4.

Circular Dichroism Spectrometry. CD spectra were acquired with a JASCO-J700 CD spectrometer at 20 °C between 190 and 250 nm in 0.4 nm increments (bandwidth: 1 nm, dwell-time: 2 s, averaged over three acquisitions). Quantitative secondary structure modeling was performed by least-squares fitting to a set of proteins of known structure using the CDsstr and Continll algorithms as implemented by the CDPRO software package (http://lamar.colostate.edu/∼sreeram/CDPRO). The basis set employed for modeling the linear peptide also included several unfolded proteins, since the fits in the absence of unfolded proteins in the basis set were unsatisfactory. The Selcon3 algorithm implemented in the same software package did yield significantly worse fits as indicated by more than four times higher RMSD values (experimental − calculated) and was therefore discarded. However, the determined percentage of helicity and disordered structure was comparable.

RESULTS

The channel peptide E102(Aoaa) MscL (102−151) was assembled using Boc chemistry SPPS following standard procedures (*35*). After chain assembly, an aminooxy acetic acid group was coupled to the N-terminus of the peptide to serve as chemoselective linker. The peptide was deprotected, cleaved, and purified using standard methods (*35*). For structural comparison, an analogous peptide that did not bear an aminooxy group (MscL(103−151) was synthesized. The template peptide (*12*) was synthesized by SPPS following the Fmoc strategy as described in the methods section (*36*). After chain assembly, pyruvic acid was coupled to five specific side-chains to serve as chemoselective ligation linkers. The TASP T_5Msc(103−155) was assembled by joining five unprotected, purified channel peptides to the purified template peptide through a chemoselective ketoxime-forming ligation (See Scheme 1). A

Scheme 1. Ketoxime-Forming Ligation by Reaction of a Pyruvic Acid Bearing Peptide (left) with an Aminooxyacetic Acid Bearing Peptide (right). The Newly Formed Oxime Bond Is Stabilized by Electron Resonance

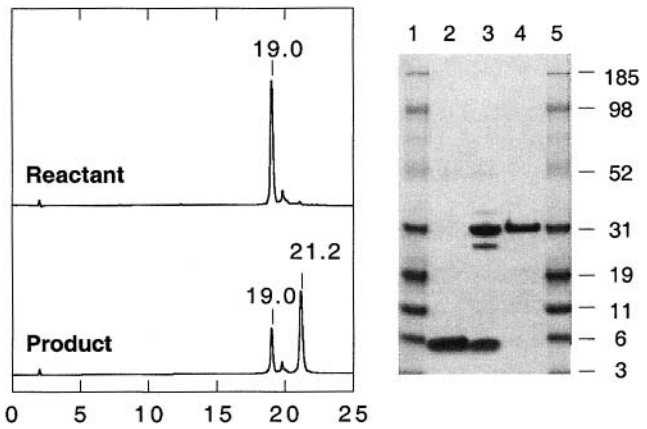


Figure 2. Analysis of oxime-forming ligation: Left: RP-HPLC traces (detected at 214 nm) monitoring the oxime-forming ligation reaction. Analytical reversed-phase HPLC was performed on aliquots with a linear gradient of 5−65% Buffer B (acetonitrile containing 0.08% TFA) versus 0.1% aqueous TFA over 24 min on a Vydac C-4 analytical column. Top: RP-HPLC trace after injection of an aliquot of the reactant peptide E102-(Aoaa)Msc(102−151). Bottom: Equivalent RP HPLC trace after the oximation reaction. Right: NuPAGE Bis-Tris (Mes) SDS−PAGE gel (4−12%) monitoring the synthesis and purification of T_5Msc(103−151). Gels were stained for protein with Coomassie blue. Lane 1 + 5: MW Standard. Lane 2: Reactant (E102Aoaa) Msc(102−151). Lane 3: Crude oximation mix. Lane 4: Purified T_5Msc(103−151).

1.5-fold molar excess (aminooxy peptide to pyruvic acid unit on the template) of E102(Aoaa) MscL (102−151) was added to a solution of the template in 50% aqueous acetonitrile containing 0.09% TFA. Figure 2 presents HPLC traces monitoring the formation of the target TASP, named T_5Msc(103−151). The linear E102(Aoaa) MscL (102−151) peptide exhibits a single dominant peak at 19.0 min. A minor peak at 19.8 min corresponds to an aminooxy-mediated dimer that is intrinsically unreactive and appears after lyophilization of the purified peptide. After the reaction mixture was dried on a Speedvac and redissolved in 50% acetonitrile containing 0.09% TFA, a new peak at 21.2 min appears. The increase of this peak is correlated with a decrease of the reactant peak. To monitor the completeness of the reaction more quantitatively, an SDS−PAGE gel of the reactant, and the product mix after dissolution in SDS sample buffer was obtained. The monomeric starting material in Lane 2 (Figure 2) shows the expected molecular weight of ∼5 kDa. The crude reaction mixture in Lane 3 indicates very high reaction efficiency. In addition to the unreacted starting material and the desired pentamer band at ∼31 kDa, only a weak band for the tetramer (<10%), but no lower oligomers, is detected in the crude reaction mix. In addition, a small population of hexameric compound is detected. Since incomplete reaction may occur at any of the five pyruvic acid sites, this result suggests that the ligation reaction is >98% complete for each aminooxyacetic−pyruvic acid ketone pair even with the modest excess (1.5-fold) of aminooxy peptide employed. After workup, reactants and products were separated by preparative RP-HPLC as described in the methods section. Fractions containing the desired TASP protein, T_5Msc(103−151), were identified by SDS−PAGE, frozen, and lyophilized. Lane 4 in the SDS−PAGE gel in Figure 2 indicates high (>98%) oligomeric purity for the purified pool of T_5Msc(103−151).

Additional analytical data characterizing purified T_5-Msc(103−151) is presented in Figure 3. The RP-HPLC trace of the purified TASP protein shows a single

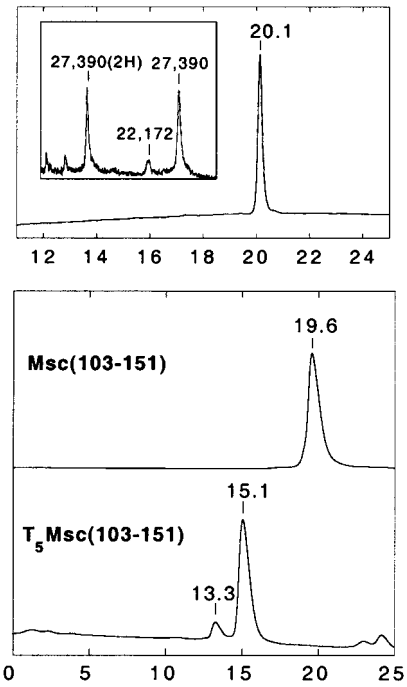

Figure 3. Analytical characterization of T_5Msc(103−151): Top: Reverse-phase HPLC chromatogram of purified T_5Msc-(103−151) construct. Analytical reverse-phase HPLC was performed with a linear gradient of 5−65% Buffer B (acetonitrile containing 0.08% TFA) versus 0.1% aqueous TFA over 24 min on a Vydac C-4 analytical column. The inset shows a MALDI-TOF mass spectrum of purified T_5Msc(103−151). Peaks originating from doubly protonated species are marked as (2H). Bottom: Size-exclusion HPLC chromatogram of the purified and "folded" T_5Msc(103−151) (Top) and Msc(103−151) (Bottom) construct. Analytical SEC HPLC was performed on aliquots using 20 mM $H_2PO_4^-$, pH 7 containing 100 mM NaCl as mobile phase on a Tosoh-Haas G2000 SWXL column (particle size 5 μM, pore size 125 Å). Size exclusion standards eluted at the following retention times: albumin (69 kDa): 14.9 min; ovalbumin (46 kDa): 15.9 min; chymotrypsin (21 kDa): 21.9 min.

dominant peak with a peptidic purity greater than 95%. Formation of the desired pentameric TASP was verified by MALDI-TOF mass spectrometry. The observed molecular weight of T_5Msc(103−151) is 27390 ± 20 Da (theoretical mass = 27389 (average isotope composition)). The impurity observed in the MALDI spectrum at ∼5 kDa below the target molecular weight is attributed to cleavage of the UV-absorbing oxime bond by the excitation laser as well as possibly a slight channel peptide tetramer impurity. The latter interpretation is confirmed by a clear laser power dependence of the relative intensity of this impurity peak.

To induce folding, T_5Msc(103−151) and Msc(103−151) were dissolved in denaturing buffer, followed by dialysis into 20 mM $H_2PO_4^-$, pH 7. Size-exclusion chromatographic analysis (Figure 3, bottom) indicates that the retention time (15.1 min) of "folded" T_5Msc(103−151) lies between the retention times of the molecular weight-standards ovalbumin (∼46 kDa) and albumin (69 kDa). The apparent discrepancy of this apparent weight to the real confirmed molecular weight can be rationalized by the expected nonglobular, possibly rodlike shape of the TASP. Rodlike proteins are expected to be more hindered when entering the pores of the size-exclusion resin, thus exhibiting higher apparent molecular weights (*37*). An alternative explanation is that a significant part of the TASP may be (a) unfolded or only loosely structured, leading to increased apparent molecular weight or (b) completely dimeric. These alternatives, while less likely,

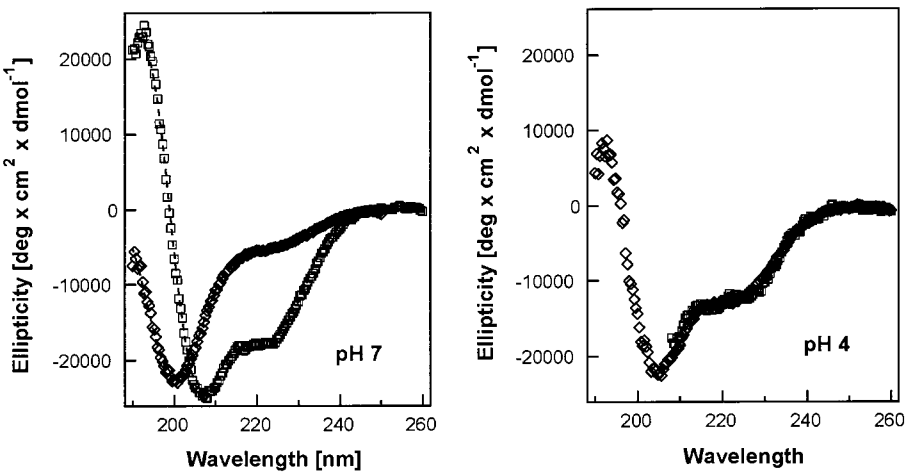

Figure 4. Left: Circular dichroism spectra of Msc(103−151) (diamonds) and T_5Msc(103−151) (squares) in 20 mM $H_2PO_4^-$ (counterion sodium), pH 7. Data fits obtained from the quantitative secondary structure modeling are also shown for the measurements at pH 7 (dashed lines). The concentrations of T_5Msc(103−151) and Msc(103−151) were 42 μg/mL (1.5 μM) and 38 μg/mL (7.4 μM), respectively. Right: Circular dichroism spectra of Msc(103−151) (diamonds) and T_5Msc(103−151) (squares) in 20 mM glycine (counterion chloride), pH 4. The concentrations of T_5Msc(103−151) and Msc(103−151) were 58 μg/mL (2.1 μM) and 84 μg/mL (16.5 μM), respectively.

will be addressed in further studies. In summary, it appears that MscL (103−151) is predominantly monomeric (>90%) with a dimeric species (retention time 13.3 min) representing the major additional population under our assay conditions up the highest concentration (∼65 μM) employed in the CD analysis.

To assess folding of T_5Msc(103−151), CD spectra were acquired of the TASP and MscL (103−151), respectively, in aqueous buffer. The final buffers were 20 mM $H_2PO_4^-$, pH 7, and 20 mM glycine buffer, pH 4, respectively. Figure 4 presents the CD spectrum of the linear Msc (103−151), and the CD spectrum of T_5Msc(103−151), respectively, under comparable total peptide concentrations in 20 mM $H_2PO_4^-$, pH 7. Inspection of the CD trace of Msc(103−151) indicates predominant random coil structure at pH 7. A significant increase in helicity is observed after lowering the pH to 4 for this peptide. SEC (size-exclusion chromatography) reveals that the peptide is monomeric at pH 4 as well (data not shown). Subsequently, the concentration dependence of the helical content was determined since for a pentameric oligomer one expects a strong dependence of the oligomeric state on the concentration. The respective CD spectra do not change significantly over the range from 7.4 to 66 μM for the peptide at pH 7 and 3.5 to 65 μM for the peptide at pH 4. Thus, peptide MscL (103−151) is intrinsically helical in the monomeric state at low pH, but predominantly in a random coil conformation at physiological pH.

By contrast, T_5Msc(103−151) exhibits a CD trace at both pH 7 as well as pH 4 typically observed for proteins with a high helical content and shows a slight decrease in helicity at pH 4 relative to pH 7. The CD spectra of T_5Msc(103−151) and Msc(103−151) at pH 4 are virtually superimposable at higher wavelengths (intrinsic absorption of UV light, most likely by the oxime bond, precluded acquisition of data beyond this region). Quantitative secondary structure modeling of the data obtained at pH 7 revealed that whereas the linear synthetic peptide exhibits ∼15% helical structure and is primarily comprised of disordered structure (61−73%), assembly of the peptides on the peptide template increases the helical content to 60−67%, with only 20% disordered structure. Whereas these numbers should not be taken literally due to the limited accuracy of quantitative CD analysis, they do confirm the trend observed by visual inspection. A small percentage of β-sheet structure (<10%) may be partially attributed to the template peptide. Related template peptides have previously been shown to form a preferred β-sheeted conformation (*38*, *39*). However, the small size of the template peptide (11 amino acid residues) relative to the total size of the T_5Msc(103−151) construct (256 amino acid residues) suggests that the template would only make a minor contribution to the CD spectrum of T_5Msc(103−151).

DISCUSSION

We describe the total chemical synthesis of the 27.3 kDa synthetic TASP protein T_5Msc(103−151) by chemoselective segment condensation of five 49-amino acid residue peptides with a structural template. The ability to synthesize T_5Msc(103−151) underlines the usefulness of using chemoselective ligations of purified, unprotected peptides for the total chemical synthesis of large and complex synthetic protein constructs (*29*, *40*, *41*). We have introduced the use of chemoselective ketoxime-forming ligation between pyruvic acid and aminooxyacetic acid for the highly efficient ligation of six unprotected peptide segments. Some advantages of the use of pyruvic acid−aminooxy acetic acid ketoxime formation are (a) very rapid and efficient ligation chemistry, (b) small linker size, and (c) direct incorporation into peptides without any need for deprotection, or oxidation of aldehyde or amino acid precursors (*23*, *29*, *42*, *43*). Pyruvic acid ketoximes are expected to be much more stable than the related levulinic acid ketoxime since the pyruvic acid ketoxime bond is resonance-stabilized by conjugation with its carbonyl group. In addition, this chemistry is not only applicable to chemoselective ligation of synthetic peptides, but for any situation in which rapid, highly efficient, and stable (oxime) linkages between a peptide/protein and any other chemical moiety are desired. This includes recombinant and natural peptides, and proteins bearing an N-terminal alanine which can be transformed into pyruvic acid by oxidative transamination of its α-amino group using glyoxylic acid/Cu^{2+} (*42*, *44*). Therefore, pyruvic acid-forming ligation may have general use in bioconjugate chemistry. Conceivable applications include the synthesis of peptide dendrimers for vaccine development (*23*, *45*, *46*) and the attachment of polymers or pharmacophores to synthetic peptides and proteins.

The lack of secondary structure in the linear channel peptide Msc(103−151) suggests that the cytoplasmic

helical pore observed in the crystal structure does not constitute a protein domain of MscL as defined by Wetlaufer (*47*). Instead, it appears to be only folded at low pH, or in the context of the full-length channel protein. In the latter case, the folded TM domain of MscL may also support folding of Msc(103−151). These findings are consistent with recent molecular dynamics simulations by Elmore and co-workers predicting that the assembly of the C-terminal domain immediately adjacent to the TM domain is energetically unfavorable at neutral pH due to the mutual repulsion of a large number of negatively charged amino acid residues in this region (*48*).

The folding of the Msc(103−151) helices is not caused by specific steric effects induced by the template. Preliminary experiments using attachment of the Msc(103−151) peptide via the thiol group of a cysteine side-chain to a much larger, cyclical template (*28*) with twice the distance between helix attachment sites showed virtually identical results. Side-chain attachment of the peptides to the helices provides for an uncapped N-terminus, and therefore helix-capping effects are neither responsible for the observed secondary structure features. The dramatic increase in helical structure after attachment of the channel peptides to the template peptide therefore suggests that folding of the C-terminal extension of MscL is at least facilitated by the attachment of the peptides to the topological template.

Our results are similar to findings by Mutter and coworkers who showed that template attachment can overcome charge repulsion in the formation of four-helical bundles of model peptides (*16*). The reduced chain entropy of the channel peptides after template attachment in the *unfolded* state of T_5Msc(103−151) significantly increases its free energy and thereby promotes folding in contrast to the unattached peptides that do not fold spontaneously at neutral pH. In T_5Msc(103−151), this effect appears to be sufficiently strong to overcome the unfavorable enthalpy of assembly of the pentameric helical pore found in the MD study and thus allows the intracellular portion of the channel peptide to acquire secondary structure that is consistent with the formation of a helical pore observed in the crystal structure. However, the large amount of α-helical structure observed in the TASP also suggests that regions beyond the helical pore observed in the crystal structure may exhibit helical secondary structure. These speculations, and the potential role of this pore destabilization in facilitating opening of the pore upon mechanical stress, will have to be verified by detailed structural and thermodynamic analysis of the synthetic TASP protein.

CONCLUSION

The synthesis of the 27.3 kDa synthetic TASP protein T_5Msc(103−151) underlines the strength of using chemoselective ligations of purified, unprotected peptides for the total chemical synthesis of large and complex synthetic protein constructs (*29*, *40*, *41*). Attachment of pyruvic acid to peptides synthesized by Fmoc chemistry is site-specific, straightforward and their rapid oxime-forming ligation yields a very stable interpeptide linkage. This chemistry may thus prove useful in the evolving field of total chemical protein synthesis.

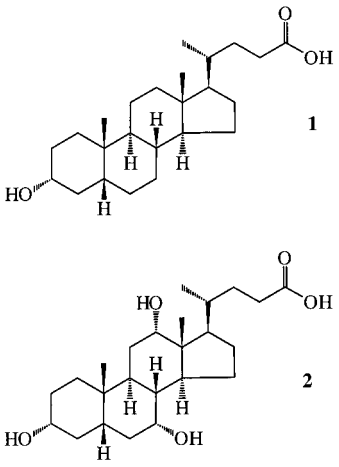
Efficient Calf Thymus DNA Condensation upon Binding with Novel Bile Acid Polyamine Amides



Andrew J. Geall, Dima Al-Hadithi, and Ian S. Blagbrough*

Department of Pharmacy and Pharmacology, University of Bath, Bath BA2 7AY, U.K. Received August 10, 2000

Polyamine amides have been prepared from lithocholic and cholic acids (5β-colanes) by acylation of tri-Boc-protected tetraamines spermine and thermine. These designed ligands for DNA are polyammonium ions at physiological pH. In NMR spectra, they display ^{14}N-^{1}H ^{1}J = 51 Hz, 1:1:1 triplets, due to the symmetry of the $R^{14}NH_3^+$ cations. The binding affinities of these conjugates for calf thymus DNA were determined using an ethidium bromide fluorescence quenching assay and compared with spermine and polylysine. DNA-binding affinities were dependent upon both salt concentration and the hydrophobicity or intermolecular bonding (facial effects) of the lipid moieties in these conjugates. Light scattering at 320 nm was used to determine DNA condensation and particle formation. The observed self-assembly phenomena are discussed with respect to DNA charge neutralization and DNA bending with loss of ethidium cation intercalation sites, ultimately leading to DNA condensation. These polyamine amides are models for lipoplex formation with respect to gene delivery (lipofection), a key first step in gene therapy.

INTRODUCTION

Among polyamine-containing natural products (*1*−*7*), polyamino-steroids form a novel, small group whose members and their analogues display a variety of interesting biological activities. Walker and co-workers have recently reported the DNA-binding affinity and in vitro gene delivery potential of various polyamines conjugated to the steroidal bile acids lithocholic **1** and cholic **2** acids

lithocholic acid **1** and cholic acid **2**

(*8*, *9*). Although most of their transfection agents contained a cationic headgroup (tetraamine spermine **3**, a polyammonium ion at physiological pH) attached to a hydrophobic tail (e.g., cholic acid spermine amide **13**), there were significant differences in the transfection activities across the series (*8*, *9*). Diamino steroids cyclobuxine (*10*), irehdiamine A, and malouetine have long been known to interact with DNA (*10*−*13*). The natural product bufotoxin, isolated from the venom of the European toad *Bufo vulgaris* (*B. bufo bufo* Linné), contains an arginyl guanidine functional group pendant from a steroid (bufotalin) nucleus and displays digitalis-like cardiac effects (*14*−*16*). Recently, Regen and co-workers reported their (so-called) molecular umbrella from cholic acid **2** and triamine spermidine, creating structures that can mask an attached agent (dansyl as a drug mimetic) from the surrounding environment (*17*−*19*). Polyamino-steroid squalamine, isolated from liver and gallbladder tissues of the dogfish shark, *Squalus acanthias*, is a spermidine-containing sterol sulfate which displays antimicrobial and fungicidal properties, and induces osmotic lysis of protozoa (*20*−*23*).

As part of our continuing studies on polyamine-mediated DNA condensation (*24*−*32*), we have synthesized polyamine amide conjugates of lithocholic **1** and cholic acids **2** in order to investigate the effects on changes in hydrophobicity on their binding affinity to DNA. Structure−activity relationships (SAR) for the binding of polyamines to DNA (*13*, *33*−*38*), and the subsequent condensation of DNA (*37*−*41*), indicate that polyammonium ions are suitable for use as gene delivery systems (*42*−*54*). Following DNA-binding studies with a short series of synthetic polyamino-steroids, up to four structural features have been shown to contribute to the strength and type of DNA interactions: cation type, total number of positive charges, regiochemical distribution of the ammonium groups, and steroid hydrophobicity (*55*−*57*). The mechanism by which these compounds cause lipofection is still poorly understood (*50*−*54*). Therefore, it is important to determine their physicochemical properties for the design of lipoplexes capable of efficient lipofection (*58*).

We are investigating how changes in the hydrophobicity of a lipopolyamine affect the condensation of DNA and hence lipoplex formation (*24*−*32*). Herein we report the design and synthesis, using our orthogonal protection strategy, of unsymmetrical polyamine amides from bile acids, two amides of lithocholic acid **1**, **11** and **12** (at position 24), and two of cholic acid **2**, **13**, and **14** (also at

position 24) (*24*). The 5β-cholane ring structure was chosen as the lipid moiety, it has found previous use in lipoplex formation (*8, 9*), and a variety of derivatives of these bile acids are readily available substituted with differing numbers of hydroxyl groups at varying positions on the ring system. Two readily available polyamines were used as the cationic headgroups: 1,12-diamino-4,9-diazadodecane **3** (spermine, 3.4.3) and 1,11-diamino-4,8-diazaundecane (thermine, norspermine, 3.3.3) **4**. Differences in the distribution of positive charges along these two polyamine headgroups and their effects on binding affinity, including salt-dependent binding of these polyamine amides of lithocholic and cholic acids have been investigated. To investigate the SAR for their binding affinities for calf thymus (CT) DNA, we used a modified ethidium bromide displacement assay (*59, 60*). Changes in binding affinity for CT DNA with respect to variations in the hydroxyl substituents on a lipopolyamine are investigated with respect to the use of bile acids in lipoplex formation, a key first step in gene therapy (*50-58*).

EXPERIMENTAL PROCEDURES

General Details and Reagents. General details, column, RP-HPLC, solvents and other chromatographic details, NMR, MS, and other spectroscopic details are as previously described (*25*, *26*). Poly-L-lysine hydrobromide (RMM 4−15 kDa) was purchased from SAF and had an average RMM of 9.6 kDa (PL 9600) (DP 46) when measured by viscosity and 8.0 kDa (DP 38) measured by LALLS. CT DNA sodium salt and all other reagents and chemicals were obtained from SAF and were of the highest grades available.

General Procedure A: Poly-Boc Protection of Polyamines. To a cold (−78 °C) methanolic solution of the polyamine was added ethyl trifluoroacetate (1 equiv) dropwise over 30 min, and then without isolation, the remaining amino functional groups were protected quantitatively by the dropwise addition of an excess of di-*tert*-butyl dicarbonate in methanol (10 mL). Trifluoroacetyl functional group removal at pH 11 with concentrated aqueous ammonia, workup, and purification as previously reported (*25*−*27*) afforded the title compound as a colorless homogeneous oil.

General Procedure B: Amide Formation. To a solution of the poly-Boc-protected polyamine in CH_2Cl_2 (10 mL) the bile acid, 1-hydroxybenzotriazole (HOBt) (0.2 equiv) and dicyclohexylcarbodiimide (DCC) (1.5 equiv) were added. Then the reaction mixture was stirred at 25 °C, under nitrogen, for 24 h. The precipitate of dicyclohexylurea was then removed by filtration. The filtrate was concentrated in vacuo and the residue purified over silica gel (CH_2Cl_2-MeOH) to afford the title compound as a white foam.

General Procedure C: Boc Removal. To a stirring solution of lipopolyamine dissolved in CH_2Cl_2 (180 mL), under nitrogen at 25 °C, was added TFA (20 mL). After 2 h, the solution was concentrated in vacuo, lyophilized, and purified by semipreparative RP-HPLC over Supelcosil ABZ+Plus (5 μm, 25 cm × 10 mm, MeOH-0.1% aqueous TFA) to afford the title compound as a white solid (poly-TFA salt).

(N^1,N^4,N^9-Tri-*tert*-butoxycarbonyl)-1,12-diamino-4,9-diazadodecane, 5. 1,12-Diamino-4,9-diazadodecane **3** (spermine, 3.4.3) (1.0 g, 5.0 mmol) was reacted according to general procedure A to afford the title compound **5** as a homogeneous oil (1.24 g, 50%). Purified over silica gel (CH_2Cl_2-MeOH-concentrated NH_3(aq) 70:10:1 to 50:10:1 v/v/v), R_f 0.5 (CH_2Cl_2-MeOH-concentrated NH_3(aq) 50:10:1 v/v/v) (*25*).

(N^1,N^4,N^8-Tri-*tert*-butoxycarbonyl)-1,11-diamino-4,8-diazaundecane, 6. 1,11-Diamino-4,8-diazaundecane **4** (thermine, norspermine, 3.3.3) (3.0 g, 16.0 mmol) was reacted according to general procedure A to afford the title compound **6** as a homogeneous oil (3.16 g, 41%). Purified over silica gel [CH_2Cl_2-MeOH-concentrated NH_3(aq) 100:10:1 v/v/v], R_f 0.18 [CH_2Cl_2-MeOH-concentrated NH_3(aq) 100:10:1 v/v/v] (*25*).

***N^1*-(3α-Hydroxy-5β-cholan-24-carbonyl-(*N^4*,*N^9*,*N^{12}*-tri-*tert*-butoxycarbonyl))-1,12-diamino-4,9-diazadodecane, 7.** Polyamine **5** (500 mg, 1.0 mmol) and lithocholic acid (375 mg, 1.0 mmol) were reacted according to general procedure B to afford the title compound **7** as a white foam (610 mg, 71%). Purified by column chromatography over silica gel (CH_2Cl_2-MeOH; 25:1 v/v), R_f 0.22 (CH_2Cl_2-MeOH; 20:1 v/v). ^{1}H NMR, 400 MHz, $CDCl_3$: 0.64 (s, 3 H, 18′-CH_3); 0.83−2.26 (m, 69 H, 2-CH_2, 6-CH_2, 7-CH_2, 11-CH_2, 3 × OC(CH_3)$_3$, 1′-CH_2, 2′-CH_2, 4′-CH_2, 5′-CH, 6′-CH_2, 7′-CH_2, 8′-CH, 9′-CH, 11′-CH_2, 12′-CH_2, 14′-CH, 15′-CH_2, 16′-CH_2, 17′-CH, 19′-CH_3, 20′-CH, 21′-CH_3, 22′-CH_2, 23′-CH_2); 2.84−3.05 (m, 12 H, 1-CH_2, 3-CH_2, 5-CH_2, 8-CH_2, 10-CH_2, 12-CH_2); 3.60−3.70 (m, 1 H, 3′-CH); 6.75−6.90 (br s, 1 H, CH_2-N*H*CO). ^{13}C NMR, 100 MHz, $CDCl_3$: 12.0 (18′-CH_3); 18.3 (21′-CH_3); 20.7 (11′-CH_2); 23.2 (19′-CH_3); 24.1 (15′-CH_2); 25.4, 25.6, 25.9 (6-CH_2, 7-CH_2, overlapping); 26.3 (7′-CH_2); 27.1 (6′-CH_2); 27.6, 28.1, 28.4, 28.7 [2-CH_2, 11-CH_2, 16′-CH_2, 3 × O-C-(*C*H_3)$_3$, overlapping]; 30.4 (2′-CH_2); 31.7 (22′-CH_2); 33.7 (23′-CH_2); 34.5 (10′-C); 35.3, 35.4 (12-CH_2, 20′-CH, 1′-CH_2); 35.8 (8′-CH); 36.3 (4′-CH_2); 37.3 (1-CH_2); 40.1 (12′-CH_2); 40.3 (9′-CH); 42.0 (5′-CH); 42.6 (13′-CH); 43.2, 43.7 (3-CH_2, 10-CH_2, overlapping); 46.6 (5-CH_2, 8-CH_2, overlapping); 56.0 (17′-CH); 56.4 (14′-CH); 71.6 (3′-CH); 79.7 (3 × quaternary OC, overlapping); 156.0, 156.4 (3 × NCOO); 173.7 (CH_2-*C*ON). In our hands, all members of this series of polyamine amides **11-14** were water soluble at 1 mg ml^{-1} (*8*, *9*).

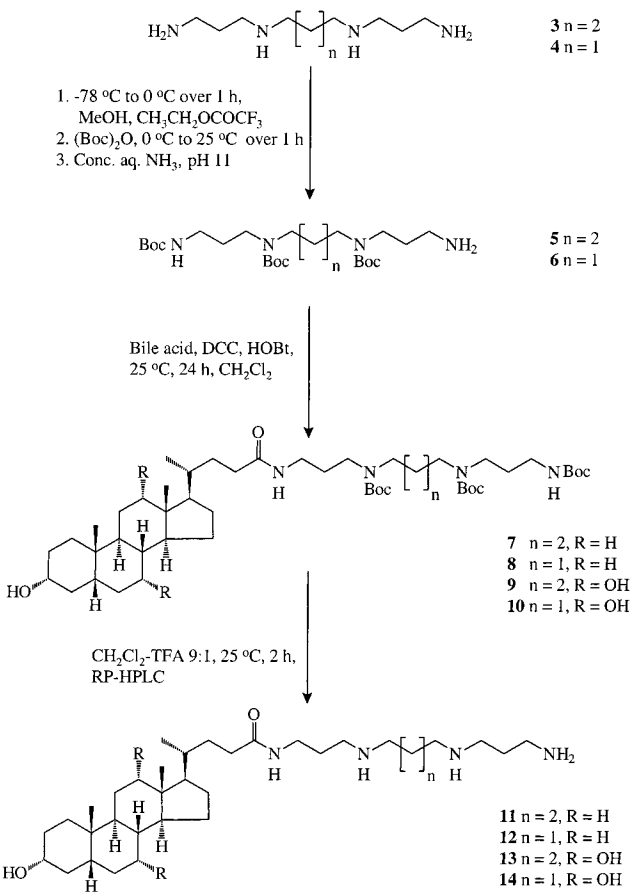
RESULTS AND DISCUSSION

Polyamines spermine **3** and thermine **4** were sequentially unsymmetrically protected with di-*tert*-butyl dicarbonate using our orthogonal protection strategy (*24*−*31*). Selective protection of one primary amine group, in each symmetrical polyamine **3** and **4**, by reaction with ethyl trifluoroacetate, afforded the respective monotrifluoroacetamides. Immediately, in these solutions, the remaining amino functional groups were Boc protected, with di-*tert*-butyl dicarbonate, to afford the fully protected polyamines. The trifluoroacetyl protecting group was then cleaved (in situ) by increasing the pH to 11 with concentrated aqueous ammonia, to afford N^1,N^2,N^3-tri-Boc protected polyamines **5** and **6**. Acylation of the free primary amine of these unsymmetrically protected polyamines **5** and **6** with lithocholic **1** and cholic acids **2** (DCC, cat. HOBt), afforded the fully protected polyamine



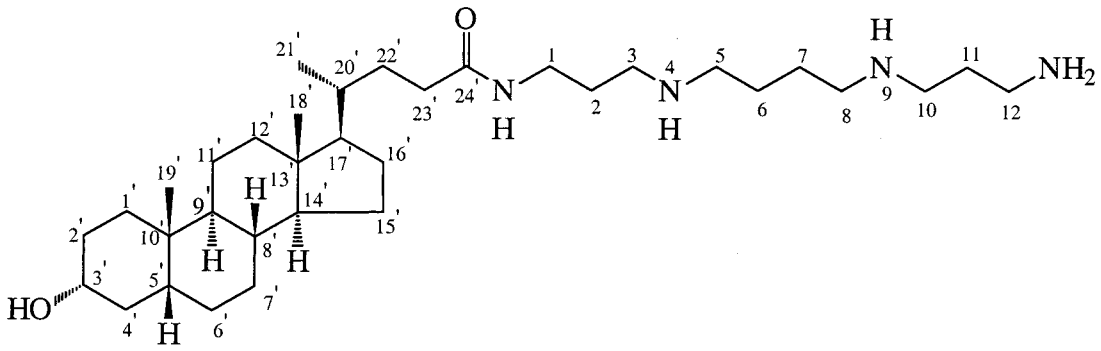


Figure 1. Synthesis of target polyamine amides **11**−**14**.

amides **7-10**. Deprotection (TFA-CH_2Cl_2, 1:9 v/v) and purification to homogeneity by RP-HPLC afforded target polyamine amides **11-14**, as their polytrifluoroacetate salts (Figure 1). The proposed structures were unambiguously assigned using ^{1}H, ^{13}C and HETCOR NMR and accurate FAB-MS.

The pK_as of the polyamine headgroups on polyamino steroids **11**−**14** were assumed to be the same as those measured potentiometrically for the cholesterol carbamates we have previously reported (*29*). The net positive charge was then calculated using the Henderson−Hasselbach equation at pH 7.4. Therefore, polyamine amides **11** and **13** (conjugates of spermine) have been assigned a net positive charge of 2.4 and polyamine amides **12** and **14** (conjugates of thermine) have been assigned a net positive charge of 2.3. We have named the target compounds **11**−**14** as their corresponding polyamine derivatives and have outlined the numbering system we used in the NMR assignments with N^1-(3α-hydroxy-5*β*-cholan-24-carbonyl)-1,12-diamino-4,9-diazadodecane **11** selected as an example.

The complete NMR spectroscopic assignment of the polyamine headgroups in this series of polyamine amides **11**−**14** is based upon calculations using additivity rules (*61*), ^{1}H, ^{13}C chemical shift correlation spectroscopy, and detailed comparisons with cholesterol carbamates previously characterized (*25*, *31*). The assignment of the 5*β*-cholane ring structure is based upon literature assignments (*62*), and the expected changes in the carbon chemical shifts due to substituent effects are entirely consistent with these assignments. Conformational isomers (populations interconverted by *σ*-bond rotation) are observed for the poly-Boc-protected polyamines, and therefore, two signals for each carbon on the methylene

Structure and numbering system for N^1-(3α-hydroxy-5β-cholan-24-carbonyl)-1,12-diamino-4,9-diazadodecane **11**

backbone of the polyamine and for each carbon on the Boc groups were typically observed. Generally ^{14}N-^{1}H couplings are not observed, but in the case of ammonium compounds, the combination of quadrupole relaxation and exchange of NH-protons is not sufficiently large to eliminate completely the coupling across one bond (*61*). Therefore, amides **11**−**14** display broad ammonium signals above δ 7.0 ppm (typically 8.0, 8.8, and 9.0 ppm, exchanged with D_2O). In addition, signals at δ 7.2 (1:1:1 t, $^1J = 51$ Hz, ^{14}N-^{1}H) were observed for these ammonium ions which we interpret as due to the symmetry of the $R^{14}NH_3^+$ cations (*61*).

Ethidium Bromide Displacement Assay. Relative binding affinities for CT DNA of the target compounds **11**−**14** were measured using a modified ethidium bromide fluorescence quenching assay, a refined displacement assay (*59*, *60*), and plotted against charge ratio (CR) as defined in the literature (*58*). The decrease in fluorescence was critically compared against polylysine (PL, average RMM 9.6 kDa, PL 9600) and spermine **3** (Figure 2) for compounds **11**−**14** at 20 mM NaCl as a function of CR (ammonium:DNA phosphate ions) (*58*). At physiological pH, spermine carries a net positive charge of 3.8 (*25*, *29*), PL 9600 a net positive charge in excess of 30. In Figure 2, polyamine amides **11** and **12**, and polycationic PL 9600 exhibit similar binding affinities for DNA. With PL 9600, complete displacement of ethidium bromide occurs as the conjugate−DNA complexes approach a charge ratio of 1. A slight excess of positive charge is required to displace the ethidium cation with the lithocholic acid conjugates **11** and **12**. This fluorescence quenching assay measures the relative binding affinities for DNA between compounds of comparable structure (*59*, *60*). Therefore, compared to spermine **3**, conjugates **11** and **12** have a greater binding affinity for DNA (Figure 2). There was no visible precipitation of the DNA. These data are consistent with complex formation between the DNA and the polyamine amide conjugates. This binding of polyamines and their conjugates to DNA is not a trivial process (*27*−*41*, *55*−*57*, *63*−*68*); they may bind preferentially to GC-rich major groove and to AT-rich minor groove regions (*63*−*66*). Covalent attachment of a lipid moiety, such as an aliphatic chain or a steroid, further enhances polyamine-mediated DNA condensation (*39*−*49*).

Cholic acid **2** is a sterol nucleus with a hydroxylated hydrophilic surface and an all-hydrocarbon hydrophobic surface, possessing the 5β-cholane ring structure (a *cis*-fused A,B-bicycle). Polyamine N^1-acylation with cholic acid **2** affords more hydrophilic polyamine amides **13** and **14** (moreso than **11** and **12**) as they contain three hydroxyl groups (compared to the one alcohol functional group of lithocholic acid) that are all located regiospecifically on the α-face of the 5β-cholane ring system. Amides **13** and **14** have a decreased binding affinity for DNA, compared to their lithocholic acid counterparts **11** and **12** (Figure 2), and they require a large excess of positive charge to displace the ethidium cation from its CT DNA intercalation sites. The differences in binding affinities between the spermine **11** and **13** and thermine **12** and **14** polyamine moieties were small (Figure 2). At 150 mM NaCl salt concentrations the binding affinity for CT DNA of PL 9600 is unaffected, but that of spermine **3** shows marked salt-dependent binding (Figure 3). Spermine amide **11**, which contains the lithocholane ring structure (with one hydroxyl moiety), requires an excess of positive charge (CR approximately 8) to displace the ethidium cation (Figure 3). The binding behavior of spermine amide **13** mimics that of spermine **3** at high salt concentrations, and the displacement of ethidium is almost completely inhibited even at a CR of >10.

DNA Condensation (Light Scattering) Assay. To investigate whether CT DNA is condensed into particles by spermine cholic acid amide **13**, the UV absorbance at 320 nm has been measured (*33*). In Figure 4, we show the apparent increase in UV absorption at 320 nm of DNA as aliquots are added at low and high salt concentrations (20 and 150 mM NaCl, respectively). At low salt concentrations, these data are consistent with particle formation and the absorption reaches a plateau at the same charge ratio (approximately 4) as essentially maximal ethidium bromide exclusion (Figure 2). However, due to the lack of sensitivity of this light-scattering assay, the DNA concentration was in a 10-fold excess compared to that used in the ethidium bromide assay. Significantly, at high salt concentrations, there are no particles formed by DNA condensation and hence no light scattering, with no visible precipitation of the DNA. These data (Figures 3 and 4) are consistent with inhibition of complex formation between the DNA and polyamine amide conjugate **13** at elevated salt concentrations.

From detailed comparisons of light-scattering assay data (Figure 4 and data not shown) together with ethidium bromide fluorescence quenching data (Figure 2 and Figure 3), we conclude that gross morphological changes occur to CT DNA as a result of polyamine amide binding. These effects are sensitive to the number of hydroxyl groups on the lipid moiety (reflecting its hydrophobicity) and are also salt concentration dependent. They are consistent with charge neutralization of CT

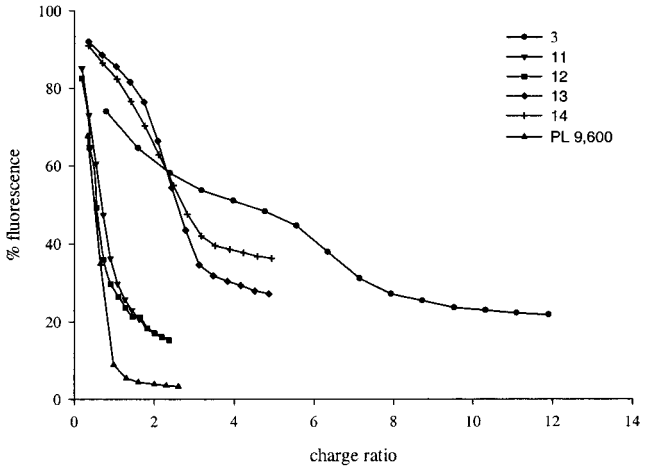

Figure 2. Ethidium bromide displacement assay of spermine **3**, amides **11**−**14**, and polylysine at 20 mM NaCl. CT DNA (6 μg in buffer, 3 mL, 20 mM NaCl, 2 mM HEPES, 10 μM EDTA, pH 7.4) was mixed with ethidium bromide (3 μL of 0.5 mg/mL) and aliquots of compound (5 μL of 0.25 mg/mL, 1 min equilibration time) were added, the fluorescence (%) determined, and plotted against the charge ratio of ammonium:DNA phosphate ions (*58*).

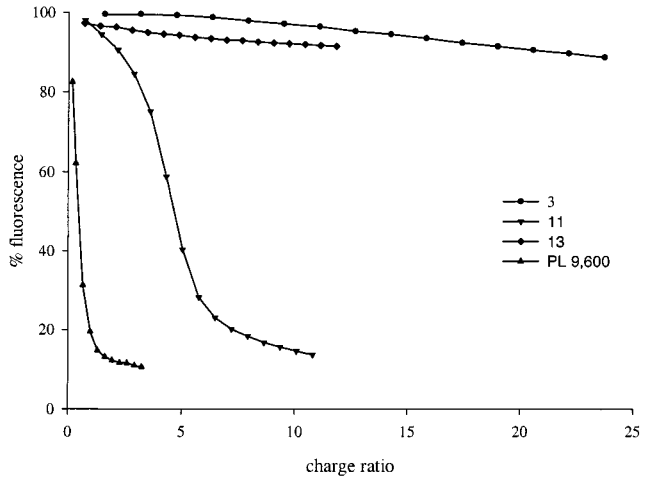

Figure 3. Ethidium bromide displacement assay of spermine **3**, amides **11** and **13**, and polylysine at 150 mM NaCl. CT DNA (6 μg in buffer, 3 mL, 150 mM NaCl, 2 mM HEPES, 10 μM EDTA, pH 7.4) was mixed with ethidium bromide (3 μL of 0.5 mg/mL) and aliquots of compound (5 μL of 0.25 mg/mL, 1 min equilibration time) were added, the fluorescence (%) determined, and plotted against the charge ratio of ammonium:DNA phosphate ions (*58*).

DNA, the loss of ethidium cation binding sites within the DNA double helix, and ultimately with DNA condensation and particle formation. These latter effects are the first key steps in gene therapy for the formation of lipoplexes.

Measurement of the ability of a drug to displace ethidium cation from DNA has been shown to be a valid measurement of DNA binding ability of both intercalative and nonintercalative drugs, including free polyamines and their conjugates (*55*−*57*, *59*, *69*−*74*). Displacement of ethidium cation from DNA provides an indirect method of measuring the binding affinity of drugs that lack a chromophore. It does not provide a direct measure of the binding constant, but offers a qualitative comparison of binding affinities within a series of compounds with similar structures. Molecular modeling studies of ethidium cation intercalation into DNA have shown that binding is accompanied by a helical screw axis displacement (or dislocation) in its structure (*75*). The helical axes are displaced approximately +1.0 Å (for B DNA), base pairs in the immediate region are twisted by 10°, giving rise to an angular unwinding of −26° and the intercalated base pairs are tilted relative to one another by 8°. These changes in DNA conformation mean that intercalation is limited to every other base pair at maximal drug-nucleic acid binding ratios, i.e., a neighbor exclusion model (*75*). These modeling studies also indicate that the conformational flexibility of DNA allows intercalation of the ethidium cation at kinked regions of the double helix. Thus, intercalation of ethidium cation occurs at regions where the base-pairs are unwound (kinked), which induces a conformational change in the double helix, restricting the total number of intercalation sites.

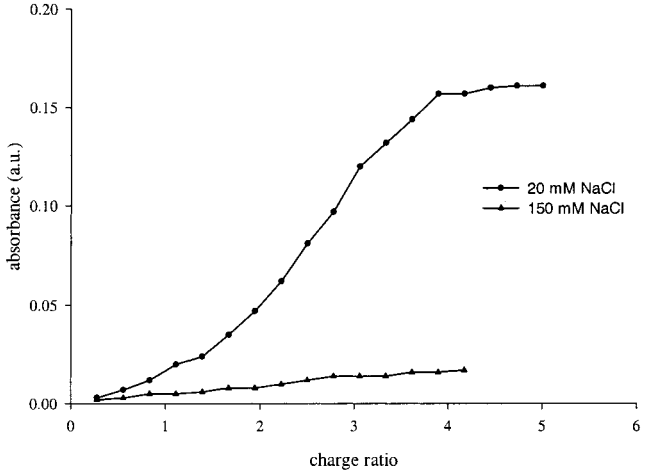

Figure 4. Light-scattering assay of polyamine amide **13** at low (20 mM NaCl) and high (150 mM NaCl) salt concentrations. CT DNA (60 μg in buffer, 3 mL, 20 mM NaCl, 2 mM HEPES, 10 μM EDTA, pH 7.4) was stirred and aliquots of compound (5 μL of 1.0 mg/mL, 1 min equilibration time) were added, the absorption (320 nm) measured, and plotted against the charge ratio of ammonium:DNA phosphate ions (*58*).

DNA collapse, by charge neutralization of cationic lipids, is thought to be a key step in lipoplex formation (*58*). This collapse is termed condensation, and affords compact, highly ordered toroids that have a possible relationship to the packaging of DNA in viruses, in particular they represent models for DNA organization within bacteriophage heads (*76*−*78*). The fluorescent intensity of the intercalated ethidium cation is not affected by increasing concentrations of cationic lipid until a specific lipid:DNA ratio is reached, upon which a large and sharp decrease of the intensity is observed. Härd et al. have demonstrated that the binding constant of ethidium cation is dependent on the molecular flexibility of DNA in linker regions of chromatin and that this flexibility is altered through cationic compaction (*79*). Thus, DNA condensation might be expected to lower the affinity of ethidium cation for DNA, and therefore, its exclusion cannot be considered to be a direct measure of a drug's binding affinity. Basu et al. also concluded that simple polyamine−DNA association was not entirely responsible for the release of ethidium cation, but that there is an associated conformational (DNA bending) change (*33*, *80*). DNA bending, induced by polyamine binding above a critical concentration, caused conformational changes within the double helix that facilitated the release of bound ethidium cation. The model for ethidium cation intercalation proposed by Sobell et al. shows the need for flexibility within the double helix of DNA to allow intercalation (*75*). Ethidium bromide exists in equilibrium between the intercalated sites and free in

solution. Therefore, loss of flexibility in the double-stranded structure of DNA through condensation will result in a shift in the binding equilibrium of ethidium cation into the solution phase, with the resultant loss in fluorescence.

Wilson and Bloomfield predicted (*81*), using the polyelectrolyte theory of Manning (*82*), that when approximately 90% of the negative (phosphate) charge on the DNA is neutralized, condensation will occur (*39*−*41*, *67*, *68*). Thus, if binding affinities of compounds causing DNA condensation are expressed in terms of the CR at which 50% (CR_{50}) of the ethidium cation fluorescence is quenched (*58*), efficient condensing agents will have CR_{50} values below 1. DNA condensation, at low salt concentrations (20 mM NaCl), is clearly an efficient process with lithocholic acid polyamine amides **11** and **12** ($CR_{50} = 0.7$ and 0.6, respectively). However, an excess of positive charges is required for cholic acid polyamine amides **13** and **14** ($CR_{50} = 2.6$ and 2.8 respectively) and for free spermine ($CR_{50} > 4.0$) to condense CT DNA, reflecting their significantly weaker binding affinities for DNA. At high salt concentrations (150 mM NaCl), DNA condensation with lithocholic acid polyamine amide **11** is salt dependent, the CR_{50} has increased from 0.7 to 4.7. The more hydrophilic cholic acid polyamine amide **13** exhibits even greater salt-dependent DNA condensation; the CR_{50} has increased from 2.6 to >12. Basu et al. have previously shown that the association of free polyamines with DNA is more sensitive to change in ionic strength than is the association of ethidium bromide with DNA (*80*). The concentration of polyamine required to release all of the intercalator dye in their studies was too high for experimental use without causing DNA aggregation (*37*, *38*, *80*). Basu and co-workers have also demonstrated that this assay is suitable for the investigation of DNA binding with simple, free polyamines, e.g., spermine **3** and thermine (norspermine) **4** where there was little fluorescence quenching at a CR of 1 (*33*, *73*, *80*). We have obtained similar results with conjugates **13** and **14** and free spermine **3** at low (20 mM NaCl) (Figure 2) and especially at high (150 mM NaCl) salt concentrations (Figure 3). Thus, while hydrophobicity is important for minor groove recognition (*83*), DNA condensation is dependent upon hydrophobicity and distance between positive charges (*84*, *85*) as well as total number of charges (*39*−*41*, *67*, *68*). These data give support to our hypotheses that both DNA binding and DNA condensation are also sensitive functions of the lipid that is covalently bound to the polyamine, as well as functions of the positively charged polyamine moiety itself. Neutral and cationic lipid-DNA interactions are a mature research area (*86*−*90*). The binding interactions between naturally occurring lipids and polynucleotides are important, and they have also been extensively studied with model membranes (*86*). The mechanisms by which these novel complexes are formed between cationic lipids and plasmid DNA have recently gained further significance with the potential of these particles in nonviral gene delivery (*87*−*90*). These new structures, both those involving cationic liposomes and those, like our studies, using cationic lipids have given rise to detailed freeze-fracture electron and atomic force microscopic studies of these particles sometimes described as "spaghetti and meatballs" (*48*, *53*, *60*, *77*, *78*, *88*, *91*−*97*). The formation of these compact particles is also directly related to the displacement of water molecules as a result of polyelectrolyte effects. Record and co-workers (*98*−*101*) have made detailed analytical studies of the effects of oligocationic ligand binding to DNA.

One mechanistic explanation of our observed self-assembly phenomena is that hydrophobic interactions between lithocholic acid moieties within **11** and **12**, but not between the more polar cholic acid moieties in **13** and **14**, cooperatively stabilize the condensed and/or condensing DNA complexes. There is some limited literature support for this possible explanation, in studies of the molecular mechanics of the complex formation of cholic acid micelles (*102*). The complex facial interactions observed with other arch-shaped or concave bile acids have been reviewed by Fuhrhop and Köning (*103*) where "micelle curvature is determined not by the hydrophobic effect, but by the molecular shape of the monomers and strong intermolecular bonding" (*103*). Regen and co-workers have recently reported, in a previous article in Bioconjugate Chem. (*104*), detailed studies on the "cloistering" of cholic acid amides due to facial effects mediated by either hydrogen bonding or van der Waals' forces between nearest-neighbors (*104*). We propose that initial charge neutralization of the polyanionic polynucleic acid by our polycationic lipo-polyammonium ions (*25*, *26*, *105*) is followed by DNA bending (*106*, *107*). After several of these bends (*106*), the induced curve is symmetrical, this is consistent with Hud's constant radius of curvature model (*77*, *78*), and adds further evidence to the microscopy pictures currently available. It has recently been shown that, depending upon the exact conditions, spermine **3** can induce condensation of DNA (*97*). Nevertheless, the key questions about any nucleotide sequence selectivity for the initial bending sites along the duplex CT DNA (*106*, *107*), and the accuracy of the constant radius of curvature model will require further experiments (*77*, *78*), preferably with designed high affinity small molecule probes and also defined DNA sequences (*38*). The polyamine amides designed and prepared herein should therefore contribute to those studies.

ACKNOWLEDGMENT

We thank the EPSRC and Celltech Chiroscience for a CASE studentship (to A.J.G.). We are grateful to a referee for helpful directions with respect to lipid−DNA interactions. We acknowledge useful discussions with Dr. Richard J. Taylor and Dr. Michael A. W. Eaton (Celltech Chiroscience), and with Dr. Ian S. Haworth (University of Southern California). I.S.B. and I.S.H. are recipients of a NATO grant (CRG 970290).

Received March 28, 2001; Revised Manuscript Received October 23, 2001

An enhancement of the target/nontarget ratio of radioactivity levels enables reliable diagnosis and therapy using polypeptide radiopharmaceuticals in nuclear medicine. In the present study, we investigated the effects of the physicochemical properties of radiometabolites on the radioactivity pharmacokinetics after administration of ^{99m}Tc-labeled polypeptides using 6-hydrazinopyridine-3-carboxylic acid (HYNIC). Four ternary ligands (L) [3-benzoylpyridine (BP), 3-acetylpyridine (AP), 3-nicotinic acid (NIC), pyridine (PY)] with different lipophilicity were selected as coligands for the preparation of ^{99m}Tc−HYNIC-polypeptides. Each of the ternary ligands tested provided ^{99m}Tc−HYNIC-labeled galactosyl-neoalbumin (NGA) and Fab fragments of high stability with high radiochemical purity. Moreover, after administration of each ^{99m}Tc−HYNIC-labeled NGA into normal mice, the respective ternary ligand [^{99m}Tc](HYNIC−lysine)(tricine)(L) complexes were generated as final radiometabolites in the hepatic lysosome. The partition coefficients of [^{99m}Tc](HYNIC−lysine)(tricine)-(BP), [^{99m}Tc](HYNIC−lysine)(tricine)(AP), [^{99m}Tc](HYNIC−lysine)(tricine)(NIC), and [^{99m}Tc](HYNIC−lysine)(tricine)(PY) were determined to be −2.21, −2.37, −2.93, and −2.73, respectively. Elimination rates of these radiometabolites from the lysosome were enhanced in the order of increasing lipophilicity of the radiometabolites. After injection of the four ^{99m}Tc−HYNIC-labeled Fab fragments into normal mice, blood clearances of radioactivity were similar while radioactivity elimination rates from the kidney were enhanced in the order of increasing lipophilicity of the radiometabolites. The present study indicated that the lipophilicity of the radiometabolites constitutes one important factor affecting their elimination rates from the tissues. Thus, as ternary ligands facilitate alteration of the physicochemical properties of radiometabolites, the use of ternary ligand complexes might be applicable for controlling the pharmacokinetics of ^{99m}Tc-labeled polypeptides.

INTRODUCTION

Radiopharmaceuticals derived from polypeptides and peptides have been shown to be useful for both diagnostic and therapeutic applications. However, high-level and prolonged retention of radioactivity has been observed in nontarget tissues such as the liver and kidney when these radiopharmaceuticals are administered. This results in a high background radioactivity in imaging diagnosis and also increases the radiation dose to the patients, thus limiting their therapeutic uses.

To decrease the radioactivity levels in nontarget tissues, attempts to conjugate polypeptides with a radiolabel via a metabolizable linkage have been made (*1*−*5*). However, the following criteria should be addressed for application of radiolabeling reagents with a metabolizable linkage to polypeptides. One important point is whether the radiolabeled compound released from the polypeptides by cleavage of the labile bond can rapidly penetrate the lysosomal membrane. Another point to be considered is whether the metabolizable linkage is stable enough in plasma so as not to impair the radioactivity in the target delivered by the polypeptides. Although radiolabeling reagents with a metabolizable linkage satisfy these criteria, they cannot be applied to polypeptides that are internalized within target cells.

Another solution to the high radioactivity levels in nontarget tissues appears to be the chemical modification of polypeptides and peptides. This strategy involves modification of isoelectric points of (poly)peptides by acylating amine residues, attachment of negatively charged polymer, or substitution of N-terminal amino acid with an acidic amino acid (*6*−*9*). Although these methods can be applied to polypeptides that are internalized within target cells, long-term retention of the radioactivity in the target tissues is required for further enhancement of the target/nontarget ratio.

Recent studies on the metabolism of radiolabeled polypeptides have shown that in vivo behaviors of radiometabolites generated after lysosomal proteolysis play a critical role in determining the radioactivity levels in tissues (*10*−*13*). These findings provide the following approaches to enhance the target/nontarget ratio of

radioactivity level. When applied to polypeptides such as antibodies against solid tumors, which are not or are only slowly internalized within target cells, generation of radiometabolites that are eliminated rapidly from the tissues constitutes one useful approach. Radiolabeled polypeptides remain bound to the surface of target cells, while their radiometabolites generated after lysosomal proteolysis are eliminated rapidly from nontarget tissues. As a consequence, the target/nontarget ratio is increased. On the other hand, when applied to internalizable (poly)-peptides within target cells, generation of radiometabolites that are eliminated slowly from the tissues would be required to prolong radioactivity retention in target tissues. Therefore, it is important for enhancement of the target/nontarget ratio to control the in vivo behaviors of radiometabolites generated after lysosomal proteolysis of polypeptide radiopharmaceuticals regardless of whether the parental molecules are internalized into target cells. However, the relationships between the physicochemical properties of radiometabolites and their elimination rates from the tissues remain unclear.

6-Hydrazinopyridine-3-carboxylic acid (HYNIC) is a representative agent used to prepare technetium-99m (^{99m}Tc)-labeled (poly)peptides with tricine as a coligand (*14*−*18*). However, it was found that the complex [^{99m}Tc]-(HYNIC)(tricine)$_2$, which is not stable and exists as multiple species, could affect the pharmacokinetics of ^{99m}Tc-labeled (poly)peptides and their radiometabolites due to exchange reaction of tricine with protein in the plasma and tissues (*19*−*22*). To decrease the problems associated with ^{99m}Tc−HYNIC-labeled small peptides, Liu et al. exploited several pyridine derivatives as ternary ligands to form ternary ligand complexes, [^{99m}Tc](HYNIC-peptide)(tricine)(pyridine derivative), with high stability and fewer isomers (*23*). On the basis of these findings, we applied a preformed chelate of tetrafluorophenol active ester of the ternary ligand complex [^{99m}Tc](HYNIC)-(tricine)[3-benzoylpyridine (BP)] to prepare ^{99m}Tc-labeled polypeptides (24). Our previous study using galactosyl-neoglycoalbumin (NGA) indicated that [^{99m}Tc](HYNIC−lysine)(tricine)(BP) was generated as a major radiometabolite in the liver and that the binding of this metabolite with lysosomal proteins was low. In addition, little plasma protein binding was observed in ^{99m}Tc−HYNIC-labeled Fab fragment derivatized with this ternary ligand complex. These findings indicated that the pyridine derivatives could serve as highly stable coligands for preparing ^{99m}Tc−HYNIC-labeled polypeptides and that the use of various pyridine derivatives would generate radiometabolites with different physicochemical properties in the tissues.

In the present study, four pyridine derivatives [BP, 3-acetylpyridine (AP), 3-nicotinic acid (NIC) and pyridine (PY)] with different lipophilicity were selected as ternary ligands to prepare ^{99m}Tc−HYNIC-labeled polypeptides. We investigated the effects of lipophilicity of the radiometabolites on the radioactivity pharmacokinetics after injection of ^{99m}Tc−HYNIC-labeled NGA. In addition, the radioactivity elimination from the kidney after injection of four ^{99m}Tc−HYNIC-labeled Fab fragments was also estimated along with the blood clearance.

MATERIALS AND METHODS

Reagents and Chemicals. [^{99m}Tc]Pertechnetate ($^{99m}TcO_4^-$) was eluted in saline solution on a daily basis from Daiichi Radioisotope Laboratory generators (Chiba, Japan). Na[^{125}I] was obtained from the Daiichi Kagaku (Tokyo, Japan) and was diluted with 0.1 M phosphate buffer (pH 7.4) to 3.7 MBq/μL. Reversed phase high performance liquid chromatography (RP-HPLC) was performed with a Cosmosil 5 C_{18}-AR-300 column (4.6 × 150 mm, Nacalai Tesque, Kyoto, Japan) at a flow rate of 1.0 mL/min with a gradient mobile phase starting from 90% A (0.1% aqueous trifluoroacetic acid) and 10% B (acetonitrile with 0.1% trifluoroacetic acid) to 50% A and 50% B at 20 min and to 100% B at 30 min (solvent system 1). RP-HPLC was also performed with a gradient mobile phase starting from 100% A to 100% B in 30 min (solvent system 2). Size-exclusion HPLC (SE-HPLC) was performed using a 5 Diol-300 column (7.5 × 600 mm, Nacalai Tesque) connected to a 5 Diol-300 guard column (7.5 × 50 mm, Nacalai Tesque), eluted with 0.1 M phosphate buffer (pH 6.8) at a flow rate of 1 mL/min. The eluent was collected with a fraction collector (RediFrac; Pharmacia Biotech, Tokyo, Japan) at 30-s intervals, and the radioactivity levels in each fraction (500 μL) were determined with an auto well counter (ARC-2000; Aloka, Tokyo). The radioactivity of liver homogenates was analyzed by gel permeation chromatography (GPC) using a Sephadex G-50 (Pharmacia Biotech) column (18 × 400 mm) equilibrated and eluted with 0.1 M phosphate buffer (pH 6.8) at a flow rate of 1 mL/min. The eluent was collected with a fraction collector at 2.5-min intervals, and the radioactivity levels in each fraction (2.5 mL) were measured with an auto well counter. TLC analyses were performed with silica plates (Merck Art 5553) with a mixture of 10% aqueous ammonium chloride−methanol (1:1) or saline as the developing solvent. Cellulose acetate electrophoresis (CAE) strips were run in veronal buffer (pH 8.6, $I = 0.05$) at a constant current of 0.8 mA for 30 min. Proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded on a Bruker AC-200 spectrometer, and the chemical shifts are reported in ppm downfield from an internal tetramethylsilane standard. Fast atom bombardment mass spectra (FAB-MS) were obtained with a JMS−HX/HX 110 A model (JEOL Ltd., Tokyo, Japan). Tricine, BP, AP, NIC, and PY were purchased from Nacalai Tesque, and other reagents were of reagent grade and used as received. To facilitate collection of urine and feces after administration of radiolabeled polypeptides, mice were housed in metabolic cages (Metabolica, MM type; Sugiyama-Gen Iriki Co. Ltd., Tokyo, Japan).

Synthesis of Galactosyl-neoglycoalbumin (NGA). Cyanomethyl-2,3,4,6-tetra-*O*-acetyl-1-β-galactopyranoside, synthesized according to the procedure of Lee et al. (*25*), was conjugated with human serum albumin (HSA, A-3782; Sigma Co. St. Louis, MO), according to the procedure of Stowell et al. (*26*). The phenol−sulfuric acid reaction (*27*) indicated that 43 galactose units were attached to each HSA molecule.

Tumor and Monoclonal Antibodies. KT005-cloned human osteogenic sarcoma was maintained by serial sc transplantation in athymic mice. Pieces of tumor tissue (~0.5 g) at ~2.5 weeks postimplantation were used for the in vivo study**.** The monoclonal antibody against osteogenic sarcoma (OST7, IgG_1), generated by the standard hybridoma technique, was purified by ammonium sulfate precipitation with subsequent protein A affinity chromatography (Pharmacia Biotech), as reported previously (*28*). The Fab fragment was prepared by the standard procedure using papain (*29*).

Synthesis of ^{99m}Tc−HYNIC Ternary Ligand Complexes. 2,3,5,6-Tetrafluorophenyl 6-hydrazinopyridine-3-carboxylate (HYNIC-TFP) was synthesized according to the procedure described previously (*24*). To a 2 mL vial were added 30 μL of HYNIC-TFP (3 mg/mL in isopropyl

alcohol), 200 μL of tricine solution (30 mg/mL in 10 mM citrate buffer, pH 5.2), 100 μL of ternary ligand solution (10 mg/mL in 10 mM citrate buffer, pH 5.2), 100 μL of $^{99m}TcO_4^-$ solution (10 mCi/mL in saline), and 25 μL of $SnCl_2 \cdot 2H_2O$ solution (1.0 mg/mL in 0.1 N HCl). The reaction mixture was heated at 95 °C for 15 min followed by cooling on ice for 10 min. Then, the reaction mixture was analyzed by RP-HPLC (solvent system 1).

Radiolabeling of Polypeptides. To a solution of NGA 100 μL (5.0 mg/mL in 0.1 M carbonate buffer, pH 9.0) was added an equal volume of ternary ligand [^{99m}Tc](HYNIC−TFP) complex solution, and the mixture was incubated for 1 h at room temperature. [^{99m}Tc]-(HYNIC−NGA) conjugate was purified by the centrifuged column procedure using Sephadex G-50 equilibrated and eluted with 0.1 M phosphate buffer (pH 7.4). Ternary ligand [^{99m}Tc](HYNIC−Fab) conjugates were prepared according to the procedure described above using 100 μL of Fab solution (5.0 mg/mL in 1 M carbonate buffer, pH 10.0) in place of NGA. Radiochemical yields were assessed by SE-HPLC, CAE, and TLC developed with saline. The levels of HYNIC molecules conjugated per NGA and Fab were determined by measuring the hydrazino groups with *p*-nitrobenzaldehyde according to the method of King et al. (*30*). [^{99m}Tc](HYNIC−Fab)(tricine)$_2$ was prepared by conjugation of 6-hydrazinopyridine-3-carboxylate hydrochloride with Fab fragments, followed by ^{99m}Tc radiolabeling with [^{99m}Tc](tricine)$_2$, according to the procedure described previously (*22*). Direct radioiodination of Fab fragments was performed by the chloramine T method according to the procedure described previously (*4*).

Synthesis of Ternary Ligand [^{99m}Tc](HYNIC−Lysine) Complexes. HYNIC−lysine was synthesized according to the method described previously (*21*). To a 2 mL vial was added 30 μL of HYNIC−lysine (3 mg/mL in 10 mM citrate buffer, pH 5.2), 200 μL of tricine solution (30 mg/mL in 10 mM citrate buffer, pH 5.2), 100 μL of ternary ligand solution (10 mg/mL in 10 mM citrate buffer, pH 5.2), 100 μL of $^{99m}TcO_4^-$ solution (370 MBq/mL in saline), and 25 μL of $SnCl_2 \cdot 2H_2O$ solution (1.0 mg/mL in 0.1 N HCl). The reaction mixture was heated at 95 °C for 15 min. After being cooled at room temperature for 10 min, the reaction mixture was analyzed by RP-HPLC (solvent system 2), CAE, and TLC developed with a mixture of 10% aqueous ammonium chloride−methanol (1:1).

Partition Coefficients of Ternary Ligand [^{99m}Tc]-(HYNIC−Lysine) Complexes. The partition coefficient was measured by mixing each ternary ligand [^{99m}Tc]-(HYNIC−lysine) complex with 3 mL each of 1-octanol and 0.1 M phosphate-buffered saline (pH 4.75). These tubes were left for 20 min at room temperature and then centrifuged for 5 min. Two precisely measured samples (1.0 mL each) from the 1-octanol and buffer layers were counted for radioactivity. The partition coefficient was then determined by calculating the ratio of the radioactivity of the octanol layer to that of the buffer layer.

Plasma Stability of ^{99m}Tc-Labeled Polypeptides. [^{99m}Tc](HYNIC−NGA) conjugates or [^{99m}Tc](HYNIC−Fab) conjugates were diluted 20-fold with freshly prepared murine plasma, and the solution was incubated at 37 °C for 24 h. After 24 h incubation, the radioactivity of each [^{99m}Tc](HYNIC−Fab) conjugate was analyzed by SE-HPLC. After 1, 3, 6, and 24 h incubation, the radioactivity of each [^{99m}Tc](HYNIC−NGA) conjugate was analyzed by CAE.

Immunoreactivity Measurement. The immunoreactivity of [^{99m}Tc](HYNIC−Fab)(tricine)$_2$ and [^{99m}Tc]-(HYNIC−Fab)(tricine)(BP) was determined using ^{125}I-Fab as a control, according to the procedure described previously (*5, 31*). Tumor cells (1.75×10^5 to 2.8×10^6) suspended in 100 μL of Dulbecco's PBS were incubated with 100 μL of [^{99m}Tc](HYNIC−Fab)(tricine)$_2$, [^{99m}Tc]-(HYNIC−Fab)(tricine)(BP), and ^{125}I−Fab for 1 h at 4 °C. After centrifugation at 10000*g* for 5 min, the supernatant was discarded and the radioactivity was determined using a well counter.

In Vivo Studies. Animal studies were conducted in accordance with our institutional guidelines and were approved by Kyoto University Animal Care Committee. Biodistribution studies were performed by the intravenous administration of [^{99m}Tc](HYNIC−NGA) conjugates or [^{99m}Tc](HYNIC−Fab) conjugates to 6-week-old male ddY mice (27−30 g) (*32*). The polypeptide concentrations of [^{99m}Tc](HYNIC−NGA) conjugates and [^{99m}Tc](HYNIC−Fab) conjugates were adjusted to 90 μg/mL and 200 μg/mL, respectively, with saline. Groups of five mice each were administered 9 μg (37−74 KBq) of [^{99m}Tc](HYNIC−NGA) conjugates or 20 μg (37−74 KBq) of [^{99m}Tc](HYNIC−Fab) conjugates prior to sacrificing the animals at 10 or 30 min, 1, 3, 6, or 24 h postinjection by decapitation. Tissues of interest were removed and weighed, and the radioactivity counts were determined with an auto well gamma counter. To determine the amounts and routes of excretion of radioactivity from the body, mice were housed in metabolic cages for 24 h after administration of [^{99m}Tc](HYNIC−NGA) conjugates or [^{99m}Tc](HYNIC−Fab) conjugates, and urine and feces were collected and the radioactivity was determined.

The subcellular distribution of radioactivity in the liver after injection of ^{99m}Tc-labeled NGAs into normal mice was investigated by perfusing the organ in situ with cold 0.25 M sucrose buffered with 10 mM phosphate buffer (pH 7.4) at 1 and 6 h postinjection of [^{99m}Tc](HYNIC−NGA) conjugates (133−266 KBq). The liver was treated according to the procedure described previously (*10, 21*). Briefly, the isolated organ was minced with scissors and suspended in 4 volumes of the same buffer prior to homogenization by hand with a Dounce homogenizer (20 strokes). This was followed by two final strokes in an ice-cooled Potter−Elvehjem homogenizer with a Teflon pestle rotated at 800 rpm. The resulting homogenate was centrifuged twice for 5 min at 340*g* at 4 °C. The isolated supernatant was then layered on top of iso-osmotic (0.25 M sucrose) 37.5% Percoll (9 mL; Pharmacia Biotech) at a density of 1.08 g/mL. After centrifugation at 20000*g* (RP 30 rotor; Hitachi Co. Ltd., Tokyo, Japan) for 90 min at 4 °C, the gradients were collected in 14 fractions. β-Galactosidase was used as a marker enzyme for lysosomes (*33, 34*), and its activity in each fraction was determined using *p*-nitrophenyl β-galactopyranoside as the substrate (*35*). The density and radioactivity counts of the respective fractions were also determined.

The radiolabeled species remaining in the liver at 1 and 6 h postinjection of [^{99m}Tc](HYNIC−NGA) conjugates (133−266 KBq) into normal mice were analyzed according to the procedure described previously (*10, 21*). Briefly, the murine liver was perfused in situ with cold 0.1 M Tris-citrate buffer (pH 6.5) containing 0.15 M NaCl, 0.02% sodium azide, 1 TIU/mL aprotinin, 2 mM benzamidine·HCl, 2 mM iodoacetamide, 1 mM phenylmethylsulfonyl fluoride, and 5 mM diisopropyl fluorophosphate before isolation of the hepatic samples (1 g each). Each tissue sample was placed in a test tube and subjected to three cycles of freezing (dry ice−acetone bath) and thawing. After addition of 5 volumes of the same buffer containing an additional 35 mM β-octyl-glucoside, the

samples were homogenized with a Polytron homogenizer (PT 10−35, Kinematica GmbH, Littau, Switzerland) at full speed with three consecutive 30-s bursts prior to centrifugation at 48000*g* for 20 min at 4 °C (Himac CS-120 Centrifuge; Hitachi Co. Ltd.). The supernatant was separated from the pellet, and the radioactivity was counted. The liver homogenate samples were analyzed immediately by SE-HPLC, CAE, and TLC after filtration through a polycarbonate membrane with a pore diameter of 0.45 μm (Nacalai Tesque). Each sample was also analyzed immediately by RP-HPLC (solvent system 2) after ultrafiltration with a 10 kDa cutoff membrane (Microcon-10; Amicon Grace, Tokyo, Japan).

The radiolabeled species excreted in the urine for 6 h postinjection of [^{99m}Tc](HYNIC−Fab) conjugates were analyzed by SE-HPLC and RP-HPLC (solvent system 2) after filtration through a polycarbonate membrane with a pore diameter of 0.45 μm and a 10 kDa cutoff ultrafiltration membrane, respectively.

Biodistribution Studies in Athymic Mice Bearing Osteogenic Sarcoma. Athymic mice bearing osteogenic sarcoma were also treated intravenously with 100 μL of [^{99m}Tc](HYNIC−Fab)(tricine)$_2$ or [^{99m}Tc](HYNIC−Fab)-(tricine)(BP) (20 μg each), and the animals were sacrificed at 3 or 6 h postinjection (five mice each). Mean weights of mice and tumors used in this study were 18.91 ± 0.95 and 0.23 ± 0.08 g, respectively. Organs of interest were removed and weighed, and the radioactivity in each tissue was determined. Tumor/blood and tumor/kidney ratios were then calculated from the corresponding %ID/g values.

Statistical Analysis. Statistical analysis was performed by applying unpaired *t*-test. $P < 0.05$ was considered statistically significant.

RESULTS

Conjugation of Ternary Ligand Complexes with Polypeptides. Ternary ligand [^{99m}Tc](HYNIC−NGA) conjugates and [^{99m}Tc](HYNIC−Fab) conjugates were prepared by conjugation of ternary ligand [^{99m}Tc](HYNIC-TFP) complexes (active esters) with the ϵ-amine residues of polypeptides. Synthesis of the ternary ligand [^{99m}Tc]-(HYNIC-TFP) complexes was accomplished in one step by direct reduction of [^{99m}Tc]pertechnetate with stannous chloride in the presence of HYNIC-TFP, tricine, and ternary ligands. This gives >75% radiochemical yields of the ^{99m}Tc chelated active esters. RP-HPLC analyses of ternary ligand [^{99m}Tc](HYNIC-TFP) complexes indicated that the major impurity in each reaction was a carboxlic acid of the ^{99m}Tc−HYNIC ternary ligand complex produced due to hydrolysis. The inability to conjugate the carboxylic acid of the ternary ligand ^{99m}Tc−HYNIC complex with polypeptides was confirmed. The conjugation of the ^{99m}Tc−HYNIC active ester with polypeptides was prepared by reaction of the active esters of ^{99m}Tc−HYNIC with ϵ-amine residues of polypeptides at room temperature for 1 h and afforded yields from 30 to 40%. After purification by the centrifuged column procedure, [^{99m}Tc](HYNIC−NGA) conjugates and [^{99m}Tc]-(HYNIC−Fab) conjugates were obtained with radiochemical purities over 95% as determined by SE-HPLC, TLC, and CAE analyses. Average numbers of HYNIC molecules conjugated per NGA and Fab were 1.7 and 0.6, respectively, as determined by measuring the hydrazine groups. In addition, we examined the binding of [^{99m}Tc]-(HYNIC−Fab)(tricine)(BP), [^{99m}Tc](HYNIC−Fab)(tricine)$_2$, and ^{125}I−Fab to KT005 cells, and no differences were observed in the cell-bound radioactivity among the three radiolabeled Fab fragments.

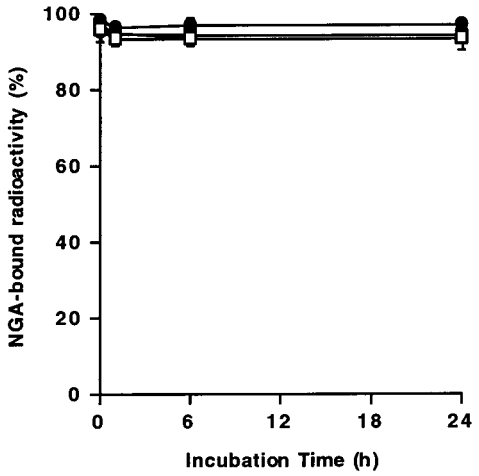

Figure 1. Percent radioactivity in NGA fractions following incubation of [^{99m}Tc](HYNIC−NGA)(tricine)(BP) (●), [^{99m}Tc]-(HYNIC−NGA)(tricine)(AP) (○), [^{99m}Tc](HYNIC−NGA)(tricine)-(NIC) (■), and [^{99m}Tc](HYNIC−NGA)(tricine)(PY) (□) in murine plasma at 37 °C. Values were determined by CAE. Each value represents the mean ± SD of three experiments.

Plasma Stability of [^{99m}Tc](HYNIC−NGA) Conjugates. Percent radioactivity after incubation of [^{99m}Tc]-(HYNIC−NGA) conjugates in freshly prepared murine plasma at 37 °C is shown in Figure 1. The percent radioactivity associated with NGA fractions were unchanged after 24 h incubation in murine plasma.

Biodistribution Study of [^{99m}Tc](HYNIC−NGA) Conjugates in Mice. Radioactivity levels in liver, urine, and feces after intravenous administration of [^{99m}Tc]-(HYNIC−NGA) conjugates are shown in Table 1. At 10 min postinjection, over 90% of the injected radioactivity was accumulated in the liver for all [^{99m}Tc](HYNIC−NGA) conjugates. After this postinjection interval, the radioactivity was gradually eliminated from the liver by hepatobiliary excretion as the major excretion route for the four [^{99m}Tc](HYNIC−NGA) conjugates. ([^{99m}Tc]-(HYNIC−NGA)(tricine)(BP) > [^{99m}Tc](HYNIC−NGA)-(tricine)(AP) > [^{99m}Tc](HYNIC−NGA)(tricine)(NIC) and [^{99m}Tc](HYNIC−NGA)(tricine)(PY)). Low radioactivity levels were observed in tissues other than the liver and intestine throughout the experimental period. No evidence of enterohepatic circulation of the radioactivity was observed.

Analyses of Radioactivity in the Liver. The representative Percoll density gradient centrifugation profiles of radioactivity in the liver at 1 and 6 h postinjection of [^{99m}Tc](HYNIC−NGA)(tricine)(NIC) are shown in Figure 2. Each liver homogenate showed a major radioactivity peak at a density of ca. 1.10 g/mL, which correlated well with the β-galactosidase activity profiles. [^{99m}Tc]-(HYNIC−NGA) conjugates using other ternary ligands (BP, AP, and PY) showed profiles similar to that of [^{99m}Tc](HYNIC−NGA)(tricine)(NIC).

The supernatants of the liver homogenates after injection of all ^{99m}Tc-labeled NGAs were obtained with radiochemical efficiencies of over 90%. Figure 3 shows GPC profiles of the liver supernatants at 1 and 6 h postinjection of [^{99m}Tc](HYNIC−NGA)(tricine)(NIC). These liver supernatants depicted a major radioactivity peak at an elution volume (82.5 mL) close to that of [^{99m}Tc]-(HYNIC−lysine)(tricine)(NIC). The radioactivity peaks in the low molecular weight fractions represented 94.2 and 96.6% of the total radioactivity at 1 and 6 h postinjection, respectively. Under these conditions, the parental [^{99m}Tc](HYNIC−NGA) conjugates had an elution

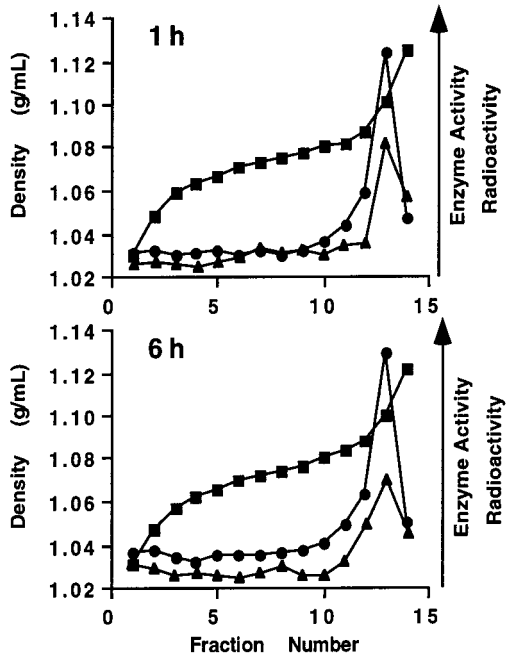

Figure 2. Percoll density gradient centrifugation profiles of liver homogenate at 1 and 6 h postinjection of [^{99m}Tc](HYNIC−NGA)(tricine)(NIC). In both preparations, a single radioactivity peak (●) that coincided with β-galactosidase activity (▲) was detected at a density (■) of ca. 1.10 g/mL.

volume of 32.5 mL. Similar results were obtained when we analyzed the liver supernatants of [^{99m}Tc](HYNIC−NGA) conjugates with the other ternary ligands (BP, AP, and PY). Figure 4 shows RP-HPLC profiles of the liver homogenates at 1 and 6 h postinjection of [^{99m}Tc](HYNIC−NGA)(tricine)(BP), [^{99m}Tc](HYNIC−NGA)(tricine)(AP), [^{99m}Tc](HYNIC−NGA)(tricine)(NIC), and [^{99m}Tc](HYNIC−NGA)(tricine)(PY). All liver supernatants had radiochromatograms identical to the respective ternary ligand [^{99m}Tc](HYNIC−lysine) complexes. These results were also confirmed by co-chromatographic analyses (data not shown). Furthermore, the liver homogenates were analyzed by TLC and CAE, and all liver homogenates showed a single radioactivity peak similar to the respective ternary ligand [^{99m}Tc](HYNIC−lysine) complexes.

Plasma Stability of [^{99m}Tc](HYNIC−Fab) Conjugates. Figure 5 shows SE-HPLC profiles of [^{99m}Tc](HYNIC−Fab) conjugates before and after incubation in freshly prepared murine plasma for 24 h. Although a small peak of radioactivity was observed in large molecular weight fractions (12 and 17 min), each [^{99m}Tc]-(HYNIC−Fab) conjugate showed a major radioactivity peak at the retention time identical to the intact Fab up to 24 h of incubation.

Biodistribution Study of [^{99m}Tc](HYNIC−Fab) Conjugates in Normal Mice. Table 2 shows elimination of radioactivity from the blood and kidneys after administration of [^{99m}Tc](HYNIC−Fab) conjugates. No significant differences were observed in radioactivity levels in the blood among the four Fab conjugates. Radioactivity levels in the kidney reached their peaks at 1 h postinjection for all Fab conjugates, and the radioactivity elimination from the kidney differed with the ternary ligands used. Among the four ternary ligands, [^{99m}Tc](HYNIC−Fab)(tricine)(BP) exhibited the fastest elimination from the kidney. The majority of radioactivity excreted from the body was detected in the urine.

Analyses of Radioactivity in the Urine. Figure 6 shows radiochromatograms of urine samples obtained by 24 h postinjection of [^{99m}Tc](HYNIC−Fab) conjugates. SE-HPLC showed two radioactivity peaks at retention times similar to those of intact [^{99m}Tc](HYNIC−Fab) conjugates (19 min) and low molecular weight compounds (25−28 min). RP-HPLC analyses after filtration with a 10 kDa cutoff membrane showed that the radioactivity in the low

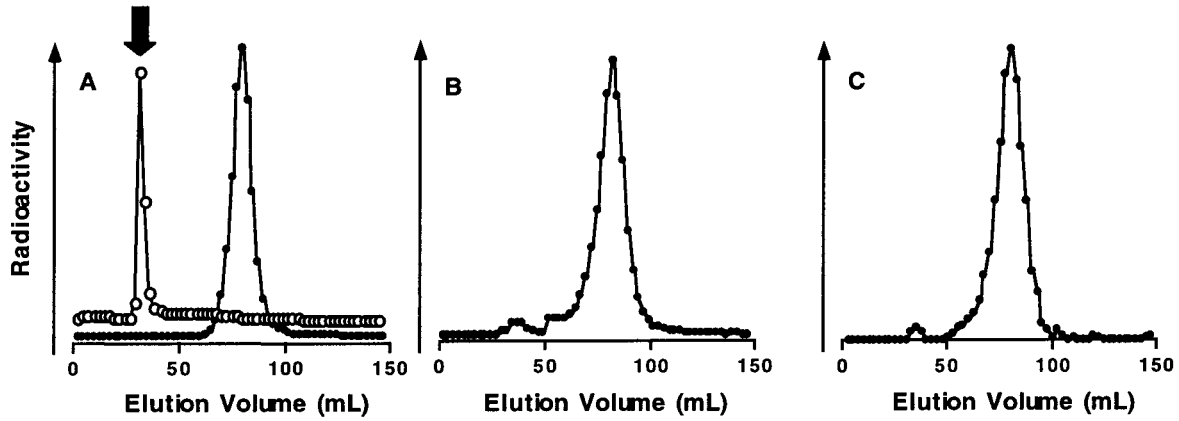

Figure 3. Analyses of liver homogenates at 1 (B) and 6 h (C) postinjection of [^{99m}Tc](HYNIC−NGA)(tricine)(NIC) by GPC. Radiochromatogram of [^{99m}Tc](HYNIC−lysine)(tricine)(NIC) (●) when analyzed by GPC (A). Under these conditions, [^{99m}Tc](HYNIC−NGA)(tricine)(NIC) (○) and blue dextran (↓) eluted at 32.5 mL (A).

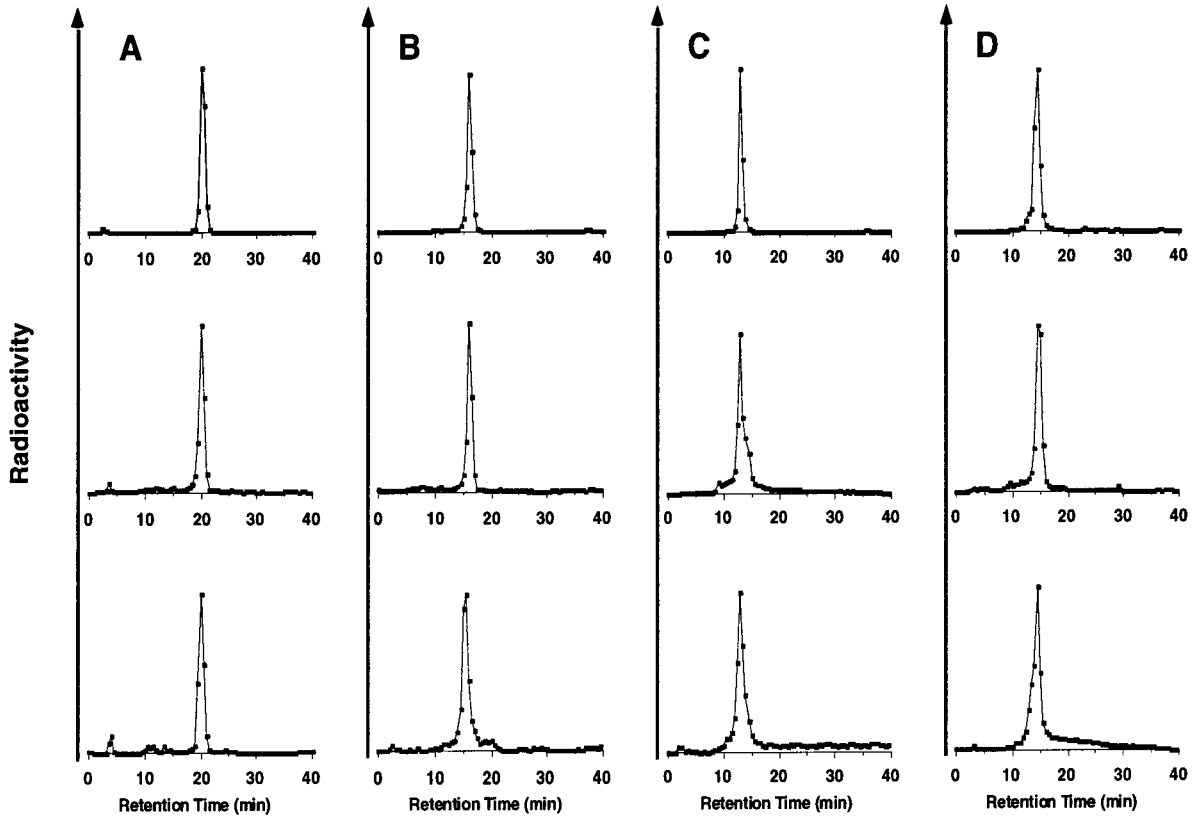

Figure 4. Analyses of liver homogenates at 1 (middle panels) and 6 h (lower panels) postinjection of [^{99m}Tc](HYNIC−NGA)(tricine)-(BP) (A), [^{99m}Tc](HYNIC−NGA)(tricine)(AP) (B), [^{99m}Tc](HYNIC−NGA)(tricine)(NIC) (C) and [^{99m}Tc](HYNIC−NGA)(tricine)(PY) (D) by RP-HPLC using solvent system 2. Radiochromatograms of [^{99m}Tc](HYNIC−lysine)(tricine)(pyridine derivative) when analyzed by RP-HPLC (upper panels).

molecular weight fraction had a retention time identical to that of the respective lysine adduct. These observations were also confirmed by cochromatographic analyses. Furthermore, on TLC, urine samples showed a single radioactivity peak similar to the ternary ligand [^{99m}Tc]-(HYNIC−lysine) complexes.

Partition Coefficients and Retention Times of Ternary Ligand [^{99m}Tc](HYNIC−Lysine) Complexes. The partition coefficients (as log PC values) and the retention times in RP-HPLC of ternary ligand [^{99m}Tc]-(HYNIC−lysine) complexes are summarized in Table 3. The rank order of the lipophilicity of ternary ligand [^{99m}Tc](HYNIC−lysine) complexes was [^{99m}Tc](HYNIC−lysine)(tricine)(BP) > [^{99m}Tc](HYNIC−lysine)(tricine)(AP) > [^{99m}Tc](HYNIC−lysine)(tricine)(PY) > [^{99m}Tc](HYNIC−lysine)(tricine)(NIC).

Biodistribution Study in Athymic Mice Bearing Osteogenic Sarcoma. Figure 7 shows the radioactivity levels in blood, kidney, and tumor at 3 and 6 h after administration of [^{99m}Tc](HYNIC−Fab)(tricine)(BP) and [^{99m}Tc](HYNIC−Fab)(tricine)$_2$ in athymic mice bearing osteogenic sarcoma. [^{99m}Tc](HYNIC−Fab)(tricine)(BP) showed significant reduction of radioactivity levels in the blood and kidney at both postinjection times compared with [^{99m}Tc](HYNIC−Fab)(tricine)$_2$, although [^{99m}Tc]-(HYNIC−Fab)(tricine)(BP) showed lower radioactivity

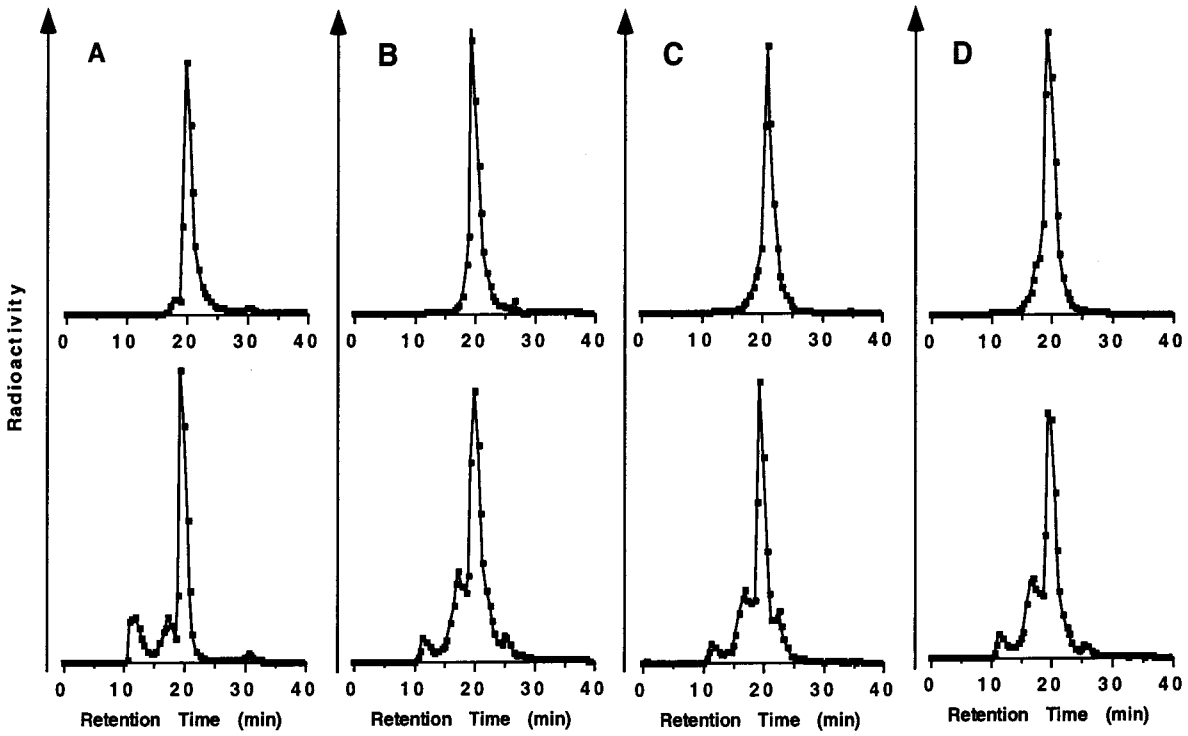

Figure 5. SE-HPLC profiles of radioactivity in murine plasma before (upper panels) and after 24 h incubation (lower panels) at 37 °C of [^{99m}Tc](HYNIC−Fab)(tricine)(BP) (A), [^{99m}Tc](HYNIC−Fab)(tricine)(AP) (B), [^{99m}Tc](HYNIC−Fab)(tricine)(NIC) (C) and [^{99m}Tc](HYNIC−Fab)(tricine)(PY) (D). Under these conditions, thyroglobulin (670 kDa), glutamate dehydrogenase (290 kDa), IgG (150 kDa), bovine serum albumin (68 kDa), Fab fragment (5 kDa) and cytochrome C (13 kDa) had retention times of 12, 14.5, 16, 18, 19, and 21 min, respectively, on SE-HPLC.

levels in the tumor than [^{99m}Tc](HYNIC−Fab)(tricine)$_2$. Thus, [^{99m}Tc](HYNIC−Fab)(tricine)(BP) provided significantly higher tumor/blood and tumor/kidney ratios of radioactivity than [^{99m}Tc](HYNIC−Fab)(tricine)$_2$ (Figure 8).

DISCUSSION

Although the relationship between solute lipophilicity and permeation across the cell membrane is well-known, there have been no systematic studies of the effects of

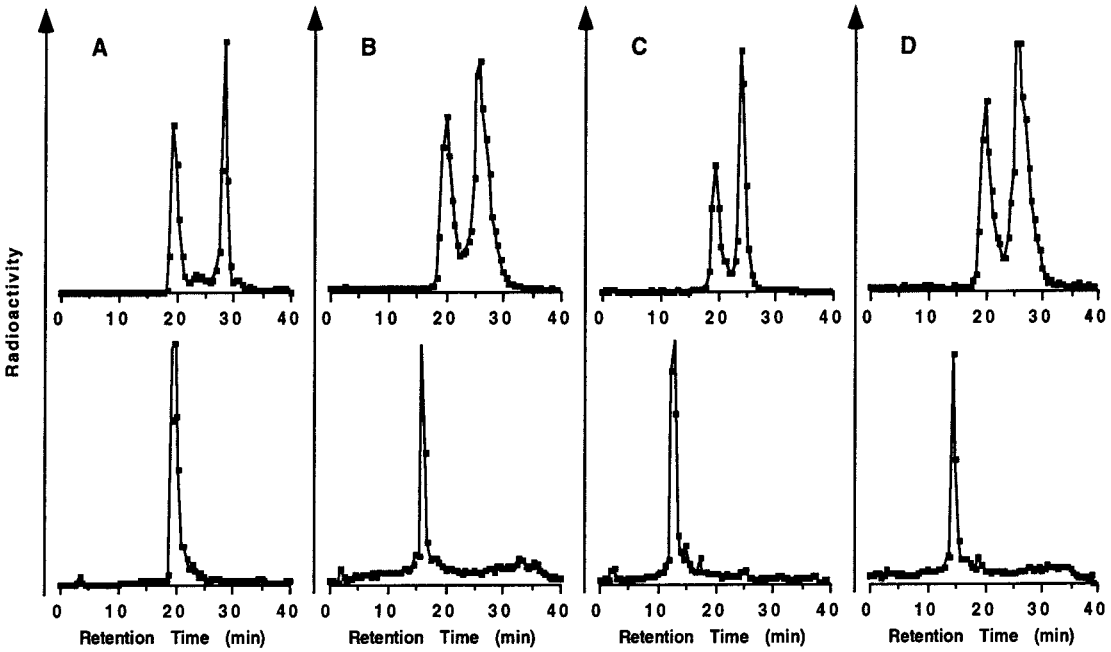

Figure 6. Radiochromatograms of urine samples obtained for 6 h postinjection of [^{99m}Tc](HYNIC−Fab)(tricine)(BP) (A), [^{99m}Tc]-(HYNIC−Fab)(tricine)(AP) (B), [^{99m}Tc](HYNIC−Fab)(tricine)(NIC) (C), and [^{99m}Tc](HYNIC−Fab)(tricine)(PY) (D) by SE-HPLC (upper panels) and RP-HPLC using solvent system 2 (lower panels). Urine samples were analyzed by SE-HPLC after filtration through a polycarbonate membrane with a pore diameter of 0.45 μm and by RP-HPLC after ultrafiltration through a 10 kDa cutoff membrane.

the lipophilicity of radiometabolites on their elimination rates from the tissue after administration of radiolabeled polypeptides. A previous study in our laboratory indicated that radiometabolites with different lipophilicity should show different permeation rates through the hepatic lysosomal membrane (*11*). As the pyridine derivative coligands could alter the lipophilicity of ^{99m}Tc−HYNIC-labeled metabolites, we used four pyridine derivatives as ternary ligands to prepare ^{99m}Tc−HYNIC-labeled polypeptides for further investigation of the effects of the lipophilicity of radiometabolites on the radioactivity elimination from the tissue.

The procedure for synthesis of ternary ligand complexes and subsequent conjugation with polypeptides has been well established as described previously (*24*). The selective conjugation of ternary ligand [^{99m}Tc](HYNIC-TFP) complexes to the ϵ-amine residues of polypeptides was supported by generating lysine adducts of HYNIC as radiometabolites (Figures 4 and 6). The rapid and quantitative accumulation of all ^{99m}Tc-labeled NGAs (Table 1) and the lack of changes in immunoreactivity of ^{99m}Tc-labeled Fab suggested that the biological reactivity of parental proteins was retained after conjugation of preformed ^{99m}Tc−HYNIC complexes.

The stability of the ^{99m}Tc−HYNIC-labeled polypeptides designed in the present study was evaluated by incubation in murine plasma. After incubation of all [^{99m}Tc]-(HYNIC−NGA) conjugates in murine plasma, almost all radioactivity was observed in the NGA fractions (Figure 1). Plasma incubation of four [^{99m}Tc](HYNIC−Fab) conjugates showed high stability of the ternary ligand ^{99m}Tc complexes against exchange reaction with plasma proteins (Figure 5), whereas [^{99m}Tc](HYNIC−Fab)(tricine)$_2$ showed significantly larger amounts of higher molecular weight radiolabeled species (over 600 kDa) (*22*). The high degree of stability of ^{99m}Tc−HYNIC ternary ligand complex against exchange reaction with plasma proteins was reflected by the faster blood clearance of ternary ligand [^{99m}Tc](HYNIC−Fab) conjugates as compared with [^{99m}Tc](HYNIC−Fab)(tricine)$_2$ (*21*). The lack of significant differences in the blood clearance of radioactivity among the four ^{99m}Tc-labeled Fab fragments indicated that the association of ternary ligand complexes with polypeptides did not affect the pharmacokinetics of the parental Fab.

Stability of radiometabolites was investigated by analysis of radiometabolites generated in hepatocytes after administration of [^{99m}Tc](HYNIC−NGA) conjugates. On GPC and RP-HPLC analyses, all liver homogenates at 1 h postinjection of four [^{99m}Tc](HYNIC−NGA) conjugates showed a single radioactivity peak at a position identical to that of the respective ternary ligand [^{99m}Tc](HYNIC−lysine) complex (Figures 3 and 4). The radiochromatograms were unchanged for up to 6 h postinjection. These findings indicated that the ternary ligand complexes remained stable against exchange reaction with proteins in the lysosomes even after catabolism to lysine adducts. Therefore, elimination rates from the liver after injection of ternary ligand [^{99m}Tc](HYNIC−NGA) conjugates would reflect those of the respective radiometabolites.

Radioactivity elimination from the tissues after administration of ^{99m}Tc−HYNIC-labeled NGAs varied with the ternary ligands used. As shown in Table 1, [^{99m}Tc]-(HYNIC−NGA) conjugates prepared using four ternary ligands were eliminated from the liver in the order of increasing lipophilicity of radiometabolites, ternary ligand [^{99m}Tc](HYNIC−lysine) complexes (Table 3). As almost all radioactivity of the [^{99m}Tc](HYNIC−lysine) complexes existed in the lysosomes of hepatocytes (Figure 2), the

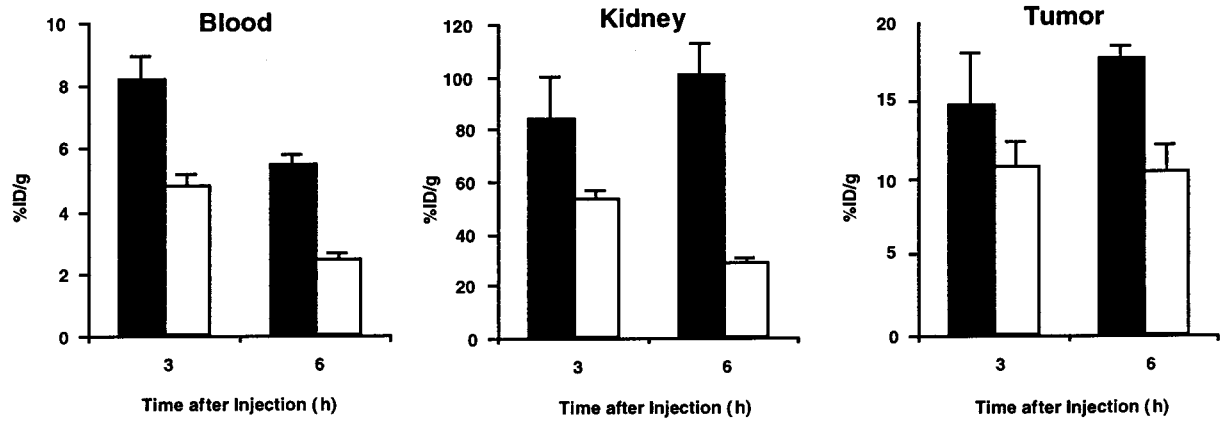

Figure 7. Comparative biodistribution of radioactivity at 3 and 6 h postinjection of [^{99m}Tc](HYNIC−Fab)(tricine)(BP) (open columns) and [^{99m}Tc](HYNIC−Fab)(tricine)$_2$ (closed columns) in athymic mice bearing osteogenic sarcoma. Each value represents the mean ± SD of five animals.

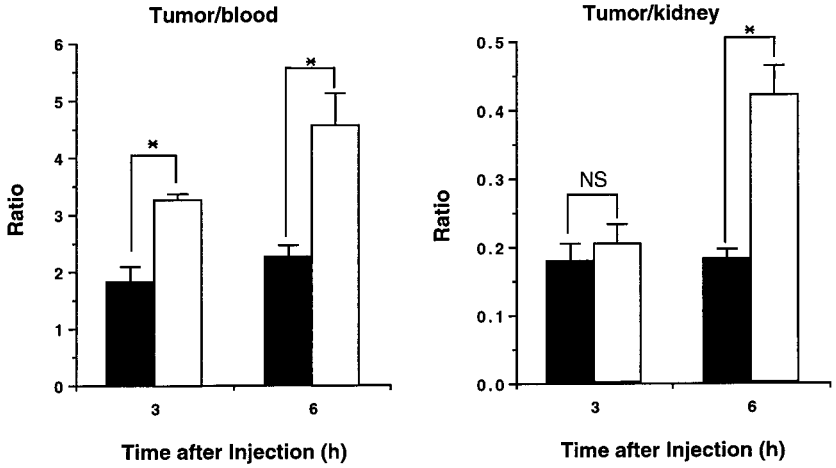

Figure 8. Tumor/blood and tumor/kidney ratios of the radioactivity at 3 and 6 h postinjection of [^{99m}Tc](HYNIC−Fab)(tricine)(BP) (open columns) and [^{99m}Tc](HYNIC−Fab)(tricine)$_2$ (closed columns) in athymic mice bearing osteogenic sarcoma. Significance was determined by unpaired *t*-test (*: $p < 0.01$, NS: not significant). Each value represents the mean ± SD of five animals.

lipophilicy of radiometabolites would affect the permeation rates through the lysosomal membrane.

Radioactivity elimination from the kidney after injection of ternary ligand [^{99m}Tc](HYNIC−Fab) conjugates differed with the ternary ligands used (Table 2). Radioactivity excreted in the urine existed as intact radiolabeled Fab fragments and ternary ligand [^{99m}Tc](HYNIC−lysine) complexes (Figure 6). As elimination of four [^{99m}Tc](HYNIC−Fab) conjugates from the kidney would be similar, the differences in radioactivity elimination from the kidney after injection of the four [^{99m}Tc](HYNIC−Fab) conjugates could reflect differences in elimination rates of the radiometabolites. Indeed, radioactivity elimination from the kidney after injection of ternary ligand [^{99m}Tc](HYNIC−Fab) conjugates increased in the order of increasing lipophilicity of the radiometabolites, ternary ligand [^{99m}Tc](HYNIC−lysine) complexes (Tables 2 and 3).

These findings indicated that the lipophilicity of radiometabolites plays an important role in the radioactivity elimination rates from the tissues after administration of radiolabeled polypeptides. The present findings also suggested that radiolabeling reagents producing lipophilic radiometabolites by lysosomal proteolysis would be useful for the enhancement of the target/nontarget ratio of radioactivity levels when using radiolabeled polypeptides that are not internalized within the target cells. To confirm the usefulness of this approach, the biodistribution study in athymic mice was performed using Fab fragments that are not internalized within tumor cells (Figures 7 and 8). BP was selected as a ternary ligand, as [^{99m}Tc](HYNIC−lysine)(tricine)(BP) exhibited the most rapid elimination from the tissues. Although [^{99m}Tc](HYNIC−Fab)(tricine)(BP) showed lower radioactivity levels in the tumor compared with [^{99m}Tc]-(HYNIC−Fab)(tricine)$_2$, [^{99m}Tc](HYNIC−Fab)(tricine)-(BP) showed significant increases of the tumor/blood and tumor/kidney ratios due to significant reduction of the radioactivity levels in the blood and kidney (Figure 8).

Determination of the relationships between the lipophilicity of radiometabolites and their elimination rates from the tissues would facilitate design of radiolabeling reagents with a metabolizable linkage. However, it is necessary for enhancement of the target/nontarget ratio not only to release the lipophilic radiometabolites in the nontarget tissues but also to stabilize the metabolizable linkage in plasma. As chemical structures of linkages and radiolabels attached to the metabolizable bonds significantly affect the stability of these bonds in radiolabeled polypeptides (*36*), radiolabeling reagents producing lipophilic radiometabolites by lysosomal proteolysis might be more useful than those that require cleavage of a metabolizable linkage.

The present findings also suggested that the reagents to radiolabel polypeptides producing hydrophilic radiometabolites would be required when applied to internalizable (poly)peptides within target cells. Use of chemically modified (poly)peptides in combination with these re-

agents could achieve further enhancement of the target/nontarget ratio.

In conclusion, the present study indicated that the lipophilicity of the radiometabolites derived from radiolabeled polypeptides constitutes one important factor affecting the elimination rate from the tissues. As pyridine derivatives could serve as stable ternary ligands in ^{99m}Tc−HYNIC-labeled polypeptides and alter the physicochemical properties of radiometabolites, the use of pyridine derivatives as ternary ligands for preparation of ^{99m}Tc−HYNIC-labeled polypeptides might be applicable for controlling the radioactivity pharmacokinetics. The findings of the present study will be useful to enhance the target/nontarget ratios of polypeptide radiopharmaceuticals.

Synthesis and Biodistribution of ^{211}At-Labeled, Biotinylated, and Charge-Modified Poly-L-lysine: Evaluation for Use as an Effector Molecule in Pretargeted Intraperitoneal Tumor Therapy

Sture Lindegren,*[,†,§] Håkan Andersson,[‡] Lars Jacobsson,[†] Tom Bäck,[†] Gunnar Skarnemark,[§] and Börje Karlsson[†]

Department of Radiation Physics, Göteborg University, Sahlgrenska University Hospital, SE-413 45 Göteborg, Sweden, Department of Oncology, Göteborg University, Sahlgrenska University Hospital, SE-413 45 Göteborg, Sweden, and Department of Nuclear Chemistry, Chalmers University of Technology, SE-412 96 Göteborg, Sweden. Received April 25, 2001; Revised Manuscript Received October 23, 2001

Poly-L-lysine (7, 21, and 204 kDa) has been evaluated as an effector carrier for use in pretargeted intraperitoneal tumor therapy. For the synthesis, the ϵ-amino groups on the poly-L-lysine were modified in three steps utilizing conjugate biotinylation with biotin amidocaproate *N*-hydroxysuccinimide ester (BANHS), conjugate radiolabeling with ^{211}At using the intermediate reagent N-succinimidyl 3-(trimethylstannyl)benzoate (m-MeATE), and charge modification using succinic anhydride, resulting in an increase in the molecular weight of approximately 80% of the final product. The labeling of the m-MeATE reagent and subsequent conjugation of the polymer were highly efficient with overall radiochemical yields in the range of 60−70%. The in vitro avidin binding ability of the modified polymer was almost complete (90−95%), as determined by binding to avidin beads using a convenient filter tube assay. Following intraperitoneal (ip) injection in athymic mice, the 13 kDa polymer product was cleared mainly via the kidneys with fast kinetics (biological half-live $T_b \approx 2$ h) and with low whole-body retention. The clearance of the 38 kDa polymer was distributed between kidneys and liver, and the 363 kDa polymer was mainly sequestered by the liver with a T_b of 8 h. Increased tissue uptake in the thyroid, lungs, stomach, and spleen following the distribution of the large effector molecules (38 and 363 kDa) suggests that degradation of the polymers by the liver may release some of the label as free astatine/astatide.

INTRODUCTION

Intraperitoneal tumors may arise from disseminated carcinomas, especially those originating from the ovaries. Generally, patients with ovarian cancer have advanced disease at the time of diagnosis (FIGO[1] stage IIB−IV) and, as a rule, tumor dissemination is restricted to the peritoneal surface. The standard treatment for ovarian cancer is surgery followed by chemotherapy. However, despite a high initial curative response, most tumors relapse and the 5-year survival is no higher than 30%. The residual and recurrent tumor cells respond weakly to further chemotherapy, and new, more effective forms of treatment are therefore urgently required.

Endoradiotherapy using radiohalogenated monoclonal antibodies has been investigated in recent years in an effort to improve the therapeutic effect of treatment of ovarian carcinomas (*1, 2*). The halogen of main interest has been the β-emitter ^{131}I, which has also been employed in clinical studies (*3, 4, 5*). Recently, ^{211}At, the heaviest element in the halogen group, has been the focus of attention for use in radioimmunotherapy (RIT) (*6, 7*). ^{211}At is a radionuclide-emitting α-particles (i.e. high-LET radiation) with a range of 50−80 μm in human tissue. As tumor spread in patients with ovarian cancer is primarily in the form of peritoneal micrometastases, ^{211}At may be a suitable choice of nuclide for adjuvant intraperitoneal radioimmunotherapy for this form of malignancy.

Despite some promising clinical reports on RIT of ovarian cancer, the clinical application of radiolabeled antibodies has so far been limited, mainly because of the unfavorable in vivo distribution, resulting in low tumor uptake, low target-to-nontarget ratios, and slow clearance rates from normal tissues (*8*).

Pretargeted radioimmunotherapy (PRIT) in which a tagged antibody is preadministered for tumor targeting, followed by administration of a labeled ligand (effector molecule) as a multistep delivery system, has been proposed to improve the pharmacokinetics of the label in vivo. For this purpose, avidin and biotin are the most commonly used intermediates because of their high-affinity binding characteristics (*9, 10*). It has been shown, utilizing various protocols based on the biotin−avidin system for PRIT that, due to a more favorable in vivo distribution of the labeled effector molecule, significantly improved tumor uptake and tumor-to-normal-tissue ratios could be achieved (*11, 12, 13, 14*). In most cases, the

effector molecule is a conjugate of a biotin and radionuclide, which exhibits rapid in vivo clearance and low uptake in normal tissue (*15, 16*).

In a few investigations, poly-L-lysine has been explored as a multicarrier of biotin and radionuclides for pretargeted radioimmunotherapy (*17, 18*). The advantages of these polymer conjugates are that increased avidity for avidin and higher specific radioactivity may be achieved. Furthermore, the available molecular weight range of poly-L-lysine may allow increased control of the biodistribution compared with the mono-derivative of biotin.

In this study, the synthesis and distribution of biotinylated, astatinated, and charge-modified poly-L-lysine, as a prospective effector molecule for use in pretargeted intraperitoneal tumor therapy, have been investigated. Three different average sizes of the polymer (7, 21, and 204 kDa) were evaluated with respect to radiolysis after astatine exposure, in vitro biotin binding capacity to avidin, and in vivo biodistribution and biological half-life in nude mice.

EXPERIMENTAL PROCEDURES

Materials. Poly-L-lysine (7, 21, and 204 kDa), biotinamidocaproate *N*-hydroxysuccinimide ester, *N*-bromsuccinimide (NBS), and *N*-iodosuccinimide (NIS) were purchased from Sigma Chemical Co. Avidin (ImmunoPure Avidin), Avidin beads (ImmunoPure Immobilized Avidin Gel), 2-(−4-hydroxyazobenzene)benzoic acid (HABA), and 2,4,6-trinitrobenzenesulfonic acid (TNBSA) were obtained from Pierce Chemical Co. All other nonradioactive commercial chemicals and solvents used were of analytical grade or better.

^{211}At was produced by the ^{209}Bi(α,2n)^{211}At reaction (*19*) on the Scanditronic MC32−NI cyclotron at the Cyclotron and PET Unit, Rigshospitalet, Copenhagen, Denmark. Na[^{125}I]I was obtained from NEN Life Science Products Inc.

General. After irradiation, the target was immediately shipped to the Department of Radiation Physics, Göteborg, and the astatine was isolated from the target by dry-distillation, according to the method described previously (*19*). The radioactivity was measured using an ionization chamber (Capintech CRC-15) utilizing proper settings for ^{211}At, cross-calibrated for the 70−90 keV ^{211}Po X-rays in a NaI(Tl) detector (Wizard Wallac γ-well counter, Finland). The biological half-life of the astatinated polymers in athymic mice was determined by measurement of whole-body radioactive content using a NaI(Tl) scintillation detector (Harshaw Chemie B.V.)

High performance liquid chromatography, HPLC, was conducted on a Waters 600/486 system with the Waters Baseline 820 analysis software. Reversed-phase chromatography was performed using a Kromasil C-18 (4.6 × 250 mm) column (EKA-Nobel AB, Sweden), and size-exclusion analysis was carried out on a Superdex-200 FPLC column (Amersham Pharmacia Biotech, Sweden). Preparative gel-permeability chromatography was conducted on disposable Sephadex G-25 PD-10 columns (Amersham Pharamacia Biotech, Sweden). Mass spectral data were obtained by inductively coupled plasma ion source mass spectroscopy (ICP-MS).

Labeling of *N*-Succinimidyl-3-(trimethylstannyl)-benzoate. The labeling of *N*-succinimidyl-3-(trimethylstannyl)benzoate, m-MeATE, was performed using the procedure previously reported (*20*). Briefly, to a 1.3-mL reaction vial containing 20−30 MBq ^{211}At as dry residue were added 0.5 nmol of *N*-iodosuccinimide and 1.0 nmol of m-MeATE in 1% acetic acid/methanol. The m-MeATE was reacted with the halogen for 15 min during gentle agitation at room temperature. The reaction was stopped by the addition of 50 nmol of $Na_2S_2O_5$. Iodination of the precursor was accomplished in essentially the same way as the astatination, except that *N*-bromosuccinimide (NBS) was used as the oxidizing agent.

The labeling efficiency was determined by running an aliquot of the reaction mixture on a reversed-phase C-18 column, isocratically eluted with acetonitrile/2 mM phosphoric acid 60:40 as the mobile phase. The product, *N*-succinimidyl-3-[^{211}At]astatobenzoate (NS[^{211}At]AtB) or *N*-succinimidyl-3-[^{125}I]iodobenzoate (NS[^{125}I]IB), was used immediately, unpurified for conjugation to the biotinylated polymer.

Modification of Poly-L-lysine. *Biotinylation.* Biotinamidocaproate *N*-hydroxysuccinimide ester (BANHS) was dissolved in dimethylformamide (DMF) to a concentration of 5−10 mg/mL. To poly-L-lysine in 0.2 M carbonate buffer pH 8.5 was added a 10−20-fold molar excess of the biotinylation reagent during vigorous agitation, and the reaction was allowed to proceed for 1 h during gentle agitation at room temperature. Further chemistry was conducted on the crude biotinylated product.

Conjugate Labeling. Prior to conjugate labeling of the biotinylated polymer, NIS in the labeling mixture was promptly reduced by the addition of 50 nmol of sodium metabisulfite, and the organic fraction of the solvent was evaporated under a gentle stream of nitrogen. To the labeling mixture was added 200 μg of the crude biotinylated poly-L-lysine to give a final volume of 50 μL, and conjugate labeling was allowed to proceed for 10 min during gentle agitation at room temperature.

Succinylation. The biotinylated and labeled polymer was finally reacted with succinic anhydride, in excess over available amines, to convert the remaining unsubstituted amino groups to carboxylic residues. Following conjugate labeling, solid succinic anhydride, in the form of flakes, was added to the reaction mixture. The pH was adjusted with 1 M carbonate buffer, pH 8.5, during the reaction in order to maintain the amino residues unprotonated. After 10 min reaction time, the polymer fraction was isolated by passage over a G-25 PD-10 column (Pharmacia, Sweden).

The final product was analyzed with respect to unbound radioactivity by methanol precipitation according to the method of Reist et al. (*21*), and the size by gel-filtration chromatography. The biotinylation efficiency was calculated using the HABA dye method (*22*), and degree of succinylation was determined using the TNBSA spectrophotometric method (*23*). The average molecular weights of the modified polylysines were estimated to be 13, 38, and 363 kDa.

Radiolysis of Poly-L-lysine after ^{211}At Exposure. To investigate radiolysis effects during labeling, nonmodified poly-L-lysine (204 kDa) was exposed to increasing activities, i.e., absorbed doses, of ^{211}At. Astatine, in chloroform, was added to Eppendorf tubes in a single point series, and the solvent was evaporated. The activities of the dry astatine residues were 0.80, 1.38, 4.85, and 11.7 MBq. A constant amount of poly-L-lysine (50 μL, 2 mg/mL) in 0.2 M carbonate buffer, pH 8.5, was then added to each tube.

The astatine was allowed to decay during agitation at 4 °C for 120 h (16.7 half-lives), resulting in absorbed doses to the volume of 0.66, 1.1, 4.0, and 9.5 kGy, as determined using basic dosimetry calculations derived from the following equations:

Number of ^{211}At decays (N):

$$N = \frac{A_0}{\lambda}(1 - e^{-\lambda t}) \text{ for complete decay } N = \frac{A_0}{\lambda}$$

where A_0 is the total radioactivity measured at the start of exposure, λ is the decay constant, and t is the total exposure time.

Absorbed dose (D):

$$D = \frac{E_{\text{abs}}}{m_{(\text{volume})}} \approx \frac{N\bar{E}_\alpha(1.6 \times 10^{-13})}{m_{(\text{volume})}}(\text{Gy})$$

where E_{abs} is the absorbed energy in the reaction volume (MeV), $\bar{E}_\alpha \approx 6.8$ MeV is the mean alpha particle energy (*24*), and m_{volume} is the mass of the solution (kg).

After radiation exposure, the polymer was labeled with ^{125}I according to the m-MeATE method and charge modified with succinic anhydride as described above. The effect of the radiation, i.e., fragmentation, was analyzed and compared with nonexposed, iodine-labeled, succinylated polymer by size-exclusion chromatography on a Superdex-200 column.

In Vitro Binding of Modified Polylysine. The biological function of the biotin moiety on the modified polylysine was examined by binding to avidin beads. Fifty microliters of the avidin bead slurry was transferred to Costar spin-x, 45 μm, filter tubes (Corning Inc., NY). An aliquot of the modified polymer (25 ng) was added, and the volume was adjusted to 150 μL with PBS. The effector molecule was reacted with the beads for 30 min at room temperature during agitation. The beads were then washed three times with PBS, and bound radioactivity was measured in a γ-well counter.

Nonspecific binding to avidin was determined by incubating nonbiotinylated, labeled polylysine with the beads, and nonspecific binding to the filter tubes was determined by incubation with the modified polymer in tubes not containing avidin beads.

Animal Experiments. The tissue distribution and whole-body retention of the 13, 38, and 363 kDa polymers were evaluated in female athymic mice (Balb/C nu/nu), 6−8 weeks of age. Following ip administration of the effector molecule (550−800 kBq in 500 μL of PBS) mice were sacrificed by cervical dislocation at 1, 3, 6, 18, and 24 h postinjection, in groups of four animals per point in time. Whole blood was collected by cardiac puncture immediately after the animals had been killed, and tissues including neck, lungs, stomach, liver, small intestine, large intestine, kidneys, spleen, intraperitoneal fat, and muscle were excised and washed in saline. The tissues were blotted dry and accurately weighed, and the radioactivity was measured in a γ-well counter. All tissue data were corrected for radioactive decay and expressed as the percent of injected radioactivity per gram of organ (%ID/g), except for the neck, where it was expressed as the percent of injected activity (%ID).

The biological half-life of the modified polymers was evaluated by following the whole-body radioactive retention in groups of 5 mice for 24, hours measured with a sodium iodide detector.

RESULTS

The radioactivity of the irradiated target was in the range of 200 to 300 MBq ^{211}At upon arrival in Göteborg. Isolation of ^{211}At was conducted by dry-distillation of the target material, and recovery yields of 70−80% of the initial ^{211}At activity were routinely obtained within a 20-min preparation time. Aliquots of the recovered astatine were immediately used for conjugate labeling via the ϵ-amino groups on poly-L-lysine, utilizing the intermediate labeling reagent m-MeATE. Radiohalogenation of the m-MeATE resulted in labeling yields of 85−95% for both the NS[^{125}I]IB and the NS[^{211}At]AtB product. Prior to the conjugate astatine labeling, the poly-L-lysine was biotinylated using biotin amidocaproate *N*-hydroxysuccinimide (BANHS) with an efficiency of 73−85% as determined by the HABA method (*22*). To avoid workup losses of radioactivity in ensuing conjugations, labeling and charge modification of the biotinylated polylysine were conducted in a single pot without purification of the labeling mixture. After conjugate labeling the poly-L-lysine was subjected to charge modification by complete conversion of the remaining unsubstituted primary amines to carboxylic residues using succinic anhydride. Because of the reaction conditions, the molecular weight of the final product was increased by approximately 80% since the modification by means of the number of substitutents per polymer were in the order ^{211}At ≪ biotin ≪ succinic acid. However, charge modification is essential, as it decreases nonspecific adsorption both in vitro and in vivo. Generalized structural formulas of the reacting species and the final product are shown in Figure 1.

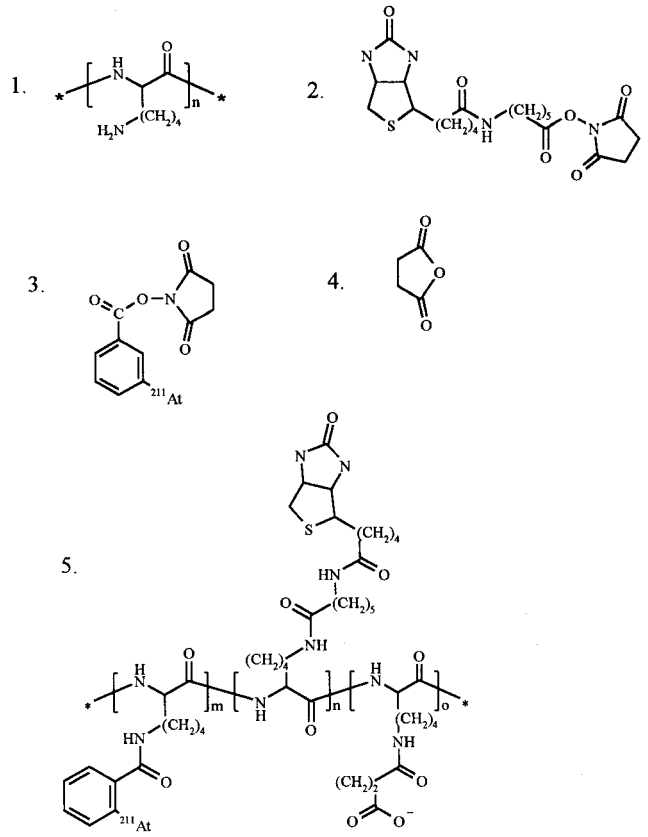

Figure 1. Generalized structural formula for (1) poly-L-lysine, (2) *N*-succinimidyl 3-[^{211}At]astatobenzoate (NS[^{211}At]AtB), (3) biotinamidocaproate *N*-hydroxysuccinimide (BANHS), (4) succinic anhydride, (5) modified poly-L-lysine (^{211}At−PL$_{suc}$−B).

Good conjugation yields of 70 ± 5% were achieved in the coupling of NS[^{211}At]AtB to polylysine, corresponding to a mean radiochemical yield of 63 ± 4%. Since the labeling procedure involved an excess of the m-MeATE reagent over astatine and the labeling reaction mixture is used in unpurified form for conjugation to the polylysine, the precursor may also be present (i.e. conjugate coupled) in the final product. Organic tin, the $Sn(CH_3)_3$

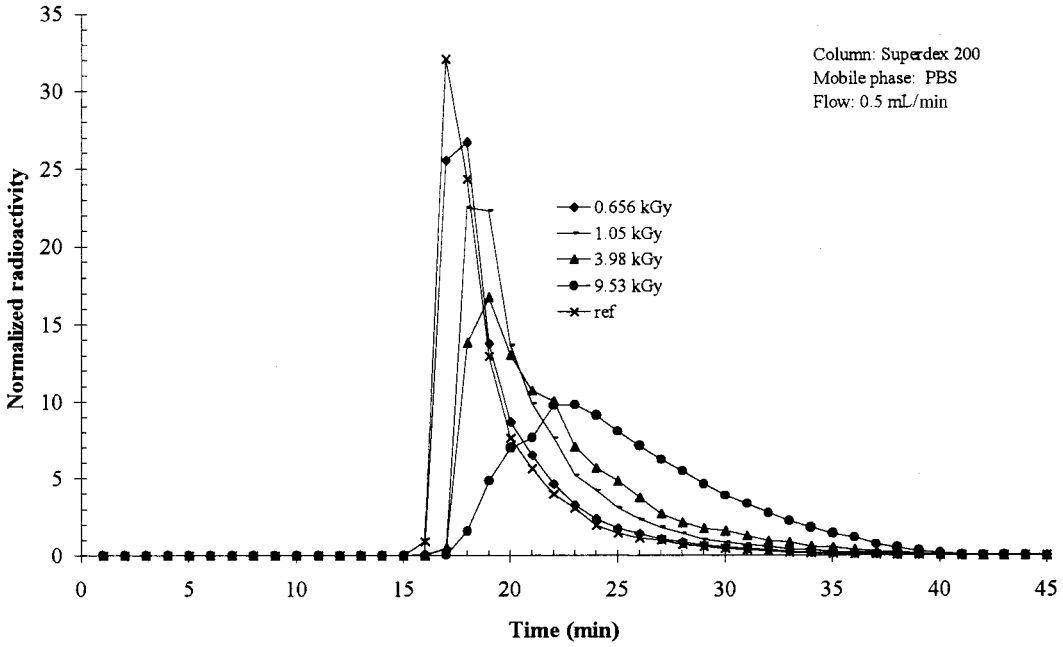

Figure 2. Size-exclusion analysis of poly-L-lysine (204 kDa) exposed to 0.656−9.53 kGy of ^{211}At. Determination were performed on the ^{125}I-labeled and succinylated derivative.

group, may be toxic if released in vivo, and the modified polymers were therefore subjected to ICP-MS analysis. Only <10 pg tin, corresponding to <0.0003% of in put amount of the m-MeATE precursor was detected in the spectra. This is probably due to differences in solubility of the precursor and the labeled reagent in the conjugation buffer.

The radiochemical purity of the products was always greater than 95%, as determined by methanol precipitation and by size-exclusion analysis. However, when subjecting the polymer to astatine activities that resulted in a high absorbed dose to the reaction volume, radiolysis effects, i.e., fragmentation, of the polylysine, occurred. As can be seen in Figure 2, the polymer is gradually decomposed when exposed to absorbed doses above 660 Gy, with an initially high degree of large fragments at 1100 Gy and increasingly smaller fragments at higher exposures.

The biotin binding ability of the modified polymer product was examined by means of its reaction with avidin beads using a fast, convenient filter tube assay. Almost complete biotin binding (90−95%) to the beads was achieved with low, nonspecific binding to the tubes. Even when labeling at high absorbed doses, in the range where fragmentation occurred, the degree of biotin binding was high. Low nonspecific binding to avidin beads was demonstrated by subjecting the beads to nonbiotinylated labeled polylysine.

The tissue distribution and whole-body retention of the 13, 38, and 363 kDa molecular weight effector molecules were evaluated in nude mice following intraperitoneal administration. The tissue distribution data for the polymers from one to 24 h are summarized in Tables 1−3. As can be seen, the distributions of the 38 and 363 kDa effector molecule show uptake in stomach (14.74 and 9.90% ID/g), lungs (6.74 and 7.48% ID/g), and spleen (7.64 and (9.48% ID/g) reaching a maximum at 1−3 h and 3−6 h postinjection. The radioactivity was thereafter slowly cleared from the tissues. The thyroid, known to accumulate astatide (*25*), shows increasing uptake at 3 to 6 h (0.65 and 1.1% ID) with a slight decrease over the remaining time of observation. Note that the thyroid was not dissected from the neck, and the results are therefore expressed as the percent of injected dose (% ID). All other organs show low uptake including the blood, which exhibited a maximum uptake of (2.48% ID/g) at 3 h.

Compared with the larger polymers, the tissue distribution of the 13 kDa effector molecule shows lower uptake in all tissues except for the kidneys, 1 h postin-

[a] Results are given as mean ± standard deviation of the percent of injected dose per gram tissue (%ID/g); n = four animals per time point. [b] n = Three animals. [c] Results are expressed as the percent of injected dose (%ID).

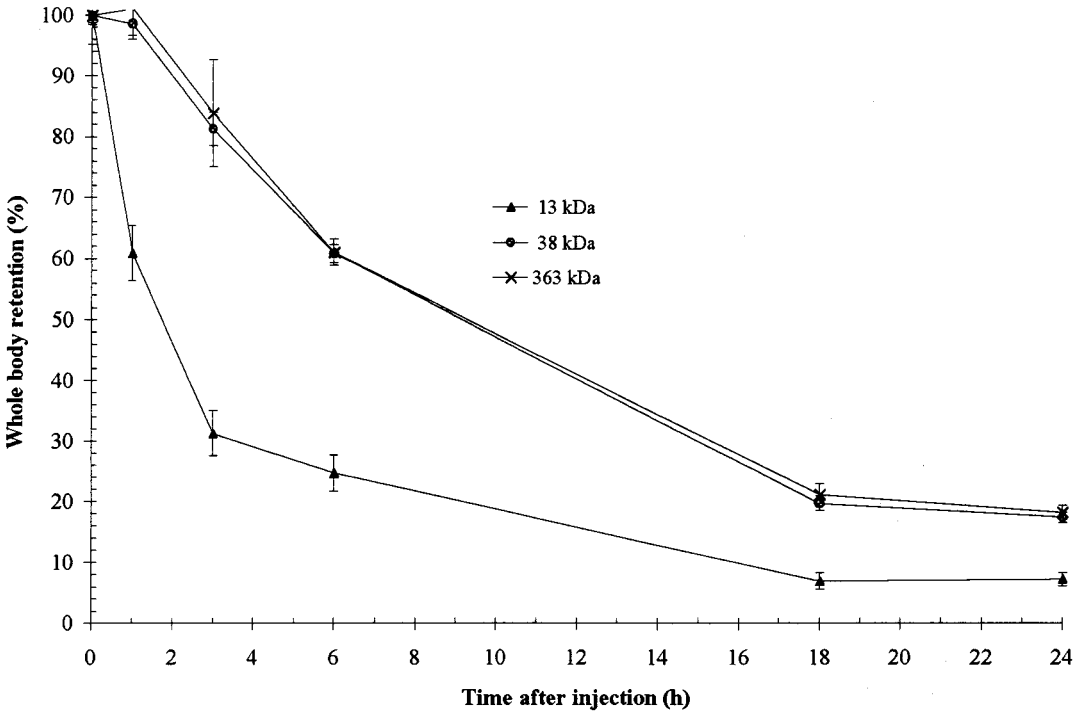

Figure 3. The whole-body retention of the 13, 38, and 363 kDa effector molecule in nude mice, following intraperitoneal administration. Results are given as mean ± SEM for four animals per time point.

jection, which may be due to the rapid clearance mainly through the kidneys. The whole-body retention of the astatinated polymers is presented in Figure 3. The results show that whole-body clearance is fast, with biological half-lives of 2 and 8 h for the low- and high-molecular-weight effector molecules, respectively. This is also reflected in the low tissue content at the later points in time.

DISCUSSION

Since the development of the hybridoma technology (*26*) monoclonal antibodies have been used for a variety of applications. Using this method it is possible to produce monoclonal antibodies specific to virtually any molecule of interest. In vivo, one of the challenges has been to develop a novel radioimmunopharmaceutical for tumor imaging and therapy. However, due to the size and passive distribution processes of in vivo administered antibodies, only a small fraction of the injected activity will bind to tumor cells. The remaining non-tumor-bound antibody is evenly distributed and slowly cleared from the body, causing undesirable background and elevated dose to normal tissue. To circumvent the unfavorable distribution of labeled antibodies, pretargeting strategies utilizing the high-affinity binding characteristics between biotin and avidin as intermediates for multistep administration, have been proposed by several investigators (*12, 13, 14*). Various biotin derivatives have been developed for cross-linking and for labeling with radionuclides to provide effector molecules for pretargeting.

The aim of this study was to produce biotin-polylysine-based effector molecules for use in pretargeted ovarian tumor therapy. Ovarian tumors disseminate primarily to the peritoneal surface as microtumors, and therefore a suitable choice of nuclide may be the α-emitter ^{211}At. Following the decay, the α-particles deposit a considerable amount of energy in a micro-volume, and calculations have shown that only a few astatine decays per cell are required to cause lethal radiation damage (*27*). Previous experiments by our research group have also demonstrated the high cell-killing effect of astatine in vitro (*28*) and in vivo (*7*) when subjecting ovarian cancer cells and microtumors to the astatine-labeled ovarian-tumor-specific monoclonal antibody MOv18. On the basis of the encouraging results of those studies, improvement in the pharmacokinetics to minimize the irradiation of normal tissue was suggested, employing a pretargeting strategy that involves polylysine as an effector carrier. Poly-L-lysine was used since each molecule, depending on the polymerization degree, contains a number of ϵ-amino groups that can readily be derivatized with different *N*-acylation reagents, thus allowing bifunctional conjugate modification. Apart from this facile chemistry, polylysine can be obtained as mono-amino acid- or copolymers of different molecular weights, which may permit increased control of the biodistribution of the effector molecule.

Applications utilizing polylysine as carriers for nuclides have previously been proposed, such as a polychelating agent for high-specific-activity metal-nuclide binding of antibodies, for use in single-photon emission computed tomography (SPECT) and magnetic resonance tomography, and for therapy (*29*). The application of polylysine as an effector carrier for use in PRIT has also been reported (*17, 18*).

In this study, polylysine (7, 21, and 204 kDa) was modified by conjugate coattachment of the biotin reagent (BANHS), the astatine-labeled reagent NS[^{211}At]AtB, and succinic anhydride in a simple three-step procedure. The product could easily be obtained, with the reaction conditions employed, ^{211}At activities of 10−20 MBq (100 kBq/μg), in a short preparation time, and preliminary experiments suggest that the procedure can be scaled up to higher astatine activities, e.g. for clinical applications. However, it should be noted that the polylysine is sensitive to radiolysis from the astatine decay in the reaction volume. The molecule can be subjected to an absorbed dose of about 700 Gy without any apparent damage, as determined by size-exclusion chromatography analysis. Increasing the dose above this level resulted in gradual fragmentation with random molecular breakdown at 700−1000 Gy and almost complete decomposition at higher doses (4000−10000 Gy). This is in good agreement with the observations of Larsen and Bruland who studied α-particle-induced radiolysis effects on antibodies and found that an absorbed dose of 1000 Gy could be tolerated with no or minor affects on the immunoreactivity (*30*).

The only biologically active part of the effector molecule is the biotin moiety which, surprisingly, was not affected to any high extent by the radiation dose, as determined by binding the effector molecule exposed to a high-absorbed dose to avidin beads. We suggest that the radiation resistance is dependent on the size of the molecule, implying that biotin could withstand much higher absorbed doses than the polymers. In this study, biotin substitution was performed with a 10−20-fold excess of reagent over polymer to ensure uniform attachment on a molar basis, which resulted in approximately 8−16 biotin molecules per polymer. Uniform biotinylatation of the low specific radioactive product was confirmed by high binding efficiency to avidin beads. A very high degree of biotin attachment to the polymer is possible, with ultimately complete biotinylation, except for the label, which would give a tremendous increase in avidity for avidin. However, most of the biotin derivatives commercially available have limited aqueous solubility, and this may affect the labeling chemistry and the solubility of the final product (*31*). Moreover, problems associated with cleavage of the biotin nuclide or carrier bond in vivo due to systemic biotinidase activity when utilizing the commercially available reagents have been reported (*32, 33*). To circumvent these problems Foulon et al. have developed new biotin compounds for labeling with radiohalogens, e.g. ^{211}At and iodine isotopes, which are resistant to biotinidase activity (*16*). Several new biotin derivatives for conjugate labeling have also been explored by Wilbur et al. with regard to solubility and avidin binding characteristics, as well as biotinidase resistance to identify the derivative with the best properties for in vivo applications (*31, 34*).

The effector molecules studied in the present work were evaluated regarding the tissue distribution following ip injection in nude mice during 24 h postadministration. Significant differences in tissue uptake between the 13 kDa and the larger polymers were seen, which are related to different clearance routes. All molecules enter the circulation from the peritoneal cavity, and their sizes predetermine that the 13 kDa polymer is cleared mainly via the kidneys, the 38 kDa polymer through liver and kidneys and the 363 kDa polymer is sequestered primarely by the liver. Compared with the 13 kDa polymer, a higher uptake of the 38 and 363 kDa polymers was observed in the thyroid gland, stomach, lungs, and spleen, which may reflect the release of astatine/astatide after degradation in the liver. This might be a limiting factor for prospective clinical use, but the astatine/astatide uptake may be decreased by the use of blocking agents, as proposed by Larsen et al., thus limiting the absorbed dose to these tissues (*35*). The normal tissue at greatest risk is the bone marrow but, because the residence time of the three effector molecules in the circulation following intraperitoneal administration is short, and provided that there are no active uptake mechanisms, the dose to the bone marrow is likely to be limited. Compared with astatinated IgG antibodies, the

radioactive content in the blood is of the order of at least 10 times less for the large polymers and a factor of 20 less for the small polymer (*36*). Therefore, increased absorbed dose to tumor tissue might be achieved in PRIT utilizing polylysine as the effector carrier as higher activities of the astatinated effector molecule can be administered without increasing the radiotoxic effects on normal tissues, i.e., the bone marrow.

In summary, the preparation, in vitro avidin binding characteristics and biodistribution of biotinylated, astatinated, and charged modified poly-L-lysine of different molecular weights for prospective use as an effector molecule in pretargeted intraperitoneal tumor therapy were investigated. Following ip administration, the three modified polymers studied showed low whole-body retention with clearance routes determined by the size of the molecules. Somewhat higher uptakes of radioactivity in normal tissues were observed for the high-molecular-weight effector molecules, suggesting that for clinical applications a low-molecular-weight poly-L-lysine should be used for derivatization. However, application using a complete pretargeted intraperitoneal tumor model may contribute to lowering normal tissue uptake due to reduced escape of the effector molecule from the peritoneal cavity by binding to its mAb−avidin conjugate at the tumor target. Therefore, further investigations will be focused on more homogeneous preparations of both high- and low-molecular-weight poly-L-lysine for the modification, new biotinidase-resistant water-soluble derivatives and scale-up of the labeling procedure to meet the requirements for patient studies.

ACKNOWLEDGMENT

We would like to thank Elisabet Warnhammar (Department Oncology, Göteborg University, Sweden) and Jörgen Elgquist (Department of Radiation Physics, Göteborg University, Sweden) for excellent technical assistance with the animal study. Thanks are due to Dr. Stig Palm (Department of Radiation Physics, Göteborg University, Sweden) for help with the dosimetry evaluation and Arvid Ödegaard-Jensen (Department of Nuclear Chemistry, Chalmers University of Technology) for help with mass spectral analysis. This work was supported by grants from the Swedish Cancer Foundation (Grant 3548) and the King Gustaf V Jubilee Clinic Cancer Research Foundation in Göteborg, Sweden.

Received July 3, 2001; Revised Manuscript Received February 25, 2002

Monodispersed dendritic poly(L-lysine)s (DPKs) of several generations were synthesized, and their characteristics as a gene transfection reagent were then investigated. The agarose gel shift and ethidium bromide titration assay proved that the DPKs of the third generation and higher could form a complex with a plasmid DNA, and the degree of compaction of the DNA was increased by the increasing number of the generation. The DPKs of the fifth and sixth generation, which have 64 and 128 amine groups on the surface of the molecule, respectively, showed efficient gene transfection ability into several cultivated cell lines without significant cytotoxity. In addition, the transfection efficiency of the DPK of the sixth generation was not seriously reduced even if serum was added at 50% of the final concentration into the transfection medium. Because we can strictly synthesize various DPK derivatives, which have several types of branch units, terminal cationic groups, and so on, they are expected to be a good object of study regarding the basic information on the detailed mechanism of gene transfection into cells. We also expect to be able to easily construct DPK-based functional gene carriers, e.g., DPKs modified by ligands such as a sugar chain, which can enable advanced gene delivery in vivo.

INTRODUCTION

Nonviral gene delivery systems into cells consist of cationic polymers, such as polylysine derivatives (*1*−*3*) and polyethleneimines (*4*), cationic lipids (*5*), or cationic oligopeptides (*6*−*10*) that electrostatically form a complex with the negatively charged DNA that can be taken up by the cells. In 1993, novel gene delivery techniques, in which cationic polyamidoamine (PAMAM[1]) cascade polymers are used as a gene carrier into cells, have been reported by Haensler et al. (*11*). The dendrimers showed high levels of transfection in a wide variety of cultivated cells with less toxicity. They then reported that stringently synthesized and purified, monodispersed PAMAM dendrimers showed low levels of transfection. However, the activity was dramatically enhanced by heat treatment in a solvolytic solvent (*12*, *13*). In those reports, they suggested that the increase in transfection efficiency after the degradation is due to the increase in flexibility that enables the degraded heterodisperse dendrimers to be compacted on forming a complex with the DNA and to swell when released from the DNA.

On the other hand, in 1981, Dankewalter et al. reported the synthesis of dendritic poly(L-lysine) using Boc-L-Lys(Boc)-OH benzhydrylamide as a core (*14*), and the properties were then described by Aharoni et al. in 1982 (*15*). The dendritic molecule is not strictly classified in the original concept of the 'dendrimer' described by Tomalia because it consists of asymmetrical L-lysine residues (*16*); however, the new concept of a dendritic molecule consisting of amino acids is expected to enable us to construct a functional gene carrier in the next generation, which is directed in a different way from a PAMAM-type dendrimer. Dendritic poly(L-lysine) can be synthesized with a well-defined molecule and a precise number of terminal amines per dendrimer. In addition, we expect to easily construct functional gene carriers, e.g., those modified by ligands such as a sugar chain, endosome disrupting agents, and an intracellular targeting signal, by selecting several protecting groups of the lysine, such as Boc, Z, and Fmoc groups (*17*). As a candidate for the gene carrier among several types of dendritic poly(L-lysine)s, block copolymers consisting of poly(ethylene glycol) and poly(L-lysine) dendrimer were reported (*18*, *19*). The copolymers formed about 100 nm of a spherical complex with DNA and did not show any cytotoxity toward NIH3T3 cells even at higher concentration (*19*). Shah et al. also reported that amphipathic asymmetric poly(L-lysine) dendrimers, in which the dendritic structure was attached to an amino group of α-amino myristic acid, had gene transfer ability into cells without significant cytotoxity (*20*).

In this study, we focused on a monodispersed and symmetric dendritic poly(L-lysine) (DPK) made of hexamethylenediamine as an initiator core proposed by Maruo et al. (*17*). To investigate the characteristics of DPK as a gene carrier into cells, we synthesized several

generations of DPKs, and their binding abilities with a plasmid DNA and the gene transfection abilities into cells were then evaluated.

EXPERIMENTAL PROCEDURES

Chemicals and Instruments. All amino acid derivatives and reagents for peptide synthesis, ethidium bromide and MTT (3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-*2H*-tetrazolium bromide) were purchased from Watanabe Chemical (Hiroshima, Japan), Wako Chemicals (Osaka, Japan), and Dojindo (Kumamoto, Japan), respectively. Mass spectra were obtained on matrix-assisted time-of-flight mass spectrometry (MALDI TOF-MS) using Applied Biosystems, Voyager Linear DE (Tokyo, Japan). Plasmid DNA which contains a luciferase gene and SV40 promoter (PicaGene control vector, PGV−C) was purchased from Toyo Ink (Tokyo, Japan). Plasmid DNA which contains a EGFP gene and CMV promoter (pEGFP−C1) was purchased from CLONTECH (Tokyo, Japan). Closed circular plasmid DNA was purified by ultracentrifugation in CsCl gradients. The plasmid preparations showed a major band of closed circular DNA and a minor amount (<20%) of nicked plasmid. DMEM, RPMI1640, kanamycine sulfate, and heat-inactivated FBS were purchased from IWAKI GLASS (Chiba, Japan). Lipofectin and SuperFect were purchased from Invitrogen (Tokyo, Japan) and Qiagen (Tokyo, Japan), respectively.

Synthesis of Dendritic Poly-L-lysine. DPKs were synthesized from hexamethylenediamine as an initiator core. Boc-L-Lys(Boc)-OH·DCHA (528 mg, 1.0 mmol) and hexamethylenediamine (58 mg, 0.50 mmol) were coupled by HBTU (379 mg, 1.0 mmol) and HOBt·H_2O (153 mg, 1.0 mmol) in 15 mL of DMF containing triethylamine (154 μL, 1.1 mmol). After incubation for 15 h at room temperature, the reaction mixture was evaporated and precipitated with 10% citrate aqueous. The precipitate was isolated by filtration, redissolved in ethanol, and precipitated once more with diethyl ether to give 325 mg (84%) of the Boc-protected DPK of first generation. In addition, we confirmed using the Kaiser Test whether the coupling was completely achieved (*21*). The Boc-protected DPK of first generation (325 mg, 0.42 mmol) was dissolved in 5 mL of TFA. After being stirred for 1 h at room temperature, the mixture was evaporated and precipitated with diethyl ether to give 323 mg (93%) of DPK of first generation.

DPK of second generations was prepared by coupling between DPK of first generation (323 mg, 0.39 mmol) and Boc-L-Lys(Boc)-OH·DCHA (823 mg, 1.6 mmol) in 30 mL of DMF containing triethylamine (238 μL, 1.7 mmol), HBTU (592 mg, 1.6 mmol), and HOBt·DCHA (239 mg, 1.6 mmol). After incubation for 15 h at room temperature, the reaction mixture was evaporated and precipitated with 10% citrate aqueous. The precipitate was collected by filtration and washed by water followed by ethyl acetate and then redissolved in ethanol and precipitated once more with water to give 540 mg (82%) of the Boc-protected DPK of second generation. Deprotection of the Boc group was performed by same manner in the case of DPK of first generation (KG1): yield 557 mg (97%).

DPKs of third to sixth generations were prepared with the same method of synthesis as that used for DPK of second generation (KG2): DPK of third generation (KG3), yield 1.00 g (86%); DPK of fourth generation (KG4), yield 1.60 g (79%); DPK of fifth generation (KG5), yield 2.15 g (67%), DPK of sixth generation (KG6), yield 3.02 g (70%).

Acid−Base Titration. The ability of DPK to protonate and obtain a positive charge over a 10 to 3 pH range was determined by acid−base titration (*22*). A 30 mL solution of 1 mM dendrimer as amino group concentration was prepared. The solution was titrated to a pH of 10 with 1 N NaOH where the pH was measured. The solution was then titrated with 0.1 N HCl given in various volume increments.

Acrylamide Gel Electrophoresis. Acrylamide gel electrophoresis under nondenaturing condition was performed by modified method of Davis (*23*). Slab gel was prepared as follows. Separation gel: 12% acrylamide gel containing 0.32% of *N,N′*-methylene bisacrylamide (Bis) and 320 mM glycine-KOH buffer (pH 7.3); stacking gel: 3% acrylamide gel containing 0.08% of Bis and 80 mM glycine-KOH buffer (pH 10.3). Four micrograms of DPKs were run for 2 h at 50 V in 200 mM glycine/imidazole running buffer (pH 8.3). Gel was stained by 2.5% Coomassie Brilliant Blue R-250 in 50% methanol, 40% water, 10% acetic acid for 1 h. Destaining was accomplished by gentle agitation in the same acid−methanol solution but in the absence of dye.

Agarose Gel Electrophoresis. Complex formation of DPKs and a plasmid DNA was examined by the electrophoretic mobility of the complex on an agarose gel stained with ethidium bromide at the various ratios of peptide to a plasmid DNA. The tests were performed by mixing 0.1 μg of the plasmid DNA (PGV−C) with the peptides in 10 μL of HBS (21 mM Hepes-NaOH buffer containing 135 mM NaCl, 5.0 mM KCl, and 0.76 mM Na_2HPO_4 pH 7.4), in which the amino groups (DPK)/phosphate groups (DNA) ratios (N/P ratios) were 0, 0.10, 0.25, 0.50, 1.0, 2.0, 4.0, and 8.0, respectively. Gel electorophoresis sample buffer was added to each sample, and it was electrophoresed on 1% (w/v) agarose gel for 40 min at 100 V. TBE (45 mM Tris-Borate and 1 mM EDTA, pH 8.0) buffer was used as an electrophoresis buffer. The gel was stained with ethidium bromide (0.5 μg/mL) for 30 min and illuminated with an UV illuminator to show the location of the DNA.

Fluorescence Titration Assay. Binding abilities of DPKs with plasmid DNA were monitored by a fluorescent titration assay (*24*). Ten micrograms of plasmid DNA (PGV−C) was mixed with DPK in 980 μL of HBS, in which the N/P ratios were 0, 0.25, 0.50, 0.75, 1.0, 1.25, 1.5, 1.75, 2.0, 2.5, 3.0, and 4.0, respectively. After standing for 20 min at room temperature, 20 μL of 20 μg/mL of ethidium bromide solution was added to the DPK−DNA mixtures. The fluorescence of the intercalated dye was measured on a spectrofluorometer F-3010 (Hitachi, Japan) by exciting at 530 nm while monitoring emmision at 590 nm, with the slits set at 20 nm. Fluorescence intensity blanks were subtracted from all values before data analysis.

Particle Size Analysis. Samples were prepared by mixing 5.0 μg of plasmid DNA (PGV−C) with DPKs in 500 μL of HBS and analyzed using a Nicomp submicron particle sizer model 370 in the solid particle mode. The mean diameter and population distribution were computed from the diffusion coefficient using functions supplied by the instrument.

Zeta Potential Analysis. Samples were prepared by mixing 10 μg of plasmid DNA (pCMVLuc) with KG6 or poly-L-lysine at N/P ratios of 1, 2, 4, and 8 in 1 mL of DMEM. After incubation for 15 min at room temperature, the zeta potential of the DNA complex was measured with a ELS-8000 (Otsuka Electronics Co., Ltd., Osaka, Japan). The measurement was performed in triplicate.

Cell Culture. CHO cells (a chinese hamster ovary, RCB accession no. RCB0285), COS-7 cells (a monkey kidney cell line, RCB accession no. RCB0539), and HeLa

cells (a human cervix, RCB accession no. RCB0271) were purchased from RIKEN Cell Bank (Tsukuba, Japan). HuH-7 cells (a human hepatoma cell line, JCRB accession no. JCRB0403) were purchased from Health Science Research Resources Bank (Osaka, Japan). CHO, COS-7, and HeLa cells were cultivated in DMEM supplemented with 10% FBS and antibiotics (30 μg/mL kanamycine sulfate) at 37 °C in a humidified atmosphere containing 5% CO_2. HuH-7 cells were cultivated in RPMI1640 supplemented with 5% FBS and the antibiotics at 37 °C in a humidified atmosphere containing 5% CO_2. These cells were plated at a density of 1.0×10^4 cells/well 48 h prior to transfection in a 24-well plate.

DPK-Mediated Gene Transfer. Just before transfection procedure, the cells in the 24-well plate were washed by 1 mL of serum free medium. Ten microliters of DPK solution was added to 240 μL of serum free medium containing plasmid DNA (PGV−C). After standing for 15 min at room temperature, the DPK−DNA mixture was poured gently to the cells. After incubation for 3 h at 37 °C, 1 mL of medium containing FBS was added, and incubation was continued for 24 h at 37 °C. The medium was replaced with 1 mL of a fresh medium containing FBS, and the cells were further incubated for 24 h. Harvesting of cells and luciferase assays were performed as described in the protocol of PicaGene luminescence kit (Toyo Ink; Tokyo, Japan). Luciferase relative light units (RLU) were analyzed by luminometer (Maltibiolumat LB9505, Berthold, Germany). The protein concentrations of the cell lysates were measured by Bradford assay using bovine serum albumin as a standard (*25*). The light unit values shown in the figures represent the specific luciferase activity (RLU/mg protein) which is standardized for total protein content of the cell lysate. The measurement of gene transfer efficiency was performed in triplicate.

Cytotoxic Activities of Peptides. Cytotoxic activities of DPKs were evaluated using MTT assay (*26*). Cells were plated at 1×10^4 cells per well in a 96-well plate and incubated for 24 h at 37 °C. Four microliters of DPK (3.2 mM of amines) solution is added to 96 μL of serum free medium containing 1.0 μg of plasmid DNA (PGV−C; N/P ratio = 4). After standing for 15 min at room temperature, the DPK-DNA mixture was poured gently to the cells. After incubation for 3 h at 37 °C, 100 μL of medium containing FBS was added, and incubation was continued for 24 h at 37 °C. The medium was replaced with 200 μL of a fresh medium containing FBS, and the cells were further incubated for 24 h. The medium was removed and replaced by 100 μL of the MTT solution (0.5 mg/mL of medium). After incubation for 4 h at 37 °C, the cells were washed by 200 μL of HBS, and then 200 μL of 0.04 N HCl/2-propanol was added. The absorbances of lysates at 540 nm were measured by 96-well microplate reader. Results are expressed as the percentage of dye reduction in cells treated with the transfection protocol compared with dye reduction in cells treated with medium only. The measurement was performed in duplicate.

RESULTS

Synthesis of Dendritic Poly-L-lysine. Dendritic poly(L-lysine)s (DPKs) were synthesized from hexamethylenediamine as an initiator core. A DPK of the first generation was synthesized by coupling Boc-L-Lys(Boc)-OH·DCHA to hexamethylenediamine by the HBTU−HOBt method (*27*). DPKs of the second to sixth generations were obtained by coupling Boc-L-Lys(Boc)-OH repeatedly after deprotection with TFA (Figure 1). At every coupling step, a Kaiser Test, which detects residual free amino groups (*21*), was performed. As a result, we confirmed that the coupling was completely achieved. DPKs of the first to sixth generations were named KG1 to KG6, respectively. The final preparations of the DPKs could be identified by MALDI TOF-MS (Table 1). Although the ion peaks of KG5 and KG6 were broad (the width at half-height was about 302 and 1200 *m/z*, respectively), the peak values corresponded to the calculated ones. To evaluate the purity of each DPK, acrylamide gel electrophoresis under nondenaturing conditions was performed (Figure 2). As a result, the KG2 and KG3 generations showed a clear single band. In the case of KG4 to KG6, a main band and its smear at the upper position were observed. However, no smear was observed in the lower position of the main band, indicating that that no small molecule originated by incomplete coupling of Boc-L-Lys(Boc)-OH existed in the final preparation. In the case of the commercially available PAMAM dendrimer of the third and fourth generations, a main band and a wide smear were observed (Figure 2, lanes 1, 2). The reason the smear at the upper position was observed would be that the electrophoresis conditions are not suitable for DPKs yet or that oligomerization of the DPKs occurred in the electrophoresis buffer with high pH.

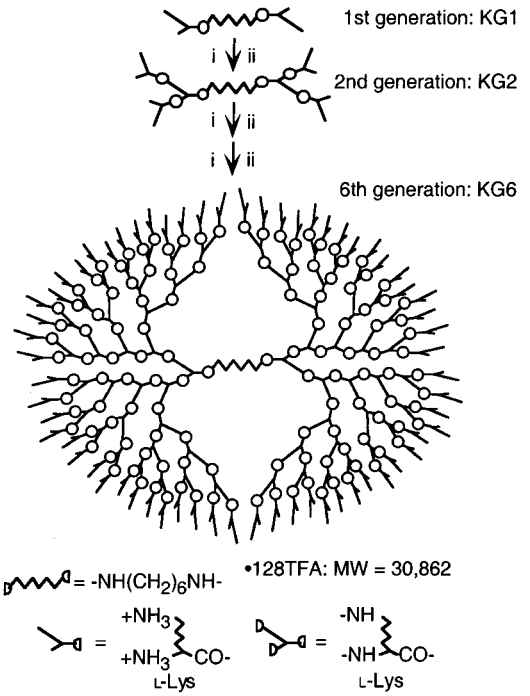

Figure 1. Structure and synthetic route of dendritic poly(L-lysine)s (DPKs). Reagents: (i) Boc-L-Lys(Boc)-OH·DCHA, HBTU, HOBt·H_2O, DIEA; (ii) TFA.

Table 1. Identification of Dendritic Poly(L-lysine)s (DPKs) by MALDI TOF-MS

DPK	formula	calculated	found
KG2	$C_{42}H_{88}N_{14}O_6$	886.3 ($[M + H]^+$)	885.5[a]
KG3	$C_{90}H_{184}N_{30}O_{14}$	1933.6 ($[M + Na]^+$)	1934.8[a]
KG4	$C_{186}H_{376}N_{62}O_{30}$	3984.4 ($[M + Na]^+$)	3985.1[b]
KG5	$C_{378}H_{760}N_{126}O_{62}$	8064.0 ($[M + H]^+$)	8062.4[b]
KG6	$C_{762}H_{1528}N_{254}O_{126}$	16267.1 ($[M + H]^+$)	16137.9[b]

[a] 3-Hydroxypicolinic acid was used as a matrix. [b] α-Cyano-4-hydrocinnamic acid was used as a matrix.

Buffer Effect of DPK. Many cationic polymers possess amines protonated at neutral pH. The acid−base titration profile was obtained for KG6 and is shown in

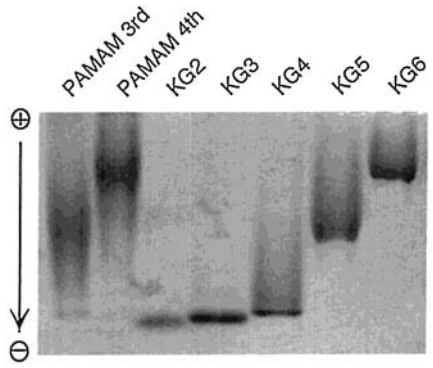

Figure 2. Acrylamide gel electrophoresis of DPKs under nondenaturing conditions. Four microliters of DPKs and commercially available PAMAM dendrimers of the third and fourth generations was applied on the gel as described in Experimental Procedures. After electrophoresis, the gel was stained by 2.5% Coomassie Brilliant Blue R-250.

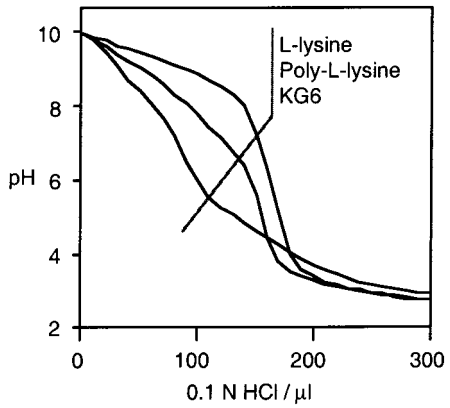

Figure 3. Acid−base titration profiles of L-lysine, poly-L-lysine, and KG6. The solution of pH 10 containing 1 mM amino groups was titrated with 0.1 N HCl given in various volume increments.

Figure 3. The titration curve of KG6 tends to be horizontal at less than pH 6, whereas the curves of L-lysine and poly-L-lysine tend to be horizontal at above pH 8. The initial protonation of the amino group of L-lysine and poly-L-lysine occurred at high pH; however, and that of KG6 showed considerable buffer capacity in a neutral and weakly acidic pH range.

Binding Ability of DPKs to DNA. The formation of the DPK−DNA complexes was examined by their electrophoretic mobility on an agarose at various N/P (amine/phosphate) ratios of DPKs to plasmid DNA (Figure 4). KG3 could completely inhibit the migration of the DNA on the agarose gel at N/P ratios of 2.0, while KG1 and KG2 could not retard the migration of the DNA even if the dendrimers were added to the DNA at an N/P ratio of 8.0. In the cases of KG4, KG5, and KG6, no migration of the plasmid DNA band occurred at an N/P ratio of 1.0, indicating that these molecules had strong binding ability compared with the lower generation ones. The retardation ability of DPK reached a maximum at the fourth generation.

The binding ability was also estimated by the ethidium bromide titration assay (*24*). DPKs bound to DNA lead to exclusion of the ethidium bromide intercalation and a decrease in fluorescence. Increasing the amount of KG3 to KG6 caused a reduction in the fluorescence. The fluorescence intensities versus charge ratio flattened out at N/P ratios above 1.5 and then reached plateaus at 40−25% (Figure 5). The reduction of the fluorescence depended on the generation of DPKs, indicating that DPKs of higher generations have a strong ability to cause

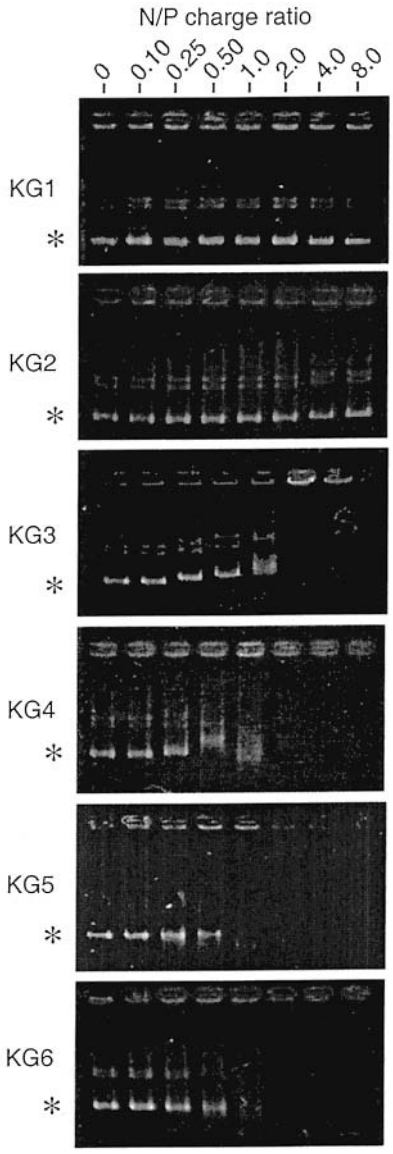

Figure 4. Agarose gel electrophoresis of the complexes of DPKs and plasmid DNA. Plasmid DNA (100 ng) and various amounts of DPKs were mixed, followed by electrophoresis on an agarose gel (1% w/v) stained with ethidium bromide. The N/P ratio (amino groups: phosphate groups) is indicated above each lane. The asterisk on the left of the gel indicates the position of the supercoiled form of the plasmid DNA.

compaction of DNA compared with the DPKs of lower generations. On the other hand, little reduction of the fluorescence was observed by the addition of KG1 and KG2. These data from the ethidium bromide titrations for DPKs correspond to those from the agarose gel shift assay.

Size and Distribution of DPK−DNA Complex. The size distribution of the DPK-plasmid DNA complexes at an N/P ratio of 4.0 was compared using dynamic light scattering data (Table 2). Populations of particles with a mean diameter of 200 to 250 nm were observed for KG3 to KG6. In the range of N/P ratio of 2.0 to 8.0, the size was not altered significantly. In the cases of KG1 and KG2, the sizes could not be estimated due to the limited light scattering of its complex with the DNA. The sizes determined by dynamic light scattering were also confirmed by observation using transmission electron microscopy with negative staining. As a result, whereas KG3 to KG6 formed several sizes of aggregates, aggregates were observed within the ranges of the size

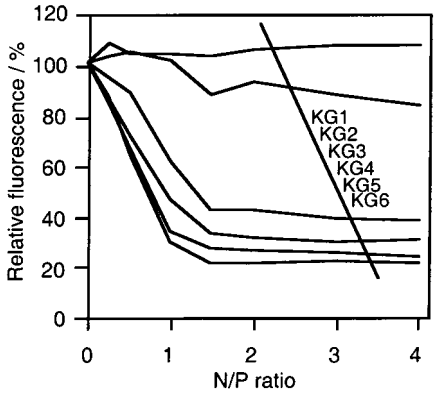

Figure 5. Fluorescence titration assay. Ten microliters of plasmid DNA was mixed with DPKs in 980 μL of HBS at various N/P ratios. After allowing the mixture to stand for 20 min at room temperature, 20 μL of 20 μg/mL of ethidium bromide solution was added to the DPK−DNA mixtures. The fluorescence was measured on a spectrofluorometer by exciting at 530 nm while monitoring emission at 590 nm.

Table 2. Size Distribution of DPK−Plasmid DNA Complexes

DPK−DNA complex[a]	N/P ratio	particle size population	
		diameter (nm)[b]	σ (nm)[c]
KG1	4.0	n.d.[d]	n.d.[d]
KG2	4.0	n.d.[d]	n.d.[d]
KG3	4.0	257	82
KG4	4.0	196	59
KG5	4.0	273	61
KG6	2.0	226	64
KG6	4.0	190	46
KG6	8.0	244	67

[a] DPK−DNA complex was prepared by mixing 0.5 μg of plasmid DNA with DPK in 50 μL of HBS. [b] Represents the mean diameter of particles. [c] Standard deviation of the population. [d] Correct values could not be determined due to little light scattering of the complex.

distributions determined using dynamic light scattering (data not shown).

Gene Transfer Abilities of DPKs in Vitro. The transfection abilities of DPKs into four kinds of cell lines were tested with the plasmid DNA, which contains a reporter gene encoding firefly luciferase (Figure 6). KG5 and KG6 showed significant transfection abilities into all cell lines, and the efficiencies were the same or greater compared with a commercially available transfection reagent, Lipofectin. In the case of KG4, the gene expression was observed in HuH-7 and COS-7 cells, not in CHO and HeLa cells. We considered that the complex of KG4 with the DNA would be different from that of KG5 and KG6 strictly (see Discussion). The difference in the character of the complex, which effects the uptake into cells and transfer to the nucleus, would be the basis for the cell specificity.

Expression of the EGFP gene in CHO cells was also examined by the same protocol as that for the luciferase gene. As a result of transfection using KG6 at an N/P ratio of 4.0, about 20% of the cells expressed the EGFP (date not shown). The efficiency of KG6 was similar to that of SuperFect as a control molecule.

Sufficient Conditions for Gene Transfection Mediated by DPKs. To determine sufficient conditions for gene transfection mediated by DPK, we measured the transfection abilities at various N/P ratios, amounts of complex, and incubation times to CHO cells cultivated in 24-well plate (Figure 7). As a result of a change in the N/P ratio, the gene expression in the case of KG5 and KG6 reached plateaus at an N/P ratio of 4.0 (Figure 7A). At an N/P ratio of 8.0, high expression was observed; however, significant cytotoxity (about 60% of cell viability) simultaneously appeared. The gene expression mediated by KG4 was increased by an increasing N/P ratio; however, the level is still lower than that of KG5 and KG6. KG3 could not show gene transfection ability even if the N/P ratio was increased to 8.0. For the amounts of the DNA complexes with KG5 and KG6, KG6 showed a considerably higher transfection ability at a low amount of complex, corresponding to a range from 0.5 to 1.5 μg of DNA compared with KG5 at an N/P ratio of 4.0 (Figure 7B). Finally, the time-course of the incubation of the complex with the cells was followed (Figure 7C). Incubation for 0.5 and 1 h was insufficient for gene transfection. However, in the case of 3 h incubation, high gene expression was observed, and the level increased gently up to 12 h. To sum up the optimum condition of gene transfection mediated by DPKs into CHO cells cultivated in 24-well plate, sufficient gene expression is observed when the complex composed of 2.5 μg of DNA and KG6 at an N/P ratio of 4.0 is incubated with the cells for 3 h.

Cytotoxic Activities of KG6 and Its DNA Complexes. Cytotoxic activities of KG6 and its complex with the plasmid DNA were also evaluated by MTT assay. Cell viabilities in the presence of KG6 and its DNA complex at an N/P ratio of 4.0 were more than 80% (Figure 8). On the other hand, SuperFect show significant cytotoxity under the conditions optimized for KG6 as described above, indicating that KG6 is advantageous over SuperFect from the point of view of cytotoxity. KG5 also showed weak cytotoxity similar to that of KG6. In contrast, little

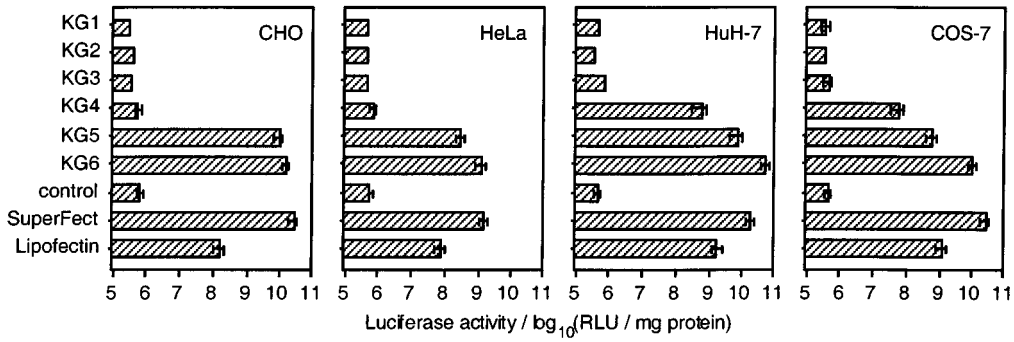

Figure 6. Transfection efficiencies of DPKs into several cell lines. The cells were incubated with DPK−DNA complex containing 2.5 μg of plasmid DNA and DPK at an N/P ratio of 4.0 for 3 h at 37 °C. Harvesting of the cells and luciferase assays were performed 48 h after transfection as described in Experimental Procedures. Data represent the mean value from $n = 3$, and the standard error from the mean.

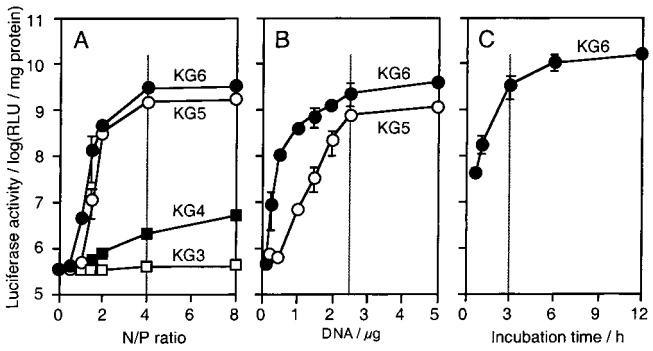

Figure 7. Sufficient conditions of gene transfection mediated by DPK into CHO cells. Transfection efficinecies were measured in various N/P ratios (Panel A), amounts of DNA complex (Panel B), and incubation time (Panel C) to CHO cells cultivated in 24-well plate. The gray lines in the graphs indicate a standard condition, which shows sufficient transfection efficiency. Data represent the mean value from $n = 3$, and the standard error from the mean.

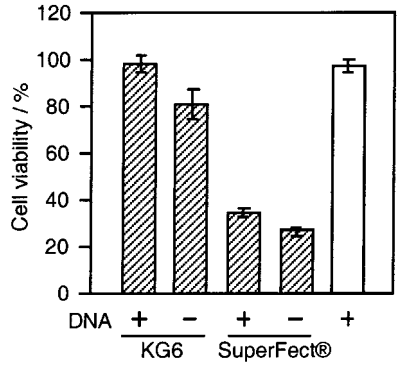

Figure 8. Cytotoxic activities of KG6 and SuperFect alone and their complexes with plasmid DNA at N/P ratio of 4.0. Cell viabilities were evaluated by MTT assay as described in Experimental Procedures. The open bar indicates cell viability in the presence of the plasmid DNA alone. Data represent the mean value from $n = 2$, and the standard error from the mean.

cytotoxities were observed in DPKs of the fourth generation and below (data not shown).

Effect of Serum on the Transfection Efficiency. It is well-known that several components of serum affect the forming of the DNA complex with gene carrier molecules, and the gene expression then generally decreases significantly. We tested the effect of serum added to the transfection medium on the transfection effciency of KG6 (Figure 9). As a result, addition of serum gradually decreased the gene expression; however, the expression in the presence of 50% serum gave 10^9 RLU/mg of cell protein, which was about one-tenth that of KG6 and corresponded to about 50 ng of luciferase protein/mg of cell protein. Concerning the high activity of KG6 still observed in the presence of serum, the surface charge of the complex with DNA is one of the important determinants of interaction with serum components (*28*). To clarify this point, we measured the zeta potential of the DNA complex of KG6 at several N/P ratios (Figure 10). Interestingly, the zeta potential of the complex of KG6 was kept in a neutral or slightly positive level (+3 mV) even when the N/P ratio was increased to 8, while that of poly-L-lysine was positive values (+20 mV) at N/P ratios of 4 and 8. This neutral surface of the complex of KG6 would contribute the inert character in the presence of serum.

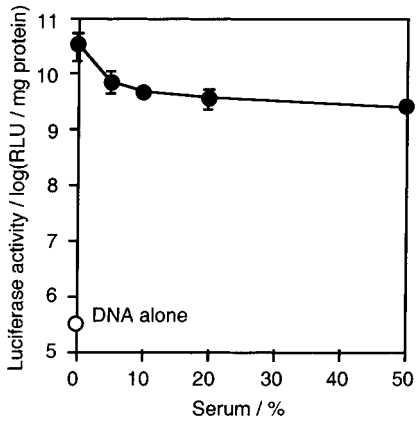

Figure 9. Effect of serum on transfection efficiency of KG6 into CHO cells. Ten microliters of KG6 solution (3.2 mM of amines) was added to serum-free medium containing 2.5 μg of the plasmid DNA (N/P ratio = 4.0), and then an appropriate amount of FBS was added. The mixture, 250 μL, is poured gently onto the cells. Harvesting of the cells and luciferase assays were performed 48 h after transfection as described in Experimental Procedures. Data represent the mean value from $n = 3$, and the standard error from the mean.

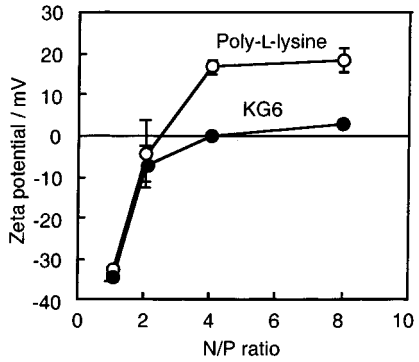

Figure 10. Zeta potentials of DNA complex of KG6 and poly-L-lysine. Closed and open circles indicate zeta potentials of the DNA complex of KG6 and poly-lysine, respectively. Data represent the mean value from $n = 3$, and the standard deviation from the mean.

DISCUSSION

Dendrimer-mediated gene or oligonucleotide delivery into cells was reported from several groups (*11*−*14*, *20*, *29*−*31*). This dendrimer-based nucleic acid-carrier molecule is expected to enable the construction of a unique carrier, which cannot be derived from linear type polymers, because of the spherical and monodispersed structure. It could be designed in response to several purposes, such as alteration of size or shape of the dendrimer, ligand modification, and so on (*17*). In this study, we focused on the dendritic molecules consisting of amino acids, L-lysine residues as a branch unit. Because the peptide-based dendrimer can be synthesized by conventional peptide synthetic chemistry, it is expected that some types of dendrimers could be designed and synthesized conveniently and would provide basic information on the relationship of structure and function as a dendritic gene carrier.

To examine the ability of DPKs to form the complex with the plasmid DNA, we employed the agarose gel shift assay, ethidium bromide titration assay, and dynamic light scattering analysis. DPKs of low generations, KG1 and KG2, showed no binding ability to the DNA. In the cases of KG3 and KG4, a slight retardation of the DNA migration on the agarose gel was observed at an N/P ratios of 0.5, and complete inhibition of the migration

occurred at N/P ratios of 2.0 and 1.0, respectively (Figure 4). For KG5 and KG6, complete inhibition of the migration occurred at N/P ratios of 1.0 without forming the intermediate complex, which was observed as a slight retardation of the DNA migration observed in the cases of KG3 and KG4. This result indicates that the change to compacted globule states from the structure of the elongated coil DNA by addition of KG5 or KG6 was all-or-none (*32*, *33*). As a result of ethidium bromide titration assay, the addition of KG5 or KG6 strongly reduced the fluorescence of the ethidium bromide compared with that of KG3 or KG4 (Figure 5), indicating that the degree of compaction occurring with KG5 or KG6 was stronger than that with KG3 or KG4. From the analysis of the size distribution of the complex, DPKs of the third to sixth generations formed about 200−250 nm of complexes with the plasmid DNA (Table 2). The sizes of the complexes of DPKs were almost the same but were not reflected by strength of the compaction of the DNA.

DPKs, especially KG5 and KG6, showed high transfection abilities into a variety of cell lines (Figure 6). In addition, we could confirm the ability into other cell lines, i.e., Caco-2, HepG2, MKN45, and a human cartilage cell line. For the Caco-2, we already reported the usage as a transfection reagent for the purpose of evaluating promoter activity (*34*). We also tested the transfection abilities of KG7 (DPK of the seventh generation). However, the transfection ability of KG7 was about one-tenth that of KG6 (data not shown). A PAMAM dendrimer showed maximal efficiency at the sixth generation, with 192 terminal amino groups (*11*). KG6 has 128 terminal amino groups; therefore, the optimum generation of DPK for transfection corresponded to that of the PAMAM dendrimer.

How was the DNA complex of DPK internalized into the cells? We have preliminary data as follows: (1) the transfection ability of KG6 was inhibited by the addition of *N*-ethylmaleimide, which inhibits the fusion between endosomes at an early stage of the endocytotic pathway (*35*); (2) that was inhibited by the addition of cytochalasin B, which depolymerizes the microfilaments of actin and blocks the uncoated pit-mediated endocytosis (macropinocytotic process) (*36*); (3) that was not significantly inhibited by the addition of chlorpromazine, an inhibitor of clathrin-dependent, receptor-mediated endocytosis (*37*). These results suggest that the uptake of the DNA complex of DPK is mediated by the endocytosis pathway, especially the macropinocytotic process. Furthermore, KG6 shows a buffering effect in a weak acidic environment (Fingure 3). It is likely that the escape of the DNA complex from the endocytotic vesicle to the cytosol was enhanced by the sponge effect of KG6 itself (*4*). This explanation is not contradictory to the fact that no effect of the addition of chloroquine to the transfection medium was observed (data not shown).

As a result of cytotoxicity measurement, 80% and higher cell viability was observed with the addition of KG6 alone and its DNA complex (Figure 8). It could be said that this cytotoxity of KG6 was sufficiently low; furthermore, its DNA complex showed less cytotoxity. In contrast, a commercially available PAMAM dendrimer-based transfection reagent, SuperFect, showed cytotoxity under our ideal conditions for DPK. Actually, a large number of cells which peeled off and then floated in the medium was observed compared with the case of KG6. Of course, under the optimized condition for SuperFect described in the instruction book, 80% and greater cell viabilities were observed. It is clear that KG6 has the advantage of low cytotoxity compared with the PAMAM dendrimer-based transfection reagent.

In this study, we introduced the usage of DPK for gene transfection in vitro. We can strictly synthesize various DPK derivatives, which have several types of branch units (e.g., lysine, ornithine, aminobutyric acid, and their D-, L-isomer), terminal cationic groups (e.g., amino, imidazole, and guanidino groups), and core structure (e.g., diamines which have several lengths of methylene chains and some triamines). The derivatives will enable us to closely discuss how the complex is advantageous for transfection into cells, what structural features and characteristics of the gene carrier are necessary for efficient transfection, and if the transfection efficiency was low, which stage was the rate-limiting step? This basic information is important for development of the transfection reagent of the next generation. Furthermore, DPK has a serum-tolerant transfection ability. This character would be due to the neutral surface of the DNA complex. From the point of view of the usage in vivo, this character is also advantageous, that is, nonspecific interaction with serum components is reduced and the half-life of circulation of the complex in blood vessel will be extended. This expectation also indicates that when DPK is carefully modified by a ligand molecule such as a sugar chain, the molecules will function as an advanced carrier that realizes highly controlled gene delivery in vivo. Usage of DPK as a gene carrier will give us basic information for the structure−function relationship of gene carriers and let us develop highly efficient and functional gene delivery systems.

Methotrexate Conjugate with Branched Polypeptide Influences *Leishmania donovani* Infection in Vitro and in Experimental Animals†

György Kóczán,‡ Asoke C. Ghose,§ Ananda Mookerjee,§ and Ferenc Hudecz*,‡

Research Group of Peptide Chemistry, Hungarian Academy of Sciences, Eötvös L. University, Budapest 112, POB 32, Hungary, H-1518 and Department of Microbiology, Bose Institute, P-1/12 C. I. T. Scheme 7M, Calcutta, 700054, India. Received July 18, 2001

Methotrexate (MTX) has been coupled to various structurally related, polycationic (poly[Lys(DL-Ala$_m$)] (AK), poly[Lys(Ser$_i$-DL-Ala$_m$)] (SAK), poly[Lys(DL-Ala$_m$-Leu$_i$)] (ALK)), or amphoteric (poly[Lys(Glu$_i$-DL-Ala$_m$)] (EAK)) synthetic branched polypeptides containing poly[L-Lys] backbone by the aid of BOP reagent. The average degree of MTX incorporation was found to be dependent on the charge properties of the polymer. Under the experimental conditions used, the molar substitution ratio achieved was higher for polycations (25%) than for the amphoteric polypeptide (10%). We have studied the effect of polycationic polypeptides on *Leishmania donovani* infection. Results demonstrated that MTX conjugates in which the drug is covalently attached to carrier have pronounced leishmanicid activity. In this communication we showed that (a) a branched polypeptide−methotrexate conjugate with a polycationic carrier (ALK) increases the effect of MTX against *Leishmania donovani* infection in mice; (b) the covalent bond between the carrier and methotrexate is essential for both in vivo and in vitro activity; and (c) the number of *Leishmania donovani* parasites in infected macrophages are markedly reduced in conjugate treated animals. In vitro observation might also indicate that the MTX conjugate exhibits an effect through an uptake by macrophages which is different from that of the free drug.

INTRODUCTON

Methotrexate (MTX,[1] L-4-amino-N^{10}-methylpteroyl-glutamic acid), a folate antimetabolite, has been in clinical use for more than 35 years. It is a potent anticancer agent of proven benefit in the treatment of acute leukemia, osteogenic sarcoma (*1*), and of rheumatological disorders (*2*−*4*). Recently its inhibitory potential has been demonstrated against a group of intracellular parasites (*Leishmania*) of macrophages (*5*). Visceral leishmaniasis or kala-azar in man is caused by the protozoan parasite *Leishmania donovani*, which proliferates intracellularly within the mononuclear phagocytes of the infected host (*6*).

Methotrexate has been linked to various macromolecules such as BSA, mannosylated-, galactosylated-, or glucosylated-BSA (*7*, *8*), mannosylated-HSA (*9*), or maleylated-BSA (*10*), for delivery into cells containing *L. donovani* parasites or to polylysine for studying the mechanism of action of cellular uptake by pinocytosis in mice and human tumor cell lines (*11*−*14*).

The methods of conjugation of methotrexate to these carriers have involved predominantly the glutamic acid moiety. Activation of α- and γ-carboxyl groups has been achieved in situ in the presence of the carrier using water soluble carbodiimide like EDC (*15*) or by ester formation with *N*-hydroxysuccinimide (*11*). (None of the above methods reported have been used for selective derivatization of α- or γ-carboxyl groups of MTX (*15*).)

MTX was also one of the first antitumor drug attached covalently to high molecular weight carriers to improve the therapeutic index by site-specific targeting and/or by changing the pharmacological properties of MTX to provide controlled release. It has been demonstrated that the biodistribution of branched polypeptide attached drugs (e.g., MTX, daunomycin, amylorid) can be strongly modified by the charge and side chain structure of the carrier resulting in elevated and more prolonged blood levels, slower drug excretion, and a longer half-life (*16*, *17*).

For the investigation of the conjugate's leishmanicid activity we have prepared a new set of methotrexate-branched polypeptide conjugates (*18*) (Figure 1). In these compounds MTX molecules are attached to polycationic poly[Lys(DL-Ala$_m$)] (AK), poly[Lys(Ser$_i$-DL-Ala$_m$)] (SAK), poly[Lys(DL-Ala$_m$-Leu$_i$)] (ALK) or amphoteric poly[Lys-(Glu$_i$-DL-Ala$_m$)] (EAK) polypeptide carrier by amide bonds. Branched polypeptides with the general formula poly-[Lys(X$_i$-DL-Ala$_m$)] (XAK) or poly[Lys(DL-Ala$_m$-X$_i$)] (AXK), where $i < 1$ and $m \sim 3$, have been used as biodegradable (*19*) macromolecular carriers for targeting antitumor

agents (*16*−*25*), radioligands (*26*, *27*), immunomodulatory peptides (*28*), or constructing synthetic antigens with T or B cell epitopes (*29*−*31*).

In this paper we describe the improved synthesis of MTX conjugates with selected polycationic and amphoteric polypeptides and the results of comparative studies against *Leishmania donovani* infection using these compounds. These conjugates have been tested and compared with that of the free drug and of free carrier in the control of *L. donovani* infection in BALB/c mice. We have also investigated the mechanism of leishmanicid activity in mouse macrophages in vitro following their treatment with MTX, MTX + branched polypeptide mixture, and MTX-branched polypeptide conjugates.

EXPERIMENTAL PROCEDURES

Abbreviations used in this paper follow the rules of the IUPAC/IUB Commission of Biochemical Nomenclature (*32*) in accord with the recommended nomenclature of graft polymers (*33*).

Materials. Methotrexate was obtained from Lederle Laboratories (Gosport, U.K.); *N*,*N*-diisopropylethylamine (DIEA), 1-hydroxybenzotriazole (HOBt), and trifluoroacetic acid (TFA) were Fluka products (Buchs, Switzerland), while benzotriazol-1-yloxytris(dimethylamino)-phosphonium hexafluorophosphate (BOP) was purchased from Bachem (Bubendorf, Switzerland). Hydroxylamin, glacial acetic acid, diethyl ether, and dimethylformamide (DMF) were purchased from REANAL (Budapest, Hungary). DMF was stored over molecular sieve. Branched polypeptides used in these studies were prepared in our laboratories as described earlier (*19*−*21*). The characteristics of these compounds are summarized in Table 1. Polylysine with $\overline{DP}_n = 60 \pm 2$ or $\overline{DP}_n = 90 \pm 2$ (EAK) and $\overline{M}_w/\overline{M}_n = 1.65 \pm 0.15$ was used.

Table 1. Characteristics of Branched Polypeptides

		amino acid composition[b]			
polypeptide	code[a]	Lys	Ala (m)	Ser/Leu/Glu (i)	$\overline{M}_w$[c] (±5%)
poly[Lys(DL-Ala$_m$)]	AK	1.00	2.06	−	16 700
poly[Lys(Ser$_i$-DL-Ala$_m$)]	SAK	1.00	4.08	0.92	28 800
poly[Lys(Glu$_i$-DL-Ala$_m$)]	EAK	1.00	5.00	0.90	41 500*
poly[Lys(DL-Ala$_m$ -Leu$_i$)]	ALK	1.00	3.00	0.97	34 800

[a] Code of branched polypeptides is based on one letter symbol of amino acids. [b] Determined by amino acid analysis after hydrolysis in 6 M HCl at 105 °C for 24 h. [c] Calculated from the number average degree of polymerization of polylysine ($\overline{DP}_n$ =60 ± 2 or $\overline{DP}_n$ = 90 ± 2*) and from the amino acid composition of branched polypeptides.

Animals. Inbred mice (BALB/c strain) were obtained from the National Institute of Nutrition, Hyderabad, India. Female mice, 6−8 weeks old and of 20−25 g body weight were used in these experiments.

Parasites. The *Leishmania donovani* strain (BI2302) was isolated from the bone marrow material of a kala-azar patient. The strain was maintained in vivo through serial passages in hamsters (*35*).

METHODS

Coupling of Methotrexate to Branched Polypeptides. Coupling was performed with BOP in the presence of 1-hydroxybenzotriazole (HOBt) and DIEA in water−DMF (1:9, v/v) mixture. Briefly: Branched polypeptide ALK (10 mg, 0.24 μmol) was dissolved in 0.5 mL of deionized water, and the clean and viscous solution was diluted with 4.5 mL of DMF (c = 2 mg/mL). Dried methotrexate (5.62 mg, 11.0 μmol) (0.5 mol calculated for amino group of side chains of the polymer), 4.88 mg (11.0 μmol) of BOP reagent, 1.7 mg (11.0 μmol) of HOBt, and 2.75 μL (22 μmol) of *N*,*N*-diisopropylethylamine (DIEA) were dissolved in 2 mL of DMF and the reaction proceeded for 10 min at 4 °C. The solution with preactivated MTX was added to the solution of branched polypeptide. The mixture was stirred at room temperature and allowed to react for 12 h at RT in the dark. The final concentration of polypeptide was 1.53 mg/mL. The input molar ratios of MTX to polypeptide were 0.1:1, 0.3:1, and 0.5:1. Since the relative amounts of α- and γ-coupled material are unknown, the error introduced by assuming no effect of coupling, although probably small, is not known accurately. After conjugation, the solvent was removed in vacuo, and the resulting oil was triturated with 5 mL of diethyl ether three times. The product was dissolved in 1 mL of glacial acetic acid and diluted with 3 mL of water. The solution was placed in Visking tubing (molecular mass cutoff 12000−14000 Da, Fisons, Loughborough, UK) and dialyzed extensively against 1.0% acetic acid for 48 h. The average degree of molar substitution ($\overline{DS}$) was estimated by amino acid analysis and spectrophotometrically at λ = 373 nm assuming that the extinction coefficient of methotrexate at λ = 373 nm is 7800 M^{-1} cm^{-1}. Analytical data on the conjugates are presented in Table 2.

Analysis of Ester Bound Methotrexate to Poly[Lys(Ser$_i$-DL-Ala$_m$)]. Ser-containing conjugate poly[Lys(MTX$_j$-Ser$_i$-DL-Ala$_m$)] (MTX-SAK) was treated with 1.1 M hydroxylamine (0.1 M final concentration) in 0.1 M carbonate buffer (pH 9.0) at 37 °C overnight, similarly

Table 2. Chemical Characterization of MTX-Branched Polypeptide Conjugates

conjugate	code[a]	$\overline{DS_j}$[b] (%)	$\overline{M_w}$[c] (±5%)
poly[Lys(MTX$_j$-DL-Ala$_m$)]	MTX-AK	26.3	24 800
poly[Lys(MTX$_j$-Ser$_i$-DL-Ala$_m$)]	MTX-SAK	25.1	36 200
poly[Lys(MTX$_j$-Glu$_i$-DL-Ala$_m$)]	MTX-EAK	10.2	53 200*
poly[Lys(MTX$_j$ -DL-Ala$_m$-Leu$_i$)]	MTX-ALK	25.0	37 800

[a] Code of conjugates is composed of the abbreviation of branched polypeptide and of methotrexate attached. [b] Average degree of substitution determined from the amino acid analysis after hydrolysis in 6 M HCl at 105 °C for 24 h. [c] Calculated from the number average degree of polymerization of polylysine ($\overline{DP_n} = 60 \pm 2$ or $\overline{DP_n} = 90 \pm 2$*) and from the amino acid composition of conjugates.

to the method of Endo et al. (*34*) with some modifications (*39*). The samples were run on RP-HPLC as described below.

RP-HPLC Analysis of MTX-Branched Polypeptide Conjugates. The HPLC system consisted of one Model 600 ternary gradient pump and controller, a Model 490E programmable multi-wavelength UV−visible detector, a Model 717 autosampler, and an in-line degasser (all from Waters, Milford, MA). All injections were made by the autosampler. Data were recorded and processed with Millenium manager software. A 15 cm × 4.6 mm column with a spherical 5 μm silica (300 Å pore size) with a C18 hydrophobic bonded phase were used (Ultrasphere, Beckman, CA). The mobile phase consisted of 0.1% (v/v) TFA in HPLC grade water (eluent A), and 0.1% (v/v) TFA in 80% (v/v) acetonitrile−water mixture (eluent B). Gradient elution was used at 1 mL/min flow rate; the B content of the eluent was increased from 5% to 60% between 5 and 35 min. All samples were dissolved in distilled water and were filtered before analysis using 0.45 μm Spartan 13 (Schleicher and Schuell, Dassel, Germany) filters. UV absorbance was monitored at $\lambda =$ 373 nm for MTX containing samples and at $\lambda = 214$ nm for free polypeptide samples. The injected volume was selected so that the absorbance value at the peak maximum was below 1.0 absorbance unit. Quantitative analysis of conjugates was performed using peak-area measurement calibrated with appropriate standards. All analyses were carried out at ambient temperature.

Amino Acid Analysis. The amino acid composition of branched polypeptides and their MTX conjugates was determined by amino acid analysis using a Beckman (Fullerton, CA) model 6300 amino acid analyzer. Prior to the analysis, samples were hydrolyzed in 6 M HCl in sealed and evacuated tubes at 110 °C for 24 h.

In Vivo Treatment of *L. donovani* Infected BALB/c Mice with MTX Alone or in Combination with MTX Conjugates. Groups of four to five mice were infected with *L. donovani* amastigotes (about 2×10^7 parasites/0.1 mL/animal) via the intracardial (ic) route. Different groups of animals received different types of treatment as per the following protocol. For initial experiments groups of animals were treated with MTX (50, 100, or 200 μg/injection/animal) by the intraperitoneal (ip) route on every alternate day starting from day 10 following the infection. Five such injections were given and animals were sacrificed on day 28 following the infection, i.e., 10 days after the last injection. The degree of parasitaemia in the sacrificed animals was determined by microscopic counting of the number of amastigotes in their liver impression smears stained with Giemsa. At least 500 nucleated cells were screened for the purpose and results are expressed as the number of amastigotes/100 cells (*36*).

Other groups of infected animals were similarly treated with five doses of MTX covalently coupled to different branched polypeptides (poly[Lys(MTX$_j$-DL-Ala$_m$)] (MTX-AK), MTX-SAK and poly[Lys(MTX$_j$-DL-Ala$_m$-Leu$_i$)] (MTX-ALK)) so that the administered compounds contained equivalent amounts of MTX (100 μg/injection/animal). Whenever required, groups of infected mice were also treated with unconjugated branched polypeptides or with a mixture of MTX and branched polypeptides using a similar protocol. The control group of infected mice received only normal saline (0.9% NaCl) injections. All mice (treated or control) were sacrificed on day 28, and parasitemia in their liver was determined microscopically as described above.

In Vitro Treatment of *L. donovani* Infected Mouse Macrophages with MTX Alone or in Combination with Branched Polypeptides. Antileishmanial activities of MTX or branched polypeptide ALK or their combinations were determined in vitro by using mouse macrophages infected with leishmania parasites (*37*). For this, peritoneal exudate cells were collected from mice pretreated with 2% (w/v) thioglycolate solution. Washed cells were resuspended in RPMI-1640 medium containing 10% heat inactivated fetal calf serum (RPMI−FCS) and overlaid on glass cover slips taken in 35 mm diameter plastic Petri dishes. Dishes were kept at 37 °C in air containing 5% CO_2 for 4 h to allow attachment of cells. Following washing, cells remaining attached to the cover slips were further incubated overnight with RPMI−FCS. Next, *L. donovani* promastigotes freshly harvested from a log phase culture of the parasite grown in a liquid culture medium (*38*) were added to the Petri dishes in a cell-to-parasite ratio of about 1:10. After incubation for 6 h at 37 °C, free parasites were removed by washing and the Petri dishes were incubated with RPMI−FCS containing appropriate doses of MTX (25 μg/mL of incubation medium) or ALK (108 μg/mL) or their mixture or poly[Lys(MTX$_j$-DL-Ala$_m$-Leu$_i$)] (MTX-ALK) conjugate. The control dish (with parasitized macrophages in cover slips) contained neither drug nor conjugates. Following incubation of the dishes for a period of 72 h, cover slips containing parasitized macrophages were taken out, fixed, stained with Giemsa, and examined microscopically to determine the number of intracellular parasites per macrophage. At least, 100 macrophages were screened in each cover slip for the purpose.

RESULTS

Synthesis and Chemical Characterization of MTX-Branched Polypeptide Conjugates. The coupling of MTX to branched polypeptide was achieved by the BOP reagent-based activation method in which one carboxyl group of the molecule was linked to the α amino group of the side chains of branched polypeptide AK, SAK, ALK, or EAK to provide covalent α-amide type bonding (Figure 1). The carboxyl groups of MTX were activated by equimolar BOP and HOBt in situ using a tertiary amine (DIEA). It should be noted that no precipitate was observed during the synthesis of the conjugate under these conditions. The MTX-XAK/AXK preparations were triturated followed by dialysis, and free MTX content was assessed by reversed-phase HPLC. The amino acid composition of purified conjugates was determined by amino acid analysis. Considering the amino acid composition of the free carrier and of the Glu content of MTX the average degree of molar substitution ($\overline{DS}$) was calculated. Characteristic values of the conjugates (MTX content, $\overline{M_w}$) are summarized in Table 2. The results presented in this table indicate that the amount of MTX

incorporation into the polypeptide conjugate depends mainly on the charge properties of the terminal amino acid residue of the side chain. The average molar substitution ratio was in the range of 10.2−26.3% expressed as % of modified side chains in the conjugates. Interestingly enough no marked differences have been observed among the respective $\overline{DS}$ values of polycationic polypeptides ($\overline{DS}$ for MTX-AK 26.0%, for MTX-SAK 25.1%, and for MTX-ALK 25.0%), while in case of MTX conjugate with amphoteric EAK only 10.2% of the side chains were substituted at 0.5:1 input MTX:EAK molar ratio. These values indicate that 10−26% of the free amino groups of branched polypeptide was modified by MTX. Consequently, all MTX conjugates studied still preserved the polycationic or amphoteric character of the branched polypeptide used.

Under these conditions the active ester derivative of MTX could react with the hydroxyl group of the Ser residue producing an ester linkage between MTX and branched polypeptide SAK. The ester bond can be cleaved by hydroxylamine (*34*, *39*). To verify the absence of ester-linked MTX two sets of MTX-SAK conjugate samples were investigated. Conjugates before and after hydroxylamine treatment were analyzed by RP-HPLC using two wavelengths to access free drug in the MTX conjugate preparations. The retention time for MTX, absorbing at $\lambda = 373$ nm, was found to be 10.1 min. Free SAK was detected at $\lambda = 214$ nm at the void volume, whereas the t_R value for MTX-SAK was 14.5 min at both $\lambda = 214$ and 373 nm, indicating the presence of covalently bound MTX. Quantitative analysis, performed on a reversed-phase HPLC column (pore size of 300 Å, gradient elution), indicated that less than 0.01% of free MTX besides the total MTX content in the conjugate samples can be detected using peak-area measurement calibrated with appropriate standards. It should be noted that no free MTX was detected in the MTX-SAK samples before hydroxylamine treatment. These data are in accord with our earlier observation that conditions for the preparation of conjugates highly influence the extent of ester bound formation between OH group and active ester derivative of MTX. The lack of free MTX in MTX-SAK samples suggests that the formation of the amide linkage between MTX and branched polypeptide is favored in a DMF−water 9:1 (v/v) solvent mixture.

After analyzing the purity of freshly synthesized compounds, their stability was investigated. Typical chromatograms of free MTX and of MTX-SAK conjugate containing free MTX as a control are shown in Figure 2. The stability data of conjugate samples obtained after 4−180 days storage at 4 °C. No free MTX was detected (data not shown).

Treatment of *L. donovani* Infected Mice with MTX Alone or in Combination with Branched Polypeptides. In preliminary experiments, different groups of *L. donovani* infected mice were treated with different doses (50−200 μg/injection/animal) of MTX, and their liver parasite load was estimated. About 20%, 36%, and 47% reduction of their liver parasite load was demonstrable following treatment with 50 μg, 100 μg, and 200 μg/injection/animal, respectively (five injections administered as per the protocol described in the Materials and Methods section). A dose of 100 μg of MTX was subsequently chosen for all subsequent experiments for the determination of any additional benefit, which may be derived from the combination therapy of MTX and MTX conjugates.

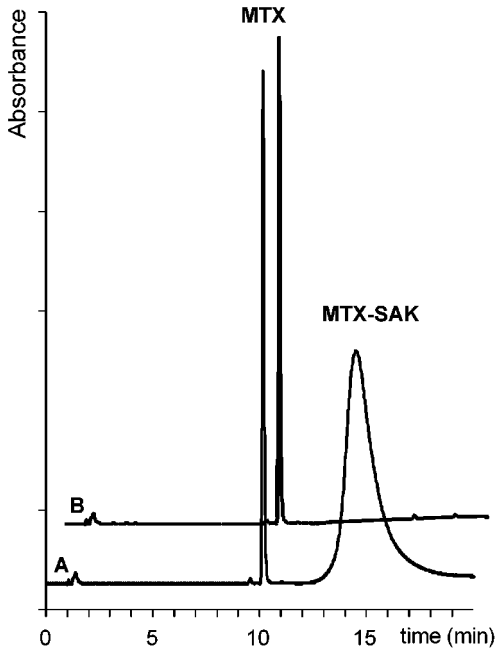

Figure 2. RP-HPLC chromatograms of a mixture of poly[Lys-(MTX$_j$-Ser$_i$-DL-Ala$_m$)] (MTX−SAK) conjugate and MTX (A) and of free MTX (B).

Initially, different groups of *L. donovani* infected mice were treated with MTX branched polypeptide conjugates (MTX-AK, MTX-SAK, and MTX-ALK). It should be noted that due to the high tendency of gel formation under experimental conditions MTX-EAK conjugate was not investigated. All three preparations showed significant levels of antileishmanial activity (data not shown). However, the conjugate MTX-ALK produced most encouraging data (>90% reduction in the number of parasite). Therefore, detailed studies were undertaken with this conjugate and with the corresponding branched polypeptide, ALK.

Table 3 shows the effect of treatment of leishmania infected mice with free MTX as well as in its conjugated form with ALK. About 42% reduction in the liver parasite burden was noted in the MTX treated group of animals as compared to those of untreated control group, and the difference was statistically significant ($0.01 < P < 0.05$). Treatment of animals with MTX-ALK conjugate, however, led to more marked reduction (~95%) of their liver parasite burden as compared to those in the control group and the difference was statistically highly significant ($P < 0.001$). The MTX-ALK conjugate treated group had also significantly ($0.001 < P < 0.01$) less number of liver parasites than that of the MTX alone treated group. Further experiments were carried out to determine the antileishmanial effect of ALK treatment alone or in the form of a mixture with MTX. Results presented in Table 3 demonstrate that treatment of *L. donovani* infected mice with free ALK did not induce any significant ($P > 0.1$) level of reduction of their liver parasite burden. On the other hand, treatment of animals with the MTX+ALK mixture produced about 35% reduction in the parasitemia as compared to that of the control group and the decrease was statistically significant ($0.001 < P < 0.01$). However, the MTX+ALK mixture treated group failed to show any significant difference ($P > 0.1$) in their liver parasitemia as compared to that of the MTX alone treatment group.

Treatment of *L. donovani* Infected Mouse Macrophages in Vitro with MTX Alone or in Combination with the Branched Polypeptide ALK. The effect

[a] n = number of animals. [b] Animals were treated with MTX (100 μg/injection/animal), with ALK (432 μg/injection/animal) or ALK+MTX (a mixture of 100 μg of MTX and 432 μg of ALK/injection/animal) or ALK−MTX (100 μg of MTX conjugated to 432 μg of ALK/injection/animal). [c] *Compared to group I. **Compared to group II.

of in vitro treatment of parasite infected mouse macrophages with MTX alone or in combination with ALK was studied, and results are presented in Table 4 and Figure 3. It may be seen that treatment of macrophages with MTX (alone) (Figure 3B) or in the form of a mixture with ALK (Figure 3C) induced only marginally significant (0.05 < P <0.1) reduction in the intracellular parasite level while ALK (alone) failed to show any reduction of this kind (P > 0.1). On the other hand, considerable (about 54%) decrease of the parasite load was noted following MTX-ALK conjugate treatment (Figure 3D vs Figure 3A), and the reduction was significant (0.001 < P < 0.01) as compared to that of the control. The MTX-ALK conjugate was also found to be more efficient than MTX + ALK mixture or MTX alone (0.01 < P <0.05) in reducing the number of amastigotes within the macrophages.

DISCUSSION

Synthetic effort with soluble carriers to discover alternate means to introduce MTX into cells could lead

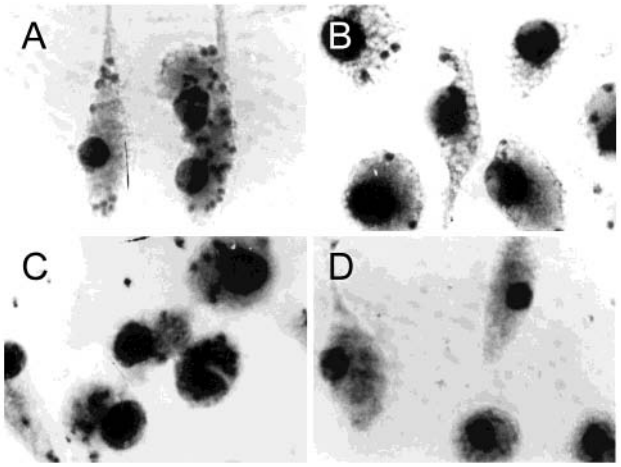

Figure 3. Effect of treatment of *L. donovani*-infected mouse macrophages in vitro with MTX (B), MTX + poly[Lys-(DL-Ala$_m$-Leu$_i$)] (ALK) mixture (C) and poly[Lys-(MTX$_j$-DL-Ala$_m$-Leu$_i$)] (MTX−ALK) conjugate (D). increased and selective uptake of the drug and thus more beneficial therapeutic effect. For the construction of macromolecule−drug conjugates it is important to provide rational basis to the selection of the proper carrier. To this end we have previously reported data on the synthesis, biodistribution and in vitro cytotoxicity of the antimetabolite drug methotrexate-branched polypeptide conjugates using osteogenic sarcoma cell line (*16*). In this contribution we extended our studies by investigation of antileishmanial effect of MTX conjugates in experimental animals. For this a new set of branched polypeptide-based conjugates was prepared by an improved synthetic procedure. After covalent coupling of MTX to the α-amino groups of AK, SAK, or ALK conjugates with a similar average degree of molar substitution the overall charge of the compounds remains positive.

It is believed that positive charge density is required for uptake of MTX−linear poly(α-amino acid) (e.g., polylysine, polyornitine) by various mouse or human tumor cells (*11, 13*). A mode of action of the conjugates involves binding to the cell-surface, subsequent endocytic internalization, localization in the lysosomal system, and degradation by lysosomal enzymes to liberate the drug (*12, 13, 40*). This hypothesis was supported by experimental results using polylysine-coupled MTX and L929 mouse fibroblast (*12*) and mouse mammary tumor MM46 cells (*40*) in vitro. MTX attached to poly(D-lysine) directly or through a Leu-Ala-Leu-Ala tetrapeptide spacer between the drug and the ϵ-amino groups of poly(D-lysine) was also investigated. No effect was observed with MTX-poly(D-lysine), while the conjugate containing MTX at the

N-terminal α-amino group of the Leu-Ala-Leu-Ala unit exhibited potent cytotoxicity, indicating that the spacer is cleaved in the secondary lysosomes (*40*). In addition, the cytotoxicity of a terner conjugate in which MTX-Leu-Ala-Leu-Ala was coupled to monoclonal antibody specific for MM46 cells was not inhibited by TPP, an inhibitor of the membrane active transport system for MTX (*40*). Taken together these data suggest that the transport pathways of MTX and of MTX−carrier conjugates are different and independent (*12*). Trouet et al. (*41*) has demonstrated that a daunorubicin conjugate with Ala-Leu-Ala-Leu spacer and succinylated BSA carrier was stable in serum but was cleaved by lysosomal hydrolases. These findings could be adopted for the speculation on the mechanism of action of MTX-ALK conjugate with marked antileishmania activity observed in vivo and in vito.

It has been described that MTX attached to mannose−BSA strongly inhibits the growth of *Leishmania donovani* inside macrophages. This conjugate was 100 times more active than the free MTX. In contrast MTX conjugated to BSA or other nonspecific neoglycoproteins such as galactose−BSA and glucose−BSA have leishmanicidal effects comparable to that of the free MTX (*7*). Further results indicated that mannose−BSA based MTX conjugate binds specifically to mannose-specific receptor of macrophages and is internalized and degraded in lysosomes, releasing the active drug to act on *Leishmania* parasites (*8, 9, 42*). These data suggest that the uptake mechanism of mannose-containing conjugates is related to the presence of mannose receptor of infected macrophages. On the other hand, our findings clearly indicate that MTX conjugates without a mannose moiety could also be introduced into macrophages.

Recently it has been documented that *Leishmania* and other trypanosomatid protozoa require reduced pteridines (pterins and folates) for growth, suggesting that inhibition of these pathways could be targeted for effective chemotherapy (*43*). Findings suggest that successful antifolate chemotherapy in *Leishmania* will have to target simultaneously both dihydrofolate reductase (DHFR) and pteridine reductase 1 (PTR1). It is attractive to speculate on the mechanism of action of branched polypeptide attached MTX. On the basis of published data outlined above and our own observations reported in this communication, it is likely that MTX released from MTX-branched polypeptide conjugate might act as an inhibitor of enzymes involved in the unusual pteridine metabolism in this lower eukaryote.

CONCLUSION

These studies have indicated that synthetic branched polypeptides can be considered as potential candidates for constructing suitable conjugates for methotrexate delivery into *Leishmania donovani* infected macrophages. In this communication we showed that (a) a branched polypeptide−methotrexate conjugate with a polycationic carrier (ALK) increase the leishmanicid activity of MTX in mice; (b) the covalent bond between the carrier and methotrexate is essential for the effect; and (c) the number of *L. donovani* parasites in infected macrophages are markedly reduced in conjugate treated animals. The latter observation might indicate that the MTX conjugate exhibits its effect throught an uptake by macrophages which is different from that of the free drug. Further comparative studies are in progress to clarify the mechanism of action.

Received August 1, 2001; Revised Manuscript Received January 15, 2002

A simple procedure for the preparation of oligonucleotide−peptide conjugate was developed. *p*-Hydroxybenzoic acid was used as a linker for the connection of the fragments of peptide and oligonucleotide. It was found that such formed linkage was stable under the conditions of conjugate synthesis. The designed conjugate targeting to GLUT-1 showed up to 50% inhibition of cell proliferation in HepG-2 and MCF-7 cells. Comparing to the results from the expressed antisense RNA in cancer cells, it was proposed that the conjugate of signal peptide mimic and antisense oligonucleotide could improve the permeability of antisense oligonucleotide through cell membrane.

INTRODUCTION

The selective inhibition of expression of specific genes by oligodeoxynucleotides (ODNs) via an antisense or antigene strategy provides an attractive and elegant approach to drug discovery (*1*). Several requirements must be fulfilled by a potential antisense oligonucleotide including rapid penetration into cells, and stability against the degradation by nuclease (*2*−*4*).

Antisense oligonucleotides with phosphorothioate backbones exhibit several advantages over other forms, including relatively high nuclease resistance as well as the ability to induce degradation of the target sequence by RNase H (*1*, *3*). On the other hand, chemical modifications with kinds of tethered groups that increase the lipophilic properties of the ODNs have also accumulated. The conjugates of ODNs with liphophilic groups such as cholesterol (*5*), lipid, psoralen, acridine, or alkyl chain (*6*−*11*) which associated with increased activity and in some cases with actual increased intracellular concentration have been described. Recently, studies focused on the increase of both the cell uptake and the biological stability toward nuclease involve peptide modification of antisense ODNs. It was reported that several types of peptides, such as nuclear transport signal sequence, viral fusion peptides, hydrophobic peptides, and signal peptides, have shown intrinsic ability to perturb cell membrane (*12*−*17*). It would be interesting to investigate whether such kinds of peptide conjugates could be used for the purpose of improving their cell membrane permeability. It has long been shown that glucose transporter genes (GLUT) are overexpressed in many human cancer cells, providing extra energy for the rapid growth of cancer cells (*18*), and the antisense oligonucleotides with phosphorothioate backbone (5′-CCA TGG CAG CGC TGC-3′) against GLUT-1 gene exhibited about 25% inhibition of proliferation in HL-60 cells (*19*). We have also reported the synthesis of a spin-labeled conjugate of peptide and peptide nucleic acid (*20*). In this paper, we described the synthesis of the conjugate of antisense oligodeoxynuleotide (S-oligos) with a signal peptide mimic and discussed its growth inhibition in cancer cells. In most cases, nucleases digest ODNs in a 3′-exo-cleavage manner (*21*); therefore, it is reasonable to design the conjugate antisense oligonucleotide with a peptide at the 3′-end.

The incompatibility of peptide chemistry and nucleic acid chemistry constitutes the major challenge for the synthesis of an intact peptide−ODNs conjugate. The accumulated data and concepts provided a wider range of methods for preparation of this defined structure (*13*−*16*, *22*−*33*). In this paper, we use *p*-hydroxybenzoic acid as a linker to connect the fragments of peptide and oligonucleotide, the consecutive assembly of the peptide, and then the ODN on a solid support was applied with much concern for a simple, convenient, and efficient preparative procedure.

EXPERIMENTAL SECTION

(1) Synthesis of Peptide on CPG. (*a) Hydroxylation of AP−CPG (22).* To aminopropyl controlled pore glass (AP−CPG, PE product, pore size 500 Å, 0.5 g, amino group loaded: 0.22 mmol/g), 30 mL of γ-butyrolactone and 13 mg of 4-(dimethylamino)pyridine (DMAP) were added, and the mixture was placed in an incubator at 60 °C for 7 days under shaking. The extent of the reaction was monitored by the disappearance of the primary amino groups by the ninhydrin analysis (*34*).

(b) Loading of the First Amino Acid on CPG. The CPG obtained in the previous step was drained and washed with dichloromethane (DCM), methanol, and DCM and then reacted with *N*-α-Fmoc-*N*-ε-Boc-L-lysine (57.4 mg, 0.11 mmol) and DMAP (3 mg) in 2 mL of dimethylformamide (DMF) and DCM (3:1, v/v) for 2 min. To the mixture was added 0.2 mL of dicyclohexylcarbodiimide (DCC) (1 M), and the reaction was performed at 37 °C for 24 h. After the sample was washed with DCM and methanol, a small amount of CPG was deprotected by

trifluoroacetic acid (TFA) to determine the extent of the reaction by ninhydrin assay; the major CPG were treated with acetic anhydride (Ac_2O) and triethylamine (TEA) in DCM (3 mL, 1:1:2, v/v) for 20 min to protect the residual hydroxyl groups. The CPG was washed with DCM and methanol alternately and finally by DCM.

(c) Elongation of Peptide. The Boc group at the first amino acid on the resulted CPG was removed by treatment with 33% TFA in DCM (v/v) at room temperature for 30 min. The CPG was washed (DCM and MeOH) and neutralized (10% TEA in DCM, v/v 10 min). Further peptide synthesis was carried out on the manual peptide synthesizer using standard Boc chemistry. The coupling reaction was performed sequentially using 2.5-fold molar excess of *N*-α-Boc protected L-amino acids (A, L, L, A and L) (Penisular products) and DCC with the reaction concentration of 0.1 M in DCM at room temperature for 2 h. The extent of the condensation was determined by ninhydrin assay. The yield of each coupling reaction is over 99%. The retained amino groups were acetylated as before. To determine the component of the peptide, partial resulted CPG was treated by 33% TFA followed by concentrated ammonium hydroxide at 55 °C for 14 h. After the sample was purified on HPLC, the peptide was identified by MALDI-TOF MS and amino acid analysis. MALDI-TOF MS *m/z*: 628.07 (M + 1), calculated for $C_{30}H_{57}N_7O_7$: *m/z*: 627.43; amino acid analysis: Lys:Ala:Leu = 1:2:3.

(d) Loading of Linker on CPG. Following the described procedure of Boc-deprotection at the terminal amino acid, the CPG was reacted with *p*-hydroxybenzoic acid (35 mg, 0.25 mmol) in 2 mL of DCM/DMF (1/1, v/v) using DCC (0.25 mmol) as coupling reagent at room temperature for 2 h, and the extent of the reaction was determined by ninhydrin assay using a small amount of washed CPG. After the sample was washed with DCM, MeOH, and DMF alternately, the majority of CPG were drained and dried for the next step.

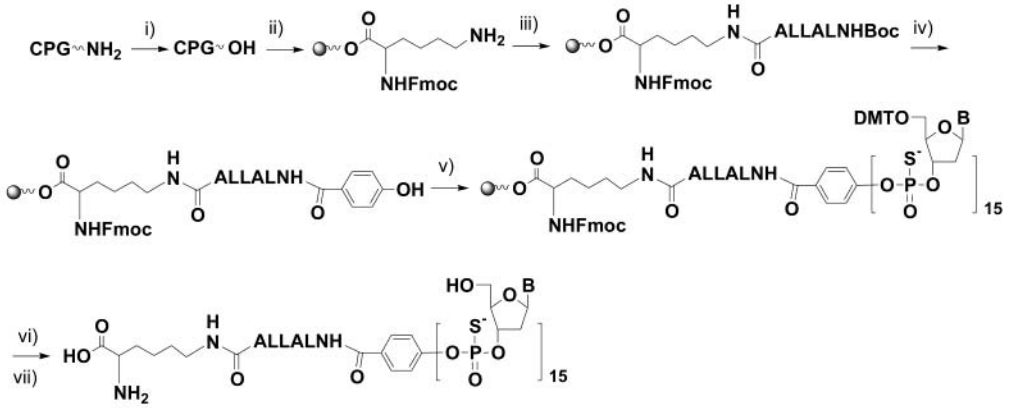
(2) Synthesis of ODNs on CPG. A total of 30 mg of the resultant CPG obtained from previous reaction was served as the solid phase support and submitted to cartridge of Applied Biosystem 931 DNA synthesizer for the synthesis of the desired sequence of *S*-oligonucleotide. The reaction cycles were carried out in 1−2 μM scale using cyanoethyl protected nucleoside phosphoramidites as coupling blocks, the procedures were set in compliance with the protocols recommended except prolonged 60 s of the capping wait step with the DMAP/Ac_2O solution. Stepwise sulfurization was performed with the standard reagent. The yield of each coupling reaction is 95−97%. The reaction was stopped at DMT-on. Normal cleavage and deprotection were completed with aqueous ammonia to obtain the peptide conjugated oligonucleotide (DMT-on). The oligomer was purified using oligonucleotide purification cartridges (OPC, Applied Biosystems). The DMT-on conjugates were purified by HPLC using Delta-Pak C18 column (Waters, 100 Å, 15 μm, 7.8 × 300 mm). The gradient was 0−40% B in 25 min, 40−100% B in 15 min (mobile phase A is 0.1 M triethylammonium acetate (pH 7.0), and mobile phase B is acetonitrile). The purified DMT-on conjugates were detritylated through OPC. After concentration, the hybrid molecules were purified by HPLC using NUCLEOSIL C18 column (Phenomenex, 100 Å, 10 μm, 4.6 × 250 mm). The gradient was the same as above, but here the mobile phase A is 0.02 M triethylammonium acetate (pH 7.0), and the mobile phase B was 50% acetonitrile in water. The resulting product appeared as a white solid (190 μg) after dried, and the sample was identified by MALDI-TOF MS or ESI-TOF MS. Antisense oligomer *m/z*: calculated 5603.33; found: 5603.58; sense oligomer *m/z*: calculated 5644.87; found: 5643.63.

(3) Effects on the Inhibition of Growth of HepG-2 and MCF-7 Cells by Peptide-ODNs Conjugate. Cells were seeded in 96-well culture plates at a concentration of 5000 cells/well (40−50% confluence). After overnight culture, the complete medium was replaced by plain medium. The peptide−ODNs conjugate was dissolved in sterilized phosphate-buffered saline (PBS). Conjugate and liposome complex was prepared (2.5 μM, DNA: liposome = 1:1) and added into the well. After 5-h incubation at 37 °C, the complex was removed and complete medium was added. For Northern analysis, 6-well culture plate was used instead but the cell confluence, and the conjugate concentration remained unchanged.

MTT assay (*35*): For adherent cells, the medium was first removed before 30 μL of 3-4,5-dimethylthiazol-2,5-diphenyl tetrazolium bromide (MTT) (5 mg/mL in PBS) was added in each well. The cells were incubated at 37 °C for 2 h. Then, 100 μL of DMSO was added and the cells were incubated for 5 min. After all crystal was dissolved, optical density was read by an ELISA plate reader at 540 nm. Northern hybridization was described in ref *19*.

Western hybridization: Total protein was extracted from the cells by lysing the cells with lysis buffer. A total of 30 μg of protein was loaded into each lane of SDS−PAGE with 7.5% separating gel and 5% stacking gel. After the protein was transferred to a PVDF membrane, the membrane was blocked by 5% nonfat milk. Then, it was followed by goat anti-human GLUT-1 antibody (Diagostic Research) and HRP-conjugated anti-goat secondary antibody. Finally, the signal was detected by ECL Western blotting detection reagents (Amersham Pharmacia).

RESULTS AND DISCUSSIONS



The synthesis of peptide−oligonucleotide conjugate was shown in Scheme 1. The hydroxylation of aminopropyl CPG was completed with γ-butyrolactone and DMAP at a higher temperature. The hydroxyl group can be used to load the first lysine by formation of an ester bond that can also be cleaved under basic conditions in concordance with ordinary ODN synthesis. To fulfill the designed peptide sequence, α-Fmoc-ε-Boc-lysine was selected as the first loaded amino acid on the CPG. The ε-amino group of lysine was used to prolong the peptide sequence, and the α-amino group would play the role of positive charge in the constructed peptide−ODN conjugate. The peptide synthesis was carried out on the CPG with standard solid phase peptide synthesis (SPPS) via Boc strategy. The major concern involved the adverse cleavage of the ester bond between peptide and CPG caused by acidic deprotection procedure. We checked every deprotection and coupling reaction by ninhydrin analysis during the whole process of peptide assembly; fortunately, the adverse cleavage of the ester bond between peptide and CPG did not happen. According to the MALDI-TOF MS, the molecular weight of the final product is concordant with the calculated value of the designed sequence.

The hydroxycarboxylic acid is frequently used as a linker for the connection of peptide and oligonucleotides, and the hydroxyl group from the linker can be reacted for the formation of the phosphate diester bond which could connect with 3′-activated nucleoside blocks by the phosphoramidite or phosphotriester chemistry (*26*, *27*).

5′-GCAGCGCTGCCATGG-LALLAK (Sense)

[a] (i) γ-Butyrolactone, DMP, 60 °C, 7 days; (ii) α-Fmoc-ε-Boc-Lys-OH, DCC, DMAP/DMF/DCM; (iii) Solid-phase peptide synthesis. (a) Deprotection: TFA/DCM, (b) coupling: Boc-Aa-OH, DCC/DCM, (c) capping: Ac_2O/TEA/DCM, (d) repeating (a), (b), (c); (iv) (a) TFA/DCM, (b) *p*-hydroxy benzoic acid, DCC; (v) Standard DNA synthesis of PS oligonucleotide; (vi) (a) Ammonium cleavage, (b) OPC purification; (vii) 5% CF_3COOH.

But in some cases the phosphate diester bond derived from aliphatic hydroxyl is unstable in basic condition; β elimination is a common reason for the interruption of the synthesis of peptide−oligonucleotide conjugate (*36*, *37*). An alternative approach is incorporation of thiol-containing groups that could serve as the linker for the connection of peptide and oligonucleotide. The thioester is more stable, but the preparation seems more complex to accomplish (*25*, *30*). The phosphate diester bond formed from the aromatic hydroxyl, such as the hydroxyl of tyrosine, is much more stable in the basic conditions (*38*, *39*). For this purpose, we suggested that *p*-hydroxybenzoic acid could be designed for serving as linker with the improved stability. After the condensation of *p*-hydroxybenzoic acid on the N-end of peptide, the resultant CPG was submitted to further synthesis of phosphorothioated ODN and showed the high stepwise loading efficiency of nucleoside phosphoramidites same as that of ordinary CPG. The normal basic condition (aqueous ammonia) was adopted to conduct the cleavage of the conjugate from CPG and the deprotection of nucleobase as well as the removing of Fmoc group of lysine.

The signal peptide mimic was designed according to the common sequence pattern consisting of a stretch of hydrophobic amino acids and a basic residue (Lys) at the end of peptide; the conformation of peptide bears the highest α-helix tendency according to computer-aided design (Insight II/Discover). Compared to the control sample (the conjugate of peptide-sense oligonucleotide), the designed conjugate showed up to 50% inhibition of cell proliferation in HepG-2 and MCF-7 cells as shown in Figure 1 and Figure 2. Also, the expression of mRNA and protein of GLUT-1 were decreased by the analysis of Northern and Western hybridization (Figure 3, Figure 4). In a previous paper, the same antisense oligonucleotide without peptide conjugated only showed a transient inhibition of HL-60 cell proliferation of about 25%. However, when comparing the efficiency between synthetic antisense oligonucleotides and expressed antisense RNA in inhibiting GLUT-1 gene expression, expressed antisense RNA produced over 50% inhibition of HL-60 cell proliferation (*19*). Considering all of the data, the efficiency of the designed peptide−antisense oligonucleotide conjugate in inhibiting proliferation of HepG-2 and MCF-7 cells is same as the expressed antisense RNA in HL-60 cells. It seems that the designed peptide sequence could improve the properties of antisense oligonucleotide for the penetration through the cell membrane.

Signal peptide is an N-terminal extension of premature secretary protein and directs the translocation of protein through the membrane of endoplasmic reticulum of eukaryotes or the inner membrane of prokaryotes. They typically consist of a hydrophobic core consisting of a stretch of hydrophobic amino acids with high tendency of α-helix, basic residues near the N-terminal, and some neutral residues at the C-terminal (*40*, *41*). The cellular mechanism involved in translocation of signal peptide is complex, but it is hypothesized that the transportation of the polypeptide chain is related to the hydrophobic property, conformation, and charge nature of the signal peptide sequence, with the cooperative function of signal peptide on the lipid bilayer membrane (*16*, *17*). It was reported that the long h-region sequence which had been applied as a carrier of certain protein domain enables the whole polypeptide to get through the cell membrane (*41*), and some kind of amphiphilic anionic peptide with over 20 amino acids shows the great potential of mediating cytosol and nuclear delivery of coincubated oligonucleotides with its disturbance effect on the membrane (*42*). In this paper, a short peptide antisense oligonucleotide conjugate was designed, and it may provide a simple method for the modification of antisense oligonucleotides.

In conclusion, a short signal peptide mimic was designed, and a simple procedure for the preparation of peptide−oligonucleotide conjugate was developed. It was found that the designed conjugate could inhibit the proliferation of HepG-2 and MCF-7 cells, and the efficiency is same as the expressed antisense RNA.

ACKNOWLEDGMENT

Received August 10, 2001; Revised Manuscript Received December 27, 2001

A monoreactive NOTA (1,4,7-triazacyclononane-1,4,7-triacetic acid) derived prochelator (1-(1-carboxy-3-carbo-*tert*-butoxypropyl)-4,7-(carbo-*tert*-butoxymethyl)-1,4,7-triazacyclononane (NODAGA(tBu)$_3$)) was synthesized in five steps with an overall yield of 21%. It is useful for the coupling to the N-terminus of peptides on solid phase and in solution; it was coupled to [Tyr^3]-octreotide (TOC) on solid phase, and the resulting peptide, NODAGA-Tyr^3-octreotide (NODAGATOC), was labeled with the radiometals ^{111}In and ^{67}Ga in high yields and good specific activities. [^{67}Ga]− and [^{111}In]−NODAGA-Tyr^3-octreotide appear to be useful to visualize primary tumors and metastases which express somatostatin receptors subtype 2 (sstr2), such as neuroendocrine tumors, because of their high affinity to this receptor subtype with $IC_{50} = 3.5 \pm 1.6$ nM and 1.7 ± 0.2 nM, respectively. NODAGATOC could be used as a SPECT and PET tracer, when labeled with ^{111}In, ^{67}Ga, or ^{68}Ga, and even for therapeutic applications. Surprisingly, [^{111}In]−NODAGATOC shows 2 times higher binding affinity to sstr2, but also a factor of 4 higher affinity to sstr5 compared to [^{67}Ga]−NODAGATOC. [^{67}Ga]−NODAGATOC is very stable in serum and rat liver homogenate. There is no difference in the rate of internalization into AR4-2J rat pancreatic tumor cells; both radioligands are highly internalized, at 4 h a 3 times higher uptake compared to [^{111}In]−DOTA-Tyr^3-octreotide ([^{111}In]−DOTATOC) was found. The biodistribution of [^{67}Ga]−NODAGATOC in AR4-2J tumor bearing nude mice is very favorable at short times after injection; there is fast excretion from all nontarget organs except the kidneys and high uptake in sst receptor rich organs and in the AR4-2J tumor. Again it is superior to [^{111}In]−DOTATOC in this respect. The results indicate an improved biological behavior which is likely due to the fact that an additional spacer group separates the chelate from the pharmacophoric part of the somatostatin analogue.

INTRODUCTION

Peptides are important regulators of growth and cellular functions in normal tissue but also in tumors. Tumors often overexpress receptors for different regulatory peptides. Certain types of tumors also respond to the growth inhibiting or growth promoting signals of certain peptides. This effect has become important in the treatment of some tumors in man. An important example are analogues of SRIF[1] (somatostatin release inhibiting factor) which are being used in the treatment of symptomatic neuroendocrine tumors and in acromegaly (*1*). A development of the last 10 years or so has been the use of radiolabeled versions of regulatory peptide analogues in the in vivo localization of tumors (*2*−*8*). Of paramount importance is the DTPA-derivatized somatostatin analogue octreotide labeled with [^{111}In] which is commercially available under the trade name OctreoScan (*9*, *10*). As this type of peptide−chelate conjugates show very rapid blood clearance and diffusion into different tissues, the use of short-lived positron emitters becomes feasible. We have introduced a few strategies that use

[^{68}Ga], a 68 min half-life-generator-produced metallic positron emitter coupled to somatostatin analogues (*11*−*13*). Whereas the use of the bifunctional chelator desferrioxamine-B (DFO) led to a radiopeptide which showed very good tumor targeting and visualization in a tumor-bearing rat model, the same conjugate was not very successful in patients because of a slow blood clearance (*14*).

The DOTA monoamide conjugated peptide [Tyr^3]-octreotide (DOTA-Tyr^3-octreotide = DOTATOC) showed very promising in vitro and in vivo properties if labeled with ^{67}Ga, ^{111}In, and ^{90}Y (*11*, *15*). The IC_{50} value of Ga^{III}−DOTATOC, if measured in an assay using a sstr2 receptor expressing cell line, and [^{125}I]-[Leu^8, D-Trp^{22}, Trp^{25}]-somatostatin-28 was 2.5 ± 0.5 nM compared to 11.4 ± 1.7 nM of the corresponding Y^{III}−DOTATOC (*16*). In addition, a Scatchard analysis using rat brain cortex membranes gave a K_d value of 0.46 ± 0.1 nM for [^{67}Ga]−DOTATOC (*16*) and 2.57 ± 0.2 nM for [^{111}In]−DOTATOC, respectively (*15*). The uptake of the respective radioligands in a tumor-bearing mouse model (AR4-2J rat pancreatic tumor cell line) was 13% of the injected dose per g (%ID/g) tumor for [^{111}In]−DOTATOC and 30% ID/g tumor for [^{67}Ga]−DOTATOC at 4 h postinjection. Interestingly, the [^{67}Ga]−DOTATOC showed a lower uptake and shorter residence time in the kidney compared to [^{111}In]−DOTATOC. The respective radioactivities in the kidney at 1, 4, 24, and 48 h for [^{111}In]−DOTATOC were 15, 12.5, 8, and 4% ID/g, whereas for [^{67}Ga]−DOTATOC the radioactivities in the kidneys were 8.5, 7.5, 4, and 2.5% ID/g at the same time points (*11*).

The reason for these differences are not fully understood yet. The metal ion dependence may stem from structural differences within the coordination environment. The X-ray crystal structures of the model peptides Ga^{III}−DOTA-D-PheNH$_2$ and Y^{III}(In^{III}, manuscript in preparation)−DOTA-D-PheNH$_2$ showed remarkable differences. In the Ga^{III} complex, DOTA adopts a cis-pseudooctahedral geometry with a folded macrocyclic unit (2424 conformation) (Figure 1). The equatorial plane is formed by two transannular nitrogens of the macrocyclic ring and the oxygens of the corresponding carboxylate groups. The axial positions are occupied by the remaining two ring nitrogens. Two potential coordination sites of the chelator are free, namely one carboxylate group and the amide carboxy oxygen (*11*). This structural feature may contribute to the somewhat more efficient kidney clearance, and the latter leads to a spacer function between chelate and bioactive peptide (Figure 1). This may consequently introduce less steric strain and improve receptor binding affinity and concomitantly tumor uptake in vivo. Unlike the Ga^{III} structure in Y^{III}(In^{III})−DOTA-D-PheNH$_2$, the coordination number of Y^{III} (In^{III}) is eight and includes the amide carbonyl oxygen. This may lead to some steric scrambling and lower the receptor affinity compared to a chelate which is somewhat remote from the pharmacophoric part of the peptide as in the Ga^{III} complex.

The purpose of this study therefore is to synthesize a NOTA-based [Tyr^3]-octreotide derivative (NODAGA-Tyr^3-octreotide, NODAGATOC) which should allow to carry a spacer function between the ^{67}Ga (^{111}In) complexing chelator and the peptide. This should demonstrate the importance of the spacer for improved receptor binding affinity. The first step was the synthesis of a bifunctional NOTA-derived prochelator which can be conveniently coupled to peptides on solid support and in solution. In addition, we studied SRIF-receptor affinity, biodistribution as well as internalization and externalization of the ^{67}Ga (^{111}In) labeled peptide compared to our "gold standard" of somatostatin receptor scintigraphy [^{111}In]−DOTA-Tyr^3-octreotide in the rat pancreas tumor cell line AR4-2J and a corresponding nude mice tumor model. NOTA was used because of the known high stability of the Ga^{III}−NOTA and In^{III}−NOTA complexes which makes any interference and false interpretation of biological and pharmacological data due to a potential transchelation chemistry rather unlikely.

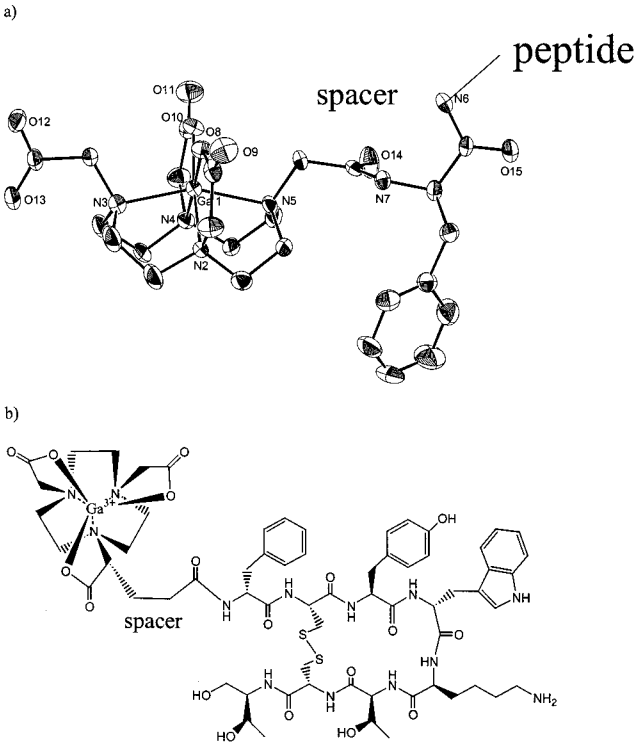

Figure 1. (a) ORTEP plot of the crystal structure of Ga^{III}−DOTA-D-PheNH$_2$. (b) Structural formula of NODAGA-Tyr^3-Octreotide.

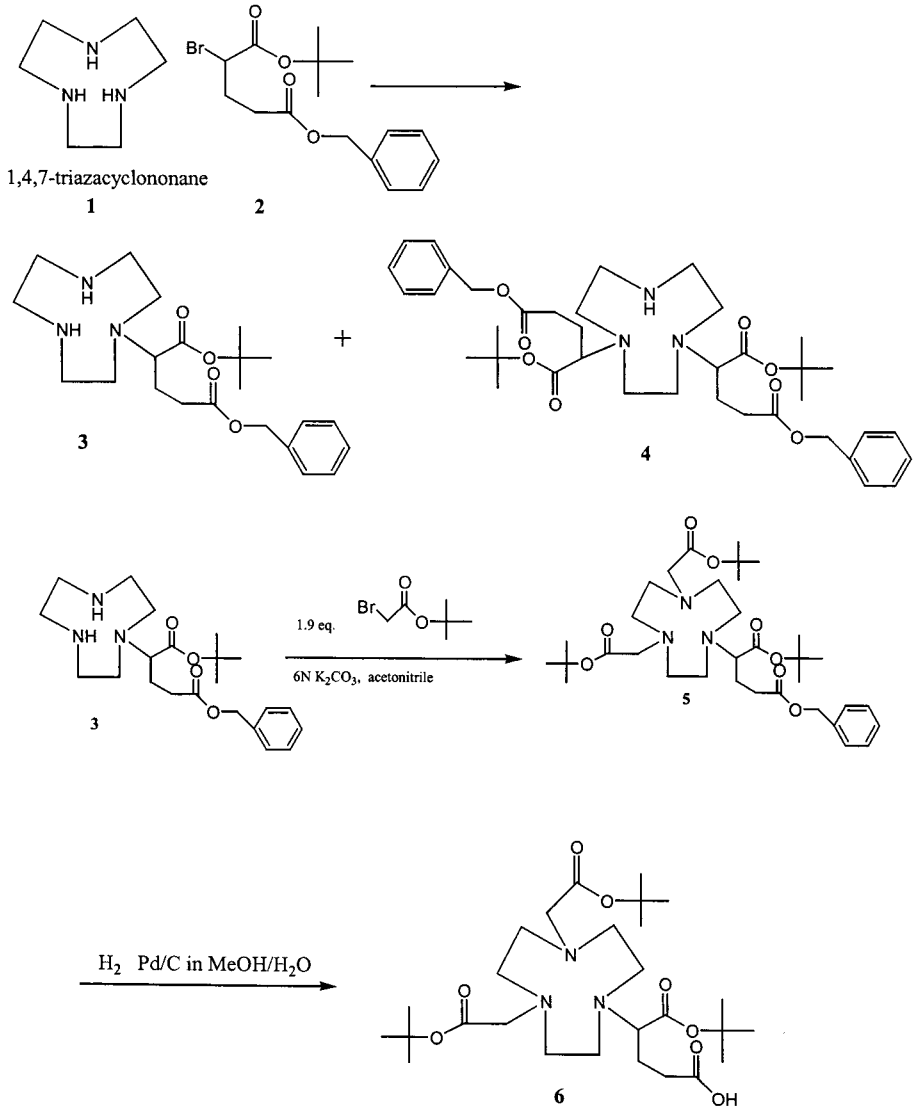
The interest in peptide chelator conjugates for labeling with gallium radionuclides comes from their desirable physical properties (*17*, *18*). Three gallium radionuclides exist with decay characteristics that are suitable for γ-scintigraphy, PET imaging, and receptor-mediated radiotherapy: ^{68}Ga is a 68 min half-life-generator-produced positron emitter which is of interest because of the 280 d half-life of the parent ^{68}Ge. This gives the generator a long half-life of more than 1 year and allows PET imaging at institutions without on-site cyclotron.



^{67}Ga has a half-life of 78.3 h and decays via electron capture with 3 γ-emissions at 93 keV (38%), 185 keV (24%), and 300 keV (16%) which are useful for planar scintigraphy and single photon emission tomography (SPET). In addition, ^{67}Ga is also a reasonably efficient Auger-emitter for use in internal radiotherapy if the vectors used to bring the radionuclide to the tumor cell are being internalized and the radionuclide comes close to the nucleus.

^{66}Ga again is a positron emitter with an attractive intermediate half-life of 9.5 h which is of current interest because of its longer half-life, more suitable to the pharmacokinetics of a variety of biomolecules (*19*, *20*). It is cyclotron-produced and emits positrons with an abundance of 56% and E_{mean} = 1.7 MeV.

EXPERIMENTAL SECTION

Materials and Methods. *General Methods.* All chemicals were obtained from commercial sources and used

Scheme 1. Synthesis of NODAGA(tBu)$_3$ (6)

without further purification. 1,4,7-Triazacyclononane was commercially available (Macrocyclics, Dallas, TX). Octreotide was commercially available as Sandostatin (Novartis). [^{111}In]Cl_3 and [^{67}Ga]Cl_3 were purchased from Mallinckrodt Med. (Petten, The Netherlands). Chemical reactions were monitored by thin-layer chromatography (TLC) on Merck plates precoated with silica gel 60 F_{254} (0.25 mm). Spots were visualized either by UV light or iodine. Flash chromatography was performed on silica gel 60 (Fluka). Electrospray ionization (ESI) mass spectroscopy was carried out with a Finnigan SSQ 7000 spectrometer or fast atom bombardment (FAB) mass spectroscopy with a VG 70SE spectrometer. Analytical and semipreparative HPLC was performed on a Hewlett-Packard 1050 HPLC system with a multiwavelength detector and a flow-through Berthold LB 506 Cl γ-detector with a Macherey-Nagel Nucleosil 120 C_{18} column and preparative HPLC on a Metrohm HPLC system LC−CaDI 22−14 with a Macherey-Nagel VP 250/21 Nucleosil 100−5 C_{18} column. Quantitative γ-counting was performed on a COBRA 5003 γ-system well counter from Packard Instrument. ^{1}H and ^{13}C NMR was performed with either a Brucker spectrometer at 360/99 MHz or a Varian VXR 400 at 400/101 MHz. Chemical shifts reported are relative to trimethylsilane (TMS). Solid-phase peptide synthesis was performed on a semiautomatic peptide synthesizer commercially available from Rink Combichem (Bubendorf, Switzerland). The cell culture medium was Dulbecco's minimal essential medium (DMEM) from GibcoBRL. DOTA-Tyr^3-octreotide (DOTATOC) was synthesized as described before (*11*).

Synthesis. Starting from the commercially available glutamic acid 5-benzyl ester, α-bromoglutaric acid diester (**2**) (Scheme 1) was synthesized in two steps as described before (*21*).

1-(1-Carbobenzyloxy-3-carbo-*tert*-butoxypropyl)-1,4,7-triazacyclononane (3). A solution of 513 mg (1.44 mmol) of α-bromoglutaric acid 1-*tert*-butyl ester 5-benzyl ester (**2**) in 20 mL of chloroform was added over a period of 3 h to a solution of 557 mg (4.31 mmol) of 1,4,7 triazacyclononane in 20 mL of chloroform. The mixture was stirred over 3 d at room temperature and concentrated to a brown oil. The crude product was purified by column chromatography with silica gel 60 (5 × 20 cm; eluents: 250 mL of ethanol/ammonia 95:5; 300 mL of chloroform/ethanol/ammonia 7:3:0.5). Yield: 404 mg (69.2%) of a colorless oil. Unreacted 1,4,7-triazacyclononane was recovered and can be reused after distillation. ^{1}H NMR [$CDCl_3$, RT]: δ 1.5 (s, 9H, C(CH_3)$_3$); 2.2−1.85 (m, 2H, CHNCH_2); 2.9−2.5 (m, 14H, NCH_2, CH_2COOBzl); 3.25 (dd, 1H, C*H*Br); 5.1 (s, 2H, CH_2Ph); 7.35 (m, 5H, arom); ^{13}C NMR [$CDCl_3$, RT]: δ 24.7, 25.2 (CH_2CHN);

28.1 (C(CH_3)$_3$); 31.0 (CH_2COOBzl); 46.5, 46.6, 49.8 (NCH_2); 65.4, 65.7 (HCNCH_2); 66.1 (COOCH_2Phe); 81.0 (C(CH$_3$)$_3$); 126.6, 126.9, 128.1, 128.2, 128.4 (arom); 135.8 (arom) 172.0, 172.7, 173.0 (*C*OOtBu, *C*OOBzl); IR (KBr, cm^{-1}): 2931 (ν as, CH_2); 2850 (ν sym, CH_2); 1725 (ν as C=O, COOtBu, COOBzl); 1368 (δ C(CH_3)$_3$); 1152 (ν C−O); 753, 699 (arom). EI-MS (*m*/*z* (%)): 406.1 (46, [M + H]$^+$); 350.1 (100, [M − C_4H_9]$^+$).

Analytical data of the side product 1,4-(1-carbobenzyloxy-3-carbo-*tert*-butoxypropyl)-1,4,7-triazacyclononane (**4**): ^{1}H NMR [$CDCl_3$, RT]: δ 1.0 (s, 18H, C(CH_3)$_3$); 1.35−1.7 (m, 4H, CHNCH_2); 1.9−2.45, 2.6−2.8 (2m, 16H, NCH_2, CH_2COOBzl); 3.2 (m, 2H, C*H*Br); 4.6 (s, 4H, CH_2Ph); 6.8 (m, 10H, arom); EI-MS, *m*/*z* (relative intensity): 682.3 (100, [M + H]$^+$); 626.2 (15, [M − C_4H_9]$^+$); 570.1 (10, [M − 2C_4H_9]$^+$).

1-(1-Carbobenzyloxy-3-carbo-*tert*-butoxypropyl)-4,7-bis(carbo-*tert*-butoxymethyl)-1,4,7-triazacyclononane (5). A 390 mg (0.963 mmol) amount of [1-(1-carbobenzyloxy-3-carbo-*tert*-butoxypropyl)-1,4,7-triazacyclononane] (**3**) in 30 mL of dry acetonitrile is cooled to 4 °C. A 255 μL (1.733 mmol) amount *tert*-butylbromoacetic acid was added dropwise over a period of 15 min. The reaction mixture was stirred for additional 15 min before adding 728 mg (5.271 mmol) of dry potassium carbonate and allowed to warm slowly to room temperature over 4 h. The mixture was filtered afterward over Celite and evaporated to dryness to afford the crude product (540 mg, 95%) which can be used for the next step without further purification. Purification was also done by silica gel chromatography (5 × 20 cm; eluents: 80 mL of ethyl acetate; 100 mL of $CHCl_3$/EtOH 20:1; 100 mL of $CHCl_3$/EtOH 4:1). ^{1}H NMR [$CDCl_3$, RT]: δ 1.5 (s, 27H, C(CH_3)$_3$); 1.85−3.6 (m, 21H, C*H*NCH_2, NCH_2, CH_2-COOBzl, CH_2COOtBu); 5.1 (s, 2H, CH_2Ph); 7.35 (m, 5H, arom); ^{13}C NMR [$CDCl_3$, RT]: δ 24.7, 25.3 (*C*H$_2$CHN); 27.3, 27.7, 28.1, 28.3 (C(*C*H$_3$)$_3$); 30.9, 31.0, 31.3 (*C*H$_2$-COOBzl, *C*H$_2$COOtBu)); 50.5, 51.5, 53.1, 58.2 (N*C*H$_2$); 65.4 (H*C*NCH$_2$); 66.4 (COO*C*H$_2$Phe); 81.3, 81.7, 82.1 (*C*(CH$_3$)$_3$); 127.0, 127.5, 128.2, 128.3, 128.7 (arom); 136.0 (arom) 170.7, 171.4, 172.1, 172.8, 173.1 (*C*OOtBu, *C*OOBzl); IR (KBr, cm^{-1}): ν = 2975, 2927 (ν as, CH_2); 2854 (ν sym, CH_2); 1734 (ν as C=O, COOtBu, COOBzl); 1368 (δ C(CH_3)$_3$); 1153 (ν C−O); 753, 699 (arom). EI-MS, *m*/*z* (relative intensity): 635, 634 (100, [M + H]$^+$).

1-(1-Carboxy-3-carbo-*tert*-butoxypropyl)-4,7-(carbo-*tert*-butoxymethyl)-1,4,7-triazacyclononane (NODAGA(tBu)$_3$) (6). A 150 mg (0.237 mmol) of 1-(1-carbobenzyloxy-3-carbo-*tert*-butoxypropyl)-4,7-(carbo-*tert*-butoxymethyl)-1,4,7-triazacyclononane (**5**) was dissolved in 20 mL of 2-propanol and 50 mg 10% Pd/C suspended in 0.5 mL of H_2O was added. The mixture was treated by bubbling hydrogen through the solution over 18 h, filtered over Celite, and evaporated to dryness. The residue was chromatographed on silica gel 60 (2-propanol/ammonia 95:5) to obtain 85 mg (66%) of a yellow oil. ^{1}H NMR [$CDCl_3$, RT]: δ 1.5 (s, 27H, C(CH_3)$_3$); 2.0 (m, 2H, CH_2COOH); 2.5 (m, 2H, NCHCH_2); 2.8−3.2 (m, 12H, NCH_2); 3.45−3.75 (m, 5H, C*H*NCH$_2$, CH_2COOtBu); ^{13}C NMR [$CDCl_3$, RT]: δ 25.1, 25.2 (*C*H$_2$CHN); 27.8, 28.0 (C(*C*H$_3$)$_3$); 32.7 (*C*H$_2$COOH, *C*H$_2$COOtBu)); 49.3, 51.7, 52.6, 57.2 (N*C*H$_2$); 65.5 (H*C*NCH$_2$); 81.1, 82.0 (*C*(CH$_3$)$_3$); 169.4, 171.1 (*C*OOtBu); 176.5 (*C*OOH); IR (KBr, cm^{-1}): ν = 2977, 2932 (ν as, CH_2); 1727 (ν as C=O, COOtBu, COOH); 1368 (δ C(CH_3)$_3$); 1251 (ν C−OH); 1156 (ν C−O). EI-MS, *m*/*z* (relative intensity): 1088 (10, [2M + H]$^{2+}$); 567, 566 (12, [M + Na]$^+$); 545, 544 (100, [M + H]$^+$).

Synthesis of NODAGATOC (8). D-Phe^1-Cys(Acm)^2-Tyr(tBu)^3-D-Trp(Boc)^4-Lys(Boc)^5-Thr(tBu)^6-Cys(Acm)^7-Thr(tBu)^8-ol (**7**) was assembled on a trityl chloride resin (TCP, Pepchem, Tübingen, Germany) using standard Fmoc (9-fluorenylmethoxycarbonyl) strategy (*22*) with diisopropylcarbodiimide (DIC) as coupling reagent. The coupling of the chelator was done as follows: 81 mg of octapeptide (18.3 μmol peptide, 0.9 mmol/g resin) assembled on TCP-resin was incubated for 4 h with a mixture of a 40 min preincubated solution of 30 mg (0.055 mmol) (**6**) and 21 mg (0.055 mmol) of HATU (*O*-(7-azabenzotriazol-1-yl)-*N*,*N*,*N*',*N*'-tetramethyluronium-hexafluoro-phosphate) in 2 mL of NMP (*N*-methylpyrrolidone). The pH was adjusted to 7−8 using DIPEA (diisopropylethylamine, 10 μL, 0.06 mmol). The peptide was cleaved from the resin with 20% acetic acid in dichloromethane (five times 3 mL) and coevaporated three times with toluene (100 mL) to remove the acetic acid. Then it was cyclized with 10 equiv of iodine in methanol/water 9:1, deprotected with TFA/phenol/thioanisole/water 85:5:5:5 for 4−6 h, and purified by preparative HPLC (Macherey-Nagel Nucleosil 100−5 C_{18}, flow: 15 mL/min; eluents: A = 0.1% trifluoroacetic acid (TFA) in water and B = acetonitrile; nonlinear gradient: 0 min, 85% A; 20 min, 70% A). MS ((−)EI, *m*/*z* (%)): 1391.1 (100, [M − H]$^-$); ((+)EI, *m*/*z* (%)): 1392.9 (8, [M + H]$^+$), 697.3 (100, [M + 2H]$^{2+}$). The overall yield based on the first Fmoc cleavage is 31.5%.

Ga−NODAGATOC (9). The ^{69,71}Ga^{III} complex was synthesized according to the methods previously described (*11*, *16*). A mixture of 500 μg (0.34 μmol) (**8**) in 500 μL of 0.4 M sodium acetate buffer (pH 5) was incubated with 102 μL of a 0.01 M aqueous solution of Ga(III) nitrate nonahydrate (1.02 μmol) for 25 min at 95 °C, cooled to room temperature, and purified over a SepPak C_{18} cartridge preconditioned with 10 mL of ethanol and 10 mL of water. The cartridge was eluted with 10 mL of 0.4 M sodium acetate (pH 5) followed by 3 mL of methanol resulting in 400 μg (76%) of Ga−NODAGATOC after evaporation of the methanol. MS ((−)EI, *m*/*z* (%)): 1495 (12, [M − H]$^-$); ((+)EI, *m*/*z* (%)): 1461 (14, [M + H]$^+$), 742 (100, [M + 2H]$^{2+}$).

In−NODAGATOC (10) was synthesized as (**9**) using $InCl_3$·5H_2O.

Radiotracer for Internalization Experiments. [^{111}In]−NODAGATOC was prepared by dissolving 10 μg of NODAGATOC (7.2 nmol) in sodium acetate buffer (100 μL, 0.4 M, pH 5); after the addition of $^{111}InCl_3$ (3.5 mCi), the solution was heated at 95° for 25 min. A 1.5 molar excess of $InCl_3$·5H_2O was added and the final solution heated at 95 °C for 25 min. [^{67}Ga]−NODAGATOC (10 μg of ligand, 3 mCi of $^{67}GaCl_3$) was prepared in the same way, using Ga(III) nitrate nonahydrate. In a modification of this protocol, acetate buffer was replaced by HEPES (150 μL, 0.1 M, pH 5.8). The final labeling solution had a pH 2.5. This protocol gave yields >95% at a specific activity of 40 GBq/μmol^{-1}. Subsequently radiolabeled peptides were purified utilizing a SepPak C_{18} cartridge preconditioned with 10 mL of methanol and 10 mL of water; the cartridge was eluted with 3 mL of water, followed by 2 mL of ethanol, to afford the very pure radioligand with a specific activity ≥15 GBq μmol^{-1}. A quality control was performed by HPLC (eluents: A = 0.1% TFA in water and B = acetonitrile; gradient: 0−30 min, 55% A, 30−36 min, 100% B, 36−40 min, 95% A).

Metal/Ligand Stability Studies. The chemical stability of the radiometal complexes [^{67}Ga]− and [^{111}In]−NODAGATOC was studied by measuring the rate of exchange of the radiometal in the presence of 10^5 molar excess of DTPA at pH 5. Solutions were stored at 37 °C,

and at periods up to 10 days aliquots were removed and analyzed by HPLC using the gradient described above.

Serum Stability. To 3 mL of fresh human serum, previously equilibrated in a 5% CO_2 (95% air) environment at 37 °C, was added 5 μCi of the [^{67}Ga]−NODAGATOC standard solution. The mixture was incubated in a 5% CO_2, 37 °C environment. At appropriate periods of time (0, 30 min, 1, and 4 h), 100 μL aliquots (in triplicate) were removed and treated with 200 μL of ethanol. Samples were then cooled (4 °C) and centrifuged for 15 min at 500*g* and 4 °C to precipitate serum proteins. One hundred microliters of supernatant was removed for activity counting in a γ well-counter. The sediment was washed twice with 1 mL of ethanol and counted. The activity in supernatant was compared with the activity in the pellet to give the percent peptide not bound to proteins.

The peptide structure in the supernatant was checked by HPLC using the equipment mentioned above.

Receptor Autoradiography and Binding Affinity. Determination of peptide conjugate concentrations and receptor autoradiography was described previously (*16*). Concentrations of peptides were determined spectrophotometrically using $\epsilon_{280} = 6800\ M^{-1}\ cm^{-1}$. IC_{50} values using autoradiographic methods were determined as described (*16*).

In brief, cells stably transfected with sst1-sst5 were kindly provided by Drs. T. Reisine and G. Singh (University of Pennsylvania, Philadelphia, PA). They were washed twice with and scraped into ice-cold 0.05 M Tris-HCl (pH 7.4), collected by centrifugation, and homogenized using a rotor/strator slash system (Polytron, Kinematica Inc., Littau, Switzerland) in the same buffer. After centrifugation at 120 g for 5 min at 4 °C, the supernatant was collected and centrifuged again at 48.000 g for 30 min at 4 °C. The resulting pellet was resuspended in ice-cold Tris buffer, transferred into a microfuge tube, and centrifuged at 20.000 g for 15 min at 4 °C. After withdrawal of the supernatant, the membrane pellet was stored at −80 °C.

Receptor autoradiography was performed on 20-μm-thick cryostat (Leitz 1720, Rockleigh, NJ) sections of the membrane pellets, mounted on microscope slides and then stored at −20 °C. For each of the tested compounds, complete displacement experiments were performed with the universal somatostatin radioligand [^{125}I]-[Leu^{8},D-Trp^{22},Trp^{25}]somatostatin 28 using increasing concentrations of the unlabeled peptide ranging from 0.1 to 1000 nM. As a control, somatostatin 28 was run in parallel using the same increasing concentrations. IC_{50} values were calculated after quantification of the data using a computer-assisted image processing system as described previously (*23*). Tissue standards (autoradiographic [^{125}I]-microscales, Amersham), containing known amounts of isotopes, cross-calibrated to tissue-equivalent ligand concentrations, were used for quantification (*24*).

Radiotracers Used in Biodistribution Studies. [^{67}Ga]−NODAGATOC and [^{111}In]−DOTATOC were prepared with the methodology described in the previous section, without addition of cold metal but using lower peptide amounts. If necessary, radioligands were purified by SepPak C_{18} cartridge and after evaporation of ethanol were diluted in NaCl (0.1% BSA, pH 7.4) to afford the very pure radioligands with a specific activity of ca. 40 GBq/μmol conjugate. The radiotracers were subjected to quality control by HPLC as described above.

Cell Culture. AR4-2J (ATCC, Manassas, VA) rat pancreatic tumor cells were cultured in Dulbecco's minimal essential medium (DMEM). DMEM was supplemented with vitamins, essential and nonessential amino acids, L-glutamine, antibiotics (peniciline/streptomycine), fungicide (amprotencine), and 10% fetal calf serum (FCS) as described elsewhere (*25*).

Internalization/Externalization Studies. Internalization and externalization experiments were performed as indicated in previous publications in six-well plates (*25, 26*). Briefly, the cells were washed twice with internalization medium [DMEM supplemented with 0.1% FCS, vitamins, essential and nonessential amino acids, L-glutamine, antibiotic (penicillin/streptomycin), and fungicide (amprotencin)], and they were allowed to adjust to the medium for 1 h at 37 °C. Approximately 3.7 kBq (2.5 pmol) of radioligand were added to the medium, and the cells, 10^6 cells per well, were incubated (in triplicates) for 4 h at 37 °C, 5% CO_2, with or without excess cold octreotide (300 μL of a 1 μM solution) to determine nonspecific internalization. The final volume was 3 mL. At appropriate time periods, the internalization was stopped by removal of the medium and washing the cells with ice-cold phosphate-buffered saline. Cells were then treated with glycine buffer twice for 5 min at room temperature (0.05 M glycine solution, pH adjusted to 2.8 with 1 N HCl) to distinguish between cell surface-bound (acid releasable) and internalized (acid resistant) radioligand. Finally, cells were treated with 1 N NaOH and incubated at 37 °C for 10 min to detach them from plates, and the radioactivity was measured in a γ-counter. For externalization the AR4-2J cells were allowed to internalize the radioligands for periods of 2 and 4 h and then were exposed to an acid wash, as described in the previous section, to dissociate cell-surface-receptor-bound radioligand. Three milliliters of culture medium were added to each well, cells were incubated at 37 °C in a 5% CO_2 environment, and externalization of the cell-incorporated radioactivity was studied during 3 h.

Biodistribution Experiments in AR4-2J Tumor-Bearing Nude Mice. Six to ten week old Swiss female nude mice (IFFA-CREDO, France) were implanted subcutaneously with 5 million AR4-2J rat pancreatic tumor cells, previously expanded in Dulbecco's minimal essential medium (DMEM, GibcoBRL). DMEM was supplemented with vitamins, essential and nonessential amino acids, L-glutamine, antibiotics (penicilline/streptomycine), fungicide (amprotencine), and 10% fetal calf serum (FCS).

Fourteen days after inoculation, the tumors weighed 50−100 mg, and the mice were injected in the lateral tail vein with 5 μCi of [^{67}Ga]−NODAGATOC or [^{111}In]−DOTATOC, diluted in NaCl (0.1% BSA, pH 7.4, total injected volume = 200 μL). For determination of nonspecific uptake in tumor or receptor-positive organs, a group of four animals was injected in the tail vein with 50 μg of cold octreotide in NaCl (injected volume, 200 μL), 30 min before radiotracer injection. At 4, 24, and 48 h mice (in groups of three or four) were sacrificed and organs of interest collected, rinsed of excess blood, weighed, and counted in a γ-counter. The percentage of injected dose per gram (% ID/g) was calculated for each tissue. The total counts injected per animal were determined by extrapolation from counts of an aliquot taken from the injected solution. Urine samples were analyzed for possible metabolites by HPLC.

All animal experiments were performed in compliance with the Swiss regulation for animal treatment (Bundesamt für Veterinärwesen, approval no. 789).

RESULTS

Synthesis and Radiolabeling. An important step toward the synthesis of NOTA-derivatized bioactive

Scheme 2. Synthesis of NODAGATOC (8)

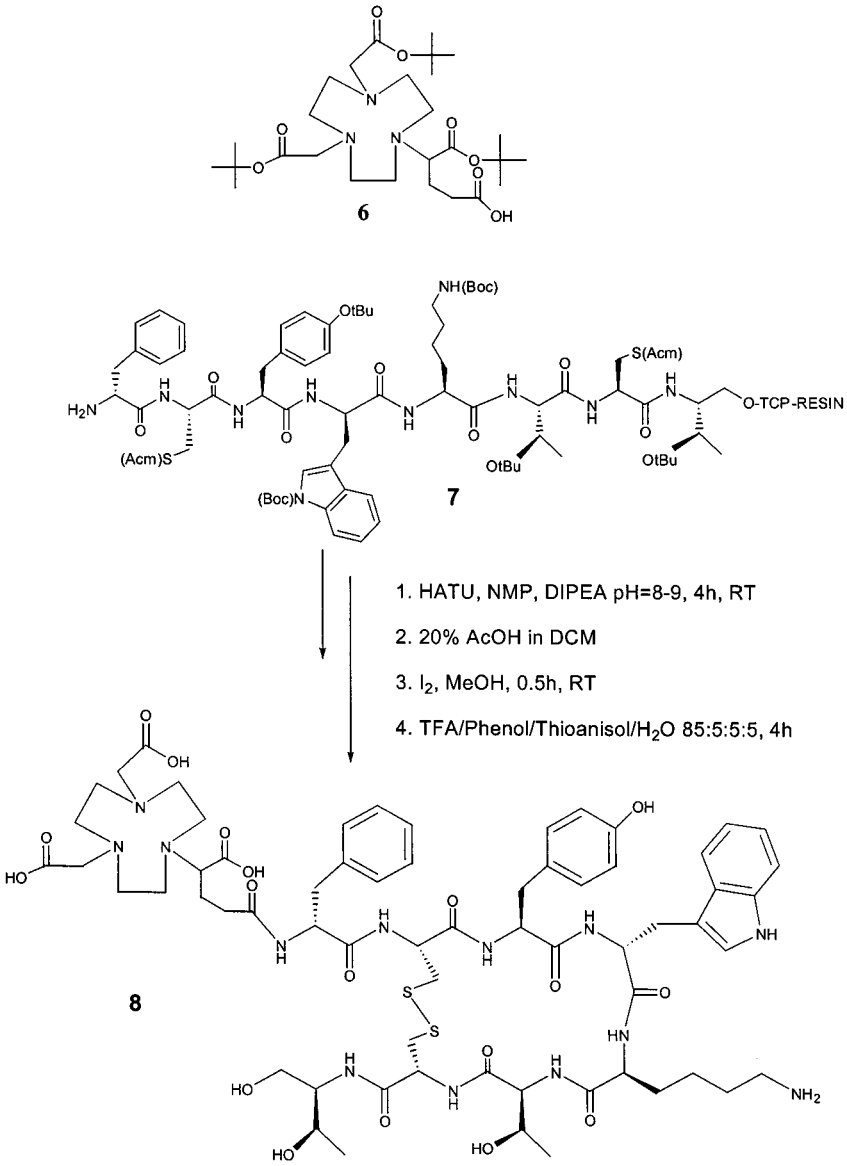


Table 1. Yields of the Monoalkylation of 1,4,7-Triazacyclononane (1) with *β*-Bromoglutaric Acid 1-*tert*-Butyl Ester 5-Benzyl Ester (2)

ratio of **1** to **2**	% yield of monoalkylated product	% yield of dialkylated product

2:1	50.9	20
3:1	69.2	>5

peptides is the development of the corresponding prochelator NODAGA(tBu)$_3$ (**6**) (Scheme 1). The monoreactive NODAGA-prochelator was synthesized in five steps with an overall yield of 21% (Schemes 1 and 2). Two side reactions decreased the yields of steps 3 and 4. The monoalkylation of 1,4,7-triazacyclononane (**1**) with α-bromoglutaric acid 1-*tert*-butyl ester 5-benzyl ester (**2**) gave more than 20% of the dialkylated product 1,4-bis(1-carbobenzyloxy-3-carbo-*tert*-butoxypropyl)-1,4,7-triazacyclononane (**3a**) if the ratio of **1**:**2** was 2. Only the use of a 3-fold excess of **1** over **2** gave yields based on **2** of about 70% (Table 1). In step 4, overalkylation to a quarternary ammonium salt was found even if stoichiometric ratios were used. Therefore only 1.9 equiv of bromoacetic acid *tert*-butyl ester were employed. In addition, cooling to 4 °C appeared to be advantageous to avoid overalkylation.

After these partially optimized synthetic steps, **6** was obtained in a reasonable overall yield of 21%. The linear side chain protected octapeptide D-Phe^1-Cys(Acm)^2-Tyr-(tBu)^3-D-Trp(Boc)^4-Lys(Boc)^5-Thr(tBu)^6-Cys(Acm)^7-Thr-(ol)(tBu)^8 **(7)** was assembled on a TCP resin using Fmoc-strategy (*22*) with DIC as coupling reagent. **6** (3 equiv) was coupled to **7** on the resin with the use of HATU (*O*-(7-azabenzotriazol-1-yl)-*N*,*N*,*N*',*N*'-tetramethyluronium hexafluorophosphate) as coupling reagent. The protected peptide was mildly cleaved from the resin (20% CH_3-COOH), cyclized with I_2 in methanol, deprotected, and purified by preparative HPLC analogous to Arano et al. (*27*) (Scheme 2). Reversed phase HPLC afforded the peptide in ≥95% purity. The composition and structure of NODAGATOC were verified by MS-ESI and by the retention of a high-binding affinity to sstr2. NODAGATOC was labeled with the radiometals of interest (^{67}Ga, ^{111}In) using acetate buffer (pH 5, 0.4 M) by heating (95 °C, 25−30 min); the labeling yields were >99% (^{111}In) and >60% (^{67}Ga) at a specific activity >40 GBq μmol^{-1}. It could be shown by an accidental labeling protocol that using HEPES (pH ≈ 2.5) better labeling yields (≥95% at 40 GBq μmol^{-1}) of [^{67}Ga]NODAGATOC were obtained. We assume that this is due to the lower pH which may

favor the $^{67}Ga^{3+}$ over the metal impurities present. An expansion of this finding was outside the scope of this work.

Receptor Binding. Table 2 shows the newly synthesized NODAGATOC somatostatin analogues investigated and their respective IC_{50} values for the five somatostatin receptor subtypes. As controls, somatostatin 28 (SS28), which binds with high affinity to all five somatostatin receptor subtypes, and our gold standards Ga/Y-DOTATOC were included. Ga−NODAGATOC shows high affinity only to sstr2 with an IC_{50} of 3.5 ± 1.6 nM close to the one of Ga-DOTATOC (2.5 ± 0.5 nM) whereas it binds significantly better to sstr2 than Y-/In-DOTATOC. Measurable affinity was also found to sstr3 and sstr5. Interestingly, In−NODAGATOC binds with higher affinity to sstr2 (1.7 ± 0.2 nM) and also has distinctly higher affinity to sstr4/sstr5 than Ga−NODAGATOC. A remarkably low IC_{50} value was found for sstr5, and no binding affinity was found to sstr1.

Stability of the Radiotracers. Our studies had demonstrated that with both radiolabeled peptides no radiolysis breakdown products were observed and that there is no appreciable release of ^{67}Ga even under extreme conditions (10^5 times excess of DTPA). The pseudo first-order dissociation rate constant for [^{67}Ga]−NODAGATOC was shown to be $<10^{-8}$ s^{-1} compared to 3.5×10^{-6} s^{-1} for [^{111}In]−NODAGATOC.

Stability in Serum. Incubation of [^{67}Ga]−NODAGATOC in fresh human serum shows high metabolic stability as well as high stability with regard to transchelation. At 4 h, 98.3% of the activity remained in the nonproteic fraction. We found also, by HPLC, that the radioactivity present in this fraction, after 4 h of incubation, was still peptide bound and represents intact radioligand indicating that no transchelation or appreciable metabolic decay did take place.

Stability in Rat Liver Homogenate. The possible degradation of [^{67}Ga]−NODAGA-Tyr^3-octreotide was studied in 30% rat liver homogenate, a medium rich in peptidases and proteinases. The analysis was carried out by HPLC and until 4 h of incubation no degradation products were observed.

[^{67}Ga]/[^{111}In]−NODAGATOC Internalization and Externalization Results. The AR4-2J rat pancreatic carcinoma cell line is known to express sstr2 receptors both in vivo and in vitro (*28*). The two radioligands were internalized by AR4-2J cells in a time dependent way, as shown in Figure 2. Both radiopeptides showed a fast and time dependent cell uptake by endocytosis which did not reach a plateau within 4 h of incubation at 37 °C. There was no difference between the two radioligands. Both show about 18% (of the added activity) specific internalization after 2 h compared to only about 6% of [^{111}In]−DOTATOC (Figure 3). Internalization was strongly reduced in the presence of 0.1 μM unlabeled octreotide

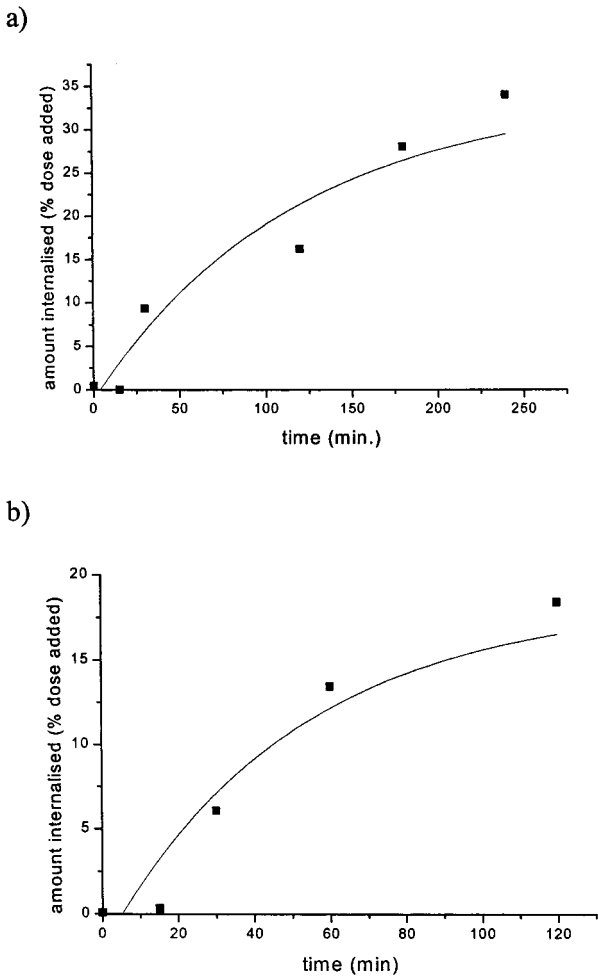

Figure 2. Uptake kinetics on rat pancreatic tumor AR4-2J cells of (a) [^{111}In]−NODAGA-Tyr^3-octreotide and (b) [^{67}Ga]−NODAGA-Tyr^3-octreotide. Data result from two independent experiments with triplicates in each experiment.

(data not shown). In fact, nonspecific internalization was <3% of the added activity. The surface bound peptide (acid removable) was <7% of the added activity. The externalization of both peptides was studied with cells exposed 2 and/or 4 h to the radioligand as described for internalization (Figure 4). Again a time dependent externalization was found which appears to depend somewhat on the time period cells were allowed to internalize as well as on the radioligand studied. Interestingly, the externalized radiopeptides were shown to be intact by HPLC as they coelute with the original radiopeptides.

Animal Biodistribution Studies. Biodistribution data were obtained by comparing [^{67}Ga]−NODAGATOC with our gold standard for sstr2 receptor targeting [^{111}In]−DOTATOC. The biodistribution of the latter was

[a] Blocked with 50 μg of octreotide 30 min before injection of radiopeptide. [b] Unblocked.

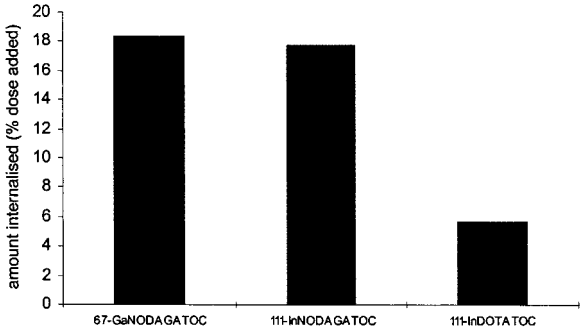

Figure 3. Uptake on rat pancreatic tumor AR4-2J cells of [^{67}-Ga]−NODAGA-Tyr^3-octreotide, [^{111}In]−NODAGA-Tyr^3-octreotide, and [^{111}In]−DOTA-Tyr^3-octreotide, 2 h after incubation with ca. 0.09 μCi of the radiolabeled peptides in a 37 °C, 5% CO_2 environment.

reported before (*11*, *25*, *26*, *28*) and was used as a reference because a new batch of AR4-2J cells was used. Data obtained with nude mice bearing the AR4-2J pancreatic tumor are presented in Table 3 as % of injected dose per gram of tissue (% ID/g) as a function of time.

Both peptides displayed rapid blood clearance with only 0.05−0.07% ID/g remaining in blood at 4 h which can be associated with a fast elimination of radioactivity from the sstr-negative tissues not involved in the excretion process. In accordance with previous results (*28*) using [^{111}In]−DOTATOC and [^{67}Ga]−DOTATOC, [^{67}Ga]−NODAGATOC is excreted mainly by the kidney pathway, leading to very low liver uptake. Moreover, our HPLC studies in mouse urine demonstrated that the [^{67}Ga]−NODAGATOC is excreted unchanged in the first 4 h after radiotracer injection. [^{67}Ga]−NODAGATOC shows high uptake values in sst receptor expressing organs such as adrenals, pancreas, and stomach, and in the AR4-2J tumor. In addition, a very rapid clearance from all other organs and tissues except the kidneys was found. The results of an in vivo competition experiment using large excess of octreotide preinjected iv resulted in a >83% reduction of tumor uptake and also in a reduction of the uptake in the sstr-positive organs (80% in pancreas, 82% in stomach, 76% in adrenals). The injection of the blocking dose had no significant influence on the uptake in nontarget organs except the kidneys where the uptake is increased by a factor of >2.

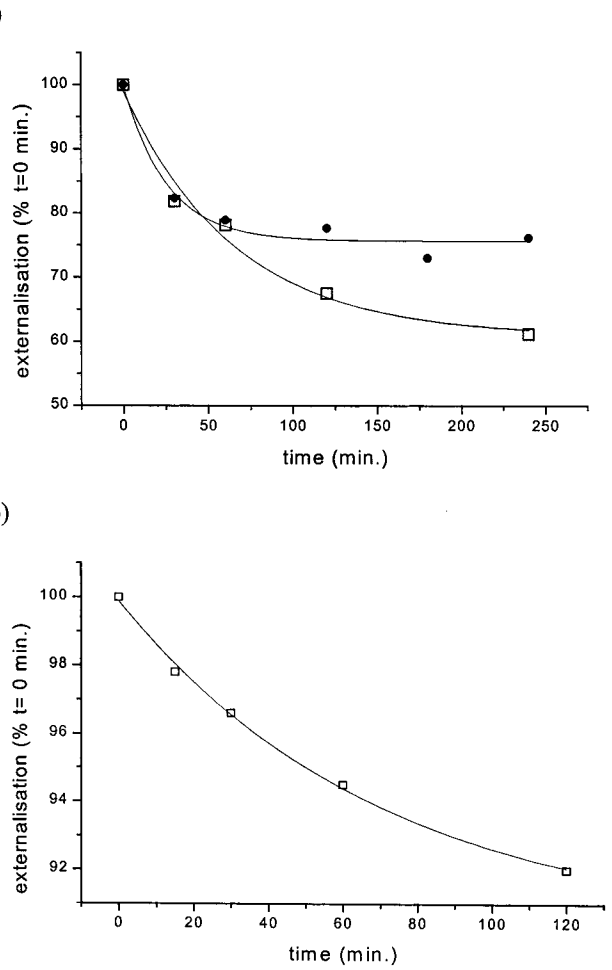

Figure 4. Externalization kinetics of (a) [^{111}In]−NODAGA-Tyr^3-octreotide and (b) [^{67}Ga]−NODAGA-Tyr^3-octreotide, by rat pancreatic AR4-2J tumor cells. Efflux of the radiolabeled peptides is expressed in percentage of radioactivity associated with the cells after acid wash retained in the cell compared with the uptake at 2 h (squares) or 4 h (circles) considered as 100%. After this period, the cells were exposed to an acid wash to remove cell surface bound radioligand. Each point represents two experiments carried out in triplicate.

[^{67}Ga]−NODAGATOC has a higher uptake in all sstr-positive tissues than [^{111}In]−DOTATOC at 4 h (tumor, 21.2 ± 3.5% ID/g vs 12.5 ± 0.65%; pancreas, 1.25 ± 0.67%

ID/g vs 1.1 ± 0.25; stomach, 4.8 ± 0.67% ID/g vs 2.77 ± 0.75% ID/g; adrenals, 2.9 ± 0.43% ID/g vs 1.46 ± 0.35% ID/g). A further remarkable result of the new radiopeptide is the very favorable tumor:kidney ratio which is 3.0 at 4 h compared to 1 for ^{111}In−DOTATOC, the ratio even increases at 24 h to 5.7 whereas it remains 1 at 24 h for ^{111}In−DOTATOC. Additional tumor/unspecific tissue ratios at 4 h can be seen from Table 3. They are as follows (in parentheses the data for ^{111}In−DOTATOC are given): 424 (188) for tumor/blood and 133 (54) for tumor/liver. These very favorable ratios indicate the high potential of this radiopeptide for early time point, highly sensitive diagnostic tumor imaging. An unexpected result is the relatively quick washout from the tumor and receptor-positive organs. In the tumor, the dose dropped from 21.2% ID/g at 4 h to 2.6% ID/g at 24 h and 0.73% ID/g at 48 h. A similar rate of decline is found in the other receptor-positive organs. Somewhat fortunately, this decline is even faster in the kidneys. The residence time of ^{111}In−DOTATOC is distinctly longer in receptor-positive tissues but also in the kidneys.

DISCUSSION

In the past few years several SRIF-derived positron-emitting radiopeptides have been developed (*12, 13, 29*−*32*), and some of them had been or are currently being investigated for PET imaging of SRIF receptor-positive tumors in patients (*33*−*35*). An ideal PET tracer will allow to answer many important questions in the new and rising field of tumor targeting with use of radiopeptides, e.g., receptor regulation due to pharmacologic and chemotherapeutic intervention, receptor quantification and potential receptor downregulation due to receptor mediated radiopeptide therapy. The radiopeptides discussed in this manuscript were designed to answer questions arising from earlier developments in our laboratory and to offer new conjugates for studies with the Ga^{III}, In^{III}, and Cu^{II} (*36*) radioisotopes. The macrocyclic chelator NOTA satisfies the coordination requirements of the respective metal ions in the indicated oxidation states. The NODAGATOC differs from our gold standard DOTA−[Tyr^3]-octreotide (DOTATOC) by the coupling of a new macrocyclic chelator to [tyr^3]-octreotide. We synthesized first a new bifunctional derivative of NOTA which had to fulfill two criteria:

(1) Compatibility with peptide synthesis; in other words, an orthogonally carboxylic acid group protected NOTA derivative has to be synthesized which upon specific deprotection of one carboxylic acid group is soluble in the common solvens used in solid-phase synthesis and may be used as an amino acid surrogate for coupling to the N-terminus of a requested peptide. (2) In addition, three acetate arms should be retained for metal coordination necessitating preparation of a C-functionalized NOTA. Different syntheses of bifunctional NOTA derivatives have been reported before by Parker et al. (overall yield: 7.7%) (*37*), Meares and Studer (yield: 1.34%) (*38*), and McMurray et al. (yield: 6.4%) (*36*). Their syntheses used intra- or intermolecular cyclization strategy as key steps affording NOTA's functionalized on a carbon of the macrocyclic ring. They were not designed for coupling to peptides, and harsh conditions for deprotection and reduction were necessary. Our aim was to introduce the carboxy function for coupling on the methylene group of a carboxymethyl arm, allowing one to start with commercially available triaazacyclononane, thus avoiding a cyclization step. A similar strategy was used by Brechbiel et al. (*39*) to yield a bifunctional NOTA for antibody modification in 9% overall yield. In addition, this strategy was used in the functionalization of DOTA (*21, 40*−*41*). The key steps are the synthesis of an orthogonally protected bromoalkyl dicarboxylic acid diester and the monoalkylation of the triazacyclononane macrocycle. The latter step was performed using 3 equiv of 1,4,7-triazacyclononane over the alkylating diester to give **3** (69.2%). **5** was obtained in 90% yield using somewhat less than 2 equiv of bromoacetic acid *tert*-butyl ester to avoid overalkylation. The overall yield of the five steps was about 21%. The coupling of **6** to the linear octapeptide (appropriately protected) assembled on the TCP-resin was straightforward. The cleavage was followed by oxidative cyclization using I_2 and deprotection in a mixture of TFA/phenol/thioanisole/water. The crude mixture was purified by preparative HPLC.

We have proposed earlier the use of a similar bifunctional chelator (NODASA = 1,4,7-triazacyclononane-1-succinic acid-4,7-diacetic acid) and the use of the radiogallium complex in a prelabeling approach (*42*). Although this approach is very attractive and was proven to work well with model peptides and with the nonradioactive Ga^{III}, it proved not to be practical for larger amounts of radioactivity because of relatively low coupling yields of [^{67}Ga]−NODASA to the peptide due to low solubility. This caused a large waste of radioactivity. The coupling of the present prochelator works well under peptide synthesis conditions and allows the preparation of a kit-formulated version of the conjugate.

Receptor Binding Studies. One of the aims of this study was to probe the hypothesis that the higher sstr2 affinity of [Ga^{III}]−DOTA-Tyr^3-octreotide vs [Y^{III}]−DOTA-Tyr^3-octreotide and [In^{III}]−DOTA-Tyr^3-octreotide can be explained by the different metal complex geometries of the respective metal DOTA-D-Phe coordination compounds which result in a spacer function between the Ga^{III} complex and the pharmacophoric peptide. This is due to the fact that the carboxyamido group connecting the two entities is not participating in the metal coordination contrary to the octadentate nature of the chelate unit in [Y^{III}]−DOTA-D-Phe. If this were true, [Ga^{III}]−NODAGATOC should have a receptor affinity closer to Ga^{III}−DOTATOC than [Y^{III}(In^{III})]DOTATOC. Indeed, we interpret the value of 3.5 ± 1.6 nM, which is very close to the value of [Ga^{III}]−DOTATOC, as originating from the structurally introduced ethylene spacer function. It is remarkable and not foreseen that [In^{III}]−NODAGATOC shows significant differences compared to [Ga^{III}]−NODAGATOC not only with regard to the sstr2 affinity which with 1.7 ± 0.2 nM is significantly higher than the one of [Ga^{III}]−NODAGATOC. Also, the affinity to sst4 and sst5 is significantly higher for the [In^{III}]−NODAGATOC vs [Ga^{III}]−NODAGATOC. The structural factors contributing to this difference are not clear. Both metals fit well into the cavity offered by NOTA. X-ray structural data point at potential differences. Whereas In^{III} (ionic radius = 0.80 Å, CN6; 0.92 Å, CN8) (*43*) prefers coordination number 7 or 8, the smaller Ga^{III} (ionic radius = 0.62 Å) is perfectly satisfied by hexadentate ligands and fits well into the cavity offered by NOTA and functionalized derivatives of it (*42, 44*). In this context, it is interesting to note that in the solid-state In^{III}−NOTA is crystallizing with one Cl^- ion in a pentagonal bipyramidal coordination environment (*44*). We propose as a possible explanation of the above-mentioned affinity differences that in the biological fluids used in our assays either Cl^- or H_2O are being coordinated to In^{III}.

Stability of Tracers. [^{67}Ga]−NODAGATOC and [^{111}In]−NODAGATOC proved to be more or less stable

with regard to radiometal transfer. The ^{67}Ga-labeled peptide is $>10^3$ times more stable than [^{111}In]−NODAGATOC which correlates well with the thermodynamic stability of most of the triaza complexes of these two metals (e.g., log *K* (GaNOTA) = 30.98, log *K* (InNOTA) = 25.9 (*45*). Also, the metabolic stability is very high in fresh human serum and surprisingly in a rat liver homogenate (data not shown).

Cell Uptake and Release. The internalization and release of the two new radiopeptides was studied in the AR4-2J cell line known to express sstr2 receptors (*28*). The cell uptake at 4 h was the same for both radiopeptides but was a factor of 3 higher than for [^{111}In]−DOTATOC at 2 h (18% vs about 6%). The fast internalization indicates that—according to the current knowledge that only agonistic drugs can internalize (*46*)—[^{67}Ga]− and [^{111}In]−NODAGATOC are both powerful agonists for sstr2 and parallel the improved binding affinity of the two radiopeptides over [^{111}In]−DOTATOC. Internalization was inhibited by the addition of excess octreotide. In the time interval of the study (30 min to 4 h) no steady state was reached yet but the distinct leveling-off indicates the close approach to it which can be explained with the beginning efflux.

If the cells upon internalization of the radioligand for 2 and/or 4 h were exposed to the culture medium, again a time-dependent efflux of the radiopeptides could be observed, indicating a rapid recycling of the radiopeptides to the extracellular medium. A steady state is reached already after 2−4 h of release studies. This is due to the reactivation of the receptor by the released radiopeptide which was shown to be intact by HPLC as it coelutes with the original radiopeptides. It appears that already 25−40% of the externalized agonist are enough to stimulate the receptor to undergo reendocytosis. At steady state, about 60−75% of the radioactivity are located inside the cell and can be routed to lysosomes for degradation. The finding that the amount of externalized radiopeptide and the earlier reaching of a steady state appear to depend on the time internalization was allowed (Figure 3) indicates that this mechanism may be valid. On the other hand, it may just reflect that the steady state is reached earlier because the absolute value of 4 h internalization is higher than the one of 2 h internalization. A distinction between the two possibilities can only be made after careful structural analysis of the peptide contained inside the cells. The interpretation above is in keeping with the conclusion of data obtained by Koenig et al. (*47*), using ^{125}I-labeled somatostatin analogues in sstr2-expressing CHO cells.

Biodistribution Studies. The biodistribution studies in AR4-2J-tumor bearing (sstr2-positive) nude mice showed a higher uptake of [^{67}Ga]−NODAGATOC in sstr-bearing organs and the tumor compared to [^{111}In]−DOTATOC by up to a factor of 2 at 4 h postinjection paralleling the higher binding affinity and higher rate of internalization. Compared to [^{67}Ga]−DOTATOC (data published earlier) the new tracer shows almost the same performance, i.e., a somewhat lower tumor uptake but a higher tumor-to-blood, tumor-to-liver, tumor-to-heart, and a comparable tumor-to-kidney ratio.

In addition, using the same animal model it is far superior to ^{111}In-DTPA-octreotide which showed only 3.03% ± 0.26% ID/g in the tumor at 4 h and an inferior tumor-to-normal organ ratio, e.g. tumor/blood = 7.6, tumor/liver = 4 at the same time point (*28*).

Unforeseen is the fast washout (short residence time) of the tumor and sstr2-positive organs. It is faster compared to other somatostatin-based radiopeptides studied in this laboratory. The approximate biological half-life in the tumor is 7 h. The reason for this is not known yet. Our original hypothesis that it is due to metabolic instability of the exposed peptide bond between NODAGA and D-Phe due to the coupling via the carboxy ethyl spacer compared to the DOTA monoamide coupled peptides was not confirmed by studies with liver homogenate and fresh serum. In the latter cases a protection of the same bond is accomplished due to the fact that the amidocarboxy oxygen is involved in the coordination to the metal. The short tumor retention time resembles somewhat the behavior of most of the [^{64}Cu]−TETA−SRIF analogues discussed by Lewis et al. (*48*). Also, as discussed above, internalization and release studies do not give any clue as to the reason for the fast washout.

In conclusion, NODAGATOC most likely is a peptide−chelator conjugate with very promising properties for human studies if labeled with the short-lived positron emitters ^{68}Ga and ^{66}Ga. Because of the relatively fast washout from tumors, its suitability for a potential therapeutic application with the Auger electron emitter ^{67}Ga has to be shown in other animal models and in patients.

In addition, we developed a new chelator−somatostatin analogue for selective tumor targeting which is also suitable for ^{111}In and because of favorable complex stability most likely for ^{64}Cu and ^{55}Co labeling and their use in the targeting of sstr2-positive tumors in patients.

ACKNOWLEDGMENT

We wish to thank the Swiss National Science Foundation (31-52969.97) and Mallinckrodt Med. for financial support of this work and Novartis for analytical support. M.I.M. Prata acknowledges a grant from Fundaçao Calouste Gulbenkian (Portugal). We are grateful to the group of Prof. Krähenbühl for support with the rat liver homogenate experiment.

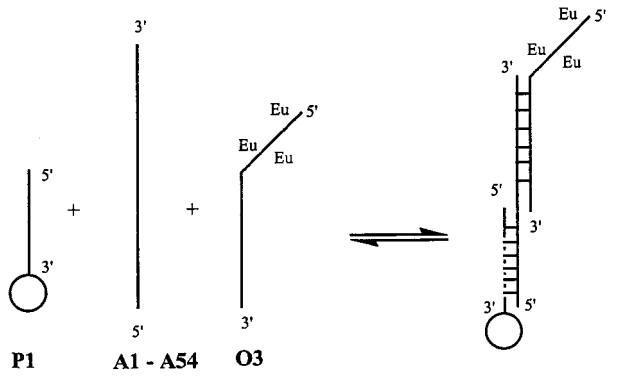
Mixed-Phase Hybridization of Short Oligodeoxyribonucleotides on Microscopic Polymer Particles: Effect of One-Base Mismatches on Duplex Stability

Kaisa Ketomäki, Harri Hakala,† and Harri Lönnberg*

Department of Chemistry, University of Turku, FIN-20014 Turku, Finland. Received September 5, 2001; Revised Manuscript Received December 27, 2001

Hybridization of short oligonucleotides (10- and 11-mers) to complementary probes immobilized to microscopic polymer particles was quantified by a sandwich type mixed-phase hybridization assay based on a time-resolved fluorometric measurement of a photoluminescent europium(III) chelate from the surface of a single particle. Among the 54 sequences that were studied, 21 were fully complementary to the particle-bound probes, while 33 contained an internal one-base mismatch. The observed affinities were compared to those predicted by the nearest-neighbor model. In addition, various factors, such as the pore size of the particle, the linker structure, the charge type of the probe, and the efficiency of agitation, that might be expected to affect the kinetics of mixed-phase hybridization have been examined.



INTRODUCTION

We have recently described a mixed-phase hybridization assay that is based on the use of a mixture of categorized polymer microparticles as the solid phase (*1*). The method allows simultaneous screening of several potential base mutations or deletions from a single PCR-amplified sample, and it hence offers an alternative for the widely used oligonucleotide microarrays (*2*−*6*). Each particle bears, in addition to a given oligonucleotide probe, prompt fluorophores that allow recognition of the particle category when the particles after hybridization are subjected one by one to the fluorescence measurement. The hybridization is, in turn, quantified by time-resolved fluorometry. On application of a sandwich type protocol, the PCR-amplified oligonucleotide forms first in solution a duplex with an appropriately designed oligonucleotide probe labeled with a photoluminescent lanthanide chelate, and hybridizes then with the particle-bound probe (Scheme 1). The lanthanide ion emission is measured directly from a single particle after complete quenching of the emission of the prompt fluorophores (*7*). The photoluminescent lanthanide chelates exhibit as markers one major advantage over organic dyes; the Stokes shift, i.e., the difference between the wavelengths of emission and excitation, is large, and hence, the concentration quenching is negligible. Accordingly, the intensity of the emission signal measured from an individual particle is strictly linearly related to the number of chelates on the particle over 5−6 orders of magnitude (*8*−*10*). For this reason, the method suits quantitative analysis of the concentration of oligonucleotides in the sample exceptionally well (*1*).

All mixed-phase hybridization assays, using either microarrays or categorized microparticles, are eventually based on the dependence of the stability of solid-supported duplexes on the sequence. It has been well established (*11*−*17*) that the stability of oligodeoxyribonucleotide duplexes in aqueous salt solutions may be rather reliably predicted by applying the so-called nearest-neighbor model for helix propagation. The same approach has more recently been used to determine the nearest-neighbor parameters for all possible internal point mismatches (*16*, *18*−*21*). Since the applicability of a mixed-phase hybridization assay is largely determined by the selectivity of hybridization, it is important to know how well the nearest-neighbor parameters referring to hybridization in solution may be used to predict the affinity for particle-bound probes.

We have shown previously (*1*, *8*) that the microparticle approach described above allows, at least in favorable cases, unequivocal detection of a point mutation or deletion, provided that the length of the complementary region is carefully optimized. For example, a single AG or CT mismatch in the middle of a 12-mer complementary sequence has been shown to decrease the affinity for the particle-bound probe by 2 orders of magnitude (*8*). Deletion of a single internal A or C has also been shown to retard the hybridization of a 12−14-mer probe by up to 2 orders of magnitude, although the destabilization

Published on Web 03/28/2002

appears to be rather sequence dependent (*1*, *8*). It is, however, known that all base mismatches are not as strongly destabilizing in solution. In fact, the so-called linearly independent nearest-neighbor $\Delta G°$ parameters for dimeric 5′-NX-3′ fragments, where X stands for a mismatched nucleoside, range from −1.1 to 1.3 kcal/mol (*16*, *18*−*21*), while those for the corresponding fully Watson−Crick bonded fragments fall between −2.2 and −0.6 kcal/mol (*17*). To find out how much various internal one-base mismatches in various molecular environments decrease the affinity of oligonucleotides for particle-bound probes, 21 fully complementary short oligonucleotides (10- and 11-mers) and 33 oligonucleotides having one internal point mismatch have been subjected to the sandwich type mixed-phase hybridization assay described in Scheme 1. The observed affinities are compared to those predicted by the nearest-neighbor model. In addition to these equilibrium studies, various factors, such as the pore size of the particle, the linker structure, the charge type of the probe, and the efficiency of agitation, that might be expected to affect the kinetics of mixed-phase hybridization have been examined.

EXPERIMENTAL PROCEDURES

Preparation of Oligonucleotide-Coated Microparticles. The polymer particles used to immobilize the oligonucleotide probes were the products of SINTEF. They were made of a copolymer of glycidyl methacrylate (40%) and ethylene dimethylacrylate (60%), and functionalized with primary amino groups (1 mmol/g) obtained by reacting the particle-bound epoxy groups with diethylenetriamine. The particles were uniformly sized, having a diameter of either 50 (**P1**) or 59 μm (**P2**). The smaller particles (**P1**) had an average pore size of 30 nm, a total pore volume of 0.822 mL/g, and a surface area of 137 m^2/g, and the larger ones (**P2**) had a pore size of 50 nm, a total pore volume of 1.469 mL/g, and a surface area of 92 m^2/g. A desired proportion (10−30 μmol/g, i.e., 1−3%) of the amino groups of **P1** and **P2** was acylated with (4,4′-dimethoxytrityloxy)acetic acid, and the rest of the groups were carefully capped by repeated acetylations (*22*). The oligonucleotide probes were assembled on these supports via a normal phosphoramidite strategy, as described previously (*10*) in detail.

Oligonucleotides and Their Fluorescently Tagged Conjugates. Oligonucleotides were assembled via a normal phosphoramidite strategy and purified by ion-exchange HPLC. Preparation of the fluorescently tagged oligonucleotides, **O1**−**O3**, has been described previously (*8*, *9*).

Hybridization Assays. The hybridization assays in kinetic measurements were carried out by shaking 50 particles (**P1** or **P2**) in 10 μL of Tris buffer (50 mM, pH 7.5, containing 0.5 M NaCl and 0.01% Tween 20) that contained **O1** at a concentration of 17 nmol/L (*9*). The reaction temperature was 25 °C, and aliquots were withdrawn from 15 min to 24 h. The particles were thoroughly washed, and a single particle was subjected to a time-resolved fluorescence measurement (*7*).

The sandwich type hybridization assays used to study the dependence of the duplex stability on sequence were carried out by shaking 50 particles (**P1**) in 10 μL of the Tris buffer described above. The concentration of both the target oligonucleotide (**A1**−**A54**) and the fluorescently tagged oligonucleotide (**O3**) was 17 nmol/L. The reaction temperature was 25 °C and the reaction time 24 h. The particles were washed, and the fluorescence emission was quantified by the single-particle technique (*7*). Typically, 10 individual particles were measured, the standard deviation ranging from 5 to 20%.

Calibration. To convert the fluorescence emission measured from a single particle to the number of fluorescently tagged oligomers attached to this particle, two sets of particles **P1a** were subjected to hybridization with tagged oligomer **O1** or **O3**, the initial concentration of which was varied from 5.1 to 51 nmol/L. After incubation for 20 h, one set of the particles was subjected to fluorescence measurement by the single-particle technique (*7*), while from the other set, europium(III) ion was released to solution and quantified according to the DELFIA protocol (*25*). Additionally, the concentration of **O1** or **O3** in solution before and after the hybridization was determined by the DELFIA protocol. The calibration line was measured separately for every particle that was employed.

RESULTS AND DISCUSSION

Preparation of Oligonucleotide-Coated Microparticles and Characterization of Their Hybridization Properties. Two different types of uniformly sized porous particles made of a copolymer of glycidyl methacrylate (40%) and ethylene dimethylacrylate (60%) and functionalized with amino groups were used as the solid support in the mixed-phase hybridization assays. Usually, 50 μm particles (**P1**) having an average pore size of 30 nm and a surface area of 137 m^2/g were employed. However, slightly larger (59 μm) particles (**P2**) having a larger pore size (50 nm) and a smaller surface area (92 m^2/g) were also used for comparative purposes.

To allow the assembly of oligonucleotides on the particles according to the normal phosphoramidite protocol, a desired proportion of the amino functions was acylated with (4,4′-dimethoxytrityloxy)acetic acid (DMTrOCH$_2$COOH), while the rest were carefully capped by repeated acetylations (*22*). The level of *N*-(DMTrOCH$_2$CO) loading of the particles, when determined by the DMTr cation assay (*23*), ranged from 12 to 28 μmol/g. The oligonucleotide chains were then assembled on the deprotected hydroxy function. The amide linker that was employed turned out to be entirely resistant to deprotection of the base moieties by ammonolysis. We have previously shown that oligonucleotide synthesis on similar polymer particles gives full-length 16-mer sequences in an only 30% yield, the rest of the sequences being truncated (*10*). Despite this heterogeneity of the oligonucleotide probe, the hybridization efficiency and selectivity of such particles have been demonstrated to be comparable to those obtained by postsynthetic immobilization by purified fully homogeneous probes (*10*).

A fluorescently tagged 42-mer oligodeoxyribonucleotide, 5′-d(**CTATATTCATCATAGG**AAACACCAAAGATGATAATTX$_5$C)-3′ (**O1**), was used to elucidate the hybridization properties of the oligonucleotide-coated particles. Here, X stands for N^4-(6-aminohexyl)-2′-deoxycytidine tethered to a photoluminescent europium(III) chelate, {2,2′,2″,2‴-[(4′-{4‴-[(4,6-dichloro-1,3,5-triazin-2-yl)amino]phenyl}-2,2′:6′,2″-terpyridine-6,6″-diyl)bis(methylenenitrilo)]}tetrakis(acetato)europium(III) (*24*). The sequence complementary to the particle-bound 16-mer is indicated in bold. The kinetics of the binding of **O1** to the particles was followed by shaking 50 particles in 10 μL of Tris buffer (50 mM, pH 7.5, containing 0.5 M NaCl and 0.01% Tween 20) that contained **O1** at a concentration of 17 nmol/L at 25 °C. The particles were thoroughly washed, and a single particle was subjected to a time-resolved fluorescence measurement (*7*). To

Table 1. Effect of the Oligo(T) Linker on the Efficiency and Kinetics of the Hybridization of the Fluorescently Tagged Oligonucleotide (O1) to a Complementary Oligonucleotide Probe Assembled on Microparticles P1 and P2

[a] The half-life for hybridization at 25 °C. [b] The abbreviation [oligo] stands for the common hybridizing sequence 3′-d(GATATAAGTAGTATCC)-5′. [c] A methylphosphonate oligodeoxyribonucleotide. [d] A2′-*O*-Methylribonucleotide oligomer.

estimate the contribution of unspecific adsorption of the labeled oligomer to the particles, a comparative study with a noncomplementary fluorescently tagged 32-mer, 5′-d(X_{20}ATCATCTTTGGT)-3′ (**O2**), was carried out. Consistent with previous results (*8*−*10*), the unspecific binding was in all cases almost negligible; less than 1% of the **O2** was attached to the particles. The fluorescence emission of a single particle was converted to the number of fluorescently tagged oligomers (**O1**) attached to the particle with the aid of a calibration line, which was obtained by plotting the emission intensities measured from a single particle against the amount of europium(III) released to solution and quantified by the DELFIA protocol (*25*). The amount of europium(III) in solution before and after the hybridization, i.e., the concentration of **O1**, was determined similarly. The decrease in the concentration of **O1** upon hybridization always agreed with the amount of europium(III) released from the particles after hybridization, which lent considerable support to the reliability of the determination. The calibration line that was obtained was essentially similar to that reported earlier for a closely related system (*8*).

We have shown previously that the mixed-phase hybridization assays described above suffer from one major shortcoming, viz., slow binding of oligonucleotides from the solution phase to the particle-bound probes (*8*−*10*). On using five particles per 1 μL sample, the half-life of the equilibration is on the order of hours at 25 °C. The half-life is inversely proportional to the number of particles in a unit volume of the sample, and the process may hence simply be accelerated by using more particles (*9*). This, however, leads to decreased sensitivity; the analyte is distributed among a larger number of particles, and the emission from an individual particle is reduced. Accordingly, faster kinetics of hybridization is highly desirable.

One might a priori assume that insertion of a long hydrophilic spacer between the hybridizing oligonucleotide sequence and the solid support accelerates the hybridization. To test this assumption, oligonucleotide probes consisting of a 16-nucleotide 5′-terminal hybridizing sequence, 3′-d(GATATAAGTAGTATCC)-5′, and a 3−100-nucleotide 3′-terminal oligo(T) spacer were assembled on **P1** and **P2**. Unfortunately, introduction of such a spacer did not result in the desired acceleration. As seen from Table 1, the kinetics was not markedly affected either by the length of the spacer or by the pore size of the particle. Within the limits of experimental errors, the half-life remained constant (7 h) with both particles. In contrast, the hybridization efficiency, i.e., the mole fraction of **O1** bound to the particle, seemed to be moderately affected by these factors. With porous particles **P2**, having a large pore size (50 nm), the hybridization efficiency (60%) did not depend on the length of the spacer, but with particles **P1** having smaller pores (30 nm), the efficiency was decreased to less than half of the original value when the spacer was longer than 30 nucleotide units.

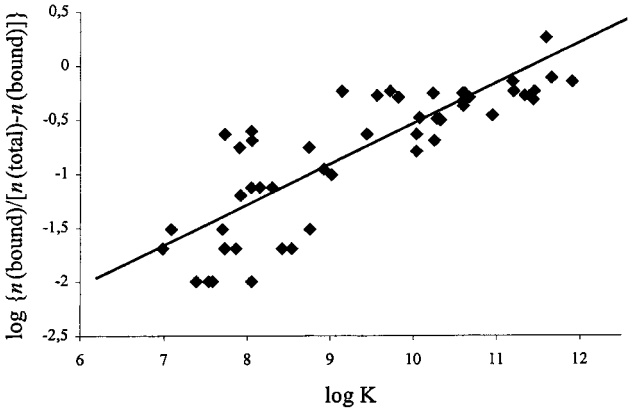

Figure 1. Logarithmic equilibrium constants, log{*n*(bound)/[*n*(total) − *n*(bound)]}, for the binding of oligonucleotides **A1**−**A54** to their complementary particle-bound probes (see Table 2) plotted vs the logarithmic stability constants of the respective duplexes in solution.

Addition of a detergent to the hybridization buffer also had some effect on the efficiency but not on the kinetics of hybridization. In the presence of 0.01% Tween 20, the hybridization efficiency was slightly increased, when the concentration of the target oligonucleotide was low. At high concentrations, the influence remained negligible.

The chemical nature of the support-bound probe did not have any effect on the hybridization kinetics. In addition to oligodeoxyribonucleotide probes, deoxyribonucleotide methylphosphonate and 2′-*O*-methylribonucleotide oligomers were assembled on particles **P1**, and their ability to bind **O1** was studied. The methylphosphonate probes exhibited a markedly reduced hybridization efficiency (5%) compared to the unmodified deoxynucleotide probes (60%), while the 2′-*O*-methylribonucleotide oligomers exhibited a slightly enhanced affinity for **O1**. Unfortunately, no positive effect on the hybridization kinetics could be observed in either case.

The only factor that, in addition to the number of particles in a unit volume, had any influence on the hybridization kinetics was the efficiency of agitation. When the solution of **O1** containing five particles (**P1**) in 1 μL was mixed by rotating a sealed tube at a rate of 20 rpm, the half-life of hybridization was ∼7 h at 25 °C. Ultrasonic mixing reduced the half-life to ∼3 h and efficient agitation with a planar shaker (Vortex) to ∼1 h (data not shown). This observation, together with the fact that the hybridization is accelerated with the increasing number of particles in the sample, strongly suggests that the rate of hybridization is limited by the diffusion of the oligonucleotide in solution, and not by the binding event itself.

Dehybridization of **O1** from support **P1g**, bearing a 14-mer sequence complementary to **O1**, was also studied. At 25 °C, the half-life for the release of **O1** from **P1g** was ∼15 h. Accordingly, the particles may well be rapidly washed without any loss of the hybridized oligonucleotide. However, at 40 °C, the dehybridization was surprisingly fast, the half-life being <1 h.

Table 2. Hybridization Efficiencies, *n*(bound)/*n*(total), of Oligonucleotides (A1−A54) with Their Solid-Supported (P1) Complementary Probes at 25 °C (pH 7.5; $I = 0.5$ M with NaCl)[a]

[a] Refers to equilibration of 50 particles with 10 μL of a 17 nmol/L solution of **A1**−**A54**. [b] The abbreviation [oligo] stands for the sequence 5′-GT*ACACCAAAGATGATA*TT-3′, in which the italic nucleotides were used to bind the fluorescently tagged oligonucleotide **O3**. [c] The sequence engaged in duplex formation indicated in bold. [d] The Gibbs free energies of duplex formation calculated from the nearest-neighbor parameters reported in the literature (*16*−*21*). [e] The mismatched base underlined.

Relationship between the Sequence and Duplex Stability in Mixed-Phase Hybridizations. The binding of 54 oligonucleotides having a 10- or 11-nucleotide 5′-terminal region complementary to the solid-supported probe was quantified by the sandwich type assay depicted in Scheme 1. Among these oligonucleotides, 21 (**A1**−**A21**) were fully complementary to the support-bound probe over this 10−11-nucleotide sequence, while the remaining 35 (**A22**−**A54**) contained one internal point mismatch. Each of these oligonucleotides contained in its 3′-terminus the same 16-nucleotide sequence used to bind a fluorescently tagged probe, 5′-d(CX_5ATATCATCTTTGG-TGT)-3′ (**O3**). The complementarity over 16 nucleotides is sufficient to warrant virtually quantitative duplex

[a] Given as *n*(bound)/*n*(total) for the mutated sequence compared to the corresponding value for the fully complementary sequence. The values in parentheses are the changes in $\Delta G°$ in kilocalories per mole expected on the basis of the nearest-neighbor parameters referring to aqueous salt solutions. [b] Taken from ref *8*.

formation between **O3** and the target oligonucleotide (**A1**−**A54**) (*8*). Table 2 lists all the sequences that were employed. The table also records the hybridization efficiencies, *n*(bound)/*n*(total), obtained by equilibrating 50 particles with 10 μL of 17 nmol/L oligonucleotide (**A1**−**A54**) solution. In Figure 1, the logarithmic distribution coefficients, log{*n*(bound)/[*n*(total) − *n*(bound)]}, are plotted against the logarithmic equilibrium constant of the duplex formation in aqueous salt solution. The latter values have been calculated from the Gibbs free energies of duplex formation obtained in an additive manner from the linearly independent nearest-neighbor $\Delta G°$ parameters reported for the formation of fully complementary duplexes (*16*) and point-mutated (*16*, *18*−*21*) sequences in solution phase. While these two quantities expectedly correlate, the individual points are vastly scattered, the correlation coefficient being only 0.7. In other words, the nearest-neighbor parameters referring to aqueous salt solutions allow only a rough estimation of the affinity for particle-bound probes. The slope of the correlation line in Figure 1 is 0.4 ± 0.1, which means that mixed-phase hybridization is less sensitive to the sequence than that in solution. When the equilibrium constant for the duplex formation in solution is decreased by 1 order of magnitude, the mixed-phase distribution coefficient is diminished by a factor of only 2.5.

Table 3 summarizes the effects of various one-base mismatches on the particle-supported duplex stability. The data suggest that a single-point mismatch reduces the hybridization efficiency by 1−2 orders of magnitude when present in the central part of a 10−12-mer complementary region. This appears to be the case at least with C·T, G·T, A·C, and A·G mismatches. As indicated in Table 3, the destabilization (change in $\Delta G°$) expected for these mismatches on the basis of the nearest-neighbor parameters ranges from 3.4 to 5.4 kcal/mol. This means that the equilibrium constant for duplex formation in solution may be expected to be decreased by a factor of 260−7000. Accordingly, the observed 14- to >100-fold diminution of the affinity for particle-bound probes is expected on the basis of the relationship shown in Figure 1; a 60−1800-fold drop in affinity is predicted by this relationship.

If the mutated base is in the penultimate position at the 3′-end, the nearest neighbors seem to play a more dominant role. An almost 100-fold decrease in the affinity is observed with base triplets that in solution destabilize the duplex by more than 5 kcal/mol: 5′-C**T**C-3′/3′-G**C**G-5′, 5′-C**A**C-3′/3′-G**C**G-5′, and 5′-C**C**C-3′/3′-G**C**G-5′. In cases where the destabilizing effect of the base triplet is on the order of 3 kcal/mol, the affinity is decreased by only ≤1 order of magnitude: 5′-C**A**C-3′/3′-G**G**G-5′ (8%), 5′-C**T**C-3′/3′-G**G**G-5′ (17%), and 5′-C**G**C-3′/3′-G**G**G-5′ (25%). Since the particle-bound probe is immobilized through its 3′-end, the mismatched base pair in the support-bound duplex is situated rather distant from the particle surface. In contrast, a mismatch at the penultimate site at the 5′-end of the target oligonucleotide in solution leads

to a support-bound duplex containing the mismatched base pair close to the particle surface. This appears to result in markedly reduced selectivity. All 5′-mutated oligonucleotides listed in Table 3 show only moderately reduced affinity compared to their fully complementary counterpart, and in some cases, the mismatch appears even to increase the affinity. This appears to be the case, in particular, when the 5′-terminal and the penultimate nucleotides of the fully complementary sequence are either A or T. Accordingly, when solid-supported oligonucleotide arrays or particle libraries are constructed and used to screen sequences in solution, one should bear in mind that the discriminating ability of the solid-supported probes may be markedly impaired at the end through which the probe is tethered to the support.

Received September 6, 2001; Revised Manuscript Received November 29, 2001

Polycation-based gene delivery agents are generally polydisperse populations whose properties are averaged among the different molecular weight species. Therefore, to understand the physicochemical properties of polycations and their relationships to cellular gene transfer, one needs to control the molecular weight of the polymer as well as its cationic charge density. To investigate the structure−function correlation of polycations with respect to the degree of polymerization (DP) and charge density, a series of model materials based on aliphatic ionenes was synthesized and fractionated into distinct molecular weight fractions with DP range from 14 to 32. The aliphatic ionene fractions and their polyelectrolyte complexes (PEC) with DNA were studied using physicochemical and biological methods. Ionene polymers were shown to possess low cytotoxicity (minimal viability of the P388D1 murine macrophage cells 80%). DP and charge density of the ionenes were shown to be the factors of effective control of PEC dissociation in water−salt solutions, with a diminished role of charge density upon lengthening the ionene chain. These polymer characteristics were also important for DNA−ionene PEC resistivity to DNase activity and the ability of ionenes to serve as gene delivery vectors in vitro and exhibited good correlation with the results of salt-induced dissociation of PEC. These data may be useful for developing correlations and mathematical models to predict synthetic gene delivery vector efficiency.

INTRODUCTION

With the advent of modern molecular biology and the potential to not only identify the genetic basis of disease, but also potentially treat diseases at the genetic level, came the promising field of gene therapy. However, while new targets for gene therapy are discovered at an extraordinary pace, the discovery of safe and effective gene delivery vehicles has lagged behind. Currently, there are approximately 400 gene therapy protocols in clinical trials worldwide (see http://www.wiley.co.uk/genetheraphy/clinical/coutries.html) and the success of these clinical trials is directly influenced by the efficiency of the delivery system.

The most effective vectors for transfection are those based on viruses and viral peptide sequences (*1*). However utilization of these agents is substantially hindered by immunologic issues. Therefore attempts are being made to create nonviral gene-delivery agents, such as liposomes and polycations (*1*). The latter effectively bind to negatively charged DNA, which results in substantial DNA compaction. Moreover, if the polyelectrolyte complex (PEC) has an overall positive charge it significantly increases the interaction of PEC with negatively charged cell membranes. Different groups have studied DNA−polycation interactions with respect to the delivery of DNA in vitro and in vivo. The structure of the polycation and its affinity to DNA has a substantial influence on transfection level (*1*−*3*).

While the field of gene transfer with polycationic agents is maturing, to date, general data reporting the correlation between macromolecular characteristics, such as degree of polymerization (DP) and charge density, on the transfection capacity of the polycation are unavailable in the literature. In fact, there is discrepancy in the literature regarding polymer structure and transfection capacity. Godbey et al. (*4*) studied transfection with complexes of DNA with polyethylenimine (PEI) and found that the level of reporter gene expression increases with increasing PEI molecular weight. Similar results were obtained by Wolfert et al. (*5*) for systems based on methacrylate-derived polycations. This was also true in the case of polymers with quaternary ammonium ions as positive moieties in the side chain, although the observed transfection levels were rather low (*5*). In contrast, Schaffer et al. (*6*) showed that the dependence of transfection efficiency as a function of polylysine DP has a maximum at DP ≈ 36. Other properties of polycations were also shown to be dependent on DP and charge density and sometimes contrast with the efficiency of transfection. For example cytotoxicity of polycations

increased with growing polymer charge density (*7*). Plank et al. (*8*) showed that activation of the complement system by synthetic DNA complexes is a potential barrier for gene delivery and that long chain polylysines are much stronger activators compared to short chain samples.

One approach to the design of better polycation-based vectors is to describe the steps of complexation in physicochemical terms. In other words there is a need for mathematical descriptions of the kinetics and thermodynamics of the vector pathway from administration to gene expression, and efforts have been made to create such models (*9*, *10*). However, to date, no model can fully predict the efficiency of a novel vector. Thus detailed studies of the connection between the physicochemical and biological properties of the DNA-containing PEC could be useful.

The goal of this study was to investigate the influence of DP and charge density of polymeric quaternary ammonium salts upon complexing with DNA and biological properties of PEC formed in order to correlate physicochemical features of the polycations and its biological activity.

To accomplish this we used model polycations with charged quaternized nitrogen atoms in the polymer backbone (Scheme 1). Such polymers constitute the family of polyelectrolytes called ionenes (*11*). These polymers are attractive in the scope of this study, as the charge density of ionenes is solely determined by the choice of starting materials for synthesis and thus can be changed at will in a wide range. Moreover, with these materials it is possible to vary one parameter while keeping the other constant. For example, it is possible to obtain samples with the same degree of polymerization but different charge density, or to keep the intercharge spacing constant and alter the polymer chain length.

EXPERIMENTAL SECTION

3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), ethidium bromide, TAE, and HEPES buffer were purchased from Sigma (St. Louis, MO). DNAse I was purchased from USB Corporation.

P388D1 mouse macrophage cell line was a kind gift from Zycos (Cambridge, MA). Cell culture was grown in RPMI medium 1640 with 10 vol % of FBS, and the medium also contained penicillin (100 units/mL) and streptomycin (100 μg/mL). Immortalized African green monkey kidney fibroblasts (COS7) were purchased from American Type Culture Collection (Manassas, VA) and grown in Dubelco's Eagle Modified Medium (DMEM) containing 10 vol % FBS, 100 units/mL penicillin, 100 μg/mL streptomycin. All cell culture growth and incubation was conducted at 37 °C in 5% CO_2 atmosphere.

Sodium salt of highly polymerized calf thymus DNA (~10000 base pairs) was purchased from Sigma and used without purification. Concentration of DNA phosphate groups was determined by UV absorbance measurements at 260 nm assuming molar extinction coefficient $\epsilon_{260} = 6500$ L mol^{-1} cm^{-1}. pCMV−Luciferase was purchased from Elim Biopharmaceuticals, Inc. (San Francisco, CA).

Polymer Synthesis. 2,4-, 2,8-, and 2,10 ionenes were synthesized, fractionated, and purified as described elsewhere (*12*).

Gel Retardation. DNA−ionene complexes were formed by mixing 50 μL of pCMV−Luciferase DNA solution (0.2 mg/mL in 10 mM HEPES buffer, pH 7.2) and 50 μL of solution of ionene at a desired concentration with vortexing. Complexes were allowed to form for 30 min at room temperature. After that, 20 μL of the solution was loaded onto 1% agarose gel in TAE buffer and ran at 90 V for 60 min. The gels were visualized with ethidium bromide.

Complex Size and Zeta-Potential Measurement. Polyelectrolyte complexes were formed as described above for the gel retardation assay. The mixture was diluted to 1.6 mL with HEPES buffer. Complex particle size and zeta potentials were measured at room temperature using Zeta-pals dynamic light scattering detector (Brookhaven Instruments, Holtsville, NY) with a 15 mV laser and incident laser beam at 676 nm. Correlation functions were collected at a scattering angle of 90°. Particle sizes were calculated using multiple angle sizing option of the instruments particle-sizing software. Particle sizes are expressed as effective diameters assuming log-normal distribution. Zeta potentials were calculated using the Smolukowsky model for aqueous suspensions.

DNAse Resistivity. Stoichiometric DNA−polycation complexes, prepared as described above, were placed into 1 mL of 10 mM PBS buffer containing 5 mM $MgCl_2$ at 25 °C. To this solution was added 10 units of DNAse I, and optical density of the solution at 260 nm was recorded for 30 min.

Fluorescence Quenching. Fluorescence intensity was measured using Jobin-Yvon-3CS Spectrofluorimeter (France) in a water-thermostatic stirred cell holder. The measurements were performed in a quartz fluorescence cell with continuous stirring. The excitation and emission wavelengths were 535 and 595 nm, respectively. Concentration of calf thymus DNA, expressed in concentration of phosphate groups, was $[P] = 4 \times 10^{-5}$ base-mol L^{-1} in all experiments. Solutions of polyelectrolyte complexes were prepared directly in the fluorimetric cell by mixing of definite volumes of stock solutions of the polymers. Fluorimetric titration was performed by successive addition of 4 M NaCl solution and measuring the intensity of fluorescence. Time interval between the additions was 5 min.

Cytotoxicity. Cytotoxicity of the polymers was evaluated using the MTT assay (*13*). P388D1 cells were grown in 96-well plates at initial cell density of 10000 cells per well in 0.2 mL of growth medium for 24 h, after which time the media was replaced with growth medium containing polymers at various concentrations and incubated at 37 °C for 24 h. At this time 25 μL of MTT solution (5 mg/mL) in sterile PBS buffer was added to each well and incubated for 2 h, after which 100 μL of extraction buffer (20% w/v SDS in 50:50 v/v DMF−water, pH 4.7) was added to each well and incubated for 24 h at 37 °C. The optical densities were measured using a microplate reader (Dynatech MR5000) at 560 nm. The results are expressed as percent relative to the control (no polymer added) cells.

Transfection. Immortalized African monkey kidney fibroblasts (COS-7) were grown in six-well plates at initial densities of 200000 cell per well in 2 mL of growth media for 24 h. After this the growth medium was

replaced with 2 mL of reduced serum media and polymer complexes were added to the corresponding wells. Polymer complexes were prepared as described for the gel assay analysis. Each sample contained 10 μg of DNA. After 4 h of incubation the media was changed to DMEM and cells were allowed to grow for 36 h. At this time growth media was removed, and cell lysates were formed and analyzed for luciferase activity (Promega luciferase assay kit) and total protein content (BCA assay, Pierce).

RESULTS AND DISCUSSION

The first report of ionenes dates back to the 1930s (*14*). In the 1940s Rembaum et al. (*11*) conducted an extensive research on ionene formation kinetics and thermodynamics. In 1961 Kimura et al. (*15*) isolated three samples of hexadimethrine bromide, 3,6-ionene, with different molecular weights and studied toxicity of these samples on mice. They found that LD_{50} significantly decreases with the lengthening of the ionene chain length. Efimov et al. (*16*) performed similar experiments and showed that the LD_{50} is also dependent on the charge density of ionenes: the longer the intercharge spacing along the ionene chain the lower the value of LD_{50}. To the best of our knowledge, the only report of the use of ionene polymers for gene delivery is that of Aubin et al. who used *3,6*-ionene for DMSO-assisted transfection (*17*). However this study was focused on optimization of DMSO-assisted transfection, rather than influence of the ionene characteristics on its ability to induce gene delivery. Yet until recently there was no efficient way to fractionate polydisperse ionene samples. Thus the experimental results could be masked by broad molecular weight distribution of ionene samples.

Recently (*12*) we described a method of effective fractionation of polydisperse samples of ionenes, which allowed us to obtain samples of 2,4-, and 2,8-ionenes in the range of DP 10 to 30 and study the physicochemical properties of ionene-containing polyelectrolyte complexes with poly(methacrylic acid). In this paper we investigate the physicochemical properties of DNA-containing PEC with ionenes and correlate them to ability of the ionenes to serve as gene delivery agents. For simplicity a sample of *x,y*-ionene with a certain DP will be denoted as ionene-[*x,y*/DP], where DP equals to the number of charged nitrogen atoms per ionene chain. In all cases the charge ratio of the polyelectrolytes is expressed in the ratio of the base-mole concentrations of charged moieties, $\varphi \equiv [+]/[-]$.

Complexes of plasmid DNA (pCMV−Luciferase) with ionenes were formed at different charge ratios of polyelectrolytes, and agarose gel electrophoresis was subsequently performed. This method allows visualization of the interaction of DNA and polycations. Uncomplexed or incompletely neutralized DNA, $\varphi < 1$, migrates in the electric field toward the anode, whereas stoichiometric complexes or complexes with an excess of positive charges do not migrate. Staining the gel with ethidium bromide (EB) provides a picture of the complexes' position on the gel. A representative picture for different ionenes is presented in Figure 1. As anticipated, in all the studied cases the complete retardation of DNA migration is observed at $\varphi \geq 1$.

The same complexes were analyzed for size using dynamic light scattering. The complex particle size as a function of ionene−DNA charge ratio for ionene-[2,4/20] is plotted in Figure 2. The increase of ionene content is accompanied by a substantial decrease in PEC particle size. This is true up to the charge ratio of unity, where the particles are neutral and form aggregates. With

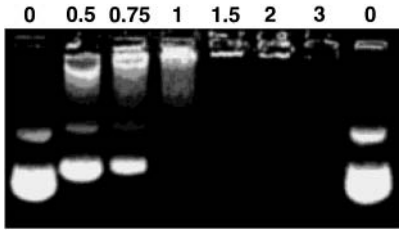

Figure 1. Electrophoretic retardation of pCMV−luciferase by ionene-[2,4/20]. Numbers signify the ionene−DNA charge ratios.

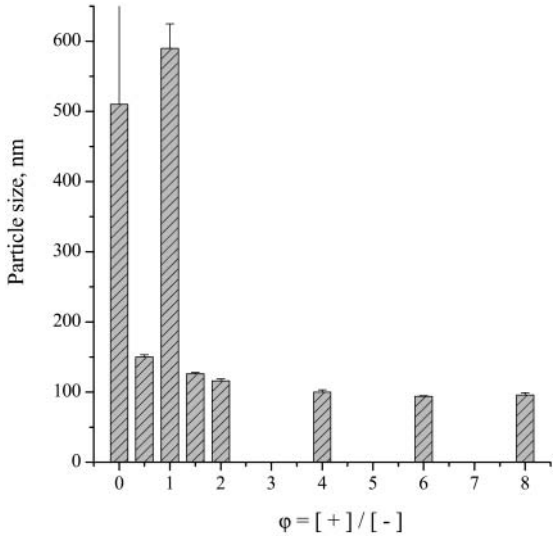

Figure 2. Dependence of the DNA−ionene-[2,4/20] complex particle size on the charge ratio of the polyelectrolytes.

excess polycation, charged complex particles do not aggregate, and at charge ratios of the polymers 2:1 the particle size is ~100 nm. This means that DNA−ionene-[2,4/20] complexes meet the requirement to form complexes less than 150 nm diameter, making endocytosis feasible (*18*).

Analogous dependencies were obtained for all utilized ionene samples (data not shown). All ionenes formed complexes with DNA with a particle size about 100 nm at charge ratios of the polymers greater than 2:1 regardless of charge density or chain length of the polycation. This correlates well with the results of Wolfert et al. (*5*), who showed, that regardless of DP and the nature of the charged moiety, polycations can complex DNA into small particles.

With excess polycation, soluble complex particles are thought to have an overall positive charge. To investigate this with ionenes, zeta potentials of the complex particles were determined (Figure 3). At $\varphi > 1$ the surface charge of DNA−ionene complex particles is positive, as is the case for all studied samples of ionenes regardless of polycation chain length and charge density.

The incorporation of DNA into a PEC can substantially hinder its accessibility to DNAse and thus dramatically decrease nuclease activity. Figure 4 shows the results of experiments in which DNA (curve 1) and DNA−ionene [2,8/29] complex $\varphi = 1$ (curve 2) were treated with DNAse I. Nuclease activity was monitored by the change in optical density at 260 nm (*19*). These data show that accessibility of nucleic acid to DNAse is much lower in the case of PEC compared to uncomplexed DNA.

Dependencies analogous to those presented in Figure 4 were obtained for each DNA−ionene complex and the ΔA_{260} ($\Delta t = 30$ min) was calculated (Figure 5). On this plot the greater the value of $1/\Delta A_{260}$, the more stable the

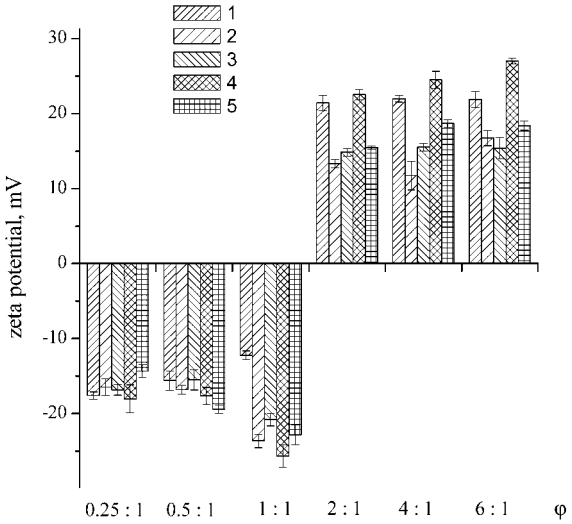

Figure 3. Zeta potentials of DNA-containing complexes with ionene-[2,4/20] (1), [2,8/14] (2), [2,8/20] (3), [2,8/29] (4) and [2,10/20] (5) at different charge ratios of the polyelectrolytes, $\varphi = [+]/[-]$.

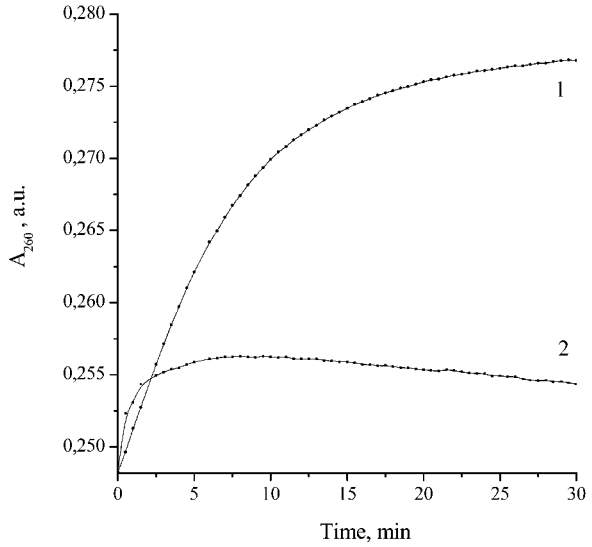

Figure 4. Dependence of optical density at 260 nm in solutions of DNAse I and DNA (1) and DNA−ionene-[2,4/29] PEC, $\varphi = 1$ (2); PBS buffer, 0.005 M $MgCl_2$.

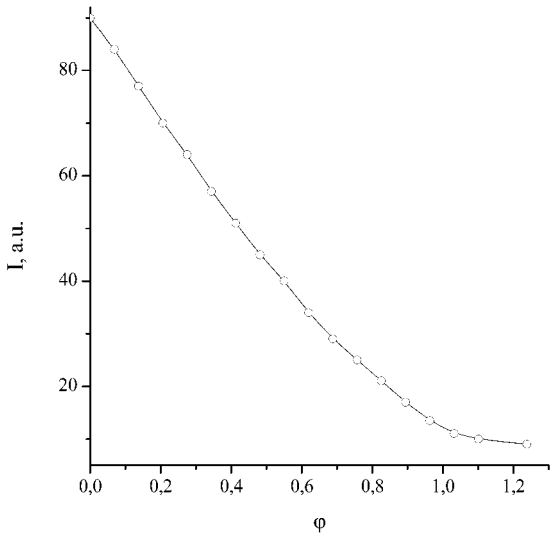

Figure 6. Dependence of fluorescence intensity I of the DNA−ionene-[2,4/20] solution on charge ration of the polymers, $\varphi = [+]/[-]$. $[P] = 4 \times 10^{-5}$ M; [P]/[EB] = 20/1; Tris buffer, pH 9.0; 25 °C.

complex upon DNAse treatment. Comparing data for different ionenes with the same DP shows that a decrease of ionene charge density is followed by a decrease in the resistance of its complex with DNA to nuclease activity. The increase of ionene chain length increases the ionene's ability to shield DNA from nuclease.

The stability of polyelectrolyte complexes formed by calf thymus DNA and ionenes in water−salt solutions was studied using a fluorescence quenching technique (*5, 20*) employing ethidium bromide as a fluorescent probe. The results of titration of DNA with ionene-[2,4/20] are presented in Figure 6. As seen, the introduction of ionene into the solution of DNA−EB complex leads to a pronounced decrease of fluorescence intensity, I, which suggests the formation of a PEC (*20*). This is true up to the charge ratio of the polymers equal to unity, where quenching ceases.

The dissociation of DNA−ionene complex ($\varphi = 1.2$) in water−salt solutions was determined by NaCl titration in the presence of EB. The fluorescence intensity of the polyelectrolyte mixture I was normalized by I_0: intensity of fluorescence of DNA−EB complex at the same salt concentration. In all experiments the ratio of DNA (expressed in concentration of phosphate groups, [P]) to EB was [P]/[EB] = 20/1. As a quantitative measure of the stability of PEC to dissociation in water−salt solution, we define the value C^*_{NaCl}, which is the value of C_{NaCl} that corresponds to the midpoint of the curve of fluorescence ignition. Figure 7 presents the dependence of C^*_{NaCl} vs DP of the ionene for complexes of DNA with 2,4-ionene (curve 1) and 2,8-ionene (curve 2).

As follows from curve 1, the stability of DNA-containing complexes with 2,4-ionene significantly increases with the lengthening of the chain of polycation. Likewise, C^*_{NaCl} for the complex DNA−ionene-[2,4/8] is 0.13 mol L^{-1}, whereas for the complex with ionene-[2,4/20] this value is equal to 0.27 mol L^{-1}. It is noteworthy that in the region of the shortest chains of 2,4-ionene the stability of DNA-containing complexes decreases particularly rapidly. This correlates well with the concept that the value of cooperative binding length for most

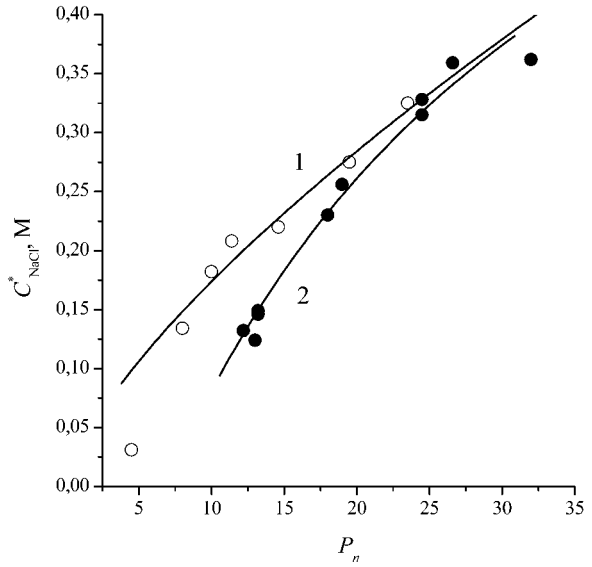

Figure 7. Dependence of C^*_{NaCl}, M on the degree of polymerization of the ionene in solutions of PEC formed by DNA with 2,4-ionene (1) and 2,8-ionene (2). $\varphi = 1{,}2$; other conditions as in Figure 6.

examined pairs of polyelectrolytes lies in the range 4 to 7 monomer units (*21*).

The dependence obtained for the complexes of DNA with 2,8-ionenes of different DP (Figure 7, curve 2) is similar to that for DNA−2,4-ionenes. In this case the growth of the stability of the complex with the increase of polycation chain length is even more pronounced. For short chains of ionenes the stability of 2,4-ionene containing complexes is higher than for the complexes with 2,8-ionene, as would be expected from higher charge density of 2,4-ionene (*12, 20*). Strikingly, upon lengthening of the ionenes chains the difference in stability of the complexes decreases, and on attainment of 20−25 monomer units, the difference between the ionenes as partners for complexation with DNA becomes vanishingly small. In other words, the charge density proved to be the factor controlling stability of DNA-containing PEC only in the case of the ionenes with relatively low DPs.

The cytotoxicity of the ionenes was studied using P388D1 macrophages (Figure 8). The minimum viability of the cells exposed to solutions of ionenes at various concentrations of polycation is 80% relative to controls, indicating low cytotoxicity of ionenes compared to polyethyleneimine and polylysine (*22*), which is critical to normalize the polymer effects in the cell-based transfection assays.

As the whole range of viability of cells treated with different ionenes is within experimental error, it is difficult to deduce the influence of the DP and intercharge spacing of ionenes on their toxicity. However, our data indicate that the influence of these parameters on sample cytotoxicity in vitro is substantially lower than that found in vivo (*15, 16*). The data obtained also suggest that the cytotoxicity is a function of the nature of the polycation charged moiety (primary, secondary, tertiary, or quaternary amine group) rather than the DP of the macromolecule or its charge density.

Polymeric quaternary ammonium salts possess little activity as gene delivery agents. While most of the polycations with different types of charged moieties are able to condense DNA into small particles with an overall positive surface charge, the efficiency of transfection dramatically drops from polylysine-based vectors to quaternary ammonium polymers (*5*).

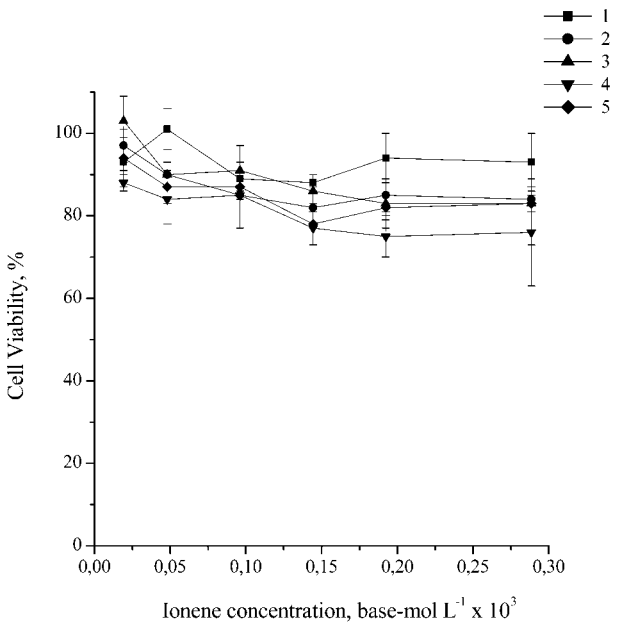

Figure 8. In vitro cytotoxicity as a function of ionene base-mole concentration for ionenes [2,4/20] (1), [2,8/14] (2), [2,8/20] (3), [2,8/29] (4) and [2,10/20] (5).

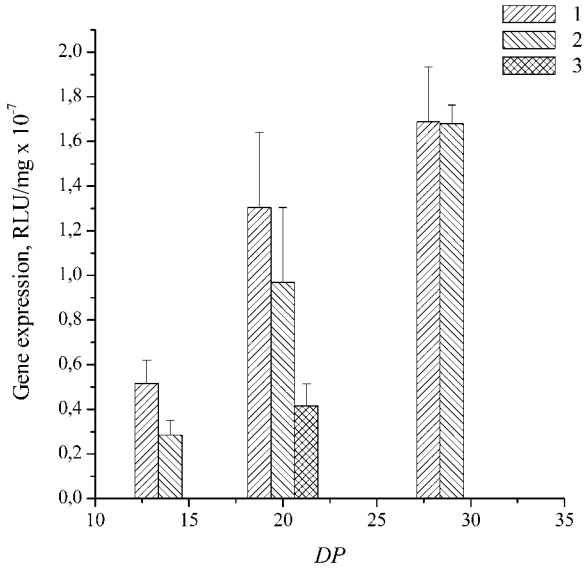

Figure 9. pCMV-Luciferase expression as a function of ionene DP for 2,4-ionene (1), 2,8-ionene (2), and 2,10-ionene (3).

Nevertheless, even this relatively low activity allows examining the ability of ionenes to induce nucleic acid delivery with respect to the influence of polycation macromolecular characteristics. It is well documented that most polymer properties change rapidly in the region of low DP values, while at a certain DP one would expect a property−structure plateau (*23*). For this reason we studied low DP trends using aliphatic ionenes (Figure 9).

To determine the optimal charge ratio of the polymers for transfection, COS-7 cells were exposed to DNA−ionene-[2.4/20] complexes with different ionene contents. These experiments showed that the highest levels of reporter gene expression are observed at a charge ratio 4:1 (data not shown). In all further experiments, cells were treated with DNA−ionene complexes at $\varphi = 4$.

Using samples of ionenes with the same charge density and different chain lengths revealed the influence of polycation chain length on the transfection level. Figure

9 shows that increase of chain length of the ionene leads to a pronounced increase of reporter gene expression. This observation is true for both 2,4- and 2,8-ionene. This result corresponds well with those obtained for synthetic gene delivery vectors based on polyethyleneimine (*4*) and other polycations (*5*). It is also consistent with the data obtained by Schaffer et al. (*6*), who showed that the transfection level as a function of polylysine DP has a maximum at DP $\approx$ 36. As stability of DNA−ionene complexes is lower than that with polylysine (*20*), one can expect the appearance of such maximum in case of ionene-based vectors at DPs higher than 36 monomer units. Unfortunately, we could not isolate ionene samples with DP higher than 30; this is a subject of ongoing research.

To scrutinize the influence of polymer charge density we performed transfections with complexes of DNA with ionenes of the same chain length but different intercharge distance, ionenes [2.4/20], [2.8/20], and [2.10/20]. Data, presented in Figure 9, show that the increase of ionene charge density is followed by a pronounced increase in transfection level. Likewise, in the case of 2,4-ionene, the observed value of RLU/mg is ~1,5 times higher than for 2,8-ionene. For the latter, in turn, it is 2 times higher than for 2,10-ionene, for which the level of transfection is only slightly higher than that observed for uncomplexed DNA.

Another interesting notion comes from comparing the data in Figures 5, 7, and 9. The influence of ionene charge density and chain length on PEC stability in water−salt solutions and tolerance to DNAse action correlate well with transfection efficiency. Moreover, it can be observed that different ionenes which complexes with DNA possess similar stability to dissociation in water−salt solutions induce equivalent DNA expression.

This finding shows the strong influence of polymer microstructure and molecular weight on the PEC properties. According to the revealed correlation, physicochemical results may be useful for predictions of PEC applicability for transfection. The revealed extraordinary correlation between the results obtained by different approaches (stability of the complexes toward dissociation in water−salt solutions, resistivity toward DNase restriction and transfection efficiency) certainly does not imply that the results of different approaches are directly transferable, yet it shows that physicochemical evaluation of the system can give a reasonable prediction of the biological usefulness of the system and can be used for creating mathematical models for prediction of a novel vector.

ACKNOWLEDGMENT

Authors would like to thank Dr. D. Lynn, Dr. D. Anderson, Dr. C. Gentry, and D. Ting for significant contribution to the work. Financial support of the study by NIH grant # 2-R01-6M26698-21, BPEC grant # EEC-9843342 and Russian Fund of Fundamental Research 99-03-33399a are gratefully acknowledged.

Near-Infrared Fluorescent Nanoparticles as Combined MR/Optical Imaging Probes

Lee Josephson,* Moritz F. Kircher, Umar Mahmood, Yi Tang, and Ralph Weissleder

Center for Molecular Imaging Research, Massachusetts General Hospital, Charlestown, Massachusetts. Received September 14, 2001; Revised Manuscript Received December 21, 2001

A number of quantitative three-dimensional tomographic near-infrared fluorescence imaging techniques have recently been developed and combined with MR imaging to yield highly detailed anatomic and molecular information in living organisms (*1, 2*). Here we describe magnetic nanoparticle based MR contrast agents that have a near-infrared fluorescence (NIRF) that is activated by certain enzymes. The probes are prepared by conjugation of arginyl peptides to cross-linked iron oxide amine (amino-CLIO), either by a disulfide linkage or a thioether linker, followed by the attachment of the indocyanine dye Cy5.5. The NIRF of disulfide-linked conjugate was activated by DTT, while the NIRF of thioether-linked conjugate was activated by trypsin. Fluorescent quenching of the attached fluorochrome occurs in part due to the interaction with iron oxide, as evident by the activation of fluorescence with DTT when nanoparticles that have less than one dye attached per particle. With a SC injection of the probe, axillary and brachial lymph nodes were darkened on MR images and easily delineated by NIRF imaging. The probes may provide the basis for a new class of so-called smart nanoparticles, capable of pinpointing their position through their magnetic properties, while providing information on their environment by optical imaging techniques.

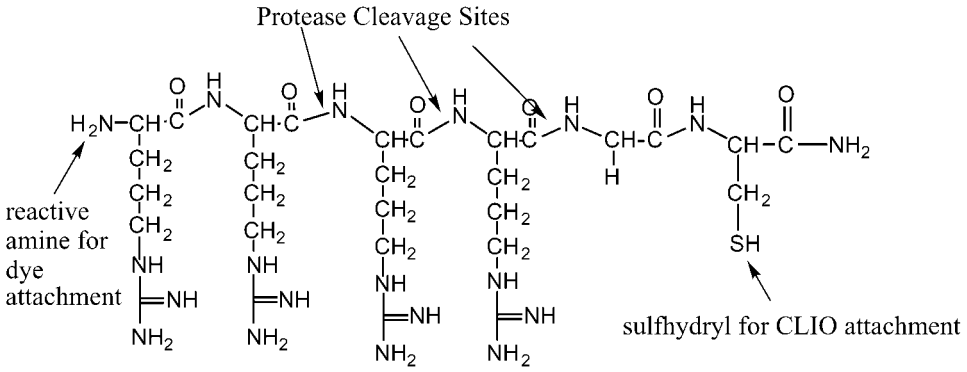
INTRODUCTION

Magnetic nanoparticles are now well established as magnetic resonance (MR) reporters for detecting pathologies in the liver, spleen, and lymph nodes where, after phagocytosis, their presence is evident primarily by a darkening effect on T2 weighted images. After injection, magnetic nanoparticles accumulate in target tissues and are degraded over a period of several days, providing a convenient time interval to determine nanoparticle disposition. MR is now capable of providing high spatial resolution images (on the order of tens of microns per voxel resolution) of nanoparticle disposition in vitro, in small animals, and in humans. Nanoparticles can be identified in normal human lymph nodes, generally less than about 10 millimeters in diameter, and millimeter-sized metastases can be visualized within the node (*3*−*5*). Current magnetic nanoparticles, while providing superb information on their spatial disposition, are not designed to provide information on the molecular environment surrounding the nanoparticle.

We have recently developed novel enzyme-activated near-infrared fluorescent (NIRF) probes that can image the activity of specific proteases in the local environment of the probe in vivo (*6*−*8*). Probes have been synthesized by the attachment of the NIRF dye Cy5.5 to a poly-lysine derivatized with PEG, a material termed poly(ethylene glycol) graft copolymer Cy5.5-PGC (PGC, PEG graft copolymer) (*7, 9*). In vivo the polylysine backbone is cleaved by cathepsin B, while in vitro it can be cleaved by trypsin. However, current optical imaging methods acquire the NIRF signal against a nonfluorogenic background and hence provide little spatial/anatomic information. The development of optical tomographic imaging techniques offers the prospect of providing a lower detection limit for fluorochromes, and a higher spatial resolution, but a second imaging modality will still be required to obtain anatomical background.

In this communication, we report on a new type of magnetic nanoparticle that acts as an MR contrast agent providing information on the location of the probe and, as a probe for optical imaging, providing information on the molecular environment of the probe. Contrast enhancement by MR results from a core of superparamagnetic iron oxide, while the NIRF signal results from cleavable Cy5.5-derivatized peptides attached to the surface of the nanoparticle. Amino-CLIO, a magnetic nanoparticle with a surface of aminated, cross-linked dextran, has been used to attach a variety of biological molecules, including the tat peptide of the HIV tat protein (*10*), transferrin (*11*), and oligonucleotides (*12*), and provides a convenient platform for the attachment of Cy5.5 peptides.

Two chimeric nanoparticle probes are described. The first exhibits NIRF fluorescence when activated by a reducing environment, while the second exhibits NIRF fluorescence when activated by proteases. These novel probes may provide the basis for a new class of so-called smart nanoparticle probes, whose position can be ascertained by MR imaging and which provide information on their molecular environment through NIRF.



EXPERIMENTAL PROCEDURES

Two dye−arginyl peptide nanoparticle conjugates were synthesized according to Figure 1 and are denoted Cy5.5-R4−SS−CLIO and Cy5.5-R4−SC−CLIO. The designation "SS" denotes a disulfide linkage between the peptide and the iron oxide while "SC" denotes a thioether linkage, while the R4 stands for four arginyl peptides in the L configuration. The primary amine of a dextran-coated

3. Synthesis of Cy5.5-arginyl peptide -CLIO Conjugates

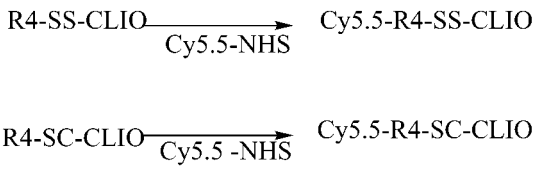

Figure 1. Scheme for synthesis of Cy5.5-arginyl-CLIO conjugates.

cross-linked iron oxide (amino-CLIO) was reacted with one of two activating agents, either *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP) or succinimidyl iodoacetate (SIA), to produce two reactive forms of CLIO as shown in Figure 1. The L-arginyl peptide R−R−R−R−G−C ("R4") is attached to the activated CLIO's through a C-terminal cysteine residue to the SPDP or succinimidyl iodoacetate CLIO, followed by the N terminal residue with *N*-hydroxylsuccinimidyl (NHS) ester of Cy5.5 to yield Cy5.5-R4−SS−CLIO and Cy5.5-R4−SC−CLIO.

Synthesis of Aminated-CLIO. Aminated CLIO was prepared as described (*10, 11*). It consists of a core of superparamagnetic iron oxide, a cross-linked coating of dextran with amino groups.

Peptide Synthesis. Peptides were synthesized on an automatic synthesizer (PS3, Rainin, Woburn, MA) at a 0.1 mmol scale using Fmoc chemistry with HBTU and HOBT. They were cleaved from Rink amide HBHA resin (Novabiochem, San Diego, CA) with 5 mL of TFA/thioanisole/ethanedithiol/anisole (90/5/3/2) and purified by C18 reversed phase chromatography. Peptides were the L-arginyl peptide R−R−R−R−G−C−NH_2 ("R4") and the d-arginyl peptide r−r−r−r−G−C−NH_2 ("r4"). By MALDI-MS R4 was 802.93 calculated versus 803.3 found (M + 1). For the peptide r4 M + 1 was 803.63.

Synthesis of Cy5.5 Nanoparticle Conjugates. To synthesize the thioether-bonded conjugate R4−SC−CLIO, amino-CLIO (22 mg Fe, 1.5 mL) was added to 0.5 mL of 0.1M Na_2HPO_4 and 0.5 mL of 150 mM SIA in DMSO. The reaction was allowed to sit for 1 h at room temperature and the addition of succinimidyl-iodoacetate repeated. Iodoacetyl-CLIO was separated from iodoacetic acid using a Sephadex G-25 column equilibrated with 0.025 M Citrate pH 6.5 at 4 °C. To the void volume, 5 mL, was added 6−7 mg of R4 in 0.6 mL of citrate buffer and the reaction incubated overnight at room temperature. Unreacted peptide was removed by dialysis against 3 L of 0.025 M citrate pH 8.2 using a 14 kDa cutoff membrane.

To synthesize the disulfide linked conjugate R4−SS−CLIO, amino-CLIO was activated with SPDP as described (*10*) and reacted with R4 as above except that the pH of the citrate buffer was 8.2 for chromatography and storage (Figure 1).

To attach Cy5.5 to arginyl-CLIO conjugates, 200 μL of 1 M $NaHCO_3$ (pH 8.3) was added to 2 mL of R4−SC−CLIO (7.2 mg Fe). Four hundred forty microliters was then added to each of the five tubes of lyophilized Cy5.5 (Amersham Pharmacia, Piscataway, NJ). After 2 h at room temperature, unreacted dye was removed using PD-10 columns run in a spin separation mode. Columns were washed with 0.025 M citrate pH 8.2 and spun dry. A one milliliter sample was added to columns that were spun at 2500*g* for 7 min.

To synthesize Cy5.5-R4−SS−CLIO conjugates with varying ratios of dye attached, various amounts of dye

Table 1. Physical Properties of Cy5.5-arginyl-CLIO Conjugates

conjugate	size (nm)	R1 (s^{-1} mM^{-1})	R2 (s^{-1} mM^{-1})	peptides per particle	fluorochromes per particle
Cy5.5-R4−SS−CLIO	68 ± 13	27.8	91.2	11.9	1.19
Cy5.5-R4−SC−CLIO	62 ± 7	29.9	92.5	15.5	1.79

were reacted with a fixed amount of conjugate. R4−SS−CLIO (0.1 mg) was added to between 10 and 160 μL of a tube of NHS−Cy5.5 reconstituted with 500 μL of water immediately before use. Additional water and buffer was added so that the reaction with dye occurred in a volume of 275 μL of 0.05 M $NaHCO_3$. After 2 h at room-temperature, unreacted dye was removed using PD-10 columns as above.

Physical Properties of Nanoparticles. The number of peptides per CLIO was determined as the number of reactive primary amino groups using fluorescamine (*13, 14*). Five to fifty microliters of arginyl-CLIO nanoparticles or various amounts of the standard peptide (R4) were diluted into 500 μL of 0.1 M borate, pH 8.5. The weight of R4 was determined by amino acid analysis. Two hundred fifty microliters of fluorescamine (4 mg in 20 mL of acetyl nitrile) was added, and the mixture was allowed to stand overnight at room temperature. Fifty microliters of trypsin (1 mg/mL in 0.1 M phosphate) was added, and samples were allowed to stand for 2 h at room temperature. Fluorescamine fluorescence, ex 390, em 475, was measured after separating the iron oxide from low molecular weight materials by ultrafiltration (*10*). Iron concentration was determined by absorbance (*11*). The peptide-to-crystal ratio was obtained from concentrations of peptide and iron, assuming 2064 iron atoms per crystal (*15*).

Dye/Particle Ratios. Spectra of conjugates were taken using a Hitachi 3500 spectrophotometer. The number of dyes per crystal attached was taken from the absorption at 675 nm and an extinction coefficient of 250000 $M^{-1}cm^{-1}$ and assuming 2064 iron atoms per crystal.

Activation of NIRF. For Cy5.5-R4−SS−CLIO or Cy5.5-R4−SC−CLIO, activation by trypsin or DTT was determined in a microtiter plate with volume of 350 μL of 0.01 M phosphate pH 7.4 with a concentration conjugate of approximately 80 μg Fe/mL. Either trypsin (10 μg/mL, Sigma Chemical St. Louis, MO) or DTT (5 mM) were present. The plate was incubated at room temperature for various times up to 200 min and Cy5.5 fluorescence determined (ex 660, em 695) using a fluorescent microtiter plate reader (Spectra Max, Molecular Devices, Sunnyvale, CA). Activation was defined as a dimensionless number obtained by dividing fluorescence obtained with trypsin (or DTT) by fluorescence obtained without trypsin (or DTT), after subtraction of background fluorescence (*16*).

Magnetic and Size Measurements. The R1 and R2 relaxivities were measured using a 0.47 T tabletop relaxometer as described (*10, 11*). Size was determined by laser light scattering using a Coulter N4 particle size analyzer.

MR and Optical Imaging. For the determination of tissue signal intensities after intravenous (iv) injection (Figure 4), C57 BL/6 mice (National Cancer Institute) were injected through the tail vein with Cy5.5-R4−SC−CLIO (5.1 mg Fe/kg, 2 nmoles dye, 150μL). After 18 h, animals were euthanized with pentobarbital sodium (200 mg/kg, ip), and tissues (approximately 200 mg) were placed in a 96-well microtiter plate. MR imaging was performed on a clinical GE Signa 1.5T imager using a standard 3 in. surface coil to acquire signal. A T2 weighted pulse sequence TR/TE 3000/100 was used (1.0 mm slice thickness, 256 × 256 matrix, 8 cm FOV).

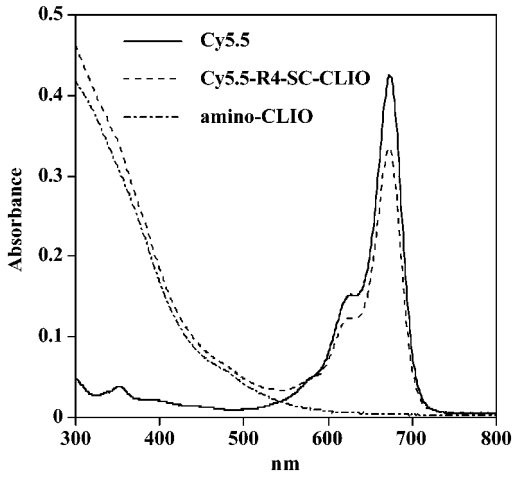

Figure 2. Absorption spectra of Cy5.5, amino-CLIO and Cy5.5-R4−SC−CLIO.

For imaging lymph nodes after subcutaneous (SC) injection (Figure 5), a nu/nu nude mouse (Taconic Farms, Tarrytown, NY) was injected with Cy5.5-R4−SC−CLIO (2.2 mg Fe/kg, 0.85 nmol dye, 30 μL) under the skin of the left front extremity. After 24 h, animals were anesthetized with ketamine/xylazine (80/10 mg/kg, ip) and imaged in the magnet with the coil above. A T1 weighted pulse sequence (TR/TE 500/17) was used (1.5 mm slice thickness, 256 × 256 matrix, 6 cm FOV).

Optical imaging was performed using a whole mouse imaging system, a modification of a commercially available chemiluminescence system, as described (*17*). Cy5.5 fluorescence was obtained with a band-pass filter at 630 ± 20 nm (model # 630RDF30 Omega Optical, Brattleboro, VT) and a 700 nm long pass filter (700 EFLP; Omega Optical). Animals were handled according to institutional guidelines.

RESULTS

The physical properties of Cy5.5-R4−SC−CLIO and Cy5.5-R4−SS−CLIO are summarized in Table 1. The nanoparticles are similar in size and have the high relaxivity characteristics of superparamagnetic iron oxides (*15*).

The absorption spectrum of Cy5.5-R4−SS−CLIO is shown in Figure 2. Cy5.5-R4−SS−CLIO had an absorption maximum of 680 nm, which is slightly shifted from the maximum of 675 nm for Cy5.5. The spectrum of amino-CLIO is also shown, which is dominated by the absorption of iron oxide in the ultraviolet region of the spectrum and which shows little absorption in the near-infrared portion of the spectrum. The distinct spectral properties of amino-CLIO and Cy5.5 suggest that the iron oxide would have little effect on the NIRF of Cy5.5 though evidence for such an interaction is presented below.

Figure 3A shows the effect of treating the nanoparticle conjugates Cy5.5-R4−SS−CLIO and Cy5.5-R4−SC−CLIO with DTT. DTT cleaves disulfide bonds and provides gentle conditions for separating intact molecules from the surface of magnetic nanoparticles (*11, 12*).

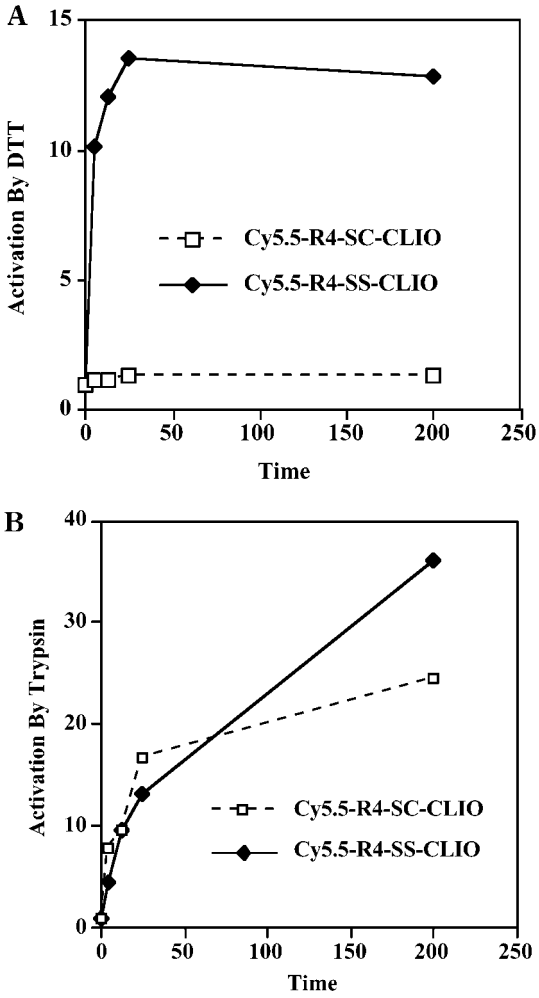

Figure 3. Activation of optical magnetic nanoparticle conjugates by DTT (A) or trypsin (B).

Incubation of Cy5.5-R4−SS−CLIO with DTT resulted in a 12.8-fold increase in NIRF. On the other hand, the NIRF of the thioether-linked nanoparticle Cy5.5-R4−SC−CLIO was not activated by DTT. Trypsin incubation activated the near-infrared fluorescence of Cy5.5-R4−SS−CLIO and Cy5.5-R4−SS−CLIO 36.2 and 27.4-fold (Figure 3B), respectively, by cleaving peptide bonds and releasing a number of degradation products (Cy5.5-R−R, Cy5.5-R−R−R−). Activation by trypsin was notably slower than that with DTT presumably because the concentration of DTT employed (5 mM) was high enough to produce a nearly instantaneous cleavage of disulfide bonds. Activation was notably higher with trypsin than with DTT (36.2 versus 12.8), which may reflect intramolecular interactions between the negatively charged Cy5.5 dye and positively charged peptide obtained when Cy5.5-R4−SS−CLIO is treated with DTT (Cy5.5-R−R−R−R−G−C−NH_2). To further prove the specificity of conjugate activation, a conjugate denoted Cy5.5-r4-SS−CLIO was synthesized, where r4 indicates a peptide identical to "R4" but with all amino acids in the protease-resistant D configuration. Cy5.5-r4-SS−CLIO was activated by DTT but was resistant to activation by trypsin (Josephson, unpublished observations).

Enzyme-activatable Cy5.5 probes generate signals when exposed to proteases primarily because multiple fluorochromes attached to a single carrier molecule quench due to interactions with each other (*3, 8, 17*). Proteolysis cleaves bonds between fluorochromes, increasing the distance between them and activating the

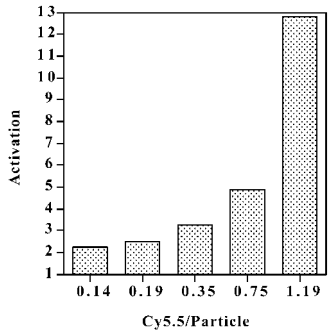

Figure 4. Activation of the disulfide linked nanoparticle conjugate Cy5.5-R4−SS−CLIO with different numbers of fluorochromes (Cy5.5) attached. Activation was with DTT.

NIRF signal. The quenching/activation attained with less than two dye molecules per nanoparticles suggests that quenching may result from an interaction of Cy5.5 with CLIO rather than between Cy5.5 molecules, an interaction which if present occurs despite the lack of spectral overlap between iron oxide and Cy5.5.

To further analyze the activation of fluorescence obtained, a series of Cy5.5-R4−SS−CLIO conjugates were made at different ratios of Cy5.5 to iron oxide. Figure 4 shows the activation of Cy5.5-R4−SS−CLIO conjugates ranging from 0.14 Cy5.5 molecules per particle to 1.19 Cy5.5 molecules per particle. Remarkably, fluorescence increased 2.28-fold with a conjugate that had an average of 0.14 mol of Cy 5.5 per particle, suggesting that quenching is occurring, at least in part, from an interaction between the dye and the iron oxide. Activation increased to 12.8-fold as the number of Cy5.5 molecules was increased to 1.19 Cy5.5's per particle.

To demonstrate the ability of Cy5.5-R4−SC−CLIO to act as a combined MR/optical imaging probe, we injected the agent into mice by the IV and SC routes of administration and obtained MR images and NIRF images. With the IV injection (Figure 5), the animal was sacrificed and MR and NIRF images were obtained from tissues after dissection. Uptake of Cy5.5-R4−SC−CLIO, through the presence of magnetic iron oxide in the spleen and lung, is evident from the lower signal intensity (darkening) of those tissues on MR images, compared to tissues from an uninjected animal. With NIRF fluorescence, no signal was obtained with tissues from an uninjected animal, reflecting the absence of fluorochromes in the range of 610 to 650 nm used to excite Cy5.5. With the injected animal on the other hand, a high intensity NIRF signal was obtained from the liver and spleen and a weak NIRF signal was obtained from the kidney. The low intensity signal from the kidney probably results from proteolytic degradation of the conjugate and excretion of low molecular degradation products.

With the SC injection (Figure 6), MR imaging and NIRF images were obtained on a single live mouse. Figure 6A shows transverse MR images of the axillary and brachial nodes after injection into the front extremity. Axillary and brachial nodes are evident as points of very low signal intensity in two different transverse planes. The darkening of the axillary node due to Cy5.5-R4−SC−CLIO is further shown in the coronal view in Figure 6B. Similar points of low signal intensity are not evident for the contralateral, uninjected side of the animal. Figure 6C shows a white light, reflectance image determined by the surface topography of the animal. However, with the corresponding NIRF image (Figure 6D) background light is negligible, and fluorescent signal

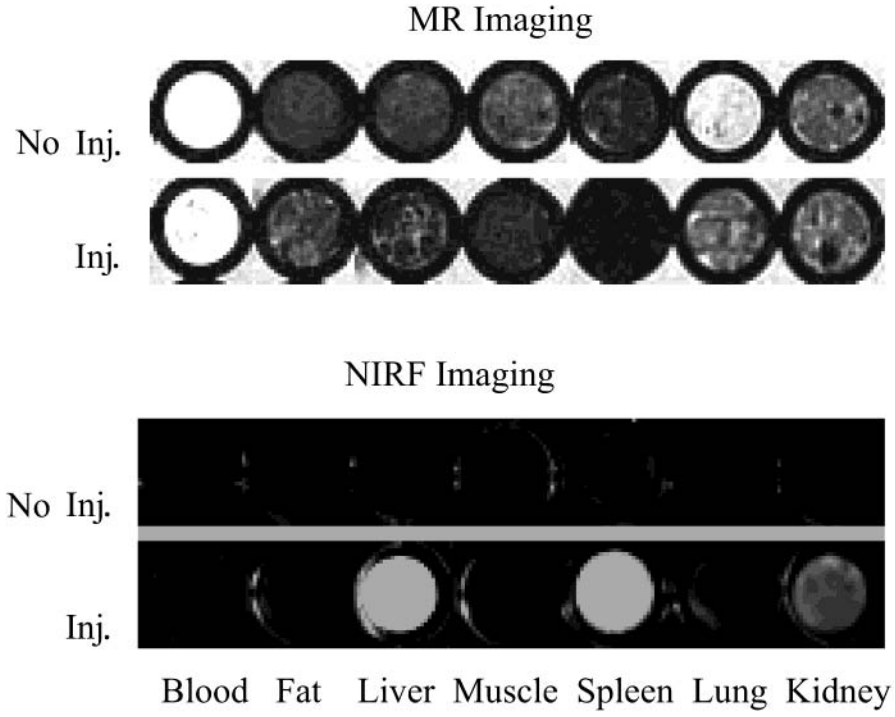

Figure 5. MR and NIRF images from tissues of animals injected iv with Cy5.5-R4−SC−CLIO.

from the brachial and axillary nodes passes through the skin, permitting the nodes to be seen as bright centers or points of light.

DISCUSSION

We have designed magnetic nanoparticles that serve both as magnetic resonance contrast agents and NIRF optical probes. With SC administration the conjugate denoted Cy5.5-R4−SC−CLIO produced contrast-enhanced MR images of lymph nodes that were free of the susceptibility artifact that can accompany the use of iron oxide based contrast agents (*18, 19*). The procedure also provided a NIRF signal sufficiently strong to be seen with our simple imaging equipment consisting of a relatively low power halogen lamp and CCD camera described in detail elsewhere (*17*). However, SC administration used here is a technique that allows nanoparticles to concentrate at high doses in lymph nodes, such as the brachial and axillary nodes, that drain the injection sites of the front extremity (*20*). More sensitive means of visualizing fluorochrome distribution, such as diffuse optical tomography (*1, 21*), may enable the detection of far lower tissue concentrations of Cy5.5 than possible with our equipment.

It has recently been recognized that colloidal materials, rather than organic molecules, can act as efficient quenchers of fluorescence. For example molecular beacons based on the hybridization of target oligonucleotides to single stranded hairpins use a pair of organic molecules (EDANS/DABCYL) as a donor/quencher pair (*22*). However, 1.4 nm colloidal gold can replace DABCYL for hairpin-based molecular beacons (*23*). In this example oligonucleotides are attached to gold through a 5′ terminal phosphate through a $(CH_2)_6-SH$ group, while a dye couple is coupled to a 3′ hydroxyl group through a $(CH_2)_6-NH_2$ linker. Fluorescence is quenched until the hairpin opens due to hybridization, which increases the distance between gold and the fluorophore. With magnetic nanoparticles, treatment with DTT or trypsin cleaves covalent bonds between the fluorophore and the

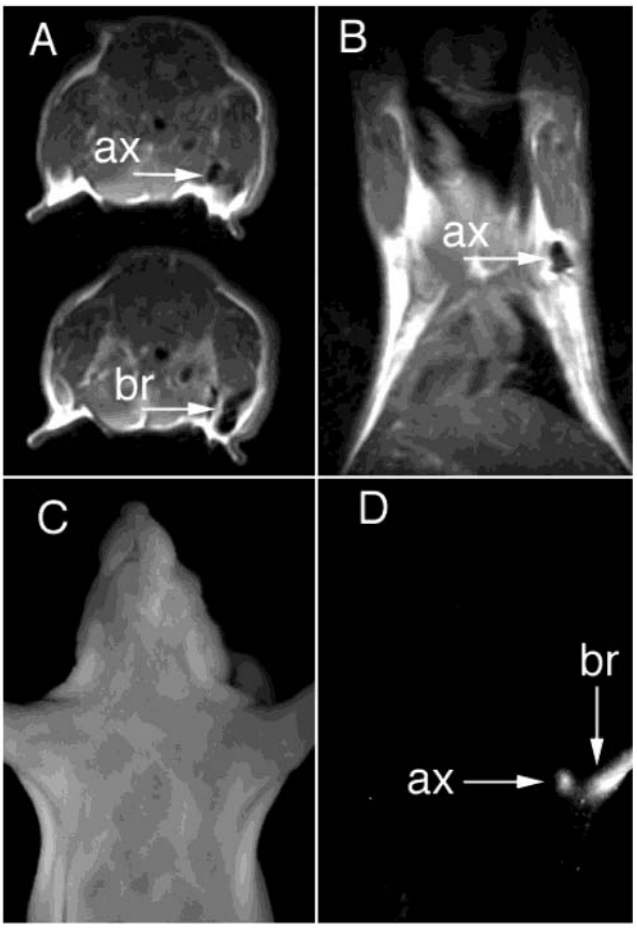

Figure 6. MR and NIRF images from tissues animals injected with Cy5.5-R4−SC−CLIO after SC injection. A. Contrast enhanced MR images of lymph nodes where ax = axillary and br = brachial. B. Contrast enhanced coronal image of the axillary node. C and D. White light and NIRF images, respectively, showing intense regions of NIRF in axillary and brachial nodes.

nanoparticle, permitting the fluorophore to leave the local environment of the nanoparticle and distribute through the bulk media. Interestingly, fluorophores ranging from fluorescein (ex 494, em 520) to Cy 5 (ex 649, em 670) were highly quenched by colloidal gold (*23*). We have noted that the attachment of fluorescein to magnetic nanoparticles is associated with a profound quenching effect (Josephson, unpublished observations). The fluorescence quenching of magnetic nanoparticles may be due to nonradiative energy transfer between the dye and iron oxide or to collisions between the Cy5.5 and the nanoparticle. In the case of colloidal gold nonradiative energy transfer is believed to be the dominant mechanism of fluorescence quenching (*23*).

The chemistry we have employed (Figure 1) offers many options for the design of optically activatable nanoparticles. It can be used to synthesize nanoparticles designed for activation by any protease by selecting peptides that are selective substrates for any protease. The method requires only that the peptide have a C-terminal cysteine, a reactive N-terminal amino that reacts with the *N*-hydroxysuccinimide esters of *fluorochromes* and a lack of primary amino groups elsewhere on the peptide. The R4 peptide meets these *requirements*, since the guanidyl groups of the arginine are unreactive NHS esters (*24*).

The optical nanoparticle probes we have designed utilize polyarginyl peptides to link the fluorophore Cy5.5 to the nanoparticle. Sequences of basic amino acids such as polyarginine can be cleaved by trypsin, a convenient protease for in vitro studies with specificity for basic amino acids. In vivo Cy5.5-R4−SC−CLIO can be activated by proteases with a specificity for basic amino acids such as cathepsin B, which cleaves optical probes such as Cy5.5-PGC which has a polylysine backbone (*7, 17*). Cathepsin B is a widely distributed enzyme found in high concentrations in the organs of the reticuloendothelial system (RES) (*25, 26*). It has been proposed to play a role in tumor invasiveness (*27, 28*) and been examined as a prognostic marker in breast cancer (*29, 30*) and small cell lung carcinomas (*31, 32*).

The attachment of polyarginyl nanoparticles to nanoparticles may result in particles with membrane translocating properties similar to tat-CLIO (*10, 33*). Positively charged peptides derived from the tat protein of HIV (GRKKRRQRRRPPQ) or from homeoprotein transcription factors (RQIKIWFQNRRMKWKK) act as internalization signals for a wide variety of cells (*33*−*35*). We have recently demonstrated that after iv injection a Tat-CLIO nanoparticle is translocated into cells and concentrated in the nucleus, in a manner similar to that obtained when the reagent is incubated with cells in culture (Wunderbaldinger, Josephson and Weissleder, in preparation). Since the guanidine headgroup of arginine seems to be all that is required for a substantial degree of membrane translocating activity (*36, 37*) nanoparticles with simple polyarginyl peptides may be able to efficiently enter cells other than macrophages.

The importance of macrophage activation for a variety of medically important conditions, the association of macrophage activation with elevated levels of proteases, and the ability of macrophages to concentrate nanoparticles after intravenous injection suggest that the optical magnetic nanoparticle probes described here might initially be employed to measure macrophage activation in vivo. The activation state of macrophages is a key element in a wide range of diseases, ranging from the host defense against cancer cells (*38*) to the response to infectious microorganisms (*39*). Immunological activation of macrophages in response to stimuli such as mineral oil, thioglycolate and gamma-interferon is associated with increased levels of proteases such as cathepsins B and D (*40, 41*). The development of macrophage-targeted optically active nanoparticles is aided by the fact that similar particles are in clinical use and accumulate in macrophages of the liver, spleen, and lymph nodes (*4, 5, 42*). Following the chemistry developed here, nanoparticle probes might be designed which reveal the location of macrophages that clear nanoparticles from circulation, while providing a fundamentally new type of information on the immunological activation state of the macrophages that have sequestered them. The ability to obtain satisfactory MR and optical images with the nanoparticle/optical probe described here, together with use of more sensitive and sophisticated equipment for fluorochrome detection in vivo, suggests that future materials of this type might be developed for eventual clinical use.

In Vitro and in Vivo Evaluation of a Technetium-99m-Labeled Cyclic RGD Peptide as a Specific Marker of $\alpha_V\beta_3$ Integrin for Tumor Imaging

Zi-Fen Su, Guozheng Liu, Suresh Gupta, Zhihong Zhu, Mary Rusckowski, and Donald J. Hnatowich*

Division of Nuclear Medicine, Department of Radiology, University of Massachusetts Medical School, Worcester, Massachusetts 01655. Received September 20, 2001; Revised Manuscript Received March 11, 2002

Three amino acids residues, Arg-Gly-Asp (RGD), in vitronectin and fibronectin show affinity for $\alpha_V\beta_3$ integrins expressed in vascular endothelial cells. That tumor growth can upregulate the expression of these integrins on tumor cells for invasion and metastasis and in tissue neovasculature suggests the potential of developing radiolabeled RGD peptides as antagonists of $\alpha_V\beta_3$ integrins for broad spectrum tumor specific imaging. The polypeptide RGD-4C, which contains four cysteine residues for cyclization, has shown preferential localization on integrins at sites of tumor angiogenesis. Both RGD-4C and RGE (Arg-Gly-Glu)-4C (as control) were purchased and conjugated with 6-hydrazinopyridine-3-carboxylic acid (HYNIC) for ^{99m}Tc radiolabeling. After purification of the conjugated peptides by a C18 Sep-Pak cartridge with 20% methanol, both peptides were radiolabeled using tricine. For cell binding studies, both ^{99m}Tc peptides were further purified by SE HPLC. High specific radioactivity of labeled cyclized RGD/E (cyclized RGD/E will be simplified as RGD/E through out the text) of about 20 Ci/μmol was achieved. Both ^{99m}Tc complexes were stable in the labeling solution for over 24 h at room temperature. In the human umbilical vein endothelial (HUVE) cell studies, the binding at 1 h of radiolabeled RGD/E was determined at 4 °C and at concentrations in the picomolar to nanomolar range. Under these conditions, cell accumulation of ^{99m}Tc in the case of RGD was as much as 16 times greater than the control RGE. As a check on specificity, 7 nM of native cyclized RGD blocked 50% of the binding of ^{99m}Tc-labeled RGD to cells. The binding percentage of ^{99m}Tc-labeled RGD to purified $\alpha_V\beta_3$ integrin protein, as determined by SE HPLC, increased with the concentration of the integrin while ^{99m}Tc-labeled RGE showed no binding. The association constant for ^{99m}Tc-RGD was modest at 7×10^6 M^{-1}. In both human renal adenocarcinoma (ACHN) and human colon cancer cell line (LS174T) nude mouse tumor models, the accumulation of ^{99m}Tc-labeled RGD/E exhibited no statistical difference. In conclusion, possibly because of limited numbers of $\alpha_V\beta_3$ integrin receptors per tumor cell and low binding affinity, radiolabeled RGD peptides may have limitations as tumor imaging agents.

INTRODUCTION

Tumors must establish a neovasculature to grow. To do so, the endothelial cells need to organize themselves into capillaries anchored to the extravascular matrix. The organization of the vascular endothelial cells is accomplished by an interaction of dimerized single-transmembrane glycoproteins (vitronectin, fibronectin, and von Willebrand factor), named $\alpha_V\beta_3$ integrin, with triplet peptides Arg-Gly-Asp (RGD) sequenced in the proteins of the extracellular matrix (*1*, *2*). The $\alpha_V\beta_3$ integrins are also expressed on cancer cells (*3*, *5*) and therefore play an important role in the invasion (*6*), metastasis (*7*, *8*), proliferation (*9*), and apoptosis of cancer (*10*, *11*). Because the expression of $\alpha_V\beta_3$ integrins is reported to be strong on activated endothelial cells but restricted on normal cells (*12*, *13*), synthetic RGD containing small peptides have been proposed as antagonists (*14*, *15*) against vascular endothelial cell and tumor growth. The RGD peptides, by binding to $\alpha_V\beta_3$ integrin of either endothelial or tumor cells, are capable of inhibiting cell−matrix interaction (*16*), interrupting signal transmission (*17*), affecting cell migration (*18*, *19*), and causing tumor cell regression (*20*, *21*) or apoptosis (*22*, *23*).

The detection of early stage cancer is important in preventing cancer cell metastasis. However, the sensitivity and specificity of current methods for cancer detection especially in early stages are not ideal (*24*). Radiolabeled RGD peptides could be used as a class of tumor (i.e. tumor angiogenesis) specific markers in cancer detection (*25*, *26*). Haubner et al. (*27*) have prepared two ^{125}I-labeled RGD peptides, [^{125}I]-3-iodo-D-Tyr^4-cyclo(-Arg-Gly-Asp-D-Tyr-Val-) and [^{125}I]-3-iodo-D-Tyr^5-cyclo(−Arg-Gly-Asp-D-Phe-Tyr-), as tumor $\alpha_V\beta_3$ integrins antagonists. The accumulation of the ^{125}I-RGD in xenotransplanted melanoma M21 tumors in mice was 1.3−2% ID/g at 1 h postinjection and decreased with time. To improve the tumor uptake, a sugar group was introduced into the cyclic peptides (*28*). The tumor uptake of the glycosylated ^{125}I-RGD remained at 3% ID/g 1 to 4 h postinjection.

It has been reported that the aspartic acid residue of RGD is highly susceptible to chemical degradation leading to the loss of biological activity (*29*). This degradation was prevented when the RGD-containing peptide was cyclized via disulfide linkage (*29*, *30*). In addition to improved stability, these cyclic peptides show higher potency than the linear peptides in inhibiting the attachment of vitronectin (*31*) to cells. Peptide RGD-4C contains four cysteine residues forming two disulfide

linkages in the molecule. In phage display studies, only phage carrying the RGD-4C peptide accumulated in tumor whereas phage carrying another linear RGD peptide did not (*31*, *32*). Preliminary xenotransplanted tumor imaging studies from this laboratory suggested that ^{99m}Tc-labeled cyclic RGD-4C, (Cys^1-Cys^9, Cys^3-Cys^7) H_2N-Cys-Asp-Cys-Arg-Gly-Asp-Cys-Phe-Cys-COOH, may localize on integrins at sites of tumor angiogenesis (unpublished data). However, high specific radioactivity labeling would be required for $\alpha_V\beta_3$ integrin imaging if the number of integrins expressed on tumor vascular cells was low as reported by others (*33*). In this study, we prepared purified ^{99m}Tc-labeled RGD-4C as positive and RGE-4C, (Cys^1-Cys^9, Cys^3-Cys^7)H_2N−Cys-Asp-Cys-Arg-Gly-Glu-Cys-Phe-Cys-COOH, as negative control peptides at high specific radioactivity, carried out an in vitro $\alpha_V\beta_3$ positive human umbilical vein endothelial (HUVE) cell (*34*, *35*) binding test, and imaged the biodistributions of the ^{99m}Tc complexes in nude mice bearing either xenotransplanted human ACHN or LS174T tumors.

EXPERIMENTAL PROCEDURES

Materials and Methods. RGD/E peptides were purchased from Advanced ChemTech (Louisville KY). Succinimidyl 6-hydrazinopyridine-3-carboxylate (NHS−HYNIC) was synthesized as described (*36*). *N*-tris-(hydroxymethyl)methylglycine (tricine), *N*-[2-hydroxylethyl]piperazine-*N*′-[2-ethanesulfonic acid] (HEPES), trifluroacetic acid (TFA), dimethyl sulfoxide (DMSO), and d_6-DMSO were purchased from Aldrich (Milwaukee, WI) or Sigma (St. Louis, MO). Na^{99m}TcO$_4$ was obtained from ^{99}Mo/^{99m}Tc generator (DuPont Pharma, Billerica, MA). C18 Sep-Pak cartridges were produced by Waters Corporation (Milford, MA). The human $\alpha_V\beta_3$ integrin protein (MW 237 kDa, stored in a solution of 20 mM Tris-HCl, pH 7.5, 150 mM NaCl, 2 mM $MgCl_2$, 0.1 mM $CaCl_2$, 0.2% Triton X-100) was obtained from Chemicon International, Inc. (Temecula, CA). Human umbilical vein endothelial (HUVE) cells, endothelial cell basal medium (EBM), and endothelial cell growth medium (EGM) were provided by Clonetics (Walkersville, MD). Human renal adenocarcinoma (ACHN) cell line and human colon cancer cell line (LS174T) were obtained from American Type Culture Collection (Manassas, VA). Minimum essential medium (MEM) and fetal bovine serum (FBS) were purchased from Gibco BRL Products (Gaithersburg, MD). NIH Swiss nude mice were provided by Taconic Labs (Germantown, NY). Nembutal was from Abbott Laboratories (North Chicago, IL).

Zorbax SB300 C18 reversed phase (RP) column (4.6 × 250 mm, 5 μm) was manufactured by Agilent Technologies (Palo Alto, CA). Size exclusion (SE) Superdex Peptide HR 10/30 column (1.0 × 30 cm) was produced by Pharmacia Biotech AB (Uppsala, Sweden). The high performance liquid chromatography (HPLC) system consisted of a 501 and a 510 pump and a 2487 dual channel UV detector (Waters, Milford, MA) fitted with a homemade in-line radiation detector. Radioactive samples were counted in a Packard Cobra II well counter. The centrifuge (Biofuge fresco) was produced by Kendro Laboratory Products (Newtown, CT). Fast-atom-bombardment (FAB-MS) and electrospray ionization (ESI-MS) mass spectra were measured by a JEOL JMS-AX505HA mass spectrometer (JEOL USA, Inc., Peabody, MA).

NHS−HYNIC Conjugation. The RGD/E peptides (1 mg, ∼1 μmol) dissolved in 1 mL of 0.1 M pH 8.0 HEPES buffer were stirred at room temperature. To each solution

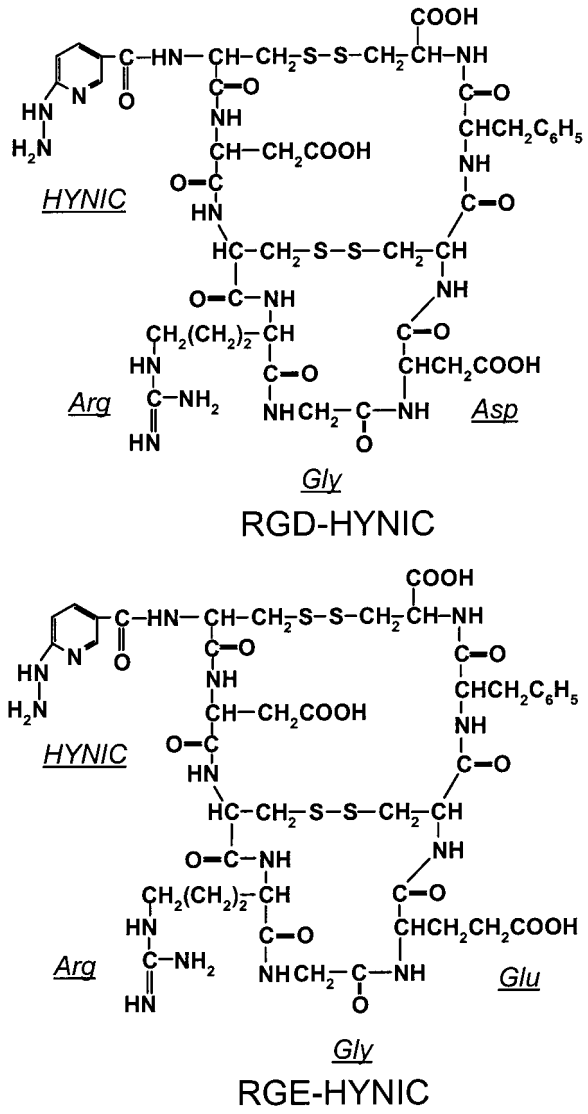

Figure 1. Proposed structures of RGD−HYNIC and RGE−HYNIC.

was added 5 μmol (1.4 mg) of NHS−HYNIC dissolved in 50 μL of dry *N*,*N*-dimethylformamide (DMF, dried over 4 Å molecular sieve). After 1−2 h, the coupling solution was loaded on a C18 Sep-Pak cartridge, preconditioned with 5 mL of methanol followed by 5 mL of water. The loaded cartridge was first washed with 5 mL of water, and 0.3 mL fractions were collected using 20% of MeOH as eluant. Each fraction was analyzed by RP (reversed phase) HPLC with water/acetonitrile solvents pair containing 0.1% TFA as mobile phase with gradient from 100% water to 10% water over 25 min. The fractions with the highest concentration of RGD or RGE, as indicated by UV absorption at 240 and 254 nm, were pooled and lyophilized. Approximately 70% of the theoretical yields were obtained in both cases. The expected structures of RGD/E-HYNIC are shown in Figure 1 and differ only in the extra methylene group of RGE (Glu vs Asp).

Technetium-99m Labeling. The influence of pH values and concentrations of all reagents on the ^{99m}Tc labeling efficiency of RGD/E was investigated. The percentage of pertechnetate and reduced ^{99m}Tc oxide colloid were determined by thin layer and paper chromatography, such as ITLC−SG with saline and Whatman No. 1 paper strip with acetone as developing solvent. The radiochemical purity, recovery, and stability of the ^{99m}Tc-labeled peptides were evaluated by RP HPLC with

either water/acetonitrile or water/acetonitrile containing 0.1% TFA as mobile phase. In this way, labeling conditions were optimized.

The general procedure for ^{99m}Tc labeling of the conjugated peptides was as follows: 0.05 μg to 0.2 μg (0.043−0.17 nmol) of RGD/E-HYNIC in 5 to 20 μL of water, 15 μL of 100 mg/mL tricine in water, 50 μL of 0.25 M pH 5.2 NH_4OAc buffer, 1 to 5 mCi of ^{99m}Tc pertechnetate generator eluant, and 4 to 8 μg of $SnCl_2$ in 10 μL 0.04 N HCl solution were mixed. After incubation at room temperature for 20 min, the labeling solution was analyzed. For in vivo and in vitro tests, the ^{99m}Tc-labeled peptides were purified by SE HPLC collecting every 0.7 mL. The purity of the fraction with the highest radioactivity was tested before use by reanalysis on SE HPLC with 0.1 M pH 7.2 phosphate buffer (PB). The ^{99m}Tc-labeled native RGD/E and NHS−HYNIC were used to identify HPLC peaks due to the radiochemical impurities. Fractions containing the major peaks off RP and SE HPLC for both ^{99m}Tc-labeled peptides were collected separately. The collected fractions were reinjected into both HPLC systems as a check on retention times, radiochemical purity, recovery, and stability.

Binding of Labeled RGD/E to $\alpha_V\beta_3$ Integrin. To establish whether ^{99m}Tc-labeled RGD, like native RGD, shows binding affinity to the $\alpha_V\beta_3$ integrin, both SE HPLC purified labeled RGD and RGE were separately mixed with purified $\alpha_V\beta_3$ integrin protein and analyzed by SE HPLC. Before mixing, the $\alpha_V\beta_3$ integrin protein appeared as a sharp single peak in the UV with retention time of 10.4 min, and the purified ^{99m}Tc complexes of RGD/E appeared in the radioactivity profile as a single peak at 22 min. Purified ^{99m}Tc-RGD ($1.7-2.6 \times 10^{-14}$ mol) along with $2-3 \times 10^{-12}$ mol of unlabeled conjugated RGD and the purified ^{99m}Tc-RGE ($1.9-3.3 \times 10^{-14}$ mol) along with $2-3 \times 10^{-12}$ mol of unlabeled conjugated RGE were mixed with various amounts of the $\alpha_V\beta_3$ integrin protein (5 μg, 10 μg, and 15 μg, $2.1-6.3 \times 10^{-11}$ mol) and analyzed by SE HPLC.

HUVE, ACHN, and LS174T Cells. HUVE cells are known to express $\alpha_V\beta_3$ integrin.[35,37] This cell line was cultured in EGM (500 mL of EBM with supplements of 0.5 mL of 10 ng/mL human recombinant epidermal growth factor (hEGF), 0.5 mL of 1.0 μg/mL of hydrocortisone, and 2.0 mL of a 3 mg/mL solution of bovine brain extract (BBE), 0.5 mL of 50 μg/mL gentamicin, 0.5 mL of 50 ng/mL amphotericin B) containing 10% FBS in a 37 °C incubator with 5% CO_2. The cells were harvested in 0.05% trypsin/0.02% EDTA. After cell counting using a trypan blue dye exclusion assay, the cells were suspended in either EGM, EBM, or PBS at a concentration of 2 to 3×10^6 cells/mL for use. It is assumed that the volume of 500 million HUVE cells is roughly 1 mL.

ACHN and LS174T cell lines were grown in MEM containing 2 mM L-glutamine, 1.5 g/L sodium bicarbonate, 0.1 mM nonessential amino acids, 1.0 mM of sodium pyruvate, 10% FBS, and 100 mg/mL of penicillin−streptomycin. After being harvested and rinsed with trypsin/EDTA, the cells were suspended in MEM with 0.1% human serum albumin (HSA) to a concentration of about 10^7 cells/mL for animal implanting.

Binding of Labeled RGD/E to HUVE Cells. HUVE cells were cultured in EGM containing 10% FBS. After being harvested, the cells were washed in PBS and suspended in either PBS, EBM, or EGM at a concentration of 2 to 3×10^6 cells/mL. To the cell suspension was added 0.01−15 μCi of the SE HPLC purified labeled RGD or RGE. The cell suspension was incubated at 4 °C for 30 min and then centrifuged at 2000 rpm for 4 min. A 30 μL volume of the supernatant was transferred to a plastic tube for radioactivity counting. The cell pellets were washed with cold fresh medium three times and separated from the supernatant for counting. The count (*38*) of the cell pellet was defined as C_{cell}. The count of an equal volume of the supernatant was defined as C_{medium}.

Binding Competition of Labeled RGD and Native RGD to HUVE Cells. Various amounts (final concentration between 50 pM to 58 μM) of native RGD was added to Eppendorf vials containing $2-3 \times 10^6$ HUVE cells suspended in EGM. After incubation at 4 °C for 30 min, the labeled RGD (0.17 μCi) was added, and the cells were incubated for a further 1 h at 4 °C. The vials were centrifuged, and 30 μL of supernatant was transferred for counting. After being washed three times with cold fresh EGM, the cell pellet in the Eppendorf tip was placed in a plastic test tube for counting.

In Vivo Biodistribution of Labeled RGD/E in Tumor-Bearing Mice. LS174T cells (10^6) in MEM containing 0.1% HSA were implanted in one thigh in each of four nude mice. After the tumor grew to approximate 1 cm in any dimension, two animals each received approximately 0.17 μg (0.16 nmol, 24 μCi) of the purified ^{99m}Tc-RGD or RGE. Animals were imaged at 6 h postinjection and were then sacrificed for biodistribution. Radioactivity of the tissue samples was measured against a standard of each injectate.

Each of 10 nude mice was implanted with 10^6 ACHN cells in one thigh. After the tumor size was 1 cm in any dimension, each animal received approximately 4.7 ng (4.1 pmol, 24 μCi) of the purified labeled RGD or RGE. Thus each ACHN-bearing animal received only about 3% of the peptide dosage received by each of the LS174T-bearing animals. The animals were imaged at 6 h postinjection and sacrificed.

Imaging. Mice anesthetized with Nembutal (1.5 mg/25 g mouse) were placed horizontally on the face of the upright collimator. Scintigrams were taken with an Elscint (Hackensack, NJ) APEX 409 M portable large field of view scintillation camera equipped with a parallel hole, medium-energy collimator and an Elscint APEX F1 computer. Images were acquired for a preset time using a 256 × 256 matrix with a 30% energy window set at 140 keV.

RESULTS

HYNIC Conjugation. The molecular mass of RGD measured by FAB-MS was 1017.2714 ($[M + H]^+$, $C_{37}H_{53}N_{12}O_{14}S_4$), calcd 1017.2687, while that of RGE was 1031.2850 ($[M + H]^+$, $C_{38}H_{55}N_{12}O_{14}S_4$), calcd 1031.2843. The errors of the measurements were 2.6 and 0.6 ppm, respectively. The molecular mass of HYNIC-coupled RGD detected by ESI-MS was 1152.3 ($[M + H]^+$, $C_{43}H_{58}N_{15}O_{15}S_4$), calcd 1152.3, whereas the molecular ion of the RGE−HYNIC was not seen on the spectrum. The RGE−HYNIC was then further purified by RP HPLC, lyophilized, and measured by ESI-MS, ES-MS, and FAB-MS, but no expected molecular ion was detected. This may possibly be due to the instability of RGE−HYNIC. C18 Sep-Pak cartridges were used as a simple and effective method to separate the labeled peptides from most of the impurities, such as NHS−HYNIC, hydrated HYNIC, HEPES, and solvents such as DMF. After the purification, the ratio of peptide-HYNIC to uncoupled peptides was in the range of 6 to 10 as indicated by UV absorbance on RP HPLC. Neither native RGD/E exhibited a maximum absorption in the range of 240 nm to 600 nm, while both of the coupled peptides revealed

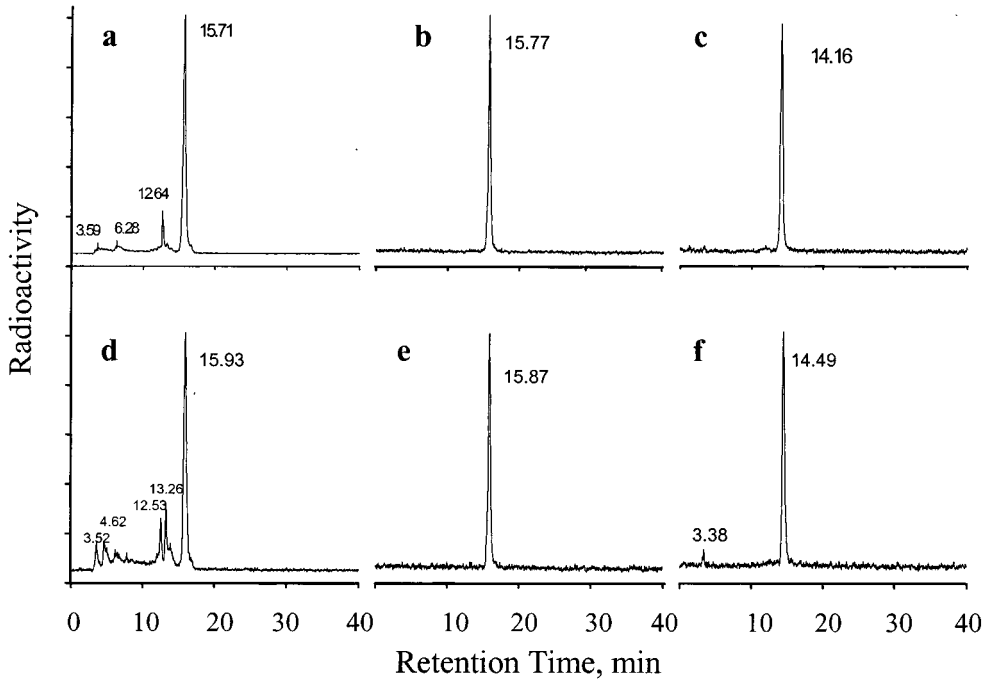

Figure 2. RP HPLC radiochromatograms of ^{99m}Tc-labeled RGD (panel a) and ^{99m}Tc-labeled RGE (panel d) with water/acetonitrile containing 0.1% TFA as mobile phase. The major peak of panels a and d was isolated, re-injected, and analyzed by RP HPLC with (panel b for ^{99m}Tc-RGD and panel e for ^{99m}Tc-RGE) and without 0.1%TFA in the eluant (panel c for ^{99m}Tc-RGD and panel f for ^{99m}Tc-RGE, respectively).

maximum absorption at 283 nm with extinction coefficient of 1.1×10^4 cm^2/mol. The retention times of the native RGD/E on RP HPLC were 15.0 and 15.2 min, respectively. When coupled with HYNIC, the peptides became less hydrophilic than the native peptides and the retention times increased to 15.5 and 15.7 min, respectively. The presence of unlabeled peptides did not significantly affect the ^{99m}Tc labeling of the coupled peptides.

Technetium-99m Labeling. The labeling efficiency of both HYNIC-coupled RGD/E was identical at about 85−90% compared to 10−30% for native, uncoupled RGD/E. Figures 2a and 2d show RP HPLC radiochromatograms (with water/acetonitrile containing 0.1% TFA as mobile phase) of ^{99m}Tc-labeled RGD (retention time 15.7 min) and RGE (15.9 min), respectively. The major peak in Figure 2a was isolated and reinjected into the RP column with (Figure 2b) or without (Figure 2c) 0.1% TFA in the mobile phase. Similarly, the major peak in Figure 2d was isolated and reanalyzed by RP HPLC with (Figure 2e) or without (Figure 2f) 0.1% TFA in the mobile phase. The reanalysis indicated that the purified radiolabeled peptides were pure and stable in the two solvent systems. The ^{99m}Tc labeling of RGD/E without HYNIC produced broad peaks (retention times from 12 to 17 min) on RP HPLC not seen in the labeling of HYNIC coupled RGD/E. Free NHS−HYNIC did not show significant ^{99m}Tc labeling under the same conditions (data not shown). When the labeling was carried out in neutral media, such as water or 0.1 M PB pH 7.2, the impurity peaks at 12.6 to 13.3 min (Figure 2a, 2d) could be as high as 44% but were much lower at 11−22% when the labeling was carried out in 0.25 M acetate buffer pH 5.2. Little pertechnetate remained but approximately 10−15% of ^{99m}Tc was present as radiocolloids. Presumably for this reason, approximately 30−50% of ^{99m}Tc was retained on the RP or SE column during the HPLC purification of the labeled peptides. The formation of radiocolloids could be reduced through the use of ^{99m}Tc-gluconate or ^{99m}Tc-tartrate as transfer ligands, but the labeling efficiency then decreased possibly because of competition of these transfer ligands with tricine. It was primarily to remove ^{99m}Tc colloids that the labeled RGD (Figure 3a) and labeled RGE (data not shown) were purified by SE HPLC before use. The purified ^{99m}Tc peptides were reanalyzed by RP HPLC, which showed a major sharp peak at 15.4 min in the radiochromatograms identical to that of the unpurified sample. This indicated that the major peak on both RP and SE HPLC was due to the desired ^{99m}Tc complexes.

The radiochemical purity, recovery, and the percentage of ^{99m}Tc colloid remained unchanged on standing for the unpurified labeled peptides over 20 h. After the HPLC purification, the radiochemical purity and recovery of both labeled RGD/E were over 95% by RP HPLC with or without 0.1% TFA in the mobile phase. Reanalysis by SE HPLC showed a single peak in both cases with a retention time of 23 min and recovery of 78−85% (Figure 3b). This indicated that the ^{99m}Tc-labeled peptides are stable in either acidic or neutral media (e.g. water or 0.1 M pH 7.2 PB).

High Specific Activity Preparation of Labeled RGD/E. High specific radioactivity could be achieved by labeling as little as 0.4 pmol to 4.3 nmol of both peptides with a large excess of ^{99m}Tc. The minimum molarity providing adequate radiolabeling by RP HPLC was about 4.3 pmol (5 ng), and in this case the labeling efficiency was only 10%. Labeling of higher amounts of peptide generally resulted in higher radiochemical yield, but the radiochemical recovery from RP HPLC remained unchanged (52−55%) due to ^{99m}Tc colloid formation. To optimize specific radioactivity, especially for cell binding studies, labeling of 43 pmol (50 ng) RGD/E with increasing amounts of ^{99m}Tc was investigated. The results, illustrated in Figure 4, show that the maximum specific radioactivity was approximately 20−30 Ci/μmol for both peptides (depending somewhat on the quality of ^{99m}Tc pertechnetate generator eluant). Therefore, in practice, 43 to 86 pmol (50 to 100 ng) of the peptide was labeled

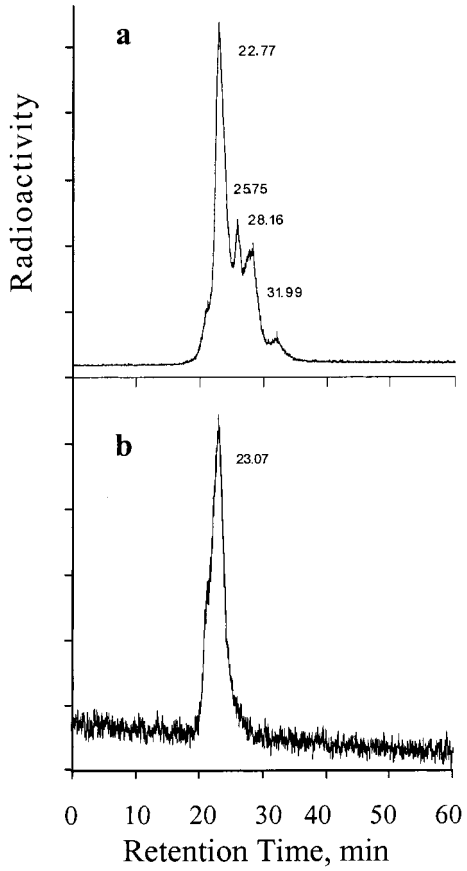

Figure 3. SE HPLC radiochromatograms of ^{99m}Tc-labeled-RGD before (panel a) and after the major peak was isolated and re-injected (panel b).

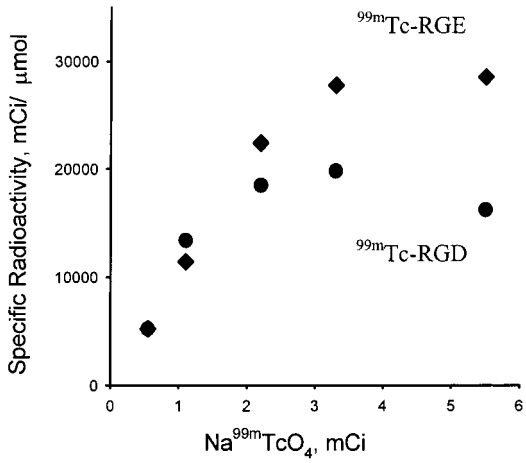

Figure 4. Influence on specific radioactivity of ^{99m}Tc-RGD (circles) or -RGE (squares) with increasing ^{99m}Tc radioactivity ranging from 0.5−5.5 mCi.

for both cell binding and animal studies. To ensure sufficient quantities of purified labeled peptides (100−300 μCi in 0.7 mL of phosphate buffer) for five animal injections, 86 to 129 pmol (0.1−0.15 μg) of peptide was used for each of the labelings.

Integrin Protein Binding. Figure 5 illustrates the UV chromatogram of 15 μg of $\alpha_V\beta_3$ integrin protein (top panel), the radiochromatograms of the mixture of 15 μg of integrin protein with 13 μCi of purified RGD (middle panel) or with 17 μCi of RGE (bottom panel). By comparison with labeled RGE, the ^{99m}Tc complex of RGD exhibited a shift with $\alpha_V\beta_3$ integrin protein on the chromatogram indicating specific binding. The binding

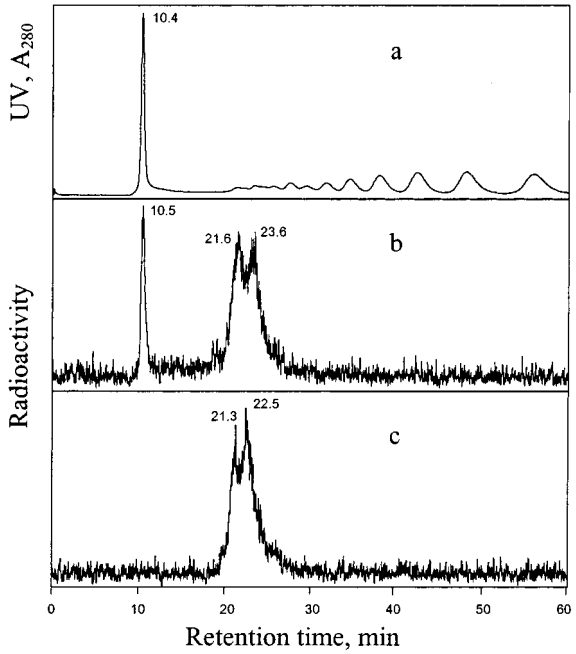

Figure 5. SE HPLC chromatograms of the $\alpha_V\beta_3$ integrin protein at 10.4 min in the UV (panel a) and the radioactivity profiles resulting from the addition to the $\alpha_V\beta_3$ integrin protein of ^{99m}Tc-RGD (panel b) and ^{99m}Tc-RGE (panel c) under similar conditions. A shift in the radioactivity profile to the retention time of the integrin is seen only in the case of RGD.

percentage of labeled RGD to $\alpha_V\beta_3$ integrin protein increased from 7.5% to 20.4% with a corresponding increase in the concentration of the integrin (0.2−0.5 μmol). By contrast, no significant binding was seen for labeled RGE. It is interesting that the majority of the label remained unbound even though the molarity of the integrin used was greater than the sum of the labeled and unlabeled RGD. This implies a weak association constant of RGD−HYNIC with the integrin. It may be assumed that one molecule of RGD binds with one integrin, and the binding equilibrium can be described by eq 1:

$$^{99m}\text{Tc-RGD} + \text{Integrin} = \text{Integrin} - (^{99m}\text{Tc-RGD}) \quad (1)$$

Then, if K is the equilibrium constant, eq 1 can be rewritten as eq 2:

$$\log\{[^{99m}\text{Tc-RGD}]_b/[^{99m}\text{Tc-RGD}]_f\} = \log K + \log[\text{Integrin}]_f \quad (2)$$

where $[^{99m}\text{Tc-RGD}]_b$ and $[^{99m}\text{Tc-RGD}]_f$ are the concentrations of the bound and the free ^{99m}Tc-RGD, respectively, while $[\text{Integrin}]_f$ is the concentration of the free $\alpha_V\beta_3$ integrin protein. The $[\text{Integrin}]_f$ was estimated from the difference of the total integrin used minus the integrin bound. Assuming that the labels, free or bound, and the unlabeled RGD were not decomposed when passing through the SE HPLC, the association constant K (eq 2) can be estimated from a log−log plot of the ratio of bound to free ^{99m}Tc-RGD, as detected by SE HPLC, vs the concentration of the free integrin. The plot (data not shown) exhibited a straight line with a slope of 1.17 (correlation coefficient $r = 0.98$) and an intercept of 6.8. The slope suggested that roughly one RGD was bound to each integrin protein, whereas the intercept indicated that the association constant of ^{99m}Tc-RGD−HYNIC with $\alpha_V\beta_3$ integrin protein was modest ($\sim 7 \times 10^6$ M^{-1}).

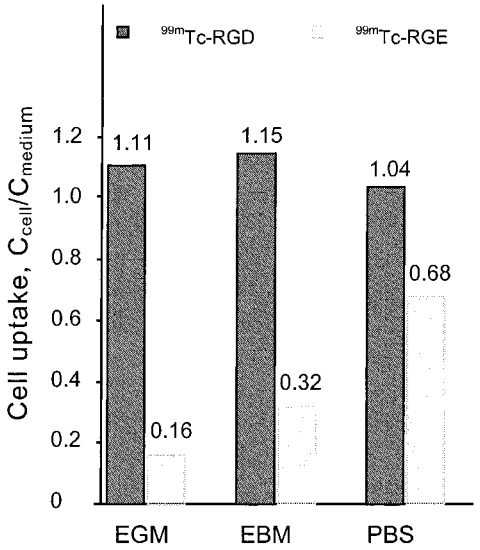

Figure 6. Histograms showing the ratio of counts in the pellet to counts in the supernatant i.e., C_{cell}/C_{medium}) for ^{99m}Tc-RGD and ^{99m}Tc-RGE added to HUVE cell incubated in three different media.

[a] The RGD and RGE radiolabels were purified by SE HPLC before use.

Cell Binding. SE HPLC purified labeled RGD/E were used as positive and control for HUVE cells binding, respectively. The results revealed that the ^{99m}Tc complexes exhibited important differences in cell binding as expected. For example, labeled RGD showed 5- to 16-fold higher binding than that of the control (Table 1). Cell uptake of both ^{99m}Tc complexes improved slightly when the specific radioactivity increased. However, this improvement in C_{cell}/C_{medium} was surprisingly small in comparison to the large change in specific radioactivity. Furthermore, the type of media influenced the binding of ^{99m}Tc-RGE but not ^{99m}Tc-RGD. The C_{cell}/C_{medium} ratios of ^{99m}Tc-RGD in HUVE cells in the three media were similar, while those of ^{99m}Tc-RGE varied with the media (Figure 6).

It was important in this research to estimate the average number of $\alpha_V\beta_3$ integrin expressed per cell since this value is a direct determinant of the potential of tumor imaging with ^{99m}Tc-labeled RGD. Scatchard plot is a common method used in determining the number of binding sites per cell by using ^{125}I-labeled macro molecules (*39*). However, an excessive molarity of peptide is usually required for the labeling with ^{99m}Tc (the ratio can be 100:1 or larger), and thus the unlabeled peptide would compete with the label for $\alpha_V\beta_3$ integrin protein binding. For this reason, using Scatchard plots to determine the cell-binding site with ^{99m}Tc-labeled peptide was assumed to be inappropriate (*40*). However, it was advisable to test the dependence of cell uptake on the concentration of labeled RGD in the medium. After 30 min incubation

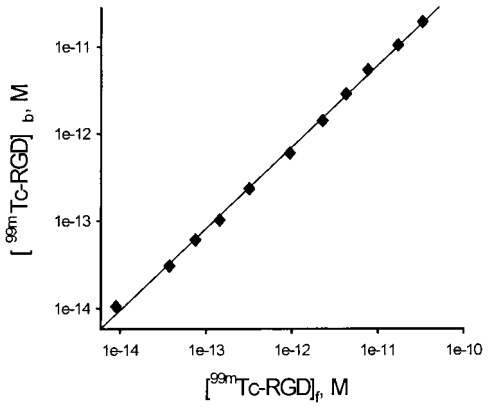

Figure 7. Log−log plot of concentration of ^{99m}Tc-RGD bound vs the complex present in supernatant. The subscript "b" stands for "bound" whereas "f" for "free".

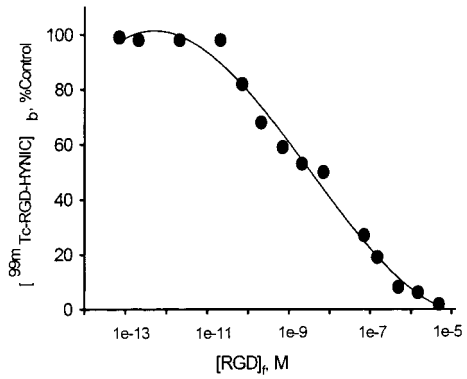

Figure 8. Semilog plot showing increasing inhibition of binding of purified ^{99m}Tc-RGD to HUVE cells with increasing concentrations of native RGD. Plotted as the percentage of bound ^{99m}Tc-RGD vs concentration of unlabeled RGD in supernatant. The subscript "b" stands for "bound" whereas "f" for "free".

with labeled RGD at temperatures close to 4 °C, the HUVE cells were isolated from the medium; the radioactivity in the cell pellets and in the supernatant was measured separately and expressed in terms of concentration (assuming 500 million HUVE cells have a volume of 1 mL). Figure 7 illustrates the log−log plot of concentration of the labeled RGD bound to HUVE cells vs that of the free drug in the medium. That a straight line with a slope of unity resulted suggested that the ^{99m}Tc-RGD was partitioned almost equally between cells and the medium. Accordingly, the uptake of labeled RGD in these cells under this experimental condition might not be generated from the binding with $\alpha_V\beta_3$ integrin protein but rather by a mechanism of passive diffusion or internalization. This diffusion might happen at the lowest concentration (10^{-14} M) of ^{99m}Tc-RGD tested. If this diffusion occurred after the saturation of the $\alpha_V\beta_3$ integrin by RGD, the number of binding sites on the cell must then be small and easily saturated.

Binding Competition Test. The above results show that $\alpha_V\beta_3$ binding sites on HUVC cells can be easily saturated. Since unlabeled RGD will compete with labeled RGD for a limited number of binding sites, a specific radioactivity as high as possible was necessary for the cell binding tests and for the animal imaging. After purification, 0.4 pmol of labeled RGD was added to 2.1×10^6 HUVE cells preincubated with increasing amounts of native RGD. Figure 8 shows the percent of labeled RGD bound vs the concentration of the native RGD added. The binding decreased with increasing

concentration of native RGD as expected with 50% binding blocked by approximately 7×10^{-9} M of native RGD.

In Vivo Animal Tests. Both LS174T and ACHN tumors were used for in vivo studies. While approximately the same radioactivity (24 μCi) was injected in each animal, each LS174T animal received 170 ng of labeled RGD/E while each ACHN animal received only 4.7 ng of these peptides. Images were taken 3 and 6 h postinjection. The biodistribution results at 6 h are listed in Table 2 (LS174T tumor) and in Table 3 (ACHN tumor). The accumulation in both tumors for both peptides was similar at 0.6−0.8% ID/g. Thus, the higher specific radioactivity used in the ACHN mice did not result in improved accumulations over that used in the LS174T mice.

DISCUSSION

Current methods of detecting cancer have both low specificity and sensitivity. There is, therefore, a pressing need for a widely available, noninvasive test for the diagnosis of cancer. It is likely that further gains in specificity and sensitivity can be achieved by using receptor-based imaging agents that target specific features of cancer tissue such as its neovasculature. In all neoplastic diseases, tumor growth and metastasis require persistent new blood vessels without which tumor cells become necrotic or apoptotic (41−45). Among the molecular markers associated with neovascular angiogenesis is the $\alpha_V\beta_3$ integrin, a protein that is absent or barely detectable in established blood vessels but is concentrated in forming blood vessels (*46*). Thus, the early and highly selective appearance of this integrin in tumor makes it a useful target for tumors imaging.

The cysteine-rich (*47*) cyclic polypeptide RGD-4C molecules were designed as $\alpha_V\beta_3$ integrin specific marker for tumor angiogenesis imaging. However, as reported (*33*), the number of $\alpha_V\beta_3$ integrin proteins expressed on endothelia or tumor cells may be limited. If the number of target integrins is limited, then a high specific radioactivity will be required to prevent saturation of integrin binding during imaging. Technetium may be complexed by ligands attached to biological molecules; however, thermodynamically, excessive chelator has to be applied for adequate chelation of ^{99m}Tc. It is thus difficult to achieve high specific radioactivity although there are examples. A unique method has been reported by Baidoo et al. (*48*). After the radiolabeling of a peptide containing a diaminedithiol chelator, the unlabeled peptide was removed on a iodoacetamide-derivatized gel resulting in a specific radioactivity of at least 100 Ci/μmol (the remaining unlabeled peptide was below the UV detection limit). Another successful approach to achieving high specific activity of ^{99m}Tc-labeled peptides used HYNIC as chelator and was reported by Liu et al. (*49*). A specific radioactivity of 20 Ci/mol was achieved by labeling 4.7 nmol of HYNICtide with 100 mCi of pertechnetate.

The coupling of NHS−HYNIC to RGD and RGE was convenient (*50*), and the purification of RGD−HYNIC and RGE−HYNIC by C18 Sep-Pak cartridge was simple and reproducible. Only 43−129 pmol of RGD/E (about 1% to 0.1% the amount of peptides usually used for ^{99m}Tc labeling) was successfully labeled in this laboratory at a specific radioactivity of approximately 20−30 Ci/μmol (the free RGD/E in the labeling solution was undetectable by UV) and therefore similar to the highest values reported by others (*48*, *49*). Despite the unavoidable formation of ^{99m}Tc colloids, a radiochemically pure ^{99m}Tc complex was produced as shown by a single major peak on RP and SE HPLC. When combined with SE HPLC purification, the purity and specific activity of the ^{99m}Tc-labeled peptide was suitable for cell binding and in vivo animal imaging.

The major radioactivity peak shown on both RP and SE HPLC was believed to be the desired complex for several reasons. First, the ^{99m}Tc labeling of the coupled RGD/E always showed the same single sharp peaks on RP HPLC radiochromatograms. Second, the retention times of the ^{99m}Tc-labeled RGD/E peptides on RP HPLC were always greater than those of the unlabeled peptides, indicating the labels were more lipophilic. Third, the nonspecific ^{99m}Tc-labeled RGD and RGE showed broad peaks and a lower labeling efficiency on RP HPLC and were unstable in acidic solvents, whereas the ^{99m}Tc complexes were stable either in acidic or neutral solvents.

The labeled RGD/E were purified by SE HPLC with 0.1 M pH 7.2 PB as eluant. The purity and stability of the purified ^{99m}Tc complexes were tested by reinjection to RP and SE HPLC. The results confirmed that the major peaks in both systems were due to the same complexes, that the purification was successful and reproducible, and that the complexes were stable in either acidic solution and phosphate buffer and therefore probably stable in cell binding and in vivo animal tests.

The uptake percentage of the labeled RGE to HUVE cells was always smaller than that of the labeled RGD

almost certainly because the former does not specifically bind to the $\alpha_V\beta_3$ integrin.

The ^{99m}Tc complexes of RGD/E also showed the expected differences in $\alpha_V\beta_3$ integrin protein binding. The binding percentage of the labeled RGD rose from 7.5% to 20.4% when the concentration of the integrin increased from 0.2 to 0.5 μM while no significant increase was detected in the case of labeled RGE. This indicates a specific association of labeled RGD but not RGE with the $\alpha_V\beta_3$ integrin. That the percentage shift on SE HPLC of the labeled RGD by the addition of a molar excess of the $\alpha_V\beta_3$ integrin protein (the molar ratios of the integrin protein to the total labeled and unlabeled RGD/E peptides were 14−18) is small may be due to the weak association constant (7×10^6 M^{-1}) since the manufacturer of the integrin protein guarantees the absence of significant contamination of the integrin with matrix binding proteins.

It was seen that the binding difference of ^{99m}Tc complexes on the $\alpha_V\beta_3$ integrin protein was consistent with that seen in the HUVE cell binding tests. The data in Table 1 show a slight increase in cell binding of the labeled RGD with a large increase in the specific radioactivity, suggesting the number of the specific binding sites may be small and saturation could occur even at this low concentration of RGD peptide. The binding of antigen−antibody or receptor−ligand normally shows an increase with dosage until saturating concentrations are reached (*51*−*53*). However, the straight line of Figure 7 implies nonspecific binding even when 3×10^6 cells were incubated with lowest concentration of labeled RGD. At that point, approximately 1.7×10^7 labeled RGD molecules (3×10^{-14} M) along with 3×10^9 molecules (4.8×10^{-12} M) of unlabeled RGD were incubated with 3 million cells. If this is the case, the upper limit of the concentration of the $\alpha_V\beta_3$ integrin may be by calculation as small as 4.8×10^{-12} M. This corresponds to only one $\alpha_V\beta_3$ protein expressed on each HUVE cell. A limited $\alpha_V\beta_3$ integrin expression on HUVE (*34*, *35*, *16*) and ACHN (*54*) cell types has been confirmed but not quantified.

Taken together, the labeled RGD peptides may have limited utility as markers for tumor imaging because the binding constant of ^{99m}Tc-RGD−HYNIC to the integrin is modest (7×10^6 M^{-1}) and because of the small number of the $\alpha_V\beta_3$ integrins expressed on each tumor cell. For example the concentration of labeled RGD specifically bound to the $\alpha_V\beta_3$ integrin may be estimated: when 20 μCi purified labeled RGD ($\sim 4 \times 10^{-14}$ mol, 2.8×10^{-11} M) is injected into a mouse with a 0.2 mL xenotransplanted tumor (approximately 10^8 tumor cells) and with a blood volume of approximately 1.4 mL, it may be calculated that only one molecule of labeled RGD would get bound to 1000 tumor cells. Any accumulation exceeding this value would then be nonspecific. This assumption is in agreement with the results of our in vivo animal tests showing minimal tumor uptake of radioactivity. The fact that the tumor uptake of labeled RGE was similar to that of RGD (Tables 2 and 3) and that increasing the specific radioactivity of labeled RGD/E did not significantly improve the tumor accumulations in vivo is evidence that the uptake in endothelial or tumor cells was nonspecific.

As discussed above, the in vivo tumor uptake showed no significant difference for labeled RGD and RGE. This seemed very likely due to the small number of $\alpha_V\beta_3$ integrins expressed on either tumor capillary cells or on the tumor cells being limited and easily saturated. If this is the case, it could be difficult to use ^{99m}Tc-labeled RGD as the tumor imaging agent because the percentage of ^{99m}Tc-RGD complex bound would be extremely low with a weak association constant.

CONCLUSION

Despite the use of RGD labeled at high specific activity, the tumor uptake of ^{99m}Tc-RGD−HYNIC in $\alpha_V\beta_3$ positive tumors growing in nude mice was marginal. These results are therefore in agreement with other investigators attempting to image this receptor with cyclic RGD peptides (*28*). In this investigation, we were able to confirm that the poor imaging results are probably a result of limited numbers of these receptors on the tumor used in this investigation and probably other tumors as well.

ACKNOWLEDGMENT

We wish to thank Ms. Loretta Lee and Dr. Yumin Zhang for providing the cells used in this study. We are grateful to Dr. Bruce Line for suggesting RGE as a control peptide and for other helpful suggestions. We thank Dr. A. Mike Rauth (Ontario Cancer Institute, Toronto, ON) for kind advice and helpful suggestions to this paper. This research was funded in part by DOD grant DAMD17-00-1-03326.

Nextran Inc., 303B College Road, Princeton, New Jersey; Johns Hopkins University School of Medicine, Department of Biophysics, Baltimore, Maryland; and Baxter Healthcare Corporation, Chicago, Illinois. Received October 12, 2001; Revised Manuscript Received February 12, 2002

Porcine organs are rapidly rejected after transplantation into primate recipients due to the presence of preexisting immunoglobulins that bind to terminal galactose α1,3 galactose residues (α-galactosyl) present on porcine glycoproteins and glycolipids. Currently available immunosuppressive reagents have been largely ineffective at controlling the synthesis of these anti-Gal antibodies. Nonantigenic hapten polymers have been shown to be effective materials for blocking humoral immune responses in various model systems. We have developed a series of α-galactosyl glycoconjugate polymers and tested their ability to block anti-Gal antibody binding in vitro and in vivo. A galactose α1,3 galactose *β* 1,4 GlcNAc trisaccharide free acid (TRFA) with a hexanoic acid spacer, containing five methylene groups and a carboxylic acid, was produced and coupled to a variety of polymeric backbones including dextran, branched poly(ethylene glycol) (PEG), and poly-L-lysine. The ability of monomeric TRFA and the α-galactosyl conjugates to block anti-Gal IgG and IgM binding was determined using a competition ELISA assay on defined HSA−Gal glycoconjugates and porcine microvascular endothelial cell substrates. We show that branched PEG carriers, with a TRFA sugar attached to each branch, exhibit enhanced antibody blocking ability compared to TRFA, but at higher target antigen densities these simple PEG conjugates are no more effective then an equivalent amount of TRFA in blocking anti-Gal IgM antibody interactions. In contrast, polymers of the branched PEG conjugates and linear conjugates made using dextran and poly-L-lysine were 2000 to 70000-fold more effective inhibitors of anti-Gal antibodies. In a study using nonhuman primates, a single dose infusion of polymeric PEG or dextran glycoconjugates dramatically reduced the level of circulating anti-Gal antibodies in cynomologus monkeys for at least 72 h. Glycoconjugates similar to these might be useful both to block anti-Gal interactions in vivo and to specifically control the induced anti-Gal immune response.

INTRODUCTION

Organ transplantation is now widely viewed as the preferred treatment for end stage organ failure, on both a quality of life and overall cost basis. The demand for organs, however, is much greater than the number of people on the transplant waiting list and the availability of human organs is not likely to increase in any significant way over the next few years (Evans et al. 1992; Orians et al. 1993). The shortage of human organs has led to increased interest in both mechanical alternatives and in the use of animals to provide organs for human transplantation, the field of xenotransplantation.

For xenotransplantation, the pig, due to availability, size, and suitability for molecular engineering, is the preferred source of organs. Porcine organs, however, are rapidly rejected after transplantation into primates due to the presence of preexisting primate immunoglobulins that bind to terminal galactose α1,3 galactose residues (α-galactosyl[1]) on porcine glycoproteins and glycolipids (Good et al. 1992; Lin et al. 1997; Neethling et al. 1994; Sandrin et al. 1993; Taniguchi et al. 1996). These antibodies are responsible for initiating hyperacute rejection (HAR), and under conditions that block HAR, the strong induction of anti-Gal antibodies may contribute to the process of acute vascular xenograft rejection (Cotterell et al. 1995; Galili et al. 1997; Kozlowski et al. 1998b; McCurry et al. 1997). The immunosuppressive regimes currently used in transplantation have been largely ineffective at controlling this immune response (Alwayn et al. 1999), suggesting that alternative approaches will need to be developed.

One potential methodology to control preexisting and induced anti-Gal antibodies is through the use of nonantigenic hapten polymers. Peptide and haptens conjugated to immunoglobulins (Borel 1971; Borel and Borel 1988; Borel et al. 1996; Galanaud et al. 1975; Waldschmidt et al. 1983; Zambidis et al. 1997; Zambidis and Scott 1996), lymphocytes (Borel 1980; Cowdery et al. 1982; Li and Scott 1980), and polymeric carrier molecules (Desaymard 1977; Dintzis et al. 1990; Dintzis et al. 1989; Jones et al.

1994) have been used to establish humoral tolerance in small animal models. Dintzis and colleagues (Dintzis et al. 1990; Symer et al. 1995) demonstrated that dextran−hapten conjugates can block humoral immune responses if the conjugate density and size were carefully controlled. Although the conjugate backbone may vary, this general approach has also been applied clinically to reduce the circulation of anti-dsDNA in patients with systemic lupus erythematosus (Furie et al. 2001; Weisman et al. 1997). As a first step toward exploring the suitability of this approach in xenotransplantation, we have synthesized a series of α-galactosyl glycoconjugates and tested their ability to block anti-Gal antibody binding. A galactose α1,3 galactose β 1,4 GlcNAc trisaccharide with a five-carbon spacer arm and terminal carboxylic acid group (referred to as an hexanoic acid spacer) was coupled to a variety of polymeric backbones including dextran, branched poly(ethylene glycol) (PEG), and poly-L-lysine. All these α-galactosyl conjugates blocked anti-Gal IgG and IgM binding to an HSA−Gal glycoconjugate substrate in an ELISA assay, but the linear dextran, lysine, and polymeric PEG forms exhibited far greater activity than the simpler multivalent PEG conjugates. The in vivo effect of polymeric PEG and dextran conjugates was tested in nonhuman primates. Infusion of these conjugates was well tolerated and resulted in a dramatic reduction of the apparent titer for circulating anti-Gal IgG and IgM for up to 14 days. Compounds similar to these may be an effective method of blocking anti-Gal antibody in vivo, and these materials may have tolerative effects on anti-Gal B-cells that might lead to more profound suppression of the anti-Gal immune response.

MATERIALS AND METHODS

Synthesis of TRFA. Galactose α(1,3) galactose β(1,4) *N*-acetylglucosamine trisaccharide containing a hexanoic acid spacer (TRFA) was produced from glucosamine hydrochloride through a three-step chemoenzymatic synthesis (Figure 1). The overall synthesis consisted of two main steps, the first step being the chemical synthesis of 5-methoxycarbonylpentyl 2-acetamido-2-deoxy-β-D-glucopyranoside and the second step the enzymatic addition of galactose residues to produce 5-methoxycarbonylpentyl-α-D-galactosyl (1,3) β-D-galactosyl (1,4) 2-acetamido-2-deoxy-β-D-glucopyranoside (referred to as the trisaccharide ester). The trisaccharide ester was saponified to produce the final trisaccharide free acid (TRFA).

Synthesis of 5-Methoxycarbonylpentyl 2-Acetamido-2-deoxy-β-D-glucopyranoside. The hydroxyl groups of glucosamine hydrochloride (compound **1**) were protected by acetylation with sodium acetate and acetic anhydride in 1,2-dichloroethane. The peracetylated derivative was a mixture of the two anomers (compounds **2**). This product was not isolated but rather treated in situ with hydrogen chloride gas by bubbling for up to 7 days. The chlorine substitution proceeds with inversion of configuration, reacting only with the β-anomer for steric reasons. The mutarrotation is thus favored and equilibrium displaced until reaction completion resulting in a product with α configuration. The reaction was sequentially extracted with cold sodium bicarbonate and cold water and the organic phase dried with anhydrous magnesium sulfate. The filtrate was washed with 1,2-dichloroethane, dried, dissolved in dichloromethane, and mixed with ethyl ether and hexane. This mixture was cooled and left to crystallize. The solid was washed with hexane and dried under vacuum to give 2-acetamido-2-deoxy-α-D-glucopyranosyl chloride (compound **3**). The identity of this intermediate was confirmed by ^{1}H NMR

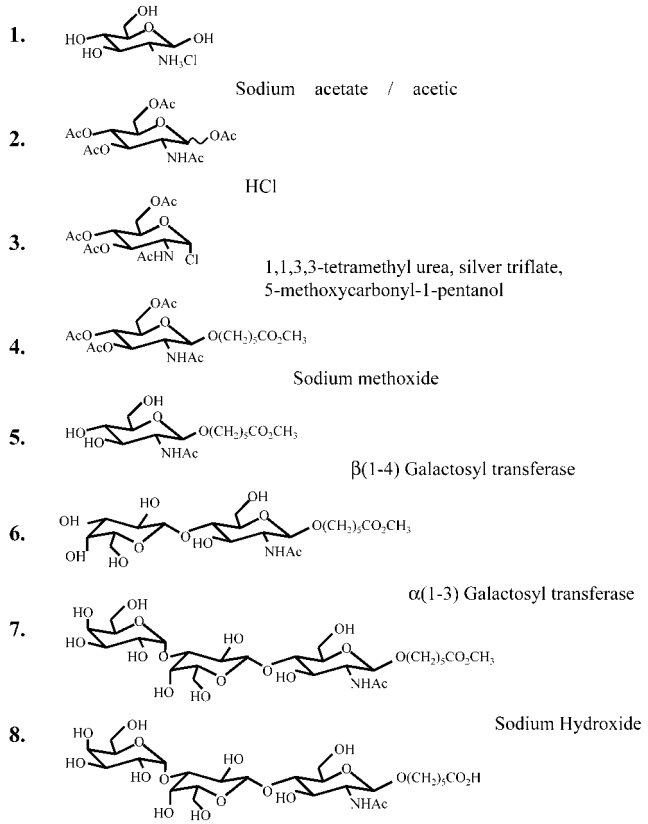

Figure 1. The starting material, glucosamine hydrochloride (compound **1**), and intermediate compounds (**2**−**7**) produced during the synthesis of galactose α(1,3) galactose β(1,4) *N*-acetylglucosamine trisaccharide containing a hexanoic acid spacer are depicted. The primary reactants used in each successive reaction are also indicated.

($CDCl_3$): δ 6.18 (1H, d, $J_{1,2}$ = 3.67 Hz, H-1), 5.32 (1H, t, $J_{3,4}$, $J_{4,5}$ = 10.62 Hz, H-4), 5.21 (1H, t, $J_{2,3}$, $J_{3,4}$ = 9.89 Hz, H-3), 2.10, 2.05, 1.98 (9H, 3s, OCOCH_3). The hexanoic acid spacer was added to the intermediate using 5-methoxycarbonyl-1-pentanol with 1,1,3,3-tetramethylurea and silver triflate in dichloromethane under the conditions of the Koenigs−Knorr glycosylation method. The reaction was filtered through a Celite 521 filter agent, and the filter cake was washed with dichloromethane. The filtrate was sequentially washed with concentrated HCl, sodium bicarbonate, and deionized water, and the organic phase was dried over sodium sulfate overnight. After filtration, the solids were dissolved in dichloromethane and mixed with ethyl ether and hexane for crystallization at −20 °C for 36−72 h. This intermediate glycoside (compound **4**) was analyzed by ^{1}H NMR where the conjugation of the hexanoic spacer was confirmed by the multiple peaks between 1.3 and 1.8 ppm. This material was deacetylated in methanol using sodium methoxide and neutralized with a Dowex 50 WX 8−200 resin to produce the monosaccharide ester 5-methoxycarbonylpentyl 2-acetamido-2-deoxy-β-D-glucopyranoside (compound **5**). The regiospecificity of the reaction was confirmed by checking the purity of compound **5** by ^{1}H NMR spectroscopy. The spectrum was compared to that of model compounds found in the literature, and the identity of this product was confirmed by ^{1}H NMR (D_2O): δ 4.45 (1H, d, $J_{1,2}$ = 8.06 Hz, H-1), 3.64 (3H, s, OCH_3), 2.38 (2H, t, CH_2CH_2-COOMe), 1.98 (3H, s, OCOCH_3), 1.56 [6H, m, $(CH_2)_3$]. The conversion of glucosamine hydrochloride (compound **1**) to the monosaccharide ester (compound **5**) results in an overall yield of 18−23% on a 2.0 kg scale.

Enzymatic Addition of Galactose. Galactose was added to monosaccharide ester by coupled enzymatic addition using β-(1,4)-galactosyltransferase, UDP-galactose-4-epimerase, pyruvate kinase, UDP-glucose pyrophosphorylase, phosphoenol pyruvate, glucose-1-phosphate, and UDP to produce the disaccharide (compound **6**). This β-galactosyltransferase cycle continued for 6−8 days until 90−95% complete as determined by TLC on silica gel. After this reaction, the material was filtered through an Alsop pad, a 1.0 mm filter, and a 10K spiral wound membrane. The pH of the solution was adjusted to 7.3−7.6 and supplemented with additional glucose-1-phosphate, UDP, pyruvate kinase, UDP-glucose pyrophosphorylase, UDP-galactose-4-epimerase, and α(1,3)-galactosyltransferase to initiate formation of the α-galactosyl trisaccharide ester (compound **7**). After this enzymatic reaction, the material was treated as described above, diafiltered over a polysulfone membrane against water, and treated with Dowex 50 WX8−200 to remove salts and ions, and the identity of compound **7** was confirmed by ^{1}H NMR in D_2O: δ 1.20−2.30 (m, 6H, $(CH_2)_3$); 2.01 (s, 3H, OAc); 2.39 (t, 2H, $CH_2C{=}O$); 3.68 (s, 3H, OCH_3); 4.47 (d, 1H J = 10.3 Hz, β-anomeric); 4.50 (d, 1H, J = 10.1 Hz, β-anomeric); 5.13 (d, 1H, J = 3.9 Hz, α-anomeric). The trisaccharide ester was converted to the final trisaccharide free acid (TRFA, compound **8**) by reacting with a molar excess of 6 N sodium hydroxide.

The enzymes β (1,4)-galactosyltransferase (secreted bovine form expressed in mouse myeloma), α (1−3)-galactosyltransferase (recombinant form from murine source expressed in mouse myeloma cells), and UDP-Gal-4-epimerase (recombinant form from *Streptococcus termophilus* overexpressed in *E. coli*) were produced at Nextran (San Diego, CA). Pryuvate kinase was obtained from Roche (Indianapolis, IN) and UDP-glucose pyrophosphorylase (from bakers' yeast) from Sigma (St. Louis, MO). The D-glucose-1-phosphate disodium salt was from Genzyme (Boston, MA). All other chemicals were obtained from commercial sources in reagent pure grade.

^{1}H Nuclear Magnetic Resonance Spectroscopy. The α-galactosyl trisaccharide acid was repeatedly exchanged in D_2O (99.96%, Aldrich Chemical Co.) with intermediate lyophilization, and finally dissolved in 500 μl of 99.996% D_2O. Spectra were recorded on a Varian JEOL 400 MHz NMR spectrometer at Acorn Inc. (Livermore, CA). Line-broadening (0.2 Hz) was applied to 1D spectra. Chemical shifts were measured relative to the residual HOD peak at 4.80 ppm. Spectral peak assignments were made by comparing the results with data in the literature and with the standard compounds. Determination of TRFA content by NMR was done by adding a known quantity of 1,2-*O*-isopropylidene-α-D-glucofuranose as internal standard and the area of the doublet at ∼5.16 ppm, corresponding to H-1 of α-galactofuranose, compared to that of the doublet of the anomeric proton of TRFA, to calculate their relative molar ratio.

HPLC Chromatography. Evaluation of TRFA content and purity was done by hydrophilic interaction chromatography using a Polyglycoplex column. The TRFA was resolved from sample impurities using 100% of solvent A (20% of 37.5 mM ammonium acetate buffer (pH 6.0) in acetonitrile, v/v) for 5 min, followed by a 5 min linear gradient to 20% of solvent A/80% of solvent B (37% of 20.3 mM ammonium acetate buffer (pH 6.0) in acetonitrile, v/v), and a final isocratic step maintaining the previous concentration for 20 min. The column was washed and reequilibrated to yield a total run time of 40 min. An injection volume of 50 μL was used at a nominal concentration of 100 mg/mL. The flow rate was 1 mL/min. Detection was accomplished using an Alltech ELSD 500 detector (temp = 95 °C; nitrogen flow = 2.00 slpm; ATTN = 1). The limit of quantitation of this method was 50 μg on column.

Fast-Atom Bombardment and Electrospray-Ionization Mass Spectrometry. The molecular weight of TRFA was evaluated by FAB-MS and ESI-MS (M-Scan Inc). FAB-MS was done using a VG Analytical ZAB 2SE high field mass spectrometer. A cesium ion gun was used to generate primary ions used to bombarded the sample dissolved in distilled water and contained in the stainless steel probe mixed with glycerol/thioglycerol as the matrix. Secondary ions were recorded in the positive mode. Mass calibration was done using cesium iodide. ESI-MS was performed using a VG Biotech Bio-Q mass spectrometer with quadrupole analyzer.

Synthesis of α-Galactosyl Conjugates. All conjugates were produced using the α-galactosyl trisaccharide acid (TRFA). The Dex40 conjugate was produced using Dextran-amine (Molecular Probes) and TRFA in 100 mL reactions containing 100 mM MES (pH 5.5) 12.5 mg/mL TRFA, 10 mg/mL dextran-amine and 25 mg/mL 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC). The reaction mixture was incubated at room temperature overnight and then extensively dialyzed to distilled water, lyophilized, and resuspended at 50 mg/mL in sterile saline. Synthesis of a poly-L-lysine conjugate (PLL300) was performed in a similar manner using 20 mL of 100 mM MES (pH 5.5) 15 mg/mL TRFA, 10 mg/mL poly-L-lysine (Sigma), and 70 mg/mL of EDC. The reaction mixture was incubated at room temperature overnight and then extensively dialyzed to distilled water, lyophilized, and resuspended at 50 mg/mL in sterile saline.

An eight-branched poly(ethylene glycol) conjugate (Nex1205) was produced using TRFA and EDC. A reaction mixture containing 100 mg/mL of branched PEG-amine (Shearwater), 106 mg/mL of TRFA, and 80 mg/mL EDC in MES (pH 5.5) was stirred for 1 h at room temperature. Additional EDC was added for a final concentration of 160 mg/mL and incubated overnight. Synthesis of the four branched PEG conjugate (Nex8507) was the same except that half the concentration of TRFA and EDC was used. The reaction was dialyzed through a 3K membrane against distilled water, lyophilized, and resuspended at 50 mg/mL in saline. Polymerized branched PEG conjugates (Nex8587 and Nex1285) were produced in a reaction containing 50 mg/mL of four or eight branched PEG amine, 28 mg/mL of *N*-hydroxysulfosuccinimide (NHSS), 250 mg/mL EDC, and 60 mg/mL of TRFA. The reaction was shaken overnight on a rotary shaker and dialyzed, lyophilized, and resuspended at 50 mg/mL in saline.

HSA glycoconjugates with variable TRFA densities were produced by conjugating TRFA to HSA using NHSS and EDC. The general reaction conditions consisted of mixing 16 mL of cold 200 mM Tris (pH 6.5) containing 1 g of HSA (Sigma) with 4 mL of 100 mM MES (pH 5.5) containing 80 mg/mL NHSS and 37.5 mg/mL EDC. The mixture was reacted at 4 °C temperature for 4 h on a rotory shaker, and the reaction was stopped by the addition of 4 mL of 1 M Tris (pH 8,5). The conjugates were dialyzed through 10K membranes against distilled water and lyophilized. Increased TRFA densities were produced by increasing the amount of EDC in the reaction. The average TRFA density in each conjugate was determined by mass spectroscopy, and each conjugate was examined by SDS−PAGE silver stained gels

and anti-Gal western blots to detect the presence of intermolecular cross linking.

Light Scattering Determination of Molecular Weight. Glycoconjugate samples containing 10−20 mg/mL in 0.15 M phosphate buffer, pH 7.2 were injected into a Superose 12 HR 10/30 high-resolution gel filtration column (Amersham Pharmacia Biotech, Piscataway, NJ). The column was pumped at 0.5 mL/min with the same phosphate buffer. The effluent flowed online directly into a capillary light-scattering cell of a Wyatt Dawn DSP light-scattering instrument (Wyatt Technology Corp. Santa Barbara, CA) and from there directly into a Hewlett-Packard 1037A refractive index detector. Data from both the light-scattering detectors (measured at 15 different angles by separate diode detectors) and the refractive index detector were recorded online by a Dell Optiplex GX1 microcomputer, using Wyatt Astra software for Windows version 4.723. The same system was calibrated against monomeric bovine serum albumin (Sigma) as a standard for determining absolute molecular weight distributions of the glycoconjugates.

Determination of α-Galactose Content. The ratio of galactose and *N*-acetylglucosamine in TRFA was determined after exhaustive acid hydrolysis using a DX500 HPLC equipped with an ED40 pulsed amperometer (Dionex Corp., Sunyvale, CA). Acid hydrolysis was performed on 100 μL of 0.1 M TRFA mixed with an equal volume of 4 M trifluoroacetic acid and hydrolyzed at 100 °C for 3 h. The material was evaporated to dryness in a Speed Vac, and residual TFA was removed by adding 100 μL of methanol and then drying in the Speed Vac. Finally the sample was resuspended in 1 mL of Nanopure water. A high-pH anion-exchange chromatography method using a CarboPac PA1 column (Dionex) coupled to the pulsed amperometer detector (HPAEC_PAD) was developed to resolve galactose and *N*-acetylglucosamine. The column was run at 1 mL/min, and the sample was eluted by an isocratic step with 40 mM sodium hydroxide. This system provided excellent resolution of the samples and could typically detect 5−10 pmol of each carbohydrate.

The amount of α-linked galactose present in the TRFA and glycoconjugates was also determined using α-galactosidase (Sigma) and galactose dehydrogenase (Roche). The assay was adapted from a commercially available kit (Boehringer) for quantifying lactose levels (Huber et al. 1975). The α-linked galactose residues are hydrolyzed by α-galactosidase to release D-galactose. In the presence of NAD and galactose, galactose dehydrogenase produces galactonic acid and NADH. The amount of NADH produced is determined by absorbance at 340 nm and is stoichiometric to the amount of galactose in the reaction.

Inhibition and Competition ELISA Assay. To estimate the ability of TRFA and glycoconjugates to block anti-Gal antibody binding, an ELISA-based assay measuring inhibition of nonhuman primate anti-Gal antibody was developed. Pooled baboon serum was diluted 1:120 into phosphate-buffered saline (PBS) with 1% HSA containing serial dilutions of TRFA or glycoconjugates and incubated for 30 min at room temperature. Samples were then placed in 96-well microtiter plates previously coated with 30 μg/mL of an HSA−Gal conjugates with the specified antigen density. For most of our analysis the HSA−Gal ELISA substrates contained on average four ($HSA-Gal_{(4)}$) or eight ($HSA-Gal_{(8)}$) TRFA epitopes for each protein monomer. Serum samples containing α-galactosyl conjugates were incubated in 96-well plates for 1.5 h at 4 °C and washed, and the amount of anti-Gal binding was determined by colorometric assay using biotin-conjugated goat anti-Human IgM or IgG (Zymed) and alkaline phosphatase-conjugated streptavidin. The degree of inhibition was determined by the formula $(OD_{total} - \text{sample } OD_{inh})/OD_{total}) \times 100$ where the OD_{total} is the optical density observed in the absence of inhibitor and the OD_{inh} is the optical density measured in the presence of TRFA or the glycoconjugate.

Antibody inhibition was also determined using 96-well plates containing porcine microvascular endothelial cells (PMVEC) as described (Platt et al. 1990). Cells were grown in Medium 199 (Gibco) supplemented with endothelial cell growth supplement (30 mg/mL), Heparin (4000 U/mL), and 10% FBS (Hyclone). At confluence the cells were fixed with 1% gluteraldehyde for 5 min, washed with PBS, and stored at −80 °C until used. To measure antibody inhibition, plates were blocked in PBS with 1% ovalbumin (OVA) and 0.1% Tween 20 at room temperature. Serum samples were preincubated for 30−60 min at room temperature in 1% OVA/PBS, with serial dilutions of TRFA or α-galactosyl conjugates in 1%OVA/PBS. Samples were added to the PMVEC ELISA plates in duplicate, and the plates were incubated for 90 min at 4 °C. Biotin-conjugated goat anti-human IgM or IgG (Zymed) diluted 1:1000 in 1% OVA /PBS was used to label bound antibody and alkaline phosphatase-conjugated streptavidin (Zymed 43−4322) diluted 1:3000 to quantify the level of activity.

An assay to detect the presence of the Nex1285 conjugate in serum was also developed. This assay measured the inhibition by Nex1285-containing serum of biotinylated human anti-Gal antibody binding to $HSA-Gal_{(8)}$-coated ELISA plates. The amount of biotinylated human anti-Gal antibody was selected to give an optical density reading of approximately 1.0 in the absence of any inhibition. A reference standard of Nex1285 (200 μg/mL) and serum samples containing Nex1285 were serially diluted into PBS containing 1% HSA. Equal volumes of serum and biotinylated human anti-Gal antibody (5 μg/mL) were mixed, incubated for 30 min at ambient temperature, and transferred to $HSA-Gal_{(8)}$-coated plates. After 1 h incubation, the plates were washed and the amount of anti-Gal antibody binding determined using alkaline phosphatase-conjugated streptavidin. The amount of Nex1285 was calculated by comparison to the reference standard.

Conjugate Infusion Studies. Groups of three cynomologus monkeys (*Macaca fascicularis*) were infused with the α-galactosyl conjugates Nex8507, Nex8587, Nex1285, and Gal−Dex−FITC or with unconjugated PEG or dextran controls at a dose of 100 mg/kg. All animals were previously equipped with surgically implanted chronic venous catheters and vascular access ports to facilitate infusion and blood collection. The test materials were prepared in normal saline and infused over a 15−60 min period. Blood samples were collected prior to the start of the infusion and at 5 and 10 min after the beginning the infusion. Additional samples were collected at 5, 10, 20, and 30 min and 1, 2, 4, 6, 8, 12, 24, 48, 72, and 336 h after completion of the infusion. Animals were individually housed and observed for clinically relevant abnormalities during infusions and at each sample collection. The experiments were conducted in accordance with NIH guidelines for Care and Use of Laboratory Animals.

RESULTS

Characterization of TRFA. An α-galactosyl trisaccharide free acid (TRFA) containing a five-carbon spacer with a carboxy terminus was prepared following the

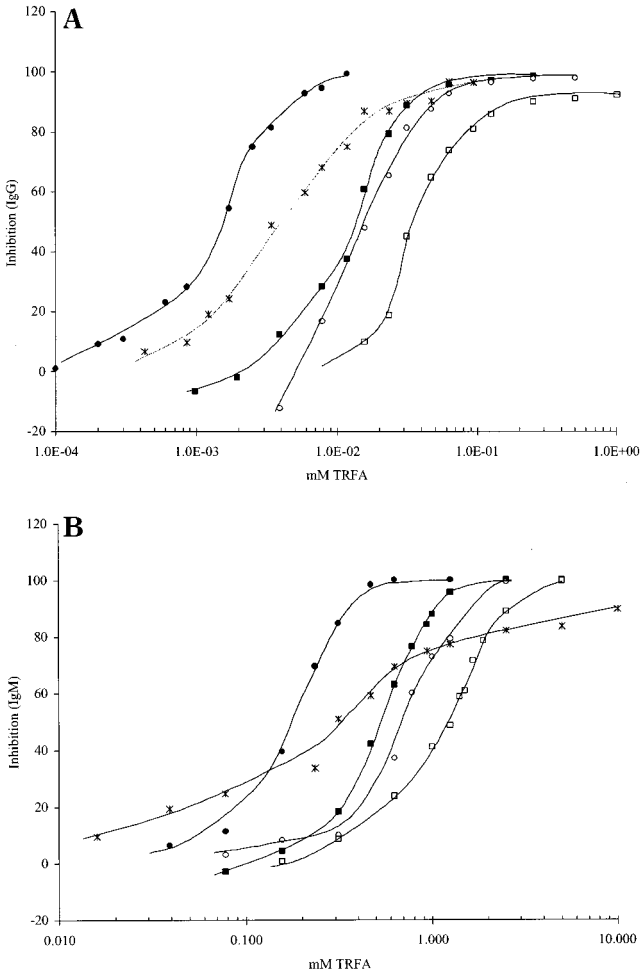

Figure 2. The inhibition of anti-Gal IgG and IgM by free α-galactosyl trisaccharide. The inhibitory effects of TRFA was determined in a competition ELISA using PMVEC cells (*) and HSA−Gal substrates containing an average α-galactosyl content of four (●), eight (■), 13 (○), and 21 (□) residues per mole. Baboon serum diluted 1:120 was mixed with α-galactosyl trisaccharide for 30 min at room temperature and then applied to the ELISA plate. A. Inhibition of anti-Gal IgG. B. Inhibition of anti-Gal IgM. Lines for this and other graphs are freehand approximations to the data.

described chemoenzymatic synthesis. This material was lyophilized, and samples were characterized by NMR, FAB-MS, ESI-MS, HPLC, and hydrolysis with α-galactosidase. The TRFA was a white powder with typical moisture content of 2.8−5.5%. Structural analysis done using ^{1}H NMR identified characteristic protons including the α-anomeric proton of galactopyranose (5.135 ppm; d, 1H, $J = 3.9$ Hz), the β-anomeric protons of galactopyranose, and 2-acetamido-2-deoxy-D-glucopyranose, at 4.47 ppm (d, 1H, $J = 10.3$ Hz) and 4.50 ppm (d, 1H, $J = 10.1$ Hz), respectively. The presence of the alkyl chain was confirmed by the methylene multiplet at ∼1.59 ppm corresponding to the internal methylene groups in the chain, by the triplet at 2.368 ppm corresponding to the methylene group contiguous to the ester, and by the multiplet at ∼1.34 ppm corresponding to the methylene group directly attached to the monosaccharide. The methyl signal of the *N*-acetyl group was at 2.023 ppm. The expected molecular weight of TRFA was 660 Da, and this was confirmed by FAB-MS and ESI-MS analysis that showed a quasimolecular ion cluster, $(M + H)^+$ at *m*/*z* 660 with the corresponding $(M + Na)^+$ cluster at *m*/*z* 682. This analysis also detected ions at *m*/*z* 336, 399, 498, and 528, and these may be associated fragments. On the basis of hydrophilic interaction chromatography using a Polyglycoplex column, with comparison to known reference standards, TRFA synthesis typically yielded material with a purity between 98% and 100%. The ratio of galactose to *N*-acetylglucosamine in TFRA was analyzed by HPAEC−PAD after complete acid hydrolysis and indicated the expected Gal:GlcNAc ratio of 2:1. Consistent with this finding, TRFA was readily hydrolyzed by α-galactosidase and yielded 1.49 mM of hydrolyzed galactose per gram of TRFA. This value was slightly less than the 1.51 mM per gram expected from a pure preparation but was entirely consistent with our physical analysis and the estimated purity of 98%.

Table 1. Inhibition of Anti-Gal Antibody on PMVEC and Variable Density HSA Conjugates[a]

conjugate density	IgG IC_{50} (mM TRFA)	IgG fold change	IgM IC_{50} (mM TRFA)	IgM fold change	IC_{50} ratio IgM/IgG
4	0.0016	1.0	0.184	1.0	118.2
8	0.0138	8.8	0.528	2.9	38.3
9	0.0129	8.2	0.490	2.6	38.1
13	0.0166	10.6	0.713	3.9	43.0
17	0.0338	21.7	1.078	5.9	31.9
21	0.0352	22.6	1.272	6.9	36.2
PMVEC	0.00367	2.4	0.308	1.7	84.0

[a] The table presents the concentration of α-Gal trisaccharide free acid (TRFA) required to inhibit 50% of anti-Gal IgG and IgM binding in baboon serum to a series of human serum albumin conjugates with different levels of α-Gal incorporation and to fixed porcine microvascular endothelial cells. Inhibition of IgG and IgM is also presented as a normalized fold change and as an IC_{50} ratio to illustrate the increased amounts of sugar required to inhibit antibody binding to higher density antigen substrates and to compete different antibody isotypes.

Inhibition of Anti-Gal Antibodies on Glycoconjugates and PMVECs. Anti-Gal antibodies binding from baboon serum in the presence of serial dilutions of TRFA was measured on HSA−Gal conjugates with 4 to 21 sugar residues per mole of protein and on fixed porcine microvascular endothelial cells (PMVEC). The amount of TRFA required to block antibody binding depended on the antibody isotype and the antigen density in the ELISA (Figure 2 and Table 1). At low antigen density anti-Gal IgG and IgM were more easily blocked compared to higher density substrates. For example, in an ELISA using the HSA−$Gal_{(4)}$ conjugate, half the anti-Gal IgG binding was inhibited by 1.6 μM of TRFA, but equivalent inhibition at higher antigen density required approximately 20-fold more TRFA. Similarly blocking anti-Gal IgM binding to high density substrates required approximately 7-fold more TRFA than needed to block antibody binding to HSA−$Gal_{(4)}$. A ratio of the TRFA concentrations required to inhibit 50% of the anti-Gal IgM and IgG binding illustrates the effects of isotype on anti-Gal inhibition. Anti-Gal IgM required more TRFA to inhibit binding than did IgG. Although this was most apparent at low antigen density, where over 100 fold more TRFA was required to block anti-Gal IgM compared to IgG, inhibition of anti-Gal IgM required 30−40-fold more TRFA at all of the antigen densities tested.

Anti-Gal antibody binding to PMVEC cells could also be blocked using TRFA and showed the same isotype dependence observed using the synthetic HSA conjugates. Blocking anti-Gal IgG binding to PMVEC cells was more sensitive to TRFA inhibition than IgM which required more then 80-fold more sugar to inhibit antibody binding. Half of the anti-Gal binding to PMVEC cells could be blocked by 3.7 μM TRFA for IgG or 0.31 mM of

Table 2. Characterization of α-Galactosyl Sugar and Sugar Conjugates[a]

material	structure	mM α-Gal (gram)	MW	IC_{50}(4) IgG	IC_{50}(8) IgG	IC_{50}(4) IgM	IC_{50}(8) IgM

[a] The table lists each conjugate, its general structure, α-galactosyl content molecular weight distribution, and IC_{50}. The α-galactosyl content (mM α-galactosyl TRFA per gram) was determined using α-galactosidase. This value was used to standardize all of the antibody blocking studies. For the branched PEG conjugates (Nex8507 and Nex1205) the expected amount of α-galactosyl is based on an idealized molecule of 10kDa with four or eight branches. The molecular weight distributions are based on light scatter analysis. The range in molecular weight and the percentage of the conjugate that falls in that range (parenthesis) is given. The IC_{50} values were calculated from ELISA assays using HSA−$Gal_{(4)}$ and HSA−$Gal_{(8)}$. The fold change in IC_{50}, in parentheses, relative to TRFA is indicated for each conjugate.

TRFA for IgM. These values were similar to the amounts of TRFA required to block IgG and IgM binding to HSA−Gal conjugates containing four or eight sugar residues per mole of protein. While these conjugates may be a good average estimation of antibody binding to PMVEC cells, the broad inhibition profile observed for PMVEC cells compared to the sharper sigmoidal profiles for the conjugates (Figure 2) suggests that the cell display a wide variety of antigen densities. This was particularly evident for anti-Gal IgM where the glycoconjugate substrates may underestimate the influence of high density α-galactosyl epitopes present on PMVEC cells. Persistent anti-PMVEC IgM binding in the presence of high amounts of TRFA is likely due to the presence of non-Gal antibodies in our pooled serum samples.

Characterization of α-Gal Conjugates. A series of α-galactosyl glycoconjugates were produced to investigate the effects of α-galactosyl density and oligomerization on the ability to block antibody binding. The conjugates used different chemical backbone structures and ranged widely in molecular weight. Three broad classes of α-galactosyl conjugates were produced. To examine the effects of multimeric TRFA, simple branched PEG conjugates containing four or eight branches with each branch capped by a TRFA molecule were produced. A second class of conjugates used the linear backbones of dextran or poly-L-lysine. These linear conjugates were produced to examine the effects of increased molecular size and highly repetitive presentation of TRFA on antibody blocking. Finally polymerized versions of the branched PEG conjugates were produced to directly compare the effects of increased conjugate size on antibody blocking. To gauge the activity of each α-galactosyl conjugate relative to monomeric TRFA, all of the materials were standardized based on the amount of trisaccharide available for hydrolysis by α-galactosidase. We focused our in vitro antibody inhibition analysis on ELISAs using HSA−Gal conjugates that contain four or eight sugars per mole of protein, since these conjugates reasonably estimated antibody binding to PMVEC cells.

Simple poly(ethylene glycol) based glycoconjugates with four or eight branches were produced by coupling the carboxylic acid group of TRFA to primary amines on the terminus of each PEG branch. This conjugation produced a peptide bond attaching an α-Gal trisaccharide sugar to each branch of the PEG backbone. Light scattering analysis of glycoconjugates containing four or eight branches (Nex8507 and Nex1205) exhibited an average molecular weight distribution consistent with the expected conjugation of one TRFA sugar to each branch of the carrier. The polydispersity (Mz/Mn) of the Nex8507 and Nex1205 conjugates was similar to the distribution of the starting material, consistent with the absence of polymerization (data not shown). Hydrolysis of these conjugates with α-galactosidase yielded 0.32 and 0.48 mM TRFA per gram of Nex8507 and Nex1205, respectively (Table 2), similar to the expected molar concentration of TRFA in an idealized conjugate.

On the basis of available free trisaccharide, the branched PEG conjugates were 40- to 50-fold more effective at inhibiting anti-Gal IgG compared to TRFA when assayed against the low antigen density HSA−$Gal_{(4)}$ (Figure 3A, Table 2). The effectiveness of anti-Gal IgG blocking was reduced, however, at higher antigen density particularly for the four-branched conjugate Nex8507 which blocked anti-Gal IgG only 8-fold more effectively than TRFA (Figure 3C). Anti-Gal IgM binding was more difficult to inhibit and like TRFA, the branched PEG conjugates required more material to effectively block anti-Gal IgM (Figure 4A and C). Although the NEX1205 conjugate with eight branches was up to 30-fold more effective at blocking anti-Gal IgM in the HSA−$Gal_{(4)}$ ELISA at higher antigen density this conjugate and the four-branched conjugate (NEX8507) were indistinguishable from TRFA (Figure 4C, Table 2).

To investigate the role that larger glycoconjugate structures with more repetitive presentation of TRFA might have on antibody inhibition, we produced linear α-galactosyl conjugates using dextran (Dex40) and poly-L-lysine (PLL300) as the backbone. The sugar was coupled to these long linear conjugates through a peptide bond, resulting in an average of one TRFA epitope every 12 (PLL300) or 19 (Dex40) residues, similar to the overall TRFA content present in the branched PEG conjugates. Due to their increased size, however, the linear conjugates contained a far greater number of sugar epitopes per molecule than the four- and eight-branched PEG conjugates. The linear conjugates inhibited anti-Gal IgG binding to both HSA−$Gal_{(4)}$ and HSA−$Gal_{(8)}$ (Figure 3B and 3D). The effectiveness of this inhibition was approximately 16-fold greater than the inhibition observed for Nex1205 (Table 2) with the larger Dex40 exhibiting

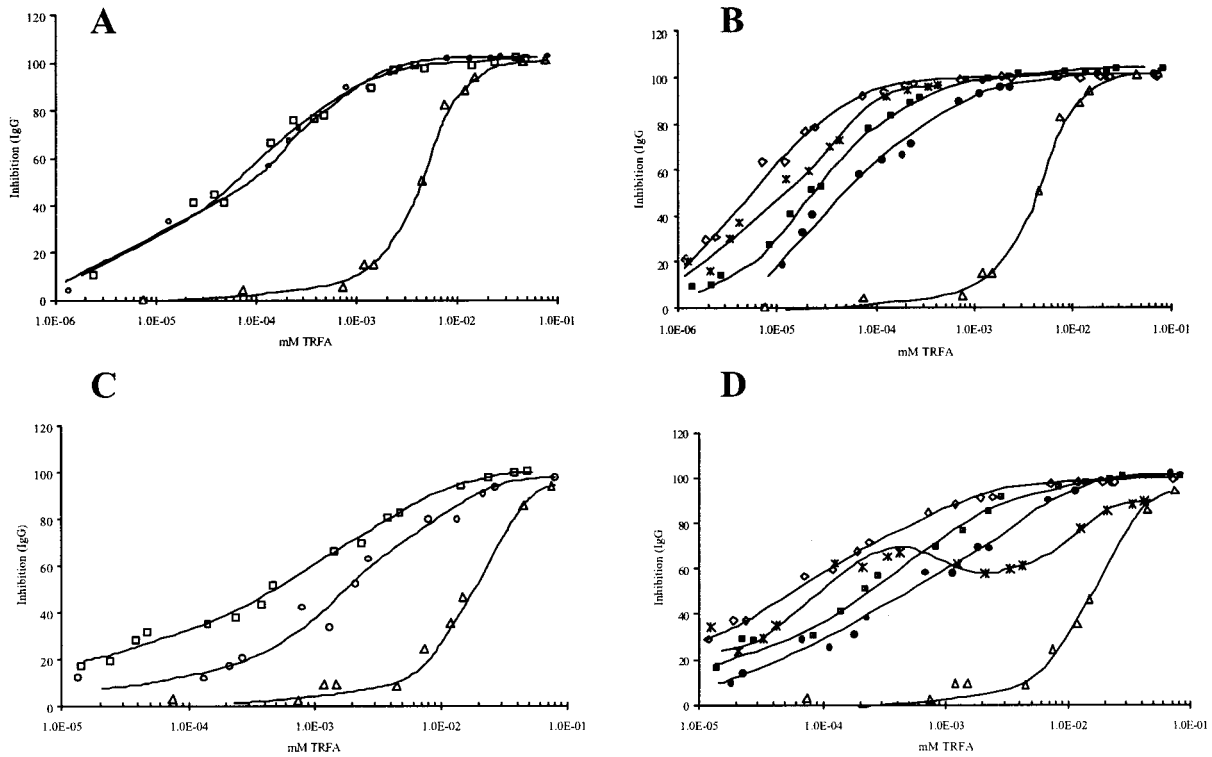

Figure 3. Inhibition of anti-Gal antibodies by TRFA and α-galactosyl conjugates. Anti-Gal IgG inhibition was determined using an HSA−$Gal_{(4)}$ (A and B) or HSA−$Gal_{(8)}$ (C and D) ELISA substrate for TRFA (△) and conjugates NEX8507 (○), NEX1205 (□), PLL300 (*), Dex40 (◇), NEX8587 (●), and NEX1285 (■). For clarity, the inhibition profiles for the simple branched conjugates (A and C) are separated from the linear and polymeric conjugates (B and D). The concentration of trisaccharide sugar and each conjugate was standardized based on their α-galactosyl content as determined by α-galactosidase hydrolysis. Each test sample was added to a 1:120 dilution of normal baboon serum and incubated at room temperature for 30 min. The mixtures were assayed for antibody binding on ELISA plates containing an HSA−Gal conjugate with four TRFA molecules per protein. Inhibition is expressed as the percentage of antibody binding relative to serum without added α-galactosyl sugar of conjugated materials.

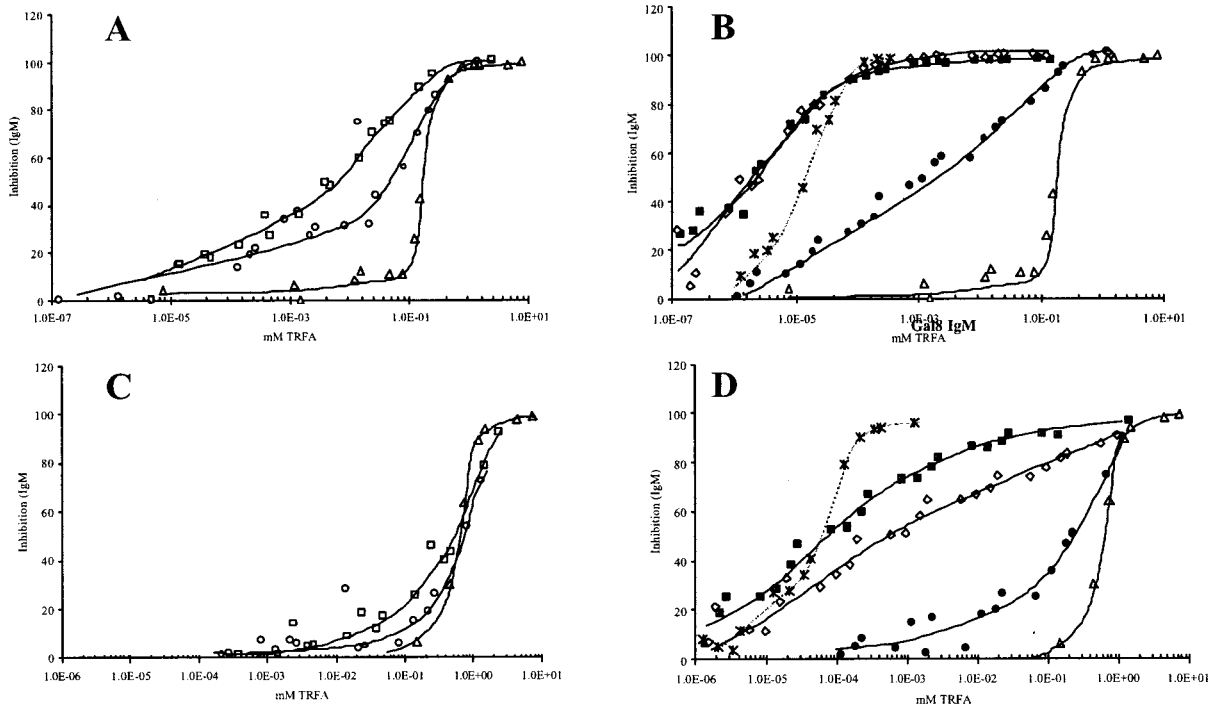

Figure 4. Inhibition of anti-Gal IgM antibodies by TRFA and α-galactosyl conjugates. Symbols are the same as described in Figure 2. Inhibition was determined using an HSA−$Gal_{(4)}$ (A and B) of HSA−$Gal_{(8)}$ (C and D) ELISA substrates. As in Figure 2 the branched conjugates (A and C) are shown separate from the linear and polymeric conjugates (B and D).

the highest inhibition at either antigen density. Both the Dex40 and PLL300 were highly effective inhibitors of anti-Gal IgM, exhibiting 13000 to 70000-fold greater inhibition than TRFA at low antigen density and 5000 to 10000-fold greater activity against the higher antigen density (Figure 4B and 4D; Table 2). Although the

α-galactosyl content of Dex40 was approximately half that observed for eight-branched Nex1205, Dex40 was 2000 to 6000-fold more effective than Nex1205 at inhibiting anti-Gal IgM (Table 2). The PLL300 conjugate was also highly effective at blocking anti-Gal IgM antibody in our ELISA assays, and this conjugate, perhaps due to the higher content of α-galactosyl residues, maintained its ability to block anti-Gal IgM, even at the higher antigen density. Unlike the other conjugates, however, antibody inhibition by PLL300 often exhibited erratic effects at concentrations above 1.2 μM TRFA (approximately 3.0 μg/mL of polymer).

The linear α-galactosyl conjugates were clearly much more effective at blocking anti-Gal IgM than the smaller branched PEG conjugates. Since both types of conjugates had a similar content of α-galactosyl sugar, we thought that the enhanced ability of linear conjugates to block IgM was likely to result from the structural difference between the conjugate types. For example, the linear conjugates might more effectively engage the pentameric anti-Gal IgM binding sites whereas the smaller branched conjugates might only bind to one or two antigen binding sites within an antibody. To investigate this further we polymerized the branched PEG conjugates into higher order structures using EDC and NHSS. Details of this reaction are under investigation but there is evidence of Peg-to-Peg, Peg-to-TRFA and TRFA-to-TRFA cross-linking in the final polymerized products, Nex8587 and Nex1285. Due to this intermolecular cross-linking, these conjugates exhibited much wider size distributions than either the original PEG amine or the simple branched Nex8507 and Nex1205 conjugates (Table 2). The Nex8587 and Nex1285 conjugates had comparable α-galactosyl content but were approximately half that observed in Nex1205 and essentially equal to the level of Dex40. These polymerized conjugates inhibited anti-Gal IgG binding at a level that was 20−200-fold more effective than TRFA (Figure 3B and 3D). The Nex1285 conjugate was similar to Dex40 in its ability to block anti-Gal IgM exhibiting 7000−70000-fold more effective antibody inhibition than TRFA depending on the ELISA substrate. In contrast the Nex8587 conjugate behaved more like the branched Nex1205 conjugate and was only 2-fold more effective than TRFA at inhibiting anti-Gal IgM against the high-density substrate (Figures 4B and 4D).

Antibody Inhibition in Primates. The polymerized PEG and linear α-galactosyl conjugates exhibited a dramatic improvement in antibody inhibition in our inhibition ELISA. To investigate if these conjugates would be effective at blocking antibody in vivo, we administered a single bolus infusion (100 mg/kg) to sets of three cynomologus monkeys for each conjugate (Figure 5A and 5B). The conjugates were infused over a 15−60 min period and serum samples were taken over a three-day period to estimate the clearance rate of the conjugate and to examine the effects on anti-Gal antibody. A follow-up serum sample, 14 days after infusion was also examined. To facilitate our analysis, a Gal−Dex−FITC conjugate was used in this study. This material contained just less than one FITC fluorochrome per mole and had an α-galactosyl density of one sugar every eight residues. This material had a smaller size distribution (97% within 10000 to 100000 Da) than the Dex40 previously described and was not as effective an inhibitor of anti-Gal IgM. All of the PEG conjugates were the same as described in Table 2. Infusion of control unconjugated PEG or dextran had no effect on circulating anti-Gal antibody levels (data not shown). In contrast, from the onset of infusion and for up to 30 min postinfusion all of the conjugates

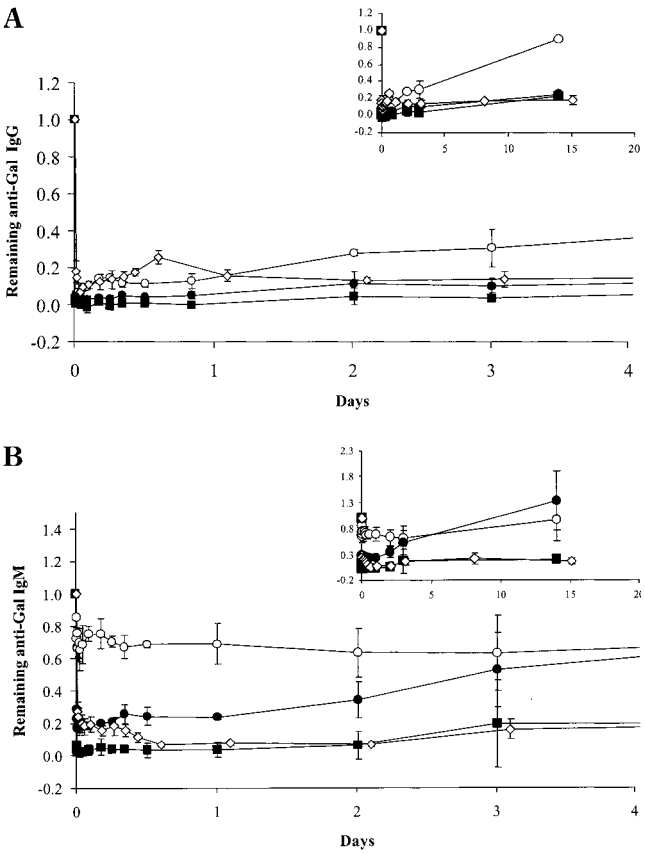

Figure 5. In vivo effects of α-galactosyl conjugates in cynomologus monkeys. The level of circulating anti-Gal IgG (A) and IgM (B) in cynomologus monkeys after a single dose infusion (100 mg/kg) of Nex8507 (○), Nex8587 (●), Nex1285 (■), and Gal−Dex−FITC (◇) was determined. Conjugates were infused at time zero. Antibody levels prior to infusion were set to 1.0. The graphs illustrate the fractional reduction of anti-Gal IgG and IgM in circulation after infusion. The Gal−Dex−FITC conjugate used in this experiment was a separate preparation, different from the Dex40 listed in Table 2. For this experiment the Gal−Dex−FITC material included a FITC moiety at a level of just less than one FITC molecule per dextran to facilitate detection. Compared to Dex40, this conjugate was not as effective at inhibiting anti-Gal antibodies in our in vitro assay exhibiting an IC50 value approximately 120-fold higher than Dex40 for inhibiting anti-Gal IgM using the HSA−$Gal_{(4)}$ substrate. Over 97% of the Gal−Dex−FITC was between 10000 and 100000 Da, smaller than Dex40, and had a substitution ratio of one α-galactosyl sugar every eight glucose residues. Error bars represent standard deviation. The insert shows the data on an expanded axis and includes the 14 day time point.

(Nex8507, Nex8587, Nex1285, and Gal−Dex−FITC) produce a 95% or greater apparent reduction in detectable anti-Gal IgG. Greater than 80% inhibition of IgG was maintained for the duration of the study (14 days) for all of the polymeric conjugates, except the simpler branched PEG conjugate (Nex8507) which showed a return to baseline levels between 7 and 14 days postinfusion (Figure 5A and insert). The effects on anti-Gal IgM were more varied (Figure 5B). The polymerized eight-branched PEG conjugate Nex1285 and the Gal−Dex−FITC conjugate effectively blocked anti-Gal IgM throughout the study period, showing more than 75% inhibition 7 and 14 days after infusion. The polymerized four-branched PEG conjugate Nex8587 conjugate was effective during the early part of the experiment, reducing apparent anti-Gal IgM by approximately 80% for the first 24 h; however, monkeys infused with NEX8587 exhibited a returned to baseline anti-Gal levels by 7−14 days postinfusion. In contrast, infusion of Nex8507 was minimally

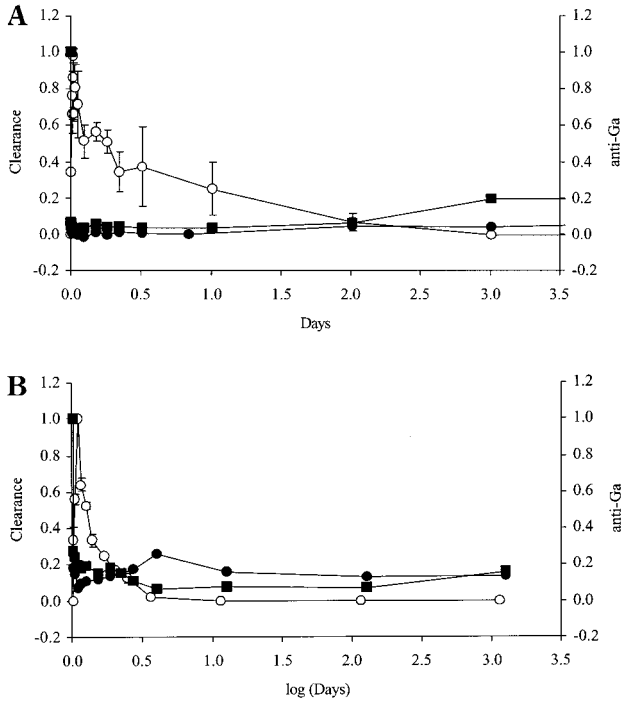

Figure 6. Clearance profiles for Nex1285 (A) and Gal−Dex−FITC (B) after infusion into cynomologus monkeys. The serum concentration of NEX1285 was determined by competition ELISA and the concentration of Gal−Dex−FITC by measuring FITC fluorescence. Each graph shows the clearance profile for the α-galactosyl conjugate (○) and the average serum anti-Gal IgG (●) and IgM (■) levels during the first 3 days postinfusion.

effective, initially reducing anti-gal IgM levels by approximately 35% with a rapid return to near baseline anti-Gal values within the first 24 h postperfusion.

These results show that the more effective conjugates can largely eliminate anti-Gal antibody activity for up to 14 days. Although we might have expected a first dose effect, due to the formation of antigen:antibody complexes, infusion of these conjugates was well tolerated with only a mild reddening of mucosal membranes noted in some animals. The slow rate of infusion may have helped to limit any first dose effect. We noted no significant changes in serum chemistry or hematological measurements during the course of the experiment.

The effects of α-galactosyl conjugates on serum anti-Gal activity in cynomologus monkeys was in broad agreement with our in vitro inhibition studies where the larger polymerized PEG and linear conjugates were more effective antibody inhibitors than the multimeric branched PEG conjugates. Antibody blocking activity may also be related to the in vivo clearance rates of the conjugates. Since anti-Gal antibody concentrations are roughly 10−50 μg/mL, our infusion protocol created a reservoir of excess α-galactosyl conjugate. This excess material might interfere with our ELISA analysis of serum anti-Gal levels. To investigate this, we examined the serum clearance of both Nex1285 and Gal−Dex−FITC since these conjugates appeared to have prolonged inhibitory effects. Clearance of Nex1285 was estimated by measuring the ability of postinfusion serum to block exogenous biotinylated human anti-Gal antibody binding to HSA−$Gal_{(8)}$-coated ELISA plates (Figure 6A). Clearance of the Gal−Dex−FITC conjugate was determined by measuring FITC fluorescence in the serum (Figure 6B). Peak inhibitory effects (Nes1285) or serum concentration (Gal−Dex−FITC) were achieved at the end of or within 20 min after the infusion. By 24 h postinfusion serum inhibition by Nex1285 was substantially reduced from the peak activity and fluorescence from Gal−Dex−FITC was no longer detectable. Serum from Nex1285 treated monkeys lost the ability to block exogenous human anti-Gal antibody by 3 days postinfusion. An analysis of these clearance profiles indicated a terminal half-life of 12 and 16 h for Gal−Dex−FITC and Nex1285, respectively. These values are similar to the serum half-life reported by Nagasaka in rats (Nagasaka et al. 1997) for linear PEG α-galactosyl conjugates. The extended in vivo circulation of the polymerized PEG and dextran conjugates may contribute to the efficiency of inhibition early after infusion; however, clearance of these materials suggests that the reduced level of serum anti-Gal antibodies observed at 7 and 14 days after infusion was not due to residual α-galactosyl conjugate but was likely due to a more prolonged inhibition of anti-Gal antibody production.

DISCUSSION

Anti-Gal antibody is the dominant specificity in human serum that binds to porcine cells, initiating hyperacute rejection, and likely contributing to acute vascular xenograft rejection. In agreement with previous publications (Neethling et al. 1996; Romano et al. 1999; Simon et al. 1998) we show here that these antibodies can be effectively blocked by incubation with carbohydrates that contain terminal Gal α1,3-Gal structures. The measured effectiveness of this inhibition was dependent on the isotype of the anti-Gal antibody and on the density of the α-galactosyl antigens. We report here the initial characterization of a series of α-galactosyl conjugates. An α-galactosyl trisaccharide sugar, which was the basis for all of the α-galactosyl conjugates, inhibits anti-Gal antibody at approximately 15 μM for IgG and 600 μM for IgM. More effective inhibition of IgG was achieved with defined oligomeric conjugates containing four or eight α-galactosyl residues per mole, but these conjugates showed only marginal improvement in inhibition of IgM. In contrast heterogeneous polymeric conjugates, using several different carrier structures, exhibited an enhanced ability to block both anti-Gal IgG and IgM. Enhanced IgM inhibition appeared to be most dependent on the size of the conjugate. These characteristics defined by in vitro inhibition assays were paralleled in a single dose infusion study in nonhuman primates. Infusion of a branched PEG conjugate with four α-galactosyl residues per carrier resulted in a greater than 80% inhibition of circulating anti-Gal IgG; however, the IgG levels returned to baseline values within 7−14 days. This same conjugate showed only marginal and transitory inhibition of IgM. In contrast, the larger heterogeneous polymeric PEG or dextran conjugates produced a profound reduction in circulating anti-Gal IgG and IgM which persisted for 14 days.

Several defined α-galactosyl oligomers and conjugates have been described previously. Nagasaka et al. (Nagasaka et al. 1997) have reported on the development of linear α-galactosyl PEG conjugates, and Rieben et al. (Rieben et al. 2000) have reported the development of oligomeric α-galactosyl molecules. These materials and the simple four- and eight-branched PEG conjugates we developed are attractive due to their defined structures; unfortunately these conjugates show rather weak ability to block antibody probably due to the low number of sugar residues and the overall small size of the conjugate. Highly repetitive conjugates of α-galactosyl sugars similar to Nex1285, PLL300, and Dex40 have also been reported (Rieben et al. 2000). These materials are usually much more effective inhibitors, but due to the more

heterogeneous nature of the carrier moiety, these polymers exhibit much wider size distribution and structural variability. Although polymeric conjugates such as these may be difficult to molecularly define, our data suggests that effective inhibition requires a large conjugate able to provide multiple α-galactosyl domains necessary to inhibit IgM.

Several groups have used α-galactosyl sugar to develop immunoabsoption methods to remove anti-Gal antibody from the circulation (Kozlowski et al. 1998a; Lin et al. 1997). This method can be highly effective and prolong xenograft survival but the depletion of anti-Gal antibody is temporary and antibody levels rebound to baseline levels within a few days (Watts et al. 2000). Our analysis of Nex1285 and Gal−Dex−FITC in cynomologus monkeys indicates that these materials have a dramatic immediate impact on circulating anti-Gal antibody and, unlike antibody absorption, suggests that infusion of α-Gal conjugates may lead to a more prolonged antibody inhibition. Pharmacokinetic analysis of Nex1285 and Gal−Dex−FITC shows that these materials have a prolonged terminal serum half-life, but that this half-life is not sufficient to account for an extended 80% reduction of IgG and IgM for 7 and 14 days after infusion. At this time we do not know if antibody:conjugate interactions leads to opsonization, and clearance of the complex or if blocked antibody continues to circulate. It is clear, however, that 3 days after infusion of Nex1285 there is no longer material in circulation that can block exogenous human anti-Gal antibody. This suggests that the reduction in anti-Gal titer observed at 7 and 14 days postinfusion results from a more long-lasting impact on the immune system.

Prolonged immunological inhibition of B-cells by haptenated conjugates has been reported previously by Dintzis and colleagues (Dintzis et al. 1976; Dintzis et al. 1985; Reim et al. 1996; Symer et al. 1995). These studies examined in detail the structural characteristics of hapten−polymer conjugates that lead to tolerogenic or immunogenic materials and suggest that haptenated polymers act directly on antigen specific B-cells to inhibit formation of antibody secreting cells. There are significant differences, however, between anti-Gal immune responses in xenotransplantation and the anti-hapten work described above. The α-Gal immune response is derived from a population of natural antibodies that probably developed in response to gut microflora. Anti-Gal B cells appear to be from the B1 or marginal zone B cell lineage (Ohdan et al. 2000) and tend to produce antibody with relatively low affinity interactions as is typical of natural anti-carbohydrate antibodies. In contrast Dintzis's work was mainly on high affinity immune responses from conventional B-cells after immunization with artificial haptens. Due to these differences the tolerogenic parameters defined for immune responses to high affinity haptens may differ from those for the anti-Gal antibodies. Interestingly, although the Gal−Dex−FITC polymer used in the infusion study was much less effective in the in vitro assay compared to Dex40 it still exhibited remarkable antibody blocking activity in cynomologus monkeys. This may suggest that smaller polymers or lower doses may be just as effective at blocking antibody in vivo. Additional primate studies will be required to determine the optimal method of using these materials and to determine if these materials are able to induce a prolonged reduction in anti-Gal antibodies. Also detailed characterization of the effects that polymeric α-galactosyl conjugates have on circulating antibody and on anti-Gal B-cells should help clarify the mechanism of action. Nevertheless, these results suggest that a high degree of anti-Gal antibody inhibition can be achieved using α-galactosyl conjugates capable of polymeric interactions. These conjugates were well tolerated in nonhuman primates, do not appear to induce a strong immune reaction and should be an effective method of controlling anti-Gal antibody during xenotransplantation.

ACKNOWLEDGMENT

Funding for the study described in this article was provided by Nextran, Inc. Under a licensing agreement between the Johns Hopkins University and Nextran, Dr. Dintzis is entitled to a share of payments received by the University from development of the licensed technology. Received October 17, 2001; Revised Manuscript Received March 13, 2002

The effect of polyrotaxane−dipeptide (Val-Lys) conjugates on the uptake of a model dipeptide (Gly-Sar) was examined via human peptide transporter (hPEPT1) on HeLa cells. Here, Val-Lys groups are introduced to α-CDs, which are threaded onto a poly(ethylene oxide) chain capped with bulky end-groups (polyrotaxane). The Gly-Sar uptake via hPEPT1 was significantly inhibited in the polyrotaxane conjugates, and this inhibitory effect was not explained by the sum of interaction between hPEPT1 and α-CD−Val-Lys conjugates. Further, the inhibition was significantly greater than those observed in dextran−Val-Lys conjugates. Therefore, our data clearly suggests that supramolecular structure in the polyrotaxane conjugates contributes considerably to the inhibitory effect via multivalent binding of Val-Lys groups with hPEPT1.

INTRODUCTION

Proteins are enzymatically digested to di- or tripeptides and/or amino acids, and these protein-digestive products are absorbed via specific transporters from the small intestine. Multiple transporters are involved in intestinal membrane transports for amino acids, while di- and tripeptides are transported only via peptide transporter, PEPT1. Besides, in terms of the intake of proteins and the absorption of some drugs, peptide transporter is expected to be more important than amino acid transporters. In particular, conjugation of poorly absorbable drugs with PEPT1-recognizable molecules such as di- or tripeptides is a powerful approach to exploit the substrate affinity of PEPT1. Kamo et al. synthesized dipeptide analogues conjugated at the ϵ-amino group of Lys in Val-Lys or Lys-Sar with fluorescent dyes as model hydrophobic drugs (*1*). They also reported that the hydrophobicity of dipeptide conjugates was an important parameter recognized by PEPT1 (*2*). The objective of their study was to enhance drug absorption through PEPT1, and thus conjugates of lower molecular weight were a minimum requirement. Dietary protein restriction is now recommended for patients of chronic renal disease (CRD),[1] but compliance is not typically high due to the effect on quality of life (QOL). In this sense, it is logical to temporarily inhibit the absorption of digested proteins via PEPT1 to improve QOL of patients. The inhibitor should be recognized by PEPT1 and have nonabsorbable properties so as to preclude kidney damage. In these points of view, multivalent ligands that display multiple sites of recognition by PEPT1 on intestinal surfaces are advantageous. Such multivalent ligands maycooperatively interact with PEPT1 and inhibit their absorption.

Cooperative affinity of ligands using synthetic or natural polymers such as tabacco mosaic virus (*3*), sugarballs (*4*), and comb-branched or dendrigraft neoglycopolymers (*5*) has been proposed as a new drug design strategy. The important factors that control the binding features include valency, architecture of the scaffolds, and orientation of the ligands. Such multivalent ligands can act as inhibitors of receptor−ligand interactions and activators of biological systems (*6*). For example, Baker, Jr. et al. studied the effect of ligand architecture, including dendrimers, comb-branched copolymers, dendrigraft copolymers, and linear-dendron architectural copolymers, on inhibitory activity and specificity (*5*). Arimoto et al. reported that a multivalent polymer of vancomycin, synthesized by ring-opening metathesis polymerization (ROMP), showed enhanced antibacterial activity against vancomycin-resistant bacteria (*7*), suggesting that multivalent ligands might be promising tools in the fight against multiresistant bacteria. Accordingly, the design of the scaffold structure is important not only for clarifying the multivalent mechanism in nature but also for designing new drugs, such as multivalent viral and toxin inhibitors.

Scheme 1. Synthesis of Polyrotaxane−Val-Lys Conjugates

We have systematically studied the design of supramolecular-structured polymers as new biomaterials and drug carriers. One of the representatives is a biodegradable polyrotaxane, in which a lot of chemically modified α-cyclodextrins (α-CDs) are threaded onto a poly(ethylene oxide) (PEO) chain capped with an amino acid or an oligopeptide (*8*). The biodegradable polyrotaxanes may have a variety of ligands, which can simultaneously bind to multivalent receptors on a cell surface, because many hydroxyl groups are available for introducing ligands on the α-CDs located along the polyrotaxane structure. In our previous study, polyrotaxane−biotin conjugates were synthesized to demonstrate the potential of multivalent ligands (*9*, *10*). On the basis of this architectural design, we have proposed the development of multivalent ligands using the polyrotaxanes as a specific inhibitor of PEPT1. In this study, polyrotaxane−dipeptide (valyllysine, Val-Lys) conjugates are synthesized and characterized, and the inhibitory effect of the conjugates on [^{3}H]glycylsarcosine ([^{3}H]Gly-Sar, a model peptide transported by PEPT1) transport in HeLa cells stably expressing human PEPT1 (hPEPT1) is evaluated in comparison with α-CD−Val-Lys and dextran−Val-Lys conjugates. Our final goal is to inhibit absorption of digested peptides in the intestinal tract via hPEPT1 transporter through multivalent binding of PEPT1-recognizable polymers.

MATERIALS AND METHODS

Materials. α-CD was purchased from Bio-Research Corporation of Yokohama (Yokohama, Japan). α-(3-Aminopropyl)-ω-(3-aminopropyl)polyoxyethylene (PEO-BA: $M_n = 4000$) was kindly supplied by Sanyo Chemical Co. (Kyoto, Japan). Benzyloxycarbonyl-L-phenylalanine (Z-L-Phe), 2-aminoethanol, *N*,*N*′-carbonyldiimidazole (CDI), and *N*,*N*′-diisopropylethylamine (DIPEA) were purchased from Wako Pure Chemical Co. Ltd., (Osaka, Japan). *N*-Hydroxysuccinimide, 1-hydroxybenzotriazole (HOBt), and Boc-Val were purchased from Peptide Institute, Inc. (Osaka, Japan). Lys-(Cbz)-O*t*Bu·HCl was purchased from BACHEM (Bubendorf, Switzerland). Water-soluble carbodiimide (1-ethyl-3-(dimethylamino)carbodiimide, WSC·HCl) and (dimethylamino)pyridine (DMAP) were purchased from DOJINDO Labs (Kumamoto, Japan). Dextran from *Leuconostoc mesenteroids* (M_n = 15000−20000) and Gly-Sar were purchased from Sigma Chemical Co. (St. Louis, MO). *N*,*N*-Dimethylformamide (DMF) and dimethyl sulfoxide (DMSO) were purchased from the Wako Pure Chemical Co. Ltd. and distilled by the usual method. All other chemicals used were of reagent grade. [^{3}H]Glycylsarcosine ([^{3}H]Gly-Sar) was purchased from Moravek Biochemicals Inc. (Brea, CA). Other chemaicals used were of the highest purity available.

Synthesis of Polyrotaxane−Val-Lys Conjugates (Scheme 1). Boc-Val-Lys-O*t*Bu·HCl was synthesized and characterized according to the previous report by Kamo et al. (*1*). A polyrotaxane, in which many α-CDs are threaded onto a PEO-BA ($M_n = 4000$) capped with Z-L-Phe, was prepared according to our method (*9*, *11*). Briefly, an inclusion complex of α-CDs and PEO-BA was prepared by simply mixing a saturated aqueous solution of α-CDs with a PEO-BA aqueous solution (1/44 equiv of α-CD). Then the succinimide ester of Z-L-Phe, prepared by a condensation reaction of Z-L-Phe and *N*-hydroxysuccinimide, was allowed to heterogeneously react with the terminal amino groups in the inclusion complex in DMSO. The chemical structure was characterized by 750 MHz ^{1}H NMR using a FT-NMR spectrometer (Varian FT-NMR Gemini750, Palo Alto, CA). The number of α-CDs was determined to be ca. 23 from the ^{1}H NMR spectra based on the comparison of integration of the signals at 4.75 (C_1H of α-CD) with those at 3.49 (CH_2CH_2O of PEO). The obtained polyrotaxane (0.17 mmol) and CDI (e.g., 15.6 mmol) were dissolved in dry DMSO (10 mL) and stirred at room temperature for 3 h. The reaction mixture was poured into excess ether, and the resulting precipitate was filtered and dried in vacuo to obtain CDI-activated polyrotaxanes. The number of *N*-acylimidazole groups per polyrotaxane molecule was determined by

Table 1. Synthesis of CDI-Activated Polyrotaxanes

sample code[a]	OH groups in polyrotaxane (mmol)	CDI (mmol)	CDI-activation (%)[b]
27aIM-α/E4-PHE-Z	3.1	3.1	27
46aIM-α/E4-PHE-Z	3.1	6.1	46
54aIM -α/E4-PHE-Z	3.1	9.2	54
57aIM -α/E4-PHE-Z	3.1	15.4	57

[a] aIM = *N*-acylimidazole group, α/E4-PHE-Z = polyrotaxane. [b] Calculated from the equation (A).

measuring the absorbance at 207 nm after hydrolysis of *N*-acyl carbonate groups using 2 M NaOH aqueous solution. Degree of the activation was calculated by the following equation (A):

$$\text{CDI-activation (\%)} = [\text{Im}]/[\text{OH}]_{\text{prx}} \times 100 \quad \text{(A)}$$

where [Im] and $[OH]_{prx}$ are, respectively, concentrations of the *N*-acylimidazole groups and total hydroxyl groups in the polyrotaxanes. The synthetic conditions and results were summarized in Table 1.

The CDI-activated polyrotaxane (*N*-acylimidazole groups per polyrotaxane molecule: 0.97 mmol), Boc-Val-Lys-O*t*Bu·HCl (e.g., 3.3 mmol), and DIPEA (1.1 equiv of Boc-Val-Lys-O*t*Bu·HCl) were dissolved in DMSO (2 mL) and stirred at room temperature for 24 h. The feed ratio of the CDI-activated polyrotaxane and Boc-Val-Lys-O*t*Bu·HCl was varied (Table 2). After that, 2-aminoethanol (33 mmol) was added to the solution and further stirred for 24 h. The solution was dialyzed against water and lyophilized to obtain a polyrotaxane−Boc-Val-Lys-O*t*Bu conjugate as white powder. Finally, the protecting groups of Boc and *t*-Bu were removed in the mixture of dichloromethane and trifluoroacetic acid (7:3), precipitated in excess ether, and dried in vacuo to obtain a polyrotaxane−Val-Lys conjugate as white powder.

Yield: ∼10%. ^{1}H NMR D_2O + NaOD, ppm: δ 7.35−7.18 (aromatics of Z-L-Phe), 7.15−6.80 (−OCONH− of carbamoyl linkages), 5.02 (C_1H of α-CD), 4.25−3.30 (C_3H, C_5H, C_6H_2, C_4H, and C_2H of α-CD), 4.19 (α-CH of Lys), 3.62 (CH_2CH_2O of PEO), 3.75 (α-CH of Val), 3.17 (CH_2 of hydroxyethyl carbamoyl groups), 2.15 (β-CH of Val), 1.38 (β-, γ-, and δ-CH_2 of Lys), 0.98 (CH_3 of Val).

Synthesis of α-CD−Val-Lys Conjugates. α-CD (0.31 mmol) and CDI (5.56 mmol) were dissolved in dry DMF (5 mL), and the solution was stirred at room temperature for 3 h. Boc-Val-Lys-O*t*Bu·HCl (0.62 mmol) and DIPEA (1.1 equiv of Boc-Val-Lys-O*t*Bu·HCl) were added to the solution and stirred at room temperature for 24 h. Then, 2-aminoethanol (5.6 mmol) was added to the solution and further stirred for 24 h. The solution was dialyzed against water and lyophilized to obtain an α-CD−Boc-Val-Lys-O*t*Bu conjugate as white powder. Finally, the protecting groups of Boc and *t*-Bu were removed in a manner similar to the polyrotaxane−Val-Lys conjugates.

Yield: ∼80%. ^{1}H NMR D_2O, ppm: δ 7.10−6.81 (−OCONH− of carbamoyl linkages), 4.93 (C_1H of α-CD), 4.00−3.33 (C_3H, C_5H, C_6H_2, C_4H, and C_2H of α-CD), 4.35 (α-CH of Lys), 3.67 (α-CH of Val), 3.13 (CH_2 of hydroxyethylcarbamoyl groups), 2.01 (β-CH of Val), 1.32 (β-, γ-, and δ-CH_2 of Lys), 0.91 (CH_3 of Val).

Synthesis of Dextran−Val-Lys Conjugates. Hydroxyl groups of dextran were activated using *p*-nitrophenyl chloroformate according to our previous method (*12*). The activated dextran (0.01 mmol, the number of *p*-nitrophenyl carbonate group per 100 glucose units: 20) was dissolved in dry DMSO (10 mL), and then Boc-Val-Lys-O*t*Bu·HCl (e.g., 0.4 mmol) was added to the solution. The reaction mixture was stirred at room temperature for 48 h. The feed ratio of the activated dextran and Boc-Val-Lys-O*t*Bu·HCl was varied according to the reaction conditions (Table 2). Then, the solution was dialyzed against water and lyophilized to obtain a dextran−Boc-Val-Lys-O*t*Bu conjugate as white powder. Finally, the protecting groups of Boc and *t*-Bu were removed in a manner similar to the polyrotaxane−Val-Lys conjugates.

Yield: ∼50%. ^{1}H NMR DMSO-d_6, ppm: δ 4.91−4.76 (O_2H, O_3H of dextran), 4.64 (C_1H of dextran), 4.59−4.40 (O_4H of dextran), 4.19 (α-CH of Lys), 3.92−3.19 (C_3H, C_5H, C_6H_2, C_2H, and C_4H of dextran), 3.75 (α-CH of Val), 2.13 (β-CH of Val), 1.33 (β-, γ-, and δ-CH_2 of Lys), 0.98 (CH_3 of Val).

Characterization. Purity of the conjugates was confirmed by gel permeation chromatography (GPC) using a column of Sephadex G-75, 0.1 M phosphate buffer, pH 7.4 as an eluent. The peaks on the GPC were detected by refractive index. The structure of the conjugates was characterized by 750 MHz ^{1}H NMR using the FT-NMR spectrometer. The number of α-CDs in the polyrotaxane was determined by the ^{1}H NMR spectra. The number of Val-Lys per one conjugate molecule was determined by the following equation (B):

$$N_{\text{VK}} = [\text{Val}]/[\text{polyrotaxane}],$$
$$[\text{polyrotaxane}] = [\text{Phe}]/2 \quad \text{(B)}$$

where N_{VK} is the number of Val-Lys per one conjugate molecule, [Val] the concentration of Val in the conjugate, [polyrotaxane] the concentration of the polyrotaxane, and [Phe] the concentration of the terminal Z-L-Phe in the polyrotaxane, which were determined by amino acid analysis using an amino acid analyzer (Hitachi L-8500A, Tokyo, Japan).

Cell Culture and Uptake Experiments Using HeLa-hPEPT1. HeLa cells that were stably transfected with human peptide transporter PEPT1-cDNA (HeLa-hPEPT1) or vector DNA (pcDNA3, Invitrogen, San Diego, CA) alone (HeLa-pcDNA3) were grown in Dulbecco's modified Eagle's medium (DMEM), supplemented with 10% FCS, 2mM glutamine and 1.0 mg/mL geneticine (G418, Sigma Chemicals, St. Louis, MO), as described previously (*13*). For the uptake study, each cell line was seeded at a density of 10^5 cells/cm^2 on multidishes (NUNC, Multidish 4 wells, Denmark) and were grown for 4 days. Uptake of [^{3}H]Gly-Sar (0.48 μM) by the cultured cells was examined at 37 °C according to our previous study (*13*).

The uptake of [^{3}H]Gly-Sar by the cells was usually measured using Hanks balanced salt solution (HBSS) consisting of 0.952 mM $CaCl_2$, 5.36 mM KCl, 0.441 mM KH_2PO_4, 0.812 mM $MgSO_4$, 136.7 mM NaCl, 0.385 mM Na_2HPO_4, 25 mM D-glucose, and 10 mM MES adjusted to pH 6.0 by HEPES. The cells cultured on the dishes were washed by HBSS and preincubated with HBSS for 5 min. Then, the uptake was initiated by changing the medium with HBSS containing radiolabeled Gly-Sar and each test compound. The uptake was terminated by removing the uptake solution and three times washing with ice-cold HBSS. The cells were dissolved in 0.25 mL aliquots of 5 N NaOH for 2 h, neutralized by 5 N HCl (0.25 mL), and mixed with the scintillation fluid Cleasol-I (Nacalai tesque, Kyoto, Japan), and then the associated radioactivities were measured with a liquid scintillation counter (LSC-5100, Aloka, Tokyo, Japan). Protein was measured by the protein-dye binding method (*14*).

[a] VK = Boc-Val-Lys-O*t*Bu·HCl, HE = hydroxyethylcarbamoyl groups, α/E4-PHE-Z = polyrotaxane. [b] Calculated from amino acid analysis. [c] Calculated from 750 MHz ^{1}H NMR spectra for the polyrotaxane−Val-Lys and α-CD−Val-Lys conjugates, and from GPC with a calibration using pullulan standard. [d] The reaction was carried out at 40 °C.

RESULTS AND DISCUSSION

Synthesis. To introduce Val-Lys groups using the hydroxyl groups of α-CDs in the polyrotaxane, the ϵ-amino group of lysine in Val-Lys was used because the α-carboxyl group and α-amino group of Val-Lys are essential for better recognition of PEPT1 (*1*). The hydroxyl groups of α-CDs in the polyrotaxane were activated by CDI. As shown in Table 1, the percentage of the activation increased with the amount of CDI. The IR spectrum of the sample displayed a strong peak around 1700 cm^{-1} after activation. These results indicate that *N*-acylimidazole groups were actually introduced to the polyrotaxane. Maximum number of the activation was found to be nine per α-CD molecule in the polyrotaxane.

From the ^{1}H NMR spectrum of the product after coupling Val-Lys with the CDI-activated polyrotaxane, the peaks attributed to Z-L-Phe, α-CDs, PEO, hydroxyethylcarbamoyl group, and Val-Lys were confirmed. There were no peaks attributed to *N*-acylimidazole groups in the spectrum, suggesting that the coupling reaction and the following washing procedure were successful. Similarly, all the peaks attributed to the Val-Lys conjugates were confirmed with regard to the α-CD−Val-Lys conjugate and the dextran−Val-Lys conjugate. Table 2 summarizes the synthesis of the polyrotaxane−Val-Lys, the α-CD−Val-Lys, and the dextran−Val-Lys conjugates. The number of Val-Lys per polyrotaxane molecule increased with the amount of Val-Lys in the feed. The maximum number of Val-Lys was ca. 46 per polyrotaxane molecule, indicating that two Val-Lys groups were introduced to every α-CD molecule. Figure 1 shows GPC chromatograms of the polyrotaxane−Val-Lys conjugate and the polyrotaxane (a), the α-CD−Val-Lys conjugate and α-CD (b), and the dextran−Val-Lys conjugate and dextran (c), respectively. It was found that the elution volume of the polyrotaxane−Val-Lys conjugate was similar to that of the hydroxyethylcarbamoyl−polyrotaxane, and there was no peak attributed to α-CD. This result indicates that free α-CD and its derivatives are not contaminated in the polyrotaxane−Val-Lys conjugate. The elution time of the α-CD−Val-Lys conjugate was shorter than that of α-CD, presumably due to association of the conjugates. Such an association behavior was not observed in the polyrotaxane−Val-Lys conjugate. Perhaps, due to the rodlike structure of the polyrotaxane, the association may be reduced. The association property of either the polyrotaxane or a drug−polyrotaxane conjugate was studied by light scattering measurements in our previous studies (*15*, *16*). The association number of the polyrotaxane molecules decreases with increasing the number of α-CDs in the polyrotaxane. Our previous study suggests that the rodlike structure of polyrotaxanes in physiological environments contribute to their reduced association. As for the dextran−Val-Lys conjugate, the elution time was found to be a little bit shorter than the peak of dextran (Figure 1c). M_n of the dextran calculated from GPC with a calibration using pullulan standard was ca. 17100, and M_n of all the dextran−Val-Lys conjugates (Table 2) was larger than that of the dextran. These results indicate that the dextran−Val-Lys conjugate exhibits an association under buffered conditions.

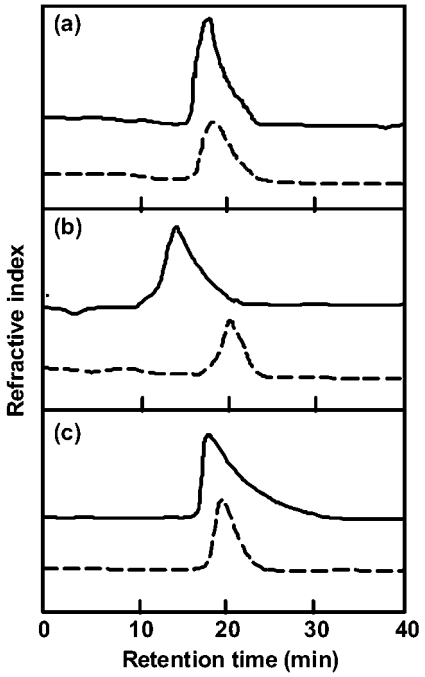

Figure 1. GPC traces of the conjugates. (a) Polyrotaxane−Val-Lys conjugate (46VK98HE-α/E4-PHE-Z, solid line) and hydroxyethyl carbamoyl polyrotaxane (dashed line), (b) α-CD−Val-Lys conjugate (1VK8HE-α-CD, solid line) and α-CD (dashed line), and (c) dextran−Val-Lys conjugate (16VK8HE-Dextran, solid line) and dextran (dashed line). Column: Sephadex G-70, Eluent: 0.1 M phosphate buffer, pH 7.4.

Inhibition of PEPT1-Mediated Transport of [^{3}H] Gly-Sar by the Conjugates. In vitro efficacy of the polyrotaxane−Val-Lys conjugates as an inhibitor of peptide transporter was evaluated by the uptake of Gly-Sar by HeLa cells stably expressing hPEPT1. Figure 2 shows the inhibitory effect of the polyrotaxane−Val-Lys conjugate and the α-CD−Val-Lys conjugate (46VK98HE-α/E4-PHE-Z and 1VK3HE-αCD in Table 2, respectively) on the uptake of [^{3}H]Gly-Sar. In Figure 2,

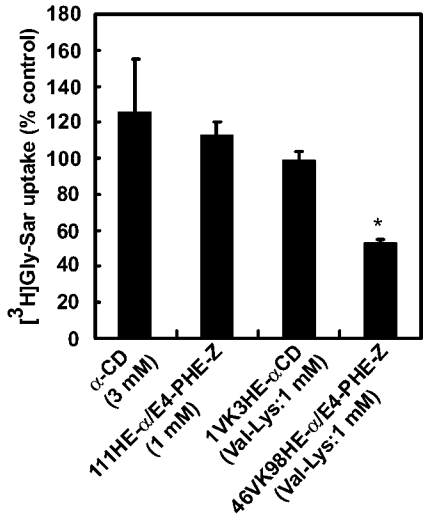

Figure 2. Inhibition of [^{3}H]Gly-Sar uptake via hPEPT1 by polyrotaxane−Val-Lys conjugate (46VK98HE-α/E4-PHE-Z), α-CD−Val-Lys conjugate (1VK3HE-αCD), hydroxyethylcarbamoyl-polyrotaxane (111HE-α/E4PHE-Z) and α-CD. Mean ± SEM (n = 4). * Significantly different (p < 0.05) from 111HE-α/E4PHE-Z.

hydroxyethylcarbamoyl-polyrotaxane (111HE-α/E4-PHE-Z) and α-CD were used as references, and the concentration was calculated based on Val-Lys residue. The uptake of [^{3}H]Gly-Sar was strongly reduced in the presence of the polyrotaxane−Val-Lys conjugate, while such a reduction was not observed for the polyrotaxane itself (111HE-α/E4-PHE-Z). The α-CD−Val-Lys conjugate showed a slight inhibitory effect with increasing Val-Lys concentration (data not shown), while α-CD itself did not. These results indicate that Val-Lys moiety immobilized on the polyrotaxane or α-CD is actually recognized by hPEPT1. Interestingly, the inhibitory effect of the polyrotaxane−Val-Lys conjugates was much greater than predicted from the Val-Lys dependency of the α-CD conjugates. The α-CD−Val-Lys conjugate can interact with one hPEPT1. On the other hand, Val-Lys moieties introduced to the polyrotaxane backbone has potential to interact with multiple hPEPT1s expressed on HeLa cells. Thus, it is considered that Val-Lys introduced to the polyrotaxane cooperatively interacts with hPEPT1. Since the molecular size of the polyrotaxane−Val-Lys conjugates is much larger than that of the α-CD−Val-Lys conjugate, the kinetics of Val-Lys−PEPT1 binding may be an important issue in the cooperative interactions. To examine this issue, the conjugates were incubated with HeLa cells at 37 °C for 30 min, prior to the measurement of [^{3}H]Gly-Sar uptake. The inhibitory potency of the polyrotaxane−Val-Lys conjugate increased by the preincubation, as opposed to not using preincubation (Figure 3). On the contrary, the preincubation of the α-CD−Val-Lys conjugate reduced the inhibitory effect. Kiessling et al. reported the enhanced interaction of neoglycopolymers with concanavalin A by preincubation (*17*). In our case, the polyrotaxane conjugate is considered to rebind with PEPT1 during the incubation, which has been kinetically proved using a model ligand and binding protein (*10*). Therefore, our results suggest the multivalent binding and/or cooperative interaction of the polyrotaxane−Val-Lys conjugates with hPEPT1.

A key feature of our designed polyrotaxane conjugates is the contribution of the supramolecular structure to the inhibitory effect. Figure 4 summarizes the inhibitory effect of the polyrotaxane−Val-Lys conjugates in comparison with the dextran−Val-Lys conjugates. The

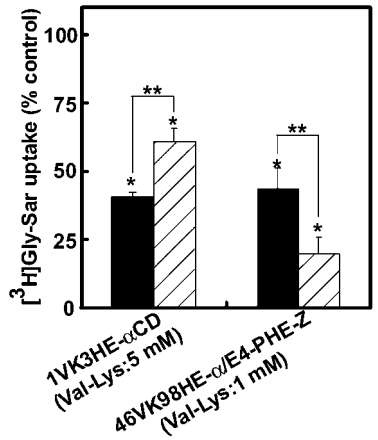

Figure 3. Effect of preincubation on the inhibition of [^{3}H]Gly-Sar uptake via hPEPT1. Mean ± SEM (n = 4). * Significantly different (p < 0.05) from control. ** Significantly different (p < 0.05) from nonpreincubation. Black bar: simultaneous addition. Slash bar: preincubation of 30 min.

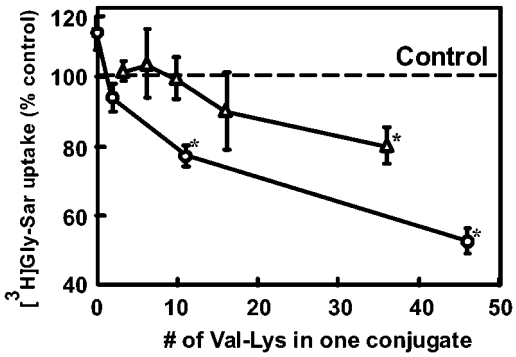

Figure 4. Inhibition of [^{3}H]Gly-Sar uptake via hPEPT1 as a function of the number of Val-Lys in one conjugate molecule. The concentration of each conjugate is 1 mM as Val-Lys basis. The polyrotaxane−Val-Lys conjugates (circle) and dextran−Val-Lys conjugate (triangle). Mean ± SEM (n = 4). * Significantly different (p < 0.05) from control.

concentration of Val-Lys in each conjugate was adjusted to be 1 mM. [^{3}H]Gly-Sar uptake in both conjugates decreased with increasing the number of Val-Lys in one conjugate molecule. The inhibition of [^{3}H]Gly-Sar uptake with the polyrotaxane−Val-Lys conjugates was significantly greater than those of the dextran−Val-Lys conjugates. In the case of conjugates between the oligopeptide and the water-soluble polymer, such as dextran−Val-Lys conjugates, the hydrophobic oligopeptide (Val-Lys) groups are likely to associate each other, owing to the flexibility of the polymer backbones, which is related with the result in Figure 1. Such association may prevent access of PEPT1 toward the Val-Lys moieties. In contrast, the Val-Lys moieties introduced in the polyrotaxane are expected to be well arrayed along the supramolecular rodlike backbone, as to easily face PEPT1 on the membrane, considering the result of Figure 1 and our previous studies. Therefore, it is suggested that the supramolecular structure of polyrotaxanes has a suitable architecture for designing polymeric inhibitors capable of multivalent binding between Val-Lys and hPEPT1.

CONCLUSIONS

The polyrotaxane−Val-Lys conjugates were found to exhibit great inhibitory effect on the uptake of a model oligopeptide, Gly-Sar, via hPEPT1. Special interest should be paid to the facts that this inhibitory effect was not explained from the monovalent interaction of hPEPT1

with Val-Lys moiety and that the polyrotaxane was superior to dextran as a conjugate pair. These results strongly suggest both the multivalent interaction of the polyrotaxane conjugate with hPEPT1 and the contribution of the supramolecular structure to this effect. The polyrotaxane−Val-Lys conjugates have been confirmed not to be absorbed from the intestine in the alternative in vivo study (*18*), suggesting that reabsorption in renal epithelial cells via PEPT2 kidney can be avoided. The polyrotaxane used in this study was not specially designed aiming at the practical use but prepared for the first fundamental research, and the in vivo efficacy of the polyrotaxane−Val-Lys conjugates is not so high (data not shown). As mentioned before, in the polyrotaxane−Val-Lys conjugates, the α-CD−Val-Lys conjugate and a linear PEO chain are noncovalently bound via mechanical locking. Sliding and rotational motion of concentrated Val-Lys groups along the polyrotaxane might contribute to the inhibitory effect reported in this study. The solubility of the polyrotaxane is also an important issue because the introduction of Val-Lys groups into the polyrotaxane reduced the solubility. Our recent study succeeded to prepare carboxyethyl ester-introduced polyrotaxanes as a calcium-chelating agent for peptide drug delivery, and these polyrotaxanes displayed excellent solubility in PBS (*19*). In this point of view, to clarify the relation of the inhibitory effect with the specific structure of the polyrotaxane, a variation of the polyrotaxane−Val-Lys conjugates is now being prepared in terms of the molecular weight of PEO, the number of α-CDs, the number of Val-Lys groups, and the degree of carboxyethyl ester groups. Therefore, our design approach on the conjugation of PEPT1-recognizable oligopeptides with supramolecular-structured polyrotaxanes is expected to be useful for retarding the progression of chronic renal disease that requires dietary protein restriction .

ACKNOWLEDGMENT

The authors are grateful to Mr. Koichi Higashimine (Japan Advanced Institute of Science and Technology) for 750 MHz ^{1}H NMR measurements. A part of this study was financially supported by Grants-in-Aid from Micromachine Center, Japan, from NOVARTIS Foundation for the Promotion of Science, Japan, and for Scientific Research on Priority Areas “Molecular Synchronization for Design of New Materials System” from the Ministry of Education, Science, Sports and Culture, Japan.

A Streptavidin−Biotin Binding System That Minimizes Blocking by Endogenous Biotin

Kevin J. Hamblett,[†] Brian B. Kegley,[‡] Don K. Hamlin,[‡] Ming-Kuan Chyan,[‡] David E. Hyre,[†] Oliver W. Press,[§,#] D. Scott Wilbur,[‡] and Patrick S. Stayton[†,*]

Departments of Bioengineering, Medicine, and Radiation Oncology, University of Washington, Seattle, Washington 98195 and The Fred Hutchinson Cancer Research Center, Seattle, Washington 98109-1024. Received October 17, 2001

Pretargeted radioimmunotherapy specifically targets radiation to tumors using antibody−streptavidin conjugates followed by radiolabeled biotin. A potential barrier to this cancer therapy is the presence of endogenous biotin in serum, which can block the biotin-binding sites of the antibody−streptavidin conjugate before the administration of radiolabeled biotin. Serum-derived biotin can also be problematic in clinical diagnostic applications. Due to the extremely slow dissociation of the biotin−streptavidin complex, this endogenous biotin can irreversibly block the biotin-binding sites of streptavidin and reduce therapeutic efficacy, as well as reduce sensitivity in diagnostic assays. We tested a streptavidin mutant (SAv-Y43A), which has a 67-fold lower affinity for biotin than wild type streptavidin, and three bivalent bis-biotin constructs as replacements for wild-type streptavidin and biotin used in pretargeting and clinical diagnostics. Biotin dimers were engineered with certain parameters including water solubility, biotinidase resistance, and linker lengths long enough to span the distance between two biotin-binding sites of streptavidin. The bivalent biotins were compared to biotin in exchange, retention, and off-rate assays. The faster off-rate of SAv-Y43A allowed efficient exchange of prebound biotin by the biotin dimers. In fluorescent competition experiments, the biotin dimer ligands displayed high avidity binding and essentially irreversible retention with SAv-Y43A. The off-rate of a biotinidase-stabilized biotin dimer from SAv-Y43A was 4.36×10^{-6} s^{-1}, over 640 times slower compared to biotin. These findings strongly suggest that employing a mutant streptavidin in concert with a bivalent biotin can mitigate the deleterious impact of endogenous biotin, by allowing exchange of bound biotin and retention of the biotin dimer carriers.

INTRODUCTION

The high affinity streptavidin (SAv[1])−biotin binding system is widely utilized in clinical diagnostic applications (*1*) and is under evaluation as a molecular component in tumor-targeted cancer therapeutics. In diagnostics, SAv is used as "molecular velcro" to bind biotinylated antibodies or other proteins that specifically capture the desired target for diagnosis. For cancer therapeutics, the biotin/SAv binding pair is being used in chemical reagents designed to optimize the targeting of radionuclides to cancer cells for therapy (*2*−*8*). In this application, termed "pretargeting", a monoclonal antibody (mAb)−SAv conjugate is injected into a patient, allowed to localize at the tumor over 24−48 h, followed by the clearing of excess reagent from blood and administration of the radiolabeled biotin derivative. The excess radiolabeled biotin is rapidly excreted via the renal system. Very encouraging results have been obtained with the pretargeting approach in preclinical therapy studies using human tumor xenografts in athymic mice (*9*, *10*).

While the high affinity of the streptavidin−biotin system is a central feature of both diagnostic and pharmaceutical applications, this tight interaction can paradoxically present a serious limitation when naturally occurring "endogenous" biotin blocks the biotin binding sites of SAv. Biotin is involved in intermediary metabolism (*11*−*13*) and is present in blood at 0.6−3.0 nM (*14*). Axworthy et al. determined that the biotin binding sites of SAv are partially blocked by endogenous biotin in pretargeting applications, impairing its efficacy (*10*). Similarly, tissue slices and blood samples used for clinical diagnostics can also contain significant levels of endogenous biotin that reduce the efficacy of biotin/SAv based detection systems (*15*−*18*).

Strategies that circumvent the blocking of the biotin-binding sites of streptavidin by endogenous biotin may therefore offer therapeutic advantages. The intrinsic challenge is to engineer a decrease in streptavidin affinity for endogenous biotin, while preserving high affinity for the biotinylated radiation carriers in the case of therapeutics, or biotinylated macromolecules (e.g., antibodies, oligonucleotides) in the case of clinical diagnostics. We

describe here how site-directed SAv binding pocket mutants can be used to achieve this goal in concert with appropriately designed bivalent biotin ligands and radiation carriers. We have utilized previously described site-directed streptavidin mutants (*19*−*22*) and bivalent biotin ligands designed to effectively reach the two adjacent biotin binding pockets of streptavidin (*23*, *24*). The lower affinities and faster biotin off-rates of the SAv mutants allows prebound endogenous biotin to quickly dissociate, while the dual binding of the bis-biotin ligand results in a striking avidity effect that leads to high affinity capture of the modified bivalent ligands. These ligands can be readily designed as biotinidase-stabilized ligands and jointly as radiation carriers.

EXPERIMENTAL PROCEDURES

General. All chemicals purchased from commercial sources were analytical grade or better and were used without further purification unless noted. Most reagents were obtained from Aldrich Chemical Co. (Milwaukee, WI). Biotin was obtained from Sigma Chemicals (St. Louis, MO). 4,7,10-Trioxa-1,13-tridecanediamine was obtained from Fluka (St. Louis, MO). biotin-4-fluorescein was obtained from Molecular Probes (Eugene, OR). 2,3,5,6-Tetrafluorophenyl trifluoroacetate (TFP-OTFA) was prepared as previously described (*25*). L-Aspartic acid α-*tert*-butyl ester was obtained from Calbiochem-Novabiochem Corp. (San Diego, CA). Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μm) prior to use. Silica gel chromatography was conducted with 70−230 mesh 60 Å silica gel (Aldrich Chemical Co.). Melting points were obtained in open capillary tubes on a Mel-Temp II apparatus with a Fluka 51 K/J electronic thermometer and are uncorrected.

Radioactive Materials. Standard methods for safely using radionuclides of iodine were employed (*26*). Na[^{125}I]I was purchased from NEN/Dupont (Billerica, MA) as high pH, high concentration solutions in 0.1 N NaOH. Measurement of ^{125}I was accomplished on the Capintec CRC-15R or a Capintec CRC-7 Radioisotope Calibrator.

Spectral Analyses. ^{1}H NMR spectra were obtained on a Bruker AC-200 (200 MHz), Bruker AC 300 (300 MHz), or Bruker AC 500 (500 MHz) instrument. Chemical shifts are expressed as ppm using tetramethylsilane as internal standard ($\delta = 0.0$ ppm). Mass spectral data (both low resolution and high resolution) of most compounds prepared in this study were obtained on a PerSeptive Biosystems Mariner electrospray time-of-flight mass spectrometer (ESI-TOF). For analysis, the samples were dissolved in 50/50 MeOH/H_2O and were introduced by an integral syringe infusion pump. Some mass spectral data (low resolution) were obtained on a VG Analytical (Manchester, England) VG-70 SEQ mass spectrometer with associated 11250J Data System. These mass spectral data were obtained by fast atom bombardment (FAB^+) in a matrix of 2-hydroxyethyl disulfide (2HEDS) and poly(ethylene glycol) 300 or 600 containing thioglycolate. High resolution mass spectral data were used for compound identification. Compounds containing Sn isotopes had five matching isotopic masses, but only one is provided as identification. ^{1}H NMR and HPLC were used to assess purity of nonradioactive compounds (these data are provided in the Supporting Information).

Chromatography. HPLC separations of nonradioactive compounds were obtained on Hewlett-Packard quaternary 1050 gradient pumping system with a variable wavelength UV detector (254 nm) and a Varex ELSD MKIII evaporative light-scattering detector. Analysis of the HPLC data were conducted on Hewlett-Packard HPLC ChemStation software. All reactions were monitored by HPLC. Reversed-phase HPLC chromatography was carried out using an Alltech Altima C-18 column (5 μm, 250 mm × 4.6 mm) using a gradient solvent system at a flow rate of 1 mL/min. A gradient of MeOH and H_2O/0.1% HOAc was used. Starting with 40% MeOH, the initial solvent mixture was held for 2 min; then the gradient was increased to 100% MeOH over the next 10 min and then held at 100% MeOH for 8 min. Retention times (t_R) under these conditions for biotin conjugates are provided with the experimental procedures.

HPLC separations of radioiodinated biotin derivatives were conducted using a gradient system which consisted of two Beckman model 110B pumps, a Beckman 420 controller, a Beckman model 153 UV detector (254 nm), and a Beckman model 170 radioisotope detector. The separations were obtained using HPLC conditions described above, except the gradient was started with 30% MeOH.

Compound Preparation. The following compounds were prepared as previously described: **1**, **4** (*23*); **8** (*27*); **11**, **12** (*24*); **13**, **14**, [^{125}I]**13** (*28*); **17** (*29*); **21**, and **22** (*30*).

***N*-(*tert*-Butyloxycarbonyl)-5-aminoisophthalate Bis-tetrafluorophenyl Ester (3).** To 236 mL of a 1:1 mixture of DMF/H_2O containing 5-aminoisophthalic acid (25.28 g, 140 mmol) and NaOH (12.3 g, 307 mmol) at ice/H_2O temperature was added di-*tert*-butyl dicarbonate (32.1 g, 147 mmol). The reaction was allowed to come to room temperature while stirring for 30 h. The reaction mixture was acidified slowly with 3 N HCl (111 mL), and the mixture was diluted with an additional 100 mL of H_2O. The precipitate was collected, washed with water, and dried to yield 28.8 g (73%) of the *t*-Boc protected aminoisophthalic acid mp > 300 °C. ^{1}H NMR (DMSO-d_6, 200 MHz): δ 1.50 (s, 9H), 8.08 (t, $J = 1.5$ Hz, 1H), 8.31 (d, $J = 1.5$ Hz, 2H), 9.80 (s, 1H). HRMS calcd for $C_{13}H_{16}NO_6$ $(M + H)^+$: 282.0977. Found: 282.0981. HPLC: t_R =11.3 min.

A quantity (5 g, 18 mmol) of the *t*-Boc protected 5-aminoisophthalic acid was dissolved in 40 mL of DMF, and tetrafluorophenol (6.5 g, 39 mmol) was added. To this mixture was added a solution containing EDC in 30 mL of DMF. The reaction was stirred at room temperature for 16 h, and the DMF was removed under vacuum. The crude product was divided into two portions, and each portion was purified on a silica column (200 g) eluting with 5% EtOAc/hexanes. The fractions containing product (by HPLC) were evaporated under vacuum and combined to provide 6.8 g (67%) of 3 as a white solid, mp 159.7−161.8 °C dec ^{1}H NMR ($CDCl_3$, 200 MHz): δ 1.55 (s, 9H), 6.83 (s, 1H), 7.08 (m, 1H), 8.54 (d, $J = 1.5$ Hz, 2H), 8.67 (t, $J = 1.5$ Hz, 1H). HRMS calcd for $C_{25}H_{15}F_8NNaO_6$ $(M + Na)^+$: 600.0669. Found: 600.0674. HPLC: $t_R = 16.3$ min.

***N′*,*N″*-Bis(8-biotinamido-3,6-dioxaoctanylamino)-5-(*N*-*tert*-butyloxycarbonyl)aminoisophthalamide (5).** A quantity of **4** (321 mg, 0.86 mmol) was dissolved in 4 mL of DMF, and Et_3N (60 μL, 0.43 mmol) was added. In a separate flask, a quantity of **3** (50 mg, 0.086 mmol) was dissolved in 10 mL of DMF. The solution of **3** was dripped slowly into the solution of **4** over a 1 h period. The solvent was removed under vacuum, and the crude product was dissolved into a minimal amount of MeOH. This solution was loaded onto a silica gel column (8 g) and was eluted using EtOAc (400 mL) and then MeOH/EtOAc mixtures increasing in the percentage of MeOH. The product eluted using a mixture of 60% EtOAc/40% MeOH. Fractions containing product were taken to dryness under

vacuum to yield 65 mg (79%) of **5** as a colorless solid, mp 94−95 °C; ^{1}H NMR (MeOH-d_4, 200 MHz) 1.0−1.6 (br m, 10H), 1.4 (s, 9H), 2.0 (m, 4H), 2.5 (m, 2H), 2.8 (m, 2H), 3.0 (m, 2H), 3.2 (m, 8H), 3.4 (m, 16H), 4.1 (m, 2H), 4.3 (m, 2H), 4.5 (s, 2H), 7.7 (m, 1H), 7.9 (m, 2H); HRMS calcd for $C_{45}H_{72}N_9O_{12}S_2$ (M + H) 994.4749 found 994.4742; HPLC: t_R= 10.9 min.

***N′,N″*-Bis(8-biotinamido-3,6-dioxaoctanylamino)-5-((*N*-*tert*-butoxycarbonyl)-13-amino-4,7,10-trioxatridecane-thioureido)isophthalamide (9).** A quantity of **5** (356 mg, 0.36 mmol) was dissolved in 1 mL of TFA. The reaction was allowed to stir for 10 min, and the excess TFA was removed under a gentle stream of argon (in a fume hood). The residue was dissolved in a minimal amount of MeOH, and an excess of Et_3N (1 mL) was added. The mixture was stirred for 10 min, and the excess Et_3N and solvent were removed under vacuum. The crude amino-biotin dimer, **6**, was further dried under vacuum to yield 302 mg (94%). HRMS calcd for $C_{40}H_{63}N_9O_{10}NaS_2$ (M + Na) 916.4041, found 916.4043; HPLC: t_R= 7.5 min.

The isolated **6** was added to a solution of thiocarbonyldiimidazole (66 mg, 0.37 mmol) in 4 mL of DMF. The reaction was stirred at room temperature for 0.5 h and then taken to dryness under a stream of argon to yield **7** which was directly used in the following step. A quantity of the *t*-Boc-protected trioxadiamine **8** (113 mg, 0.35 mmol) was added to the solution, and the reaction was stirred for 0.5 h at room temperature. The reaction mixture was then triturated with 50 mL of ether and stirred for 1 h until the solution became clear. The ether was decanted, and the crude product was dissolved in a minimal amount of MeOH. The crude material was loaded onto silica gel column (40 g). The column was eluted with EtOAc (100 mL) and then with increasing concentration of MeOH in EtOAc until the product eluted (50% MeOH). Fractions containing product (by HPLC) were taken to dryness to yield 125 mg (31%) of **9** as a tacky solid; ^{1}H NMR (MeOH-d_4, 200 MHz) 1.4 (s, 9H), 1.6 (m, 8H), 1.9 (m, 2H), 2.2 (t, J = 7.3 Hz, 4H), 2.7 (d, J = 12.5 Hz, 4H), 2.9 (dd, J = 5.1, 12.8 Hz, 2H), 3.1 (t, J = 6.9 Hz, 1H), 3.2 (m, 2H), 3.3 (m, 8H), 3.3 (m, 4H), 3.6 (m, 28H), 4.2 (m, 2H), 4.4 (m, 2H) 4.5 (s, 2H), 8.0 (d, J = 1.4 Hz, 2H), 8.0 (t, J = 1.4 Hz, 1H); HRMS calcd for $C_{56}H_{93}N_{11}O_{15}NaS_3$ (M + Na) 1278.5929 found 1278.5912; HPLC: t_R= 11.2 min.

***N′,N″*-Bis(8-biotinamido-3,6-dioxaoctanylamino)-5-((13-amino-4,7,10-trioxatridecane)thioureido)-isophthalamide (10).** A quantity of **9** (125 mg, 0.1 mmol) was dissolved in 1 mL of TFA. The reaction was stirred for 10 min, and the excess TFA was removed under a gentle stream of argon. The product was dissolved in a minimal amount of MeOH, and an excess of Et_3N (1 mL) was added and was allowed to stir for 10 min. Excess Et_3N and solvent were removed under vacuum, and the product was dried under vacuum to yield 107 mg (93%) of **10**. HRMS calcd for $C_{51}H_{86}N_{11}O_{13}S_3$ (M + H) 1156.5560 found 1156.5569; HPLC: t_R= 7.5 min. This material was of sufficient purity (>95% by HPLC) to be used directly in subsequent reactions.

***N′,N″*-Bis(8-biotinamido-3,6-dioxaoctanylamino)-5-((13-(*N*-(*p*-iodo)benzamido-4,7,10-trioxatridecane)-thioureido)isophthalamide (15).** A quantity of **10** (50 mg, 0.04 mmol) was dissolved in 4 mL of DMF. Et_3N (15 μL, 0.08 mmol) and *p*-iodobenzoate TFP ester **11** (18 mg, 0.04 mmol) were added, and the reaction was stirred for1 h at room temperature. The mixture was triturated with 50 mL of ether and stirred for an additional 1 h. The ether was decanted, and the product was dried under vacuum to yield 54 mg (90%) of **15** as a tacky solid; ^{1}H NMR (MeOH-d_4, 500 MHz) 1.4 (s, 4H), 1.6 (m, 8H), 1.9 (m, 4H), 2.2 (t, J = 7.4 Hz, 4H), 2.7 (d, J = 12.9 Hz, 2H), 2.9 (dd, J = 4.9, 12.9 Hz, 2H), 3.2 (m, 4H), 3.3 (m, 4H), 3.3 (m, 20H), 3.6 (m, 12H), 3.7 (m, 8H), 4.3 (m, 2H), 4.5 (m, 2H) 4.6 (s, 4H), 7.5 (d, J = 8.6 Hz, 2H), 7.8 (d, J = 8.6 Hz, 2H), 8.0 (s, 2H), 8.0 (s, 1H); HRMS calcd for $C_{58}H_{88}N_{11}O_{14}NaS_3I$ (M + Na) 1408.4612 found 1408.4617; HPLC: t_R= 12.0 min.

***N′,N″*-Bis(8-biotinamido-3,6-dioxaoctanylamino)-5-((13-(*N*-(*p*-tri-*n*-butylstannyl)benzamido-4,7,10-trioxatridecane)thioureido))isophthalamide (16).** This compound was prepared as described for **15** (above) except the stannylbenzoate TFP ester, **12** (25 mg, 0.04 mmol) was added in the place of **11**. The reaction yielded 48 mg (77%) of **16** as a tacky solid; ^{1}H NMR (MeOH-d_4, 500 MHz) 0.9 (t, J = 6.8 Hz, 9H), 1.1 (m, 4H), 1.3 (m, 8H), 1.6 (m, 12H), 1.9 (m, 6H), 2.2 (t, J = 7.4 Hz, 8H), 2.7 (d, J = 12.3 Hz, 4H), 2.8 (s, 4H), 2.9 (dd, J = 4.9, 12.3 Hz, 2H), 3.0 (s, 2H), 3.2 (m, 4H), 3.3 (m, 8H), 3.4 (m, 4H), 3.6 (m, 12H), 3.6 (m, 8H), 4.3 (m, 2H), 4.5 (m, 2H), 7.5 (d, J = 8.0 Hz, 2H), 7.7 (d, J = 0.80 Hz, 2H), 8.0 (s, 2H), 8.1 (s, 1H); LRMS calcd for $C_{70}H_{115}N_{11}O_{14}NaS_3Sn$ (M + Na) 1571 found 1571; HPLC: t_R= 16.0 min.

Preparation of [^{125}I]15. To a solution containing *p*-tri-*n*-butylstannybenzoate NHS ester **13** (50 μg in 1 mg/mL solution MeOH/5%AcOH) and Na[^{125}I]I (3 μL in 0.1 N NaOH, 977 μCi) was added NCS (10 μL in 1 mg/mL solution MeOH). The reaction mixture was stirred for 5 min at room temperature. Sodium metabisulfite (10 μL in 1 mg/mL solution H_2O) was then added to quench the reaction. The reaction mixture was dried under a stream of air (through charcoal filter), and a solution containing **10** (200 μL of 1 mg/mL solution in DMF) and Et_3N (10 μL) was added. This mixture was stirred for 0.5 h at room temperature, and the product was purified by HPLC to give a 75% radiochemical yield of [^{125}I]**15**.

***N*-(Biotinyl)-α-*tert*-butyl-*β*-*N*-(8-amino-3,6-dioxaoctanyl)aspartamide (19).** A quantity (100 mg, 0.18 mmol) of **17** was dissolved into 2 mL of anhydrous DMF. This solution was added slowly (1 h) into a solution of dioxadiamine **18** (260 μL, 1.78 mmol) in 2 mL of anhydrous DMF. After the addition was complete, the reaction was allowed to stir for an additional 1 h at room temperature. The reaction mixture was then triturated with 100 mL of ether, and this mixture was stirred for 1 h. The ether was decanted, and an additional 100 mL of ether was added and stirred for another 1 h. After that time, the ether was decanted, and the product was dried under vacuum to yield 74 mg (76%) of **19** as a tacky solid; ^{1}H NMR (MeOH-d_4, 200 MHz) 1.4 (s, 9H), 1.6 (m, 4H), 2.2 (t, J = 7.3 Hz, 2H), 2.6 (m, 4H), 2.9 (m, 2H), 3.23 (m, 1H), 3.3 (m, 4H), 3.5 (m, 4H), 3.6 (m, 4H), 4.3 (dd, J = 4.4, 8.0 Hz, 1H), 4.4 (dd, J = 4.4, 7.7 Hz, 1H), 4.6 (t, J = 6.2, 1H); HRMS calcd for $C_{24}H_{43}N_5O_7NaS$ (M + Na) 568.2810, found 568.2781; HPLC: t_R= 6.5 min.

***N′,N″*-Bis(*N*-(biotinyl)-*β*-*N*-(8-amino-3,6-dioxaoctanyl)aspartamidyl-5-*N*-(*p*-iodobenzamido)aminoisophthalamide (23).** A quantity of **19** (500 mg, 0.77 mmol) was dissolved in 3 mL of TFA. The reaction was stirred for 10 min and the excess TFA was removed under a gentle stream of argon. The residue was washed several times with 5 mL portions of ether to remove any remaining TFA. The residue was then dried under vacuum to yield **20** as the TFA salt. The isolated **20** was >95% pure (by HPLC) and was used directly in next reaction step. HPLC: t_R = 3.0 min.

Quantities of **20** (370 mg, 0.757 mmol), **21** (267 mg, 0.378 mmol), and Et_3N (160 μL, 1.13 mmol) were dis-

solved in 5 mL of DMF. This mixture was stirred for 0.5 h and then triturated with 100 mL of ether. The resultant solid was collected by filtration and dried on vacuum. A yield of 350 mg (68%) **23** was obtained as a white solid; mp 80−81 °C; ^{1}H NMR (MeOH-d_4, 200 MHz) 1.4 (m, 4H), 1.6 (m, 6H), 2.2 (t, J = 7.3 Hz, 4H), 2.6 (m, 4H), 2.8 (s, 2H), 2.9 (dd, J = 4.7, 12.8 Hz, 2H), 3.3 (m, 6H), 3.5 (t, J = 5.1 Hz, 8H), 3.6 (m, 12H), 4.2 (m, 2H), 4.4 (m, 2H), 4.5 (m, 2H), 7.7 (d, J = 8.7 Hz, 2H), 7.9 (d, J = 8.4 Hz, 2H), 8.0 (t, J = 1.4 Hz, 1H), 8.3 (d, J = 1.4 Hz, 2H); HRMS calcd for $C_{55}H_{75}N_{11}O_{17}Na_2S_2I$ (M−H+2Na) 1398.3628, found 1398.3624; HPLC: t_R = 11.2 min.

***N′,N″*-Bis(*N*-(biotinyl)-*β*-*N*-(8-amino-3,6-dioxaoctanyl)aspartamidyl-5-*N*-(*p*-(tri-*n*-butylstannyl)benzamido)aminoisophthalamide (24).** A quantity (300 mg, 0.613 mmol) of **20** (prepared as described above), **22** (266 mg, 0.306 mmol), and Et_3N (130 μL, 0.92 mmol) was dissolved in 5 mL of DMF. That solution was stirred at room temperature for 0.5 h and then triturated with 100 mL of ether. The precipitate was collected by filtration, dissolved in minimal amount of MeOH, and loaded onto silica gel column (20 g). The column was first eluted using EtOAc (300 mL), and then MeOH was added to the eluant in increasing proportions until the product eluted (50% methanol). The solvent was removed from fractions containing product (determined by HPLC). The residue was dried under vacuum to yield 149 mg (32%) of **24** as a white solid; mp 174−176 °C; ^{1}H NMR (DMSO-d_6, 300 MHz) 0.8 (t, J = 7.2 Hz, 9H), 1.0(t, J = 7.7 Hz, 6H), 1.3 (m, 10H), 1.5 (m, 12H), 2.0 (t, J = 6.7 Hz, 4H), 2.3 (m, 2H), 2.5 (s, 2H), 2.5 (s, 2H), 2.8 (dd, J = 4.6, 12.9 Hz, 2H), 3.0 (m, 2H), 3.1 (m, 4H), 3.2−3.7 (m, 20H), 4.1 (m, 2H), 4.2 (m, 2H), 4.3 (m, 2H), 7.5 (d, J = 7.2 Hz, 2H), 7.5 (d, J = 7.2 Hz, 2H), 8.0 (d, J = 8.3 Hz, 2H), 8.2 (s, 1H), 8.3 (s, 2H), 8.5 (s, 2H), 8.9 (s, 2H), 10.7 (d, J = 9.8 Hz, 1H); HRMS calcd for $C_{67}H_{101}N_{11}O_{17}Na_3S_2Sn$ (M − 2H + 3Na) 1584.5426, found 1584.5533; HPLC: t_R= 15.7 min.

Preparation of [^{125}I]23. To a 50 μL solution of **24** (1 mg/mL in 5%AcOH/MeOH) was added 7 μL of Na^{125}I (2.8 mCi) in 0.1 N NaOH. To the resultant solution was added 15 μL of a 1 mg/mL solution of NCS in MeOH. The reaction was quenched after 5 min with 15 μL of a 1 mg/mL solution of sodium metabisulfite in H_2O. Radio-HPLC analysis indicated that the reaction gave >75% radiochemical yield, and 1.5 mCi (54%) [^{125}I]**23** was isolated from the HPLC effluent; t_R= 15.6 min.

Streptavidin. The production and purification of streptavidin, SAv-WT and the site-directed mutant, SAv-Y43A, has been previously described (*22*). Briefly, SAv was expressed in BL21(DE3) cells containing the pET-21a plasmid with the SAv gene. Cells were grown in 3 L of 2xYT media until an OD_{600} between 0.6 and 0.9 was reached, at which time induction was initiated by the addition of isopropyl beta-D-thiogalactoside to a final concentration of 0.1 mM. Cells were grown for 3 h and harvested by centrifugation. Cells were lysed to liberate the inclusion bodies, followed by washing of the inclusion bodies. The inclusion bodies were solubilized using 6 M Gdn-HCl and refolded by dilution in Tris-Saline at 4 °C. SAv-WT and SAv-Y43A were purified using an iminobiotin column. All experiments performed report SAv concentration as the monomer concentration not the standard tetramer concentration.

Molecular Modeling. Simulations of the distances between biotin carboxylate carbons were obtained from the computer program ChemDraw 3D (CambridgeSoft Corporation, Cambridge, MA) after the structures were energy minimized in their fully extended, planar conformation.

Binding Stoichiometry Determination. SAv-Y43A monomer concentration was determined by spectrophotometric analysis at 280 nm (ϵ = 34000 $M^{-1}cm^{-1}$). 2-(4-Hydroxyphenylazo)benzoic acid (HABA) was added, and the absorbance was measured at 500 nm. Biotin, biotin dimer **1**, biotin dimer **15**, or biotin dimer **23** were titrated separately and the OD_{500} was measured to determine the percent change in HABA occupied biotin binding sites. The ratio of biotin moieties to biotin sites was calculated as the cumulative concentration of biotin added to the sample divided by the total concentration of biotin binding sites (*31*).

Fluorescence Assays of Ligand-Binding Kinetics. Quantitation of ligand binding kinetics and ligand exchange with biotin-4-fluorescein were performed on a Hitachi spectrophotofluorometer F4500 with excitation at 494 nm and emission monitored at 525 nm, 5 nm excitation and emission slit widths. The off-rate of biotin-4-fluorescein (Molecular Probes, Eugene OR) from SAv-Y43A was determined at 37 °C by adding equimolar amounts of mutant to biotin-4-fluorescein at 380 nM, followed by addition of a 1000-fold excess of biotin. The fluorescence was measured continuously for 1 h after the addition of the biotin. The off-rate of biotin-4-fluorescein was determined to be 7.6 × 10^{-4} s^{-1} at 37 °C. Ligand exchange experiments were performed in which biotin, biotin dimer **1**, biotin dimer **15**, and biotin dimer **23** were competed with biotin-4-fluorescein. Five equiv of competitor (biotin, biotin dimer **1**, biotin dimer **15**, or biotin dimer **23**) were added to prebound SAv-Y43A, and the fluorescence emission was measured continuously for 1 h. The experiment was also performed with SAv-WT.

^{3}H-Biotin Ligand Competition Experiments. Competition assays were performed as previously described (*22*) in which biotin, biotin dimer **1**, biotin dimer **15**, and biotin dimer **23** were directly compared to ^{3}H-biotin (Amersham Pharmacia). SAv-Y43A at a subunit concentration of 10 nM was mixed with 10 nM ^{3}H-biotin. Unlabeled competitor (biotin, biotin dimer **1**, biotin dimer **15**, or biotin dimer **23**) at defined concentrations between 0 and 500 nM was added to the mixture, and the reactions were incubated at 37 °C for 2.5 h. A 100 μL volume of the reaction was added to 200 μL of 0.2 M $ZnSO_4$, followed by the addition of 200 μL of 0.2 M NaOH. The mixture was vortexed for 15 s to precipitate the protein and any bound ligand. Samples were centrifuged at 14000 rpm for 1−3 min to pellet the precipitate. Radioactivity of 200 μL of the supernatant was quantified using a scintillation counter.

^{125}I-Biotin Dimer Off-Rate Assay. The biotin dimer **23**[^{125}I] was used to determine the dissociation rate from SA-Y43A. Biotin dimer **23**[^{125}I] was mixed with a 100-fold excess of SA-Y43A. Separation of the unbound biotin dimer **23**[^{125}I] from biotin dimer **23**[^{125}I] bound to SA-Y43A was achieved by using ultrafiltration concentrators (Millipore, Bedford, MA) with a 10000 molecular weight cutoff. Prerinsing concentrators with biotin dimer **23** was necessary to prevent nonspecific binding of biotin dimer **23**[^{125}I] to the membrane. The unbound biotin dimer **23** at time zero was roughly 5% of the total activity present in the sample. This mixture was allowed to equilibrate at 37 °C for 45 min, and 30 μL of the reaction was removed to measure the total radioactivity in cpm. A 200 μL volume of the reaction was then removed and filtered through a concentrator for 2 min at 10000 rpm. A 30 μL volume of the flow-through was removed and the radioactivity measured as the zero time point. A 2800-fold excess of biotin dimer **23** was added to the mixture to start the assay, and at various time points 200 μL was

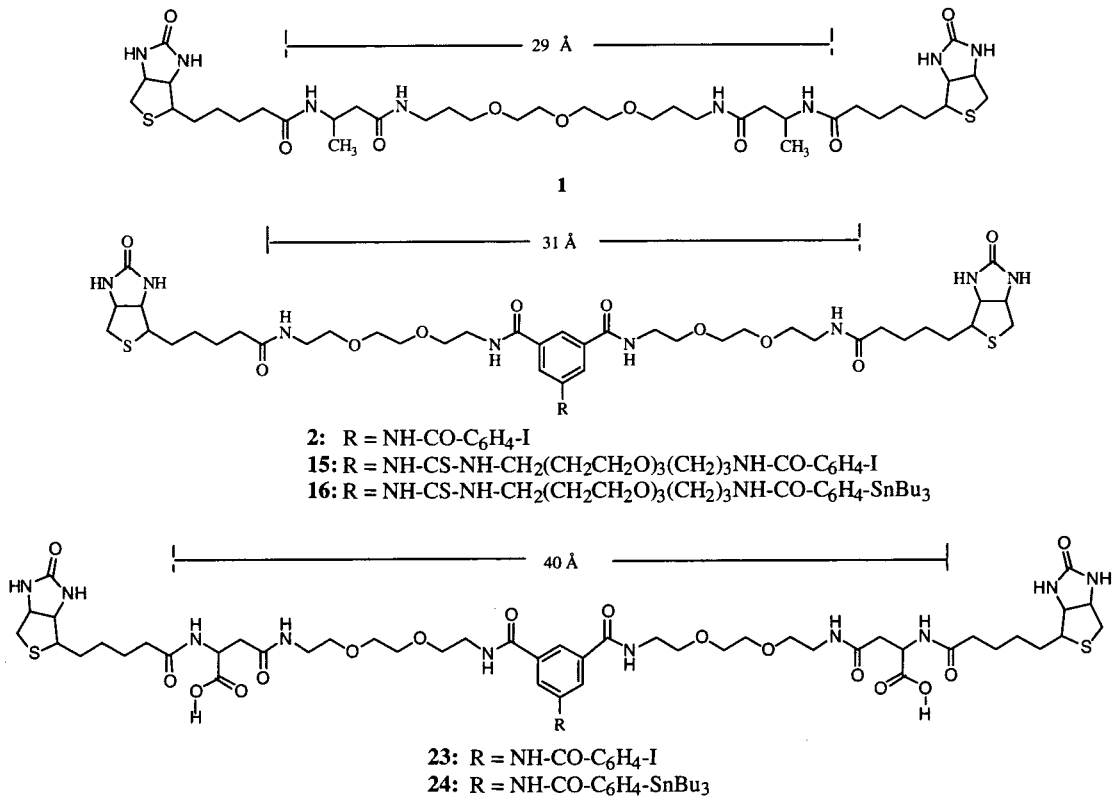

Figure 1. Structures of biotin dimers with the estimated distance between biotin carboxylate carbons.

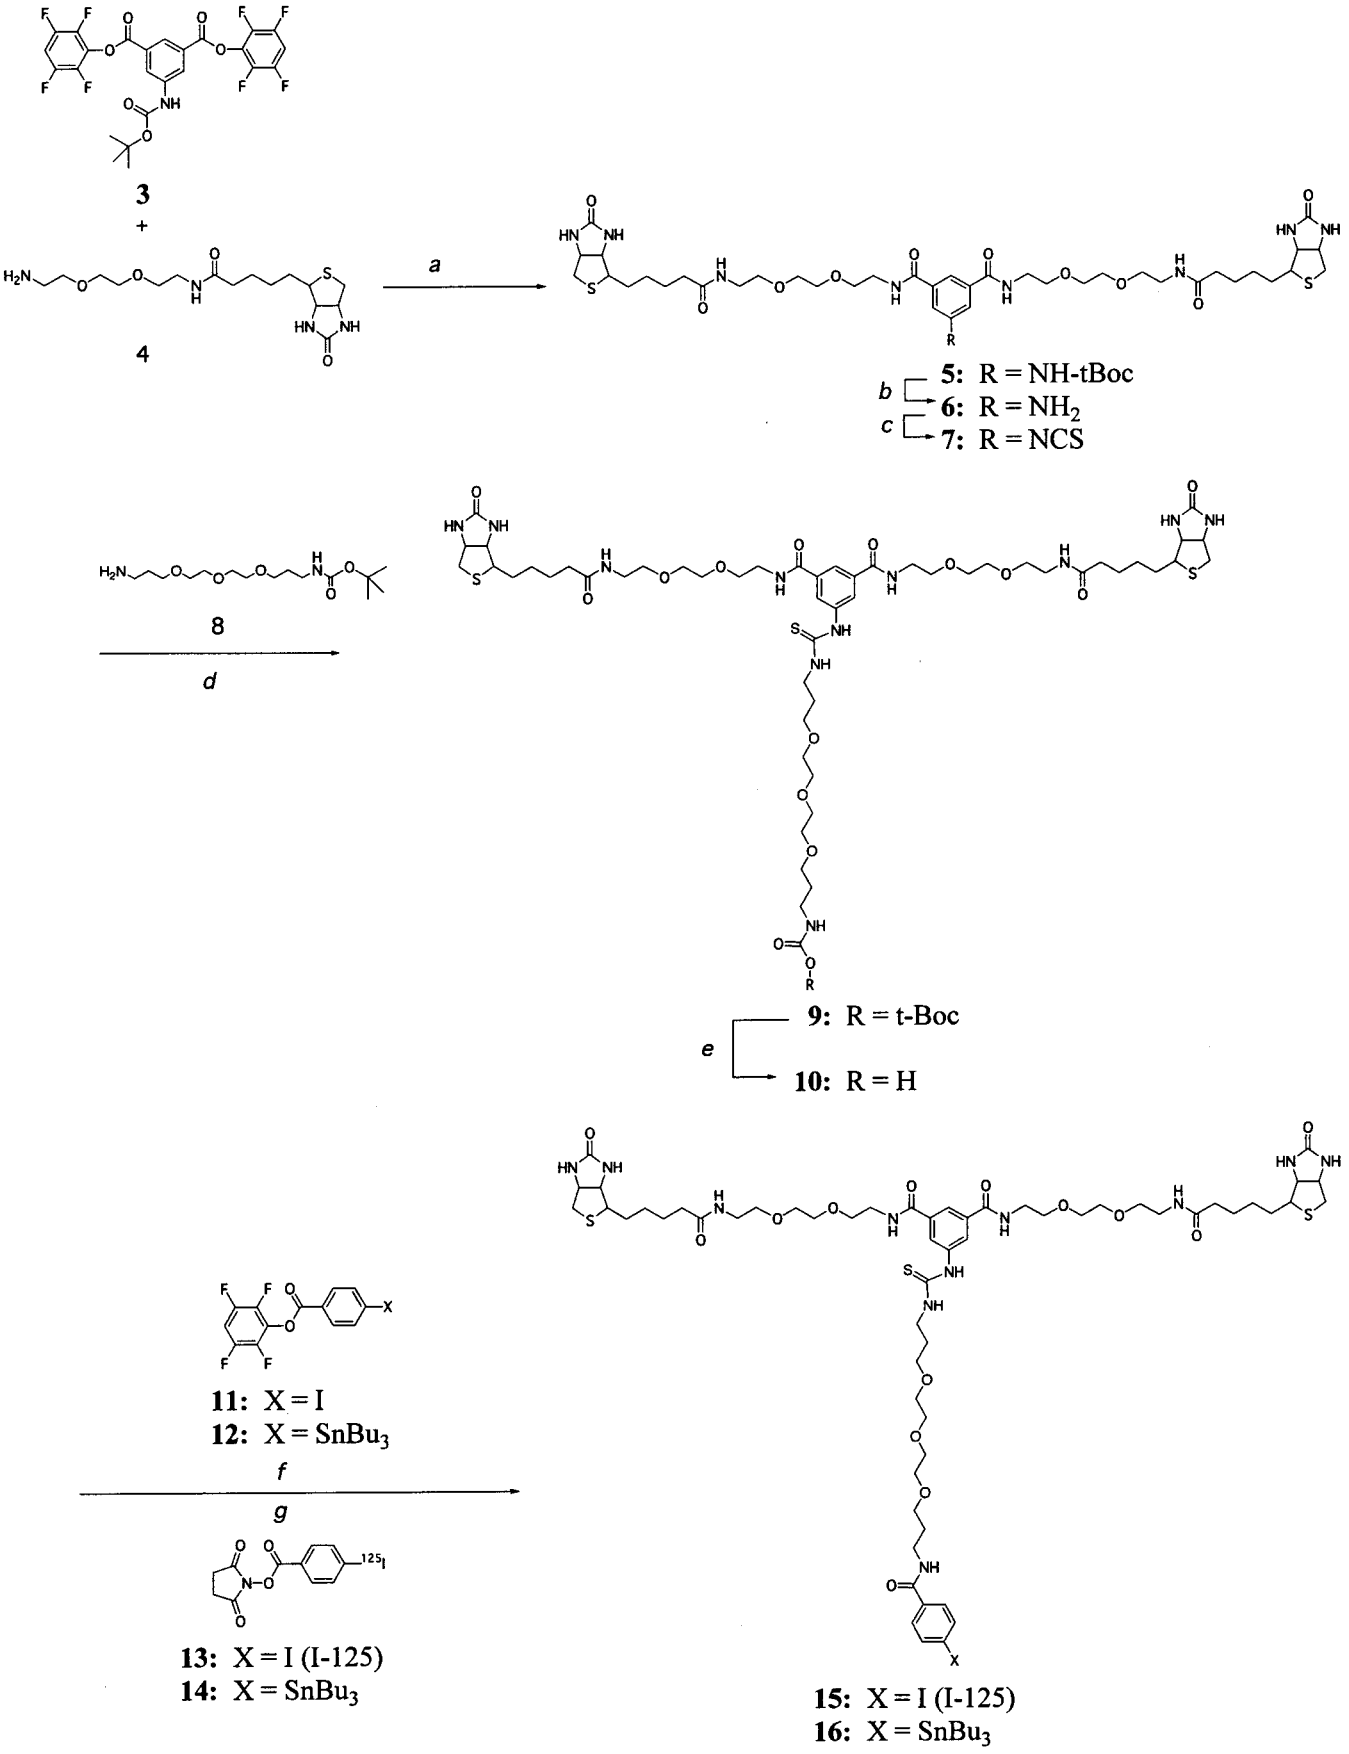
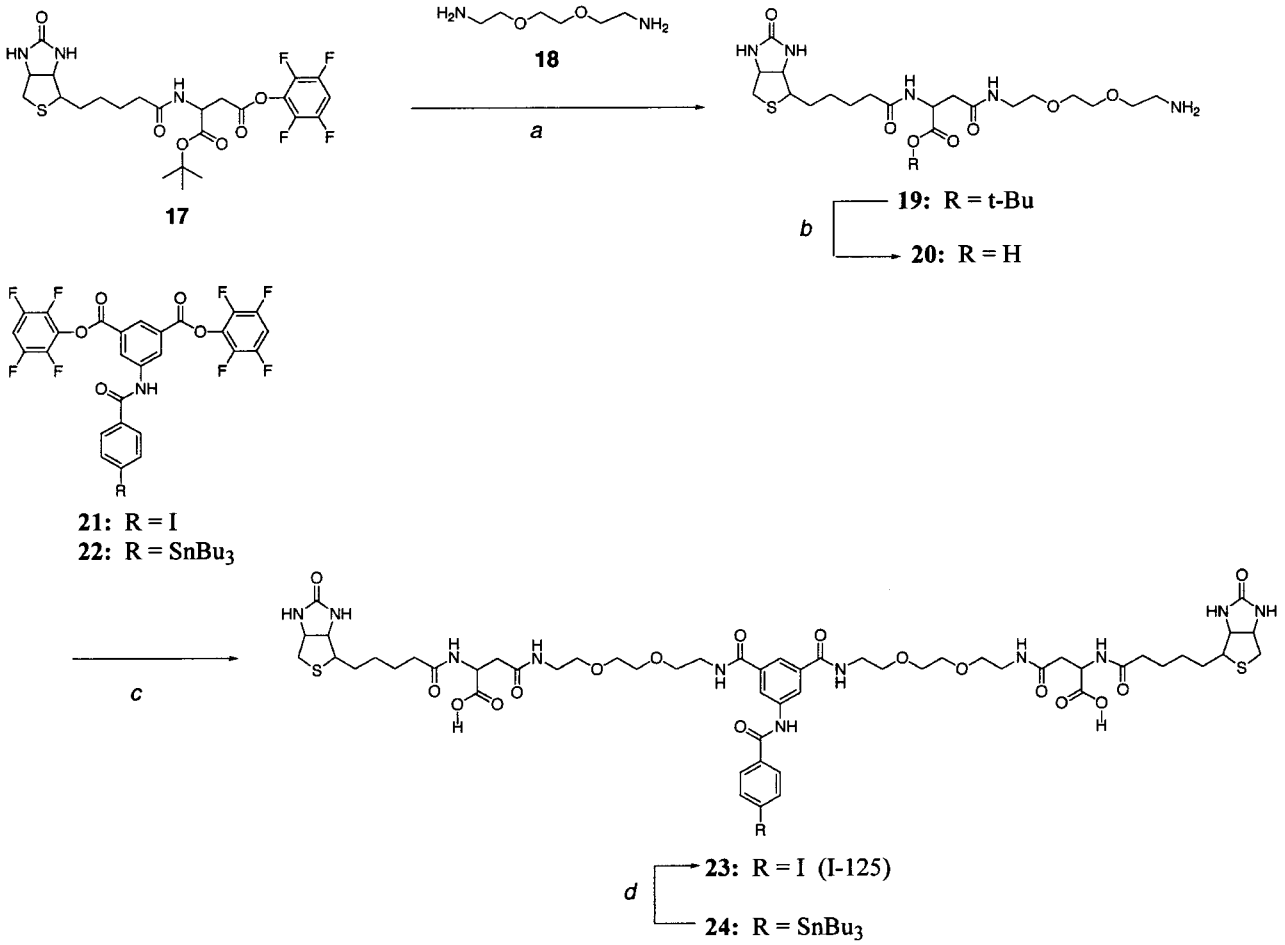
removed and filtered through the concentrator. A 30 μL volume of the flow-through was removed and the radioactivity measured.



Data Analysis. Linear regression to determine off-rates were performed using GraphPad Prism version 3.02 for Windows, GraphPad Software, San Diego, CA, www.graphpad.com.

RESULTS

Biotin Dimer Synthesis. The structures of the biotin dimers, **1**, **15**, and **23**, prepared for these studies are shown in Figure 1. The first biotin dimer used in the studies, **1**, was prepared by reaction of 2 equiv of 3-(biotinamide)butyrate tetrafluorophenyl ester with 4,7,10-trioxa-1,13-tridecanediamine in DMF as previously described (*23*). The second biotin dimer used in the studies, **15**, was prepared as depicted in Scheme 1. Reaction of the trifunctional cross-linking reagent, *N*-Boc-5-aminoisophthalate bis-TFP ester, **3**, with the dioxaoctanediamine adduct of biotin, **4**, and triethylamine in DMF provided the *t*-Boc protected biotin dimer **5** in 79% purified yield. Deprotection of the *t*-Boc group with trifluoroacetic acid (TFA) was nearly quantitative, and the anilino product was pure enough to be used directly for the preparation of the isothiocyanate, **7**. The aryl isothiocyanate containing biotin dimer, **7**, was prepared by reaction of **6** with thiocarbonyldiimidazole in DMF at room temperature. Biotin dimer **7** was converted to the thiourea adduct **9** in 31% purified yield by reaction with mono-*t*-Boc-protected trioxatridecanediamine **8**. The *t*-Boc group was removed from **9** in nearly quantitative yield in neat TFA to yield **10**, and that material was reacted with the benzoate TFP esters **11** and **12** to prepare the desired biotin dimers, **15** (90%) and **16** (77%), respectively. The third biotin dimer used in the studies, **23**, was prepared as depicted in Scheme 2. In that synthesis, the TPF ester of the α-amino adduct of biotin and aspartic acid β-*tert*-butyl ester, **17**, was first prepared as previously described (*29*). Reaction of **17** with the dioxaoctanediamine **18** provided the adduct **19** in 76% purified yield. Due to a concern that the tri-*n*-butylstannyl group would not be stable to TFA, the deprotection step was carried out on **19**. The deprotection provided **20** in nearly quantitative yield. Reaction of **20** with the iodobenzoyl- and stannylbenzoylaminoisophthalate bis-TFP esters, **21** and **22**, provided the targeted iodobenzoyl-biotin dimer **23** and the stannylbenzoylbiotin dimer **24** in 68% and 32% isolated yields.



Preparation of Radioiodinated Biotin Dimers, [^{125}I]15 and [^{125}I]23. Arylstannane intermediates have been shown to efficiently introduce radioiodine into a variety of molecules (*32*, *33*). Therefore, we chose to prepare biotin dimers **16** and **24** to use as intermediates for the preparation of [^{125}I]**15** and [^{125}I]**23**. The corresponding iodobenzoyl-biotin dimers **15** and **23** were prepared for binding studies with ^{3}H-biotin and as HPLC reference standards for the radioiodinated compounds. In initial radioiodination studies, the arylstannane **16** was reacted with *N*-chlorosuccinimide (NCS) in a mixture of methanol and acetic acid. Although radioiodination of arylstannanes are generally very facile under those conditions, very low radiolabeling yields were obtained with **16**. We are uncertain of the reason for this, but believe that the thiourea functionality in **16** may interfere with the radioiodination. We have obtained similar results with other compounds that contain thiourea functionalities (*34*). After several radioiodination attempts with **16**, we decided to prepare [^{125}I]**15** via an alternative route. In the alternative route, the aminobiotin dimer **10** was reacted with *p*-[^{125}I]iodobenzoate *N*-hydroxysuccinimide (NHS) ester, **13**, which was prepared from *p*-tri-*n*-butylstannylbenzoate NHS ester, **14**, as previously described (*28*). This provided the desired

Scheme 1. Synthetic Route for Preparation of Biotin Dimer 15 and Radioiodination Methods To Produce [^{125}I]15[a]

[a] (a) Et_3N, DMF, 1 h, rt, 79%; (b) TFA, 10 min, rt, 94%; (c) TCDI, DMF, 30 min; (d) **8**, DMF, 30 min, rt, 31%; (e) TFA, 10 min, rt, 93%; (f) **11** or **12**, DMF, Et_3N, 1 h, rt, 90% or 77%; (g) [^{125}I]**13**, Et_3N, DMF, 30 min, rt, 75%.

Scheme 2. Synthetic Route for Preparation Biotin Dimer 23 and Radioiodination To Form [^{125}I]23[a]

[a] (a) **18**, DMF, 1 h, rt, 76%; (b) TFA, 10 min, rt, 95%; (c) **21** or **22**, DMF, Et_3N, 30 min, rt, 68% or 32%; (d) Na[^{125}I], NCS, MeOH, HOAc, 5 min, 75%.

[^{125}I]**15** in good yield (75%). Contrary to the thiourea containing **16**, direct radioiodination of stannylbenzoyl-biotin dimer **24** with NCS in a methanol/acetic acid solution provided high yields of the desired [^{125}I]**23**.

Stoichiometry of Bis-Biotin Ligand Binding. The binding stoichiometry of the bivalent bis-biotin ligands was determined with a HABA displacement assay (*31*). Biotin and the bivalent biotin ligands were titrated into a solution containing HABA-saturated SAv-Y43A, which permits the determination of the quantity of HABA displaced per quantity of ligand added. The HABA displacement assays are plotted as the percent change in HABA occupied biotin binding sites versus the ratio of biotin moiety added to the biotin binding-site concentration (Figure 2). As expected, a ratio of one biotin moiety per one streptavidin binding site was obtained for biotin, i.e., 4 equiv of biotin was needed to displace 4 equiv of HABA per SAv-Y43A tetramer. The HABA assay revealed that one of the bivalent biotins did not bind to SAv in a true bivalent fashion. Biotin dimer **1** bound the streptavidin tetramer at an average of three bis-biotin molecules per streptavidin tetramer at saturation (i.e., one bis-biotin ligand bound bivalently and two bis-biotin ligands bound through one biotin moiety), compared to the expected ratio of two molecules per streptavidin tetramer observed with biotin dimer **15** and biotin dimer **23**. This finding emphasizes that the distance between biotin groups and the steric properties of the spacer arms play an important role in determining the binding properties of the bis-biotin ligands.

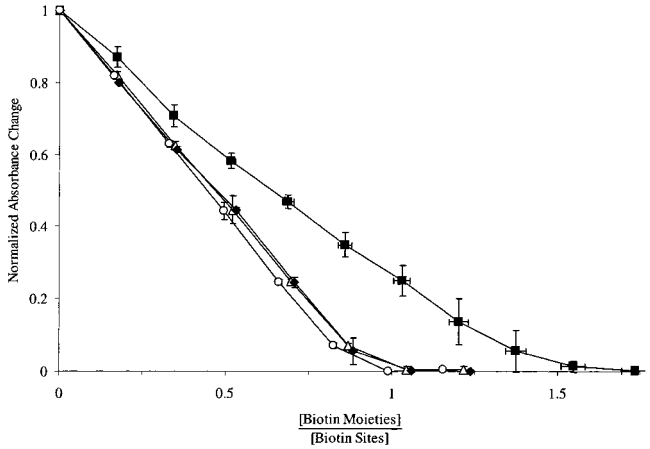


Figure 2. Bis-biotin binding stoichiometry determination. SAv-Y43A was mixed with HABA and the OD_{500} measured. Competitor was added in fixed aliquots and the OD_{500} measured. The percent change in the OD_{500} is plotted versus the ratio of the competitor biotin moiety concentration to the concentration of biotin binding sites. The competitors are biotin (diamonds), biotin dimer **1** (filled squares), biotin dimer **15** (filled triangles), and biotin dimer **23** (circles).

Exchange of Bound Biotin Ligands with Bis-Biotin Ligands. Previous thermodynamic and kinetic characterization of site-directed SAv mutants (*19*−*22*) led to the selection of the SAv-Y43A mutant as one that would allow exchange of bound endogenous biotin at 37 °C, while retaining sufficiently high affinity to efficiently

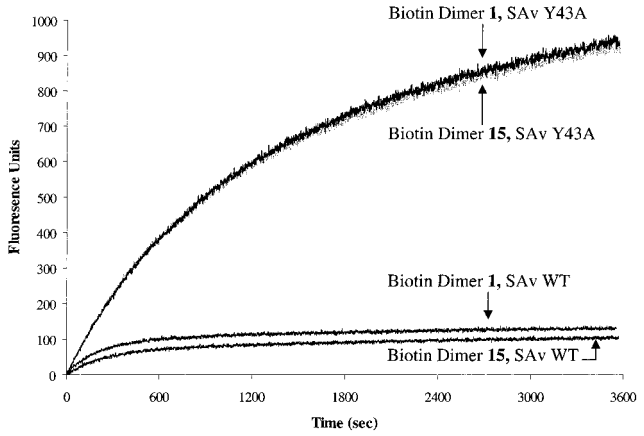

Figure 3. Bis-biotin exchange properties. SAv-Y43A and SAv-WT were incubated with an equimolar amount of biotin-4-fluorescein. A 5-fold molar excess of competitors was added and the fluoresence measured for 1 h. For each protein two competitors are shown (biotin dimer **1** and biotin dimer **15**). The biotin dimer **15**/SAv-Y43A experiment is shown in gray due to its close proximity to biotin dimer **1**/SAv-Y43A.

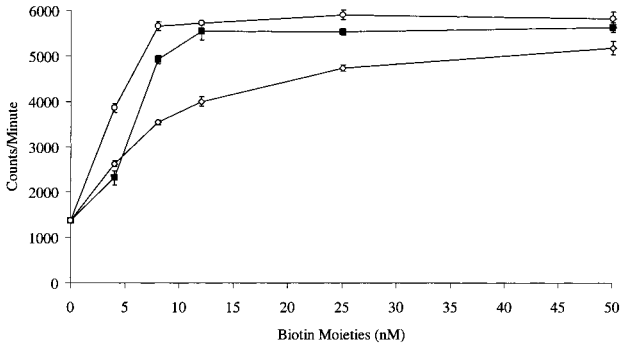

Figure 4. Ligand competition assay. SAv-Y43A was incubated with an equimolar concentration of ^{3}H-biotin and various concentrations of competitor. The free ^{3}H-biotin was separated from protein and bound ligand and the radioactivity measured. Free ^{3}H-biotin is plotted versus the competitor biotin moiety concentration. The competitors are biotin (diamonds—bottom line), biotin dimer **1** (filled squares—middle line), and biotin dimer **23** (circles—top line).

capture bis-biotin ligands. The biotin off-rate from SAv-Y43A is $28 \times 10^{-4} s^{-1}$ at 37 °C and the K_a is reduced by 67-fold from SAv-WT (*22*). The impact of this faster off-rate on ligand exchange can be observed by comparing the exchange of prebound biotin-4-fluorescein from SAv-WT versus SAv-Y43A by the bis-biotin ligands. This kinetic exchange was followed by the appearance of biotin-4-fluorescein fluorescence in the unbound state. Representative curves for the exchange with biotin dimers **1** and **15** are shown in Figure 3. Over the time period of 1 h, corresponding to four half-lives, there is no significant exchange of the bound biotin-4-fluorescein for SAv-WT, while nearly 100% of expected ligand exchange is observed with SAv-Y43A, based on the stoichiometry of biotin-4-fluorescein to added free biotin. The kinetic approach to equilibrium with the SAv-Y43A mutant proceeds with the expected off-rate of 7.7×10^{-4} s^{-1} for biotin-4-fluorescein at 37 °C. A direct comparison of the biotin derivatives to biotin was performed with ^{3}H-biotin ligand competition experiments. At equivalent competitor concentrations (in biotin moieties), biotin dimers **1**, **15**, and **23** (data not shown) displace more ^{3}H-biotin than biotin does, indicating that they all have a significantly higher affinity for SAv-Y43A than biotin (Figure 4).

Retention Properties of Bis-Biotin Ligands. While the kinetic exchange properties of bound biotin are a direct function of its off-rate, the retention properties of the bis-biotin ligand are dependent on its affinity and kinetic parameters. The retention of the biotin dimers **1** and **15** was directly tested by pre-binding them to SAv-Y43A and then adding a 1-fold equivalent of biotin-4-fluorescein. When biotin was pre-bound to SAv-Y43A, the fluorescence of added biotin-4-fluorescein was quenched by 73% at this 1:1 stoichiometry due to the exchange with biotin and binding of this modified ligand to SAv-Y43A (Figure 5). However, there was only 8% quenching of fluorescence upon addition of biotin-4-fluorescein after 1 h when biotin dimer **1** or **15** is prebound to SAv-Y43A, within experimental error of zero exchange. To directly quantitate the off-rate properties of the bis-biotin ligands, the biotin dimer [^{125}I]**23** was prebound with SAv-Y43A at 37 °C and the unbound fraction monitored as a function of time after addition of excess biotin (Figure 6). The off-rate was determined to be 4.36×10^{-6} s^{-1} which is approximately 640-fold slower than biotin from SAv-Y43A. This places the likely K_a for the biotin dimer **23** as higher than biotin for SAv-WT, and thus a very high affinity protein—ligand couple.

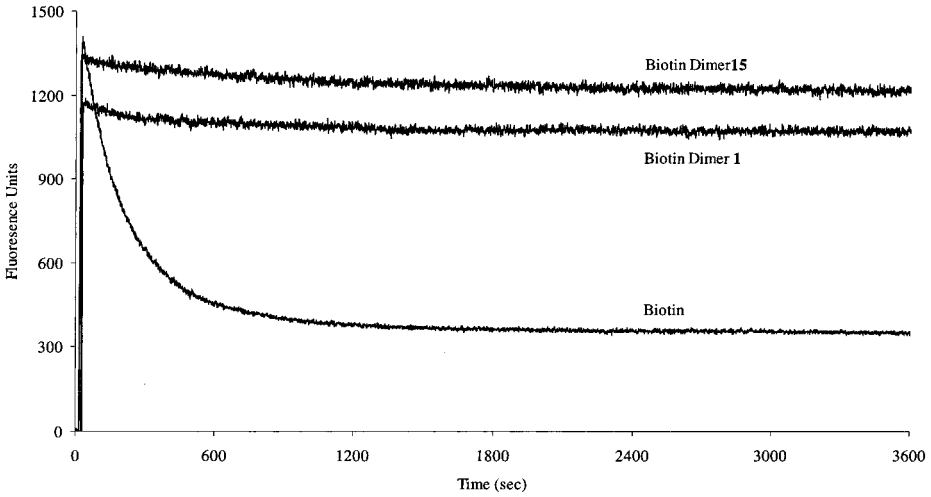

Figure 5. Bis-biotin retention properties. The biotin dimers **1** and **15** and biotin were prebound to SAv-Y43A, followed by the injection of 1 equiv of biotin-4-fluorescein. Fluorescence was measured continuously for roughly 1 h.

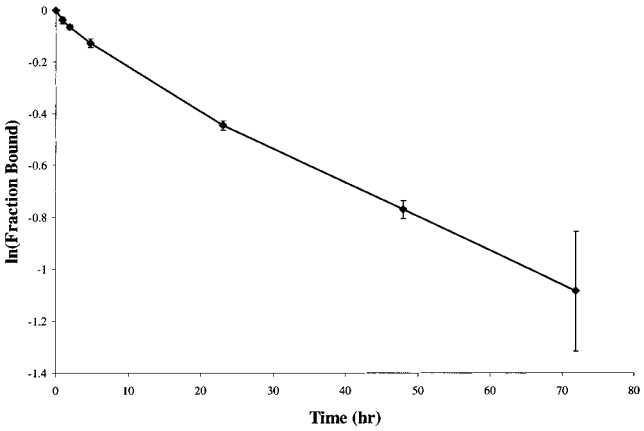

Figure 6. Determination of bis-biotin ligand off-rate. SAv-Y43A was incubated with [^{125}I]biotin dimer **23**, and at time = 0 a 2800-fold molar excess of nonradioactive biotin dimer was added. Radioactivity of the unbound [^{125}I]biotin dimer **23** was measured at various time points and the natural log of the fraction bound [^{125}I]biotin dimer **23** plotted against time. Data points are connected by lines.

DISCUSSION

The very high binding affinity of biotin with avidin (Av) and streptavidin (SAv) has led to the use of these binding pairs in a wide variety of in vitro and in vivo applications. A potential limitation of this system in clinical diagnostic and therapeutic applications is the significant level of endogenous biotin present in serum and tissues (*14*). In cancer therapeutics, the endogenous biotin can bind with SAv prior to injection of the radiolabeled biotin and effectively block its binding due to the slow dissociation rate (*35*). To circumvent this problem in animal studies, mice are placed on avidin-supplemented diet for two weeks (*36*) or biotin deficient diets for 5−7 days (*10*). However, this does not completely remove endogenous biotin, as it can be released from storage in the liver (*37*). Therefore, a large quantity of mAb−SAv is injected (300−400 μg/mouse) such that endogenous biotin does not block a significant amount of the radiolabeled biotin at the tumor. Although the concentration of biotin present in serum and tissue in humans is lower than found in mice (*35*, *38*), large amounts of mAb−SAv conjugate have also been used in clinical studies (i.e., 125 μg conjugate/mL plasma volume, or approximately 400 mg/average size patient) (*39*). In addition to decreasing the amount of radioactivity delivered to the cancer cells, the large quantities of injected mAb−SAv are likely to increase the immunogenicity of that reagent and increase the cost of the materials significantly.

We have thus investigated the dual use of a site-directed streptavidin mutant with a modified biotin ligand to circumvent the limitation of endogenous biotin in clinical diagnostics and therapeutics. The general design criteria for a streptavidin/bis-biotin ligand-binding system requires that endogenous biotin be exchangeable, while the modified biotin ligand remains strongly bound and retained to SAv. These criteria were met with the SAv-Y43A mutant that displayed an accelerated biotin off-rate, and the bis-biotin ligands that displayed high affinity for the mutant due to the ligand bivalency and concomitant avidity effect. Previous work in the Wilbur group on the structural design of biotin derivatives has shown that they should (1) have linkers which provide adequate space between the biotin and the attached moiety to retain the high affinity binding, (2) have good water solubility, and (3) have structural features which result in blockage of the enzyme biotinidase without decreasing the binding affinity (*24*, *29*, *40*). For cancer therapeutics, the radionuclide carrying moiety was designed such that the length did not become too long (i.e. >50 Å).

A great advantage of a repertoire of modified biotins and affinity mutants is the ability to engineer the system for a specific application. Bivalent biotin can be designed for specific applications, where for example, a biotinidase-resistant bis-biotin ligand (e.g., biotin dimer **23**) is needed for therapeutic or clinical applications. For other in vitro applications, other biotin dimers might suffice. A SAv affinity mutant can be selected to obtain a specific exchange rate of endogenous biotin. The intrinsic challenge is to engineer a decrease in streptavidin affinity for endogenous biotin to the proper range for a specific application, given the situational conditions of protein/ligand concentrations and potentially of flow kinetics, while preserving high affinity for the bis-biotin ligands. In therapeutic applications, over 95% of ^{90}Y-DOTA−biotin is cleared from the blood within 2 h (*41*). At 37 °C the half-life of biotin binding to SAv is 6.5 h. Any endogenous biotin bound to mAb−SAv is unlikely to be exchanged with the ^{90}Y-DOTA−biotin given the quick pharmacokinetics of the therapeutic and the slow dissociation of any endogenous biotin. Improving the exchange rate of biotin can be achieved using a SAv affinity mutant such as SAv-Y43A in lieu of SAv-WT. However, in many applications this would not prove useful without increasing the retention of a therapeutic molecule compared to endogenous biotin. In these studies, bivalent biotins were shown to bind to SAv-Y43A more tightly than biotin to SAv-WT, and this general approach should be applicable to either therapeutic or diagnostic systems where endogenous biotin acts as an interference.

A ^{99m}Tc(I)-Postlabeled High Affinity Bombesin Analogue as a Potential Tumor Imaging Agent

R. La Bella,[†,‡] E. Garcia-Garayoa,*[,†] M. Bähler,[‡] P. Bläuenstein,[†] R. Schibli,[†] P. Conrath,[§] D. Tourwé,[§] and P. A. Schubiger[†,‡]

Center for Radiopharmaceutical Science, Paul Scherrer Institute, CH-5232 Villigen, Switzerland, Department of Applied Biosciences, Swiss Federal Institute of Technology, CH-8057 Zurich, Switzerland, and Department of Organic Chemistry, Vrije Universiteit Brussels, B-1050 Brussels, Belgium. Received October 26, 2001; Revised Manuscript Received March 22, 2002

The overexpression of neuropeptide receptors observed in many cancers provides an attractive target for tumor imaging and therapy. Bombesin is a peptide exhibiting a high affinity for the gastrin releasing peptide (GRP) receptor, which is overexpressed by a variety of tumors such as breast or prostate cancer. In the present study, we have evaluated if the bombesin analogue [N_α-histidinyl acetate]-bombesin(7−14), radiolabeled with the novel $[^{99m}Tc(OH_2)_3(CO)_3]^+$, has the potential to be used as a diagnostic radiopharmaceutical. Receptor saturation studies, carried out on the GRP receptor-expressing PC-3 human prostate cancer cell line, revealed for [^{99m}Tc(CO)$_3$−N_α-histidinyl acetate]-bombesin(7−14) K_d values in the subnanomolar range. Competitive binding assays, using the cold rhenium(I)-labeled analogue as a surrogate for the ^{99m}Tc-conjugate, also showed high affinity binding. Incubation of the radioconjugate with PC-3 cells resulted in a rapid temperature- and time-dependent specific internalization. At 37 °C more than 70% was internalized within the first 15 min and remained constant up to 2 h. Despite the weak proteolytic stability of [^{99m}Tc(CO)$_3$−N_α-histidinyl acetate]bombesin-(7−14) in vitro, biodistribution studies, performed in PC-3 tumor-bearing mice, showed low uptake in the tumor (0.89 ± 0.27% ID/g 30 min pi) but high uptake into the pancreas (7.11 ± 3.93% ID/g 30 min pi), a GRP receptor-positive organ. Blockade experiment (coinjection of 300 μg bombesin/mouse with the radioligand) showed specificity of the uptake. Despite the low tumor uptake, tumor-to-blood ratios of 2.0 and 2.7 and tumor-to-muscle ratios of 8.9 and 8.0 were obtained at 30 min and 1.5 h postinjection, respectively. The promising results merit the future in vivo investigation of ^{99m}Tc/^{188}Re-tricarbonyl-labeled bombesin analogues.

INTRODUCTION

The discovery that certain tumor types overexpress receptors for neuropeptides dates back to the mid 1980s (*1*). To date, radiolabeled receptor binding peptides emerged as a new class of radiopharmaceuticals (*2*). Peptides show some favorable characteristics: they are readily synthesized, inexpensive, and can withstand harsh chemical conditions for modifications and radiolabeling. Furthermore, they offer several advantages over antibodies: they are less likely to induce immunogenic responses and they are expected to have a better pharmacokinetic profile inherent in a faster blood clearance, a better tissue penetration, a higher tumor uptake and therefore more favorable tumor-to-background ratios. The amphibian 14-amino acid peptide bombesin (BB) is part of the superfamily of bombesin-like peptides that also includes the mammalian homologue gastrin releasing peptide (GRP) and the related neuromedin B (NMB). These neuropeptides effect a broad range of physiological responses through G protein-coupled receptors with seven transmembrane domains. Besides being naturally localized in the central nervous system and in peripheral tissue (*3*, *4*), the GRP receptor is also expressed in a number of neuroendocrine tumors. Prostate and breast cancer might be of clinical significance as recent findings indicated a massive receptor overexpression in neoplastic transformed prostate and breast tissue (*5*, *6*). Bombesin has been shown to cause through the GRP receptor a tumor growth effect in cancer cell lines in culture or as xenografts in nude mice (*7*−*9*). The mechanism by which tumor growth stimulation occurs does not appear to be constant but in general seems to involve transactivation and up-regulation of epidermal growth factor receptors (*10*, *11*). Importantly, the tumor growth-stimulating effect of bombesin can be blocked by GRP receptor antagonists (*9*, *12*, *13*). Therefore, the use of GRP receptor antagonists and/or GRP receptor-targeting cytotoxic peptide conjugates could be an efficient chemotherapeutic approach. In nuclear medicine, ^{99m}Tc-labeled bombesin analogues could probably allow early noninvasive diagnosis of GRP receptor-positive tumors by γ-scintigraphy. Application of therapeutic radionuclides likes the β^--emitting rhenium-186 and rhenium-188 might even allow radiotherapy of these types of tumors.

The aim of the present work was the in vitro and in vivo characterization of a new bombesin analogue functionalized with a N_α-histidinyl acetate bifunctional chelator (BFC) and radiolabeled with the organometallic precursor $[^{99m}Tc(OH_2)_3(CO)_3]^+$. The study involved the synthesis of [^{99m}Tc(CO)$_3$−N_α-histidinyl acetate]bombesin-(7−14), **1**, as well as the pharmacological evaluation in

vitro and in vivo including binding properties, internalization, chemical stability, metabolic stability, and biodistribution of the radioconjugate in nude mice bearing PC-3 prostate adenocarcinoma xenografts.

MATERIAL AND METHODS

Reagents and materials were obtained from following sources: Fmoc-protected amino acids and 4-(2′,4′-dimethoxyphenyl-Fmoc-aminoethyl)-phenoxy resin were purchased from NovaBiochem (Läufelingen, Switzerland). Bombesin and Neuromedin B were obtained from Bachem (Bubendorf, Switzerland). [^{125}I-Tyr^4]bombesin was purchased from NEN Life Science Products (Zaventem, Belgium). The ^{99}Mo/^{99m}Tc generator was obtained from Mallinckrodt (Petten, The Netherlands). Culture medium Dulbeccos's MEM with GLUTAMAX I, fetal bovine serum, antibiotic/antimycotic solution, trypsin/EDTA, bovine serum albumin and soybean trypsin inhibitor were obtained from GIBCO BRL Life Technologies AG (Basel, Switzerland). HEPES, chymostatin, and bacitracin were from Sigma (Buchs, Switzerland). The cold binding buffer contained 50 mM Hepes, 125 mM NaCl, 7.5 mM KCl, 5.5 mM $MgCl_2$, 1 mM EGTA, 5 g/l BSA, 2 mg/L chymostatin, 100 mg/L soybean trypsin inhibitor, 50 mg/L bacitracin, pH 7.4. Further chemicals were obtained from Fluka (Buchs, Switzerland). The peptides were synthesized on a semiautomated Labortec peptide synthesizer SP640B. Correct mass was identified by electron spray-mass spectrometry (Micromass VG Trio 2000, Manchester, England). RP-HPLC analyses were performed on a Merck-Hitachi L-7000-system equipped with an L-7400 tunable absorption detector and a Berthold LB 506 B radiometric detector. For analyses and purification a Macherey-Nagel CC Nucleosil 100−5 C18 reverse phase column (10 μm, 250 × 4.6 mm) was used. HPLC solvents consisted of (A) water with 0.1% trifluoroacetic acid and (B) acetonitrile with 0.1% trifluoroacetic acid. The HPLC system started with a linear gradient 95% A/5% B to 40% A/60% B from 0 to 30 min. The gradient remained at 40% A/60% B for 5 min before switching back to 95% A/5% B for another 5 min. The flow rate was 1.5 mL/min. Radioactive samples from in vitro and in vivo experiments were measured with a NaI-γ-counter (Packard Canberra Cobra II).

Cell Culture. The human PC-3 adenocarcinoma cell line was obtained from European Collection of Cell Cultures (Salisbury, United Kingdom). Cells were maintained in Dulbecco's MEM with GLUTAMAX I supplemented with 1% fetal bovine serum, 100 units/mL penicilline G sodium, 100 μg/mL streptomycin sulfate and 0.25 μg/mL amphotericin B. Cells were cultured at 37 °C in a humidified incubator under an atmosphere containing 7.5% CO_2 and passaged weekly.

Peptide Synthesis. Solid-phase synthesis of [N_α-histidinyl acetate]bombesin(7−14) was carried out using Fmoc-strategy. The cold rhenium(I)-labeled conjugate was obtained by mixing 100 μL of 1 mM [N_α-histidinyl acetate]bombesin(7−14), 20 μL of 5.5 mM $(TEA)_2Re(CO)_3Br_3$, 20 μL of 15 mM NaOH, and adding up to 200 μL with water. The mixture was heated for 6 h at 75 °C. The peptides were analyzed by ES-MS and RP-HPLC.

Radiolabeling. $[^{99m}Tc(OH_2)_3(CO)_3]^+$ was prepared according to earlier descriptions (*14*). Depending on the needs, 0.1 to 0.3 mL of the neutralized technetium-99m tricarbonyl solution were mixed with 10−30 μL of 1 mM [N_α-histidinyl acetate]bombesin(7−14) and again heated to about 75 °C for 1 h. The product was analyzed and purified (for determination of K_d) by RP-HPLC.

Receptor Binding Studies. Inhibition assays with PC-3 cells were performed as previously described (*15*). In brief, cells were placed at confluence in 48-well plates with 25000 cpm of [^{125}I-Tyr^4]bombesin in the presence of increasing concentrations of the different bombesin analogues (0−3000 nM). After 1 h at 37 °C, cells were washed twice with cold binding buffer and then solubilized with 1 N NaOH. Radioactivity was determined using a NaI-γ-counter. For saturation studies, cells were incubated in triplicate with increasing concentrations (1 to 500 pM, equivalent to 2 to 1000 kBq of ^{99m}Tc activity) of the ^{99m}Tc(I)-labeled bombesin analogue for 1 h at 37 °C. The concentrations of active ^{99m}Tc were calculated as described by Bauer and Pabst (*16*) and Hill et al. (*17*). After two washing steps with binding buffer, cells were solubilized with 1 N NaOH at 37 °C. Nonspecific binding was determined with 1 μM bombesin.

Internalization Studies. Internalization of the ^{99m}Tc(I)-labeled bombesin analogue was performed as previously described (*18*, *19*). Briefly, PC-3 cells were incubated in six-well plates in triplicate with about 200000 cpm of compound **1** with or without excess of 1 μM cold bombesin for 2 h at 4 °C. Then they were washed three times with ice-cold culture medium to discard free peptide and incubated with previously warmed culture medium for 0, 5, 15, 30, and 120 min at 37 °C for internalization. After these times, cell-surface bound radioligand was removed by two steps of acid wash (50 mM glycine-HCl/100 mM NaCl, pH 2.8) at room temperature for 5 min. Subsequently, the cells were solubilized by incubation with 1 N NaOH at 37 °C to determine internalized radioligand. Release of internalized radioconjugated peptide was determined by incubating PC-3 cells at confluence in tissue culture dishes (60 × 15 mm) with about 2 × 10^5 cpm of **1** for 1 h at 37 °C. The cells were then washed three times with ice-cold culture medium and cell-surface bound radioligand was removed by two steps of acid wash. After having washed twice with culture medium, the cells were incubated for different time periods at 37 °C. At each time point (30 min, 1, 2.5, 5, and 24 h) the radioactivity present in the medium (released) as well as the acid wash (cell-surface bound) and the acid wash resistant (internalized) were determined with a NaI-γ-counter. Results were expressed as percentage of total activity in the wells (released + cell-surface bound + internalized).

Histidine and Cysteine Challenge. Challenging assays were done according to the method of Stalteri et al. (*20*) with some modifications. A 10 μL amount of the ^{99m}Tc(I)-labeled peptide were added to 90 μL of 0.01 M histidine or cysteine (1000-fold molar excess of challenging agents). The resulted solutions were incubated at 37 °C, and progress of the reaction was followed by RP-HPLC with radiometric detection.

In Vitro Stability. Studies of metabolic stability were performed with compound **1** in human plasma and whole blood. Plasma and blood from healthy donors were incubated at 37 °C with the ^{99m}Tc(I)-labeled peptide at a concentration of 0.2 pmol peptide/mL for different time periods. After incubation, plasma samples were precipitated with acetonitrile/ethanol and then centrifuged (4 °C, 2 × 10^4 g), whereas the blood samples were centrifuged previously to the precipitation to remove first blood cells. After repeated precipitation and centrifugation, the supernatants were then analyzed by RP-HPLC.

In Vivo Stability. To evaluate the in vivo degradation of the conjugate, blood of sacrificed PC-3 xenografted CD-1 nu/nu mice (1.5 h pi) was collected. The samples were centrifuged, and the supernatant was precipitated

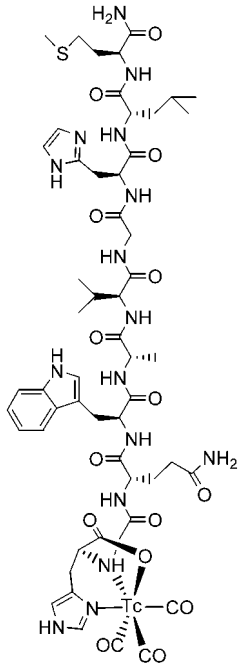

Figure 1. Proposed structure of [^{99m}Tc(CO)$_3$−N_α-histidinyl acetate]bombesin(7−14).

with acetonitrile/ethanol (1:1) and centrifuged again at 4 °C. The final supernatants were analyzed by RP-HPLC.

Animal Studies. Biodistribution of the radioconjugate was estimated in female CD-1 nu/nu mice (6- to 8-weeks old). Human PC-3 prostate adenocarcinoma xenografts were induced by subcutaneous injection of 8×10^6 cells/mouse. Ten days after the tumor induction the mice received the ^{99m}Tc(I)-labeled bombesin analogue (3.5−4 MBq/mouse) intravenously into the tail vein. Organs and tissue (blood, heart, lung, spleen, kidneys, stomach, pancreas, ileum, colon, liver, muscle, bone, brain, and tumor) were excised from the sacrificed animals at 30 min, 1.5, and 24 h postinjection. All tissues were weighed, and the radioactivity was determined by γ-counting. Results were expressed as percentage of injected dose per gram (% ID/g) of tissue. An in vivo receptor blocking study was also carried out. In this study, each animal received 300 μg of cold bombesin by coinjection with the radiolabeled bombesin analogue (in 95% saline/5% ethanol). The animals were sacrificed at 30 min postinjection, all tissues were removed, weighed, and γ-counted, and the % ID/g tissue was calculated.

RESULTS

Radiolabeling. HPLC analyses revealed a single main peak (>95% of total activity) after the labeling, which corresponded to the ^{99m}Tc−peptide conjugate (Figure 1). Generally, pertechnetate and free ^{99m}Tc(I)-tricarbonyl represented only 0−5% and 0−1%, respectively, of the total radioactivity after 1 h of labeling.

Receptor Binding Studies. All bombesin analogues tested showed the typical sigmoid curves in the displacement assays (Figure 2). The synthesized conjugates inhibited the binding of [^{125}I-Tyr^4]bombesin in the same concentration range as the natural peptide itself (Table 1).

In saturation studies, receptor binding of [^{99m}Tc−N_α-histidinyl acetate]bombesin(7−14) to intact PC-3 cells was found to be saturable (Figure 3, A). Specific binding rapidly increased in the concentration range of 1 to 100 pM radioconjugate and reached a plateau at 250 pM.

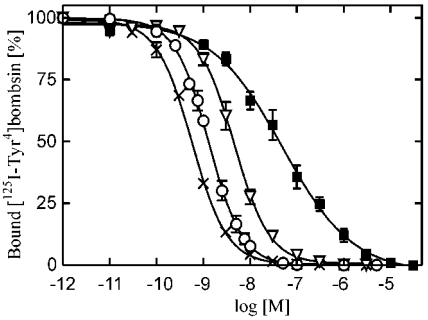

Figure 2. Displacement curves of [^{125}I-Tyr^4]bombesin binding to GRP receptors on the human prostate cancer cell line PC-3 by bombesin (○), [N_α-histidinyl acetate]bombesin(7−14) (▽), [Re(I)-N_α-histidinyl acetate]bombesin(7−14) (×), and neuromedin B (■).

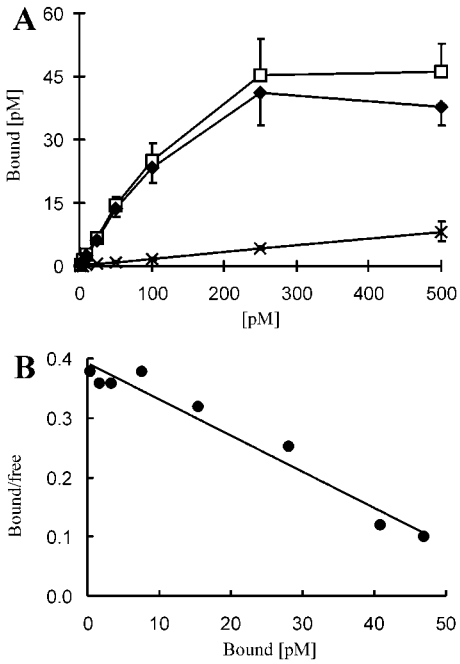

Figure 3. A: Binding of [^{99m}Tc(CO)$_3$−N_α-histidinyl acetate]-bombesin(7−14) to PC-3 cells as a function of ligand concentration. The cells were incubated with 1 to 500 pM [^{99m}Tc(CO)$_3$−N_α-histidinyl acetate]bombesin(7−14) in the absence (□, total binding) or presence (×, nonspecific binding) of 1 μM bombesin for 1 h at 37 °C. Specific binding (◆) was calculated as the difference between total and nonspecific binding. B: Scatchard analysis of these data. Each point means the value of triplicate determinations.

Table 1. Inhibition of [^{125}I-Tyr^4]Bombesin Binding to PC-3 Cells by Different Bombesin Analogues

compound	IC_{50} [nM]
bombesin	1.5
[N_α-histidinyl acetate]bombesin(7−14)	4.3
[Re(I)-N_α-histidinyl acetate]bombesin(7−14)	0.6
neuromedin B	73.9

Scatchard analysis of the binding data indicated the presence of a homogeneous population of binding sites with high affinity for the used cell line (Figure 3, B). At 37 °C, the calculated dissociation constant (K_d) was 2.1×10^{-10} M.

Internalization Studies. The rate of internalization of [^{99m}Tc(CO)$_3$−N_α-histidinyl acetate]bombesin(7−14) was time and temperature dependent (Figure 4). At 4 °C, cell-surface binding toward GRP receptors occurred but no internalization (<1%).

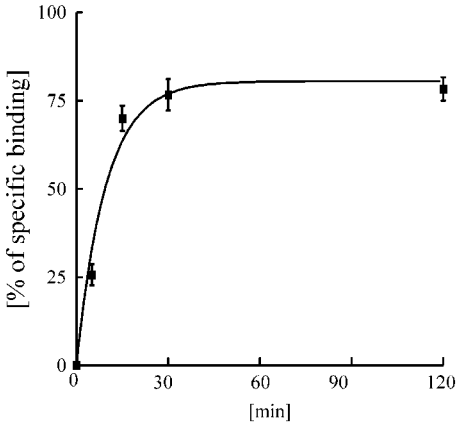

Figure 4. Time course internalization of [^{99m}Tc(CO)$_3$−N_α-histidinyl acetate]bombesin(7−14) in PC-3 cells at 37 °C. Data are percentage of acid-resistant (internalized) radioactivity in the cells.

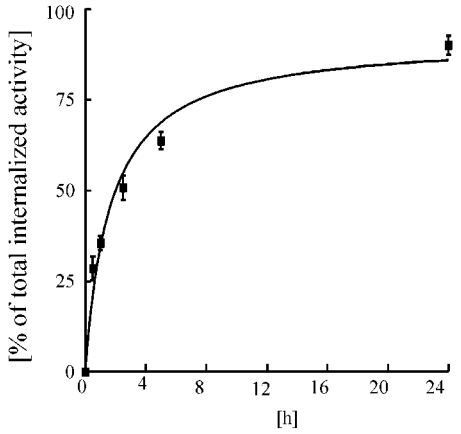

Figure 5. Time-dependent release of internalized radioactivity from PC-3 cells at 37 °C, after incubation with [^{99m}Tc(CO)$_3$−N_α-histidinyl acetate]bombesin(7−14) for 1 h at 37 °C.

Table 2. Percentage of ^{99m}Tc(I)-tricarbonyl Remaining Bound to the Bombesin Analogue after Incubation with 1000× Molar Excess of Histidine and Cysteine at 37 °C

	intact conjugate [%] after		
reagent	1 h	4 h	24 h
histidine	97 ± 3	94 ± 5	90 ± 3
cysteine	99 ± 2	97 ± 4	95 ± 4

After incubation at 37 °C bound radioligand was rapidly transformed from an acid-strippable (cell-surface bound) to an acid-resistant form (internalized). Specifically, after 5 min at 37 °C, 25 ± 3% of cell-associated radioactivity was internalized, and the maximum was reached at 30 min with 70 ± 4% internalized radioactivity. Despite this high internalization rate, there was no long-term retention of radioactivity in the cells (Figure 5).

The internalized radioactivity was quickly released. After 30 min at 37 °C, 27 ± 3% of internalized radioconjugate was already released. More than 50 ± 2% was released after 2.5 h and about 90 ± 4% after 24 h.

Histidine and Cysteine Challenge. Stability of the labeled peptide at pH 7 and 37 °C to a challenge with histidine and cysteine at a molar ratio of 1/1000 was analyzed by RP-HPLC (Table 2).

There was only insignificant reoxidation of the radioconjugate to [^{99m}TcO$_4$]$^-$ after 24 h at 37 °C (<1%). In general, only little ligand exchange occurred, whereby with an excess of histidine, the ligand was slightly more displaced than in the presence of excess cysteine.

[a] Data are percentage of injected dose per gram (% ID/g) of tissue ± SD by reference of total injected dose (n = 3).

In Vitro Stability. The stability of the radioconjugate was tested both in human plasma and whole blood. The results are summarized in Table 3.

The peptide was rapidly metabolized when incubated in human plasma. After 5 min, about 80% remained intact and only 20% were intact after 1 h. Using whole blood, the enzymatic degradation was even quicker. Only 70% of the radioconjugate was intact after 5 min of incubation. After 60 min, less than 10% remained intact, and after 2 h of incubation, the radiolabeled peptide was almost totally degraded. However, reformation of free ^{99m}TcO$_4^-$ during incubation in plasma and blood could not be detected.

In Vivo Stability. The metabolism of **1** was also estimated in vivo. The analyzed blood (from 1.5 h postinjection sacrificed mice) still contained about 7% intact radioconjugate (identified by coinjection with the reference). Besides the intact radiopeptide there were five main metabolites, from which three seemed to be identical with those found in the in vitro stability studies.

Animal Studies. In the biodistribution study, performed with **1**, a rapid distribution and clearance was observed in PC-3 xenografted nude mice (Table 4). High uptake was observed in the kidneys and the liver (9.47 ± 2.06% ID/g and 3.33 ± 0.28% ID/g, 30 min pi). However, there was a rapid clearance of the radioactivity from all organs (e.g., 0.49 ± 0.24% ID/g kidney and 0.60 ± 0.18% ID/g liver 24 h after iv injection). Second highest uptake was observed in the pancreas, a GRP receptor-positive organ (7.11 ± 3.93% ID/g, 30 min pi). In the tumor, only low uptake was found (0.89 ± 0.27% ID/g 30 min after iv injection).

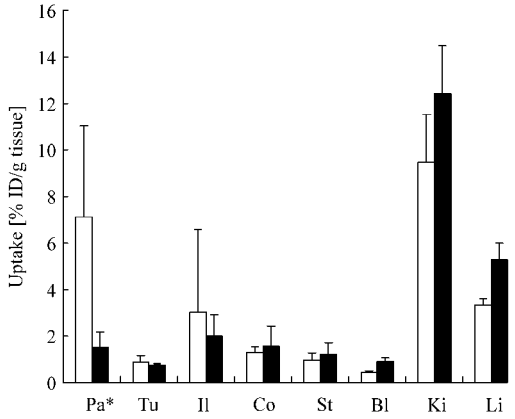

Figure 6. Receptor blockade study: biodistribution of [^{99m}Tc-(CO)$_3$−N_α-histidinyl acetate]bombesin(7−14) 0.5 h pi with (black bars) and without (white bars) coinjection of 300 μg of bombesin/mouse for blocking the GRP receptors. Data are percentage of injected dose per gram (% ID/g) of tissue ± SD by reference of total injected dose (n = 4). Pa = pancreas, Tu = tumor, Il = ileum, Co = colon, St = stomach, Bl = blood, Ki = kidneys, Li= liver. * P < 0.01, t-test.

In the study of GRP receptor blockade, a dose of 300 μg bombesin/mouse was able to reduce specifically the uptake of the radioconjugate (Figure 6). However, the uptake was significantly reduced only in the pancreas. A partial reduction could be observed in the ileum. No reduction was obtained in the tumor as well as in all other organs tested.

DISCUSSION

Radiolabeling of the BFC-derived 8-amino acid sequence of bombesin was very effective. The N-terminal introduction of N_α-histidinyl acetate as BFC made general post labeling yields of more than 95% possible. Despite the fact that bombesin(7−14) has one endogenous histidine in the peptide sequence (a potential anchor group for [^{99m}Tc(OH$_2$)$_3$(CO)$_3$]$^+$), the formation of a single radiolabeled species has been observed under the applied labeling conditions. This proved suitability of tridentate N_2O structures, like N_α-histidinyl acetate, as BFCs for the [^{99m}Tc(OH$_2$)$_3$(CO)$_3$]$^+$ (*21*) even in the presence of competing functionalities within the peptide/protein sequence. In addition, challenging assays with histidine (N_2O ligand) and cysteine (NOS ligand) revealed only little ligand exchange and/or decomposition and therefore confirmed the kinetic inertness of the built complex (*21, 22*). Only little reoxidation to [^{99m}TcO$_4$]$^-$ (less than 5%) took place.

Maintenance of GRP receptor-affinity was tested in the PC-3 human prostate adenocarcinoma cell line. The bioconjugate retained high affinity binding (Table 1). [Re-(CO)$_3$−N_α-histidinyl acetate]bombesin(7−14) even revealed higher GRP receptor-affinity than the natural ligand probably due to the lipophilicity of the "Re(CO)$_3$"-core. However, in receptor saturation experiments the higher GRP receptor affinity could not be confirmed, as the Scatchard plot analysis revealed for [^{99m}Tc(CO)$_3$−N_α-histidinyl acetate]bombesin(7−14) a similar K_d value as for the native (iodinated) peptide (*23*). Internalization studies with the ^{99m}Tc(I)-labeled bombesin derivative revealed a time- and temperature-dependent uptake into PC-3 cells, 70 ± 4%, after 30 min at 37 °C (Figure 4). This uptake into the target cells is highly desired, as it should result in increased tumor-to-background ratios. Furthermore, as internalization of G protein-coupled receptor ligands is mostly specific for agonists (*24*), it is believed that the radioconjugate **1** is an agonist. Internalization of ligand/GRP receptor complexes involves the final entrapment of the ligands in lysosomes, where—in case of peptides—they are quickly degraded (*25, 26*). Due to this immediate lysosomal degradation, no long-term retention of radioactivity in the cells is to be expected. Studies of radioactivity release from PC-3 cells confirmed this prediction, as 2.5 h after internalization of the radiopeptide, already 50 ± 2% was released, and after 24 h, 90 ± 4% (Figure 5).

Obviously, for longer entrapment of the radioconjugate in the cell, stabilization of the peptide might be needed. Therefore, metabolic stability of **1** was tested in vitro as well as in vivo. Degradation in vitro was quick with a half-life of 28 min in human plasma (Table 3). An even faster in vitro degradation was obtained when incubated in human blood ($t_{1/2}$ = 18 min), comparable to the in vivo stability in mouse blood, which did confirm comparability of in vitro and in vivo stability testing at least. In terms of desired stabilization, this may be achieved by replacement of glycine at position 11 by a D-alanine (*27*).

Biodistribution studies were performed in PC-3 xenografted CD-1 nu/nu mice to evaluate pharmacokinetics and specificity of in vivo GRP receptor targeting. There was a rapid clearance from blood and all nontargeted tissues (Table 4). Uptake into the GRP receptor-bearing pancreas was highest at 30 min pi, with 7.11 ± 3.93% ID/g tissue. The difference in the uptake of compound **1** into the pancreas with and without coinjection of 300 μg of bombesin was significant (7.11 ± 3.93% ID/g and 1.51 ± 0.68% ID/g, respectively), demonstrating the ability of the radioconjugate to specifically target in vivo GRP-expressing cells (Figure 6). However, only low uptake was observed in the tumor (0.89 ± 0.27% ID/g tissue). An explanation might be that the GRP receptor-bearing acini cells in the pancreas were well accessible to the blood stream, whereas the PC-3 tumors were weakly vascularized.

CONCLUSION

We could show that bombesin derivatives can readily be functionalized with relatively small, tridentate BFC for the radiolabeling with the organometallic precursor [^{99m}Tc(OH$_2$)$_3$(CO)$_3$]$^+$. The radioactive label reveals a high in vitro and in vivo stability. The labeled peptide retained fully the biological activity. The simple and organometallic labeling approach will allow the effective labeling of small peptides under mild conditions. Therefore, it can potentially be useful for therapeutic application of receptor avid substances in the future using the rhenium isotopes Re-186/188.

Novel Near-Infrared Cyanine Fluorochromes: Synthesis, Properties, and Bioconjugation

Yuhui Lin, Ralph Weissleder, and Ching-Hsuan Tung*

Center for Molecular Imaging Research, Massachusetts General Hospital, Harvard Medical School, Charlestown, Massachusetts 02129. Received October 29, 2001; Revised Manuscript Received January 31, 2002

Recently, near-infrared (NIR) fluorescence light has been applied to image various biological events in vivo, because it penetrates tissue more efficiently than light in the visible spectrum. Compounds exhibiting fluorescent properties in the NIR range are key elements for this upcoming optical imaging technology. In this paper, we report the synthesis of four new, water-soluble NIR cyanine fluorochromes which have superior chemical stability and optical properties. Each fluorochrome was designed with a monoreactive carboxyl group for labeling purposes. When multiple fluorochromes were attached to a single macromolecule, fluorescence quenching was observed. On the basis of this property, a novel autoquenched enzyme sensitive NIR fluorescence probe was prepared.

INTRODUCTION

Noninvasive imaging with light photons represents an intriguing avenue for extracting biological information from living subjects. While light in the visible range is routinely used for intravital microscopy, imaging of deeper tissues (>500 μm to cm) requires the use of near-infrared (NIR) light, as hemoglobin and water, the major absorbers of visible and infrared light, respectively, have their lowest absorption coefficient in the NIR region (650−900 nm). Light photons can be used to measure different native parameters of tissue through which they travel, such as absorption, scattering, polarization, spectral characteristics, and fluorescence. Near-infrared fluorescence imaging in particular is expected to have a major impact in biotechnology and medicine because of its high sensitivity and the fact that no radiation is necessary for acquisition and the versatility of different reporter probes. The recent descriptions of targeted NIR fluorochromes (*1*, *2*), activatable NIR fluorochromes (*3*), red-shifted fluorescent proteins (*4*), and bioluminescent probes (*5*) has lent further credence to the field. Conversely, a number of reflectance (*6*) and tomographic imaging systems have recently been developed to detect NIR fluorescence in deep tissues (*7*) including patients (*8*, *9*).

At the heart of NIR imaging lies the need for biocompatible fluorochromes. While indocyanine green (ICG) has been used clinically for over 20 years with few side effects (*10*), its use in designing targeted agents is limited primarily because of the nonavailability of monoderivatized activated precursors. Additional disadvantages are its hydrophobicity, high albumin binding, nonlinear fluorescence, and other intrinsic properties (*11*). Recently, several new derivatives such as tricarbocyanines (*2*) and cyptates (*12*) have been described and synthesized by different groups.

General problems with the synthesis of NIR fluorochromes compared to visible light fluorochromes are (1) significant spectral broadening as the wavelength increases, (2) low quantum yield, (3) photoinstability, (4) chemical instability with increasing red-shift, and (5) the tendency to aggregate because of hydrophobicity. The ideal NIRF reporters for in vivo imaging should have the following characteristics: (1) a peak fluorescence close to "700−900 nm", (2) high quantum yield, (3) narrow excitation/emission spectrum, (4) high chemical and photostability, (5) nontoxicity, (6) good biocompatibility, biodegradability and excretability, (7) availability of monofunctional derivatives as platform technology, and (8) commercial viability and scalable production for large quantities required for human use.

We describe here the synthesis of a number of highly stable NIR fluorochromes designed with the above prerequisites in mind. The agents contain multiple hydrophilic groups and have been prepared as monohydroxy succinimide esters for binding to biomolecules such as peptides, metabolites, proteins, and other affinity ligands.

MATERIALS AND METHODS

Chemicals. 6-Amino-1,3-naphthalene disulfonic acid disodium salt, 1,4-butanesultone, 4-hydrazinobenzoic acid, 3-methyl-2-butanone, iodoethane, diisopropylcarbodiimide (DIPCDI), and *N*-hydroxysuccinimide (NHS) were purchased from Aldrich (Milwaukee, WI). Glutaconaldehyde dianil hydrochloride, malconaldehyde dianil hydrochloride, and *p*-hydrazinobenzenesulfonic acid were purchased from TCI America (Portland, OR). All other reagents and solvents were purchased from Aldrich and were used as received.

Purification and Spectroscopic Analysis. Purification of dyes was performed on a Rainin preparative HPLC instrument (Woburn, MA) using a C18−RP preparative column (Vydac, Hesperia, CA; flow rate = 6 mL/min; eluant A, water with 0.1% TFA; eluant B, 90% of acetonitrile and 10% of eluant A; starting at 90% A for 5 min and then a linear gradient over 40 min to 50% A). The dual HPLC detector was set at 240 and 360 nm. Dyes were collected, and solvent was removed by Speed-vac concentrator (Savant, Holbrook, NY). Absorbance spectra were measured on a U-3000 spectrophotometer (Hitachi, San Jose, CA). Fluorescence spectra were recorded using

a F-4500 fluorophotometer (Hitachi). The proton NMR spectra were recorded in D_2O in a 400 MHz FT-NMR spectrometer.

Synthesis of Cyanine Dyes. 1,1,2-Trimethylbenzindoleninium 1,3-disulfonate (*13*), 5-carboxy-1-(4-sulfobutyl)-2,3,3-trimethyl-3*H*-indolenine **2** (*14*), and 1-(4-sulfonatobutyl)-2,3,3-trimethylindoleninium-5-sulfonate **5** (*15*) were synthesized according to the literature. All compounds were used in crude form because conventional chromotagraphy and/or recrystalization proved to be difficult for the highly hydrophilic compounds.

***N*-Ethyl-2,3,3-trimethylbenzindoleninium 5,7-Disulfonate 1.** In a 50 mL round-bottomed flask were placed 4.7 g of 1,1,2-trimethylbenzindoleninium 1,3-disulfonate dipotassium salt, 8 mL of ethyl iodide, and 50 mL of 1,2-dichlorobenzene. The mixture was heated under argon atmosphere at 90 °C for 12 h and then at 125 °C for another 10 h. After being cooled to room temperature, 1,2-dichlobenzene was decanted and the solid was washed three times with an acetone/ether mixture. The solid was filtered off and dried under vacuum to result in 4.1 g of crude **1**.

Intermediate 3. In a 50 mL round flask were placed 1.92 g of **1**, 1.12 g of glutaconaldehyde dianil hydrochloride, 20 mL of acetic anhydride, and 5 mL of glacial acetic acid. The mixture was heated at 120 °C for 3 h and was then precipitated from ethyl acetate upon cooling. After filtration, the solid was washed twice with ethyl acetate and dried under vacuum to yield 2.2 g of crude intermediate **3**.

NIR1. A mixture of 0.60 g of intermediate **3**, 0.33 g of 5-carboxy-1-(4-sulfobutyl)-2,3,3-trimethyl-3*H*-indolenine **2**, 0.49 g of potassium acetate, 12 mL of acetic anhydride, and 5 mL of glacial acetic acid was stirred and heated at 120 °C under argon atmosphere for 30 min. After being cooled to room temperature, the mixture was poured into 200 mL of ethyl acetate and the precipitate was collected by centrifugation and then dried to result in 0.86 g of crude NIR1. The crude product was further purified by reverse phase HPLC to give 14% (based on the crude product) of pure NIR1. ^{1}H NMR (D_2O): δ 1.24 (6H, s), 1.28 (3H, t), 1.54 (6H, s), 1.80 (4H, broad m), 2.90 (2H, broad t), 3.86 (2H, broad), 4.12 (2H, broad q), 5.76 (1H, broad), 6.03 (2H, broad), 7.04 (2H, broad), 7.21 (1H, d), 7.33 (1H, broad), 7.53 (1H, broad), 7.58 (1H, s), 7.65 (1H, d), 7.73 (1H, d), 8.19 (1H, s), 8.52 (1H, s), 8.71 (1H, d).

Intermediate 4. In a 50 mL round flask were placed 1.70 g of **1**, 0.93 g of malonaldehydedianil hydrochloride, 20 mL of acetic anhydride, and 5 mL of glacial acetic acid. The mixture was then heated at 120 °C for 3 h. Upon being cooled, the mixture was precipitated in ethyl acetate. After filtration the solid was washed twice with ethyl acetate and dried under vacuum to yield 1.5 g of crude intermediate **4**.

NIR2. A mixture of 0.58 g of intermediate **4**, 0.35 g of 5-carboxy-1-(4-sulfobutyl)-2,3,3-trimethyl-3*H*-indolenine **2**, 0.49 g of potassium acetate, 12 mL of acetic anhydride, and 5 mL of glacial acid was stirred and heated at 120 °C under argon atmosphere for 30 min. After being cooled to room temperature, the mixture was poured into 200 mL of ethyl acetate. The precipitate was collected by centrifugation and dried to result in 0.9 g of crude NIR2. The crude product was then purified by reversed phase HPLC to give 21% (based on the crude product) of pure NIR2. ^{1}H NMR (D_2O): δ 1.19 (3H, t), 1.24 (6H, s), 1.52 (6H, s), 1.80 (4H, broad m), 2.90 (2H, broad t), 3.90 (2H, broad m), 4.02 (2H, broad q), 5.82 (1H, broad d), 5.85 (1H, broad d), 6.14 (2H, t), 7.08 (1H, d), 7.56 (1H, s), 7.61−7.77 (4H, m), 8.19 (1H, s), 8.51 (1H, s), 8.70 (1H, d).

Intermediate 6. In a 50 mL round flask were placed 0.80 g of 1-(4-sulfonatobutyl)-2,3,3-trimethylindoleninium-5-sulfonate **5**, 0.50 g of glutaconaldehyde dianil hydrochloride, 10 mL of acetic anhydride, and 5 mL of glacial acetic acid. The mixture was then heated at 120 °C for 3 h. Upon cooling, the mixture was precipitated from ethyl acetate. After filtration the solid was washed twice with ethyl acetate and dried under vacuum to yield 0.88 g of crude intermediate **6**.

NIR3. A mixture of 0.88 g of intermediate **6**, 0.55 g of 5-carboxy-1-(4-sulfobutyl)-2,3,3-trimethyl-3*H*-indolenine **2**, 0.85 g of potassium acetate, 12 mL of acetic anhydride, and 5 mL of glacial acetic acid was stirred and heated at 120 °C under argon atmosphere for 30 min. After being cooled to room temperature, the mixture was poured into 200 mL of ethyl acetate. The precipitate was collected by centrifugation and dried to result in 0.9 g of crude NIR3. The crude product was then purified by reverse phase HPLC to give 6.7% (based on the crude product) of pure NIR4. ^{1}H NMR (D_2O): δ 1.36 (6H, s), 1.42 (6H, s), 1.56−1.81 (6H, broad m), 1.81−1.89 (2H, broad m), 2.84−2.90 (4H, m), 3.92 (2H, broad t), 4.06 (2H, broad t), 5.85 (1H, broad d), 6.10 (2H, broad), 6.28 (1H, broad t), 7.17 (2H, broad m), 7.26 (1H, d), 7.45 (1H, broad), 7.53 (1H, broad), 7.67−7.77 (4H, m).

Intermediate 7. In a 50 mL round flask were placed 0.80 g of 1-(4-sulfonatobutyl)-2,3,3-trimethylindoleninium-5-sulfonate **5**, 0.45 g of malonaldehydedianil hydrochloride, 10 mL of acetic anhydride, and 5 mL of glacial acetic acid. The mixture was then heated at 120 °C for 3 h. Upon cooling, the mixture was precipitated from ethyl acetate. After filtration the solid was washed twice with ethyl acetate and dried under vacuum to yield 0.74 g crude intermediate **7**.

NIR4. A mixture of 0.74 g of intermediate **7**, 0.45 g of 5-carboxy-1-(4-sulfobutyl)-2,3,3-trimethyl-3*H*-indolenine **2**, 0.70 g of potassium acetate, 12 mL of acetic anhydride, and 5 mL of glacial acid were stirred and heated at 120 °C under argon atmosphere for 30 min. After being cooled to room temperature, the mixture was poured into 200 mL of ethyl acetate. The precipitate was collected by centrifugation and dried to result in 0.9 g of crude NIR4. The crude product was then purified by reverse phase HPLC to give 8.1% (based on the crude product) of pure NIR3. ^{1}H NMR (D_2O): δ 1.29 (6H, s), 1.39 (6H, s), 1.71−1.78 (6H, broad m), 1.84−1.88 (2H, broad m), 2.79−2.87 (4H, m), 3.92 (2H, broad t), 4.04 (2H, broad t). 5.82 (1H, d), 6.06 (1H, d), 6.23 (1H, t), 7.20 (1H, d), 7.25 (1H, d), 7.60−7.75 (6H, m).

Determination of the Extinction Coefficients and Fluorescence Quantum Yield. All NIR dyes were purified by preparative HPLC twice as described above. The K^+ ions were replaced with H^+ by ion-exchange chromatography in deionized water (cation-exchange resin, Dowex-50, 8% cross-link, 100−200 mesh). About 20 mg of a dye was dissolved in 100 mL of deionized water. The absorbance was measured individually in three dilutions of the stock solution in deionized water or in ethanol (95%). The fluorescence emission maxima and intensities of the dyes were obtained using dilute solutions in water and exciting at both the main absorption peak as well the short-wavelength shoulder of the main absorption peak. In cases of NIR2 and NIR4, the quantum yields were calculated relative to a standard solution of Cy5.5 (Amersham-Pharmacia, Piscataway, NJ) with quantum yield of 0.29, whereas in cases of NIR1 and NIR3. The calculations were performed relative to a standard solution of Cy7 (Amersham-Pharmacia) with a quantum yield of 0.28.

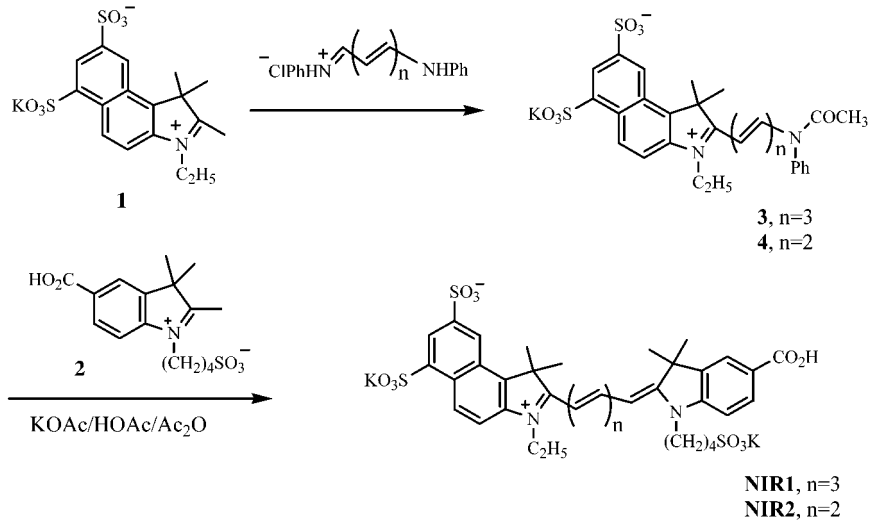

Figure 1. Synthetic scheme of NIR1 and NIR2.

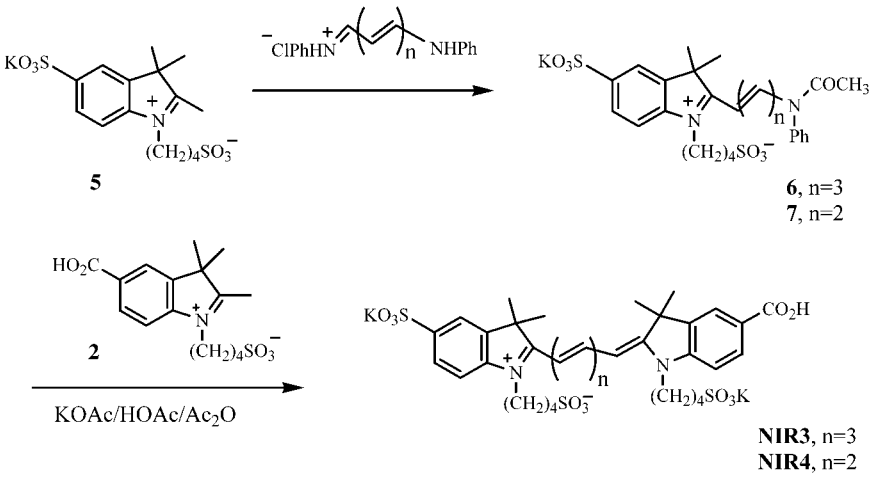

Figure 2. Synthetic scheme of NIR3 and NIR4.

Activation of Cyanine Dyes. In a typical experiment, 10 mg of dye, 30 μL of diisopropylcarbodiimide, 50 μL of *N*-methylmorpholine, 22.0 mg of NHS, and 0.5 mL of dry DMF were placed in a small round-bottomed flask under argon atmosphere. The mixture was stirred at room temperature for 3 h and then precipitated in ether. After centrifugation, the ether was decanted and the solid was washed four more times with ether and dried in a vacuum. The HPLC result indicated that more than 98% of dye was converted to active ester.

Imaging of NIR Dyes. Imaging was performed using a previously developed NIRF reflectance imaging system (*6*). Briefly, the system consisted of a light-tight chamber equipped with a halogen white light source and excitation band-pass filters providing the excitation wavelengths of 610−650 nm or 750−770 nm (Omega Optical, Brattlebore, VT). Equalmolar NIR dyes and ICG were loaded to individual wells (0.16 nmol in 200 μL) in a clear-bottom 96-well plate (Corning, Corning, NY). Fluorescence was detected by a 12-bit monochrome CCD camera (Kodak, Rochester, NY) equipped with a 12.5−75 mm zoom lens and emission band-pass filters at 680−720 nm or 800−820 nm (Omega Optical, Brattlebore, VT). Exposure time was 10 s per image. Images were analyzed using commercially available software (Kodak Digital Science 1D software, Rochester, NY).

Synthesis of Enzyme Sensitive Probe with Various Amounts of NIR2. The enzyme sensitive probes were synthesized similar to the described protocol (*3*). Briefly, partially PEGylated polylysine (0.1 mg, MW = 500000 Da. (*16*)) was reacted with various amounts of NIR2−NHS ester, whose concentration was 0.4, 2, 4, 8, 20, 40, or 80 μM in 20 mM $NaHCO_3$, at room temperature for 3 h. The NIR2-labeled polymers were then separated from excess low molecular weight reagents using a 50 kDa cutoff microconcentrators (Amicon, Beverly, MA). Based on NIR2 absorption measurement at 662 nm, the average numbers of NIR2 fluorochrome per PGC are 0.2, 0.8, 1.4, 2.4, 4.3, 5.7, and 7.0, respectively.

Trypsin Activation of NIR2−PGC Probes. The activation of the NIRF probe was done in a 96-well plate with various NIR2−PGC probes. In each well, NIR2−PGC (40 pmole) in 200 μL of PBS was incubated with 10 μL of trypsin solution (0.05% trypsin, 0.53 mM EDTA, Mediatech, Herndon, VA). The reactions were monitored using a fluorescence microplate reader (Spectramax, Molecular Devices, Sunnyvale, CA) with excitation and emission wavelength at 662 and 684 nm, respectively. The reactions were purformed in duplicate.

RESULTS AND DISCUSSION

Synthesis of Nonsymmetrical Cyanine Dyes. The synthetic pathways for the four new cyanine dyes are outlined in Figures 1 and 2. The synthesis of NIR1 and NIR2 was carried out starting from 1,1,2-tri-

methylbenzindoleninium 1,3-disulfonate dipotassium salt, which was converted to **1** by treating with ethyl iodide. Reaction of **1** with malconaldehyde dianil hydrochloride or glutaconaldehyde dianil hydrochloride resulted in the intermediates **3** and **4**. Intermediates **3** and **4** were stable at room temperature and in aqueous solution, and no significant decomposition could be observed over more than two weeks. The asymmetrical dyes NIR1 and NIR2 were assembled by reacting **3** or **4** with 5-carboxy-1-(4-sulfobutyl)-2,3,3-trimethyl-3*H*-indolenine **2**. Similarly, the synthesis of NIR3 and NIR4 was started with 1-(4-sulfonatobutyl)-2,3,3-trimethylindoleninium-5-sulfonate **5**, which was converted to intermediates **6** or **7** by the reaction with malconaldehyde dianil hydrochloride or glutaconaldehyde dianil hydrochloride. Like intermediates **3** and **4**, intermediates **6** and **7** were also stable at room temperature. Reaction of intermediate **6** or **7** with 5-carboxy-1-(4-sulfobutyl)-2,3,3-trimethyl-3*H*-indolenine **2** yielded the asymmetrical dyes NIR3 and NIR4, respectively.

The multistep synthesis of the described compounds showed several peculiarities. First, the intermediateries were difficult to purify, leading us to use mixtures for subsequent reactions followed by final HPLC purification. We assume that purification of the intermediaries was difficult because of their extremely high water solubility. Irrespective of this step, we showed that the final products were >98% pure as determined by HPLC. Clean NMR spectra were obtained, except for the integration of one or two bridged methine protons, which might be due to the resonance structure of the cyanine dyes. Indeed similar finding about NMR spectra of cyanine dyes have been reported (*17*).

Unlike previously described and commercially available near-infrared cyanine dyes (*2*, *13*, *18*), the ones reported here bear two different heterocyclic ring systems including a 3-ring and a 2-ring heterocyclic system. The rationale for this design is severalfold, including the ability to fine-tune spectral properties for imaging compounds and the improvement in the typically mitigating self-aggregation of large planar dyes. The latter is of particular concern since self-aggregating fluorochromes may be poorly soluble, as is the case for ICG. To further improve solubility, we chose to also include a constant and large number of sulfonate groups in all dyes.

Spectral Properties of Dyes. The absorption spectra of NIR1−4 are shown in Figure 3A. As in other cyanine dyes, the difference in absorbance maximum between indodicarbocyanine dye and indotricarbocyanine dye was about 100 nm. The terminal ring system contributes very little to the absorbance maximum compared to that of the bridging methine unit. The difference in absorbance maximum between 3/2 ring systems (e.g., NIR2) compared to 2/2 homocycles (e.g., NIR4) was only 10 nm. Excitation and emission spectra of NIR1 and NIR2 are shown in Figure 3B. Indodicarbocyanine dyes had a 20 nm Stokes shift of the fluorescence emission maximum, while indotricarbocyanine dyes exhibited a 30 nm Stokes shift of the fluorescence maximum. The dyes had high molar extinction coefficient above 250000, similar as the range published for other compounds. Quantum yields of the different fluorochromes varied from 0.23 to 0.43. Optical properities of the compounds were summarized on Table 1.

Activation of Dyes. The cyanine dyes were converted to reactive *N*-hydroxysuccinimide esters by DICPDI and NHS in the presence of *N*-methylmorpholine in DMF (Figure 4). An almost quantitative yield (typically >98%) was observed using reversed phase HPLC (Figure 4). As

Table 1. Optical Properties of NIR Fluorochromes

compd	solvent	$\lambda_{max,abs}$ (nm)	$\lambda_{max,em}$ (nm)	Stokes shift (nm)	ϵ (L mol^{-1} cm^{-1})	QY
NIR1	H_2O	761	796	35	268000	0.23
	EtOH	769				
NIR2	H_2O	662	684	22	250000	0.34
	EtOH	667				
NIR3	H_2O	750	777	27	275000	0.28
	EtOH	756				
NIR4	H_2O	650	671	21	260000	0.43
	EtOH	654				

seen in Figure 4, the elution times for NIR2 and its active ester were 27.1 and 29.0 min, respectively. The active ester was remarkably stable. Even in water, less than 10% of the active ester was hydrolyzed over a period of 20 days (4 °C), based on HPLC analysis. A test reaction was done by reacting NIR2−NHS active ester with benzylamine. The resultant NIR2−benzylamine conjugate showed an elution time of 32.1 min (HPLC results not shown).

Imaging of NIR Dyes. In subsequent studies we utilized a home-built imaging system (*6*) to image the newly synthesized NIR dyes and compared them to ICG. The images were acquired with two sets of filters. One has 610−650 nm excitation and 680−720 nm emission; the other has 750−770 nm excitation and 800−820 nm emission. As shown in Figure 5, the fluorescence signals of NIRs are well resolved in this fluorescence imaging system. At 700 nm, only NIR2 and NIR4 were detectable, while NIR1 and NIR 3 were detectable at 800 nm. Moreover, the NIR1 and NIR3 showed significantly better optical property than ICG. The signal intensity of NIR1 and NIR3, as compared to ICG, were 7- and 12-fold higher, respectively.

Enzyme Activatable NIRF Probe. Recently, we have developed a panel of biocompatible molecular probes for the in vivo detection of specific protease activity, particularly for those proteases that play key roles in different aspects of cancer growth, metastases formation, and angiogenesis (*3*, *19*, *20*). In those studies, a commercially available fluorochrome (Cy5.5) was used as the fluorescence reporter. In this study the newly synthesized

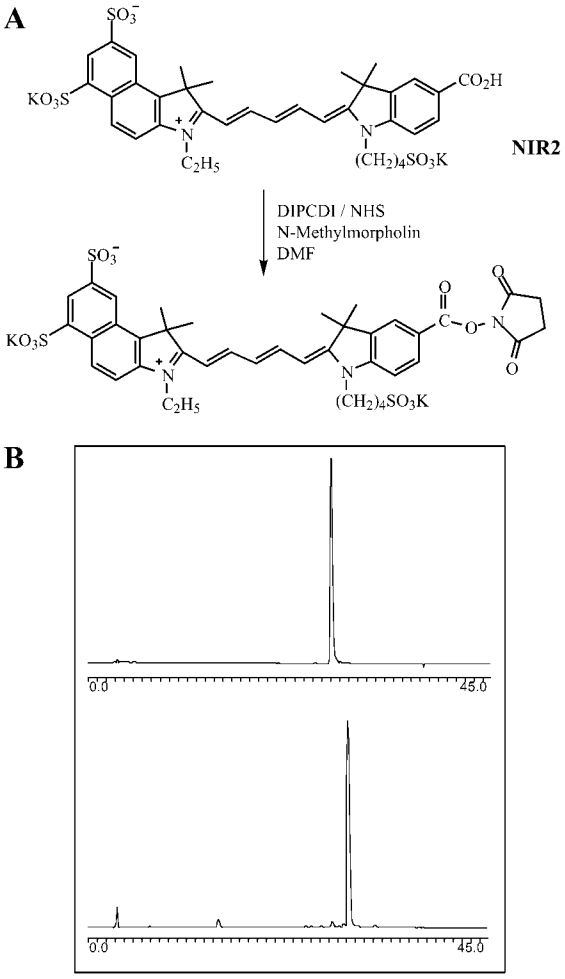

Figure 4. A. Activation of NIR2. B. HPLC traces before (top) and after modification (bottom).

NIR fluorochromes as alternative reporters was tested. The fluorochromes were attached to a partially peglyated graft coplymer (PGC), which has a polylysine backbone (*21*). The probes were designed to have minimum fluorescence signal in their native states and become highly fluorescent after enzyme-mediated release of fluorochromes, resulting in signal amplification. To reduce the initial fluorescence signal, a high local concentration of fluorochromes was desired to have significant self-quenching. Since the lysine residues on PGC were only partially pegylated, free amino groups on the unmodified lysine side chain could be used for fluorochrome attachment. Nevertheless, additional free lysine residues were also needed for trypsin recognition. As a consequence, the number of fluorochromes per polymer had to be optimized in order to maximize the fluorescence increase after enzymatic cleavage.

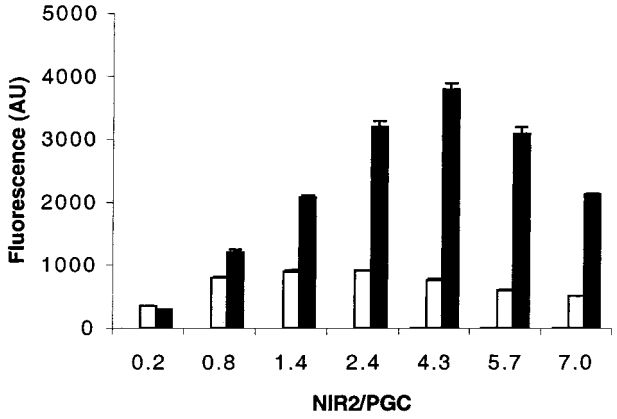

Figure 6. Fluorescence measurement of NIR−PGC probes before (white bars) and after (black bars) cleavage by trypsin for 3 h.

For this purpose, PGC probes were labeled with different amounts of NIR2. Overall, seven conjugates with 0.2, 0.8, 1.4, 2.4, 4.3, 5.7, and 7.0 NIR2 residues per PGC molecule were prepared. The white bars in Figure 6 shows the fluorescent signal of the labeled polymers before trypsin treatment. As expected, there is an increase in the signal from 0.2 to 0.8 dyes/polymer, while at higher dye/polymer ratio, considerable self-quenching is observed. The black bars in Figure 6 show the fluorescence signals obtained after 3 h of tryptic cleavage. Maximum recovery was found for 4.3 NIR2 per PGC. At this ratio, the fluorescence signal increased 5-fold in 3 h and 9-fold in 24 h. Interestingly, recovery was lower when more NIR2 was attached to the backbone, presumably due to the less enzyme-accessible cleavage sites on the backbone. These studies demonstrate the importance of the proposed optimization studies which are required to maximize the dequenching effect upon enzymatic cleavage.

The self-quenching phenomenon of NIRF cyanine dyes was not only shown by NIR2, as similar results were obtained when NIR1 was used in the preparation (data not shown). Extensive self-quenching was also reported with Cy5, Cy5.5, and Cy7 (*22*). The fluorescence signal was not enhanced by attaching multiple labels onto one molecule; on the contrary, it was significantly reduced due to serious self-quenching. We have applied this negative effect in a positive way to design several quenched probes as previously described and used them to imaging tumor-associated protease activity in vivo (*3*, *19*, *20*).

In summary, we describe the synthesis and properties of a number of nonsymmetrical cyanine dyes. The dyes are characterized by high stability, high quantum yield, and water solubility. Likewise, the monoactivated hydroxysuccinimide esters of the fluorochromes were exceptionally stable, yet fully reactive with primary amines. We are currently testing the use of fluorochrome-tagged molecules for imaging of tumors and other diseases in vivo. It is anticipated that the developed fluorochromes have a range of biotech applications extending beyond imaging.

Recombinant streptavidin (rSAv) is of interest as a carrier of α-emitting radionuclides in pretargeting protocols for cancer therapy. Due to the inherently high kidney localization of rSAv, modification of this protein is required before it can be useful in pretargeting. Previous studies (Wilbur, D. S., Hamlin, D. K. et al. (1998) *Bioconjugate Chem*. *9*, 322−330) have shown that succinylation of rSAv using succinic anhydride decreases the kidney localization appreciably. In continuing studies, the biotin binding characteristics and biodistribution in mice of rSAv modified by reaction with succinic anhydride (amine modification) or 1,2-cyclohexanedione (arginine modification) have been compared. Modification of rSAv was conducted using 5−50 mol equiv of succinic anhydride and 60−200 mol equiv of 1,2-cyclohexanedione. Most studies were conducted using rSAv modified with the highest quantities of reagents. Succinylation of rSAv did not alter binding with biotin derivatives, but a small increase in the biotin derivative dissociation rate was noted for arginine-modified rSAv. Amino acid analysis of 1,2-cyclohexanedione-treated rSAv indicated about 40% of the arginine residues, or an average of 1.6 residues per subunit, were modified, whereas none of the lysine residues were modified. IEF analyses showed that the pI of the arginine-modified rSAv was 5.3−6, whereas the pI for the succinylated rSAv was approximately 4. Electrospray mass spectral analyses indicated that one to three conjugates of 1,2-cyclohexanedione, and two to three conjugates of succinic anhydride, were obtained per subunit. Both modification reactions resulted in greatly decreasing the kidney localization of rSAv (normally 20−25% ID/g at 4, 24, and 48 h pi). However, the kidney concentration for the succinylated rSAv continued to decrease (5% ID/g to 1.5% ID/g) from 4 to 48 h pi, whereas the concentration (5% ID/g) remained constant over that period of time for the arginine-modified rSAv. In contrast to this, the liver concentration appeared to be slightly higher (3% ID/g vs 2% ID/g) at the later time points for the succinylated rSAv. When less than 50 mol equiv of succinic anhydride were employed in the modification of rSAv, a correlation between increasing kidney localization with decreasing equivalents reacted was observed. Although the differences in the two modified rSAv are not substantial, succinylated rSAv appears to have more favorable properties for pretargeting studies.

INTRODUCTION

Selective targeting of therapeutic radionuclides to cancer cells in patients, termed "Targeted Radiotherapy" or "Endoradiotherapy" holds great potential for cancer therapy, particularly in the killing of disseminated cancer cells present in metastatic disease. Radiolabeled monoclonal antibodies (mAbs[1]) have been shown to be very effective at targeting cancer cells, but inherent problems have, thus far, limited their use in cancer therapy (*1*−*6*). To circumvent the problems associated with directly labeled mAbs, alternative approaches utilizing the cancer cell targeting of mAbs are under investigation. One particularly promising approach is termed "pretargeting" (*7*,*8*). In that approach, a mAb conjugate is used to target cancer cells and a separate molecule that binds with the mAb conjugate is used to carry the therapeutic radionuclide. Although this alternative approach involves multiple administrations of reagents, it permits optimization of important parameters, such as pharmacokinetics, route of excretion, and stabilization of the radionuclide-carrying molecule from metabolic processes. Indeed, promising therapy results have been obtained with the pretargeting approach (*9*−*11*).

In our previous studies, a pretargeting approach which uses biotinylated mAb Fab′ fragments with radiolabeled recombinant streptavidin (rSAv) was investigated (*12*). Those studies demonstrated that each biotinylated Fab′ bound in the tumor xenograft captured one radiolabeled rSAv molecule. However, an inherently high kidney localization of SAv molecules (*13*) was problematic with

the approach. It has been hypothesized that the kidney localization observed comes from specific recognition of a surface RYD (Arg, Tyr, Asp) amino acid sequence which is similar to the fibronectin binding RGD (Arg, Gly, Asp) sequence (*14*,*15*) and results in a specific localization in the renal cortex (*16*). Studies in this laboratory demonstrated that the kidney localization could be alleviated by succinylation of rSAv (*17*). This result is thought to due to the high anionic surface charge produced on rSAv and not to an alteration in the RYD sequence on the surface of the protein.

Our continued interest in the use of rSAv as a carrier of radionuclides in pretargeting protocols led us to further investigate methods of decreasing kidney localization of this protein. We were particularly interested in the chemical modification of the RYD sequence in rSAv investigated by personnel at NeoRx Corporation.[2] They found that specific chemical modification of arginine residues using 1,2-cyclohexanedione (*18*−*20*) decreased the kidney localization. Those results prompted us to conduct an investigation comparing the biotin binding properties and tissue distributions of rSAv modified using succinic anhydride and 1,2-cyclohexanedione. The results of that investigation are reported herein.

EXPERIMENTAL PROCEDURES

General. All chemicals purchased from commercial sources were analytical grade or better and were used without further purification. Chloramine-T (ChT) and phosphate-buffered saline (PBS) were obtained from Sigma (St. Louis, MO). 1,2-Cyclohexanedione, and most other chemicals, were obtained from Aldrich Chemical Co. (Milwaukee, WI). Recombinant streptavidin was obtained from Boehringer Mannheim (Indianapolis, IN). Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μm) prior to use. The biotin derivatives **1**−**3**, containing the cyanocobalamin chromophore, were obtained as previously described (*21*). Biotin-deficient diet chow with 10% egg white solids (TD 96343) was obtained from Harlan Teklad (Madison, WI, www.harlan.com). Centricon-10 centrifugation concentrators were obtained from Amicon (Beverly, MA).

Na[^{125}I]I and Na[^{131}I]I were purchased from NEN/Dupont (Billerica, MA) as high concentration/high specific activity radioiodide in 0.1 N NaOH. Measurement of ^{125}I and ^{131}I was accomplished on the Capintec CRC-15R. Tissue samples were counted in a Wallac 1480 Wizard gamma counter with the following window settings: 15−85 keV for I-125 and 260−430 keV when ^{125}I and ^{131}I are counted together. The ^{125}I counts are compensated for spillover counts from the ^{131}I in the calculations.

Chromatography. HPLC separations of the modified rSAv were obtained on Hewlett-Packard isocratic system consisting of a Model 1050 pumping system and a Model 1050 Multiple Wavelength Detector (280 nm). Proteins were evaluated on a Protein Pak 300 SW glass size exclusion column (10 μm, 8 mm × 30 cm, Waters Corporation, Milford, MA) run at 0.75 or 1.0 mL/min eluting with 50 mM sodium phosphate buffer (pH 6.8) which contained 300 mM NaCl, 1 mM EDTA, and 1 mM sodium azide. Analysis of the HPLC data was conducted on Hewlett-Packard HPLC ChemStation software. Retention times (t_R) for rSAv, arginine-modified rSAv, and succinylated rSAv were 27.6−27.8 min (0.75 mL/min flow) or 15.4−15.6 min (1.0 mL/min flow).

[2] Mallett, R., and Meyer, D. NeoRx Corporation, Seattle, WA, unpublished results.

Radiolabeled Proteins. Size-exclusion chromatography was also used to evaluate radioiodinated rSAv. HPLC separations of radioiodinated proteins were conducted on a system that consisted of a Waters Model 510 pump, a Waters Lambda-Max UV detector, and a Beckman model 170 radioisotope detector. The detectors were connected to a computer through a Hewlett-Packard Model 35900 interface, and data from the chromatograms was obtained on a computer running Hewlett-Packard ChemStation Software. The proteins were separated on a BioSelect SEC250−5 size exclusion column (7.8 mm × 300 mm, BioRad, Hercules, CA), eluting with a solvent mixture of 25 mM Tris-HCl, 75 mM NaCl, and 1 mM EDTA, pH 7.2, at a flow rate of 0.70 mL/min. Retention time (t_R) for rSAv was 13.4 min on this system.

Mass Spectral Analyses. Electrospray mass spectra were obtained by atmospheric pressure chemical ionization on a Micromass Quattro II Tandem Quadrupole Mass Spectrometer (Micromass Ltd., Manchester, U.K.). The sample was introduced directly. The mass spectral data was obtained on a PC running Windows NT based Micromass MaxEnt software.

Arginine Modification of Streptavidin. Two experimental procedures for modification of rSAv were used in the studies. All studies used modified rSAv produced by Method A, except for the amino acid analyses.

Method A. To 0.8 mL of rSAv (24.2 mg/mL, 19.4 mg, 0.37 μmol) in PBS was added 0.2 mL 1.0 M NaOH. To this mixture was added 8.6 mg (77 μmol) of solid 1,2-cyclohexanedione. The mixture was stirred for 1 h and then eluted through a Sephadex G-25 column using a 20 mM sodium phosphate, 60 mM NaCl, pH 7.0 solution. The protein gained a slight yellow coloration during the modification.

Method B. To 0.4 mL of 25.4 mg/mL solution of rSAv (10.2 mg, 0.19 μmol) in PBS was added 8 μL of 10 M NaOH to prepare a final concentration of 0.2 M. To that solution was added 1.3 mg (11.4 μmol) 1,2-cyclohexanedione, and the reaction was allowed to proceed for 5 h at ambient temperature. The modified rSAv solution was exchanged into PBS using a G-25 size exclusion column. From this procedure, 8.3 mg (81%) of modified rSAv was obtained following the buffer exchange.

Succinylation of Streptavidin. The succinylation reactions were conducted in a manner similar to that previously described (*17*). Briefly, a 200 μL aliquot of a 5 mg/mL solution of rSAv (1 mg, 1.9×10^{-2} μmol) was added to 370 μL of 50 mM $NaHCO_3$ buffer (pH 8.5). To this solution was added varying quantities [5 equiv: 9.4 μg (9.4×10^{-2} μmol); 10 equiv: 19 μg (19×10^{-2} μmol); 25 equiv: 47 μg (4.7×10^{-2} μmol); 50 equiv: 94 μg (94×10^{-2} μmol)] of succinic anhydride in 2−20 μL DMSO. After 30 min at room temperature, the contents were transferred to a Centricon-10 and concentrated to 50 μL. PBS (500 μL) was added, and the solution was again concentrated to 50 μL. This wash step was repeated five times. The final concentrations of protein (2.4−3.6 mg/mL) and recovery yields (92−100%) were determined for each succinylation reaction.

Electrophoresis. Two electrophoresis instruments and methods were used in the studies. The IEF gel shown in Figure 1 was obtained on a Novex PowerEase 500 instrument with the XCell II chamber using Invitrogen (Novex) precast gels, pH 3−10 (1.0 mm × 12 well) running under the standard IEF Program. The protein was stained with GelCode Blue Stain (Pierce). IEF standards were from Serva Electrophoresis GmbH: pH 10.7, cytochrome C; 9.5, ribonuclease A; 8.3, 8.0, 7.8, lectin; 7.4, 6.9, myoglobin; 6.0, carbonic anhydrase; 5.3,

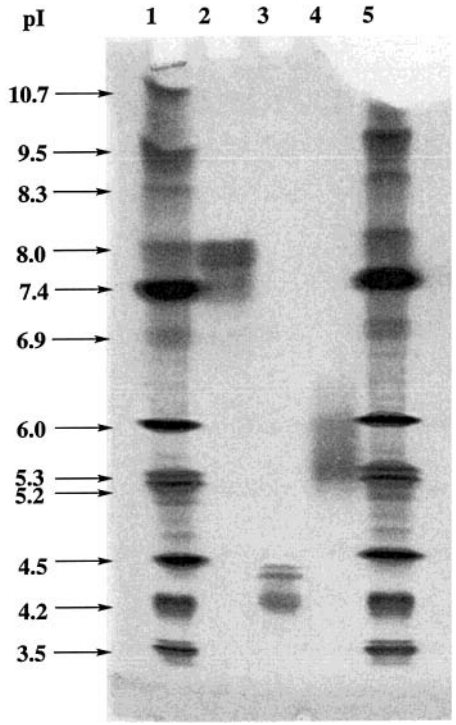

Figure 1. Digitized image of IEF gel comparing pI of unmodified rSAv with succinylated and arginine-modified rSAv. Lanes 1 and 5: IEF standards (Serva IEF markers 3−10). Lane 2: unmodified rSAv (control). Lane 3: succinylated rSAv. Lane 4: arginine-modified rSAv.

5.2, β-lactoglobulin; 4.5, trypsin inhibitor; 4.2, glucose oxidase; 3.5, amyloglucosidase. The IEF gels shown in Figures 5A and 5B were obtained on a PhastSystem electrophoresis apparatus (Pharmacia LKB, Uppsala, Sweden) using the optimized method for IEF described in "Separation Technique File #100". The IEF were run using PhastGel IEF 3−9 precast gels. Protein staining was accomplished by the silver stain method described in "Development Technique File #210". IEF was conducted with samples running in opposite directions. The electrophoresis standards were from the Broad pI Kit (pI 3.5−9.3) (Amersham Pharmacia Biotech, NJ) and are composed of: pI 9.30, trypsinogen; 8.65, 8.45, 8.15, lentil lectin; 7.35, 6.85, myoglobin; 6.55, 5.85, carbonic anhydrase B; 5.20, lactoglobulin A; 4.55, trypsin inhibitor; 3.75, methyl red; 3.50, amylglucosidase.

Amino Acid Analysis. Amino acid analyses of hydrolyzed 1,2-cyclohexanedione-modified and -unmodified rSAv were conducted according to the procedure described by Heinrikson R. L. et al. (*22*). The modified rSAv samples were hydrolyzed with 6 N HCl in the vapor phase at 200 °C for 75 min and then derivatized with phenyl isothiocyanate (PTC) using an Applied Biosystems Model 420 H automated hydrolyzer/derivatizer. The PTC-AA mixture was next injected onto a reversed-phase C-18 column configured on an Applied Biosystems Model 130A HPLC system. The column effluent was monitored at 254 nm and the chromatogram analyzed using the Applied Biosystems Model 610 data acquisition system.

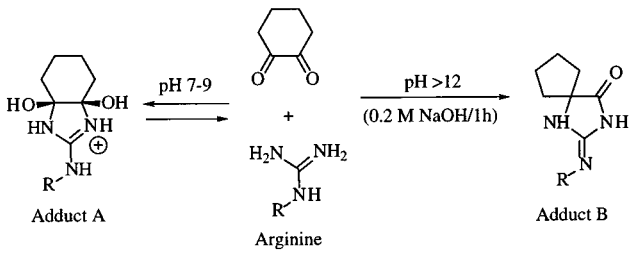
Biotin Binding Studies. Biotin derivative binding studies were conducted as previously described (*21*). Briefly, to 300 μL of a 1 mg/mL solution (300 μg; 5.65 nmol) of rSAv, arginine-modified rSAv, or succinylated rSAv in a plastic microcentrifuge vial was added 4 equiv (22.6 nmol) of a biotin conjugate (**1**−**3**) dissolved in 30 μL of a 10% aqueous DMSO solution. The rSAv/biotin derivative mixture was incubated for 1 h at room temperature, and 100 μL of the solution was assayed on the HPLC. To the remaining rSAv/biotin derivative solution was added 40 μL of a 1 mg/mL solution (40 μg; 164 nmol) of biotin in 10% aqueous DMSO. That solution was incubated for 3 h, and 100 μL was removed for analysis by HPLC. Areas under the peaks for bound and unbound biotin derivative provided the relative dissociation values in Table 1. In some examples, there was a slight excess (<10%) of the biotin derivative (**1**−**3**) that was not bound prior to the addition of excess biotin. The percent dissociation was adjusted for that material.

Table 1. Relative Dissociation of Biotin Derivatives from rSAv and Modified rSAv[a]

biotin derivative	rSAv, %	succinylated rSAv, %	arginine-modified rSAv, %
biotin-CN-Cbl, **1**	96	99	85
biotin-sarcosine-CN-Cbl, **2**	9	58	8
biotin-aspartate-CN-Cbl, **3**	91	91	80

[a] Values represent the percent of biotin derivative remaining bound after 3 h at room temperature in the presence of a large excess of biotin. Structures of biotin derivatives are shown in Figure 3.

Radioiodination of Proteins. Radioiodination reactions were conducted using chloramine-T as previously described (*23*). Radioiodination yields of 90−96% were obtained for ^{125}I-labeled rSAv and succinylated rSAv. Radioiodination yield of ^{125}I-labeled arginine-modified rSAv was 31%. Radioiodination yield of ^{131}I-labeled rSAv was 84% and of ^{131}I-labeled succinylated SAv was 95%.



Biodistributions. *General.* Animal use and procedures were approved by the University of Washington's Institutional Animal Care and Use Committee (IACUC). Animal care and use was conducted in accordance with the NIH guidelines.[3] Male athymic mice (BALB/c nu/nu), 4−5 weeks of age were obtained from Charles River Laboratories (Hollister, CA). All injections of reagents were administered to mice in a total volume of approximately 100 μL (injectate weighed) via the lateral tail vein. Injections and sacrifice of the animals were done at predetermined times. The tissues excised are listed in Figures 4A, 4B, and 6, and in Tables 2 and 3 in Supporting Information. Blood samples were obtained by cardiac puncture immediately before sacrifice. Urine samples were obtained by syringe bladder tap at the time the tissues were excised. Excised tissues were blotted free of blood, weighed, and counted. Calculation of the percent injected dose (%ID) and percent injected dose per gram (%ID/g) in the tissues was based on internal standards containing 1 μL of the injected dose. Total blood volume was estimated to be 8% of body weight for the calculations (*24*).

Comparison of Modified rSAv. In the experiment, 15 mice, which had been placed on biotin-free diets for 7 days prior to beginning the study, were used. Each mouse was injected with a mixture containing 50 μg of succinylated [^{131}I]rSAv and 50 μg of arginine-modified [^{125}I]-rSAv, prepared as described above. The specific activity of the succinylated [^{131}I]rSAv was 0.12 μCi/μg and of the arginine-modified [^{125}I]rSAv was 0.13 μCi/μg. Groups of five mice each were sacrificed at 4, 24, and 48 h postinjection, and the tissue distribution of radioactivity was obtained as described above.

Succinylated rSAv. In the experiment, 20 mice were used. rSAv that had been reacted with 5, 10, 25, or 50

[3] NIH guidelines are described in NIH Publication 86-23: *Guide for the Care and Use of Laboratory Animals.*

Scheme 1: Reaction of Arginine with 1,2-Cyclohexanedione Showing the Two Different Product Pathways at pH 7−9 vs pH >12

equiv of succinic anhydride were radiolabeled with ^{125}I (four preparations). The specific activities of ^{125}I-labeled succinylated rSAv preparations were: 5 equiv, 0.74 μCi/μg; 10 equiv, 0.79 μCi/μg; 25 equiv, 0.84 μCi/μg; 50 equiv, 0.93 μCi/μg. A control that contained unmodified radiolabeled [^{131}I]rSAv was prepared for coinjection. The control ^{131}I-labeled rSAv had a specific activity of 1.49 μCi/μg. Each mouse was injected with a mixture containing 15 μg succinylated [^{125}I]rSAv and 15 μg [^{131}I]rSAv. Tissue biodistributions were obtained at 24 h postinjection as described above.

RESULTS

Modification of rSAv. Modification of rSAv was conducted by its reaction with either succinic anhydride in $NaHCO_3$ buffer at pH 8.5 or with 1,2-cyclohexanedione in PBS containing 0.2 M NaOH, pH 12. Succinic anhydride can react with a number of protein functional groups (e.g., amines, thiols, phenols, and imidazoles). All of the succinic anhydride reactions with protein side chain functional groups are reversible in the basic media (*19*) except for the reaction of amine to form amide bonds, making this modification selective for amino groups on proteins. Reaction of proteins with 1,2-cyclohexanedione is highly selective for guanidine functionality of arginine. There are two reaction products that can be obtained, depending on the pH of the reaction solution. As depicted in Scheme 1, reaction of cyclohexanedione with arginine at pH 7−9 produces a bicyclic chemical adduct (adduct A). However, this reaction is not desirable for our application as the formation of that adduct is reversible, potentially resulting in some, or all, of the arginine residues being unmodified when tested in vivo. The syndiol, adduct A, may be stabilized by boric acid (*18*), but this reaction is also reversible making the stability in vivo still an issue. At high pH, a reaction occurs which results in the irreversible formation of a spiro-bicyclic compound (adduct B). Fortunately, rSAv is like avidin in that it is quite stable to highly alkaline conditions (*25*,*26*), making this reaction useful for our application.

Characterization of Modified rSAv. The modified rSAv was analyzed by size-exclusion HPLC. Although there were small differences in retention times noted (e.g., 0.1−0.2 min), no reproducible link could be made for a modification resulting in a longer or shorter retention time. Because the modification reactions alter the charges on the protein, IEF analyses were conducted. An IEF comparing rSAv, succinylated rSAv and arginine-modified rSAv is shown in Figure 1. The unmodified rSAv (lane 2) has two primary bands with pI of around 7.6−7.8. The succinylated rSAv (lane 3) has a primary band with a pI around 4.2 and two small bands with pI around 4.5. The arginine-modified rSAv (lane 4) has a primary band with a pI around 5.3 and a diffuse area between pI 5.3−6.0.

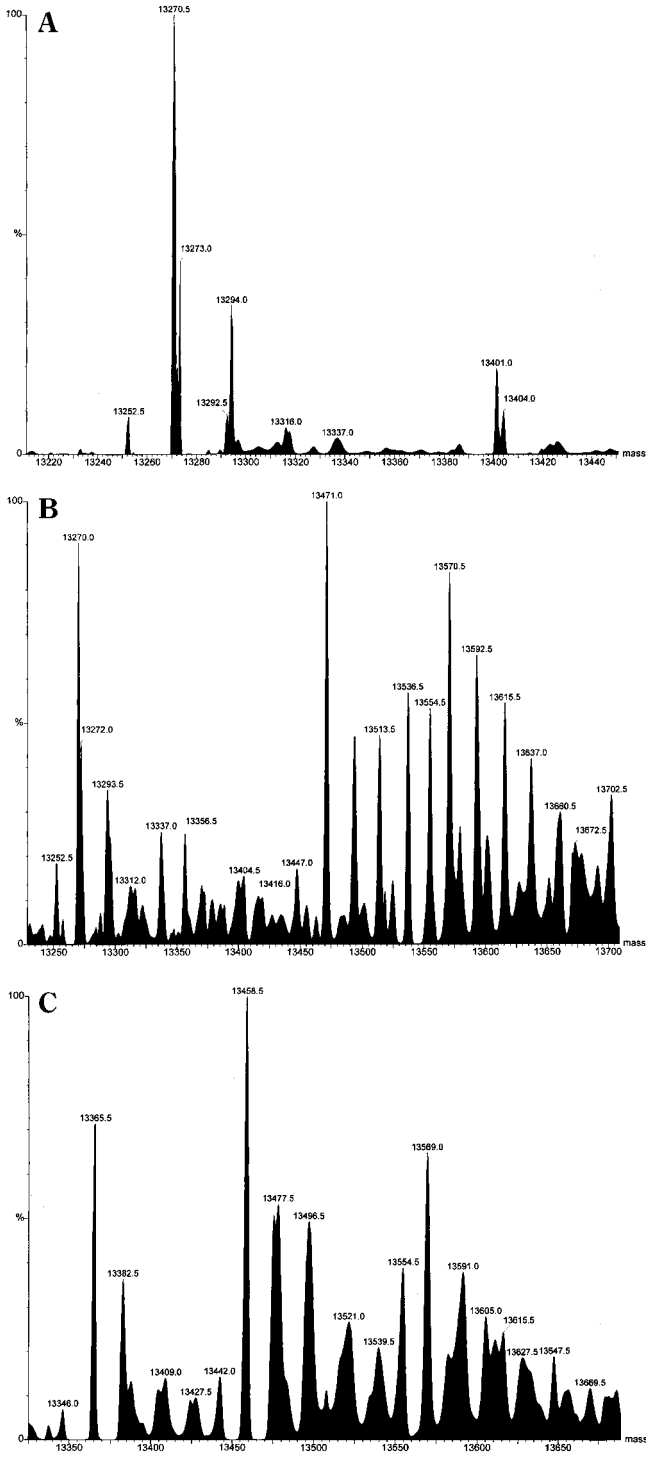


Figure 2. Digitized images of electrospray mass spectra of unaltered rSAv (2A), succinylated rSAv (2B), and arginine-modified rSAv (2C). Note that in Figure 2B, unaltered rSAv has been added as an internal reference.

Electrospray mass spectral data was obtained on samples of rSAv, succinylated rSAv, and arginine-modified rSAv to obtain information on the number of conjugates per subunit. Mass spectra for these materials are shown as Figures 2A−C. The mass spectrum of unaltered wild-type rSAv (Figure 2A) shows the mass of a subunit is 13270.5 amu (total mass of tetramer is 53082 amu). The mass spectrum for succinylated rSAv is shown in Figure 2B. Note that rSAv was added as an internal standard (i.e., peaks at 13270 amu and 13294 amu). Aside from peaks for the rSAv standard, the major peaks for the modified rSAv subunits reacted with 50 equiv of

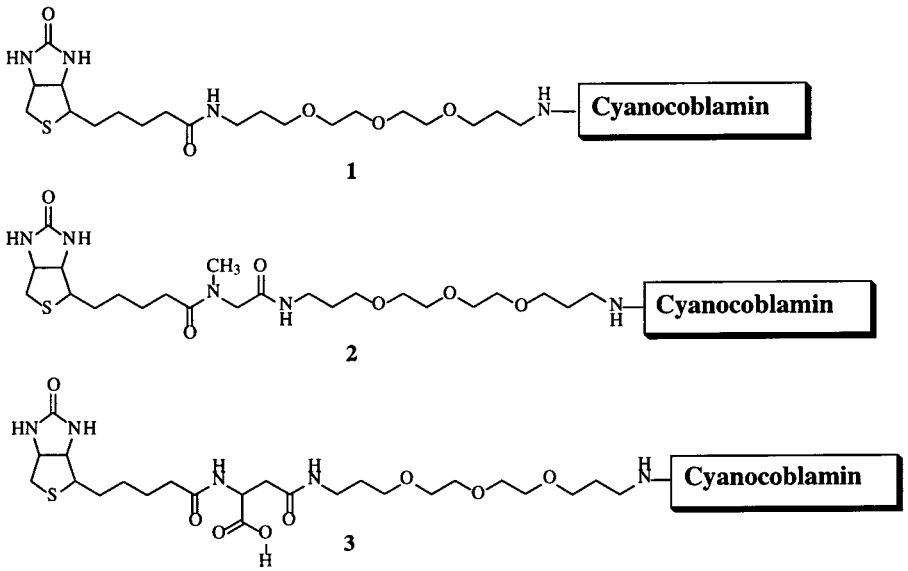

Figure 3. Structures of biotin derivatives **1**−**3** used in rSAv binding studies. The cyanocobalamin chromophore (360 nm) allows UV quantification without interference from protein absorbance (i.e., 280 nm). The biotin derivatives were obtained as previously described (*21*).

succinic anhydride have masses of 13471 amu (100%;+200 amu over rSAv) and 13571 amu (85%; +300 amu) with a number of additional peaks present being due to sodium adducts. Since conjugation of a succinic anhydride adds a mass of 100 amu to the protein, the mass spectral data indicates that the majority of subunits have two or three succinic anhydride molecules conjugated. The mass spectrum for arginine-modified rSAv is shown in Figure 2C. Conjugation of 1,2-cyclohexanedione to form adduct A (Scheme 1) increases the mass of the protein by 112 amu, but rearrangement to form adduct B (Scheme 1) results in a mass increase of only 94 amu. Reaction of 200 equiv of 1,2-cyclohexanedione with rSAv produces a mixture of modified proteins with mass peaks for modified subunits of 13366 amu (72%; +95 amu), 13383 (46%; +112 amu; B), 13459 (100%; + 188 amu), 13478 (53%; +207 amu), 13497 amu (48%; +226 amu); 13555 amu, (38%; +284 amu), 13569 amu (63%; + 299 amu) and 13569 (37%; +320 amu). The mass spectral data indicate that both adducts (A and B) are obtained under the conjugation conditions employed in this investigation. The data indicate that there were one to three adducts per rSAv subunit, and the molecular weight increases correlate with the two types of adducts being present on rSAv (from the listing above) in the following combinations; rSAv plus: B (+94 amu), A (+112 amu), BB (+188 amu), BA(+206 amu), AA(+224 amu), BBB(+282 amu), BBA(+300 amu), and BAA(+318 amu).

The specificity for arginine versus lysine residues in the conjugation with 1,2-cyclohexanedione was assessed by conducting amino acid analyses. Unmodified rSAv was run as a control. The analyses indicated that about 40% of the arginine residues were modified (i.e., amount of arginine decreased) by reaction with 1,2-cyclohexanedione. This implies that an average of 1.6 arginine residues per subunit reacted. Importantly, no change in the quantity of lysine was found, confirming that the cyclohexanedione reaction was specific for arginine residues.

The biotin binding of modified rSAv was of interest. Although it is important to diminish the kidney localization of rSAv for in vivo pretargeting application, it is most desirable that this is done with the retention of the very high biotin binding affinity. Three biotin derivatives containing the cyanocobalamin chromophore (compounds **1**−**3**, Figure 3) were prepared as previously described (*21*), and their binding with rSAv, succinylated rSAv, and 1,2-cyclohexanedione modified rSAv was evaluated. All rSAv samples displayed similar association kinetics for the three biotin derivatives (data not shown). Of more interest were the relative rates of dissociation of rSAv-bound biotin derivatives. In that assay, 4 equiv of the biotin derivative are bound with the rSAv, a large excess of biotin is added, and the amount of released (dissociated) biotin derivative is measured at a 3 h time point (*27*). The relative dissociation rates obtained in this investigation are listed in Table 1. The results indicate that succinylated rSAv retains a slow dissociation rate for the biotin−cyanocobalamin adduct **1**, but arginine-modified rSAv appears to have a slightly faster dissociation rate. In our previous studies, it was shown that biotin adducts containing a sarcosine (*N*-methylglycine) moiety (e.g., **2**) have an increased dissociation rate. It was of interest to determine if the modified rSAv showed similar relative dissociation rates. Indeed, arginine-modified rSAv displayed similar dissociation kinetics to that of unaltered rSAv. Interestingly, the succinylated rSAv appeared to have a slower dissociation rate. The α-aspartate adduct of biotin, **3**, was also evaluated as biotin derivatives currently under investigation incorporate this structural feature to block the biotinamide cleaving action of biotinidase (*28*). Importantly, only a small decrease was noted for the dissociation of **3** from rSAv and succinylated rSAv. Binding of **3** with arginine-modified rSAv showed a somewhat faster dissociation rate.

Comparative Tissue Distribution Studies. A tissue distribution study was conducted to compare succinylated rSAv with arginine-modified rSAv. In the study, the proteins were labeled (^{125}I or ^{131}I) and were coinjected into athymic mice so that a direct comparison could be made. Unlike most proteins, direct radioiodination of rSAv provides a radiolabel that is not susceptible to in vivo deiodination (*23*), presumably because the rSAv is highly resistant to protease degradation. Importantly, use of radioiodination methods that employ conjugates, such as [I*]iodobenzoates (*29*), was not an attractive alternative for these studies, as a decrease in kidney localization had been previously observed when rSAv was radioiodinated with a *p*-[I*]]iodobenzoyl labeling moiety (*23*). Thus,

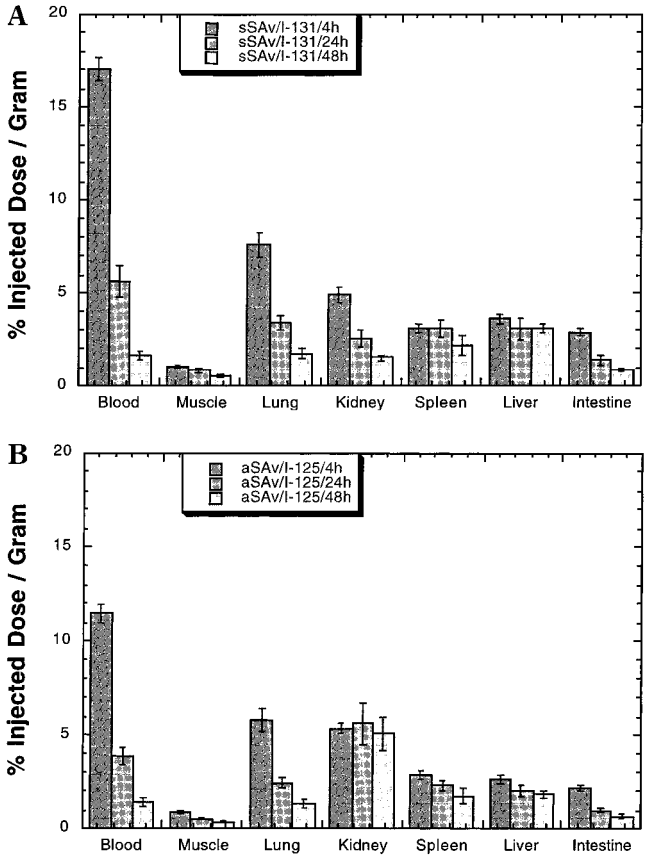

Figure 4. Graphs of the data obtained from the biodistribution of (coinjected) arginine-modified [^{125}I]rSAv and succinylated [^{131}I]rSAv in 15 athymic mice. The data obtained for each reagent (radionuclide) is shown in a separate graph for simplicity. Graph 4A shows the tissue distribution of succinylated (50 equiv) [^{131}I]SAv at 4, 24, and 48 h pi. Graph 4B shows the plotted data for arginine-modified [^{125}I]rSAv at 4, 24, and 48 h pi. The mice were placed on biotin-free diets for 7 days prior to the initiation of the experiment. Five animals were used per time point.

methods of radiolabeling that modified the surface amine groups could not be used because that would complicate the interpretation of the effect of arginine modification on the kidney localization.

We chose to use athymic mice, to place them on biotin-free diets for 7 days prior to the study, and to administer a total of 100 μg of rSAv to each mouse so that the results would reflect their distribution in the athymic mouse xenograft model used in our pretargeting studies. The results of the biodistribution of succinylated [^{131}I]rSAv and arginine-modified [^{125}I]rSAv at 4, 24, and 48 h pi are shown graphically in Figures 4A and 4B, respectively (full data provided as Tables 2 and 3 in Supplemental Information). While kidney localization at 4 h pi is similar for the two modified rSAvs, kidney retention of radioactivity at 24 and 48 h pi is much higher for arginine-modified rSAv. As noted in previous studies (*17*), the retention of the succinylated rSAv in blood is higher than that of the arginine-modified rSAv. It also appears that there are higher concentrations of succinylated rSAv in the liver and spleen than for the arginine-modified rSAv, but this may be due in part to the higher blood concentration.

Varying Levels of Succinylation. An evaluation was conducted to determine how the extent of rSAv modification with succinic anhydride affected kidney localization. In the experiment, 5, 10, 25, and 50 equiv of succinic anhydride were reacted with rSAv. As an initial step in

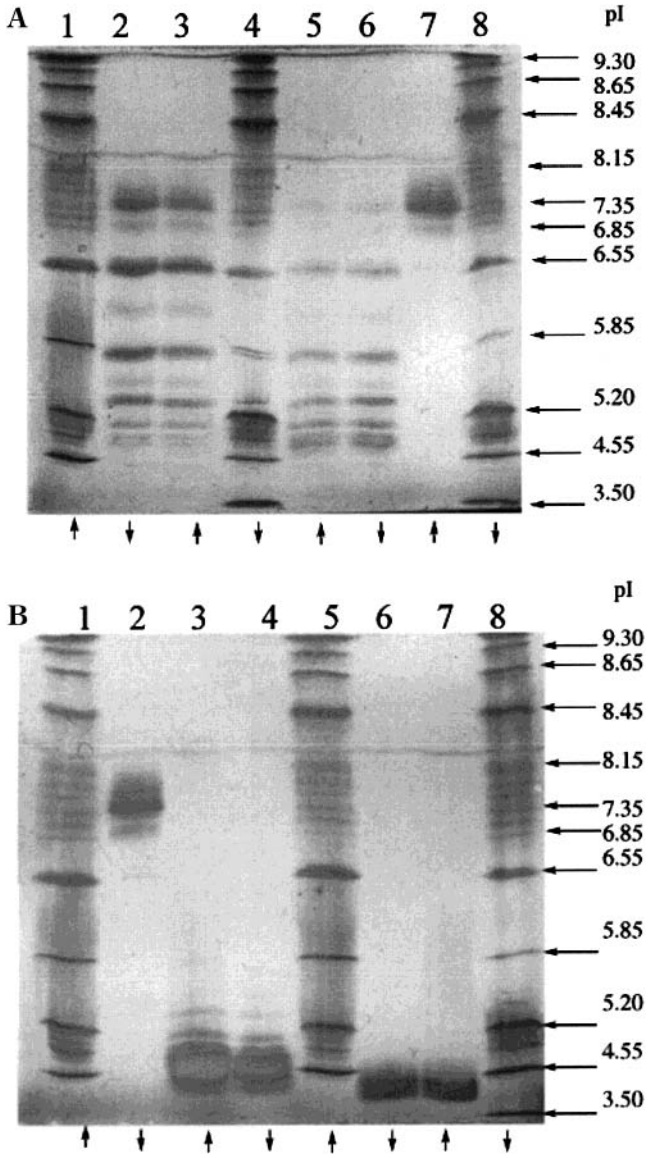

Figure 5. Digitized images of IEF gels (A and B) showing the rSAv products obtained when modified with various quantities of succinic anhydride. Samples were placed on opposing sides of the gel and run in two different directions to ensure equilibrium was reached. Arrows at bottom of lanes depict direction of sample movement. (A) Lanes 1, 4, and 8: IEF standards (isoelectric calibration kit, broad pI; 3−10) run in opposite direction to application of the adjacent sample. Lanes 2 and 3: rSAv succinylated with 5 equiv of succinic anhydride. Lanes 5 and 6: rSAv succinylated with 10 equiv of succinic anhydride. Lane 7: rSAv which has not been succinylated (control). (B) Lanes 1, 5, and 8: IEF standards (isoelectric calibration kit, broad pI; 3−10) run in opposite direction to application of the adjacent sample. Lane 2: rSAv which has not been succinylated (control). Lanes 3 and 4: rSAv succinylated with 25 equiv of succinic anhydride. Lanes 6 and 7: rSAv succinylated with 50 equiv of succinic anhydride.

the evaluation, the product of each of these reactions was evaluated by IEF. The IEF obtained are shown in Figure 5A and 5B. Modification of rSAv by reaction with 5 equiv of succinic anhydride yielded a major component (pI ∼6.6) and four minor components (pI ∼6.0, 5.8 5.3, 5), but left 50% of the rSAv unmodified (pI ∼7.4−7.8). The modified rSAv from the reaction of 10 equiv of succinic anhydride contained only a trace of unaltered rSAv and a small quantity of the component at pI ∼6.6, but had four major components (pI ∼5.8, 5.3, 5, and 4.7). The modified rSAv from the reaction of 25 equiv had all components in a

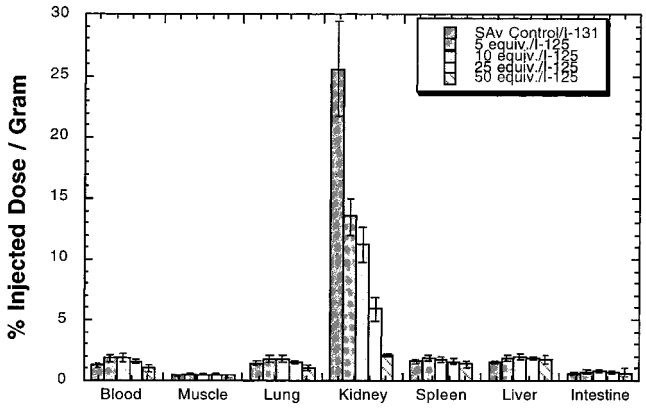

Figure 6. Graph of the biodistribution of [^{125}I]rSAv that has been modified with 5, 10, 25, or 50 equiv of succinic anhydride. A control [^{131}I]rSAv was coinjected with each of the preparations, and an example is shown for comparison in the graph. The biodistribution was obtained in 20 athymic mice (five per time point) at 24 h pi.

broad band (pI $\sim$ 4−5). The modified rSAv obtained in the reaction of 50 equiv of succinic anhydride was very acidic, with all components merging in a broad band at pI $\sim$3.8−4.5.

Biodistributions were determined for each of the rSAv preparations that had been modified with varying amounts of succinic anhydride. In contrast to the direct comparison of 1,2-cyclohexanedione and succinic anhydride modified rSAv, (1) the mice were not placed on biotin free diets, (2) smaller quantities of protein were administered (i.e., 30 μg/mouse), and (3) the distributions were examined at only one time point (i.e., 24 h pi). These changes were made to simplify the study, as it was believed that the conditions in the previous study were not required for this evaluation. The results of the study are shown graphically in Figure 6. The data indicate that the level of succinylation dramatically influences the kidney concentration of streptavidin. Although lower absolute concentrations (%ID/g) were observed in the blood in this study, a similar increase in concentration of succinylated rSAv over the unmodified rSAv was noted. The lower blood concentrations are believed to be due to the smaller amount of protein administered, but may also be due to the fact that the mice were not placed on biotin-free diets prior to conducting the biodistribution, or due to other factors that are not obvious.

DISCUSSION

The purpose of this investigation was to compare succinic anhydride-modified rSAv with arginine-modified rSAv, both being potential reagents for use as carriers of radionuclides in "two-step" pretargeting protocols. Although a number of studies have been conducted to evaluate the use of SAv as a carrier of radionuclides in pretargeting protocols (*30*−*36*), more recently most pretargeting studies have been focused on using biotin derivatives as carriers of the radionuclide. Our laboratory is particularly interested in the application of α-particle emitting radionuclides, such as At-211 and Bi-213, to therapy of metastatic cancer. At present it appears that the most promising approach to deliver these radionuclides to cancer cells in vivo is to use a monoclonal antibody-based pretargeting protocol. Thus, we have been developing new biotin and SAv pretargeting reagents for this application (*37*). While we are investigating the use of biotin derivatives as radionuclide carriers in pretargeting, we are also interested in using rSAv as a carrier. The rationale for using rSAv as a carrier molecule is based on the fact that it is cleared much more slowly from the blood than biotin derivatives (*24*), its slow degradation may provide stability to the radiolabel, and its increased blood circulation time may permit injection of smaller quantities of these expensive isotopes. Further, we believe that the toxicity of α-emitting radionuclides that decay while circulating in the blood stream will be minimal due to the short path length of the α particle. Preliminary studies involving the use of monoclonal antibodies labeled with α-emitters for bone marrow conditioning in transplantation seem to support that belief (*38*).

SAv has an inherently high and sustained kidney localization (*13*,*30*). This fact could preclude its use as a carrier of radionuclide in pretargeting protocols, so methods of decreasing the kidney localization have been of interest. The ideal rSAv for carrying radionuclides in pretargeting protocols would circulate freely in the blood without localization to tissues other than tumor sites. While kidney localization is dramatically decreased after modification, inspection of the biodistributions of succinylated rSAv (Figure 4A) and arginine-modified rSAv (Figure 4B) indicates that neither of these proteins are ideal carriers. This statement is made, as the concentration of radioactivity in spleen and liver of the mouse model does not diminish as the blood concentration decreases in the distribution of either modified rSAv. Perhaps more troubling is the fact that the kidney concentration of the arginine-modified rSAv does not decrease, suggesting that the radioactivity is trapped there. The biotin binding characteristics of an ideal rSAv molecule for pretargeting is less obvious. It seems likely that the 10−15% faster dissociation rates observed for biotin derivative, **1** or **3**, binding with arginine-modified rSAv versus succinylated rSAv would have little effect when short half-lived (α-emitting) radionuclides are used for in vivo applications. A factor that supports use of succinylated rSAv over arginine-modified rSAv is the fact that it is less heterogeneous (by mass spectral analysis, Figure 2B and 2C).

While the properties of succinylated rSAv may be only marginally better than arginine-modified rSAv, we will continue to use it in the development of pretargeting protocols for α-emitting radionuclides. To improve succinylated rSAv's properties, it will need to be optimized. Evaluation of the amount of succinylation required to attain low levels of kidney localization was conducted by studying the products obtained from reaction of 5, 10, 25, and 50 equiv of succinic anhydride. The results obtained from that evaluation clearly indicate that high levels of succinylation are required to eliminate the inherent kidney localization. The IEF (Figures 5A/5B) and biodistributions (Figure 6) of modified rSAv obtained from varying levels of succinylation show that the pI must be lower than 4.5 to diminish the kidney concentration to blood levels. This can be contrasted to the observation that the pI of arginine-modified rSAv is higher (5.2−6), but achieves a similar level of kidney localization at 4 h pi (Figure 4). Although these data provide the basis for using high levels of succinic anhydride to modify the lysine residues, it is interesting to assess the number lysine amines modified in rSAv. The gene for streptavidin encodes for a protein that has eight lysine residues per subunit (*39*); however, postsecretory modification of SAv (*40*) provides a "core" protein that is truncated at both the C and N termini, resulting in a protein that has only four lysine residues per subunit (*41*). Recombinant "core" streptavidin, depending on the

termini chosen, may have three or four lysine residues per subunit (*42*, *43*). In the rSAv studied, there are three lysine residues. The mass spectral data indicates that two to three lysines per subunit are modified when 50 equiv of succinic anhydride are reacted for 30 min at room temperature.

Our goal for this research was to evaluate whether one method provided a more optimal rSAv for use in pretargeting; however, some interesting observations can be made pertaining to kidney localization of SAv. It has been hypothesized by Wilcheck et al. that the high kidney localization of SAv is due to a surface sequence of amino acids, RYD, which they propose is close enough to the fibronectin binding sequence RGD to bind receptors (*14*,*15*). It appeared that a simple test of this hypothesis might be to modify one of the amino acids in the RYD sequence. Arginine was thought to be the best candidate for modification, as it appeared to be the easiest to selectively modify. Fortunately, the amino acid sequences for SAv and rSAv are known (*39*,*42*), and crystal structures for many SAv variants are available from the Brookhaven Protein Data Bank. For recombinant SAv, molecular modeling has indicated that one of the four arginine residues (R53) present per subunit is on the surface formed by the amino terminal sequence in residues ~13−57, and another arginine residue (R84) is on a loop between β-strands in a buried section of the surface (*43*). Both of these arginine residues appear to be solvent accessible, making it likely that they could be modified. The other two arginine residues (R59 and R103) appear to be in the buried hydrophobic regions. Interestingly, the RYD sequence is present as R59,Y60,D61, of which the aspartic acid residue (D61) appears to be surface-exposed whereas the arginine and tyrosine are not. However, it is possible this sequence could become exposed to the surface at the high pH used in the modification reaction after ionization of the carboxylate of the aspartic acid and the phenol of the tyrosine residues. Therefore, one might predict that 1−3 arginine residues could be modified in the reaction with 1,2-cyclohexanedione, and that is what was found.

Despite the data presented herein that suggests a modification of a minimum of two lysine residues per subunit are required to alleviate kidney localization, other data seem to indicate that modification of as few as one lysine, or one arginine, per subunit may be all that is required. For example, mass spectral data from the modification of arginine with 1,2-cyclohexanedione that displayed low kidney concentrations had only one arginine residue blocked. This would seem to indicate that modification of one specific arginine (per subunit) is required to diminish kidney localization. Additionally, it was noted that minimal derivatization of rSAv with succinic anhydride (e.g., 5 equiv offered per SAv tetramer) decreased the kidney localization by 50% (Figure 6). In that preparation, the IEF indicated that about 50% of the rSAv subunits were not modified, and the remainder of rSAv subunits may have only a single modification site. Further, previous studies have shown that conjugation of only one [^{125}I]iodobenzoate[4] to the SAv tetramer resulted in a decrease in the kidney concentration by 25% (*17*). These results seem to indicate that a single (solvent accessible) lysine amine per subunit is required for kidney localization. Even if modification of only one residue is required, complete modification of the four identical lysine or arginine residues in the tetrameric SAv requires an excess of reagents, and it can be expected that other lysine amines or arginine residues would be modified under those conditions. Interestingly, the lysine and arginine modification results are consistent with both the RYD binding hypothesis and another hypothesis put forth by Mogensen and Solling (*44*). They hypothesized that tubular reabsorption of proteins comes about by binding between a free positive amino or guanidinium group in the protein molecule and a negative site on the tubular cell surface. Our results appear to be consistent with this hypothesis as well. The results obtained indicate that modification of either lysine or an arginine residue greatly diminishes kidney localization over that of rSAv that is not modified. Whether a combination of these functionalities in close proximity is required for kidney localization has not been delineated.

These studies have not provided adequate evidence to state that a specific amino acid sequence, such as the RYD sequence, or that a specific amino or guanidinium functionality is required for kidney localization. We previously proposed that altering the charge on the rSAv to be highly negative with succinylation blocked its ability to cross the glomerular wall (*17*). This possibility has not been substantiated or refuted in these studies. Based on the observation that radioiodinated rSAv is retained in cells when internalized, the fact that the kidney concentration of succinylated rSAv continues to decrease with time may indicate that it is not internalized by the proximal tubular cells in the kidney. Since the kidney concentration in the arginine-modified rSAv does not change with time, it seems likely that it is internalized by the proximal tubular cells. Perhaps the best method to determine whether specific amino acids or amino acid sequences are responsible for kidney localization is to conduct site-directed amino acid substitutions of arginine and/or lysine found at the surface of the rSAv structure and examine the biodistributions of those proteins. We hope to undertake such studies at a later time.

Summary. rSAv was modified by reaction with succinic anhydride and 1,2-cyclohexanedione. The reaction of succinic anhydride is selective for conversion of amine functionalities to succinamide derivatives. The modified rSAv obtained after succinylation was found to bind biotin derivatives with nearly the same affinity as unaltered rSAv. The reaction of 1,2-cyclohexanedione is selective for conversion of guanidinium functionalities on arginine residues to produce a mixture of adducts at high pH. From the biotin derivative binding studies, it appears that biotin binding with arginine-modified rSAv has slightly lower affinity. Differences in the in vivo data were not striking. In both reactions, the modified rSAv was found to have relatively low concentration in kidneys of mice. However, the kidney concentration of the succinylated rSAv continued to decrease with time, whereas it remained constant in the arginine-modified rSAv. Additional studies demonstrated that high levels of succinylation were required to obtain the lowest kidney concentrations. The data obtained from these studies indicate that succinylated rSAv has properties that make it a better choice as a radionuclide carrier in pretargeting protocols than arginine-modified rSAv.

ACKNOWLEDGMENT

We would like to thank personnel at NeoRx Corporation for their discussion of the arginine modification approach. That discussion led to the investigation de-

[4] It is probable that only one [^{125}I]iodobenzoate group was conjugated per SAv tetramer because of the very small quantity of high specific activity radiolabeled compound used in the conjugation reaction.

Surface-Tethered DNA Complexes for Enhanced Gene Delivery

Tatiana Segura[†] and Lonnie D. Shea[†,‡,*]

Departments of Chemical Engineering and Biomedical Engineering, Northwestern University, 2145 Sheridan Road E156, Evanston, Illinois 60208-3120. Received November 2, 2001; Revised Manuscript Received February 6, 2002

Overcoming the barriers to efficient gene transfer is a fundamental goal of biotechnology. A versatile approach to enhance the delivery of nonviral DNA involves complexation with cationic polymers, which can be designed to overcome the barriers to effective gene transfer. More recently, DNA release from a polymer substrate or scaffold has been shown to enhance gene transfer, likely by increasing DNA concentrations in the cell microenvironment. We propose a novel approach that combines these two strategies in which cationic polymer/DNA complexes are tethered to a substrate that supports cell adhesion. The cationic polymers package the DNA for efficient internalization and the surface tethering functions to maintain elevated concentrations in the cell microenvironment for cells adhered to the substrate. The cationic polymer polylysine (degree of polymerization equal to 19 or 150) was modified with biotin groups, which was confirmed by mass spectrometry and biochemical analysis. Complex formation of DNA with biotinylated-polylysine, or mixtures of biotinylated and nonbiotinylated polylysines, was confirmed by gel electrophoresis. Plasmid DNA encoding for the reporter gene β-galactosidase was complexed with different mixtures of biotinylated and nonbiotinylated polylysine and incubated on neutravidin (nonglycosylated avidin)-coated surfaces. DNA surface densities ranging from 0.1 to 4.3 μg/cm^2 were observed and found to be a function of the number of biotin groups, the molecular weight of the polylysine, and the amount of DNA. HEK293T or NIH/3T3 cells were then seeded onto the DNA-modified surfaces, and transfection was quantified at 48 and 96 h. Transfection by the DNA surfaces was observed with both cell lines, and expression levels up to 100 fold greater than bulk delivery of the complexes was obtained. Transfection was found to be a function of the surface DNA quantities and the number of tethers on the complex. Transfected cells were observed only in the region in which DNA complexes were tethered, suggesting that the location of transfected cells can be specifically controlled. Surface tethering of DNA represents a promising approach to enhancing gene transfer and spatially controlling gene delivery, which may have applications to a multitude of fields ranging from tissue engineering to functional genomics.

INTRODUCTION

Developing systems capable of controlled and efficient gene transfer is a fundamental goal of biotechnology, with applications ranging from basic science to clinical medicine. In the area of basic science, increasing or decreasing the expression level of a gene within a cell has the power to reveal or confirm the roles of specific components of signaling pathways and can lead to a mechanistic understanding of cell behavior, disease pathogenesis, and drug action (*1*, *2*). Assays based on cellular responses to altered gene expression allow gene function to be examined within a biological context that is more representative of the physiological situation (*3*, *4*). The growing collection of gene sequences and cloned cDNAs has led to the development of microarrays of cell clusters expressing gene products as a high-throughput approach to screen for a phenotype of interest (*5*). Alternatively, therapeutic strategies using gene delivery are under development for inherited genetic disorders, cancer, and tissue regeneration (*6*, *7*). The successful application of gene transfer for basic science and clinical medicine requires the ability to manipulate the expression of target genes in the desired cell population. Numerous techniques are under development to overcome the barriers to gene transfer, which includes processes such as cellular internalization, endosomal escape, and nuclear trafficking.

Cationic polymers provide a versatile approach for gene transfer, as the polymers can be designed or modified to overcome the barriers to gene transfer (*8*, *9*). Complexation with cationic polymers functions to condense DNA, to produce a complex with a less-negative surface charge, to enhance cellular internalization of DNA, and to protect the DNA from degradation. Although many types of cationic polymers have been explored (*10*−*13*), polymers based on poly(L-lysine) (PLL) (*14*−*16*), poly(ethylenimine) (PEI) (*17*−*19*), and poly(amidoamine) (PAMAM) (*20*, *21*) are among the most commonly utilized. Numerous studies have examined the relationship between the physical properties of the cationic polymer (e.g., molecular weight) with the ability to condense DNA and to efficiently transfer the DNA to cells (*17*, *22*). Complexes are formed at nitrogen:phosphate ratios ranging from 0.5:1 to 20:1 and typically produces complexes with sizes ranging from 50 to 150 nm (*23*−*25*). An advantage of the cationic polymers is that functional domains can be covalently incorporated to design a synthetic vector capable of overcoming the barriers to gene transfer. Fusogenic peptides and other functional groups have been attached to enhance endosomal escape of the DNA complexes (*26*,

27). Alternatively, ligands that bind to specific cell surface receptors have been attached to increase binding of the DNA complexes to the cell surface and can enhance cellular internalization (*28*−*31*).

Recently, the polymeric systems that were developed to deliver biologically active proteins have been adapted to deliver nonviral DNA. Polymeric scaffolds have been fabricated from a variety of materials, both natural (e.g., collagen) and synthetic (e.g., poly(lactide-*co*-glycolide)), which function as a support for cell adhesion and migration (*7*). These scaffolds act to increase the local concentration of DNA within the cellular microenvironment either by providing a sustained release of DNA (*32*) or by maintaining the DNA locally (*33, 34*). Enhanced gene transfer by these polymer scaffolds in vivo likely results from an increased concentration at the cell surface, which has been shown to enhance gene transfer in vitro (*35*).

We present a novel approach toward enhancing DNA delivery that combines DNA complexation with polymeric delivery. DNA is complexed with a cationic polymer and subsequently tethered to a substrate the supports cell adhesion. The cationic polymer polylysine is covalently modified with biotin groups, complexed with DNA, and the resulting complexes are bound to a neutravidin-coated surface. The quantity and location of DNA on the surface can be controlled and cells cultured on the surface are transfected by the surface-associated DNA.

EXPERIMENTAL PROCEDURES

Materials. Plasmid DNA encoding for β-galactosidase (pNGVL1-β-gal) was purified from bacteria culture using Quiagen (Santa Clara, CA) reagents and stored in Tris-EDTA buffer solution (10 mM Tris, 1 mM EDTA, pH = 7.4). Fluorescein tagged β-galactosidase vector (Fl-β-gal) was purchased from Gene Therapy Systems (San Diego, CA). Two polylysine (PLL) peptides were used for DNA complexation: Cys-Trp-Lys_{19} (K_{19}, BioPeptide, San Diego, CA) and Lys_{150} (K_{150}, average molecular weight of 20000, Sigma, St Louis, MO). Avidin and biotin reagents for peptide modification and surface tethering were purchased from Pierce (Rockford, IL). All other reagents were obtained from Fisher Scientific (Fairlawn, NJ) unless otherwise noted.

Synthesis of Biotinylated Polylysine. The peptide K_{19} was modified with a biotin group through the terminal cysteine residue by reaction of the sulfhydryl group with the iodoacetyl group of the biotinylation reagent, EZ-link-PEO-iodoacetyl-biotin. The peptide K_{19} (10 mg) was dissolved in 850 μL of buffer (50 mM Tris, 5 mM EDTA, pH = 8.3) that was previously bubbled with nitrogen gas. The EZ-link-PEO-iodoacetyl-biotin (3.8 mg) was also dissolved in 150 μL of buffer (0.1 M sodium phosphate, 5 mM EDTA, pH = 6.0). The biotin solution was added dropwise to the peptide solution, mixed gently, covered with aluminum foil, and incubated for 90 min. The starting peptide solution and the reaction mixture were analyzed by HPLC to determine if the reaction had gone to completion. The starting peptide solution and the reaction mixture were resolved by injecting 20 μg through a C18 RP-HPLC column eluted with water (0.1% trifluoroacetic acid (TFA)) and an acetonitrile gradient (0.1% TFA, 0 to 95% over 50 min at 60 °C) while detecting the absorbance at 260 nm. For purification, sephadex (G15) was equilibrated in deionized water for 30 min prior to packing in a glass column (2 cm diameter × 12 cm height). The reaction mixture was passed though the column using deionized water. Twenty fractions were collected, and the presence of the tryptophan side chain was examined by measuring the absorbance at 260 nm (Beckman Instruments Inc., Fullerton, CA). The fractions with the greatest absorbance at 260 nm were lyophilized (Labconco Corp., Kansas City, MO) and analyzed by mass spectrometry. The purified biotinylated peptide (K_{19}-B) was stored as a powder at −20 °C.

The peptide K_{150} was biotinylated using succinimide ester (NHS)/amine chemistry. K_{150} (10 mg) was dissolved in 1 mL of phosphate buffered saline (PBS, pH = 7) and EZ-link-Sulfo-NHS-LC-biotin (2.8 mg) was added directly to the solution, mixed gentlyb and incubated for 2 h at 4 °C. The reaction mixture was purified using dialysis cassettes immersed in deionized water. The dialyzed product was further purified using a monomeric avidin column to separate the biotinylated components from nonbiotinylated species. The biotinylated product was eluted with 10 mL of a 10 mM biotin solution and dialyzed to remove the unconjugated biotin. The purified biotinylated peptide (K_{150}-B) was then lyophilized and stored as a powder at −20 °C. The degree of biotinylation of K_{150}-B was determined by quantifying the mole ratio of biotin to K_{150} using 2-(4′-hydroxyazobenzene)benzoic acid (HABA). The absorbance at 500 nm of a HABA/avidin solution in PBS was recorded before and after the addition of the K_{150}-B and used to calculate the molar ratio of biotin to K_{150}.

Complex Formation and Surface Tethering. The ability of the biotinylated and nonbiotinylated polylysine (K_{150}, K_{150}-B, K_{19}, K_{19}-B) to condense DNA was assessed by gel electrophoresis. Biotinylated and nonbiotinylated peptides were mixed and added in a stepwise manner (1 μL of 1 mg/mL) to a DNA solution (200 μL of 20 μg/mL). After each addition step, the solution was vortexed for 4 s and incubated for 10 min and a sample (10 μL) removed. Upon complete addition of peptide, trypsin was added to digest the polylysine. Gel electrophoresis was performed to assess the extent of complex formation for the samples and the trypsin-digested DNA solution.

DNA/PLL complexes were incubated on surfaces to specifically tether the complexes through the biotin−neutravidin binding. DNA (90 μL of 44.4 μg/mL) was complexed at a charge ratio (±) of 5.5:1 with the four peptides (K_{150}, K_{150}-B, K_{19}, or K_{19}-B) individually or with mixtures of biotinylated and nonbiotinylated peptides. The number of tethers on each complex is varied by mixing biotinylated and nonbiotinylated PLLs prior to complexation with DNA. Complexes were incubated after mixing for 30 min at room temperature and then allowed to bind to prewashed neutravidin coated surfaces for 2 h. The unbound complexes were then removed from the wells and washed with tris-buffered saline (TBS). The surface quantities of DNA were determined by incubating with trypsin (100 μL) at 37 °C for 2 h to degrade the PLL and release the DNA into solution. The quantity of DNA was measured with a fluorometer (Turner Designs TD-360) using the Hoechst dye. Tethered DNA complexes were visualized by fluorescence microscopy using the Fl-tagged β-galactosidase vector before and after washing with TBS.

Cell Culture and Transfection. Transfection of cells on the DNA-modified surfaces was examined using a β-galactosidase plasmid and two cell lines (HEK293T and NIH/3T3). Polyethyleneimine (PEI, 22 kDa, MBI−Fermentas, Hanover, MD, 0.5 μL of 10 μM) was added to DNA-modified surfaces and incubated for 5 min. Cells were then plated and cultured on the surfaces for 48−96 h and then lysed for assay of the β-galactosidase enzyme activities (Promega, Madison, WI) and protein levels (BioRad, Hercules, CA). Alternatively, cells were

stained with X-gal to determine the location of transfected cells. HEK293T and NIH/3T3 were cultured at 37 °C and 5% CO_2 in Dubelcco's modified eagle medium (DMEM, Life Technologies, Gaithersburg, MD) supplemented with 10% heat inactivated FBS and 1% penicillin/streptomycin.

Control experiments to characterize the effectiveness of surface-mediated delivery were performed by using bulk delivery of DNA complexed with the nonbiotinylated K_{150} or K_{19}. For bulk delivery of K_{150}/DNA complexes, the quantity of DNA delivered was determined based on the amount of surface associated DNA obtained when DNA was complexed only with K_{150}-B. For bulk delivery of K_{19}/DNA, the quantity of DNA delivered was determined based on the amount of surface-associated DNA obtained when DNA was complexed with a mixture of K_{150}-B/K_{19}, which had a predominance of K_{19} over K_{150}-B. Upon formation of the K_{150}/DNA and K_{19}/DNA complexes, PEI was added at the same molar ratio of DNA:PEI that was used for the substrate-mediated delivery. For the bulk delivery experiments, HEK293T and NIH/3T3 cells were plated at 1 day prior to transfection and cultured in complete media.

RESULTS

PLL Biotinylation and DNA Complexation. Polylysine was covalently modified with biotin residues either through an N-terminal cysteine side chain (K_{19}) or through an amine (K_{150}). HPLC analysis of the initial peptide (K_{19}) and the peptide reaction mixture (K_{19}-B) demonstrated that the reaction proceeded to completion (Figure 1a), as evidenced by the increase in molecular weight in the reaction mixture and the absence of the lower molecular weight K_{19} peak. Mass spectrometry (Figure 1b) suggests that the approach for modifying the peptide K_{19} results in the attachment of a single biotin group. A good correspondence was found between the theoretically expected molecular weight for K_{19} modified with a single biotin (3158 Da) and the experimentally obtained molecular weight (3157.66 ± 0.77 Da). Alternatively, the chemistry employed for modification of K_{150} allows for multiple biotin residues to be attached per PLL. The K_{150}-B synthesis resulted in a 3.1:1 molar ratio of biotin to K_{150} by using a 10:1 molar ratio of biotinylation reagent to K_{150} in the reaction mixture.

Biotinylated and nonbiotinylated peptides were subsequently analyzed for their ability to complex with DNA using gel electrophoresis. The nonbiotinylated peptides (K_{19}, K_{150}) completely eliminate the electrophoretic mobility at charge ratios of 3.1 and 1.2, respectively (Figure 2a,c). However, the presence of the biotin group on the peptide affected the charge ratio at which the mobility is eliminated, which is 4.6 and 4.9 for K_{19}-B and K_{150}-B, respectively (Figure 2b,d). Mixtures of K_{150}-B with K_{19} were also examined by gel electrophoresis for DNA complexation at a charge ratio of 5.5:1. The inhibition of mobility was observed for all combinations of the two peptides (Figure 2e−g). The results of Figure 2 illustrate that the biotinylated peptides, nonbiotinylated peptides, and mixtures of biotinylated and nonbiotinylatd peptides are capable of electrostatically neutralizing plasmid DNA and eliminating its electrophoretic mobility.

Surface Tethering of DNA/PLL Complexes. DNA complexed with biotinylated PLL was examined to determine if the biotin groups on the PLL were available for tethering to a surface using the affinity of biotin for neutravidin (nonglycosylated avidin). Surface-associated DNA was visualized for DNA complexed with K_{150}-B.

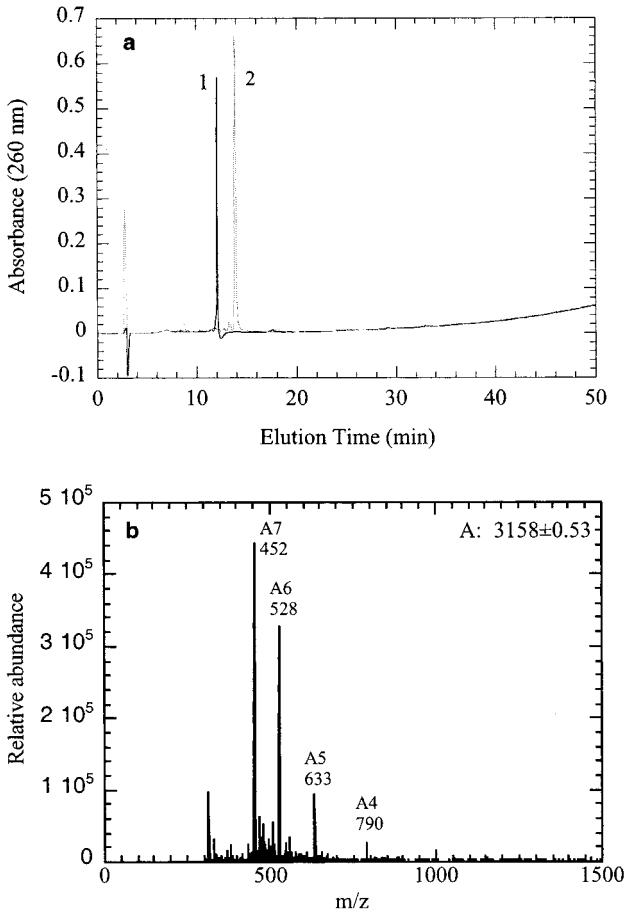

Figure 1. HPLC and mass spectrometry confirm the formation of biotyinylated K_{19}. (a) HPLC of the K_{19} starting material **1** and the reaction mixture **2**. The shift in molecular weight between **1** and **2** and absence of the low molecular weight peak in **2** confirmed that the reaction went to completion. (b) Mass spectrometry of the purified reaction mixture.

Fluorescence images taken after the initial incubation on the surface and before the wash demonstrates the presence of complexes across the entire surface (Figure 3a). Thorough washing of the surfaces resulted in a reduction of the quantity of surface-associated DNA (Figure 3b). All subsequent studies used surfaces that were thoroughly washed to ensure binding specificity of the complexes.

The quantity of surface associated DNA was subsequently measured as a function of the PLL peptides and the number of biotin groups per complex. Nonbiotinylated peptides used for DNA condensation resulted in low surface densities (<0.1 μg DNA/cm^2) due to nonspecific adsorption. The use of biotinylated peptides for DNA complexation increased the surface density of DNA relative to the conditions lacking biotin groups ($p < 0.05$), suggesting that biotin groups are available on the DNA complexes for interactions with the surface-associated neutravidin. The maximal amount of surface-associated DNA was observed for DNA complexes formed solely with biotinylated peptides ($p < 0.001$), with densities of 2.9 and 4.3 μg DNA/cm^2 obtained for K_{150}-B and K_{19}-B, respectively (Figure 4a,b). Complexes formed from either K_{150}-B or K_{19}-B are calculated to have an average number of biotin groups equal to 1705 and 4342, respectively. These surface densities correspond to a tethering efficiency (mass DNA on surface/mass DNA added) of 24% (K_{150}) and 35% (K_{19}). For the K_{150}-B and K_{19}-B, decreasing the amount of DNA incubated on the surface was found

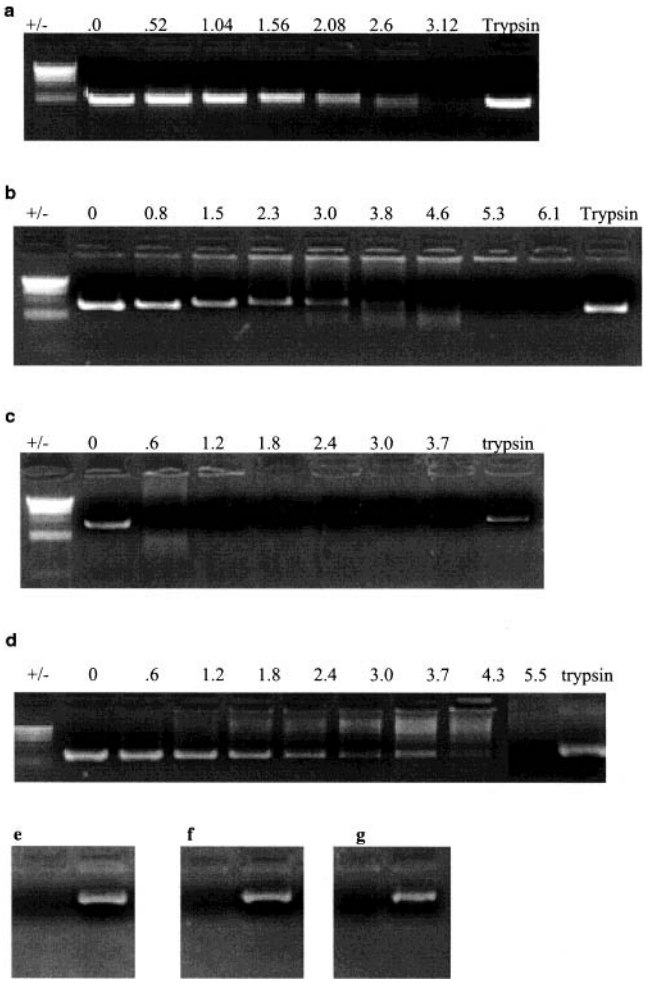

Figure 2. Electrophoretic retardation of DNA complexed with mixture of biotinylated and nonbiotinylated polylysine. (a) Nonbiotinylated K_{19}, (b) biotinylated K_{19}, (c) nonbiotinylated K_{150}, and (d) biotinylated K_{150} were examined at a range of charge ratios. Condensation of DNA with mixtures of K_{150}-B and K_{19} were examined at a charge ratio of 5.5:1. The conditions examined were (e) 50% K_{150}-B/50%K_{19}, (f) 25%K_{150}-B/75%K_{19}, and (g) 5% K_{150}-B/95%K_{19}, where the percentages indicate the amount of each component based on the number of amine groups.

to decrease the amount of surface-associated DNA (data not shown). The quantity of surface-associated DNA was also found to decrease as the number of biotin groups in the DNA/PLL complex decreased. The molecular weight of polylysine, both biotinylated and nonbiotinylated also affected the quantity of surface-associated DNA. For the biotinylated peptide K_{150}-B, fewer numbers of biotin groups were required to obtain an equivalent amount of surface associated DNA as for the peptide K_{19}-B. However, the use of the nonbiotinylated peptide K_{19} for complexation resulted in increased DNA surface densities relative to the use of K_{150}.

Transfection. Culture of HEK293T and NIH/3T3 cells on the DNA-modified surfaces led to cellular transfection at 48 h, with levels of protein production equal to or greater than that obtained by bulk delivery. The transfection experiments used mixtures of K_{150}-B and K_{19} for DNA complexation because this combination had an increased amount of surface associated DNA relative to the other peptide mixtures, particularly when the complexes had few numbers of biotin groups. Quantification of protein expression levels for HEK293T demonstrated that complexes with 28 and 426 biotin groups produced

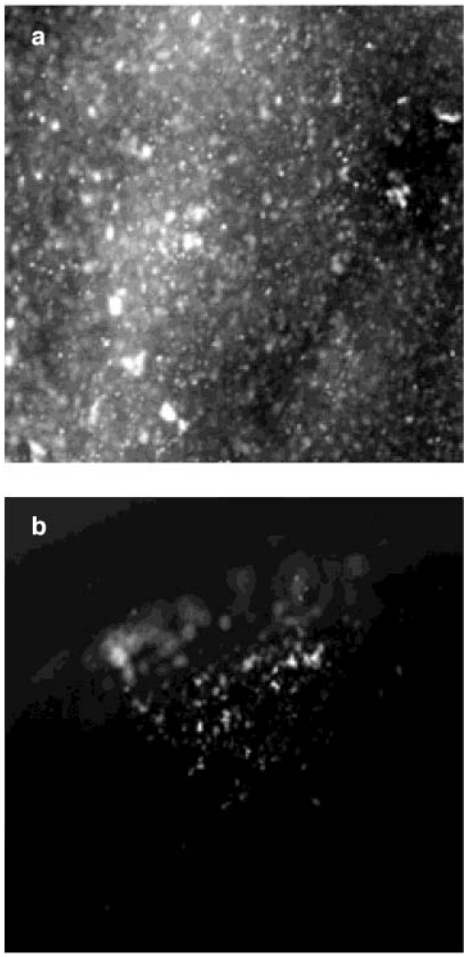

Figure 3. Fluorescence photomicrograph of surface-associated DNA. Fluorescence images taken (a) immediately after surface incubation and (b) after thorough washing.

the maximal transfection (Figure 5a), which was statistically greater ($p < 0.05$) than other conditions with greater numbers of biotin groups. Expression levels obtained for surface-associated complexes with 1705 and 853 biotin groups were not significantly different from the control conditions, which consisted of bulk delivery of DNA complexes formed from either K_{150} or K_{19}. For bulk delivery, the amount of DNA added in complexes with K_{150} or K_{19} corresponded to the surface quantities of DNA for K_{150}-B (1705 biotin groups) and K_{150}-B/K_{19} (28 biotin groups), respectively. These conditions were chosen as the control conditions to represent the limiting cases of surface associated delivery regarding DNA quantities (0.7 μg and 0.16 μg) and PLL composition (K_{150}, K_{19}). For the NIH/3T3 cells, expression levels obtained by surface associated complexes with 28, 426, and 853 biotin were significantly greater than those obtained with complexes containing 1705 biotin residues ($p < 0.05$). No significant difference between complexes with 28 biotin groups and its bulk control ($p > 0.05$) and 1705 biotin groups and its bulk control ($p > 0.05$) were found. The distribution of transfected cells throughout the cell population also differed between the delivery mechanisms. For bulk delivery, transfected cells were seen throughout the cell population (not shown); however, surface-mediated delivery resulted in cells that were transfected in clusters (Figure 6). Additionally, the location of transfected cells on the surface was consistent with the location of surface-associated DNA seen with the fluorescently tagged plasmid (Figure 3b).

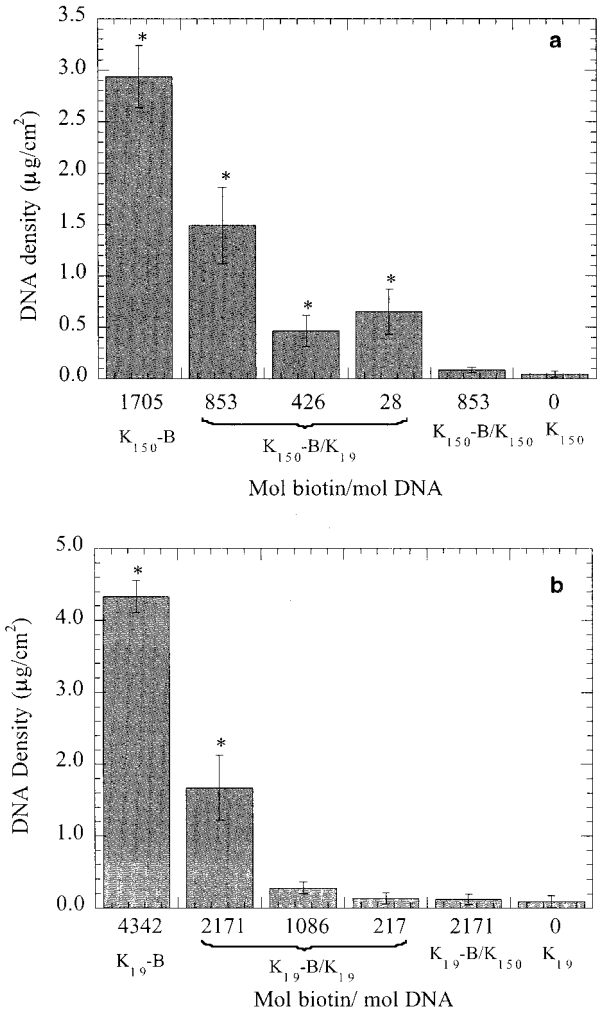

Figure 4. Density of surface-associated DNA. Complexes were formed by mixing DNA with (a) K_{150}-B or (b) K_{19}-B with either K_{19} or K_{150} at a charge ratio of 5.5. The moles of biotin per mole DNA (i.e., average number of biotin groups per complex), which varied from 28 to 1705 for K_{150}-B and 217 to 4342 for K_{19}-B, are listed beneath each bar. The symbol * indicates statistical significance ($p < 0.05$) in the surface densities relative to complexes without biotin.

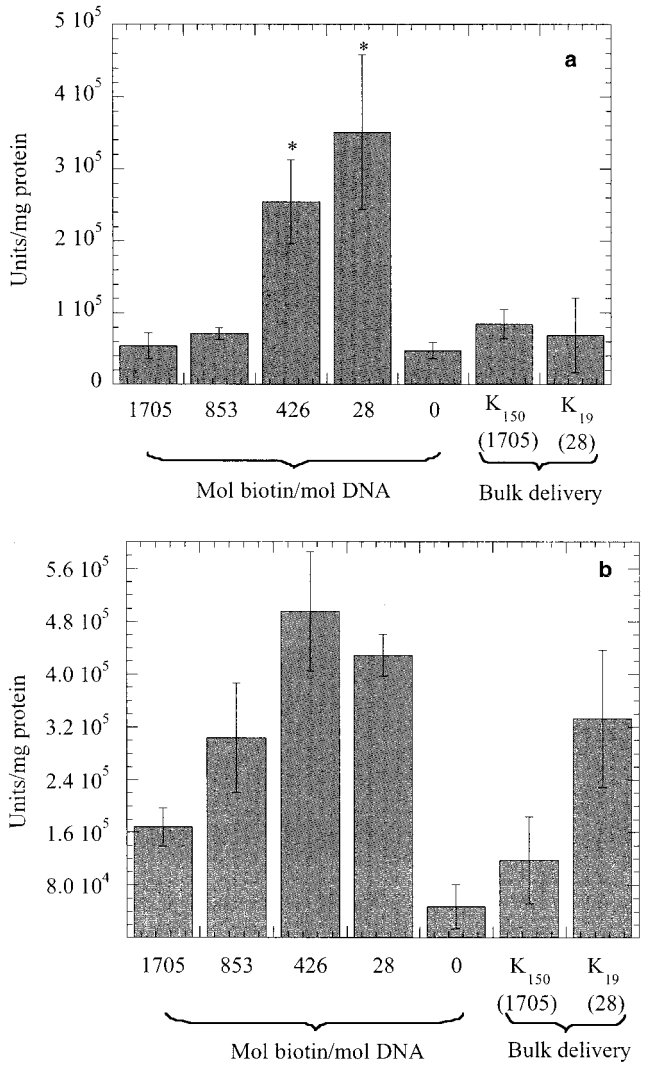

Figure 5. Expression levels by surface mediated transfection after 48 h of incubation. The expression levels for (a) HEK293T and (b) NIH/3T3 cells were determined using an assay for β-galactosidase activity. Bulk delivery of complexes resembling the limiting conditions for surface-associated DNA, 1705 and 28 biotin groups, respectively, were used as a control. For bulk delivery of K_{150}/DNA complexes, the quantity of DNA delivered was determined based on the amount of surface-associated delivery for K_{150}-B that has 1705 biotin groups. For bulk delivery of K_{19}/DNA complexes, the quantity of DNA delivered was determined based on the amount of surface-associated DNA for K_{150}-B/K_{19} that has 28 biotin groups, which has a predominance of K_{19} over K_{150}. The symbol * indicates statistical significance in transfection levels ($p < 0.05$) relative to both bulk delivery conditions.

The expression levels of protein at 96 h by cells cultured on DNA-modified surfaces increased relative to the that observed at 48 h and, for all biotinylated DNA complexes, was greater than that obtained by bulk delivery. Maximal expression levels by HEK293T cells was obtained for the complexes containing 28 biotin groups and was statistically significant from all other conditions tested ($p < 0.05$) (Figure 7a). The expression level decreased as the average number of biotin groups on the complex increased ($p < 0.05$). The complexes formed with K_{150}-B (1705 biotin groups) had the lowest transfection level of the surface associated delivery; however, the expression level was significantly greater than the bulk control ($p < 0.01$). The expression levels for the NIH/3T3 cells were less dependent on the number of biotin groups, yet the decreasing expression levels for increasing numbers of biotin groups was again observed. For all conditions tested with surface associated delivery of DNA complexes tethered to the surface with biotin groups, an increased level of transfection was observed relative to the delivery of nonbiotinylated DNA complexes and the bulk delivery of DNA complexes ($p < 0.01$).

DISCUSSION

This report presents a novel approach to DNA delivery that combines DNA condensation with polymeric delivery by tethering DNA complexes to a surface that supports cell adhesion in order to enhance gene transfer by increasing the concentration of DNA in the cellular microenvironment. In the first step of the process, cationic peptides are covalently modified with a functional group. A mixture of modified and unmodified cationic peptides are then complexed with nonviral DNA, and the resulting complexes are tethered to a substrate, which can support cell adhesion, through the functional group on the cationic peptide. Surface densities of DNA ranging from 0.1 to 4.3 μg DNA/cm^2 were obtained with coupling efficiencies up to 35%. The density of surface-associated DNA was determined to be a function of the

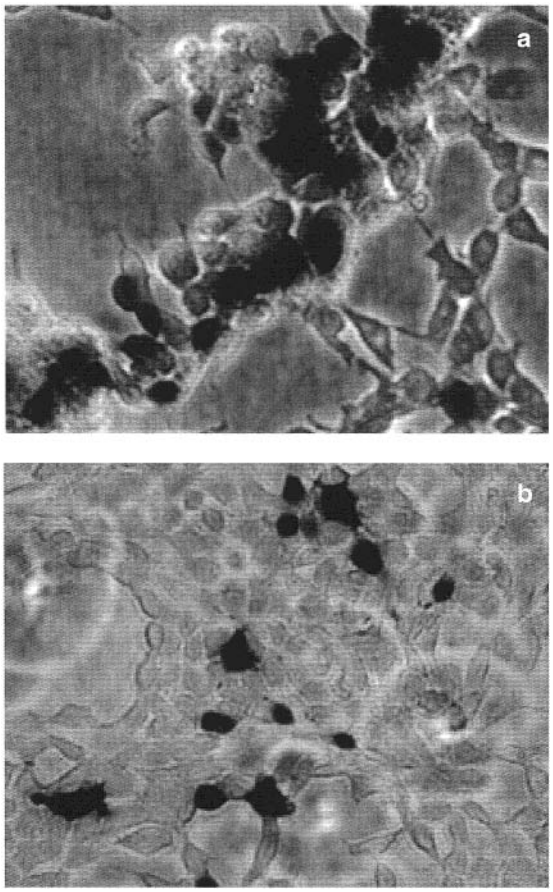

Figure 6. Photomicrograph of cells transfected by surface-associated delivery. (a) HEK293T and (b) NIH/3T3 were stained with X-gal after incubation on surfaces for 48 h.

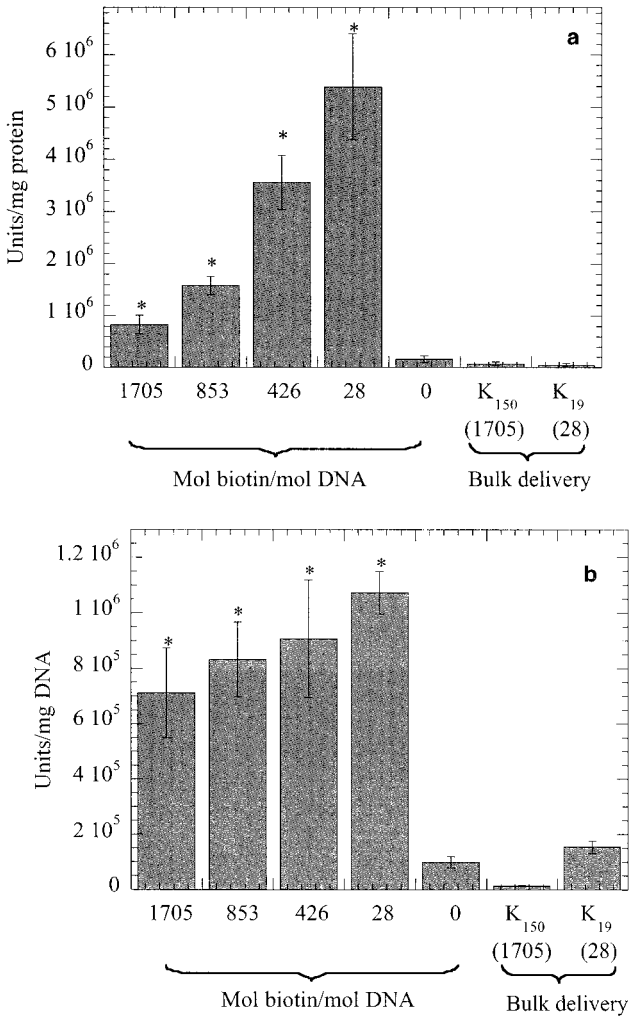

Figure 7. Expression levels by surface-mediated transfection after 96 h of incubation. The expression levels for (a) HEK293T and (b) NIH/3T3 were determined using an assay for β-galactosidase activity. The bulk controls were performed as previously described. The symbol * indicates statistical significance in transfection levels ($p < 0.05$) relative to both bulk delivery conditions.

number of tethers, the molecular weight of the cationic peptide, and the initial amount of DNA. Cells cultured on these surfaces express the transgene, and the level of transgene expression is dependent upon the exposure time of cells to the DNA and the surface tethering. At 96 h of culture, surface-mediated delivery resulted in significantly greater expression of the transgene than that obtained by bulk delivery of similar DNA complexes. Interestingly, the location of transfected cells was consistent with the location to which DNA was tethered.

Cationic polymers are a leading class of transfection reagents, which results from their ability to complex DNA, and their molecular diversity enables the physicochemical properties of the DNA complexes to be manipulated. PLL has been shown capable of condensing DNA into toroidal nanostructures with a radius of gyration less than 150 nm (*23, 24*). However, PLL does not generally produce extensive transfection, and several approaches have been undertaken to enhance its gene transfer efficiency. The internalization of PLL/DNA complexes can be enhanced by the covalent attachment of ligands, such as transferrin (*29*), folate (*36*), lectins (*37*), epidermal growth factor (EGF) (*30*), and RGD peptides (*38*). The ligand functions to direct the DNA complex to the cell surface by specifically binding to a receptor, thus increasing the quantity of DNA at the cell microenvironment (*30*). The approach described in this report utilizes a similar philosophy to enhance the concentration of DNA at the cell surface, with the primary difference being that the "ligand" in our system binds to a substrate, onto which cells can adhere. This strategy of nucleic acid complexes binding to the extracellular matrix to enhance gene transfer has been employed by retroviruses. The different domains of fibronectin can separately support the binding of cells (through integrin receptors) and retroviruses, which results in colocalization of the target cell and the virion and may lead to an enhancement of gene transfer (*39*). Synthetic systems have also been developed that increase cell-surface concentrations of DNA by adsorbing DNA complexes to the surface (*35, 40, 41*) or by releasing or entrapping DNA within a polymeric scaffold (*32, 34*).

The molecular weight of the cationic polymer impacts the ability of the polymer to complex with DNA and, ultimately, the ability of complexes to bind to the surface. Previous reports with polylysine have identified that the optimal molecular weight of the unmodified polymer represents a balance between effective condensation and cytotoxicity. Relative to low-molecular weight, the high-molecular weight PLL forms tighter and smaller condensates that are more resistant to the effects of salt concentration and sonication (*24, 42*). However, cytotoxicity has been found to be inversely related to particle size, potentially due to the high molecular weight PLL (*22*). Our results with the peptides K_{150} and K_{19} on DNA condensation and the electrophoretic mobility are con-

sistent with these reports and suggest that the peptide K_{150} has a higher affinity for DNA than does K_{19}. The attachment of biotin groups affected the ability of polylysine to complex with DNA, as evidenced by the change in the amount of polylysine required to completely eliminate the electrophoretic mobility of the DNA (Figure 2a,c).

For complexes formed with low numbers of biotin groups (28 mol biotin/mol DNA), the mixture of biotinylated, high-molecular weight PLL (K_{150}-B) and nonbiotinylated low molecular weight PLL (K_{19}) proved to be most effective combination for the binding of DNA to the substrate. The increased binding of DNA complexes to the substrate with K_{150}-B as the source of biotin groups was hypothesized to result from the degree of polymerization increasing the probability that the biotin groups are incorporated into the complex and that the incorporated biotins are available for binding. The studies on the elimination of electrophoretic mobility suggest that K_{150}-B and K_{19} have a similar binding affinity for DNA (Figure 2a,d); thus, mixtures of the two peptides with DNA are not expected to favor either peptide for DNA complexation. The increased binding of the K_{150}-B/K_{19}/DNA complexes to the substrate relative to either K_{150}/DNA or K_{19}/DNA suggests that both the biotinylated and nonbiotinylated peptides were incorporated into the complex. The complexes are completely condensed, indicating that K_{19} is involved with complexation (Figure 2g). Additionally complexes are bound to the substrate at levels greater than control, suggesting that biotinylated K_{150} is present in the complex. Our results are consistent with previous studies with EGF modified polylysine (*30*). EGF was attached to a high molecular weight polylysine with the inclusion of a spacer arm, which produced a more nativelike EGF-receptor binding. Conversely, the nonbiotinylated peptide employed had a low degree of polymerization (K_{19}), which was thought to have a reduced affinity for DNA and was thus less likely to displace the biotinylated polylysine.

The number of functional groups incorporated into the DNA complex was found to determine the surface densities of DNA and influence the ability of cells to internalize the DNA. The number of tethers within the complex was regulated through combinations of biotinylated and nonbiotinylated peptide. Increases in the number of tethers per complex led to more surface-associated DNA; however, greater transfection was observed with fewer tethers per complex. This observed relationship between the number of functional groups, the surface quantities of DNA, and the transfection may be explained by the strength of adhesion between the complexes and the surface. Insight regarding the binding of DNA complexes to the surfaces can be obtained from the models that have been developed to describe the binding of multivalent ligands to multivalent receptors (*43, 44*). An increased number of functional groups in the complex would provide more sites for surface-association and thus an increase in the adhesion strength relative to complexes with fewer functional groups. The increased adhesion strength would likely increase the amount of DNA that would remain following the washing procedure. Nevertheless, the increased adhesion strength between the complex and the surface may limit cellular internalization. The DNA must be internalized by the cell and transported to the nucleus for transfection, which may be inhibited if the DNA complex is tightly associated with the surface.

The ratio of lysine/nucleotide that has been used for DNA complexation can range from approximately 0.5 to 6.0. An increase in this ratio produces a more complete condensation of the DNA (e.g., Figure 2) for improved protection against degradation. Additionally, nonspecific adsorption of the complexes to the cell surface has been shown to increase as the lysine/nucleotide ratio increased (*30*). Ratios between 0.9 and 1.3 are expected to have minimal effects due to charge interaction and are more effective for studies with specific cell targeting through attached ligands. The charge ratio used for these studies (5.5) takes advantage of the nonspecific interaction between the DNA complex and the cell. In addition to complexing the DNA, the polylysine may act to modulate the cellular interactions with the surface. Polylysine coating is a commonly used surface treatment for in vitro cell culture experiments. An additional advantage of the increased lysine/nucleotide ratio is the increased number of biotin groups that could associate with the complex and tether the complexes to the surface. The increased lysine/nucleotide ratio may also reduce the strength of interaction between the surface bound polylysine and the DNA complex, which could facilitate cellular internalization.

An interesting result from these studies is that the expression levels increased significantly between 48 and 96 h for the surface mediated DNA delivery but not for the bulk delivery. This result suggests that the DNA is not internalized only at the initial exposure to the DNA, but increasing amounts may be internalized as the cells are adhered to the surface. These effects may result from either a decrease in the number of tethers with time, which would enable more complexes to be internalized over time, or from an increased stability of the complexes. The number of tethers per complex may decrease due to release of the complex from the surface, such as by dissociation of the DNA complex from the biotinylated PLL that is surface bound, or by degradation of polylysine by cell-secreted proteases. Alternatively, the increased gene expression may arise from an increased stability of the complexes over time. DNA complexed with polylysine is known to aggregate over time in the presence of serum (*45, 46*), which may decrease the transfection competence of the complex over time. However, complexes tethered to the surface would be prevented from aggregating and would thus retain their transfection competence. The concept of increased stability due to surface tethering has been demonstrated for proteins, where the tethering of transferrin or insulin to poly(methyl methacrylate) resulting in higher levels of activity that either soluble or physically adsorbed proteins (*47*). Additionally, tethering of EGF to poly(ethyleneoxide)-based hydrogels has also been found to increase its stability and activity when compared to physically absorbed EGF (*48*).

In conclusion, we have described a process to enhance gene transfer through a surface-mediated delivery of DNA complexes. DNA complexes are tethered to surfaces that support cell adhesion through functional groups attached to the cationic polymers. Cells cultured on these surfaces are transfected by the surface-associated DNA and express the transgene. Importantly, transfected cells are localized to the sites at which DNA is tethered, potentially providing a mechanism to spatially regulate gene delivery. This approach may be applied to the development of microarrays of living cells expressing predefined genes for research into functional genomics or to the field of tissue engineering as a means to precisely direct cellular functions within a developing tissue.

ACKNOWLEDGMENT

Development of a Nonviral Gene Delivery Vehicle for Systemic Application

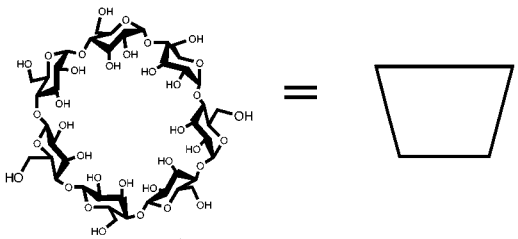
Suzie Hwang Pun[†,‡] and Mark E. Davis*[,†]

Chemical Engineering, California Institute of Technology, Pasadena, California 91125 and Insert Therapeutics Inc., 2585 Nina Street, Pasadena, California 91107. Received November 2, 2001; Revised Manuscript Received January 30, 2002

Polycation vehicles used for in vitro gene delivery require alteration for successful application in vivo. Modification of polycations by direct grafting of additional components, e.g., poly(ethylene glycol) (PEG), either before or after DNA complexation, tend to interfere with polymer/DNA binding interactions; this is a particular problem for short polycations such as linear, β-cyclodextrin-containing polycations (βCDPs). Here, a new method of βCDP polyplex (polycation/DNA composite structures) modification is presented that exploits the ability to form inclusion complexes between cyclodextrins and adamantane. Surface-PEGylated βCDP polyplexes are formed by self-assembly of the polyplexes with adamantane−PEG conjugates. While unmodified polyplexes rapidly aggregate and precipitate in salt solutions, the PEGylated βCDP polyplexes are stable at conditions of physiological salt concentration. Addition of targeting ligands to the adamantane−PEG conjugates allows for receptor-mediated delivery; galactosylated βCDP-based particles reveal selective targeting to hepatocytes via the asialoglycoprotein receptor. Galactosylated particles transfect hepatoma cells with 10-fold higher efficiency than glucosylated particles (control), but show no preferential transfection in a cell line lacking the asialoglycoprotein receptor. Thus, surface modification of βCDP-based polyplexes through the use of cyclodextrin/adamantane host/guest interactions endows the particles with properties appropriate for systemic application.

Cationic polymers are routinely used as transfection reagents for DNA delivery to cultured cells (*1*−*3*). These polycations self-assemble with and condense DNA into small particles termed polyplexes (*4*). When formulated with a net positive charge, polyplexes bind to cell surfaces and are internalized (*5*). Despite laboratory success with polyplexes, cationic polymers are often highly toxic and therefore currently not used in human trials for gene delivery. In addition, polyplex formulations optimized for in vitro delivery are typically not amenable for in vivo use because successful systemic delivery requires very different particle characteristics. After intravenous injection, cationic polyplexes interact with serum proteins and are quickly eliminated from the bloodstream by phagocytic cells (*6*, *7*). Additionally, these polyplexes rapidly aggregate at physiological ionic strengths (150 mM salt concentration). Finally, gene delivery vehicles should ideally target specific cells in the body while cationic polyplexes tend to be primarily taken up by liver Kupffer cells (*8*, *9*). Therefore, cationic polyplexes require modification before they can be successfully applied for systemic gene delivery.

One method of preventing polyplex self-aggregation and undesired interactions with non-self-entities employs steric stabilization of polyplexes with hydrophilic polymers. Poly(ethylene glycol) (PEG) has been conjugated to different nonviral gene carriers, and the resulting PEGylated particles have demonstrated increased salt and serum stability (*10*−*14*). PEG can be grafted onto the reactive primary amine functional groups of cationic polymers. This method has been used for PEGylating polyethylenimine (PEI) and poly(L)lysine (PLL) in order to impart steric stabilization to the particles thus formed (*11*, *15*). In doing so, the charge density of the polymers is reduced. Therefore, this method is often ineffective for short polymers that have lower DNA binding constants, i.e., the polymer−DNA condensation interactions are disrupted (*16*, *17*). An alternative PEGylation approach requires complexation of the cationic polymer with DNA followed by reaction of surface-available amines with activated PEG (*14*). While postcomplexation PEG grafting successfully stabilizes PEI-based polyplexes, PEGylation of low molecular weight polymers by this method may result in disruption of polyplex structure.



Stabilized particles may be directed to the desired organ or cells of interest by the attachment of a ligand for receptor-mediated targeting. For example, conjugation of galactose or other ligands for the asialoglycoprotein receptor can result in targeting to hepatocytes (*6*, *18*−*20*).

A family of β-cyclodextrin-containing polymers (βCDPs) suitable for DNA delivery has been described (*21*, *22*). These polymers contain β-cyclodextrins (cyclic oligomers of glucose) in the polymer backbone and are cationic due to repeating amidine groups. βCDP-based polyplexes show low in vitro (IC_{50} = 1.1 mM) and in vivo (LD_{40} = 200 mg/kg of polymer alone in mice) toxicity and are therefore promising in vivo agents. These polyplexes are subject to the same aggregation and nonspecific interactions noted above for other polyplexes. The goal of our work is to develop a method of modifying βCDP-based polyplexes for in vivo use that mitigates nondesirable

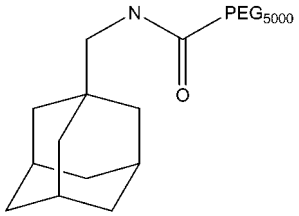
interactions that would be encountered after i.v. administration.

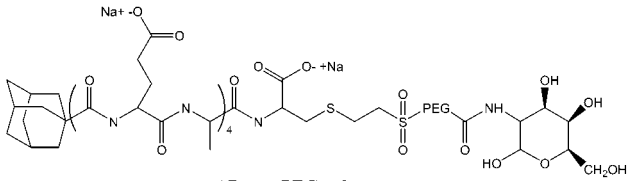


Cyclodextrins have the capability of forming inclusion compounds with hydrophobic moieties. With some molecules, this association can be quite strong. For example, adamantane derivatives have *β*-cyclodextrin association constants (K_a) on the order of 10^4-10^5 (*23*). Complexes between adamantane end-capped poly(ethylene oxide) and cyclodextrin copolymers have also been described (*24*, *25*). Here, we exploit cyclodextrin/guest compound complexation to develop a new method for modifying *β*CDP-based polyplexes. Adamantane is conjugated to a desired polyplex modifier such as PEG, and the resulting compounds are exposed to *β*CDP-based polyplexes for self-assembly between adamantanes and cyclodextrins. This method is applied to *β*CDP-based polyplexes to provide particles that are stable in salt solutions and to formulate galactose-modified particles that demonstrate targeted delivery to hepatoma cells.

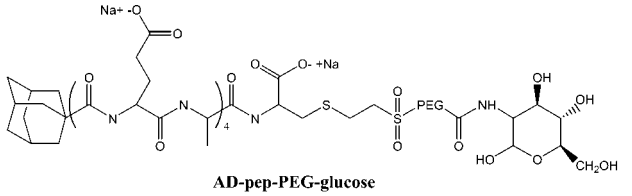
EXPERIMENTAL PROCEDURES

Polycation Synthesis. *βCDP6.* *β*CDP6 (6 denotes the number of methylene groups separating the charges) was synthesized according to previously described procedures and is shown in Chart 1 (*21*, *22*). The average molecular weight of the polycation corresponds to a "z" of approximately 4 (*21*, *22*).

βCDP6−PEG$_{3400}$. *β*CDP6 (20.3 mg, 3 *μ*mol) and FMOC−PEG$_{3400}$−NHS (10 equiv, 190 mg, 60 *μ*mol, Shearwater Polymers) were added to a glass vial equipped with a magnetic stirbar and dissolved in 1 mL of 50 mM $NaHCO_3$, pH 8.5. The solution was stirred in the dark at room temperature for 20 h and then lyophilized. The solid was dissolved in 0.5 mL of 20% piperidine in DMF and stirred for 30 min for FMOC deprotection. The solvent was removed in vacuo and the remaining viscous liquid dissolved in water and the pH brought below 6.0 with 0.1 M HCl. Complete PEG coupling and FMOC deprotection was verified by TNBS amine quantification (*26*). The polymer was separated from unreacted PEG by anion-exchange chromatography and lyophilized to yield a white fluffy powder (Chart 2).



Synthesis of Adamantane Conjugates. *Adamantane−PEG$_{5000}$* (*AD−PEG$_{5000}$*). PEG$_{5000}$−SPA (674 mg, 135 *μ*mol, Shearwater Polymers) was added to a glass vial equipped with a magnetic stirbar. 1-Adamantanemethylamine (5 equiv, 675 *μ*mol, Aldrich) dissolved in 10 mL of dichloromethane was then added and the solution stirred overnight at room temperature. The solvent was removed in vacuo, and water was added to the remaining solution. The solution was centrifuged at 20K rcf for 10 min, whereupon the adamantanemethylamine phase separated as a denser liquid. The aqueous portion was collected and dialyzed for 24 h (Slide-A-Lyzer, MWCO = 3500) against water. The solution was lyophilized to yield 530 mg of a white, fluffy powder (75% yield, structure of product shown below). The product was analyzed on a Beckman Gold HPLC system equipped with a Richards Scientific ELS detector and a C18 column and found to be pure (retention time of PEG$_{5000}$−NHS: 10.7 min; retention time of product: 12.0 min; acetonitrile/water gradient). AD−PEG$_{3400}$ was synthesized using a similar protocol (56% yield; product confirmed by Maldi-TOF analysis).



Adamantane-PEG_{5000}

Adamantane−Anionic Peptide−PEG_{3400}−Galactose/Glucose (*AD−pep−PEG−gal/glc*). An anionic peptide (sequence: E-A-E-A-E-A-E-A-C) was synthesized by the Biopolymer Synthesis Facility (Beckman Institute, California Institute of Technology) using an automatic synthesizer. Before cleaving the peptide from the resin, adamantanecarboxylic acid (ACA, Aldrich) was conjugated to the N-terminal end of the peptide with DCC coupling chemistry. The resulting peptide (AD-E-A-E-A-E-A-E-A-C, MW 1084) was cleaved from the resin and analyzed by Maldi-TOF.

Galactose− and glucose−PEG_{3400}−vinyl sulfone (gal/glc-PEG_{3400}−VS) were prepared with approximately 95% yield by reacting NHS− PEG_{3400}−VS (Shearwater Polymers) with 20 equiv of glucosamine or galactosamine (Sigma) in phosphate-buffered saline, pH 7.2, for 2 h at room temperature. The solution was dialyzed extensively against water and then lyophilized. The thiols of the anionic peptide (2 equiv) were reacted with galactose−PEG_{3400}−VS or glucose−PEG_{3400}−VS in 50 mM sodium borate buffer (pH 9.5) containing 10 mM TCEP. The solution was acidified, and the precipitated peptide (insoluble below pH 9.0) was removed by centrifugation. The supernatant was collected, dialyzed extensively, and lyophilized. The desired products were confirmed by Maldi-TOF analysis (schematic shown below).

AD-pep-PEG-galactose

AD-pep-PEG-glucose

Polyplex Preparation and Characterization. *Plasmids.* Plasmid pGL3-CV (Promega, Madison, WI), containing the luciferase gene under the control of the SV40 promoter, was amplified by *Esherichia coli* and purified using Qiagen's Endotoxin-free Megaprep kit (Valencia, CA).

Physicochemical Characterization. pGL3-CV (2 μg) in 600 μL of dH_2O was mixed with an equal volume of βCDP6 (in dH_2O) at a charge ratio of 5+/−. Particle size and zeta potential were measured using a ZetaPals dynamic light scattering detector (DLS, Brookhaven Instruments Corporation, Holtsville, NY).

Post-DNA-Complexation PEGylation by Grafting. The procedure used was modified from Ogris et al. (*14*). pGL3-CV (5 μg) in 500 μL of dH_2O was mixed with an equal volume of PEI (in dH_2O) at 3+/− or 6+/− (stage 1). βCDP6 complexes were prepared in the same manner at a charge ratio of 5+/−. The polyplex diameters were measured by DLS. After complex formation, 10 mg/mL of PEG_{5000}−SPA in DMF (Shearwater Polymers) was added to the solution and mixed at room temperature for 2 h (stage 2). After particle size determination, 500 μL of PBS, pH 7.2, were added to the solution. The solution was incubated for 30 min at room temperature before final particle sizes were measured by DLS (stage 3). A schematic of this procedure is illustrated in Scheme 1.

Post-DNA-Complexation PEGylation by Inclusion Compound Formation. pGL3-CV (2 μg) in 600 μL of dH_2O was mixed with an equal volume of βCDP6 (in dH_2O) at a charge ratio of 5+/−. The desired amount of AD−PEG (10 mg/mL in dH_2O) was added and particle size determined by DLS. PBS (600 μL), pH 7.2, was added to the solution and particle size monitored in 1 min intervals for 10 min. For serum stability determination, polyplexes (0.05 mg/mL DNA, CDP at 3+/−) and polyplexes PEGylated by inclusion compound formation (CDP at 3+/−, 100% adamantane to cyclodextrin by mol %) containing 5 μg of plasmid DNA were prepared by adding equal volumes of polymer solutions (50 μL) to DNA solutions. An aliquot of MEM media containing 10% fetal bovine serum (900 μL) was added to the polyplex solutions and allowed to incubate for 5 min before centrifuging at 14000 rpm for 100 min. Media was then removed, and the remaining pellet was washed with water and then resuspended in 1 mL of dH_2O. The amount of DNA in the pellet was quantified by UV adsorbance at 260 nm.

Formulation of Glycosylated Particles. Cyclodextrin-based polyplexes were prepared as described previously (*22*) at 5+/−. Adamantane-conjugated modifier was dissolved in dH_2O at the desired concentrations and added to the polyplexes at 5 μL of AD−pep−PEG−sugar/μg DNA. For physicochemical characterization, glycosylated particles containing 2 μg of pGL3-CV plasmid were prepared as described and diluted with the addition of 1.2 mL of dH_2O. Particle size and zeta potential of the modified polyplexes were determined by DLS.

Transmission Electron Microscopy. Polyplexes, PEGylated polyplexes, and glycosylated polyplexes were prepared as described in the previous sections in 10 μL final volume. For salt stability studies, 5 μL of PBS was added to the solutions and used 10 min after salt addition. Grids were prepared and visualized as described previously (*21*).

Cell Culture and Transfection Experiments. *Cells.* HepG2 (hepatoma) and HeLa (cervical carcinoma) cells were purchased from the ATCC, and HuH-7 cells (hepatoma) were purchased from the Japan Health Sciences Foundation. Cells were cultured according to recommended procedures. Media and supplements were purchased from Gibco BRL (Gaithersburg, MD).

Transfections. HepG2, HeLa, and HuH-7 cells were transfected in the presence of serum with modified and unmodified βCDP6-based particles containing the pGL3-CV plasmid as described previously for other adherent cell lines (*22*). Determination of cell viability and total protein concentration was conducted by Lowry protein assay, also described previously (*22*). For inhibition studies, transfections were conducted following a similar protocol except cells were preincubated for 15 min at 4 °C with 1 mg/mL asialofetuin (Sigma), after which polyplexes were added directly to the AF-containing media. Transfection media was removed after 1 h and replaced with 1 mL complete media/well.

Scheme 1

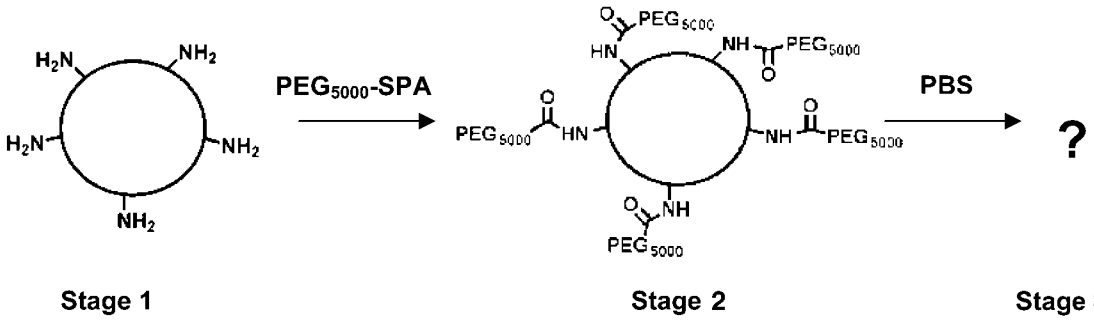


Table 1. Particle Sizes of PEI and βCDP6 Polyplexes during Post-DNA-Complexation Pegylation by Grafting[a,b]

polyplex	PEG	stage 1 (nm)	stage 2 (nm)	stage 3 (nm)
PEI 3+/−	10:1	58	65	115
PEI 6+/−	10:1	55	60	78
βCDP6 5+/−	100%	70	67.4	303
βCDP6 5+/−	150%	70	X*	N/A
βCDP6 5+/−	200%	70	X*	N/A
βCDP6 5+/−	100% PEG**	67	81	700

[a] For stage 1, 5 μg of DNA plasmid (in 500 μL of dH_2O) was mixed with PEI or βCDP6 (in 500 μL of dH_2O) at the indicated ratios. PEG_{5000}−SPA (10 mg/mL in DMF) was then added to the polyplexes in stage 2. The PEG_{5000}−SPA was allowed to react with the polymer primary amines. After 2 h, 500 μL of PBS, pH 7.2, was added to solution. The solution was incubated for 30 min before particle size measurement. All particle sizes were determined by dynamic light scattering and reported as the mean of three measurements. [b] *Poor correlation function; no size measurements possible. **PEG_{10000} added instead of PEG_{5000}−SPA.

RESULTS

Salt Stabilization by PEGylation. The following PEGylation approaches to the βCDP6 polycation were examined: pre-DNA-complexation PEGylation, post-DNA-complexation PEGylation by grafting, and post-DNA-complexation PEGylation by inclusion compound formation. The results from each method are provided below.

Pre-DNA-Complexation PEGylation. PEG_{3400}−NHS was coupled to the βCDP6 amine end groups to give the polymer CDP6−PEG_{3400}. The PEGylated polymer was mixed with plasmid DNA for particle size measurements. While βCDP6 condenses plasmid DNA to uniform particles with hydrodynamic diameter, ∼130 nm, PEGylated βCDP6 is unable to condense DNA.

Post-DNA-Complexation PEGylation by Grafting. Ogris et al. PEGylated transferrin/PEI (polyethylenimine) and PEI after complexation with plasmid DNA by reacting some of the primary amino groups of PEI with PEG_{5000}−SPA (*14*). PEI polyplexes were formulated at 3+/− and 6+/− while the βCDP6 polyplexes were formulated at 5+/− for stage 1. PEG_{5000}−SPA was added to PEI at 10:1 w/w according to the procedure published by Ogris et al. (*14*). βCDP6 was PEGylated with 100%, 150%, and 200% PEG:amine (mol %). As a control, PEG_{10000} (terminated with hydroxyl groups) was also added to βCDP6 at 100%. The particle diameters obtained at each stage are presented in Table 1. The PEI polyplexes increased slightly in size upon PEGylation (58 nm to 65 nm for 3+/− and 55 nm to 60 nm for 6+/−). PEGylation protected the PEI polyplexes against salt-induced aggregation. Although unmodified PEI particles increase in diameter to ∼800 nm after salt addition, PEGylated PEI polyplexes increased slightly in size to 78 nm (for 6+/−) and 115 nm (for 3+/−).

The particle size of CDP-based polyplexes was maintained at 67 nm after PEGylation with 100% PEG_{5000}−SPA. However, the monitoring of particle size as a function of time revealed that the particles were disrupted for approximately 30 s after PEG addition. The small particles were again observed after that time. Therefore, the addition of 100% PEG_{5000}−SPA may PEGylate a fraction of the βCDP6. Because the polycation is added in excess with respect to the DNA (at a 5+/−), the particles could then rearrange such that the unmodified polycations form polyplexes with the plasmid DNA while most of the PEGylated polycation remains free in solution. Salt addition to these particles results in particle aggregation (300 nm), although not to the extent of unmodified βCDP6 polyplexes (700 nm). The addition of 150% and 200% PEG_{5000}−SPA to βCDP6-based polyplexes results in particle disruption; particle counts drop drastically and no consistent correlation function was observed.

Post-DNA-Complexation PEGylation by Inclusion Compound Formation. The approach to post-complexation PEGylation developed here is to use the ability of cyclodextrins to form inclusion complexes with guest molecules, and the method is schematically illustrated in Figure 1A. Adamantane was conjugated to various PEG molecules. The adamantane−PEG (AD−PEG) molecules were added to solutions of preformed polyplexes at 100% adamantane to cyclodextrin (mol %). A schematic of this self-assembly process for post-DNA-complexation PEGylation by inclusion compound formation is depicted in Figure 1B. PBS was then added to the solutions and the particle size monitored by DLS in 1 min intervals (Figure 2A). The average diameter of βCDP6 polyplexes increases from 58 to 272 nm within 10 min after salt addition. The presence of free PEG_{5000} in solution does not prevent aggregation (average diameter of 278 nm after salt addition). However, PEGylation with AD−PEG molecules reduces particle aggregation in a length dependent matter. Ten minutes after salt addition, particles PEGylated with AD−PEG_{3400} aggregate to 204 nm in diameter while particles PEGylated with AD−PEG_{5000} only increased in diameter to 95 nm 10 min after salt addition. Additionally, the particles PEGylated with AD−PEG_{5000} demonstrate sustained stability in physiological salt concentration (150 mM). The stabilization also occurs in a PEG density-dependent manner (Figure 2B). The average particle diameter measured 10 min after salt addition increases by 4.7-fold for unmodified polyplexes (58 nm to 272 nm) but only 1.2-fold for polyplexes modified with the addition of 150% or 200% PEG−adamantane to cyclodextrin.

The stabilization in salt by PEGylation of βCDP6 polyplexes via inclusion compound formation was verified by transmission electron microscopy. βCDP6-based polyplexes formulated in water appear as discrete, uniform

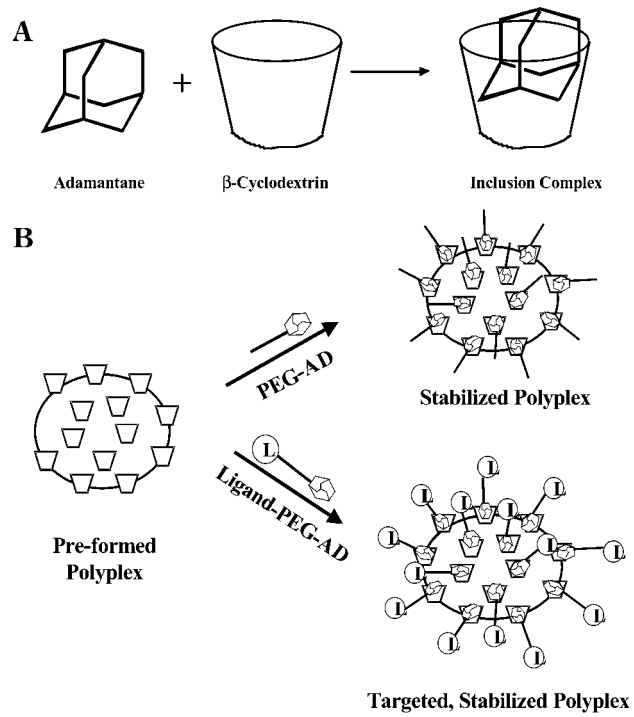

Figure 1. (A). Schematic of inclusion compound formation. (B). Schematic for post-DNA-complexation PEGylation by inclusion compound formation by PEG−AD and ligand−PEG−AD. PEG is conjugated to adamantane. Adamantane forms an inclusion complex with β-cyclodextrin on the polyplex surface and brings with it PEG or PEG−L to decorate the polyplex and provide steric stabilization and targeting.

particles with diameters around 100 nm (Figure 3A). PEGylated βCDP6-based polyplexes (100% PEG:CD by mole) formulated in water are also uniform particles with diameters around 100 nm (Figure 3B). An aliquot of PBS (150 mM salt concentration) was then added to the polyplexes to give a final salt concentration of 50 mM. After 10 min, the solutions were loaded onto a grid and visualized by electron microscopy. Unmodified polyplexes in 50 mM salt aggregated; no discrete particles were observed (Figure 3C). Electron micrographs similar to Figure 3C have been observed previously by Goula et al. for PEI-based polyplexes (*27*). To the contrary, βCDP6-based polyplexes modified with AD−PEG_{5000} were resistant to salt-induced aggregation. Electron microscopy revealed discrete particles (~110 nm in diameter, Figure 3D). Thus, successful stabilization of βCDP6-based polyplexes by AD−PEG_{5000} modification is demonstrated by both DLS measurements and electron microscopy.

The PEGylated polyplexes are also stable in culture media containing 10% serum. Unmodified and PEGylated polyplexes were exposed to serum-containing media for 10 min and then centrifuged to pellet aggregated complexes. The pellets were resuspended in water and the amount of DNA in the pellet was quantified by UV adsorption. All of the DNA from the unmodified polyplexes were recovered in the pellets, indicating that the polyplexes aggregate rapidly in the presence of physiological salt and serum. In addition, proteins were precipitated with the unmodified polyplexes (on average 6 μg protein/μg DNA). However, only ~18% of the DNA from PEGylated polyplexes was recovered in the pellets, demonstrating increased stabilization in the presence of serum.

Galactose-Mediated Delivery to Hepatocytes. *Preparation and Characterization of Galactose and Glucose-Modified Polyplexes.* βCDP6-based polyplexes require formulation at a net positive charge for complete condensation of DNA (*21*). However, these positively charged polyplexes indiscriminately transfect cultured cells. To differentiate between charge-mediated transfection and receptor-mediated transfection, the polyplexes should ideally possess neutral or negative zeta potentials and contain a targeting ligand directed at the receptor of interest. Adamantane−anionic peptide−PEG_{3400}−galactose (AD−pep−PEG−gal) was prepared for βCDP6 polyplex modification. The adamantane serves as the guest for forming inclusion complexes with the βCDP6-based polyplexes, the anionic peptide increases the binding affinity of the AD−pep−PEG−gal compound for the cationic polyplex while also decreasing the zeta potential of the polyplex to eliminate charge-mediated entry, and the PEG provides steric stabilization and serves as a spacer between the polyplex and the galactose molecules that act as the targeting ligands to hepatocytes. A glucose analogue (AD−pep−PEG−glc) was prepared as a control.

The zeta potentials of βCDP6 polyplexes (prepared at 5+/−) modified with various amounts of AD−pep−PEG−gal/glc were determined and are shown in Figure 4A. Unmodified polyplexes are positively charged, with zeta potential around +10 mV. The addition of the glycosylated adamantane compounds to the complexes decreases the zeta potential of the particles. The alteration of charge plateaus at around 50% AD−pep−PEG−gal/glc (% PEG to CD by mole) with zeta potential approximately −7 mV. Little differences between the zeta potentials of the galactose and glucose-modified polyplexes are observed. The size of the two types of particles is also very similar. Electron micrographs of the galactosylated particles (50% galactose:CD by mole) show particles with average diameters around 100 nm (Figure 4B), while measurements by DLS reveal particles with diameters around 120 nm (data not shown). Although these particles are negatively charged, the particles look similar to the unmodified polyplexes (Figure 3A), demonstrating that modification by inclusion compound formation does not significantly affect polyplex morphology.

Galactosylated and glucosylated βCDP6 particles containing the luciferase gene were prepared at 0, 20, 40, 60, 80, and 100% PEG and exposed to HepG2 (hepatoma) cells (Figure 5A). Unmodified polyplexes yielded the highest transfection (2×10^8 RLU/mg protein). At 20% PEG, the galactosylated and glucosylated particles have reduced but positive zeta potentials and gave similar transfection efficiencies. At 40% PEG, the particles are anionic (~−5 mV) and the transgene activity from glucosylated polyplexes is reduced by 2 orders of magnitude from that of the polyplex alone, while activity from galactosylated polyplexes is reduced by 1 order of magnitude. As the PEG concentration increases to 100%, the luciferase activity of glucosylated polyplexes continues to decrease; however, activity of galactosylated polyplexes remains 1 order of magnitude higher than the glucosylated polyplexes. Another hepatoma cell line, HuH-7, was transfected with the modified polyplexes and the same trend is observed. The glycosylated polyplexes transfect HuH-7 cells with the same efficiency when formulated at net positive charges. However, when formulated at net negative charges, galactosylated polyplexes consistently transfect with higher efficiencies, with up to 15-fold higher luciferase activity (at 50% PEG). HeLa cells that do not express the asialogylcoprotein receptor were transfected with the modified polyplexes. No preferential transfection of galactosylated polyplexes to HeLa cells was observed (Figure 5B).

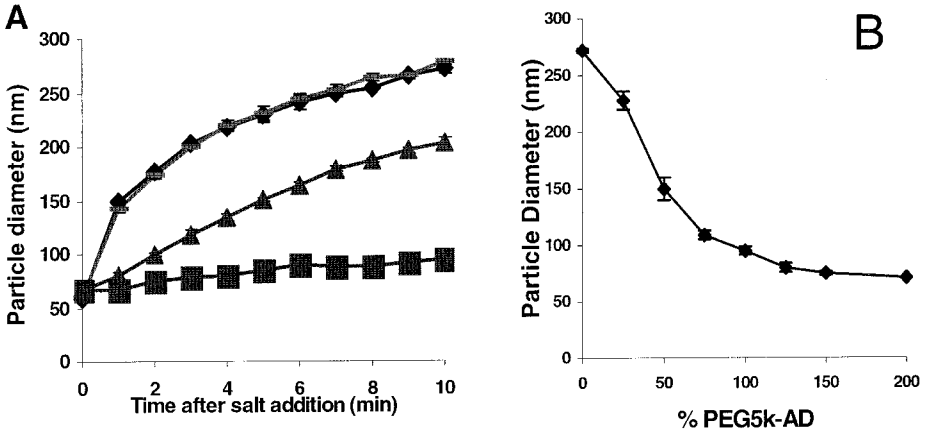

Figure 2. Salt stabilization of polyplexes by PEGylation. Plasmid DNA was mixed with βCDP6 at 5+/−, and then PEG compounds were added to the complexes for a total volume of 1.2 mL. PBS (600 μL) was added to the solutions, and the particle sizes were monitored by dynamic light scattering. (A) The effect of PEG length on salt stabilization. Polyplexes were mixed with various PEG compounds. Particle sizes were monitored by dynamic light scattering for 10 min after salt addition. (♦: polyplex, —: polyplex + PEG_{5000}, ▲: polyplex + AD−PEG_{3400}, ■: polyplex + AD−PEG_{5000}). (B). The effect of AD−PEG_{5000} concentration of salt stabilization. Various amounts of AD−PEG_{5000} were added to polyplexes before exposure to 50 mM PBS. Particle sizes were measured 10 min after salt addition.

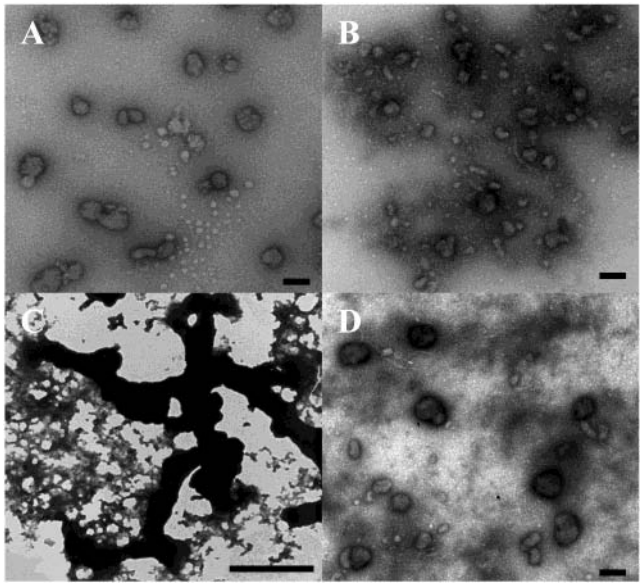

Figure 3. Transmission electron micrographs of (A) unmodified βCDP6 polyplexes, (B) βCDP6 polyplexes PEGylated by AD−PEG_{5000} modification, (C) unmodified βCDP6 polyplexes in 50 mM salt, and (D) PEGylated βCDP6 polyplexes in 50 mM salt. (Bar is 100 nm for A, B, D and 1000 nm for C).

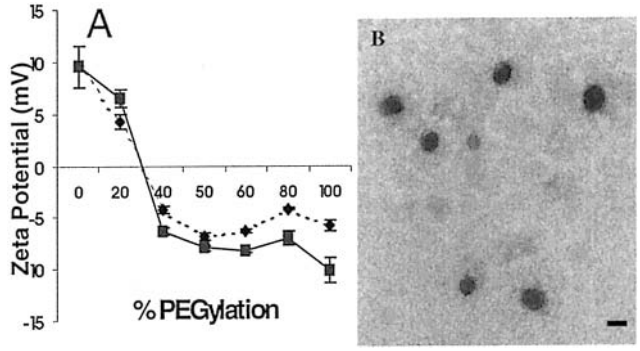

Figure 4. (A). Zeta potential of glycosylated polyplexes. Polyplexes were prepared at 5+/− in water and modified with various amounts of AD−pep−PEG−gal or AD−pep−PEG−glc (100% PEG = 1 mol PEG/1 mol CD). Polyplexes were diluted in water to 2 μg DNA/1.2 mL dH_2O and zeta potential determined by DLS measurements. (Solid line, galactosylated polyplexes; dashed line, glucosylated polyplexes.) (B). Transmission electron micrograph of galactosylated particles modified with 50% AD−pep−PEG−gal (bar is 100 nm).

To verify cell entry via the asialoglycoprotein receptor, transfections were performed in the presence of an excess of asialofetuin, a high affinity ligand for the asialoglycoprotein receptor (Figure 6). Asialofetuin did not affect polyplex or glucosylated polyplex transfection but decreased transfection with galactosylated polyplexes by 4-fold.

The toxicities of the βCDP polyplexes and modified particles were measured by determining total cellular protein 48 h after transfection. βCDP-based polyplexes have been shown to be well-tolerated to high doses both in vitro and in vivo (*21*, *22*). The adamantane-based compounds do not impart significant added toxicity to the βCDP particles (93% cell survival with galactosylated polyplexes vs 96% survival with unmodified polyplexes).

DISCUSSION

This work describes the development of a new method for modifying the surface properties of βCDP-based polyplexes that will now allow for their study as systemic, in vivo, gene delivery agents. Two features necessary for a successful systemic carrier are stability at physiological conditions and selective delivery to sites of interest (*28*). These issues are addressed here by PEGylation of the βCDP-based polyplexes and by the attachment of a galactose ligand for delivery to hepatocytes.

PEGylation has been shown to stabilize colloidal particles (*28*). Three different approaches to βCDP-based polyplex PEGylation were assessed: pre-DNA-complexation PEGylation, post-DNA-complexation PEGylation by grafting, and post-DNA-complexation PEGylation by inclusion compound formation. PEG was covalently conjugated to the amine termini of βCDP6. While βCDP6 self-assembles with and condenses DNA to small particles (*21*, *22*), the presence of PEG_{3400} at the polymer termini inhibits DNA condensation. Choi et al. report successful albeit reduced DNA binding with PEGylated PLL (*11*). However, they used PLL with MW 25000, that contains on average 170 amines/polymer strand. The long polycation provides for strong DNA binding. The βCDP6 possesses approximately 10 charges/polymer strand, and PEGylation doubles the molecular weight. Therefore, it

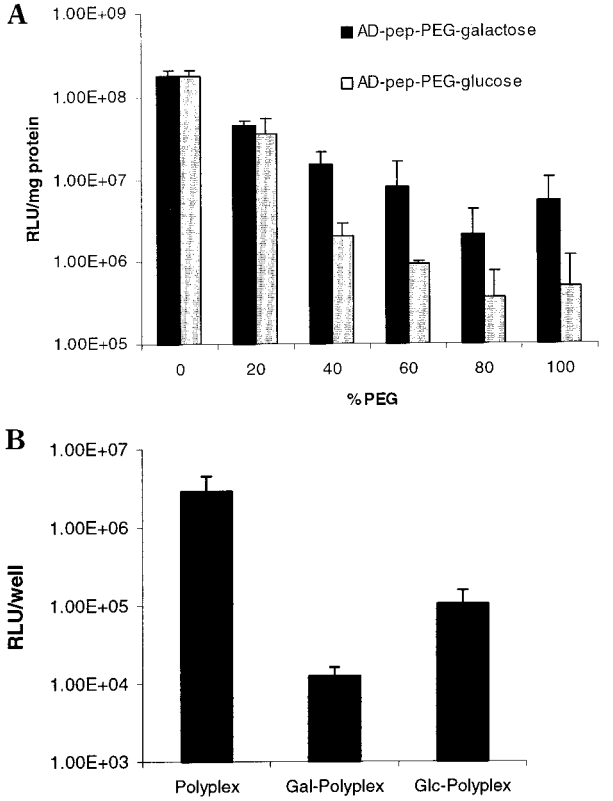

Figure 5. A. Galactose- and glucose-mediated transfection of HepG2 hepatoma cells. Cells were transfected with 1 μg of luciferase gene-containing plasmid complexed with βCDP6 at 5+/− and modified with various amounts of AD−pep−PEG−galactose or AD−pep−PEG−glucose (100% PEG = 1 mol PEG/1 mol CD). Luciferase protein activity is reported as the mean +/− SD of three samples in RLU/mg of total protein (protein concentration determined by Lowry protein assay). Black bars, galactosylated polyplexes; hatched bars, glucosylated polyplexes. DNA alone = 1,000 RLU/mg protein. B. Galactose- and glucose-mediated transfection of HeLa cells that do not express the asialoglycoprotein receptor. Cells were transfected with 1 μg of luciferase gene-containing plasmid complexed with βCDP6 at 5+/− and modified with various amounts of AD−pep−PEG−galactose (Gal-Polyplex) or AD−pep−PEG−glucose (Glc−Polyplex, 100% PEG = 1 mol PEG/1 mol CD). Luciferase protein activity is reported as the mean ± SD of three samples in RLU/mg of total protein (protein concentration determined by Lowry protein assay).

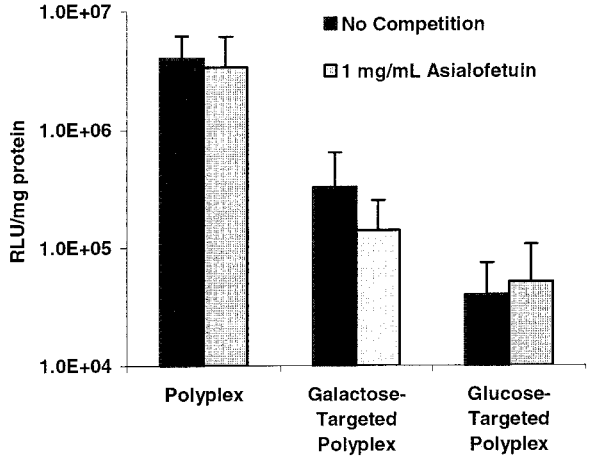

Figure 6. HepG2 cells were transfected with polyplexes (unmodified or modified with 50% AD−pep−PEG−galactose/glucose) prepared at 5+/−. Luciferase protein activity was determined 48 h after transfection and reported as RLU/mg total protein (total protein determined by Lowry assay). Data are presented as mean ± SD of three samples. Competitive inhibition of galactose-mediated delivery. HepG2 cells were transfected in the presence (hatched bars) and absence (black bars) of asialofetuin (amounts larger than 1 mg/mL significantly altered cell proliferation behavior and therefore were not used).

is not surprising that PEGylation of the βCDPs eliminates its ability to condense to plasmid DNA.

Post-complexation PEGylation as described by Ogris et al. (*14*) and Oupicky et al. (*29*) first requires the formation of the polyplex followed by PEGylation of the particles. This method involves the conjugation of surface-available, primary amines and thus reduces polyplex instability that can result from the interference in the DNA condensation process when using PEG−grafted polycations. This approach is effective for polymers such as PEI and HPMA but results in particle disruption for βCDP6-based polyplexes (Table 1). Thus, post-DNA-complexation PEGylation by reaction with accessible polymer functional groups is likely to be effective for high molecular weight polymers with high charge densities. However, reaction with low molecular weight βCDP6 destabilizes the polyplex structure.

The approach to surface modification developed here involves the use of PEG conjugated to moieties that are in turn exploited as anchors to the polyplex surface by inclusion compound formation in cyclodextrins (Figure 1). We hypothesized that use of the cyclodextrin cups for the site of modification would cause minimum disturbance to preformed polyplexes. This is because the βCDPs bind to DNA via electrostatic interactions of the cationic amidine groups on the βCDP and the anionic phosphate groups on the DNA. The cyclodextrin cups should therefore be available on the polyplex surface for complexation. Adamantane−PEG conjugates were added to βCDP6-based polyplexes, and the resulting particles remained small and disperse with only slightly increased diameters (Figures 2 and 3A). PEGylation introduced salt stability to the polyplexes in a PEG length and PEG density-dependent manner (Figure 2).

The salt stability of PEGylated βCDP6-based polyplexes was confirmed by electron microscopy. While unmodified polyplexes form large aggregates in 50 mM salt, PEGylated βCDP6-polyplexes remain discrete and condensed (Figure 3A−D). In addition, PEGylated βCDP6-based polyplexes have increased stability in the presence of serum. Other investigators have reported interference of polymer/DNA condensation by PEGylation. For example, PEGylation of PEI (MW 2000) results in thick thread and donut morphologies rather than densely compacted structures (*16*) and PEGylation of PLL (MW 4000) altered polyplex structure from toroids to rods (*12*). Here, it is shown that PEGylation by inclusion compound formation stabilizes βCDP6-based polyplexes without disrupting the polyplex structure.

The PEGylated particles maintained small sizes in the presence of 150 mM salt for hours. The adamantane is integral to forming protected polyplexes; the addition of free PEG_{5000} has no effect on salt stabilization. The addition of adamantane (in DMSO) eliminates the salt stability of the modified polyplexes by displacing the AD−PEG from the polyplexes. Thus, it is clear that the adamantane in the AD−PEG_{5000} forms an inclusion complex with the β-cyclodextrins on the surface of the polyplexes.

PEGylation of polyplexes alleviates salt-induced aggregation by providing a steric layer around the particles. The steric layer prevents close contact between particles by keeping the van der Waals attraction forces, that are dependent on the interparticle distance, lower than the

thermal energy of the particles. Therefore, there should be a critical polymer length greater than the range of van der Waals attraction between particles that results in polymer stabilization. For many colloidal systems, the necessary distance is ~5 nm (*30*). The lengths of PEG_{3400} and PEG_{5000} are estimated to be 3.5 and 4.3 nm, respectively (*30*). PEG_{5000} is long enough to stabilize βCDP6 polyplexes in salt while PEG_{3400} does not provide enough steric stabilization under the experimental conditions. Interestingly, Gref et al., working with PEG-coated poly(lactic acid) (PLA) nanoparticles of 160−270 in diameter, also found 5000 to be the minimum PEG molecular weight necessary for significant reductions in the plasma protein binding to the nanoparticles (*31*).

The association between the AD−PEG molecules and the βCDP6 polyplexes was empirically found to be very strong. PEGylated particles with DNA concentrations as dilute as 1 μg/mL remained stable under physiological salt conditions. The high association may be a result of decreased diffusional mobility of the adamantane away from the cyclodextrin because it is tethered to the PEG molecule and the high local concentration of cyclodextrin molecules on the polyplex surface, i.e., when an adamantane molecule exits one cyclodextrin cup, it is likely to go back in the same or a nearby cyclodextrin rather than going into solution (distances between cyclodextrins is very small relative to what they would be for individual cyclodextrins in solution).

Based on the success of PEGylating βCDP-based polyplexes by inclusion compound formation, an anionic, galactosylated adamantane compound was evaluated as a modifier to target βCDP-based polyplexes to hepatocytes. These adamantane modifiers contain four elements: (i) the adamantane, to attach the compound to the polyplex surface, (ii) an anionic peptide to change the polyplex surface charge and thereby reduce nonspecific transfection due to charge, (iii) PEG to serve as a tether for the ligand and as a stabilizing agent, and (iv) galactose as a targeting ligand to the asialoglycoprotein receptor (ASGP−R) or glucose as a low affinity ligand as a control. As demonstrated by the data shown in Figure 4A, the addition of these compounds to polyplexes causes the zeta potential to decrease. The drop in surface charge confirms modification of polyplexes. Additionally, the zeta potentials and particle sizes of the galactose and glucose-modified polyplexes are very similar (approximately −7 mV, 120 nm). Electron microscopy reveals that the galactosylated particles, although having different surface charge, retain approximately the same morphology and size as the unmodified polyplexes (Figures 3 and 4B). Therefore, differences in transfection ability between these particles are due to the ligand rather than physicochemical differences in the particles.

The glycosylated particles were exposed to the HepG2 cell line for uptake and transgene expression experiments. Uptake experiments were conducted at a variety of conditions (different degrees of polyplex modification, polyplex charge, and polyplex exposure time to cells) using fluorescently labeled plasmid DNA for analysis by flow cytometry. As expected, uptake efficiency was dependent on several parameters. However, uptake of galactosylated polyplexes into the hepatoma cells was consistently higher than uptake of glucosylated polyplexes. When formulated at positive zeta potentials (0, 10, or 20% PEG), no difference in transfection efficiency is observed between glucosylated and galactosylated polyplexes. This is not surprising because when the polyplexes are positively charged, they are efficiently and indiscriminantly internalized by nonspecific interactions with proteoglycans (*5*). When the particles are formulated at net negative charges (PEG−pep ≥ 40%), selective transfection by the galactosylated formulation is observed. In fact, the luciferase activity from galactose-mediated transfection is consistently an order of magnitude higher than from glucosylated polyplexes.

The glucosylated polyplexes also demonstrate a AD−pep−PEG−glc-dependent response to surface modification. Addition of the anionic adamantane derivative reduces the surface charge, resulting in a precipitous drop in transfection ability beyond 20% PEGylation. In contrast, the effect of PEGylation on transfection observed with galactosylated polyplexes is not so pronounced most likely because the cells continue to internalize these particles by receptor-mediated endocytosis via the ASGP−R. The gene expression from galactosylated polyplexes is approximately 1 order of magnitude lower than that of unmodified polyplexes. Other investigators report increased transfection to hepatocytes upon galactosylation of polyplexes (*18*, *32*, *33*). However, in those systems, charged-mediated delivery is not eliminated upon galactosylation, and uptake should occur by both charge and receptor-mediated delivery. Here, charge-mediated delivery of galactosylated βCDP particles is minimized by formulating anionic βCDP6 particles with the galactose ligand. Galactosylated βCDP particles are mainly endocytosed by the ASGP−R-mediated pathway. The reduction in expression from galactosylating the βCDP particles is therefore not surprising as uptake studies with unmodified and galactosylated polyplexes demonstrated that receptor-mediated endocytosis provides for less cellular uptake than nonspecific, charge-mediated uptake (data not shown). Reduction of nonspecific, charge-mediated uptake and gene expression is likely to be essential for effective, systemic, in vivo application.

Delivery via the ASGP−R is confirmed by two methods. First, transfection in the presence of asialofetuin, a high affinity ligand to the receptor, specifically decreases transfection of galactosylated polyplexes without affecting transfections with unmodified and glucosylated polyplexes (Figure 6). Second, luciferase activity is not observed for transfections of HeLa cells (do not express the ASGP−R) with galactosylated polyplexes (Figure 5B). Luciferase activity is observed only with unmodified polyplexes. The targeted delivery system demonstrates no toxicity over the unmodified polyplex. The low toxicity of these particles make them attractive for in vivo delivery applications.

For future work, receptor−ligand interactions can be further optimized by using different conjugation chemistries between the galactose ligand and the PEG. In this study, galactosamine was conjugated to the adamantane modifier via the C2 position. David et al. report that conjugation via the galactose C1 position results in higher uptake into hepatoma cells than conjugation via the C2 position (*34*). In addition, asialofetuin, a natural ligand for the ASGP−R binds to the receptor via a triantennary galactose residue. In fact, the affinity constants for the ASGP−R has been established with tri- ≫ bi- ≫ monoantennary galactose with affinity constants of about 10^{-9}, 10^{-6}, and 10^{-3} M, respectively (*35*). Therefore, incorporation of a C1-conjugated galactose residue or a multiantennary galactose ligand into the adamantane−PEG modifier could further improve the targeting ability of the galactosylated polyplexes.

In conclusion, a new method of modifying the surface of βCDP-based polyplexes through the use of cyclodextrin/adamantane host/guest interactions is presented. The inclusion complex formation is not restricted to adaman-

tane and β-cyclodextrin, as a multitude of guest/host materials are known. Also, the method should be applicable to other cyclodextrin-containing polymers that should be capable of forming of forming polyplexes, e.g., polyamidoamine dendrimers (*36*), polyallylamines (*37*), PEI (*38*), and chitosan (*39*). Here, we have demonstrated stabilization and galactose-mediated targeting of surface-modified particles without any increase in cell-associated toxicity. This method of adapting polyplexes for in vivo use imposes no interference with polyplex formation, occurs by self-assembly, and is modularly adaptable for various applications including the addition of agents that effect intracellular trafficking, codelivery of small molecules, different targeting agents, or combinations thereof (*40*). This system is currently being studied in animal models.

Formation of Fibrinogen-Based Hydrogels Using Phototriggerable Diplasmalogen Liposomes

Zhi-Yi Zhang,[†] Pochi Shum,[†] Melinda Yates,[†] Phillip B. Messersmith,[‡] and David H. Thompson[†,*]

Department of Chemistry, Purdue University, West Lafayette, Indiana 47907-1393, and Biomedical Engineering Department, Northwestern University, 2145 Sheridan Road, Evanston, Illinois 60208. Received November 22, 2001; Revised Manuscript Received December 4, 2001

We report the triggered release of Ca^{2+} from liposomal compartments to induce rapid gelation of protein-based hydrogels. Phototriggerable liposomes were designed by entrapping $CaCl_2$ within liposomes composed of 38:57:5 diplasmenylcholine (DPPlsC):disteroylphosphatidylcholine (DSPC): bacteriochlorophyll (Bchl). These liposomes release >80% of their entrapped Ca^{2+} within 15 min when irradiated at 800 nm (800 mW/cm^2). A precursor solution, containing liposomes suspended in aqueous human fibrinogen and transglutaminase (TGase), remained fluid for several hours in the dark, but gelled rapidly when exposed to 800 nm excitation, as a result of photosensitized Ca^{2+} release and TG-induced fibrinogen cross-linking. TGase and hrFXIII activities, determined using a fluorimetric dansylcadaverine assay, were found to depend strongly on irradiation time and reaction temperature. SDS−PAGE of the photolyzed reaction mixture revealed that gelation arises from enzyme-catalyzed cross-linking of predominately the α and γ chains of fibrinogen. This approach to the phototriggered formation of protein hydrogels creates new opportunities for biomaterials applications in drug delivery, tissue engineering, and wound healing.

INTRODUCTION

Development of new strategies and materials to facilitate rapid and efficient wound healing and localized drug delivery are major thrusts of biomaterials research. Fibrinogen hydrogels are potentially important biomaterials for drug delivery applications. Protein-based hydrogels such as these can be created by exploiting various Ca^{2+}-dependent enzymes to catalyze the enzyme-mediated cross-linking of polypeptide precursors (*1*, *2*). One such family of Ca^{2+}-dependent enzymes are the transglutaminases, which promote the formation of cross-links between glutamine and lysine residues on neighboring proteins (*3*−*7*) (Figure 1a). An area of considerable interest is the development of injectable biomaterials that undergo a rapid sol−gel transformation in-situ to form semisolid hydrogels. These materials may be potentially useful for site-directed drug delivery, wound healing, and in the emerging field of tissue engineering (*8*). Light activation is a particularly promising way to achieve in-situ formation of biomaterials since it provides a very broad range of adjustable parameters (e.g. pulse duration, intensity, pulse cycle, and wavelength) that can be optimized for biological compliance and clinical efficacy. Moreover, fiber optic light sources are common clinical devices that can offer a convenient means for triggering useful chemical reactions within confined regions. For example, UV and visible light activated photopolymerization systems have been developed for rapid in vivo gelation of monomeric liquids for drug delivery and tissue repair (*9*−*11*).

Efforts in our laboratories have been aimed at developing stimuli-responsive liposome strategies for site-specific drug delivery (*12*−*21*) and in-situ formation of resorbable biomaterials (*22*−*27*). The ability of stimuli-responsive liposomes to release sequestered reagents in response to an applied stimulus (temperature, light, pH, etc. (*15*, *16*)) can be exploited to trigger in-situ formation of mineral-, polymer-, and peptide-based biomaterials.

In this work, we use phototriggered release of liposomal Ca^{2+} as an initiator of enzyme-mediated formation of fibrinogen hydrogels. The basic strategy of this approach is to utilize calcium-loaded phospholipid vesicles to physically isolate calcium ions from Ca^{2+}-dependent enzymes contained within the surrounding aqueous medium (Figure 1b); photoactivated release of Ca^{2+} converts the enzyme from an inactive to an active state. Previously, Wymer et al. used this concept to photochemically control the activity of a calcium-dependent phospholipase A_2 in a cascade triggering approach (*20*). This work employs Ca^{2+}-dependent transglutaminase (TGase)[1] enzymes (protein−glutamine:amine γ-glutamyltransferase, EC 2.3.2.13), which catalyze an acyltransfer reaction between the γ-carboxamide groups of peptide-bound glutamine residues and the ϵ-amino groups of lysine residues in proteins (*3*−*7*). In this case, photoactivated release of Ca^{2+} from liposomes results in the cross-linking of a soluble protein (fibrinogen) through the formation of ϵ-(γ-glutamyl)lysine isopeptide side-chain bridges as shown in Figure 1. This paper describes a method for producing transglutaminase-cross-linked hydrogels based on photooxidative triggering of Ca^{2+} release from diplasmalogen (DPPlsC) liposomes, with subsequent

activation of transglutaminase-catalyzed cross-linking of fibrinogen. The gelation rate and physical properties of these hydrogels have been characterized by dansylamine fluorescence assay, SDS−PAGE, and cryogenic scanning electron microscopy (C−SEM) to determine the rate and extent of protein cross-linking.

MATERIALS AND METHODS

Materials. Diplasmenylcholine (DPPlsC) was synthesized as described (*21*). Human recombinant Factor XIII (hrFXIII) was generously supplied by ZymoGenetics Corporation (Seattle, WA). 1,2-Disteroyl-*sn*-glycerol-3-phosphatidylcholine (DSPC), bacteriochlorophyll *a* (Bchl), Arsenazo III (AIII), NaCl, $CaCl_2$, human fibrinogen (93% clottable), tissue transglutaminase (TGase), dithiothreitol (DTT), HEPES, and EDTA were all used as received.

Preparation of Liposomes. Calcium chloride-loaded phospholipid vesicles were prepared by the interdigitation−fusion approach as previously described (*23*, *28*). A lyophilized powder of 38:57:5 (mol %) DPPlsC:DSPC:Bchl was hydrated in the presence of 0.2 M $CaCl_2$ for 15 min at 65 °C with occasional vortexing. The resulting vesicle suspension was sonicated under an inert atmosphere at 65 °C for 30 min, cooled to room temperature, and then centrifuged at 3000*g* for 3 min to remove metal particles released from the sonicator probe tip. Absolute ethanol was added to the supernatant to achieve a final ethanol concentration of 4 M. The solution was mixed vigorously and then incubated at 22 °C for 15 min. Ca^{2+}-encapsulated interdigitation−fusion vesicles (Ca−IFVs) were obtained by flushing the suspension with dry Ar at 65 °C for 60 min and at 23 °C for an additional 30 min to remove the remaining EtOH. Extravesicular Ca^{2+} was removed from the liposome suspension by repeated centrifugation (20000*g*) for 3 min with isotonic 0.3 M NaCl solution (containing 1 mM EDTA in 10 mM HEPES at pH 7.4, HBS) and decanting of the supernatant. This process was repeated until Ca^{2+} was no longer detected in the supernatant using the Arsenazo III spectrophotometric assay (see below) (*29*). The Ca−IFV's were resuspended in isotonic HBS solution to a final lipid concentration of 20 mg/mL and then stored at 4 °C until use. The average Ca−IFV diameter, determined via quasielastic light scattering using a Coulter N4−Plus instrument and the manufacturers' analysis software, was approximately 1.9 μm.

The amount of Ca^{2+} encapsulated within the Ca−IFV was determined using the calcium sensitive dye, Arsenazo III (AIII, $\lambda_{max} = 560$ nm), which undergoes a color change upon complexation with Ca^{2+} (Ca^{2+}-AIII, $\lambda_{max} = 656$ nm) (*29*). A 5 μL aliquot of Ca−IFV suspension was added to 3 mL of AIII solution (0.2 mM AIII in 20 mM HEPES, 0.3 M NaCl, pH 7.4) in a 1 × 1 cm cuvette. The mixture was vigorously stirred for 30 s with a micromagnetic stir bar and then the UV absorption at 656 nm measured. Subsequent addition of 10% Triton X-100 (30 μL) to this mixture leads to vesicle disruption and complete release of Ca^{2+}. Control experiments showed that this assay was linear over 5−100 μM calcium concentration ranges.

Light-Triggered Ca^{2+} Release from Ca−IFV. Liposome solutions (1.5 mL in 13 × 100 mm culture tubes) were illuminated using a SDL 820 Al−Ga−As diode laser (Spectro Diode Labs, San Jose, CA, $\lambda_{em} = 800$ nm) coupled to a 1 mm diameter optical fiber, the emitting end of which was mounted perpendicular to the side plane of an irradiation cuvette. Incident light intensities were measured using a MAX 5100 power meter (Molectron Detector, Portland, OR). A 10 μL aliquot of liposome sample was added to 3 mL of AIII solution. Release of Ca^{2+} from the liposomes was followed as a function of time by measuring the absorption intensity at 656 nm before and after the addition of 10% Triton X-100 solution and the amount of Ca^{2+} released calculated as previously described (*27*).

Light-Activation of hrFXIII and Liver TGase via Ca−IFVs. The activity of hrFXIII and liver TGase in the presence of Ca−IFV's was determined using the fluorometric dansylcadaverine assay (*30*), modified to account for the presence of Ca−IFVs (see below). Sample temperature control was provided by a water-jacketed cell holder, which was connected to a thermostated water bath. Bicine buffer (50 mM in 0.29 mM NaCl, pH 9.0; 1.2 mL), Tris buffer (50 mM in 0.175 mM NaCl, pH 7.5; 1.0 mL), and monodansylcadaverine (2 mM in 50 mM Tris buffer, pH 7.5; 40 μL) were combined in a 1 cm × 1 cm quartz fluorescence cuvette. After temperature equilibration, 0.2 mL of dimethylcasein (2% in distilled H_2O, cooled to 5 °C) was added. The solution temperature initially dropped by approximately 1 °C, but returned to the set temperature within 1−2 min. Thrombin (500 units/mL; 20 μL) was then diluted with 0.1 mL of distilled water and immediately combined with 10 μL of hrFXIII (10 mg/mL), and the entire volume transferred to the monodansylcadaverine-containing cuvette.[2] DTT (50 μL in 50% glycerol) was then added, followed by a volume of the Ca−IFV suspension (35 mM Ca^{2+}; 60 μL). Time-dependent fluorescence data collection was then started ($\lambda_{ex} = 360$ nm; $\lambda_{em} = 500$ nm; slit widths = 20 nm). After 5 min incubation in the dark, the samples were illuminated at 800 nm as described above. The distance between the end of optical fiber and the solution surface was approximately 3 cm. Incident light power was measured at the surface of the suspension.

Light Triggered Gelation of Precursor Suspensions. Fluid hydrogel precursor solutions were prepared by suspending Ca−IFV in a solution containing TGase and fibrinogen. The hydrogel precursor solution was produced by first combining 200 μL of human fibrinogen solution (50 mg/mL in HBS), 10 μL of TGase (0.02 units/μL), and 10 μL of 0.5 M DTT in a 10 × 13 cm culture tube, followed by addition of 200 μL of Ca−IFV solution with mixing. The culture tube was immersed in a water bath held at 37 °C and the tip of the laser fiber positioned 3 cm away from the surface of the precursor solution. The laser power was then adjusted to give the desired power density without introducing heating effects.

Transglutaminase-catalyzed cross-linking of fibrinogen was detected by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS−PAGE) according to the method of Laemmli (*31*). TGase solution (10 μL) was combined with Ca−IFV's (200 μL) and fibrinogen solution (at 2 mg/mL in HBS; 200 μL), and the samples were irradiated for 40 min at 37 °C. Aliquots of the reaction mixture were withdrawn at 10 min intervals during the irradiation and immediately analyzed by SDS−PAGE.

[2] Alternatively, tissue-TG (2 units) was diluted into 0.1 mL of H_2O, but otherwise treated in the same manner.

Cryogenic Scanning Electron Microscopy (C−SEM). Samples were frozen by plunging into N_2 slush. The samples were then fractured and sublimated at −70 °C for 30 min prior to sputter-coating for 4 min with Au at approximately −160 °C. Samples were imaged at −140 °C in a JEOL JSM-840 SEM using a 4 kV accelerating voltage. The structures observed were consistent in numerous areas viewed.

RESULTS

Thompson et al. have previously shown that Ca-loaded DPPlsC:Bchl liposomes can rapidly release Ca^{2+} upon irradiation at 800 nm (*20*, *32*). This study employed the same photooxidatively based triggering chemistry, except that DSPC was used as the major membrane lipid component to keep the dark leakage rates low and minimize the amount of DPPlsC required (Figure 2). Phototriggered calcein release experiments showed that formulations containing 38% DPPlsC were capable of releasing more than 80% of their cargo when irradiated for 30 min at 800 nm, 1 W/cm^2 (Figure 3). To further reduce the lipid requirements of this system, we used the interdigitation fusion technique to make large vesicles that were capable of very high trapping efficiencies. This approach enabled 53 mM Ca^{2+} encapsulation efficiencies using only 20 mg/mL of total lipid. By comparison, liposomes prepared by conventional freeze−thaw-extrusion (FTE) methods were capable of encapsulating only 13 mM of Ca^{2+} at the same lipid concentration.[3] As shown in Figure 4, more than 90% of the entrapped Ca^{2+} was released upon irradiation of 38:57:5 DPPlsC:DSPC:Bchl Ca−IFV at 800 nm for 45 min.

Our approach to photoinitiated triggering of hydrogel formation is based on the well-known dependence of TGase activity on free Ca^{2+} concentrations (*7*). We first sought to verify this dependence using Ca−IFV to initiate hrFXIII and TGase activity by photooxidative triggering. For this purpose, the fluorescence based assay that monitors monodansylcadaverine incorporation into casein (*30*) was employed. This assay is based on fluorescence intensity increases that result when the dansyl group becomes enzymatically coupled to casein via amide bond formation. Figures 5 and 6 show the fluorescence intensity increases as a function of time for reaction mixtures containing *N*′,*N*′-dimethylcasein, Ca−IFV, and either liver TGase (Figure 5) or hrFXIII (Figure 6) at both 24 °C and 37 °C. At 24 °C with 100 s irradiation time, the fluorescence intensity of both enzymes rises only slowly during the first 60 min (Figure 5 and 6). However, the fluorescence intensity rises rapidly at 37 °C, indicating that hrFXIII and TGase more efficiently catalyze the incorporation of monodansylcadaverine into *N*′,*N*′-dimethylcasein via a photoinitiated release of Ca^{2+} at higher temperature.

To test the concept of phototriggerable TGase-catalyzed fibrinogen gelation, Ca−IFV were mixed with fibrinogen and liver TGase to form a precursor solution which did not gel in the dark at 37 °C for 120 min. Mild irradiation (0.4 W/cm^2) of these samples at 37 °C, however, led to the formation of a dense gel within 40 min (Figure 7a). Gelation time could be reduced to 15 min by increasing the laser power to 0.8 W/cm^2 or by increasing the TGase concentration to 0.6 units (data not shown). Cryo-SEM analysis (Figure 7b and 7c) of the irradiated sample from

[3] The Ca^{2+} concentrations reported here, 53 mM and 13 mM, for Ca−IFV and Ca−FTE, respectively, refer to the *bulk* Ca^{2+} concentrations (i.e., after complete escape of Ca^{2+} from the inner vesicle compartment due to Triton X-100 addition).

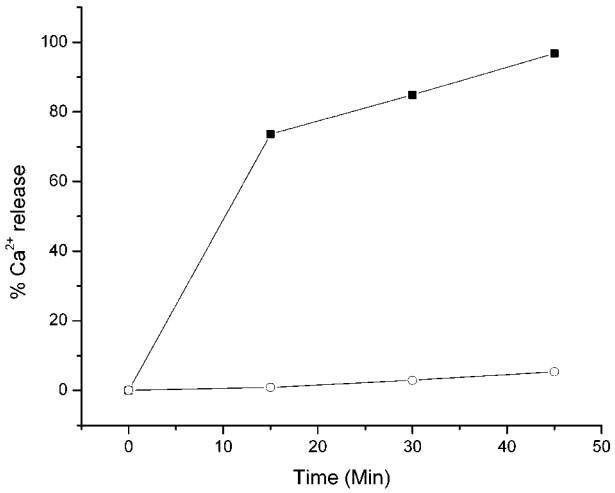

Figure 4. Photoinduced Ca^{2+} release from interdigitation−fusion vesicles at 37 °C. ■, 1.3 W/cm^2; ○, dark. Total lipid concentration, 1.5 mg/mL in HBS; laser intensity, 1.3 W/cm^2 @ 800 nm; bulk Ca^{2+} concentration when completely released, 3.25 mM.

Figure 7a reveals the formation of a microporous network structure whose pores are approximately the diameter of the Ca−IFV. The pores of this hydrogel material may be imprinted by the vesicle precursors, i.e., the vesicles themselves may serve as both the Ca^{2+} source and as a template for the TGase-catalyzed cross-linking reaction.

SDS−PAGE analysis of photoinitiated Ca−IFV/TGase/fibrinogen samples was performed as a function of irradiation time to observe the TGase-induced changes in protein MW upon cross-linking (Figure 8). For samples incubated in the dark at 37 °C, SDS−PAGE revealed no observable protein cross-linking through 40 min, as indicated by the persistence of the fibrinogen α-, β-, and γ-bands. By contrast, irradiation of the samples at 800 nm (400mW/cm^2, 37 °C) resulted in extensive loss of both the α and γ chains of fibrinogen within 10 min, as well as a gradual loss of the β-band over 40 min. At the same time, weakly staining higher molecular weight bands emerged, along with a densely stained, very high molecular weight band which did not penetrate the gel.

DISCUSSION

The goal of this project is to formulate aqueous protein solutions, which can expeditiously gelate upon transglutaminase catalysis in the presence of Ca^{2+} ions. Our method employs phototriggered liposomal release of Ca^{2+} to initiate the rapid enzymatic cross-linking of fibrinogen solutions to form hydrogels. Phototriggerable liposomes were designed by entrapping $CaCl_2$ within liposomes composed of 38:57:5 DPPlsC:DSPC:Bchl. These liposomes

could release ∼90% of entrapped Ca^{2+} when irradiated at 800 nm for 30 min (Figure 4). Photochemical control of TGase enzyme and FXIII activity was clearly demonstrated using the dansylcadaverine enzyme assay as shown in Figures 5 and 6. When Ca−IFV's were used as the sole source of Ca^{2+}, virtually no enzyme activity was observed in the dark control sample (i.e., nonirradiated). FXIII and TGase became active, however, in the presence of the millimolar concentrations of Ca^{2+} that were

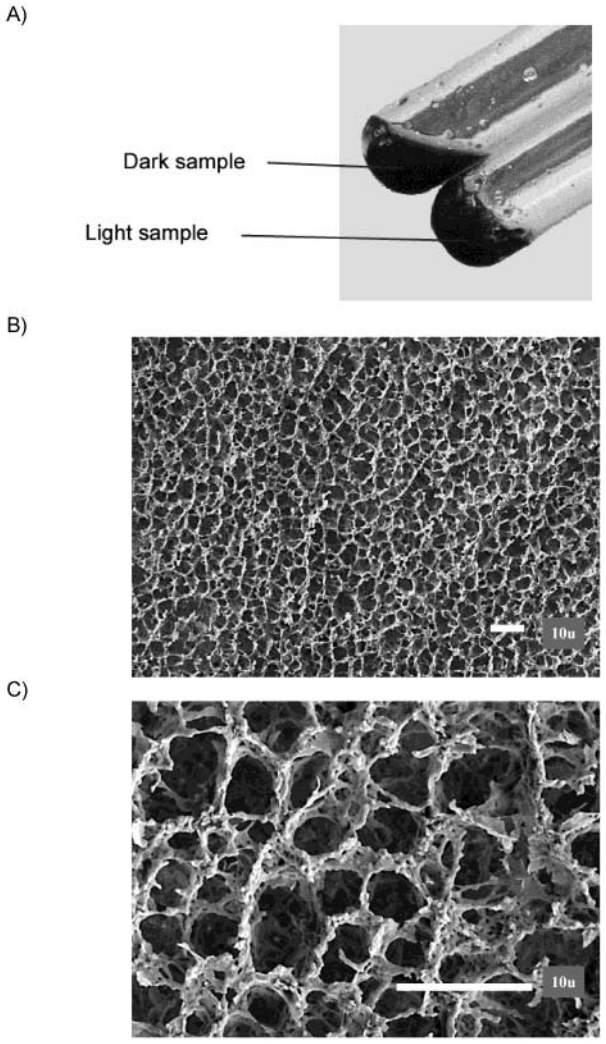

Figure 7. A: Macroscopic appearance of fibrinogen precursor solutions without (top) and with (bottom) exposure to 800 nm excitation (40 min @ 0.4 W/cm^2). B and C: C−SEM of cryofractured sample of phototriggered fibrinogen hydrogel.

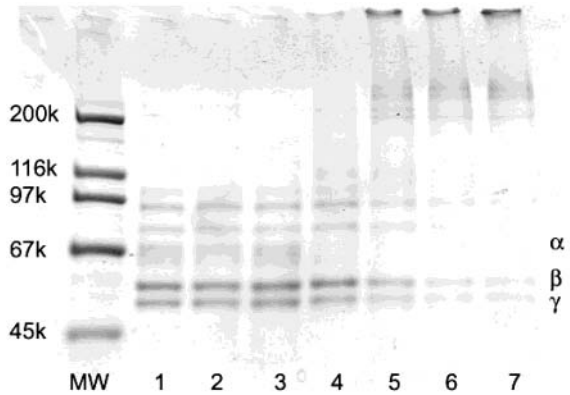

Figure 8. SDS−PAGE of fibrinogen solutions sampled at various irradiation times. MW, molecular weight marker lane; lanes 1−4 dark control samples at 0, 10, 20, and 40 min, respectively; lanes 5−7 irradiated samples (800 nm, 400 mW/cm^2, 37 °C), respectively at 10, 20, and 40 min.

released by the Ca−IFV after irradiation at 800 nm for only 100 sec at 24 °C. As expected, higher enzyme activities were observed after irradiation of the suspensions at 800 nm for 100 sec at 37 °C.

The phototriggered Ca^{2+} release from Ca−IFV was used to activate enzyme-catalyzed cross-linking of pro-

teins to form hydrogels within 40 min, as confirmed by visual observations and SDS−PAGE experiments. Figure 8 showed that the intensity of the α- and γ-bands decreased when the suspensions were irradiated at 800 nm for 10 min. Densely stained wells at the origins of lanes 5−7 indicate the formation of macromolecules in the cross-linking reaction that cannot penetrate into the gel. When higher laser power or TGase concentrations were applied to the precursor solution at 800 nm and at 37 °C, gelation time was reduced to 15 min.

Commercially available, fibrin-based adhesives produce strong, biodegradable gels very quickly (<10 min) and are used as surgical glues, tissue sealants, and drug delivery devices (*33*). These materials consist of fibrinogen, FXIII, thrombin, and Ca^{2+} and are typically delivered via a dual syringe device that separates fibrinogen and FXIII from Ca^{2+} and thrombin during storage. Mixing of the components during discharge from the syringe results in thrombinolysis of fibrinogen to create fibrin, which self-assembles into a gel that is later cross-linked by Ca^{2+}-activated FXIII. This sequence of reactions closely mimics the manner in which fibrin and activated FXIII are formed in vivo (*4*). Through extensive cross-linking of the protein substrate by FXIII, resistance to both mechanical and enzymatic degradation is imparted to the material (*34*). Our approach relies on Ca^{2+}-activation of FXIII as well; however, there are several key differences between the fibrinogen hydrogels described in this paper and conventional fibrin tissue adhesives. For example, our formulations do not contain thrombin, which plays a key role in formation of both fibrin and activated FXIII in vivo. Because of this, the molecular (and supramolecular) structure of the fibrinogen gels are expected to be distinctly different from fibrin gels. Furthermore, the absence of thrombin could be an advantage in clinical use, since many current fibrin tissue formulations utilize bovine thrombin, which can induce anaphylactic and autoimmune responses in patients (*35*).

CONCLUSIONS

We recently reported the use of near-infrared (NIR) sensitive liposomes to trigger gelation of a self-assembling peptide (*26*); however, to the best of our knowledge, this is the first example of triggered protein hydrogel formation using NIR light. Since NIR has good tissue penetration relative to visible or UV light, one can conceivably (1) trigger the gelation of these suspensions in a noninvasive fashion using an external NIR source, (2) temporospatially modulate the release of drugs from NIR-sensitive liposomes entrapped within an implanted hydrogel, (3) produce hydrogels that possess unique gradient or microstructural properties. These experiments demonstrate that this approach to the phototriggered formation of protein hydrogels creates new opportunities for biomaterials applications in drug delivery, tissue engineering and wound healing. Experiments to explore these opportunities are currently in progress.

Dendrimers as Carrier Protein Mimetics for IgE Antibody Recognition. Synthesis and Characterization of Densely Penicilloylated Dendrimers

Francisco Sánchez-Sancho,[†] Ezequiel Pérez-Inestrosa,*[,†] Rafael Suau,[†] Cristobalina Mayorga,[‡] María J. Torres,[‡] and Miguel Blanca[§]

Departamento de Química Orgánica, Facultad de Ciencias, Universidad de Málaga, Campus de Teatinos, E-29071 Málaga, Spain, Research Unit for Allergic Diseases, Hospital Carlos Haya, Málaga, Spain, and Allergic Service, Hospital Universitario La Paz, Madrid, Spain. Received November 26, 2001; Revised Manuscript Received February 4, 2002

The synthesis of benzylpenicilloyl-containing dendrimers has been achieved by a convenient procedure involving quantitative functionalization of the terminal amino groups of the three Starbust PAMAM generations used (**G$_n$**; $n = 0, 1, 2$). All these densely penicilloylated dendrimers (**G$_n$P**) exhibit similar, simple NMR spectroscopic data suggesting highly symmetric structures and a monodisperse nature, and the results obtained from MALDI-TOF-MS demonstrate their exact chemical composition. The use of PAMAM dendrimers has allowed us to synthesize, for the first time, carrier benzylpenicilloyl conjugates (**G$_n$P**) of precisely defined chemical structure. The attempts to synthesize **G$_2$P** show that forced experimental conditions are not always useful for the functionalization of the dendrimer, especially in introducing bulky groups. The initial results with sera from patients with different RAST levels were positive and thus suggestive that inhibition occurs, so recognition exists; we can therefore conclude that the hapten−carrier (dendrimer) conjugates studied mimic recognition with natural hapten−carrier (protein) conjugates.

INTRODUCTION

In contrast to linear polymers, dendrimers are highly branched macromolecules with a regular treelike structure of well-defined three-dimensional architecture (*1*). Dendrimers are promising polymeric materials to be used as skeleton building blocks for the development of clusters by virtue of their precisely defined structure (*2*). At the molecular level, dendrimers are potential diagnostic agents thanks to the ease with which they can incorporate multiple functionalities leading to a high activity through multiple interactions that result in increased sensitivity (*3*). Dendritic substances have provided crucial advances; they have already been tested in preclinical studies, particularly as contrast media for magnetic resonance applications (*4*). Dendrimers containing multiple identical ligands are very attractive from the pharmacochemical point of view, since these structures can exhibit amplified substrate binding. Enhanced substrate binding originates either from statistical or cooperativity effects (*5*).

The idea of using a dendritic multifunctional platform to amplify substrate binding has also been exploited to generate antibodies, the improved immunoresponse of which has been ascribed to their high antigen content (*6*). Poly(amidoamine) dendrimers (PAMAM) (*7*) have been used for drug delivery and biomedical applications (*8a*) such as coupling to antibodies to develop immunoassays combining the advantages of hetero- and homogeneous immunoassays (*8b*). The synthesis of several saccharide residues attached to the periphery of preformed PAMAM dendritic cores has been reported, and an increased binding affinity for certain proteins when compared with the individual monomeric sugar unit was demonstrated (*9*).

Current projects in our laboratories are focused on the development of β-lactam hapten−carrier conjugates for quantifying IgE antibodies to penicillins (*10*). Evaluation of subjects with an immediate allergic reaction requires an adequate clinical history plus in vivo and/or in vitro tests (*11*). β-Lactams need to be conjugated with a protein carrier to induce specific IgE antibodies (*12*), and the nature of this molecule is important in the sensitivity of the in vitro test used to detect these antibodies. Since the in vitro tests for detecting specific IgE antibodies to β-lactams are not so sensitive as skin tests, an improvement of in vitro techniques is needed to enhance diagnosis in allergic patients. In this paper we report on the preparation and properties of PAMAM dendrimers functionalized with peripheral benzylpenicilloyl (BPO) units. The benzylpenicilloyl group is the major determinant responsible for the allergic response to β-lactam antibiotics (*13*).

The general aim of this research was to design and synthesize a sequence of precisely defined molecular structures to achieve hapten−carrier conjugates of increasing benzylpenicilloyl density at the periphery of preformed PAMAM dendritic cores and exploiting their exo-receptor properties.

Conventional peptide carrier conjugates, human serum albumin (HSA) or poly-L-lysine (PLL), have the disadvantage of a nonprecise density of haptens in their structure; also, the haptens are randomly distributed in the large protein or peptide carriers. Although tradition-

ally considered the natural globular carrier, HSA has the limitation of its intrinsic low hapten−carrier density, in addition to the difficulty of establishing the exact structure of its conjugates (*10a*). On the other hand, PLL conjugates—even those with increased hapten−carrier ratios—actually consist of a combination of several structures because PLL is always an average of heterogeneous molecular weight peptides. As a result, this type of conjugate features low reproducibility and reliability in antibody recognition tests (*10b*). Furthermore, the flexibility of polymer chains makes the three-dimensional structures rather variable and difficult to predict. However, the surface and interior of dendrimers are considered segregated (*14*) so all the peripheral haptenic ligands of the conjugates obtained from them should be accessible for binding. Conversely, linear polymers, depending on their conformations, may envelop a substantial fraction of appended ligands.

We chose PAMAM dendrimers due to their availability, generally globular shape and solubility for all molecular sizes. The novel *functional dendritic molecules* (*15*) synthesized from them, reported herein, are part of our program to develop a new in vitro test to quantify *IgE* antibodies to specific β-lactam conjugates with a view to improving the existing methods for diagnosing allergy to this type of antibiotics.

The dendrimers studied, $\mathbf{G_0}$ to $\mathbf{G_2}$, are shown in Chart 1. The chemical properties of the penicilloylated dendrimers were studied and compared with those of the model monomer compound **1** (Chart 1). Covalent coupling of benzylpenicillin to the dendrimers produces novel compounds with unique properties of solubility, high charge density, and specificity. Moreover, these compounds have the ability to remain in an aqueous solution throughout an analytical process (a property considered to be particularly important) (*16*). The structural recogni-

tion of the new compounds from IgE antibodies has been evaluated and compared with that of classical BPO−PLL conjugates.

EXPERIMENTAL PROCEDURES

General. Starburst PAMAM dendrimers (generations zero to two) were purchased from Aldrich as 20 wt % solutions in methyl alcohol. Penicillin G sodium salt was purchased from CEPA, S. L. Standard chemicals were from Aldrich or Merck and used without further purifications. SephadexTM G-10 was purchased from Amersham Pharmacia Biotech AB. The compound **1** was prepared according to the previously reported procedure (*17*). ^{1}H and ^{13}C NMR spectroscopic measurements were carried out on a Bruker WP200 SY or DRX400 BB spectrometer, and chemical shifts (δ) are given in ppm relative to the residual solvent peak. All NMR spectra were recorded using D_2O as solvent (with Na_2CO_3 to ensure a basic pD $\cong$ 11) at room temperature. The MALDI-TOF mass spectra were acquired using a PE Biosystems Voyager System 2081 and were recorded by dissolving the product in 1:1 H_2O/CH_3CN containing 0.1% trifluoroacetic acid (TFA) and using 2,4,6-trihydroxyacetophenone (THAP) (**G_0P** and **G_1P**) or 3,5-dimethoxy-4-hydroxycinnamic acid (sinapinic acid) (**G_2P**) as the matrix. The FAB-MS spectrum was obtained using a VG Quattro mass spectrometer and was recorded by using 3-nitrobenzyl alcohol (3-NBA) as the matrix.

General Procedure for the Synthesis of Dendrimers G_nP (n = 0, 1, 2). Penicillin G sodium salt, was added to a stirred solution of the corresponding Starburst PAMAM dendrimer, in 0.02 M aqueous carbonate buffer, pH 10.8, at 20 °C (**G_0P** and **G_1P**) or 4 °C (**G_2P**). The mixture was stirred for the time stated in each case and then purified by gel filtration, using Sephadex G-10 as stationary phase and distilled water as eluent. The solvent was then evaporated in vacuo to obtain the corresponding pure product.

RAST Inhibition Studies. Three sera from patients allergic to penicillins were collected, and specific IgE antibodies were determined by radioallergosorbent tests (RAST) as reported (*17*) using in the solid-phase benzylpenicillin conjugated to PLL (BPO−PLL). Results, expressed as a percentage of maximum label uptake, were considered positive when higher than 2.5%, this being the mean + 2SD of the negative control group (*17*). To study the capacity of the different dendrimers to bind specific IgE antibodies and compare them with the classical monomer used in different studies bound to butylamine **1**, RAST inhibition studies were made as described (*17*). This was carried out using the same solid phase, BPO−PLL. In the fluid phase the sera from patients allergic to penicillin were incubated with three different penicilloylated dendrimers at three 10-fold concentrations, ranging from 25 mM to 0.25 mM for **G_0P**, from 12.5 mM to 0.125 mM for **G_1P**, from 6.25 mM to 0.0625 for **G_2P**, and from 100 mM to 1 mM for **1**. The results were expressed as inhibition percentages.

RESULTS AND DISCUSSION

Penicillins are reactive to a variety of nucleophilic reagents such as alcohols, amines and thiols. The result of this nucleophilic attack is the cleavage of the β-lactam amide bond, which yields penicilloic acid derivatives such as **1**. The rate of reaction of the β-lactam ring in penicillins with amines and other nucleophiles resembles carboxylic acid anhydrides in their acylating capability (*18*). We used this reactivity as the strategy to functionalize the amino terminal groups on the periphery of PAMAM dendrimers. To determine the reaction rate, we previously reacted benzylpenicillin sodium salt with butylamine at NMR scale using D_2O as solvent. The characteristic ^{1}H chemical shifts for protons H-6 and H-5 in the β-lactam ring of benzylpenicillin were used to monitor the progress of the reaction. These two protons resonate at 5.53 and 5.41 ppm ($J_{5,6}$ = 3.9 Hz) in benzylpenicillin, and at 4.85 and 4.30 ppm ($J_{5,6}$ = 8.5 Hz) when the β-lactam ring is open. The reaction was very fast and completed within 15 min. Furthermore, only the product corresponding to the aminolysis of the β-lactam ring was detected (compound **1**). The efficiency and rate of this coupling reaction encouraged us to use the same procedure to synthesize the functionalized dendrimers (**G_nP**).

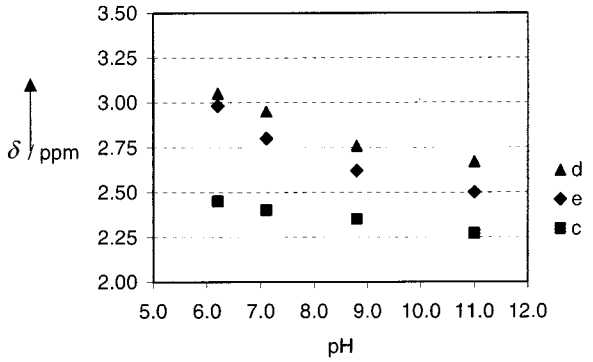

Figure 1. Influence of pH on δ for the inner protons in **G_0P** (for assignments, see Chart 1).

Three different generations of dendrimers were employed (n = 0−2), the reactions being carried out in an aqueous carbonate buffer at pH 10.8 (to ensure that every terminal amino group in the PAMAM dendrimer was deprotonated), using excess benzylpenicillin and controlling the temperature, which turned out to be a strongly influential factor. All products were purified by size-exclusion chromatography and provided essentially pure dendrimers (**G_0P**−**G_2P**) the chemical structure of which was unequivocally assigned by mass spectrometry and ^{13}C and ^{1}H NMR spectroscopy.

The reaction of the zero-generation dendrimer (**G_0**) was monitored by ^{1}H NMR in D_2O, using basic pD obtained by addition of Na_2CO_3. Under these conditions, the ^{1}H NMR spectrum was very clear and contained a single set of signals each of which integrated correctly with the expected number of protons, according to the chemical structure. The resonances for the methylene protons directly bonded to the terminal amino groups were very useful as they clearly reflected deshielding of this signal from 2.70 to 3.22 ppm as the coupling reaction developed. On the other hand, the ^{1}H NMR spectrum recorded in D_2O containing no Na_2CO_3 exhibited two sets of signals that can be assigned to the presence of protonated species (*19*). Therefore, recording the NMR spectra at a basic pD was crucial with a view to evaluating the synthesized dendrimers. Figure 1 shows the influence of pH on the ^{1}H chemical shift (δ) of the inner protons in dendrimer **G_0P**.

The ^{13}C NMR spectrum (Figure 2) was very useful to confirm the structural homogeneity of this compound. While carbons (a) and (b) appeared at 42.78 and 40.82 ppm, respectively, in the zeroth-generation PAMAM dendrimer, they resonated at virtually the same frequency (39.50 and 39.61 ppm) in **G_0P**. The absence of signals for carbons bonded to unsubstituted amino groups confirmed the efficiency of the coupling process.

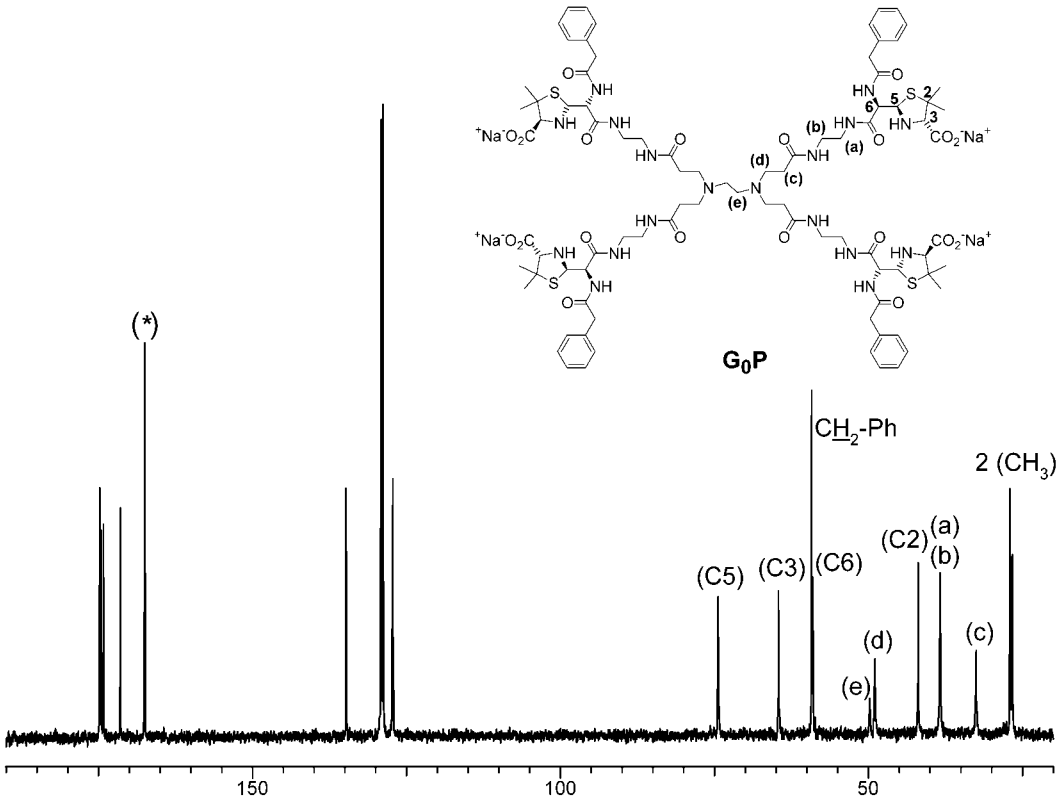

Figure 2. ^{13}C NMR spectrum [100 MHz, D_2O + Na_2CO_3(*)] for dendrimer **G_0P**.

Table 1. Molecular Masses for the Synthesized Dendrimers

		molecular weight	
compound	molecular formula	calculated	observed
G_0P(Na)	$C_{86}H_{116}N_{18}O_{20}S_4Na_4$	1942	1943 $[M+H]^+$ [a]
G_0P(H)	$C_{86}H_{120}N_{18}O_{20}S_4$	1854	1855 $[M+H]^+$ [b]
G_1P(H)	$C_{190}H_{272}N_{42}O_{44}S_8$	4105	4106 $[M+H]^+$ [b]
G_2P(H)	$C_{398}H_{576}N_{90}O_{92}S_{16}$	8606	8607 $[M+H]^+$ [b]

[a] FAB-MS. [b] MALDI-TOF-MS.

Mass spectrometry analysis was carried out using the fast atom bombardment (FAB) and matrix-assisted laser-desorption ionization time of flight (MALDI-TOF) techniques (Table 1). The zeroth-generation dendrimer (**G_0P-(Na)**) was analyzed by FAB-MS, which afforded a molecular ion at $m/z = 1943$ in the spectrum, corresponding to its $[M + H]^+$ adduct. The best conditions for recording the MALDI-TOF mass spectrum for this compound were dissolving the product in 1:1 H_2O/CH_3CN containing 0.1% trifluoroacetic acid (TFA) and using 2,4,6-trihydroxyacetophenone (THAP) as matrix. Under these conditions, the carboxylic moieties in **G_0P** are expected to be protonated (**G_0P(H)**), so a peak corresponding to this structure was found at higher m/z values in the spectrum ($[M + H]^+$).

The first-generation penicilloylated dendrimer (**G_1P**) was synthesized in the same manner, starting from first generation PAMAM dendrimer and using excess benzylpenicillin. The ^1H NMR and ^{13}C NMR spectra were very similar to those for the zeroth-generation dendrimer; the mass spectrometry analysis was performed by using the MALDI-TOF technique under the above-described conditions. A peak matching $[M + H]^+$ for **G_1P(H)** was found in the molecular ion region corresponding to the dendrimer with carboxylic acid moieties in the penicilloyl portions (Table 1).

All attempts at obtaining the functionalized second-generation dendrimer (**G_2P**) under the same conditions as **G_0P** and **G_1P** failed; the result was the second-generation dendrimer with incomplete peripheral substitution. The ^{13}C NMR spectrum showed small signals that could be assigned to carbons bonded to unsubstituted amino groups, as later confirmed by the MALDI-TOF-MS analysis. Attempts involving more drastic conditions (e.g., a higher temperature, an increased concentration of benzylpenicillin, a prolonged reaction time), starting either from the second generation PAMAM dendrimer or the isolated, partially functionalized dendrimer, provided no improvement.

The dendritic structure is a dynamic system (*20*) and, as such, due to the apparent conformational mobility (*21*) it might result in a statistically higher spatial volume engaged with every bulky terminal penicilloyl group. This fact could introduce additional steric hindrance in benzylpenicillin approach to unsubstituted terminal amino groups. However, this restrictive factor could be reduced decreasing the mobility of the partially functionalized dendrimer. Similar observations were reported for a completely different dendrimer family (*9b*) in whitch formation of a "sugar ball" dendrimeric precursor was attempted by terminating the reaction at low temperature.

Bearing in mind this consideration, and the proven efficiency of the coupling process employed, we synthesized **G_2P** at a low temperature (4 °C) to ensure complete peripheral substitution. The penicilloylated dendrimer obtained with this method **G_2P** exhibited ^1H NMR and ^{13}C NMR spectra similar to those for **G_0P** and **G_1P**. The mass spectrometry analysis of the second generation dendrimer, performed using the MALDI-TOF technique and 3,5-dimethoxy-4-hydroxycinnamic acid as matrix, revealed the expected peak at $m/z = 8607$ ($[M + H]^+$,

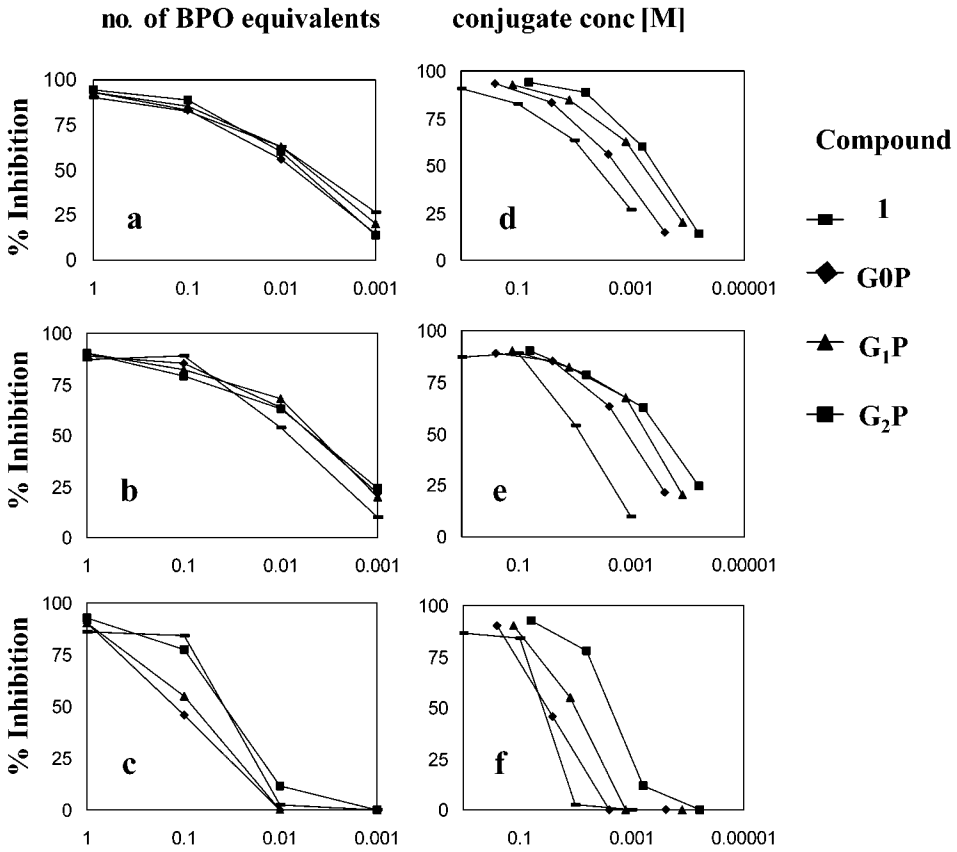

Figure 3. RAST inhibition assay. Sera from patients allergic to penicillins with different specific IgE antibody levels were tested. Specific IgE antibody levels were 7.24 for sera of low affinity (a/d), 9.14 for sera of medium affinity (b/e), and 13.41 for sera of high affinity (c/f). BPO−PLL disks were used in the solid phase. Different dendrimers conjugated to benzylpenicillin **G_0P**, **G_1P**, and **G_2P** and butylamine conjugated to benzylpenicillin **1** were used as inhibitors in the fluid phase.

$G_2P(H)$, Table 1), which confirmed the complete peripheral functionalization of this compound.

To compare the capacity of different dendrimers conjugated to penicillin to bind specific IgE antibodies, RAST inhibition studies were carried out using sera from patients allergic to penicillin. Figure 3 shows the inhibition curves obtained with sera from three patients with different specific IgE antibody levels (ranging from 7 to 13%) determined previously by RAST. As seen, these dendrimers are recognized by the specific IgE antibody from patients allergic to penicillin. We first compared the results obtained with the different conjugates using the same number of penicillin equivalents (Figures 3a, 3b, and 3c). For this, different concentrations of the inhibitors were used, but as they had the same number of penicillin equivalents, there were no differences between the dendrimers and the monomer of butylamine, the pattern being similar in all the sera studied. When we compared these results in terms of conjugate concentrations (Figures 3d, 3e, and 3f), there were clear differences in the capacity of the different dendrimers and butylamine conjugate to bind to specific IgE antibodies. The maximum inhibition in all three cases studied was with **G_2P**, followed by **G_1P**, **G_0P**, and finally **1**. This indicates that a concentration of **1** approximately 100 fold higher than that for **G_2P** is needed to obtain the same percentage inhibition. The differences with the other dendrimers are less clear, although there was a direct correlation between the molecular weight of the dendrimer and the specific IgE antibody binding capacity.

In summary, we synthesized and characterized a series of densely penicilloylated dendrimers (**G_nP**, $n = 0-2$) with precisely defined chemical structures. These dendrimers exhibit very similar, simple ^{1}H NMR and ^{13}C NMR spectra that are suggestive of highly symmetric structures and of the monodisperse nature of these compounds. Furthermore, the mass spectrometry analysis of these functional dendrimers confirmed their exact chemical composition. This constitutes significant progress compared with conventional benzylpenicilloyl conjugates (BPO−HSA and BPO−PLL).

The proposed approach to the synthesis of dendrimer **G_2P** can be a useful tool for the functionalizing of this type of dendrimer provided the coupling process employed is efficient enough. As noted earlier, the use of "forcing conditions" led to no improved results.

Preliminary RAST inhibition studies have confirmed the usefulness of penicilloylated dendrimers as conjugates for the recognition of IgE antibodies from patients allergic to penicillin. We are now ready to evaluate the relevance of the size of the hapten−carrier conjugate and hapten density profile in recognition, simply by changing the generation of the starting dendrimer (in our study there was an increase in the percent RAST inhibition from generation 0 to 2). Thus, presenting many penicillin determinants to specific IgE antibodies using structures able to carry many hapten molecules would increase in vitro sensitivity. Consequently, these compounds can be considered promising candidates for use in the development of a new in vitro test, with increased sensitivity for the diagnosis of allergy to β-lactam antibiotics compared to the test used until now. Work is in progress in our laboratories.

ACKNOWLEDGMENT

This work was supported by funds granted for the realization of the FEDER Project 1FD97-0516. F.S-S is grateful for the award of a fellowship related to this project. The authors are also grateful to Prof. E. Giralt (Departamento de Química Orgánica, Universidad de Barcelona, Spain) for recording the MALDI-TOF-MS spectra and to Dr. M. Maestro (SXAIN, Universidad de La Coruña, Spain) for the FAB-MS spectrum.

Supporting Information Available: Preparation procedure, chemical structure, ^{1}H and ^{13}C NMR data, and MALDI-TOF-MS data and spectra for **G_0P**, **G_1P**, and **G_2P**; FAB-MS data for **G_0P**. This material is available free of charge via the Internet at http://pubs.acs.org.

Radiolabeled peptides are emerging tools for diagnosis and therapy of tumors overexpressing receptors. However, binding to receptors expressed by nontumor tissues may cause toxicity. The objective of this study was to specifically enhance the binding affinity of labeled peptides to tumor cells, as opposed to receptor-positive nontumor cells, to ensure targeting selectivity. This was achieved by the simultaneous binding of hapten-bearing peptides to their receptor and to a tumor-associated antigen, mediated by a bispecific antibody directed to the tumor antigen and to the hapten. Binding of labeled neurotensin analogues bearing the DTPA(indium) hapten (NT−DTPA(^{111}In)) to human colorectal carcinoma cells (HT29), which express the neurotensin receptor (NTR1) and carcinoembryonic antigen (CEA), was studied in the presence of a bispecific antibody (BsmAb) directed to CEA and to DTPA-(indium). In vitro dual binding of NT−DTPA in the presence of BsmAb was about 6.5-fold higher than monovalent binding to NTR1 and 3.5-fold higher than the sum of the monovalent bindings to NTR1 or to CEA, suggesting cooperativity. Increased binding under bivalent conditions translated into increased internalization. In vivo pretargeting with BsmAb enhanced tumor uptake and tumor retention. Hapten bearing peptides binding simultaneously an overexpressed cell-surface receptor and a tumor antigen show increased selectivity to target tumor cells as compared to cells only expressing the cell surface receptor. Better resistance to enzymatic degradation and optimized administration protocols should further enhance in vivo targeting selectivity and may allow the development of radiopharmaceuticals labeled with isotopes suitable for radiotherapy such as ^{131}I or ^{90}Y.

INTRODUCTION

Many tumors overexpress receptors for small biologically active peptides, such as hormones or neuromediators. Their radiolabeled analogues are potential tools for tumor targeting. Their fast diffusion in tumor tissue offers a major pharmacokinetic advantage as compared to antibodies. In addition, internalization of receptor-bound ligands offers an opportunity for isotope accumulation in target cells. The potential of peptide radiopharmaceuticals is illustrated by the successful development of somatostatin analogues to visualize tumors and more recently by therapeutic applications (*1*, *2*). Labeled analogues of peptide ligands for several other receptors, overexpressed by tumors (*3*), such as CCK (*4*, *5*), gastrin (*4*), vasoactive intestinal peptide (*6*), melanocyte stimulating hormone (*7*), and neurotensin (*8*) are under investigation. However, the background due to receptor-positive nontumor tissues contributes to decrease tumor to normal tissue uptake ratios and is expected to cause toxicity (*9*).

Enhancement of the affinity of a peptide for tumor cell surface, as opposed to receptor-positive nontumor tissue, would increase targeting selectivity and might be a key step to the development of more efficient therapeutic agents. It is well-known that affinity is enhanced by the cooperativity of multivalent binding. The aim of the present study was to evaluate the feasibility of increasing the binding affinity of a labeled peptide for receptor-positive tumor cells by the simultaneous targeting of an endogenous receptor and an antigen at the tumor cell surface. With an adequate choice of the antigen and of the receptor, no affinity enhancement will occur on nontumor tissue expressing only one of these targets. Hence, double targeting will enhance selectivity for tumor cells.

The binding of an anti-hapten x anti-antigen bispecific antibody (BsmAb) to a selected tumor-associated antigen provides hapten-binding sites at the tumor cell surface. Then a labeled hapten-bearing ligand can bind simultaneously to a tumor-overexpressed receptor and to the bispecific antibody (Figure 1).

To evaluate this approach we have chosen carcinoembryonic antigen (CEA) and type 1 neurotensin receptor (NTR1) dual targeting as a model. CEA and NTR1 expression is encountered on some colorectal carcinomas, breast, small cell lung carcinoma, and pancreatic carcinoma cells. The HT29 colorectal carcinoma cell line was used to investigate this approach (*10*, *11*). The diethyl-

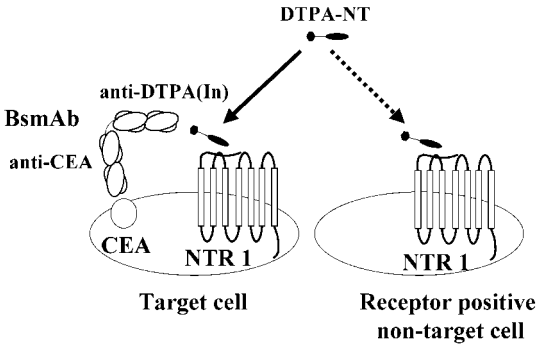

Figure 1. Schematic representation of enhanced tumor targeting specificity of a hapten-bearing peptide by dual targeting of a receptor and an antigen. At the tumor cell surface the dual binding of DTPA(indium)−NT analogue to NTR1 and to the BsmAb bound to CEA will provide affinity enhancement. This will not occur at the surface of receptor-positive antigen-negative nontumor cells. (DTPA: diethylenetriaminepentaacetic acid, NT: neurotensin, BsmAb: anti-CEA x anti-DTPA(indium) bispecific antibody).

enetriaminepentaacetic acid (DTPA)−indium complex (DTPA(indium)) was used as a hapten. Two neurotensin analogues bearing the DTPA(indium) hapten (DTPA−NT) were synthesized. Their dual binding to NTR1 and to CEA at HT29 cell surface, in the presence of anti-CEA x anti-DTPA(indium) BsmAb, was studied in vitro and in vivo.

MATERIAL AND METHODS

Cells. HT29 cells (ATCC, Rockville, MD) are human colorectal carcinoma cells that express the high affinity neurotensin receptor (NTR1) (*10*) and CEA (*11*) at their surface. These cells were grown in DMEM medium (Gibco, France) supplemented with 10% fetal calf serum (FCS), 1% glutamine, and 0.1% gentamycin at 37 °C in 5% CO_2.

For binding experiments, cells were treated as described by Velcich et al. (*11*) in order to increase CEA expression. Briefly, cells were distributed into 12-well Corning dishes (6×10^5 cells per well in 1 mL) and incubated at 37 °C for 24 h using the culture conditions described above. Culture medium was then replaced by 1 mL of low serum medium (0.05% FCS). Twenty-four hours later, cells were treated with low serum medium supplemented with 10 μg/mL forskolin (Sigma, France).

Synthesis of the DTPA−NT Analogues. DTPA-dianhydride (Aldrich, France) was reacted with the lysine ϵ-NH_2 of neurotensin (pGlu-Leu-Tyr-Glu-Asn-Lys-Pro-Arg-Arg-Pro-Tyr-Ile-Leu) (Neosystem, France) or with the α-NH_2 of a neurotensin analogue (Gly-Glu-Leu-Tyr-Glu-Asn-Lys(Ac)-Pro-Arg-Arg-Pro-Tyr-Ile-Leu) (Neosystem, France) to obtain, respectively, pGlu-Leu-Tyr-Glu-Asn-Lys(DTPA)-Pro-Arg-Arg-Pro-Tyr-Ile-Leu (hereafter referred to as [Lys(DTPA)]−NT) and DTPA−Gly-Glu-Leu-Tyr-Glu-Asn-Lys(Ac)-Pro-Arg-Arg-Pro-Tyr-Ile-Leu (DTPA−Gly−NT).

Briefly, 1.8 μmol of a neurotensin solution (220 μL) in HEPES buffer (0.6 M, pH 8.2, filtered through Chelex 100 (Biorad, France)) was added with stirring to 14.5 μmol of DTPA dianhydride (Aldrich, France) in solution in DMSO (220 μL). The pH was maintained at 8.2 until the reaction was completed. After evaporation of the solvents, the crude product was dissolved in water and trifluoroacetic acid to reach pH 2. The solution was filtered through Chelex 100. DTPA−NT analogues were purified by C18 reverse phase chromatography (Nucleosil, Shandon, France) using a linear 15-min gradient (A: H_2O/TFA(0.05%), B: acetonitrile) from 0% to 26% B and a linear 20-min gradient from 26% to 30%. Purity was checked by C18 reverse phase chromatography under isocratic conditions (acetonitrile 30%, H_2O/TFA 0.05%). Both peptides were purified to at least 95% purity. The DTPA−NT analogues were characterized by mass spectrometry 2048.16 found, 2048.32 calculated for [Lys-(DTPA)]−NT, 2165.50 found and 2165.37 calculated for DTPA−Gly−NT using a Nermag R10−10 mass spectrometer with an electrospray ion source (Analytica of Branford) equipped with an iron guide.

Antibodies. All antibodies used in this work were kindly provided by Immunotech S.A., France. The anti-CEA (clone F6) is a mouse $IgG_{1,\kappa}$ monoclonal antibody specific for human CEA (*12*). The antibody directed to the DTPA(indium) complex is an $IgG_{1,\lambda}$ (*13*).

The anti-DTPA(indium) Fab′ fragment was biotinylated and immobilized on avidin-coated tubes (Immunotech S.A., France) to determine DTPA(indium)−NT immunoreactivity (1 μg per tube) or equilibrium affinity constants (0.1 μg per tube). The anti-CEA x anti-DTPA-(indium) BsmAb was prepared as already described (*14*) by chemical coupling of the two reduced Fab′ fragments using *o*-phenylenedimaleimide. Equilibrium affinity constant (K_a) for the binding of anti-CEA x anti-DTPA-(indium) BsmAb to CEA expressed at HT29 cell surface was determined as $2.6 \pm 1.4 \times 10^8$ M^{-1} by competition binding experiments between ^{125}I-labeled Bsmab (prepared by the iodogen method (*15*)) and increasing concentrations of unlabeled Bsmab (1×10^{-10} M to 1×10^{-8} M). Nonspecific binding was evaluated in the presence of excess unlabeled anti-CEA IgG (2×10^{-7} M). The number of binding sites per HT29 cell was $2.1 \pm 0.1 \times 10^4$ after a 24-h treatment by forskolin, about 6-fold higher than that determined without forskolin treatment ($3.5 \pm 0.7 \times 10^3$). All subsequent experiments were performed on forskolin-treated HT29 cells. The anti-CEA immunoreactivity of the BsmAb was 87% (*16*) and the anti-DTPA(indium) immunoreactivity of the BsmAb determined by incubating trace amounts of ^{125}I-labeled BsmAb in DTPA(indium)-coated tubes was 85%.

Radiolabeling. The DTPA−NT analogues (0.2 nmol) were labeled with indium-111 ($^{111}InCl_3$, 11.1 MBq, CIS bio international, France) in 100 mM acetate−10 mM citrate buffer pH 5.0 during 22 h at room temperature. Then, since the anti-DTPA(indium) antibody is specific to the DTPA(indium) complex, free DTPA groups were saturated with nonradioactive $InCl_3$ (2 nmol) in the same buffer. Excess free indium was removed on a Sep-Pak cartridge (Waters, Milford, MA) in acetate−citrate buffer, followed by elution of the labeled DTPA−NT analogues in acetate−citrate buffer/ethanol (50/50, v/v). ^{111}In-labeling of both DTPA−NT analogues led to a chelation of indium-111 of 88 ± 5% for ^{111}In-labeled [Lys(DTPA)]−NT and 85 ± 4% for DTPA(^{111}In)−Gly−NT. Their specific activities were very similar: 179 ± 16 and 177 ± 12 MBq/nmol, respectively.

Computer Simulations. Delaage and co-workers (*17*, *18*) have introduced several years ago a methodology to calculate binding equilibrium under complex situations. This methodology has been implemented as an add-in to Microsoft Excel 97 run on an ordinary PC (*19*). The multiple equilibrium system is described by a partition function, and the program calculates the free concentrations of all interacting species by minimizing the partition function for a given set of parameters. Then parameter estimation is obtained by variance-weighted nonlinear least-squares regression. Results are given as the best-fit estimation ± SD. This program allowed us to deter-

mine unknown parameters such as binding affinity, receptor density, or accessibility factors to interpret binding experiments. In addition it allowed us to test for the cooperativity of peptide-binding to target cells (*19*). This program is available on request to J. B. (Jacques.Barbet@nantes.inserm.fr).

Briefly, steps to model the multiple binding system are described as follows. F1 is the free NT-DTPA(In) concentration, F2 the free BsmAb concentration, F3 the NTR concentration, F4 the CEA concentration, P1 the affinity binding constant (K_a) of NT-DTPA to the antibody, P2 the K_a for binding of the antibody to CEA, P3 the K_a for binding of NT-DTPA to NTR, P4 an accessibility factor (taking into account a loss in affinity for a simultaneous binding of NT−DTPA to the receptor and the BsmAb), and P5 a cooperativity factor (reflecting the enhanced binding in dual binding condition). The concentrations of the various complexes formed are [NT-DTPA-(In)+BsmAb]:F1.F2.P1; [BsMAb+CEA]: F2.F4.P2; [NTR+NT-DTPA(In)]: F1.F3.P3; [NTR+NT-DTPA(In)+ BsmAb]:F1.F3.P3. F2.P1.P4; [NTR+NT-DTPA(In)+ BsmAb+CEA]:F1.F3.P3. F2.P1.P4.F3.P3.P5. Binding affinity constants were set to the values determined in independent experiments, and the number of CEA and NTR binding sites and the accessibility and cooperativity factors were estimated, from experimental data, by the program.

NT−DTPA Analogues Binding Parameters Determination. Equilibrium affinity binding constant (K_a) and immunoreactivity of ligands were evaluated from binding experiments on cells or on antibody-coated tubes. Binding parameters were then determined from experimental results by curve-fitting to experimental bound-to-total ratios for all available data using the program described above. Every result is expressed as mean ± standard deviation.

Determination of DTPA−NT Analogues Binding Affinities to the Anti-DTPA(Indium) Antibody. Affinity constants of each ^{111}In-labeled DTPA−NT analogue for anti-DTPA(indium) antibody were determined by incubating trace amounts of the ^{111}In-labeled [Lys-(DTPA)]−NT and increasing concentrations of unlabeled DTPA−NT analogue saturated with nonradioactive $InCl_3$ (5.1×10^{-11} M to 10^{-6} M) in anti-DTPA(indium)-coated tubes (0.1 μg) in a final volume of 1 mL of phosphate-buffered saline (PBS) supplemented with 0.2% bovine serum albumin (BSA) for 2.5 h at 37 °C under shaking. Then 100 μL of supernatant were collected and counted. Tubes were washed twice with 0.9% NaCl and 0.002% Tween 20 and counted. Nonspecific binding was evaluated in the presence of excess unlabeled DTPA−NT analogues (saturated with nonradioactive indium, 10^{-6} M) (two experiments in duplicate).

Determination of DTPA−NT Analogues Binding Affinities to NTR1. Neurotensin (NT) was labeled with iodine-125 by the lactoperoxidase method (*20*) and purified by ion-exchange chromatography. Cells were incubated in the presence of trace amounts of ^{125}I-neurotensin and increasing concentrations of unlabeled DTPA−NT analogues saturated with nonradioactive indium (4×10^{-10} M to 1×10^{-6} M) in 500 μL of binding medium (DMEM/0.2% BSA/0.8 mM 1,10-phenanthroline). For each experiment, nonspecific binding was evaluated in the presence of an excess of unlabeled neurotensin (1×10^{-6} M). After 1 h at 37 °C, 50 μL of the supernatant were taken off. Cells were washed twice with ice-cold DMEM/BSA 0.2% and removed from the wells by addition of 900 μL 0.1 M NaOH and counted. An aliquot of the supernatant was counted (three experiments in triplicate).

Binding of DTPA−NT Analogues to HT29 Cells in the Presence of Anti-CEA x Anti-DTPA(Indium) Bispecific Antibody. As HT29 cells simultaneously express CEA and NTR1, monovalent binding of DTPA−NT analogues to CEA, mediated by the BsmAb, was evaluated in the presence of excess unlabeled neurotensin in order to saturate NTR1 at cell surface. This condition mimics cells expressing CEA alone. Monovalent binding of DTPA−NT analogues to NTR1 in the presence of BsmAb was studied using excess anti-CEA IgG to saturate CEA at cell surface, mimicking cells expressing NTR1 alone. Dual binding was studied in parallel in absence of neurotensin or anti-CEA IgG.

The following protocol (protocol 1) was used in most experiments unless otherwise stated. A solution of BsmAb (300 μL, binding medium) was preincubated on the cells. After 2 h of incubation at 37 °C, ^{111}In-labeled-DTPA−NT analogues (200 μL binding medium) were added without washing. Then, the cells were incubated for 1 h at 37 °C. Final concentrations: DTPA(^{111}In)−NT 0.15×10^{-9} M, BsmAb as indicated. The cells and the supernatant were counted as above. For NTR1 monovalent binding experiments, the BsmAb solution contained excess anti-CEA IgG (2×10^{-7} M, final concentration), and for CEA monovalent binding experiments, the ^{111}In-labeled-DTPA−NT analogue solution contained excess neurotensin (1×10^{-6} M, final concentration).

In protocol 2, BsmAb was preincubated as above, and after 2 h at 37 °C, cells were washed once with ice-cold DMEM/0.2% BSA and incubated with 500 μL of ^{111}In-labeled-DTPA−NT analogues for 1 h at 37 °C. In protocol 3, the ^{111}In-labeled-DTPA−NT analogues were incubated with BsmAb in 500 μL of binding medium for 30 min at 37 °C before a 1-h incubation with the cells.

Binding kinetics and internalization experiments were performed with a 2-h pretargeting of the BsmAb without washing (protocol 1), with a final BsmAb concentration of 6×10^{-9} M and of 0.15×10^{-9} M ^{111}In-labeled-DTPA−NT analogues. At selected time intervals (15, 30, 60, 120, and 240 min), supernatant and cells were removed and counted as above for binding determination. The internalized fraction was evaluated by treating the cells for 15 min at 4 °C with DMEM/0.2% BSA adjusted to pH 2.0 with 1 M HCl. This last procedure dissociated surface-bound ligands. Cells were then washed twice with ice-cold DMEM/0.2% BSA. The radioactivity of the cells was counted. Internalization was expressed as the percentage of the total incubated activity that remained associated with the cells after acid wash. As above, for each condition the monovalent binding to CEA or NTR1 was determined in the presence of excess neurotensin or anti-CEA IgG, respectively.

In Vivo Experiments. Animal experiments were performed in compliance with the regulations of the institution and with generally accepted guidelines governing such work.

Animals. Female SWISS nu/nu mice, 6−8 weeks old (Iffa Credo, France), were grafted by subcutaneous injection in the flank with 2×10^6 HT29 human colorectal carcinoma cells. Biodistribution studies were performed two weeks later.

Biodistribution. Mice were given anti-CEA x anti-DTPA(indium) or an irrelevant anti-CD20 x anti-DTPA-(indium) BsmAb (40 pmol in 150 μL of PBS) or vehicle only by intravenous injection. Twenty-four hours later, ^{111}In-labeled [Lys(DTPA)]−NT (15−30 pmol, 25 MBq/

nmol) or an irrelevant ^{111}In-DTPA-bearing peptide AG5.1 (Ac-Lys(DTPA)-GABA-D-Tyr-GABA-Lys(Gly succinyl-histamine)-NH_2) (*19*) (15 pmol, 25 MBq/nmol) was injected iv. Mice were weighed and sacrificed at selected time intervals (1, 3, and 24 h). Tumor, organs, and blood were collected, and the radioactivity in these samples was determined. The injected doses were corrected for losses during injection and subcutaneously injected material remaining in the animal tail.

Tumor Imaging. For imaging studies, mice were administered with relevant BsmAb (40 pmol) or vehicle 24 h before ^{111}In-labeled [Lys(DTPA)]−NT (30 pmol) as described above. Images of the two groups were recorded simultaneously at 3, 6, and 24 h after injection of the labeled analogue. Mice were anesthetized and positioned on the head of the gamma-camera (Picker Prism2000XP). Acquisition was performed for 15 min with 163−183 keV and 237−257 keV energy windows.

Statistical Analysis. Student t test was used to evaluate the significance of in vitro results. For in vivo experiments, statistical analysis of differences in the tissue uptake values and tumor-to-organ ratios was performed using ANOVA variance analysis followed by the Newman−Keuls test. Differences at $p < 0.05$ were considered significant.

RESULTS

Synthesis of the DTPA−NT Analogues. Two neurotensin analogues, pGlu-Leu-Tyr-Glu-Asn-Lys(DTPA)-Pro-Arg-Arg-Pro-Tyr-Ile-Leu ([Lys(DTPA)]−NT) and DTPA−Gly-Glu-Leu-Tyr-Glu-Asn-Lys(Ac)-Pro-Arg-Arg-Pro-Tyr-Ile-Leu (DTPA−Gly−NT), bearing the hapten DTPA, which is a chelating agent suitable for ^{111}In-labeling, have been synthesized by coupling DTPA to an NH_2 group as described in Materials and Methods. Both peptides were purified to at least 95% purity and identified by mass spectrometry.

Equilibrium Affinity Constants of DTPA−NT Analogues Binding to Anti-DTPA(Indium) Antibody. Equilibrium affinity constants for the binding of DTPA−NT analogues to anti-DTPA(indium) antibody were determined by competition experiments. The affinity constant of [Lys(DTPA)]−NT for binding to anti-DTPA-(indium) antibody was $8.4 \pm 0.7 \times 10^8$ M^{-1}, which is in agreement with K_a values determined for peptides bearing DTPA coupled to the ϵ-NH_2 of a lysine (*19*). The K_a binding value decreased when DTPA was coupled to the α-NH_2 of the glycine residue ($1.6 \pm 0.1 \times 10^8$ M^{-1} for DTPA−Gly−NT).

Affinity Constants of DTPA−NT Analogues Binding to NTR1. Affinity parameters for the binding of DTPA−NT analogues to NTR1 were determined by competition experiments. The affinity constants were similar for both DTPA−NT analogues ($1.0 \pm 0.4 \times 10^8$ M^{-1} for [Lys(DTPA)]−NT and $8.7 \pm 3.4 \times 10^7$ M^{-1} for DTPA−Gly−NT) and about 10-fold lower than that of neurotensin ($9.7 \pm 3.0 \times 10^8$ M^{-1}) determined in the same experiment. The number of binding sites was $4.9 \pm 1.1 \times 10^4$ per cell.

Monovalent Binding of DTPA−NT Analogues to NTR1 at HT29 Cell Surface in the Presence of Anti-CEA x Anti-DTPA(Indium) Bispecific Antibody. To study the monovalent binding of DTPA−NT analogues to NTR1 in the presence of BsmAb, CEA at cell surface was saturated with 2×10^{-7} M anti-CEA IgG (no difference was observed between 2×10^{-7} M and 1×10^{-6} M). Increasing the BsmAb concentration (7.2×10^{-11} M to 5.4×10^{-8} M) decreased the binding of DTPA−NT analogues to NTR1 by about 75% (from 1189 ± 234 to 256 ± 5 molecules per cell, $P < 0.001$) for [Lys(DTPA)]−NT (Figure 2A) and about 62% (from 1231 ± 159 to 428 ± 41 molecules per cell, $P = 0.001$) for DTPA−Gly−NT (Figure 3A) at the highest BsmAb concentration tested. This reduced binding was interpreted in terms of accessibility factors (0.13 ± 0.02 for [Lys(DTPA)]−NT and 0.11 ± 0.04 for DTPA−Gly−NT expressing steric hindrance in the simultaneous binding of the relatively small hapten-bearing peptide to the NT receptor and the anti-hapten antibody.

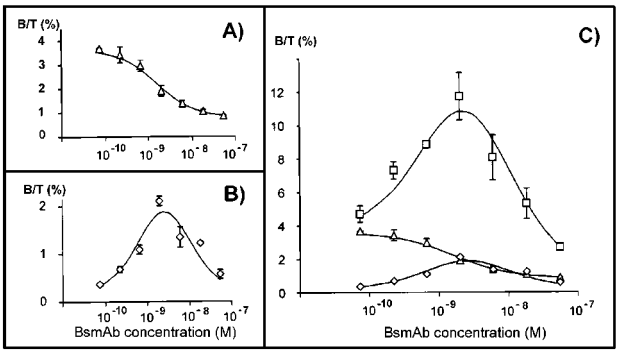

Figure 2. Binding of [Lys(DTPA)]−NT to CEA and NTR1 in the presence of increasing concentrations of pretargeted anti-DTPA(indium) x anti-CEA BsmAb. A: monovalent binding to NTR1 in the presence of excess anti-CEA IgG (2×10^{-7} M) (△: experimental, curve: computer simulation), B: monovalent binding to CEA determined in the presence of excess NT (1×10^{-6} M) (◇: experimental, curve: computer simulation), C: dual binding (□: experimental, curve: computer simulation). Final concentration of [Lys(DTPA)]−NT: 0.15×10^{-9} M. Fraction of radioactivity associated to the cells (B/T%) was counted. The mean of triplicate determinations are plotted ± standard deviation unless smaller than the point as plotted.

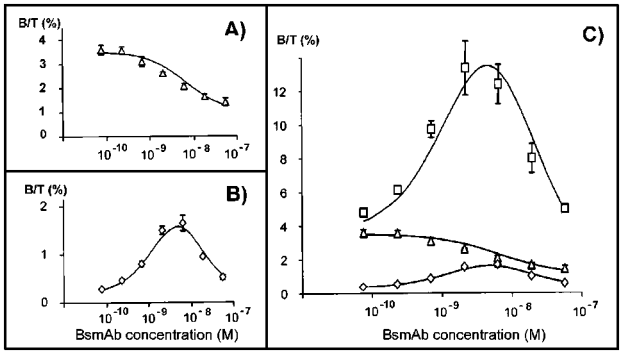

Figure 3. Binding of DTPA−Gly−NT to CEA and NTR1 in the presence of increasing concentrations of pretargeted anti-DTPA(indium) x anti-CEA BsmAb. A: monovalent binding to NTR1 in the presence of excess anti-CEA IgG (2×10^{-7} M) (△: experimental, curve: computer simulation), B: monovalent binding to CEA determined in the presence of excess NT (1×10^{-6} M) (◇: experimental, curve: computer simulation), C: dual binding (□: experimental, curve: computer simulation). Final concentration of DTPA−Gly−NT: 0.15×10^{-9} M. Fraction of radioactivity associated to the cells (B/T%) was counted. The mean of triplicate determinations are plotted ± standard deviation unless smaller than the point as plotted.

Monovalent Binding of DTPA−NT Analogues to HT29 Cell Surface CEA. The monovalent binding of the labeled DTPA−NT analogues to CEA was monitored in the presence of increasing concentrations of BsmAb (7.2×10^{-11} M to 5.4×10^{-8} M). As HT29 cells simultaneously express NTR1 and CEA, the binding to CEA was evaluated in the presence of excess neurotensin (1×10^{-6} M) to saturate NTR1. Binding increased with increasing concentrations of BsmAb to reach a maximum of 535 ±

173 molecules bound per cell at a BsmAb concentration of 2×10^{-9} M for [Lys(DTPA)]−NT (Figure 2B) and of 493 ± 42 at a BsmAb concentration of 6×10^{-9} M for DTPA−Gly−NT (Figure 3B). Then, at higher BsmAb concentrations, labeled DTPA−NT analogues were trapped by excess antibody in the supernatant and binding to cells decreased.

Bivalent Binding of DTPA-NT Analogues to CEA and NTR1. The dual binding of the ^{111}In-labeled DTPA−NT analogues to NTR1 and CEA was studied in the presence of increasing bispecific antibody concentrations (7.2×10^{-11} M to 5.4×10^{-8} M). It was compared to monovalent binding to NTR1 and to CEA in experiments run in parallel. Dual binding exhibited a bell-shaped curve, as expected from the increasing concentration of free antibody in the supernatant (Figure 2C, 3C). Maximal bivalent binding of [Lys(DTPA)]−NT was observed at a bispecific antibody concentration of 2×10^{-9} M, and of DTPA−Gly−NT at a BsmAb concentration of 6×10^{-9} M.

Bivalent binding was greater than each monovalent binding to NTR1 or to CEA ($p < 0.001$) except for DTPA−Gly−NT binding to NTR at a 7.2×10^{-11} M BsmAb concentration (Figures 2 and 3). In addition, it was higher than the sum of monovalent bindings in a large range of BsmAb concentration (2.2×10^{-10} M to 5.4×10^{-8} M, $p < 0.001$). The highest ratio between bivalent binding and the sum of the monovalent bindings was observed at a BsmAb concentration of 6×10^{-9} M. At this BsmAb concentration, 3123 ± 406 molecules of [Lys(DTPA)]−NT were bound per cell versus 461 ± 44 for monovalent binding to NTR1 and 507 ± 108 for monovalent binding to CEA, and 4218 ± 135 molecules of DTPA−Gly−NT versus 640 ± 41 for monovalent binding to NTR1 and 493 ± 42 for monovalent binding to CEA.

Because incubation time is not sufficient for receptor and antigen reexpression, the bound/internalized fractions should reflect the formation of bivalent complexes at the cell surface. Thus, binding on HT 29 cells was evaluated by computer simulation of the binding curves and nonlinear least-squares regression to estimate cooperativity factors. Affinity constants calculated in independent experiments were used to analyze experimental results. Typical curve fits are presented in Figures 2 and 3. Cooperativity factors were estimated to 1090 ± 15 for [Lys(DTPA)]−NT and 2440 ± 668 for DTPA−Gly−NT. Cooperativity far exceeded steric hindrance represented in equilibrium calculations by the accessibility factors determined above. Without the assumption of cooperative binding, satisfactory curve fitting could not be obtained in the bivalent situation.

Kinetics of Bivalent Binding and Internalization of DTPA−NT Analogues to CEA and NTR1. Kinetic experiments were performed with a 2-h pretargeting of the BsmAb (6×10^{-9} M). Binding of [Lys(DTPA)]−NT (Figure 4A) and DTPA−Gly−NT (Figure 4B) increased over the 4-h incubation under the monovalent NTR1 binding condition and bivalent binding condition. However, the ratios between bivalent binding and the sum of monovalent bindings were similar for both analogues and were not significantly increased between 2 and 4 h of incubation (3.2 ± 0.01 at 2 h and 3.7 ± 0.4 at 4 h for [Lys(DTPA)]−NT and 3.5 ± 0.01 and 3.8 ± 0.7, respectively, for DTPA−Gly−NT).

A high fraction of the peptide bound to NTR1 was internalized (86 ± 4% and 79 ± 2% for [Lys(DTPA)]−NT and DTPA−Gly−NT, respectively). A similar fraction of the bound peptide was internalized when bivalent binding was allowed (94 ± 6% and 89 ± 10%, respectively). The amount of internalized radioactivity under bivalent conditions was higher than that observed after binding to NTR1 ($p < 0.001$) for both analogues (7.7 ± 1.1-fold for [Lys(DTPA)]−NT and 6.3 ± 0.9 for DTPA−Gly−NT).

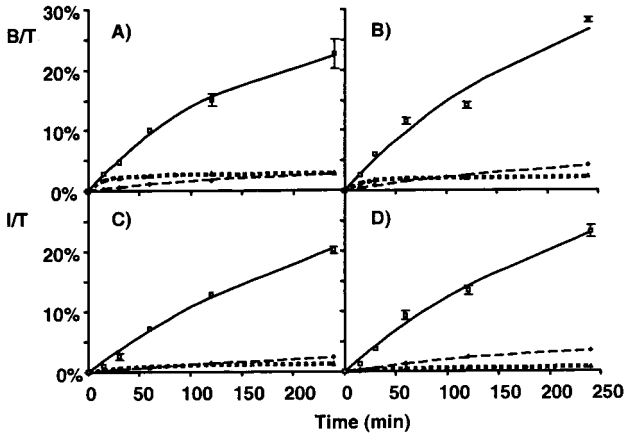

Figure 4. Binding kinetics and kinetics of internalization of DTPA−NT analogues at 37 °C in the presence of pretargeted BsmAb. Binding kinetics [Lys(DTPA)]−NT (A) and DTPA−Gly−NT (B) and kinetics of internalization of [Lys(DTPA)]−NT (C) and DTPA−Gly−NT (D) (final concentrations: 0.15×10^{-9} M DTPA−NT analogues and 6×10^{-9} M BsmAb). Bivalent binding to CEA and NTR1 (solid line) was performed after a 2 h pretargeting of the BsmAb. Monovalent binding to CEA was evaluated in the presence of excess NT (1×10^{-6} M) (dotted line) and monovalent binding to NTR1 in the presence of excess anti-CEA IgG (2×10^{-7} M) (broken line). Fraction of radioactivity associated to the cells (B/T%) or inside the cells (I/T%) was counted. The mean of triplicate determinations are plotted ± standard deviation unless smaller than the point as plotted.

Influence of the Protocol. Pretargeting of the BsmAb without a wash prior to the incubation of the peptide (protocol 1), which was performed in the above-described experiments, was compared to two other experimental conditions using a fixed BsmAb concentration (6×10^{-9} M). Protocol 2 was performed similarly except for a wash of the cells prior to the incubation of the peptide. In protocol 3, the ^{111}In-DTPA−NT analogues were mixed with the BsmAb and incubated 30 min at 37 °C before incubation (1 h) with the cells.

Monovalent binding to NTR1 or to CEA were performed in parallel in the presence of excess anti-CEA IgG or excess neurotensin as described above. Whatever the protocol used, when simultaneous binding to NTR1 and to CEA was allowed, the fraction of peptide bound to cells was increased compared to each monovalent binding conditions (Table 1). In addition, for the three protocols, the bivalent binding was higher than the sum of the monovalent bindings to NTR1 and to CEA suggesting that cooperativity is not dependent on the experimental conditions.

Biodistribution Studies in Human Colorectal Cancer Xenografted Nude Mice. In vivo dual targeting of NTR1 and CEA was studied in nude mice grafted with HT29 cells and preinjected with anti-DTPA(indium) x anti-CEA BsmAb 24 h before ^{111}In-labeled [Lys(DTPA)]−NT injection (Table 2). Radioactivity persistence in blood was increased in mice pretargeted with BsmAb (1.6 ± 0.4 at 1 h, versus 0.32 ± 0.31% ID/g, $p < 0.01$). Pretargeting with BsmAb increased tumor uptake of ^{111}In-labeled [Lys(DTPA)]−NT at 1, 3, and 24 h post peptide injection ($p < 0.01$). In addition, BsmAb pretargeting protracted tumor retention (with BsmAb 20% decrease of tumor activity between 1 h and 3 h postinjection, versus 57% in the absence of BsmAb). Dual

Table 1. Bivalent and Monovalent Bindings of DTPA−Gly−NT and [Lys(DTPA)−NT] to HT29 Cells: Comparison of Three Different Protocols[a]

B/T %	protocol	bivalent binding	monovalent binding to NTR1	monovalent binding to CEA
DTPA−Gly−NT	1	6.1 ± 0.2	1.3 ± 0.1	0.61 ± 0.04
	2	13 ± 1	3.5 ± 0.2	1.9 ± 0.1
	3	2.9 ± 0.2	1.1 ± 0.1	0.23 ± 0.02
[Lys(DTPA)−NT]	1	5.3 ± 0.2	0.62 ± 0.03	1.7 ± 0.1
	2	16 ± 1	2.6 ± 0.1	5.4 ± 1.1
	3	2.3 ± 0.2	0.56 ± 0.04	0.84 ± 0.04

[a] Protocol 1: after 2 h preincubation of BsmAb, ^{111}In-labeled-DTPA−NT analogues were incubated for 1 h; protocol 2 was performed as protocol 1 except for a wash of the cells prior to peptide incubation; protocol 3: the ^{111}In-labeled-DTPA−NT analogues were incubated with BsmAb for 30 min before a 1-h incubation with the cells. Final concentrations: BsmAb 6×10^{-9} M, DTPA(^{111}In)−NT 0.15×10^{-9} M, 37 °C. (Fraction of radioactivity associated to the cells: B/T%, mean ± standard deviation).

targeting (^{111}In-labeled [Lys(DTPA)]−NT and BsmAb) enhanced tumor to organ uptake ratios, particularly for the gastrointestinal tract at 3 and 24 h ($p < 0.01$) (stomach $p < 0.01$ at 3 and 24 h, colon and small intestine $p < 0.05$ at 3 h and $p < 0.01$ at 24 h) in comparison with NTR1 targeting (^{111}In-labeled [Lys(DTPA)]−NT, without BsmAb). Tumor-to-kidney ratios were also improved ($p < 0.01$ at 3 h and $p < 0.05$ at 24 h). Pretargeting with an irrelevant BsmAb (anti-DTPA x anti-CD20), able to bind to DTPA but not to CEA was compared to pretargeting with the relevant BsmAb. Tumor-to-organ ratios at 3 h post labeled NT−DTPA injection was significantly improved by relevant BsmAb pretargeting as compared to irrelevant for organs known to express NT receptors (stomach: $p < 0.01$, colon: $p < 0.01$ and small intestine: $p < 0.05$), while no significant difference was observed for other organs.

In mice pretargeted with the relevant BsmAb 3 h after injection of ^{111}In-labeled [Lys(DTPA)]−NT tumor uptake was higher ($p < 0.01$) than tumor uptake (0.65 ± 0.09% ID/g) of a ^{111}In-DTPA bearing peptide with no affinity for NTR1 (irrelevant-DTPA peptide: Ac-Lys(DTPA)-GABA-D-Tyr-GABA-Lys(Gly succinyl-histamine)-NH_2 (*19*)).

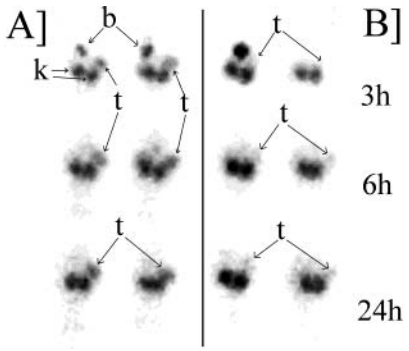

Figure 5. Tumor imaging in mice with pretargeted^{111}In-labeled [Lys(DTPA)]−NT. Images (ventral views) were recorded at 3, 6, and 24 h postinjection (Picker Prism 2000XP gamma-camera). Subcutaneously HT29-xenografted nude mice were injected with A: anti-CEA x anti-DTPA(indium) BsmAb (40 pmol) (tumor weights: left 355.6 mg, right 497.9 mg) or B: vehicle (tumor weights: left 481.7 mg, right 358.8 mg), 24 h before ^{111}In-labeled [Lys(DTPA)]−NT (30 pmol). t: tumor, b: bladder, k: kidney.

At 3, 6, and 24 h post [Lys(DTPA)]−NT injection, tumors were visualized in relevant BsmAb-pretargeted mice whereas tumors were hardly or not detected in vehicle preinjected mice. Kidneys and bladder were the major radioactivity accumulation sites in normal organs, indicating that the major route of excretion was renal.

DISCUSSION

Within the past few years, the use of low molecular weight radiolabeled peptides, which exhibit a faster clearance than antibodies and provide a higher accessibility to tumor cells, has been described. Taking advantage of the overexpression of numerous peptide receptors by various tumor cells, labeled peptides (somatostatin, MSH, VIP, neurotensin, CCK, and gastrin analogues, for example) have been developed for diagnosis and therapeutic purposes (*1*−*8*), but binding also

[a] Nude mice, grafted with HT29 cells in the flank, were given anti-CEA x anti-DTPA(indium) or vehicle or irrelevant BsmAb by iv injection. Twenty-four hours later 15 (*) or 30 (**) pmol of ^{111}In-labeled [Lys(DTPA)]−NT or 15 pmol of an irrelevant ^{111}In-DTPA-bearing peptide (Ac-Lys(DTPA)-GABA-D-Tyr-GABA-Lys(Gly succinyl-histamine)-NH_2) was injected iv. Mice were sacrificed at selected time intervals. Tumor, organs, and blood were collected, and the radioactivity in these samples was determined. Tissue radioactivity is expressed as percentage injected dose/g tissue (% ID/g mean in bold ± standard deviation). [b] Number of animals (n) indicated, except for stomach, colon, and small intestine, $n = 4$.

occurs in nontumor tissues expressing the receptors, which is expected to cause toxicity (*9*).

We have shown that bispecific antibody-mediated dual binding enhances radiolabeled bivalent hapten binding in vitro (*13, 21*) and in vivo targeting in animal models (*13*) and in the clinic (*14, 22, 23*) and that it can also provide an improved selectivity of antigen targeting (*19, 21*). Our objective is to specifically enhance the binding affinity of peptides to receptor-positive tumor cells, as opposed to receptor-positive nontumor cells, to ensure a higher targeting selectivity. The dual binding of a radiolabeled peptide to a receptor and to an antigen on tumor cell surface should enhance the binding to these cells in comparison with a monovalent binding to receptor-positive antigen-negative cells. Numerous tumor cells simultaneously bear receptors and antigens at their surface.

In the present paper, we chose neurotensin receptor (NTR1) and CEA dual targeting as a model to test the feasibility of this approach. NTR1 (*24, 25*) and CEA (*26*) are present on breast, small cell lung carcinoma, pancreatic carcinoma cells, and some colorectal carcinomas. HT29 cells were selected as a model of NTR1 and CEA coexpression. A BsmAb formed by the covalent linking of two Fab′, one directed to CEA and the other one to the DTPA(indium) hapten, was used. Binding of the BsmAb to CEA provided DTPA(indium) binding sites to the HT29 cell surface, allowing the simultaneous binding of DTPA(indium) bearing neurotensin analogues to two sites (NTR1 and CEA) at the target cell surface. All in vitro experiments with HT29 cells were performed after a 24-h forskolin treatment as this increases CEA levels at the cell surface (*11*) with no modification of the binding affinity to the CEA or to the NTR1 (data not shown). Under these conditions, expression of CEA and NTR1 was of the same order of magnitude, which is the optimal condition to evaluate the feasibility of dual binding.

Two neurotensin analogues bearing the hapten DTPA were synthesized: [Lys(DTPA)]−NT and DTPA−Gly−NT. The affinity of DTPA−Gly−NT for the anti-DTPA-(indium) antibody was about 5-fold lower than that of [Lys(DTPA)]−NT in agreement with our previous observation that the highest K_a values are obtained when the DTPA is coupled to the ϵ-NH_2 of a lysine as it is in the immunogen (*19*).

Affinity constant for the binding of [Lys(DTPA)]−NT to the neurotensin receptor NTR1 was 10-fold lower than that of neurotensin itself, determined in the same experimental conditions, in agreement with the observation of a decreased affinity of neurotensin derivatives substituted on the ϵ-amino group of the lysine (*27*). Unexpectedly the affinity constant of DTPA−Gly−NT was similar to that of [Lys(DTPA)]−NT.

As both DTPA−NT analogues were able to bind to NTR1 and to anti-DTPA(indium) antibody, we evaluated both the ability of the anti-CEA x anti-DTPA(indium) BsmAb to target DTPA−NT analogues to CEA, and the influence of BsmAb on the binding of these peptides to NTR1. The ^{111}In-labeled DTPA−NT analogues were efficiently targeted to CEA by the BsmAb. Binding in the presence of increasing concentrations of antibody followed a bell-shaped curve, due to trapping of ^{111}In-labeled DTPA−NT by excess antibody in the supernatant at high BsmAb concentrations. The BsmAb concentration necessary for maximal binding of the peptide was higher for DTPA−Gly−NT in agreement with its lower affinity for the anti-DTPA(indium) as compared to [Lys(DTPA)]−NT. The presence of BsmAb dramatically decreased but did not abrogate the monovalent binding of DTPA−NT analogues to NTR1 (more than 60% inhibition at the highest antibody concentration tested). This result suggested that the affinity of the BsmAb-DTPA(^{111}In)−NT complex for NTR1 was lower than that of the free DTPA-(^{111}In)−NT, probably due to steric hindrance.

The simultaneous binding of DTPA(^{111}In)−NT analogues to NTR1 and to CEA (bivalent binding) in the presence of BsmAb was tested using different incubation protocols with controls of monovalent binding to CEA or NTR1 performed in parallel. Whatever the operating procedure, the incubation time, and BsmAb concentration dual, binding was higher than binding to NTR1 (with a 6×10^{-9} M BsmAb concentration 6.6-fold for DTPA−Gly−NT and about 6.8-fold for [Lys(DTPA)]−NT, after 2 h incubation of the peptides). These results demonstrated the feasibility of enhanced selectivity of radioisotopes targeting to tumor cells bearing simultaneously one receptor and one antigen, compared to nontarget cells bearing only the targeted receptor.

The bivalent binding was higher than the monovalent binding to CEA (8.6-fold for DTPA−Gly−NT and 6.2-fold for [Lys(DTPA)]−NT in the same conditions). The increased selectivity toward receptor-positive/antigen-positive target cells, compared to receptor-negative/antigen-positive cells, may allow nontumor specific antigens, such as clusters of differentiation, to be considered in this context.

In addition, the binding enhancement provided by dual binding was higher than the sum of the monovalent bindings for both DTPA−NT analogues in a wide range of bispecific antibody concentrations (2.2×10^{-10} M to 1.8×10^{-8} M). Fitting these binding curves required the assumption of cooperativity for the simultaneous binding of the DTPA−NT analogues to NTR1 and to anti-CEA x anti-DTPA(indium) BsmAb bound to cell surface CEA. These results suggest that, as previously observed for double antigen targeting (*19, 21, 28*), dual targeting to a receptor and an antigen provides an affinity enhancement due to the cooperativity of dual binding. Cooperativity factors far exceeded steric hindrance, represented in calculations by an accessibility factor. Thus, the decreased binding of DTPA−NT analogues to NTR1 observed in the presence of BsmAb should translate into reduced uptake in receptor-positive antigen-negative tissues and cooperativity should restore or even provide an enhanced binding on receptor positive antigen-positive tumor cells.

In in vivo pretargeting approaches, unlabeled bispecific antibodies are injected first, and the labeled derivative is injected a few days later to allow tumor uptake and clearance of the bispecific antibody. However, at this time a significant fraction of the circulating antibody remains in the circulation. This was better reproduced in vitro by incubating the peptide without washing the BsmAb. As expected, the specific binding of the ^{111}In-labeled DTPA−NT analogue was lower under these conditions, due to trapping of the peptide by excess antibody in the supernatant, but the ratios of dual binding to the sum of the monovalent bindings were higher.

Binding of neurotensin analogues to NTR1 results in the internalization of the ligand. Bivalent binding did not prevent analogues from internalization. In fact, increased binding under bivalent conditions translated into increased internalization. This property is of major interest, as internalization is an important factor for internal radiotherapy since it may result in the accumulation of the radioisotope in the tumor and allow the use of short-range emitting isotopes such as α emitters. In this

respect, dual binding to a receptor and an antigen could afford a major advantage compared to single receptor targeting.

The method was evaluated in nude mice grafted with HT29 human colorectal cells in the flank. [Lys(DTPA)]−NT was labeled with indium-111 in order to perform biodistributions and imaging studies. The clearance of the hapten-bearing peptide was reduced in the presence of the BsmAb due to trapping in the plasma by excess antibody, as we demonstrated earlier for pretargeted bivalent DTPA haptens (*13*). Dual targeting (in the presence of BsmAb) enhanced tumor uptake in comparison with NTR1 targeting (without BsmAb). Tumor uptake was also increased by dual targeting in comparison with CEA targeting (irrelevant ^{111}In labeled-DTPA−peptide and BsmAb). In addition tumor to normal organ uptake ratios were enhanced particularly for the gastrointestinal tract (stomach, colon, and small intestine) where NT receptors are located (*29*), demonstrating that uptake increase provided by the BsmAb is higher in the tumor than in NTR1-positive tissues. Thus the targeting selectivity for tumor cells is enhanced by simultaneous targeting of NT receptor and CEA compared to monovalent targeting (NTR or CEA). Pretargeting with a relevant BsmAb (anti-CEA x anti-DTPA(indium)) provided a significant enhancement of tumor to NTR-positive organ ratios as compared to irrelevant BsmAb pretargeting (pretargeting with an anti-CD20 x anti-DTPA-(indium) unable to bind to CEA). Thus tumor to NTR1-positive organ ratios may be attributed to dual binding rather than to reduced clearance due to binding of the NT-DTPA(indium) analogue to a BsmAb.

In vitro, the analysis of NT-DTPA binding to target cells in the presence and absence of BsmAb and inhibitors allowed us to conclude that NT-DTPA binds simultaneously cooperatively to NTR1 and CEA via the BsmAb. In vivo, pretargeting with BsmAb of NT-DTPA increased tumor uptake, protracted tumor retention, and enhanced tumor to organ uptake ratios, particularly for the gastrointestinal tract, but cooperativity could not be demonstrated. One reason is the reduced clearance of hapten-bearing−NT in the presence of BsmAb, which improves tumor uptake even if the BsmAb does not bind the target cells. Other reasons are the enzymatic degradation of the peptide (in in vitro experiments 1,10-phenanthroline was added to prevent enzymatic degradation) and the possible use of nonoptimal doses of bispecific antibody and peptide. ^{111}In-labeling of NT-DTPA analogues were used in this study to evaluate the feasibility of simultaneous targeting of a receptor and an antigen. To optimize the in vivo targeting selectivity to tumor cells and to develop radiopharmaceuticals suitable for therapy, new hapten bearing receptor−ligands resistant to enzymatic degradation must be developed. Tumor-to-kidneys ratios were also improved, but peptides exhibiting a low renal accretion, such as those described by Chavatte K. et al. (*8*), labeled with isotopes suitable for internal radiotherapy, such as ^{131}I or ^{90}Y, will be necessary.

In conclusion, the double targeting of a receptor and an antigen at the tumor cell surface may be beneficial to peptide targeting of radioisotopes by increasing targeting specificity, tumor uptake, and isotope residence time in the tumor. DTPA−NT analogues, resistant to enzymatic degradation, in combination with an anti-CEA x anti-DTPA(indium) bispecific antibody, might be used in several clinical situations, including pancreatic tumors, small cell lung carcinoma, or colon carcinoma expressing both CEA and a neurotensin receptor (*24*−*26*). Successful targeting of radioactive isotopes to MTC has been performed using either anti-CEA antibodies (*22, 30*) or gastrin or CCK analogues (*4, 5*). Tumor uptake and contrast ratios in this disease could be improved by means of dual targeting. This approach might be of interest for radiopeptide therapy in many other cases of tumors overexpressing peptide receptors. For example VIP/PACAP receptors are expressed by most of human tumors such as breast, colon, or small cell lung carcinomas (*9*). These receptors are potentiel targets for VIP/PACAP ligands in vivo. The limitations for a radiotherapy using such agents include the destruction by irradiation of receptor-positive normal target tissues (*9*). Enhancing the selectivity by dual targeting of the VIP/PACAP receptor and a selected antigen may provide tumor to normal tissue uptake ratios suited for therapy. Antigens such as MDR P-glycoproteins, expressed on multidrug resistant tumors, CEA, or MUC1 expressed by various carcinomas, might be used for dual targeting of VIP/PACAP receptor positive tumors.

Numerous other receptor and antigens might be selected for dual targeting of tumors, but the antigen should not be internalizing for successful BsmAb pretargeting. With internalizing antigens, simultaneous injection of the labeled analogue and the BsmAb may be considered (*21*).

Very often antigen and receptor expression differs among tumors of the same type. Nevertheless, it is expected that a set of radiopharmaceuticals recognizing different receptors and bearing the same hapten, combined with a set of BsmAb directed to various antigens and to the hapten, will allow combinations of one radiopharmaceutical and one BsmAb able to perform dual targeting on a wide range of tumors.

Profiling Solid-Phase Synthesis Products by Free-Solution Conjugate Capillary Electrophoresis

Wyatt N. Vreeland,[†] Gary W. Slater,[‡] and Annelise E. Barron*[,†]

Department of Chemical Engineering, Northwestern University, Evanston, Illinois, and Department of Physics, University of Ottawa, Ottawa, Ontario, Canada. Received November 30, 2001; Revised Manuscript Received February 7, 2002

Solid-phase synthesis of oligomers, both natural and nonnatural, has proved to be invaluable for the development of many areas of biotechnology. A critical step in the solid-phase synthesis of any oligomer is determining the number and concentration of different constituents present in the product mixture resulting from the synthesis, both before and after purification. Most typically, this analysis is performed by reversed-phase high performance liquid chromatography (RP-HPLC), with the separated components detected by UV absorbance. Recently, we described a novel technique, free-solution conjugate electrophoresis (FSCE), for the high-resolution separation and sensitive laser-induced fluorescence (LIF) detection of uncharged, synthetic polymers, PEG in particular. In this report, we apply this bioconjugate capillary electrophoresis technique to analyze products of the solid-phase synthesis of oligomeric polyamides, namely poly(*N*-substituted glycines), or polypeptoids. When compared to more traditional RP-HPLC analysis, FSCE analysis of oligomeric peptoids results in separation resolutions that are approximately five times higher and separation efficiencies that are increased by 150%. Moreover, when FSCE with LIF detection is applied to the analysis of oligomeric polyamides after HPLC purification, impurities that are not detectable in RP-HPLC analysis are readily separated and detected. With the advent of capillary array electrophoresis (CAE), which allows for automated, parallel analysis of many different samples, we believe that FSCE will be especially applicable to the analysis of combinatorial synthesis products, by allowing researchers to evaluate many different samples in a single, highly parallel, fully automated analysis. This is in contrast to RP-HPLC analysis, in which samples must be analyzed in series.

INTRODUCTION

The solid-phase synthesis of polypeptides (*1*) has, over the past several decades, proven to be an invaluable tool for the study of molecular biology. For example, chemically synthesized polypeptides have allowed biochemists to determine the high-resolution structures of many proteins (*2*−*4*), enabling the elucidation of important biological pathways. In some cases, solid-phase peptide synthesis (SPPS) has allowed the study of proteins or protein fragments that were previously unobtainable in sufficient quantity, if at all, from natural preparations.

More recently, synthetic routes have been developed to various classes of nonnatural, sequence-specific, biomimetic oligomers, including poly-*N*-substituted glycines or "polypeptoids" (*5*−*10*), β-peptides (*11*−*14*), γ-peptides (*15*), oligoureas (*16*), and peptide nucleic acids (*17*). These biomimetic oligomers, based on backbones which are variants of the natural polypeptide (polyamide) structure, with differences also in their side chain chemistries, are of interest for their abilities to adopt stable secondary structures, and for their potential to shed light on factors that endow natural polypeptides with bioactivity (*18*−*21*). It is hoped that nonnatural oligomers can be developed as bioactive, structured peptide mimics, as well as useful materials for other applications in biotechnology such as gene therapy, genetic analysis, and bioseparations.

The ability to synthesize polypeptides on solid-phase support allows the per-monomer coupling efficiencies to be pushed to >99.9%, providing a route to the creation of long oligomers (>40 monomers in length) (*1*). Since the addition of any given monomer in the sequence never goes to 100%, when the final peptide preparation is cleaved from the solid support it represents a mixture of the desired full-length sequence with various deletion products, or if there was incomplete protection of any reactive side chains, even some branched oligomers. A critical step in the production of chemically synthesized polypeptides is the evaluation of the composition of the crude products as they are cleaved from the solid-phase resin. This is typically done by analytical, reversed-phase (RP) HPLC in small-bore columns packed with fine-mesh resin. The level of resolution of the full-length peptide sequence from deletion fragments and side products is generally quite good under the best conditions. HPLC profiling of the crude products of SPPS allows researchers to assess the success of the synthesis, and can be used on intermediary samples to track the coupling efficiency as a function of the length of the growing polypeptide chain. Generally, the predominant peak will be the desired polypeptide if the synthesis has gone well, and can be isolated by preparative RP-HPLC.[1] The final, purified polypeptide preparation will generally be characterized again by analytical RP-HPLC, as well as by

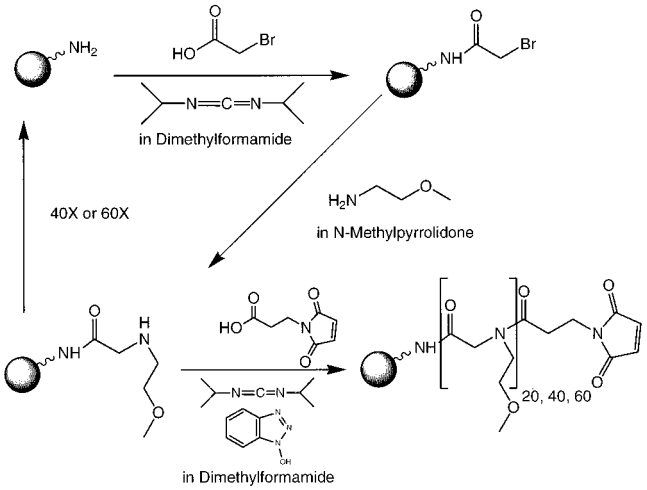
electrospray ionization mass spectrometry (ESI-MS) to assess its level of purity. For nonnatural oligomers such as polypeptoids and β-peptides, similar approaches to profiling crude products of synthesis and purification are also taken, i.e., RP-HPLC is still the critical and most widely used technique (*6*, *22*).



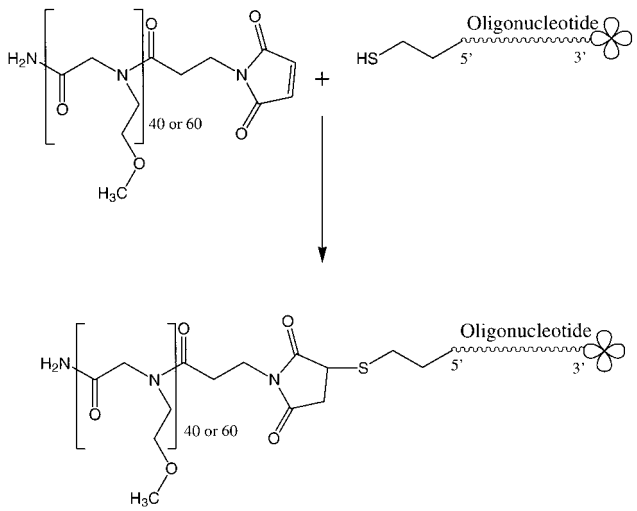
To analyze the overall quality of a crude or purified chemically synthesized polyamide, the different components of the biopolymer sample must be sufficiently separated from one another. These separated components may be quantified according to their relative abundance, their molecular mass, and/or another indicative, quantitative parameter (e.g., UV absorbance at a particular wavelength). When separation is carried out by RP-HPLC, a sample is separated by partitioning between a solid-phase packing contained in the HPLC column and a mobile liquid phase that flows through voids in the packing (*23*). The composition of the liquid mobile phase is often changed throughout the analysis, so that the sample mixture components will each elute in order of increasing hydrophobicity, and are subsequently detected by a UV absorbance detector (*24*).

RP-HPLC results in the oligomer of interest being separated based on the strength of its interaction with the solid phase. The selection of liquid mobile phase and of the chemistry of the column packing determines, in large part, the quality of the separation and of the analysis. For samples that are extremely hydrophilic or hydrophobic, the identification of an appropriate solid phase and method of solvent composition programming to achieve high resolution can be challenging (*25*).

When coupled to a UV absorbance detector, as is typical, the limit of detection (LOD) of the sample in the mobile liquid-phase of an HPLC separation is relatively high when compared to the LOD of highly sensitive laser-induced fluorescence (LIF) detectors that are currently available (*26*). Also, the use of mobile phases with appreciable UV extinction coefficients can severely limit the sensitivity of detection of sample in the eluent of an HPLC column, especially for the UV detection of extremely dilute species in a given sample. Finally, in the analysis of biopolymers that lack a unique chromophore, one must rely on detection of the chromophore of the polymer backbone (214 nm in the case of polyamides). Detecting a chromophore in the polymer backbone, which yields a chain-length dependent molar extinction coefficient, complicates the quantification of sample species, since peak area is then dependent upon both relative abundance and upon chain length.

In the past few years, capillary electrophoresis (CE) has become increasingly popular as a high-resolution, high-sensitivity technique for the separation and analysis of molecules of chemical and biochemical interest including chiral molecules (*27*), proteins (*28*), carbohydrates (*29*), and DNA (*30*−*33*). We recently reported a new capillary electrophoresis technique, which we call free-solution conjugate electrophoresis (FSCE), for the separation and effective mass spectrometry of uncharged poly(ethylene glycol) (PEG) samples (*34*). In that work, molar mass profiling of several different PEG samples was achieved via end-on conjugation of these polydisperse polymers to monodisperse, fluorescently labeled DNA oligomers, followed by free-solution electrophoretic separation of the bioconjugates in a long capillary (*34*). We show here that this technique can be extended to the separation and analysis of both crude and purified solid-phase synthesis products.

Scheme 1



In particular, we describe the application of FSCE to the analysis of both unpurified and purified oligomers produced via chemical synthesis. This method, we believe, provides an interesting alternative to HPLC for the characterization of chemically produced polyamides. The novel separation mode that we demonstrate is accomplished by end-on conjugation of each of the species present in a complex oligomer mixture with a monodisperse, fluorescently labeled DNA oligomer. The resulting DNA−oligomer conjugates are then separated by free-solution capillary electrophoresis. Specifically, we apply FSCE to a class of biomimetic molecules that are remarkably similar to polypeptides, called poly-*N*-substituted glycines, or *polypeptoids*. Exploiting the extreme sensitivity of LIF detection and the excellent resolving power of capillary electrophoresis, FSCE allows for accurate and sensitive separation of various species present in a complex sample mixture resulting from a solid-phase synthesis.

EXPERIMENTAL SECTION

Polypeptoid Synthesis. The synthesis of the oligomer samples of interest, in particular the poly-*N*-substituted glycines or "polypeptoids" used in this study, has been described elsewhere (*5*). The synthetic protocol for the particular molecules studies here is depicted in Scheme 1. All reactions were carried out on an ABI 433A automated peptide synthesizer (Applied Biosystems, Foster City, CA) with in-house modifications to the control software. Briefly, 0.25 mmol of Fmoc-rink amide resin (Nova Biochem, San Diego, CA) were deprotected by treatment with 20% (v/v) piperidine (Applied Biosystems, Foster City, CA) in dimethyformamide (DMF) (Fisher Scientific, Itasca, IL), in two consecutive 15-min treatments. The oligomer chain was then assembled with alternating cycles of bromoacetylation step and amine displacement of the bromine from the *N*-terminal alkyl halide. The bromoacetylation was accomplished by mixing 4.3 mL of 1.2 M bromoacetic acid (Aldrich, Milwaukee, WI) in DMF and 1 mL of diisopropylcarbodiimide

[1] Abbreviations: CAE, capillary array electrophoresis; CE, capillary electrophoresis; ESI-MS, electrospray ionization mass spectrometry; epoxy-pDMA, poly(dimethylacrylamide-*co*-allyl glycidyl ether); FSCE, free-solution conjugate electrophoresis; LIF, laser-induced fluorescence; LOD, limit of detection; MALDI-TOF, matrix-assisted laser desorption ionization−time-of-flight; PEG, poly(ethylene glycol); RP-HPLC, reversed-phase high performance liquid chromatography; SPPS, solid-phase peptide synthesis.

Scheme 2

(Aldrich, Milwaukee, WI) with the resin. The mixture was then vortexed for 45 min, the liquid drained, and the resin rinsed 4 times with 7 mL of DMF. Next, the resin was mixed with 4 mL of 1 M methoxyethylamine (Aldrich, Milwaukee, WI) in *N*-methylpyrrolidone and vortexed for 45 min to introduce the methoxyethyl side-chain moiety. The liquid was then drained, and the resin was again rinsed four times with 7 mL of DMF. These two reaction cycles were then alternated until the polypeptoid was of the desired length.

A reactive *N*-terminal maleimide functionality was attached to the amino terminus of the polypeptoid while it was still on the resin, to allow for facile conjugation to DNA oligomers, as depicted in Scheme 2. This was accomplished by mixing the resin with 500 μL of 1.2 M maleimidopropionic acid (Fluka, Buchs Switzerland) in DMF and 144 μL of diisopropylcarbodiimde, vortexing the resin slurry for 45 min, and rinsing the resin four times with 3 mL of DMF. Finally, the polypeptoid was cleaved from the solid support by treatment with 95% (v/v) trifluoroacetic acid (Aldrich, Milwaukee, WI) in water for 30 min. The polypeptoid-containing liquid was then passed through a filter to separate it from the solid support. Next, the crude polypeptoid solution was extracted with a water−diethyl ether mixture, and the aqueous layer retained, frozen, and lyophilized to yield a golden, viscous oil.

RP-HPLC Analysis Conditions. Unpurified and purified peptoids were dissolved in water and analyzed by RP-HPLC on C18 packing (Vydac, 5 μm, 300 Å, 2.1 × 250 mm). A linear gradient of 10−60% B in A was run over 50 min at a flow rate of 0.1 mL/min (solvent A = 0.1% TFA in water, solvent B = 0.1% TFA in acetonitrile) at 60 °C; peaks were detected by UV absorbance at 214 nm. Preparative HPLC was performed on a Vydac C18 column (Vydac, 15 μm, 300 Å, 22 × 250 mm) using the same solvent and detection systems; peaks were eluted with a linear gradient of 10−60% B in A over 50 min at 12 mL/min.

Polypeptoid−DNA Conjugation Conditions. Prior to conjugation with a monodisperse, fluorescently labeled DNA oligomer, each polypeptoid was purified from non-peptoid impurities remaining from the cleavage reaction by preparative HPLC. This was necessary because the particular solubility properties of this peptoid sequence prevented us from using ether precipitation to remove small-molecule contaminants of the cleavage products. We intend to develop a one-step, on-resin conjugation with the DNA label that will allow this step to be bypassed in the future. To accomplish the necessary purification for this study, several milligrams of unpurified polypeptoid were loaded onto the preparative HPLC column; after the elution of the initial void volume peak, the entire eluent of the HPLC analysis was collected for FSCE analysis of unpurified polypeptoids. For the FSCE analysis of HPLC-purified polypeptoids, only the desired peak, representing the full-length product, was collected. Subsequently, each sample was frozen and lyophilized from the HPLC buffer to yield a light gold, viscous oil.

Poly(*N*-methoxyethyl)glycines 40 and 60 monomers in length were each conjugated end-on to poly(thymidine)-deoxyribonucleic acid 20 bases in length (Oligos, Etc., Wilsonville, OR). DNA samples had been prepurified using gel electrophoresis by the vendor, to ensure that each DNA oligomer was monodisperse. Moreover, each DNA oligomer included a fluorescein dye on its 3′ terminus to allow for LIF detection, and a thiol (SH) functionality on its 5′ terminus to allow for conjugation with the maleimide functionality of the amino terminus of the polypeptoid. This conjugation forms a stable thioether linkage between the DNA and the polypeptoid (Scheme 2).

To ensure that the 5′-thiol terminus of the DNA was optimally reactive with the maleimide terminus of the polypeptoid, the DNA was first chemically reduced, as recommended by the vendor and previously described (*34*).

The conjugation reaction was accomplished by dissolving a given polypeptoid sample to a concentration of 12.8 mM in 0.1 M sodium phosphate buffer, 0.15 M NaCl, pH = 7.2, and adding 10 μL of each of the 12.8 mM polypeptoid solutions to the lyophilized DNA powder from the above reduction protocol. This solution was incubated at room temperature for 24 h. Finally, the resultant mixture was diluted 1:300 in distilled, deionized H_2O immediately prior to capillary injection and analysis.

Capillary Electrophoresis Analysis Conditions. All capillary electrophoretic separations were conducted in 25-μm inner-diameter fused silica capillaries, 100 cm in total length (95.4 cm effective length) (Polymicro Technologies, Phoenix, AZ), and filled with one of two buffers. For the analysis of unpurified polypeptoids, 1X TTE + 7 M urea (50 mM *N*-tris[hydroxymethyl]methyl-3-aminopropanesulfonic acid, 50 mM Tris, 2 mM ethylenediaminetetraacetic acid, 7 M urea), pH = 8.5 (Amresco, Solon, OH) buffer was used, whereas for the analysis of purified polypeptoids, 1X TTE buffer was used. All buffers were prepared with 18 MΩ distilled, deionized water (E-pure, Barnstead, Dubuque, IA). The internal surface of the capillary was dynamically coated with an adsorbed layer of a poly(dimethylacrylamide-*co*-allyl glycidyl ether) (epoxy-pDMA) to reduce electroosmotic flow mobility to negligible levels (*35*). All analyses were performed using a BioFocus 3000 Capillary Electrophoresis system equipped with a laser-induced fluorescence detector (BioRad, Hercules, CA). At the beginning of each day of analysis, the capillary was flushed for 15 min with 1 M NaOH, followed by a 5-min water rinse, and then flushed for 20 min with a 0.1% (w/v) solution of epoxy-pDMA in water. All capillary rinses were done with a syringe pump at a flow rate of 100 μL/h. Electroosmotic flow after capillary coating by this method was measured to be 3.0×10^{-10} m^2/(V·s) by the method of Williams and Vigh (*36*).

Prior to each analysis, the capillary was flushed with several column volumes of the electrophoresis buffer. Immediately prior to sample injection, the injection end

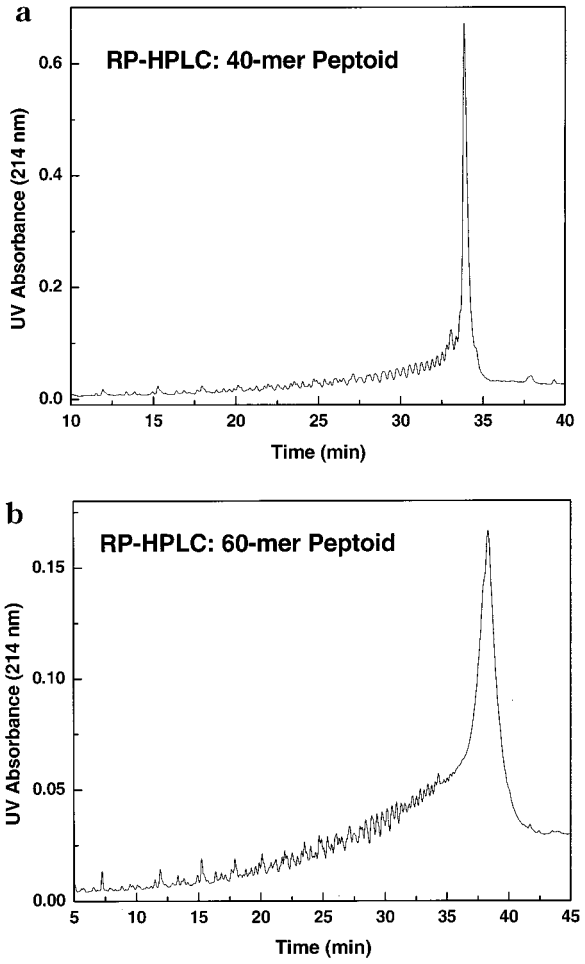


Figure 1. (a) RP-HPLC separation of a crude (unpurified) 40-monomer poly(*N*-methoxyethyl glycine). Conditions: C18 packing (Vydac, 5 μm, 300 Å, 2.1 × 250 mm). A linear gradient of 10−60% B in A was run over 50 min at a flow rate of 0.1 mL/min (solvent A = 0.1% TFA in water, solvent B = 0.1% TFA in acetonitrile) at 60 °C; peaks were detected at 220 nm. (b) RP-HPLC separation of an unpurified 60-monomer poly(*N*-methoxyethyl glycine). Conditions as in Figure 1a.

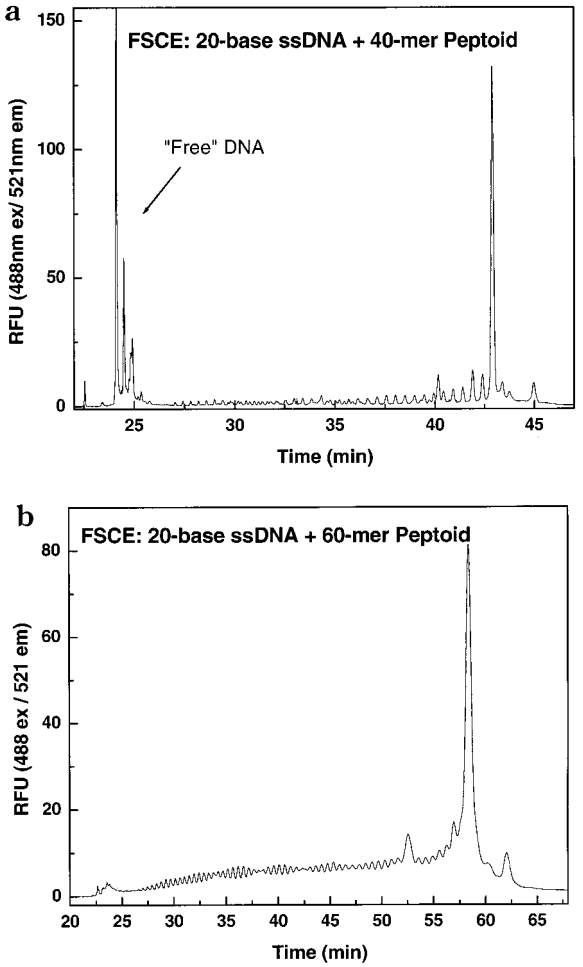

Figure 2. (a) FSCE separation of an unpurified 40-monomer poly(*N*-methoxyethyl glycine) using a 20-base ssDNA "engine". Conditions: buffer 1X TTE + 7 M urea, pH 8.5. Field Strength 300 V/cm, current ~ 4 μA. Capillary 100 cm × 25 μm (95.4 cm effective length). LIF detection, 488 nm excitation, 521 nm emission. Injection: 150 V/cm, 2 s. (b) FSCE separation of an unpurified 60-monomer poly(*N*-methoxyethyl glycine) using a 20-base ssDNA "engine". Conditions are as in Figure 2a.

of the capillary was briefly dipped into deionized water to remove residual buffer salts from the outer surface of the capillary. Sample was introduced into the capillary by an electrokinetic injection at 150 V/cm for 2 s. Electrophoresis was conducted at 300 V/cm until all peaks had eluted. Detection of the analytes was achieved with excitation of the 3′-fluorescein DNA label using the 488 nm line of an argon-ion laser, and emission detected at 521 nm.

Data Analysis. All peak parameters and migration times were determined with the PeakFit software package (SPPS, Inc., Chicago, IL).

RESULTS AND DISCUSSION

The separation mechanism of FSCE derives from the different bioconjugate properties created by the covalent linkage of the polyamide molecules to monodisperse DNA oligomers. The highly charged DNA oligomer component of the conjugate endows each molecule with an equal electromotive force during electrophoresis, while the less charged polyamide component gives each molecule a unique amount of hydrodynamic drag. Hence, the electrophoretic mobility of each bioconjugate is a precise function of the length and nature of the polyamide "tail", allowing for free-solution electrophoretic separation of each of the conjugates. The advantages of this approach can be illustrated by carrying out a direct comparison of the results of RP-HPLC and FSCE analysis of a set of model peptoid−DNA conjugates. For this study, we selected a very simple model polypeptoid molecule for illustrative purposes, composed of N-substituted glycine monomers with an uncharged, hydrophilic methoxyethyl side-chain moiety.

Electropherograms and Chromatograms for the Analysis of Unpurified Polypeptoids. Figure 1a and 1b show the results of RP-HPLC analyses of 40-mer unpurified peptoid and 60-mer unpurified peptoid oligomers prepared by solid-phase synthesis, respectively. In RP-HPLC analysis, the constituents of the complex samples are separated on the basis of their effective hydrophobicity. For peptoids composed of this particular monomer (*N*-methoxyethyl glycine), the effective hydrophobicity of the molecule increases as the peptoid chain increases in length. Thus RP-HPLC, in this case, separates the different constituents of the complex sample in order of increasing chain length. The major peak in each figure, while not fully resolved from other sample components, represents the full-length sequence (as confirmed by electrospray mass spectrometry of the material in this peak).

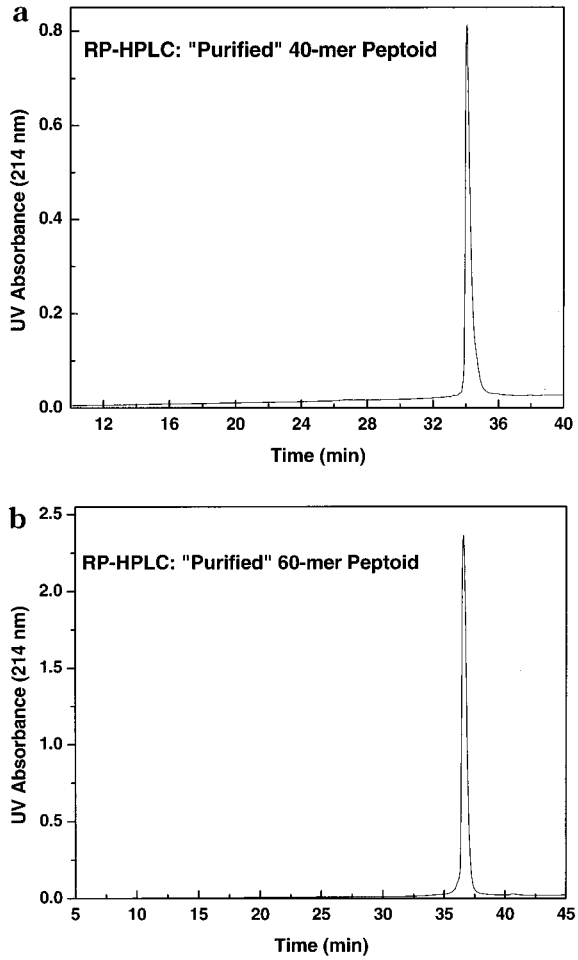

Figure 3. (a) RP-HPLC analysis of a RP-HPLC-purified 40-monomer poly(*N*- methoxyethyl glycine). Conditions as in Figure 1a. (b) RP-HPLC analysis of a RP-HPLC-purified 60-monomer poly(*N*-methoxyethyl glycine). Conditions as in Figure 1a.

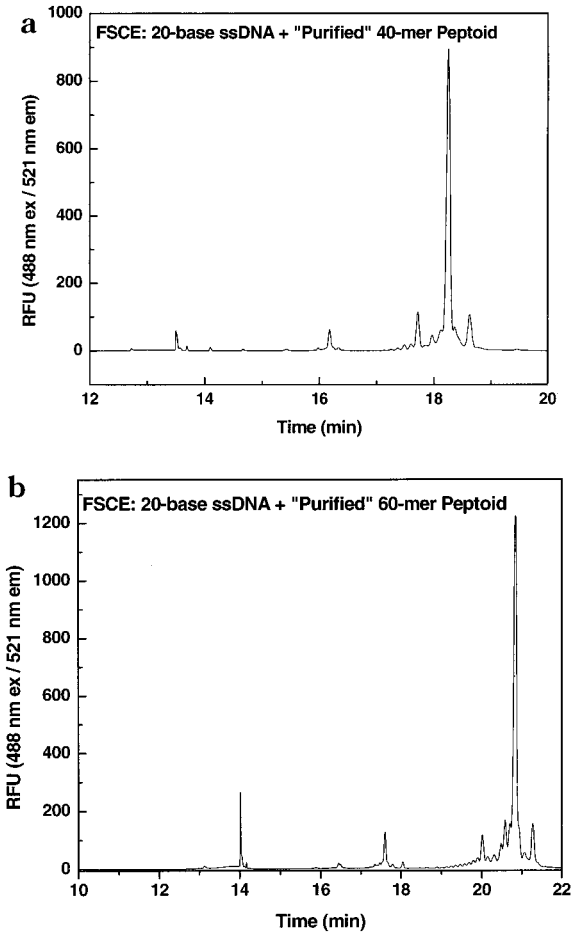

Figure 4. (a) FSCE analysis of the sample seen in Figure 3a using a 20-base ssDNA "engine". Conditions: Buffer 1X TTE, pH 8.5, other conditions as in Figure 2a. (b) FSCE analysis of the sample seen in Figure 3b using a 20-base ssDNA "engine". Conditions as in Figure 4a.

Figures 2a and 2b present the results of the FSCE analyses of a 20-base DNA + 40-mer unpurified peptoid conjugate, and of a 20-base DNA + 60-mer unpurified peptoid conjugate, respectively. Although HPLC and FSCE separate the constituents of the complex sample via different mechanisms, the qualitative results of the two separation mechanisms are similar. The FSCE analyses, however, result in the constituents of the complex sample mixture being resolved more fully when compared to RP-HPLC analyses of the same molecules. This is a result of the high selectivity of capillary electrophoresis and the exquisite sensitivity of LIF detection. The initial group of peaks in Figure 2a eluting at approximately 24 min represents various "free" residual DNA species from the conjugation reaction that were not conjugated to any peptoid oligomers. This peak is not present in Figure 2b, as the concentrations were adjusted in this reaction so that there was virtually no residual, unreacted DNA. In both Figures 2a and 2b, numerous small peaks representing DNA−peptoid conjugates, eluting in order of increasing peptoid chain length, follow the initial "free DNA" peak. The latest eluting, major peak represents the conjugate with the largest peptoid, which is the full-length desired product (confirmed by mass spectrometry).

The presence of a single fluorophore on the 3′ terminus of each of the DNA−peptoid conjugates allows one to calculate the molar percentage of each component in the original peptoid sample, simply as the ratio of the area of the peak representing that particular peptoid component to the area of all DNA−peptoid conjugate peaks in the electropherogram. Thus, the percent yield of the full-length product is simply the ratio of the area under the last eluting major peak to the sum of the areas under all DNA−peptoid conjugate peaks. Electrokinetic injections, which were used in this study, can cause a bias in the amount of higher-mobility sample components introduced into the capillary. Higher-mobility species (i.e., conjugates with short peptoid components) will tend to be injected to a greater extent than lower-mobility fragments. Formally, one must correct for this bias to obtain accurate quantitation of the relative abundance of each species present in the sample. However, in previous FSCE studies, we have determined this bias to be negligible (*34*).

Chromatograms and Electropherograms for the Analysis of Purified Polypeptoids. Figures 3a and 3b show the analytical HPLC chromatograms obtained for 40- and 60-mer polypeptoids *after* preparative HPLC purification. Notice that both RP-HPLC analyses show a single, large, relatively Gaussian peak, leading to the conclusion that the polypeptoid samples are essentially pure after the preparative HPLC purification step. That is, virtually no impurities can be detected by RP-HPLC with UV absorbance detection.

These HPLC results are in contrast to Figures 4a and 4b, which show the results of the FSCE analysis of the same, purified 40- and 60-mer peptoid samples after conjugation to 20-base DNA oligomers. Comparison of

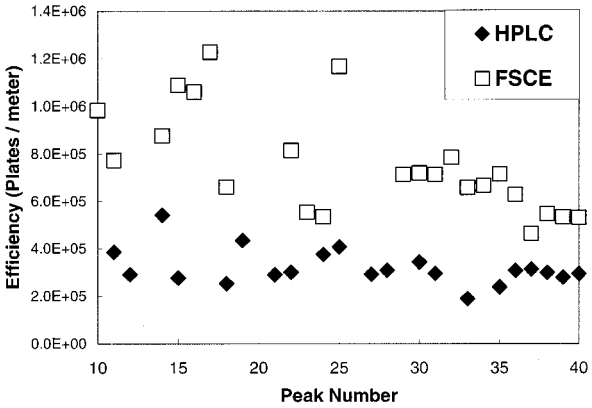

Figure 5. Plot of separation efficiency as a function of peak number for the FSCE separation (open squares) and RP-HPLC separation (filled diamonds) of the 40 monomer poly(*N*-methoxyethyl glycine) seen in Figures 1a and 2a. Peak data obtained with PeakFit software.

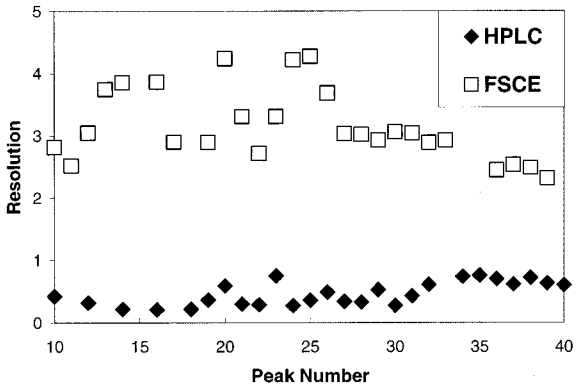

Figure 6. Plot of separation resolution as a function of peak number for the FSCE separation (open squares) and RP-HPLC separation (closed diamonds) of the 40 monomer poly(*N*-methoxyethyl glycine) seen in Figures 1a and 2a. Peak data obtained using PeakFit software.

Figures 3a and 3b with Figures 4a and 4b shows the superior separation performance and sensitivity of FSCE with LIF detection for the detection of sample impurities, when compared to standard RP-HPLC with UV detection. Impurities that are present in purified polypeptoid samples are not observed in HPLC analysis, yet are readily detected by FSCE analysis and represent substantial contamination of the desired peptoid (41% and 47%, as determined by peak integration, in Figures 4a and 4b, respectively). Thus, FSCE can lead to a more accurate and sensitive characterization of the absolute purity of a polyamide sample than is possible with standard RP-HPLC. This may be important for the evaluation of polypeptide or polypeptoid purity for applications, such as peptidomimetic pharmaceuticals, where the ultimate purity of an oligomer sample can impact not only its performance, but also the side effects it engenders.

Plate Heights. The number of theoretical plates achievable in a given separation length provides a quantitative measure of the efficiency of the separation. For separation techniques such as HPLC and CE, which are configured in a "finish-line" detection configuration in which the analytes migrate through a stationary detector, separation efficiency is manifested as the peak width. A low number of theoretical plates indicates that the separation technique or hardware has effects that are limiting the separation of the individual components in the complex sample mixture. A plot of the number of theoretical plates as a function of peptoid size, for both the HPLC and FSCE separations, is presented in Figure 5, for the 40-mer polypeptoid. In both FSCE and HPLC analyses, the last major eluting peak was assumed to be the full-length synthesis product and is assigned a peak number corresponding to the number of monomers in the polypeptoid (e.g., 40 for the 40-mer polypeptoid, 60 for the 60-mer polypeptoid). Peaks were then counted backward (i.e., decreasing in time) and assigned a peak number of one less than the peak that eluted immediately after it. Plate efficiencies were determined using the method described by Ren et al. (*37*). As can be seen in the figure, the average plate efficiency of the FSCE analysis is 2.5 times greater than that of an RP-HPLC, with several peaks displaying efficiencies well over 1×10^6 plate per meter. Higher average plate efficiency indicates that FSCE analysis produces peaks that are narrower than in HPLC; hence, we can conclude that fewer dispersive effects are limiting the FSCE separation when compared to more traditional RP-HPLC chromatographic separation techniques. Further, this shows that a greater number of species can be resolved in a given time window due to their narrower representative peaks.

Resolution. Resolution provides an overall, quantitative measure of how well each of the components in the complex sample is separated. Resolution of neighboring peaks can be calculated as:

$$R = \frac{1.18(t_b - t_a)}{(\mathrm{FWHM}_a + \mathrm{FWHM}_b)} \qquad (1)$$

where t_a and t_b are the elution times of peaks two adjacent peaks a and b, respectively, and FWHW_a and FWHW_b are the full temporal width at half the peak height of peaks a and b, respectively (*37*). Figure 6 presents the resolution of both HPLC and FSCE separations methods as a function of peptoid size for the 40mer polypeptoid. Peaks were assigned using the methodology explained in the Plate Heights section. As can be seen, the average resolution of the FSCE analysis is approximately 5 times that of RP-HPLC analysis and allows components of the complex sample mixture to be more fully resolved. Increased resolution means that the peaks are further separated from one and other and therefore are less likely to overlap in a given analysis. Peak separation leads to more accurate quantitation of each species present and thereby a more precise evaluation of the composition of the sample mixture.

The application of free-solution conjugate electrophoresis (FSCE) to the analysis of chemically synthesized oligomers, as we have demonstrated it here with maleimide−thiol linking of the DNA to the analyte, should be directly applicable to virtually any chemically synthesized oligomer, in particular polypeptides. As long as those peptides do not contain reactive thiols (cysteines), and the cleavage conditions to remove the polyamide from the solid support do not require the use of chemical that will react with the terminal maleimide, FSCE should be applicable. The addition of the maleimide functionality to the terminus of the oligomer is accomplished with standard chemicals for the synthesis of polyamides, such as peptides and peptoids and is therefore compatible with existing synthesis chemistries and protocols. However, the peptoid sequence chosen for this study did not require the use of side-chain protecting strategies, simplifying the compatibility of the maleimide linking protocol with the cleavage conditions. If more complicated and diverse side-chain chemistries are present in the polyamide analyte, alternative linking strategies will have to be

implemented to actualize FSCE profiling. Additionally, the solubility properties of this particular peptoid sequence prevented the use of standard ether precipitation workup techniques; thus, FSCE analysis was preceded by an RP-HPLC semipurification to remove small molecule contaminants. However, with optimization of chemical linking strategies to be insensitive to these contaminants, this procedure could be obviated.

CONCLUSIONS

FSCE analysis, when applied to chemically produced oligomers, results in high-resolution and high-efficiency separations. The average separation efficiency is 2.5 times greater and resolutions are 5 times higher than those obtained with RP-HPLC. When applied to HPLC-purified oligomer samples, FSCE allows for the separation and detection of impurities that are not observed in the HPLC analysis of the same samples. Thus, FSCE offers an attractive alternative for the analysis of chemically produced oligomers that may be challenging to analyze via more traditional chromatographic methods. With further development and optimization it seems likely that FSCE, with its orthogonal separation mechanism, could serve as a useful complement to HPLC that will allow for extremely sensitive and accurate characterization of polyamide samples including polypeptides of therapeutic interest. Moreover, with the advent of capillary array electrophoresis (CAE) instruments, now available commercially, FSCE with a modified conjugation strategy could allow the products of combinatorial solid-phase peptide synthesis to be analyzed in parallel. This would be impossible by HPLC, where typically only a single column is available and samples must be analyzed in series.

Synthesis and Properties of Novel Tetraalkyl Cationic Lipids

Jérôme Gaucheron,*[,†] Tabitha Wong,[†] Kim F. Wong,[†] Norbert Maurer,[†] and Pieter R. Cullis[†,‡]

Department of Biochemistry and Molecular Biology, University of British Columbia, 2146 Health Sciences Mall, Vancouver, BC, Canada V6T 1Z3 and Inex Pharmaceuticals Corporation, 100-8900 Glenlyon Parkway, Glenlyon Business Park, Burnaby, BC, Canada V5J 5J8. Received December 20, 2001

The synthesis, physical properties, and transfection potencies of two representives of a new class of divalent, tetraalkyl cationic lipids is described. These cationic lipids are dimers of *N*,*N*-Dioleyl-*N*,*N*-dimethylammonium chloride (DODAC) joined by a hydrocarbon tether three or six carbons in length (TODMAC3 and TODMAC6, respectively). It is shown that TODMAC6 can display improved transfection properties in comparison to DODAC when formulated into plasmid DNA−cationic lipid complexes. These improved transfection potencies are observed at cationic lipid to DNA charge ratios of two or higher. It is also shown that TODMAC6 exhibits equivalent or improved ability (as compared to DODAC) to induce nonbilayer structure in mixtures with anionic lipid. This is consistent with the hypothesis that the ability of cationic lipids to induce nonbilayer structures when mixed with anionic lipids is correlated to their transfection potency. Complexes containing TODMAC3 on the other hand exhibit lower transfection potencies than achieved with DODAC, behavior that is consistent with steric effects limiting the formation of ion pairs with anionic lipids. It is concluded that TODMAC6 exhibits potential as a transfection agent for in vitro and in vivo use and that the design of cationic lipids according to their ability to induce nonbilayer structure provides a useful guide for synthesis of new cationic lipids.

INTRODUCTION

Plasmid DNA-cationic lipid complexes are the leading nonviral gene therapy vectors used in the clinical setting (*1*−*4*). However the levels of gene expression that can be achieved using these complexes are substantially lower than can be achieved using viral vectors. Considerable effort has therefore been devoted to synthesizing new cationic lipids that have improved transfection properties over those currently available (*5*−*10*). These efforts are largely phenomenological due to the lack of understanding of the mechanism whereby cationic lipids facilitate the intracellular delivery of macromolecules such as plasmid DNA. In this regard recent work from this laboratory suggests that the ability of cationic lipids to facilitate intracellular delivery is related to their ability to induce the nonbilayer hexagonal H_{II} phase in combination with anionic lipids (*11*). In particular this proposal suggests that the most potent cationic lipids are those that are the most effective inducers of H_{II} phase organization.

The ability of lipids to adopt the H_{II} phase has been related to their dynamic "molecular shape" properties. Within this framework lipids with a small cross-sectional area in the headgroup region and a larger acyl chain cross-sectional area exhibit a "cone" shape compatible with H_{II} phase organization (*12*). In this regard a direct method to increase the cone-shaped character of a given lipid is to increase the number of alkyl chains associated with the headgroup. In this work we describe the synthesis and transfection properties of a new class of cationic lipids that contain four alkyl chains. It is shown that these cationic lipids can exhibit improved transfection properties compared to dialkyl cationic lipids.

Earlier studies have shown *N*,*N*-dioleyl-*N*,*N*-dimethylammonium chloride (DODAC) to be quite an effective DNA transfection agent (*13*, *14*). We thus chose a synthetic route to generate a molecule with two quaternary ammonium groups and four oleyl chains, essentially a DODAC dimer. The procedure involved alkylating dimethylamines with oleyl bromide. The polymorphic phases of these new cationic lipids were monitored by ^{31}P NMR of these lipid mixtures containing 1,2-dipalmitoyl-sn-glycero-3-[phospho-L-serine] (DPPS). The in vitro transfection potency was measured and compared with that of DODAC.

EXPERIMENTAL PROCEDURES

Materials and Reagents. All organic solvents and reagents including the Dragendorff reagent and ninhydrin reagent were obtained from Sigma-Aldrich Canada (Oakville, ON). DOPE and DPPS were purchased from Avanti Polar Lipids (Alabaster, AL). The cationic lipid DODAC was a gift from Dr. Steven Ansell of Inex Pharmaceuticals (Vancouver, BC). The plasmid pCMV-luc (5650 bp, CMV promoter, coding for luciferase) was a gift from Inex Pharmaceuticals (Vancouver, BC).

Analytical Techniques. The cationic lipids were purified by column chromatography using silica gel 60 (Merck, 70−230 mesh) and dichloromethane (CH_2Cl_2)/methanol (MeOH) mixtures. Unless stated otherwise, the ratios describing the composition of solvent mixtures represent relative volume fractions. The reaction progress was followed by thin-layer chromatography (TLC) on silica plates F_{254} (Merck). The following developing systems were used: UV light, H_2SO_4/EtOH (1/1 v/v), Dragendorff reagent (Sigma), ninhydrin reagent (Sigma). ^{1}H, ^{13}C, and ^{31}P NMR spectra were obtained employing a Bruker MSL 200 spectrometer operating at 200.13,

50.3, and 81.02 MHz, respectively. Deuterated chloroform ($CDCl_3$) was used as the solvent in the NMR experiments. Chemical shifts were measured relative to $CHCl_3$ (δ 7.24 ppm) for ^1H, relative to $CDCl_3$ (δ 77.16 ppm) for ^{13}C. The following abbreviations are used to describe the signal multiplicities: s (singlet), d (doublet), t (triplet), q (quadruplet), and m (multiplet). Chemical shifts are expressed in ppm and listed as follows: shift in ppm (multiplicity, coupling, integration and assignment). Elemental analyses were carried out by Microanalytical Service (Department of Chemistry, University of British Columbia).

Synthesis of *N,N,N′,N′*-Tetraoelyl-*N,N′*-dimethyl-1,3-propanediammonium Chloride (TODMAC3). A solution of *N,N′*-dimethyl-1,3-propanediamine (0.253 g, 2.5 mmol) and oleyl bromide (5 g, 15.1 mmol) in toluene (20 mL) and a solution of tetrabutylammonium hydrogensulfate (0.4 g, 1.2 mmol) in 1 M sodium hydroxide (20 mL) were stirred under reflux. After 4 days, 2.5 g oleyl bromide (7.5 mmol) was added and the reaction continued for another 5 days. The water phase was extracted two times with toluene. The combined organic phases were evaporated. The residue was dissolved in CH_2Cl_2 and washed six times with 3% hydrochloric acid and three times with saturated aqueous NaCl. The organic phase was evaporated and the remaining material purified by silica gel chromatography (CH_2Cl_2/MeOH from 10/0 to 9/1). **TODMAC3** was obtained as a pale yellow oil at a yield of 1.15 g (0.98 mmol, 39%). The product was washed six times with 3% hydrochloric acid and three times with saturated aqueous NaCl again.

TLC (CH_2Cl_2/MeOH 9/1, H_2SO_4/EtOH): $R_f = 0.43$. ^1H NMR ($CDCl_3$): δ 0.87 (t, $^3J = 6.6$ Hz, 12H, CH_3); 1.08−1.48 (broad s, 88H, $CH_3(CH_2)_6CH_2CH{=}CHCH_2(CH_2)_5$); 1.48−1.77 (m, 10H, CH_2CH_2N); 1.80−2.12 (m, 16H, $=CHCH_2$); 3.22−3.80 (m, 18H, CH_3, CH_2N); 5.20−5.45 (m, 8H, =CH). ^{13}C NMR ($CDCl_3$): δ 14.1 (CH_3CH_2); 22.7 (CH_3CH_2); 27.2 ($=CHCH_2$); 22.5, 26.4, 29.1, 29.2, 29.3, 29.5, 29.7 ($CH_3(CH_2)_2(CH_2)_4CH_2CH{=}CHCH_2(CH_2)_6$, $NCH_2CH_2CH_2N$); 31.9 ($CH_3CH_2CH_2$); 49.0 (NCH_3); 61.5 (NCH_2); 129.6, 130.1 (=CH). Anal. ($C_{77}H_{152}N_2Cl_2$) H, N, C: calcd, 78.58; found, 79.50.

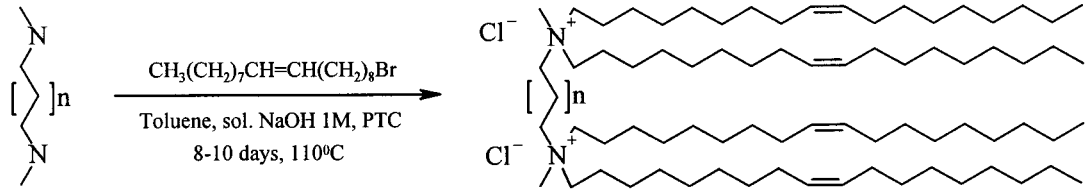
Synthesis of *N,N,N′,N′*-Tetraoelyl-*N,N′*-dimethyl-1,6-hexanediammonium chloride (TODMAC6). TODMAC6 was synthesized using the same procedure as described above for TODMAC3 by substituting *N,N′*-dimethyl-1,6-hexanediamine for *N,N′*-dimethyl-1,3-propanediamine.

TLC (CH_2Cl_2/MeOH 9/1, H_2SO_4/EtOH): $Rf = 0.61$. ^1H NMR ($CDCl_3$): δ 0.85 (t, $^3J = 6.6$ Hz 12H, CH_3); 1.00−1.46 (broad s, 92H, $CH_3(CH_2)_6CH_2CH{=}CHCH_2(CH_2)_5$, $N(CH_2)_2(CH_2)_2(CH_2)_2N$); 1.46−1.74 (m, 10H, CH_2CH_2N); 1.80−2.12 (m, 16H, $=CHCH_2$); 3.14−3.75 (m, 18H, CH_3, CH_2N); 5.20−5.45 (m, 8H, =CH). ^{13}C NMR ($CDCl_3$): δ 14.1 (CH_3CH_2); 22.7 (CH_3CH_2); 27.2 ($=CHCH_2$); 21.0, 22.5, 23.9, 26.4, 29.4, 29.6, 29.8 ($CH_3(CH_2)_2(CH_2)_4CH_2CH{=}CHCH_2(CH_2)_6$, $NCH_2(CH_2)_4CH_2N$); 31.9 ($CH_3CH_2CH_2$); 49.0 (NCH_3); 61.2, 62.7 (NCH_2); 129.7, 130.2 (=CH). Anal. ($C_{80}H_{158}N_2Cl_2$)·H_2O C, H, N.

^{31}P Nuclear Magnetic Resonance Spectroscopy. Lipid mixtures containing 40−50 mg DPPS and appropriate molar ratios of cationic lipids (DODAC, TODMAC3, TODMAC6) were prepared by drying from chloroform solution, placed in 10 mm NMR tubes, and hydrated with 1.5 mL of distilled water. Free induction decays (FIDs) corresponding to 1000 scans were obtained by using a 3.0 μs 60° pulse with a 1 s interpulse delay and a spectral width of 25000 Hz. A gated two-level proton decoupling was used to ensure sufficient decoupling with minimum sample heating. An exponential multiplication corresponding to 50 Hz of line broadening was applied to the FIDs prior to Fourier transformation. The sample temperature (±1 °C) was regulated using a Bruker B−VT1000 variable temperature unit. Chemical shifts were referenced to 85% phosphoric acid as an external standard.

Preparation of Large Unilamellar Vesicles (LUV). Mixtures of cationic lipids and DOPE in chloroform were dried under a stream of nitrogen gas, and the residual solvent was removed under high vacuum for 2 h. The resulting lipid films were hydrated with distilled water. LUVs were obtained by extruding the lipid dispersions 10 times through two stacked 100-nm pore size polycarbonate filters (Costar Nuclepore polycarbonate membrane, Northern Lipids Inc. extruder) (*15*). Phospholipid concentrations were determined by the inorganic phosphorus assays according to Fiske and Subbarow (*16*).

Preparation of Lipoplexes. Lipoplexes were prepared in distilled water at pDNA concentrations ranging from 12.5 to 25 μg pDNA/ml at positive-to-negative charge ratios between 0.5 and 5. Plasmid DNA was added under vortexing to cationic LUVs (cationic lipid/DOPE 1:1). In the absence of the helper lipid DOPE, lipoplexes were prepared by addition of the cationic lipids from ethanol solutions to an aqueous solution containing the pDNA. The amount of ethanol in these formulations was between 0.4 and 2.3%. The lipoplexes were incubated at room temperature for 30 min, diluted to a final concentration of 2.5 μg pDNA/mL with serum-free media (Dulbecco's Modified Eagle's Medium, DMEM), and subsequently applied to BHK cells.



In Vitro Transfection of BHK Cells. BHK cells, grown in DMEM supplemented with 10% fetal calf serum (FCS), 100 U/mL of penicillin, and 100 μg/mL of streptomycin, were seeded in 96-well plates at a density of 1×10^4 cells per well 24 h before transfection. The next day media was removed and replaced with 100 μL of lipoplexes dispersed in serum-free DMEM (0.25 μg pDNA/100 μL). After 4 h, lipoplexes were replaced with serum-containing DMEM and cells further incubated for 20 h. After that the culture medium was aspirated, the cells washed twice with 100 μL of PBS and then lysed through addition of 50 μL of lysis buffer (0.1% Triton X-100 in PBS). Luciferase activity was measured with a Dynex luminometer (Dynex model ML3000) using the Luciferase Assay Kit from Promega. The total protein concentration per well was determined using the BCA assay from Pierce. Means and standard deviations were calculated from three independent experiments.

Statistical Analyses. Statistical analyses were performed using a Student t test. The difference between two means was considered as significant when the probability p is 0.05.

RESULTS

Rationale for and Synthesis of the Cationic Lipids TODMAC3 and TODMAC6. As indicated in the Introduction, cationic lipids with a small cross-sectional area in the headgroup region would be expected to give rise to improved transfection properties compared to lipids with larger headgroup areas, assuming the cross-sectional area in the alkyl chain region remains constant (*11*). One method to vary the headgroup area is to create a dimer of cationic lipids joined together in the headgroup region by a tether of variable length. We chose to work with DODAC, a cationic lipid with excellent transfection properties, and construct dimers joined by hydrocarbon

n = 1 TODMAC3
n = 4 TODMAC6

tethers three and six carbons long (TODMAC3 and TODMAC6, respectively).

These cationic lipids were synthesized by nucleophilic substitution of secondary amines using oleyl bromide under phase-transfer catalytic condition as outlined in Scheme 1. The reaction was performed in toluene and 1 M sodium hydroxide in the presence of a phase-transfer catalyst for 10 days at 100 °C. The strongly basic amines required high alkaline reaction conditions so that they remained deprotonated to react with oleyl bromide. The yields were 39 and 85% for TODMAC3 and TODMAC6, respectively. The lower yield for TODMAC3 is probably due to steric hindrance as a result of the close proximity of the two positive charges. The diquaternary ammonium chlorides were characterized by ^{1}H and ^{13}C NMR as well as by elemental analysis. The NMR resonances are consistent with the diquaternary structure of the cationic lipids (see above Experimental Procedures).

Polymorphic Phase Properties of Mixtures of TODMAC3 and TODMAC6 with DPPS. The ability of cationic lipids to induce the hexagonal H_{II} phase in combination with anionic lipids correlates well with their transfection properties in plasmid DNA−cationic lipid complexes. The relative ability of cationic lipids to induce the H_{II} phase can be ascertained by measuring the bilayer-to-nonbilayer transition temperature (T_C) of the cationic lipid in equimolar mixtures (with respect to charge) with an anionic phospholipid such as DPPS. The bilayer-to-nonbilayer transition can be conveniently monitored employing ^{31}P NMR techniques (*12*). Briefly, phospholipids that are in a bilayer organization exhibit a broad (≥40 ppm) aymmetric ^{31}P NMR line shape with a low field shoulder and a high field peak whereas phospholipids in the hexagonal H_{II} phase exhibit a line shape with reversed asymmetry that is a factor of 2 narrower. Phospholipids in nonbilayer cubic phases that often occur in conjunction with H_{II} phase formation exhibit narrow "isotropic" ^{31}P NMR spectra. It should be noted that small (diameter ≤ 200 nm) phopholipid vesicles also exhibit isotropic spectra; however, in the results presented here the presence of such spectra will be attributed to nonbilayer structures as the temperature-dependent phase behavior was reversible.

In the first series of experiments the temperature-dependent polymorphism of TODMAC6/DPPS mixtures was compared to the behavior of DODAC/DPPS mixtures. As shown in Figure 1, at 25 °C both mixures exhibited ^{31}P NMR line shapes indicative of bilayer structure. However at 30 °C the mixture containing TODMAC6 has largely adopted the H_{II} phase or a structure giving rise to a narrow isotropic ^{31}P NMR peak, whereas the dispersion containing DODAC remains in a bilayer organization at 35 °C, adopting the structure giving rise to the "isotropic" ^{31}P NMR peak at 30 °C. On the basis of this behavior it would be expected that TODMAC6 should exhibit transfection properties that are comparable to or slightly better than DODAC when used in plasmid DNA−cationic lipid complexes.

The ^{31}P NMR behavior of dispersions of TODMAC3/DPPS (0.5:1; mol:mol) is illustrated in Figure 2A. At temperatures as low as 15 °C an H_{II} component is clearly visible; however, the large bulk of the phospholipid remains in the bilayer organization and the proportion in the H_{II} phase does not increase as the temperature is raised. This behavior is consistent with a limited solubility of the TODMAC3 in the DPPS component in the lipid mixture. This may be due to steric constraints associated with the need to form ion pairs between the cationic lipid and two DPPS molecules in order to form the H_{II} phase. For example, if only one DPPS molecule was able to form an ion pair with each TODMAC3, 50% of the DPPS would be unpaired and thus remain in the bilayer organization. If this is the case it would be expected that TODMAC3/DPPS systems containing higher proportions of TODMAC3 should exhibit increased preference for nonbilayer structure. The phase properties of a mixture containing equimolar proportions of TODMAC3 and DPPS were therefore investigated and, as shown in Figure 2B, this system exhibited an increased preference for H_{II} phase structure. On the basis of this behavior TODMAC3 would not be expected to be as effective a transfection agent as DODAC on a charge for charge basis.

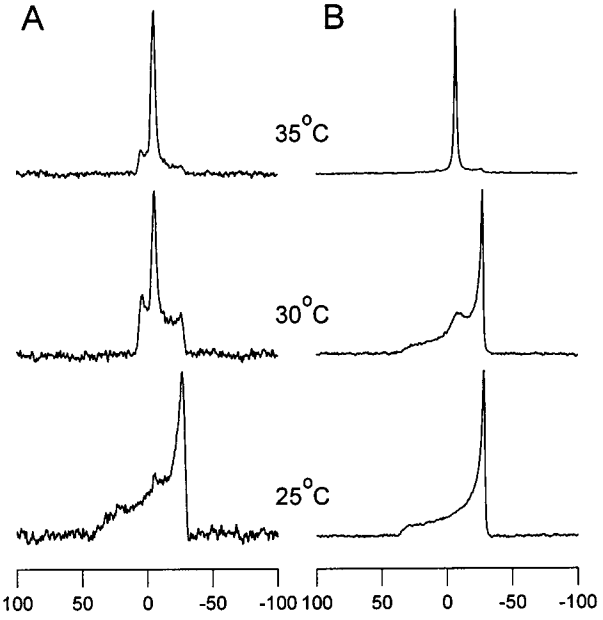

Figure 1. ^{31}P NMR spectrum obtained from an aqueous dispersion of TODMAC6/DPPS (0.5 molar ratio) (A) and of DODAC/DPPS (1 molar ratio) (B). The temperatures are indicated. Sample parameters and NMR parameters are described in Experimental Procedures.

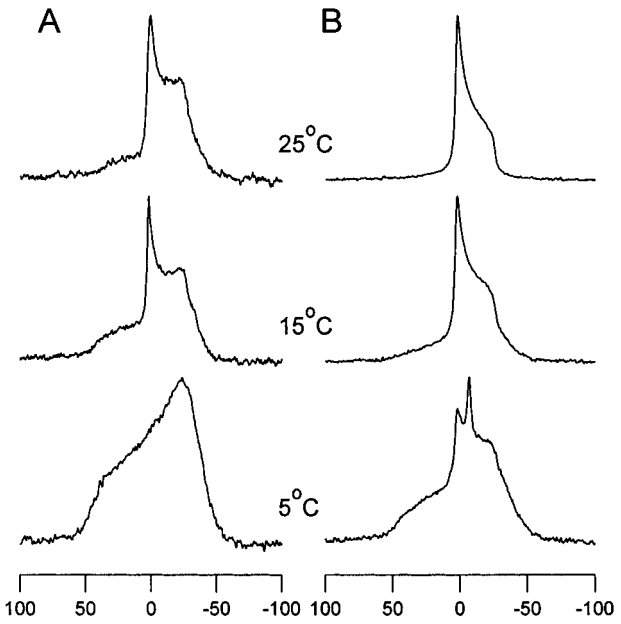

Figure 2. ^{31}P NMR spectrum obtained from an aqueous dispersion of TODMAC3/DPPS (0.5 molar ratio) (A) and of TODMAC3/DPPS (1 molar ratio) (B). The temperatures are indicated. Sample parameters and NMR parameters are described in Experimental Procedures.

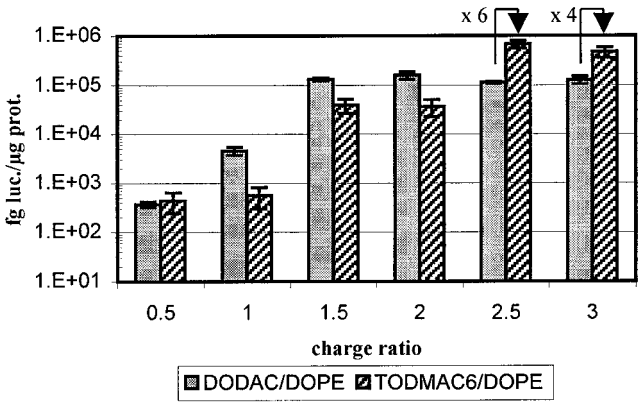

Figure 3. Transfection efficiency in BHK cells of the TODMAC6/DOPE lipoplexes, as compared with, DODAC/DOPE lipoplexes. The data presented correspond to a concentration of 0.25 μg DNA/well. The given means ± SEM were calculated from three independent experiments.

In Vitro Transfection Properties of Plasmid DNA−Cationic Lipid Complexes Containing TODMAC3 and TODMAC6. Plasmid DNA cationic lipid complexes are usually formed by mixing plasmid DNA with preformed vesicles containing the cationic lipid mixed with equimolar amounts of the "helper" lipid dioleoylphosphatidylethanolamine (DOPE) (*17*, *18*). However, it was found that vesicles could not be prepared consisting of TODMAC3/DOPE mixtures, as lipid films prepared of this lipid mixture were extremely difficult to hydrate and formed clumps that could not be extruded. Vesicles of TODMAC6/DOPE could be readily prepared, and the transfection properties of complexes formed employing TODMAC6 and DODAC and containing the L018 plasmid coding for the luciferase gene were tested in vitro using baby hamster kidney (BHK) cells. Figure 3 illustrates the transfection properties of complexes prepared at cationic lipid-to-DNA charge ratios (positive to negative) ranging from 0.5 to 5. It may be observed that the transfection potency of complexes containing TODMAC6 are comparable to or slightly lower than complexes

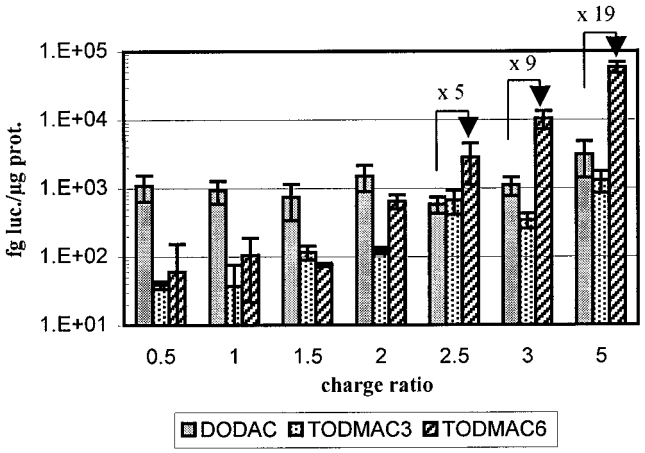

Figure 4. Transfection efficiency in BHK cells of the TODMAC6 and TODMAC3 lipoplexes, as compared with, DODAC lipoplexes. The data presented correspond to a concentration of 0.25 μg DNA/well. The given means ± SEM were calculated from three independent experiments.

containing DODAC at charge ratios or two or lower, but are greater at higher charge ratios.

To test the relative transfection potencies of DODAC, TODMAC6, and TODMAC3 a different procedure was used to associate the cationic lipid with the plasmid to form the complexes. In this method the cationic lipid dissolved in ethanol is introduced into an aqueous solution of the plasmid and DOPE is not present. The transfection properties of complexes formed in this manner are shown in Figure 4. It may be noted that at charge ratios of two and lower DODAC exhibits superior tranfection properties; however, at charge ratios above two TODMAC6 exhibits transfection properties that are superior to both DODAC and TODMAC3. Specifically, for charge ratios ≥2.5, TODMAC6 complexes gave rise to luciferase expression levels 5−20-fold higher than could be achieved with DODAC or TODMAC3.

DISCUSSION

This study describes the synthesis and transfection properties of a new class of tetraalkyl cationic lipids designed to increase the ability of cationic lipids to induce the hexagonal H_{II} phase. There are three points of interest, the first of which concerns the physical properties of these lipids in relation to their molecular shape characteristics. A second area concerns the correlation between the ability to induce H_{II} organization and the observed transfection properties. Finally, it is of interest to discuss the utility of the TODMAC3 and TODMAC6 cationic lipids and their derivatives as transfection agents. We discuss these points in turn.

The physical properties of TODMAC3 and TODMAC6 are quite different. TODMAC6 readily forms bilayer structures, both in the presence and absence of DOPE, on dispersion in an aqueous medium, whereas TODMAC3 does not. Further, when mixed with equimolar (with respect to charge) amounts of DPPS, TODMAC6 forms a homogeneous dispersion that collectively adopts nonbilayer structure in the region of 30 °C. TODMAC3 on the other hand is able to interact with only a limited subset of the DPPS but is able to induce the H_{II} phase for that subset at temperatures as low as 15 °C. At higher TODMAC3/DPPS ratios (2:1 on a charge basis), TODMAC3 is able to induce apparently complete H_{II} organization at temperatures of 25 °C or higher. These results are consistent with steric effects that limit the ability of

TODMAC3 to interact with more than one DPPS molecule due to the small size of the TODMAC3 headgroup.

The correlation between the ability of TODMAC6 and TODMAC3 to induce nonbilayer structure and their transfection properties is of obvious interest for the design of cationic lipids with optimized transfection capabilities. TODMAC6/DPPS and DODAC/DPPS liposomes exhibit bilayer−nonbilayer transitions that are close together, in the region of 30−35 °C. On this basis it would be expected that plasmid DNA−cationic lipid complexes containing TODMAC6 or DODAC should exhibit roughly equivalent transfection properties. For the complexes containing DOPE this is largely true, although somewhat higher transfection potency is observed for the complexes containing TODMAC6 at higher charge ratios. For the complexes prepared in the absence of DOPE the TODMAC6, complexes are not as effective transfection agents at charge ratios less than two but can be substantially more potent at charge ratios above two. In the case of TODMAC3 the tranfection potency of the complexes (prepared in the absence of DOPE) only become comparable to complexes containing DODAC at charge ratios above two. This could be interpreted as reflecting a need for increased amounts of TODMAC3 in order to bind to endogenous anionic lipid due to steric effects inhibiting these interactions. Overall these results suggest that while the ability to induce nonbilayer structure correlates roughly with transfection potency, other factors can also influence transfection potencies substantially. These other effects include the method of constructing the complexes, steric barriers inhibiting the formation of neutral ion pairs between cationic and anionic lipids, the ability of the cationic lipid to dissociate from the plasmid DNA following uptake into the cell, and the lipid composition of the endosomal membrane.

The final area of discussion concerns the utility of TODMAC6 and TODMAC3 as transfection agents. It would appear that TODMAC3 has limited advantages over currently available cationic lipid such as DODAC. The utility of TODMAC3 is further compromised by the inability to incorporate DOPE into complexes containing TODMAC3 due to the inability to form vesicular structures. However, TODMAC6 appears to have interesting potential, particularly at charge ratios above two. Current work is focused on exploring this potential when incorporated into "stabilized plasmid-lipid particles" (SPLP) (*19*−*21*) for in vivo applications for treatment of systemic disease.

TECHNICAL NOTES

New Fmoc Pseudoisocytosine Monomer for the Synthesis of a Bis-PNA Molecule by Automated Solid-Phase Fmoc Chemistry

Philippe Neuner* and Paolo Monaci

Istituto di Ricerche di Biologia Molecolare P. Angeletti, Via Pontina Km 30,600, 00040 Pomezia (Roma), Italy .

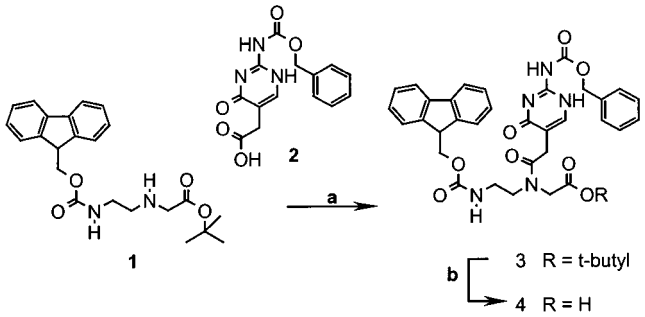
The synthesis of *N*-[2-(*N*-9-fluorenylmethoxycarbonyl)aminoethyl]-*N*-(2-*N*-(benzyloxycarbonyl)isocytosin-5-ylacetyl)glycine monomer and its incorporation into a PNA molecule via automated Fmoc solid-phase chemistry is described.



INTRODUCTION

Peptide nucleic acid (PNA) is a polynucleic acid consisting of natural or modified nucleobases linked to a peptide backbone (*1*). PNA exhibits a remarkable specificity and very high affinity in recognizing complementary DNA or RNA strands (*2*). Here we focus on a dimeric PNA molecule (bis-PNA) consisting of a homopyrimidine PNA oligomer (C/T) connected via a flexible linker (2-aminoethoxy-2-ethoxyacetic acid) to a second PNA sequence (J/T, where J is pseudoisocytosine). This bis-PNA has been shown to form highly stable triple helix conjugates $(PNA)_2$/DNA by strand invasion in a P-loop structure form. The formation and stability of the triple strand complex is only slightly influenced by pH in the neutral range, mainly due to the stabilizing effect of the protonated N1 position of the J residue at physiological pH (*3*). Early synthesis of PNA was essentially based on the manual assembly of monomers via *tert*-butyloxycarbonyl (Boc) chemistry on solid support (*4*). More recently, the design and preparation of sets of fluorenylmethoxycarbonyl (Fmoc)/acid labile PNA building blocks, the development of instrumentation, and optimization of synthesis protocols have led to the rapid and efficient synthesis of PNA probes by the mild and well-known Fmoc chemistry (*5*, *6*). However, the only reported strategy for synthesising a bis-PNA-containing pseudoisocytosine still relies on the Boc chemistry (*7*). The lack of an Fmoc automated synthesis procedure for the preparation of this molecule led us to attempt the synthesis of the *N*-[2-(*N*-9-fluorenylmethoxycarbonyl)aminoethyl]-*N*-(2-*N*-(benzyloxycarbonyl)isocytosin-5-ylacetyl)glycine monomer, which is fully compatible with Fmoc chemistry, commercial PNA building blocks, and synthesizer.

EXPERIMENTAL PROCEDURES

Synthesis of the required *tert*-butyl *N*-[2-(*N*-9-fluorenylmethoxycarbonyl)aminoethyl]glycine **1** and N^2-(benzyloxycarbonyl)isocytosin-5-ylacetic acid **2** were carried out as described in the literature (*5*, *7*). The base acetic acid **2** was reacted with **1**, leaving the intermediate **3** in good yield after flash chromatography (*8*). Removal of the *tert*-butyl ester with TFA in DCM gave **4** (Scheme 1) without significant loss of the N^2-benzyloxycarbonyl-protecting group (*9*).

Scheme 1[a]

[a] Reagents: (a) *N*-methylmorpholine, HOBt, HBTU/DMF; (b) TFA/DCM.

A key aspect of the synthesis of the bis-PNA using Fmoc (J^{Cbz}) was removal of the N^2-benzyloxycarbonyl protecting group of the pseudoisocytosine. In a standard protocol, treatment of the synthesis resin with a TFA/*m*-cresol (4:1) mixture efficiently released the polymer from the solid support and cleaved the cytosine benzhydryloxycarbonyl (Bhoc) blocking group. In a preliminary experiment, this deprotection 'cocktail' proved to be too mild to cleave the pseudoisocytosine benzyloxycarbonyl (Cbz), even after overnight treatment of the polymer (data not shown). Thompson et al. chose hydrogen fluoride (HF) in their work to cleave the *N*-benzyloxycarbonyl group (5). As an alternative, we chose a single treatment with a mixture of TFMSA/TFA/*m*-cresol to release and efficiently cleave the blocking group from the polymer.

RESULTS AND DISCUSSION

The solid-phase synthesis of the bis-PNA (NH2-LL-TCTCTCTC-LLL-JTJTJTJT-CONH2) was performed on a PerSeptive Biosystems Expedite 8909 automated synthesizer using the manufacturer's protocols. All reagents including Fmoc C (Bhoc), Fmoc T, Fmoc AEEA spacer (L = 2-aminoethoxy-2-ethoxyacetic acid), and HATU were

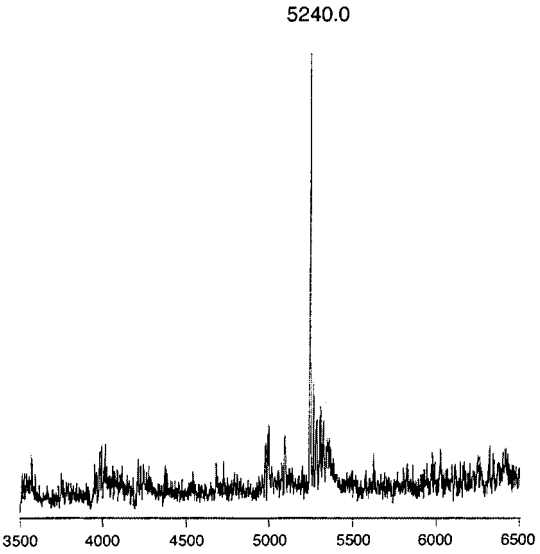

Figure 2. Mass spectrum of bis-PNA Fluo-HN-LL-TCTCTCTC-LLL-JTJTJTJT-$CONH_2$ (L = 2-aminoethoxy-2-ethoxyacetic acid). M (calcd) for $C_{219}H_{284}N_{78}O_{77}$ = 5241.18; M (experimental) = 5240.00.

obtained from PerSeptive Biosystems. The PNA monomers were dissolved in NMP at a 0.2 M concentration. Synthesis using either XAL or PAL columns synthesis (2 μmol scale) were investigated and showed no significant difference in yield. After oligomerization, the resin was dried and transferred to a screw-cap vial. The vial was cooled on ice, and 200 μL of a mixture TFMSA/TFA/*m*-cresol (18:73:9) was added. Reaction proceeded at room temperature for 90 min. Solid support was separated by filtration and the filtrate poured into 10 volumes of ice-cold Et_2O. Centrifugation gave a pellet, which was purified by HPLC.

Preparative RP C18 HPLC purification was performed using a SymmetryPrep C18 (7.8 × 150 mm) reverse-phase column (Waters). Eluant A: 99.9% water, 0.1% TFA; eluant B: 10% water, 89.9% acetonitrile, 0.1% TFA; a linear gradient of 5−30% eluant B over 25 min at a flow rate of 2.0 mL/min monitored at 260 nm (Figure 1). The expected bis-PNA eluted at 21.8 min. The average yield was usually 20−25% (1−1.25 mg) of purified oligomer

Final product was analyzed for purity by mass determination on a LCQ quadrupole ion trap mass spectrometer Finningan-MAT (San Jose, CA).

Labeling of the Bis-PNA in Solution. The bis-PNA synthesized above was routinely labeled in solution with various dyes (Biotin, Fluorescein, Rhodamine) according to the general protocol described here:

To 12 OD (optical density) units of bis-PNA in ultrapure water was added a solution of 1 mg of *N*-succinimidyl ester dye (Fluka) in 100 μL of DMF, followed by 20 μL of a 10% NMM (aq). The solution was thoroughly vortexed, and the reaction proceeded for 3 h in the dark. The volume was taken to 0.5 mL by adding ultrapure water, and the reaction mixture was purified by RP-HPLC using conditions described above. An average yield of 40−60% of the labeled PNA was easily obtained.

In conclusion, we have described the synthesis of a new PNA pseudoisocytosine building block with orthogonal protecting groups (Fmoc/Cbz) and its use in the synthesis of a bis-PNA on an automated synthesizer. It was our experience that the versatile and economical automated assembly of the bis-PNA molecule described here facilitates the collinear synthesis of PNA−peptide chimeras by standard Fmoc chemistry (*6*). To our knowledge, no detailed description of the synthesis of the monomer and its incorporation into a PNA fragment by Fmoc chemistry has been previously reported. Until now, our attempts to protect the N2 exocyclic of the pseudoisocytosine with a mild acid-labile protecting group (Boc and Bhoc) using the standard methodologies have resulted in poor yields (*10*). We are currently investigating other strategies and new blocking groups.

A Simple Two-Step Approach for Introducing a Protected Diaminedithiol Chelator during Solid-Phase Assembly of Peptides

Jean Gariépy,* Sandrine Rémy, Xiuguo Zhang, James R. Ballinger,† Eleonora Bolewska-Pedyczak, Michael Rauth, and Stuart K. Bisland

Department of Medical Biophysics, University of Toronto, and Division of Molecular and Structural Biology, Ontario Cancer Institute, Princess Margaret Hospital, 610 University Avenue, Toronto, Ontario, Canada M5G 2M9. Received August 27, 2001; Revised Manuscript Received December 10, 2001

A simple synthetic strategy is described to incorporate a protected diaminedithiol (N_2S_2) chelator during Fmoc solid-phase synthesis of short peptides. The resulting constructs could be efficiently labeled with technetium-99m (^{99m}Tc). The chelator was assembled at the N-terminus of peptides in a two-step procedure where the deprotected terminal amino group was first reacted with di-Fmoc-diaminopropionic acid (Fmoc-DAP-[Fmoc]-OH). The two protected amino groups were then simultaneously deprotected and subsequently reacted with *S*-benzoylthiolglycolic acid (TGA) to generate a protected N_2S_2 chelator. This metal binding site was introduced into di- and tripeptides. Each peptide construct was composed of a C-terminal lysine residue and an N-terminal diaminopropionic moiety modified to create the chelator site. The ϵ-amino group at the C-terminal lysine was further derivatized with a nitroimidazole group to facilitate cellular retention. The resulting constructs were then cleaved from the resin support, purified, and labeled with [^{99m}Tc]pertechnetate. Six constructs were prepared differing by a single amino acid inserted between the diaminopropionic acid and lysine residues. Optimal labeling yields of >70% were achieved around neutral pH and heating at 75 °C for 10 min. Purified ^{99m}Tc-labeled constructs were found to accumulate in Chinese hamster ovary (CHO) cells in vitro as a function of charge and hydrophobicity.

INTRODUCTION

Technetium-99m (^{99m}Tc) is the most commonly used radionuclide in nuclear medicine (*1*). Its short half-life (~6 h) and ease of production and the advent of ^{99m}Tc chelators that can be covalently linked to peptides, proteins, and other biologically active molecules represent key features promoting its use in diagnostic imaging. More importantly, peptides and related peptidomimetics can now be rapidly assembled by solid-phase synthesis approaches, offering the prospect of developing new and powerful classes of ^{99m}Tc-labeled radiopharmaceuticals. Peptides can be designed to incorporate specific sequences enabling them to achieve a desired biodistribution (i.e., targeted to receptors) or pharmacokinetic response (a function of their mass, charge, or lipophilicity). Short peptides are also less immunogenic than proteins such as monoclonal antibodies. Strategies for labeling peptides with ^{99m}Tc (*2*−*11*) and their application in medicine have recently been reviewed (*12*−*14*). At the present time, most technetium chelators are thiol-containing agents, which are susceptible to oxidation events if left unprotected prior to labeling. Histidine tags have also been suggested as potentially useful ^{99m}Tc chelators when introduced into recombinant proteins (*15*). More importantly, differences in chelators as well as peptides have been shown to influence the in vivo properties of the resulting ^{99m}Tc-labeled peptides (*16*, *17*). Most approaches used to date do not provide a systematic design strategy to incorporate a well-established protected thiol-containing chelator anywhere into peptides. The present report describes a simple strategy for assembling a diamidedithiol (N_2S_2)[1] chelator during solid-phase peptide synthesis. The N_2S_2 group was incorporated at the N-terminus of six peptide constructs containing a C-terminal 2-nitroimidazole group.

EXPERIMENTAL PROCEDURES

Chemicals and Reagents. Benzoyl chloride, L-2,3-diaminopropionic acid hydrochloride (DAPA), 1,4-dioxane, 2-bromoethyl acetate (BEA), and 2-nitroimidazole were purchased from Sigma-Aldrich Fine Chemicals (St. Louis, MO). 9-Fluorenylmethyl choroformate (Fmoc-Cl) was obtained from Advanced ChemTech (Louisville, KY). Di-Fmoc-aminopropionic acid can now be directly purchased from Chem-Impex International (Wood Dale, IL) or Bachem BioScience Inc. (King of Prussia, PA). Thioglycolic acid (TGA; mercaptoacetic acid) was obtained from Fischer Scientific (Cedarlane Laboratories Ltd., Hornby, ON). SepPak C_{18} solid-phase extraction cartridges (1.5 mL capacity) were purchased from Waters (Milford, MA). Sodium [^{99m}Tc]pertechnetate was obtained from Mallinckrodt Medical Inc. (Mississauga, ON) or from a ^{99}Mo/^{99m}Tc radionuclide generator (Dupont, Billerica, MA).

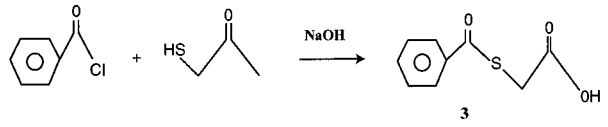
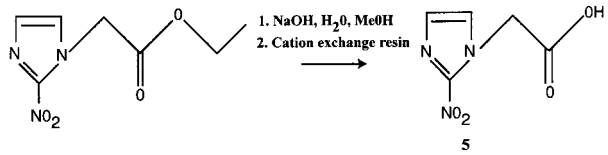


Scheme 2



Peptide Synthesis Reagents. *N*-α-9-Fluorenylmethyloxycarbonyl (Fmoc) protected amino acids, peptide-amide linker (PAL) resin, [2-(1*H*-benzotriazol)-1-yl]-1,1,3,3-tetramethyluronium tetrafluoroborate (TBTU), and *N*-hydroxybenzotriazole·H_2O (HOBt) were obtained from Calbiochem-NovaBiochem Corp. (San Diego, CA). 1,3-Dicyclohexylcarbodiimide (DCC), diisopropylethylamine (DIEA), trifluoroacetic acid (TFA), triisopropylsilane (TPS), *N*,*N*-dimethylformamide (DMF), and dichloromethane (DCM) were purchased from Schweizerhall Pharma (Piscataway, NJ). HPLC-grade acetonitrile (ACN) was purchased from BDH Inc. (Toronto, ON). Other buffers and inorganic salts and reagent chemicals were purchased from Sigma-Aldrich (St. Louis, MO).

Synthesis of Di-Fmoc-diaminopropionic Acid (Scheme 2). The two amino groups of L-diaminopropionic acid (DAPA) were protected with 9-fluorenylmethyl (Fmoc) groups following a standard protocol utilizing 9-fluorenylmethyl choroformate (Fmoc-Cl; ref *18*). Briefly, DAPA (4.18 g, 30 mmol) was dissolved in 100 mL of 10% Na_2CO_3 in water. Fifty milliliters of dioxane (peroxide-free) was then added to the solution, and the resulting mixture was stirred in an ice−water bath. Fmoc-Cl (15.6 g, 60.24 mmol) dissolved in 75 mL of dioxane was then added in small portions to the DAPA solution. The reaction mixture was subsequently stirred for 1 h at 0 °C followed by an additional 12 h period at room temperature. Dioxane was evaporated on a rotary evaporator and the reaction mixture poured into 1.5 L of distilled water. The aqueous solution was washed twice with 200 mL of ethyl acetate to remove unreacted Fmoc-Cl and

Scheme 3

Scheme 4

cooled to 0 °C. Ethyl acetate (800 mL) was further added to the aqueous phase, and the suspension was acidified to pH 2 under vigorous stirring with concentrated HCl. The organic phase was recovered and washed with water to pH 7 and finally dried over anhydrous Mg_2SO_4. The ethyl acetate was evaporated and the oily residue macerated with hexane. The resulting solid crude product was recrystallized from ethyl acetate/hexane. Thin-layer chromatography (Analtech Uniplate silica gel GF plates; solvent system, 90:8:2 $CHCl_3$:MeOH:AcOH), pure product: R_f 0.52 (79% yield). Analyses for di-Fmoc-diaminopropionic acid (**1**): MS *m*/*z* observed 549 [M+H$^+$], calcd 549; melting point 178−180 °C. Di-Fmoc-aminopropionic acid can now be purchased directly from Chem-Impex International (Wood Dale, IL) or Bachem BioScience Inc. (King of Prussia, PA).

Synthesis of *S*-Benzoylthioglycolic Acid (Scheme 3). *S*-Benzoylthioglycolic acid (**3**) was synthesized according to the protocol of Schneider et al., 1984 (*19*). Sodium hydroxide pellets (3.05 g; 75 mmol) and thioglycolic acid (7 g, TGA; 75.9 mmol) were mixed and dissolved into a 50 mL solution of toluene/water (1:2.5) at 5 °C. Benzoyl chloride (8.82 mL; 62.7 mmol) was then added to this solution over 30 min, maintaining the temperature between 5 and 15 °C. The reaction was allowed to proceed for an additional 30 min at room temperature. The mixture was then diluted to twice its volume with water and the aqueous phase washed twice with benzene (100 mL). The organic phase was discarded, and the aqueous layer was subsequently chilled to 4 °C and acidified to pH 1.0−1.5 with HCl (6 N). The precipitate was filtered off, washed in cold distilled water, and finally dried under vacuum. The precipitate was recrystallized from ethyl acetate (EtOAc): yield 7.5 g (76.5%), white crystalline product; melting point 102−103 °C. Analyses for *S*-benzoylthioglycolic acid [$\varnothing COS(CH_2)_nCO_2H$]: MS *m*/*z* observed 197 [M+H$^+$], calcd 197; ^{1}H NMR ($CDCl_3$/tetramethylsilicone): 7.99 (d, 2H$^+$, ortho position of benzoyl ring), 7.61 (t, 1H, ρ position of benzoyl ring), 7.48 (t, 2H$^+$, meta position of benzoyl ring), 3.92 (S, 2H$^+$, SCH_2CO).

Synthesis of 2-Nitroimidazole Ethyl Acetate (2-NIEA). 2-Bromoethyl acetate (BEA; 1.08 mL, 6.46 mmol) was added to a solution of 2-nitroimidazole (2-NI; 1 g, 8.84 mmol) and potassium carbonate (6 g) in dry acetonitrile (50 mL). The mixture was reacted with constant stirring for 36 h at room temperature, and the resulting precipitate was filtered and washed with acetone. Evaporation of the organic filtrate under reduced pressure yielded a yellow oil (1.8 g). Analytical TLC revealed a major product combined with two other side products; R_f 0.66 (CH_2Cl_2/MeOH/NH_3, 50:7:1). The pure product was isolated from the crude oil using flash chromatography (silica gel) eluted with CH_2Cl_2/MeOH/NH_3 (50:7:1) as yellowish oil: 1.05 g (60% yield); TLC, one spot, R_f 0.66. Analyses for 2-nitroimidazole ethyl acetate: MS *m*/*z*

observed 200 [M+H$^+$], calcd 200; ^{1}H NMR ($CDCl_3$/tetramethylsilicone) δ_H ($CDCl_3$): 7.202 (d, 1H, *H*-imidazole ring), 7.095 (d, 1H, *H*-imidazole ring), 5.12 (s, 2H, NCH_2COO), 4.28 (q, 2H, OCH_2CH$_3$), 1.30 (t, 3H, OCH2CH_3); δ_c ($CDCl_3$): 166.0 (C═O), 128.5 (*C*H-imidazole ring), 126.5 (*C*H-imidazole ring), 62.6 (NCH_2COO), 50.9 (OCH_2CH$_3$), 14.0 (OCH$_2$CH_3).

Preparation of 2-Nitroimidazole Acetic Acid (2-NIAA; Scheme 4). The purified oil of nitroimidazole ethyl acetate (0.9 g) was mixed into a solution of NaOH (4 N, 2.5 mL), water (10 mL), and MeOH (10 mL). The resulting solution was stirred at room temperature until no ester derivative was evident by TLC (~30 min), at which point a cation-exchange resin (H$^+$, Bio-Rad, 4 g), which had been protonated by washing with H_2SO_4 (1 N; 30 mL) and distilled water, was used to convert the basic solution to its acetic derivative (**5**; pH 2.5). Subsequent filtration and drying of the filtrate yielded a dark yellow paste (1.16 g). Chromatography of crude product on silica gel [eluent, CH_2Cl_2/CH_3CN/HCOOH (30:10:1)] yielded a white crystal: 0.28 g; mp >140 °C (decomposed); R_f 0.30 (CH_2Cl_2/CH_3CN/HCOOH, 30:10:1), 0.61 (CH_2Cl_2/CH_3CN/HCOOH (10:10:1)]. Analyses for 2-nitroimidazole acetic acid: MS *m*/*z* observed 172 [M+H$^+$], calcd 172. ^{1}H NMR ($CDCl_3$/tetramethylsilicone) (DMSO-d_6): δ_H 7.55 (1H, d, *H*-imidazole ring), 7.17 (1H, d, *H*-imidazole ring), 5.15 (2H, s, NCH_2COO), 3.90 (1H, broad, COOH); δ_c (DMSO-d_6): 169.1 (C═O), 129.0 (*C*H-imidazaole ring), 128.3 (*C*H-imidazole ring), 51.3 (NCH2COOH).

Synthesis, Purification, and Characterization of Peptides (Scheme 1). Peptides were assembled using standard Fmoc chemistry protocols and a peptide-amide linker (PAL) resin support. Briefly, 2.2 g (1.5 mmol) of peptide-amide linker (PAL) resin with a substitution of 0.69 mmol/g was deprotected with 20% piperidine in *N*,*N*-dimethylformamide (DMF) for 20 min. Two equivalents (3 mmol) of Fmoc-Lys-(Mtt)-OH was then coupled to the deprotected resin using molar equivalents of *N*-hydroxybenzotriazole·H_2O (HOBt) and [2-(1*H*-benzotriazol)-1-yl]-1,1,3,3- tetramethyluronium tetrafluoroborate (TBTU) in 10 mL of DMF for 5 min at room temperature with constant rocking. Two milliliters of diisopropylethylamine (DIEA) was then added to the slurry and the reaction allowed to continue for a further 40 min. The resin was deprotected and washed as described above and subsequently dried overnight under vacuum. The resulting resin was then dispensed into six equivalent (0.2 mmol) portions. Each resin fraction was then reacted with 5 equiv of either Fmoc-Gly (A), Fmoc-Asp(OtBu) (B), Fmoc-Lys(Boc) (C), Fmoc-Asn (D), or Fmoc-Ala (E) or left untreated (F; no amino acid added). Coupling was conducted in the presence of 1 mmol of HOBt and 1 mmol of TBTU, as described above. The reaction was completed after 2 h at room temperature (>99% coupling) as confirmed by the lack of ninhydrin color (absence of remaining free amino groups; ref *20*). Each peptide-resin sample was then deprotected in 20% piperidine in DMF and Fmoc-DAP-(Fmoc)-OH (**1**; 1.3 g; 0.4 mmol) prepared in 10 mL of DMF as well as 0.2 mmol of HOBt and TBTU dispensed into each slurry. DIEA (0.3 mL) was dispensed into each slurry, and the reactions were allowed to proceed for 2 h. All coupling reactions went to completion as confirmed by ninhydrin tests (*20*). The Fmoc groups on DAP (**2**) were then removed, and 4 equiv (8 mmol) of *S*-benzoylthiolglycolic acid (**3**), HOBt, and dicyclohexylcarbodiimide (DCC) was added to each resin sample to complete the scaffold of the protected diaminedithiol chelator (**4**). Following the coupling of 2-nitroimidazole acetic acid (**5**) to the ϵ-amino group at the C-terminal lysine residue of each construct (next paragraph, **6**), the peptides were cleaved from their resin support, analyzed, and purified to homogeneity by reverse-phase HPLC on a Zorbax SB-C_{18} column (5 μm, 0.94 cm × 25 cm) prior to ^{99m}Tc radiolabeling (**7A**−**7F**). The column was equilibrated in 0.1% trifluoroacetic acid (TFA)/20% acetonitrile in water (eluent A), and the peptides were separated using a 40 min linear gradient going from 0% to 100% eluent B [where eluent B was 0.1% TFA/70% acetonitrile containing 0.1% (v/v) trifluoroacetic acid]. All peptides eluted at around 40% acetonitrile/water. Peptide peaks were detected at 214 nm, and the flow rate was 1 mL/min. A Waters HPLC apparatus (model 510) equipped with a Lambda-Max variable-wavelength detector was used for the purification steps. Analytical HPLC profiles of the ^{99m}Tc-labeled peptides were recorded using a Beckman HPLC (Fullerton, CA) system incorporating a radiometric detection set on a ^{99m}Tc window (Beckman 171 radioisotope detector with a modified yttrium silicate scintillant). The Vydac reversed-phase (R-P) C_{18} column (5 μm, 0.46 cm × 25 cm) was first equilibrated in 10% acetonitrile/90% water/0.1% TFA, and the peptides were eluted using a 25 min gradient increasing from 0 to 100% of eluent B (90% acetonitrile/10% water/0.1% TFA). The column flow rate was 1.5 mL/min. ^{1}H NMR (δ_H) and ^{13}C NMR (δ_C) spectra were recorded on a Bruker 300AC spectrometer at 500 and 126 MHz, respectively. Electrospray mass spectra (ESMS) were obtained on a Sciex API(N°3) mass spectrometer in the positive ion mode. Radioactivity of syringes and vials was measured in a Capintec CRC-15R dose calibrator while radioactivity in in vitro samples was measured in a Picker Pace II automatic gamma counter.

Coupling of 2-Nitroimidazole Acetic Acid to the N_2S(benzoyl)$_2$-Containing Peptides and Release of Constructs from the Solid Support. The 4-methyltrityl (Mtt) protecting the ϵ-amino group at the C-terminal lysine residue was removed by treating the resin samples with 1% trifluoroacetic acid (TFA)/5% triisopropylsilane (TPS) in dichloromethane for 20 min at room temperature. The nitroimidazole group (**5**) was then coupled to this site by dispensing 0.5 mmol of NIAA, HOBt, and TBTU prepared in 0.3 mL of DIEA into each peptide-resin reaction vessel. The coupling reaction was completed within 3 h at room temperature. *S*-Benzoyl-protected peptides were cleaved from their solid support in the presence of 95% TFA/2.5% H_2O, 2.5% TPS. Total yields of product ranged from 20 to 30%. The peptides were purified to homogeneity by reverse-phase HPLC using a linear gradient as described earlier in this section (Figure 1). MS: *m*/*z* Peptide A: X = Gly, observed 798 [M+H$^+$], calcd 798; Peptide B: X = Asp, observed 839 [M+H$^+$], calcd 839; Peptide C: X = Lys, observed 869 [M+H$^+$], calcd 869; Peptide D: X = Asn, observed 855 [M+H$^+$], calcd 855; Peptide E: X = Ala, observed 812 [M+H$^+$], calcd 812; Peptide F: observed 741 [M+H$^+$], calcd 741.

Labeling N_2S(benzoyl)$_2$-Containing Constructs with Technetium-99m. Initial conditions to label the N_2S_2-containing peptides were based on methods described elsewhere (*21*, *22*). In brief, N_2S(benzoyl)$_2$-containing peptides were first dissolved in 2% DMSO/water to give a final stock concentration of 0.4 mg/mL. Aliquots (100 μL) of each solution were dispensed into test tubes, together with 100 μL of a stannous tartrate solution [composed of 1 mL of disodium tartrate (13 mg/mL in water) and 10 μL of a stock solution of stannous chloride (20 mg/mL in 1 N HCl)]. These mixtures were defined as composed of a 1:1 volume ratio of Sn tartrate to peptide. The final pH of these solutions (either pH 2, 7.5, or 9) was adjusted by a dropwise addition of either 1 N HCl or sodium bicarbonate (42 mg/mL prepared in

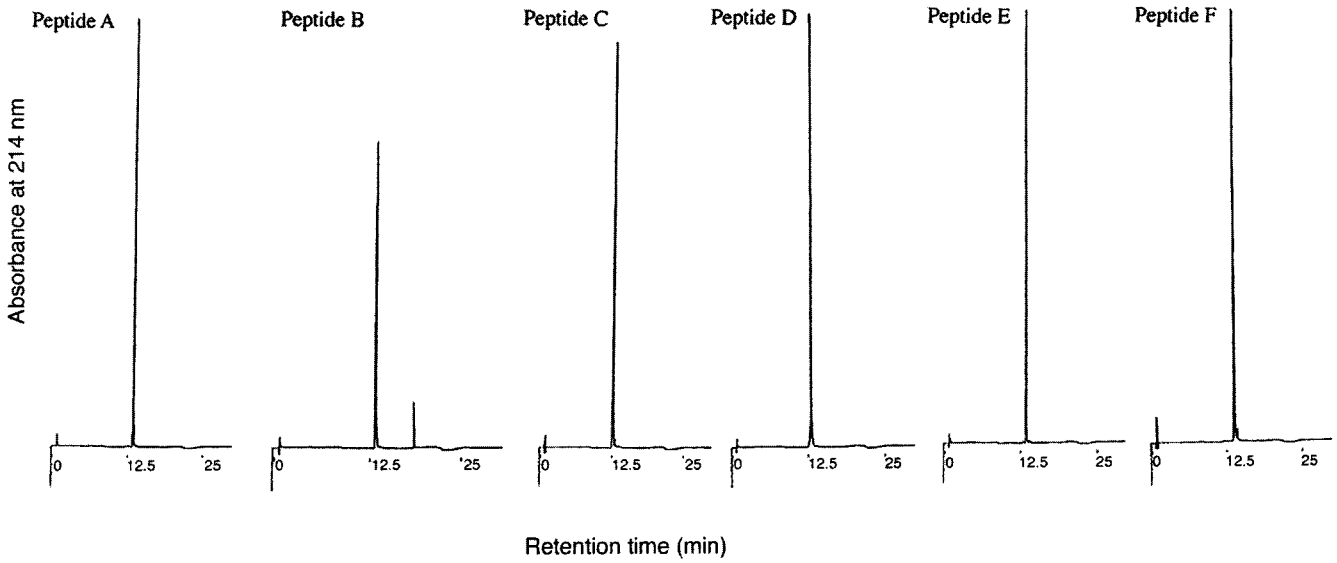


Figure 1. Elution profiles of purified N_2S(benzoyl)$_2$-containing peptides. Peptides were injected onto an analytical Zorbax SB-C_{18} column and eluted using a linear gradient going from 0 to 100% eluent B over a 25 min period. Eluent A: 0.1% TFA in 10% acetonitrile/water. Eluent B: 0.1% TFA in 90% acetonitrile/water. The column flow rate was 1.5 mL/min. All peptides eluted with a similar retention time near 12.5 min. Peptide A, N_2S(benzoyl)$_2$-**Gly**-Lys(2-NIAA)-amide, MW = 797. Peptide B, N_2S(benzoyl)$_2$-**Asp**-Lys(2-NIAA)-amide, MW = 838. Peptide C, N_2S(benzoyl)$_2$-**Lys**-Lys(2-NIAA)-amide, MW = 868. Peptide D, N_2S(benzoyl)$_2$-**Asn**-Lys(2-NIAA)-amide, MW = 854. Peptide E, N_2S(benzoyl)$_2$-**Ala**-Lys(2-NIAA)-amide, MW = 811. Peptide F, N_2S(benzoyl)$_2$-Lys(2-NIAA)-amide, MW = 740.

0.75 M ammonium hydroxide). An aliquot (100 μL) of sodium [^{99m}Tc]pertechnetate ($^{99m}TcO_4^-$; 50−80 MBq) was finally added to each tube, and each tube was then sealed and heated at 75 °C for 10−20 min. Parameters such as the volume ratio of Sn tartrate to peptide (3:1, 1:1, 1:4, and 1:10) and the reaction temperature (50, 75, 90, and 100 °C) were also modified to optimize the labeling procedure. Samples were purified using disposable C_{18} SepPak cartridges (Waters). The SepPak columns were equilibrated in distilled water. The radiolabeled samples were then injected into the cartridges and the columns subsequently washed with distilled water to remove unbound [^{99m}Tc]pertechnetate and [^{99m}Tc]tartrate. Labeled peptides were eluted from the SepPak with ethanol (3 fractions; 0.5, 0.5, and 1 mL, respectively). The extent of ^{99m}Tc-labeling was expressed as the percentage of radioactivity in the ethanol fractions (eluent) divided by the total radioactivity in all of the fractions combined.

In Vitro Cellular Uptake of ^{99m}Tc-Labeled N_2S_2-Containing Peptides. Chinese hamster ovarian (CHO) cells (subclone AA 8-4) were grown at 37 °C and 5% CO_2 as a suspension in α-minimal essential medium containing 10% (v/v) fetal calf serum. A 45 mL solution of cells (1×10^6 cells/mL of growth media) was prepared, from which 9.7 mL aliquots were dispensed into each of four sterile glass vials. Cells were allowed to equilibrate for 40 min in glass vials as stirred cell suspensions before being exposed to labeled peptide. All cell cultures were maintained at 37 °C. ^{99m}Tc-labeled peptide samples were initially diluted with water to a final radioactive concentration of 10 MBq/mL. Three hundred (300) microliters of each ^{99m}Tc-labeled peptide sample was then dispensed into each cell suspension using a syringe. Duplicate aliquots (300 μL) of cell suspensions were removed at selected time intervals following the addition of labeled peptides to cells (5 min, 1 h, 2 h, 3 h, and 4 h) and placed into microcentrifuge tubes containing 1 mL of ice-cold saline. Collected samples were then centrifuged (12000*g* for 2 min), and 100 μL of each supernatant was transferred into 5 mL polypropylene tubes. The radioactivity of the supernatant gives a measure of ^{99m}Tc-labeled peptide that had not been internalized into the CHO cells (C_{out}). The remaining supernatant was removed and the cell pellet washed again with ice-cold saline. The radioactivity of the cell pellet indicates the amount of intracellular ^{99m}Tc-labeled peptide (C_{in}). The overall amount of internalized radiolabeled sample is expressed as the ratio C_{in}/C_{out} (*7*).

RESULTS AND DISCUSSION

Solid-Phase Assembly of N_2S(benzoyl)$_2$-Containing Peptides. The objective of this study was to provide a simple synthesis strategy for incorporating a protected form of a diaminedithiol chelator into peptide constructs. Six peptides (Peptide A to Peptide F; **7A**−**7F**, Scheme 1) were assembled on a 431A peptide synthesizer (Applied Biosystems) using standard Fmoc solid-phase peptide synthesis protocols (Experimental Procedures). The chelator was assembled at the N-terminus of each peptide while a nitroimidazole group was introduced on the side chain of their C-terminal lysine residue. Chromatograms confirming the purity of each final construct are presented in Figure 1.

Concurrent Removal of Protecting Groups and Labeling of the Chelator with ^{99m}Tc Can Be Achieved in the Presence of Stannous Chloride and Disodium Tartrate. *S*-Benzoyl-protected peptides were simultaneously deprotected and radiolabeled using an exchange reaction with [^{99m}Tc]tartrate. Several parameters relating to pH, temperature, and the volume ratio of stannous tartrate to peptide used were evaluated for Peptide F to establish appropriate labeling conditions (Figure 2). Conditions which proved useful for radiolabeling the constructs were as follows: temperature of 75 °C for 10 min, pH 7.5, and a 1:1 volume ratio of stannous tartrate [100 μL of a stock solution composed of 1 mL of disodium tartrate (13 mg/mL in water) and 10 μL of a stock solution of stannous chloride (20 mg/mL in 1 N HCl)] to peptide (100 μL; 40 μg). Under these conditions, ^{99m}Tc-labeling of >70% could be consistently attained for Peptides A, B, C, D, and F, when quantified by reverse-phase HPLC (gradient from 10% to 90% acetonitrile in 25 min at a flow rate of 1.5 mL/min;

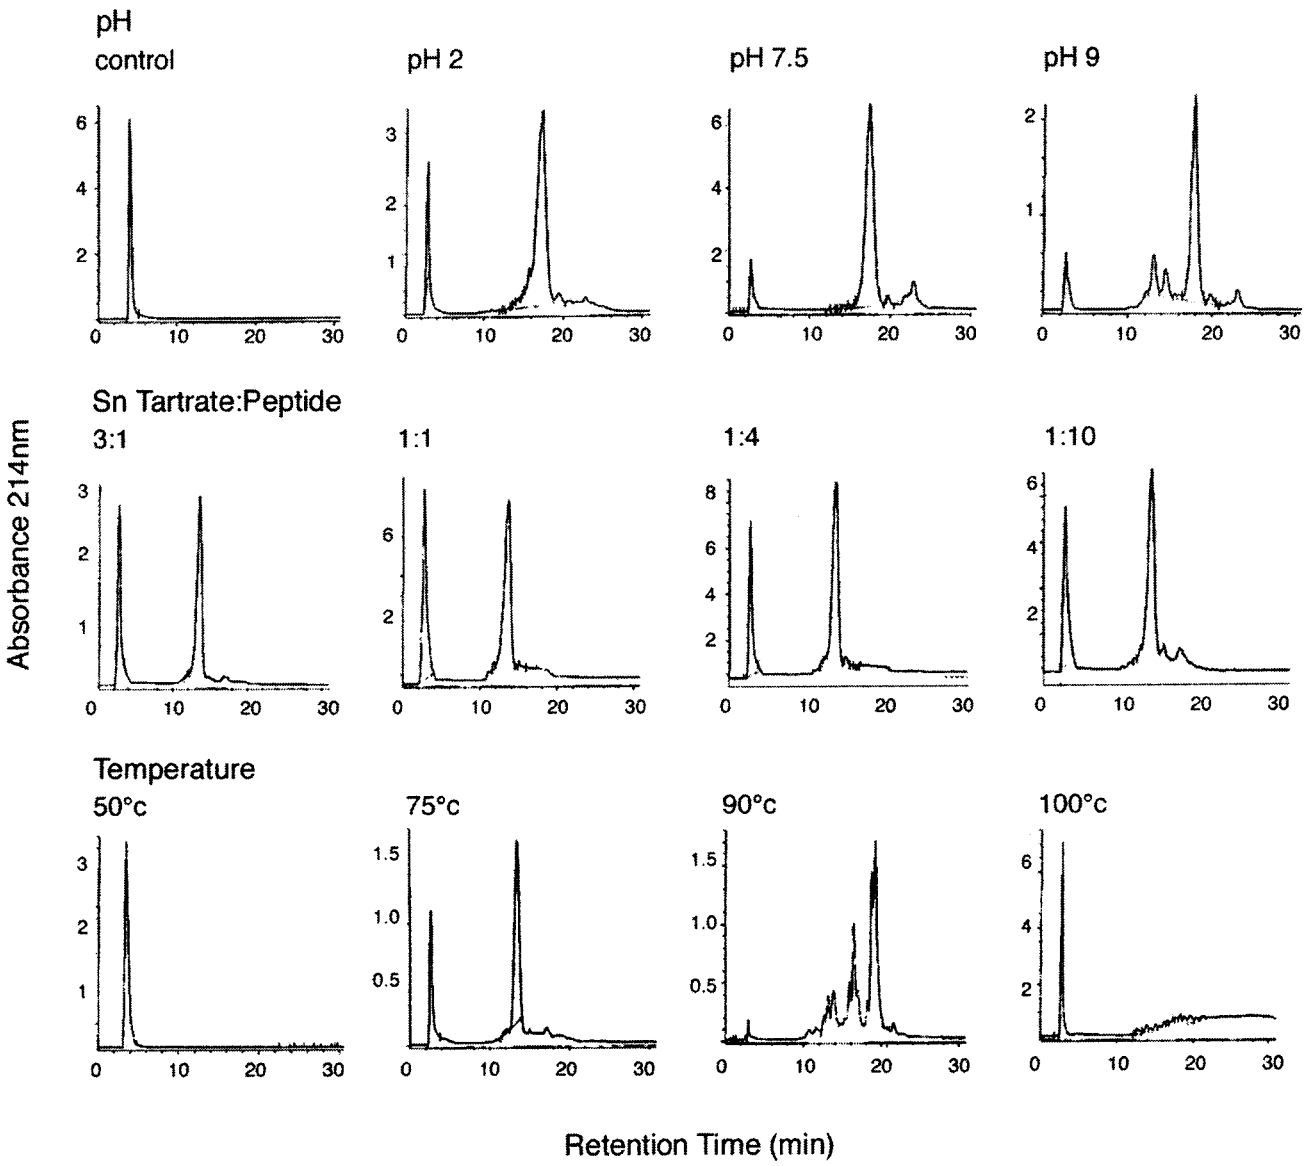

Figure 2. Reversed-phase HPLC profiles showing the effect of pH, temperature, and stannous tartrate to peptide ratio on the ^{99m}Tc labeling of Peptide F. Top Row: Effect of altering pH conditions. The top left chromatogram depicts the elution profile of tartrate/[^{99m}Tc]tartrate complex in the absence of peptide. Peptide F was treated for 10 min at 75 °C with a 1:1 volume ratio of stannous tartrate to peptide (100 μL of Sn tartrate stock solution to 100 μL of 0.4 mg/mL peptide solution). Middle Row: Effect of changing the stannous tartrate to peptide volume ratio. Peptide F was treated for 10 min at 75 °C and pH 7.5. Lower Row: Effect of changing the reaction temperature. Peptide F was treated for 10 min at pH 7.5 with a 1:1 volume ratio of stannous tartrate to peptide. Chromatograms of the radiolabeled peptides were obtained on a Vydac reversed-phase C_{18} column (5 μm, 0.46 cm × 25 cm), using a linear gradient going from 10 to 90% acetonitrile in 25 min. The flow rate was 1.5 mL/min, and radioactive peaks were recorded on a Beckman 171 radioisotope detector. Eluent A: 0.1% TFA/10% acetonitrile/water; eluent B: 0.1 TFA/90% acetonitrile in water.

radioactive detection). Other conditions increased the heterogeneity of the final labeled products (Figure 2: pH >7.5, temperatures above 75 °C) or resulted in poor labeling (temperatures below 75 °C). The specific activity of the constructs typically ranged in values from 2 to 10 Ci/mmol. The resulting ^{99m}Tc-labeled peptides were purified and subsequently tested for their ability to accumulate in mammalian cells in vitro. Cellular uptake measurements performed on Chinese hamster ovary cells indicated that the insertion of charged or polar amino acids (Asp, Asn, Lys) at position X results in labeled constructs harboring a weak ability to enter cells (C_{in}/C_{out} values ranging from 0.4 to 1.8 with a value of 1.0 representing free diffusion in and out of cells). In contrast, peptides with a hydrophobic residue (Ala) at position X or simply lacking residue X (Peptide F) accumulated more readily into CHO cells (C_{in}/C_{out} values ranging from 2.9 to 3.2).

Positioning a Diaminedithiol Chelator at Selected Sites within Peptides. This study describes the insertion of a protected chelator at the N-terminus of peptides during Fmoc-based solid-phase peptide synthesis. A simple strategy to incorporate this chelator elsewhere into peptide constructs is to make use of Fmoc-Lys(Dde) or its homologue, Fmoc-Lys(ivDde) (*23*−*25*). These lysine derivatives have an ϵ-amino protecting group [(4,4-dimethyl-2,6-dioxocyclohex-1-ylidene)ethyl, **Dde**; (4,4-dimethyl-2,6-dioxocyclohex-1-ylidene)-3-methylbutyl, **ivDde**; Calbiochem-Novabiochem Corp., San Diego, CA) which can be removed in the presence of 2% hydrazine. Fmoc-Lys(Dde) or (ivDde) can be positioned at a nonessential site in any peptide during solid-phase peptide synthesis. An important step in this approach is to insert a tBoc-protected amino acid as the last residue in the peptide prior to the removal of the Dde or ivDde-protecting group on the lysine side chain with hydrazine.

The free ϵ-amino group can then be modified with Fmoc-DAP-(Fmoc)-OH followed by *S*-benzoylthiolglycolic acid as described in this paper to create the protected diaminedithiol chelator. The peptide can then be released from the support in the presence of trifluoroacetic acid, which also removes the N-terminal tBoc group.

CONCLUSION

A simple and reproducible method for introducing a benzoyl-protected N_2S_2 chelator into peptides was developed using standard protocols for Fmoc solid-phase peptide synthesis (Scheme 1). The thiol-protecting benzoyl groups are stable under the acidic conditions (trifluoroacetic acid) associated with the cleavage of synthetic peptides from resins following Fmoc-based peptide assembly. Six peptides containing the protected N_2S_2 chelator at their N-terminus were prepared and purified to homogeneity by reverse-phase chromatography prior to labeling with ^{99m}Tc (Figure 1). The benzoyl groups were efficiently removed following heating (75 °C for 10 min) at neutral pH in the presence of a stannous tartrate solution (Figure 2). Ligand exchange between [^{99m}Tc]-pertechnetate and the deprotected diaminedithiol chelator also occurs under these conditions, yielding ^{99m}Tc-labeled peptides.

Note Added in Proof: Technetium labeling efficiencies of >97% have recently been achieved by Drs. Mathew Thakur (Thomas Jefferson University) and Mick Welling (Leiden University Medical Center, The Netherlands) for two different peptides assembled by our group using the procedure stated in this paper.

Preparation and Tumor Cell Uptake of Poly(*N*-isopropylacrylamide) Folate Conjugates

Denis Dubé,[‡] Mira Francis,[†] Jean-Christophe Leroux,[†,§] and Françoise M. Winnik*[,‡,†]

Department of Chemistry and Faculty of Pharmacy, Université de Montréal, C. P. 6128, succursale Centre Ville Montréal QC Canada H3C 3J7. Received September 3, 2001; Revised Manuscript Received January 7, 2002

Folate conjugates (PNIPAM-NH−FA) of a copolymer of *N*-isopropylacrylamide (NIPAM) and amino-*N*′-ethylenedioxy-bis(ethylacrylamide) were prepared by an efficient synthesis leading to random grafting, via a short dioxyethylene spacer, of ∼7 folic acid residues per macromolecule. The chemical composition of the copolymer was characterized by ^{1}H NMR and UV/vis spectroscopy. A fluorophore-labeled folate PNIPAM conjugate was tested by in vitro assays performed with cultured KB-31 cells overexpressing the folate receptor. The cellular uptake of the copolymer was found to be temperature dependent and was competitively decreased by free folic acid, indicating that the polymer uptake is mediated specifically by the folate receptor. Hydrophobically modified folate conjugates of NIPAM, amino-*N*′-ethylenedioxy-bis(ethylacrylamide) copolymers, bearing a small number of *n*-octadecyl groups were prepared following a modified synthetic procedure for use in future studies of FA-targeted liposomes.

INTRODUCTION

The modification of liposomes with synthetic polymers is a promising approach toward the development of new highly efficient drug carriers. By coating the surface of liposomes with carefully designed water soluble polymers, several major improvements may be achieved, such as increase in liposome circulation time, responsiveness to external stimuli, and specific targeting. For example, it has been recognized several years ago that poly(ethylene glycol) (PEG)-modified liposomes are endowed of exceptional stability in vivo (*1*). Formulations incorporating small PEG-coated vesicles are used clinically (*2*). In these systems, the brushlike coat of PEG chains that covers the lipid bilayer is believed to act as a sterically repulsive shield against nonspecific opsonization by plasma proteins. While the PEG chains are particularly effective in this role, other water-soluble polymers have been shown to offer some level of protection, together with additional enabling functions, such as temperature- or pH-responsiveness. Extensively studied systems include complexes between liposomes and the pH-sensitive polyelectrolyte poly(2-ethylacrylic acid) (*3*) and the temperature-responsive neutral polymer, poly(*N*-isopropylacrylamide) (PNIPAM) (*4*). The performance of polymer-modified liposomes as drug carriers depends, to a large extent, on the reliable anchoring of the polymer within the lipid bilayer. In the case of PNIPAM, anchoring of the polymer on the bilayer is effected via a small number of long alkyl chains attached to the polymer backbone, an approach pioneered by Ringsdorf and co-workers (*5*), and employed effectively by several research teams (*6*, *7*, *8*). Anchoring PNIPAM chains onto liposome bilayers results in a decrease of the adsorption of serum proteins, at least below the lower critical solution temperature of PNIPAM (*9*) and increases the liposome circulation times in vivo (*10*). The cytotoxicity of PNIPAM and its derivatives still remains to be assessed in depth. Toxicity data on this polymer are scarce. Matsumaru et al. (*11*) showed that PNIPAM did not present any sign of acute toxicity after intravenous administration to mice. Recently, Fujimoto and co-workers (*12*) reported that a copolymer of NIPAM and *N*-methacryloyloxysuccinimide displayed no cytotoxicity toward U-937 cells below 4 mg/mL. We also observed that copolymers of NIPAM, octadecylacrylate, and methacrylic acid generated no acute local and systemic inflammatory response in rat following subcutaneous injection (*13*).

For efficient drug delivery, a carrier system should also promote tumor or lesion targeting and intracellular access. Internalization of the drug carrier may be achieved by coupling to the carrier a normally endocytosed ligand, taking advantage of natural endocytosis pathways. Using this strategy, a variety of ligands, such as antibodies, growth factors, or cytokines, are used to facilitate the uptake of carriers inside target cells (*14*). In the work reported here, we have sought to take advantage of the mechanism of folic acid (FA) uptake by cells to promote targeting and internalization, a methodology exploited previously to facilitate entry of attached drugs (*15*, *16*), antibodies (*17*), imaging agents (*18*), macromolecules (*19*, *20*, *21*), or liposomes (*22*, *23*) into cells. Folic acid is transported into cells via potocytosis, a receptor-mediated endocytosis (*24*, *25*, *26*). In this process, the ligand-bound receptor is sequestered in caveolae, internalized into postcaveolar plasma vesicles, released from the receptor via an intravesicular reduction in pH, and subsequently transported into the cytoplasm. The ligand-free receptor is then recycled to the cell surface by reopening of the caveolae. The folate receptor is known to be overexpressed on the surface of cancer cells in the case of epithelial malignancies, such as ovarian, colorectal, and breast cancer, whereas in most normal tissue it is expressed in very low levels (*27*, *28*, *29*).

We are currently assessing applications of folate−PNIPAM conjugates as coating of liposomes internalized via receptor-enhanced cellular uptake. We designed a

family of *N*-isopropylacrylamide (NIPAM) copolymers carrying a small number of octadecyl groups and folic acid residues grafted along the chain via a short ethylenedioxy chain (Figure 1). The FA conjugates were obtained by amidation, with folic acid, of an aminated precursor copolymer. The folic acid molecule (Figure 1) possesses two carboxyl groups, termed α and γ, which can act as handles for covalent attachment. It has been demonstrated that folate linked via its γ-carboxyl group retains a strong affinity toward its receptor, whereas its α-carboxyl derivatives are not recognized as readily (*30*, *31*). We chose to attach the folate to the distal end of a short ethylenedioxy chain in order to increase the range of accessible receptor sites. We report here the synthesis and characterization of folate−PNIPAM conjugates and a preliminary in vitro evaluation of their targeting potential, using fluorescently labeled folate−PNIPAM conjugates that do not carry hydrophobic chains, which may interfere with the selected assays. Cytotoxicity assays confirmed that the folate−PNIPAM conjugates bind specifically to KB cells without harming the cells. Direct competition experiments with free folate demonstrated that the PNIPAM−folate conjugates effectively target the cells even at folate concentration above normal serum levels.

EXPERIMENTAL PROCEDURES

Materials. Water was deionized using a Milli Q water purification system (Millipore). *N*-Isopropylacrylamide, obtained from Fisher Scientific (Pittsburgh, PA), was recrystallized from acetone/heptane 2/3 v/v. *N*,*N*-Azobis(isobutyronitrile), trifluoroacetic acid, 2,2′-(ethylenedioxy)-bis(ethylamine), di-*tert*-butyl dicarbonate, acryloyl chloride, 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC), folic acid dihydrate, and 2,4,6-trinitrobenzenesulfonic acid (TNBS), were purchased from Aldrich Chemical Co (Milwaukee, WI). *N*-*n*-Octadecylacrylamide was prepared as described previously (*32*). Fluorescein dichlorotriazine (5-DTAF), sodium chloride, dibasic sodium phosphate, monobasic sodium phosphate, Triton X-100, and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) were obtained from Sigma Chemical Co (St Louis, MO). Bicinchoninic acid (BCA) was obtained from Pierce Co (Rockford,IL). N−BOC-ethylenedioxy-bis(ethylamine) was prepared as described previously (*33*). Dioxane and tetrahydrofuran (THF) were dried by distillation over sodium. Triethylamine was dried by distillation over potassium hydroxide, Dichloromethane was dried by distillation over calcium hydride. All other solvents were reagent grade and used as received. Phosphate buffers of pH 4.7 [20 mM NaH_2PO_4 + HCl (0.1M)], pH 7.4 (50 mM KH_2PO_4, NaOH 3.91 mmol), and a borate buffer of pH 9.5 (12.5 mM Borax, 0.8 mM NaOH) were prepared from the corresponding salts. Phosphate buffered saline pH 7.2 (PBS) was prepared from 75 mM NaCl, 53 mM Na_2HPO_4 and 13 mM NaH_2PO_4. Silica gel (60−200 mesh) was purchased from Baker. The ion-exchange resin AG 501-X8(D) and DOWEX 2 × 8−400 were obtained from BioRad Laboratories and Supelco, respectively. Spectra/Por membranes (3500 MW cutoff) were employed for dialysis.

Instrumentation. NMR spectra were recorded on a Bruker ARX-400 400 MHz spectrometer. Infrared spectra were recorded on a Bomem Hartmann & Braun IR spectrometer fitted with a Bomem Grams/32 data analysis software. UV/Visible spectra were measured with a Hewlett-Packard 8452A photodiode array spectrometer. Viscometry measurements were carried out with an Ubbelhode semi-microdilution viscometer at 27 °C.

Monomer and Polymer Synthesis. *N-BOC-N′-(Ethylenedioxy-bis(ethylacrylamide) (EDBE).* A solution of acryloyl chloride (0.7 mL, 8.5 mmol) in dichloromethane (10 mL) was added dropwise into a solution of *N*-BOC-ethylenedioxy-bis(ethylamine) (1.94 g, 8.0 mmol) and triethylamine (2.35 mL, 17 mmol) in dichloromethane (40 mL) kept at 0 °C. At the end of the addition, the mixture was kept at 0 °C for 1 h and allowed to warm to room temperature. The mixture was washed with water, 1 N aqueous acetic acid, aqueous saturated sodium bicarbonate, and brine. The organic layer was dried over anhydrous sodium sulfate, filtered, and concentrated in vacuo. The yellow viscous oil which was purified by flash chromatography over silica eluted with hexane/ethyl acetate 1/3 v/v yielding *N*-BOC-*N′*-(ethylenedioxy-bis(ethylacrylamide) (1.20 g, 50% yield) as a pale yellow viscous oil. ^{1}H NMR ($CDCl_3$, δ): 1.38 (s, 9H, $(CH_3)_3C$), 3.26 (q, 2H, J = 5 Hz, CH_2NHCOO), 3.52 (m, 10 H, CH_2 of ethylenedioxy), 4.95 (br s, 1H, N*H*), 5.58 (dd, 1H, J = 0.6, 10 Hz, *H*(*Z*)HC═), 6.10 (dd, 1H, J = 10, 17 Hz, H_2C═C*H*), 6,26 (dd, 1H, J = 0.6, 17 Hz, *H*(*E*)HC═) ppm; FTIR ($\bar{\nu}$, cm^{-1}) 1170 (O−$C(CH_3)_3$ stretching), 1527 (CONHR carbonyl stretching), 1711 (urethane carbonyl stretching), 2930 (alkene stretching).

Copolymerization of N-Isopropylacrylamide (NIPAM) and N-BOC-N′-Ethylenedioxy-bis(ethylacrylamide). A solution of NIPAM (0.456 g, 4.0 mmol) and *N*-BOC-*N′*-ethylenedioxy-bis(ethylacrylamide) (0.270 g, 1.0 mmol) in dioxane (10 mL) was degassed for 30 min by vigorous bubbling of nitrogen. The mixture was heated to 60 °C. AIBN (3.4 mg, 0.021 mmol) was added at once. The polymerization mixture was stirred at 60 °C for 18 h. It was cooled to room temperature. The polymer, PNIPAM-NHBOC, was isolated by precipitation into diethyl ether (500 mL) and further purified by two precipitations from THF into diethyl ether. It was dried in vacuo (yield: 72 (%); ^{1}H NMR ($CDCl_3$, δ) 1.13 (br s, $(CH_3)_2CHNH$), 1.44 (s, $(CH_3)_3C$), 3.30−3.62 (m, CH_2 of ethylenedioxy group and main chain), 3.99 (br s, $(CH_3)_2CHNH$) ppm.

Deprotection of PNIPAM-NHBOC. Trifluoroacetic acid (0.18 mL, 2.4 mmol, 10 equiv per BOC equiv) was added to a solution of PNIPAM-NHBOC (150 mg) in dichloromethane (6.0 mL) cooled in an ice/water bath. The reaction mixture was warmed to room temperature and stirred for 18 h. The solvent was evaporated. The polymer, PNIPAM-$NH_3^+CF_3COO^-$, was purified by two precipitations from THF into diethyl ether and dried in vacuo (yield: ∼100%). Dowex 2 × 8−400 (100 mg) was added to a solution of PNIPAM-NH_2 (130 mg) in water. The mixture was stirred at room temperature for 2 h.

The resin was separated by filtration. The polymer was isolated by lyophilization (70 mg, yield: 63%). ^{1}H NMR (D_2O, δ) 1.17 (s, $(CH_3)_2CHNH$), 3.19−3.74 (m, CH_2 of ethylenedioxy group and of main chain), 3.90 (s, $(CH_3)_2$-CHNH) ppm.

Preparation of PNIPAM-NH−FA. A solution of EDC (53 mg, 0.28 mmol) and folic acid (59 mg, 0.12 mmol) in anhydrous DMSO (2 mL) was prepared and stirred at room temperature for 1 h. It was then added to a solution of PNIPAM-NH (100 mg, 0.165 mmol amine groups) in phosphate buffer (25 mL, pH 4.7). The resulting mixture was stirred at room temperature and in the dark for 16 h. It was brought to pH 9.0 by dropwise addition of diluted aqueous NaOH and dialyzed first against pH 7.4 phosphate buffer for 3 days and then against water for 3 days. The polymer was isolated by lyophilization (115 mg, 80%). ^{1}H NMR (D_2O, δ) 1.14 (s, $(CH_3)_2CHNH$), 3.19−3.76 (m, CH_2 of ethylenedioxy and main chain), 3.90 (1H, $(CH_3)_2CHNH$), 6.75 (d, $J = 7$ Hz, 3′, 5′ H of folate group), 7.63 (d, $J = 7$ Hz, 2′, 6′ H of folate group), 8.77 (s, C_7-H of folate group) ppm; UV/vis (phosphate buffer pH 7.4) 363 nm; folate content: 0.336 mmol g^{-1} polymer).

PNIPAM-NH−DTAF. A solution of fluorescein dichlorotriazine (3.9 mg, 0.0071 mmol) in aqueous borate buffer (5 mL, pH 9.5) was added to a solution of PNIPAM-NH (85 mg, 0.140 mmol amine) in the same buffer (25 mL). The reaction mixture was stirred at room temperature for 2 h. It was dialyzed against pH 9.5 borate buffer for 16 h and against water for 3 days. The polymer was isolated by lyophilization (70 mg, 71%). ^{1}H NMR (D_2O, δ) 1.08 (s, $(CH_3)_2CHNH$), 3.19−3.76 (m, CH_2 of ethylenedioxy and main chain), 3.90 (1H, $(CH_3)_2CHNH$) ppm; UV/vis (pH 9.5 borate buffer) 490 nm; DTAF content: 0.095 mmol g^{-1} polymer).

PNIPAM-NH−FA−DTAF. The polymer was prepared as described for the preparation of PNIPAM-NH−DTAF, starting from PNIPAM-NH−FA (83 mg); 72% yield; 1.10 (s, $(CH_3)_2CHNH$), 3.08−3.64 (m, CH_2 of ethylenedioxy), 3.85 (1H, $(CH_3)_2CHNH$), 6.74 (d, $J = 7$ Hz, folate aromatic protons), 7.62 (d, $J = 7$ Hz, folate aromatic protons) ppm; UV/vis (borate buffer pH 9.5) 492 nm; DTAF content: 0.043 mmol g^{-1} polymer).

Preparation of PNIPAM-NH−FA−ODA. The copolymer was prepared following the three-step procedure outlined for the preparation PNIPAM-NH−FA, starting from NIPAM (0.574 g, 4.84 mmol), *N*-BOC-*N*′-ethylenedioxy-bis(ethylacrylamide) (0.780 g, 2.5 mmol) and *N*-octadecylacrylamide (101 mg, 0.308 mmol).

PNIPAM-N-t-BOC−ODA: yield: 77%; ^{1}H NMR ($CDCl_3$, δ) 0.87 (t, $J = 17$ Hz, $H_3CC_{17}H_{34}$), 1.14 (br s, $(CH_3)_2$-CHNH), 1.45 (s, $(CH_3)_3C$), 2.10 (br, main chain protons and CH_2 of octadecyl group), 3.31−3.63 (m, CH_2 of ethylenedioxy), 3.99 (br s, $(CH_3)_2CHNH$) ppm.

PNIPAM-NH−ODA: yield: 59%; ^{1}H NMR (D_2O, δ) 0.89 (br t, $H_3CC_{17}H_{34}$), 1.14 (br s, $(CH_3)_2CHNH$), 3.19−3.76 (m, CH_2 of ethylenedioxy), 3.90 (br s, $(CH_3)_2CHNH$) ppm.

PNIPAM-NH−FA−ODA: yield: 50%; ^{1}H NMR (D_2O, δ) 0.89 (br t, $H_3CC_{17}H_{34}$), 1.14 (br s, $(CH_3)_2CHNH$), 3.19−3.3.76 (m, CH_2 of ethylenedioxy), 3.90 (br s, $(CH_3)_2CHNH$) ppm.; UV/vis (phosphate buffer, pH 7.4) 363 nm; folate content 0.196 mmol g^{-1} polymer.

UV/Vis Analysis. *Folate Content.* The content of folate in the conjugates was determined by quantitative UV spectrophotometry of polymer solutions in aqueous phosphate buffer (pH 7.4) using the molar extinction coefficient value of 6197 mol^{-1} cm^{-1} at $\lambda = 363$ nm (*34*).

DTAF Content. The content of DTAF in the conjugates was determined by quantitative UV spectrophotometry of polymer solutions in aqueous borate buffer (pH 9.2) using the molar extinction coefficient value of 70000 mol^{-1} cm^{-1} at $\lambda = 490$ nm (*35*).

Colorimetric Determination of the Free Amine Groups (*36*). A known amount of polymer (5 mg) was dissolved in a solution of excess TNBS (0.01 M) in sodium hydrogen carbonate (2.0 mL, 20 g L^{-1}, pH 8.2). The solution was kept for 2 h at 40 °C. It was cooled to room temperature and made up to 10 mL with a water/THF solution (v/v). The amount of TNBS-derivatized amines in a sample was determined from the absorbance at λ 345 nm, using TNBS-derivatized *N*-BOC-ethylenedioxy-bis(ethylamine) ($\epsilon_{345\ nm} = 8700$ L mol^{-1} cm^{-1}) as reference compound. A solution of TNBS without added polymer was treated under the same conditions. Its absorbance at 345 nm was subtracted from that of the TNBS-derivatized polymers to correct for its residual absorbance at this wavelength.

Cell Culture, Cytotoxicity, and FA Uptake Studies. *Cell Lines.* KB-31 cells, a human nasopharyngeal epidermal carcinoma cell line overexpressing surface receptors for folic acid (a gift from Dr. Daryl Drummond, Research Institute, California Pacific Medical Center, San Francisco, CA), were maintained in a monolayer culture in folate-free RPMI 1640 medium containing L-glutamine (Gibco laboratories). The medium was supplemented with 10% (v/v) heat-inactivated fetal bovine serum (FBS, Gibco laboratories) and 1% (v/v) penicillin−streptomycin antibiotics (10000 U mL^{-1} penicillin G and 10000 μg mL^{-1} streptomycin, Gibco laboratories) solution (100 U mL^{-1} penicillin G, 100 μg mL^{-1} streptomycin). Cultured cells were incubated at 37 °C in a humidified atmosphere containing 5% CO_2.

Cytotoxicity Assay. KB-31 cells were seeded in triplicate in 96-well plates at 5×10^4 cells/well. Cells were allowed to adhere for 4 h at 37 °C in a humidified atmosphere of 5% CO_2 in air. Solutions of PNIPAM-NH−FA−DTAF or PNIPAM-NH−DTAF in culture medium (0−1 mg mL^{-1}) were added to the cells. After several different incubation times (2−24 h), cell viability was determined by a MTT test, according to the procedure described by Mosmann (*37*). The test is based on mitochondrial dehydrogenase cell activity as an indicator of cell viability. Ten microliter aliquots of a MTT solution in PBS (5 mg mL^{-1}) were added to each well. After incubation for an additional 4 h at 37 °C, a 2-propanol solution of HCl (100 μL, 0.4 N HCl) was added to each well to ensure solubilization of formazan crystals. The optical density values were determined using a multiwell-scanning spectrophotometer (Bio-Tek Instruments Inc.) at 570 nm.

Fluorescence Microscopy. Cells were plated at a concentration of 5×10^5 cells per 35 mm dish in a six-well plastic culture plate 24 h prior to the assay. They were then incubated for 1 h at 37 °C with a solution of PNIPAM-NH−FA−DTAF or PNIPAM-NH−DTAF in culture medium (0.2 mg mL^{-1}). For free folate competition studies, 1 mM folic acid was added to the incubation medium. After incubation, the cells were washed five times with 2 mL of PBS to remove free polymer. Cell-associated fluorescence was viewed with an Axiovert inverted fluorescence microscope (Zeiss) equipped with a filter set that produces excitation in the range 465−495 nm and allows observation of fluorescence emission in the range 515−555 nm with a long wave path dichroic mirror and barrier filter. Cells were photographed using a 1310C DVC digital camera (DVC Company Inc.).

Quantitation of the Uptake of PNIPAM-NH−FA−DTAF by KB-31 Cells. Cells were plated at a concentration of 5×10^5 cells per 35 mm dish in a six-well plastic

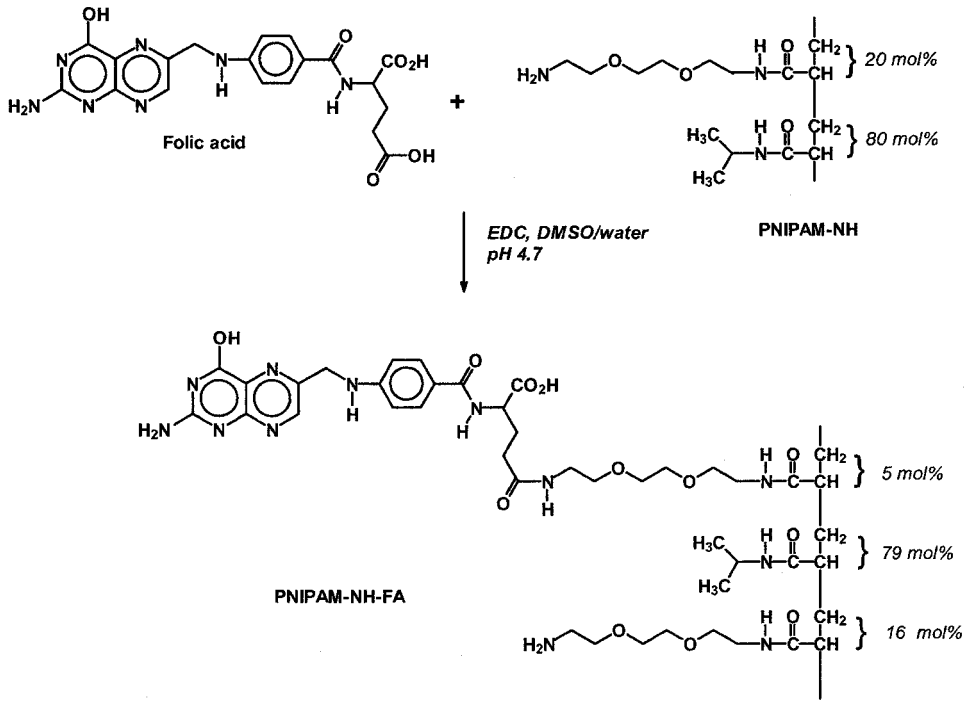

Figure 2. Synthetic sequence for the preparation of the copolymer PNIPAM-NH−FA

culture plate 24 h prior to the assay. They were then incubated for 1 h at 37 °C and 2 h at 4 °C with PNIPAM-NH−FA−DTAF or PNIPAM-NH−DTAF (0.2 mg mL^{-1} in culture medium). For free folate competition studies, 1 mM folic acid was added to the incubation medium. After incubation, the cells were washed five times with 2 mL of PBS. The cells were then solubilized in Triton X-100 solution (2 mL, 1% w/v final concentration in PBS). Cell-associated fluorescence was measured using a series 2 Aminco Bowman (Spectronic Instruments Inc.) fluorescence spectrometer. Samples were excited at 492 nm, and fluorescence emission intensity was monitored at 516 nm. The amount of cell-associated polymer was calculated using a predetermined standard curve and calibrated with protein cell content determined by a bicinchoninic acid (BCA) protein assay (Pierce).

RESULTS AND DISCUSSION

Preparation and Characterization of Folate Conjugates. Folate−PNIPAM conjugates were prepared by postmodification of a copolymer of *N*-isopropylacrylamide (NIPAM) and amino-*N′*-ethylenedioxy-bis(ethylacrylamide) as shown in Figure 2. The copolymer PNIPAM-NH was obtained by free radical copolymerization in dioxane of NIPAM and *N*-BOC-*N′*-ethylenedioxy-bis-(ethylacrylamide) followed by deprotection of the terminal primary amine groups. The composition of the BOC-protected copolymer was determined by ^{1}H NMR spectroscopy, using the singlet at δ 1.14 ppm, assigned to the resonance of the *tert*-butyl protons of the BOC units, and the broad singlet at δ 3.90 ppm, assigned to the resonance of the methine NIPAM protons, to calculate the molar ratio of EDBE and NIPAM units, respectively (Figure 3). The disappearance of the signal at δ 1.14 ppm in the ^{1}H NMR spectrum of PNIPAM-NH confirmed that the deprotection step went to completion. A primary-amine-specific colorimetric assay was performed with PNIPAM-NH to ascertain the composition of the deprotected copolymer. This copolymer is soluble in water and in PBS at all temperatures between 0 and 60 °C, unlike the homopolymer PNIPAM, which in aqueous solution exhibits a cloud point at 31 °C. This enhanced water solubility is attributed to the presence of the hydrophilic ethylenedioxy-containing residues along the polymer chain.

Coupling of the folate residue to the polymer was achieved via an EDC-mediated reaction of folic acid and the primary amine functions linked to the polymer. The success of the linkage was confirmed by the presence of signals at δ 6.75−8.77 ppm in the ^{1}H NMR spectrum of PNIPAM-NH−FA and by an absorbance at $\lambda = 363$ nm in the UV spectrum of the copolymer. It is known that carbodiimide-activated folic acid can couple either via the α or the γ carboxyl group of its glutamate residue, although EDC has been shown to favor linkage of the distal γ carboxyl residue. Wang et al. (*31*) used ^{1}H NMR spectral data to ascertain the regiochemistry of the linkage of folate derivatives and ethylenediamine. Unfortunately, in the ^{1}H NMR spectrum of PNIPAM-NH−FA (Figure 3), the relevant signals are masked by broad and strong signals due to the resonances of the protons associated to the polymer residues. Thus, we were unable to determine the regiochemistry of the folate linkage in PNIPAM-NH−FA. It is expected to consist mostly of the γ-linked isomer, due to the reaction conditions selected and also to the steric constraints imposed by the polymer chain.

Hydrophobically modified PNIPAM−folate conjugates were obtained via the same synthetic sequence, starting with a copolymer of NIPAM, amino-*N′*-ethylenedioxy-bis-(ethylacrylamide), *N*-*n*-octadecylacrylamide (Figure 2). The level of hydrophobic group incorporation in the HM−folate conjugate could not be determined on the basis of the ^{1}H NMR spectrum of its aqueous solution, which exhibited significant line broadening indicative of the formation of micellar structures and concomitant motional restriction of the alkyl chains (*38*). The octadecyl group content of the precursor, PNIPAM-N-t-BOC−ODA, could be determined accurately from the ^{1}H NMR spectrum of its solution in $CDCl_3$, using the triplet at δ 0.87 ppm, attributed to the resonance of the terminal methyl protons of the octadecyl chain and the broad singlet at δ

4.0 ppm, attributed to the resonance of the NIPAM methine proton (Figure 4). The physical properties and the composition of the PNIPAM−FA−ODA are listed in Table 1.

Cellular Uptake of PNIPAM−Folate Conjugates. The cytotoxicity of PNIPAM-NH−FA−DTAF and PNIPAM-NH−DTAF on KB-31 cells was evaluated after

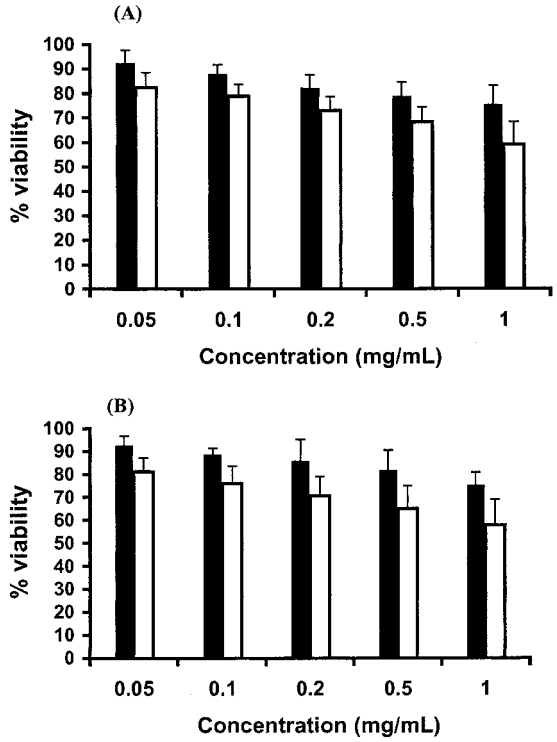

Figure 5. Effect of PNIPAM-NH−FA−DTAF (A) and PNIPAM-NH−DTAF (B) concentration on KB-31 cell viability determined by MTT assay after a 2-h (closed columns) or 24-h (open columns) incubation time. Mean ± SD (n = 3).

incubation at 37 °C for 2 and 24 h (Figure 5). The two polymers exhibited nearly identical toxicity profiles. Cell viability reached a value of approximately 75% and 60% after incubation of 2 and 24 h, respectively, for the highest polymer concentration tested (1 mg/mL). These results corroborate our previous results on the cytotoxicity on macrophage-like J774 cells where a pH-sensitive NIPAM copolymer was evaluated (*39*) which exhibited an LD_{50} in excess of 1 mg/mL after a 24-h incubation period.

To assess the uptake of PNIPAM-NH−FA by cells overexpressing the folate receptor, the fluorescently

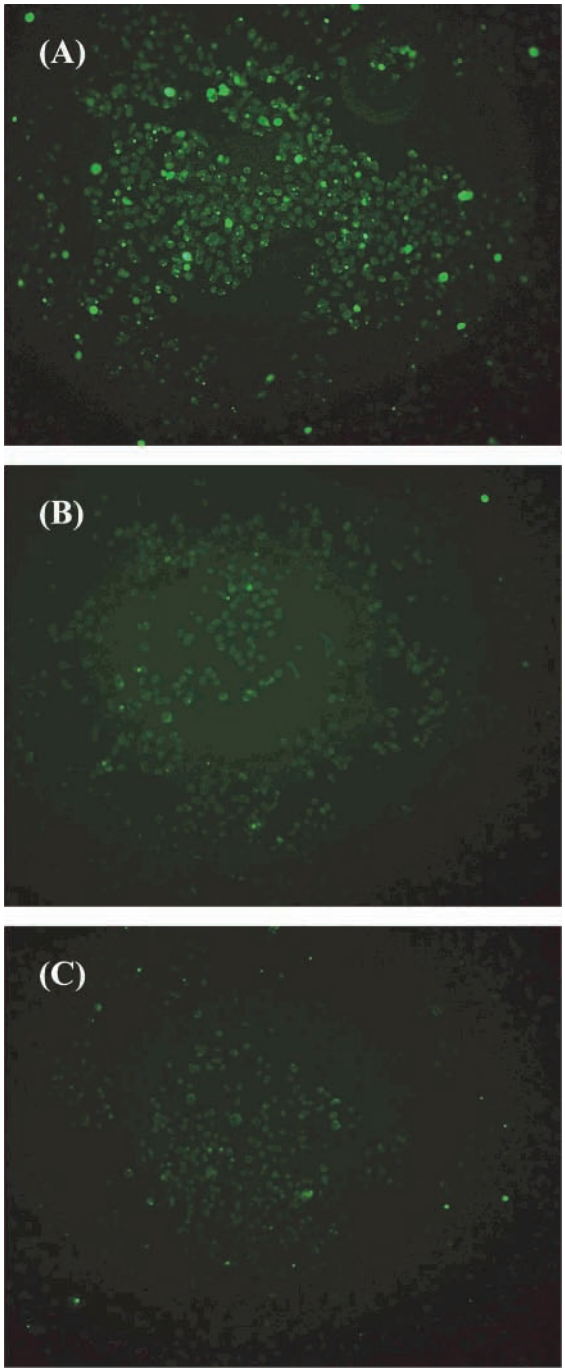

Figure 6. Fluorescence micrographs of KB-31 cells incubated at 37 °C for 1 h with PNIPAM-NH−FA−DTAF (A, B) or PNIPAM-NH−DTAF (C) (0.2 mg/mL). Cells were incubated in the absence (A, C) or presence (B) of 1 mM free folic acid.

labeled polymer and its precursor were incubated for 1 h at 37 °C with KB-31 cells. Fluorescence micrographs of cells exposed to the folate-bearing polymer PNIPAM-NH−FA−DTAF displayed an intensive and diffuse fluorescence indicating binding of the polymer on the cell membrane (Figure 6A). Some cells displayed a punctuated fluorescence pattern suggesting that the polymer was localized also in endocytic vesicles. In contrast, cells incubated with the fluorescently labeled nontargeted polymer PNIPAM-NH−DTAF displayed only very weak fluorescence attributed to low nonspecific uptake of the polymer (Figure 6B). The role of cell surface folate receptors in polymer binding was assessed further by incubating KB-31 cells with PNIPAM-NH−FA−DTAF in the presence of 1 mM free folic acid used as competitive

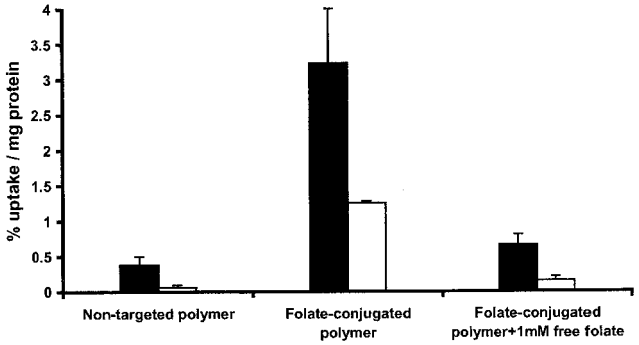

Figure 7. Uptake of PNIPAM-NH−FA−DTAF or PNIPAM-NH−DTAF (0.2 mg/mL) by KB-31cells in the absence or presence of 1 mM folic acid. The cells were incubated at 37 °C for 1 h (closed columns) or 4 °C for 2 h (open columns). Mean ± SD ($n = 3$).

inhibitor of cellular uptake. Fluorescence micrographs of the cells incubated for 1 h (Figure 6C) show that the presence of free folic acid effectively inhibited uptake of PNIPAM-NH−FA−DTAF by the cells.

The uptake of folate-conjugated and nontargeted polymer by KB-31 cells was quantified by fluorescence spectroscopy. The cells were incubated with each copolymer for 1 h at 37 °C and for 2 h at 4 °C (Figure 7). After incubation at 37 °C, the uptake of PNIPAM-NH−FA−DTAF was 8.5 times higher than that of PNIPAM-NH−DTAF. The level of uptake of the folate-conjugated polymer was reduced by 80% in the presence of 1 mM free folic acid. Incubation at 4 °C resulted in a 2.5-fold decrease in cell association of PNIPAM-NH−FA−DTAF, compared to the uptake upon incubation at 37 °C. The uptake of the nontargeted polymer upon incubation at 4 °C was barely detectable by fluorescence. As the endocytic process is strongly inhibited at 4 °C, fluorescence of cells incubated at this temperature in the presence of labeled polymer can be attributed only to polymer bound on the cell surface. The folate-conjugated polymer still displayed a 19-fold increase in uptake versus its nontargeted counterpart. The addition of 1 mM free folic acid resulted in an 88% decrease of fluorescence, demonstrating the specific receptor-mediated binding of PNIPAM-NH−FA−DTAF. The fact that 100% inhibition was not achieved upon addition of free folic acid may be an indication of some level of nonspecific uptake of the copolymer. It may also reflect the stronger avidity of the copolymer as a result of multivalent interaction (*9*, *16*), as each polymer chain bears several folic acid residues (*40*) with an average of seven folic acid molecules.

CONCLUSIONS

In this report, we described an efficient and flexible synthesis of noncytotoxic PNIPAM folate conjugates. We have demonstrated that selective recognition of the conjugates by the folate receptors is maintained upon linking of folate to the macromolecule. We recently demonstrated that pH-sensitive amphiphilic NIPAM copolymers could facilitate the transfer of liposomal content from the endosomes/lysosomes to the cytoplasm (*39*). Therefore, by combining the tumoral targeting ability of folic acid with the unique physicochemical properties of NIPAM copolymers, one could design highly efficient liposomal systems for the cytoplasmic delivery of a variety of active compounds. Indeed, it is now clearly established that folate mediates endocytosis of macromolecules, drugs, and colloidal carriers into vesicles that become rapidly acidified to a pH of about 5 (*41*). Although

the folate-targeting approach has been successful in a number of studies (16), endosomally targeted materials, which do not cross easily cell membranes, do not escape from the endosome in the absence of a triggerable membrane destabilization/fusion pathway. Therefore, for the delivery of macromolecules, such as DNA, or of highly hydrophilic drugs, inefficient translocation into the cytosol may compromise the folate targeting approach. To circumvent this problem, folic acid can be conjugated to a copolymer exhibiting endosomolytic properties (e.g., polyethylenimine) (*16*) or attached to fusiogenic liposomes (*42*). Future investigations will focus on the design of delivery systems consisting of serum-stable liposomes modified with a pH- and/or temperature-sensitive folate-conjugated NIPAM copolymer and their uptake in various cell models overexpressing the folate receptor.

ACKNOWLEDGMENT

This work was supported by grants of the Canadian Institutes of Health Research (CIHR) to J.C.L. and of the Natural Sciences and Engineering Research Council of Canada (NSERC) to F.M.W. Transition Metal−Carbonyl Labeling of Biotin and Avidin for Use in Solid-Phase Carbonyl Metallo Immunoassay (CMIA)

Michèle Salmain,[†] Nathalie Fischer-Durand,[†] Laure Cavalier,[†] Bogna Rudolf,[‡] Janusz Zakrzewski,[‡] and Gérard Jaouen[†,*]

Ecole Nationale Supérieure de Chimie de Paris, Laboratoire de Chimie et Biochimie des Complexes Moléculaires (UMR CNRS 7576), 11 rue Pierre et Marie Curie, 75231 Paris Cedex 05, France, and University of Lodz, Department of Organic Chemistry, 90-136 Lodz, Narutowicza 68, Poland. Received October 25, 2001; Revised Manuscript Received December 7, 2001

The preparation of several transition metal−carbonyl tracers of biotin and avidin is described. Multiple labeling of avidin was achieved by acylation of some of its amine-bearing residues with *N*-succinimidyl 4-pentynoate (dicobalt hexacarbonyl). By varying the initial amount of this complex, protein conjugates with the extent of derivatization of up to 13 were obtained. Biotin was labeled with one (η^5-cyclopentadienyl)manganese tricarbonyl moiety by reaction of biotin hydrazide, whereas multiple labeling was reached by successive conjugation of biotin and *N*-succinimidyl 4-pentynoate (dicobalt hexacarbonyl) or (η^5-cyclopentadienyl)iron dicarbonyl (η^1-*N*-maleimidato) to poly-L-lysine or fourth generation Starburst dendrimer. All the conjugates displayed a good to excellent bioaffinity toward their respective counterparts, as measured by competitive enzymatic assays.

INTRODUCTION

The biotin−avidin system is now widely exploited as a bioanalytical tool, particularly in immunoassays (*1*). It takes advantage of the exceptionally high affinity constant of the biotin−avidin association ($K_a = 1 \times 10^{15}$ M^{-1}) and the fact that biomacromolecules can be biotinylated without loss of activity. Furthermore, the protein avidin is a tetramer with four biotin binding sites arranged in two pairs on opposed faces of the molecule, allowing up to four biotinylated species to be bound to a single avidin molecule (*2*). The biotin−avidin system is particularly useful to mediate the binding of the reporter group (enzyme, fluorophore, etc.) to the antibody (*3*). The three basic designs are the labeled avidin−biotin (LAB)[1], the bridged avidin−biotin (BRAB), and the avidin−biotin complex (ABC) systems. These three systems allow the amplification of the detection signal in ELISA techniques as compared to the direct enzyme-antibody labeled methods (*4*).

Labeling of (strept)avidin and biotin with conventional reporter groups has been reported several times in the literature. Regarding (strept)avidin, most of the labeling methods involve their lysine residues (*5*), whereas biotin is exclusively derivatized from its carboxylic acid function with the addition of a spacer arm to enhance the efficiency of formation of the complex between the biotinylated molecule and avidin (*6*).

We have described an immunoassay method named Carbonyl Metallo ImmunoAssay (CMIA) that associates transition metal−carbonyl reporter groups and Fourier transform infrared (FTIR) spectroscopy as the detection method. The principle of this immunoassay consists so far in labeling the antigen (in our case a hapten) with a transition metal−carbonyl complex unit which is then involved in a competitive liquid-phase immunoassay with specific polyclonal antibodies and the analyte. Following extraction of the free fraction of tracer with an organic solvent, its amount is quantitated by taking advantage of the specific and intense absorption bands of the transition metal carbonyl complex unit in the mid-infrared spectral range (1800−2150 cm^{-1}). Assay of the major antiepileptic drugs and cortisol has been described (*7*−*10*). However, this format just described is unsuitable for the assay of high molecular weight molecules (antigens) and is not readily automated. Furthermore, most of the immunoassays are based on the immobilization of the capture system onto a solid-phase to facilitate separation steps. Among the most popular solid phases are 96-well microtiter plates made of plastic (polystyrene). These are compatible with colorimetric detection. Other plates (white or black) are well suited for fluorescence detection. We had tried to adapt polystyrene microtiter plates to direct IR transmission measurement of transition metal−carbonyl tracers but, even though this material presents a transmission window in the range of absorption of these tracers, the sensitivity of detection was far above the level suited for typical immunoassays (*11*). Thus, the need for signal amplification is obvious and the biotin−avidin system appears very attractive for this purpose as seen above. We have set about to synthesize transition metal−carbonyl derivatives of both biotin and avidin in view of using them in a solid-phase amplified CMIA based on the LAB, BRAB, or especially the ABC systems.

EXPERIMENTAL PROCEDURES

Materials. *N*-Succinimidyl 4-pentynoate (dicobalt hexacarbonyl) **1** was synthesized as previously described (*12*). Complex (η^5-cyclopentadienyl carboxaldehyde)manganese tricarbonyl **2** was synthesized as previously described (*13*). (η^5-cyclopentadienyl)iron dicarbonyl (η^1-*N*-maleimidato) **5** was synthesized according to a previously published procedure (*14*). Avidin, poly-L-lysine hydrobromide (PL, average molecular weight = 235 kDa, average polymerization degree = 1125), biotin, biotin hydrazide, horseradish peroxidase biotinamidocaproyl (HRP-biotin), 4′-hydroxyazobenzene-2-carboxylic acid (HABA) orthophenylene diamine (OPD) and *N*,*N*-diisopropylethylamine (DIPEA) were purchased from Sigma. PAMAM Starburst dendrimer fourth generation was purchased from Aldrich. Neutravidin (NAV) was purchased from Pierce Chemicals, *N*,*N*,*N*′,*N*′-tetramethyl-(*O*)-(*N*-succinimidyl)uronium tetrafluoroborate (TSTU) and 2,2,2-trifluoroethanol (TFE) were purchased from Fluka.

Instrumentation. ^{1}H NMR spectra were recorded on an AM 200 FT spectrometer (Bruker) operating at 200 MHz. Infrared spectra were recorded on an MB100 FT spectrometer equipped with an MCT detector. UV−visible spectra were recorded on an UV/mc^2 spectrometer (Safas). The ESI mass spectrum was recorded at the "Service de spectrométrie de masse" of the Université Pierre et Marie Curie, Paris, France.

Methods. *Preparation of Cymantrenyl Biotin Hydrazone **3**.* Biotin hydrazide (0.08 g, 0.3 mmol) was dissolved in 10 mL of TFE. Complex **2** (0.07 g, 0.32 mmol) was added to the mixture that was stirred 24 h at room temperature in the dark. The yellow-brown solution was concentrated under vacuum and chromatographed on an alumina column (50−160 μm particle diameter). Excess compound **2** was eluted with dichloromethane, and compound **3** was eluted with dichloromethane/methanol 3/2. After workup, 0.06 g of **3** was obtained as a brown solid (yield = 60%). ^{1}H NMR (methanol-d_4) δ in ppm/TMS 1.4−1.8 (m, 6H) -$(CH_2)_3$, 2.30 (t, 2H, 7.9 Hz) CH_2−CO, 2.71 (d, 1H, 12 Hz) CH_2−S, 2.94 (dd, 1H, 4.2 and 12 Hz) CH_2−S, 3.25 (br m, 1H) CH−S, 4.32 (m, 1H) CH, 4.50 (m, 1H) CH, 5.49 and 5.39 (s, 4H) Cp, 7.74 and 7.57 (s, 1H) CH=N. IR (KBr) ν in cm^{-1} 2020, 1935 $\nu_{C\equiv O}$, 1700 $\nu_{C=O}$. MS (MeOH) *m*/*z* 495 (M + Na), 357 (M + Na − Mn-$(CO)_3$)

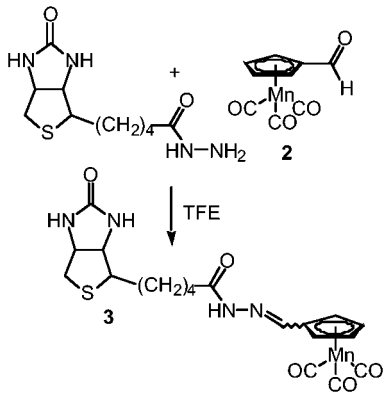
*Preparation of Biotin−PL−Dicobalt Hexacarbonyl **4**.* A solution of biotin (0.11 mg/mL, 0.46 mM) in anhydrous DMF was treated with 1.1 mol equiv of DIPEA and TSTU. The mixture was stirred 2 h at room temperature. A solution of PL (1 mg/mL, 4.2 μM) was prepared in borate buffer pH 9.3. To 9 volumes of this solution was added 1 volume of the solution of activated biotin. In these conditions, the initial biotin-to-PL ratio was 12 (initial biotin/NH_2 functions = 0.01). This mixture was stirred overnight at room temperature. To 9 parts of this solution was added 1 part of a freshly prepared 14 mM solution of **1** in acetonitrile. In these conditions the initial **1** to PL ratio was 400 (initial **1** to NH_2 functions ratio = 0.35). The reaction mixture was stirred 14 h in the dark, centrifuged 30 min at 4000 rpm, and dialyzed in 2 L of PBS overnight at 4 °C to remove unreacted biotin and **1**.

*Preparation of Biotin−Dendrimer−Fp **6**.* Fourth generation PAMAM Starburst dendrimer (43 μL, 10% solution in MeOH) was added to a 0.01 M solution of the *N*-succinimidyl ester of biotin in DMF prepared as above (0.2 mL). The mixture was stirred 2 h at room temperature, 0.35 mL of a 0.04 M solution of compound **5** in methanol was added, and the mixture incubated 18 h at 35 °C. The solvent was evaporated under vacuum, and the residue was dissolved in 2 mL of water and washed with 10 mL of chloroform. The aqueous phase was passed on a 10-mL gel filtration column (Kwiksep dextran, Pierce chemicals), and the dendrimer conjugate was eluted with water.

Preparation of NAV−Dicobalt Hexacarbonyl Conjugate. A solution of neutravidin (2 mg/mL, 33 μM) was prepared in borate buffer pH 8.5. To 1 mL of this solution was added 0.05 mL of a 6.6 mM solution of **1** in acetonitrile. The initial **1**-to-protein ratio was 10. The reaction mixture was stirred 1 h at room temperature, centrifuged 10 min at 4000 rpm, and dialyzed overnight in 2 × 0.5 L of 25 mM HEPES buffer pH 7.4 containing 0.1% NaN_3 at 4 °C. This experiment was repeated with 13.2 or 19.8 mM solutions of **1** (20 and 30 mol equiv, respectively).

Analysis of the Conjugates. The concentration of accessible biotin fragments bound to **4** and **6** was assayed by the HABA dye assay (*15*). The concentration of dicobalt hexacarbonyl probes $[Co_2(CO)_6]_f$ bound to tracer **4** was assayed by FTIR at 2054 cm^{-1} (k = A/[**1**] = 39 M^{-1}) as previously described (*11*). The concentration of Fp (Fp = (η^5-cyclopentadienyl)iron dicarbonyl) probes bound to tracer **6** was measured spectroscopically at 370 nm (ϵ_{370} = 1000 M^{-1} cm^{-1}). The concentration of dendrimer residual amino groups was measured colorimetrically by the trinitrobenzene sulfonic acid assay (*16*). The concentration of neutravidin $[NAV]_f$ was assayed by the Coomassie Blue assay taking neutravidin solutions as standards (*17*).

*Competitive Binding Assay of **3**.* Standard solutions of biotin and **3** in PBS−1% BSA in the range 0−20 μM were applied to two series of Micronic tubes (0.4 mL per tube), and then 0.4 mL of a 10 ng/mL solution of HRP-biotin was added to each tube. A 0.2 mL amount of each solution was added in triplicate to streptavidin-coated polystyrene microtiter plates (Combiplate streptavidin, Labsystems). Plates were incubated 50 min at 4 °C in the dark and washed five times with PBS−0.05% Tween 20, and 0.2 mL of OPD solution (0.7 mg/mL in citrate buffer pH 5 + 0.16% H_2O_2 v/v) was added to the wells. After 20 min, the enzymatic reaction was stopped by 0.05 mL of 2.5 M H_2SO_4, and the absorbance at 490 nm was read with a microtiter plate reader (Biorad).



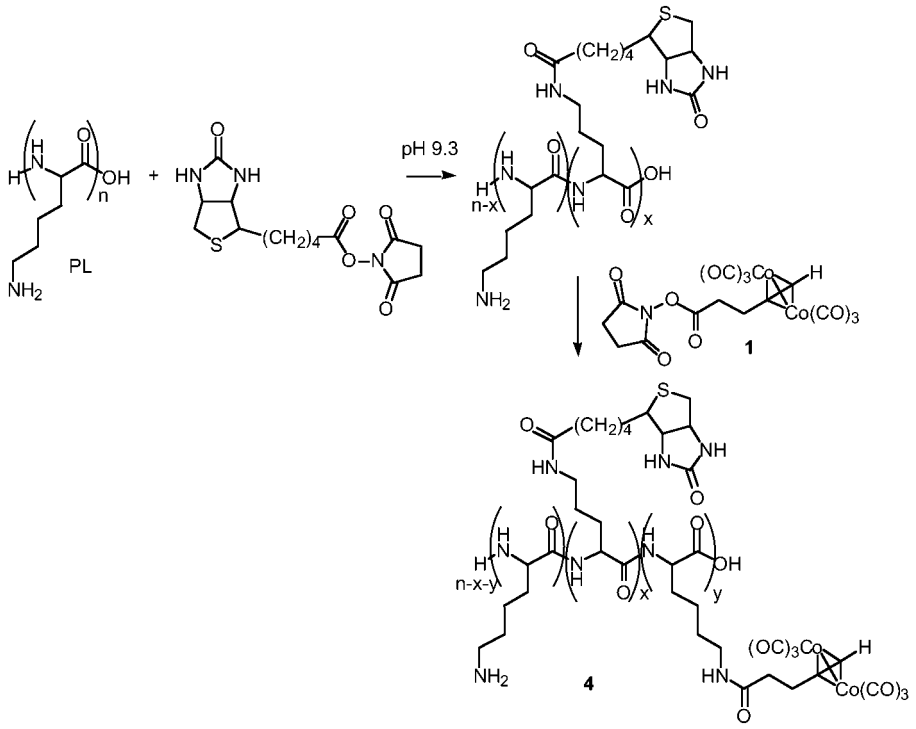
*Competitive Binding Assay of **4**.* The procedure was essentially the same as for **3** except that the streptavidin-coated plates were preincubated with a 10 μM solution of PL in PBS and that BSA was omitted in the incubation buffer.

Competitive Binding Assay of NAV−Dicobalt Hexacarbonyl Conjugate. A 0.1 mL amount of standard solutions of NAV or NAV conjugate in the range 0−1.8 μM made up in PBS−1% BSA was applied in duplicate to streptavidin-coated microtiter plates, followed by addition of HRP−biotin (0.1 mL of a 10 ng/mL solution). Plates were incubated 50 min at 4 °C in the dark. Washing and revelation steps were similar as above.

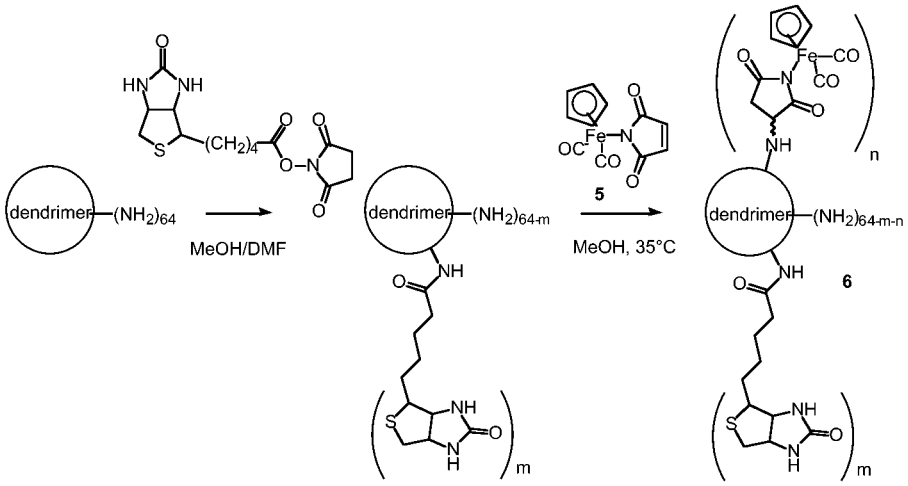
RESULTS AND DISCUSSION

Several synthetic pathways were tried to prepare a transition metal−carbonyl tracer of biotin. First, commercially available biotin hydrazide was added to a solution of compound **1** in TFE, a powerful solvent to dissolve both biotin hydrazide and **1**. No coupling adduct was formed as monitored by reverse phase HPLC and addition of activators such as 1-hydroxybenzotriazole

Scheme 1. Synthesis of Biotin Tracer 3



and/or DIPEA had no effect on the reaction. Instead, degradation of the activated ester was observed at length. It was concluded that the *N*-succinimidyl ester **1** was not reactive enough to acylate biotin hydrazide, conversely to the *N*-succinimidyl ester of cortisol 3-(*O*)carboxymethyl)oxime (*18*). As biotin hydrazide is a common reagent to biotinylate antibodies through their oxidized carbohydrate sites, we decided to use (η^5-cyclopentadienyl carboxaldehyde) manganese tricarbonyl **2** as transition metal−carbonyl labeling agent. Biotin hydrazide was allowed to react with a slight excess of **2** in TFE and after purification by chromatography on alumina, the hydrazone **3** was obtained in 60% yield (Scheme 1). ^{1}H NMR analysis of **3** showed two singlets at 7.57 and 7.74 ppm for the CH of the hydrazone, indicating that this compound was a mixture of two stereoisomers of the *E* and *Z* configurations at the C−N double bond. IR spectroscopy of **3** showed the presence of two intense $\nu_{C\equiv O}$ bands at 2020 and 1935 cm^{-1}, which are characteristic of the (η^5-cyclopentadienyl) manganese tricarbonyl moiety.



One way to amplify the IR signal of the biotin tracer would be to attach several transition metal−carbonyl units to it. As biotin is a small molecule with few functions, it is not straightforward. Nevertheless, some authors suggested use of poly-L-lysine (PL) to covalently bind both biotin and the reporter groups with a chosen ratio (*19, 20*). Other hapten tracers have been prepared in this manner (*21*−*23*). High molecular weight polypeptides and polyvinylamine have also been used in this purpose (*24*−*27*). We applied this principle to synthesize in a one-pot procedure the biotin tracer **4** with a favorable biotin to transition metal−carbonyl label ratio, as illustrated in Scheme 2. PL of average polymerization degree of 1125 was first reacted with a 12 molar excess of biotin *N*-succinimidyl ester in aqueous buffer at pH 9.3 and then with a molar ratio of **1** to PL of 400. The PL conjugate **4** was purified by extensive dialysis in phosphate buffer to remove any unbound or loosely bound biotin and transition metal−carbonyl complex. The concentration of biotin bound to PL was measured by the HABA dye assay and the concentration of bound transition metal−carbonyl units by IR spectroscopy. The calculated final label-to-biotin ratio *y*/*x* was 115. This tracer is characterized by the presence of 3 intense $\nu_{C\equiv O}$ bands at 2094, 2050, 2018 cm^{-1} (KBr pellet).

Full generation PAMAM Starburst dendrimers are another type of molecule with a high content of primary amine functional groups. For example, the commercially available fourth generation PAMAM dendrimer has a total of 64 surface amine groups for conjugation to biotin and a suitable transition metal−carbonyl reagent. The synthesis of the biotin−dendrimer−Fp conjugate **6** was achieved by first reacting fourth generation Starburst dendrimer with biotin *N*-succinimidyl ester followed by reaction with maleimide **5** at 35 °C (Scheme 3). Indeed we have previously shown that alkylation of **5** by amines occurred at basic pH and high temperature (*28*). The dendrimer conjugate **6** was purified by aqueous gel filtration chromatography and its homogeneity proved by reverse phase HPLC. Spectroscopic measurements indicated that **6** contained 45 Fp groups, 4 biotin entities, and 15 residual amine functions. Therefore, the Fp-to-biotin ratio *m*/*n* was found equal to ca. 11. This tracer is

Table 1. Labeling of NAV with Complex 1

initial NAV-to-**1** ratio	$[NAV]_f$ (μM)[a]	$[Co_2(CO)_6]_f$ (μM)[b]	DG[c]	yield, %
10	23.3	175	7.5	75
20	30.8	308	10.0	50
30	31.9	432	13.5	45

[a] The protein concentration $[NAV]_f$ was measured by the Coomassie blue assay. [b] The concentration of transition metal−carbonyl units $[Co_2(CO)_6]_f$ was measured by IR spectroscopy at 2054 cm^{-1} by deposition of 10 μL samples on nylon membranes and subsequent air drying ($[Co_2(CO)_6]_f = A_{2054}/39$). [c] Degree of conjugation DG = $[Co_2(CO)_6]_f/[Nav]_f$ of the protein conjugates.

characterized by the presence of two intense $\nu_{C\equiv O}$ bands at 2050 and 2000 cm^{-1}.

Labeling of neutravidin (NAV), a commercially available deglycosylated form of avidin with an isoelectric point of 6.3 ± 0.3 with transition metal−carbonyl units was also achieved by reacting the protein in borate buffer pH 8.5 with compound **1** (Scheme 4). The initial ratio between metal−carbonyl complex **1** and NAV was varied from 10 to 30 in a similar manner as previously described (*11*). After 1 h, the protein conjugates were purified by gel filtration chromatography and analyzed by spectroscopic methods to measure their degree of conjugation DG = $[Co_2(CO)_6]_f/[NAV]_f$. Results are summarized in Table 1.

Thus, chemical modification of NAV by complex **1** allowed a maximum of ca. 13 transition metal−carbonyl units to be covalently bound to the protein molecule. We suspect that higher degrees of conjugation are not reachable because some binding sites (i.e. lysine residues) may be more sterically demanding or highly derivatized conjugates may become insoluble in aqueous medium.

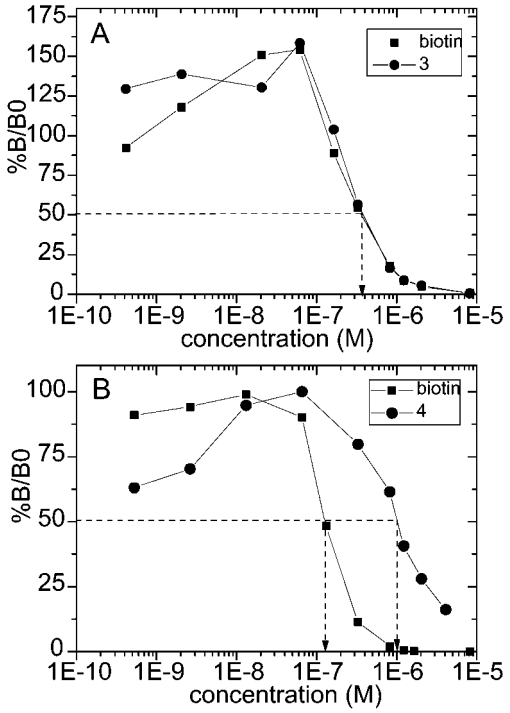

Figure 1. Competitive binding assay of biotin tracers. A. **3**. B. **4**.

The avidin tetramer contains 32 lysine residues (+ 4 N-terminal sites), i.e., a total of 36 potential sites for covalent binding of **1**. These amines are all located at the surface of the protein and away from the biotin binding sites as seen from the X-ray structure of the avidin/biotin complex (*29*). Thus the second explanation is the most probable, as we have observed protein precipitation at length.

To assess the usefulness of such transition metal−carbonyl tracers in bioassays, we performed competitive enzymatic binding assays using commercially available streptavidin-coated microtiter plates and HRP−biotin as tracer. For biotin metal−carbonyl conjugates, the assay consisted of competing biotin or biotin conjugate with HRP−biotin for the binding to immobilized streptavidin (Figure 1). For the NAV−$Co_2(CO)_6$ conjugate with a degree of conjugation of 10, the assay consisted in the competition between NAV or NAV−$Co_2(CO)_6$ conjugate and immobilized streptavidin for the binding of HRP−biotin (Figure 2). The amount of surface bound HRP−

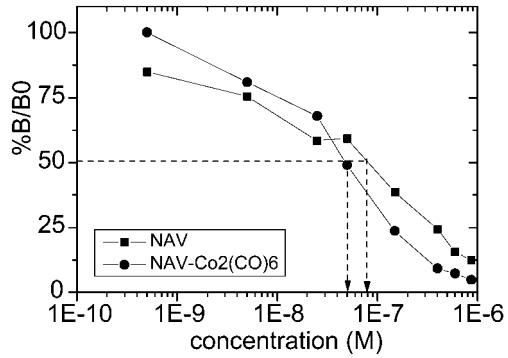

Figure 2. Competitive binding assay of neutravidin−dicobalt hexacarbonyl conjugate.

biotin was quantified with OPD/H_2O_2 as substrates. In the conditions of assay, the IC_{50} of NAV was 0.05 mM while that of the NAV−$Co_2(CO)_6$ conjugate was 0.085 μM. The conjugation of 10 transition metal−carbonyl entities altered very slightly the molecular recognition of the NAV conjugate by HRP−biotin. On the other hand, biotin and biotin tracer **3** had identical IC_{50} (0.4 μM in the assay), indicating that the conjugation of the (η^5-cyclopentadienyl) manganese tricarbonyl to the hydrazide function of biotin hydrazide did not alter in the least its binding affinity to streptavidin. Conversely, the polymeric tracer **4** had an IC_{50} eight times higher than that of biotin (IC_{50} = 1 μM versus 0.13 μM in the assay). Two factors may be put forward to explain this discrepancy. Either covalent binding of biotin to PL decreased its affinity toward streptavidin or not all biotin molecules are accessible for binding to immobilized streptavidin because of steric hindrance. The latter explanation seems more plausible so we anticipate that one biotin out of eight is accessible to binding to immobilized streptavidin.

In conclusion, we have prepared and characterized three transition metal−carbonyl labeled biotin tracers and several avidin conjugates. These tracers were shown to display good to excellent bioactivities toward streptavidin and biotin, respectively. Amplification of the IR signal is anticipated for the conjugates with a favorable reporter group-to-ligand ratio (10-to-1 for neutravidin, 115-to-1 or 11-to-1 for biotin), as no quenching occurs for IR detection. Their use in a solid-phase CMIA is under way, as we have recently shown that the binding of a NAV−$Co_2(CO)_6$ conjugate to self-assembled monolayers of biotin molecules on gold substrates could be successfully transduced by FT-IR spectroscopy in the reflection−absorption mode (*30, 31*).

Novel Cyanine Dye-Labeled Dideoxynucleoside Triphosphates for DNA Sequencing

R. Scott Duthie, Inta M. Kalve,† Sui Bi Samols,‡ Scott Hamilton, Inna Livshin,‡ Mahesh Khot, Satyam Nampalli, Shiv Kumar,* and Carl W. Fuller*

Amersham Biosciences, 800 Centennial Avenue, Piscataway, New Jersey 08855. Received June 27, 2001; Revised Manuscript Received March 24, 2002

Single color cyanine dye-labeled (Cy 5.0 and Cy 5.5) dideoxynucleoside-5′-triphosphates, or 'terminators', containing different spacer lengths were synthesized and evaluated for efficacy in DNA sequencing methods using a modified thermally stable DNA polymerase. The single color cyanine dye terminators were formulated into two separate sets of sequencing mixes, one for Cy 5.0 and the other for Cy 5.5, and evaluated on different automated sequencing platforms. Each set of mixes included two pyrimidine terminators with 17-atom linkers and two purine terminators with 10-atom linkers between the dye and the nucleotide. The two sets of cyanine dye-labeled terminators chosen for this cycle sequencing study produced improved band patterns with band uniformity similar to that obtained with dye-primer sequencing methods.

INTRODUCTION

Fluorescent sequencing was first reported using dye-labeled primers (*1*), but methods using dye-labeled dideoxynucleoside triphosphates (ddNTPs; terminators) (*2*, *5*) have also gained acceptance in recent years. The advantage of using dye-labeled ddNTPs instead of labeled primers is that only properly terminated fragments are labeled (*2*). Strong stops associated with polymerase pausing or falling off the template without proper termination of the nascent DNA strand is not seen. Use of dye-labeled ddNTPs in automated sequencing has helped reduce the need to resequence problematic areas where polymerase stops are prevalent. Additionally, synthesis of labeled, specific primers is not required for the sequencing reactions. One major weakness of using dye-labeled terminators is the unevenness of the resulting sequencing peak heights or areas with cycle sequencing methods (*4*−*6*).

Most of the fluorescent dyes used for dye-terminator DNA sequencing have been applied to the four-color instruments of Applied Biosystems and E. I. Du Pont (*2*, *5*). These instruments have 488 nm lasers, so the dyes were all chosen for excitation at this wavelength. Most of these dyes have been either fluorescein or rhodamine derivatives. Since the instruments must distinguish four colors of fluorescence at once, there have even been attempts to use fluorescence energy transfer to obtain efficient four-color sets of dyes that can all be excited at 488 nm (*7*−*9*). These approaches have required the use

of complex, multiccolor optics for fluorescence detection. The use of fluorescein and rhodamine dyes has also been limited by their extinction coefficients (approximately 80000 M^{-1} cm^{-1}). Furthermore, it is desirable to use longer wavelength light for excitation because background fluorescence is considerably lower with 635 or 675 nm excitation than it is with 488 nm excitation (*12*−*14*).

We have instead focused on the use of simpler, single-color instruments, such as ALFexpress and SEQ4X4 (Amersham Biosciences, Piscataway, NJ) and Clipper and Long-Read Tower (Visible Genetics, Toronto, Canada). These instruments use inexpensive 635 and 675 nm lasers, which are ideally suitable for excitation of the cyanine dyes—Cy 5.0 and Cy 5.5 (*12*). While these instruments require 2−4 lanes for determination of a single DNA sequence, they are much simpler and less expensive than the four-color instruments that need only a single lane per sequence. Additionally, the cyanine dyes have significantly higher extinction coefficients (250000 M^{-1} cm^{-1}) than the fluorescein and rhodamine dyes, so they act as more efficient collectors of the excitation light.

To produce fully functional sets of cyanine-labeled dideoxynucleotides, a number of criteria had to be met. Preliminary experiments indicated that direct coupling of the cyanine dye NHS esters with simple propargylamino-modified pyrimidine nucleotides resulted in dye-labeled nucleotides that were relatively poor substrates for DNA polymerases. In addition, dyes with different charges resulted in labeled fragments that had widely differing mobilities upon electrophoresis through gels. After considerable experimentation with many combinations of dyes, linkers and nucleotides (*10*, *11*), we have come up with two optimal sets of novel labeled dideoxynucleotides for DNA sequencing on single-color instruments (vide supra). Herein, we describe these two sets of dye-labeled terminators and show their performance with Thermo Sequenase DNA polymerase (*15*, *16*) as monitored using the single-color sequencing instruments. These sequences have remarkably even band intensities for dye-terminator sequencing methods (*18*). In fact, they rival better dye-primer sequences for high data quality.

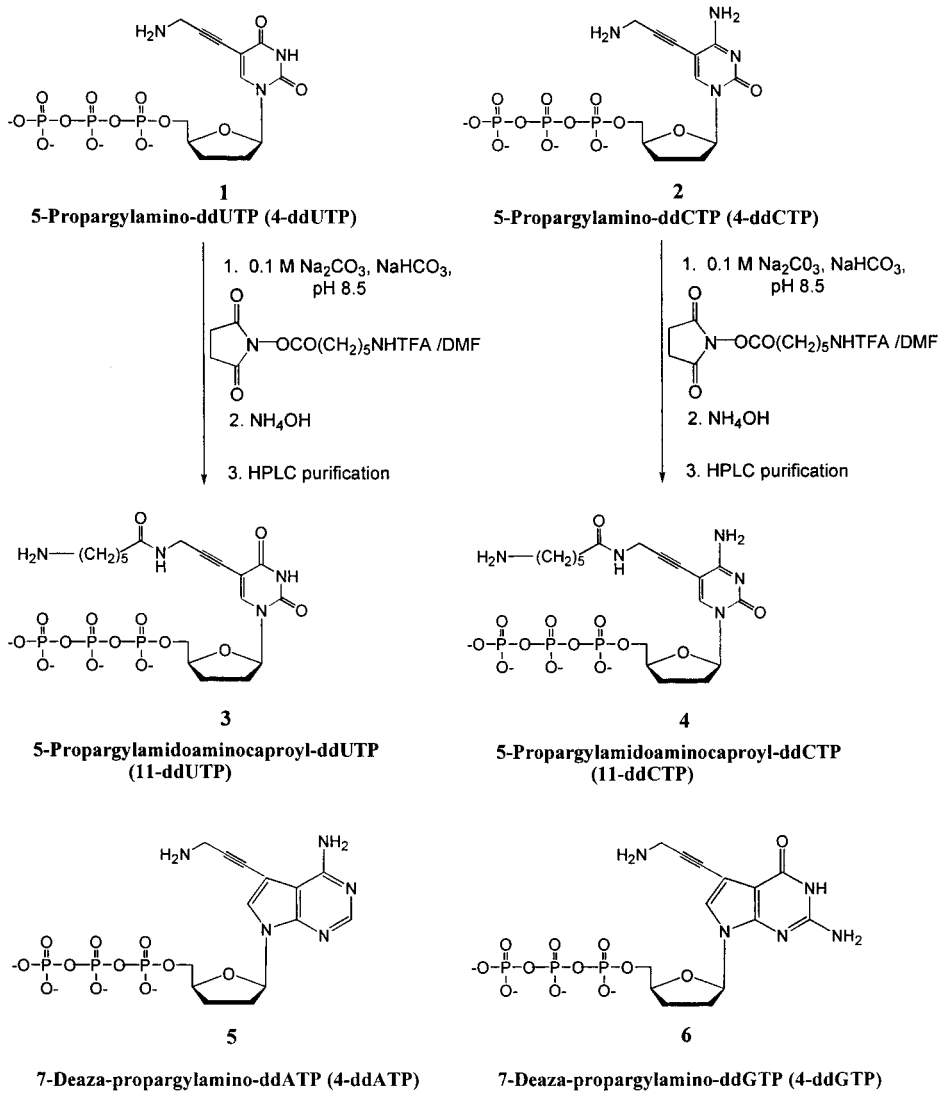
MATERIALS AND METHODS

The following reagents were obtained from Amersham Biosciences: Thermo Sequenase DNA polymerase, M13mp18(+) strand DNA, four-color dye terminators, HLA DRB*plus* Typing Kit, GFX PCR DNA and Gel Band Purification Kit.

Genomic DNA from immortalized B-lymphocyte cell lines AMAI and WT51 was obtained from ProtoProbe, Inc., Milwaukee, WI.

Synthesis of Dye-Labeled ddNTPs. The propargylamino dideoxy nucleotides **1**−**6** (Scheme 1), required for synthesis of Cy 5.5 and Cy 5.0 conjugates **7**−**14** (Scheme 2), were prepared following the procedure described by Hobbs and Cocuzza (*3*). Cy 5.5- and Cy 5.0-NHS esters used in these conjugation reactions were purchased from Amersham Biosciences (Piscataway, NJ). Preceding the name of each ddNTP are numbers which denote how many atoms are between the dye moiety and the attachment site on the base, either the C5 position of pyrimidines or the C5 position of pyrrolopyrimidines. Yields of the dye−nucleotide conjugates were determined by UV−vis spectrophotometer readings in TE buffer, pH 7.5, using a λ_{max} of 648 nm for Cy 5.0 conjugates (ϵ = 250000 M^{-1} cm^{-1}) or 675 nm for Cy 5.5 conjugates (ϵ = 250000 M^{-1} cm^{-1}). The formula for this determination was the following:

Concentration = (absorbance at either λ_{648} for Cy 5.0 or λ_{675} for Cy 5.5 ÷ extinction coefficient of 250000)-(dilution factor). Micro Mass LCT was used to analyze the dye−nucleotide terminators.



Synthesis of 11-ddUTP (3) 11-ddCTP (4). A 50 mg (63 μmol) amount of 5-propargylamino-ddUTP (4-ddUTP, **1**) (*10*) or 5-propargylamino-ddCTP (4-ddCTP, **2**) in 3 mL of 0.1 M Na_2CO_3−$NaHCO_3$ (pH 8.5) was stirred individually at room temperature with 2.5 equiv of N-TFA-aminocaproic acid-NHS ester (51 mg; 160 μmol) in 1 mL of anhydrous DMF. After 1 h of stirring, the solutions were evaporated under reduced pressure. The resulting residues were treated with 5 mL of 30% aqueous NH_4OH for 2 h at RT to remove the TFA group and then dried as before. The products were purified by HPLC using a Delta Pak (Waters) C18 column (5 cm × 30 cm, 15 μm, 100 Å) eluted with a gradient of 0.1 M TEAB (buffer A, pH 7.0) and 3:1 0.1 M TEAB:CH_3CN (buffer B, pH 7.0) in 30 min with a flow rate of 130 mL/min. Identical fractions were pooled and evaporated under reduced pressure to obtain 11-ddUTP, **3** (40 mg, 70%), and 11-ddCTP, **4** (30 mg, 52%).

Conjugation of 11-ddUTP (3) with Cy 5.5-NHS ester: Formation of Cy 5.5−17-ddUTP (7, Scheme 2). To a magnetically stirred solution of 11-ddUTP (12 μmol) in 0.1 M Na_2CO_3−$NaHCO_3$ (1 mL, pH 8.5) at room temperature was added 1 mL of an anhydrous DMF solution of Cy 5.5-NHS ester (20 mg, 18 μmol, 1.6 equiv). After 1 h, the reaction mixture was evaporated under reduced pressure and the product purified by silica gel column (32 cm × 2 cm) chromatography. Excess dye and unwanted byproducts were eluted with 1:1 MeOH/$CHCl_3$ (3 × 30 mL) followed by neat MeOH (2 × 30 mL). The desired Cy 5.5−17-ddUTP (**7**) was then eluted with 6:3:1 iso-PrOH:NH_4OH:H_2O (4 × 40 mL). Identical fractions were pooled and evaporated, and the resulting residue was further purified by HPLC using a Delta Pak (Waters) C18 column (19 mm × 30 cm, 15 μm, 100 Å) using a gradient of 0.1 M TEAB (buffer A, pH 7.0) and 1:1 0.1 M TEAB:CH_3CN (buffer B, pH 7.0) in 30 min at a flow rate of 20 mL/min. The HPLC retention time for this compound was 19 min. Identical fractions were pooled and evaporated under reduced pressure to obtain 4.36 μmol (39%) of Cy 5.5−17-ddUTP (**7**). TOF MS ES-, *m*/*z* in water, MS 1516.25, observed M^{-1} 1515.24.

Synthesis of Cyanine Dye−Nucleotide Conjugates (Scheme 2). Following the same methods used for Cy 5.5−17-ddUTP, syntheses of Cy 5.5−17-ddCTP (**8**), Cy 5.5−10-ddATP (**9**), and Cy 5.5−10-ddGTP (**10**) were accomplished with yields ranging from 30 to 45%. HPLC retention times for these compounds were 19, 22, and 23 min, respectively. **8**: TOF MS ES-, *m*/*z* in water, MS 1515.26, observed M^{-1} 1514.25; **9**: TOF MS ES-, *m*/*z* in water, MS 1425.19, observed M^{-1} 1424.19; **10**: TOF MS ES-, *m*/*z* in water, MS 1441.19, observed M^{-1} 1440.18.

Nucleotide derivatives 11-ddUTP, 11-ddCTP, 4-ddATP, and 4-ddGTP were also conjugated with Cy 5-NHS ester to synthesize their conjugates, Cy 5.0−17-ddUTP (**11**), Cy 5.0−17-ddCTP (**12**), Cy 5.0−10-ddATP (**13**), and Cy 5.0−10-ddGTP (**14**). Yields from these reactions were in the range of 30−50%. HPLC retention times for these compounds were 20, 7, 9, and 10 min, respectively. **11**: TOF MS ES-, *m*/*z* in water, MS 1256.30, observed M^{-1} 1255.29; **12**: TOF MS ES-, *m*/*z* in water, MS 1255.32, observed M^{-1} 1254.31; **13**: TOF MS ES-, *m*/*z* in water,

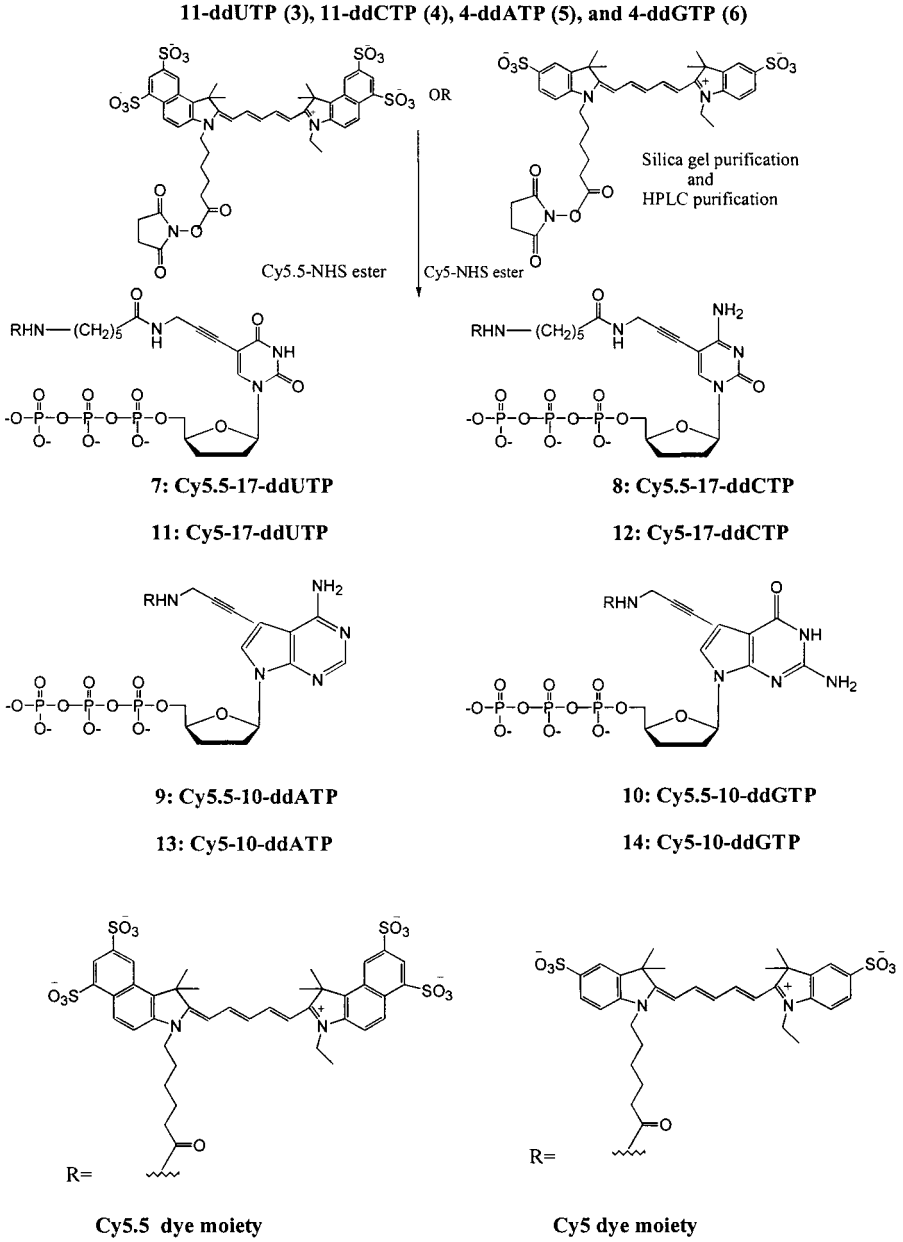
Polymerase Chain Reactions. Typical reaction volumes were 25−50 μL containing 15 mM Tris-HCl, pH, 8.3, 200 μM each dATP, dCTP, dGTP, and dTTP (Amersham Biosciences), 1.5−2.5 units of *Taq* DNA polymerase (Amersham Biosciences), 1−200 ng of template, and 1−10 pmol of primers. Typical thermal cycling conditions consisted of a 1−2 min initial heat denaturation step at 95 °C and then 25−30 cycles, each consisting of the following steps:

95 °C for 30 s, 45− 60 °C for 30 s, 72 °C for 120 s. Reactions were held at 4 °C once thermal cycling had been completed. PCR products were purified using GFX PCR DNA and Gel Band Purification Kit.

Sequencing Reactions. The basic procedure involved mixing 10−20 units of Thermo Sequenase DNA polymerase, 1−10 pmol of primer, 50−500 ng of template, deoxynucleoside triphosphates (dNTPs; Amersham Biosciences), and a specific dye-labeled ddNTP in a total volume of 6−8 μL. Four separate reactions were required to sequence a template, each reaction containing a different dye-labeled ddNTP. Reactions were subjected to a thermal cycling protocol followed by postreaction workup of the cyanine dye terminator-labeled Sanger fragments by either ethanol precipitation or column chromatography. Purified products were then analyzed on an automated DNA sequencing instrument. A typical Cy 5.0 dye-labeled terminator sequencing reaction contained the following mixture:

14.6 mM Tris-HCl, pH 9.5; 3.4 mM $MgCl_2$; 150 μM each of dATP, dCTP, dGTP, and dTTP; and either 0.2 μM Cy 5.0−10-ddATP, 0.16 μM Cy 5.0−17-ddCTP, 0.4 μM Cy 5.0−10 ddGTP, or 0.325 μM Cy 5.0−17-ddUTP.



A typical DNA sequencing reaction using Cy 5.5 dye-labeled terminators contained the following mixture:

14.6 mM Tris-HCl, pH 9.5; 3.4 mM $MgCl_2$; 75 μM each of dATP, dCTP, dGTP, and dTTP; and either 1.5 μM Cy 5.5−10-ddATP, 1.5 μM Cy 5.5−17-ddCTP, 1.5 μM Cy 5.5−10-ddGTP, or 1.5 μM Cy 5.5−17-ddUTP.

Typical thermal cycling conditions consisted of a 1−2 min initial heat denaturation step at 95 °C, and then 25−30 cycles each consisting of 95 °C for 30 s, 45−60 °C for 30 s, and 72 °C for 120 s. Reactions were held at 4 °C until purification and analysis.

Reaction products were purified by precipitation with the addition of 2 μL of 7.5 M ammonium acetate and 30 μL of chilled absolute ethanol. After being mixed and incubated on ice for 20 min, DNA was pelleted by centrifugation at room temperature for 15 min using a standard lab bench microcentrifuge set on high speed (10000−16000*g*). Supernatants were carefully removed

Scheme 2. Synthesis of Cy-Dye Conjugates

by aspiration, and each DNA pellet was rinsed with 200 μL of ice-cold 70% ethanol. The tubes were recentrifuged for 5 min, and supernatants were again removed. DNA pellets were stripped of liquid under vacuum at room temperature for about 2 min without taking them to complete dryness. Each tube had 6−8 μL of formamide loading dye (95% formamide, 50 mM EDTA, pH 8.0, 0.2 mg/mL new fuchsin) added and was then mixed, using a vortex mixer fitted with a tube holder, for 10−15 min at room temperature. Resuspended DNA was denatured at 70−72 °C for 2.5−3 min, and the tubes were immediately quenched on ice. Aliquots, 1.5−8 μL, were then loaded in wells of sequencing gels for analysis.

Alternatively, sequencing reaction products were purified using AutoSeq G-50 columns (Amersham Biosciences). In this alternative procedure, each completed reaction mixture was diluted with distilled water to a volume of 15−25 μL and the entire sample loaded on a prespun column. The separate column effluents were stripped of liquid using a speed-vac, treated, and loaded on sequencing gels for analysis (vide supra).

Primers. Various primers were employed during the course of this study for both PCR and cycle sequencing reactions. Their sequences and how they are defined in the body of the text are as follows:

M13−40 primer, 5′-d[CGC CAG GGT TTT CCC AGT CAC GAC]-3′.

Reverse sequence primer (RSP), 5′−d[CAG GAA ACA GCT ATG AC]-3′.

M13 Universal primer, 5′−d[GTA AAA CGA CGG CCA GT]-3′.

Universal cycle primer, 5′-d[GTT TTC CCA GTC ACG ACG TTG TA]-3′.

Sequencing Instruments. The following DNA sequencing instruments were used in this study: ALFexpress DNA Analysis System (Cy 5.0 dye; Amersham Biosciences, Piscataway, NJ), SEQ4X4 Personal Sequencing System (Cy 5.5 dye; Amersham Biosciences, Piscataway, NJ), and both Clipper and Long-Read Tower System (Visible Genetics, Inc., Toronto, Ontario, Canada; both Cy 5.0 and Cy 5.5 dyes) (*17*).

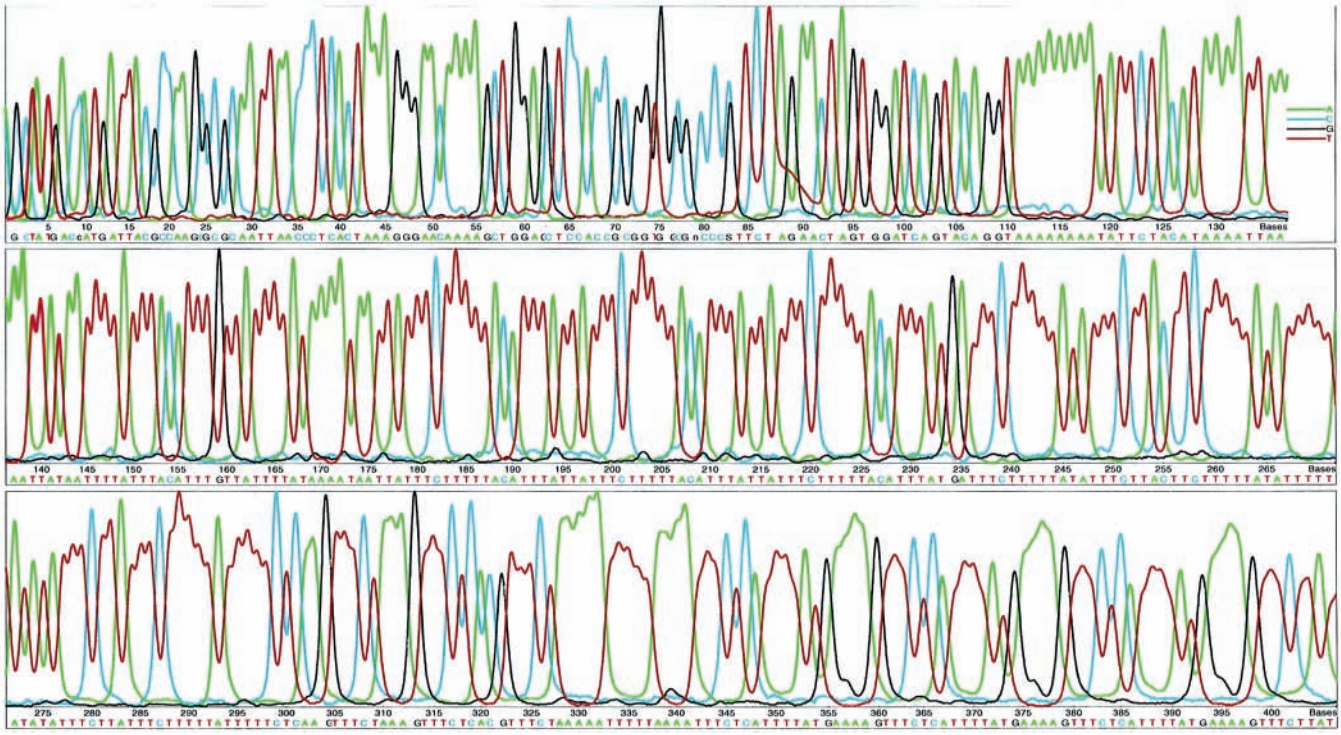

Figure 2. A 600-base PCR product generated by amplification of a pUC18 clone containing a 385-base insert of AT rich *Tetrahymena thermophilia* genomic DNA. The product was gel-purified and 300 ng of the resulting material sequenced using Thermo Sequenase DNA polymerase and Cy 5.0 dye terminators with detection on the ALF*express* DNA Analysis System.

RESULTS AND DISCUSSION

Thermo Sequenase DNA polymerase (Amersham Biosciences) contains a single amino acid modification which increases the rate of ddNTP incorporation by more than 1000-fold (*15*). When used in cycle sequencing reactions with unmodified ddNTPs, DNA polymerases containing this amino acid modification produce band patterns with

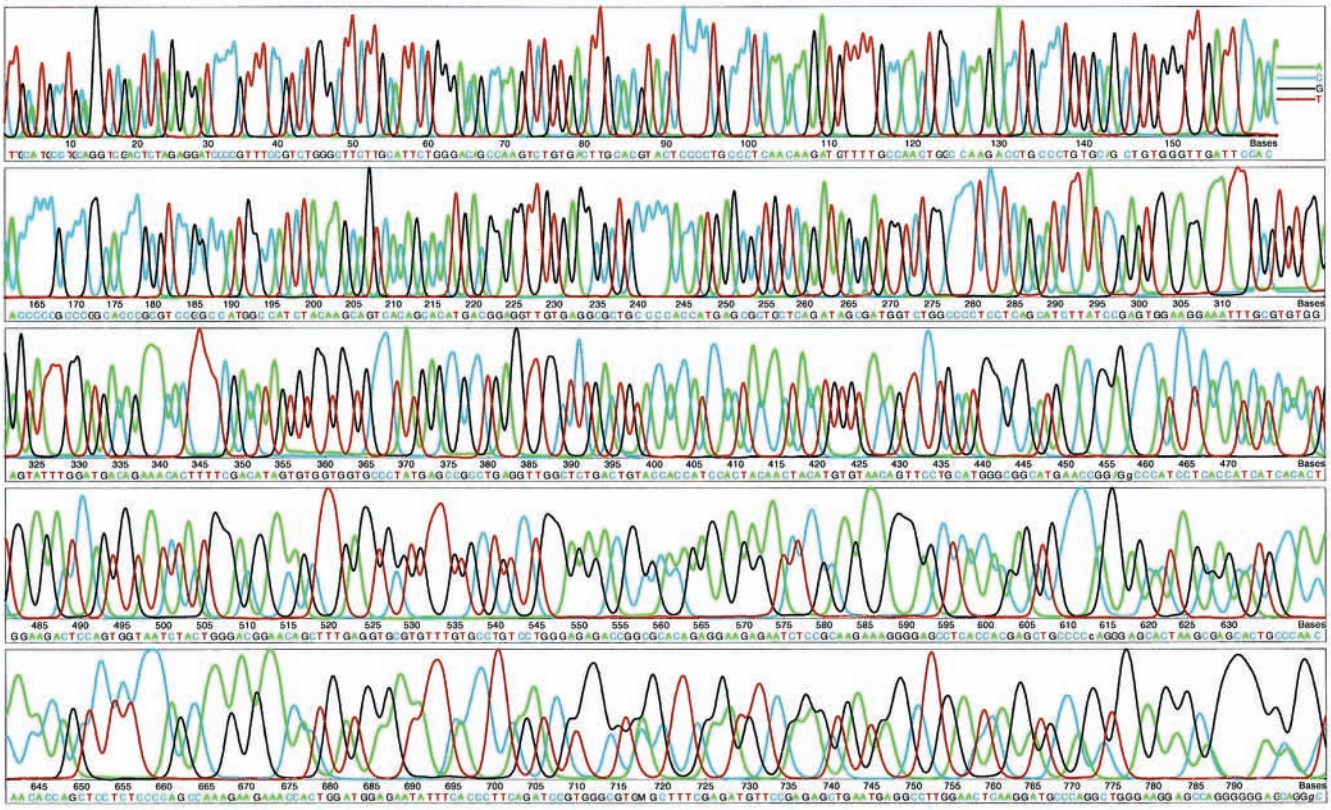

Figure 3. Sequence of pUC18 containing about an 800-base insert of p53 DNA using Thermo Sequenase DNA polymerase and Cy 5.0 dye terminators with detection on ALF*express* DNA Analysis System.

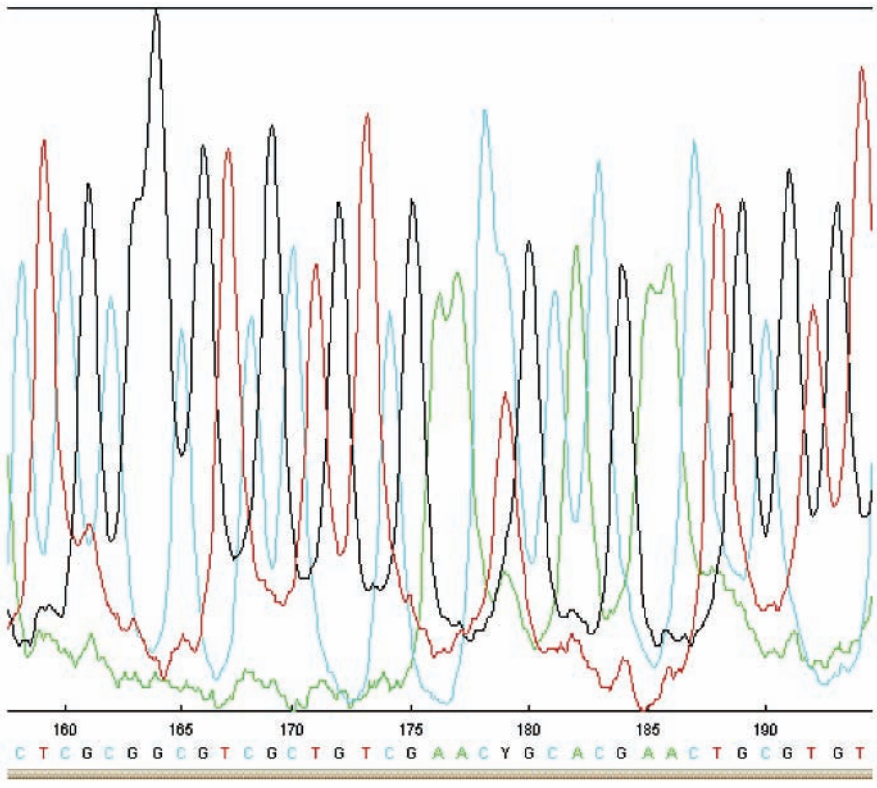

Figure 4. Heterozygote determination using Cy 5.0 dye terminators and Thermo Sequenase DNA polymerase with detection on ALF*express* DNA Analysis System.

very uniform peak intensities. In contrast, when performing similar reactions with dye-labeled ddNTPs, the same DNA polymerases generate peak heights that can fluctuate over approximately a 20-fold range in intensity (*18*).

A comparative peak height variation study (*5*) was performed between the Cy 5.5 terminators and other fluorophore reporting systems used in DNA sequencing. The peak height variation was standardized using bases between 50 and 350 of M13mp18(+) DNA sequenced with

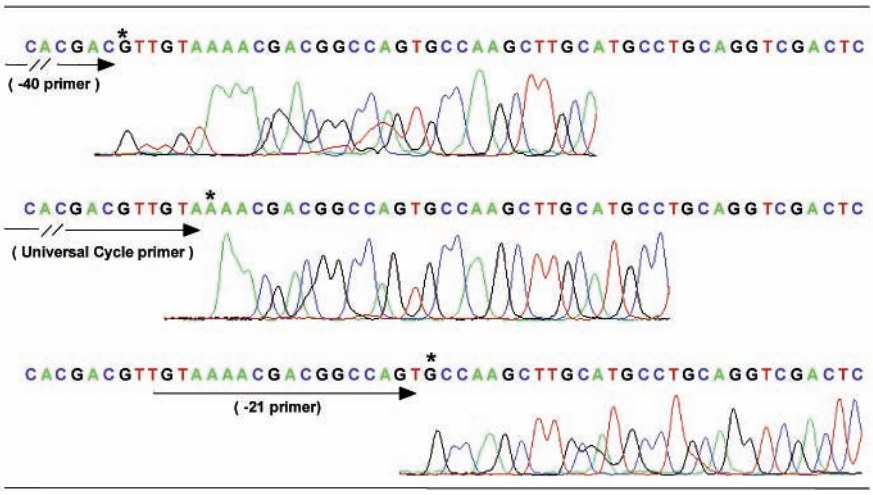

Figure 5. PCR products of M13mp18(+) strand sequenced with the indicated primers. Note that the first base of each product is readable using SEQ4X4 Personal Sequencing System.

the M13−40 primer. Sequence data within this region was examined prior to peak variation analysis to ensure that the sequence was correct. Briefly, peak height data were fit to a second-degree polynomial equation comparing height to scan plot position. This corrected for the normal systematic variation in intensities found in DNA sequences. The data were then normalized by dividing the peak height at a given scan position by the polynomial estimate at that same position. The values reported are the variance of the normalized peak heights. Thus, smaller values indicate better, more uniform band intensities. Figure 1 represents some examples showing peak height variation obtained with different terminators and different DNA polymerases. Sequencing reactions using dye-primers and T7 DNA polymerase had the best peak height variation with a value of 0.07. Peak height variation for the Cy 5.5 terminators was found to be considerably better than the value (approximately 0.3) found for the four-color dye terminators currently used in the majority of high throughput sequencing facilities (*8*, *9*).

We investigated the ability of four new dye terminators to resolve stretches of either GC- or AT-rich base pairs. The Cy 5.0 dye-terminator protocol was tested with two plasmid constructs, one highly AT-rich that was used as a template to generate a 600-base pair PCR product for sequencing, and the other GC-rich where the plasmid was itself sequenced. Figure 2 presents sequence data from a 600-base pair PCR product containing *Tetrahymena thermophilia* DNA cloned into pUC18. A PCR product was first generated with this template using both the M13−40 primer and RSP. The purified material (∼300 ng) was sequenced using the M13 universal primer. Between bases (Figure 2**)** 110 and 298 the number of AT base pairs compared with the total number of base pairs is 91%, with the entire fragment comprising 76% AT. Of the 406 bases of sequence data (Figure 2), only one ambiguity at position 83 was observed to be caused by the base-calling software, and that may be resolved with manual intervention as a 'G'. Also notice that the base-calling software has added an extra base at position 79 (n).

Figure 3 presents sequence data from an 807-base insert in pUC18 of a p53 cDNA clone covering part of exon 4, all of exons 5 through 9, and part of exon 10. Between base 163 and 285 in Figure 3 is an area that is 71% GC-rich, with an overall GC content of the presented sequence at 58%. The first ambiguity was identified at base 718 and could not be resolved by manual intervention because of gel resolution.

Another important characteristic of these dye-terminator systems is unambiguous and reliable detection of heterozygotes. PCR products of separate amplifications of AMAI and WT51 genomic DNA were performed according to the manufacturer's instructions found in the HLA DRB*plus* Typing Kit. These products were purified with GFX PCR DNA and Gel Band Purification Kit and the concentration determined by spectrophotometer measurement. A mix of two of the PCR products was then sequenced using Cy 5.0 terminators. Figure 4 demonstrates heterozygote determination when 120 ng of WT51 and 80 ng of AMAI PCR products were mixed and sequenced. The 'Y' at position 179 in Figure 4 represents either a 'C' or 'T'. With this mixture of genomic DNA templates both a 'C' and a 'T' would be expected at this position as observed.

We also investigated the ability of our sequencing system to elucidate either the first base following the primer or the last base of an amplicon. For the first base determination 50 ng of M13mp18(+) strand DNA was amplified and then sequenced using three different M13 primers: −40, Universal Cycle, or Universal. Figure 5 demonstrates that the first base following the primer is visible in each reaction, even when the primer was immediately followed by a multiplet of the same base. Last base determination was accomplished using a PCR product of the human beta globin locus purified by Exo/SAP treatment. All sequence from the 128 base pair fragment is visible in Figure 6, demonstrating our system has the capability of elucidating as much sequence data as possible from a PCR template.

CONCLUSIONS

In this paper we have reported the synthesis of cyanine dye-labeled dideoxynucleoside triphosphates and their utility in single-color DNA sequencing methods. We have also demonstrated the ability of these two sets of cyanine dye-labeled terminators, when combined with a suitable DNA polymerase, to generate excellent quality sequencing data using simple and inexpensive instrumentation.

Establishment of Intein-Mediated Protein Ligation under Denaturing Conditions: C-Terminal Labeling of a Single-Chain Antibody for Biochip Screening

Jens R. Sydor, Maria Mariano, Steve Sideris, and Steffen Nock*

Zyomyx, Inc., 26101 Research Road, Hayward, California 94545. Received March 26, 2002; Revised Manuscript Received June 3, 2002

Intein-mediated protein ligation is a recently developed method that enables the C-terminal labeling of proteins. This technique requires a correctly folded intein mutant that is fused to the C-terminus of a target protein to create a thioester, which allows the ligation of a peptide with an N-terminal cysteine (*1*, *2*). Here we describe the establishment of this method for the labeling, under denaturing conditions, of target proteins that are expressed insolubly as intein fusion proteins. A GFPuv fusion protein with the *Mycobacterium xenopi gyrA* intein was expressed in inclusion bodies in *Escherichia coli* and initially used as a model protein to verify intein cleavage activity under different refolding conditions. The intein showed activity after refolding in nondenaturing and slightly denaturing conditions. A construct of the same intein with an anti-neutravidin single-chain antibody was also expressed in an insoluble form. The intein-mediated ligation was established for this single chain antibody−intein fusion protein under denaturing conditions in 4 M urea to prevent significant precipitation of the fusion protein during the first refolding step. Under optimized conditions, the single-chain antibody was labeled with a fluorescent peptide and used for antigen screening on a biochip after final refolding. This screening procedure allowed the determination of binding characteristics of the scFv for avidin proteins in a miniaturized format.

INTRODUCTION

Inteins are self-splicing protein elements that excise themselves out of a precursor protein, ligating the flanking polypeptide sequences together. Since their discovery in 1990 (*3*, *4*), inteins have been used for a variety of protein engineering techniques including the C-terminal ligation of proteins to peptides or protein fragments (*5*−*8*). In this case, the C-terminus of a target protein is fused to an intein mutant that is unable to splice itself out of the precursor protein, but is still capable of generating a thioester at the C-terminus of the target protein. An N-terminal cysteine-containing peptide or protein fragment is then ligated to the C-terminal thioester of the target protein (Figure 1). This is usually achieved by the aid of another thiol compound that releases the target protein from the intein in a transthioesterification reaction. This C-terminal thioester is then reacted with a peptide containing an N-terminal cysteine, the thiol of which exchanges with the low molecular weight thiol compound. Finally, the thioester formed between the target protein and the peptide spontaneously rearranges to generate a native amide bond (*1*, *2*). This technique has proven useful in protein engineering to incorporate unnatural modifications such as fluorophores or isotope labels into proteins (*9*−*11*).

An important prerequisite for intein-mediated protein ligation (IPL) is that the fusion protein is in a correctly folded conformation to allow the intein-mediated formation of the thioester. Unfortunately, a significant number of proteins, including those fused to inteins, can only be obtained in insoluble form in inclusion bodies when expressed in *E. coli*. The protein isolation from inclusion bodies generally requires a denaturation and refolding step. So far, there are only a limited number of examples that describe the refolding of intein fusion proteins into active conformations. For example, the refolding of intein fusions into nondenaturing buffer has been performed, although with a low yield of refolded protein and intein cleavage activity (*12*). Additionally, low concentrations of denaturants such as guanidine hydrochloride have been added to increase the solubility of peptides during the ligation without affecting intein activity (*10*). A general method that could be applied to a variety of

proteins expressed as insoluble intein fusions would, therefore, expand the applicability of the IPL.

One application of this technique could be the C-terminal site-specific labeling of single-chain antibodies, which are very important binding reagents used for the detection of biomolecules (*13*−*15*). The expression and isolation of active single-chain antibodies is usually problematic, however, due in part to the reducing environment in the cytoplasm, which inhibits the formation of the disulfide bonds within these antibody fragments. Production of active scFv's[1] is usually accomplished by expressing them in the periplasm, which is an oxidizing environment, or in inclusion bodies, with a subsequent refolding and oxidation step (*16*−*19*). The amount of scFv's isolated from the periplasm is usually low, however, and refolding of scFv's from inclusion bodies is usually unsuccessful.

To overcome these limitations, we describe a method that results in a high yield of functional scFv's that have been labeled by IPL. The basis of this method is to first express the scFv as an insoluble intein-fusion protein. The protein is then fully resolubilized and denatured, after which it is transferred into a mildly denaturing buffer in which the intein is functional, but where the denaturant allows the partially folded scFv to remain soluble. Correctly folded fusion proteins then undergo IPL, becoming labeled in the process. IPL under mildly denaturing conditions was tested on two unrelated proteins fused to the gyrase A intein from *Mycobacterium xenopi*. We also describe the utilization of scFv's with a C-terminal fluorescent tag for antigen screening in a biochip format.

This strategy also offers a variety of other possibilities for the C-terminal labeling of scFv's, such as the introduction of other unnatural modifications for oriented capture agent immobilization on surfaces.

EXPERIMENTAL PROCEDURES

Materials. For the cloning procedures, oligonucleotides were supplied by MWG (High Point, NC) and enzymes and chitin beads by New England Biolabs (Beverly, MA). Denaturants, urea and guanidine-hydrochloride, were purchased from Fisher Scientific (Pittsburgh, PA). Roche Molecular Biochemicals was the supplier of the 1,4-dithiothreitol (Inidianapolis, IN). Ethanethiol was purchased from Fluka (Milwaukee, WI). 2-Mercaptoethanesulfonic acid, sodium salt (MESNA), and all other inorganic salts were obtained from Sigma Chemical Company (St. Louis, MO). Pierce Chemical Company (Rockford, IL) was the supplier of neutravidin, avidin, and streptavidin.

Cloning and Expression of Intein Fusion Constructs. The DNA sequence of the target proteins was cloned into pTXB1 (New England Biolabs, Beverly, MA) that was modified by the introduction of a His-tag between the intein and the chitin-binding domain as well as SfiI and NotI restriction sites in the MCS for cloning of the scFv or GFPuv in frame with the *Mxe* gyrA intein (Figure 1). The sequence for GFPuv was obtained from Clontech (Palo Alto, CA), and the sequence for the scFv was published elsewhere (*20*).

Transformation of this plasmid into *E. coli* BL21(DE3) was done by electroporation according to the manufacturer's instructions (Stratagene, La Jolla, CA). BL21-(DE3) cells contain a chromosomal copy of the T7 RNA polymerase gene under the control of the IPTG-inducible lacUV5 promoter. Expression was induced by the addition of 0.1 mM IPTG. Six hours after induction and incubation at 30 °C, cells were harvested by centrifugation at 4 °C, which yielded ∼8 to10 g of wet cell pellet per liter cell culture. The cells were stored at −80 °C until further use.

Synthesis of the myc Peptide with and without Rhodamine Label. Solid-phase peptide synthesis (*21*) was performed manually or on a CS536 peptide synthesizer from CSBio (San Carlos, CA), using in situ neutralization/2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate activation protocols for stepwise Boc-chemistry chain elongation on an MBHA resin (*22*). The rhodamine derivative 5-(and 6)-carboxytetramethylrhodamine (TAMRA) was coupled to the lysine side chain with the following procedure. The ϵ-amino group of the lysine side chain was protected with an Fmoc group. After chain elongation, the amino group was deprotected by two 5 min incubations of the resin with 20% piperidine in DMF and subsequent washing with DMF. TAMRA was then activated and coupled like other amino acids, described in the general protocol (*22*). After HF cleavage, the peptides were purified with a C18-column from Vydac (Hesperia, CA) by using linear gradients of buffer B (acetonitrile, 0.1% trifluoroacetic acid) in buffer A (H_2O, 0.1% trifluoroacetic acid) and UV detection at 215 nm.

Isolation and Solubilization of Inclusion Bodies. Cells were resuspended in cell lysis buffer (200 mM NaCl, 20 mM sodium phosphate, pH 7.3, 1 mM EDTA) and lysed in a microfluidizer (Microfluidics International Corporation, Newton, MA). The crude inclusion body (IB) fraction was isolated by centrifugation at 31000 g for 10 min at 4 °C and resuspended in 0.1 M Tris, pH 7, 1mM EDTA. A 0.5 volume of 60 mM EDTA, 6% Triton X-100, 1.5 M NaCl, pH 7, was added and the suspension incubated at 4°C for 30 min with stirring. The IB fraction was isolated by centrifugation as described above and resuspended in wash buffer (50 mM sodium phosphate, pH 7.3, 1 mM EDTA). Centrifugation was repeated to isolate the IB pellets, which were subsequently stored at −20 °C (2 weeks) or −80 °C (>2 weeks). From a 1L culture, 1.5−2 g of IB were typically obtained. Inclusion bodies were solubilized in wash buffer plus 6 M GuHCl and 100 mM DTT for 2 h at RT with constant stirring. The pH was adjusted to 3−4 by the dropwise addition of 1 N HCl. Finally, the sample was centrifuged at 10000 g for 30 min at 4 °C to remove the insoluble cellular debris from the solubilized protein, which was then filtered.

Partial Refolding and IPL under Denaturing Conditions. The solubilized protein sample (10 mg/mL) in 6 M GuHCl was rapidly diluted at a rate of 0.1 mL/min into refolding buffer (wash buffer plus 4 M urea) at RT to give a final 1:10 dilution. The diluted sample was dialyzed against refolding buffer overnight at RT and then centrifuged at 10000 g for 30 min at 4 °C. The target protein-*Mxe*gyrA-His6-CBD fusion in the supernatant was purified by binding to a chitin resin at RT and

washing with 5 column volumes of refolding buffer. The IPL was induced by the addition of 1 volume of 200 mM MESNA and 4 mM of peptide to 1 volume of the chitin beads containing the intein fusion protein in the same buffer and incubated for 36 h at RT. The supernatant was isolated, and the beads were washed with the refolding buffer. The wash fractions were combined with the supernatant, and the sample was dialyzed using one of the following methods: (1) directly into PBS with 10% glycerol, (2) directly into PBS, 10% glycerol, 3 mM/0.3 mM reduced/oxidized glutathione and then into PBS, 10% glycerol, or (3) stepwise dialysis into 2 M urea, 50 mM sodium phosphate, pH 7.3, 1 mM EDTA, 3 mM/0.3 mM reduced/oxidized glutathione, and then into 1 M urea in the same buffer and finally into PBS, 10% glycerol.

Determination of scFv Activity by ELISA. The wells of a Nunc-Immuno Plate Maxisorp Surface (Nalge Nunc International, Denmark) were coated with 100 μL of 2 μg/mL neutravidin (or 5 μg/mL BSA as a negative control) in 0.1 M sodium carbonate, pH 9.6, overnight at 4 °C. The wells were then blocked with 200 μL of 3% w/v nonfat dried milk in PBS, 0.1% v/v Tween-20, followed by the addition of 100 μL of scFv-myc in PBS, 0.1% v/v Tween-20, and incubated for 1 h at 37 °C. The wells were washed three times with PBS, 0.1% v/v Tween-20, followed by the addition of 100 μL of anti-myc antibody at a 1:1000 dilution in 3% w/v nonfat dried milk in PBS, 0.1% v/v Tween-20, with incubation for 1 h at 37 °C. The wash step described earlier was repeated, and an HRP-conjugated goat anti-mouse IgG (Jackson ImmunoResearch Laboratories, Inc., West Grove, PA) was added at a 1:2000 dilution in 3% w/v nonfat dried milk in PBS, 0.1% v/v Tween-20, and incubated at 37 °C for 1 h. After repeating the same washing step, OPD peroxidase substrate (SigmaFast *o*-phenylenediamine dihydrochloride tablets; Sigma, St. Louis, MO) was added first and then 3 N HCl to deactivate the enzyme. The optical density readings at 490 nm were recorded as relative units.

Antigen Screening on Protein Biochips. The preparation of the protein microarray surfaces was performed with an in-house microarrayer as described elsewhere (*23*). Briefly, a silicon chip with a 20 nm layer of TiO_2 was incubated with a solution of PLL-*g*-PEG-B30% for 1 h at room temperature to form the biotin surface. Neutravidin, avidin, and streptavidin (Pierce, Rockford, IL) were arrayed at varying concentrations onto the biotin-activated chip. After being washed, a microfluidic channel array was positioned onto the TiO_2 surface to create individual channels on the chip. The surface in the channels was then incubated with 100 nM scFvE9-myc-TAMRA in PBS, 0.05% Tween-20, 1% (w/v) BSA, and washed with PBS and then with H_2O.

The chips were scanned in a confocal fluorescence scanner (ScanArray 5000; GSI Lumonics, Billerica, MA) with a 543 nm excitation laser and a 578 nm emission filter.

Signal intensities for given spot sizes were determined with the program QuantArray Version 3.0 (Packard BioScience, Billerica, MA).

RESULTS AND DISCUSSION

Initial Refolding Studies for the *Mxe* gyrA Intein with GFPuv as a Model Protein. In a first set of experiments, we chose GFPuv as a model protein to test the refolding capability of the *Mxe* gyrA intein in a target protein-intein-His6-CBD fusion (Figure 1). This GFPuv−intein construct can be expressed as a soluble or insoluble intein fusion protein in *E. coli*, depending on the growth conditions, and its refolding can be monitored by the intrinsic fluorescence properties. We made the observation in our experiments that, in contrast to expression at 15 °C, expression of a GFPuvK238Y-*Mxe*gyrA-His6-CBD intein fusion protein at 30 °C in *E. coli* gave mostly insoluble fusion protein (Figure 2). This construct gave us the opportunity to test whether we could regain activity of this particular intein from *Mycobacterium xenopi* after refolding. The inclusion bodies were isolated and solubilized in 6 M GuHCl by a procedure which is similar to the one published by Rudolph et al. (*24*, *25*).

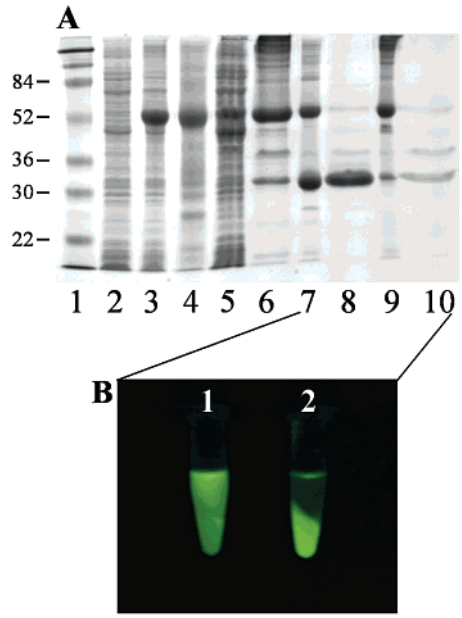

Figure 2. SDS−PAGE and fluorescence analysis of expression and intein-mediated cleavage of the GFPuvK238Y-*Mxe*gyrA-H6-CBD construct. The fusion protein was isolated from inclusion bodies after expression and refolded in nondenaturing PBS buffer containing 10% glycerol. Cleavage was performed after binding to chitin beads for 36 h at 4 °C with 2% ethanethiol. A, SDS−PAGE analysis. Lane 1: Protein marker (molecular weight in kDa). Lane 9: Protein fraction bound to the chitin beads in the control incubation without ethanethiol. Lane 10: Supernatant fraction of the control incubation without ethanethiol. B, Fluorescence analysis. UV irradiation of the microcentrifuge tubes containing the intein-mediated cleavage samples after centrifugation. Tube 1 contains the reaction with 2% ethanethiol, tube 2 contains the control reaction without ethanethiol. Lane 7−10 in the SDS−PAGE analysis represent the chitin beads fractions and supernatants of these reaction tubes.

The GFPuv−intein fusion protein was refolded by dialysis into nondenaturing PBS buffer containing 10% glycerol. The solubilized protein in denaturing buffer showed no fluorescence upon irradiation with UV light whereas the refolded sample clearly showed GFPuv fluorescence which indicated a correct folding of the soluble fraction. There was, however, also a significant amount of precipitated protein in the dialyzed sample. After centrifugation, the supernatant was loaded onto chitin beads and incubated with 2% ethanethiol for 36 h at 4 °C.

The results presented in Figure 2 show that a fraction of the gyrase A intein mutant is able to generate a thioester at its N-terminus after refolding, which leads

to the cleavage of GFPuv from the beads by an attack of the thioester with ethanethiol. GFPuv accumulates in the supernatant of the reaction with ethanethiol whereas there is only a minor cleavage of GFPuv in the control reaction without ethanethiol. This might be due to some hydrolysis of the thioester (Figure 2). About 50% of the refolded construct contains an active intein, estimated from the relative protein concentrations in the SDS−PAGE, which gives reasonable amounts of target protein in the supernatant. In this case, several milligrams of GFPuv could be obtained from 1 L of cell culture by this procedure, which proves that a *Mxe* gyrA intein fusion protein can be successfully refolded to an active intein conformation.

Intein-Mediated Ligation under Denaturing Conditions for the C-Terminal Labeling of an scFv. As mentioned above, the refolding of the GFPuv−intein fusion protein led to significant amounts of protein loss due to precipitation. Also, unlike GFPuv, which is relatively easy to refold, more challenging proteins, such as scFv's, largely precipitated as intein fusion proteins during this refolding step.

For this reason, we wished to establish a refolding and cleavage procedure that could be applied for target proteins that are difficult to refold into active conformations.

As a model system to develop such a procedure, we constructed a vector which directs the cytoplasmic expression of a fusion construct of the *Mxe* gyrA intein with a single-chain Fv against neutravidin (*20*). This fusion protein, like that of the GFPuv construct, was expressed in an insoluble form in *E. coli* (Figure 3A). The inclusion body fraction containing the fusion protein was isolated and solubilized in 6 M GuHCl.

Instead of a direct transfer of the fusion protein into physiological buffer conditions, we first diluted it into an intermediate buffer that is mildly denaturing. This was intended to allow partial refolding of the intein and the chitin-binding domain to active conformations, thus allowing for protein immobilization and intein-mediated protein ligation. At the same time, it was intended to prevent the precipitation of the fusion protein that was observed when dialyzing directly into physiological buffer conditions. We first tried to perform the IPL in buffers with varying concentrations of GuHCl. Although the CBD was still able to bind to the chitin beads to some extent at low GuHCl concentrations, the intein showed no cleavage activity (data not shown). Ayers et al. have shown that intein cleavage activity in a soluble fusion protein can be mostly retained upon addition of up to 2 M GuHCl (*10*). In our case, however, the fusion protein had already been insoluble and needed to be solubilized in 6 M GuHCl before a transfer to lower GuHCl concentrations, and so the conditions are not directly comparable.

In our next experiments, we transferred the fusion protein from 6 M GuHCl to a buffer containing the milder denaturant urea in order to prevent precipitation of the fusion protein and regain activity of the intein by the same time. A variety of different transfer protocols were compared, and the best results regarding intein activity were achieved by a stepwise dilution approach into 4 M urea (*24*, *25*). In this case, 10 mL of a 10 mg/mL solution of the scFv−intein−CBD fusion protein was slowly added to 90 mL of a 4 M urea buffer at room temperature with a flow rate of 0.1 mL/min with constant stirring. This stepwise dilution approach lowers the concentration of the denatured protein during the refolding process and therefore prevents aggregation of folding intermediates (*24*, *25*). The dilution was followed by another dialysis step into 4 M urea overnight at room temperature to ensure the removal of GuHCl.

The protein sample was then bound to 1 mL chitin beads for the purification of the intein fusion protein. We then added the thiol additive and the peptide with the N-terminal cysteine. The IPL releases the target protein coupled to the modifying peptide into the supernatant while retaining the intein−CBD fusion protein on the beads. The ligation was carried out for 36 h at RT with a 50% chitin beads suspension in 4 M urea containing 100 mM MESNA and 2 mM peptide.

The SDS−PAGE analysis of this reaction, performed with the scFv against neutravidin and a myc peptide with an N-terminal cysteine (NH_2-CGGEQKLISEEDLN-$CONH_2$), showed results that were consistently seen in our investigations (Figure 3). The use of MESNA as a thiol additive improves the cleavage of the target protein from the intein fusion on the chitin beads in comparison to ethanethiol. The ligations at room temperature gave slightly higher amounts of product than ligations at 4 °C, without affecting the activity of the scFv (as measured by ELISA, see below). The addition of the peptide slightly increased the fraction of the fusion protein that cleaves from the intein, but also increased the amount of precipitated byproduct, as can be seen in the chitin bead fraction, which appears to contain some insoluble product. This approach, however, yielded significant amounts of ligated scFv in the supernatant. The yield of the intein cleavage was up to 20% under these conditions, based on the estimation of protein concentrations, using the protein standards of the SDS−PAGE analysis. The overall yield was approximately 2 mg of labeled scFv per liter of culture. In comparison, the amounts of scFv obtained from an *E. coli* periplasmic expression system is usually in the microgram range. The additional label-

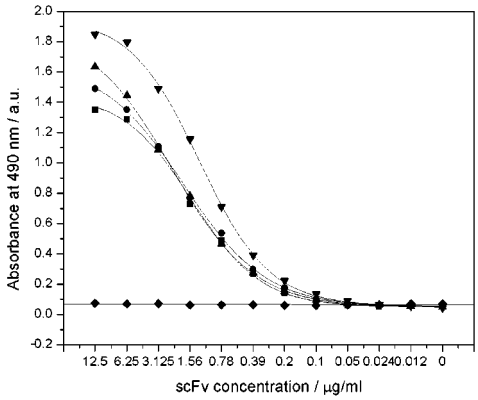

Figure 4. ELISA with the scFv E9 against the antigen neutravidin after different final refolding conditions. ELISA signals for the (▲) myc peptide labeled scFv E9 after stepwise dialysis from 4 M urea to PBS, 10% glycerol buffer with an oxido-shuffling system, (●) direct dialysis in PBS, 10% glycerol buffer with an oxido-shuffling system, and (■) direct dialysis in PBS, 10% glycerol buffer. (▼) ELISA signal of the same scFv expressed with a C-terminal myc tag in a soluble form in the periplasm of *E. coli* as a positive control and (◆) ELISA signal for the negative control with BSA as an antigen.

ing of the antibody fragment makes this procedure particularly useful.

In the last step, we used different final dialysis procedures to transfer the labeled scFv into nondenaturing PBS buffer and compared these products by ELISA to the same scFv that was solubly expressed in the *E. coli* periplasm with the same C-terminal myc tag. This ensures that a given dialysis protocol leads to a correctly folded and site-specifically labeled scFv with a specific activity, which is comparable to an scFv obtained from soluble periplasmic expression. We used the following three dialysis protocols to transfer the IPL products from the 4 M urea buffer into physiological buffer: (1) directly into PBS, 10% glycerol with reduced/oxidized glutathione as an oxido-shuffling system to ensure proper formation of disulfide bonds. (2) PBS, 10% glycerol without an oxido-shuffling system. (3) Stepwise dialysis into 2 M urea in PBS, and then into 1 M urea in PBS, and finally into PBS, 10% glycerol with reduced/oxidized glutathione. The ELISA assay was performed on neutravidin-coated plates (BSA as a negative control) in which the myc-tagged scFv's were detected by a mouse anti-myc antibody, followed by an HRP-conjugated goat anti-mouse IgG.

The final transfer protocol of the IPL-labeled antibody fragment does not have a significant effect on the specific activity, as the three different dialysis conditions led to about the same activity in the ELISA assay (Figure 4). The comparison with the myc-tagged scFv that was solubly expressed in the *E. coli* periplasm shows that the activity is in the same range. The slightly lower signal for the myc-tagged scFv's that were obtained from the IPL under denaturing conditions is probably due to the fact that the conditions of the IPL usually lead to some cleavage of the scFv without ligation of the peptide, so the total signal resulting from the peptide label of the scFv is slightly reduced.

The periplasmic expression of the scFv-myc construct, however, led to much lower overall yields and does not allow the labeling of the antibody fragment with unnatural modifications such as fluorophores.

The expression and isolation of scFv's in a soluble form usually shows limited success, and the yields are very low. On the other hand, the expression in inclusion bodies

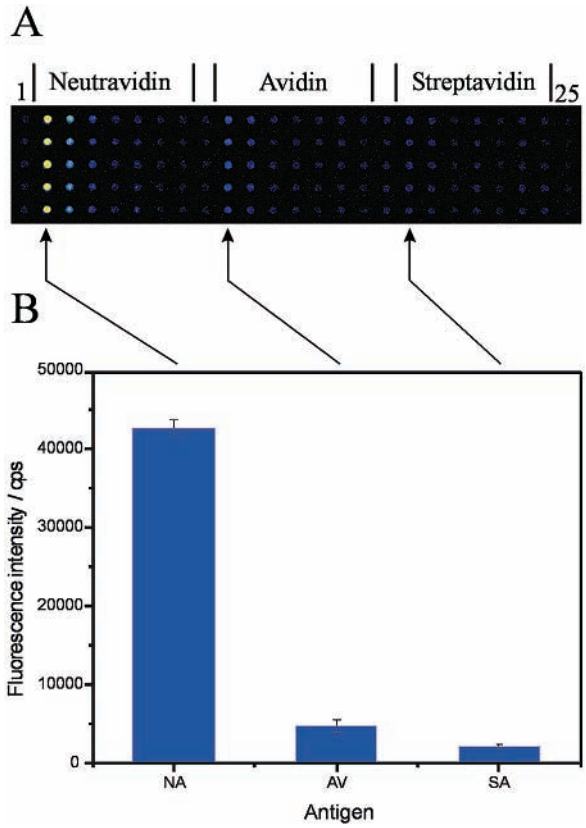

Figure 5. Biochip screening of the fluorescently labeled scFv E9 with different surface-immobilized antigens. A, Microarray surface with 50 μm spots containing different concentrations of the analytes and additional spots with no analyte as a control. Column 1: no analyte; columns 2−8: neutravidin spotted at concentrations of 500, 250, 125, 65, 31, 16, and 8 μg/mL; column 9: no analyte; column 10−16: avidin spotted at concentrations of 500, 250, 125, 65, 31, 16, and 8 μg/mL; column 17: no analyte; column 18−24: streptavidin spotted at concentrations of 500, 250, 125, 65, 31, 16, and 8 μg/mL; column 25: no analyte. B, Averaged fluorescence signals from the five spots with the highest concentration of the antigens (indicated by arrows), NA = neutravidin, AV = avidin, SA = streptavidin. Error bars represent the standard deviations of the averaged signals from the five replicates in each column. The averaged signals were not background subtracted.

results in higher expression yields, but the refolding to an active conformation is generally very difficult and also of limited success. Our technique circumvents these problems and adds the additional opportunity of C-terminal labeling of a single-chain antibody with unnatural modifications such as fluorophores.

Antigen Screening with a Fluorescently Labeled scFv in a Biochip Format. This advantage was further demonstrated by site-specific intein-mediated labeling of the scFv with a rhodamine-containing myc peptide (NH_2-CGGEQKLISEEDLNGGK(TAMRA)-$CONH_2$) using an identical protocol to that described above. To test the utility of the resulting fluorescent scFv, we used a biochip assay. The preparation of the surface was published elsewhere (*23*). The analyte neutravidin and two control proteins, avidin and streptavidin, were microarrayed on a TiO_2 chip containing a biotin-derivatized poly(L-lysine)-poly(ethylene glycol) copolymer (PLL-*g*-PEG-B30%), and the chips were then incubated with a 100 nM solution of the scFv-myc-TAMRA by interfacing the chip with a microfluidic channel array. After the chips were washed, the fluorescence on the chips was analyzed with a fluorescence scanner (Figure 5). The fluorescence intensity was quantified and averaged for five spots in each

row containing the antigens at varying concentrations. The results clearly show the binding properties of the fluorescently labeled scFv in a chip assay format. The specific binding of neutravidin compared to streptavidin and the weak cross-reactivity with avidin are in good correlation with BIAcore experiments that we performed (data not shown).

In contrast to ELISA's, chip-based assays can be performed in a more miniaturized format to ensure higher throughput and smaller sample consumption (*23*). The microfluidic channels interfacing the microarray have a volume of about 10 μL and contain 250 features with a 50 μm diameter. Therefore, the assay can be performed on a significantly smaller scale compared to other immunoassay formats.

In conclusion, the site-specific intein-mediated labeling of single-chain antibodies under denaturing conditions for biochip assays offers new possibilities in the work with antibody fragments. This technique can produce large amounts of active and site-specifically labeled scFv for different applications. The antibody fragment can initially be labeled with a fluorophore for antigen screening in a chip assay format. The same fusion protein can then also be used to introduce other modifications for an oriented immobilization of the antibody fragment on surfaces.

ACKNOWLEDGMENT

We thank Walter Khu and Zhenni Ding for the synthesis of the peptides. In addition, we thank David Wilson and Hans Beernink for critical reading of the manuscript.

Peptide Arrays for Highly Sensitive and Specific Antibody-Binding Fluorescence Assays

Oleg Melnyk,*,† Xavier Duburcq,*,‡,§ Christophe Olivier,§ Florence Urbès,§ Claude Auriault,‡ and Hélène Gras-Masse†

UMR CNRS 8525, UMR CNRS 8527, and Sedac-Therapeutics, Biological Institute of Lille, 1 rue du Pr Calmette, 59021 Lille, France. Received November 27, 2001; Revised Manuscript Received March 6, 2002

We report a novel generation of peptide arrays fabricated by site-specific ligation of glyoxylyl peptides onto glass slides covered by a semicarbazide sol−gel layer. These arrays allowed the highly sensitive and specific detection of antibodies in very small blood samples from infected individuals using three model peptidic epitopes (HCV Core and NS4, EBV Capsid) in an immunofluorescence assay. Comparison with standard enzyme-linked immunosorbent assays (ELISAs) demonstrated a large gain in sensitivity and specificity. These unique properties, combined with the possibility to immobilize glycoproteins such as antibodies, offer the possibility to perform sandwich immunofluorescent assays in a highly parallel format.

INTRODUCTION

Today, the miniaturization of biological assays is at the origin of crucial biological research and medical advances. In this respect, the design of miniaturized devices for the simultaneous highly sensitive and specific detection of antibodies from complex biological samples should represent a breakthrough. Over the past decade, the trends toward miniaturization of high-throughput screening systems have generated a great deal of interest in the scientific community. Microfabricated analytical devices have found applications in the field of gene expression profiling (*1*) or large-scale functional analysis of peptides (*2*−*4*) or proteins (*5*−*7*). Owing to the possibility to implement simultaneously a large variety of assays based on antibody or antigen detection, microarrays may revolutionize the diagnostic of infections. So far, applications of protein arrays to the detection of antibodies have displayed high background levels, low signal intensities, and cross-reactivities (*8*−*12*). As a result, the design of miniaturized devices for the highly sensitive and specific detection of antibodies from complex biological samples has not been achieved to date (*13*).

Here we report that a novel generation of peptide arrays, assembled by site-specific semicarbazone ligation of medium-sized peptides onto glass slides, allows the highly sensitive and specific detection of antibodies in very small blood samples from infected individuals. Three model peptidic epitopes (HCV Core and NS4, EBV Capsid) were used for antibody detection studies based on an immunofluorescent assay. The peptide arrays were analyzed with a fluorescence array scanner. A collection of referenced sera permitted demonstration of a large gain in sensitivity and specificity for our arrays as compared to the standard ELISA tests.

EXPERIMENTAL PROCEDURES

Peptide Synthesis. The peptides were synthesized in an automated peptide synthesizer (model Pioneer, Perseptive Biosystems Inc., MA) using the Fmoc/*tert*-butyl strategy (*14*).

Peptides **3** and **5**−**7** were synthesized on a poly(ethylene glycol) polyacrylamide copolymer (amino PEGA resin (*15*), Novabiochem, Meudon, France) derivatized with an isopropylidene tartrate linker as described in refs *27*−*29*. The peptides were purified by preparative RP-HPLC (C18−VYDAC, buffer A: deionized water containing 0.05% TFA; buffer B: acetonitrile/deionized water: 4/1 by vol. containing 0.05% TFA).

Peptide **3**, yield 21%, MALDI-TOF $[M + H]^+$ calcd 3587.0 found 3587.0. Peptide **5**, yield 21%, MALDI-TOF $[M + H]^+$ calcd 3733.1, found 3732.7. Peptide **6**, yield 25%, MALDI-TOF $[M + H]^+$ calcd 2755.4, found 2755.7. Peptide **7**, yield 34%, MALDI-TOF $[M + H]^+$ calcd 2606.3, found 2606.5.

For peptide **8** (0.1 mmol scale), peptide elongation was followed by acylation with diglycolic anhydride/DIEA: 4 equiv/4 equiv in DMF during 30 min. The peptidyl resin was washed with DMF (4 × 2 min) and then treated successively with 10 equiv of 4,7,10-trioxa-1,13-tridecanediamine (TTD), 3 equiv of DIEA, and 2 equiv of PyBOP (Novabiochem, Meudon, France) in DMF. After 30 min of reaction, the beads were washed with DMF (4 × 2 min) and acylated with Fmoc-L-Ser(O*t*Bu)-OH/HBTU/HOBt/DIEA: 10 equiv/10 equiv/10 equiv/30 equiv in DMF during 45 min. The resin was washed with DMF (4 × 2 min) and deprotected with DMF/piperidine: 4/1 by vol. The resin was washed with DMF (4 × 2 min) and CH_2Cl_2 (4 × 2 min) and dried. Deprotection and cleavage from the solid support was performed with TFA/H_2O/TIS: 95/2.5/2.5 by vol (2 h). The peptide was precipitated in cold ether, redissolved in aqueous acetic acid, and lyophilized. Periodic oxidation was performed in a pH 7.0 0.1 M phosphate buffer with 2 equiv of $NaIO_4$ (5 min). The peptide was purified by RP-HPLC on a C18 Nucleosil 320 × 12 mm column (100 Å, 5 μm), detection at 220 nm, 50 °C, 3 mL/min, 0−20% B in 20 min. Peptide **8**, yield 25%, MALDI-TOF $[M + H]^+$ calcd 2722.4, found 2722.5.

Published on Web 06/04/2002

For peptide **4** (0.1 mmol scale), peptide elongation was followed by acylation with Fmoc-L-Lys(Mtt)-OH. Removal of the Mtt group (*16*) with 1% TFA in CH_2Cl_2 (*17*) was followed by acylation with Fmoc-L-Ser(O*t*Bu)-OH as described for peptide **8**. The peptide was deprotected, cleaved with TFA/phenol/H_2O (10 mL/0.5 mL/0.75 g) (2 h), and precipitated in cold diethyl ether. The crude peptide was then oxidized with periodate as described for peptide **8**. Peptide **4** was purified by RP-HPLC on a C3 Zorbax 250 × 15 mm column, detection at 225 nm, 60 °C, 4 mL/min, 0−80% B in 60 min. Peptide **4**, yield 18%, MALDI-TOF $[M + H]^+$ calcd 3544.0, found 3543.8.

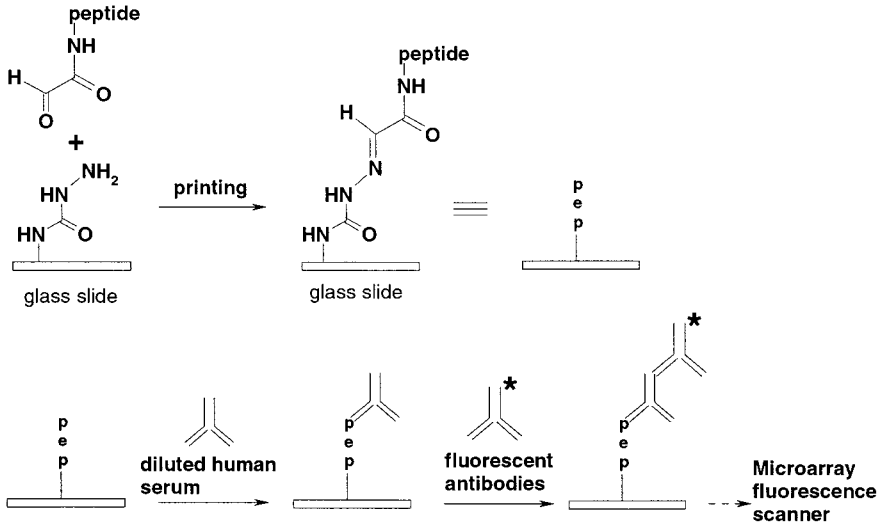
Amino acid composition of all the peptides was determined on a Beckman amino acid analyzer (model 7300, ninhydrin detection) following hydrolysis of aliquots in 6 N HCl/phenol (10/1 by vol) (48 h at 110 °C).

Semicarbazide Slides. Full details of semicarbazide glass slide optimization, characterization, and preparation will be reported elsewhere. Rapidly, glass slides (Esco, 114 slides at a time) cleaned with a H_2SO_4/H_2O_2 (1/1 by vol) solution were silanized with 3-aminopropyltrimethoxysilane. The amino slides were treated with triphosgen/diisopropylethylamine in 1,2-dichloroethane and Fmoc-$NHNH_2$ in DMF, respectively, to install the semicarbazide functions. Finally, removal of the Fmoc groups was performed with piperidine/DBU in dimethylformamide. Four slides were used for the quality control. Three slides were immersed 1 h at 37 °C in a 10^{-4} M solution of Rho-Lys-Arg-$NH(CH_2)_3NH-CO-CHO$ (synthesized according to ref 27−28, where Rho is (5)-6-carboxytetramethylrhodamine). One slide was treated with the control peptide Rho-Lys-Arg-NH_2. The fluorescence intensity of the slides was quantified using an Affymetrix 418 Array Scanner (MWG). Typically, the mean fluorescence intensity of semicarbazide slides treated with the glyoxylyl-rhodaminated probe was found to be 36260 (SD 3940) at L35, PMT50 scanner sensitivity (control slide: mean fluorescence 3450, SD 486). Both fluorescent probes were found to adsorb similarly on untreated slides (mean fluorescence for the glyoxylyl probe: 7790, SD 670, mean fluorescence for the amide probe: 5270, SD 930, L35, PMT50).

Human Sera. Sera were collected from the clinical laboratory of the Centre Hospitalier Régional (Lille, France). The reactivity of HCV-referenced sera was determined with the AxSYM HCV version 3.0 Abbott ELISA kit (30 HCV-negative and 100 HCV-positive individuals). The reactivity of EBV-referenced sera (36 HCV-positive and 15 HCV-negative individuals) was determined using an immunofluorescence assay (anti-VCA IFA, Immunoconcept).

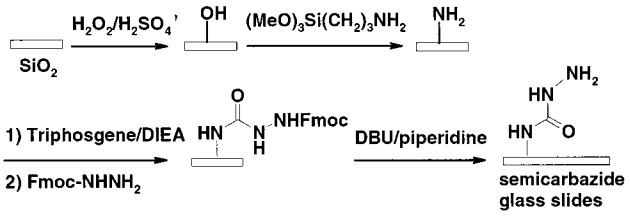
ELISAs. Microtiter plate wells (Carbo-bind, Costar, Corning Inc., NY) were coated 60 min at 37 °C with the peptide (5 μg/mL in 0.1 M acetate buffer pH 5.5). The wells were washed and then saturated with 2.5% milk in PBS (0.01 M phosphate buffer supplemented with 1.8% NaCl pH 7.4) at 37 °C. After four washings with PBS 0.05% Tween 20 (PBS-T, Sigma-Aldrich, Saint Quentin Fallavier, France), human sera diluted 1/100 in PBS plus 0.5% Tween 20 plus 2.5% milk were incubated in coated wells for 120 min at 37 °C. After four washings, the peroxidase-conjugated goat antibodies to human IgG-A-M (Diagnostic Pasteur, Marnes la Coquette, France), diluted 1/10000 in PBS plus 0.5% Tween 20 plus 2.5% milk, were incubated for 60 min at 37 °C. Bound conjugated antibodies were detected using *o*-phenylenediamine dihydrochloride substrate (Sigma) plus H_2O_2 in 0.05 M citrate buffer pH 5.5, for 30 min in the dark at room temperature. The reaction was blocked by addition of 2 N H_2SO_4. The absorbance was recorded against a blank at 492 nm through a multichannel automatic plate-reader (M_R 5000, Dynatech, Grafton, Ohio). Mean at 492 nm + 3 standard deviation (SD) of HCV-sera were used as cutoff values in the ELISAs. The ELISAs were performed at least twice to assess their reproducibility.

Peptide Arrays. A manual arrayer (Microarray Printer XMM 47832, Xenopore, Hawthorne, NJ) equipped with 32 pins was used to print the slides. Similar results were obtained using an Affymetrix 417 arrayer. The printed slides were incubated overnight at 37 °C in a humid chamber and stored until use at room temperature for a period ranging from days to several months. The slides were washed and incubated during 120 min at 37 °C under microscope slide with 50 μL of human sera diluted 1/50 in PBS plus 0.5% Tween 20 plus 2.5% milk. After four washings, 50 μL of the rhodamine(TRITC)-conjugated goat antibodies to human IgG-A-M (Jackson ImmunoResearch Laboratories, Baltimore, MD), diluted 1/100 in PBS plus 0.5% Tween 20 plus 2.5% milk, were incubated for 60 min at 37 °C under cover glass. The slides were then washed, dried, and scanned with an Affymetrix 418 Array Scanner (MWG). The data where analyzed using the ScanAlyse software (Stanford University).



Immobilization of Antibodies on Semicarbazide Slides. The antibodies (donkey IgG anti-goat IgG F(c), Rockland, Gilbertsville, PA, or goat IgG anti-human Ig G−A-M, Jackson ImmunoResearch Laboratories, Baltimore, MD) were oxidized as described in ref 32. Following oxidation, the antibodies (600 μg) were dialyzed (nanosep tubes, Pall Gelman Laboratory, Ann Arbor, MI) against acetate buffer pH 5.5 0.1 mM (six washings), solubilized in 40 μL of acetate buffer pH 5.5 0.1 mM and placed in a 384-well plate. Ten slides were printed using a manual Xenopore XMM 47832 printer and incubated one night at 37 °C in a humid chamber. The slides were washed and incubated under cover glass with 50 μL of rhodamine conjugated goat IgG F(c) fragment (Rockland, Gilbertsville) diluted 1/100 in PBS plus 0.5% Tween 20 plus 2.5% milk (60 min at 37 °C). The slides were washed, dried in air, and analyzed with an Affymetrix 418 Array Scanner. The data were processed with the ScanAlyse software.

RESULTS AND DISCUSSION



Glass Slide Design and Preparation. The design of miniaturized devices for the highly sensitive and specific detection of antibodies from complex biological samples represents a challenge which, besides the selection of the probes, relies mainly upon the surface properties of the array. We first hypothesized that the optimal surface for antibody detection would be uncharged at neutral pH and highly hydrated. Indeed, neutral hydrophilic polymers have been found to reduce protein adsorption on different surfaces (*18, 19*). Second, the surface should be chemically inert toward immunoglobulins but should allow the covalent site-specific and dense immobilization of synthetic polypeptides so as to favor the antigen accessibility and to reach high signal-to-noise ratios. Glass slides covered by a semicarbazide sol−gel layer were found to meet all these criteria, and in conjunction with the well developed chemistry of glyoxylyl peptides (*20*) were used to elaborate a novel generation of peptide arrays assembled by semicarbazone site-specific ligation (Scheme 1).

The optimization, characterization, and preparation of semicarbazide glass slides will be reported in a paper devoted to the fabrication of oligodeoxynucleotide mi-

Scheme 1. Semicarbazone Assembled Peptide Arrays

Scheme 2. Preparation of Semicarbazide Glass Slides

croarrays using a similar immobilization strategy (*21*, *22*). Very rapidly as shown in Scheme 2, microscope glass slides were cleaned with H_2SO_4/H_2O_2 (piranha solution) and silanized with 3-aminopropyltrimethoxysilane. The amino slides were then treated successively with triphosgen/DIEA and Fmoc-$NHNH_2$ (*23*) in DMF to install the semicarbazide groups. Finally, removal of the Fmoc groups was performed with piperidine/DBU in dimethylformamide. The density and homogeneity of the semicarbazide sol−gel layer was evaluated by immersing the slides in a solution of a glyoxylyl dipeptide labeled with (5)-6-carboxytetramethylrhodamine (Rho-Lys-Arg-NH-$(CH_2)_3$NH−CO−CHO, peptide **1**) followed by quantification of the fluorescence using the Cy3 channel of a DNA microarray scanner. Immobilization through site-specific semicarbazone formation was demonstrated by several control experiments using either underivatized dipeptide **2** Rho-Lys-Arg-NH_2 on semicarbazide slides or glyoxylyl peptide **1** on slides lacking the semicarbazide functionality (see Experimental Section).

Synthesis of Model Glyoxylyl Peptide Antigens. The three model sequences selected for our study are derived from immunodominant and conserved regions of hepatitis C virus (HCV, core p21 15−45 (*24*), NS4 1925−1947 (*25*)) and Epstein−Barr virus (EBV, VCAp18 153−176 (*26*)). The corresponding glyoxylyl peptides are shown in Figure 1. For the HCV core p21 antigen, the glyoxylyl group was placed either at the N-terminus at the extremity of a Lys side-chain (peptide **4**) or at the C-terminus. In this later case, two different spacers were used to document the influence of the distance between the peptide and the glass surface upon the detection of antibodies (peptides **3** and **5**). N- or C-glyoxylyl derivatives were also synthesized for the EBV VCAp18 peptide (peptides **7** and **8**). Only one derivative was evaluated for the HCV NS4 peptide (peptide **6**).

Peptides **3**, **5**−**7** were synthesized on the solid phase using an isopropylidene tartrate-based linker and the Fmoc/*t*Bu strategy as described elsewhere (*27*, *28*, *29*). Peptides **4** and **8** were obtained from the corresponding seryl precursors by treatment with $NaIO_4$ according to Geoghegan et al. (*30*). For H-Lys(Ser)−HCV core p21 15−45, the peptide elongation step using the Fmoc/*t*Bu strategy was followed by coupling with Boc-L-Lys(Fmoc)-OH. The Fmoc group was removed with piperidine and the ϵ-amino group was acylated with Fmoc-L-Ser(O*t*Bu)-OH. The peptidyl resin was deprotected and cleaved from the solid support as usual with concentrated trifluoroacetic acid. For the seryl precursor of peptide **8**, the peptidyl resin was treated with diglycolic (DG) anhydride to introduce a carboxylic acid function on the N-terminus.

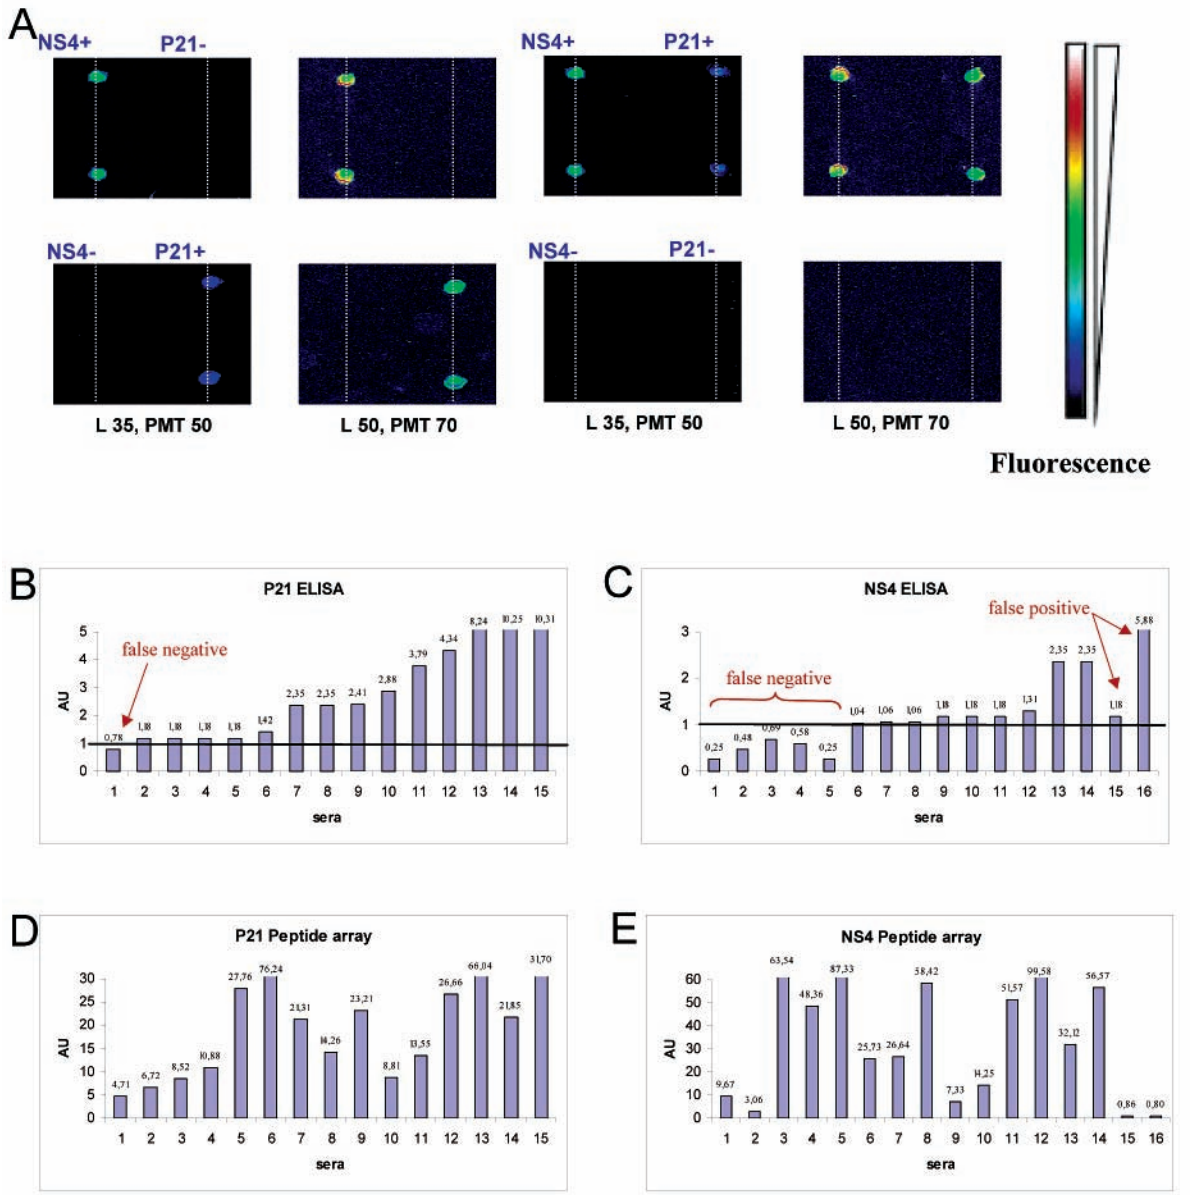

Figure 2. Detection of antibodies to peptides **5** (HCV p21) and **6** (HCV NS4) expressed in arbitrary units (AU). AU = signal value/cutoff. (Cutoff = 1 AU = mean of the background + 3 SD). (a) Scanning image of HCV+ (NS4+P21+, NS4+P21-, NS4−P21+) and HCV− sera at a low (L35, PMT50) or high (L50, PMT70) scanner sensitivity. (b) Detection of antibodies to peptide **5** by ELISA for 15 sera. (c) Detection of antibodies to peptide **6** by ELISA for 16 sera. (d) Peptide **5** array fluorescence for the same sera as b. (e) Peptide **6** array fluorescence for the same sera as c.

In situ activation of the carboxylic acid group with PyBOP in the presence of 4,7,10-trioxa-1,13-tridecanediamine (TTD) was followed by acylation with Fmoc-L-Ser-(O*t*Bu)-OH. Deprotection and cleavage from the support afforded H-Ser-TTD-DG-EBV VCAp18 peptide.

Peptide Array Spotting. The glyoxylyl peptides were printed using a manual arrayer from Xenopore, which led to a spot diameter of about 550 μm. Similar results were obtained using an Affymetrix 417 arrayer (spot diameter of 160 μm) showing that the data did not depend on the printing technology. As for rhodaminated probe **1**, the presence of a glyoxylyl group on the HCV p21 peptide is essential for an efficient immobilization on semicarbazide slides. The glyoxylyl antigens were printed at a concentration of 10^{-4} M in a pH 5.5 acetate buffer. HCV p21 and NS4 peptides were also printed as a 1/1 mixture using the same experimental conditions. The slides were incubated overnight in a humid chamber at 37 °C and then directly used for antibody detection. Importantly, no further chemical treatment for the capping of the remaining semicarbazide groups was found to be necessary before the incubation with the sera.

Detection of Antibodies by an Immunofluorescent Assay. Comparison with Enzyme-Linked Immunosorbent Assays. The peptide arrays were utilized for the detection of antibodies as shown in Scheme 1. Incubation with diluted human sera was followed by detection of immobilized antibodies with a rhodamine-labeled anti-human Ig-G-A-M antibodies. These two steps were performed under a cover glass and required minutes quantities of sera (1μL) and labeled antiboby (1 μg). The slides were imaged using the Cy-3 channel of a DNA microarray scanner.

A referenced collection of 130 sera of HCV infected (100) or not (30) individuals was analyzed using the peptide array technology and by ELISA (AxSYM HCV version 3.0 Abbott, or ELISA with p21 or NS4 antigens coated on carbo-bind plates). The background noise of the arrays, defined as the fluorescence signal between the printed spots, was found to be very low for all the tested

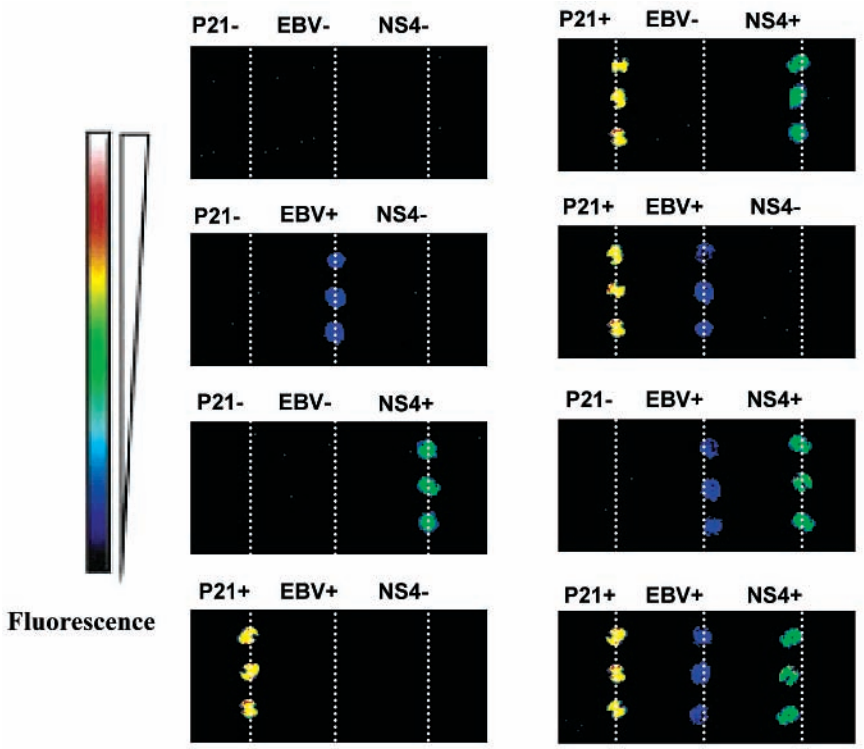

Figure 3. Scanning image of HCV+ (NS4+P21+, NS4+P21−, NS4−P21+), HCV−, and EBV VCAp18+ or EBV VCA p18- sera at a L35, PMT50 scanner sensitivity (peptides **5**, **6**, and **8**).

sera and corresponded to 0.1% of the highest signal observed. Interestingly, the fluorescence obtained with the sera of noninfected individuals was always found to be below the mean of the background + 3 SD, even at a high scanner sensitivity (Figure 2A).

Analogously, no fluorescence was observed for HCV+p21- or HCV+NS4- sera with p21 or NS4 peptides, respectively. Thus, to the contrary of ELISAs, no nonspecific binding could be detected with peptide arrays. Consequently, the cutoff value of positivity was defined as the mean of the background + 3 SD. The data collected in Table 1 show that peptide arrays and ELISAs were in agreement for 117 sera (entries 1, 2, and 8).

For the 13 sera, where discrepancies were observed between the different tests (entries 3−7, Table 1), an additional analysis was performed using a western-blot assay (CHIRON RIBA HCV 3.0 SIA, Ortho-Clinical Diagnostics), which is the most sensitive and specific test for HCV antibodies detection. The western-blot assay confirmed the peptide array results, and that these sera were false positive or false negative by ELISA. Thus, at least for the selected model epitopes, peptide arrays displayed 100% of sensitivity and specificity. In addition, the arrays were found to be much more sensitive than ELISAs, since comparison of ELISA and peptide array data indicated an average gain in sensitivity of about 8. Figure 2b−e detail the fluorescence and absorbance values for HCV+p21+ or HCV+NS4+ sera just above the cutoff value in ELISA, expressed in arbitrary units (AU) as defined in the legend of Figure 2. The consequence of this gain in sensitivity is that false negative sera or sera just above the ELISA cutoff were detected without ambiguity using the peptide arrays.

The same sensitivity and specificity levels were reached with the VCAp18 EBV peptides **7** or **8**. Indeed, 36 EBV-positive sera were found positive with the peptide array technology, whereas the fluorescence values associated with the 15 EBV-negative sera were always below the cutoff value of positivity (as for HCV sera, background + 3SD). Interestingly, when peptides **5**, **6**, and **8** were printed on the same slide, no cross-reaction was observed between a particular peptide and antibodies specific for the two others (Figure 3). These data illustrate the high specificity of this peptide array technology, an essential characteristic to permit the application of the array format for the simultaneous detection of different antibodies.

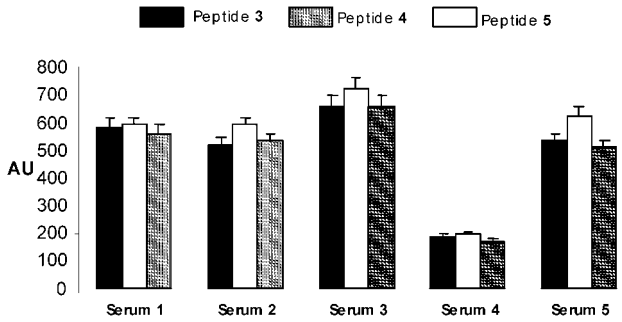

Figure 4. Influence of the spacer and of the glyoxylyl group position upon the detection of antibodies directed against HCV core p21 15−45 antigen, HCV+ sera, L35, PMT 50.

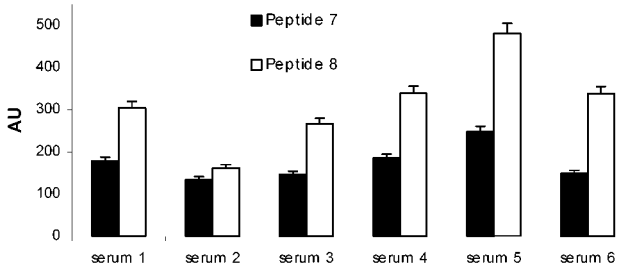

Figure 5. Influence of the glyoxylyl group position upon the detection of antibodies directed against EBV VCAp18 antigen, data expressed in arbitrary units (AU), HBV+ sera, L35, PMT50.

Influence of the Spacer and of the Glyoxylyl Group Position. Peptides **3**−**5** permitted us to evaluate both the influence of the spacer separating the peptide from the glass surface and of the site of immobilization for the HCV p21 antigen. The data presented in Figure 4 show that no significant difference could be observed between these three peptides. For the site-specific immobilization through the C-terminus, the size of the spacer seemed to have little or no effect on antigen recognition.

To the contrary of HCV p21, detection of antibodies directed against EBV VCAp18 antigen was found to be highly dependent upon the site of attachment to the glass surface (Figure 5). Indeed, peptide **8** permitted to improve significantly the detection of antibodies in the cases where peptide **7** displayed low ratios. Nevertheless, both peptides displayed the same levels of sensibility and specificity for the serodetection of EBV infections, at least for the tested sera.

Quality Control, Reproducibility, Stability upon Storage. An important aspect of antibody detection is the reproducibility of the assay. To document the spot to spot reproducibility, peptide **5** was spotted 600 times on the same slide. The array was incubated with an HCV p21 + serum and treated as described before (Figure 6a). The standard deviation (SD) of the fluorescence for 600 spots was found to be 5.1%. Figure 6b details the fine structure of a spot and shows that the fluorescence inside the spot was uniform, an essential characteristic for the automation of fluorescence measurements.

Another important aspect of the peptide array methodology is the possibility to reach high slide to slide reproducibility levels. To check this point, 12 slides were spotted with peptide **5** (600 spots) and treated with the same HCV+ serum. The SD between the mean fluorescence of the spots and of the background for the different slides was found to be only 4.5%.

Finally, the peptide arrays were also tested for their stability upon storage. For peptides **5**−**7**, no significant variation in fluorescence intensity of the spots and of the background was observed following up to 6 months of aging at 37 °C in a humid chamber (Figure 7). This feature can be attributed to the high chemical stability of the semicarbazone linkage and of the sol−gel layer.

Site-Specific Immobilization of Antibodies. To broaden the utility of this methodology, we have also shown that semicarbazide slides allow the immobilization of glycoproteins and thus can be used for the preparation of protein arrays or mixed peptide−proteins arrays. Indeed, periodic oxidation is a well established and mild method for generating aldehyde groups on glycoproteins (*31*, *32*). The reaction of these aldehyde groups with semicarbazide functionalized slides leads to the covalent immobilization of the proteins. For example, oxidized donkey IgG anti goat IgG Fc and goat IgG anti human

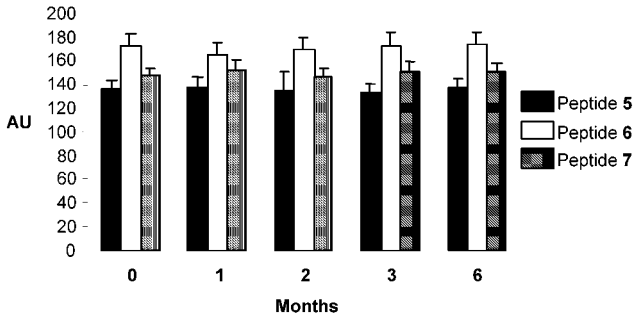

Figure 7. Stability of peptide arrays upon accelerated aging, peptides **5**−**7**, HCV+ and EBV+ referenced sera, data expressed in arbitrary units (AU), L35, PMT50.

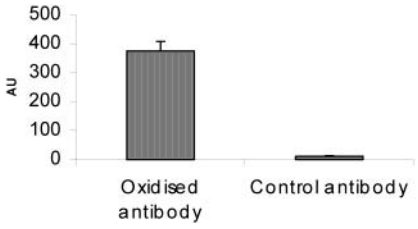

Figure 8. Site-specific immobilization of oxidized antibodies, scanner sensitivity L35, PMT50.

IgG-A−M were immobilized on semicarbazide slides and incubated with goat IgG Fc fragment labeled with rhodamine. Figure 8 shows that the fluorescence associated with donkey antibodies was found to be high, whereas fluorescence associated with the control goat antibodies corresponded to the background. Importantly, the slides were printed, washed, and incubated using the procedures employed for peptide arrays. Since these conditions retained the binding capacity and the specificity of immobilized antibodies, the simultaneous detection of antibodies and of circulating antigens on the same slide seems conceivable.

CONCLUSION

At the origin, microarrays were developed to utilize the huge amount of information provided by genome projects, but they have clear potential for many other fields where multiple tests have to be performed using very small biological samples. We have demonstrated that arrays, assembled by semicarbazone site-specific ligation of synthetic polypeptides to glass slides, displayed very high sensitivities and specificities for antibodies directed toward several model peptidic epitopes. These unique properties combined with the possibility to immobilize glycoproteins should find many applications such as sandwich immunofluorescent assays, detection of circulating antigens, epitope mapping, and high throughput screenings.

ACKNOWLEDGMENT

We thank CNRS, Université de Lille 2, Institut Pasteur de Lille and Sedac-Therapeutics for financial support, Rémi Desmet, Annick Blanpain, and Eric Diesis for technical assistance, Frédéric Malingue for data studies, David Hot and Ludovic Huot for fluorescence measurements, Thomas Heim for AFM studies, and Steven Brooks for proofreading the manuscript. We thank Pr Yves Lemoine for giving us an access to the Affymetrix 418 array scanner and Affymetrix 417 arrayer.

DOTA−D-Tyr[1]-Octreotate: A Somatostatin Analogue for Labeling with Metal and Halogen Radionuclides for Cancer Imaging and Therapy

Wen Ping Li,[†] Jason S. Lewis,[†] Joonyoung Kim,[†] Joseph E. Bugaj,[‡] Michael A. Johnson,[‡] Jack L. Erion,[‡] and Carolyn J. Anderson*[,†]

Mallinckrodt Institute of Radiology, Washington University School of Medicine, St. Louis, Missouri 63110 and Mallinckrodt, Inc. 675 McDonnell Blvd., St. Louis, Missouri 63134. Received December 10, 2001; Revised Manuscript Received April 25, 2002

The goal of this study was to evaluate a somatostatin receptor ligand, DOTA−D-Tyr[1]-octreotate (DOTA-DY1-TATE), that has the chelator 1,4,7,10-tetraazacyclotetradecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA) attached to the D-Tyr[1] residue, allowing radiolabeling with both radiohalogens and radiometals. A potential advantage of having a chelator attached to the Tyr[1] residue is that halogen radiolabels may residualize or remain trapped in tumor cells rather than clear from the tumor. DOTA-DY1-TATE was synthesized by solid-phase methods and radiolabeled with ^{61}Cu, ^{64}Cu, and ^{125}I in high radiochemical purity and specific activity. A competitive binding assay demonstrated that ^{nat}Cu-DOTA-DY1-TATE and DOTA-^{nat}I-DY1-TATE had comparable affinity to ^{nat}In-DTPA-OC in AR42J rat pancreatic tumor cells membranes. ^{61}Cu-DOTA-DY1-TATE had a dissociation constant (K_d) of 176.4 pM and a receptor concentration (B_{max}) of 244.4 fmol/mg. A tumor uptake of 1.515 %ID/g was determined for ^{64}Cu-DOTA-DY1-TATE and 0.814 %ID/g for DOTA-^{125}I-DY1-TATE in AR42J tumor bearing Lewis rats at 1 h postinjection. DOTA-^{125}I-DY1-TATE remained in the tumor at a higher concentration out to 4 h postinjection, suggesting that the iodine may have residualized in the tumor cells. MicroPET imaging of ^{64}Cu-DOTA-DY1-TATE in AR42J tumor bearing rats and SCID mice at 2 h postinjection showed significant uptake and good contrast in the thigh tumors in the rat model and in the neck and thigh tumors of the mouse. This study demonstrates that DOTA-DY1-TATE is a somatostatin analogue that can be labeled with both metal and halogen radionuclides, and its ^{64}Cu- and ^{125}I-radiolabeled compounds showed somatostatin receptor-mediated uptake in normal and tumor tissues.

INTRODUCTION

Over the last 15 years, considerable progress has been made in the investigation of radiolabeled somatostatin analogues as radiotherapeutic agents for somatostatin receptor-positive tumors. A number of studies have focused on improving the target tissue uptake of radiolabeled somatostatin analogues. It has been shown that changing the C-terminus from an alcohol to a carboxylic acid increases uptake of the peptide in somatostatin subtype 2 receptor (SSTR2)-positive tissues (*1*−*3*). It has further been shown that replacing the N-terminal D-Phe in octreotide with D-Tyr allows iodination of the N-terminus and subsequent residualization of the iodinated D-amino acid (*4*). Therefore, in this current study we synthesized DOTA−D-Tyr[1]-octreotate (DOTA-DY1-TATE, Figure 1) to allow both radiolabeling with halogens (e.g., ^{124}I, ^{125}I, ^{131}I, ^{76}Br, ^{77}Br), as well as radiometals (e.g., ^{86}Y, ^{90}Y, ^{68}Ga, ^{177}Lu, ^{111}In, ^{64}Cu). One of our goals is to achieve higher somatostatin receptor binding affinity and better target tissue uptake as well as allow halogen radionuclides to residualize in target tissues.

The use of positron-emitting halogen radionuclides, specifically ^{124}I ($t_{1/2}$ = 4.2 d) and ^{76}Br ($t_{1/2}$ = 16 h), to label radiopharmaceuticals for PET imaging has increased greatly over the past decade. For example, ^{76}Br has been labeled to octreotide (*5*) and ^{76}Br-labeled bromodeoxyuridine has been investigated as a tumor and brain imaging agent (*6*, *7*). Iodine-124 is currently used to produce [^{124}I]-5-iodo-2′-fluoro-1-β-D-arabinofuranosyl-uracil (FIAU) which has been used to image gene expression (*8*). Copper-64 [$t_{1/2}$ = 12.8 h; 40% β^- (0.656 MeV); 19% β^+ (0.6 MeV); 38% EC] has diverse applications in radiopharmaceutical chemistry for PET imaging as well as therapy (*9*, *10*). Copper-61 [$t_{1/2}$ = 3.35 h; 60% β^+ (1.21 MeV); 40% EC] is another cyclotron-produced positron-emitting radionuclide that is made at Washington University using the same targetry system as is used for ^{64}Cu (*11*). Moreover, ^{61}Cu and ^{64}Cu can be produced on demand in high yield and in high specific activity on a small biomedical cyclotron (*11*, *12*).

The AR42J rat pancreatic carcinoma cell line is known to express SSTR2 both in vitro and in vivo (*13*, *14*). AR42J cells grown in culture were utilized to evaluate the in vitro binding affinity and were implanted in

immature, normal Lewis rats for in vivo biodistribution and microPET imaging. In this study, we determined the in vitro binding affinity of copper-labeled DOTA-DY1-TATE to AR42J tumor cell membranes and investigated the in vivo biodistribution of ^{64}Cu-DOTA-DY1-TATE and DOTA-^{125}I-DY1-TATE in AR42J tumor bearing rats. MicroPET imaging studies of ^{64}Cu-DOTA-DY1-TATE were carried out in the AR42J tumor-bearing SCID mice and immature Lewis rats.

MATERIALS AND METHODS

Materials and Analyses. ^{61}Cu and ^{64}Cu were produced on a Cyclotron Corporation CS-15 biomedical cyclotron at Washington University of School of Medicine, using previously reported methods (*11*, *12*). Sodium[^{125}I]-iodide was purchased from NEN LifeScience (Boston, MA). Indium-111-chloride ($^{111}InCl_3$) was obtained from Mallinckrodt, Inc. (St. Louis, MO). IODO-GEN precoated iodination tubes were purchased from Pierce (Rockford, IL). Reversed-phase extraction C-18 SepPak Light cartridges were obtained from Waters (Milford, MA). Ammonium acetate (NH_4OAc) was purchased from Fluka Chemical Co. (Ronkonkoma, NY); Copper acetate (99.99%) and indium acetate (99.95%) were purchased from Alfa Morton Thiokol Inc. (Danvers, MA). Trifluoroacetic acid (TFA) was obtained from J. T. Baker (Chicago, IL). All other chemicals were purchased from Aldrich Chemical Co., Inc. (Milwaukee, WI). All solutions were prepared using ultrapure water (18 MΩ-cm resistivity). Thin-layer chromatography (TLC) was performed using Whatman $MKC_{18}F$ reversed phase plates with 10% ammonium acetate:methanol (30:70) as the mobile phase. Radio-TLC detection was accomplished using a BIOSCAN System 200 Imaging Scanner (Washington, DC). Analytical reversed-phase HPLC was accomplished on a Waters (Milford, MA) 600E chromatography system with a Waters 991 photodiode array detector and an Ortec Model 661 (EG&G Instruments, Oak Ridge, TN) radioactive detector. Millenium 32 software (Waters, Milford, MA) was used to quantify chromatograms by integration. All HPLC samples were analyzed on a Vydac Protein & Peptide C-18 column (2.2 × 25 cm). The mobile phase was H_2O (0.1% TFA) (solvent A) and 90% acetonitrile (ACN) (0.1% TFA) (solvent B). The gradient consisted of 5% B to 75% B in 25 min (1.0 mL/min flow rate). Radioactive samples were counted using a Beckman 8000 automated well-type counter (Fullerton, CA).

Preweaned (21-day old, 40−50 g) male Lewis rats were purchased from Charles River Laboratories (Boston, MA) and Female SCID-Fox Chase CB-17 mice (29−35 days old, 25−30 g) were purchased from Taconic Farms Inc (Germantown, NY). The AR42J tumor line was obtained from American Type Culture Collection (ATCC, Rockville, MD).

Synthesis of DY1-TATE and DOTA-DY1-TATE. The synthesis of DYI-TATE and DOTA-DY1-TATE were accomplished by using similar methods previously described (*3*). Briefly, solid-phase peptide synthesis (SPPS) was carried out on an Applied Biosystems model 432A "Synergy" peptide synthesizer using the Fmoc (9-fluorenylmethoxy-carbonyl) methodology. Activated Fmoc-protected amino acids (25 μmol) were required by the instrument protocol. Activation was performed by combining 1-hydroxybenzotriazole (HOBt) and 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU). DOTA-tris(*tert*-butyl ester) (Macrocyclics, Dallas, TX) was activated and coupled to Fmoc-protected amino acid. Final purifications of the peptides were accomplished by reversed-phase HPLC, employing a Vydac Protein & Peptide C-18 column (2.2 × 25 cm).

Preparation of Radiolabeled Somatostatin Analogues. DTPA-OC was labeled with ^{111}In as previously described (*15*). Radiolabeling with ^{61}Cu and ^{64}Cu was carried out by addition of 1−5 mCi (37−185 MBq) of ^{61}Cu or ^{64}Cu in 0.1 M ammonium acetate (pH 6.5) to 1−5 μg of the peptide in 0.1 M ammonium acetate followed by 30 min incubation at 65 °C as previously reported (*16*). The $^{64/61}$Cu-labeled DOTA-DY1-TATE was purified on a C-18 SepPak Light cartridge, using 100% ethanol as the elution solvent, and radiochemical purity was determined by radio-TLC or radio-HPLC.

Radioiodinated DOTA-DY1-TATE was synthesized using the IODO-GEN method (*17*, *18*). Briefly, Na[^{125}I] [300−400 μCi (11.1−14.8 MBq)] was added to 10 μg of DOTA-DY1-TATE diluted with 0.01 M PBS (100 μL) in a glass vial coated with IODO-GEN (50 μg). The reaction mixture was removed from the reaction vessel following 25 min of incubation at room temperature. The solution was then diluted with 3 mL of water. The resulting solution was eluted through a C-18 reversed-phase extraction cartridge, which was preconditioned with 5 mL of 70% ethanol and subsequently activated with 5 mL of 2-propanol. The cartridge was rinsed successively with 5 mL of distilled water and 5 mL of 0.5 M acetic acid. The radioiodinated peptide was eluted in 5 mL of 96% ethanol, and the solvent was evaporated at room temperature under a gentle stream of nitrogen. The dry residue was reconstituted in 1−3 mL of 0.9% NaCl.

The cold copper and indium agents (^{nat}Cu-DOTA-DY1-TATE, ^{nat}Cu-DOTA-Y3-TATE, ^{nat}In-DTPA-OC) for the receptor binding assays were prepared by the reaction of copper and indium acetate using the same procedure described above for radiolabeling of DOTA-DY1-TATE with ^{61}Cu, ^{64}Cu, and ^{111}In. DOTA-^{nat}I-DY1-TATE was synthesized by following the same procedure as for DOTA-^{125}I-DY1-TATE, and the reaction yield was confirmed by HPLC.

In Vitro Receptor Binding Assay. The binding affinity of Cu-DOTA-DY1-TATE was measured in AR42J rat pancreatic tumor membranes using methods previously described with minor modifications (*9*). Briefly, ^{61}Cu-DOTA-DY1-TATE was displaced with increasing concentrations of ^{nat}Cu-DOTA-DY1-TATE. A competitive binding assay was performed by displacing ^{111}In-DTPA-OC with the competing ligands ^{nat}Cu-DOTA-DY1-TATE, ^{nat}Cu-DOTA-Y3-TATE, ^{nat}In-DTPA-OC and DOTA-^{nat}I-DY1-TATE. Assays were carried out using the Millipore Multiscreen system (Bedford, MA) (*9*). The best-fit IC_{50} values, the dissociation constant (K_d), and the number of SSTR2 binding sites (B_{max}) for the AR42J cells were calculated using PRISM (Graphpad, San Diego, CA).

Animal Models. All animal experiments were performed in compliance with the Guidelines for the Care and Use of Research Animals established by Washington

University's Animal Studies Committee. For AR42J tumor-bearing mice, AR42J cells were grown as xenografts in female SCID mice. Briefly, AR42J cells (1×10^7), grown in F-12K Nutrient mixture medium containing 20% fetal calf serum (FCS) were injected subcutaneously, bilaterally, into flanks and necks of female SCID mice (*19*). The tumors were allowed to grow 10−12 days until 0.5−0.9 g in size. Male Lewis rats (21 d old) were implanted with AR42J tumors in the necks or/and left legs from tumor obtained from Mallinckrodt, Inc (St. Louis, MO) (passage 36) and maintained by serial passage in animals. Tumor was excised from euthanized rats and was rinsed with sterile saline and placed on ice in a Petri dish containing Gibco Media 199 (Sigma Chemical Co., St. Louis, MO). Connective and necrotic tissue were removed, and the material was diced into small pieces (2×2 mm). The freshly dissected pieces were delivered to the left flank of the animal via a 13-gauge trocar inserted subcutaneously. AR42J tumor growth was observed for 2 weeks after implantation, and tumors achieved a solid, palpable mass of 1.0−1.5 g in size by ∼14 days postimplantation.

Biodistribution of ^{64}Cu-DOTA-DY1-TATE and DOTA-^{125}I-DY1-TATE. Biodistribution studies were carried out using immature (∼33 day old) male Lewis rats bearing AR42J tumors (12 days post-implant) in the left flank. Anesthetized animals received a coinjection of ^{64}Cu-DOTA-DY1-TATE and DOTA-^{125}I-DY1-TATE (32 μCi for ^{64}Cu, 5 μCi for ^{125}I, 0.68 μg peptide for each compound) via the tail vein. The animals were euthanized at 1, 4, 24, and 72 h postinjection. A group of 5 rats were coinjected with a blocking dose of DY1-TATE (150 μg) and sacrificed 1 h postinjection. Following euthanization, the tissues and organs of interest were removed and weighed, and the radioactivity was measured in a gamma counter. Standards ($n = 5$) were prepared to verify the counting efficiency of the gamma counter for each radionuclide. Samples were first counted for ^{64}Cu using a specific energy window that did not have detectable crossover for ^{125}I. After allowing for complete decay of the ^{64}Cu (>12 half-lives), the samples were then counted using the energy window specific for ^{125}I. The percent injected dose per gram (% ID/g) and percent injected dose per organ (% ID/organ) were calculated by comparison with standards representing the injected dose per animal. A group of five rats that were sacrificed at 72 h postinjection were housed in individual metabolism cages for the collection of urine and feces at various time points from 1 to 72 h for determination of the %ID excreted.

MicroPET Images. Positron emission tomography (PET) imaging was performed on the first commercially available microPET (Concorde Microsystems, Knoxville, TN) which was based on the design of Cherry and colleagues (*20*). Imaging studies were carried out on four SCID mice and four male Lewis rats carrying AR42J tumors. Two mice bearing tumors on the neck and left leg and four rats (two rats had tumors on neck and left leg, the other two rats had tumors on left legs only) were imaged on the microPET at selected times postinjection. Two tumor-bearing mice were each injected with 1 mCi ^{64}Cu-DOTA-DY1-TATE (1 mCi/μg for control, 1 mCi/50 μg for blocked) and imaged at 10 min, 1, 2, and 4 h postinjection. The two mice were imaged side by side and remained in the same bed position for all time points. Four rats were each injected with 2.5 mCi ^{64}Cu-DOTA-DY1-TATE (2.5 mCi/μg for control, 2.5 mCi/150 μg for blocked) and imaged at 10 min, 1, 2, and 4 h. Each rat was imaged in two bed positions. Immediately after imaging, the %ID/g of tumor from the rats was determined by measuring the dissected tumors in a dose calibrator (Capintec, Ramsey, NJ). Tumor, kidney, and liver activities of ^{64}Cu were generated by measuring regions of interest (ROIs) that encompassed the entire organ from the microPET images in AR42J tumor-bearing SCID mice and Lewis rats after 2 and 4 h postinjection.

Statistical Methods. To compare differences between the data, a student's t-test was performed using Prism (Graphpad, San Diego, CA). Differences at the 95% confidence level ($p < 0.05$) were considered significant.

RESULTS

Chemistry and Radiochemistry. The DY1-TATE and DOTA-DY1-TATE were analyzed by analytical reversed-phase HPLC (UV detection 214 nm) using conditions described in the Methods section and by LC-MS. DY1-TATE: HPLC retention time = 17.9 min; MS, *m/z* calculated for $C_{49}H_{64}N_{10}O_{12}S_2$ $(M + H)^+ = 1048.4$, found 1049.3. DOTA-DY1-TATE: HPLC retention time = 20.4 min; MS, *m/z* calculated for $C_{65}H_{90}N_{14}O_{19}S_2$ $(M + H)^+ = 1434.7$, found 1435.6. ^{111}In-DTPA-OC and $^{61/64}$Cu-DOTA-DY1-TATE were prepared in ≥98% radiochemical purity. Specific activities for both ^{111}In- and $^{61/64}$Cu-labeled conjugates ranged from 1500 to 3500 Ci/mmol (56000 to 111000 GBq/mmol). The radiochemical purity of DOTA-^{125}I-DY1-TATE was confirmed to be greater than 98% by radio-HPLC. DOTA-DY1-TATE was typically labeled with ^{125}I to a specific activity of 300 Ci/mmol (11000 GBq/mmol). The reaction yields for "cold" somatostatin analogues were greater than 98% as confirmed by radio-TLC of an exchange reaction between natural Cu^{2+} or In^{3+} with ^{64}Cu or ^{111}In, respectively.

In Vitro Receptor Binding Assay. A homogeneous competitive binding assay was performed using AR42J tumor membranes, where ^{61}Cu-DOTA-DY1-TATE was challenged with increasing concentrations of ^{nat}Cu-DOTA-DY1-TATE. The IC_{50} value for ^{nat}Cu-DOTA-DY1-TATE was determined to be 1.35 nM, with a 95% confidence interval (CI) of 1.02 to 1.8 nM (Figure 2A). Scatchard analysis of the data showed a K_d of 176.4 pM (95% CI 158.4 to 201.3 pM) and a somatostatin B_{max} in the AR42J membranes of 244.4 fmol/mg (95% CI 219.7 to 274.1 fmol/mg) of membrane protein (Figure 2B).

A competitive binding assay was performed between four somatostatin analogues vs ^{111}In-DTPA-OC. The concentration of the radioligand in the binding assays was 0.05 nM. The IC_{50} values were 1.78 nM for Cu-DOTA-Y3-TATE, 4.62 nM for Cu-DOTA-DY1-TATE, 4.8 nM for DOTA-I-DY1-TATE, and 4.87 nM for In-DTPA-OC (Figure 3 and Table 1). These results suggest that Cu-DOTA-DY1-TATE and DOTA-I-DY1-TATE have similar binding affinity to AR42J cells as In-DTPA-OC, while the analogue with Tyr in the 3-position has somewhat higher binding affinity.

Biodistribution Studies. Summaries of the biodistribution data are shown in Figure 4. Rapid clearance of the radioactivity from the blood circulation was observed for both compounds. At all times of analysis the average uptake of ^{64}Cu activity in tumors was approximately twice as high as ^{125}I activity ($p < 0.03$). The highest tumor uptake of ^{64}Cu-DOTA-DY1-TATE (1.515 ± 0.154 %ID/g) was found after 1 h postinjection, and was 1.247 ± 0.250 %ID/g at 4 h postinjection, suggesting that the ^{64}Cu was residualized in the tumor out to at least 4 h postinjection. A similar trend was observed for DOTA-^{125}I-DY1-TATE (0.814 ± 0.058%ID/g at 1 h, 0.543 ± 0.016

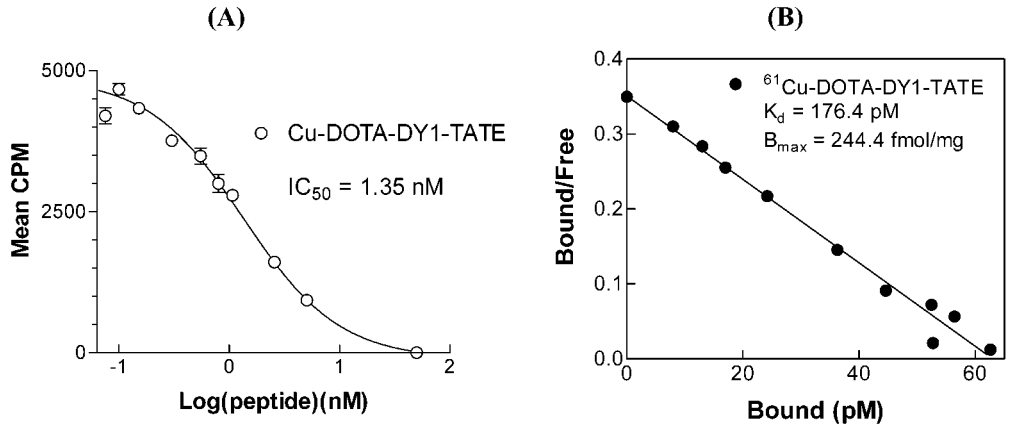

Figure 2. The in vitro binding affinity of ^{61}Cu-DOTA-DY1-TATE to AR42J rat pancreatic tumor membranes blocked with increasing concentrations of unlabeled Cu-DOTA-DY1-TATE ($n = 6$ for each data point).

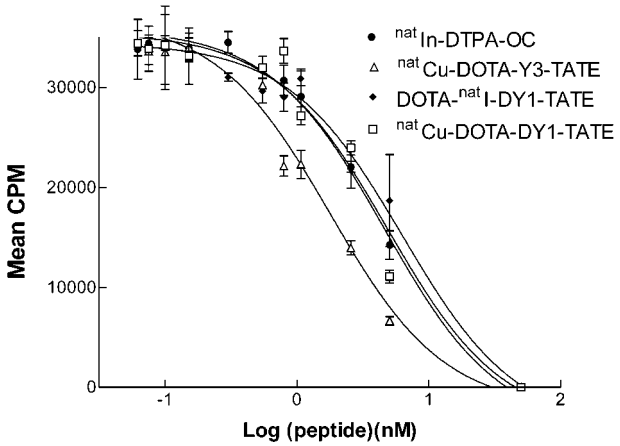

Figure 3. Competitive binding assay of Cu-DOTA-DY1-TATE, DOTA-I-DY1-TATE, Cu-DOTA-Y3-TATE, and In-DTPA-OC displacing ^{111}In-DTPA-OC in AR42J tumor membranes ($n = 3$ for each data point).

Table 1. IC_{50} Values for Competitive Binding Assay of ^{nat}Cu-DOTA-DY1-TATE, DOTA-^{nat}I-DY1-TATE, ^{nat}Cu-DOTA-Y3-TATE, and ^{nat}In-DTPA-OC Displacing ^{111}In-DTPA-OC in AR42J Tumor Membranes ($n = 3$ for each data point)

competing ligand	IC_{50} (nM)	95% CI (nM)
^{nat}Cu-DOTA-Y3-TATE	1.78	1.29−2.46
^{nat}Cu-DOTA-DY1-TATE	4.62	3.28−6.52
DOTA-^{nat}I-DY1-TATE	4.58	3.13−6.69
^{nat}In-DTPA-OC	4.87	3.98−5.96

%ID/g at 4 h) in the tumors. In the rats that received the co-injected blocking dose, the uptake in the tumor of ^{64}Cu-DOTA-DY1-TATE (0.468 ± 0.046 %ID/g) and DOTA-^{125}I-DY1-TATE (0.323 ± 0.016 %ID/g) was significantly lower at 1 h postinjection ($p < 0.02$) (Table 2). The higher uptake of ^{64}Cu-labeled conjugate in the tumor compared to ^{125}I-labeled conjugate may be due to a greater degree of retention of ^{64}Cu-DOTA-DY1-TATE in the tumor compared to DOTA-^{125}I-DY1-TATE. Since time points earlier than 1 h were not evaluated for the biodistribution studies, it is difficult to know whether the uptake of DOTA-^{125}I-DY1-TATE in the tumor peaked prior to 1 h.

The uptake in the pituitary and the pancreas at 1 h postinjection was significantly higher with ^{64}Cu-DOTA-DY1-TATE (1.985 ± 0.334 %ID/g for pituitary, 1.490 ± 0.337 %ID/g for pancreas) compared with DOTA-^{125}I-DY1-TATE (1.246 ± 0.160 %ID/g for pituitary, 0.850 ± 0.203 %ID/g for pancreas) ($p < 0.05$). Uptake in the SSTR2-rich pituitary, adrenals, and pancreas was blocked with unlabeled DY1-TATE for both the ^{125}I and ^{64}Cu-labeled peptides, suggesting receptor-mediated uptake of both compounds in these tissues (Table 2). No appreciable differences were observed for non-somatostatin-receptor-positive tissues between rats that received a coinjection of blocking dose and unblocked rats.

Liver uptake for DOTA-^{125}I-DY1-TATE at all times of analysis was lower than for ^{64}Cu-DOTA-DY1-TATE. However, the kidney uptake of DOTA-^{125}I-DY1-TATE (9.761 ± 1.036 %ID/g at 1 h, 9.450 ± 0.255 %ID/g at 4 h, 8.190 ± 0.646 %ID/g at 24 h, 5.921 ± 0.880 %ID/g at 72 h) was 3-fold higher than that of ^{64}Cu-DOTA-DY1-TATE (2.888 ± 0.187 %ID/g at 1 h, 2.389 ± 0.202 %ID/g at 4 h, 1.740 ± 0.061 %ID/g at 24 h, 1.206 ± 0.158 %ID/g at 72 h). The kidney clearance of DOTA-^{125}I-DY1-TATE maintained a level of 5.921 ± 0.880 %ID/g even after 72 h postinjection. This high kidney uptake and longer retention time of DOTA-^{125}I-DY1-TATE was similar to that of ^{125}I-DY1-TATE and DTPA-^{125}I-DY1-TATE (*4*). This is most likely due to the longer residence time of the DOTA-^{125}I-DY1 residue in the kidneys compared to ^{125}I-L-amino acids. Except for ^{125}I activity in thyroid, normal tissue uptake of DOTA-^{125}I-DY1-TATE decreased throughout the period.

The highest tumor:blood ratios were found at 4 h postinjection for both ^{64}Cu- and ^{125}I-labeled DOTA-DY1-TATE in AR42J tumor-bearing Lewis rats (7.8 ± 1.5 and 8.8 ± 0.9, respectively). For DOTA-^{125}I-DY1-TATE, the tumor-to-blood ratio maintained at high levels out to 24 h postinjection (6.4 ± 1.0), while for ^{64}Cu-DOTA-DY1-TATE the ratio dropped to 2.6 ± 0.6. Tumor:muscle ratios were similar for ^{64}Cu- and ^{125}I-labeled DOTA-DY1-TATE, with the peak ratio occurring at 4 h (19.2 ± 3.8 and 21.9 ± 2.5, respectively).

The excretion data demonstrated that 59.18 ± 21.05 %ID for ^{64}Cu and 64.22 ± 19.93 %ID for ^{125}I was excreted from the urine by 4 h postinjection. By 24 h postinjection, ∼75 %ID of ^{64}Cu-DOTA-DY1-TATE activity was found in the urine and feces, and ∼85 %ID of DOTA-^{125}I-DY1-TATE activity was excreted (Table 3).

MicroPET Images. Figure 5A shows the coronal microPET images of AR42J tumor-bearing SCID mice, 2 h postadministration of ^{64}Cu-DOTA-DY1-TATE, with and without a coinjected blocking dose of DY1-TATE. Uptake in the neck and thigh tumors was visible at 2 h postinjection for the control mouse (left). Conversely, the other mouse (right) that received a blocking dose showed reduced uptake at both tumor sites. Prominent uptake was observed in the liver and kidneys in both animals.

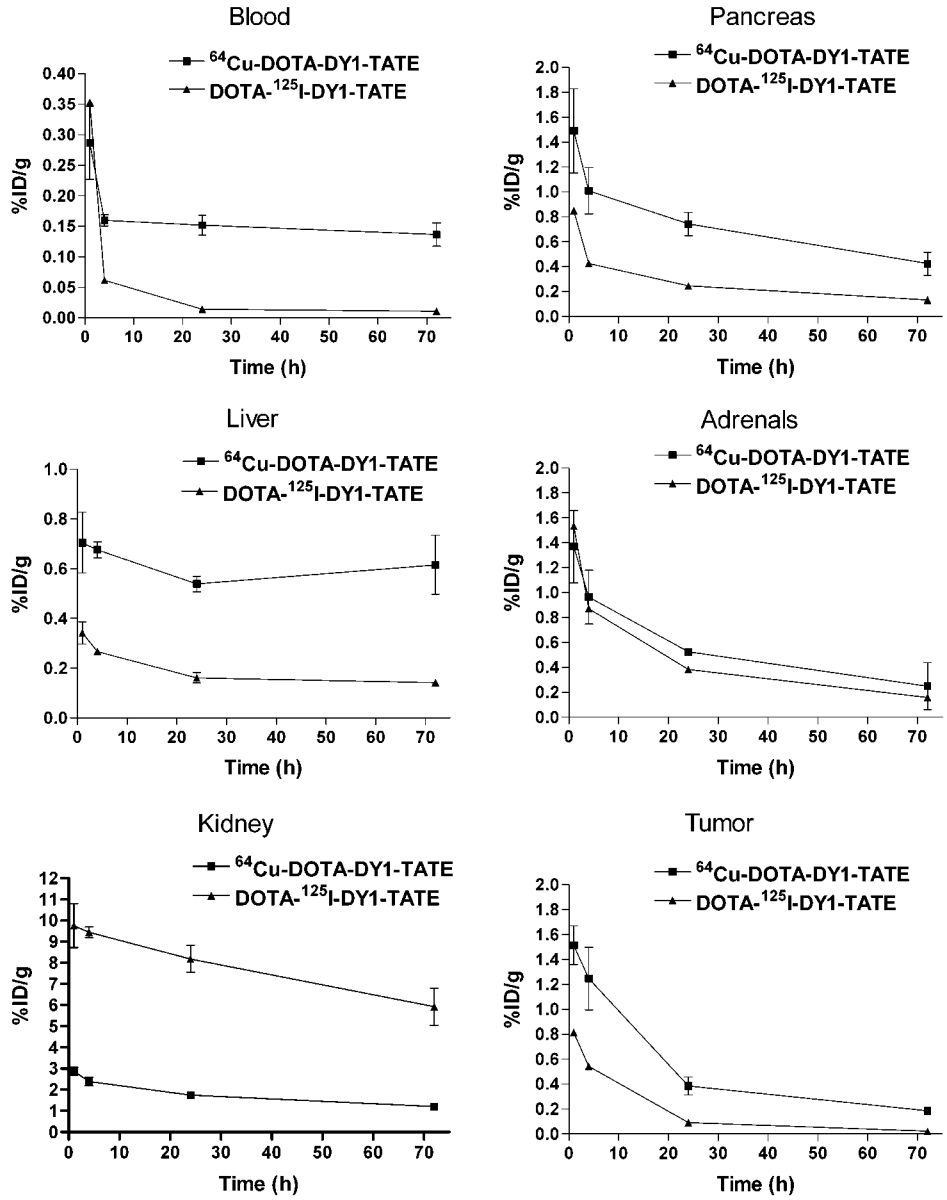

Figure 4. Biodistribution data of ^{64}Cu-DOTA-DY1-TATE and DOTA-^{125}I-DY1-TATE in normal and SSTR2 positive tissues (blood, liver and kidneys, pancreas, adrenals, tumor). Data are presented as %ID/g ± SD, $n = 5$ for each time point.

Table 2. Biodistribution of ^{64}Cu-DOTA-DY1-TATE and DOTA-^{125}I-DY1-TATE in AR42J Tumor Bearing Lewis Rats at 1 h, with and without a Coadministration of Blocking Agent[a]

tissue	^{64}Cu, 1 h	^{64}Cu, 1 h block	^{125}I, 1 h	^{125}I, 1 h block
blood	0.287 ± 0.060	0.361 ± 0.065	0.354 ± 0.073	0.434 ± 0.064
liver	0.705 ± 0.122	0.981 ± 0.199	0.342 ± 0.045	0.352 ± 0.036
kidney	2.888 ± 0.187	3.626 ± 0.176	9.761 ± 1.036	10.895 ± 0.863
pituitary	1.985 ± 0.334	0.516 ± 0.456	1.246 ± 0.160	0.325 ± 0.208
adrenals	1.369 ± 0.291	0.234 ± 0.066	1.534 ± 0.351	0.212 ± 0.036
pancreas	1.490 ± 0.337	0.409 ± 0.059	0.850 ± 0.203	0.270 ± 0.024
tumor	1.515 ± 0.154	0.468 ± 0.046	0.814 ± 0.058	0.323 ± 0.016
thyroid	0.307 ± 0.040	0.388 ± 0.083	1.357 ± 0.131	1.234 ± 0.023

[a] Data are presented as % ID/g ± SD ($n = 5$).

Four hours after administration of ^{64}Cu-DOTA-DY1-TATE, both tumor sites in the nonblocked animal could still be easily identified, as well as showing higher uptake than other normal organs.

Figure 5B shows the microPET images in Lewis rats bearing AR42J tumors of ^{64}Cu-DOTA-DY1-TATE obtained after 2 h postinjection with and without the addition of DY1-TATE as a blocking agent. Imaging was performed at 1, 2, and 4 h postinjection. Similar to the AR42J tumor-bearing mice images, tumor uptake was also observed in the tumor-bearing rats. The most prominent region of ^{64}Cu-DOTA-DY1-TATE uptake was the bladder, due to the rapid excretion of this compound into the urine. In addition, significant uptake in the SSTR2-rich pituitary was observed.

Uptake of radioactivity in the tumor, kidney, and liver measured from the microPET images in the AR42J tumor-bearing SCID mice and Lewis rats after 2 and 4

Table 3. Excretion of ^{64}Cu-DOTA-DY1-TATE and DOTA-^{125}I-DY1-TATE in AR42J Tumor-Bearing Lewis Rats[a]

	^{64}Cu-DOTA-DY1-TATE			DOTA-^{125}I-DY1-TATE		
	4 h	24 h	48 h	4 h	24 h	48 h
urine	59.18 ± 21.05	65.36 ± 19.88	66.29 ± 20.35	64.22 ± 19.93	74.93 ± 21.77	77.76 ± 20.34
feces	<0.1	9.08 ± 9.45	11.12 ± 9.87	<0.1	9.79 ± 8.97	12.39 ± 5.42

[a] All data are reported as % ID ± SD (n = 5).

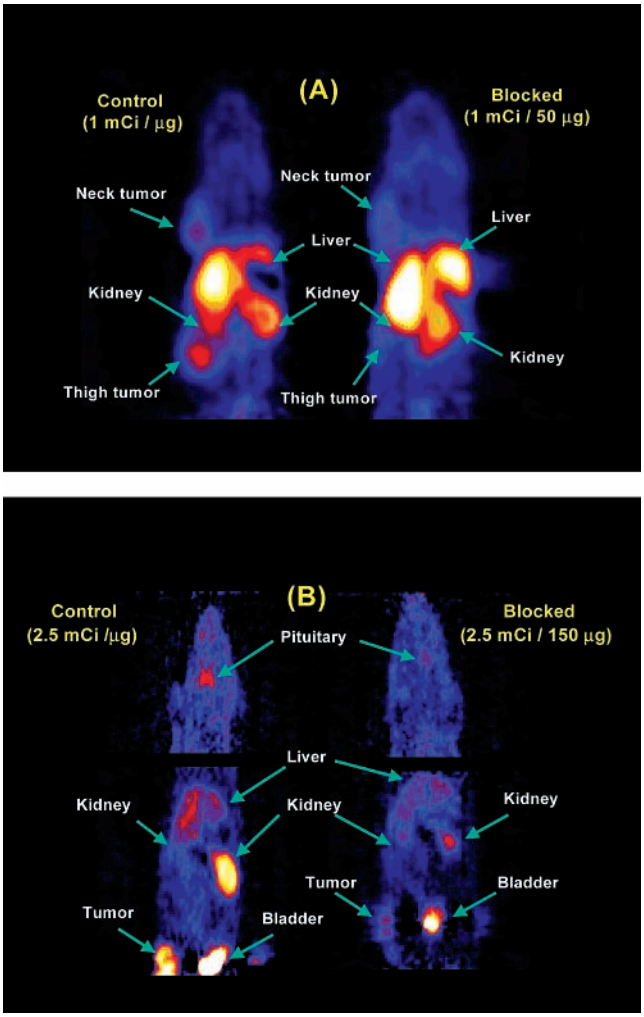

Figure 5. (A) Coronal microPET images of AR42J tumor-bearing SCID mice after 2 h postadministration of ^{64}Cu-DOTA-DY1-TATE, with and without a coinjected blocking dose (2.5 mCi/μg, left; 2.5 mCi/μg coinjected with 50 μg of DY1-TATE, right). (B) Coronal microPET images of AR42J tumor-bearing Lewis rats (2 bed positions) after 2 h postadministration of ^{64}Cu-DOTA-DY1-TATE, with and without a coinjected blocking dose (2.5 mCi/μg, left; 2.5 mCi/μg coinjected with 150 μg of DY1-TATE, right).

h postinjection are given in Figures 6A and 6B. In the SCID mice, the results suggested tumor activity in the control mice (0.02 μCi/μL at 2 h pi, 0.02 μCi/μL at 4 h pi) was about 2-fold higher than in blocked mice (0.01 μCi/μL for 2 h pi, 0.01 μCi/μL for 4 h pi). In SCID mice, the tumor activity was similar at both 2 and 4 h postinjection. In the 'blocked' Lewis rats, a similar reduction in activity was observed compared to control Lewis rats. Tumor activity in the control rats (0.03 μCi/μL for 2 h pi, 0.02 μCi/μL for 4 h pi) was 2−3-fold higher than in 'blocked' rats (0.01 μCi/μL for 2 h pi, 0.01 μCi/μL for 4 h pi). These results agreed with tumor uptake measurements that were determined by measuring the activity of the dissected tumor in a dose calibrator, where 4.14 ± 0.01 %ID/g was found in the control tumor and 1.46 ± 0.00 %ID/g was in the tumor of the rat coinjected with blocking agent. These data confirmed that tumor uptake was blocked with an excess of DY1-TATE. Moreover, blocking of tumor activity in the rats appeared to be more effective than in mice, which probably reflects the crossover activity from liver/kidney in mice that obscures the tumor, especially in the blocked mice when measuring regions of interest (ROIs) that encompassed the entire organ.

DISCUSSION

The utility of radiolabeled somatostatin analogues for imaging and therapy of cancer is well described in the literature. The majority of newly developed somatostatin analogues were specifically designed for labeling radiometals (*1*−*3*). The goal of this research was to design a somatostatin analogue for labeling both radiometals and halogens, with the added feature of having the halogen residualized in target tissue. Here we investigated DOTA-DY1-TATE, where the *C*-terminal alcohol of octreotide was replaced with a *C*-terminal acid (TATE). This analogue was labeled with ^{64}Cu and ^{125}I and compared in in vitro receptor binding assays and in vivo somatostatin-receptor-positive tumor-bearing animal models. Having a somatostatin analogue that allows the ability for labeling both metals and halogens will allow direct comparisons of these analogues with the only modification being the radionuclide used for labeling.

Receptor binding experiments using AR42J rat pancreatic tumor membranes were performed to verify the IC_{50} values of the new somatostatin analogues compared to ^{111}In-DTPA-OC. Scatchard analysis was performed with $^{61/nat}$Cu-DOTA-DY1-TATE to determine the K_d of this analogue. The unlabeled iodinated and copper complexed DOTA-DY1-TATE analogues had binding affinity that were comparable to In-DTPA-OC while the IC_{50} for Cu-DOTA-Y3-TATE was about 2−3-fold lower. These data are encouraging, since it demonstrates that the binding affinity was not compromised with the DY1-TATE analogues compared to the DTPA-OC and DOTA-Y3-TATE analogues. Another DY1 analogue (DTPA-^{125}I-DY1−OC) was described by Breeman et al. (*4*); however, this analogue had an IC_{50} value vs ^{125}I-Y3-OC that was 200-fold higher than ^{125}I-Y3-OC itself.

The biodistribution of ^{64}Cu- and ^{125}I-labeled DOTA-DY1-TATE were performed in one coinjection experiment in AR42J tumor-bearing Lewis rats. This model has several advantages compared to the typically utilized animal models, AR42J tumor-bearing nude/SCID mice, and CA20948-tumor bearing rats. AR42J cells grow both in cell culture and in animal models, which allows the advantage of comparing in vitro receptor binding studies and tumor-bearing animal studies using the same tumor cell line. The use of young rats (21 d) also allows the AR42J tumor cells to be implanted into immunocompetent rodents, rather than immunocompromised nude or SCID mice.

Greater somatostatin-receptor-mediated uptake was observed with ^{64}Cu-DOTA-DY1-TATE than DOTA-^{125}I-DY1-TATE in the pancreas as well as the AR42J tumor (p < 0.02), whereas the uptake was similar in the
