Bioconjugate Chemistry

EDITORIAL: What's New

We welcome the new members of the *Bioconjugate Chemistry* Editorial Advisory Board for 2002:

Dr. Sylvia Daunert, Department of Chemistry, University of Kentucky

Dr. Alexander V. Kabanov, Department of Pharmaceutical Sciences, University of Nebraska Medical Center

Thanks to Our Reviewers

It is a pleasure to acknowledge the contributions of the reviewers of manuscripts submitted in 2001 for publication in *Bioconjugate Chemistry*. Their unselfish service has been essential in the shaping of the twelfth volume of the journal. The scientific community is fortunate that its members are willing to share their time and specialized knowledge in this way. The reviewers are listed on the following page.

Claude F. Meares

Editor-in-Chief

Gold Nanoparticle-Mediated Transfection of Mammalian Cells

Kulmeet K. Sandhu,[†] Catherine M. McIntosh,[†] Joseph M. Simard,[†] Sallie W. Smith,[‡] and Vincent M. Rotello*,[†]

Department of Chemistry and Department of Veterinary & Animal Science, University of Massachusetts, Amherst, Massachusetts 01003. Received August 16, 2001

Mixed monolayer protected gold clusters (MMPCs) functionalized with quaternary ammonium chains efficiently transfect mammalian cell cultures, as determined through β-galactosidase transfer and activity. The success of these transfection assemblies depended on several variables, including the ratio of DNA to nanoparticle during the incubation period, the number of charged substituents in the monolayer core, and the hydrophobic packing surrounding these amines. Complexes of MMPCs and plasmid DNA formed at w/w ratios of 30 were most effective in promoting transfection of 293T cells in the presence of 10% serum and 100 μM chloroquine. The most efficient nanoparticle studied (MMPC **7**) was ~8-fold more effective than 60 kDa polyethylenimine, a widely used transfection agent.

Gene transfer can be performed using either viral or synthetic gene delivery systems (*1*−*11*). While viral vectors are widely used, synthetic transfection systems provide several advantages including their ease of production *(7)* and the reduced risk of cytotoxicity (*7*, *12*) and immune responses (*3*, *4*, *7*, *12*, *13*). A variety of cationic systems have been studied for complexation and transport of negatively charged DNA, including peptides (*2*, *7*), liposomes containing cationic lipids (*14*), poly(lysine) (*6*), polyethylenimine (*3*), cationic polymers (*4*, *11*), PAMAM dendrimers (*1*, *5*, *10*), and more recently, silica nanoparticles (*8*, *9*).

Mixed monolayer protected gold clusters (MMPCs) represent a unique platform for transfection because of their ease of fabrication, especially in contrast to the complex synthesis required to produce the higher-generation dendrimer counterparts (*15*). In addition to simple hydrogen bonding or electrostatic moieties, biological tags capable of targeting the plasmid to a specific cell type are available (*7*) and can be introduced in postfabrication steps since subsequent modification of the monolayer is also facile. Cationic MMPCs bind very efficiently to DNA; in recent studies we have demonstrated that the interaction between cationic gold nanoparticles and DNA is efficient enough to totally inhibit in vitro DNA transcription by T7 RNA polymerase (*16*).

To explore the utility of MMPCs for transfection, MMPCs featuring a 2 nm gold core, with a total diameter of 6 nm, were fabricated. In comparison with other nanoparticle systems studied (*8*, *9*), we expect that the smaller size of the MMPCs should increase the efficiency of both the DNA−MMPC complex internalization and the subsequent release of the plasmid from the cationic MMPC surfaces. For our studies, we fabricated MMPCs modified with quaternary ammonium salts and tested their ability to transfect plasmid DNA (Figure 1).[1] The effect of varying cationic coverage was explored by comparing MMPCs **1**−**5**, constructed using differing

[1] MMPCs were prepared as previously described in Simard, J., Briggs, C., Boal, A. K., and Rotello, V. M. (2000) *Chem. Commun.* 1943. Briefly, for **1**−**5**, 50 mg of octanethiol colloid was stirred for two days in THF with 10−100 mg of *N*,*N*,*N*-trimethyl(11-mercaptoundecyl)ammonium chloride. For **6** and **7**, 62 mg of undecanethiol colloid and 50 mg of tetradecanethiol colloid were stirred with 50 mg of ammonium thiol, respectively. After exchange, the MMPCs were purified by mulitple precipitations from dichloromethane. The colloids were characterized using UV, NMR, and TEM methods.

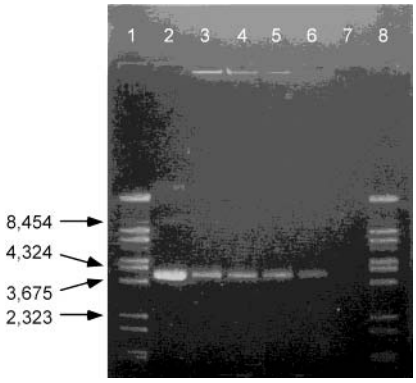

Figure 2. Agarose gel electrophoresis of the MMPCs and DNA. Exterior lanes contain molecular weight markers. The second lane is DNA alone at 9.5 nM; lanes 3−7 contain increasing amounts of MMPC **3** (2.4 μM, 3 μM, 4 μM, 6 μM, and 12 μM, respectively). As the nanoparticle concentration increases, more DNA is retained at the baseline, with complete complexation observed at 12 μM MMPC **3** or at a 790:1 MMPC **3** to DNA mole ratio. Decreasing fluorescence of the DNA fraction at the baseline may be due to absorption of the emitted light by the gold cores or the exclusion of ethidium bromide from the bound and condensed DNA (*17*).

ratios of octanethiol to ammonium thiol.[2] The effect of alkyl chain length on transfection was studied using MMPCs **6** and **7**, prepared with undecanethiol and tetradecanethiol, respectively.

Preliminary evidence for efficient MMPC−plasmid association was provided by the complete inhibition of electrophoretic mobility of the plasmids upon addition of cationic MMPCs. Gel electrophoresis of pET16B plasmids after incubation with MMPC **3** for 0−30 min showed the presence of only two bands of DNA: one at the baseline and one at the expected molecular weight for a single plasmid (Figure 2).[3] The ability of the nanoparticles to completely inhibit the DNA from progressing toward the positive electrode and the lack of any intermediate assemblies indicates either that the complexes formed were completely charge neutralized or that the resultant complexes were too large to enter the gel.[4]

Preliminary investigations focused on optimization of transfection conditions. Transfection was first compared in different environments: in the presence of both serum and chloroquine (chlq), transfection was improved in comparison to controls, as demonstrated using MMPC **3** (Figure 3a). For all further studies, a medium containing 100 μM chloroquine[5] and 10% serum was used.[6] To determine the optimal MMPC−plasmid ratio, increasing amounts of MMPC **3** were added to 250 μL of medium containing 5 μg of β-galactiosidase plasmid (Figure 3b).[7] Maximum transfection of β-galactosidase reporter gene

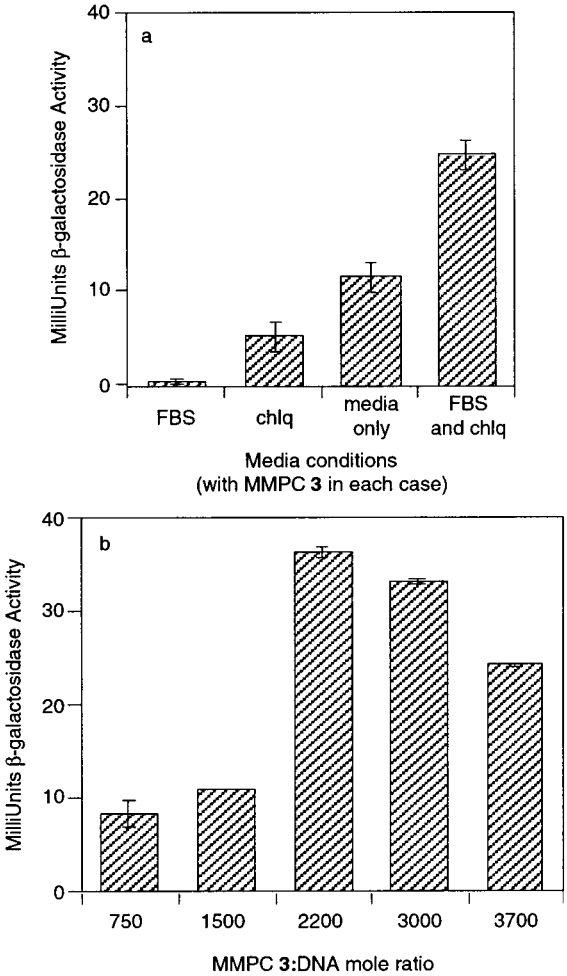

Figure 3. Efficiency of transfection as a function of (a) chloroquine (chlq) and serum (FBS) with a 2200:1 MMPC **3**:DNA ratio and (b) varying MMPC concentrations.[9] Levels of β-galactosidase were determined by comparison to a standard curve using known protein concentrations.

plasmid into 293T cells occurred at a MMPC:plasmid mole ratio of 2200:1. Further increases in MMPC concentration above this value resulted in a slow decrease in transfection efficiency.[8] Significantly, the optimal DNA−MMPC ratio for transfection was higher than that required for complete retardation of electrophoretic mobility (vide supra). This is consistent with previous studies that have shown overall net-positively charged assemblies to provide more efficient transfection (*9*, *18*, *19*).

[2] Cationic coverage of each MMPC was calculated by end-group analysis using NMR integration.

[3] Gels were prepared with 0.6% agarose, run for 60−90 minutes at 80 V, and visualized using ethidium bromide. pET16B plasmids encoding cellular retinoic acid binding protein consist of approximately 6200 base pairs. The molecular weights are composed of linear DNA, whereas the DNA of the pET vector (seen at approximately 4000 base pairs) corresponds to a circular strand. The small band evident in lane 2 at a higher MW is most likely due to incomplete purification of the DNA and is not expected to bias the results observed.

[4] Similar DNA:MMPC assemblies were prepared and characterized via methods in reference 16.

[5] Cholorquine is believed to disrupt the endosomal vesicle, resulting in increased passage of the transfection vector to the cytosol (*1*, *2*, *9*, *11*).

[6] β-Galactosidase plasmid DNA at 0.02 mg/mL was mixed with MMPC at 5 mg/mL. The complexes were then diluted with DMEM containing 10% FBS and 100 mM chloroquine. The human embryonic kidney cells (293T) were washed once with PBS and incubated with the MMPC/DNA complexes for 3 h at 37 °C in 5% CO_2. The cells were washed once with PBS and incubated for 48 h in DMEM + 10% FBS. The enzyme activities were then assayed using a β-galactosidase kit (Promega). The BCA assay (Pierce) was used to determine total protein content. Control experiments performed using naked DNA, nanoparticles alone, and neither DNA nor nanoparticles exhibited no measurable β-galactosidase activity (results not shown).

[7] The CMV-β-galactosidase plasmid is composed of approximately 7200 base pairs.

[8] Decreasing levels of β-galactosidase expression may be due to low level toxicity of the MMPCs (LD_{50} = 1.8 μM (a 2900:1 MMPC:DNA molar ratio) as determined for MMPC **3** using a WST-1 assay). This is ~165-fold higher than that of PEI (*9*).

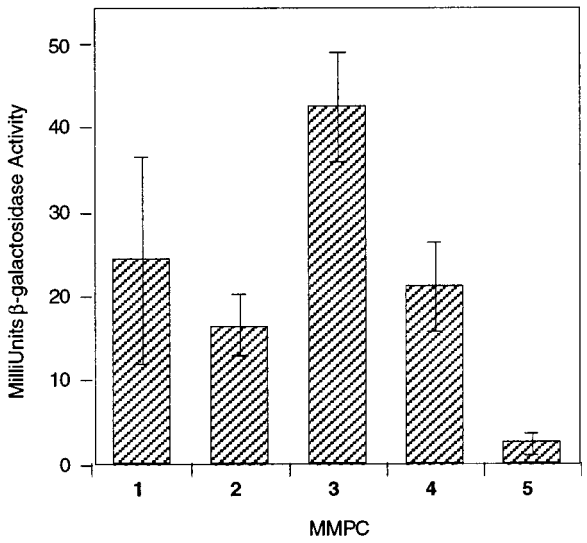

Figure 4. Transfection of β-galactosidase mediated by formation of various MMPC−DNA complexes at 2200:1 nanoparticle/DNA ratio.

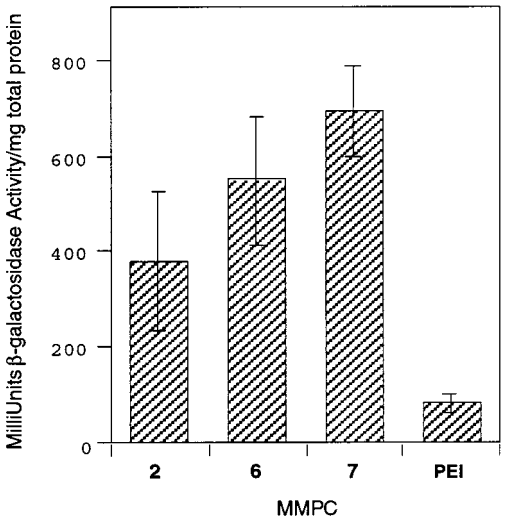

Figure 5. Transfection with MMPCs **2**, **6**, **7** (2200:1 nanoparticle/DNA ratio) and PEI (60 kDa).

We next explored the effect of the ratio of quaternary ammonium endgroups to hydrophobic chains (Figure 4). All of the gold nanoparticles were able to promote transfection in the presence of chloroquine and serum, with MMPC **3** proving to be the most effective of the octanethiol substituted particles. This suggests that either the charge/particle ratio or the hydrophobicity of the MMPCs is an important determinant of transfection efficiency.

The effect of the chain length of the monolayer was determined by testing the transfection efficiency of MMPCs **6** and **7** (Figure 5). In these studies, increasing transfection efficiency was observed with increasing chain length. All three nanoparticles were more efficient than polyethylenimine (PEI), with MMPC **7** being approximately eight times as effective as PEI.[10]

In summary, we have demonstrated the efficient transfection of plasmids encoding β-galactosidase into 293T cells, confirming the viability of MMPCs as transfection agents. The efficiency of the transfection process is determined by several parameters, including the ratio of MMPC:DNA used in initial complexation, the surface coverage of quaternary ammonium salts, and the length of the uncharged thiol chain. Further studies of the role of monolayer structure and functionality are currently underway and will be reported in due course.

[9] MMPC concentrations were determined by weight (based on an average molecular weight of 60000 for the nanoparticle, see ref 20) and DNA concentrations measured by UV-vis.

[10] PEI experiments performed as described in ref 9.

ACKNOWLEDGMENT

We thank Lila Gierasch and Jennifer Habink for the donation of cells containing the pET16B plasmid. We also thank Barbara A. Osborne for the use of her tissue culture facility. This research was supported by the National Science Foundation (DMR-9809365 for MRSEC instrumentation) and the National Institutes of Health (GM-59249 and GM-62998). V.M.R. acknowledges the Alfred P. Sloan Foundation, the Camille and Henry Dreyfus Foundation, and is a Cottrell scholar of Research Corporation. ARTICLES

In Vivo Tumor Delivery of a Recombinant Single-Chain Fv::Tumor Necrosis Factor: A Fusion Protein

Stephen P. Cooke,* R. Barbara Pedley, R. Boden, Richard H. J. Begent, and Kerry A. Chester

CRC Targeting and Imaging Group, Academic Department of Oncology, Royal Free and University College Medical School, University College, London, NW3 2PF, U.K. Received December 20, 2000

Locoregional and intratumoral administration of tumor necrosis factor α (TNFα) has been successful in obtaining inhibition or regression of tumor growth in the clinic. This potent antitumor activity of TNFα has not yet been exploited as a systemic agent in cancer therapy, mainly due to high levels of toxicity to normal tissues before a therapeutic dose of TNFα in the tumor has been achieved. To address this, we have targeted TNFα using antitumor antibodies. We have used a genetic fusion of human recombinant TNFα with MFE-23, a single-chain Fv antibody fragment directed against carcinoembryonic antigen. MFE-23::TNFα fusion protein is isolated in high yields (28 mg/L) from bacterial inclusion bodies and purified to homogeneity by affinity chromatography. It is a 144 kDa trimer in native form and possesses the antigen-binding activity of the sFv and the cytotoxicity to both WEHI 164 and a human adenocarcinoma cell line (LoVo) of rhTNFα. Radiolabeled MFE-23::TNFα binds both human and mouse TNF receptor 1 in vitro and is able to localize effectively in nude (nu/nu) mice bearing human LS174T xenografts; tumor/tissue ratios of 21:1 and 60:1 are achieved 24 and 48 h after intravenous injection. These studies indicate that MFE-23::TNFα will provide an effective means for systemically administered cancer therapy with TNFα.

INTRODUCTION

Tumor necrosis factor α (TNFα) is a pleiotropic cytokine produced by a variety of human cells particularly activated macrophages and monocytes. It has the ability to kill tumor cells by binding to two cell surface receptors, TNFR1 and TNFR2 (p55 and p75), thereby inducing apoptosis by activation of the death pathway (Laster et al., 1988; Itoh and Nagata, 1993). Studies involving regional (Lejeune, 1995; Moritz et al., 1989; Abbruzzese et al., 1989; Mavligit et al., 1992) or intratumoral (Watanabe et al., 1994) injection of TNFα in humans, where high tumor levels of the cytokine can be achieved, have demonstrated tumor regression, especially when administered in combination with interferon-γ. This has been particularly impressive in trials involving isolated limb perfusion (Lejeune, 1995; Abbruzzese et al., 1989) and raises the question of whether these results could be matched using TNFα administered to patients via a simple intravenous injection.

The use of TNFα as a systemic agent for cancer therapy is restricted by the short circulatory half-life of the molecule and its severe side effects ranging from headache, chills, and fever to systemic shock and sepsis (Asher et al., 1987; Rosenberg et al., 1988). Thus, normal tissue toxicity is limiting before a therapeutic dose to the tumor can be achieved, and therefore, the potent antitumor activity of TNFα remains unharnessed for systemic therapy. Various targeting strategies have been developed to address this with the aim of achieving higher doses of TNFα at the tumor site coupled with a low systemic concentration. Systemic delivery of TNFα by liposomes (Manusama et al., 1998) or dextran and metal coordination to improve tumor penetration and retention of TNFα (Tabata et al., 1999) have been explored, but more specific targeting can be achieved using tumor-selective antibodies. Indirect approaches using bispecific (antitumor/anti-TNFα) antibodies to capture TNFα at the tumor site (Robert et al., 1996) or avidin−antibody complexes to target biotinylated TNFα (Moro et al., 1997; Gasparri et al., 1999), have met with some success, but these systems are complex. More straightforward approaches using antibodies directly linked to TNFα are attractive and have shown efficacy in animal models using chemical conjugates of whole antibody coupled to TNFα (Gillies et al., 1993; Pietersz et al., 1998). However, chemical conjugates have demonstrated poor tumor penetration (possibly due in part to their large size), which results in low amounts of TNFα localizing in the tumor tissue. Attempts to optimize the direct antibody targeting approach by using recombinant fusion proteins of TNFα with single-chain Fv antibody fragments (sFvs) have shown encouraging results such as specific cytotoxicity in vitro (Hoogenboom et al., 1991; Yang et al., 1995) and reduction in tumor volume in mice bearing Le^{Y+} xenografts (Scherf et al., 1996). However, these promising therapies were hampered by poor yield of fusion protein, preventing further study and development of a clinically useful product. We describe the production, purification, characterization, and tumor targeting of MFE-23::TNFα fusion protein, which overcomes this obstacle.

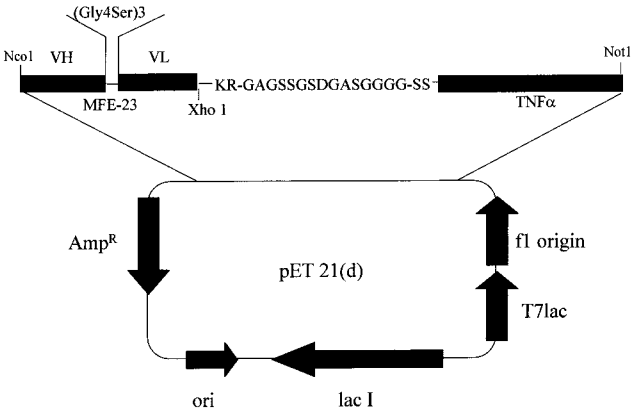

Figure 1. Schematic of MFE-23::TNFα/pET21(d). MFE-23::TNFα was inserted into pET21(d) via Nco1 and Not1 restriction sites. The flexible linker between the sFv and the TNFα is also shown.

MFE-23 is a filamentous bacteriophage-derived sFv (Chester et al., 1994) that has been shown to localize safely and effectively to carcinoembryonic antigen (CEA) expressing tumors in clinical trials (Begent et al., 1996; Mayer et al., 2000). CEA was chosen as a target because, with highly specific antibodies, it is only detectable on tumors and on the luminal surface of the gut, which is not accessible to IgG antibodies. CEA is expressed on most gastrointestinal carcinomas and on a proportion of breast, lung, and ovarian carcinomas. MFE-23 is readily expressed in bacteria and was selected to bind with high affinity ($K_D = 2 \times 10^{-9}$ M) for CEA (20). The MFE::TNFα fusion protein aims to reduce sequestration and increase tumor concentrations of systemically administered TNFα.

EXPERIMENTAL PROCEDURES

Subcloning of MFE-23::TNFα Plasmid. The expression vector pUC119SNpolymyc containing the MFE23::TNFα fusion protein (a kind gift from Philipp Holliger, LMB, Cambridge, UK) was purified from the *Escherichia coli* strain TG1 using standard methods. The MFE-23::TNFα gene was released from the plasmid by digestion with restriction endonucleases Nco1 and Not1 (5 units/μg DNA; 4 h; 37 °C) and ligated into the expression vector pET21(d) prior to electroporation into *E. coli* strain BL21(DE3)pLysS. A schematic of the resulting expression vector pET21(d) MFE-23::TNFα is shown in Figure 1.

Expression in Inclusion Bodies. Five individual colonies of BL21 (DE3 pLysS) containing the MFE-23::TNFα gene and controls containing the "empty" pET 21(d) vector alone were selected and grown in 50 mL culture broth (2TY + 0.1% glucose + 100 mg/mL ampicillin). When an OD_{600} of 0.9 was reached, the cultures were induced with 2 mM isopropylthiogalactoside (IPTG) for 16 h at 30 °C. Cultures were then centrifuged at 4000 rpm for 15 min, and the pellet was incubated in lysis buffer (0.1 M Tris, 20 mM EDTA pH8.0 containing 200 mg/mL lysozyme) for 1 h at room temperature followed by the addition of NaCl to 0.5 M and Triton-X 100 to a final concentration of 2%. After the pellet was incubated a further 3 h, tubes were centrifuged at 25000*g* for 1 h to isolate the inclusion body fraction. Inclusion bodies were washed three times in wash buffer (0.1 M Tris, 20 mM EDTA pH 8.0) before freezing at −70 °C overnight. The inclusion body pellet was resuspended in a second lysis buffer (0.1 M tris pH 8.0, 2 mM EDTA, 300 mM DTE, 8 M urea) and incubated overnight at room temperature. Tubes were centrifuged at 30000*g*, and the supernatant was recovered. Aliquots were analyzed for protein production by SDS−PAGE (stained with Coomassie Blue). The supernatants containing protein of the expected molecular weight were pooled and dialyzed extensively against 8 M urea to remove all DTE prior to refolding.

Refolding and Purification by Affinity Chromatography. The refolding protocol was based on that of Scherf et al. (1996). Single aliquots (5−10 mL) of supernatant were added every 30 min to 1 L of refolding buffer (0.1 M Tris pH 8.0, 2 mM EDTA, 1 mM reduced glutathione (GSSG), 1 mM oxidized glutathione (GSG), 0.5 M L-arginine) and allowed to refold at 4 °C for 96 h with constant agitation. The resulting protein solution (1200 mL) was filtered to remove aggregates before passage through an CNBr-activated Sepharose-CEA affinity column. The solution was circulated though the column via a peristaltic pump, and the column was washed with 50 mL of PBS before bound protein was eluted by the addition of 5 mL aliquots of 50 mM diethylamine. Optical density measurements were taken ($OD_{280\ nm}$), and fractions containing protein were pooled and dialyzed into PBS before being sterile filtered, aliquoted, and stored at −70 °C. This affinity chromatography procedure was repeated three times.

SDS−PAGE and Western Blot Analysis. For the initial analysis of the crude supernatants and controls obtained after inclusion body lysis, 20 μL samples were loaded into the wells of a 10% polyacrylamide gel under reducing conditions alongside molecular markers covering a range of molecular weights from 250 to 4 kDa. After electrophoresis, gels were stained with Coomassie Blue and destained in water/acetic acid/methanol until bands were visible.

After refolding of the fusion protein from the inclusion body supernatant and purification by affinity chromatography, 20 μL samples were loaded into the wells of a 10% polyacrylamide gel under reducing conditions. After electrophoresis, the gels were cut in half and proteins transferred to PVDF membranes. After being blocked in 5% Marvel, blots were incubated with either rabbit anti-MFE or rabbit anti-human TNFα polyclonal antibodies diluted 1:500 in 1% Marvel in PBS/0.1% Tween-20 for 1 h. After being washed with PBS/0.1% Tween-20, blots were incubated with goat anti-rabbit IgG conjugated to horseradish peroxidase (HRP) diluted 1:2000 for 1 h prior to visualization with diaminobenzidine/H_2O_2.

Assessment of CEA Binding Activity. ELISA plates were coated with CEA at 2 μg/mL and blocked for 1 h with 5% Marvel in PBS/0.1% Tween-20. Fusion protein was serially diluted in PBS/0.1% Tween-20 and 100 mL added to the wells in duplicate. Plates were washed, and 100 mL rabbit anti-MFE or rabbit anti-human TNFα polyclonal antibodies were added at 1:500 for 1 h followed by 100 μL of goat anti-rabbit IgG conjugated to HRP at 1:2000 for a further 1 h. Plates were developed by addition of 100 μL of *o*-phenylenediamine (OPD)/H_2O_2 in citrate buffer pH 5.0. The reaction was stopped by the addition of 50 μL of 4 M HCl and plates read at 490 nm on an ELISA plate reader.

Native Molecular Weight Determination. One hundred micrograms of purified fusion protein was loaded onto a Superose 12 size-exclusion column and analyzed by fast-performance liquid chromatography. One milliliter fractions were collected, and absorbance at $OD_{280\ nm}$ was used as the readout. The column was first calibrated by addition of 100 μg each of protein of known molecular weight (MFE-23; 28 kDa, IgG; 150 kDa, b-amylase; 205 kDa, apoferritin; 440 kDa and thyroglobu-

lin; 690 kDa) and a calibration curve of molecular weight versus elution volume constructed. The fraction number of the eluted peak was determined relative to these standards and the molecular weight estimated from the calibration curve.

Cytotoxicity Assay for TNFα Activity. The TNFα-sensitive cell line WEHI 164 was used in this assay. Cells were plated at 2×10^5 cells/well in 96-well plates and incubated overnight at 37 °C/5%CO_2. Cells were treated with actinomycin D at 10 μg/mL before addition of fusion protein or rhTNFα controls in tripling dilutions (adjusted to yield from 1000 pg/mL to 4 pg/mL w/v TNFα), in triplicate in 200 μL culture medium. sFv MFE-23 alone was used as control (also at 1000 pg/mL to 4 pg/mL). Culture medium alone was used as a negative control. Plates were incubated overnight before addition of 10 μL of a 5 mg/mL solution of MTT [3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide]/well. After a further 4 h incubation at 37 °C, cells were lyzed by addition of 100 μL of 10% SDS in 0.01 N HCl. Color development was allowed to proceed overnight at 37 °C, and plates were read at 570 nm on an ELISA plate reader. The reduction in optical density is a measure of decreased cell viability. Results were expressed in terms of percentage cytotoxicity using the formula $[(OD_{max} - OD_{sample})/(OD_{max} - OD_{min})] \times 100$, where OD_{max} is the optical density of wells containing culture medium alone and OD_{min} is the optical density at which no viable cells were visible by phase-contrast microscopy. The differences between sets of triplicate wells were tested for significance using a nonpaired, single tail students t-test, and significance in the text refers to a p value of <0.05.

In Vivo Studies. *Xenograft.* The human colon adenocarcinoma cell line LS174T was used to develop a xenograft model in the flank of female (nu/nu) mice. Subsequent passaging was by s.c. implantation of small tumor pieces (~1 mm^3). The tumor is a moderately differentiated CEA-producing adenocarcinoma with small glandular ascini, which secretes no measurable CEA into the circulation (Pedley et al., 1993).

Radiolabeling and Biodistribution Studies. Fusion protein was labeled at 0.15 MBqmg^{-1} with $Na^{125}I$ by the chloramine T method (Fraker and Speck, 1978). Briefly, 18 MBq $Na^{125}I$ was added to the fusion protein (100 mg). After mixing, 100 mL of chloramine T (2 mg/mL) was added and reaction stopped after 30 s by the addition of 100 mL of L-tyrosine (2 mg/mL). Radiolabeled protein was separated from free ^{125}I by passage down a PD-10 desalting column. Incorporation of radiolabel was assessed by thin-layer chromatography and CEA binding activity by affinity chromatography. Four groups of nude mice bearing LS174T human tumor xenografts (4 mice per group) were injected with 1.1 MBq (6.2 μg) radiolabeled fusion protein and sacrificed 3, 6, 24, and 48 h postinjection. Selected normal tissues and tumors were then removed for comparative assessment using a gamma counter as previously described (Pedley et al., 1996). Results were expressed as percentage injected dose per gram of tissue and as tumor:tissue ratios.

Isolation of Intact Fusion Protein from Excised Tumors. Tumors were excised from host animals as described previously (Bhatia et al., 2000) 2 and 4 h postinjection of 28 μg of radiolabeled MFE-23::TNFα fusion protein, snap frozen, and stored at −70 °C before use. Blood samples were also taken, and the serum obtained was stored at −70 °C. Tumors were thawed, weighed, and homogenized in 20 mM HEPES buffer containing 2 mM EDTA and 100 μg/mL protease inhibitor cocktail (Sigma, Poole, UK). Samples of tumor homogenate and serum were loaded into the wells of 12% polyacrylamide gels and subjected to electrophoresis. A radiolabeled sFv was loaded as a control along with molecular weight markers. Gels were stained with Coomassie blue and destained in water/acetic acid/methanol until protein bands were visible. Gels were then exposed to phosphor image plates (Amersham Pharmacia Biotech UK, Little Chalfont, U.K.) for 120 h before analysis on a phosphor imager (Amersham Pharmacia Biotech UK, Little Chalfont, U.K.).

TNF Receptor Binding Studies. Fusion protein was radiolabeled with $Na^{125}I$ as described above. Labeled protein (~0.5 μg/0.05 MBq) was added to 200 μL of PBS and injected onto a Superose 12 size-exclusion column, and 2 mL fractions were collected. The fractions were then counted on a γ counter. For receptor binding studies, the fusion protein (~1 μg) was incubated with 3 μg of recombinant human TNF receptor 1/Fc chimera or recombinant mouse TNF receptor 1/Fc chimera (R&D Systems, Oxford, U.K.) for 15 min at room temperature prior to injection onto the column. Fractions were collected and counted as for fusion protein alone. The peak position was related to protein standards and molecular weight estimated by reference to the calibration curve constructed as above.

Cytotoxicity to Human Tumor Cells. The human colon adenocarcinoma cell line LoVo was used in this assay. Cells were plated at 1×10^5/well in culture medium and grown overnight. The cytotoxicity assay was carried out as outlined above for the WEHI cells. Fusion protein or rhTNFα controls were added in 10-fold dilutions (adjusted to yield from 1000ng/mL to 1pg/mL w/v TNFα), in triplicate in 200 μL culture medium. sFv MFE-23 alone was used as control (at the same proportion relative to TNFα as present in the fusion protein: 1530 ng/mL to 1.53 pg/mL). Percent cell death was calculated as outlined above for WEHI cells.

RESULTS

Expression and Purification of MFE-23::TNFα. MFE-23::TNFα was the major protein expressed in *E. coli* inclusion bodies after subcloning into the expression vector pET 21(d). The major protein band was seen in all five separate inclusion body extracts that were tested for fusion protein expression by SDS−PAGE prior to refolding. All five samples showed a major band of 48 kDa (Figure 2a), which is the estimated molecular weight of a MFE-23::TNFα monomer. This band was absent in the control cells. Approximately 10−14% of the extracted MFE-23::TNFα was subsequently refolded into the correct conformation for CEA binding as determined by the yields of CEA-binding material eluted from Sepharose-coupled CEA column. The CEA binding material eluted from this column was analyzed by SDS−PAGE, and the results are shown in Figure 2b. These indicate high-grade purity of MFE-23::TNFα since only a single band of 48 kDa remains. From the optical density measurements it was calculated that the yield of purified, refolded MFE-23::TNFα was 27.65 μg/mL bacterial culture.

Western Blot Analysis and CEA Binding ELISA. Both these methods of analysis demonstrated that the fusion protein comprised MFE-23 and TNFα. Western blot analysis showed that the protein was intact and antibodies to both MFE-23 and human TNFα reacted with the 48 kDa molecule. Antibody to MFE-23 also indicated some breakdown of the molecule, but the amount of smaller molecular weight proteins was low compared with the amount of intact fusion protein

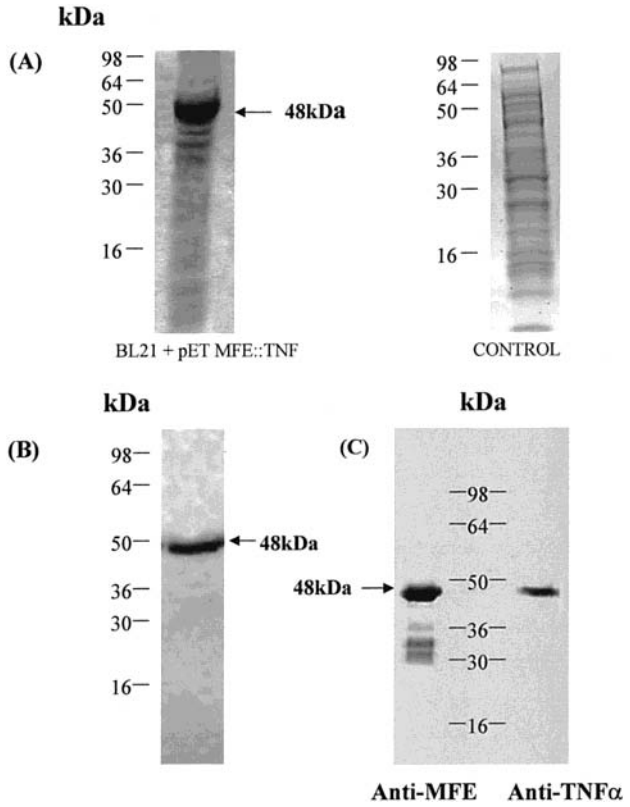

Figure 2. (A) Reducing SDS−PAGE gel showing expression of the 48 kDa MFE::TNFα fusion protein in inclusion body extracts. Twenty microliters of protein solution was loaded into each lane and stained with Coomassie blue. The 48 kDa protein comprises the majority of the total protein extracted from the bacterial inclusion body pellet; control cells do not show any major band at this molecular weight. (B) MFE-23::TNFα after refolding in redox buffer for 96 h and purification by affinity chromatography on a CEA column. (C) western blot analysis of MFE-23::TNFα showing reactivity of the 48kDa fusion protein with both anti-MFE-23 and anti-TNFα polyclonal antibodies. A small amount of breakdown product is also detected by the anti-MFE-23 antibody. Ten microliters of SeeBlue marker was loaded onto all gels to facilitate size estimation. M = molecular weight markers.

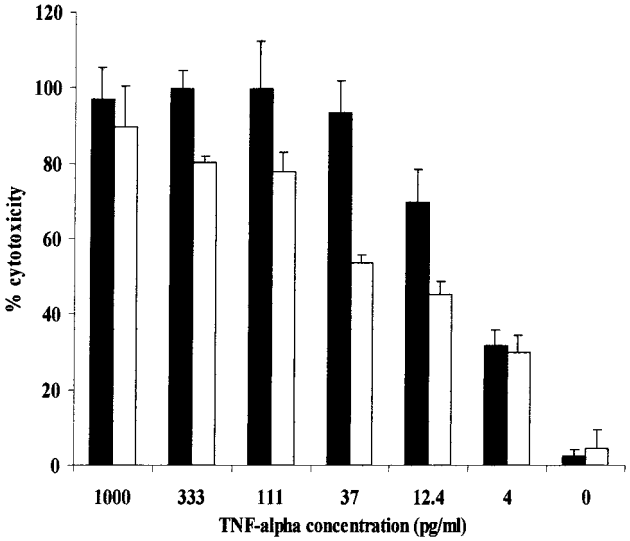

Figure 3. Cytotoxicity assay for TNFα bioactivity against actinomycin D-treated, TNFα-sensitive WEHI 164 cells. Recombinant human TNFα and MFE-23::TNFα were diluted from 1000 to 4 pg/mL (w/vTNFα) before addition to the assay plates. Medium alone represented no cytokine. Recombinant human TNFα yields maximum toxicity (no viable cells remaining) at a concentration of 100 pg/mL. MFE-23::TNFα is significantly less cytotoxic ($p < 0.05$) at all doses except 1000 and 4 pg/mL and on average 19% less toxic over the dose range tested. Control protein MFE-23 showed no toxicity to the WEHI 164 cells (data not shown). Results are expressed as mean ± SD of triplicate wells are representative of three separate experiments. TNFα, solid black; MFE-23::TNFα, white.

(Figure 2c). ELISA analysis of CEA-coated wells confirmed that the MFE-23::TNFα had specificity for CEA and reacted with antibodies to TNFα (data not shown).

Native Molecular Weight Determination. To determine the molecular weight of MFE-23::TNFα in its native form, 100 μg was passed down a Superose 12 size-exclusion column and the molecular weight estimated by comparison of the position of the eluted peak to those of molecular weight standards on a calibration curve for the column. A single peak was obtained centered around fraction 26 which corresponded to an estimated molecular weight of 144 kDa (91% of the injected protein) confirming that the fusion protein assumed a trimeric structure upon refolding. A smaller peak at around fraction 32−34 corresponded to the molecular weight of free MFE-23 (approximately 28 kDa) comprising 9% of the injected protein. No free TNFα was detected. Experiments performed after six weeks of storage at −70 °C gave identical results suggesting that the fusion protein is stable under these storage conditions (data not shown).

Cytotoxicity of MFE-23::TNFα. ***WIHI 164 Cells.*** We used the TNFα-sensitive cell line WEHI 164 to demonstrate that the fusion protein retained TNFα-mediated cytotoxicity in a standard MTT assay. The MFE-23::TNFα fusion protein exhibited a dose-dependent cytotoxic effect upon the WEHI cells that was significantly lower than that of recombinant human TNFα (rhTNFα) at 333, 111, 37, and 12 pg/mL but not so at 1000 and 4 pg/mL. However, MFE-23::TNFα was only on average 19% less cytotoxic over the dose range tested in the assay demonstrating that fusion to MFE-23 did not result in loss of cytotoxicity. Cell death was maximal (no intact cells visible by phase contrast microscopy) at a rhTNFα concentration of 100 pg/mL. There was no toxicity observed when cells were treated with MFE-23 alone (data not shown). Figure 3 shows the data for rhTNFα and MFE-23::TNFα expressed in terms of mean percent cytotoxicity.

Biodistribution Studies. Four groups of nude mice bearing LS174T human tumor xenografts (four mice per group) were injected with 1.1 MBq (6.2 μg) of radiolabeled MFE-23::TNFα fusion protein. Mice were sacrificed 3, 6, 24, and 48 h postinjection and tissues harvested and assessed using a γ counter. Figure 4a shows percent injected dose of fusion protein per gram tissue (% ID/g) at 3, 6, 24, and 48 h post intravenous administration of MFE-23::TNFα. Rapid clearance of the fusion protein was observed from all tissues tested within 24 h with selective retention of the molecule in the tumor. A maximum of 4.33% ID/g tumor was seen 6 h postinjection, falling to 1.99 and 1.58% ID/g tumor after 24 and 48 h, respectively. The same results are expressed as tumor/tissue ratios in Figure 4b to illustrate this tumor selectivity more clearly. Here, the retention of the fusion protein within the tumor is highlighted with tissue:blood ratios of 21:1 and 60:1 being achieved after 24 and 48 h, respectively. Liver and kidney were the only normal tissues to show retention of the fusion protein at these time points (liver = 0.14 and 0.087% ID/g; liver:blood ratio 2.12 and 4.4: kidney = 0.23 and 0.16% ID/g tissue; kidney/blood ratio 3.62 and 8.02) after 24 and 48 h,

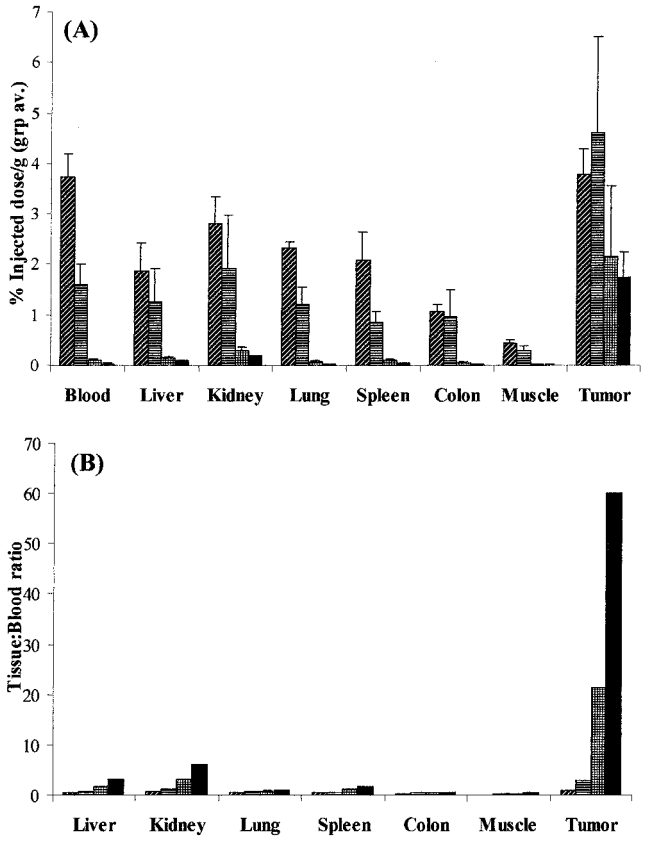

Figure 4. (A) Biodistribution of ^{125}I-MFE-23::TNFα in nude mice bearing the LS174T xenograft. Mice were injected with 1.1 Mbq (6.2 μg) ^{125}I-labeled MFE-23::TNFα and tissues excised 3, 6, 24, and 48 h post-fusion protein injection. After digestion in 7 M KOH, tissues were counted on a γ counter and radioactivity was assessed. Rapid clearance of the fusion protein was observed from all tissues tested within 24 h with selective retention of the molecule in the tumor. A maximum of 4.33% ID/g tumor was seen 6 h post-injection, falling to 1.99 and 1.58% ID/g tumor after 24 and 48 h, respectively. Columns, means of groups of four animals; bars, SD. (B) Tumor-to-tissue ratios obtained 3, 6, 24, and 48 h post-fusion protein injection. Tumor/blood ratios of 21:1 and 60:1 were achieved after 24 and 48 h, respectively. Columns, means of groups of four animals. Key: 3 h post-injection, diagonal cross-hatch; 6 h post-injection, horizontal cross-hatch; 24 h post-injection, black check; 48 h post-injection, solid black.

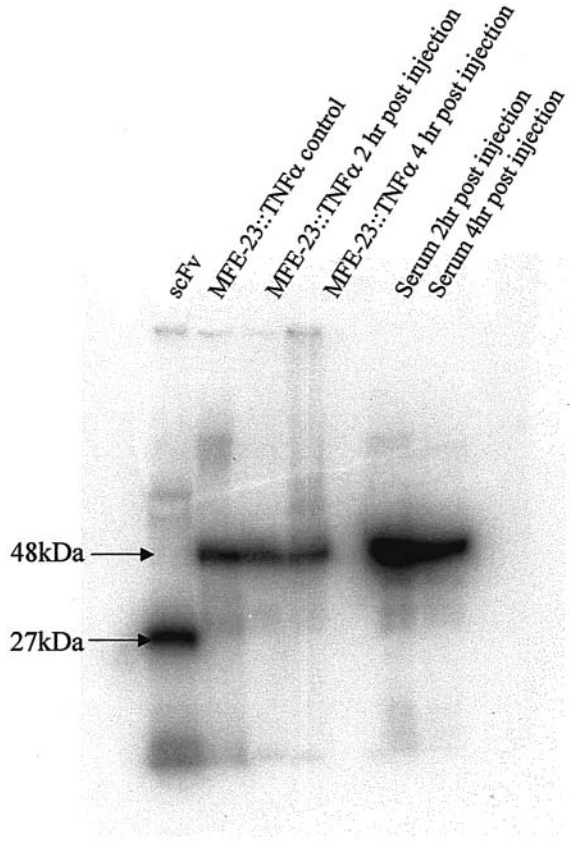

Figure 5. Extraction of intact MFE-23::TNFα from tumor homogenates and mouse serum. Mice were injected with 28 μg of ^{125}I MFE-23::TNFα and sacrificed 2 and 4 h post-injection. Blood and tumor were then taken. After homogenization and SDS−PAGE, a band of approximately 48 kDa can clearly be seen in the tumor extracts both 2 and 4 h post-injection of radiolabeled fusion protein. A band of the same molecular weight is seen in the serum. A ^{125}I-labeled sFv was loaded as a molecular weight control (27 kDa).

respectively. These data clearly demonstrate that MFE-23::TNFα shows high tumor specificity coupled with low uptake and retention by normal tissues or blood.

Isolation of MFE-23::TNFα from Tumors. Phosphor image analysis of the polyacrylamide gels showed a strong band of approximately 48 kDa in both tumor and blood samples (Figure 5). The intensity of the bands in the serum samples is greater at 2 h than at 4 h postinjection suggesting clearance of the fusion protein from the blood, supporting the evidence obtained from the biodistribution data. No free MFE or TNFα can be seen in any of the samples suggesting that the fusion protein is stable in vivo. This supports in vitro data obtained by incubating the fusion protein with human serum for 1 h or mouse serum for 2 and 4 h at 37 °C followed by analysis by FPLC. No degradation of the fusion protein was evident from these experiments (data not shown). Early time points were selected to give the best chance of detecting the fusion protein while still in the circulation to assess its resistance to degradation. The 48 kDa band present on the gels represents MFE-23::TNFα monomer, as the hydrophobic interactions which hold the TNFα trimer together are destroyed by SDS-sample buffers.

TNFα Receptor Binding Studies. To demonstrate that MFE-23::TNFα was able to bind TNF receptors after the radiolabeling procedure, ^{125}I-MFE-23::TNFα was preincubated with either recombinant human TNF receptor 1/Fc or mouse TNF receptor 1/Fc before loading onto a Superose 12 size-exclusion column for analysis by gel filtration chromatography. The results are shown in Figure 6. Radiolabeled, trimeric fusion protein was eluted from the column in fractions that corresponded to a molecular weight of approximately 144 kDa (Figure 6a) as read off the column calibration curve. After a 15 min incubation at room temperature with recombinant human TNF receptor 1/Fc chimera (which is a homodimer of approximately 120 kDa in native form), the peak was seen to shift from around fraction 26 to fractions 18−21 indicating an increase in the molecular weight of the radiolabeled species. This peak corresponded to a range of molecular weights consistent with the TNF trimer binding between one and three receptor molecules (Figure 6b). The peak was centered around fraction 19 suggesting the predominant species was a TNF trimer bound to two receptor molecules (estimated mw = 360 kDa, theoretical mw = 384 kDa). Similar results were obtained when ^{125}I-MFE-23::TNFα was preincubated with recombinant mouse TNF receptor 1/Fc chimera, indicating that the fusion protein effectively bound and complexed both human and murine TNF receptor mol-

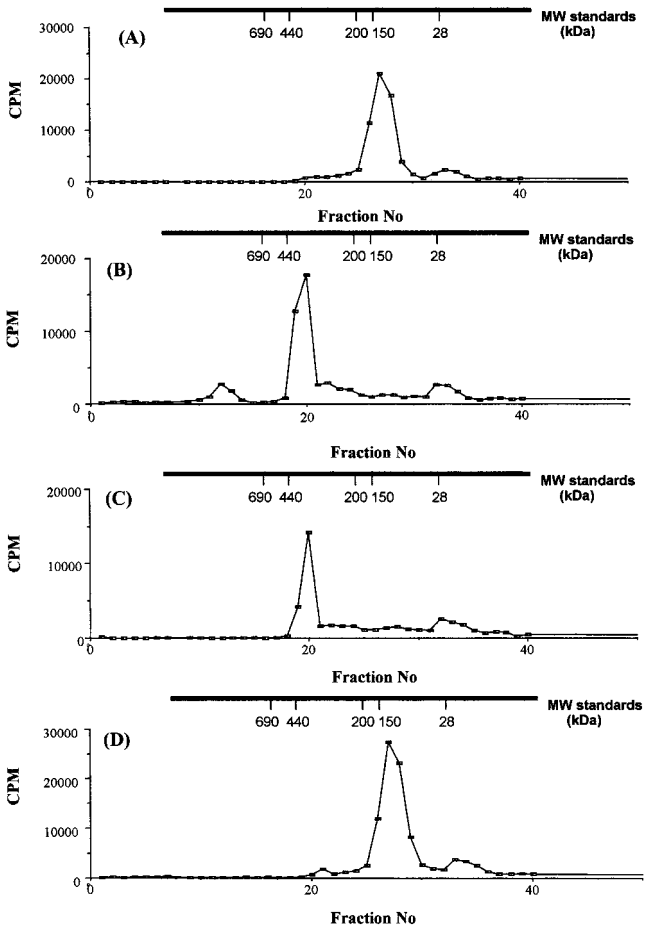

Figure 6. MFE-23::TNFα was preincubated for 15 min at room temperature with either human TNF R1/Fc or mouse TNF R1/Fc prior to loading onto a Superose 12 size-exclusion column calibrated with proteins of known molecular weight. After incubation with recombinant human (b) or recombinant mouse (c) TNF R1/Fc, an increase in molecular weight was seen (represented by the protein eluting at a lower fraction number; ~18−21 as opposed to ~26) indicating complex formation. Native fusion protein (a), or fusion protein incubated 0.1% BSA/0.1% HSA prior to loading (d) eluted with a molecular weight of ~144 kDa representing uncomplexed trimer. Molecular weight standards are indicated at the top of the figure.

ecules (Figure 6c). To control for the effects of the human serum albumin (HSA) and bovine serum albumin (BSA) included in the buffer solutions used to resuspend the recombinant receptor molecules, the fusion protein was incubated with PBS containing 0.1% BSA/0.1% HSA (concentrations identical to those in the buffers). The peak eluted in its original position around fraction 26 (Figure 6d). These data is consistent with the fusion protein retaining the ability to bind to TNFα receptors after radiolabeling.

Cytotoxicity to Human Tumor Cells (LoVo). LoVo cells were chosen for this assay because, unlike LS174T, they are susceptible to TNF-mediated cytotoxicity. Figure 7 shows that MFE-23::TNFα is as effective as TNFα alone at killing LoVo cells in vitro. Both the fusion protein and TNFα show identical LD_{50} values of 0.6 ng/mL. MFE-23 alone was used as a control and did not show any cytotoxic effects above background. Trypan blue exclusion showed 18% of cultured LoVo cells were not viable and this was taken as a measure of the background cell death in the cytotoxicity assays. These results confirm that MFE-23::TNFα is able to kill human tumor cells at the same concentrations as native TNFα.

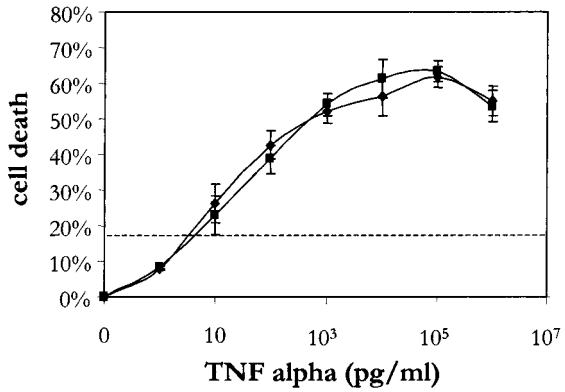

Figure 7. Cytotoxicity assay for TNFα cytotoxicity against actinomycin D-treated, LoVo tumor cells. Recombinant human TNFα and MFE-23::TNFα were diluted from 1000 to 1 pg/mL (w/vTNFα) before addition to the assay plates. Medium alone represented no cytokine. Both TNFα and the fusion protein show identical LD_{50} values of 0.6 ng/mL. Control protein MFE-23 showed no toxicity to the tumor cells above background (- - -) (data not shown). Results are expressed as mean + SD of triplicate wells and are representative of three separate experiments. TNFα, diamonds; MFE-23::TNFα, squares.

DISCUSSION

This study demonstrates that it is possible to localize TNFα to tumors in vivo by fusing it to a high-affinity antitumor antibody, despite the molecule retaining affinity for TNF receptors in normal tissues. MFE-23::TNFα was successfully refolded from bacterial inclusion bodies as a biologically active trimer with a yield of ~28 μg/mL. The molecule bound both human and murine TNF receptor 1, localized effectively to human tumor xenografts in a mouse model and killed tumor cells in in vitro assays.

Over the past decade, recombinant technology has been applied by a number of other groups to produce TNFα-linked antibodies. Some of the earliest used hybridoma cells engineered to produce an anti-transferrin receptor Fab linked to TNFα (Hoogenboom et al., 1991). The fusion protein had cytotoxic activity but it could not be isolated in sufficient amounts to enable tumor specificity studies to be undertaken. Another promising fusion protein incorporated TNFα fused to a sFv (B1) directed to the Le^{Y+} antigen (Scherf et al., 1996). This bacterially expressed fusion protein showed specificity for target cells and inhibited tumor growth in mice bearing MCF-7 (Le^{Y+}) tumors using a dose of 75 μg B1::TNFα injected on days 10, 12, and 14 after tumor implantation. However, the major problem was, again, that the fusion protein was only produced at a final concentration of 0.4 μg/mL. These reports highlighted a major problem facing workers attempting to produce TNFα-based fusion proteins for cancer therapy, namely low yields. This poses a significant problem as larger amounts are required for clinical use. Better yields (10 μg/mL) were obtained with an anti-TAG 72 sFv fused to TNFα (Yang et al., 1995). This fusion protein had anti-TAG 72 immunoreactivity and was cytotoxic in vitro but it was expressed as a mixture of monomer, dimer and trimer. TNFα is only fully biologically active in its trimeric form. In contrast to these reports, MFE-23::TNFα was expressed at high yields (~28 μg/mL) and exclusively as a trimer. This high expression may be due, in part, to the fact that the parent sFv can be expressed at high concentrations (~25 μg/mL) as a soluble protein and has been found to be particularly stable. This coupled with the slow refolding protocol in a "redox" environment may contribute significantly to the

yield of correctly folded MFE-23::TNFα recovered. This yield will be substantially improved by the use of fermenter technology and alternative expression systems such as *Pichia pastoris*.

An advantage conferred by the fact that MFE-23::TNFα is expressed as a trimer was that it retained its toxicity in standard WEHI 164 cell cytotoxicity assays. This will to be a major advantage if the molecule is successfully targeted to tumors without causing significant side effects due to "nontumor-specific" TNF receptor binding.

MFE-23::TNFα also proved cytotoxic to a human tumor cell line (LoVo) after treatment with actinomycin-D, showing LD_{50} values identical to that of recombinant human TNFα alone. Because LoVo cells express high levels of TNF receptors (data not shown), enhanced specificity due to the MFE-23 was not evident in the assays. The MFE-23 moiety did, however, rapidly localize the TNFα to the tumor and so did impart specificity in vivo although not in vitro.

The specific effects of TNFα on tumors include induction of necrosis (Abbruzzese et al., 1989), vascular hemorrhage (Watanabe et al., 1988), augmentation of the lethal effects of radiation against certain tumor cell lines (Chen et al., 1995; Mauceri et al., 1996), and an increase in vascular permeability (Rowlinson Busza et al., 1995). The effective harnessing of these properties while at the same time minimizing the less desirable effects to normal tissues is an important goal. MFE-23::TNFα represents a significant step in this direction. Reduction in cytotoxicity of the TNFα molecule is desirable if systemic side effects or sequestration of the protein by cellular and soluble receptors is to be avoided. It is the uptake of TNFα by TNF receptors by normal cells that results in poor tumor localization because of the reduction in the amount of injected TNFα able to reach the tumor. Indeed, natural mechanisms such as soluble TNF receptors in the blood, which are there primarily to protect against the nonspecific effects of endogenous TNFα, are a possible barrier to high tumor uptake of TNFα-based fusion proteins (Engelmann et al., 1989).

Reduction in cytotoxicity due to receptor sequestration can be countered by the rapid sFv-directed accumulation of the cytokine at the tumor site. Thus, high local doses may be achieved with lower, less toxic doses administered systemically. This argument is supported by the data presented here. We have shown that radiolabeled MFE-23::TNFα rapidly and efficiently localizes to tumors even though it is still able to bind both human and mouse TNF receptor type 1 (p55). In our in vitro experiments, all fusion protein was bound by receptor after a fifteen-minute incubation. These data, coupled with that shown by the biodistribution experiments, clearly demonstrate that ^{125}I-labeled MFE-23::TNFα is able to "bypass" blood-borne receptors and localize in LS174T human tumor xenografts with a positive (1.45) tumor/blood ratio observed as early as 3 h postinjection. This rises rapidly, culminating in a ratio of 60:1 after 48 h, corresponding to 1.58% injected dose/gram tumor (the maximum being 4.33% ID/g after 6 h). Most importantly, the phosphor image experiments on homogenized tumor extracts show unequivocally that the figures are due to localized, intact fusion protein and not free MFE-23 or TNFα. The high affinity of MFE-23 for CEA may play a large part in this, coupled with the overall size of the fusion protein (144 kDa) which gives good tumor retention. It is possible therefore, to target TNFα specifically to tumors without unacceptable "losses" en route.

It should be noted that TNFα binds with a higher affinity to human receptors than to murine receptors and also binds both human TNF R1 and TNF R2 (as opposed to TNF R1 only in the mouse model). This suggests that sequestration may be more of a problem in patients than in mice. The engineering of mutant TNFα molecules with reduced affinity for human TNF receptors will provide a way forward if this presents obstacles in the clinic (Cha et al., 1998). Another approach may be to use TNFα molecules specifically engineered to have sole affinity for human TNF R1, the receptor thought to be primarily responsible for inducing cytotoxic activity (Sato et al., 1998) rather than TNF R2, that is thought to be responsible for cellular activation (and thus unwanted side effects). Scherf et al. (1996) addressed the problem of nontumor specific toxicity by fusion the TNFα to the scFv via its C-terminus. This had the effect of reducing the cytotoxicity in in vitro assays 50-fold as the fusion protein was severely compromised in its ability to form active trimers. We have shown that this may not be necessary if the targeting scFv is of sufficiently high affinity to localize the fusion protein rapidly. MFE-23 has an affinity of 2×10^{-9} M, much higher than the anti-LeY antigen scFv used by Scherf et al. (of the order of 10^{-6} M). This higher affinity may mean that lower doses of a more active molecule may be given in a clinical situation with fewer side effects.

The fact that MFE-23::TNFα is a trimeric molecule also brings advantages in terms of avidity and consequent tumor retention. We have shown in other studies that higher avidity and a larger size will facilitate the retention of antibody-targeted therapeutics in viable areas of the tumor long after they have cleared from the blood and other tissues (Flynn et al.; in press). This is supported by the tumor:tissue ratios obtained with MFE-23::TNFα which increase up to 48 h postinjection.

Other workers have attempted to localize TNFα to tumors in animal models by a variety of different methods not involving fusion proteins. Robert et al. (1996) were successful in obtaining a high degree of localization of ^{125}I-labeled TNFα (^{125}I-TNFα) in tumor-bearing mice after prior injection of a bispecific mAb (BAb) directed against CEA and TNFα. Mice were treated with 3 μg of BAb followed by 1 μg of ^{125}I-TNFα 24 h later. At all time points, the Bab-injected mice showed specific tumor uptake of ^{125}I-TNFα.

The tumor/tissue ratios improved if a delay of 48 h before ^{125}I-TNFα injection was utilized. High doses of free ^{125}I-TNFα did diffuse rapidly into the tumors in control mice however, but this was followed by a rapid decrease in %ID/g tumor tissue and at no time was a significant, positive tumor/tissue ratio obtained. Although administration of the bispecific antibody followed by TNFα did result in tumor localization of the cytokine, the major advantage of our fusion protein-based approach is that no pre-injection of capture antibody is necessary and so this would be much more practical for clinical application. Similarly, a genetic fusion protein is likely to provide a simpler therapeutic option than other methods of targeting such as Cu2+-dextran (Tabata et al., 1999) or TNFα-biotin conjugates (Moro et al., 1997; Gasparri et al., 1999) which are all multistep approaches. MFE-23::TNFα is also a very "adaptable" molecule. The genetic "cassette" can be easily modified, both in terms of the sFv used to target or the cytokine used as effector, making this an agent that can be tailored to different tumors or cell types depending upon there susceptibility to certain agents.

In summary, we have produced a sFv::TNFα fusion protein in high yield that is biologically active in its

native form and retains affinity for both CEA and for both murine and human TNF receptors. Most importantly, despite its receptor binding capability, the fusion protein is still able to localize rapidly and effectively to tumors in vivo. This work indicates that MFE-23::TNFα has potential to deliver TNFα-meditated cancer therapy in the clinic.

Development of a Conjugate of ^{99m}Tc-EC with Aminomethylenediphosphonate in the Search for a Bone Tracer with Fast Clearance from Soft Tissue

Kristin Verbeke,[†,§] Jef Rozenski,[‡] Bernard Cleynhens,[†] Hubert Vanbilloen,[†] Tjibbe de Groot,[†] Nancy Weyns,[†] Guy Bormans,[†] and Alfons Verbruggen*[,†]

Laboratory of Radiopharmaceutical Chemistry, University Hospital Gasthuisberg, Herestraat 49, B-3000 Leuven, and Rega Institute for Medical Research, University of Leuven, Belgium. Received December 29, 2000; Revised Manuscript Received August 30, 2001

For the currently used ^{99m}Tc-labeled diphosphonates such as ^{99m}Tc-MDP and ^{99m}Tc-HDP, the required interval of 2.5 to 3 h between injection and the scintigraphic bone imaging is an inconvenience. The present study was set up in an attempt to develop a technetium-99m-labeled diphosphonate with efficient bone uptake and more rapid clearance from blood and soft tissue by renal extraction and excretion so that it would be possible to start imaging as early as 1 h after injection. A conjugate of the new renal tracer agent ^{99m}Tc-ethylene dicysteine (^{99m}Tc-L,L-EC), covalently bound via one of its carboxylates with aminomethylenediphosphonic acid (AMDP), was synthesized in seven steps. EC-AMDP could be labeled easily and efficiently with ^{99m}Tc at pH ≥12 and room temperature. Analysis using ion pair reversed phase high performance liquid chromatography showed the formation of a mixture of two main compounds with reproducible relative ratios, which were stable as a function of time. In a baboon, the scintigraphic images obtained with the new agent showed good quality bone scans, with clear visualization of the skeleton and low soft tissue activity at respectively 1 and 2 h after injection.

INTRODUCTION

Radionuclide bone imaging is the most common clinical investigation in nuclear medicine. Since the mid-1970s, the bone scan has replaced the X-ray skeletal survey because of its 95% sensitivity in detecting metastatic disease and because this radioisotopic technique allows detection of some lesions several months earlier than with X-ray examination. The reason for the latter lies in the fact that the bone scan demonstrates osseous remodeling, which must precede and is the cause of structural changes seen on the X-ray image (*1*).

For more than 20 years, ^{99m}Tc-labeled diphosphonates have been the radiopharmaceuticals of choice for radioisotopic bone scanning. The tracer agents most widely used at present are complexes of ^{99m}Tc with methylenediphosphonate (^{99m}Tc-MDP) and hydroxymethylenediphosphonate (^{99m}Tc-HMDP) (*2*−*4*).

Despite their wide clinical use, ^{99m}Tc-diphosphonates suffer from a number of suboptimal properties. First, they are fairly weak chelates and, therefore, tend to degrade with time and produce pertechnetate as an impurity. The use of a suitable antioxidant such as ascorbic acid, gentisic acid, or *p*-aminobenzoic acid helps to overcome this problem (*5*). Second, ^{99m}Tc-diphosphonates are not single, well-defined chemical species, but mixtures of short- and long-chain polymers in which one or more technetium atoms are bridged by two or several phosphate and hydroxyl ligands. Different polymers can have a different degree of ionization and biological behavior. Analysis by high-pressure liquid chromatography (HPLC) has also revealed that the relative amounts of the different species in a ^{99m}Tc-diphosphonate preparation vary as a function of time after reconstitution (*6*−*10*). In addition, the diphosphonate group is necessary both for the complexation of ^{99m}Tc and the uptake of the complex in the skeleton (*11*). This may have the disadvantage that a phosphonate group involved in the binding of ^{99m}Tc has a reduced ability of binding to the bone surface. Following intravenous administration, the uptake of ^{99m}Tc-diphosphonates in bone is almost complete 1 h after injection, but the clearance from soft tissue proceeds more slowly (*12*). For this reason, a time interval of 2 to 4 h is required between injection of the radiopharmaceutical and the bone scanning. This necessary delay is an important inconvenience for the nuclear medicine personnel and for the patients, especially for children.

Therefore, it would be a major improvement for nuclear medicine if the ^{99m}Tc-diphosphonates could be modified in such a way that:

(a) they still have a high and rapid uptake in the skeleton with the same lesion-to-normal bone activity ratio;

(b) the clearance from soft tissue by the kidneys followed by excretion into the urine would be much faster. In an ideal situation, it should be possible to obtain good quality scintigraphic images already 1 h after injection with the same clinical information as now after 3−4 h.

Therefore, the aim of the present study was the development of a "new generation" bone-seeking radiopharmaceutical with the above-described characteristics. For this purpose, a strategy was designed in which a diphosphonate is conjugated to a stable and easy to

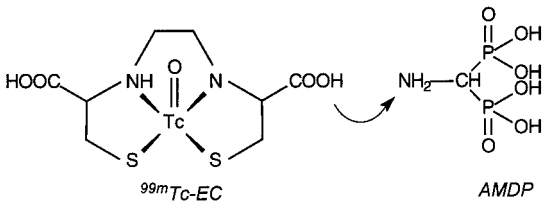

Figure 1. Structure of ^{99m}Tc-EC and aminomethylenediphosphonate (AMDP).

prepare ^{99m}Tc complex with known very rapid active renal excretion. In this conjugate, the diphosphonate would be "free" (i.e., not bound to Tc) and thus retain its full ability for binding to the bone surface. On the other hand, the ^{99m}Tc-labeled renal agent would ensure both a stable binding of the radionuclide (^{99m}Tc) and a rapid urinary elimination of the fraction of the tracer agent not bound to the skeleton.

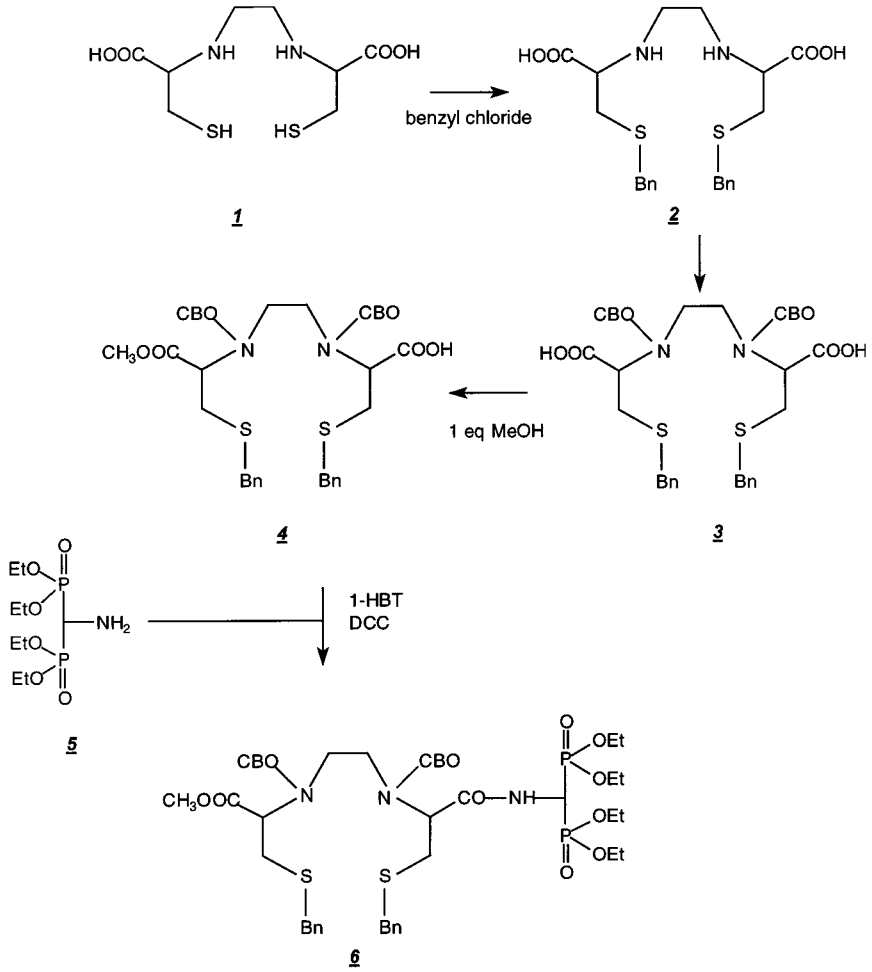
For different reasons, we selected the complex of ^{99m}Tc with L,L-ethylene dicysteine (^{99m}Tc-L,L-EC, Figure 1) as the ^{99m}Tc-labeled renal agent to which the diphosphonate can be bound. It is a very stable and easy to prepare ^{99m}Tc complex with the highest plasma clearance by renal extraction ever reported for a ^{99m}Tc-compound (*13*). In humans the 1-h plasma clearance of ^{99m}Tc-L,L-EC is 75% of the Hippuran clearance as compared to about 60% for ^{99m}Tc-MAG3 (*14*, *15*). Moreover, it has in its structure two carboxylic groups of which one can be omitted without significantly affecting the renal excretion characteristics (*16*). This means that one of the carboxylates can be used for coupling to a diphosphonate bearing an amino group in its structure. Aminomethylenediphosphonate (AMDP, Figure 1) is such a diphosphonate and was selected as the diphosphonate part of our new compound. Preliminary experiments have demonstrated that during labeling of equimolar amounts of EC and a diphosphonate with ^{99m}TC, the radionuclide exclusively binds to the EC ligand and not to the diphosphonate (*17*), which in this way retains its full ability for binding to the bone surface.

MATERIALS AND METHODS

Materials. Thin-layer chromatography (TLC) was carried out using precoated TLC plates (Alugram SIL G/UV254, Macherey-Nagel, Düren, Germany). For purification by column chromatography, silica gel (MN Kieselgel 60, 70−230 mesh ASTM, Macherey-Nagel) was used. L,L-Ethylene dicysteine (***1***) and the tetraethyl ester of 1-aminomethylenediphosphonic acid (***5***) were prepared as described elsewhere (*18*−*20*).

^{1}H and ^{13}C NMR spectra were obtained on a Varian Gemini 200 spectrometer (Varian, Palo Alto, CA). Chemical shifts are reported in ppm relative to the standard reference tetramethylsilane. Liquid secondary ion mass spectra (LSIMS) were recorded on a Kratos Concept IH mass spectrometer (Kratos Analytical, Manchester, UK) controlled by a Masspec II data system (MSS, Manchester, UK) and obtained in a negative (-LSIMS) ion mode. Negative mode electrospray ionization (-ESI) mass spectra were acquired on an orthogonal acceleration time-of-flight mass spectrometer (qTof-2, Micromass, Manchester, UK).

^{99m}Tc-MDP was prepared by reconstitution of a conventional MDP labeling kit with sodium [^{99m}Tc]pertechnetate solution from a ^{99m}Tc generator (Ultratechnekow-FM, Mallinckrodt Medical, Petten, The Netherlands).



***S,S′*-Bis-benzyl-L,L-1,2-ethylene Dicysteine (2).** 1,2-L,L-Ethylene dicysteine (**1**, 41.37 g, 154 mmol) was dissolved in liquid ammonia (1000 mL) in a two-necked flask with a dewar cooler, and the mixture was stirred vigorously. Sodium (12.8 g, 555 mmol) was added until a blue color persisted for at least 15 min. Ammonium chloride was then added in portions till decoloration. After dilution with liquid ammonia (400 mL), benzyl chloride (40 mL, 320 mmol) was added dropwise. After stirring for 30 min, the liquid ammonia was removed by evaporation at room-temperature overnight. Water (600 mL) was then added, and the solution was washed with ether (3 × 200 mL). The water layer was acidified to pH 2 with 6 M HCl. The precipitate formed was filtered off and washed successively with water, ethanol, acetone, and finally with ether and dried under vacuum to yield 25.99 g (60%) of a white product (Scheme 1).

***N,N′*-Bis-carbobenzyloxy-*S,S′*-bis-benzyl-1,2-L,L-ethylene Dicysteine (3).** In a 2000-mL beaker *S,S′*-bis-benzyl-1,2-L,L-ethylene dicysteine **2** (27.2 g, 60 mmol) was suspended in water (1000 mL) and dissolved by addition of 1 M NaOH up to pH 11. After cooling to 0−5 °C, benzyl chloroformate (27 mL, 180 mmol) was added dropwise over a period of 30 min while the pH was maintained at 11 by addition of 4 M NaOH. After washing with ether (300 mL), the water layer was acidified to pH 2 with 6 M HCl and extracted with EtOAc (3 × 300 mL). The combined organic layers were dried over Na_2SO_4 and evaporated to yield a yellow oil which was purified by column chromatography using gradient mixtures of methanol in CH_2Cl_2/acetic acid (100:1, V/V). Evaporation of the fractions containing the pure main compound as shown by TLC (CH_2Cl_2−methanol−HOAc, 95:5:1, R_f = 0.7) yielded 26.8 g of a colorless oil. ^{1}H NMR: ($CDCl_3$): δ 2.6−3.1 (4H, m, 2 x CH−CH_2−S); 3.3−3.5 (4H, m, 2 x CH_2−N-); 3.7 (4H, 2 x s, 2 x S−CH_2−Ar); 4.3 (2H, m, 2 x N−C*H*−COO-); 5.5 (4H, m, 2 x Ar−CH_2−O−CO-); 7.3 (20H, m, 4 x CH_2−*Ar*); 9.0 (2H, br s, 2 x CH−COO*H*).

***N,N′*-Bis-carbobenzyloxy-*S,S′*-bis-benzyl-1,2-L,L-ethylene Dicysteine Monomethyl Ester (*4*).** To a solution of **3** (3.58 g, 5 mmol) and (dimethylamino)-pyridine (DMAP, 61 mg, 0.5 mmol) in a mixture of methanol (0.2 mL, 5 mmol) and CH_2Cl_2 (50 mL) at 5 °C was added dicyclohexylcarbodiimide (DCC, 1.031 g, 5 mmol), and the reaction mixture was stirred overnight at room temperature. After removal of the precipitate (dicyclohexylurea), the filtrate was evaporated and the residual oil purified by column chromatography using gradient mixtures of hexane and CH_2Cl_2 as the mobile phase. A colorless oil (1.56 g, 42%) was obtained. ^{1}H NMR: ($CDCl_3$): δ 2.5−3.1 (4H, m, 2 x CH−CH_2−S); 3.3−3.8 (4H, m, 2 x CH_2−N-; 3H, s, COOCH_3); 3.6 (4H, 2 x s, 2 x S−CH_2−Ar); 4.1−4.6 (2H, m, 2 x N−C*H*−COO-); 5.1 (4H, m, 2 x Ar−CH_2−O−CO-); 7.3 (20H, m, 4 x CH_2−*Ar*); 8.3 (H, br s, CH−COO*H*).

Ethylene-l-(*S*-benzyl-*N*-carbobenzyloxycysteine methyl ester)-2-*S*-benzyl-*N*-carbobenzyl-oxy-cysteinylmethylenediphosphonic Acid Tetraethyl Ester (6). To a solution of **4** (1.56 g, 2.14 mmol) and 1-hydroxybenzotriazole (HBT, 0.29 g, 2.14 mmol) in acetonitrile (20 mL) at 0−5 °C was added DCC (0.442 g, 2.14 mmol), and the mixture was stirred for 30 min. After addition of 1-aminomethylenediphosphonic acid tetraethyl ester (**5**) (0.648 g, 2.14 mmol) in one portion, stirring was continued overnight at room temperature. The precipitate was removed by filtration, the filtrate evaporated, and the residue purified by column chromatography using gradient mixtures of methanol in CH_2Cl_2 to yield **6** as a colorless oil (1.1 g). ^{1}H NMR ($CDCl_3$): δ 1.25 (12H, m, 4 x O−CH_2−CH_3); 2.5−2.9 (4H, m, CH−CH_2−S); 3.4 (1H, m, CO−NH−C*H*); 3.3−3.8 (11H, m, COOCH_3,

Scheme 1. Synthesis of the Fully Protected EC-AMDP Conjugate (6)

2 x CH_2−N, 2 x S-CH_2−Ar); 4.2 (8H, m, 4 x O−CH_2−CH_3); 4.4 (2H, m, N−C*H*−CO); 5.1 (4H, m, 2 x Ar−CH_2−O−CO); 7.3 (20H, m, 4 x CH_2−*Ar*). ^{13}C NMR ($CDCl_3$): δ 16.3 (O−CH_2−*C*H_3); 30.8, 30.9 (2 x CH−*C*H_2−S); 35.5 (CO−NH−*C*H); 36.1, 36.3 (2 x S−*C*H_2−Ar); 45.8, 46.4 (*2* x *C*H_2−N); *52*.3 (COO*C*H_3); 58.2,60.1 (2 x N−*C*H−CO); 63.6 (O−*C*H_2−CH_3); 67.6,68.0 (2 x Ar−*C*H_2−O−CO); 127.1, 128.5, 135.9, 137.4 (Ar); 156.8 (Ar−CH_2−O−*C*O); 170.4 (*C*O−NH−CH); 170.9 (*C*OOCH_3). MS LSIMS (nba): $[M - H]^-$ 1015.6.

Ethylene-l−L-cysteine-2-L-cysteinyl-aminomethylenediphosphonic Acid (7b). To a solution of **6** (1.016 g, 1 mmol) in CH_2Cl_2 (10 mL) at 0 °C was added trimethylsilyl bromide (TMSBr, 2 mL, 15 mmol). After stirring at room temperature for 72 h, the reaction mixture was evaporated, and to the residue was added methanol (10 mL). After stirring during 1.5 h, the methanol was removed by evaporation, and the residue was dried in a vacuum over P_2O_5. After addition of a mixture of methanol (10 mL) and 1 M NaOH (6 mL), the mixture was refluxed during 2 h. The solvent was evaporated, and the residual solid was stirred in methanol (20 mL). The white precipitate was filtered off, washed with methanol, and dried under a stream of nitrogen (intermediate **7a**, Scheme 2). MS-ESI: *m/z* calcd for $C_{39}H_{44}N_3O_{13}P_2S_2$ $[M - H]^-$ 888.1790; found 888.1780.

The precipitate (50 mg) was dissolved in liquid ammonia (20 mL), and pieces of sodium were added until a blue color persisted for 4 h. After decoloration with NH_4-Cl, the ammonia was removed under a stream of nitrogen, and the residual solid (**7b**, Scheme 2) was dried in a vacuum and used as such for labeling experiments.

Labeling with ^{99m}Tc and Analysis. Direct labeling of **7b** with ^{99m}Tc was performed by addition of 100 μg of $SnCl_2 \cdot 2H_2O$, dissolved in 25 μL of 0.05 M HCl, and 1 mL of eluate of a commercial generator containing 370−3700 MBq ^{99m}Tc in the form of sodium pertechnetate to a labeling vial containing 1 mg of **7b** (EC-AMDP) dissolved in 1 mL of 0.2 M NaOH.

After incubation for a few minutes at room temperature, the labeling reaction was analyzed by ion-pair reversed phase high-pressure liquid chromatography (IP-RP-HPLC). The system consisted of a Merck-Hitachi ternary gradient pump (model L-6200 intelligent pump, Merck, Darmstadt, Germany), a Valco N6 injector (Alltech, Deerfield, IL), and a 250 mm × 4.6 mm Hypersil ODS 5 μm column (Shandon Scientific, Maidstone, England). After application of the sample, the column was eluted with gradient mixtures of water, methanol, 0.008 M tetrabutylammonium hydroxide, and 0.0013 M MDP (pH 7.5) (see Table 1). The radioactivity in the column effluent was monitored with a 2-in. NaI(T1) scintillation detector and recorded on an IBM-compatible PC equipped with an integration program (Rachel, Lablogic, Sheffield, England).

Biodistribution in Rats. The ^{99m}Tc-EC-AMDP labeling mixture was used as such or its main components were isolated using the RP-HPLC described above. The labeling reaction mixture or the HPLC isolated peaks were diluted to a concentration of 0.37 MBq/mL with saline. Male rats (body mass 60−80 g) were sedated by im injection of 0.1 mL of a 1 to 4 diluted solution of Hypnorm (Duphar, Weesp, The Netherlands). Then, 0.2 mL of the diluted tracer solution was injected via a tail

Scheme 2. Deprotection of the Fully Protected Intermediate To Obtain the EC-AMDP Conjugate

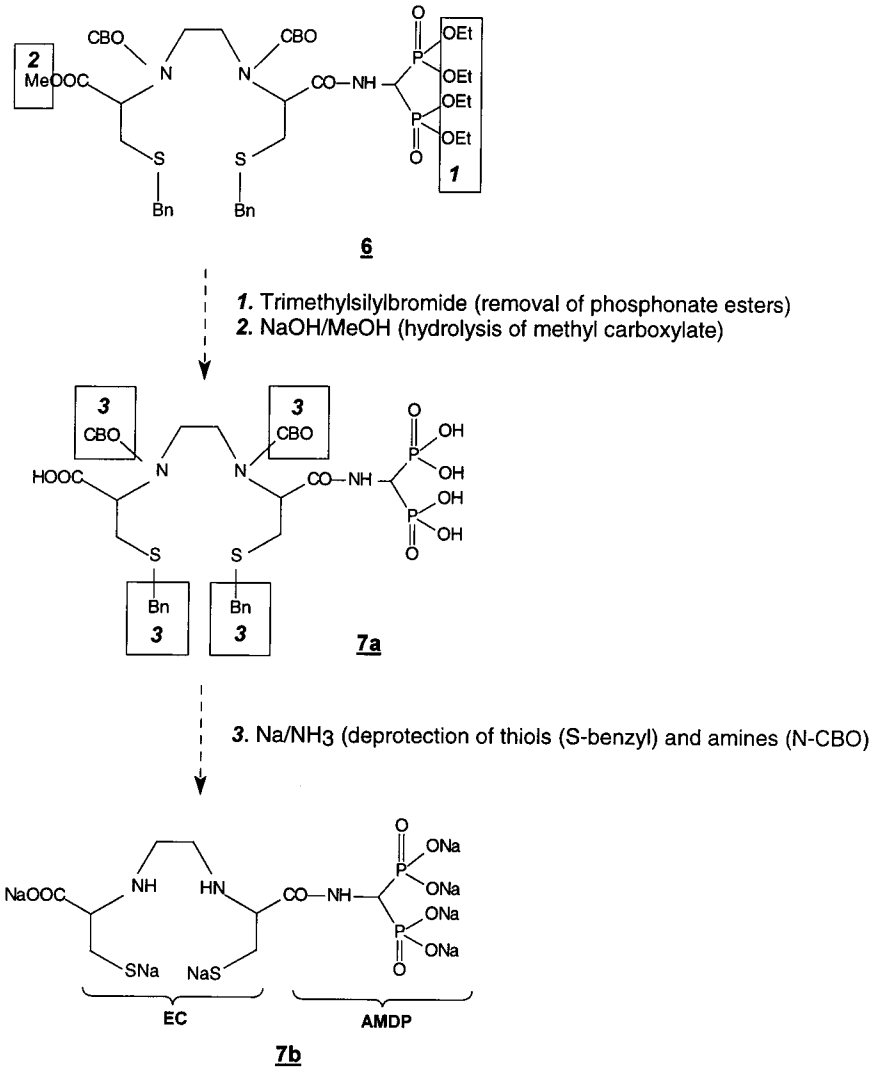


Table 1. Composition of the Mobile Phase Used in the HPLC Analysis as a Function of Time (linear gradient)[a]

time (min)	% A	% B
0	100	0
5	50	50
10	50	50
25	0	100
30	0	100
35	100	0

[a] A: water containing 10% MeOH, 0.008 M tetrabutylammonium hydroxide (TBAH) and 0.0013 M MDP (pH 7.5). B: water−methanol (40:60, V/V), containing 0.008 M TBAH and 0.0013 M MDP (pH 7.5). Flow rate: 1 mL/min.

vein into each of six rats. The rats were sacrificed by decapitation at fixed time intervals (two rats at 30, 60, and 120 min postinjection (p.i.), respectively) and the organs were dissected. The left and right femur were carefully cleaned and weighed. The activity in all organs and other body parts was counted in an automated sample counter (1480 Wizard3", Wallac, Turku, Finland) and corrected for background radiation and physical decay during counting. Results were expressed as percentage of injected activity, equal to the sum of the net activity in all organs. Blood was assumed to be 7% of the body mass.

Biodistribution in Rabbits. ^{99m}Tc-MDP or ^{99m}Tc-labeled EC-AMDP (without HPLC purification) were diluted with saline to a concentration of 37 MBq/mL. A male albino rabbit (body mass 3.0 kg) was sedated by im injection of 0.75 mL of Imalgène (Rhône Mérieux, Lyon, France), and 1 mL of the diluted tracer solution was injected via an ear vein. After 60 min, whole body images were acquired during 6 min using a gamma camera (BIAD XLT 24, Trionix, Twinsburg, OH), equipped with a low energy ultra resolution parallel collimator (LEUR-parallel) and connected to a data system SUN (Sparc station 10, Trionix).

Evaluation in a Baboon. A male baboon (body mass approximately 21 kg) was anaesthetized by intramuscular injection of 75 mg of ketamine (Imalgène). Anaesthesia was sustained with Fluothane. Then, 185 MBq of the radiolabeled preparation (^{99m}Tc-MDP or ^{99m}Tc-EC-AMDP, both without HPLC-purification), adjusted to pH 7 with 0.2 M phosphate buffer, was injected via a limb vein. Whole body images were taken at different time intervals postinjection using a dual head gamma camera as described above for the rabbit study. At fixed time intervals (2, 5, 7, 10, 15, 20, 30, 45, 60, 80, 100, 120 min p.i.) a 2-mL blood sample was taken in heparinized tubes (Monoject H100, Sherwood Medical, Balleymoney, Ireland). After centrifugation for 10 min at 1000 g plasma samples of approximately 0.5 g were pipetted in tubes, weighed, and counted as described above.

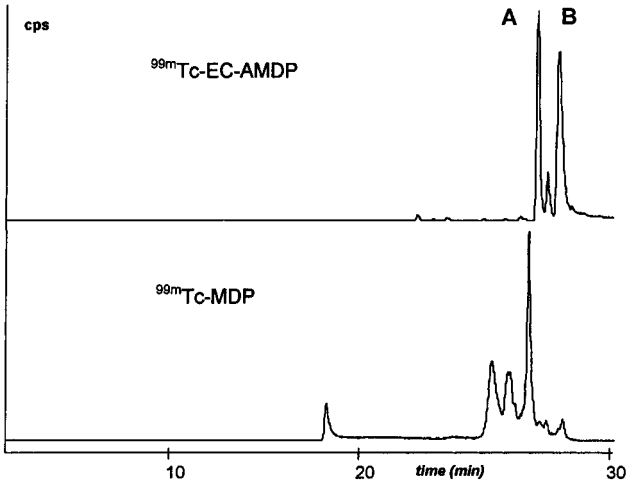

Figure 2. Ion pair RP-HPLC chromatograms of ^{99m}Tc-EC-AMDP and ^{99m}Tc-MDP. For conditions: see Materials and Methods.

RESULTS AND DISCUSSION

Synthesis of the EC-AMDP Conjugate. A multistep procedure has been designed to obtain the conjugate of ethylene dicysteine with aminomethylenediphosphonate in reasonable yields (Schemes 1 and 2). Since EC contains in its structure six functional groups (2 thiols, 2 amines, 2 carboxyl functions), a complex strategy of protection and deprotection of the respective functional groups had to be applied. The thiols were protected with a benzyl group, the amines with a carbobenzyloxy (CBO) group, and one of the carboxylates as a methyl ester (Scheme 1). The preparation of the monomethyl ester was performed by reaction of the diacid with 1 equiv of methanol in the presence of DMAP and DCC, followed by purification of the reaction product. In this way, a reasonable yield (42%) of the monoester was obtained. In addition, the four phosphonate groups of AMDP had to be protected as their ethyl ester to allow purification and confirmation of the identity of the precursors, the intermediates, and the fully protected EC-AMDP conjugate. Removal of the different protective groups was performed successfully in three steps using trimethylsilyl bromide for the phosphonate esters, alkaline hydrolysis of the methyl ester of the EC-moiety, and finally treatment with sodium in liquid ammonia to remove the *S*-benzyl and N-CBO groups (Scheme 2). Characterization of the intermediates by either NMR or mass spectrometry was possible up to intermediate **7a**, but was unsuccessful for the final fully deprotected conjugate **7b** because of high salt concentrations in the reaction product. In fact, the compound obtained after deprotection of the *S*-benzyl and N-CBO groups by treatment of **7a** with sodium in liquid ammonia was not further purified due to the small amounts available and the difficulty of chromatographic desalting of the highly polar conjugate **7b** and it was used as such for labeling with technetium-99m.

Table 3. Femur to Blood Activity Ratios for ^{99m}Tc-MDP and ^{99m}Tc-EC-AMDP (total preparation and HPLC-isolated peaks) in Rats (n = 2)

		30 min	60 min	120 min
^{99m}Tc-MDP		12.4	35.8	48.4
^{99m}Tc-EC-AMDP	total	19.9	55.1	98.0
	peak A	23.9	106.3	363.5
	peak B	26.9	50.2	745.9

Labeling of EC-AMDP with ^{99m}Tc and Analysis. Labeling of the conjugate with ^{99m}Tc was performed in the same conditions as described for EC, i.e., by a direct labeling procedure at alkaline pH and room temperature. As mentioned higher, previous experiments had indicated that the complexation strength of the N_2S_2-ligand EC is much higher than that of the diphosphonate. Therefore, there is no doubt that technetium is bound only by the N_2S_2-ligand and not by the diphosphonate moiety. Analysis of the labeling reaction product by ITLC showed that the solution did not contain measurable amounts of pertechnetate or ^{99m}Tc in colloidal form. Further analysis by IP-RP-HPLC showed the formation of a mixture of three compounds, of which the relative amounts were reproducible and constant as a function of time after preparation (Figure 2). The different peaks could easily be separated by HPLC and were stable after isolation. The HPLC-chromatogram of ^{99m}Tc-MDP clearly shows different complexes of which the relative amounts varied as a function of time after reconstitution and which were not reproducible. When one of the components of ^{99m}Tc-MDP was isolated by HPLC, it gradually converted to the other components as a function of time. In the biodistribution studies, ^{99m}Tc-MDP was always used as the complete preparation.

Biological Evaluation in Rats. The results of the biodistribution studies in rats of ^{99m}Tc-MDP and ^{99m}Tc-EC-AMDP (total preparation) at 30, 60, and 120 min p.i. are shown in Table 2. The activity in the femur is almost identical for ^{99m}Tc-MDP and ^{99m}Tc-EC-AMDP at 30 and 60 min p.i., whereas at 120 min p.i. ^{99m}Tc-EC-AMDP has a clearly higher uptake in bone than ^{99m}Tc-MDP. At each time point, the residual activity in the blood is lower for the new ^{99m}Tc-labeled conjugate, and as a result, the femur to blood activity ratios found with the total preparation are significantly higher for ^{99m}Tc-EC-AMDP than for ^{99m}Tc-MDP (Table 3). The femur to blood activity ratio of the ^{99m}Tc labeled EC-diphosphonate conjugate at 1 h p.i. is higher than the same ratio for ^{99m}Tc-MDP at 2 h p.i. In biodistribution studies with the isolated peaks A and B, the femur to blood activity ratios are significantly higher than for the total preparation. This indicates that the total preparation contains some constituents, possibly not eluted from HPLC, with lower affinity for the bone. In the muscles and the hepatobiliary system, the activity is low at all tested time points for each of the preparations tested. The activity not taken up in the bone is excreted rapidly via the kidneys to the urine, and its percentage is almost similar for the two preparations.

Table 2. Biodistribution in Rats of ^{99m}Tc-MDP (n = 2) and ^{99m}Tc-EC-AMDP (n = 6) at 30, 60, 120 min p.i.

		% of injected dose				
	time p.i. (min)	kidneys+urine	liver+intestines	blood	%/g muscle	%/g femur
^{99m}Tc-MDP	30	22.0	1.8	4.5	0.2	12.9
	60	24.4	1.2	1.9	0.4	15.1
	120	24.2	1.2	1.3	0.1	15.4
^{99m}Tc-EC-AMDP	30	26.7	1.7	2.7	0.2	12.7
	60	22.4	1.3	1.2	0.1	14.8
	120	26.4	0.8	0.5	0.0	29.4

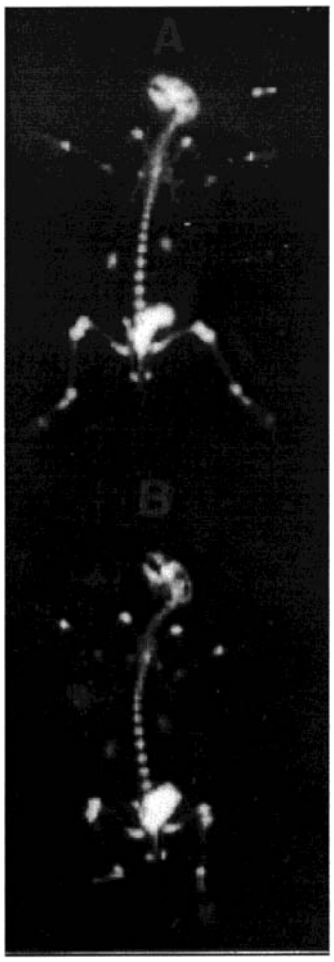

Figure 3. Whole body images of a rabbit 1 h after injection of ^{99m}Tc-EC-AMDP (A) and ^{99m}Tc-MDP (B) (*total preparation*).

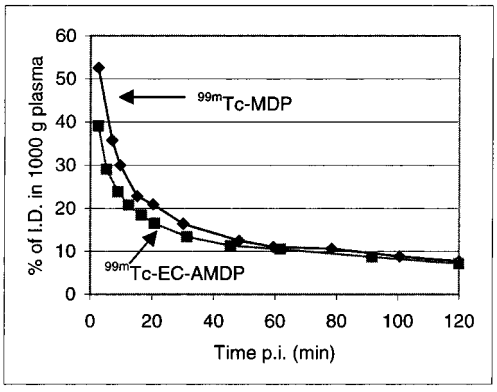

Figure 4. Plasma disappearance curves in a baboon for ^{99m}Tc-MDP and ^{99m}Tc-EC-AMDP.

Evaluation in a Rabbit. The scintigraphic images obtained in a rabbit at 1 h p.i. are shown in Figure 3. Both tracer agents allow a clear visualization of the skeleton and a net distinction between the respective vertebrae and ribs. Uptake in soft tissue is low, and it is clear that the activity not bound to the skeleton is excreted through the kidneys. The image quality is quite similar for both compounds.

Biological Evaluation in a Baboon. Figure 4 shows the plasma disappearance curve in a baboon for ^{99m}Tc-MDP and ^{99m}Tc-EC-AMDP (total preparation) during 2 h after injection. Both tracer agents behave in nearly the same way, although the clearance of ^{99m}Tc-EC-AMDP from plasma is somewhat faster. This may be related to a slightly faster renal extraction or to a faster distribution to the extravascular space. Whole body scintigraphic images obtained 2 h after injection of both agents are shown in Figure 5. As in the rabbit study, nearly identical images are obtained with the two radiopharmaceuticals. This means that the newly developed ^{99m}Tc-diphosphonate conjugate has the characteristics of a suitable bone scanning agent, with almost the same contrast between soft tissue and bone as obtained with ^{99m}Tc-MDP.

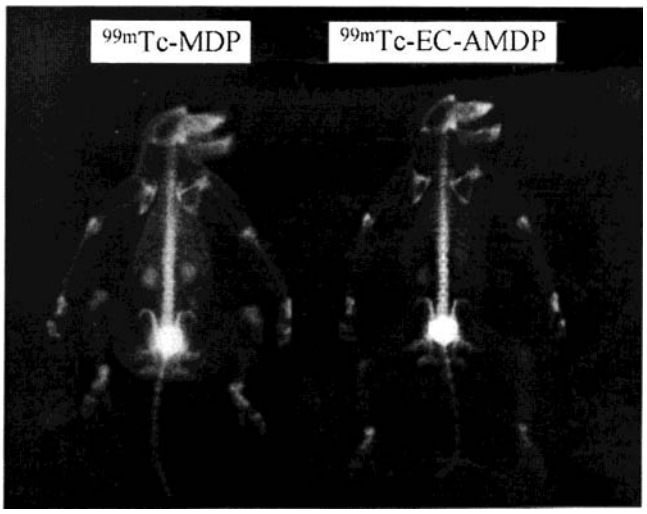

Figure 5. Whole body images 2 h after injection of ^{99m}Tc-MDP and ^{99m}Tc-EC-AMDP in a baboon.

CONCLUSION

The results shown in this paper are part of a research project with the aim to develop a "new generation" bone scanning agent with improved characteristics as compared to the currently used ^{99m}Tc-diphosphonates. The intended improvements concern the stability of the tracer agent, its clearance rate from soft tissue, and its uptake in the bone. For this purpose, a ^{99m}Tc-labeled renal tracer agent with known rapid active renal excretion (^{99m}Tc-ethylene dicysteine) was conjugated to a diphosphonate. In this concept, the EC moiety of the new tracer agent is assumed to be responsible for both the stable binding of the ^{99m}Tc radionuclide and the rapid urinary excretion of the fraction not bound to the bone. The diphosphonate moiety in this compound is not involved in the binding of ^{99m}Tc and thus fully available for binding to the skeleton.

Up to now, the most favorable results have been obtained with the ^{99m}Tc-complex of the conjugate between ethylene dicysteine and aminomethylenediphosphonate, coupled by amide formation between a carboxylate of EC and the amine of AMDP. We have synthesized several other conjugates and evaluated them as their ^{99m}Tc-complexes (*21*) (to be submitted for publication).

In rats, ^{99m}Tc-EC-AMDP showed very promising characteristics with clearly higher femur to blood and femur to muscle activity ratios than ^{99m}Tc-MDP. Especially when the HPLC-isolated peaks A and B were used, these ratios were favorably high. This suggested that an optimized preparation containing only peak A and peak B of ^{99m}Tc-EC-AMDP would constitute a bone-seeking radiopharmaceutical with more rapid clearance from soft tissue and higher uptake in the skeleton than the currently used ^{99m}Tc-diphosphonates.

In the rabbit and the baboon, the scintigraphic images obtained with the new agent (total preparation) showed good quality bone scans with clear visualization of the

skeleton and low soft tissue activity at respectively 1 and 2 h after injection. The fact that the plasma activity disappearance in the baboon was only slightly faster for ^{99m}Tc-EC-AMDP than for ^{99m}Tc-MDP indicates that the new tracer is a good bone-scanning agent, but in this species not a significant improvement as compared to the currently available ^{99m}Tc-diphosphonates. On the other hand, the new ^{99m}Tc-labeled EC-AMDP conjugate has the clear advantage over the common ^{99m}Tc diphosphonates of a high stability and a constant composition as a function of time.

The development and evaluation of further derivatives on the basis of the new concept may eventually result in a ^{99m}Tc-labeled tracer agent with the intended biological characteristics.

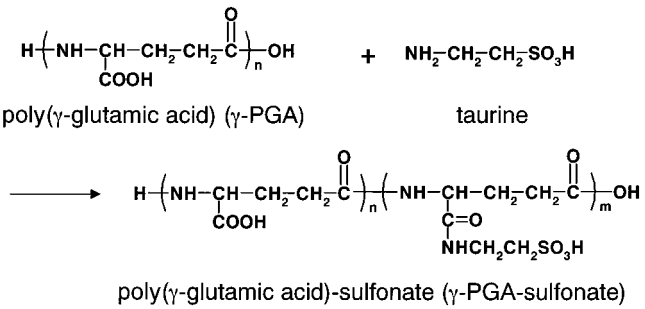
Received January 29, 2001; Revised Manuscript Received August 15, 2001



γ-Poly(glutamic acid) (γ-PGA), which is produced by *Bacillus subtilis*, was sulfonated using 2-aminoethane-1-sufonic acid (taurine) in the presence of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (WSC) to give sulfonated γ-PGA (γ-PGA-sulfonate). From ^{1}H NMR spectroscopy and IR spectroscopy, it was confirmed that taurine was introduced to the side chain of γ-PGA via an amide linkage. By altering the synthetic conditions, it was possible to control the content of sulfonate in γ-PGA-sulfonate. Anticoagulant activity was investigated in order to evaluate the biological activity of γ-PGA-sulfonate by the Lee−White test. The clotting time was prolonged when the concentration of γ-PGA-sulfonate on the degree of sulfonation was increased. It becomes clear that γ-PGA-sulfonate is potentially useful for various medical applications, such as drug delivery, tissue engineering, and medical materials.

INTRODUCTION

Biodegradable polymers are used in a wide variety of applications, such as suture materials, bone fixation materials, environmental materials, and in drug delivery systems. Recently, further application of biodegradable polymers has been desired in many situations, such as a simuli−responsible drug delivery system and tissue engineering. However, it is difficult to prepare such functional biodegradable polymers because most biodegradable polymers have a simple chemical structure and lack reactive main or side chains. Some researchers have tried to prepare the functional biodegradable polymers. Ohya and co-workers have studied polydepsipeptides, which are copolymers of α-amino acids and α-hydroxy acids having a reactive side chain (*1*, *2*). Mikos and co-workers have synthesized poly(propylene fumarate) (PPF), which is a reactive unsaturated functional biodegradable polymer (*3*, *4*). These polymers have unique properties and are further improved in performances as compared with the conventional ones; however, there are so many aspects of the demands to biodegradable polymers.

For tissue engineering applications, there are some special demands to biodegradable polymers (in many cases, to scaffolds). A typical one is the ability of incorporating growth factors. Others are the fabrication of a complex shape, degradation rate control, and stimuli responsibility. On the other hand, when biodegradable polymers are used in biomedical fields, the polymers should be metabolized in biological systems at a final stage. So, α-hydroxy acids, amino acids, and lipids are currently used. When one would synthesize novel functional biodegradable polymers, one should use the same resources, which have functional groups or double bonds in their chemical structure.

Scheme 1. Synthesis of Poly(γ-glutamic acid Sulfonate) (γ-PGA-Sulfonate)

Poly(γ-glutamic acid) (γ-PGA) is bioproduct which is secreted by a *Bacillus subtilis* strain, *B. subtilis F-2-01* (*5*), and is mass produced by fermentation. The molecular weight of γ-PGA is very high (100 000−1 000 000), and this is a unique character of γ-PGA. Some researchers have tried to use γ-PGA as a novel biodegradable polymer by modifying the γ-PGA side chain. Kubota et al. have reported alkaline hydrolysis of γ-PGA (*6*) and esterification of the carboxyl group for the purpose of providing better solubility in organic solvents (*7*) or for the preparation of fiber (*8*). Kunioka et al. have studied the cross-linking reaction of γ-PGA by γ irradiation (*9*, *10*). Hara has reported the preparation of γ-PGA hydrogel for applications as an environmental material (*11*). We have also reported the polyion complex formation between γ-PGA and chitosan (*12*) and polymer drug (*13*). For further applications, we tried to prepare the sulfonated γ-PGA (γ-PGA-sulfonate).

Generally, it is well-known that heparin has many biological activities, such as anticoagulant activity, stabilizing activity of growth factors, antiviral activity, and

plasma clearing activity. Various heparinoids were synthesized, and their biological activities were studied. Sulfated naturally occurring polysaccharides have been studied, such as dextran, chitin, and chitosan (*14*−*17*). Synthetic polymers, such as poly(vinyl sulfonate) and polysaccharide derivatives having sulfamide and *O*-sulfonic acid groups (*18*, *19*), are the examples. The heparinoid, having antiviral activity or cell growth stimulation activity, are also the examples (*20*−*23*).

In this study, the sulfonic group was introduced into γ-PGA by using 2-aminoethane-1-sulfonic acid (taurine) in order to obtain sulfonated γ-PGA (γ-PGA-sulfonate). γ-PGA-sulfonate was inspired from the chemical structure of heparin, which is well-known to have anticoagulant activity and biodegradability. Biodegradable γ-PGA-sulfonate could be termed "a bioinspired material" and is expected to have heparin-like biological activities.

Taurine is one of the most abundant amino acids in animal tissues and is described as an essential amino acid for human and other mammalian species. Taurine has been reported to have several putative roles, functioning as a neurotransmitter, a neuromodulator, and a neurogrowth factor and functioning in membrane stabilization. Studies of sulfonation by conjugation with taurine have been reported in amino acids and oligopeptides (*24*, *25*). Sulfonation of γ-PGA using taurine is a new trial in the meaning of the modification of γ-PGA in aqueous media. Because of the high molecular weight and poor solubility to aqueous media, the chemical modification of γ-PGA was done in organic media. In this study, the preparation of γ-PGA aqueous solutions and esterification reactions were studied (in detail). The anticoagulant activity of γ-PGA-sufonated was also investigated.

MATERIALS AND METHODS

Materials. γ-PGA (MW 1 230 000, MW/M_n 1.20) was kindly donated by Meiji Seika Kaisya, Ltd. (Tokyo, Japan) and was used without further purification. Sodium hydrogen carbonate, 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (WSC), taurine, and sodium dextran sulfate (DS) were purchased from Wako Pure Chemical Industries (Osaka, Japan). Heparin sodium salt, polyvinyl sulfuric acid potassium salt (PVS), and calcium chloride were purchased from Nacalai Tesque (Kyoto, Japan). Poly(*p*-styrenesulfonic acid sodium salt) (PSS) was purchased from Tokyo Kasei (Tokyo, Japan).

Synthesis of γ-PGA-Sulfonate. Adequate amounts of sodium hydrogen carbonate, γ-PGA, WSC, and taurine were dissolved in 30 mL of pure water under magnetic stirring for 30 min at 0 ∼ 4 °C. The reaction solution was maintained for 24 h at ambient temperature. The reaction solution was dialyzed using a Spectra/Pore membrane (wt off molecular weight of 50 000) for 3 days. γ-PGA-sulfonate was obtained by freeze-drying for 3 days. The reaction conditions are shown in Table 1.

Anticoagulant Activity Test (Lee−White Test). The Lee−White test was carried out as follows. One milliliter of human whole blood, which was collected with a 21-gauge needle, was added to tubes each containing 1 mg/mL of each sample solution (sample tubes) and to an empty tube (reference tube). These tubes were allowed to stand for 3 min at 37 °C. After 3 min, the reference tube was tilted, and if the reference tube was not clotted, the tube was tilted every 30 s until clotting occurred. When the reference tube had clotted, the sample tubes were tiled every 30 s until the contents of these tubes were clotted. In vitro clotting time was evaluated using the following equations:

Lee−White clotting time =
time which sample tube was clotted −
time which reference tube was clotted

Table 1. Preparation of γ-PGA-sulfonate[a]

runs	γ-PGA (mmol)	taurine (mmol)	WSC (mmol)	yield (%)	sulfonate content[b] (%)
1	5	5	2.5	58	25
2	5	5	5	61	51
3	5	5	10	64	81
4	5	0.5	5	53	13
5	5	2.5	5	61	37
6	5	5	5	61	51
7	5	10	5	56	54
8	5	50	5	63	48

[a] Reaction time was 24 h at room temperature. [b] The sulfate content against total carboxyl groups was estimated by a ^{1}H NMR spectrum.

Hydrolysis Testing of γ-PGA and γ-PGA-Sulfonate. γ-PGA (MW = 350 000) and γ-PGA-sulfonate (10% and 90%, MW = 150 000) were dissolved in a 0.2 M phosphate buffer (pH = 7.4), and the concentration of samples was prepared at 0.1 wt %. Samples were stored at 80 °C until several hydrolysis times, molecular weights, and molecular weight distributions were measured by gel permeation chromatography (GPC) (TSK-GEL G5000PW and G4000PW$_{xL}$ column; flow rate was 1.0 mL/min), calibrated with pullulan (Shodex STANDARD P-82) standards.

RESULTS AND DISCUSSION

Synthesis of γ-PGA-Sulfonate. Figure 1 shows the ^{1}H NMR spectra of γ-PGA, taurine, and γ-PGA-sulfonate (the synthetic condition is no. 2 in Table 1). All of the peaks corresponding to γ-PGA and the CH_2 of taurine were observed after the reaction. The peak of a CH_2 next to a nitrogen atom was shifted from 3.4 ppm in taurine to 3.6 ppm in γ-PGA-sulfonate, indicating that taurine was introduced into γ-PGA by an amide linkage.

Figure 2 shows the FT-IR spectra of γ-PGA and γ-PGA-sulfonate. The peaks at 1100−1200 and 1350 cm^{-1} for γ-PGA-sulfonate show the asymmetric and symmetric stretching vibration modes of S (=O_2), respectively. These peaks were not observed for γ-PGA. The peaks at 1600 cm^{-1} of amide I and 1650 cm^{-1} of amide II were similarly observed for γ-PGA and γ-PGA-sulfonate. It was also confirmed that a carboxyl group of the side chain of γ-PGA was converted to an amide group, because a peak at 1750 cm^{-1} which corresponds to carbonyl vibration mode of carboxyl groups in γ-PGA was reduced in γ-PGA-sulfonate. These results indicated that γ-PGA-sulfonate was prepared by the conjugation of taurine with γ-PGA.

Sawa et al. has reported the molecular structure analysis of γ-PGA by IR spectra and by optical rotatory dispersion curves (*26*). Their report indicated that H-α-PGA (COOH type) was an α-helix structure, H-γ-PGA (COOH type) was a parallel β structure, and Na-γ-PGA (COONa type) was a random structure. In this study, Na-γ-PGA (COONa type) was used, so γ-PGA-sulfonate was thought to be a random structure. In Figure 2, when the FT-IR spectrum of γ-PGA is compared with that of γ-PGA-sulfonate, the reduction of a carboxyl group peak and the increase of sulfone group peaks were observed. Other changes of spectra were not observed. Accordingly,

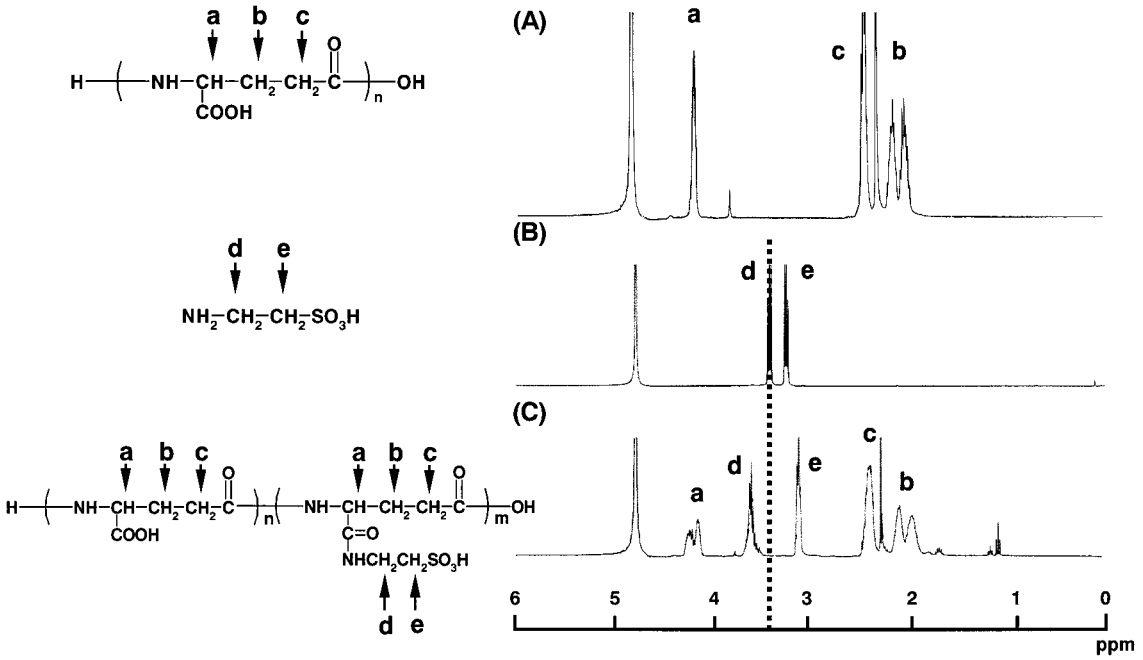

Figure 1. ^{1}H NMR spectra of (A) γ-PGA, (B) taurine, and (C) γ-PGA-sulfonate in D_2O.

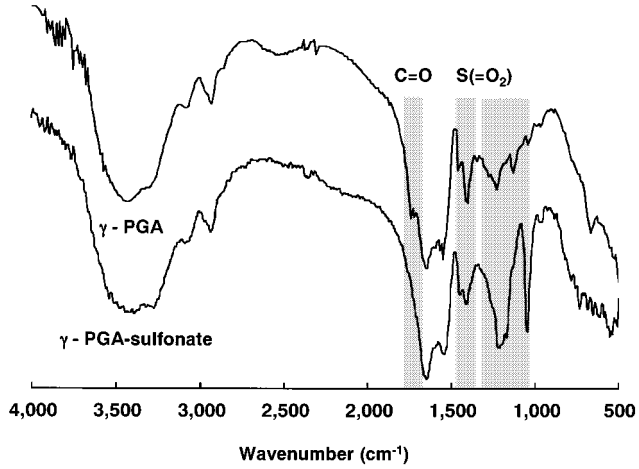

Figure 2. FT-IR spectra of γ-PGA and γ-PGA-sulfonate.

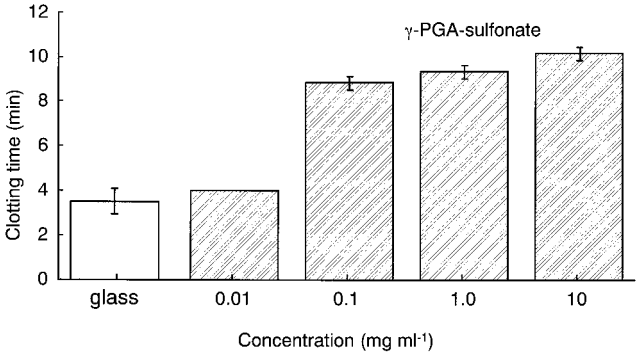

Figure 3. Effect of concentration on anticoagulant activity ($n = 3$).

the molecular structure of γ-PGA-sulfonate is confirmed to be a random structure. γ-PGA-sulfonate is thought to have an extended structure, because of ion repulsion by a sulfonic group.

It is expected that the solubility of γ-PGA-sulfonate is different from that of γ-PGA by sulfonic group. The solubility of γ-PGA was compared with that of γ-PGA-sulfonate. γ-PGA was dissolved in a pH > 7.4 aqueous solution. However, it was only dissolved in DMF, NMP, and DMSO and was not dissolved in other organic solvents. The solubility of γ-PGA-sulfonate was better than that of γ-PGA. For example, γ-PGA-sulfonate was dissolved in all pH's for aqueous solutions, and it had a good solubility in organic solvents (DMF, NMP, and so forth). This result confirmed that the properties of γ-PGA-sulfonate were different from those of γ-PGA.

Control of Sulfonate Content. The amount of taurine and WSC in feed was varied in order to control the sulfonate content. The yield and sulfonate content in the γ-PGA-sulfonate are shown in Table 1. The sulfonate content increased with increasing WSC in feed, resulting in a maximum content of 81%. On the other hand, when the amount of taurine in feed was also increased in the presence of a constant concentration at WSC (5 mmol), the sulfonate content was not increased to more than approximately 50%. Yields were around 60% under all preparing conditions. These results indicated that, in order to control sulfonate content, changing the WSC amount is most valuable.

Anticoagulant Activity Test (Lee−White Test). It is expected that γ-PGA-sulfonate has various biological activities. In this study, anticoagulant activity was investigated as a typical bioactive evaluation of γ-PGA-sulfonate. Anticoagulant activity was evaluated by the Lee−White test. Figure 3 shows the dependence of the clotting time on the γ-PGA-sulfonate concentration. The clotting time increased with an increase in the γ-PGA-sulfonate concentration. This result indicates that the anticoagulant activity of γ-PGA-sulfonate was concentration-dependent. Figure 4 shows the dependence of the anticoagulant activity on the degree of sulfonation. The clotting time of all γ-PGA-sulfonate samples were prolonged when they were compared to those of γ-PGA. This result indicates that γ-PGA-sulfonate obtained anticoagulant activity as a result of introducing taurine. Moreover, the clotting time increased with an increase in the degree of sulfonation.

Figure 5 compares the anticoagulant activity of γ-PGA-sulfonate, heparin, dextran sulfate (DS), poly(vinyl sul-

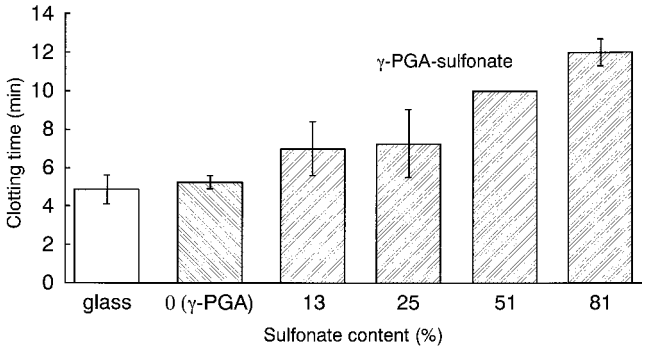

Figure 4. Effect of sulfonate content on anticoagulant activity ($n = 3$). Solution concentration was 1 mg mL^{-1}.

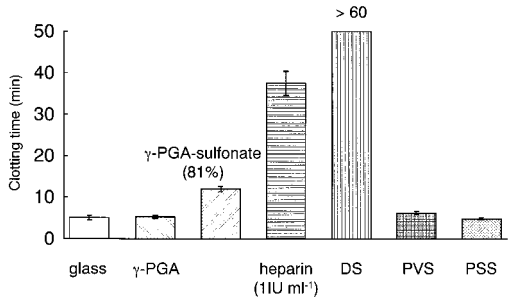

Figure 5. Comparison of anticoagulant activity between γ-PGA-sulfonate, heparin, dextran sulfate (DS), poly(vinyl sulfuric acid) (PVS), and poly(styrene sulfonic acid) (PSS) ($n = 3$). Solution concentration was 1 mg mL^{-1}.

furic acid) (PVS) and poly(styrene sulfonic acid) (PSS). The concentration of each solution was 1 mg mL^{-1}, and heparin was used at a concentration of 1 IU mL^{-1} (approximately 6 μg/mL). The anticoagulant activity of γ-PGA-sulfonate was not high as compared with heparin or DS. However, it was possible to realize the anticoagulant activity on γ-PGA by the introduction of taurine. γ-PGA-sulfonate can be prepared on a large scale, suggesting that the sulfonation of γ-PGA has significant implications.

In this study, the anticoagulant activity of γ-PGA-sulfonate was evaluated by the Lee−White test using human whole blood. It was indicated that γ-PGA-sulfonate has higher anticoagulant activity than synthetic sulfated polymers, such as PSS and PVS. However, it is difficult to clarify the mechanism of anticoagulant activity by the Lee−White method. We have reported that not only the interaction with antithrombin III but also activated partial thromboplastin time (aPTT), prothrombin time (PT), thrombin time (TT) tests recognize the mechanism of anticoagulant activity of poly(glucosyloxyethyl methacrylate)sulfate [poly(GEMA)-sulfate] (*27*, *28*). The results described that the antioagulant activity mechanism of poly(GEMA) sulfate was different from heparin. The mechanism of anticoagulant activity of γ-PGA-sulfonate will be evaluated in the future.

Hydrolysis Testing of γ-PGA and γ-PGA-Sulfonate. The hydrolysis of γ-PGA has been reported in detail. Kubota et al. have investigated the alkaline hydrolysis of γ-PGA for the purpose of obtaining various molecular weights of γ-PGA (*6*). It was possible to obtain the expected molecular weight of γ-PGA by controling the NaOH concentration. Kunioka et al. have also reported the effect of temperature on the hydrolysis of γ-PGA hydrogel prepared by γ irradiation. The rate of hydrolysis increased with an increase in hydrolysis temperature. On

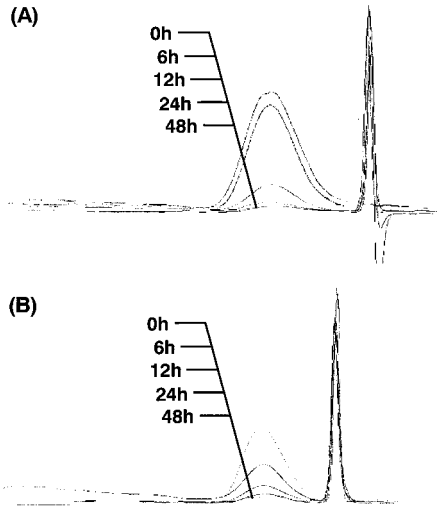

Figure 6. Degradation behavior of (A) γ-PGA and (B) 10% γ-PGA-sulfonate.

the basis of these observations, it is expected that γ-PGA-sulfonate is biodegradable polymer. In this study, the hydrolysis of γ-PGA and γ-PGA-sulfonate (10 and 90%) was evaluated in a phosphate buffer (pH = 7.4) at 80 °C.

After 6, 12, 24, 48 h, the hydrolysis reaction was stopped by cooling at 4 °C, and the molecular weight of each sample was measured by GPC. Figure 6 shows the GPC profiles of the hydrolysis of γ-PGA and γ-PGA-sulfonate (10%). High molecular weight polymers and oligomers coexisted without any intermediate molecular weight polymers. The ratio of high molecular weight polymers against its oligomer (molecular weight of about 2000) increased with an increase in time, indicating the hydrolysis of the polymers. Ninety percent of the γ-PGA-sulfonate showed a similar tendency (data not shown). Figure 7 indicated the existence ratio of high molecular weight polymer and oligomer estimated by GPC. The change of existence ratio of oligomer γ-PGA and γ-PGA-sulfonate has a similar tendency; however, the existence ratio of oligomer γ-PGA-sulfonate was more rapidly changed as compared to that of γ-PGA. It was confirmed that the hydrolysis ratio of γ-PGA-sulfonate was more rapid than that of γ-PGA. Further, the hydrolysis ratio of 90% γ-PGA-sulfonate was faster than that of 10% γ-PGA-sulfonate, indicating that the introduction of sulfonic groups to γ-PGA accelerate the polymer hydrolysis.

The hydrolysis mechanisms of γ-PGA and γ-PGA-sulfonate were suggested as follows. γ-PGA-sulfonate was thought to be more extended than γ-PGA, because of electrostatic repulsion of sulfonic groups. Accordingly, it was presumed that water molecules can readily attach the polymers, resulting that the hydrolysis of γ-PGA-sulfonate was easier and faster than that of γ-PGA. The hydrolysis ratio of 90% γ-PGA-sulfonate was faster than that of 10% γ-PGA-sulfonate, because 90% γ-PGA-sulfonate has many sulfonic groups. In addition, the pH of the neighborhood of the polymer seemed to be lowered by the introduction of a sulfonic group, resulting that the acid hydrolysis of the polymers was accelerated. For these reasons, the hydrolysis rate of γ-PGA-sulfonate was dependent on the degree of sulfonation.

The hydrolysis of γ-PGA and γ-PGA-sulfonate had high molecular weight polymers and oligomers without any intermediate molecular weight polymers. It was thought that when hydrolysis was started, hydrolysis of γ-PGA

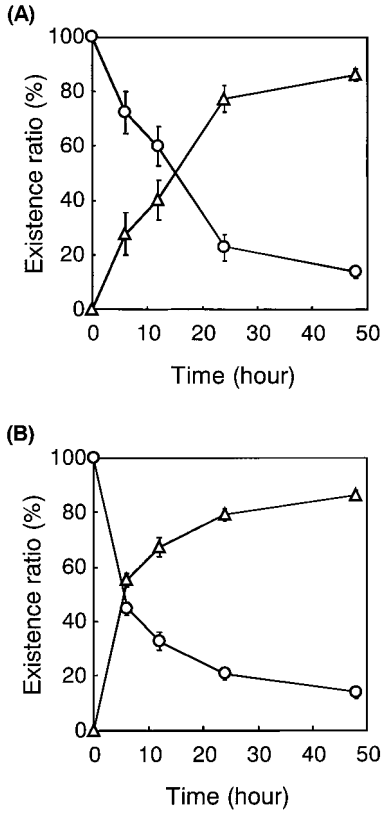

Figure 7. Existence ratio of (○) high molecular weight polymers and (△) oligomers was estimated by GPC: (A) γ-PGA and (B) 10% γ-PGA-sulfonate.

and γ-PGA-sulfonate seemed to rapidly proceed to the oligomer level. So, it was presumed that Figure 6 was only confirming the high molecular weight polymer and low molecular weight polymer (oligomer) peaks. This result was not clear in this study. Accordingly, further study of the hydrolysis mechanism of γ-PGA and γ-PGA-sulfonate will be done in the future.

It was confirmed that γ-PGA and γ-PGA-sulfonate had degradability. In this study, a hydrolysis test was carried out at 80 °C as an acceleration test. It is expected that γ-PGA-sulfonate will be hydrolyzed in vivo.

γ-PGA is a component of Japanese traditional food *Natto*; in other words, γ-PGA is edible natural product. In the meaning of toxicity, γ-PGA is very safe; however, the biocompatibility of γ-PGA is now investigated. Taurine exists in animal tissues, and is an essential amino acid for mammalian species. So, the toxicity of taurine is thought to be very low. It is expected that γ-PGA-sulfonate is a nontoxic material. The toxicity test of γ-PGA-sulfonate will be done in the future.

CONCLUSION

γ-PGA-sulfonate was prepared by the reaction of taurine with γ-PGA. Results indicated that the sulfonate content could be controlled by changing the WSC amount. γ-PGA-sulfonate was found to have anticoagulant activity. Anticoagulant activity was dependent on the concentration and sulfonate content of γ-PGA-sulfonate. γ-PGA-sulfonate has the potential to combine with cytokines, such as basic fibroblast growth factor, and to form polyion complexes with cationic biodegradable polymers. γ-PGA-sulfonate is expected to have applications in a wide variety of areas, such as drug delivery systems, environmental materials, tissue engineering, and medical materials.

Received January 31, 2001; Revised Manuscript Received August 15, 2001

Cyclopentadienyltricarbonyl rhenium ($CpRe(CO)_3$) systems can be prepared from ferrocenes and perrhenate by a double ligand transfer (DLT) reaction that gives reasonable yields and shows excellent functional group tolerance. We used this reaction for the direct preparation of $CpRe(CO)_3$−phenyltropane conjugates. Such agents, when labeled with technetium-99m, might function as imaging agents for the dopamine transporter (DAT) system that would be useful for assessing the onset and severity of Parkinson's disease. Of the $CpRe(CO)_3$−tropane conjugates prepared by the DLT reaction (as well as other analogues prepared by related methods), those substituted at the *N*-8 position seem most promising; their affinity for the DAT in all cases was high, and their ferrocene precursors for the DLT reaction can be prepared in a convenient manner. By contrast, the 3*β*-conjugates were poor DAT binders. The modular nature of these systems offers considerable flexibility that could be used to improve the binding characteristics of these compounds further.

INTRODUCTION

The dopamine transporter (DAT) serves a critical modulatory role in dopamine (DA) neurotransmission, removing released transmitter from the synapse by transporting it back into the presynaptic terminal (*1*). Because of its crucial function, DAT is a target for drug therapy (e.g., Ritalin for attention deficit and hyperactivity disorder) and for drugs of abuse (e.g., cocaine) and has been extensively studied both by in vitro methods and through in vivo imaging. Because DAT serves as a marker of DA terminal innervation of the striatum, DAT-based images have been proposed as an early diagnostic test for Parkinson's disease (PD) (*2*). The development of DAT imaging as an objective biological marker for PD would be extremely useful for assessing potential agents for neuroprotection and approaches to neuronal restoration (*3*, *4*). In addition, it might also provide a secondary marker in individuals with varying clinical symptoms that would allow for the mapping of disease subsets (*5*).

To date, radionuclide imaging of the DAT has been dominated by compounds such as the iodophenyltropane *β*-CIT (**I**, Figure 1), labeled with iodine-123 (*6*). However, production of the I-123 radionuclide requires daily delivery from cyclotrons, limiting its availability and increasing its cost. Because of this limitation, several research groups have developed DAT-binding radiotracers that use technetium-99m as a practical and widely available, low-cost alternative radionuclide, together with single photon emission computed tomography (SPECT) DAT imaging.

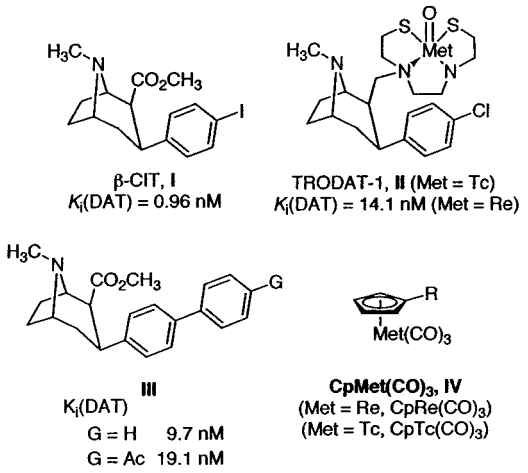

Figure 1. Synthetic ligands for the DAT.

Kung and co-workers reported successful SPECT DAT imaging using a technetium-99m complex of an N_2S_2 chelate conjugated at the 2*β*-position of 3*β*-(4-chlorophenyl)-8-methyl-8-azabicyclo[3.2.1]octane (TRODAT-1 (**II**), Figure 1) (*7*−*9*). The in vivo pharmacological specificity of this agent was shown in animal experiments by selective blocking with the DAT binding agent, *β*-CIT (**I**). The corresponding rhenium analogue displayed an inhibition constant (K_i) of 14.1 nM toward DAT. Madras and co-workers have reported a similar result with one of a series of N_2S_2 chelate analogues of the fluorophenyltropane CFT conjugated at the *N*-8 position (*10*). Together,

Scheme 1

these studies demonstrate that technetium-99m can be incorporated into a radiotracer that has a high affinity for the target site, crosses the blood−brain barrier, and concentrates in the appropriate target regions in the brain. However, both tracers showed relatively high nonspecific uptake, which may be a consequence of the high molecular weight of these agents and their large lipophilic metal complexes.

In a related effort, we have investigated the use of the stable substituted η^5-cyclopentadienyltricarbonyl rhenium and technetium organometallic complexes for radiolabeling biologically interesting molecules; these complexes are abbreviated collectively as $CpMet(CO)_3$ complexes (Met = metal) or individually as cyclopentadienyltricarbonyl rhenium ($CpRe(CO)_3$) for the rhenium and $CpTc(CO)_3$ for the technetium analogues (**IV**, Figure 1). As compared to the more widely used high oxidation state metal−oxo complexes (e.g., **II**, Figure l), $CpMet(CO)_3$ complexes exhibit high chemical and metabolic stability, are lipophilic and relatively small, and, unlike many inorganic chelates, do not possess additional stereocenters (Figure 1) (*11*−*13*). Thus, they appear to be promising for the development of novel metal-labeled DAT imaging agents. However, until recently, the synthesis of these organometallic species has required harsh conditions and multistep procedures. Recent reports describing the preparation and use of low valent (i.e., $Met(CO)_3^+$) technetium and rhenium are encouraging (*14*−*18*).

The suitability of tropane $CpMet(CO)_3$ conjugates as DAT ligands was shown by a series of $CpRe(CO)_3$ and manganese conjugates with nanomolar affinity (*19*). One of these, the ester of 2β-hydroxymethyl-3β-(4-[^{123}I]-iodophenyl)tropane with carboxycyclopentadienyltricarbonyl rhenium radiolabeled with iodine-123 ([^{123}I]YP116), was shown to bind specifically to striatal DAT in rats and baboons and showed SPECT regional uptake curves similar to those of [^{123}I]FPCIT (*20, 21*).

The first practical radiochemical preparation of substituted $CpMet(CO)_3$ complexes was the double ligand transfer (DLT) reaction, originally reported by Martin Wenzel in 1992 (*22*). We recently reported an improved version of the DLT reaction that minimized formation of unwanted byproducts (Scheme 1) (*23*). This remarkable transformation involves the in situ reduction/carbonylation of the permetalate species, followed by selective ring transfer from an appropriately substituted ferrocene precursor. The reaction occurs in a single pot and in most cases is limited to ferrocenes substituted with electron-withdrawing groups. However, the major drawback in the initial uses of the DLT reaction for labeling biomolecules is in the additional steps needed to conjugate the substituted $CpMet(CO)_3$ to the biological molecule of interest (*24*). Recent developments in our laboratory, which provide alternative routes to $CpRe(CO)_3$ complexes without a requirement for substitution with an electron-withdrawing group, include the "three-component condensation" reaction (*25*−*27*) and the stannane approach (*28*).

To extend the DLT methodology further and to expand structure−activity relationships for organometallic DAT imaging agents, we designed a direct version of the DLT reaction, applied it to a series of ferrocenyl phenyltropane conjugates, and measured the binding affinity of these new compounds to monoamine transporters. Although the rhenium compounds could be made more efficiently without going through the ferrocene intermediate, the purpose was to develop methods that could be applied to short-lived γ-emitting radiotracers. Additional ligands were made by the three-component condensation. Besides the innate interest in the rhenium compounds as organometallic DAT ligands, they serve as analogues of radioactive rhenium and technetium agents that could serve for SPECT imaging. Clearly, the conditions for metal incorporation (high temperature and pressure in organic solvent, chromatographic purification) are far from the characteristics of commercial ^{99m}Tc radiopharmaceutical kits, namely, mild reduction and complexation in aqueous solution. Stepwise investigation of the approach involved first determining the feasibility with respect to making the metal compounds and suitable biological properties. In a preliminary report (*29*), the technetium-99m analogue of one candidate, *N*-(4-$CpRe(CO)_3$-4-oxobutyl)norCCT (**5a**), was prepared and found to bind specifically to mouse striatum in vivo.

EXPERIMENTAL SECTION

General Comments. In general, the product was isolated by quenching of the reaction in an aqueous solution, exhaustive extraction with an organic solvent, drying over an anhydrous salt, filtration, evaporation on a rotary evaporator, and purification by flash chromatography (*30*) on Woelm silica gel (0.040−0.063 mm). Workup is indicated by the phrase "product isolation" followed, in parentheses, by a listing of quenching agent, extraction solvent, and drying agent if not $MgSO_4$, which is not listed and "purification" followed, in parentheses, by the elution solvent used in the flash chromatography.

All reactions were performed under a dry (Drierite) argon atmosphere. Unless otherwise specified, reagents and solvents used in this study were obtained from commercial sources (Aldrich, Strem, or Fluka) and were used without further purification. Temperatures refer to that of the reaction bath. Acetonitrile, triethylamine, methylene chloride, and toluene were distilled from calcium hydride under a nitrogen atmosphere. Oxalyl chloride was distilled from and stored over calcium hydride before use. Tetrahydrofuran (THF) was distilled from sodium/benzophenone ketal under a nitrogen atmosphere. Dimethylformamide (DMF) was dried with barium oxide and distilled from and stored over 4 Å molecular sieves. Methanol was distilled from magnesium activated with iodine and stored over 3 Å molecular sieves. Hexanes (mixed isomers) were distilled from $CaSO_4$ before use in flash chromatography. Butyllithium (Aldrich) was titrated using *N*-pivaloyl-*o*-toluidine according to a literature method (*31*).

Reaction progress was monitored by analytical thin-layer chromatography (TLC) on 0.25 mm Merck F-254 silica gel glass plates, visualizing with potassium permanganate or Dragendorff's reagent or quenching of UV illumination at 254 nm.

Melting points were determined using a Thomas−Hoover melting point apparatus and are uncorrected. ^{1}H and ^{13}C nuclear magnetic resoance (NMR) spectra were recorded on a U400, U500, or KECK750 Varian FT-NMR spectrometer. Chemical shifts (δ) are reported in parts per million (ppm) downfield from internal tetramethylsilane or by reference to proton resonances resulting from

incomplete deuteration of the NMR solvent. Low resolution electron impact (EI) mass spectra were obtained on a Finnigan MAT CH5 or VG Instruments 70-VSE spectrometer. High-resolution EI mass spectra were obtained on a Finnigan MAT 731 spectrometer. Both low-resolution and high-resolution chemical ionization (CI) mass spectra were obtained on a VG Instruments 70-VSE spectrometer. All fast atom bombardment (FAB) mass spectra were obtained on a VG Instruments ZAB-SE mass spectrometer. Elemental and DSC analyses were performed by the Microanalytical Service Laboratory of the University of Illinois.

Ferrocenecarbonyl chloride (*32*) and cyclopentadienyltricarbonyl rhenium carbonyl chloride (*33*) have been previously prepared. Ferrocenecarboxylic acid is available commercially, whereas cyclopentadienyltricarbonyl rhenium carboxylic acid was prepared by DLT reaction of 1,1′-methoxycarbonylferrocene followed by saponification. Iodocyclopentadienyltricarbonyl rhenium was prepared by an existing method (*34*). 8-Methyl-3β-[4-(trimethylstannanyl)phenyl]-8-azabicyclo[3.2.1]octane-2-carboxylic acid methyl ester (*35*), 3β-[4-chlorophenyl]-8-azabicyclo-[3.2.1]octane-2-carboxylic acid methyl ester (nor-CCT, **1**) (*36*), and 1-(*tert*-butyldimethylsiloxy)-4-iodobutane (**17**) (*37*) were prepared as previously described. Reactions performed using palladium catalysts were degassed using a standard freeze−pump−thaw method.

Cautionary Note for the DLT Reactions (*23*). Pressure tubes were placed within a specially made solid aluminum block containing holes drilled deep enough to admit the tubes to about three-fourths of their height and wide enough to allow room for some added mineral oil. The tubes and aluminum base were covered with a matching hollow aluminum screw cap, equipped with a small hole aligned with one drilled in the base (to the same depth as those for the pressure tubes) to hold a metal thermometer. This containment device minimized the potential danger of explosions during heating, allowed for the efficient stirring of the reactions, and enabled the reaction temperature to be monitored readily. All manipulations of sealed reaction tubes during and after the reactions were done in a fume hood with suitable protective equipment: blast shield, full face visor, and heavy gloves.

(4-Bromobutanoyl)ferrocene (4) (*38*). To a suspension of aluminum chloride (1.40 g, 10.5 mmol) in CH_2Cl_2 (4 mL) was added 4-bromobutanoyl chloride (1.16 mL, 10.0 mmol) as a solution in CH_2Cl_2 (4 mL) dropwise via a cannulus at room temperature. After 2 h, the now homogeneous solution was cooled to −10 °C and added via a cannulus to a solution of ferrocene (1.86 g, 10.0 mmol) in CH_2Cl_2 (24 mL) cooled to 0 °C. The now purple solution was allowed to warm to room temperature and stirred for 16 h. This solution was then diluted with CH_2Cl_2 and poured over ice-H_2O. Product isolation (saturated $NaHCO_3$, CH_2Cl_2), filtration through Celite, and purification (R_f 0.45 in CH_2Cl_2) afforded an orange solid (2.78 g, 83%); mp 58.0−61.1 °C. This solid should be stored in the freezer to prevent decomposition. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 4.81 (t, 2H, J = 1.80 Hz), 4.52 (t, 2H, J = 1.86 Hz), 4.22 (s, 5H), 3.57 (t, 2H, J = 6.23 Hz), 2.94 (t, 2H, J = 6.83 Hz), 2.27 (quin, 2H, J = 6.54 Hz). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 203.0, 78.8, 72.3, 69.8, 69.2, 37.2, 34.0, 26.9. MS (CI, CH_4): m/z (relative intensity) 337 (M + 3, 29), 336 (M + 2, 27), 335 (M + 1, 29), 334 (M^+, 25), 255 (100). High-resolution mass spectroscopy (HRMS) calcd for $C_{14}H_{15}Br^{56}FeO$, 333.9656; found, 333.9656. Anal. Calcd for $C_{14}H_{15}BrFeO$: C, 50.19; H, 4.51; Br, 23.85. Found: C, 50.02; H, 4.19; Br, 24.20.

3β-(4-Chlorophenyl)-8-(4-ferrocenyl-4-oxobutyl)-8-azabicyclo[3.2.1]octane-2β-carboxylic Acid Methyl Ester (5). To a solution of **1** (246.4 mg, 0.881 mmol) and **4** (885.2 mg, 2.64 mmol) in toluene (12.3 mL) were added triethylamine (12.3 mL, 88.1 mmol) and KI (27.7 mg, 0.220 mmol) successively. The mixture was then heated to reflux and stirred overnight. After the solution was cooled to room temperature, all volatile material was removed in vacuo. Purification (R_f 0.14 in 2% Et_3N/18% Et_2O/80% hexanes) afforded an orange solid (318 mg, 68%). ^{1}H NMR ($CDCl_3$, 500 MHz): δ 7.23 (AA′ of AA′XX′, 2H, J_{AX} = 8.78 Hz, J_{AA} = 2.14 Hz), 7.19 (XX′ of AA′XX′, 2H, J_{AX} = 8.55 Hz, J_{XX} = 2.3 Hz), 4.80 (m, 2H), 4.48 (m, 2H), 4.22 (s, 5H), 3.73 (dd, 1H, J = 6.84, 2.67 Hz), 3.52 (s, 3H), 3.40 (dt, 1H, J = 6.62, 2.61 Hz), 2.95 (m, 3H), 2.65 (ddd, 1H, J = 16.77, 7.63, 5.97 Hz), 2.59 (td, 1H, J = 12.60, 3.4 Hz), 2.33 (m, 2H), 2.11 (m, 1H), 2.01 (m, 1H), 1.85 (tt, 1H, J = 13.83, 6.71 Hz), 1.66 (m, 4H). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 204.8, 171.8, 141.8, 131.4, 128.6, 128.0, 79.1, 72.1, 72.0, 69.8, 69.4, 69.2, 62.6, 61.5, 52.7, 52.6, 51.0, 36.7, 34.0, 33.8, 26.0, 25.9, 23.4. MS (CI, CH_4): m/z (relative intensity) 534 (M + 1, 100), 292 (40), 255 (15), 228 (69). HRMS calcd for $C_{29}H_{33}Cl^{56}FeNO_3$, 534.1498; found, 534.1493.

[3β-(4-Chlorophenyl)-8-(4-ferrocenyl-4-oxobutyl)-8-azabicyclo[3.2.1]oct-2β-yl]methanol (6). To a solution of [3β-(4-chlorophenyl)-8-azabicyclo[3.2.1]oct-2-yl]-methanol (**2**, 36.3 mg, 0.144 mmol) and **4** (145 mg, 0.433 mmol) in toluene (1.7 mL) were added triethylamine (1.71 mL, 12.3 mmol) and KI (5.3 mg, 0.032 mmol) successively. The mixture was then heated to reflux and stirred overnight. After the mixture was cooled to room temperature, all volatile material was removed in vacuo. Purification (R_f 0.15 in 2% Et_3N/48% Et_2O/50% hexanes) afforded an orange solid (68.2 mg, 94%). ^{1}H NMR ($CDCl_3$, 500 MHz): δ 7.29 (m, 4H), 4.82 (m, 2H), 4.50 (t, 2H, J = 1.99 Hz), 4.21 (s, 5H), 3.77 (dd, 1H, J = 11.12, 2.06 Hz), 3.62 (dd, 1H, J = 6.65, 1.37 Hz), 3.49 (dt, 1H, J = 6.48, 3.24 Hz), 3.37 (dd, 1H, J = 11.14, 2.53 Hz), 3.10 (dt, 1H, J = 12.58, 5.95 Hz), 2.84 (td, 2H, J = 7.15, 2.03 Hz), 2.51 (td, 1H, J = 13.18, 3.10 Hz), 2.43 (t, 2H, J = 7.07 Hz), 2.10 (m, 2H), 1.95 (quin, 2H, J = 7.16 Hz), 1.75 (m, 2H), 1.66 (ddd, 1H, J = 12.80, 5.40, 3.00 Hz), 1.52 (dq, 1H, J = 5.83, 2.61 Hz). ^{13}C NMR ($CDCl_3$, 189 MHz): δ 204.0, 141.1, 131.8, 129.7, 128.3, 78.8, 72.2, 72.1, 69.8, 69.3, 69.2, 66.9, 65.1, 60.1, 52.9, 45.3, 37.0(2), 36.8, 26.6, 25.4, 23.0. MS (FAB): m/z (relative intensity) 506 (M + 1, 2), 460 (4), 424 (2), 366 (3), 307 (35), 289 (17), 154 (100), 136 (56). HRMS calcd for $C_{28}H_{33}Cl^{56}FeNO_2$, 506.1549; found, 506.1548.

3β-(4-Iodophenyl)-8-(4-ferrocenyl-4-oxobutyl)-8-azabicyclo[3.2.1]octane-2β-carboxylic Acid Methyl Ester (7). To a solution of 3β-(4-iodophenyl)-8-azabicyclo-[3.2.1]octane-2β-carboxylic acid methyl ester (norCIT (**3**), 180 mg, 0.485 mmol) and **4** (812 mg, 2.42 mmol) in toluene (20 mL) were added triethylamine (11.5 mL, 82.6 mmol) and KI (13.6 mg, 0.108 mmol) successively. The mixture was then heated to reflux and stirred overnight. After the mixture was cooled to room temperature, all volatile material was removed in vacuo. Purification (R_f 0.24 in 2% Et_3N/28% Et_2O/70% hexanes) afforded an orange solid (210 mg, 69%). ^{1}H NMR ($CDCl_3$, 500 MHz): δ 7.29 (AB, 4H, J_{AB} = 8.45 Hz), 4.80 (m, 2H), 4.48 (m, 2H), 4.22 (m, 5H), 3.73 (dd, 1H, J = 6.00, 3.10 Hz), 3.52 (s, 3H), 3.39 (dt, 1H, J = 5.80, 2.08 Hz), 2.94 (m, 3H), 2.64 (ddd, 1H, J = 16.54, 7.38, 6.00 Hz), 2.57 (td, 1H, J = 12.57, 2.43 Hz), 2.33 (m, 2H), 2.11 (m 1H), 2.00 (m, 1H), 1.84 (tt, 1H, J = 13.57, 6.79 Hz), 1.66 (m, 4H). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 204.7, 171.8, 143.1, 136.9,

129.5, 127.9, 79.3, 72.2, 72.1, 69.8, 69.4, 69.3, 62.8, 61.4, 52.7, 52.6, 51.0, 36.8, 34.0, 33.9, 26.1, 26.0, 23.5. MS (CI, CH_4): *m*/*z* (relative intensity) 626 (M + 1, 100), 384 (61), 22 (74). HRMS calcd for $C_{29}H_{33}I^{56}FeNO_3$, 626.0855; found, 626.0846.

8-(3-Benzyloxycarbonyl-propyl)-3*β*-(4-Chlorophenyl)-8-azabicyclo[3.2.1]octane-2*β*-carboxylic Acid Methyl Ester (8). To a solution of **1** (1.20 g, 4.30 mmol) and 4-bromobutyric acid benzyl ester (1.32 g, 5.10 mmol) in toluene (40 mL) were added triethylamine (5 mL) and KI (50.0 mg, 0.397 mmol) successively. The mixture was then heated to reflux and stirred overnight. After the mixture was cooled to room temperature, all volatile material was removed in vacuo. Purification (5% Et_3N/30% Et_2O/65% hexanes) afforded a colorless oil (1.4 g, 75%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 7.35 (m 5H), 7.21 (dd, 4H, J = 8.7 Hz), 5.12 (s, 2H), 3.65 (m, 1H), 3.42 (s, 3H), 3.39 (m, 1H), 2.90 (m, 2H), 2.60−2.40 (m, 4H), 2.27 (m, 2H), 2.00 (m, 2H), 1.85−1.60 (m, 4H).

8-(3-Carboxypropyl)-3*β*-(4-Chlorophenyl)-8-azabicyclo[3.2.1]octane-2*β*-carboxylic Acid Methyl Ester (9). A solution of **8** (1.00 g, 2.20 mmol) and 100 mg of 3% Pd/C in methanol (20 mL) was stirred under an atmosphere of hydrogen (35 psi) for 2 h. Filtration over Celite and removal of the solvent gave **9** as a colorless oil (740 mg, 95%), which was used without further purification. ^{1}H NMR (CD_3COCD_3, 300 MHz): δ 7.29 (dd, 4H, J = 8.4 Hz), 4.3 (m, 1H), 3.75−3.55 (m, 2H), 3.40 (s, 3H), 3.35 (m, 1H), 3.20−3.05 (m, 2H), 2.74 (dt, 1H, J = 12.8, 5.0 Hz), 2.48−2.10 (m, 6H), 1.98−1.85 (m, 3H).

3*β*-(4-Chlorophenyl)-8-(4-cyclopentadienyltricarbonyl rhenium butanoyl)-8-azabicyclo[3.2.1]octane-2*β*-carboxylic Acid Methyl Ester (10). $(Et_4N)_2[ReBr_3(CO)_3]$ (50 mg, 0.065 mmol) was dissolved in acetonitrile (2 mL) and treated with silver trifluoromethanesulfonate (53.4 mg, 0.208 mmol) in one portion. The mixture was stirred for 5 min, and the yellow silver bromide precipitate was removed by filtration using a Pasteur pipet fitted with a cotton plug. The resulting colorless solution was added directly to a previously prepared solution containing **9** (40.4 mg, 0.110 mmol) and triethylamine (36 μL, 0.260 mmol) in acetonitrile (1 mL). The mixing of the two solutions resulted in the formation of a white precipitate. To this suspension was added (102.5 mg, 0.195 mmol, 1.90 mmol CpN_2/g polymer) in one portion. The mixture was then fitted with a reflux condenser and heated to 80 °C for 45 min. After the mixture was cooled to room temperature, the mixture was concentrated under a stream of nitrogen. Purification (R_f 0.11 in 2% Et_3N/13% EtOAc/85% hexanes) afforded a pale yellow oil (38 mg, 70%). ^{1}H NMR ($CDCl_3$, 500 MHz): δ 7.28 (dd, 4H, J = 8.4 Hz), 5.55 (t, 2H, J = 2.3 Hz), 5.15 (t, 2H, J = 2.4 Hz), 3.67 (dd, 1H, J = 7.3, 3.3 Hz), 3.45 (s, 3H), 3.37 (dt, 1H, J = 6.6, 2.5 Hz), 2.94 (dt, 1H, J = 12.8, 5.0 Hz), 2.89 (t, 1H, J = 4.3 Hz), 2.58−2.40 (m, 4H), 2.28 (m, 2H), 2.07 (m, 1H), 1.98 (m, 1H), 1.81−1.56 (m, 4H). MS (FAB): *m*/*z* (relative intensity) 700 (M + 1, 4), 460 (4), 307 (36), 289 (17), 154 (100), 136 (59). HRMS calcd for $C_{27}H_{28}ClNO_7{}^{187}Re$, 700.1112; found, 700.1112.

Ferrocenecarbonyl Chloride (12). Ferrocenecarboxylic acid (200 mg, 0.869 mmol) was suspended in dry CH_2Cl_2 (5 mL) at 0 °C. Oxalyl chloride (100 μL, 1.13 mmol) was then added dropwise, followed by several drops of DMF. Vigorous gas evolution ensued, and the mixture became a dark red homogeneous solution. After 1 h, the solution was warmed to room temperature, and all of the volatile material was removed under a stream of nitrogen. The residue was dissolved in hot petroleum ether and filtered through paper. The petroleum ether was then removed in vacuo to afford a dark red solid (200 mg, 93%). This compound was used without purification directly in the preparation of compound **14**.

Cyclopentadienyltricarbonyl Rhenium Carbonyl Chloride (13). Cyclopentadienyltricarbonyl rhenium carboxylic acid (200 mg, 0.527 mmol) was suspended in dry CH_2Cl_2 (5 mL) at 0 °C. Oxalyl chloride (60 μL, 0.685 mmol) was then added dropwise, followed by several drops of DMF. Vigorous gas evolution ensued. After 1 h, the solution was warmed to room temperature, and all of the volatile material was removed under a stream of nitrogen. The residue was dissolved in hot hexanes and filtered through paper. The hexanes were then removed in vacuo to afford a white solid (120 mg, 62%). This compound was used without purification directly in the preparation of compound **14a**.

8-Methyl-3*β*-(4-ferrocenylphenyl)-8-azabicyclo-[3.2.1]octane-2*β*-carboxylic Acid Methyl Ester (14). To a solution of **12** (143 mg, 0.575 mmol) and benzyl bis-(triphenylphosphino) palladium chloride (2.2 mg, 2.9 μmol) in chloroform (1 mL) was added 8-methyl-3*β*-[4-(trimethylstannanyl)-phenyl]-8-azabicyclo[3.2.1]octane-2*β*-carboxylic acid methyl ester (*35*) (**11**, 255.1 mg, 0.604 mmol) as a solution in chloroform (1 mL). The flask was fitted with a reflux condenser, and the solution was heated to reflux for 1 h or until palladium black precipitated from the solution. After the solution was cooled to room temperature, the now red solution was placed directly on a silica column. Purification (R_f 0.26 in 2% Et_3N/58% Et_2O/40% hexanes) afforded a red solid (100 mg, 37%). ^{1}H NMR ($CDCl_3$, 500 MHz): δ 7.84 (AA′ of AA′XX′, 2H, J_{AX} = 8.47 Hz, J_{AA} = 1.95 Hz), 7.35 (XX′ of AA′XX′, 2H, J_{AX} = 8.10 Hz, J_{XX} = 2.28 Hz), 4.90 (m, 2H), 4.56 (m, 2H), 4.20 (s, 5H), 3.60 (dd, 1H, J = 7.47, 3.35 Hz), 3.52 (s, 3H), 3.40 (dt, 1H, J = 6.62, 3.31 Hz), 3.06 (dt, 1H, J = 12.76, 5.06 Hz), 2.98 (ddd, 1H, J = 5.01, 3.47, 1.11 Hz), 2.64 (td, 1H, J = 12.61, 2.93 Hz), 2.24 (m, 1H), 2.24 (s, 3H), 2.13 (m, 1H), 1.75 (m, 2H), 1.64 (ddd, 1H, J = 13.20, 9.43, 4.12 Hz). ^{13}C NMR ($CDCl_3$, 189 MHz): δ 198.7, 172.0, 147.3, 137.3, 128.1, 127.2, 78.5, 72.3, 72.2, 71.6, 71.5, 70.2, 65.3, 62.2, 52.6, 51.2, 42.0, 33.9, 33.8, 25.9, 25.2. MS (EI, 70 eV): *m*/*z* (relative intensity) 471 (M^+, 84), 97 (64), 83 (100). HRMS calcd for $C_{27}H_{29}{}^{56}FeNO_3$, 471.1497; found, 471.1493.

8-Methyl-3*β*-[4-(carbonyl cyclopentadienyltricarbonyl rhenium)phenyl]-8-azabicyclo[3.2.1]octane-2*β*-carboxylic Acid Methyl Ester (14a). To a solution of cyclopentadienyltricarbonyl rhenium carbonyl chloride (**13**, 38.5 mg, 96.8 μmol) and benzyl chloro-bis-(triphenylphosphino) palladium (0.37 mg, 0.48 μmol) in chloroform (1 mL) was added **11** (42.9 mg, 0.102 mmol) as a solution in chloroform (1 mL). The flask was fitted with a reflux condenser, and the solution was heated to reflux for 1 h or until palladium black precipitated from the solution. After the solution was cooled to room temperature, the yellow solution was placed directly on a silica column. Purification (R_f 0.24 in 2% Et_3N/68% Et_2O/30% hexanes) afforded a white solid (55 mg, 92%). ^{1}H NMR ($CDCl_3$, 500 MHz): δ 7.72 (AA′ of AA′XX′, 2H, J_{AX} = 8.32 Hz, J_{AA} = 1.95 Hz), 7.35 (XX′ of AA′XX′, 2H, J_{AX} = 8.35 Hz, J_{XX} = 2.15 Hz), 6.06 (t, 2H, J = 2.26 Hz), 5.44 (t, 2H, J = 2.30 Hz), 3.60 (dd, 1H, J = 6.56, 2.92 Hz), 3.51 (s, 3H), 3.39 (m, 2H), 3.04 (dt, 1H, J = 12.69, 5.20 Hz), 2.96 (m, 1H), 2.61 (td, 1H, J = 12.52, 2.78 Hz), 2.24 (m, 1H), 2.24 (s, 3H), 2.13 (m, 1H), 1.73 (m, 2H), 1.62 (ddd, 1H, J = 13.29, 9.51, 4.14 Hz). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 192.0, 189.3, 171.9, 148.9, 134.8, 128.3, 127.6, 96.1, 89.7, 89.6, 85.2, 65.2, 62.1, 52.5, 51.2, 41.9, 33.9, 33.7, 25.8, 25.1. MS (EI, 70 eV): *m*/*z* (relative intensity) 621 (M^+,

24), 97 (53), 83 (100). HRMS calcd for $C_{25}H_{24}NO_6{}^{187}Re$, 621.1161; found, 621.1155.

(7*R*,5*S*)-7-(4-Chlorophenyl)-5-pyrrolidin-1-yl-cyclohept-1-enecarboxylic Acid Methyl Ester (15). To a solution of **1** (44.4 mg, 0.159 mmol) and 1-bromo-4-chlorobutane (91 μL, 0.794 mmol) in toluene (10 mL) were added triethylamine (250 μL, 1.79 mmol) and KI (6.6 mg, 0.040 mmol) successively. The mixture was then heated to reflux and stirred overnight. After the mixture was cooled to room temperature, all volatile material was removed. Purification (R_f 0.21 in 2% Et_3N/68% Et_2O/30% hexanes) afforded a colorless oil (34 mg, 58%). ^{1}H NMR ($CDCl_3$, 500 MHz): δ 7.24 (AA′ of AA′XX′, 2H, $J_{AX} = 8.49$ Hz, $J_{AA} = 2.30$ Hz), 7.19 (d, 1H, $J = 9.20, 5.95$ Hz), 7.15 (XX′ of AA′XX′, 2H, $J_{AX} = 8.39$ Hz, $J_{XX} = 2.41$ Hz), 4.02 (ddd, 1H, $J = 11.72, 6.77, 1.55$ Hz), 3.57 (s, 3H), 2.78 (ddtd, 1H, $J = 14.57, 12.35, 6.20, 1.94$ Hz), 2.57 (m, 6H), 2.28 (dddd, 1H, $J = 14.60, 9.06, 5.37, 3.01$ Hz), 2.09 (m, 2H), 1.95 (ddd, 1H, $J = 14.29, 12.06, 9.88$ Hz), 1.77 (m, 5H). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 167.9, 143.4, 140.8, 134.7, 131.9, 128.6, 128.6, 59.8, 51.7, 50.7, 45.6, 36.6, 30.0, 23.3, 22.6. MS (EI, 70 eV): *m*/*z* (relative intensity) 333 (M^+, 11), 318 (4), 304 (10), 274 (6), 208 (48), 97 (100). HRMS calcd for $C_{19}H_{24}ClNO_2$, 333.1496; found, 333.1491.

Benzoylferrocene (16). To a suspension of aluminum chloride (376.3 mg, 2.82 mmol) in CH_2Cl_2 (1 mL) was added benzoyl chloride (312 μL, 2.69 mmol) as a solution in CH_2Cl_2 (1 mL) dropwise via a cannulus at room temperature. After 2 h, the homogeneous solution was cooled to −10 °C and added via a cannulus to a solution of ferrocene (500 mg, 2.69 mmol) in CH_2Cl_2 (5 mL) cooled to 0 °C. The now purple solution was allowed to warm to room temperature and stirred for 16 h. This solution was then diluted with CH_2Cl_2 and poured over ice-H_2O. Product isolation (saturated $NaHCO_3$, CH_2Cl_2), filtration through Celite, and purification (R_f 0.21 in CH_2Cl_2) afforded red crystals (631 mg, 81%); mp 107.3−108.9 °C. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 7.90 (m, 2H), 7.55 (m, 1H), 7.47 (m, 2H), 4.91 (t, 2H, $J = 1.88$ Hz), 4.59 (t, 2H, $J = 2.00$ Hz), 4.21 (s, 5H). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 199.2, 139.8, 131.5, 128.2, 128.1, 78.1, 72.5, 71.5, 70.2. MS (EI, 70 eV): *m*/*z* (relative intensity) 290 (M^+, 100), 197 (10), 141 (10), 133 (14), 56 (12). HRMS calcd for $C_{17}H_{14}{}^{56}FeO$, 290.0394; found, 290.0395.

4-*tert*-Butyldimethylsilyloxy-1-(cyclopentadienyltricarbonyl rhenium)butane (18). To a solution of cyclopentadienyltricarbonyl rhenium (335.3 mg, 1.00 mmol) in THF (10 mL) at −78 °C was added BuLi (617 μL, 1.00 mmol). After 3 h at −78 °C, **17** (628.6 mg, 2.00 mmol) was added and the temperature was maintained for an additional 2 h. The solution was then allowed to warm to room temperature and stirred overnight. Product isolation (H_2O, EtOAc) and purification (R_f 0.23 in 5% EtOAc/hexanes) afforded a colorless oil (250 mg, 48%). ^{1}H NMR ($CDCl_3$, 500 MHz): δ 5.24 (s, 4H), 3.62 (m, 2H), 2.43 (m, 2H), 1.58−1.54 (m, 4H), 0.89 (s, 9H), 0.05 (s, 6H). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 194.6, 111.6, 83.5, 82.9, 62.7, 32.3, 28.2, 27.9, 25.9, 18.3,−5.3. MS (EI, 70 eV): *m*/*z* (relative intensity) 523 (M + 1, 18), 507 (16), 465 (41), 409 (15), 391 (100). HRMS calcd for $C_{18}H_{27}O_4{}^{187}ReSi$, 522.1236; found, 524.1399.

4-Hydroxy(cyclopentadienyltricarbonyl rhenium)-butane (19). To a solution of silyl ether **18** (240 mg, 0.460 mmol) in THF (5 mL) was added a 1 M solution of Bu_4NF in THF (920 μL, 0.920 mmol) dropwise at 0 °C. After 1 h at 0 °C, TLC indicated complete conversion of the starting material to a more polar compound. Product isolation (H_2O, Et_2O) and purification (R_f 0.26 in 50% EtOAc/hexanes) afforded a colorless oil (180 mg, 96%). ^{1}H NMR ($CDCl_3$, 500 MHz): δ 5.25 (s, 4H), 3.68 (m, 2H), 2.46 (m, 2H), 1.67−1.57 (m, 4H). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 194.5, 111.3, 83.6, 82.8, 62.4, 32.2, 27.9 (2). MS (EI, 70 eV): *m*/*z* (relative intensity) 408 (M^+, 45), 380 (23), 348 (31), 322 (100), 304 (23), 263 (34), 85 (35), 71 (48), 57 (67). HRMS calcd for $C_{12}H_{13}O_4{}^{187}Re$, 408.0371; found, 408.0372.

4-*p*-Toluenesulfonyloxy-1-(cyclopentadienyltricarbonyl rhenium)butane (20). Alcohol **19** (90 mg, 0.221 mmol) was dissolved in pyridine (5 mL) and cooled to 0 °C. *p*-Toluenesulfonyl chloride (63.2 mg, 0.331 mmol) was added in one portion, and the solution was placed in the freezer overnight. Product isolation (saturated $CuSO_4$, Et_2O) and purification (R_f 0.33 in 30% EtOAc/Hexanes) afforded a yellow oil (100 mg, 81%). ^{1}H NMR ($CDCl_3$, 500 MHz): δ 7.79 (AA′ of AA′XX′, 2H, $J_{AX} = 8.36$ Hz, $J_{AA} = 2.05$ Hz), 7.36 (m, 2H), 5.24 (t, 2H, $J = 2.16$ Hz), 5.19 (t, 2H, $J = 2.26$ Hz), 4.04 (t, 2H, $J = 6.33$ Hz), 2.46 (s, 3H), 2.37 (m, 2H), 1.71 (m, 2H), 1.53 (m, 2H). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 194.3, 144.9, 132.9, 129.9, 127.9, 110.4, 83.7, 82.9, 69.8, 28.4, 27.6, 27.4, 21.6. MS (EI, 70 eV): *m*/*z* (relative intensity) 562 (M^+, 68), 534 (63), 478 (51), 332 (100), 91 (52). HRMS calcd for $C_{19}H_{19}O_6S^{187}Re$, 562.0460; found, 562.0458.

3β-(4-Chlorophenyl)-8-(4-cyclopentadienyltricarbonyl rhenium-butyl)-8-azabicyclo[3.2.1]octane-2β-carboxylic Acid Methyl Ester (21). To a solution of **1** (49.8 mg, 0.178 mmol) and tosylate **20** (100 mg, 0.178 mmol) in toluene (10 mL) were added triethylamine (250 μL, 1.79 mmol) and KI (5.6 mg, 0.045 mmol) successively. The mixture was then heated to reflux and stirred overnight. After the solution had cooled to room temperature, all volatile material was removed in vacuo. Purification (R_f 0.24 in 2% Et_3N/28% Et_2O/70% hexanes) afforded a yellow oil (61 mg, 51%). ^{1}H NMR ($CDCl_3$, 500 MHz): δ 7.23 (AA′ of AA′XX′, 2H, $J_{AX} = 8.59$ Hz, $J_{AA} = 2.29$ Hz), 7.18 (XX′ of AA′XX′, 2H, $J_{AX} = 8.54$ Hz, $J_{XX} = 2.59$ Hz), 5.24 (m, 4H), 3.66 (dd, 1H, $J = 7.12, 3.29$ Hz), 3.48 (s, 3H), 3.38 (dt, 1H, $J = 6.63, 3.32$ Hz), 2.97 (dt, 1H, $J = 12.80, 5.06$ Hz), 2.89 (m, 1H), 2.54 (td, 1H, $J = 12.37, 2.99$ Hz), 2.39 (m, 2H), 2.25 (ABt, 2H, $J_{AB} = 12.19$ Hz, $J_t = 6.68$ Hz), 2.09 (tdd, 1H, $J = 12.70, 7.10, 4.09$ Hz), 1.99 (tdd, 1H, $J = 12.76, 6.57, 4.66$ Hz), 1.71 (ddd, 1H, $J = 13.35, 9.45, 4.28$ Hz), 1.65 (dddd, 1H, $J = 12.45, 4.74, 3.40, 1.18$ Hz), 1.61 (ddd, 1H, $J = 13.39, 9.43, 4.28$ Hz), 1.52 (m, 2H), 1.43 (m, 2H). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 194.6, 171.9, 141.8, 131.4, 128.7, 128.0, 111.8, 83.6, 82.9, 82.8, 62.9, 61.3, 52.9, 52.8, 51.0, 34.0, 33.8, 29.2, 28.5, 27.9, 26.0. MS (EI, 70 eV): *m*/*z* (relative intensity) 669 (M^+, 62), 638 (9), 610 (14), 458 (51), 429 (38), 292 (100), 97 (56). HRMS calcd for $C_{27}H_{29}ClNO_5{}^{187}Re$, 669.1292; found, 669.1297.

8-Methyl-3β-[4-(Cyclopentadienyltricarbonyl rhenium)phenyl]-8-azabicyclo[3.2.1]octane-2β-carboxylic Acid Methyl Ester (22). Compound **11** (70 mg, 0.166 mmol) and iodocyclopentadienyltricarbonyl rhenium (33.4 mg, 0.166 mmol) were dissolved in DMF (5 mL) at room temperature. Bis(triphenylphosphino)-dichloro palladium (2.3 mg, 3.3 μmol) was added to the solution, which was subsequently degassed and stirred overnight. Product isolation (saturated LiCl, Et_2O) and purification (R_f 0.22 in 2% Et_3N/68% Et_2O/30% hexanes) afforded a white powder (63 mg, 64%). ^{1}H NMR ($CDCl_3$, 400 MHz): δ 7.22 (AA′ of AA′XX′, 2H, $J_{AX} = 8.40$ Hz, $J_{AA} = 2.20$ Hz), 7.14 (m, 2H), 5.64 (m, 2H), 5.29 (m, 2H), 3.49 (dd, 1H, $J = 6.80, 2.80$ Hz), 3.40 (s, 3H), 3.29 (tt, 1H, $J = 6.40, 3.20$ Hz), 2.93 (dt, 1H, $J = 12.40, 5.20$ Hz), 2.83 (m, 1H), 2.50 (td, 1H, $J = 12.40, 2.80$ Hz), 2.15 (s, 3H), 2.12 (m, 1H), 2.03 (m, 1H), 1.64 (m, 2H), 1.54 (ddd,

1H, J = 13.20, 9.60, 4.40 Hz). ^{13}C NMR ($CDCl_3$, 100 MHz): δ 194.6, 172.5, 144.2, 129.5, 128.1, 126.4, 109.4, 84.6, 84.5, 82.0, 81.9, 65.7, 62.6, 53.1, 51.6, 42.3, 34.3, 33.9, 26.3, 25.5. MS (EI, 70 eV): *m/z* (relative intensity) 593 (M^+, 73), 565 (15), 534 (19), 97 (68), 83 (100). HRMS calcd for $C_{24}H_{24}NO_5{}^{187}Re$, 593.1212; found, 593.1212.

Typical Experimental Procedure for DLT Reactions (See Cautionary Note at the Start of the Experimental Section). Reactions were performed in 4 mL threaded pressure tubes sealed with Teflon screw caps with O-rings (all purchased from Ace Glass). An egg-shaped (1 cm) stir bar was used to stir each reaction. Potassium perrhenate (1 molar equiv), chromium hexacarbonyl (5.61 equiv), chromium chloride (2.01 equiv), and the appropriate ferrocene (3.13 equiv) were combined in an oven-dried 4 mL pressure tube containing a magnetic stir bar. Dry methanol (500 μL) was added, and the tube was flushed with argon and then rapidly sealed. The heterogeneous mixture was placed in the reaction vessel described above and heated to 160 °C for 30 min. The tube was then carefully removed and placed directly into a water bath at room temperature: the solution was homogeneous when it came out of the reaction vessel. After 10 min, ice was added to the bath. Following an additional 10 min, the tube was transferred to a −78 °C bath before it could safely be opened. The reaction mixture was then diluted with CH_2Cl_2 and transferred to a 20 mL scintillation vial. The volatile components were removed under a stream of nitrogen, and the residue was purified on silica.

3β-(4-Chlorophenyl)-8-(4-cyclopentadienyltricarbonyl rhenium-4-oxobutyl)-8-azabicyclo[3.2.1]octane-2β-carboxylic Acid Methyl Ester (5a). The typical procedure for the DLT reaction, given above, was used with potassium perrhenate (8.7 mg, 0.030 mmol), chromium hexacarbonyl (36.9 mg, 0.168 mmol), chromium chloride (9.5 mg, 0.060 mmol), and ferrocene **5** (50 mg, 0.094 mmol). Purification (2% Et_3N/48% Et_2O/50% hexanes) afforded a dark brown oil (9.7 mg, 47%). ^{1}H NMR data for this compound were identical to that previously reported in the literature (*33*).

[3β-(4-Chlorophenyl)-8-(4-cyclopentadienyltricarbonyl rhenium-4-oxobutyl)-8-azabicyclo[3.2.1]oct-2β-yl]methanol (6a). The typical procedure for the DLT reaction, given above, was used with potassium perrhenate (11.0 mg, 0.038 mmol), chromium hexacarbonyl (46.8 mg, 0.213 mmol), chromium chloride (12.1 mg, 0.076 mmol), and ferrocene 6, 60 mg, 0.119 mmol). Purification (R_f 0.16 in 2% Et_3N/68% Et_2O/30% hexanes) afforded a dark brown oil (6.6 mg, 27%). ^{1}H NMR ($CDCl_3$, 500 MHz): δ 7.28 (m, 4H), 6.05 (ddt, 2H, J = 9.06, 3.14, 1.67 Hz), 5.40 (m, 2H), 3.75 (dd, 1H, J = 11.27, 2.23 Hz), 3.57 (dd, 1H, J = 6.94, 2.08 Hz), 3.45 (dt, 1H, J = 6.48, 2.86 Hz), 3.33 (dd, 1H, J = 11.12, 2.58 Hz), 3.09 (dt, 1H, J = 12.57, 5.95 Hz), 2.72 (ABt, 2H, J_{AB} = 16.88 Hz, J_t = 7.20 Hz), 2.47 (td, 1H, J = 13.13, 3.24 Hz), 2.36 (t, 2H, J = 6.93 Hz), 2.08 (m, 2H), 1.91 (quin, 2H, J = 7.25 Hz), 1.73 (m, 2H), 1.64 (ddd, 1H, J = 12.84, 5.59, 2.90 Hz), 1.50 (dq, 1H, J = 6.12, 2.37 Hz). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 194.9, 191.9, 141.1, 131.9, 129.7, 128.4, 96.0, 88.0, 87.9, 85.5, 85.3, 66.9, 65.1, 60.2, 52.5, 45.3, 36.9, 36.7, 36.3, 26.5, 25.4, 23.0. MS (FAB): *m/z* (relative intensity) 656 (M + 1, 11), 307 (31), 289 (16), 154 (100), 136 (72). HRMS calcd for $C_{26}H_{28}ClNO_5{}^{187}Re$, 656.1214; found, 656.1223.

3β-(4-Iodophenyl)-8-(4-cyclopentadienyltricarbonyl rhenium-4-oxobutyl)-8-azabicyclo[3.2.1]octane-2β-carboxylic Acid Methyl Ester (7a). The typical procedure for the DLT reaction, given above, was used with potassium perrhenate (4.6 mg, 0.016 mmol), chromium hexacarbonyl (21.1 mg, 0.096 mmol), chromium chloride (5.1 mg, 0.032 mmol), and ferrocene **7** (10 mg, 0.016 mmol). Purification (R_f 0.26 in 2% Et_3N/28% Et_2O/70% hexanes) afforded a dark brown oil (6.5 mg, 52%). ^{1}H NMR ($CDCl_3$, 500 MHz): δ 7.58 (AA′ of AA′XX′, 2H, J_{AX} = 8.46 Hz, J_{AA} = 2.15 Hz), 7.00 (m, 2H), 6.06 (ABt, 2H, J_{AB} = 3.08 Hz, J_t = 1.62 Hz), 5.39 (dtd, 2H, J = 10.95, 2.76, 1.72 Hz), 3.66 (m, 1H), 3.48 (s, 3H), 3.36 (m, 1H), 3.10 (ABd, 2H, J_{AB} = 7.29 Hz, J_d = 4.76 Hz), 2.92 (m, 2H), 2.83 (dt, 1H, J = 16.89, 7.38 Hz), 2.55 (m, 2H), 2.27 (t, 2H, J = 6.10 Hz), 2.07 (m, 1H), 1.98 (m, 1H), 1.70 (m, 4H). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 195.9, 192.0, 171.9, 143.0, 136.9, 129.4 (2), 96.4, 88.1, 88.0, 85.5, 85.0, 62.9, 61.2, 58.4, 52.5, 52.2, 51.0, 35.9, 33.9, 26.0, 25.9, 23.5. MS (CI, CH_4): *m/z* (relative intensity) 776 (M + 1, 95), 650 (18), 397 (100), 271 (19). HRMS calcd for $C_{27}H_{28}INO_6{}^{187}Re$, 776.0519; found, 776.0523.

8-Methyl-3β-[4-(carbonyloxycyclopentadienyltricarbonyl rhenium)phenyl]-8-azabicyclo[3.2.1]octane-2β-carboxylic Acid Methyl Ester (14a). The typical procedure for the DLT reaction, given above, was used with potassium perrhenate (3.3 mg, 0.011 mmol), chromium hexacarbonyl (14 mg, 0.064 mmol), chromium chloride (3.6 mg, 0.023 mmol), and ferrocene **14** (5.6 mg, 0.012 mmol). Purification (R_f 0.24 in 2% Et_3N/68% Et_2O/30% hexanes) afforded a dark brown oil (3.1 mg, 42%). ^{1}H NMR data for this compound were identical to those for the compound synthesized by palladium coupling described above.

Benzoylcyclopentadienyltricarbonyl Rhenium (16a). The typical procedure for the DLT reaction, given above, was used with potassium perrhenate (31.9 mg, 0.110 mmol), chromium hexacarbonyl (135.9 mg, 0.618 mmol), chromium chloride (35 mg, 0.221 mmol), and ferrocene **16** (100 mg, 0.345 mmol). Purification (R_f 0.06 in 10% EtOAc/hexanes) afforded an orange solid (25 mg, 50%), which could be recrystallized from ethanol/water to afford white crystals. Spectroscopic data for this compound matched that previously reported (*39*). ^{1}H NMR ($CDCl_3$, 500 MHz): δ 7.78 (m, 2H), 7.59 (m, 1H), 7.48 (m, 2H), 6.06 (t, 2H, J = 2.46 Hz), 5.46 (t, 2H, J = 2.33 Hz). MS (EI, 70 eV): *m/z* (relative intensity) 440 (M^+, 50), 412 (28), 356 (100), 328 (51), 302 (38). HRMS calcd for $C_{15}H_9O_4{}^{187}Re$, 440.0058; found, 440.0051.

Monoamine Transporter Binding Affinity Assays. Competitive binding assays were used to measure affinity of the new ligands to the DA, serotonin (5-HT), and norepinephrine (NE) transporters, using previously published methods (*40*−*42*). Briefly, brain tissue was obtained from adult male Sprague−Dawley rats, dissecting out striatum (caudate−putamen) for DAT and frontoparietal cortex for 5-HTT (serotonin transporter) and norepinephrine transporter (NET). Tissue was homogenized and washed in ice-cold assay buffer (see below); tissue pellets were stored at −70 °C until use and then suspended in assay buffer.

Radioligands for the competitive binding assay were [*propylene*-2,3-^{3}H]GBR-12935 (13 Ci/mmol; Kd = 1.0 nM) for DAT, [*phenyl*-6′-^{3}H]paroxetine (20 Ci/mmol, Kd = 150 pM) for 5-HTT, and [*N*-methyl-^{3}H]nisoxetine (85 Ci/mmol; Kd = 800 pM) for NET, all obtained from NEN/Dupont (Boston, MA).

Binding assays were carried out in triplicate at 100, 1000, and 10 000 nM with the following assay buffer, radioligands, and ligands for defining nonspecific binding: for DAT, Tris citrate buffer (50 mM, pH 7.4, containing 120 mM NaCl and 4 mM $MgCl_2$) with radioligand [^{3}H]GBR-12935 at a test concentration (*C*) of 400 pM, for 45 min on ice, using excess (2.5 μM) unlabeled

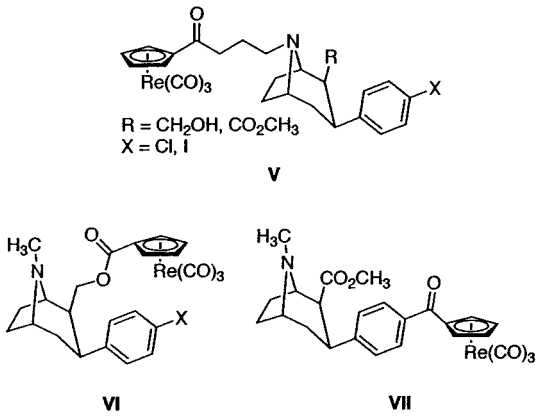

Figure 2. New $CpRe(CO)_3$ phenyltropane conjugates.

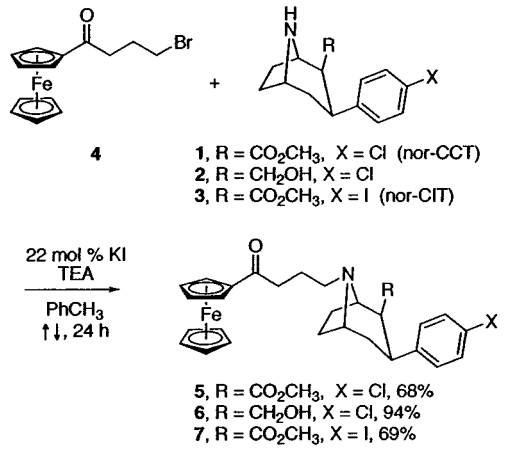
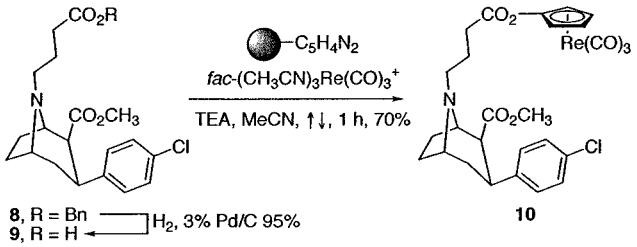
GBR-12909 (RBI, Natick, MA); for 5-HTT, Tris HCl buffer (50 mM, pH 7.4, with 120 mM NaCl and 5 mM KCl), radioligand [^{3}H]paroxetine ($C = 200$ pM) for 60 min at 20 °C, using excess (2 μM) fluoxetine HCl (Lilly Labs) as blank; for NET, Tris HCl buffer (50 mM, pH 7.4, with 300 mM NaCl and 5mM KCl), radioligand [^{3}H]nisoxetine ($C = 270$ pM) for 180 min at 4 °C, using excess (2 μM) desipramine HCl (RBI) as blank.



Concentration−inhibition curves were analyzed by the Allfit program (*43*) adapted to the Macintosh (*42*) to determine $IC_{50} \pm$ SE, and converted to $K_i \pm$ SE (nM) by the Cheng−Prusoff equation $K_i = IC_{50}/(1 + C/K_d)$ (*44*).

RESULTS AND DISCUSSION



Compound Design. Structure−activity relationships in the phenyltropane series (*45*) show tolerance at the 2β-, 3β-, and 8-(*N*-) position with respect to DAT binding affinity; results of substitution on the 4′-(para) position of the 3β-phenyl group depend on the specific structures (*46*, *47*). For *N*-substitution, a chain length of four is in the effective range for obtaining high affinity ligands for DAT (*48*). Coupling this information with the requirement for an electron-withdrawing group on the cyclopentadienyltricarbonylmetal substituent for the DLT reaction to proceed efficiently (*23*) suggested the structures in Figure 2 (V−VII) as the primary targets. Compounds **10**, **21**, and **22** were selected as representative structures that could be made by techniques other than the DLT reaction. These three compounds were prepared to explore further structure−affinity relationships of $CpRe(CO)_3$-substituted tropanes as ligands for the monoamine transporters. Preliminary experiments to make $CpRe(CO)_3$ or $CpTc(CO)_3$ ester VI (Figure 2) by the DLT were largely unsuccessful (*49*), probably because of transesterification with the methanol solvent during the DLT reaction (*23*); thus, the preparation of compounds in this series was not explored further. Methanolysis of the C-2β methoxycarbonyl group in V and VII, on the other hand, regenerates the same compound and is of no consequence.

***N*-Alkylation of Nortropanes.** *N*-Alkylation of the nortropanes is readily accomplished with alkyl halides and sulfonates, using the weak base triethylamine; stronger bases, such as carbonates, result in significant epimerization of the C-2β methoxycarbonyl group to the thermodynamically more stable C-2α isomer (*50*). Systems with a four-atom linker between the nitrogen and the metallocene (**5**−**7**) were prepared using (4-halobutanoyl)ferrocenes (Scheme 2). These alkylating agents can be prepared by Friedel−Crafts monoacylation of ferrocene with the (4-halobutanoyl)chlorides, under carefully controlled conditions (*38*). Although (4-chlorobutanoyl)ferrocene was unreactive in tropane *N*-alkylations, the corresponding bromo compound **4** afforded the desired ferrocenyl phenyltropanes (**5**−**7**) in moderate yields.

Scheme 2

Scheme 3

Ester **10** was made by the three-component condensation (Scheme 3), through which carboxylic acids can be attached directly as acyloxy links to the cyclopentadienyl ring of $CpMet(CO)_3$ systems (*25*). The required carboxylic acid precursor **9** was prepared by alkylation of **1** with benzyl 4-bromobutanoate to afford the benzyl ester **8**. Removal of the benzyl ester protecting group by hydrogenolysis was initially accompanied by aromatic ring dechlorination. However, reducing the catalyst loading to 3% Pd/C resulted in selective removal of the benzyl ester. The acid **9** was converted to the desired $CpRe(CO)_3$ phenyltropane complex **10** in good yield by the three-component condensation, using *fac*-$(CH_3CN)_3Re(CO)_3^+$ and polymer-supported diazocyclopentadiene (*26*).

Substitution at the Para Position of the 3β-Phenyl Group. We initially intended to prepare the differentially substituted diaryl ketones **14** and **14a** (Scheme 4) from β-CIT (**I**) using a Suzuki carbonylative cross-coupling reaction (*51*, *52*). We tested a model Suzuki reaction of ferroceneboronic acid with 4-iodotoluene in the presence of bis(triphenylphosphine)dichloro palladium and potassium carbonate under one atmosphere of carbon monoxide, obtaining 20% yield of coupling product. The low yield might be explained by steric hindrance in the ferroceneboronic acid (*27*). Nevertheless, we attempted this reaction on the hydroxymethyl analogue of CIT (rather than on β-CIT itself, to avoid the risk of epimerization at C-2 by potassium carbonate), but we did not obtain any cross-coupled product.

We were able to prepare the desired ketones using the Stille reaction, however (*53*). Compound **11**, which has been used for the preparation of iodine-123-labeled β-CIT (**I**), can be synthesized directly from β-CIT by treatment with hexamethyldistannane in the presence of a palladium catalyst (*35*). Ferrocenecarbonyl chloride (**12**) and

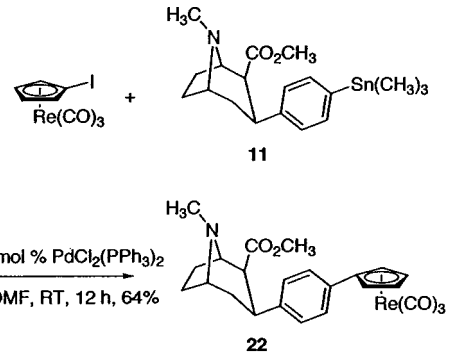
cyclopentadienyltricarbonyl rhenium carbonyl chloride (**13**) were prepared by treatment of the corresponding carboxylic acids with oxalyl chloride. They reacted with the tin precursor **11** and bis(triphenylphosphino)dichloro palladium to afford the desired biaryl ketones **14** and **14a** (Scheme 4). These reactions were performed on recrystallized acid chlorides; reaction yields were significantly lower with unpurified material.

DLT Reactions of Ferrocenyl Phenyltropanes. DLT reactions of ferrocenes with rhenium (Table 1; cf. Scheme 1) gave yields of 27−52%, in keeping with previously reported results on simpler molecules. The DLT reaction continues to display an impressive tolerance for functional groups. Previous reports had shown that ferrocene amides and monoketones were unaffected by this reaction, whereas aldehydes and alkynes underwent methanol addition (*25*). Esters underwent transesterification with the methanol solvent but successfully underwent the DLT (*25*). The present results show that alcohols, tertiary amines, and aryl halides also survive the high temperature and reducing conditions of this reaction. We considered that the extended conjugation in the biaryl ketone linkage of structure **VII** (Figure 2) might provide additional activation for the DLT reaction. As it turned out, ferrocene **14** underwent DLT with yields (42%) in the high range of examples tested, similar to the alkyl ketones (e.g., **5** and **7**). To determine whether the tropane part of the structure might be responsible

Scheme 5

Scheme 6

for lowering yields, the simpler benzophenone analogue **16** was synthesized. However, the DLT reaction reaction yield with this precursor was similar to that of **14**.



Directly Linked CpRe(CO)$_3$ Phenyltropanes. Although it would be difficult to prepare systems such as the alkyl CpRe(CO)$_3$ derivatives **21** and **22** by the DLT reaction because they lack the activating carbonyl link, our recently described approach using cyclopentadienyl tin precursors could ultimately be used to prepare the technetium-99m compounds (*28*). Initially, the planned synthetic route to these complexes was by alkylation of a suitable haloalkyl tropane precursor with the lithium anions generated from CpRe(CO)$_3$. However, when we attempted to prepare a potential 4-chlorobutyl-tropane alkylating precursor by the reaction of **1** with 1-bromo-4-chlorobutane, we obtained the ring-opened material **15** as the exclusive product (Scheme 5), presumably the result of double alkylation to form a spiro quaternary ammonium salt that then underwent β-elimination.

To avoid this difficulty, we reversed the sequence of alkylation steps, preparing first a 4-halobutyl CpRe(CO)$_3$ system (Scheme 6) and then coupling it to the *N*-8 position of the nortropane. The anion of CpRe(CO)$_3$, generated by treatment with butyllithium, underwent reaction with **17** to give 4-(*tert*-butyldimethylsilyloxy)-1-(cyclopentadienyltricarbonyl rhenium)-butane (**18**) (Scheme 6), which underwent smooth deprotection upon treatment with tetrabutylammonium fluoride. Reaction of the *p*-toluenesulfonate ester (**20**) of alcohol **19** with nortropane **1** afforded the desired CpRe(CO)$_3$ phenyltropane conjugate (Scheme 6).

The biarene **22**, an analogue of conjugate **14a**, was synthesized in a manner analogous to the method described previously (cf. Scheme 4). Iodocyclopentadienyltricarbonyl rhenium was coupled with aryl stannane **11** in the presence of a palladium catalyst to afford the desired biarene **22** (Scheme 7). The three-component condensation or our more recent approach using cyclopentadienyl tin precursors might provide an efficient route for preparing the analogous technetium-99m compound (*27*, *28*).

DAT Binding Affinities of CpRe(CO)$_3$ Phenyltropane Conjugates. The three monoamine transmitters—DA, 5-HT, and NE—have distinct functions in the brain,

Scheme 7

with corresponding significance for ligands that bind to them. For instance, disturbances in DA are associated with psychosis and motion disorders, and disturbances in 5-HT and NE are associated with mood disorders (*54*, *59*, *60*). Cocaine binds with similar affinity to DAT and 5-HTT (*55*), leading to its spectrum of pharmacological effects, and phenyltropanes display a range of selectivities, mostly for DAT and 5-HTT. A selective ligand for NET would be of interest because none is yet known that would be suitable for in vivo imaging. Selectivity is not so critical for quantitating DAT in the striatum, where the transporter is highly concentrated (>90%). Thus [^{123}I]β-CIT, which has comparable affinity to DAT and 5-HTT (*56*), is effective in measuring DAT in striatum but less so for detecting DAT in low-density extrastriatal areas.

A competitive in vitro radioligand binding assay was used to determine the affinity of the new tropane derivatives for the three monoamine transporters in rat brain tissue (Table 2, listed in order of decreasing DAT affinity). Overall, the DAT binding affinity pattern of the nine compounds reported in Table 2 is reflected in their affinities to the other two transporters, 5-HTT and NET: For comparison, β-CIT (**I**) has an affinity $K_i = 0.96$ nM for DAT in the same assay (*56*). The *N*-8-substituted tropanes (compounds **5**, **5a**, **6**, **6a**, **10**, and **21**) had high or at least moderate affinities, whereas the 3β-substituted systems (compounds **14**, **14a**, and **22**) had negligible affinities. Within the former, high-affinity group, however, there were some differences. The rank order for the six highest affinity compounds for the 5-HTT was nearly the same as that for the DAT, with the exception of compound **5**, which had a much higher affinity for 5-HTT, and compound **21**, which was fifth ranked on DAT but third ranked on 5-HTT. By contrast, the affinity for NET was uniformly low, with only ferrocene **6** having affinity in the low nanomolar range. (*56*, *25*, *27*, *28*).

The low affinity of the 3β-phenyl conjugates **14** and **14a** was unexpected in the light of the affinity (K_i 10−19 nM) of the biphenyl derivatives **III** (*47*). To see if this difference was a result of the overall bulk or to the different steric and electronic configuration of a biphenyl vs benzoyl type linkage, we synthesized and tested the biphenyl analogue **22**. The binding affinity was in the same range as the benzoyl analogues, showing that the ketone was not the deciding factor. These results agree with observed trends that the effect of substituents at the para position of the 3β-phenyl substituent cannot be predicted reliably with our current knowledge. Notably, the ferrocene precursors **5**, **6**, and **14** had binding profiles similar to the rhenium compounds, suggesting that the second cyclopentadienyl ligand on divalent iron in the sandwich compound has an effect similar to that of the tricarbonyl−rhenium(I) moiety. These properties make minimization of the ferrocene precursor in the final radiopharmaceutical necessary, either by purification or by clever choice of reaction conditions to selectively inactivate the iron compound.

As compared to other rhenium and technetium complexes targeting DAT, the *N*-substituted CpRe(CO)$_3$ analogues showed more favorable binding characteristics. The affinity of the rhenium analogue of TRODAT-1 is on the order of 14.1 nM for DAT and 360 nM for 5-HTT (*57*), and these are reflected in the modest in vivo target-to-background ratio (striatum/cerebellum = 3−3.5) as compared to a value of 4−7 for [^{123}I]β-CIT (*35*). The rhenium analogue of technepine was reported to have a K_i of 6.0 nM to DAT and 124 nM to 5-HTT (*58*), but quantitative in vivo data have not appeared. An imaging study in baboons with a tropane-CpRe(CO)$_3$ radiotracer labeled with ^{123}I showed an in vivo uptake and distribution similar to that of [^{99m}Tc]TRODAT-1 (*20*).

CONCLUSIONS

In this work, we present the first application of the DLT reaction for the direct preparation of CpRe(CO)$_3$−phenyltropane conjugates. In the new examples, we show that the DLT gives reasonable yields and continues to show broad functional group tolerance. In principle, the synthetic utility of this direct synthesis is greater for preparing radioactive rhenium and technetium compounds, where metal incorporation must be close to the final step in the synthesis. Technetium may be predicted to be more reactive chemically, although this is offset with technetium-99m because of the very low concentration of metal under practical conditions of labeling. Initial attempts to synthesize the technetium-99m analogue of **5a** have in fact shown that high levels of incorporation could be achieved, albeit at high temperature and pressure (*47*). Additional work will be needed to make the labeling conditions practical for routine radiopharmaceutical preparation. Of the CpRe(CO)$_3$−tropane conjugates we have investigated, those substituted at the *N*-8 position seem most promising; their affinity for the DAT in all cases was high, and their ferrocene precursors can be prepared in a convenient manner. By contrast, the 3β-conjugates showed low DAT binding. The modular nature

of these systems, however, allows considerable synthetic flexibility, which might be used to further improve the behavior of these compounds.

ACKNOWLEDGMENT

We are grateful for support of this research through a fellowship from the U.S. Army Breast Cancer Research Program (DAMD17-97-1-7292 to R.R.C.), a National Cancer Institute traineeship (PHS 5 T32 CA09067 to R.R.C.), and research grants from the Department of Energy (DE FG02 86ER60401 to J.A.K. and DE FG02 84ER60218 to R.M.B.) and Department of Veterans Affairs (Merit Review to R.B.I.). NMR spectra were obtained in the Varian Oxford Instrument Center for Excellence in NMR Laboratory. Funding for this instrumentation was provided in part from the W. M. Keck Foundation, the National Institutes of Health (PHS 1 S10 RR104444-01), and the National Science Foundation (NSF CHE 96-10502). Mass spectra were obtained on instruments supported by grants from the National Institute of General Medical Sciences (GM 27029), the National Institutes of Health (RR 01575), and the National Science Foundation (PCM 8121494).

An Anti-CD33 Antibody–Calicheamicin Conjugate for Treatment of Acute Myeloid Leukemia. Choice of Linker

Philip R. Hamann,*,† Lois M. Hinman,† Carl F. Beyer,† Delores Lindh,† Janis Upeslacis,† David A. Flowers,‡ and Irwin Bernstein‡

Wyeth-Ayerst Research, 401 North Middletown Road, Pearl River, New York 10965 and Fred Hutchinson Cancer Research Center, 1124 Columbia Street, Seattle, Washington 98109. Received February 19, 2001; Revised Manuscript Received October 15, 2001

The anti-CD33 antibody, P67.6, has been chosen to target the potently cytotoxic calicheamicin antitumor antibiotics to acute myeloid leukemia (AML) due to the presence of CD33 on >80% of patient samples and its lack of expression outside the myeloid cell lineages, especially its lack of expression on pluripotent stem cells. Previous calicheamicin conjugates relied on the attachment of a hydrazide derivative to the oxidized carbohydrates that occur naturally on antibodies. This results in a "carbohydrate conjugate" capable of releasing active drug by hydrolysis of a hydrazone bond in the lysozomes where the pH is low. Conjugates have now been made that are formed by reacting a calicheamicin derivative containing an activated ester with the lysines of antibodies. This results in an "amide conjugate" that is stable to hydrolysis, leaving the disulfide that is present in all calicheamicin conjugates as the likely site of drug release from the conjugate. In this article, these two classes of calicheamicin–antibody conjugates are compared for potential use in AML with the anti-CD33 antibody P67.6. Conjugates of P67.6 are shown to require the site of hydrolytic release afforded by the carbohydrate conjugates in order to retain good potency and selectivity in vitro, in vivo, and ex vivo. The P67.6 carbohydrate conjugate of calicheamicin is selectively cytotoxic at <0.006 ng/mL of calicheamicin equivalents (cal equiv) toward HL-60 promyelocytic leukemia cells in tissue culture. Long-term, tumor-free survivors are seen in xenograft models when mice bearing HL-60 subcutaneous tumors are treated with the P67.6 carbohydrate conjugate at a dose of 300 μg/kg cal equiv given three times. This conjugate also selectively inhibits the formation of colonies from AML marrow samples at 2 ng/mL cal equiv. The P67.6 carbohydrate conjugate of calicheamicin therefore appears to have promise as an antibody-targeted chemotherapeutic agent for CD33-positive diseases such as AML.

INTRODUCTION

The calicheamicins are highly potent antitumor antibiotics of the enediyne family. Originally isolated from a broth extract of the soil microorganism *M. echinospora* ssp. *calichensis*, the calicheamicins were detected in a screen for potent DNA damaging agents (*1*). The parent of this family of xenobiotics, calicheamicin γ_1^I (**1**, Figure 1), has been shown to associate with the minor groove of DNA and, following reduction with glutathione (*2*), to cause sequence-specific, double-stranded DNA cleavage (*3*, *4*). Due to their unique mode of action and potency, several analogues of the calicheamicins have been tested in preclinical models as potential antitumor agents. Their development as single agent therapies has not been pursued because of delayed toxicities that limit the therapeutic dose range for treatment. However, their potency makes them ideal for antibody-targeted chemotherapy, where limits in antigen expression make the potency of the cytotoxic agent crucial (*5*, *6*).

A series of conjugates of the calicheamicins and the CTM01 anti-MUC1 antibody has previously been reported (*7*, *8*). Initial examination of the structural requirement for the calicheamicin portion of the conjugate led to the selection of the "carbohydrate conjugate" (**4**) which contains NAc-gamma calicheamicin[1] as the calicheamicin core, a disulfide stabilized by two adjacent methyl groups, and a hydrazone linkage to the oxidized carbohydrates of the antibody as a site of hydrolytic release. It is unknown why the N-acylated calicheamicin derivatives make better conjugates, but the stabilized disulfide is likely to prevent the premature release of calicheamicin from a conjugate by circulating reduced thiols, such as glutathione. Further work showed that the inclusion of the hydrazone was not necessary for this anti-MUC1 antibody, and that the "amide conjugate" (**7**) that lacks this site of hydrolysis was equivalent or superior in all preclinical models examined, especially against resistant cell lines.[2] This article describes an extension of this work to an anti-CD33 antibody.

P67.6 is a murine IgG_1 antibody that targets CD33-positive cells of the myeloid lineage. In the hematopoietic cascade, expression of cell surface markers changes as a function of differentiation. The earliest cells which are capable of self-renewal and differentiation are the PSCs. PSCs are CD33-negative and, as they mature, they undergo extensive changes (*9*). Through one branch of hematopoiesis, PSCs differentiate into CD33-positive myeloid stem cells. AML is a disorder that is believed to result predominantly from a malignant transformation of CD33-positive myeloid stem cells, but not from PSCs. Greater than 80% of AML patients show expression of the CD33 antigen (a 67 kD cell surface glycoprotein) on the leukemic cell population (*10*).

Clinical studies with ^{125}I-labeled P67.6 demonstrate that this antibody has high selectivity for tumor targets, and that it is rapidly and efficiently internalized into antigen positive cells (*11, 12*). Internalization is widely held to be important for good activity for antibody-targeted chemotherapy. On the basis of our previous experience with the targeted delivery of the calicheamicins, P67.6 should be an excellent candidate for targeted chemotherapy for the treatment of AML by rapidly and effectively delivering the calicheamicin into CD33-positive cells. Any nonleukemic CD33-positive myeloid cells, which might also be destroyed during the course of therapy, can be regenerated by differentiation of the nonmalignant, CD33-negative PSCs (*13*).

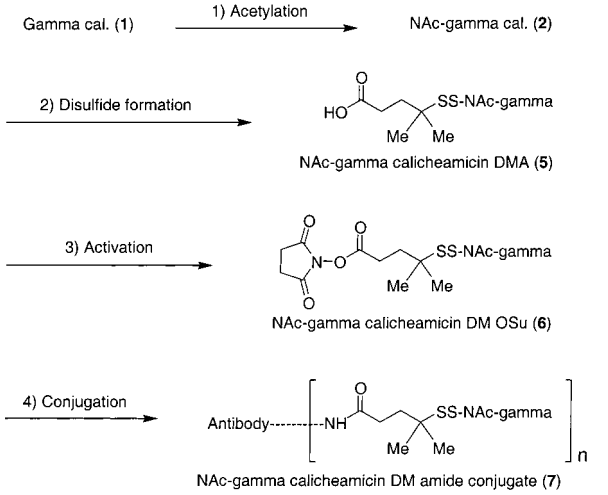

Figure 2. Synthetic scheme for preparation of amide conjugates.

This article summarizes the biological activities of two classes of calicheamicin conjugates made with the P67.6 antibody, a carbohydrate conjugate that contains a site of hydrolytic release and an amide conjugate that does not. It is clear from the results, which contrast with that of the CTM01 antibody, that the disulfide present in all calicheamicin conjugates is insufficient for efficient release of the calicheamicin from P67.6 and that the site of hydrolytic release offered by the hydrazone is essential for activity. With such a site of release, the carbohydrate conjugate is an exciting potential treatment for AML.

EXPERIMENTAL PROCEDURES

Monoclonal Antibodies. Antibodies were prepared by Celltech Therapeutics, Ltd., Slough, UK (now Celltech Chiroscience, plc). P67.6 was purified from tissue culture supernatants. MOPC-21, a murine plasmacytoma antibody (*14*) that does not bind to human tumor cells, was used as a negative control. P67.6 was radiolabeled with [^{125}I]diiodinated Bolton-Hunter reagent purchased from New England Nuclear as previously published (*7*).

Calicheamicin Derivatives. The synthesis of NAc-gamma calicheamicin DMH (**3**, Figure 1) has been previously reported (*7*). The synthesis of NAc-gamma calicheamicin DMA, *N*-hydroxysuccinimide ester (**6**) is as follows. (See Figure 2.)

The required linker, 4-mercapto-4-methylpentanoic acid (**8**), was made by routine synthetic procedures as follows. Reaction of epoxymethylpropane with potassium thiocyanate was followed by distillation of the organic layer to give 2,2-dimethylthiirane. Reaction of the thiirane with the sodium anion of ethyl cyanoacetate in ethanol was followed by filtration, concentration, precipitation with water, and drying in vacuo to give 2-imino-5,5-dimethyl-tetrahydro-thiophene-3-carboxylic acid ethyl ester. This compound was hydrolyzed under reflux with sodium hydroxide followed by acidification with HCl, extraction with methylene chloride, and evaporation to an oil which was heated at 165 °C followed by distillation to give 5,5-dimethyl-dihydro-thiophen-2-one. Hydrolysis of this compound followed by carefully acidifying with HCl, extracting with methylene chloride, and concentrating gave 4-mercapto-4-methylpentanoic acid (**8**) as an oil. This compound was characterized by mass spectroscopy, ^{1}H NMR, ^{13}C NMR, and elemental analysis.

To NAc-gamma calicheamicin (**2**) at a concentration of 2 mg/mL in acetonitrile at −15 °C was added 5 mol equiv

of 4-mercapto-4-methylpentanoic acid (**8**) and 6 mol equiv of triethylamine. After 24 h at −15 °C, the volatile organic solvents were evaporated at reduced pressure, and the crude product was chromatographed on Bio-Sil A using a gradient of 0 to 5% methanol in chloroform. Pure fractions, as assessed by TLC, were pooled, evaporated to a glass, dissolved in chloroform, and added to rapidly stirring hexane to produce a flocculent solid. Filtration and drying in vacuo gave the 4-mercapto-4-methylpentanoic acid disulfide derivative of *N*-acetyl γ_1^I calicheamicin (NAc-gamma calicheamicin DMA, **5**) as an amorphous, white powder.

To NAc-gamma calicheamicin DMA (**5**) at a concentration of 5 mg/mL in acetonitrile at ambient temperature was added 3 mol equiv of N-hydroxysuccinimide and 5 mol equiv of 1-(3-(dimethylamino)propyl)-3-ethylcarbodiimide hydrochloride (EDCI). After 3 h the volatile organic solvents were evaporated at reduced pressure and the crude product was chromatographed on Bio-Sil A using a gradient of 0 to 5% methanol in chloroform. Pure fractions, as assessed by TLC, were pooled, evaporated to a glass, dissolved in chloroform, and added to rapidly stirring hexane to produce a flocculent solid. Filtration and drying in vacuo gave NAc-gamma calicheamicin DMA, *N*-hydroxysuccinimide ester (**6**) as an amorphous, white powder.

These calicheamicin derivatives were well characterized by mass spectroscopy, ^{1}H NMR, ^{13}C NMR, elemental analysis, and IR and UV spectroscopy.

Antibody Conjugates. The synthesis of the carbohydrate conjugates (**4**) of NAc-gamma calicheamicin DMH have been reported previously (*7*). Drug loadings of 2 to 3 mol of calicheamicin per mole of antibody were seen, and free calicheamicin (structure **3**) was normally 1−3%.

Conjugates of NAc-gamma calicheamicin DMA, *N*-hydroxysuccinimide ester (amide conjugates, **7**) were prepared as follows. Four to six molar equivalents of NAc-gamma calicheamicin DMA, *N*-hydroxysuccinimide ester (**6**) in DMF (final concentration of DMF, 15%) were added to the antibody of interest at a concentration of 2 to 5 mg/mL in 50 mM phosphate buffer, pH 7.4, with 100 mM NaCl. After gently shaking the reaction overnight, the solvent was exchanged on a Sephadex G-25 column to remove the small organic species, and the product was purified by size exclusion on S-200 gel using the above buffer system to remove aggregates. Pooled monomer was concentrated by ultrafiltration, and the resultant amide conjugate (**7**) showed 1−3% aggregate by size exclusion HPLC (Zorbax GF-250, 0.2 M phosphate, pH 7.0) and no significant free drug (<0.5%) by reversed-phase HPLC. Drug and protein concentrations were determined spectroscopically using the extinction coefficients of the calicheamicin at 333 nm and the antibody at 280 nm as well as a correction factor for the absorbance of calicheamicin at 280 nm (mg/mL cal equiv = A_{333}/2.85, mg/mL protein = ($A_{280} - 3 \times A_{333}$)/1.43) cal equiv (calicheamicin equivalents) are in terms of either NAc-gamma calicheamicin DMA or DMH, which have the same molecular weight. Typically, recovery of antibody in the final product was 80%, drug loadings were 2 to 3 mol of calicheamicin per mole of antibody, and free calicheamicin (Structure **5**) was 0.5−1%.

Relative Immunoaffinity Assay. Relative immunoaffinities of P67.6 conjugates were determined in a competitive binding assay in which varying concentrations of test conjugate were allowed to compete with a fixed amount of [^{125}I]-P67.6 for binding to a fixed number of viable cells. The concentration of test conjugate required to obtain 50% inhibition of binding of the labeled antibody was compared with the concentration of a reference preparation of native hP67.6 required for 50% inhibition.

HEL 92.1.7 cells were collected by centrifugation, counted, resuspended in fresh medium at 10^7 cells per mL, and chilled on ice. Samples for assay were adjusted to 200 mg protein/mL in medium, and six serial 4-fold dilutions of each were prepared, for a total of seven concentrations of each sample. The reference hP67.6 was diluted in the same way: 0.05 mL of each dilution was transferred to a 12 × 75 mm plastic tube, and 0.05 mL of [^{125}I]-P67.6 was added. The tubes were mixed and incubated at 4 °C. Then 0.1 mL of chilled cell suspension was added to each tube, and all tubes were mixed again and incubated for 1 h at 4 °C. The final concentration of [^{125}I]-P67.6 was 1 μg/mL.

Controls to determine maximal binding and nonspecific binding were included in each assay. Maximal binding was determined by mixing 0.05 mL of medium, 0.05 mL of [^{125}I]-P67.6, and 0.1 mL of cells; nonspecific binding was determined by mixing 0.05 mL of 500 μg/mL of P67.6, 0.05 mL of [^{125}I]-P67.6, and 0.1 mL of cells.

At the end of the incubation, cells were washed twice with 3 mL of cold PBS by centrifugation and resuspension. The cells were resuspended in 0.5 mL of PBS and transferred to clean tubes, and radioactivity was determined in a γ-counter. The percent inhibition of binding was calculated, and the concentration required to inhibit 50% of binding was determined from a plot of inhibition versus binding.

Cells and Culture Methods. HL-60 human promyelocytic leukemia (CCL 240), Raji human Burkitt lymphoma (CCL 86), and HEL 92.1.7 human erythroleukemia (TIB 180) were obtained from the American Type Culture Collection. The standard methods used for cell culture have been described previously (*1*), except that 10% fetal calf serum was used for HL-60 cells.

In Vitro Testing. Concentrations of the test substances were all normalized to equivalents of calicheamicin (NAc-gamma DMH or NAc-gamma DMA, which have the same molecular weight), and a medium control was included. Triplicate 0.1 mL aliquots of cell suspension were added to microtiter wells already containing 0.1 mL aliquots of sample. The cells were incubated for 3 days, at which time 0.1 mL of supernatant was removed and replaced with 0.2 uCi of [^{3}H]thymidine in 0.1 mL of fresh medium. Incubation was resumed for an additional 24 h at which point the cells were harvested and counted. Growth inhibition curves of each drug or conjugate were plotted and the IC_{50} value (concentration of drug equivalents needed for 50% [^{3}H] thymidine uptake inhibition) of each sample was determined.

In Vivo Testing. The HL-60 human xenograft tumor was developed from the line received from the American Tissue Culture Collection and was passaged as an ascites in athymic mice. The ascites were harvested from donor mice, and 8×10^6 cells were routinely implanted subcutaneously into other athymic mice. Tumors were staged to a size of about 150 mg prior to drug treatment, and test samples were injected intraperitoneally, usually as three doses, 4 days apart (QD 4 × 3). Treatment started the day after tumor staging, which was usually 6 days after implantation. Control animals were injected with saline. There were usually 10 animals in a control group and five in each test group. Tumor mass was determined by measuring the tumor diameter once weekly for at least 28 days after the start of treatment.

Ex Vivo Testing. Samples of marrow from pediatric patients enrolled on CCSG protocol 213 were collected

in preservative-free heparin and sent to Seattle at initial diagnosis. These specimens were separated by Ficoll-Hypaque density centrifugation (specific gravity 1.077 g/mL) (Pharmacia, Inc., Piscataway, NJ). The mononuclear cells were pelleted and suspended in 10% dimethyl sulfoxide (Sigma, St. Louis, MO) and 90% newborn calf serum (Hyclone Laboratories, Loan, UT), at a concentration of 10^7 cells/mL and aliquoted in 1 mL volumes in cryovials (Nalge Co., Rochester, NY). Cells were then allowed to freeze overnight in a −80 °C mechanical freezer after which they were transferred to either a liquid nitrogen freezer or a −135 °C mechanical freezer. Samples previously found to grow colonies in the colony-forming assay were used for testing.

Cells were thawed in a 37 °C water bath and transferred to 10 mL of RPMI containing 10% fetal bovine serum and 100 U/mL deoxyribonuclease 1 Type II (Sigma). Cells were then washed twice in RPMI/10% FBS, counted, and suspended to a concentration of 10^6 viable cells/mL in RPMI containing 2% FBS. Cells were then incubated at 37 °C in the dark for 2 h in the presence of a CD33-antibody conjugate or, as a nonbinding control, a MOPC-21 antibody conjugate. After incubation, cells were washed three times in RPMI/2% FBS and suspended in 300 μL of human placental conditioned medium. Cells were then placed in triplicate 35-mm culture dishes (Nunc, Naperville, IL) containing 900 μL of Iscove's Modified Dulbecco's Medium, 0.9% methylcellulose (Stem Cell Technologies Inc., Vancouver, BC, Canada), supplemented with 20% FBS, 1% bovine serum albumin (Intergen Co., Purchase, NY), 1×10^{-4} mol/mL 2-mercaptoethanol (Sigma, St. Louis, MO), and 10% human placental conditioned medium, IL-3 (100 ng/mL) and erythropoietin (epo, 2 U/mL, Amgen, Thousand Oaks, CA). Cells were cultured at a concentration of 50000 cells per dish at 37 °C in a 5% CO_2 in air-humidified atmosphere. Colonies were counted after 10−12 days of incubation.

RESULTS

Carbohydrate and Amide Conjugates of P67.6. P67.6 was conjugated to calicheamicin by two methods. One method involved oxidizing the naturally occurring carbohydrates of the antibody (*15*) and reacting the resultant aldehydes with a calicheamicin derivative referred to as NAc-gamma calicheamicin DMH (**3**) (see Figure 1 for structures). This method produces a "carbohydrate conjugate" that has a hydrazone bond that is hydrolytically labile, especially at the low pH found in lysosomes (*16*, *17*). The second method (Figure 2) involves reacting the ϵ-amino groups of lysines on the antibody with a calicheamicin derivative referred to as NAc-gamma calicheamicin DMA, OSu ester (**6**). This method produces an "amide conjugate" which does not have a bond that is hydrolytically labile under physiological conditions. Both of these conjugates contain a disulfide bond that can react with glutathione to release an active calicheamicin derivative from the antibody and must be fully reduced by glutathione in the course of the cytotoxic mechanism of the calicheamicins (*2*). Both of these conjugates also contain a disulfide stabilized by two methyl groups and an aminosugar that is acetylated, as was shown to be optimum for calicheamicin conjugates (*7*).

Comparative in Vitro Activity. The in vitro cytotoxic activities of these conjugates are shown in Table 1. Both conjugates and various reference samples were incubated with CD33-positive HL-60 cells and CD33-negative Raji cells, and the IC_{50} values are given in cal equiv. The P67.6 carbohydrate conjugate was more than 7000-fold more potent than the P67.6 amide conjugate toward the antigen-positive cells. The specificity index of the P67.6 carbohydrate conjugate was greater that 100-fold, while the P67.6 amide conjugate showed modest specificity for antigen-positive cells. Both types of conjugates retained good immunoaffinities. Also presented in Table 1 are results for several controls, which showed that P67.6 alone was not toxic to either cell type, that the admixture of P67.6 and NAc-gamma calicheamicin DMH was not different than NAc-gamma calicheamicin DMH (**3**) alone, and that the calicheamicin derivatives were less potent than the carbohydrate conjugate toward the HL-60 target cells.

Table 1. Comparison of the in Vitro Cytotoxicity of Carbohydrate and Amide Conjugates of P67.6

sample	rel affinity[a]	IC_{50} (ng/mL)[b] HL-60	Raji	Raji/ HL-60[c]
P67.6 carbohydrate conjugate (**4**)	0.87	<0.006	0.79	>132
P67.6 amide conjugate (**7**)	0.79	44.1	353	8
NAc-γ DMH (**3**) + P67.6	0.88	0.74	1.07	1.4

[c] Ratio of the two IC50's. [d] Concentration of antibody alone equivalent to that of either conjugate at the dose of cal equiv given in table. Actual concentration of antibody 4 μg/mL.

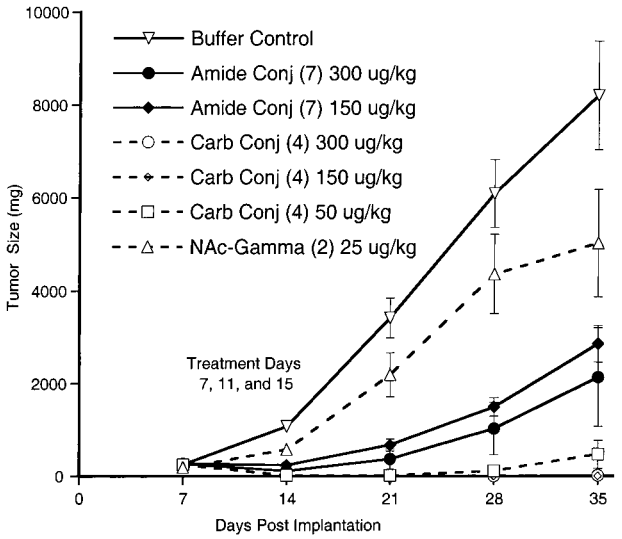

Figure 3. Time-course of the response of HL-60 xenograft tumors to amide and carbohydrate conjugates of P67.6. The doses are given in cal equiv. The corresponding amount of antibody is 40-fold greater. This experiment is representative of the general results seen with these conjugates.

Comparative in Vivo Activity. Carbohydrate and amide conjugates of P67.6 were further compared in vivo for antitumor effects against HL-60 tumor xenografts implanted subcutaneously in nude mice. The results of one such test are presented in Figure 3. The two conjugates and NAc-gamma calicheamicin (**2**) were administered three times at the doses indicated spaced by 4 days starting on day seven post tumor implantation. In this test, no deaths were noted in the conjugate-treated groups during the 42-day duration of the study, while in the group treated with NAc-gamma calicheamicin (**2**), one

sample	no. of patients	no. with specific inhibition 25−59%	60−89%	≥90%
P67.6 amide conjugate (**7**)	12	4	2	0
P67.6 carbohydrate conjugate (**4**)	12	1	4	4

of five animals had died at the 75 μg/kg dose and all were dead at the 150 μg/kg dose (data not shown). This experiment showed that the P67.6 carbohydrate conjugate was significantly more active than the P67.6 amide conjugate at all three doses tested. The P67.6 carbohydrate conjugate produced nine tumor-free survivors out of 10 treated animals in the 300 and 150 μg/kg × 3 treatment groups, whereas no tumor-free animals were seen with the P67.6 amide conjugate at any dose.

Comparative ex Vivo Activity. Testing of the P67.6 amide and carbohydrate conjugates was carried out on pediatric AML patient samples. In one experiment, eight pediatric AML samples were tested with these two conjugates as well as control conjugates made with the nonbinding antibody CTM01 and also appropriate unconjugated drug controls. The data, shown in Table 2, indicate that at 2 ng/mL cal equiv only the targeting antibody conjugate made with a hydrolyzable linker is capable of inhibiting colony formation in the majority of samples, as indicated by the averages. Although there were individual patient samples that were inhibited by the amide conjugate, the average of all eight patients showed no statistical difference from media alone. In a total of three experiments, run with various combinations of the available samples, 12 different pediatric AML samples were tested with both the P67.6 amide and carbohydrate conjugates. The results, summarized in Table 3, show that at 2 ng/mL cal equiv there was some growth inhibition of AML colony-forming cells using the amide conjugate, while substantially more growth inhibition was seen using the carbohydrate conjugate.

DISCUSSION

Antibody-targeted chemotherapy has been studied for many years by numerous academic and pharmaceutical research groups. Aside from the requirement for an antibody that targets a pertinent, internalizing antigen, there appears to be two major criteria that need to be satisfied for activity. The first of these is that the antigen must be capable of carrying enough of the drug into the cell to deliver a toxic dose. Three factors come into play here: the antigenic density and turnover rate, the molar loading of drug on the antibody, and the inherent potency of the drug. The antigenic density and turnover rate is difficult to alter in patients, while the drug loading is difficult to increase significantly beyond a certain level. The potency of the drug, however, can vary by many orders of magnitude, depending on the choice an investigator makes (*5*, *18*). The calicheamicins are one of the most potent classes of natural products, and this allows calicheamicin conjugates to target a relatively broad range of antigens, including those with relatively low expression, such as CD33 (*19*).

The second requirement for antibody-targeted chemotherapy is that a mechanism must be incorporated into the conjugate design to allow for drug release after internalization into the target cells. Two of the most common sites of drug release are disulfide linkages and hydrazones. The former allows for reductive release of the drug, presumably through interaction with glutathione, while the latter allows for hydrolytic release in the acidic lysozomes where many antibody/antigen complexes end up after internalization.

Conjugates of calicheamicin, by the nature of their structure and mechanism of DNA damage, always have a disulfide present that can serve as a site of release of the calicheamicin from the antibody. Indeed, increasing the stability of this disulfide leads to a marked improvement in the therapeutic index of the conjugates (*8*). However, the desire to have site-selective conjugation led to the initial use of the procedure developed by Cytogen that involves the oxidation of the naturally occurring carbohydrates in the hinge region of the antibody and reacting the resultant aldehydes with nucleophiles, usually hydrazides. The carbohydrate conjugates that are formed are capable of releasing active drug by hydrolysis in the lysozomes where the pH is low (*16*, *17*).

A new class of calicheamicin conjugate has now been made that is based on the reaction of an activated ester derivative with the lysines on the antibody. The resultant amide conjugate does not contain a hydrazone bond and is therefore stable to hydrolysis under physiological conditions, but still contains a disulfide bond. These conjugates can therefore be used to answer a basic question about the requirements for efficient release of a cytotoxic agent such as the calicheamicins from various antibodies. The results in this article show that for the anti-CD33 antibody P67.6, the amide conjugates do not exhibit potent, selective cytotoxicity while the carbohydrate conjugates do. Thus, the disulfide bond does not appear to be an efficient site of release with this antibody.

Although carbohydrate conjugates were initially made with calicheamicin because the use of the carbohydrates precludes reactions near the antigen-binding site, the amide conjugate of P67.6 retains virtually all of its binding affinity when an amide conjugate is produced. Indeed, only one out of almost two dozen antibodies has lost any significant immunoaffinity when a calicheamicin amide conjugate was made (data not shown).

In vitro, the P67.6 amide conjugate is about 100-fold less potent than the calicheamicin reference drugs. This is indicative of unproductive metabolism due to insufficient release of an active calicheamicin derivative intracellularly. On the other hand, the P67.6 carbohydrate conjugate is at least 100-fold more cytotoxic than the calicheamicin reference compounds. This perhaps surprising result may be due to the efficient internalization, release, and utilization of the calicheamicin once carried into the cell by the antibody. The significant cytotoxicity of the P67.6 carbohydrate conjugate against the CD33-negative Raji cells during long-term exposure is presumed to be due to the result of the slow extracellular release and subsequent uptake of the NAc-gamma calicheamicin DMH (**6**) from the conjugate.

In vivo, the P67.6 amide conjugate does show significant inhibition of tumor growth of the HL-60 tumor in nude mice but was incapable of producing any long-term, tumor-free survivors, even at the highest doses tested.

In contrast, the P67.6 carbohydrate conjugate was capable of eradicating the tumors routinely at the two highest doses tested. Similar conjugates of other antibodies which do not bind to HL-60 cells show no significant effects on HL-60 xenografts, and conjugates of P67.6 do not show significant effect on xenograft tumors that do not express the CD33 antigen (data not shown). The unconjugated calicheamicin derivatives that have been tested as controls in this and similar experiments show at best modest antitumor effects at the MTD.

Ex vivo experiments were done to examine the response of a number of AML biopsies, thereby giving reassurance that the results with the HL-60 cells were not dependent on some unusual property of that cell line. A comparison of the activity of the two P67.6 conjugates in the ex vivo experiments clearly shows that the carbohydrate conjugate is superior and is capable of inhibiting colony formation in a significant percentage of patient samples. It should be noted that 100% inhibition is not necessarily desirable in this assay, as the formation of normal colonies from CD33-negative precursors is possible. The absolute predictive value of this assay is questionable, because only about 25% of AML patient samples grow colonies under these conditions. However, the results clearly show a difference for the two classes of conjugate and also indicate the possibility of selective cytotoxicity toward leukemic cells in at least a subset of patients.

The consistent results from these three test systems, in vitro, in vivo, and ex vivo, clearly show the need for a site of hydrolytic release in the linker between the calicheamicin and the P67.6 antibody even though a disulfide is present. Preliminary experiments indicated that reduction of the hydrazone bond in the carbohydrate conjugate of P67.6 with cyanoborohydride led to a conjugate that resembled the amide conjugate in its properties (data not shown). This would tend to preclude any special effect of attaching the calicheamicin to a carbohydrate reside being responsible for the observed activity.

It is unclear at this point why a site of hydrolytic release is necessary. HL-60 cells are relatively small and rich in lysozomes. Processed fragments of antibody appear in the cell supernatant quickly after treatment with radiolabeled antibody (*20*). Perhaps the calicheamicin is externalized with such fragments when only the disulfide bond is available for calicheamicin release, but when a hydrazone bond is present, the calicheamicin is released from the antibody before these fragments leave the cell. This is consistent with the known internalization of P67.6 into lysozomes (*20*) and the acid nature of this subcellular compartment (*16*, *17*). Initial experiments with tritium-labeled calicheamicin derivatives to explore this issue have been unsuccessful because of the unavailability of tritiated reagents with high enough specific activity to follow the low levels of the very potent calicheamicin derivatives in cells. It should be noted that although both disulfides and hydrazones are viewed as acceptable sites for cleaving chemoimmunoconjugates to release an active drug, there is no prior publication that examines the comparison of a drug conjugate made with a disulfide with that made with a hydrazone.

For calicheamicin conjugates the results with P67.6 have been shown not to be general. Indeed, for the anti-MUC1 antibody, CTM01 (*21*), a hydrolyzable bond had no benefit, and the amide conjugate was equivalent or superior in all preclinical models that were examined, especially against resistant cell lines.[2,3] The combined results for these two antibodies indicate that one optimal design of conjugate does not exist for all antibodies. Each antibody must be examined separately, and a variety of different types of conjugates must be tried in order to individually optimize a specific delivery system. The contrasting results obtained with the anti-P67.6 and anti-MUC1 antibody conjugates probably depend more on the physiology of the target cells and the antigen that is targeted than on any specific properties of the antibodies or cytotoxic agent.

In conclusion, a calicheamicin conjugate of the anti-CD33 antibody is a potent and selective agent targeted toward CD33-positive cells in cell culture, in xenograft experiments, and in ex vivo models of AML, as long as a site of hydrolytic release is present. Thus, the P67.6 carbohydrate conjugate of calicheamicin was envisioned to be an effective new agent for the treatment of AML and other CD33-positive diseases. The P67.6 antibody has been humanized and, as the result of an unexpected problem, the carbohydrate conjugate has been abandoned and replaced by a conjugate containing a bifunctional linker that attaches to lysines on the antibody, but that allows for formation of the hydrazone that is needed for activity (*22*). This improved conjugate, referred to as CMA-676 and assigned the generic name of gemtuzumab ozogamicin, has successfully completed initial clinical trials (*23*, *24*) and has been approved under the name Mylotarg by the FDA as the first antibody-targeted chemotherapeutic agent.

ACKNOWLEDGMENT

We would like to thank Irwin Hollander for helpful discussion, technical help, and editorial assistance, George Ellestad for helpful scientific discussions, and Martha Godwin and J. Philip James for technical support.

CD33 is expressed by acute myeloid leukemia (AML) cells in >80% of patients but not by normal hematopoietic stem cells, suggesting that elimination of $CD33^+$ cells may be therapeutically beneficial. A conjugate of a calicheamicin hydrazide derivative attached via hydrazone formation to the oxidized carbohydrates of the anti-CD33 murine antibody P67.6 had been chosen for use in AML prior to humanization of this antibody. However, the CDR-grafted humanized P67.6 could not be used to make the carbohydrate conjugate because of the unexpected sensitivity of this antibody to periodate oxidation. Exploration of a series of bifunctional linkers resulted in a new class of calicheamicin conjugates, termed the hybrid conjugates, that allows for the attachment of the calicheamicin to lysines but incorporates the site of hydrolytic release, a hydrazone, previously shown to be required for activity. The optimized conjugate chosen for clinical trials, gemtuzumab ozogamicin ("gem-ozo", Mylotarg, formerly designated CMA-676), was significantly more potent and selective than the carbohydrate conjugate it replaced. It was selectively cytotoxic to HL-60 leukemia cells in tissue culture with an IC_{50} in the low to sub-pg cal/mL range (cal = calicheamicin equivalents). Doses of gem-ozo as low as 50 μg cal/kg given three times to mice bearing HL-60 xenografts routinely resulted in long-term, tumor-free survivors, while a nonbinding control conjugate was relatively inactive. Gem-ozo at a concentration of 2 to 10 ng cal/mL selectively inhibited leukemia colony formation by marrow cells from a significant proportion of AML patients. Gem-ozo has also shown significant activity against AML in Phase II trials and is the first antibody-targeted chemotherapeutic agent approved by the FDA.

INTRODUCTION

In the 25 years since the development of methods for preparing monoclonal antibodies, there have been numerous attempts to use these proteins as effective vehicles for targeting cytotoxic agents to human cancers. Although there are now several antibodies approved for treatment and various radioimmunoconjugates appear to be progressing toward eventual approval, conjugates of cytotoxic agents such as phytotoxins and traditional chemotherapeutic agents have met with little or no general success due to a variety of problems (*1*). What may be required are agents that are less immunogenic than toxins, such as ricin, yet more potently cytotoxic than traditional anticancer drugs. Potential agents would include antitumor antibiotics such as the potently cytotoxic calicheamicins. These potently cytotoxic natural products are members of the enediyne family of antitumor antibiotics that, even at sub-picomolar concentrations, produce double-stranded DNA cleavage (*2*, *3*). They may offer significant advantages over previous antibody-targeted agents, because they are roughly 1000-fold more cytotoxic than clinically used anticancer agents but have much lower immunogenicity than ricin. Conjugates of other potent cytotoxic agents have been published (*4*, *5*), but no direct comparison with calicheamicin conjugates is possible due to differences in the antibodies and testing systems.

AML[1] is a malignancy that affects 2.4/100000 people each year in the US and, although the majority of patients show a response to initial chemotherapy, less than 30% of patients survive for 3 years. The targeted CD33 antigen of this report is a 67 kD cell surface glycoprotein that is expressed by leukemia cells from >80% of AML patients (*6*). Although CD33 is expressed on normal progenitor and mature myeloid cells, it is not expressed on immature pluripotent stem cells that account for in vivo transplantation of hematopoietic function (*7*−*10*). CD33 was also selected because it is internalized (*11*), a property widely accepted to be crucial for successful antibody-target chemotherapy.

Evidence suggests that in some leukemias, $CD33^-$ precursors are essentially normal in origin since they establish nonclonal hematopoiesis in long-term marrow

cultures (*12, 13*). Thus, any nonleukemic $CD33^+$ myeloid cells killed during therapy would be regenerated from differentiating nonmalignant $CD33^-$ stem cells. However, one study appeared to show that primitive hematopoietic precursors isolated from AML specimens engrafted leukemic hematopoiesis in immunodeficient mice (*14*). This observation has been taken to suggest that the predominant cells of malignant origin in this case were $CD33^-$. This discrepancy might ultimately be clarified by clinical trials of an anti-CD33 immunoconjugate.

Studies of a radiolabeled anti-CD33 antibody have demonstrated rapid binding and efficient internalization by $CD33^+$ cells in spleen, marrow, and blood, suggesting that a toxic agent could be efficiently delivered to target cells (*15, 16*). However, the level of CD33 expressed on leukemia cells appears to be relatively low, which limits the amount of a cytotoxic agent that can be delivered by a conjugate. For example, in HL-60 promyelocytic leukemia cells, CD33 expression was estimated at 10^4 copies per cell (*17, 18*). It is therefore crucial that a potent cytotoxic agent, such as the calicheamicins, be used for conjugates that target this antigen (*19*).

The calicheamicins are highly potent antitumor antibiotics of the enediyne family. Originally isolated from a broth extract of the soil microorganism *Micromonospora echinospora*, ssp. *calichensis,* the calicheamicins were detected in a screen for potent DNA damaging agents (*20*). The parent of this family of xenobiotics, calicheamicin γ_1^I, has been shown to associate with the minor groove of DNA and, following reduction with glutathione (*21*), to cause sequence-specific DNA cleavage (*2, 3*). Due to their mode of action and potency, several analogues of the calicheamicins have been tested in preclinical models for their usefulness as antitumor agents. They have not been pursued as single agent therapies because of delayed toxicities in animal models that limit the therapeutic dose range for treatment and because of the ideal properties of the calicheamicins for targeted delivery.

Earlier work with calicheamicin conjugates of the murine, anti-CD33 antibody P67.6 showed that a site of hydrolytic release, as supplied by a hydrazone, was necessary for potent and selective cytotoxicity in tissue culture and for maximum efficacy in xenograft models of AML in athymic mice (*22*). A carbohydrate-based conjugate (Figure 1) was chosen that was made by oxidizing the naturally occurring carbohydrate-residues in P67.6 with periodate and reacting the resultant aldehydes with a hydrazide derivative of calicheamicin, NAc-gamma calicheamicin DMH (*23*). This conjugate showed potent, specific antitumor activity in models of AML. To minimize the potential for immune responses in human trials, the P67.6 antibody has been humanized by CDR-grafting with the intent of doing clinical trials with the hP67.6-NAc-gamma calicheamicin DMH conjugate. In this article is described the unexpected problem that arose in making this conjugate and the redesign of the conjugate that not only solved the problem but resulted in a more potent and selective agent. This conjugate, gemtuzumab ozogamicin (Mylotarg, formerly known as CMA-676), has now shown activity in clinical trials for AML (*24, 25*) and has been approved by the FDA for the treatment of relapsed AML.

EXPERIMENTAL PROCEDURES

Syntheses of the Bifunctional Hybrid Linkers. The following linkers were purchased: 4-formylbenzoic acid (Linker **b)** (Aldrich), 4′-formylphenoxyacetic acid (Linker **f)** (Fluka), and 4-(4′-acetylphenyl)butanoic acid (Linker **i)** (Salor). All other starting materials, solvents, and reagents were purchased from Aldrich and were used as received.

4-[4′-(4″-Fluorobenzoyl)phenoxy]butanoic Acid (Linker a). A solution of 3.98 g (18.4 mmol) of 4-fluoro-4′-hydroxybenzophenone and 5.37 g (27.6 mmol) of ethyl 4-bromobutyrate in 1 mL of anhydrous DMF was stirred for 48 h under an atmosphere of dry nitrogen with 7.64 g (55.2 mmol) of potassium carbonate and 0.31 g (1.84 mmol) of potassium iodide. The reaction mixture was then evaporated under vacuum, and the residue was partitioned between ether and water. The organic phase was separated, washed three times with water, dried with magnesium sulfate, filtered, and evaporated under vacuum. The crude yellow solid product was recrystallized from ether providing 2.97 g (49%) of 4-[4′-(4″-fluorobenzoyl)phenoxy]butanoic acid, ethyl ester as white crystals. Mp 57−59 °C; IR (KBr): 1735, 1645 cm^{-1}; FAB-MS: 311 ($M + H^+$). Anal. Calcd for $C_{19}H_{19}O_4F$: C, 69.08; H, 5.80; F, 5.75; O, 19.37. Found: C, 69.09; H, 5.62; F, 5.95; O, 19.34.

To a stirred solution of 0.48 g (1.45 mmol) of 4-[4′-(4″-fluorobenzoyl)phenoxy]butanoic acid, ethyl ester in 25 mL of methanol/water (3:2) was added 0.32 g (2.25 mmol) of potassium carbonate, and the reaction was stirred for 18 h under an argon atmosphere. Next, the reaction mixture was evaporated under vacuum and the residue dissolved in 20 mL of a 0.1 N solution of sodium hydroxide. This basic solution was washed with ether, the aqueous phase acidified by addition of sodium bisulfate, and the resulting mixture extracted with ethyl acetate. This solution was then dried with magnesium sulfate, filtered, and evaporated. The crude white solid was recrystallized from an ether−hexane mixture leaving 0.16 g (36%) of 4-[4′-(4″-fluorobenzoyl)phenoxy]butanoic acid as white crystals. Mp 109−111 °C; IR (KBr): 1735, 1700 1640 cm^{-1}; ^1H NMR ($CDCl_3$, 400 MHz): 10.5−9.65 (br s, 1H, COOH), 7.79 (m, 4H, C2″, C6″, C3′, and C5′), 7.15 (t, 2H, $J = 8.6$ Hz, C3″ and C4″), 6.95 (d, $J = 8.8$ Hz, 2H, C2′ and C6′), 4.12 (t, $J = 6.0$ Hz, 2H, C4), 2.62 (t, $J = 7.2$ Hz, 2H, C2), 2.17 (m, 2H, C3); FTMS: 301.08799 ($M - H^+$, theoretical 301.08816), Anal. Calcd for $C_{17}H_{15}O_4$ F: C, 67.54; H, 5.00; F, 6.28; O, 21.18. Found: C, 67.28; H, 4.89; F, 6.41; O, 21.42.

4-(4′-Formyl-2′-methoxyphenoxy)butanoic Acid (Linker c). 4-Hydroxy-3-methoxybenzyl alcohol (1 g, 6.49 mmol) was treated under dry nitrogen with 1.73 g (7.13

mmol) of ethyl 4-bromobutyrate, 2.69 g (19.5 mmol) of potassium carbonate, and a catalytic amount (97.2 mg, 0.65 mmol) of sodium iodide in 2 mL of anhydrous DMF for 48 h. The reaction mixture was then evaporated under vacuum, and the residue was partitioned between ether and water. The organic phase was separated, washed three times with water, dried with magnesium sulfate, filtered, and evaporated under vacuum to give 821 mg of 4-[4′-(hydroxymethyl)-2′-methoxyphenoxy]butanoic acid, ethyl ester as a light brown oil (47%). IR (neat): 3500, 1730, 1620, 1600 cm^{-1}; CI-MS: 269 ($M + H^+$), 251, 223, 195. This material was taken on to the following step without additional purification or further characterization.

4-[4′-(Hydroxymethyl)-2′-methoxyphenoxy]butanoic acid, ethyl ester (431 mg, 1.61 mmol) was dissolved in 100 mL of methylene chloride and stirred with 1.0 g (4.8 mmol) of pyridinium chlorochromate for 4 h before filtering through a Celite pad. The reaction mixture was then diluted with an equal volume of ether, precipitating out salts. This mixture was then filtered through a silica gel pad using ether, and the filtrate evaporated, giving 280 mg (65%) of 4-(4′-formyl-2′-methoxyphenoxy)butanoic, ethyl ester as a colorless oil. IR (neat): 1730, 1690, 1600, 1580 cm^{-1}. This material was taken on to the following step without additional purification or further characterization.

4-(4′-Formyl-2′-methoxyphenoxy)butanoic acid, ethyl ester (240 mg, 0.90 mmol) was dissolved in 3 mL of methanol/water (3:2) and treated with 435 mg (3.15 mmol) of potassium carbonate. The reaction was stirred for 18 h under an argon atmosphere. Next, the reaction mixture was evaporated under vacuum and the residue dissolved in 200 mL of a 0.1 N solution of sodium hydroxide. This basic solution was washed with ether, the aqueous phase acidified by addition of sodium bisulfate, and the resulting mixture was extracted with ethyl acetate. This solution was then dried with magnesium sulfate, filtered, and evaporated to give 125 mg (58%) of 4-(4′-formyl-2′-methoxyphenoxy)butanoic acid as a white powder. Mp 143−148 °C; ^1H NMR ($CDCl_3$, 400 MHz): 9.85 (s, 1H, CHO), 7.45−7.40 (m, 2H, C3′ and C4′), 6.98 (d, $J = 8.4$ Hz, 1H, C5′), 4.17 (t, $J = 6.2$ Hz, 2H, C4), 3.92 (s, 3H, OCH_3), 2.64 (t. $J = 7.1$ Hz, 2H, C2), 2.22 (m, 2H, C3); IR (KBr): 3575, 3500, 1720, 1700, 1680, 1600, 1585 cm^{-1}; FTMS: 239.09131 ($M + H^+$, theoretical 239.09140).

4-(2′-Oxoethoxy)benzenepropanoic Acid (Linker d). A mixture of 4′-hydroxybenzenepropanoic acid (500 mg, 3.01 mmol), 892 mg (7.52 mmol) of allyl bromide, and 1.28 g (10.8 mmol) of potassium carbonate in 4 mL of anhydrous DMF was stirred at room temperature for 12 h. This mixture was diluted with 20 mL of ether and washed five times with 20 mL of water. The organic layer was then washed successively with 20 mL of saturated sodium bicarbonate solution and 20 mL of saturated sodium chloride solution. The organic layer was separated, dried over magnesium sulfate, filtered, and concentrated under vacuum to give 610 mg (82%) of 2-propenyl-4-(2′-propenyloxy)benzenepropanoic ester as a colorless oil. IR (neat): 3450, 1740, 1650, 1610, 1510 cm^{-1}; CI-MS: 247 ($M + H^+$), 229, 215, 187, 175. This material was taken on to the following step without additional purification or further characterization.

A solution of 2-propenyl-4-(2′-propenyloxy)benzenepropanoic ester (271 mg, 1.1 mmol) in 9 mL of methanol/water (3:2) at room temperature was treated with 0.14 mL (1.4 mmol) of 10 M aqueous sodium hydroxide. The solution was allowed to stir for 1 h then acidified with 5 mL of 10% sodium bisulfate solution and extracted with 25 mL of ethyl acetate. The organic layer was washed with saturated sodium chloride solution, dried over magnesium sulfate, and concentrated under vacuum to give 196 mg (86%) of 4-(2′-propenyloxy)benzenepropanoic acid as a white powder. Mp 88−89 °C; IR (KBr): 3200, 1720, 1700, 1610 cm^{-1}; CI-MS: 207 ($M + H^+$), 189, 175, 147; Analysis calc′d for $C_{12}H_{14}O_3$: C, 69.89; H, 6.84; found: C, 69.87; H, 6.68. This material was taken on to the following step without additional purification or further characterization.

A solution of 4-(2′-propenyloxy)benzenepropanoic acid (120 mg, 0.58 mmol) in 5 mL of methylene chloride was cooled to −78 °C. Ozone was introduced by bubbling the gas into the solution through a glass tube until a blue color persisted. The solution was then purged with a stream of argon, and 1 mL of methyl sulfide was added. The solution was diluted with 20 mL of ether and washed with water. The organic layer was separated and allowed to stand over magnesium sulfate and then concentrated under vacuum to give 100 mg (82%) of 4-(2′-oxoethoxy)-benzenepropanoic acid as a white powder. Mp 95−100 °C; ^1H NMR ($CDCl_3$, 300 MHz): 9.86 (s, 1H, CHO), 7.15 (d, $J = 8.6$ Hz, 2H, C2′ and C6′), 6.83 (d, $J = 8.6$ Hz, 2H, C3′ and C5′), 4.55 (s, C1′), 2.91 (t, $J = 7.4$ Hz, 2H, C2), 2.65 (t, $J = 7.4$ Hz, C1); IR (KBr): 3400, 1740, 1720, 1610 cm^{-1}; FTMS: 207.06638 ($M - H^+$, theoretical 207.06628).

4-(4′-Formylphenoxy)butanoic Acid (Linker e). 4-Hydroxybenzyl alcohol (1 g, 8.06 mmol) was stirred with 1.73 g (8.86 mmol) of ethyl 4-bromobutyrate, 3.34 g (24.2 mmol) of potassium carbonate, and a catalytic amount (120 mg 0.81 mmol) of sodium iodide in 1.80 mL of anhydrous DMF for 48 h under an atmosphere of dry nitrogen. The reaction mixture was then evaporated under vacuum, and the residue was partitioned between ether and water. The organic phase was separated, washed three times with water, dried with magnesium sulfate, filtered, and evaporated under vacuum to give 1.73 g of 4-[4′-(hydroxymethyl)phenoxy]butanoic acid, ethyl ester as a light brown oil (90%). IR (neat): 3400, 1730, 1610, 1580, 1510 cm^{-1}; CI-MS: 238 (M^+), 221, 115. This material was taken on to the following step without additional purification or further characterization.

A mixture of 230 mg (0.97 mmol) of 4-[4′-(hydroxymethyl)phenoxy]butanoic acid, ethyl ester, 624.2 mg (2.9 mmol) of pyridinium chlorochromate, and 3 g of powdered 4 Å molecular sieve was stirred in 2 mL of methylene chloride at room temperature for 3 h. The mixture was diluted with 20 mL of ether, filtered, and concentrated under vacuum to give 175 mg (76%) of a light yellow oil. The oil (150 mg, 0.63 mmol) was dissolved in 2.3 mL of methanol/water (3:2) and treated with 307 mg (2.22 mmol) of potassium carbonate and stirred in 6 mL of methanol/water (3:2) at room temperature for 8 h. The solution was then concentrated under vacuum. The residue was dissolved in 10 mL of 0.1 N sodium hydroxide solution and washed with 20 mL of ether. The aqueous layer was separated and acidified with sodium bisulfate and extracted with ethyl acetate. The resulting organic layer was washed with saturated sodium chloride solution and then dried over magnesium sulfate. The mixture was then filtered and concentrated under vacuum to give 100 mg (75%) of 4-(4′-formylphenoxy)butanoic acid as a white powder. ^1H NMR ($CDCl_3$, 400 MHz): 9.89 (s, 1H, CHO), 7.83 (d, $J = 8.4$ Hz, 2H, C3′ and C5′), 7.00 (d, $J = 8.4$ Hz, 2H, C2′ and C6′), 4.13 (t, $J = 6.1$ Hz, 2H, C4), 2.61 (t, $J = 7.2$ Hz, 2H, C2), 2.17 (m, 2H, C3); IR (KBr): 3000, 1740, 1660 cm^{-1}; FTMS: 209.08080 ($M + H^+$, theoretical 209.08084).

4-[(2′-Acetyl-1′-naphthalenyl)oxy]butanoic Acid (Linker g). A 3.42 g (18.37 mmol) sample of 1-hydroxy-2-acetonaphthone and 5.0 g (50 mmol) of ethyl 4-bromobutyrate in 10 mL of anhydrous DMF was stirred for 48 h under an atmosphere of dry nitrogen with 13.7 g (100 mmol) of potassium carbonate and 0.5 g (3.3 mmol) of potassium iodide. The reaction mixture was then evaporated under vacuum, and the residue was partitioned between ether and water. The organic phase was separated, washed three times with water, dried with magnesium sulfate, filtered, and evaporated under vacuum. The crude product was dried under high vacuum at 60 °C to give 5.21 g (94%) of 4-[(2′-acetyl-1-naphthalenyl)oxy]butanoic acid, ethyl ester as a golden liquid. IR (neat): 1730, 1665 cm^{-1}; FAB-MS: 301($M + H^+$). Anal. Calcd for $C_{18}H_{20}O_4$: C, 71.98; H, 6.71. Found: C, 72.11; H, 6.58.

A sample of 2.84 g (9.46 mmol) of 4-[(2′-acetyl-1′-naphthalenyl)oxy]butanoic acid, ethyl ester was dissolved in 150 mL of methanol/water (3:2), with stirring. Then 2.1 g (15 mmol) of potassium carbonate was added, and the reaction was stirred for 18 h under an argon atmosphere. Next, the reaction mixture was evaporated under vacuum and the residue dissolved in 200 mL of a 0.1 N solution of sodium hydroxide. This basic solution was washed with ether, the aqueous phase acidified by addition of sodium bisulfate, and the resulting mixture extracted with ethyl acetate. This solution was then dried with magnesium sulfate, filtered, and evaporated. The crude product was recrystallized from ethyl acetate/ether to give 1.15 g (45%) of 4-[(2′-acetyl-1′-naphthalenyl)oxy]-butanoic acid as golden crystals. Mp 104−06 °C; IR (KBr): 1720, 1640 cm^{-1}; ^1H NMR ($CDCl_3$, 400 MHz): 8.18 (m, 1H, C8′), 7.85 (m, 1H, C5′), 7.69 (d, $J = 8.6$ Hz, 1H, C3′), 7.63 (d, $J = 8.6$ Hz, 1H, C4′), 7.60−7.54 (m, 2H, C6′ and C7′), 4.08 (t, $J = 6.4$ Hz, 2H, C4), 2.75 (s, 3H, $COCH_3$), 2.73 (t, $J = 7.3$ Hz, 2H, C2), 2.29 (m, 2H, C3); FTMS: 295.09396 ($M + Na^+$, theoretical 295.09408). Anal. Calcd for $C_{16}H_{16}O_4$: C, 70.58; H, 5.92. Found: C, 70.40; H, 5.89.

4-(4′-Acetylphenoxy)butanoic Acid (Linker h). A solution of 0.90 g (6.61 mmol) of 4-hydroxyacetophenone and 1.93 g (9.92 mmol) of ethyl 4-bromobutyrate in 1.80 mL of anhydrous DMF was stirred for 48 h under an atmosphere of dry nitrogen with 2.74 g (19.8 mmol) of potassium carbonate and 0.110 g (0.66 mmol) of potassium iodide. The reaction mixture was then evaporated under vacuum and the residue partitioned between ether and water. The organic phase was separated, washed three times with water, dried with magnesium sulfate, filtered, and evaporated under vacuum to give a brown solid. This was recrystallized from ether/hexane. The beige crystals were air-dried, leaving 0.84 g (51%) of 4-(4′-acetylphenoxy)butanoic acid, ethyl ester. Mp 59−61 °C; IR (KBr): 1740, 1670 cm^{-1}; FAB-MS: 251.1283 ($M + H^+$, theoretical 251.1285). Anal. Calcd for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25;. Found: C, 67.16; H, 7.16. This material was taken on to the following step without additional purification or further characterization.

A sample of 0.25 g (1.00 mmol) of 4-(4′-acetylphenoxy)-butanoic acid, ethyl ester was dissolved in 15 mL of methanol/water (3:2). Then, 0.21 g (1.50 mmol) of potassium carbonate was added, and the reaction was stirred for 18 h under an argon atmosphere. Next, the reaction mixture was evaporated under vacuum and the residue dissolved in 20 mL of a 0.1 N solution of sodium hydroxide. This basic solution was washed with ether, the aqueous phase acidified by addition of sodium bisulfate, and the resulting mixture extracted with ethyl acetate. This solution was then dried with magnesium sulfate, filtered, and evaporated, leaving an off-white solid, which was recrystallized from ethyl acetate by the addition of an equal volume of ether. This provided 0.18 g (80%) of 4-(4′-acetylphenoxy)butanoic acid as light beige crystals. Mp 148−50 °C; IR (KBr): 3063, 2918, 2666, 2593, 2575, 2515, 1729, 1644, 1597, 1514, 1366, 1314, 1264, 1017, 881, 848 cm^{-1}; UV (CH_3OH): 273 nm (a = 76.2 $Lg^{-1}cm^{-1}$), 218 nm (a = 49.4 Lg^{-1} cm^{-1}); ^1H NMR (DMSO-d_6, 400 MHz): 12.18 (br s, 1H, COOH), 7.92 (d, $J = 8.9$, 2H, C3′ and C5′), 7.03 (d, $J = 8.9$ Hz, 2H, C2′ and C6′), 4.08 (t, $J = 6.4$ Hz, C4′), 2.52 (s, 3H, CH_3), 2.40 (t, $J = 7.3$ Hz, C2′), 1.97 (m, 2H, C3′); ^{13}C NMR (DMSO-d_6, 400 MHz): 196.2 (C═O), 174.0 (COOH), 162.4 (C1), 130.5 (C3 and C5), 129.9 (C4), 114.2 (C2 and C6), 67.0 (C4′), 30 (C2′), 26.4 (CH_3), 24.1 (C3′); FTMS: 223.09649 ($M + H^+$, theoretical 223.09649). Anal. Calcd for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35. Found: C, 64.82; H, 6.28.

Synthesis of Calicheamicin Derivatives. HPLC retention times refers to a C_{18} Vydac analytical column (250 × 4.6 mm) run at 1 mL/min with a linear gradient of 35−65% acetonitrile/50 mM $NH_4H_2PO_4$. UV spectra were run in acetonitrile at approximately 5 μg/mL.

Synthesis of Hydrazone 2h. *N*-Acetyl gamma calicheamicin DMH (**1**) (5 mg) was dissolved in 250 μL of anhydrous ethyl alcohol containing 3.8 mg (5 equivalents) of hybrid Linker **h** and 15 μL of acetic acid. The reaction was allowed to stir for 18 h at 37 °C. The solvents were then removed under vacuum, and the crude product was purified on BioSil-A using a gradient of 0 to 20% methanol in chloroform. Removal of the solvents gave 4.6 mg (80%) of hydrazone **2h** as a glassy solid. Precipitation of this material from chloroform containing 5% methanol into a 1:1 mixture of ether and hexanes gave hydrazone **2h** as a slightly off white, amorphous powder. HPLC retention time: 6.4 min, FAB-MS: 1682.7 ($M + H^+$), required for $C_{73}H_{96}IN_5O_{25}S_3 + H^+$, 1682.5; ^1H NMR ($CDCl_3$ + 5% CD_3OD, 300 MHz): 9.2 (s, 1H, COOH), 9.1 (br s, 1H, 18C−NH−N═), 7.72 (d, $J = 8.7$ Hz, 2H, 22), 6.92 (d, $J = 8.7$ Hz, 2H, 23), 6.42 (br t, $J = 7$ Hz, 1H, 14), 6.25 (d, $J = 1.5$ Hz, 1H, 8), 5.92 (d, $J = 9.5$ Hz, 1H, 4), 5.81 (dd, $J = 9.5$, 1.5 Hz, 1H, 5), 5.66 (d, $J = 1.5$ Hz, 1H, 1D), 5.61 (br d, $J = 2.2$ Hz, 1H, 1E), 5.05 (dd, $J = 11.5$, 1.6 Hz, 1H, 1B), 4.72 (m, 1H, 5E), 4.62 (d, $J = 7.8$ Hz, 1H, 1A), 4.56 (m, 1H, 3E), 4.47 (m, 1H, 2D), 4.26 (m, 1H, 3B), 4.19 (m, 1H, 5D), 4.10 (m, 2H, 25), 4.08 (m, 1H, 5B), 4.06 (m, 1H, 3A), 4.02 (m, 1H, 15), 3.89 (s, 3H, 2C-OCH_3), 3.84 (s, 3H, 3C−OCH_3), 3.82 (m, 1H, 3D), 3.74 (m, 1H, 15), 3.67 (m, 1H, 4B), 3.65 (m, 1H, 5A), 3.63 (bs, 3H, 10-$NHCOOCH_3$), 3.62 (m, 1H, 2A), 3.6 (m, 1H, 4D), 3.57 (s, 3H, 3D-OCH_3), 3.4 (m, 1H, 5E), 3.37 (s, 3H, 3E-OCH_3), 3.30 (m, 2H, 4E-NCH_2CH_3), 3.12 (d, $J = 17.6$ Hz, 1H, 12), 3.0 (m, 1H, 4E), 2.85 (d, $J = 17.6$ Hz, 1H, 12), 2.54 (m, 2H, 27), 2.52 (m, 2H, 17), 2.4 (m, 1H, 2E), 2.33 (m, 1H, 4A), 2.20 (s, 3H, 19), 2.10 (m, 2H, 26), 2.08 (s, 3H, 4E-$NCOCH_3$), 1.99 (m, 1H, 2B), 1.76 (m, 1H, 2B), 1.48 (s, 3H, 16a), 1.454 (s, 3H, 16b), 1.42 (d, $J = 6.2$ Hz, 3H, 6B), 1.34 (m, 1H, 2E), 1.30 (d, $J = 6.1$ Hz, 3H, 6A), 1.28 (d, $J = 6.1$ Hz, 3H, 6D), 1.19 (t, $J = 7.2$ Hz, 3H, 4E−N−CH2CH_3); ^{13}C NMR ($CDCl_3$ + 5% CD_3OD, 300 MHz): 192.4 (C1C-CO), 192.4 (C11), 175.5 (C28), 173.0 ($NCOCH_3$), 172.8 (C20), 172.3 (C18), 166.5 (C21), 159.9 (C24), 155.0 ($NHCOOCH_3$), 151.5 (C4C), 150.4 (C2C), 146.7 (C3C), 142.9 (C13), 135.9 (C10), 133.4 (C9), 133.2 (C6C), 130.2 (C1C), 128.1 (C14), 127.5 (C22), 125.0 (C4), 122.4 (C5), 114.4 (C23), 102.8 (C1D), 101.3 (C1A), 101.1 (C2), 99.8 (C1B), 97.5 (C1E), 97.2 (C7), 93.5 (C5C), 87.2 (C3), 82.4 (C6), 80.7 (C3D), 77.6 (C2A), 72.5 (C3E), 71.9 (C4D), 71.7 (C5D), 71.2 (C1), 70.9 (C8), 70.6 (C3A), 69.4 (C5A), 69.2

Anal. Calcd for $C_{73}H_{96}IN_5O_{26}S_3$: C, 52.11; H, 5.75; N, 4.16; I, 7.54; S, 5.72. Found: C, 51.98; H, 5.68; N, 3.95; I, 7.56; S, 5.54.

The rest of the hydrazones were made by the same procedure. The ^1H NMR spectra were analogous to that of hydrazone **2a**. The resonances due to the calicheamicin portion were virtually identical to those found in either *N*-acetyl gamma calicheamicin DMH (**1**) or hydrazone **2h**, with the variation in shifts being less than 0.1 ppm. The resonances from the hybrid linker portion of the hydrazones were also very close to those of the starting material, with the obvious exception of the hydrogens very close to the hydrazone itself. The methyl group from the acetophenones appeared at around 2.2 ppm, the hydrogen from aldehydes was shifted upfield by about 2.0 ppm, and aromatic protons adjacent to the hydrazones were shifted upfield by around 0.2 ppm.

Additional data for these compounds is as follows.

Hydrazone 2a: HPLC retention time: 8.4 min, FAB-MS: 1762.6 ($M + H^+$), 1779.5 ($M + NH_4^+$); required for $C_{78}H_{97}FIN_5O_{26}S_3 + H^+$, 1762.5, for $+ NH_4^+$, 1779.5; UV_{max} at 284 nm.

Hydrazone 2b: HPLC retention time: 5.2 min, FAB-MS: 1610.2 ($M + H^+$), 1627.0 ($M + NH_4^+$); required for $C_{69}H_{88}IN_5O_{25}S_3 + H^+$, 1610.4, for $+ NH_4^+$, 1627.4; UV_{max} at 292 and 302 nm.

Hydrazone 2c: HPLC retention time: 5.5 min, FAB-MS: 1699.2 ($M + H^+$); required for $C_{73}H_{96}IN_5O_{27}S_3 + H^+$, 1698.5; UV_{max} at 284, 300, and 316 nm.

Hydrazone 2d: HPLC retention time: 6.0 min, FAB-MS: 1669 ($M + H^+$), 1686 ($M + NH_4^+$); required for $C_{72}H_{94}IN_5O_{26}S_3 + H^+$, 1668.4, for $+ NH_4^+$, 1685.4.

Hydrazone 2e: HPLC retention time: 6.1 min, FAB-MS: 1668.4 ($M + H^+$), required for $C_{72}H_{94}IN_5O_{26}S_3 + H^+$, 1668.4; UV_{max} at 291 nm.

Hydrazone 2f: HPLC retention time: 4.4 min, FAB-MS: 1641.0 ($M + H^+$), required for $C_{70}H_{90}IN_5O_{26}S_3 + H^+$, 1640.5; UV_{max} at 291 and 305 nm.

Hydrazone 2g: HPLC retention time: 7.8 min, FAB-MS: 1732.1 ($M + H^+$), 1749.6 ($M + NH_4^+$); required for $C_{77}H_{98}IN_5O_{26}S_3 + H^+$, 1731.5, for $+ NH_4^+$, 1748.5.

Hydrazone 2i: HPLC retention time: 6.4 min, FAB-MS: 1666.5 ($M + H^+$), 1683.3 ($M + NH_4^+$); required for $C_{73}H_{96}IN_5O_{25}S_3 + H^+$, 1666.5, for $+ NH_4^+$, 1683.5; UV_{max} at 281 nm.

Synthesis of *N*-Hydroxysuccinimide Ester 3h. Hydrazone **2h** (3.5 mg) was reacted with *N*-hydroxysuccinimide (5 equiv) and EDCI (10 equiv) in 1 mL of 5% DMF/acetonitrile at room temperature for 5 h. The reaction was stripped to dryness under reduced pressure. The product was purified on BioSil-A with a step gradient of 0 to 20% methanol in chloroform. Removal of the solvents gave 3.0 mg (80%) of *N*-hydroxysuccinimide ester **3h** as a glassy solid. Precipitation of this material from chloroform containing 5% methanol into a 1:1 mixture of ether and hexanes gave *N*-hydroxysuccinimide ester **3h** as a slightly off white, amorphous powder. HPLC retention time: 7.5 min. $[\alpha]^{25} = -156.5$ °C; ^1H NMR ($CDCl_3 + 5\%$ CD_3OD, 400 MHz): 8.69 (s, 1H, 18C−NH−N═), 7.75 (d, $J = 8.7$ Hz, 2H, 22), 6.95 (d, $J = 8.7$ Hz, 2H, 23), 6.38 (br t, $J = 7$ Hz, 1H, 14), 6.23 (d, $J = 1.5$ Hz, 1H, 8), 5.90 (d, $J = 9.5$ Hz, 1H, 4), 5.80 (dd, $J = 9.5$, 1.5 Hz, 1H, 5), 5.72 (d, $J = 1.5$ Hz, 1H, 1D), 5.63 (br d, $J = 2.2$ Hz, 1H, 1E), 5.03 (dd, $J = 11.5$, 1.6 Hz, 1H, 1B), 4.70 (m, 1H, 5E), 4.61 (d, $J = 7.8$ Hz, 1H, 1A), 4.6 (m, 1H, 3E), 4.49 (m, 1H, 2D), 4.31 (m, 1H, 3B), 4.20 (m, 1H, 5D), 4.10 (m, 2H, 25), 4.07 (m, 1H, 5B), 4.03 (m, 1H, 3A), 3.91 (m, 1H, 15), 3.89 (s, 3H, $2C-OCH_3$), 3.84 (s, 3H, $3C-OCH_3$), 3.8 (m, 1H, 3D), 3.76 (m, 1H, 15), 3.75 (m, 1H, 4B), 3.65 (m, 1H, 5A), 3.63 (bs, 3H, 10-$NHCOOCH_3$), 3.62 (m, 1H, 2A), 3.6 (m, 1H, 4D), 3.57 (s, 3H, $3D-OCH_3$), 3.4 (m, 1H, 5E), 3.37 (s, 3H, $3E-OCH_3$), 3.30 (m, 2H, $4E-N-CH_2CH_3$), 3.12 (d, $J = 17.6$ Hz, 1H, 12), 3.0 (m, 1H, 4E), 2.85 (m, 2H, 27), 2.85 (bs, 4, 30), 2.72 (d, $J = 17.6$ Hz, 1H, 12), 2.5 (m, 2H, 17), 2.4 (m, 1H, 2E equatorial), 2.33 (m, 1H, 4A), 2.25 (m, 2H, 26), 2.18 (s, 3H, 19), 2.08 (s, 3H, $4E-N-COCH_3$), 2.0 (m, 1H, 2B), 1.8 (m, 1H, 2B), 1.50 (s, 3H, 16a), 1.44 (s, 3H, 16b), 1.42 (d, $J = 6.2$ Hz, 3H, 6B), 1.4 (m, 1H, 2E axial), 1.31 (d, $J = 6.1$ Hz, 3H, 6A), 1.31 (d, $J = 6.1$ Hz, 3H, 6D), 1.19 (t, $J = 7.2$ Hz, 3H, $4E-N-CH_2CH_3$); ^{13}C NMR ($CDCl_3$, 400 MHz): 192.1 ($C1C-CO$), 191.9 (C11), 172.6 ($NCOCH_3$), 172.2 (C20), 169.1 (C29), 169.0 (C18), 168.2 (C28), 165.9 (C21), 165.9 (C24), 155.0 ($NHCOOCH_3$), 151.5 (C4C), 150.6 (C2C), 143.2 (C3C), 143.0 (C13), 136.6 (C10), 133.4 (C9), 133.2 (C6C), 130.2 (C1C), 127.6 (C14), 127.6 (C22), 124.6 (C4), 123.1 (C5), 114.6 (C23), 102.6 (C1D), 101.3 (C1A), 101.1 (C2), 99.7 (C1B), 98.2 (C7), 97.8 (C1E), 93.5 (C5C), 87.0 (C3), 83.0 (C6), 80.8 (C3D), 77.6 (C2A), 72.5 (C3E), 71.8 (C4D), 71.6 (C5D), 71.1 (C1), 71.1 (C8), 70.5 (C3A), 69.1 (C5A), 69.1 (C5B), 68.4 (C4A), 68.4 (C3B), 67.0 (C2D), 66.0 (C25), 64.4 (C4E), 61.7 ($C2C-OCH_3$), 60.9 ($C3C-OCH_3$), 58.9 (C5E), 57.2 ($C3D-OCH_3$), 57.0 ($C3E-OCH_3$), 53.1 (C12), 52.4 ($NHCOOCH_3$), 51.7 (C4B), 49.7 (C16), 47.6 (NCH_2CH_3), 42.9 (C27), 41.4 (C15), 36.9 (C2B), 36.7 (C2E), 28.4 (C17), 27.9 (C16b), 27.8 (C16a), 25.6 (C30), 25.3 ($C6C-CH_3$), 24.4 (C26), 22.6 (C19), 22.4 ($NCOCH_3$), 19.0 (C6B), 17.8 (C6A), 17.6 (C6D), 13.9 (NCH_2CH_3); IR (KBr): 3420 (br), 2700, 1815, 1785, 1739, 1675, 1635 (sh), 1617, 1521, 1420, 1150, 1140, 1110, 1070, 800−600, 570, 480 cm^{-1}; UV (CH_3CH_2OH): 285 nm ($a = 18.60$ Lg^{-1} cm^{-1}); FAB-MS: 1779.5 ($M + H^+$), required for $C_{81}H_{101}IN_6O_{28}S_3 + H^+$, 1779.5; HR−FAB-MS: 1801.458 ($M + Na^+$) (requires 1801.461). Anal. Calcd for $C_{81}H_{101}IN_6O_{28}S_3$: C, 51.96; H, 5.61; N, 4.72; S, 5.41; I 7.13. Found: C, 51.63; H, 5.71; N, 4.39; S, 5.25; I, 7.43.

The rest of the *N*-hydroxysuccinimide esters were made by the same procedure. The ^1H NMR spectra were virtually identical to those of the corresponding hydrazone made with the same hybrid linker, with the variation in shifts being less than 0.1 ppm, except for the appearance of the succinimide protons as a broad singlet at around 2.8 ppm and a slight downfield shift of the protons alpha to the *N*-hydroxysuccinimide ester.

Additional data for these compounds is as follows.

***N*-Hydroxysuccinimide ester 3a:** HPLC retention time: 9.3 min, FAB-MS: 1860 ($M + H^+$), 1877 ($M + NH_4^+$); required for $C_{82}H_{100}IN_6O_{28}S_3 + H^+$, 1859.5, $+ NH_4^+$, 1876.5; UV_{max} at 284 nm.

***N*-Hydroxysuccinimide ester 3b:** HPLC retention time: 6.6 min, FAB-MS: 1708 ($M + H^+$), 1725 ($M + NH_4^+$); required for $C_{73}H_{91}IN_6O_{27}S_3 + H^+$, 1707.4, for $+ NH_4^+$, 1724.4; UV_{max} at 310 nm.

***N*-Hydroxysuccinimide ester 3c:** HPLC retention time: 6.6 min, FAB-MS: 1795.8 ($M + H^+$), required for $C_{77}H_{99}IN_6O_{29}S_3 + H^+$, 1795.5.

***N*-Hydroxysuccinimide ester 3d:** HPLC retention time: 7.1 min, FAB-MS: 1765.2 ($M + H^+$), 1783 ($M + NH_4^+$); required for $C_{76}H_{97}IN_6O_{28}S_3 + H^+$, 1765.4, for $+ NH_4^+$, 1782.4.

***N*-Hydroxysuccinimide ester 3e:** HPLC retention time: 7.0 min, FAB-MS: 1765.3 ($M + H^+$), required for $C_{76}H_{97}IN_6O_{28}S_3 + H^+$, 1765.5, UV_{max} at 289 nm.

***N*-Hydroxysuccinimide ester 3f:** HPLC retention time: 6.5 min, FAB-MS: 1737.4 ($M + H^+$), required for $C_{74}H_{93}IN_6O_{28}S_3 + H^+$, 1737.4.

***N*-Hydroxysuccinimide ester 3g:** HPLC retention time: 9.4 min, FAB-MS: 1829 ($M + H^+$), 1846 ($M + NH_4^+$); required for $C_{81}H_{101}IN_6O_{28}S_3 + H^+$, 1828.5, for $+ NH_4^+$, 1845.5.

***N*-Hydroxysuccinimide ester 3i:** HPLC retention time: 7.7 min, FAB-MS: 1763.7 ($M + H^+$), required for $C_{77}H_{99}IN_6O_{27}S_3 + H^+$, 1763.5.

Conjugates. The synthesis of the carbohydrate conjugates of NAc-gamma calicheamicin DMH (Figure 1) have been reported previously (*26*). Drug loadings of 2 to 3 mol of calicheamicin per mole of antibody were seen and free calicheamicin (hydrazide **1**) was normally 1−3%.

The general procedure for the synthesis of hybrid conjugates of calicheamicin is exemplified by the synthesis of conjugate **4h**.

To hP67.6 at pH 7.8 in phosphate buffer (50 mM sodium phosphate, 100 mM NaCl) containing 60 mM sodium caprylate was added 6 equiv of NAc-gamma calicheamicin DMH AcBut, *N*-hydroxysuccinimide ester (**3h**) in sufficient propylene glycol to give a final concentration of 30% propylene glycol. After 3 h at 25 °C, the product was filtered through a Millex HV filter and purified by gel filtration on Sephacryl S-200 using 50 mM phosphate, 100mM NaCl at pH 7.4. The final monomeric product represented a 60% yield of protein and had a loading of 2.5 mol/mol of the calicheamicin derivative as assessed by UV (protein at 280 nm and drug at 333 nm).

Antibody and Cell Lines. MOPC-21, hP67.6, and hCTM01 were prepared at Celltech, Ltd., Slough, England (now Celltech Chiroscience, plc.). The HL-60 promyelocytic leukemia cells are ATCC CCL 240 and Raji human Burkitt lymphoma cells are ATCC CCL 86. HEL 92.1.7 human erythroleukemia (TIB 180) were obtained from the American Type Culture Collection.

Relative immunoaffinity of the antibodies and conjugates was measured by a competitive radioimmunoassay (RIA) in which several dilutions of the test sample competed with radioiodinated mP67.6 for binding to live cells. For each assay, 10^6 HEL 92.1.7 cells in 0.1 mL were incubated with 0.05 mL of 4 μg/mL ^{125}I-mP67.6 (Bolton-Hunter labeling, specific activity about 0.3−0.5 μCi/μg) and serial 4-fold dilutions of the test samples, the highest concentration being 200 μg/mL. After a 1 h incubation at 0−4 °C, the cells were washed three times with cold Dulbecco's phosphate-buffered saline (PBS) and transferred to fresh tubes and counted. Binding inhibition curves were plotted and IC_{50} values for each conjugate were compared with that of the unmodified control antibody as a relative measure of retention of immunoaffinity.

In Vitro Testing. Test samples were adjusted to 1 or 0.1 μg cal/mL (cal = calicheamicin equivalents) in medium (RPMI-1640 containing 5% heat-inactivated fetal bovine serum, 5 μg/mL insulin, 5 μg/mL transferrin, 5 ng/mL sodium selenite, 100 U/mL penicillin, and 0.1 μg/mL streptomycin) and six serial 10-fold dilutions were made. CD33-positive HL-60 cells or CD33-negative Raji cells were mixed with the sample dilutions in 12 × 75 mm plastic tubes (final cell concentrations 50,000/mL) and incubated at 37 °C in 5% CO_2/air for 1 h. Cells were washed twice by centrifugation, resuspended in fresh medium at 10,000/mL, and plated in triplicate in 96-well flat-bottom tissue culture plates at 200 μL/well. Cells were labeled with [^{3}H]thymidine during the final 24 h of a 3-day culture period. The percent inhibition of [^{3}H]-thymidine incorporation was plotted versus sample concentration, and the concentration that gave 50% inhibition was interpolated. Maximal inhibition was determined from the highest concentration of NAc gamma that killed all cells, and no inhibition was determined from medium controls.

In Vivo Testing. The HL-60 human xenograft tumor was developed from the ATCC line and was passaged as ascites in athymic mice. The ascites were harvested from donor mice, and 8×10^6 cells were implanted subcutaneously into athymic mice. Tumors were staged to a size of 200 mg prior to intraperitoneal treatment with three doses spaced 4 days apart (days 1, 5, and 9). Control animals were injected with the same phosphate-buffered saline used for the conjugates and conjugates were dosed at 25 (except for the MOPC-21 conjugate), 50, 150, and 300 μg cal/kg. There were 10 animals in the control group and five in each test group. Tumor mass was determined by measuring the tumor diameter once weekly for a minimum of 35 days after the start of treatment.

Ex Vivo Testing. Leukemia samples giving rise to colonies in semisolid medium were used. Cells were thawed in a 37 °C water bath and transferred to 10 mL of RPMI containing 10% calf bovine serum and 100 U/mL deoxyribonuclease 1 Type II (Sigma). Cells were then washed twice in RPMI/10% FBS, counted, and suspended to a concentration of 10^6 viable cells/mL in RPMI containing 2% FBS. Cells were then incubated at 37 °C in the dark for 2 h in the presence of gem-ozo or, as a nonbinding control, the equivalent CTM01 conjugate (for adult samples) or MOPC-21 conjugate (for pediatric samples). After incubation, cells were washed three times in RPMI/2% FBS and suspended in 300 μL of human placental conditioned medium. Cells were then placed in triplicate 35-mm culture dishes (Nunc, Naperville, IL) containing 900 μL of Iscove's Modified Dulbecco's Medium, 0.9% methylcellulose (Stem Cell Technologies Inc., Vancouver, BC, Canada), supplemented with 20% FBS, 1% bovine serum albumin (Intergen Co., Purchase, NY), 1×10^{-4} mol/mL 2-mercaptoethanol (Sigma, St. Louis, MO), and 10% human placental conditioned medium, IL-3 (100 ng/mL) and erythropoietin (epo, 2 U/mL, Amgen, Thousand Oaks, CA). Cells were cultured at a concentration of 50000 cells per dish at 37 °C in a 5% CO_2 in air-humidified atmosphere. Colonies were counted after 10−12 days of incubation. Previously frozen samples from pediatric patients were obtained from the Children's Cancer Group AML reference laboratory, and adult samples were obtained from patients enrolled in SWOG protocol 8600 were graciously provided by Dr. Cheryl Willman, University of NM.

RESULTS

Humanization. A conjugate consisting of a calicheamicin hydrazide derivative attached to the oxidized carbohydrates on the anti-CD33 antibody P67.6 had been selected for further development. To avoid HAMA responses to conjugates of murine P67.6 in AML patients, a humanized version of the antibody, hP67.6, was constructed which contains the complimentarity-determining regions of the murine version but human IgG_4 kappa sequences in the remainder (*27*). Competitive

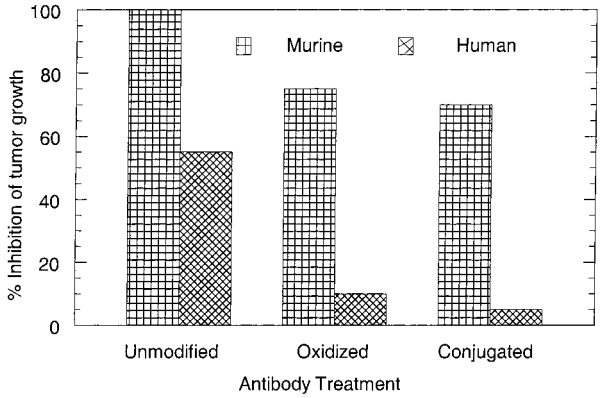

Figure 2. Relative affinity of murine and human P67.6 in the native, oxidized, and conjugated state as determined in a competitive radioimmunoassay.

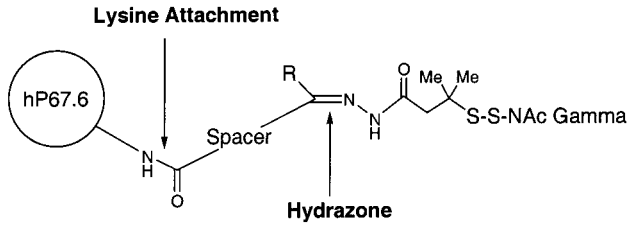

Figure 3. Strategy for hybrid conjugates.

binding assays with radiolabeled antibodies indicated roughly 50% less immunoreactivity with hP67.6 versus the murine antibody (see Figure 2). However, the periodate oxidation required in preparing a hP67.6 calicheamicin carbohydrate conjugate resulted in a virtually total loss of immunoreactivity, and alternative oxidation techniques or the use of potentially protective additives were unsuccessful. Milder oxidation with periodate reduced drug loading by about 50%, but resulted in a conjugate that still retained around 50% of its original immunoreactivity (i.e., 25% that of the murine antibody). These detrimental changes were reflected in a 4-fold loss of potency of the conjugate against HL-60 cells in vitro, while in HL-60 bearing athymic mice, only 6 of 33 survivors were rendered tumor-free with this conjugate as compared with 13 of 14 in the corresponding groups treated with the mP67.6 conjugate ($p < 0.001$).

Conjugate Redesign. One solution to the inability to make suitably active hydrazone conjugates via oxidation of the carbohydrates was to design a conjugate that utilizes lysine attachment, but which incorporates a hydrazone bond. This can be achieved as shown in Figure 3. Lysine attachment via amide bonds avoids the use of the carbohydrate oxidation technology. The spacer allows for separation of the two reactive functionalities in the bifunctional linker and, along with the R group, allows the hydrolytic stability of the hydrazone bond to be varied. The synthesis of such "hybrid" conjugates is shown in Figure 4, where an aryl group (Ar) was chosen as the spacer. The same calicheamicin derivative, NAc-gamma calicheamicin DMH (**1**), that was released from the earlier carbohydrate conjugate of P67.6 is condensed with a carbonyl compound. This calicheamicin hydrazone **2** then has the appended carboxylic acid activated to form derivative **3** before reaction with an antibody to form a hybrid conjugate **4**.

A broad variety of carbonyl-containing carboxylic acids were examined as linkers. This included both aliphatic as well as aromatic aldehydes and ketones and one benzophenone. The carboxylic acid included both ali-

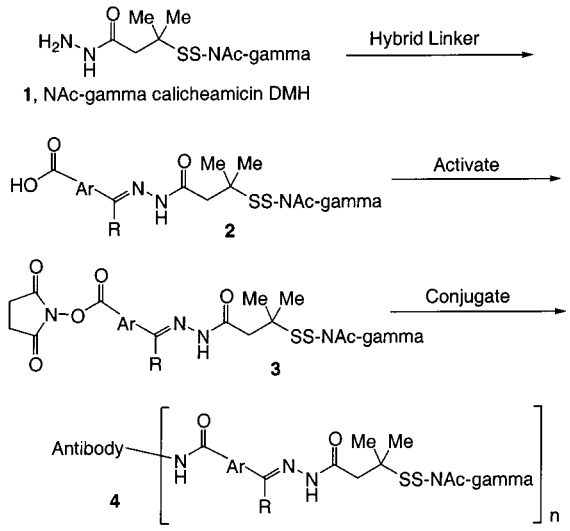

Figure 4. Synthesis of hybrid conjugates.

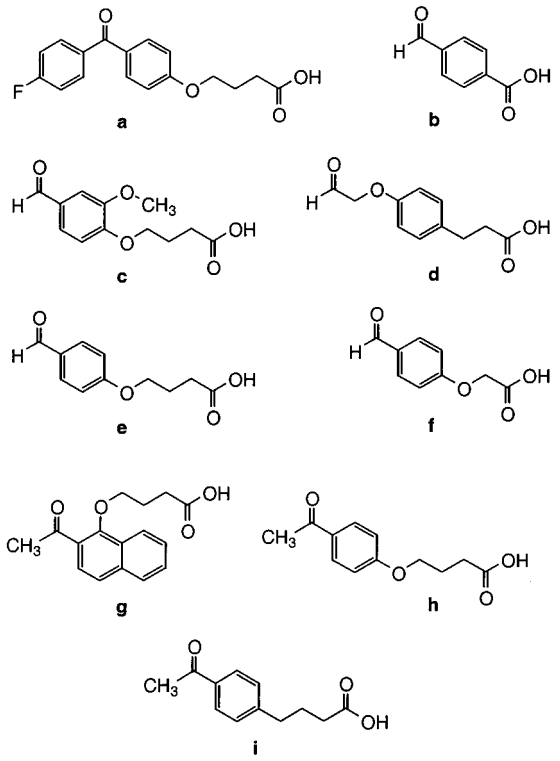

Figure 5. Selected hybrid linkers.

phatic and aromatic acids. One common factor in all these structures was the inclusion of an aromatic spacer, in part to preclude interaction of the two reactive ends. Of the 36 hybrid linkers examined (*28*), the structures of nine representative compounds are shown in Figure 5.

Selection of a Hybrid Linker. All of the linkers reacted smoothly to form hydrazones **2** (Figure 4), although benzophenones such as Linker **a** required more forcing conditions than the other types of carbonyls. Reaction of the carboxylic acid to form activated esters **3** and conjugation to hP67.6 was possible for all of the linkers, but with some notable differences. α-Phenoxy acids such as **2f** gave more impurities and lower yields on activation and conjugation. Activated aromatic acids such as **3b** reacted more sluggishly and required longer reaction times. Numerous aromatic substituents were examined (those illustrated plus halo, nitro, amino, and

[e] Percent inhibition of colony formation at 1 μg cal/mL with AML patient marrow samples versus nonbinding control conjugate. [f] Made with AcBut linker.

ester), but none had any beneficial effect on activity of the conjugates of hP67.6.

To provide an estimate of the relative stability of the new hydrazones (**2**, Figure 4) as an estimate of the hydrolytic stability of their conjugates, they were examined by incubating a dilute aqueous solution at 37 °C in pH 4.5, 5.5, 6.5, and 7.4 buffers for 3 h and 24 h and monitoring the disappearance of hydrazone and the appearance of NAc-gamma calicheamicin DMH (**1**) by reversed-phase HPLC. The degree of hydrolysis varied greatly, and representative data from samples at pH 7.4 and 4.5 are included in Table 1, columns 1−3. These two pH's were considered most important because they approximate the pH in circulation and in lysosomes, respectively.

Reasonable loadings of these calicheamicin hydrazone derivatives on antibody (>1.5 mol/mol) were obtained only at the expense of protein recovery due to significant aggregate formation. This was particularly the case for the murine antibody, but even hP67.6 gave more aggregate than seen in the past with the earlier two classes of calicheamicin conjugates (*22*). Modification of the conjugation conditions was required to circumvent this problem and make monomeric conjugates in a manner appropriate for clinical trials (*29*).

Initial biological testing of these conjugates relied on in vitro cytotoxicity and selectivity, as given in Table 1, columns 4−6. In vivo and/or ex vivo testing was done on selected conjugates to further characterize some of the more promising conjugates, as included in Table 1, columns 7 and 8. Of all the conjugates tested, the ones made with Linker **h** (nicknamed the AcBut linker) gave the most consistent activity in all the tests. This linker was therefore chosen as the basis for the hP67.6 conjugate taken on to clinical trials. The hP67.6-NAc-gamma calicheamicin DMH AcBut conjugate (Figure 6) was given the trivial designation of CMA-676 and has been assigned the generic name gemtuzumab ozogamicin (gem-ozo) and the trade name of Mylotarg.

Characterization of Gem-Ozo. The in vitro assay comparing the cytotoxicity of gem-ozo with the mP67.6-NAc-gamma calicheamicin DMH conjugate (the previously characterized carbohydrate conjugate) shown in Table 2 indicates that gem-ozo was 45-fold more potent against HL-60 cells and 70-fold more specific than the carbohydrate conjugate relative to control cells. Gem-ozo was also 100,000-fold more cytotoxic than the corresponding AcBut-linked conjugate of MOPC-21, an antibody which does not bind to either cell line. Gem-ozo, as well as the P67.6 carbohydrate conjugate, was more cytotoxic toward $CD33^+$ cells than the calicheamicin derivative from which they were made.

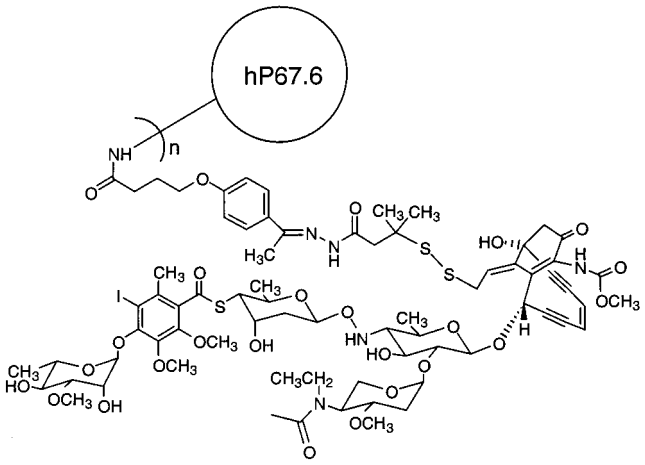

Figure 6. Gemtuzumab ozogamicin (gem-ozo) or Mylotarg. The drug loading, *n*, is 2 to 3 mol/mol.

Table 2. In Vitro Cytotoxicity and Selectivity of Gem-Ozo

	IC_{50} (ng cal/mL)[a]		
sample	HL-60 Cells	Raji Cells	IC_{50} (Raji) ÷ IC_{50} (HL-60)
gem-ozo	0.00046	35.7	78000
mP67.6-carbohydrate conjugate	0.0205	23	1100
MOPC-21 AcBut conjugate	42	52	1.2
NAc-gamma calicheamicin DMH (**1**)	9.2	4.7	0.5

[a] Doses are given in equivalents of NAc-gamma calicheamicin DMH. The corresponding amount of antibody is on average 40-fold greater.

In athymic mice implanted with HL-60 xenografts, both gem-ozo and the earlier carbohydrate conjugate induced complete tumor regression by day 28 with no tumor regrowth at day 100 in 5 out of 5 mice in each of the top two doses examined (300 and 150 μg cal/kg times 3 doses) (cal = calicheamicin equivalents) (Figure 7). However, gem-ozo was more efficacious than the carbohydrate conjugate at the lowest dose given (25 μg cal/kg times three doses). A chemically equivalent AcBut conjugate of the MOPC-21 antibody showed no significant effects at lower doses. At the highest dose used (300 μg cal/kg times three doses), there were no tumor free survivors compared to 5/5 in the gem-ozo treated group. Figure 8 shows the time course of this response for the three gem-ozo treatment groups. The maximum tolerated

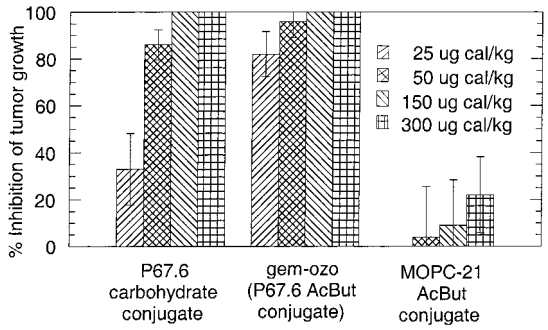

Figure 7. Response of HL-60 xenograft tumors to gem-ozo. The loading of calicheamicin on antibody is 2.5 mol/mol. Doses in protein equivalents are therefore 40-fold higher. Error bars represent the standard error of the mean.

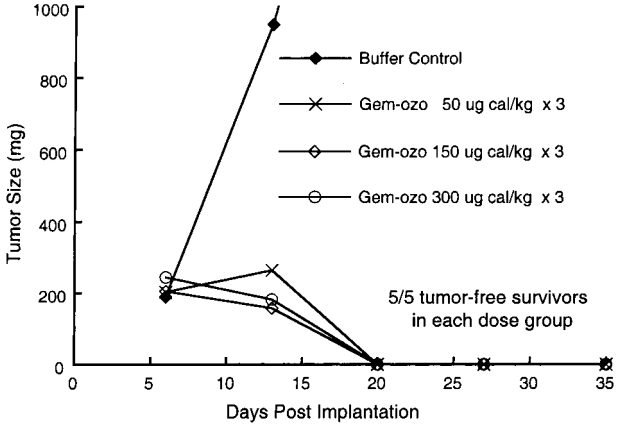

Figure 8. Time-course of the response of HL-60 xenograft tumors to gem-ozo. The loading of calicheamicin on antibody is 2.5 mol/mol. Doses in protein equivalents are therefore 40-fold higher.

[a] Equivalents of NAc-gamma calicheamicin DMH. The corresponding amount of antibody is 40-fold greater.

dose for gem-ozo in these experiments varied from 300 to 400 μg cal/kg given three times.

Analysis of the ability of gem-ozo to inhibit leukemia colony formation in diagnostic marrow specimens from 27 adult and 15 pediatric AML patients indicated effective inhibition of colony formation at doses of either 2 or 10 ng cal/mL (Table 3). The percent inhibition given in the table is with respect to that of an assay done with a calicheamicin control conjugate made from a nonbinding antibody. This control conjugate was prepared with the same linker and calicheamicin derivative and a nonbinding antibody, either MOPC-21 or the humanized anti-PEM antibody hCTM01 (*30*). Growth inhibition was less marked in the adult samples due presumably to differences between the leukemias occurring in the two age groups, although, at a dose of 10 ng cal/mL, 6 out of 27 adult samples showed >90% inhibition with respect to a nonspecific control conjugate. Although significant cytotoxic effects against AML cells were not observed in all patient samples tested, the factors predictive of response or lack thereof to gem-ozo by the colony-forming cells in a given leukemia sample were not obvious. Some of the colonies that did form following treatment with the conjugate could have been derived from normal $CD33^-$ precursors; however, some appeared to have abnormal morphology consistent with leukemic colonies.

DISCUSSION

Background. A series of conjugates of the calicheamicins and the anti-MUC1 antibody CTM01 has previously been reported (*26, 31*). Initial examination of the structural requirements for the calicheamicin portion of these conjugates was made using carbohydrate conjugates, which contain a hydrolytically labile hydrazone linkage between a calicheamicin hydrazide derivative and the oxidized carbohydrates of the antibody. The optimal conjugates contained NAc-gamma calicheamicin as the calicheamicin core and a disulfide stabilized by two adjacent methyl groups. Further work showed that the inclusion of the hydrazone was not necessary for the CTM01 antibody and that an "amide" conjugate that was lacking this site of hydrolysis was equivalent or superior in all preclinical models examined, especially against resistant cell lines (*32, 33*). This work with CTM01 is in dramatic contrast to that with P67.6. For this antibody, the carbohydrate conjugate was shown to be superior to the amide conjugate (*22*), presumably due to the need for hydrolytic release of the calicheamicin from the antibody in the acidic lysosomes.

The reason calicheamicin conjugates of P67.6 are significantly more potent and selective when the linker contains a site for intracellular hydrolytic release is unclear, but it is consistent with the fact that P67.6 is internalized into lysosomes (*34*), an acidic compartment (*35, 36*) that would provide an environment for greatly enhanced hydrolysis over that seen at the pH found in circulation. HL-60 cells are metabolically very active and thus may require the rapid release of an active calicheamicin derivative by hydrolysis, which would be faster in the endosomes/lysosomes than disulfide exchange would likely be. Overall, the data summarized above for P67.6 and CTM01 indicate the importance of designing linkers specific for the individual target cell type.

Although the murine P67.6 carbohydrate conjugate is a potent, selective agent in models of AML, the humanized antibody could not be oxidized to make the desired conjugate without significant losses in immunoaffinity and/or drug loading. Preliminary experiments indicated that an oxidatively sensitive methionine residue near the CDR's that originated with the human sequences might be the reason for this sensitivity to oxidation. This necessitated the design of a new class of calicheamicin conjugates.

Design and Chemistry of Hybrid Conjugates. The hybrid conjugates (Figure 3), which were envisioned as the replacement for the P67.6 carbohydrate conjugate, contain both lysine attachment to the antibody through amide formation, which obviates the need for oxidation of the carbohydrates, and a hydrazone linkage, which allows for the necessary hydrolytic release. The choice of the spacer and the R group affects the stability of the hydrazone and allows for variation in the degree of hydrolyzability. Not only can the chemical properties of the linker be varied to optimize the efficacy of the conjugate, but only a single species of hydrazone is produced. With the carbohydrates as the source of aldehydes, multiple species are present which all hydrolyze at different rates, some slower and others faster than

what is optimum for best activity. These new hybrid conjugates therefore have the potential to be even more active and more selective than the carbohydrate conjugates.

Selection of a Hybrid Linker. Numerous linkers were examined (Figure 5) to ascertain the structural properties necessary for optimal activity. Past experience indicates a reasonable correlation between in vitro, in vivo, and ex vivo activity for conjugates of P67.6. Therefore, initial screening of the hybrid conjugates of hP67.6 relied on in vitro data. The results with 36 hybrid linkers showed a good correlation between the ability to hydrolyze the hydrazone bond in the calicheamicin-linker adducts, **2**, and the in vitro potency and selectivity, with certain exceptions noted below. Table 1 shows representatives of the broad variety of the linker structural types that were examined. Various benzaldehyde and acetophenone derivatives made conjugates with good activity. No substituents on the aromatic ring were found that appeared to improve activity, consistent with the functional nature of the linkers. Benzophenones such as Linker **a** made poor conjugates, consistent with the greater stability of the hydrazone to hydrolysis.

One exception to the correlation between ease of hydrolysis and activity is the group of conjugates made with aliphatic aldehydes and ketones, exemplified by Linker **d**. The hydrazone bond in this conjugate is too unstable. Even freshly prepared batches of conjugate contained significant amounts of unconjugated calicheamicin, and conjugates examined after the biological testing contained almost all of the calicheamicin in unconjugated form. Conjugates made with other linkers contained significantly lower amount of unconjugated calicheamicin (1−3%).

One other exception to the correlation between hydrolyzability and cytotoxicity is the group of conjugates made with linkers containing naphthylene spacers, exemplified by Linker **g**. Conjugates made with such linkers were more active, especially in vitro, than would be expected based on their relatively slow hydrolysis. Although the reasons for this unexpected activity are unclear, conjugates containing such linkers did not prove to be the best overall in terms of in vivo, in vitro, and ex vivo activity.

The best conjugates were made with unsubstituted acetophenones, and the "AcBut" linker (Linker **h**, 4-(4-acetylphenoxy)butanoic acid), which appeared to afford the most favorable balance between hydrolytic stability in physiological buffers (pH 7.4) and efficient drug release at the pH of lysosomes (∼4), was chosen for its good overall activity. The resultant conjugate with hP67.6 was designated CMA-676 and given the generic name of gemtuzumab ozogamicin (gem-ozo).

Characterization of Gem-Ozo. Gem-ozo has a drug loading of 2−3 mol of calicheamicin per mole of antibody, comparable to that seen with calicheamicin carbohydrate or amide conjugates. The hybrid calicheamicin conjugate gem-ozo showed higher potency and selectivity than the earlier carbohydrate conjugate in cell culture, perhaps because the calicheamicin derivative is released at close to maximum efficiency from gem-ozo. Indeed, the 2000-fold increase in potency of gem-ozo over that of the parent drug is unusual for antibody-targeted chemotherapy, which often lose 100-fold potency upon derivatization and conjugation.

In addition to the remarkably high potency and selectivity in cell culture, gem-ozo is curative of the HL-60 xenograft in nude mice over a roughly 6-fold dose range. A comparable conjugate of a nontargeting antibody is virtually inactive in this model, while the previous carbohydrate conjugate shows somewhat less activity at the lowest dose tested. In ex vivo colony-forming assays, a significant percent of marrow samples are inhibited by gem-ozo. Attempts to elucidate the factors responsible for a response or lack thereof by looking at such factors as MDR and antigen expression have so far met with failure. However, it is clear that gem-ozo has significant activity in a subpopulation of patient samples in this assay. It is impossible to quantify the fraction of the total population that might be treated successfully from these data, as only about 25% of patient bone marrow samples form colonies in this assay. Taken together, the preclinical data presented in this article indicate that the hybrid conjugates as exemplified by this AcBut conjugate constitute a new, improved class of calicheamicin conjugates.

The effectiveness of gem-ozo in preclinical models as well as in clinical trials (vida infra) is attributed to the use of a potent cytotoxic agent, an internalizing target antigen with restricted expression and easy accessibility, and a custom-made, well-controlled, hydrolyzable bond with the AcBut linker. The hydrolytic release of the drug from the conjugate that results from the use of this novel, bifunctional linker (presumably in the acidic endosomes/lysosomes of the target cells) appears to be very important for the intracellular trafficking of the calicheamicins when targeting $CD33^+$ myeloid leukemia cells (*22*).

Aside from these considerations of design and mechanism of action, gem-ozo has demonstrated an acceptable safety profile in clinical trials as a single agent while achieving remissions in 38% of patients with AML in first relapse (*24*, *25*). In addition, as indication of the significantly decreased tendency for immune responses in patients in comparison to ricin conjugates, where virtually every patient shows an anti-ricin response, there were only two immune responses reported to gem-ozo in the Phase I trial (*24*) and none reported in the Phase II trial (*25*).

The clinical efficacy of the immunoconjugate described in these studies has recently been demonstrated in clinical trials using gem-ozo as single-agent therapy. In a Phase I dose escalation trial (*24*), 40 patients with advanced $CD33^+$ AML were treated to determine the toxicity and maximally tolerated dose of gem-ozo. In contrast to the significant toxicity observed with most therapies for AML, treatment with gem-ozo was remarkably well tolerated, with fever and chills as the most common clinical side effect. Furthermore, a relatively long half-life of approximately 2 days was observed. Clinical responses were observed in this group of patients with advanced disease, with leukemia cells eliminated from blood and marrow in eight patients, three of whom also showed complete recovery of normal hematopoietic function with a duration of response of from 140 to >623 days.

In a Phase II single-agent trial (*25*) to establish efficacy in patients with AML who relapsed after an initial remission in response to conventional chemotherapy, analysis of the 142 patients enrolled in three separate trials revealed 30% remissions as defined by disappearance of morphologically detectable leukemia from the blood and marrow, recovery of the peripheral granulocyte count to greater than 1,500/mm^3, and independence from platelet transfusion. Median relapse-free and landmark survival for these patients was 6.8 months and 12 months, respectively. The probability of survival at one year for all patients that underwent treatment was 31%. The toxicity profile of Mylotarg appears to be different

from that of traditional chemotherapy for AML, with lower incidences of mucositis and infections being noteworthy.

These results overall support the notion that the pluripotent stem cells may be predominately, if not completely, normal in some patients with AML, enabling reestablishment of normal hematopoiesis by remaining $CD33^-$ cells. Based on the preclinical and clinical data presented here, gem-ozo appears promising as an effective and, in some respects, less toxic new therapy for AML. On the basis of phase II data, Mylotarg, a representative of the new, improved hybrid class of calicheamicin conjugates, has become the first antibody-targeted chemotherapeutic agent approved by the FDA.

Polycationic Telomers and Cotelomers for Gene Transfer: Synthesis and Evaluation of Their an Vitro Transfection Efficiency

Nathalie Van Craynest,[†] Catherine Santaella,[†,‡] Otmane Boussif,[§,||] and Pierre Vierling*[,†]

Laboratoire de Chimie Bio-Organique, UMR 6001 CNRS, Université de Nice Sophia-Antipolis, Faculté des Sciences, 06108 Nice Cédex 2, France, and Transgène SA, 11 rue de Molsheim, 67082 Strasbourg Cédex, France. Received March 2, 2001; Revised Manuscript Received May 15, 2001

We report on the synthesis of a series of lipopolyamine telomers, [I(Asp)-14,n_A(NH), I(His)-18,n_A(NH), I-18,n_B(NMe), Gal-n_A(NH)], and random cotelomers, [I-18,n_A(NH)-n_B(NMe) and I-18,n_A(NH)-n_C(OH)], and on their in vitro gene transfer capability. They were obtained by a telomerization process of various amino-acrylamide taxogens with various lipophilic thiol telogens which might also contain an aspartic or a histidine residue or with a thiogalactosyle derivative. For *N*/*P* ratios (*N* = number of (co)telomer amine equivalents, *P* = number of DNA phosphates) from 0.8 to 10, these polyamine (co)telomers condensed DNA, with or without the use of DOPE, forming (co)teloplexes of mean sizes less than 200 nm, except for *N*/*P* 1.25 for which precipitates were observed. Some trends, structure−transfection efficiency relationships, were established. Thus, aspartic-containing telomers were found to lead to efficient formulations for plasmid delivery to A549 cells and for *N*/*P* ratios from 1.25 to 5.

INTRODUCTION

Transgene expression mediated by (poly)cationic lipid- or polymer-plasmid DNA complexes (lipoplexes or polyplexes, respectively) represents an attractive alternative to the use of viral vectors in gene therapy. Synthetic nonviral gene transfer vectors, which are free from the risks associated with viral vectors, may represent more suitable gene delivery systems for repetitive use and will be of considerable potential to the gene therapy field. Although viral vectors are very efficient for gene delivery, their use suffers indeed from a number of disadvantages, including safety (possible presence of replication-competent virions, insertional mutagenesis, and specific immune response) and practical issues relating to quality control and high-cost and problematic large-scale production (*1*).

Over the past decade, a large variety of (poly)cationic lipids, liposomes (including highly fluorinated ones (*2*)), lipopolymers, and (co)polymers (*3*−*11* and references therein), have been used extensively to deliver genes to a large variety of cell lines and tissues. Several studies have shown that in vitro and in vivo transfection with complexed DNA can vary in function of, among others, the cationic components (lipid, polymer), the lipid composition of the lipoplexes (presence of helper lipids), and the size of the complexes. Currently, little is known concerning the intracellular traffic after endocytosis of the DNA complexes, and the ongoing research remains empirical. Consequently, there is a need to develop new compounds, especially cationic ones, with characteristics and properties different from those already described. Recently, as a contribution into this field, some of us have reported on teloplexes (e.g., DNA complexes formulated with lipopolyamine telomers) as alternative efficient gene transfer agents (*12*). These lipopolyamine telomers were obtained from telomerizing one polymerizable acrylamide M monomer, comprising a (poly)amine precursor, in the presence of a hydrophobic long-chain thiol (L-SH). The lipopolyamine telomers thus obtained, of formula L-S-(M)*n*-H, show lower degrees of polymerization ($1 \leq n < 200$) (*10*, *12*) and, hence, rather lower molecular weights than (M)*n* compounds obtainable with classic polymerization processes ($n \gg 200$) (*8*−*10*, *12*).

We report herein on the synthesis of new (lipo)polyamine telomers and random cotelomers (Figure 1), on their capabilities of compacting and transferring DNA into a cell, and on their effect on cell viability. This second generation of cationic (lipo)polyamine telomers and cotelomers shows a modular structure aimed at modulating the physicochemical and biological properties (e.g., chemical stability, biodegradability, toxicity, biodisponibility, and transfection efficacy) of the teloplexes and cotelolexes they form with DNA. This modular structure design was partly deduced from the SAR analysis performed with the first generation of telomers (*12*). The telomer's or cotelomer's polar moiety includes a variable number (from 15 to 90) of primary or tertiary amine functions or a random combination of primary and tertiary amine or polyol (tris(hydroxymethyl)methyl THM) functions, respectively. This polar moiety is connected to a hydrophilic galactosyl or a hydrophobic residue which might also contain an aspartic or a histidine amino acid. The galactosyl residue was selected in order to show the importance, with respect to transfection, of the hydrophilic or hydrophobic character of the moiety connected to the polyamine polar head. The neutral, hydrophilic THM and also the galactosyl residue were selected for improving the cell viability of the DNA complexes (*7*, *9*). The two amino acids were selected for the pK_a of their acid (pK_a 3.9) or imidazole (pK_a 6.1) functions, respectively, which could increase the buffering capacity of the DNA complexes inside the endosomes or lysosomes,

causing their disruption and, thus, enhancing DNA cytoplasmic delivery (*4*, *13*); for example, the transfection efficiency of polylysines was improved when these polymers were partially substituted with histidyl residues (*11*). As the use of colipids such as DOPE (*14*, *15*) (which, when used alone, do not enhance gene transfer) was found in several cases to enhance transfection, we report also on the transfection efficacy of the lipotelomers used in conjunction with DOPE.

EXPERIMENTAL SECTION

General Experimental and Analytical Conditions. Most of the reactions were performed in anhydrous solvents under dry and oxygen-free nitrogen. The purifications by column chromatography were carried out using silica gel 60 (Merck, Whitehouse Station, NJ; 70−230 mesh) and chloroform ($CHCl_3$), dichloromethane (CH_2Cl_2), methanol (MeOH), diethyl ether (Et_2O), or mixtures thereof as indicated. The advance of the polymerization reaction was followed by thin-layer chromatography (TLC) on silica plates F_{254} (Merck). The following developing systems were used: UV light, $KMnO_4$, H_2SO_4/MeOH, DTNB (5,5′-dithiobis(2-nitrobenzoic acid)), and ninhydrin reagent (Sigma, St. Louis, MO). The syntheses of telogen I-SH and of taxogen **A** (*N*-[2-[(BOC)-aminoethyl]]acrylamide) have been performed as described in ref *12*. Taxogen **C** (*N*-tris(hydroxymethyl)-methylacrylamide) was purchased from Aldrich.

^1H and ^{13}C NMR spectra were recorded at 200 and 50.3 MHz, respectively, on a Bruker AC-200. Chemical shifts were measured relative to $CHCl_3$ (δ 7.27) or CH_3OD (δ 3.35) for ^1H, relative to $CDCl_3$ (δ 76.9) for ^{13}C, and expressed indirectly in relation to TMS. The following abbreviations are used to describe the signal multiplicities: s (singlet), d (doublet), t (triplet), q (quadruplet), and m (multiplet). Chemical shifts are expressed in ppm and listed as follows: shift in ppm (multiplicity, integration, coupling, and attribution). Mass spectra (MS) were recorded on a Finningan MAT TSQ 7000 equipped with an atmospheric pressure ionization (API) source. Electrospray ionization mass spectrometry (ESI-MS) was used depending on the polar moiety of the molecules to be studied. This method used in positive mode can give either a $M + H^+$ or a $M + Na^+$ signal.

Synthesis of Telogen I(Asp(OBzl))-SH. *H-Asp(OBzl)-N,N-ditetradecanamide TFA,* ***(1)***. A total of 126 mg (0.31 mmol) of ditetradecylamine (*12*), 0.12 mL (0.92 mmol) of NEt_3, and 144 mg (0.31 mmol) of PyBrop (Novabiochem) were added to a solution of 100 mg (0.31 mmol) of BOC-Asp(OBzl)-OH (Bachem) in 2 mL of CH_2Cl_2. After 24 h of reflux, $CHCl_3$ was added, and the organic phase was washed successively with $KHSO_4$ 5%, $NaHCO_3$ 8%, and H_2O and then dried over Na_2SO_4. The residue obtained after evaporation was chromatographed on a silica gel column ($CHCl_3$ to $CHCl_3/CH_3OH$, 99/1, v/v), giving 156 mg (0.22 mmol, 71%) of BOC-Asp(OBzl)-*N*,*N*-ditetradecanamide as a colorless oil. [TLC ($CHCl_3/CH_3OH$, 85/15, ninhydrin): $R_f = 0.8$. ^1H NMR ($CDCl_3$): 0.80 (t, 6H, J = 6.0 Hz, CH_3), 1.05−1.35 (m, 44H, $(CH_2)_{11}$), 1.35−1.60 (m, 13H, Me(BOC)), CH_2CH_2N), 2.55 and 2.76 (AB part of an ABX system, 2H, $^2J_{AB}$ = 15.6 Hz, $^3J_{AX}$ = 7.0 Hz, $^3J_{BX}$ = 6.0 Hz, CH_2CH), 3.00−3.40 (m, 4H, CH_2N), 4.80−4.95 (m, 1H, CH), 5.02 (s, 2H, CH_2Ph), 5.32 (d, 1H, J = 9.4 Hz, NH), 7.25 (s, 5H, Ph). ^{13}C NMR ($CDCl_3$): 14.2

(CH_3); 22.7 (CH_2CH_3); 28.3 (Me(BOC)); 26.9, 27.0, 27.5, 29.3, 29.4, 29.6, 29.7 ((CH_2)$_{11}$); 32.0 ($CH_2CH_2CH_3$); 38.4 (CH_2CO); 46.4, 47.4, 48.0 (CH_2N, CH_2Ph); 66.6 (CH); 79.9 (C(BOC)); 128.2, 128.3, 128.5 (CH=CH(Ph)); 135.8 (C=CH(Ph)); 154.9 (CO(BOC)); 170.3 (CO_2); 170.5 (CON).] This compound was then placed into 4.2 mL (54.5 mmol) of trifluoroacetic acid (TFA; Aldrich) for 1 h at room temperature (RT). Excess TFA was eliminated by evaporation with cyclohexane, giving 126 mg (0.22 mmol, 100%) of **1** as a colorless oil. [TLC ($CHCl_3$/CH_3OH, 95/5, ninhydrin): $R_f = 0.6$. ^{1}H NMR ($CDCl_3$): 0.83 (t, 6H, J = 6.0 Hz, CH_3), 1.05−1.75 (m, 48H, (CH_2)$_{12}$), 2.70−3.60 (m, 6H, CH_2N, CH_2CH), 4.55−4.75 (m, 1H, CH), 5.08 (m, 2H, CH_2Ph), 7.28 (s, 5H, Ph). ^{13}C NMR ($CDCl_3$): 14.2 (CH_3); 22.8 (CH_2CH_3); 26.9, 27.1, 27.3, 28.8, 29.3, 29.5, 29.6, 29.8 ((CH_2)$_{11}$); 32.0 ($CH_2CH_2CH_3$); 35.4 (CH_2CO); 46.7, 47.3, 48.0 (CH_2N,CH_2Ph); 67.7 (CH); 128.7 (CH=CH(Ph)); 135.1 (C=CH(Ph)); 161.9 (q, $^2J_{CF}$ = 35 Hz, CF_3CO_2); 167.1 (CO_2); 169.7 (CON).]

3-Mercaptopropanamide-Asp(OBzl)-N,N-ditetradecanamide, [I(Asp(OBzl))-SH]. To 154 mg (0.21 mmol) of **1** were added 0.1 mL (0.72 mmol) of NEt_3 and 2 mL (0.30 mmol) of a 0.15 M 3-mercaptopropionic acid (Aldrich) in CH_2Cl_2. After being cooled to 0 °C, 45 mg (0.33 mmol) of HOBt (Sigma), then 64 mg (0.33 mmol) of EDC (Aldrich), and 1 mL of CH_2Cl_2 were added. After 17 h at RT, $CHCl_3$ was added, and the organic phase was washed successively with $NaHCO_3$ 8%, $KHSO_4$ 5%, and then H_2O. After being dried over Na_2SO_4, evaporation, and chromatography (CH_2Cl_2/hexane, 8/2, v/v to CH_2Cl_2), one obtained 65 mg (0.09 mmol, 43%) of I(Asp(OBzl))-SH as a colorless oil. [TLC ($CHCl_3$, ninhydrin, DTNB): $R_f = 0.2$. ^{1}H NMR ($CDCl_3$): 0.80 (t, 6H, J = 6.0 Hz, CH_3), 1.05−1.75 (m, 48H, (CH_2)$_{12}$), 1.49 (t, 1H, J = 8.2 Hz, SH), 2.39 (t, 2H, J = 6.5 Hz, CH_2CONH), 2.50−2.90 (m, 4H, CH_2SH, CH_2CH), 3.00−3.45 (m, 4H, CH_2N), 5.02 (s, 2H, CH_2Ph), 5.22 (td, 1H, J = 7.5 Hz and J = 6.5 Hz, CH), 6.94 (t, 1H, J = 6.5 Hz, NH), 7.26 (s, 5H, Ph). ^{13}C NMR ($CDCl_3$): 14.2 (CH_3); 20.4 (CH_2SH); 22.8 (CH_2CH_3); 26.9, 27.1, 29.3, 29.5, 29.8 ((CH_2)$_{11}$); 32.0 ($CH_2CH_2CH_3$); 38.2 (CH_2CO_2); 40.2 (CH_2-CONH); 46.0, 46.6, 48.2 (CH_2N, CH_2Ph); 66.8 (CH); 128.4, 128.5, 128.6 (CH=CH(Ph)); 135.7 (C=CH(Ph)); 170.1, 170.3 (CO).]

Synthesis of Telogen I(His(BOC))-SH. *H-His(BOC)-N,N-dioctadecanamide, (**2**).* To a solution of 500 mg (1.04 mmol) of Fmoc-His(BOC)-OH (Bachem) in 2 mL of $CHCl_3$ were added 0.15 mL (1.04 mmol) of NEt_3 and 488 mg (1.04 mmol) of PyBrop and then 1.09 g (2.09 mmol) of dioctadecylamine (Fluka) in 15 mL $CHCl_3$. The resulting mixture was stirred for 4 h at RT. The organic phase was washed with H_2O, dried over Na_2SO_4, concentrated, and then chromatographed ($CHCl_3$), yielding 550 mg (0.56 mmol, 53%) of Fmoc-His(BOC)-*N,N*-dioctadecanamide as a colorless oil. [TLC ($CHCl_3$/CH_3OH, 99/1, $KMnO_4$): R_f = 0.7. ^{1}H NMR ($CDCl_3$): 0.84 (t, 6H, J = 6.0 Hz, CH_3), 1.05−1.50 (m, 64H, (CH_2)$_{16}$), 1.50−1.80 (m, 9H, Me-(BOC)), 2.75−3.70 (m, 6H, CH_2N, CH_2im), 4.10−4.45 (m, 3H, CH_2CH(Fmoc)), 4.94 (td, 1H, J = 8.0 Hz, J = 8.7 Hz, $CHCH_2$im), 5.90 (d, 1H, J = 8.7 Hz, NH), 7.15 (s, 1H, CH=C(im)), 7.05−7.45 (m, 4H, Fmoc), 7.55 (d, 2H, J = 8.0 Hz, Fmoc), 7.70 (d, 2H, J = 8.0 Hz, Fmoc), 7.96 (s, 1H, CH=N(im)). ^{13}C NMR ($CDCl_3$): 14.2 (CH_3); 22.7 (CH_2CH_3); 27.9 (Me(BOC)); 27.0, 27.1, 27.7, 29.5, 29.8 ((CH_2)$_{14}$); 32.0 ($CH_2CH_2CH_3$); 33.0 (CH_2im); 46.4, 47.3 (CH_2NCO); 48.0 (CH_2CH(Fmoc)); 51.1 ($CHCH_2$im); 67.2 (CH_2CH(Fmoc)); 85.4 (C(BOC)); 114.8 (CH=C(im)); 136.8 (CH=C(im)); 139.0 (CH=N(im)); 120.0, 125.3, 127.1, 127.7 (CH=CH(Fmoc)); 141.3, 144.1 (C=C(Fmoc)); 147.0 (CO(BOC)); 155.8 (CO(Fmoc)); 171.2 (CO).] Fmoc deprotection of 390 mg (0.39 mmol) of this compound was performed in 10 mL of a $^1/_2$ morpholine/DMF mixture at RT for 2 h, affording, after evaporation and chromatography of the residue ($CHCl_3$ to $CHCl_3$/CH_3OH, 99/1, v/v), 187 mg (0.24 mmol, 62%) of **2** as a colorless oil. [TLC ($CHCl_3$/CH_3OH, 9/1, UV, ninhydrin): $R_f = 0.5$. ^{1}H NMR ($CDCl_3$): 0.80 (t, 6H, J = 6.0 Hz, CH_3), 1.05−1.30 (m, 60H, (CH_2)$_{15}$), 1.30−1.45 (m, 4H, CH_2CH_2NCO), 1.45−1.60 (m, 9H, Me(BOC)), 2.50 and 2.85 (AB part of an ABX system, 2H, $^2J_{AB}$ = 14.0 Hz, $^3J_{AX}$ = 8.0 Hz, $^3J_{BX}$ = 5.5 Hz, CH_2im), 2.90−3.55 (m, 4H, CH_2NCO), 3.90 (X part, 1H,$^3J_{XB}$ = 8.0 Hz, $^3J_{XA}$ = 5.5 Hz, $CHCH_2$im), 7.10 (s, 1H, CH=C(im)), 7.98 (s, 1H, CH=N(im)).]

3-Mercaptopropanamide-His(BOC)-N,N-dioctadecanamide, (I(His(BOC))-SH). To a solution of 120 mg (0.16 mmol) of **2** in 1.5 mL of CH_2Cl_2 at 0 °C, were added 14 μL (0.15 mmol) of 3-mercaptopropionic acid, 23 mg (0.17 mmol) of HOBt, and 33 mg (0.17 mmol) of EDC. After 12 h at RT, $CHCl_3$ was added, and the organic phase was washed with 8% $NaHCO_3$ and H_2O and then dried over Na_2SO_4. After evaporation and chromatography (CH_2Cl_2 to CH_2Cl_2/Et_2O, 9/1, v/v), 31 mg (0.03 mmol, 23%) of I(His(BOC))-SH as a colorless oil was obtained. [TLC ($CHCl_3$/CH_3OH, 98/2, UV, DTNB, $KMnO_4$): $R_f = 0.4$. ^{1}H NMR ($CDCl_3$): 0.80 (t, 6H, J = 6.0 Hz, CH_3), 1.05−1.45 (m, 64H, (CH_2)$_{16}$), 1.45−1.75 (m, 9H, Me(BOC)), 2.35−2.55 (m, 2H, CH_2CO), 2.55−3.50 (m, 8H, CH_2im, CH_2SH, CH_2N), 5.00−5.30 (m, 1H, $CHCH_2$im), 6.70−6.85 (m, 1H, NH), 7.10 (s, CH=C(im)), 7.95 (s, CH=N(im)). ^{13}C NMR ($CDCl_3$): 14.2 (CH_3); 20.4 (CH_2SH); 22.8 (CH_2CH_3); 27.9 (Me(BOC)); 26.9, 27.1, 27.6, 29.4, 29.8 ((CH_2)$_{14}$); 32.0 ($CH_2CH_2CH_3$); 32.1 (CH_2im); 40.4 (CH_2CO); 46.4, 48.0 (CH_2N); 48.8 ($CHCH_2$im); 85.5 (C(BOC)); 114.7 (CH=C(im)); 136.8 (C=CH(im)); 138.8 (C=N(im)); 147.5 (CO(BOC)); 170.0, 170.8 (CO).]

Synthesis of Telogen. *6-Deoxy-6-thio-1,2:3,4-di-O-isopropylidene-D-galactopyranose, (PGal-SH).* To a solution of 1.2 g (4.7 mmol) of 1,2:3,4-di-*O*-isopropylidene-D-galactopyranose (Aldrich) in 120 mL of toluene were added 3.7 g (14.0 mmol) of PPh_3 (Aldrich), 1.0 g (14.0 mmol) of imidazole (Aldrich), and 2.4 g (9.4 mmol) of iodine (Aldrich). After 4 h of reflux, the reaction mixture was stirred with saturated $NaHCO_3$ for 5 min. Iodine was then added until the organic phase became yellow. After 15 min, the organic phase was extracted with $Na_2S_2O_3$ until decoloration, washed with H_2O, and then dried over Na_2SO_4. After evaporation, the residue was extracted with Et_2O, concentrated, and chromatographed (petroleum ether to petroleum ether/Et_2O, 7/3, v/v), yielding 1.6 g (4.2 mmol, 89%) of 6-deoxy-6-iodo-1,2:3,4-di-*O*-isopropylidene-D-galactopyranose as a pale-yellow powder. [TLC (petroleum ether/Et_2O, 1/1, H_2SO_4): $R_f = 0.9$. ^{1}H NMR ($CDCl_3$): 1.25, 1.27, 1.36, 1.46 (s, 12H, CH_3); 3.12 and 3.24 (AB part of an ABX system, 2H, $^2J_{AB}$ = 9.9 Hz, $^3J_{AX}$ = 6.9 Hz, $^3J_{BX}$ = 6.9 Hz, $GalH_6$); 3.85 (dt, 1H, $^3J_{AX}$ = 6.9 Hz, $^3J_{BX}$ = 6.9 Hz, $^3J_{5-4}$ = 1.8 Hz, $GalH_5$); 4.22 (dd, 1H, $^3J_{2-1}$ = 5.0 Hz, $^3J_{2-3}$ = 2.5 Hz, $GalH_2$); 4.32 (dd, 1H, $^3J_{4-3}$ = 7.8 Hz, $^3J_{4-5}$ = 1.8 Hz, $GalH_4$); 4.53 (dd, 1H, $^3J_{3-4}$ = 7.8 Hz, $^3J_{3-2}$ = 2.5 Hz, $GalH_3$); 5.46 (d, 1H, $^3J_{1-2}$ = 5.0 Hz, $GalH_1$). ^{13}C NMR ($CDCl_3$): 2.3 (CH_2I); 24.4, 24.8, 25.9, 26.0 (CH_3); 68.9 ($GalC_4$); 70.5 ($GalC_3$); 71.1 ($GalC_2$); 71.5 ($GalC_5$); 96.6 ($GalC_1$); 108.8, 109.5 ($C(CH_3)_2$).] A solution of this iodo derivative (200 mg, 0.54 mmol) and 123 mg of thiourea in 1 mL of CH_3CN and 1 mL of DMF was heated at 110 °C for 36 h until complete comsumption (TLC monitoring). Then, a solution of 50 mg (1.25 mmol) of NaOH in 0.5 mL of H_2O was added, and the resulting mixture was heated at 100 °C for 3 h. After evaporation, the residue was extracted with $CHCl_3$, and the organic

phase was washed with $KHSO_4$ (pH 5) and H_2O and then dried over Na_2SO_4. Chromatography of the residue (hexane/Et_2O, 95/5 to Et_2O, v/v) yielded 128 mg (0.23 mmol, 86%) of disulfide 6-6′-dithiobis(6-deoxy-1,2:3,4-di-*O*-isopropylidene-D-galactopyranose) as a white powder. Reduction of this disulfide was performed by stirring this powder with 107 mg (0.69 mmol) of DTT (Aldrich) and 0.1 mL (0.69 mmol) of NEt_3 in 1 mL of $CHCl_3$ for 3 h. Workup, as described for the disulfide, and chromatography (petroleum ether to petroleum ether/Et_2O, 95/5, v/v) yielded 107 mg (0.38 mmol, 72% with respect to the iodo derivative) of PGal-SH as a colorless oil. [TLC (petroleum ether/Et_2O, 7/3, DTNB, H_2SO_4): $R_f = 0.6$. ^{1}H NMR ($CDCl_3$): 1.22, 1.24, 1.33, 1.43 (s, 12H, CH_3); 1.48−1.56 (m, 1H, SH); 2.48−2.73 (m, 2H, $GalH_6$); 3.67 (td, 1H, $^3J_{5-6} = 6.9$ Hz, $^3J_{5-4} = 1.8$ Hz, $GalH_5$); 4.19−4.26 (m, 2H, $GalH_2$, $GalH_4$); 4.52 (dd, 1H, $^3J_{3-4} = 7.8$ Hz, $^3J_{3-2} = 2.5$ Hz, $GalH_3$); 5.42 (d, 1H, $^3J_{1-2} = 5.0$ Hz, $GalH_1$). ^{13}C NMR ($CDCl_3$): 24.2, 24.3 (CH_3); 24.8 ($GalC_6$); 25.8, 25.9 (CH_3); 69.7 ($GalC_4$); 70.4 ($GalC_3$); 70.7 ($GalC_2$); 71.1 ($GalC_5$); 96.4 ($GalC_1$); 108.5, 109.1 ($C(CH_3)_2$).]

Synthesis of Taxogen *N*-[2-(Dimethylaminoethyl)]-acrylamide (As Its HCl Salt), (B). A solution of 2 mL (18.3 mmol) of *N*,*N*-dimethylethylenediamine (Fluka) in 25 mL of CH_2Cl_2 was added dropwise, at 0 °C and over a 3 h period, to a solution of 2.2 mL (27.4 mmol) of acryloyl chloride in 18 mL of CH_2Cl_2. After 2 h at 0 °C and 2 h at RT, the mixture was evaporated to dryness, yielding taxogen **B** as a white powder which was used without further purification. [TLC ($CHCl_3$/CH_3OH, 6/4, UV, $KMnO_4$): $R_f = 0.4$. ^{1}H NMR (CD_3OD): 3.00 (s, 6H, CH_3); 3.40, 3.72 (t, t, 2H, 2H, $^3J = 6.0$ Hz, $NHCH_2CH_2N$); 5.77 (dd, 1H, $^2J = 3.8$, $^3J = 8.1$ Hz, CH_2=CH); 6.28 (dd, 1H, $^2J = 3.8$, $^3J = 17.0$ Hz, CH_2=CH); 6.38 (dd, 1H, $^3J = 8.1$, $^3J = 17.0$ Hz, CH_2=CH). ^{13}C NMR (CD_3OD): 34.2 (CH_2NH), 42.3 (CH_3), 56.7 (CH_2N), 126.0 (CH_2=CH), 130.1 (CH=CH_2), 167.5 (CO).]

Synthesis of Telomers I(Asp)-14,n_A(NH), I(His)-18,n_A(NH), Gal,n_A(NH), Gal(O),n_A(NH), and I-18,n_B(NMe). *General Procedure for the (Co)telomerization Reactions.* An acetonitrile (or methanol) solution of telogen I(Asp(OBzl))-SH, I(His(BOC))-SH, PGal-SH, or I-SH, and of taxogen **A** or **B** or of a mixture of **A** and **B** or **A** and **C**, at a fixed taxogen(s)/telogen molar ratio, was heated to 50 °C before the addition of AIBN ($^1/_4$ to $^1/_2$ equiv with respect to telogen). The reaction medium was stirred under reflux until the telogen had disappeared (followed by TLC/DTNB) (∼24 h). The solution was then concentrated and chromatographed on a silica column (eluent was $CHCl_3$ to $CHCl_3$/MeOH, 8/2, v/v; excluding telomers and cotelomers deriving from taxogen **B**) and fractionated by gel permeation chromatography on a Sephadex LH 20 column (Sigma) with $CHCl_3$ or MeOH as eluent. The structures were determined by ^{1}H and ^{13}C NMR and by mass spectrometry. The aDP*n* (=*n*) values were determined by ^{1}H NMR on each collected fraction.

General Procedure for the TFA Deprotection of the BOC-(Co)telomers. The deprotection of telomers I(His(BOC))-18,n_A(NHBOC), PGal,n_A(NHBOC), and PGal(O),n_A-(NHBOC) and of cotelomers I-18,n_A(NHBOC),n_B(NMe) and I-18,n_A(NHBOC),n_C(OH) was quantitatively achieved by dissolving and keeping these telomers in a large excess of TFA at RT for 1 h. The excess of TFA was removed by evaporation in the presence of cyclohexane and by gel permeation on a Sephadex LH20 column. The respective telomers I(His)-18,n_A(NH), Gal,n_A(NH), and Gal(O),n_A(NH) and cotelomers I-18,n(NH),n_B(NMe) and I-18,n(NH),n_C(OH) as their TFA salts were obtained in the form of white solids.

Synthesis of Telomers I(Asp(OBzl))-14,n_A(NHBOC) and I(Asp)-14,n_A(NH). The telomerization protocol applied to telogen I(Asp(OBzl))-SH (32 mg, 0.04 mmol) and taxogen **A** (195 mg, 0.91 mmol) at a taxogen/telogen molar ratio of 20, led, after chromatography and fractionation, to telomers I(Asp(OBzl))-14,20(NHBOC) (138 mg) and I(Asp(OBzl))-14,70(NHBOC) (64 mg) of aDP*n* = 20 and 70, respectively. The aDP*n*, determined by ^{1}H NMR, is equal to 3Hx/2Hz or to 2Hy/3Hz, with Hx and Hy being the integration of the signal corresponding to the taxogen ethyldiamido methylenes and BOC methyl groups, respectively, and Hz the integration of the signal corresponding to the telogen terminal methyl groups. Telomers I(Asp)-14,n_A(NH) were obtained quantitatively by simultaneous Bzl and BOC deprotection of telomers I(Asp(OBzl))-14,n_A(NHBOC), which was achieved by dissolving and keeping these telomers in a large excess of 30% HBr/AcOH (Aldrich) at 0 °C for 2 h.

I(Asp(OBzl))-14,20(NHBOC). ^{1}H NMR ($CDCl_3$): 0.80 (t, 6H, $J = 6.0$ Hz, CH_3), 1.05−1.20 (m, 44H, $(CH_2)_{11}$), 1.20−1.60 (m, (9*n* + 4)H, CH_2CH_2N, Me(BOC)), 1.60−2.90 (m, (3*n* + 7)H, CH_2CO, CH_2S, CH_2CHCO), 2.90−4.00 (m, (4*n* + 4)H, CH_2N, CH_2NHCO), 5.05 (s, 2H, CH_2Ph), 5.10−5.40 (m, 1H, CH), 5.40−6.50 (m, *n*H, NH), 7.30 (s, 5H, Ph). ^{13}C NMR ($CDCl_3$): 14.2 (CH_3); 22.7 (CH_2CH_3); 28.5 (Me(BOC)); 26.9, 27.0, 27.5, 29.3, 29.6 ($(CH_2)_{10}$); 31.9 ($CH_2CH_2CH_3$); 46.1, 46.7, 48.1 (CH_2N, CH_2Ph); 66.7 (CH); 79.5 (C(BOC)); 128.3, 128.5 (CH(Ph)); 135.6 (C(Ph)); 156.6 (CO(BOC)); 170.2 (CO); 175.9 (CHCONH). The resonances corresponding to the CH_2CH carbons appear as a large signal between 32 and 38 ppm and those corresponding to the CH_2CH and $NHCH_2CH_2NH$ carbons between 38 and 45 ppm. The CH_2S and CH_2CO signals are not detected.

I(Asp(OBzl))-14,70(NHBOC). ^{1}H NMR ($CDCl_3$) was identical to that of I(Asp(OBzl))-14,20(NHBOC) but with $n = 70$.

I(Asp)-14,20(NH). ^{1}H NMR (CD_3OD): 0.90 (t, 6H, $^3J = 6.0$ Hz, CH_3), 1.05−1.30 (m, 44H, $(CH_2)_{11}$), 1.40−2.15 (m, (2*n* + 2)H, CH_2CH_2N, CH_2CHCO), 2.15−3.00 (m, (*n* + 9)H, CH_2CO, CH_2S, CH_2CHCO), 3.00−3.40 (m, (2*n* + 4)H, CH_2N, CH_2NHCO), 3.40−3.90 (m, 2*n*H, $CH_2NH_3^+$), 5.00−5.20 (m, 1H, CH). ^{13}C NMR (CD_3OD): 14.4 (CH_3); 23.6 (CH_2CH_3); 30.4, 30.7 ($(CH_2)_{10}$); 33.0 ($CH_2CH_2CH_3$); 38.4 (CH_2NHCO); 40.8 ($CH_2NH_3^+$); 178.3 (CHCONH). The resonances corresponding to the CH_2CH carbons appear as large signals between 32 and 38 ppm and between 40 and 45 ppm, respectively. The $COCH_2CH_2$-SCH_2 and $COCHCH_2CO$ signals are not detected.

I(Asp)-14,70(NH). ^{1}H NMR (D_2O): identical to that of I(Asp)-14,20(NH) but with $n = 70$. ^{13}C NMR (D_2O): 37.0 (CH_2NHCO), 38.9 ($CH_2NH_3^+$), 42.6 (CH_2CHCO), 177.2 (CONH). The resonances corresponding to the CH_2CH carbons appear as large signals between 32 and 38 ppm. The $COCH_2CH_2SCH_2$, $CH_3(CH_2)_{13}N$, and $COCHCH_2CO$ signals are not detected.

Synthesis of Telomers I(His(BOC))-18,n_A(NHBOC) and I(His)-18,n_A(NH). When applied to telogen I(His(BOC))-SH (20 mg, 0.02 mmol) and taxogen **A** (202 mg, 0.94 mmol) at a taxogen/telogen molar ratio of 40, the telomerization procedure yielded telomers I(His(BOC))-18,20(NHBOC) (26 mg), I(His(BOC))-18,30(NHBOC) (40 mg), and I(His(BOC))-18,90(NHBOC) (156 mg) of aDP*n* = 20, 30, and 90, respectively. The determination of aDP*n*, by ^{1}H NMR, was performed as those for telomers I(Asp(OBzl))-14,n_A(NHBOC). Deprotection of telomers I(His(BOC))-18,n_A(NHBOC) with TFA afforded telomers I(His)-18,n_A(NH).

I(His(BOC))-18,n_A(NHBOC), n_A = 20, 30, and 90. ^{1}H NMR ($CDCl_3$): 0.81 (t, 6H, J = 6.0 Hz, CH_3), 1.10−1.75 (m, 60H, $(CH_2)_{15}$), 1.40−1.80 (m, (9n + 13)H, CH_2CH_2N, Me(BOC)), 1.80−3.50 (m, (7n + 11)H, CH_2CO, CH_2S, CH_2im, CH_2N, CH_2CHCO, CH_2NHCO), 4.90−6.50 (m, (n + 1)H, CH, NH(BOC)), 6.5−8.0 (m, (n + 2)H, NH, im).

I(His)-18,n_A(NH) with n_A = 20, 30, and 90. ^{1}H NMR (CD_3OD): 0.87 (t, 6H, J = 6.0 Hz, CH_3), 1.10−1.40 (m, 60H, $(CH_2)_{15}$), 1.40−1.80 (m, 4H, CH_2CH_2N), 1.80−3.50 (m, (7n + 11)H, CH_2CO, CH_2S, CH_2im, CH_2N, CH_2CHCO, CH_2NHCO, C$H_2NH_3^+$), 4.90−5.20 (m, 1H, CH).

n_A = 20. ^{13}C NMR (CD_3OD): 14.1 (CH_3); 22.7 (CH_2CH_3); 26.9, 27.1, 27.7, 29.4, 29.7 ($(CH_2)_{14}$); 32.0 (CH_2CH_2CH_3); 37.5 (CH_2NHCO); 39.9 ($CH_2NH_3^+$); 47.0, 48.5 (CH_2N, CH); 118.0 (CH=C(im)); 118.3 (q, $^1J_{CF}$ = 292 Hz, CF_3); 134.0 (CH=C(im), CH=N(im)); 163.0 (q, $^2J_{CF}$ = 35 Hz, $CF_3CO_2^-$); 170.3, 171.1 (CO); 177.5 (CHCONH). The resonances corresponding to the CH_2CH carbons appear as large signals between 32 and 38 ppm, and between 40 and 45 ppm, respectively. The CH_2CO, CH_2S, and CH_2im signals are not detected.

n_A = 30 and 90. ^{13}C NMR (CD_3OD): 37.1 (CH_2NHCO), 39.7 ($CH_2NH_3^+$), 118.3 (q, $^1J_{CF}$ = 292 Hz, CF_3), 163.0 (q, $^2J_{CF}$ = 35 Hz, $CF_3CO_2^-$), 177.6 (CHCONH). The resonances corresponding to the CH_2CH carbons appear as large signals between 32 and 38 ppm and between 40 and 45 ppm, respectively. The $COCH_2CH_2SCH_2$, CH_3-$(CH_2)_{13}N$, and $COCHCH_2im$ signals are not detected.

Synthesis of Telomers PGal,n_A(NHBOC), PGal(O),n_A(NHBOC), Gal,n_A(NH), and Gal(O),n_A(NH), with n_A = 15 and 30. When applied to telogen PGal-SH (16 mg, 0.06 mmol) and taxogen **A** (250 mg; 0.12 mmol) at a taxogen/telogen molar ratio of 20, the telomerization protocol afforded telomers PGal,15(NHBOC) (205 mg) and PGal,30(NHBOC) (46 mg) of aDPn = 15 and 30, respectively. The aDPn, as determined by ^{1}H NMR, is equal to 5Hx/2Hz or to 5Hy/9Hz, with Hx and Hy being the integration of the signal corresponding to the taxogen ethyldiamido methylenes and BOC methyl groups, respectively, and Hz the integration of the signal corresponding to the galactosyle CH protons groups.

Oxidation of telomers PGal,n_A(NHBOC) in commercial diethyl ether under oxygen afforded quantitatively telomers PGal(O),n_A(NHBOC). Their oxidation was attested by ESI-MS.

Deprotection of PGal,n_A(NHBOC) and PGal(O),n_A-(NHBOC) with TFA afforded Gal,n_A(NH) and Gal(O),n_A-(NH), respectively.

PGal,n_A(NHBOC) and PGal(O),n_A(NHBOC), with n_A = 15 and 30. ^{1}H NMR ($CDCl_3$): 1.00−1.60 (m, (9n + 12)H, CH_3), 1.60−2.60 (m, (3n − 1)H, CH_2CHCO), 2.60−4.00 (m, (4n + 4)H, CH_2S, CH_2NHCO), 4.05−4.15 (m, 1H, $GalH_5$), 4.15−4.35 (m, 2H, $GalH_2$, $GalH_4$), 4.55−4.65 (m, 1H, $GalH_3$), 5.40−5.50 (m, 1H, $GalH_1$), 5.50−6.50 (m, nH, NH). ^{13}C NMR ($CDCl_3$): 24.4, 25.1, 26.0 ($(CH_3)_2$C); 28.5 (Me(BOC)); 70.5, 70.9, 71.8, 71.9 ($GalC_2$, $GalC_3$, $GalC_4$, $GalC_5$); 96.4 ($GalC_1$); 79.5 (C(BOC)); 108.6, 109.3 (C$(CH_3)_2$); 156.7 (CO(BOC)); 176.1 (CHCONH). The resonances corresponding to the CH_2CH carbons appear as large signals between 32 and 38 ppm and those corresponding to the CH_2CH and CH_2NHCO between 40 and 45 ppm. The CH_2S signals are not detected. ESI-MS of PGal,15(NHBOC) shows the presence of compounds with n = 2 to 21 [m/z = (276.3 + 214.2n + 23) with n = 2 to 10 in agreement with the masses calculated for $[C_{12}H_{20}O_5S + n(C_{10}H_{18}N_2O_3) + Na^+]$ and n = 2 to 10; m/2z = (138.1 + 107.1n + 23) with n = 7 to 21 in agreement with the masses calculated for $[C_{12}H_{20}O_5S + n(C_{10}H_{18}N_2O_3) + 2Na^+]/2$ and n = 7 to 21]. ESI-MS of PGal(O),15(NHBOC) shows the presence of compounds with n = 2 to 21 [m/z = (292.3 + 214.2n + 23) with n = 2 to 10 in agreement with the masses calculated for $[C_{12}H_{20}O_6S + n(C_{10}H_{18}N_2O_3) + Na^+]$ and n = 2 to 10; m/2z = (146.1 + 107.1n + 23) with n = 7 to 21 in agreement with the masses calculated for $[C_{12}H_{20}O_6S + n(C_{10}H_{18}N_2O_3) + 2Na^+]/2$ and n = 7 to 21].

Gal,n_A(NH) and Gal(O),n_A(NH), with n_A = 15 and 30. ^{1}H NMR (CD_3OD): 1.25−2.05 (m, (2n − 2)H, CH_2CHCO), 2.05−2.95 (m, (n + 5)H, CH_2S, CH_2CHCO), 2.95−3.90 (m, 4nH, NHCH_2C$H_2NH_3^+$). The $GalH_X$ resonances are not detected. ^{13}C NMR (CD_3OD): 38.3 (CH_2NHCO); 40.4 ($CH_2NH_3^+$), 118.3 (q, $^1J_{CF}$ = 292 Hz, CF_3), 163.0 (q, $^2J_{CF}$ = 35 Hz, $CF_3CO_2^-$), 178.0 (CHCONH). The resonances corresponding to the CH_2CH carbons appear as large signals between 32 and 38 ppm and between 40 and 45 ppm, respectively. The $GalC_X$ and CH_2S signals are not detected.

Synthesis of Telomers I-18,35(NMe) and I-18,80(NMe). When applied to telogen I-SH (112 mg, 0.18 mmol) and taxogen **B** (164 mg, 0.92 mmol) at a taxogen/telogen molar ratio of 5, the telomerization protocol afforded, after purification and fractionation on a Sephadex LH20 column (MeOH), telomers I-18,35(NMe) (37 mg) and I-18,80(NMe) (114 mg) of aDPn = 35 and 80, respectively. The aDPn, as determined by ^{1}H NMR, is equal to 3Hx/2Hz or to Hy/Hz, with Hx and Hy being the integration of the signal corresponding to the taxogen NCH_2CH_2N methylenes and N-methyl groups, respectively, and Hz the integration of the signal corresponding to the telogen terminal methyl protons. These telomers were isolated as their Cl^- salts.

I-18,n_B(NMe), with n_B = 35 and 80. ^{1}H NMR ($CDCl_3$ + CD_3OD): 0.80 (t, 6H, J = 6.0 Hz, CH_3), 1.10−1.30 (m, 60H, $(CH_2)_{15}$), 1.30−1.90 (m, (2n + 2)H, CH_2CH_2N, CH_2CHCO), 1.90−2.80 (m, (n + 7)H, CH_2S, CH_2CO, CH_2CHCO), 2.80−3.10 (m, 6nH, NMe), 3.10−4.00 (m, (4n + 4)H, CH_2N, CH_2NHCO). ^{13}C NMR ($CDCl_3$ + CD_3OD): 14.6 (CH_3); 23.7 (CH_2CH_3); 27.1, 28.1, 28.8, 30.4, 30.7 ($(CH_2)_{14}$); 33.0 (CH_2CH_2CH_3); 36.0 (CH_2NHCO); 44.2 (NMe); 58.1 (CH_2NMe); 177.8 (CHCONH). The resonances corresponding to the CH_2CH carbons appear as large signals between 32 and 38 ppm and between 40 and 45 ppm, respectively. The CH_2S, CH_2N, and CH_2CO signals are not detected.

Synthesis of Cotelomers I-18,n_A(NHBOC)-n_B(NMe) and I-18,n_A(NH)-n_B(NMe). *Cotelomer I-18,8(NHBOC)-17(NMe).* The general telomerization protocol, when applied to telogen I-SH (40 mg, 0.06 mmol) and taxogens **A** (140 mg, 0.65 mmol in 2 mL of CH_3CN) and **B** (117 mg, 0.65 mmol, 1 mL of CH_3OH) (i.e., at a taxogen **A** (or **B**)/telogen molar ratio of 10) afforded, after purification on a Sephadex LH20 column ($CHCl_3$), cotelomer I-18,8(NHBOC)-17(NMe) (282 mg) as a white powder.

Cotelomer I-18,10(NHBOC)-1(NMe). (555 mg) was obtained, using the telomerization protocol from telogen I-SH (129 mg, 0.21 mmol), taxogens **A** (455 mg, 2.12 mmol) and **B** (38 mg, 0.21 mmol) (i.e., taxogen **A**/telogen and taxogen **B**/telogen of 10 and 1, respectively).

The aDPn_A and aDPn_B values, as determined by ^{1}H NMR, are equal to 2Hx/3Hz and to Hy/Hz, respectively, with Hx and Hy being the integration of the signal corresponding to the taxogen Me(BOC) and N-methyl groups, respectively, and Hz the integration of the signal corresponding to the telogen terminal methyl protons.

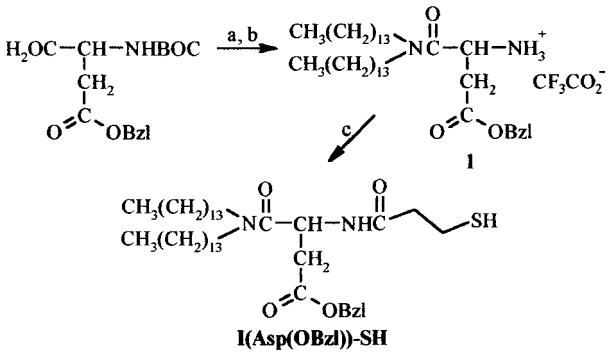
Cotelomers I-18,n_A(NH)-n_B(NMe) were obtained by deprotection of the BOC cotelomers in TFA using the general deprotection protocol. After an anion exchange

on a resin (TFA form), they were further purified on a Sephadex LH20 column and isolated as their TFA salts.

I-18,n_A(NHBOC)-n_B(NMe), with (n_A = 8, n_B = 17) and (n_A = 10, n_B = 1). ^{1}H NMR ($CDCl_3$): 0.88, (t, 6H, J = 6.0 Hz, CH_3), 1.05−1.30 (m, 60H, $(CH_2)_{15}$), 1.30−1.60 (m, ($9n_A$ + 4)H, CH_2CH_2N, Me(BOC)), 1.60−2.00 (m, ($2n_A$ + $2n_B$ − 2)H, CH_2CHCO), 2.00−2.85 (m, (n_A + n_B + 7)H, CH_2S, CH_2CO, CH_2CHCO), 2.85−3.05 (m, $6n_B$H, NMe), 3.05−3.90 (m, ($4n_A$ + $4n_B$ + 4)H, CH_2N, CH_2NHCO), 5.40−6.50 (m, n_AH, N*H*(BOC)). ^{13}C NMR ($CDCl_3$): 14.1 (CH_3); 22.7 (CH_2CH_3); 28.5 (Me(BOC)); 27.0, 27.1, 27.8, 29.4, 29.7 ($(CH_2)_{14}$); 31.9 ($CH_2CH_2CH_3$); 43.9 (NMe); 46.3, 48.2 (CH_2N); 58.1 (CH_2NMe); 79.4 (C(BOC)); 156.6 (CO(BOC)); 175.9 (CHCONH). The resonances corresponding to the CH_2CH carbons appear as a large signal between 32 and 38 ppm and those corresponding to the CH_2CH and $NHCH_2CH_2NHBOC$ between 38 and 45 ppm. The CH_2S and CH_2CO signals are not detected.

I-18,n_A(NH)-n_B(NMe), with (n_A = 8, n_B = 17) and (n_A = 10, n_B = 1). ^{1}H NMR (CD_3OD): 0.95 (t, 6H, J = 6.0 Hz, CH_3), 1.15−1.45 (m, 60H, $(CH_2)_{15}$), 1.45−2.00 (m, ($2n_A$ + $2n_B$ + 2)H, CH_2CH_2N, CH_2CHCO), 2.00−2.90 (m, (n_A + n_B + 7)H, CH_2S, CH_2CO, CH_2CHCO), 2.90−3.05 (m, $6n_B$H, NMe), 3.05−3.90 (m, ($4n_A$ + $4n_B$ + 4)H, CH_2N, CH_2NHCO). ^{13}C NMR (CD_3OD): 14.4 (CH_3); 23.6 (CH_2-CH_3); 27.7, 27.9, 30.3, 30.4, 30.7 ($(CH_2)_{14}$); 33.0 (CH_2CH_2-CH_3); 35.7, 38.2 (CH_2NHCO); 40.4 ($CH_2NH_3^+$); 43.8 (NMe); 58.0 (CH_2NMe); 118.0 (q, $^1J_{CF}$ = 292 Hz, CF_3); 162.8 (q, $^2J_{CF}$ = 35 Hz, $CF_3CO_2^-$); 177.9 (CHCONH). The resonances corresponding to the CH_2CH carbons appear as a large signal between 32 and 38 ppm and between 38 and 45 ppm, respectively. The CH_2S, CH_2N, and CH_2CO signals are not detected.

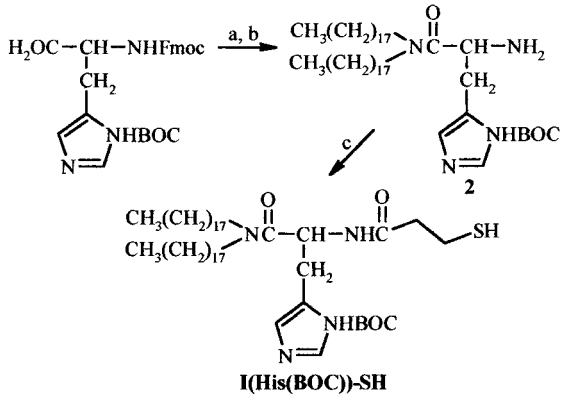
Synthesis of Cotelomers I-18,10(NHBOC)-10(OH) and I-18,10(NH)-10(OH). The general telomerization protocol when applied to telogen I-SH (57 mg, 0.09 mmol) and taxogens **A** (200 mg, 0.93 mmol) and **C** (163 mg, 0.93 mmol) (i.e., at a taxogen **A** (or **C**)/telogen molar ratio of 10) afforded, after purification on a Sephadex LH20 column (CH_3OH), cotelomer I-18,10(NHBOC)-10(OH) (369 mg) as a white powder. The aDPn_A and aDPn_C values, as determined by ^{1}H NMR, are equal to 2Hx/3Hz and to Hy/Hz, respectively, with Hx and Hy being the integration of the signal corresponding to the taxogen **A** BOC methyl group and taxogen **C** methylene CH_2OH groups, respectively, and Hz the integration of the signal corresponding to the telogen terminal methyl protons.



Cotelomer I-18,10(NH)-10(OH) was obtained by deprotection of the BOC cotelomer in TFA using the general TFA deprotection protocol.

I-18,10(NHBOC)-10(OH). ^{1}H NMR (CD_3OD): 0.88, (t, 6H, J = 6.0 Hz, CH_3), 1.15−1.35 (m, 60H, $(CH_2)_{15}$), 1.35−2.00 (m, ($11n_A$ + $2n_C$ + 2)H, CH_2CH_2N, CH_2CHCO, Me(BOC)), 2.00−3.00 (m, (n_A + n_C + 7)H, CH_2S, CH_2CO, CH_2CHCO), 3.00−3.50 (m, ($4n_A$ + 4)H, CH_2N, CH_2NHCO), 3.60−4.10 (m, $6n_C$H, CH_2OH) with n_A = 10 and n_C = 10. ^{13}C NMR (CD_3OD): 14.4 (CH_3); 23.7 (CH_2CH_3); 28.9 (Me(BOC)); 28.0, 30.4, 30.7 ($(CH_2)_{14}$); 33.0 ($CH_2CH_2CH_3$); 40.6, 41.0 (CH_2NHCO); 62.4, 63.9 ($C-CH_2OH$); 80.3 (C(BOC)); 158.4 (CO(BOC)); 177.5 (CHCONH). The resonances corresponding to the CH_2CH carbons appear as a large signal between 32 and 38 ppm and between 42 and 45 ppm, respectively. The CH_2S, CH_2CO, and CH_2N signals are not detected.

I-18,10(NH)-10(OH). ^{1}H NMR (CD_3OD): 0.90 (t, 6H, J = 6.0 Hz, CH_3); 1.15−1.40 (m, 60H, $(CH_2)_{15}$), 1.45−2.05 (m, ($2n_A$ + $2n_C$ + 2)H, CH_2CH_2N, CH_2CHCO), 2.05−3.00 (m, (n_A + n_C + 7)H, CH_2S, CH_2CO, CH_2CHCO), 3.00−3.25 (m, $2n_A$H, CH_2NHCO), 3.25−4.00 (m, ($2n_A$ + $6n_C$ + 4)H, CH_2N, $CH_2NH_3^+$, CH_2OH) with n_A = 10 and n_C = 10. ^{13}C NMR (CD_3OD): 15.8 (CH_3); 25.1 (CH_2CH_3); 29.2, 29.4, 31.8, 32.1, 32.2 ($(CH_2)_{14}$); 34.5 ($CH_2CH_2CH_3$); 39.7 (CH_2NHCO); 41.8 ($CH_2NH_3^+$); 62.8, 64.0, 65.2 ($C-CH_2OH$); 119.5 (q, $^1J_{CF}$ = 292 Hz, CF_3); 164.3 (q, $^2J_{CF}$ = 35 Hz, $CF_3CO_2^-$); 179.8 (CHCONH). The resonances corresponding to the CH_2CH carbons appear as a large signal between 35 and 39 ppm and between 43 and 46 ppm, respectively. The CH_2S, CH_2N, and CH_2CO signals are not detected.



Preparation of Complexes Composed of the Polyamine Telomer Compounds and Plasmid pTG11033. The plasmid pTG11033 was produced by Transgène SA (Strasbourg, France). The endotoxin content of the plasmid preparation was checked using a Limulus Amebocyte Lysat kit (Biogenic, France). This value was below 1 endotoxin unit (e.u.)/mg of plasmid, hence below the 5 e.u./mg of DNA recommended for in vivo protocols. The

[b] *N* = amine equivalents, *P* = plasmid phosphate equivalents. [c] Percent (%) of the overall population. [d] p = precipitate. [e] nt = not tested. [a] All of the (co)telomers listed in this table led with plasmid pTG11033 to precipitates for *N*/*P* 1.25, whether used alone or with DOPE.

desired volume of DNA solution to reach desired DNA concentration (for example, 0.1 mg/mL), as described in ref *12*. When the composition further comprises DOPE, the desired volume of a DOPE solution (10 mg/mL) in chloroform (to get mol/mol cationic telomer/DOPE) was added to the volume of polyamine (co)telomer solution (10 mg/mL in $CHCl_3$). The mixture was then transferred to a borosilicate glass tube and evaporated. The film thus obtained was dissolved in DMSO/EtOH and diluted in a 20 mM HEPES buffer to obtain a preparation at a (co)telomer concentration of 10 mg/mL, containing 10% DMSO and 10% EtOH.

Measurement of the Size of the (Co)teloplexes. The average sizes were measured by photon correlation spectroscopy using a Coulter N4Plus particle size analyzer. The analyses were performed at 25 °C, after equilibrating the sample at 25 °C for 20 min. The sample was diluted with a 20 mM HEPES in the measurement tube and homogenized. These analysis were carried out on complexes having a 20 μg/mL concentration of DNA. The formulations and analyses were reproduced twice.

Agarose Gel Electrophoresis. Each sample (0.5 μg of plasmid) was analyzed by electrophoresis for about 90 min under 75 V/cm through a 0.8% agarose gel in TAE 1x (Tris−acetate−EDTA) buffer. The DNA was visualized in 400 mL of a TAE buffer containing 40 μL of ethidium bromide (Sigma; 10 mg/mL). The plasmid integrity in each sample (0.25 μg) was confirmed by electrophoresis after decomplexing the lipoplex (10 μL of a plasmid 0.05 mg/mL) with sodium dodecyl sulfate, SDS (10 μL, 80 g/L).

In Vitro Transfection of A549 cells. Twenty-four hours before transfection, A549 cells (epithelial cells derived from human pulmonary carcinoma) were grown in Dulbeco-modified Eagle culture medium (DMEM),

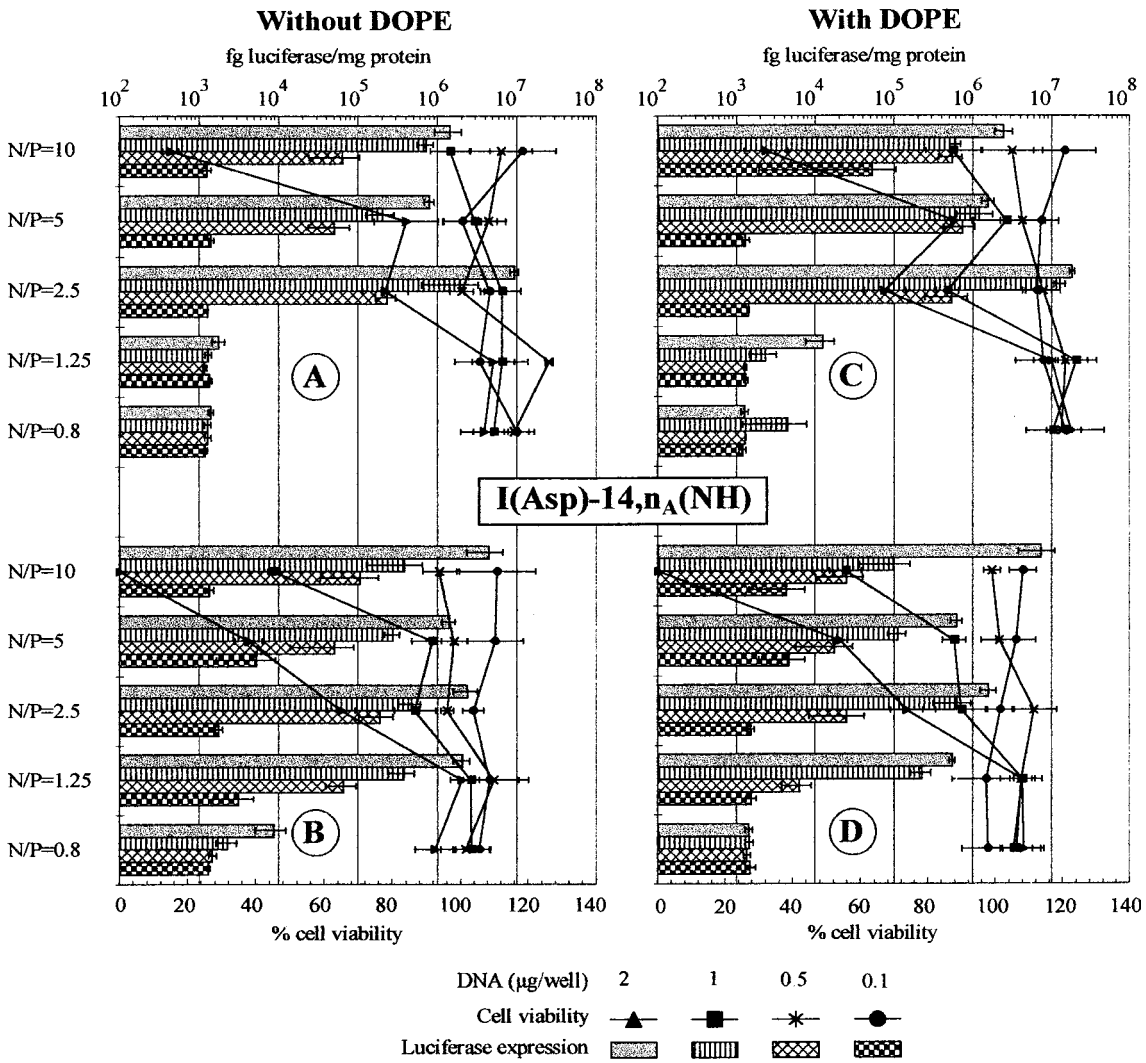

Figure 2. Luciferase expression (bars) and cell viability (points) of the pTG11033 teloplexes made with I(Asp)-14,n_A(NH) telomers or with I(Asp)-14,n_A(NH)/DOPE (1/1 mol) lipids (A and C, $n_A = 20$; B and D, $n_A = 70$) in A549 cells. Means ± SEM are given.

containing 1% glutamine (200 mM; Sigma), 0.4% gentamicine (10 μg/mL; Sigma), and 10% fetal calf serum, FCS (Gibco BRL) in 96-well plates (2×10^4 cells per well), in a wet (37 °C), and 5% CO_2/95% air atmosphere. The volume of the DNA/polyamine telomer complex (20, 10, 5, and 1 μL, respectively) was diluted to 100 μL in DMEM supplemented with 10% FCS in order to obtain various amounts of DNA (2, 1, 0.5, and 0.1 μg, respectively) in the preparation. The culture medium was removed and replaced by 100 μL of DMEM supplemented with 10% FCS and containing the desired amount of DNA. After 4 and 24 h, 50 and 100 μL of DMEM supplemented with 30% and 10% FCS, respectively, were added.

Forty-eight hours after transfection, the culture medium was discarded, and the cells were washed with 100 μL of PBS and then lysed with 50 μL of a lysis buffer (Promega). The lysates were frozen at −32 °C, awaiting the analysis of luciferase activity. This measurement was done for 10 s on 10 μL of the lysis mixture in a Berthold LB96P luminometer in dynamic mode, using the "Luciferase" determination system (Promega) in 96-well plates. The total protein concentration per well was determined using conventional techniques (BCA test; Pierce). For cells grown in the absence of DNA complexes, a well contains around 30−50 μg of proteins. Each (co)telomer/DNA complex was formulated twice, and each formulation was tested twice.

Statistical Analyses. Statistical analyses were performed using a Student *t* test. The difference between two means was considered as significant when the probability *p* is ≤ 0.05.

RESULTS AND DISCUSSION

Telogen Synthesis. Telomerization and cotelomerization reactions were performed with telogen I(Asp(OBzl))-SH, I(His(BOC))-SH, or PGal-SH (the syntheses of which are outlined in Schemes 1−3 respectively) or with I-SH whose synthesis has already been described (*12*).

I(Asp(OBzl))-SH (Scheme 1) was obtained in three steps by (i) condensing BOC-Asp(OBzl)-OH (activated by action of PyBrop) with ditetracylamine, then BOC-deprotection with TFA, followed by coupling to mercaptopropionic acid using HOBt/EDC as coupling reagents (30% overall yields). I(His(BOC))-SH (Scheme 2) was obtained from Fmoc-His(BOC)-OH using a similar strategy except the Fmoc deprotection step which was performed by action of morpholine (10% overall yields). The synthesis of PGal-SH (Scheme 3) was achieved starting from the isopropylidene-protected galactopyranose synthon, using a procedure described in the literature with some modifications (*16*). The free hydroxyl was first replaced by a iodo group by action of PPh_3/imidazole/I_2.

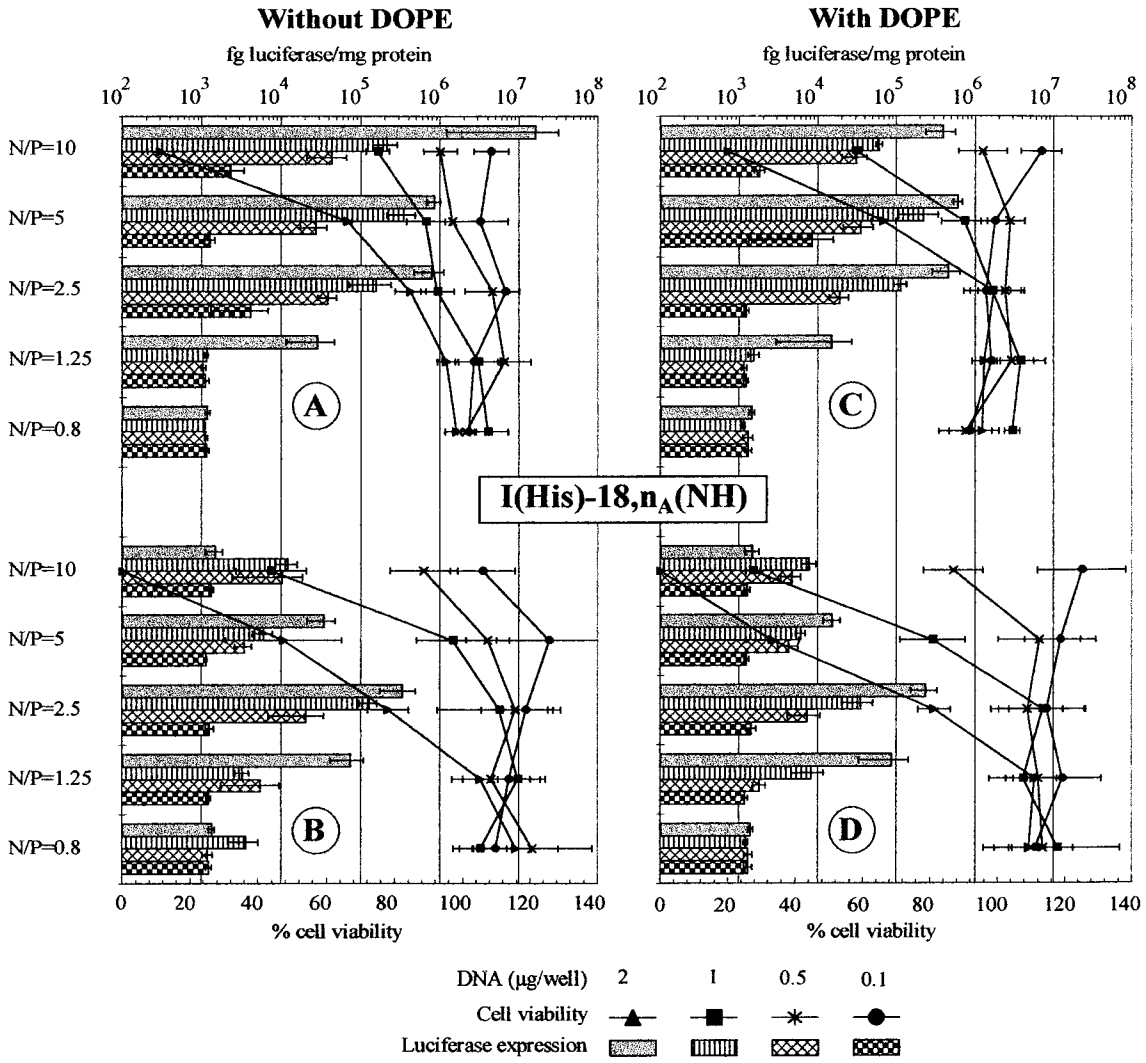

Figure 3. Luciferase expression (bars) and cell viability (points) of the pTG11033 teloplexes made with I(His)-18,n_A(NH) telomers or with I(His)-18,n_A(NH)/DOPE (1/1 mol) lipids (A and C, $n_A = 30$; B and D, $n_A = 90$) in A549 cells. Means ± SEM are given.

The iodo derivative was then converted into the corresponding disulfide by action of thiourea and oxidation and then into the PGal-SH thiol afterward by DTT reduction of disulfide.

Telomer and Cotelomer Synthesis. All telomerization and cotelomerization reactions (Schemes 4 and 5) were performed under nitrogen by refluxing in acetonitrile or in MeOH (i) taxogen **A** or **B** or a mixture of taxogens **A** and **B** or **A** and **C**, (ii) the thiols I(Asp(OBzl))-SH, I(His(BOC))-SH, PGal-SH, or I-SH in fixed taxogen/telogen concentration and ratio, and (iii) AIBN. At the end of the reaction, the solvent was evaporated under reduced pressure and the residue purified and fractionated by gel permeation chromatography on a Sephadex LH20 column and, when appropriate, chromatography on a silica column. This allows to separate the (co)telomers from AIBN and residual disulfide which has formed during telomerization. The *N*-BOC-telomers and cotelomers obtained from taxogen **A** and from telogen I(His(BOC))-SH, PGal-SH, or I-SH were deprotected in excess TFA at RT, and those obtained from telogen I(Asp(OBzl))-SH were deprotected in excess of HBr/AcOH. These (poly)cationic telomers and random cotelomers were isolated as TFA or Br salts by evaporation of excess reagent in the presence of cyclohexane followed by lyophilisation. Quantitative deprotection was confirmed by ^{1}H NMR (absence of the signal corresponding to the BOC and, when appropriate, Bzl protons of the starting material). For each telogen and taxogen(s), the different telomers isolated and their code name are reported in Table 1. Oxygen- and peroxide-free solvents were used throughout these experimental procedures in order to avoid oxidation of sulfur into sulfoxide in the (co)telomers. Oxidation of Gal,n_A(NHBOC) was indeed observed when these derivatives were placed in commercial diethyl ether, yielding Gal(O),n_A(NHBOC) (Scheme 4).

For each fraction collected, the average polymerization degrees (aDPn_A) of telomers resulting from taxogen **A** and the average copolymerization degrees (aDPn_A,n_B and aDPn_A,n_C) of cotelomers resulting from a mixture of taxogens **A** and **B** or **A** and **C**, respectively, were determined by ^{1}H NMR on the BOC-protected (co)telomers. The n_A, n_B, and n_C values were calculated by comparing the integration of the NCH_2CH_2NHBOC signals with that of (i) the terminal methyl chain protons, for the I(His)- and I(Asp)-based telomers, or the isopropylidene methyl and sugar CH protons, for the Gal-based telomers, (ii) the terminal methyl chain and NMe_2 protons for the cotelomers obtained from taxogen **A** and **B**, and (iii) the terminal methyl chain and methylene CH_2OH protons, for the cotelomers obtained from taxogen **A** and **C.** The aDPn_B values of telomers I-18,n_B(NMe) were also determined by ^{1}H NMR by comparing the integration of the NMe_2 protons with that of the terminal methyl chain

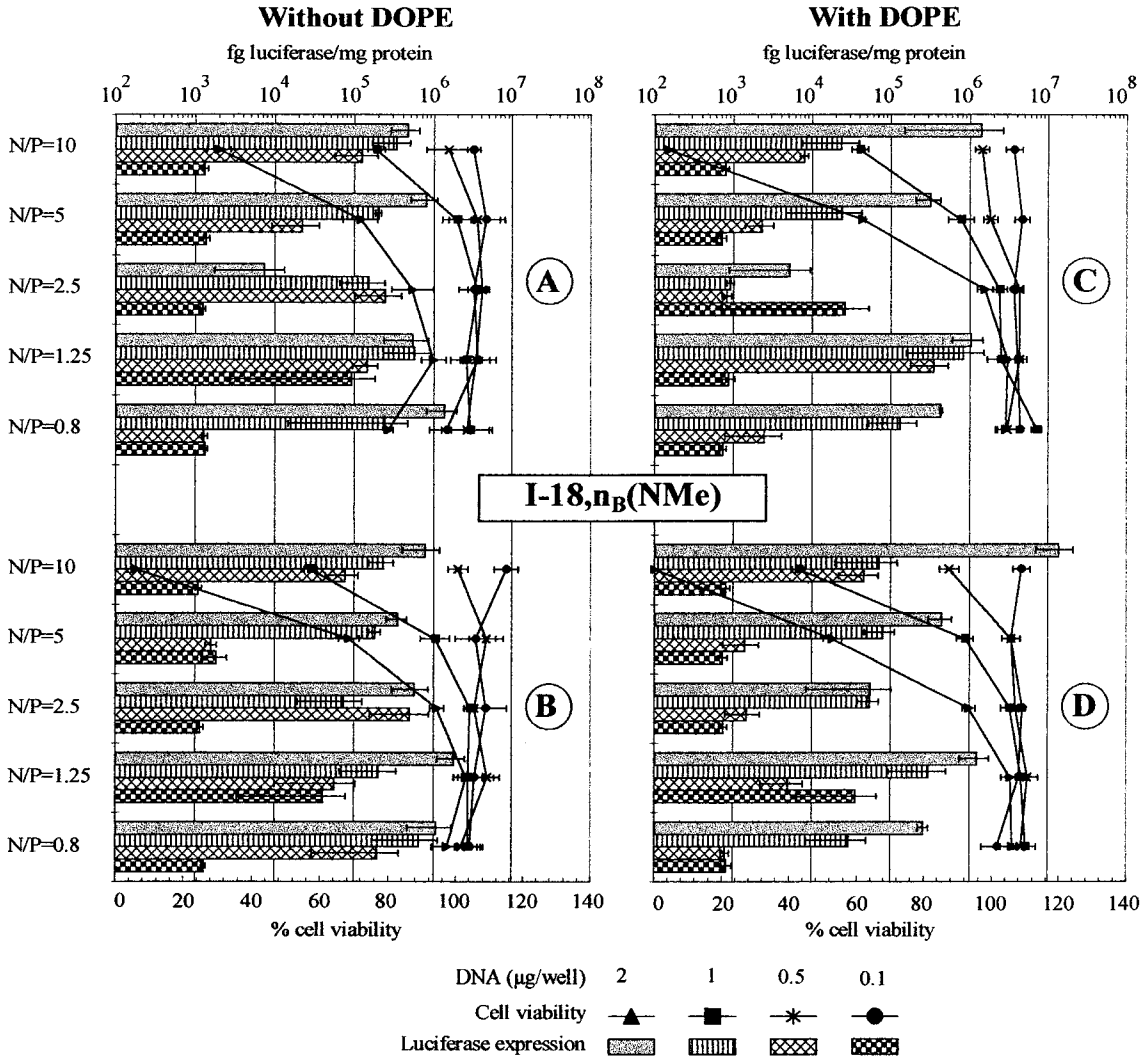

Figure 4. Luciferase expression (bars) and cell viability (points) of the pTG11033 teloplexes made with I-18,n_B(NMe) telomers or with I-18,n_B/(NMe)/DOPE (1/1 mol) lipids (A and C, $n_B = 35$; B and D, $n_B = 80$) in A549 cells. Means ± SEM are given.

protons. ESI-MS was further used to confirm the structure and polydispersity of the Gal-telomers and oxidation of sulfur into sulfoxide.

(Lipo)polyplex Formation and Characterization. The capability of the polyamine (co)telomers to condense DNA and to form (co)teloplexes was analyzed with or without an equimolar amount of the helper phospholipid DOPE except the Gal telomers which were used as unique component. The size of the DNA complexes (which is an important parameter to control when in vivo uses are contemplated or when their in vitro transfection efficiency is evaluated (*17*, *18*)) was analyzed by light scattering spectroscopy. These studies were performed with a pTG11033 plasmid, also used for the in vitro transfection assays described in the following paragraphs. The preparation of the (co)teloplexes relies on the dilution from a DMSO/EtOH lipo(co)telomer (and eventually DOPE) solution in a HEPES buffer (20 mM; pH 7.5) using *N*/*P* ratios of 10, 5, 2.5, 1.25, and 0.8 (*N* = number of amine functions of the (co)telomer, *P* = number of DNA phosphates). Table 2 collects the mean particle diameters measured for the different (co)teloplexes.

These formulations were also analyzed by gel electrophoresis, which showed the presence of fully complexed plasmid (not accessible to ethidium bromide) for all *N*/*P* 10 to 1.25 formulations and for the I-18,10(NH)-10(OH) *N*/*P* 0.8 one. Complexed DNA, but accessible to ethidium bromide, was detected, however, for the I-18,8(NH)-17(NMe) and I-18,n_B(NMe) *N*/*P* 0.8 formulations, while the presence of "free" DNA was also seen for the I(Asp)-14,n_A(NH), I(His)-18,n_A(NH), I-18,10(NH)-1(NMe), Gal,n_A(NH), and Gal(O),n_A(NH) *N*/*P* 0.8 formulations (data not shown). When gel electrophoresis of the (co)-teloplexes was performed in the presence of detergent SDS, dissociation of the complexes was observed in most cases except for teloplexes formulated with I(Asp)-14,70(NH), I(His)-18,90(NH), Gal,30(NH), and Gal(O),30(NH) whatever the *N*/*P* ratio and for teloplexes Gal,15(NH) and Gal(O),15(NH) for *N*/*P* ratios higher than 1.25. DOPE, when used as co-lipid with the lipo(co)-telomers for the formulation of the (co)teloplexes, had no effect neither on DNA complexation nor on complex dissociation by SDS.

Several conclusions concerning the influence of the (co)telomer molecular structure on the stability of the teloplexes with respect to dissociation initiated by SDS can be drawn from these experiments. As expected from the stronger phosphate/NH_3^+ interactions as compared with the phosphate/$NHMe_2^+$ ones, a greater stability was observed for the teloplexes formulated with the "NH_3^+" telomers than for those made from the "$NHMe_2^+$" telomers, whatever the polymerization degree of the telomer. However, the higher this polymerization degree, the higher the stability of the teloplexes. Indeed, teloplexes

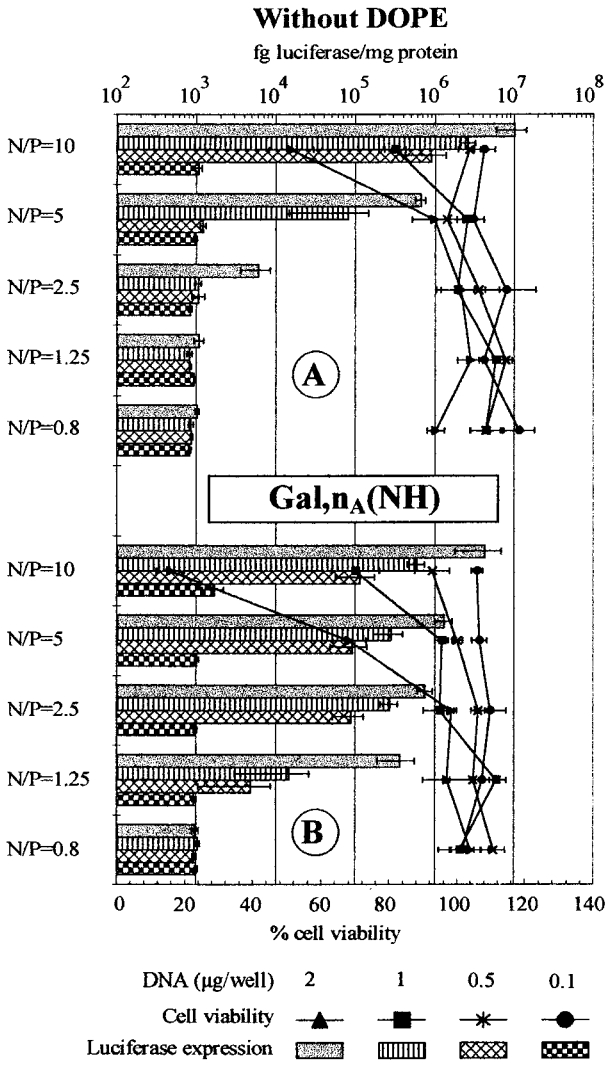

Figure 5. Luciferase expression (bars) and cell viability (points) of the pTG11033 teloplexes made with Gal,n_A(NH) telomers (A, $n_A = 15$; B, $n_A = 30$) in A549 cells. Means ± SEM are given.

formulated with telomers of aDP$n \geq 30$ were not dissociated in the presence of SDS. The stability of the teloplexes with respect to dissociation was further found to be unaffected by replacing part of the amino groups by the THM polyol residue and was increased by replacing the hydrophobic chains for the hydrophilic galactosyl residue.

Our particle size measurements showed a strong dependence of size and aggregation with the formulation's *N*/*P* ratio, as is generally found in the literature (*12*, *19*). For *N*/*P* ratios ≥ 2.5, most of the polyamine (co)telomer compounds were able, with or without the addition of an equimolar amount of DOPE, to condense DNA into (co)teloplexes of a mean size in the 100−450 nm range. In most cases, these preparations consisted further in a single population of particles. While precipitates were obtained for *N*/*P* 1.25 and frequently for *N*/*P* 2.5, larger-sized complexes (200−770 nm) were detected for *N*/*P* 0.8.

In terms of telomer chemical structure impact on teloplex size and stability (with respect to aggregation), the behavior of Gal,15(NH) telomers as compared to that of lipotelomers of similar polymerization degree is worth noting. Indeed, one often observed with Gal,15(NH) a polydisperse population of large-sized teloplexes that further tend to precipitate, while stable formulations were observed with the lipotelomers.

In Vitro Transfection. The transfection potency of the (co)telomers, with and without DOPE, was assayed in vitro on lung epithelial A549 cells, from human pulmonary carcinoma. Although transfection efficiencies with DNA complexes, including the first generation of teloplexes (*12*), are generally impaired in the presence of serum in the culture medium, these experiments were, nevertheless, run in the presence of 10% fetal calf serum. These assays were performed using the luciferase reporter plasmid pTG11033 (pCMV-intronHMG-luciferase-SV40pA; 9572 bp). All teloplex formulations, even those who precipitated, were tested. The transfection efficiency of the teloplexes (expressed in femtogram (fg) of luciferase (luc)/mg of protein) was evaluated for various amounts of DNA (2, 1, 0.5, and 0.1 μg/well) as compared to naked DNA and to the reference lipoplexes based on pcTG90/DOPE N/P 5 (1:1 molar ratio). For higher DNA amounts (e.g., 4 μg/well), the transfection, even if higher, was in most cases accompanied by a poor cell survival. The cationic pcTG90 amphiphile (see structure in Figure 1) is among the most efficient lipid for the transfection of A549 cells, with the highest level of luciferase expression being observed for the pcTG90/DOPE N/P 5 lipoplexes (these levels are further higher than those measured under the same conditions with Transfectam alone or Transfectam/DOPE (*2*), which is a highly efficient synthetic gene transfer agent widely documented in literature; see refs *4* and *8*). Cells treated with naked DNA under equivalent conditions showed expression levels of about 10^{2-3} fg of luc/mg of protein. The effect on cell viability of the (co)teloplexes was also checked by determining the total protein amount per well of the transfected cells relative to that measured for untreated cells (for which the total protein amount per well is in a 30−50 μg/well range).

The transfection and cell viability results are illustrated in Figures 2−7 for the (co)teloplexes formulated with (co)telomers I(Asp)-14,n_A(NH), I(His)-18,n_A(NH), I-18,n_B(NMe), Gal-n_A(NH), I-18,n_A(NH)-n_B(NMe), and I-18,10(NH)-10(OH), respectively. These results indicate that the polyamine (co)telomers do enable transfection of the plasmid into the cells. All of the (co)teloplexes tested so far showed indeed a higher efficiency to transfect A549 cells than naked DNA. For the lowest amount of plasmid used (i.e., 0.1 μg/well), the luciferase expression levels stood between 10^2 and 10^4 fg of luc/mg of protein.

The transfection efficiency and the cell tolerance of the (co)teloplexes depends further on the amount of DNA, on the *N*/*P* ratio as well as on the (co)teloplex formulation (DOPE added or not), and on the chemical structure of the (co)telomers. It usually increased on increasing the DNA amount from 0.1 to 2 μg/well, for which a plateau of luciferase expression (from 10^6−10^7 fg of luc/mg of protein) seemed to be reached. This plateau was often attained for a DNA amount of 0.5−1 μg/well. Irrespective of the amount of plasmid used, luciferase expression levels usually grew when the *N*/*P* ratio increased from 0.8 to 2.5−5 and then stood at a plateau. Simultaneously, cell tolerance decreased with the DNA amount or *N*/*P* ratio increase (see Figures 2−7). However, it remained very high (i) for DNA ≤ 1 μg/well, even for an *N*/*P* ratio of 10, and (ii) for DNA ≤ 2 μg/well, providing *N*/*P* ≤ 5.

This transfection efficiency and toxicity increase when raising the cationic charge of the (co)teloplexes is in line with the behavior of most lipoplexes and polyplexes reported in the literature. This is probably related to an

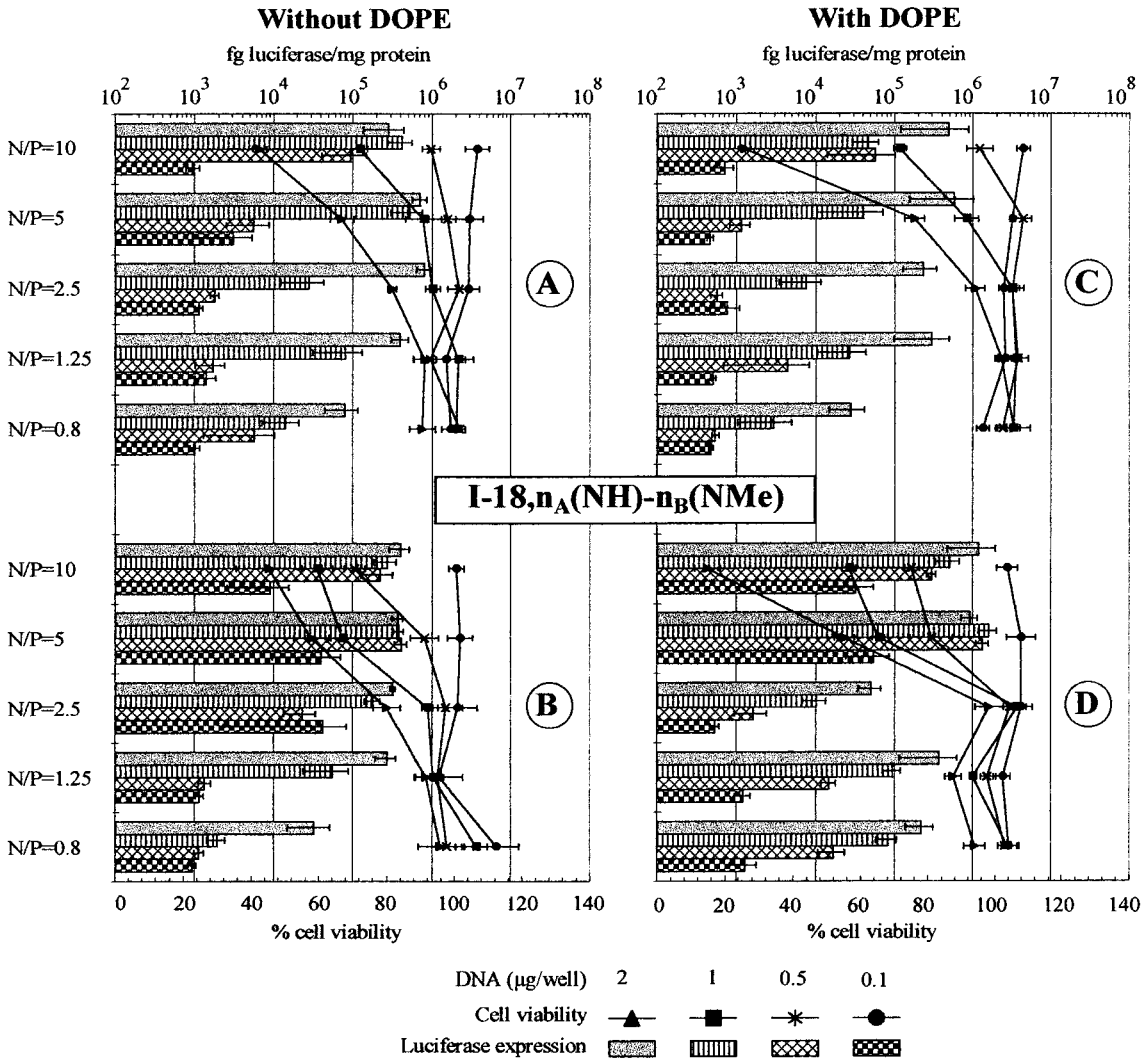

Figure 6. Luciferase expression (bars) and cell viability (points) of the pTG11033 coteloplexes made with I-18,n_A(NH)-n_B(NMe) cotelomers or with I-18,n_A(NH)-n_B(NMe)/DOPE (1/1 mol) lipids (A and C, $n_A = 8$, $n_B = 17$; B and D, $n_A = 10$, $n_B = 1$) in A549 cells. Means ± SEM are given.

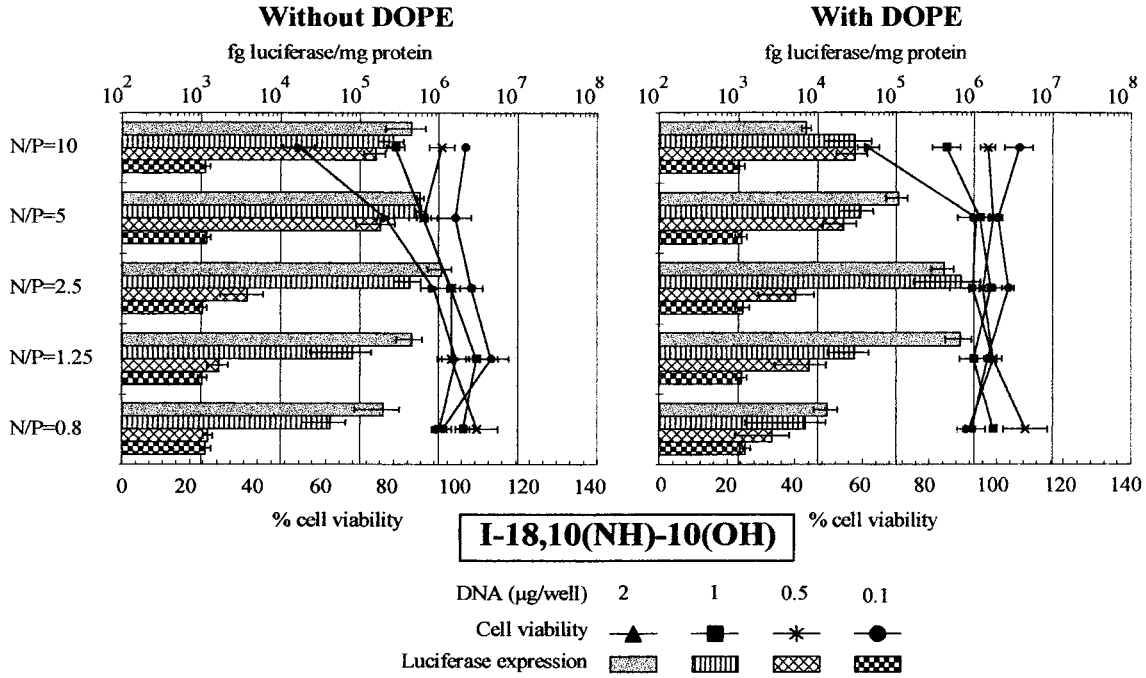

Figure 7. Luciferase expression (bars) and cell viability (points) of the pTG11033 coteloplexes made with I-18,10(NH)-10(OH) cotelomers or I-18,10(NH)-10(OH)/DOPE (1/1 mol) lipids in A549 cells. Means ± SEM are given.

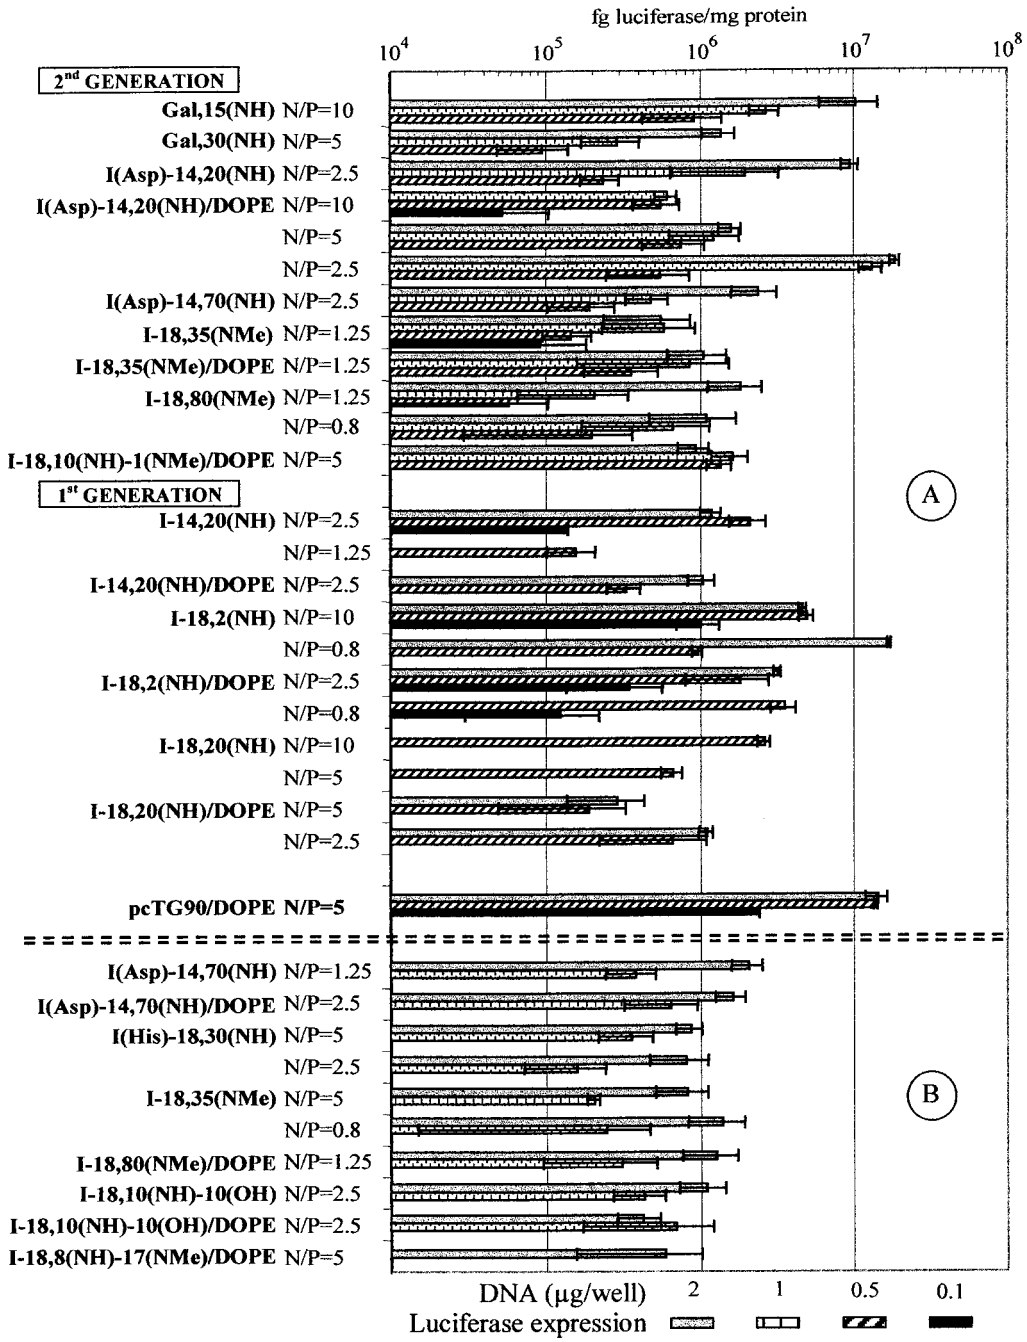

Figure 8. Most efficient second generation (co)teloplexes (selection criteria for A: transfection efficiency ≥ 10^5 fg of luc/mg of protein and cell viability > 50% for a DNA amount ≤ 0.5 μg/well; selection criteria for B: transfection efficiency ≥ 10^5 fg of luc/mg of protein and cell viability > 50% for a DNA amount ≤ 2 μg/well) described in this study as compared with the most efficient first second generation teloplexes and with the reference pcTG90/DOPE (1/1 mol; *N/P* 5) in A549 cells (data from ref *12*). Means ± SEM are given.

increase of the complex's cell uptake, which remains at a level compatible with cell growth providing that the *N/P* ratio is not higher than 5. For *N/P* 10, the (co)teloplexes became more toxic for the cells, likely as a result of a higher level of uptake, of cell membrane disruption, or as a result of the presence of a high amount of free uncomplexed (co)telomer.

When compared to the reference pcTG90/DOPE N/P 5 lipoplexes and to some teloplexes of the first generation which display a high transfection efficiency (10^6−10^7 fg of luc/mg of protein) already for DNA amounts ≤ 0.5 μg/well, several of the formulations investigated here, which are listed in panels A and B of Figure 8, were found to be as efficient in mediating DNA transfer and expression. However, such high luciferase levels were most often attained for a DNA amount ≥ 1 μg/well. When considering more severe selection criteria (DNA amounts of 0.5 and 0.1 μg/well), only a few of these (co)teloplexes (panel A of Figure 8) led to substantial transgene expression levels that are, however, in a 10^5−10^6 fg of luc/mg of protein range, hence below those measured for the reference and for the first generation of teloplexes (*12*). Overall, the transfection efficiency of the first generation of teloplexes was not found to be improved with these new (co)teloplexes (see also next section).

Concerning the effects on A549 cell transfection resulting from the formulation of the (co)teloplexes with DOPE, no helper effect of DOPE could be detected, the transfection efficiency upon DOPE addition to 180 formulations being statistically unaffected, in line with our

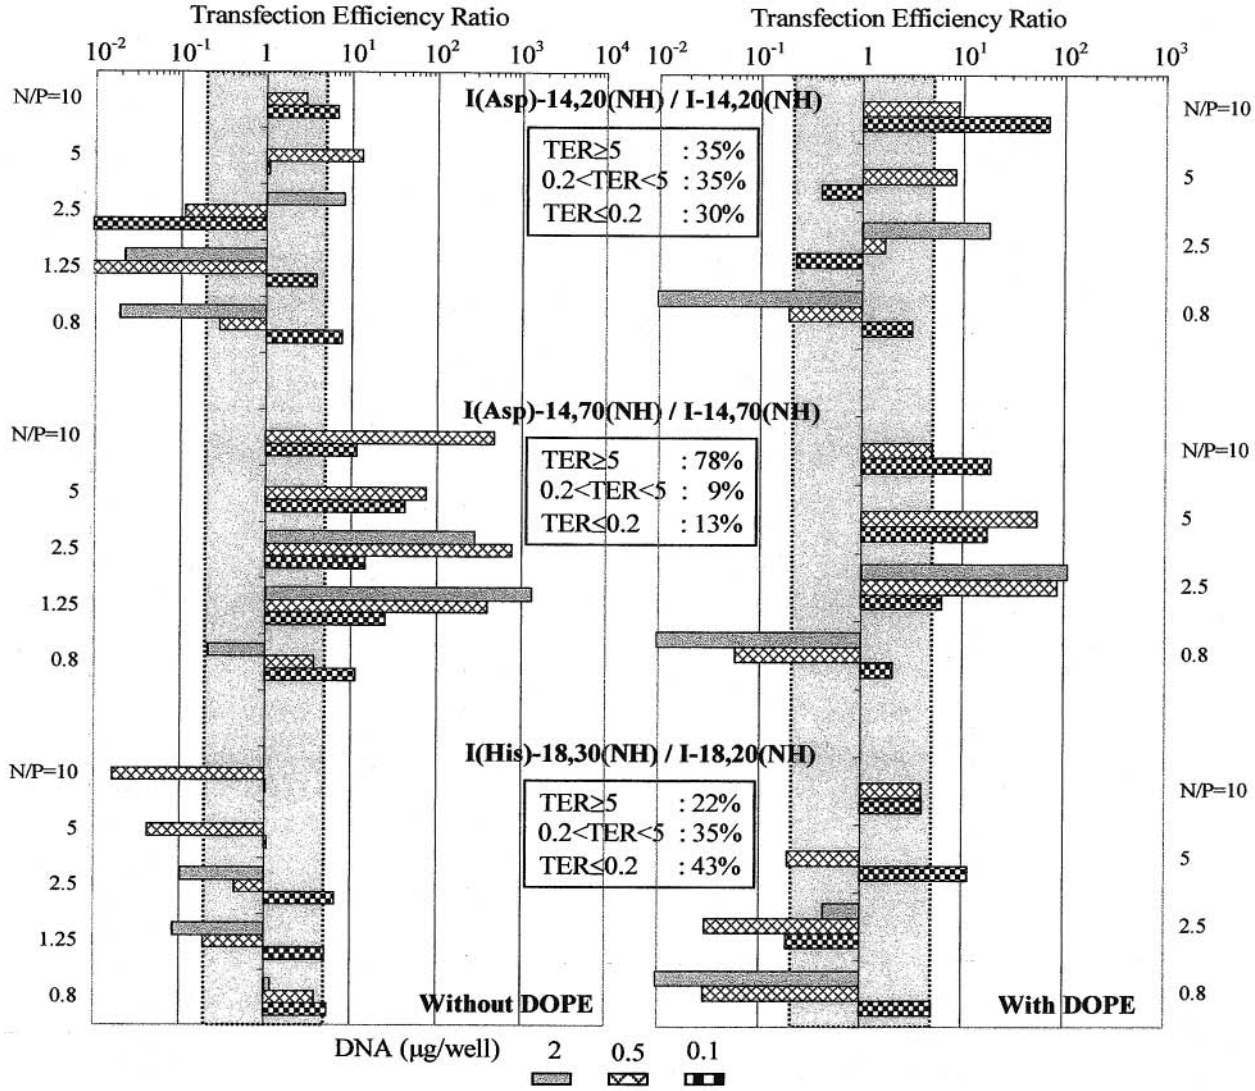

Figure 9. Impact on transfection efficiency of the aspartic or histine residue. TER is the ratio of luciferase amount measured for the formulations with telomer I(Asp)-14,n_A(NH) or I(His)-18,n_A(NH) versus that measured for the corresponding ones with the I-14,n_A(NH) or I-18,n_A(NH) homologues, respectively. The impact is significant if TER is not within the 0.2−5 range ($p < 0.05$ in a pairwise comparison). The percentages given in the boxes for each couple of telomers correspond to the percentages of formulations (with and without DOPE) for which TER were higher than 5, within the 0.2−5 range or below 0.2, respectively.

previous report on the first generation of telomers (*12*). Indeed, as compared to their respective teloplexes formed without DOPE, the luciferase expression remained unchanged for at least 73% of the formulations tested, a decrease or an increase of transfection being observed for nearly 20% or 7% of the formulations, respectively (data not shown).[1] Further, most of the 20% of formulations for which a transfection decrease was observed concerned the cotelomer- and the $NHMe_2^+$ telomer-based complexes.

Structure/Transfection Efficiency Relationships. One of the objectives of this study was also aimed at determining structural elements of the (co)telomers that favor or increase their transfection potential. The structural modifications that were investigated here concern (i) the number of amine functions, (ii) the nature of the polyamine polar head (primary vs tertiary amine, a combination of primary amines with tertiary amines, or with polyol (e.g., THM) residues), (iii) the presence of a low pK_a functional group (e.g., an aspartic or a histidine amino acid) between the lipophilic chains and the polar head, (iv) the replacement of a hydrophilic (galactosyl) moiety for lipophilic chains, or (v) the oxidation state of sulfur (thioether or sulfoxide linkage).

In the previous study concerning telomers I-m,n_A(NH) (with $m = 14$ or 18), it was shown that an optimum of transfection was attained for a number of amine functions, n_A, in the 2−20 range which decreased slightly for higher n_A values (*12*). We found here with the new series of telomers that their degree of polymerization (within the 20−90 range investigated) had almost no impact on their transfection efficiency. Indeed, when increasing the number of amine functions from 20 to 70 in the I(Asp)-14,n_A(NH) series, from 30 to 90 in the I(His)-18,n_A(NH) series, or from 35 to 80 in the I-18,n_B(NMe) series, the luciferase expression levels were statistically not affected for at least 80%, 78%, or 84% of the formulations, respectively (data not shown; see also note 1).

Where the impact on transfection of replacing part or all NH_3^+ functions by $NHMe_2^+$ ones in the polyamine

[1] The difference in transfection efficiency of two formulations is considered as significant if the ratio of luciferase amount (Transfection Efficiency Ratio (TER)) measured for the two formulations is out of the 0.2−5 range and associated with a $p < 0.05$ in a pairwise comparison. Only the formulations with cell viability > 50% were considered for TER calculations.

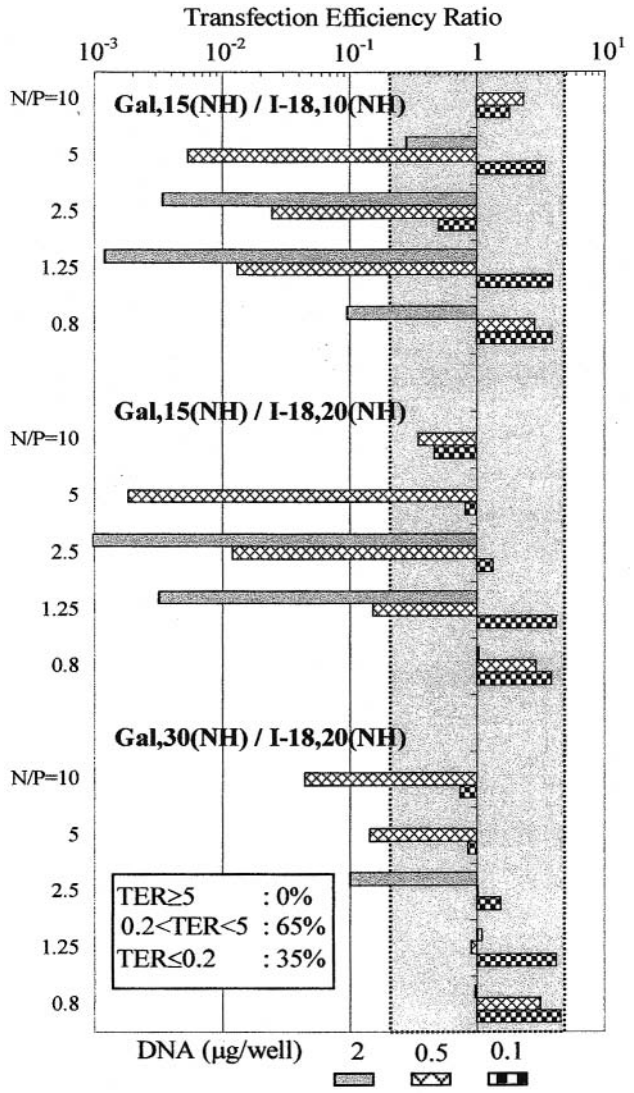

Figure 10. Impact on transfection efficiency of the hydrophilic (Gal) residue versus the hydrophobic moiety. TER is the ratio of luciferase amount measured for the formulations with telomer Gal,n_A(NH) versus that measured for the corresponding ones with I-18,n_A(NH) homologues. The impact is significant if TER is not within the 0.2−5 range ($p < 0.05$ in a pairwise comparison). The percentages given in the box correspond to the mean percentages of formulations, irrespectively of n_A, for which TER were higher than 5, within the 0.2−5 range or below 0.2, respectively.

telomers is concerned, transgene expression was statistically not modified by a partial [e.g., I-18,10(NH) vs I-18,10(NH)-1(NMe) and I-18,20(NH) vs I-18,8(NH)-17(NMe)] or a full [e.g., I-18,20(NH) or I-18,50(NH) vs I-18,35(NMe) and I-18,60(NH) vs I-18,80(NMe)] replacement for almost 50% of the formulations, the effects (increase or decrease of transfection) being rather at random for the remaining 50% of formulations (data available as Supporting Information; see also note 1). One should, however, underscore that cell viability was generally improved by the replacement of the primary amines by the tertiary ones.

Concerning the impact on transfection of replacing part of the primary amine functions by polyol THM residues, transgene expression was not modified for at least 70% of the formulations (I-18,10(NH) teloplexes versus I-18,10(NH)-10(OH) coteloplexes), while cell viability was to some extend improved (data available as Supporting Information; see also note 1). Similar results were also noticed for polylysines and polyallylamines after partial glycolylation (*7*) and for copolymers deriving from 2-(dimethylamino)ethyl methacrylate and ethoxytriethylene glycol methacrylate (*9*).

Importantly, as illustrated in Figure 9, it appeared that introducing an aspartic acid into the telomer structure of I-14,70(NH) improved its transfection efficiency (in some cases by more than 2 orders of magnitude). Seventy-eight percent of the teloplexes based on I(Asp)-14,70(NH) (some of which are as efficient as the pcTG90/DOPE N/P 5 reference; see Figure 8) gave rise to at least a 10-fold higher luciferase expression level than those formulated with I-14,70(NH). This tendency is, however, not confirmed for the I(Asp)-14,20(NH)-based teloplexes as compared to the I-14,20(NH) ones; if transfection was indeed improved for 35% of these formulations, it remained at the same level and decreased for another 35% and 30%, respectively. By contrast, insertion of histidine into the telomer backbone was statistically found to reduce transgene expression; 43% of the I(His)-18,30(NH) formulations were less efficient than their corresponding I-18,20(NH) teloplexes, while the opposite result was found for only 22% of the I(His)-18,30(NH) versus I-18,20(NH) formulations. These results contrast to some extent with the higher transfection potential found for histidylated polylysine polymers (which contained around 70 histidine residues) as compared with that of polylysines (*11*).

Replacing the hydrophobic chains for a hydrophilic galactose residue was found most frequently not to affect transfection. Indeed, 65% of the I-18,10(NH) and I-18,20(NH) lipoteloplexes displayed transgene expression levels comparable to those measured for their corresponding Gal,15(NH) and Gal,30(NH) teloplexes (Figure 10). However, this replacement led for the remaining 35% of formulations to a substantial transfection decrease (1 to 3 orders of magnitude). Concomitantly, cell viability was most often found to be improved for the galactosyl-based teloplexes. The higher transfection potential of the lipophilic telomers is in line with several reports in the literature which showed a substantial increase of the transfection efficiency for polylysines (*20*) and other polycationic polymers (*10*) upon conjugation to lipophilic residues.

Concerning the impact of the oxidation state of sulfur (thioether or sulfoxide linkage) on transfection, no significant effect could be evidenced, with Gal,n_A(NH) formulations and their Gal(O),n_A(NH) homologues giving rise to comparable luciferase expression levels (data not shown).

CONCLUSION

The present work suggests that some of the second generation of (co)telomers display a promising potential as synthetic vectors for gene delivery. The variation of structure parameters allowed the establishment of structure−activity relationships and the optimization of the (co)teloplex formulation, where both high transfection levels and cell viability were achieved. Thus, aspartic-containing telomers were found to lead to efficient formulations for plasmid delivery to A549 cells and for *N*/*P* ratios from 1.25 to 5. Some of these telomers are currently investigated for in vivo studies.

ACKNOWLEDGMENT

We wish to thank Transgène, SA (Strasbourg, France) for financial support and Dr. B. Cavallini (Transgène) for supplying with plasmid. We also thank Drs. D.

Heissler and A. Nazih (ULP Strasbourg) for the synthesis of pcTG90. Thanks to Dr. H.V.J. Kolbe for his interest into this project and for helpful discussions.

Supporting Information Available: Two figures showing the effect of DOPE and the effect of the NH_3/$NHMe_2$ or NH_3/OH (THM) replacement on the transfection efficiency of the (co)teloplexes, respectively. This material is available free of charge via the Internet at http://pubs.acs.org.

Supplementary material 1 : Effect of DOPE on the transfection efficiency of the (co)teloplexes. The transfection efficiency ratio, TER, is the ratio of luciferase amount measured for the formulation with DOPE vs that measured for the corresponding one without DOPE. The impact is significant if TER is not within the 0.2 – 5 range ($p < 0.05$ in a pair-wise comparison). The percentages given in the boxes correspond to the mean percentages of formulations, irrespectively of n_A or of n_B, for which TER is higher than 5, within the 0.2 – 5 range or below 0.2, respectively. The general mean percentages correspond to the percentages of formulations, irrespectively of the nature of the (co)teloplexes, for which TER were higher than 5, within the 0.2 – 5 range or below 0.2, respectively.

Supplementary material 2 : Effect of the $NH_3/NHMe_2$ or NH_3/OH (THAM) residue replacement on the transfection efficiency of the (co)teloplexes . The transfection efficiency ratio, TER, is the ratio of luciferase amount measured for the formulations with **I-18,n_B(NMe)**, **I-18,n_A(NH)-n_B(NMe)** or **I-18,10(NH)-10(OH)** vs that measured for the corresponding ones with **I-18,n_A(NH)**. The impact is significant if TER is not within the 0.2 – 5 range ($p < 0.05$ in a pair-wise comparison). The percentages given in the boxes correspond to the mean percentages of formulations, irrespectively of n_A and of n_B, for which TER were higher than 5, within the 0.2 – 5 range or below 0.2, respectively.

Poly[Lys-(AEDTP)]: A Cationic Polymer That Allows Dissociation of pDNA/Cationic Polymer Complexes in a Reductive Medium and Enhances Polyfection

Polyplexes of high stability resulting from the condensation of a plasmid DNA by a cationic polymer are widely used to develop polymer-based gene delivery systems. However, the plasmid must be released from its vector once inside the cells for an efficient expression of the exogenous gene in the cell nucleus. We have designed a disulfide-containing cationic polymer termed poly[Lys-(AEDTP)] which allowed for the formation of polyplexes and the release of the plasmid in a reductive medium. The amino groups of polylysine were substituted with 3-(2-aminoethyldithio)propionyl residues in order to have each amino group of poly[Lys-(AEDTP)] interacting with a phosphate DNA linked to the polymer backbone via a disulfide bond. As evidenced by agarose gel electrophoresis and ethidium bromide/pDNA fluorescence restoration, poly[Lys-(AEDTP)] polyplexes were decondensed and the plasmid released upon treatment with either dithiothreitol, glutathione in the presence of glutathione reductase, or the thioredoxin reductase. Electron microscopy showed that polyplexes exhibiting spherical particles of a mean size at about 100 nm were decondensed in the presence of glutathione and exhibited filamentous aggregates. Finally, we found that the transfection of 293T7 and HepG2 cells was 10- and 50-fold more efficient with poly[Lys-(AEDTP)] polyplexes, respectively, than with poly[Lys] polyplexes. These results indicate that disulfide-containing cationic polymers must be borne in mind for developping polymer-base gene delivery systems.

INTRODUCTION

The self-assembly of plasmid DNA (pDNA) in an aqueous solution via cooperative electrostatic interactions with cationic polymers such as polylysine is the basis of the development of synthetic vectors for gene therapy (*1*−*4*). This assembly induces the condensation of pDNA allowing for the formation of cationic polyplexes (DNA/cationic polymer complexes) and an increase of its cellular uptake. Once internalized, the intracellular trafficking of polyplexes and the mechanism allowing pDNA to reach the cell nucleus is still unclear. It is supposed that polyplexes route via endocytic vesicles, polyplexes, or pDNA are delivered in the cytosol and then imported in the cell nucleus. pDNA/polylysine complexes are highly stable, and pDNA is protected from nuclease digestion in serum and in cell extracts (*5*, *6*). However, the polyplexes stability could be a limiting factor for the transfection efficiency by preventing the pDNA release and the accessibility of gene expression machinery. The release of pDNA from polyplexes could be, indeed, required for either its delivery in the cytosol, its import in the cell nucleus, or the gene expression. Several lines of evidence suggest that a decrease of the strength of the electrostatic interactions between pDNA and polylysine favors the dissociation of polyplexes inside the cells and enhances the transfection efficiency. Indeed, the reduction of the number of positive charges on polylysine after a partial substitution of the ϵ-amino groups with uncharged residues, such as carbohydrate moieties (*7*) or polyhydroxyalcanoyl (gluconoyl) residues (*8*), was found to facilitate in vitro dissociation of polyplexes and to increase the transfection efficiency. In the same way, complexes between pDNA and an EGF−polylysine conjugate gave a better transfection when the size of polylysine was shortened because the stability of polyplexes was reduced (*9*).

Here, we describe the synthesis of a 3-(2-aminoethyldithio)propionyl-substituted polylysine conjugate, termed poly[Lys-(AEDTP)],[1] in which the lysyl ϵ-amino groups of polylysine are substituted with 3-(2-aminoethyldithio)-propionyl residues. Therefore, the amino groups of poly-[Lys-(AEDTP)] interacting with the pDNA phosphates are linked to the polymer backbone via a disulfide bond. This cationic polymer enables the formation of polyplexes with pDNA, which is expected to be released upon the cleavage of the disulfide bonds in a reductive medium, such as the cytosol and the cell nucleus. We show that these polyplexes are dissociated in the presence of reducing substances, including dithiothreitol (DTT), glu-

tathione, and thioredoxin. In addition, the transfection efficiency of poly[Lys-(AEDTP)] polyplexes is increased up to 50-fold as compared to polylysine polyplexes.

MATERIAL AND METHODS

Preparation of 3-(2-Pyridyldithio)propionyl-Substituted Polylysine (Poly[Lys-(PDP)]). Poly-L-lysine, HBr 30 000−50 000 (poly[Lys], dp = 190) (Bachem Feinchemikalien, Bubendorf, Switzerland) was changed to polylysine *p*-toluenesulfonate salt as described previously (*10*). Poly[Lys]-*p*-toluenesulfonate salt (100 mg, 1.75 μmol) in 5 mL dimethyl sulfoxide (Sigma-Aldrich, L'Isle d'Abeau Chesnes, France) in the presence of diisopropylethylamine (51 μL, 350 μmol; Aldrich) was reacted for 24 h at 20 °C with *N*-succinimidyl-3-(2-pyridyldithio)-propionate (SPDP) (110 mg, 352 μmol; Sigma). Polylysine substitution with 3-(2-pyridyldithio)propionyl residues (PDP) was monitored by thin-layer chromatography (TLC) on silica gel plates (Kieselgel 60 F_{254}, Merck, Darmstadt, Germany) in a chloroform/methanol/water (6:6:1 v/v/v) mixture under a UV lamp (polymer, R_f = 0; SPDP, R_f = 0.7) and upon ninhydin reaction. The reaction was stopped when the total substitution of the amino groups of polylysine with PDP residues was evidenced by the absence of staining after ninhydrin reaction. The polymer was precipitated by adding 10 vol of distilled water, and the precipitate was collected by centrifugation (1800*g* for 15 min) and dried under vacuum.

Preparation of 3-(2-Aminoethyldithio)propionyl-Substituted Polylysine (Poly[Lys-(AEDTP)]. Poly-[Lys-(PDP)] (45 mg, 0.95 μmol) was dissolved by warming in 4 mL of dimethyl sulfoxide and was reacted at 20 °C with mercapthoethylamine-*p*-toluenesulfonate salt. The reaction was monitored by the release of pyridine-2-thione. Briefly, 30 μL of reaction mixture was added to 200 μL of dimethyl sulfoxide; pyridine-2-thione was then extracted with 2 mL of ethyl acetate, and upon centrifugation, the absorbance of the supernatant was recorded at 377 nm. The absorbance was compared to that obtained with a sample after addition of an excess of mercapthoethylamine-*p*-toluenesulfonate salt (30 μL of 50 mg/mL). The reaction was complete after the addition of 62 mg (250 μmol) of mercapthoethylamine-*p*-toluenesulfonate salt. The polymer was purified by adding 10 vol of 2-propanol, and the precipitate was collected by centrifugation (1800*g* for 15 min). The pellet was washed with 2-propanol, collected by centrifugation (1800*g* for 15 min), dissolved in distilled water, and freezed-dried. ^{1}H NMR spectroscopy at 300 MHz in D_2O showed that the eight methylene protons ($1HC_8$, $2HC_9$, $2HC_{10}$, and $2HC_{11}$; Figure 1) corresponding to AEDTP residues exibited two equal peaks at 2.7 and 2.9 ppm. The value of one proton determined from the integration value of those peaks was equal to that from the six methylene protons ($1HC_3$, $1HC_4$, and $1HC_5$) of lysine residues, indicating that polylysine was practically completely substituted with AEDTP residues.

Plasmids. pSV2Luc was a 5 kb plasmid DNA encoding the firefly luciferase gene under the control of the SV40 large T antigen promoter (*11*). pUT650 plasmid (5.15 kb plasmid; CAYLA, Toulouse, France) was an expression vector encoding the firefly luciferase gene under the control of the human cytomegalovirus promoter. pUT650 was used to transfect the cells because the strength of the CMV promoter was higher than that of the SV40.

Release of pDNA from Poly[Lys-(AEDTP)]. *Agarose Gel Electrophoresis. Effect of DTT.* Twenty micrograms of pSV2Luc in 280 μL of 10 mM Hepes buffer (pH 7.4) (HB) was mixed with either poly[Lys-(AEDTP)] (80 μg) or polylysine (40 μg) in 120 μL of HB. After 30 min at 20 °C, 50 μL of polyplexes solution was incubated at 37 °C in the absence or in the presence of 0.1 M DTT (5 μL of a 1 M aqueous solution). Samples (20 μL) were then analyzed by agarose gel electrophoresis. Electrophoresis was performed for 2 h under 80 V/cm, through a 0.8% agarose gel containing ethidium bromide (1 μg/mL of gel) in a Tris−borate−EDTA buffer (95 mM Tris, 89 mM boric acid, 2.5 mM EDTA, and 10 mM DTT (pH 8.6)).

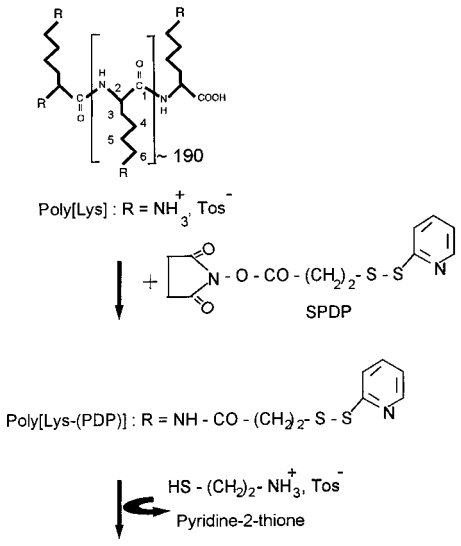

Figure 1. Schematic synthesis of poly[Lys-(AEDTP)].

Effect of Glutathione and Thioredoxin Reductase. A 0.4 M gluthatione reduced-form (Sigma) stock solution was prepared in 0.1 M potassium phosphate buffer (pH 7.5), containing 2 mM EDTA (PB) and adjusted to pH 7.5 with a 10 N NaOH solution. Complexes prepared as described previously were incubated for 2 h at 37 °C in PB in the presence of either (a) 20 mM glutathione, 2 units/mL glutathione reductase (from yeast; Roche Diagnostics, Grenoble, France), and 0.5 mM NADH (Sigma) or (b) 2 units/mL thioredoxin reductase (from *Escherichia coli*; Sigma) and 0.5 mM NADPH (Sigma). Samples (20 μL) were then analyzed by agarose gel electrophoresis as described previously.

Ethidium Bromide/pDNA Fluorescence Restoration. pSV2Luc plasmid (20 μg in 0.5 mL of HB) was mixed with either polylysine (40 μg) or poly[Lys-(AEDTP)] (100 μg) in 0.5 mL of HB. After 30 min at 20 °C, ethidium bromide (40 μL of a 0.1 mg/mL solution in HB) was then added, and polyplexes were incubated at 37 °C in the absence or the presence of either 0.1 M DTT (5 μL of a 1 M aqueous solution) or 10 mM glutathione reduced form. The fluorescence intensity of the solution was measured at 585 nm upon excitation at 540 nm.

ζ Potential and Size Measurements. Poly[Lys-(AEDTP)] (100 μg in 120 μL of HB) and polylysine (40 μg in 120 μL of HB) were complexed with pSV2Luc by mixing the polymers to 20 μg of plasmid in 280 μL of HB. The mixed solution was allowed to stand for 30 min at 20 °C before being diluted with 2 mL of HB. The ζ potential was measured by using a ZetaSizer 3000 (Malvern Instruments, Orsay, France) with the following parameters: viscosity, 0.891 cP; dielectric constant, 79; temperature, 25 °C; F (Ka), 1.50 (Smoluchowsky); maxi-

mum voltage of the current, 15 V. Measurements were performed five times with zero field correction. The ζ potential was calculated by using the Smoluchowsky approximation. The size was determined by quasi-elastic laser light scattering using the ZetaSizer 3000 with a sample refractive index of 1.59 and a viscosity of 0.89. Measurements were performed 10 times and the size was calculated by using the automatic mode. The system was calibrated by using a -50 ± 5 mV and 200 ± 5 nm standard dts 5050 from Malvern.

Cells and Cell Culture. 293T7 (human embryonic kidney-producing T7 RNA polymerase) (*12*) and HepG2 (human hepatoma cells, ATCC HB 8065) were cultured in DMEM (Gibco, Life Technologies, Renfrewshire, U.K.) and MEM, respectively. Culture media were supplemented with 10% heat-inactivated fetal bovine serum (FBS; Gibco), 2 mM L-glutamine (Gibco), and antibiotics (100 units/mL of penicillin and 100 mg/mL of streptomycin; Gibco). Cells were grown at 37 °C in a humidified atmosphere containing 5% CO_2 and 95% air. Cells were mycoplasma free, as evidenced by the bisbenzimidazole negative test (Hoechst 33258) (*13*).

Polyfection. Poly[Lys-(AEDTP)] (20 μg in 30 μL of HB) or polylysine (15 μg in 30 μL of HB) were complexed by mixing the polymers to 5 μg pUT650 in 70 μL of HB. The solution was allowed to stand for 30 min at 20 °C before diluted with 1 mL of culture medium supplemented with 10% FCS and made 100 μM chloroquine (phosphate salt; Sigma). Adherent cells ($(2-4) \times 10^5$ cells) were plated (day 0) in 4 cm^2 culture dishes (12-well culture plates). On day 1, the medium was removed, and 1 mL of polyplexes-containing medium was added into each well. After a 4 h incubation at 37 °C, the medium was removed, and cells were further incubated at 37 °C in 2 mL of the complete culture medium.

Luciferase Assay. Luciferase gene expression was measured by monitoring the luminescence activity according to De Wet et al. (*14*). The medium was discarded, and cells were washed three times with PBS. The homogenization buffer (200 μL of 8 mM $MgCl_2$, 1 mM DTT, 1 mM EDTA, 1% Triton $\times$ 100, 15% glycerol, 25 mM Tris−phosphate buffer (pH 7.8)) was poured into each well, and tissue culture plates were kept for 15 min at 20 °C. The solution was recovered and spun down (5 min at 800*g*). Ninety-five microliters of a 2 mM ATP solution in the homogenization buffer without Triton $\times$ 100 was added to 60 μL of supernatant, and the solution was shaken with a vortex. The luminescence was recorded for 4 s in a Lumat LB 9501 luminometer (Berthold, Wildbach, Germany) upon addition of 150 μL of a 167 mM luciferin solution in water. Measurements were done in duplicate. The data shown correspond to the number of relative light units (RLU) from 10^6 cells. The number of RLU of 1 pg/mL of luciferase was 2000 under these assay conditions.

Transmission Electron Microscopy (TEM). Ten micrograms of pUT650 in 70 μL of HB were complexed with 40 μg of poly[Lys-(AEDTP)] in 30 μL of HB. After 30 min at 20 °C, polyplexes were diluted with either 1 mL of HB or 1 mL of HB containing 10 mM glutathione reduced form. Samples were observed by TEM as already described (*15*). Five microliters of mixture were deposited on a carbon-coated copper grid, which was activated by a slow discharge in the presence of pentylamine. The sample was washed out with 2% uranyl acetate in water, blotted, and dried on a filter. Observation was made in the dark-field mode with a LEO-Zeiss 902 microscope, with filtering out inelastic electrons for contrast improvement.

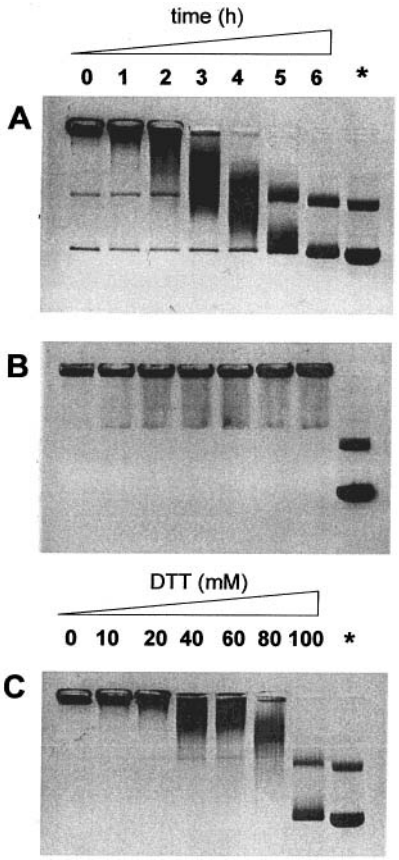

Figure 2. DTT releases pDNA from poly[Lys-(AEDTP)]. pSV2luc (20 μg in 280 μL of 10 mM HB) was mixed with either (A) poly[Lys-(AEDTP)] (80 μg) or (B) polylysine (40 μg) in 120 μL of HB. After 30 min at 20 °C, polyplexes (50 μL, 2.5 μg of plasmid) were incubated at 37 °C for various times in the presence of 0.1 M DTT. (C) Polyplexes (50 μL, 2.5 μg of plasmid) were incubated for 6 h at 37 °C in the presence of various DTT concentrations. Samples (20 μL) were analyzed by 0.8% agarose gel electrophoresis and DNA visualized with ethidium bromide.

RESULTS

Poly[Lys-(AEDTP)] was synthesized from poly-L-lysine with a degree of polymerization of 190 (Figure 1). First, poly-L-lysine was totally substituted with 3-(2-pyridyldithio)propionyl residues. The reaction was easily monitored on TLC after the reaction of the free amino groups with ninhydrin. The substitution was complete as evidenced by the absence of coloration when polylysine was reacted in the presence of 1.1 equiv of SPDP/polylysine amino group. Then, activated thiol groups were reacted with mercaptoethylamine to give 3-(2-aminoethyldithio)propionyl residues. The reaction was monitored by measuring the absorbance at 377 nm of released pyridine-2-thione. The absorbance was maximal when 1.4 equiv of mercaptoethylamine/PDP group were added; the absorbance corresponded to that obtained upon the reduction of the PDP groups in the presence of 5 equiv of mercaptoethylamine/PDP group.

Poly[Lys-(AEDTP)] was able to form complexes with pDNA via electrostatic interactions between pDNA phosphates and the amino groups of the cationic polymer. As shown by agarose gel electrophoresis, the migration of 2.5 μg of pDNA was indeed completely retarded in the presence of 10 μg of poly[Lys-(AEDTP)] (polymer/DNA molar ratio of 150, amine/phosphate ratio of 2.8; Figure 2A, line 0). Similar results were obtained with a DNA/polymer ratio of 10/50 (μg/μg). The polyplexes solution contained homogeneous particles of 110 nm in diameter

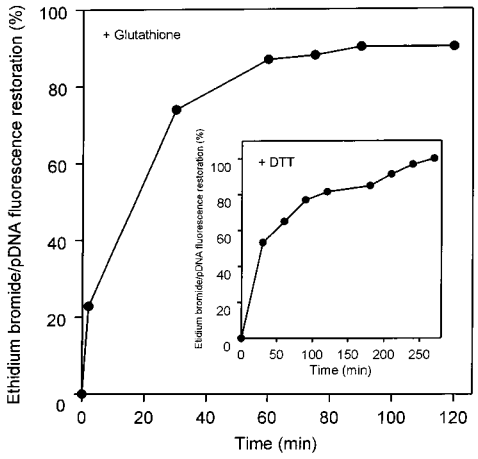

Figure 3. Glutathione-induced pDNA decondensation. Ethidium bromide/pDNA fluorescence restoration. pSV2luc (20 μg in 0.5 mL of HB) was mixed with poly[Lys-(AEDTP)] (100 μg) in 0.5 mL of HB. After 30 min at 20 °C, polyplexes were incubated for various times at 37 °C in the presence of either 10 mM glutathione or (inset) 0.1 M DTT. Ethidium bromide (40 μL of a 0.1 mg/mL solution in HB) was then added, and the fluorescence intensity of the solution was measured at 585 nm upon excitation at 540 nm.

and exhibited a ζ potential of $+15 \pm 4$ mV. Comparatively, 2.5 μg of pDNA completely condensed in the presence of 5 μg of polylysine (polymer/DNA molar ratio of 120, amine/phosphate ratio of 2.2; Figure 2B, line 0), formed polyplexes particles of 100 nm in diameter, and exhibited a ζ potential of $+17 \pm 2$ mV.

pDNA Release from Poly[Lys-(AEDTP)]. The cleavage of the disulfide bonds of poly[Lys-(AEDTP)] was expected to induce the dissociation of polyplexes and the release of pDNA. First, DTT was used in order to reduce disulfide bonds, and the release of pDNA was monitored by an agarose gel electrophoresis. After incubation of pDNA/poly[Lys-(AEDTP)] in the presence of 0.1 M DTT for 6 h at 37 °C, pDNA migrated as free pDNA, showing the total release of pDNA from poly[Lys-(AEDTP)] after cleavage of the disulfide bonds (Figure 2A). In contrast, no release of pDNA was found for pDNA/polylysine complexes in the presence of DTT (Figure 2B). The release was dependent on the DTT concentration; it was efficient with at least 40 mM DTT (Figure 2C). A cleavage of the disulfide bonds with DTT before mixing poly[Lys-(AEDTP)] with pDNA did not allow for the formation of polyplexes (data not shown). Second, the release of pDNA was also monitored by following the ethidium bromide/DNA fluorescence restoration. In the absence of poly[Lys-(AEDTP)], ethidium bromide mixed with pDNA exhibited a fluorescence emission centered at 585 nm. In polyplexes, the binding of ethidium bromide cannot intercalate between the base pairs of the DNA double helix and does not fluoresce. Conversely, when pDNA is decondensed or released from polyplexes, an intense fluorescence signal is emitted. In the presence of either poly[Lys-(AEDTP)] or polylysine with a DNA/polymer molar ratio leading to a complete condensation of the pDNA, the fluorescence intensity measured after adding ethidium bromide was 25% of that obtained with free pDNA. Thus, pDNA decondensation allowing the binding of ethidium bromide to pDNA will restore the fluorescence intensity. As shown in Figure 3 (inset), pDNA/poly[Lys-(AEDTP)] complexes incubated at 37 °C in the presence of 0.1 M DTT led to pDNA decondensation. No effect was observed with pDNA/polylysine complexes (data not shown). Although 80% of the fluorescence intensity was restored

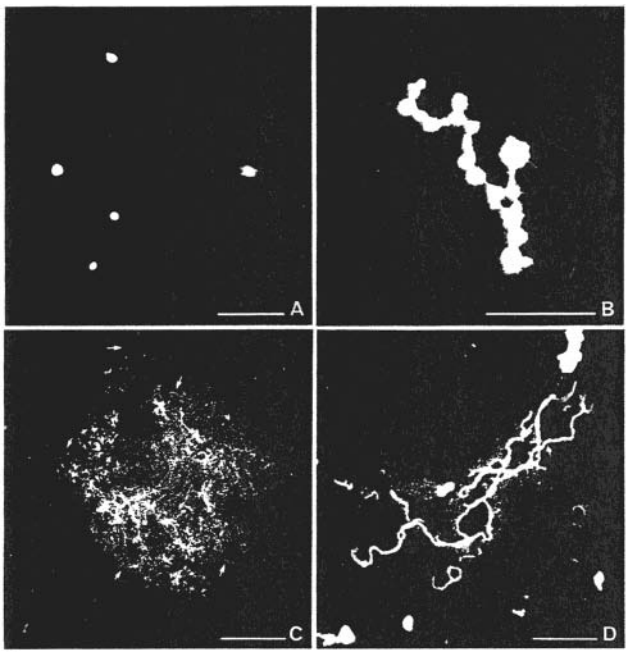

Figure 4. Electron microscopy observation of polyplexes made with poly[Lys-(AEDTP)]. Observations were performed by annular dark-field EM after adsorption of the molecules on activated carbon films and uranyl acetate staining, as described in Material and Methods. (A) After 30 min, the polyplexes were condensed in spherical particles of about 100 nm. (B) In the presence of glutathione (15 min), we observed decondensation of the complexes and fusion events. (C) Decondensation increased with time (1 or 2 h in the presence of glutathione). Arrows indicate fibrillate structures corresponding to DNA. (D) Formation of filamentous aggregates were frequently observed (same conditions). (Scale: the bars correspond to 500 nm.)

after a 2 h incubation, pDNA did not migrate under electrophoresis (Figure 2A). This indicated that pDNA was not still released. Ethidium bromide/DNA fluorescence restoration is a more sensitive method to check polyplexes modification than the mobility shift assay in agarose gel electrophoresis. The binding of ethidium bromide to pDNA does not require a complete dissociation of the polyplexes; a decondensation of pDNA after cleavage of a few disulfide bonds of poly[Lys-(AEDTP)] is enough to allow for the binding of ethidium bromide. In contrast, the migration of pDNA in an agarose gel electrophoresis requires the release of pDNA.

Attempts were also performed to check the release of pDNA under physiological conditions. The effect of glutathione on polyplexes stability, the main reductive substance contained in the cytosol, was monitored by electrophoresis and ethidium bromide/DNA fluorescence restoration. As with DTT, the incubation of poly[Lys-(AEDTP)] with 10 mM glutathione prior its mixing with pDNA did not allow for the formation of polyplexes (data not shown). As shown in Figure 3, 50% and 90% of the fluorescence intensity was restored after 20 min and 1 h incubation at 37 °C in the presence of 10 mM glutathione, respectively, suggesting that, as with DTT, glutathione induced a rapid decondensation of pDNA upon disulfide bond cleavage. However, glutathione was not as efficient as DTT to release pDNA. Indeed, when pDNA/poly[Lys-(AEDTP)] complexes were treated with glutathione for 6 h at 37 °C, only a low amount of pDNA migrated in agarose gel electrophoresis. This was sustained by electron microscopy. TEM showed the high level of condensation of polyplexes, with spherical particles of a mean size at about 100 nm (Figure 4A). In the presence of glutathione, numerous events of particles fusions appears

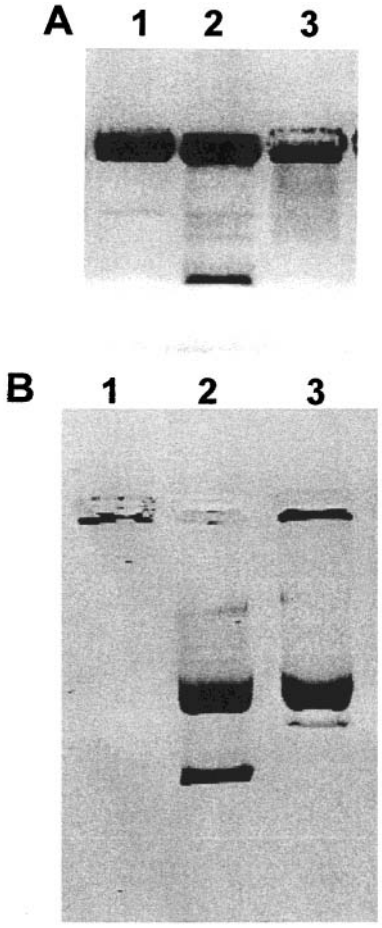

Figure 5. Release of pDNA from polyplexes made with poly-[Lys-(AEDTP)]. pSV2Luc (10 μg) was complexed with poly[Lys-(AEDTP)] (40 μg). Complexes were reduced for 2 h at 37 °C under indicated conditions, analyzed by 0.8% agarose gel electrophoresis, and DNA visualized with ethidium bromide: (A) lane 1, polyplexes before reduction; lane 2, polyplexes incubated in the presence of 20 mM glutathione, 2 units/mL glutathione reductase, and 0.5 mM NADH; lane 3, as in lane 2 but without glutathione; (B) lane 1, polyplexes before reduction; pDNA (lane 2) and polyplexes (lane 3) incubated in the presence of 2 units/mL thioredoxin reductase and 0.5 mM NADPH.

after 15 min (Figure 4B), resulting of some decondensation of the polyplexes; free pDNA molecules became visible at the periphery of the complexes. Decondensation increased with time, as illustrated in Figure 4C, after 1 or 2 h of incubation. Very frequently, complexes reorganization could occur through the formation of filamentous aggregates (Figure 4D with a granular background-containing released polymer from the complexes (parts C and D of Figure 4). However, the release of pDNA by glutathione was facilitated in the presence of glutathione reductase and NADH (Figure 5A). It was successfully induced by thioredoxin reductase itself in the presence of NADPH (Figure 5B). Despite the fact that the release of pDNA from polyplexes was not complete, these results still demonstrate that pDNA release can occur under reductive conditions inside the cells.

Enhancement of the Transfection Efficiency. HepG2 and 293T7 cells were transfected for 4 h with pCMVLuc complexed with either poly[Lys-(AEDTP)] or polylysine in the presence of 100 μM chloroquine. An enhancement of the transfection efficiency was obtained with the plasmid complexed with poly[Lys-(AEDTP)] as compared to that of the plasmid complexed with poly-

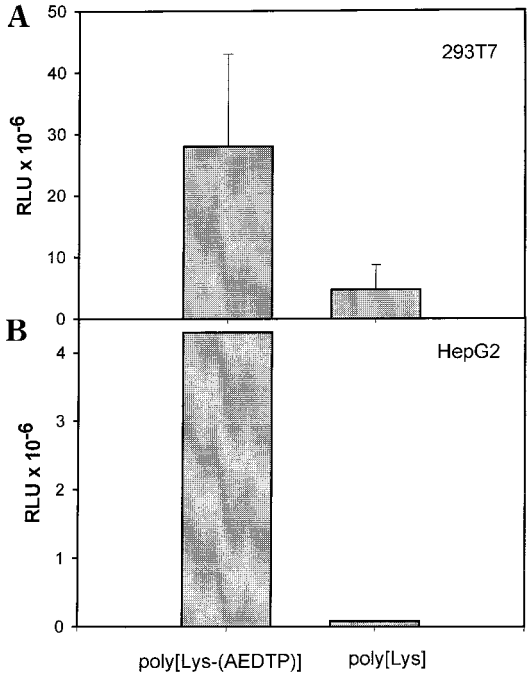

Figure 6. Poly[Lys-(AEDTP)]-mediated polyfection. (A) 293T7 cells and (B) HepG2 cells were incubated for 4 h at 37 °C with 5 μg of pUT650 complexed with either poly[Lys-(AEDTP)] (20 μg) or poly[Lys] (15 μg) in the presence of 10% FCS and 100 μM chloroquine. The luciferase activity was measured after a 48 h culture and expressed as RLU/10^6 cells.

lysine. The luciferase activity into HepG2 and 293T7 cells was 50- and 10-fold higher, respectively (Figure 6).

DISCUSSION

A disulfide-containing cationic polymer was designed to favor polyplexes dissociation and the release of the plasmid in a reductive medium. The substitution of each lysyl ϵ-amino group of polylysine with a 3-(2-aminoethyldithio)propionyl residue gave poly[Lys-(AEDTP)] in which all of the 190 amino groups were linked to the polylysine backbone via a disulfide bond. After mixing with pDNA, this cationic polymer induces DNA condensation and the formation of homogeneous particles with a diameter and a ζ potential similar to that of polyplexes made with polylysine. The main interesting feature of poly[Lys-(AEDTP)] is that pDNA can be released under reductive conditions found inside the cells either in the cytosol or the nucleus. We found that the luciferase activity was higher in cells transfected with poly[Lys-(AEDTP)] polyplexes than in cells transfected with polylysine polyplexes. Assuming a similar (i) uptake by the cells of polyplexes made with poly[Lys-(AEDTP)] or polylysine which exhibited similar size and charge and (ii) delivery of pDNA in the cytosol in the presence of chloroquine, the enhanced transfection with poly[Lys-(AEDTP)] polyplexes could be attributed to a better polyplexes dissociation upon the cleavage of the disulfide bonds of the polymer. This statement is supported by in vitro data showing that, in vitro under physiological conditions, glutathione induces a clear decondensation of pDNA with a significant release of the plasmid in the presence of glutathione reductase found in the cytosol of mammalian cells which has a broad substrate specificity.

Poly[Lys-(AEDTP)] was the first disulfide-containing cationic polymer reported for cell transfection. Conversely, it has been shown that cationic lipids such as 1′, 2′ dioleoyl-*sn*-glycero-3′-succinyl-2-hydroxyethyl dis-

ulfide ornithine conjugate (DOGSDSO) (*16*), the cholesteryl hemidithiodiglycolyl tris(aminoethyl)amine (CHD-TAEA) (*17*), spermine-derived amino acid linked via a disulfide bond to various hydrophobic entities (*18*), and lipoic acid-derived amphiphiles (*19*) were more efficient than their nondisulfide analogues in transfecting cells. The reduction of the disulfide bond in the cytosol, which released the pDNA as well as a reduced toxicity of these lipids by an increase of their degradation, were claimed to be involved in the efficiency of the transfection. In complexes with lipoic acid-derived amphiphiles, it was shown that pDNA was rapidly and largely released in the presence of thioredoxin (*19*). However, the release in the presence of glutathione alone was at the level we found for pDNA/poly[Lys-(AEDTP)] complexes. In the case of cationic polymers, it has been reported that the cross-linking of polyplexes via disulfide bonds, termed "caged DNA", allowing for a better stability in the extracellular medium of polyplexes, increased also the transfection efficiency (*20*, *21*). In this case, the elevation of the transfection efficiency was supposed to come from the reduction in the cytosol of the disulfide bonds leading to a decrease of the stability of polyplexes.

It is still ill-known whether the unpackaging of pDNA inside the cells could improved the transfection efficiency. Recent data have shown that an increase of the transfection efficiency of EGF−polylysine/DNA complexes was correlated to the unpackaging of pDNA and the decrease of the polyplexes stability according to the length of polylysine (*9*). Indeed, polyplexes made with polylysine of dp = 190 were more stable than polyplexes made with polylysine of dp = 36 but less efficient in transfecting cells. A fluorescence microscopy analysis showed that both pDNA and polymer were present inside the nucleus of few cells when EGF−polylysine polyplexes were made with polylysine of dp = 190, indicating that polyplexes were not dissociated. Conversely, only the pDNA was detected inside the cell nucleus when polyplexes were made with polylysine of dp = 36, indicating that polyplexes were dissociated. These data indicate that a better dissociation of polyplexes leads to a better accessibility of the plasmid to the nuclear machinery for the gene expression. Up to now, it is not clear in the case of nondividing cells whether a nuclear import of 100 nm polyplexes can occur through the nuclear pores, even when polyplexes carry nuclear localization signals. Thus, an unpackaging of the pDNA complexed with disulfide-containing cationic polymers such as poly[Lys-(AEDTP)] in the cytosol would favor its passage through the nuclear pores. At least, a decondensation of the plasmid without a complete release might protect it against degradation by cytosolic nucleases (*20*). Conversely, after the cell division, a disulfide-containing cationic polymer could favor the release of pDNA and facilitate the gene expression.

Disulfide-containing cationic polymers reducible in the cytosol could be also useful for the delivery of RNA and oligonucleotides. Indeed, cationic polymers have been used to deliver antisense or triple helix-forming oligonucleotides after the formation of complexes (*22*−*27*). Because, once in the cytosol, oligonucleotides penetrate rapidly by simple diffusion in the cell nucleus (*28*−*31*); a facilitated dissociation in the cytosol of oligonucleotide polyplexes could be achieved by using poly[Lys-(AEDTP)]. The self-assembly of RNA with a cationic polymer could also be a promising strategy to introduce RNA suitable to inhibit protein synthesis with a therapeutic effect or to express antigenic proteins (*32*−*34*). With this aim, we propose the use of poly[Lys-(AEDTP)]-like cationic polymers to complex mRNA in order to increase both its protection from nuclease degradation in the extracellular medium, its cellular uptake, its an unpackaging in the cytosol, and its transcription by the cytosolic machinery.

In conclusion, disulfide-containing cationic polymers could be good carriers for the delivery of plasmids, RNAs, and oligonucleotides. Further works are in progress to improve their efficiency. They include (i) the study of the influence of the number of disulfide bonds per polymer on the kinetic of the nucleic acids release under cytosolic conditions and (ii) the linkage of devices exhibiting fusogenic features such as histidyl residues to increase the escape of polyplexes from endocytic vesicles (*35*, *36*).

ACKNOWLEDGMENT

We thank Céline Zuber for her skillful technical assistance. We thank Drs. M. Brisson and L. Huang (University of Pittsburgh, Pittsburgh) for 293T7 cells. This work was partly supported by grants from Agence Nationale de Recherche sur le Sida (ANRS, n^0 97003). P.M. is Research Director at INSERM, C.P. an Assistant Professor at the University of Orléans, EL Chargé de Recherche at CNRS, and E.D. Research Director at CNRS.

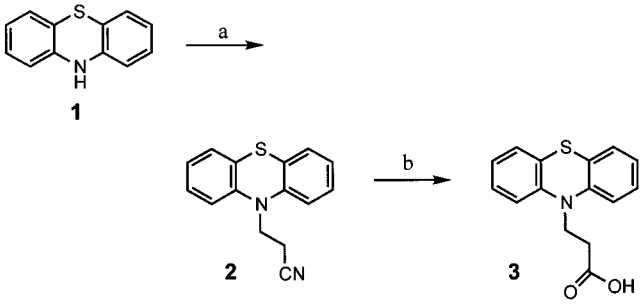
Synthesis and Characterization of Phenothiazine Labeled Oligodeoxynucleotides: Novel 2′-Deoxyadenosine and Thymidine Probes for Labeling DNA

Xi Hu, Mark T. Tierney, and Mark W. Grinstaff*

Department of Chemistry, Paul M. Gross Chemical Laboratory, Duke University, Durham, North Carolina 27708. Received April 15, 2001; Revised Manuscript Received August 15, 2001

A facile procedure for the incorporation of phenothiazine at the terminus of oligodeoxynucleotides is reported. Phenothiazine is covalently linked to the 5′-position of 2′-deoxyadenosine and thymidine. Next, the corresponding phosphoramidites are prepared, and then the labeled nucleosides are incorporated in DNA using an automated DNA solid-phase synthesizer. Phenothiazine labeled oligodeoxynucleotides form stable B-form duplexes with similar melting temperatures, CD spectra, and DSC traces compared to unlabeled DNA duplexes. The favorable photophysical properties of phenothiazine are also retained after covalent attachment to the oligodeoxynucleotide.



INTRODUCTION

Organic and inorganic chromophores possessing well-defined spectroscopic and redox properties are of interest for mechanistic studies of DNA mediated charge transfer (*1*−*15*) and for optimizing DNA diagnostic devices (*16*−*21*). Both of these interests require synthetic control over the site-specific location of the probe on the duplex. Current automated DNA synthesis technology offers a convenient and high-yielding procedure for synthesizing such duplexes. By selecting the appropriate derivatized phosphoramidite probe, this approach enables labeling at specific sites (phosphate, ribose, nucleobase) and sequence locations on the oligodeoxynucleotide. Intercalating probes such as anthraquinone and $Ru(phen)_2(dppz)^{2+}$ when covalently attached to DNA are typically tethered to the 5′- or 3′-terminal phosphate of the oligodeoxynucleotide (*1*, *2*). Yet intercalating probes alter the DNA duplex structure as evident by an increase in melting temperature and by crystallographic examination of the DNA π-stack (*22*). Nonintercalating tethered probes are less explored and provide an opportunity to assess the role of location site and the mode of attachment on duplex hybridization and on charge transfer chemistry. To expand the current repertoire of probes available for study (*23*), we are synthesizing oligodeoxynucleotides labeled at the 5-position of uridine (*24*−*27*), C8 position of 2′-deoxyadenosine (*28*), 5′-terminal phosphate (*29*, *30*), and the 5′-position of thymidine (*31*) with spectroscopic and/or redox-active chromophores. Herein, we describe the synthesis of two novel phenothiazine-2′-deoxyadenosine and -thymidine nucleosides and the incorporation of these labeled pyrimidine and purine nucleosides in oligodeoxynucleotides.

EXPERIMENTAL PROCEDURES

Reagents were purchased from Aldrich or Acros as highest purity grades and used without further purification. All solvents were freshly distilled under inert atmosphere prior to use unless otherwise noted. Dichloromethane (CH_2Cl_2) and acetonitrile (CH_3CN) were distilled from CaH_2. Ethyl ether and THF were distilled from sodium/benzophenone. Anhydrous DMF was obtained from Aldrich. All reactions were performed under inert atmosphere unless otherwise noted. Absorption spectra and melting curves were measured on a diode array spectrometer. CD spectra were recorded on a spectropolarimeter. Calorimetric data were obtained using a VP-DSC from MicroCal Inc. MALDI-TOF mass spectra of oligodeoxynucleotides were obtained using a PerSeptive Biosystems Voyager-DE Biospectrometry Workstation operating in the negative ion mode using a hydroxypicolinic acid matrix. NMR spectra were recorded on a spectrometer operating at 400 MHz. Fast atom bombardment mass spectra (FABMS) were obtained on a JEOL JMS-SX102A spectrometer using a 3-nitrobenzyl alcohol matrix.

Syntheses. *3-Phenothiazin-10-ylpropionitrile* ***2***. In a modification of a previous report by Godefroi and Wittle (*32*), phenothiazine (2.0 g; 1.0 mmol) was suspended in acrylonitrile (15 mL) and cooled to 0 °C. Tetrabutylammonium hydroxide (50% in water; 0.1 mL) was added and the mixture allowed to slowly warm to room temperature (Scheme 1). An exothermic reaction occurred immediately. Once the reaction subsided, dioxane (25 mL) was added and the mixture was heated to reflux for 1 h. The mixture was poured in water with vigorous stirring, and the resulting tan solid was filtered. Recrystallization from

acetone gave **2** as a white solid (2.2 g; 87% yield). This material was used directly in the next step.

3-Phenothiazin-10-ylpropionic Acid ***3***. This compound was prepared from **2** using the hydrolysis method described by Godefroi and Wittle (56% yield) (*32*). FAB-HRMS calcd (found) for $C_{15}H_{13}NO_2S$ (M^+) 271.0667 (271.0666).

6-N-Benzoyl-2′-deoxyadenosine ***4c.*** The reaction was performed following the literature procedure by Jones (*33*) to afford **4c** in 93% yield. This procedure also required transient protection of the 5′- and 3′-hydroxyls by TMS-Cl in pyridine, followed by addition of benzoyl chloride to protect the free amine and subsequent deprotection of the hydroxyls by ammonium hydroxide (*33*). ^{1}H NMR (DMSO-d_6): δ 2.32−2.40 (m, 1H, C2′), 2.77−2.83 (m, 1H, C2′), 3.51−3.67 (m, 2H, C5′), 3.90 (q, J = 2.8 Hz, 1H, C4′), 4.45−4.46 (m, 1H, C3′), 5.05 (s, 1H, 5′-OH), 5.39 (s, 1H, 3′-OH), 6.48 (t, J = 6.8 Hz, 1H, C1′), 7.55−8.06 (m, 5H, benzoyl), 8.69 (s, 1H, C2), 8.75 (s, 1H, C8), 11.20 (s, 1H, amide). FAB-MS calcd (found) for M^+ + H: 356.13 (356.09).

5′-O-Methanesulfonylthymidine ***5a.*** The reaction was based on a literature procedure (*34*). Thymidine **4a** (2.90 g, 12.0 mmol) was dissolved in 10 mL of dry pyridine and cooled to −10 °C. Next, mesyl chloride (14 mmol) was added dropwise over a period of 20 min (Scheme 2). The reaction mixture was then held at 0 °C for 12 h. The next day, 10 mL of methanol was added to quench the reaction, and the solvents were evaporated via high vacuum. The resulting crude product was checked by TLC and purified by column chromatography (silica gel, CH_3OH:$CHCl_3$ = 1:9). A white solid **5a** was obtained (2.95 g, 77% yield). ^{1}H NMR (DMSO-d_6): δ 1.78 (s, 3H, 5-methyl), 2.08−2.22 (m, 2H, C2′), 3.22 (s, 3H, mesyl), 3.98 (q, 1H, C4′), 4.23−4.28 (m, 1H, C3′), 4.36−4.39 (m, 2H, C5′), 5.49 (d, J = 4.4 Hz, 1H, 3′-OH), 6.22 (t, J = 7.2 Hz, 1H, C1′), 7.48 (s, 1H, C6), 11.25 (s, 1H, N3). FAB-MS calcd (found) for M^+ + H: 321.07 (321.06).

5′-O-Methanesulfonyl-6-N-benzoyl-2′-deoxyadenosine ***5b.*** Synthesized from **4c** in a similar manner as **5a**, 75% yield. ^{1}H NMR (DMSO-d_6): δ 2.40−2.47 (m, 1H, C2′), 2.88−2.96 (m, 1H, C2′), 3.16 (s, 1H, mesyl), 4.11−4.15 (m, 1H, C4′), 4.38−4.49 (m, 2H, C5′), 4.54−4.56 (m, 1H, C3′), 5.64 (d, J = 4.0 Hz, 1H, 3′-OH), 6.54 (t, J = 6.8 Hz, 1H, C1′), 7.55−8.06 (m, 5H, benzoyl), 8.65 (s, 1H, C2), 8.76 (s, 1H, C8), 11.20 (s, 1H, amide). FAB-MS calcd (found) for M^+ + H: 434.11 (434.10).

5′-Azido-5′-deoxythymidine ***6a***. A solution of **5a** (1.84 g, 5.75 mmol) in 15 mL of DMF containing lithium azide (1.60 g, 32.6 mmol) was refluxed at 90 °C under nitrogen. After 3 h, the reaction was stopped and the solvent was removed under vacuum. The resulting crude product was purified by column chromatography (silica gel, CH_3OH:$CHCl_3$ = 1:9) to afford **6a** (1.12 g, 73% yield). ^{1}H NMR (DMSO-d_6): δ 1.78 (s, 3H, 5-methyl), 2.16−2.34 (m, 2H, C2′), 3.38−3.56 (m, 2H, C5′), 3.92 (q, J = 4.8 Hz, 1H, C4′), 4.31−4.33 (m, 1H, C3′), 5.50 (s, 1H, 3′-OH), 6.13 (t, J = 7.2 Hz, 1H, C1′), 7.48 (s, 1H, C6), 11.25 (s, 1H, N3). FAB-MS calcd (found) for M^+ + H: 268.10 (268.12).

5′-Azido-6-N-benzoyl-2′,5′-dideoxyadenosine ***6b.*** Synthesized from **5b** in a similar manner as **6a**, 76% yield. ^{1}H NMR (DMSO-d_6): δ 2.45 (m, 1H, C2′), 2.97 (m, 1H, C2′), 3.51−3.67 (m, 2H, C5′), 3.99−4.03 (m, 1H, C4′), 4.47−4.49 (m, 1H, C3′), 5.52 (d, J = 4.0 Hz, 1H, 3′-OH), 6.52 (t, J = 6.8 Hz, 1H, C1′), 7.52−8.04 (m, 5H, benzoyl), 8.68 (s, 1H, C2), 8.76 (s, 1H, C8), 11.20 (s, 1H, amide). FAB-MS calcd (found) for M^+ + H: 381.13 (381.14).

5′-Amino-5′-deoxythymidine ***7a.*** A solution of 5′-azido-2′-deoxythymidine **6a** (1.12 g, 4.2 mmol) in 30 mL of methanol containing 10% Pd/C was shaken under 50 psi of hydrogen for 5 h. The catalyst was removed by filtration, and the filtrate was then concentrated to

dryness via evaporation. The resulting crude product was purified by column chromatography (silica gel, CH_3OH:$CHCl_3$ = 1:7) to yield **7a** (0.91 g, 90% yield). ^{1}H NMR DMSO, δ 1.78 (s, 3H, 5-methyl), 2.08−2.18 (m, 2H, C2′), 2.75 (s, 2H, amine), 3.50−3.60 (m, 2H, C5′), 3.64 (q, J = 3.2 Hz, 1H, C4′), 4.18−4.20 (m, 1H, C3′), 5.20 (s, 1H, 3′-OH), 6.14 (t, J = 7.2 Hz, 1H, C1′), 7.68 (s, 1H, C6). FAB-HRMS calcd (found) for $C_{10}H_{16}N_3O_4$ (MH^+): 242.1143 (242.1141).

5′-Amino-6-N-benzoyl-2′,5′-dideoxyadenosine ***7b.*** Synthesized from **6b** in a similar manner as **7a**, 62% yield.^{1}H NMR (DMSO-d_6): δ 2.31−2.36 (m, 1H, C2′), 2.71−2.89 (m, 3H, C5′+C2′), 3.16 (s, 2H, amine), 3.81 (q, J = 4.4 Hz, 1H, C4′), 4.43−4.45 (m, 1H, C3′), 5.31 (s, 1H, OH), 6.45 (t, J = 6.8 Hz, 1H, C1′), 7.52−8.05 (m, 5H, benzoyl), 8.70 (s, 1H, C2), 8.74 (s, 1H, C8). FAB-HRMS calcd (found) for $C_{17}H_{19}N_6O_3$ (MH^+): 355.1520 (355.1518).

N-(5′-Amino-5′-deoxythymidine)-3-phenothiazin-10-ylpropionamide ***8a.*** A solution of 3-phenothiazin-10-ylpropionic acid **3** (0.28 g, 1.0 mmol) and carbonyldiimidazole (CDI[1]) (0.24 g, 1.5 mmol) in 8 mL of dry DMF was stirred under nitrogen for 1 h at 25 °C. The mixture was then diluted with 17 mL of dry THF, followed by addition of the LH-20 resin (0.43 g, excess) to quench the excess CDI. An hour later, LH-20 was removed, and **7a** (0.24 g, 1.0 mmol) was added to the reaction mixture. After stirring for 12 h, the reaction was stopped, and the solvents were removed. Column chromatagraphy (silica gel, CH_3OH:$CHCl_3$ = 1:9) yielded a white solid (0.40 g, 81% yield). ^{1}H NMR (DMSO-d_6): δ 1.72 (s, 3H, 5-methyl), 1.98−2.08 (m, 2H, C2′), 2.55 (t, J = 7.2 Hz, 2H, PTZ N-CH_2), 3.20−3.38 (m, 2H, C5′), 3.68−3.69 (m, 1H, C4′), 4.07−4.12 (m, 3H, carbonyl-CH_2 and C3′), 5.24 (d, J = 4.4 Hz, 1H, 3′-OH), 6.08 (t, J = 7.2 Hz, 2H, C1′), 6.87−7.16 (m, 8H, aromatic H of PTZ), 7.42 (s, 1H, C6), 8.08 (t, J = 6.0 Hz, 1H, amide NH), 11.25 (s, 1H, C3). ^{13}C NMR: δ 13.0, 34.1, 39.4, 41.9, 43.9, 72.1, 84.6, 85.8, 110.6, 116.3, 123.5, 124.1, 128.0, 128.6, 137.1, 145.3, 151.4, 164.6, 171.3. FAB-HRMS calcd (found) for $C_{25}H_{26}N_4O_5S$ (M^+): 494.1618 (494.1621).

N-(5′-Amino-6-N-benzoyl-2′,5′-dideoxyadenosine)-3-phenothiazin-10-ylpropionamide ***8b.*** Synthesized from **7b** in a similar manner as **8a**, 82% yield. ^{1}H NMR (DMSO-d^6): δ 2.25−2.31 (m, 1H, C2′), 2.55−2.60 (m, 2H, PTZ-N-CH_2), 2.75−2.78 (m, 1H, C2′), 3.27−3.43 (m, 2H, C5′), 3.86−3.90 (m, 1H, C4′), 4.03−4.08 (m, 2H, carbonyl-CH_2), 4.37 (m, 1H, C3′), 5.37 (d, J = 4.0 Hz, 1H, 3′-OH), 6.41 (t, J = 6.8 Hz, 1H, C1′), 6.84−7.14 (m, 8H, PTZ), 7.48−8.01 (m, 5H, benzoyl), 8.12 (t, J = 6.0 Hz, 1H, PTZ amide), 8.62 (s, 1H, C2), 8.68 (s, 1H, C8), 11.14 (s, 1H, benzoyl amide). ^{13}C NMR: δ 34.1, 39.5, 42.1, 43.9, 72.5, 84.8, 86.8, 116.4, 123.4, 124.1, 127.1, 128.0, 128.6, 129.4, 133.4, 134.3, 144.4, 145.3, 151.4, 152.4, 152.8, 166.6, 171.2. FAB-HRMS calcd (found) for $C_{32}H_{29}N_7O_4S$ (M^+): 607.2002 (607.1996).

N-(5′Amino-3′-cyanoethoxydiisopropylaminophosphine-5′-deoxythymidine)-3-phenothiazin-10-ylpropionamide ***9a.*** 2-Cyanoethyl *N,N′*-diisopropylcholophosphoramidite (140 μL, 0.62 mmol) was added to a solution of **8a** (0.191 g, 0.39 mmol) in 20 mL of dry CH_3CN containing diisopropylethylamine (0.31 mL). The reaction mixture was stirred under nitrogen for 2 h. The solvent was then removed and the product checked by ^{31}P NMR($CDCl_3$): δ 149.5 and 149.9 observed. TLC: >95% yield.

N-(5′-Amino-3′-cyanoethoxydiisopropylaminophosphine-6-N-benzoyl-2′,5′-dideoxyadenosine)-3-phenothiazin-10-ylpropionamine ***9b.*** Synthesized in a similar manner as **9a**. ^{31}P NMR($CDCl_3$): δ 149.6 and 150.0 observed. TLC: >95% yield.

Oligodeoxynucleotide Syntheses. Oligodeoxynucleotide syntheses were performed on an ABI 395 DNA synthesizer from the 3′ to 5′ end using standard automated DNA synthesis protocols as shown in Scheme 3 (1.0 μmol scale). A 0.1 M solution of **9a** (or **9b**) in dry acetonitrile was prepared and installed on the DNA synthesizer in a standard reagent bottle. Normal solid-phase oligodeoxynucleotide synthesis was performed. In the last step, the PTZ-modified phosphoramidite was introduced and allowed to react with the oligodeoxynucleotide for 15 min. The PTZ-labeled oligodeoxynucleotides were cleaved from the column and deprotected in 30% NH_4OH at 55 °C for 16 h. MALDI mass spectrometry of the PTZ-oligodeoxynucleotides confirmed their formation.

	10	**11**	**12**	**13**	**14**

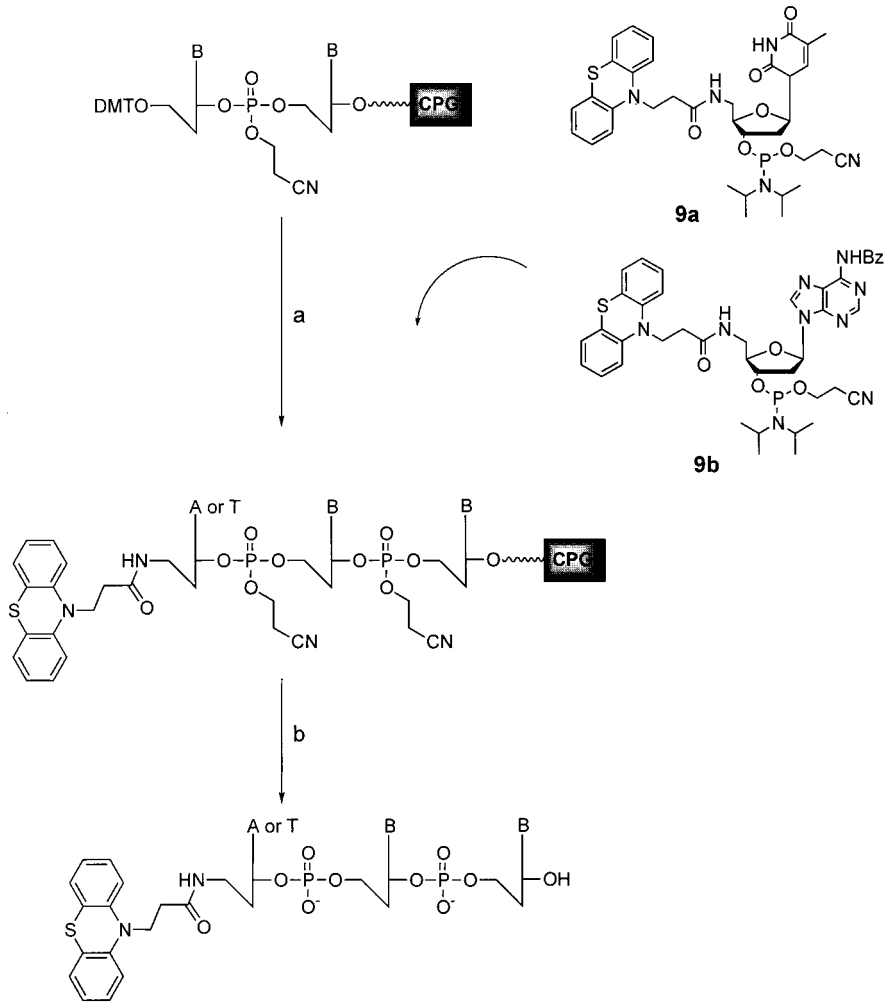
found	5437.8	5128.5	4207.1	5448.4	5144.7



HPLC Purification of the Oligodeoxynucleotides. HPLC purification of the PTZ-labeled oligodeoxynucleotides was accomplished on a Rainin HPLC instrument. Reverse phase chromatography was performed on a C18 column (25 cm × 4.6 mm) with acetonitrile (ACN) and 0.1 M triethylamine acetate (TEAA) as eluting solvents. A flow rate of 3 mL/min was used, and the concentration of ACN was increased from 5% to 50% over 40 min. The retention times of the labeled oligodeoxynucleotides were well separated from those of the unlabeled oligodeoxynucleotide products (12−13 min).

Melting Curves. The stability of the duplex formed between two complementary oligodeoxynucleotides was determined from the melting curve profiles as a function of temperature. The T_m value was determined from the first derivative. The concentrations of stock solutions of oligodeoxynucleotide single strands were determined from the UV−vis absorbance spectra. Enzyme digestion of the oligdeoxynucleotides to yield the individual nucleotides with Nuclease P1 *Penicillium citrinum* was performed by the addition of 1 μL of a 1 mg/mL solution of enzyme to 5.0 μL of oligodeoxynucleotide single strand solution and 44.0 μL of 20 mM sodium acetate buffer at pH 5.5. The solutions were incubated at 55 °C for 30 min. A sample of 20.0 μL of digest solution was diluted to 2.00 mL with water, and the absorption spectrum was measured. The total molar absorptivity was determined from the sum of all the individual contributions of each nucleoside and PTZ. The concentrations of the stock solutions were then calculated. Equimolar amounts of each single strand were measured out of the stock solutions, combined, and diluted with phosphate buffer (5 mM NaH_2PO_4, 50 mM NaCl, pH = 7) to the appropriate concentration for UV−vis measurements. The solution was heated to 90 °C for 3 min and allowed to slowly cool to room temperature. After cooling, the thermal denaturation experiment was performed using the following parameters on a HP UV−vis: (a) monitoring wavelength, 260 nm, (b) temperature range, 25−70 °C, (c) temperature step, 1.0 °C, (d) averaging time constant, 15 s, (e) 0.5 °C rate of change.

Calorimetry. A VP-DSC from MicroCal Inc. with a cell volume of 0.5136 mL was used to determine the calorimetric profiles of labeled and unlabeled DNA

[1] [1]Abbreviations: DIPEA = *N,N*-diisopropylethylamine; CDI = carbonyldiimidazole; DMT = dimethoxytrityl; PTZ = phenothiazine.

Scheme 3. Synthesis of PTZ-Labeled Oligodeoxynucleotides[a]

[a] Key: (a) normal synthesis; (b) 30% NH_3, 55 °C, 16 h. B = A, C, G, or T.

duplexes. Samples were scanned from 10 °C to 80 °C using a constant rate of 30 °C/h. Prior to each experiment, the buffer was scanned to produce a stable baseline, and then the DNA sample (37.5 μM) was scanned repeatedly until a reproducible calorimetric transition curve was obtained. Subtraction of buffer baseline and normalization of sample concentration yielded the desired heat capacity versus temperature curve. The enthalpy of transition during the melting process was determined from the area under this heat capacity peak.

RESULTS AND DISCUSSION

To capitalize on solid-phase DNA synthesis technology and the flexibility that this automated and modular approach brings to the synthesis of site-specifically labeled oligodeoxynucleotides (*35*), we require redox probes that are (1) sufficiently soluble as the labeled nucleoside phosphoramidite in acetonitrile for solid-phase reactions, (2) stable to the standard oligodeoxynucleotide syntheses and deprotection reactions so as to prevent undesired side reactions leading to loss of Watson−Crick base pairing selectivity (*36*) or decomposition, and (3) amenable to covalent attachment to both purine and pyrimidine nucleosides. The chromophore, phenothiazine (PTZ), satisfies these requirements and is known to be a low potential reductant ($PTZ^{+\bullet}$/PTZ; 0.59 V vs SCE) (*37*). The one-electron oxidized product, $PTZ^{+\bullet}$, is also spectroscopically characterized (λ_{max} = 510 nm) (*38*, *39*). Moreover, previous reports have successfully described the use of PTZ with photoexcited inorganic chromophores such as $*Ru(bpy)_3^{2+}$ to study reductive electron-transfer reactions in peptide (*37*, *39*) and DNA (*40*) assemblies.

The PTZ-derivatized 5′-deoxythymidine and *N*-benzoyl-2′,5′-dideoxyadenosine phosphoramidites, **9a** and **9b**, respectively, for automated DNA synthesis were synthesized as shown in Schemes 1−3. The 3-phenothiazin-10-ylpropionic acid, **3**, was prepared by first reacting PTZ with acrylonitrile in the presence of tetrabutylammonium hydroxide (87% yield), followed by hydrolysis with sodium hydroxide in aqueous methanol to afford the product in 56% yield (*32*). As shown in Scheme 2, the 5′-position of thymidine was converted from a hydroxyl to an amine in three consecutive steps. First, thymidine was treated with an equal amount of methanesulfonyl chloride in dry pyridine to afford **5a** (*34*). Next, the 5′-mesyl group was substituted with lithium azide to yield **6a**. Finally, **6a** was reduced with H_2 and Pd/C to give the 5′-amino-5′-deoxythymidine, **7a** in 90% yield. This reduction method was preferred to that of using triphenylphosphine and ammonium hydroxide (72% yield). The primary hydroxyl of 2′-deoxyadenosine was converted to an amine in a similar manner, except that the primary amine was first protected with a benzoyl group (Scheme 2). This step required transient protection of the 5′- and 3′-hydroxyls by TMS-Cl in pyridine, followed by addition of benzoyl chloride and subsequent deprotection of the hydroxyls by ammonium hydroxide (*33*). Unlike the thymidine synthesis, the reduction of **6b** to **7b** was best achieved using

Pd/C hydrogenation. The carboxylic acid derivatized PTZ, **3**, was then coupled to 5′-amino-5′-deoxythymidine (**7a**) or *N*-benzoyl 5′-amino 2′,5′-dideoxyadenosine (**7b**) in DMF using CDI (Scheme 2). Other amide forming strategies using DCC or the NHS activated ester were explored, but yielded less product. Finally, **8a** and **8b** were reacted with 2-cyanoethyl-*N*,*N*′-diisopropylchlorophosphoramidite in dry CH_3CN to afford the PTZ-phosphoramidite, **9a** and **9b**. The PTZ-thymidine and PTZ-2′-deoxyadenosine phosphoramidites were now ready for use in an oligodeoxynucleotide synthesizer (ABI 392).

Standard solid-phase oligodeoxynucleotide syntheses were performed (*35*, *41*), except that in the last coupling step the PTZ-modified thymidine or 2′-deoxyadenosine phosphoramidite was introduced as shown in Scheme 3. All syntheses were performed at the 1.0 μmol scale using the standard coupling protocol except that the final step proceeded for 15 min to ensure sufficient reaction time for **9a** and **9b**. Collection and analysis of the DMT-fractions during automated synthesis showed efficient phosphoramidite couplings throughout the procedure, with both the standard pyrimidine and purine nucleosides (>98%) and **9a** and **9b** coupled in ≈80%. Once synthesized, the PTZ-labeled oligodeoxynucleotides were cleaved from the column, and the nitrogenous bases and phosphate groups were deprotected in 30% ammonium at 55 °C. The oligodeoxynucleotides (see Table 1) were subsequently purified by RP-HPLC and analyzed by MALDI mass spectrometry.

A temperature change of approximately 1 °C is observed in the melting temperature between the unlabeled and PTZ-dA or PTZ-dT labeled oligodeoxynucleotides as determined by temperature-dependent optical measurements (see Figure 1 and Table 2). This difference in melting temperature is small indicating that labeling the 5′-terminal nucleotide of the oligodeoxynucleotide does not dramatically alter the DNA duplex structure. Differential scanning calorimetry (DSC) data provide additional insight into the thermodynamic consequences of PTZ labeling at the ribose (*42*, *43*). As shown in Table 2, the transition enthalpies ($\Delta H°$) of the PTZ-T and PTZ-A labeled and unlabeled 16-mer duplexes are 71.0, 70.6, 66.8, and 68.0 kcal/mol, respectively. The differences in transition enthalpy change ($\Delta\Delta H°$) for the unlabeled and labeled dT and dA duplexes are 0.4 and 1.2 kcal/mol, respectively. These $\Delta H°$ values are deduced from the heat capacity/temperature relationship, such as the one shown in Figure 2 for the PTZ-dT (**11•21**) labeled and unlabeled (**16•21**) duplex. The free energies ($\Delta G°$) at 25 °C for the PTZ-dT and -dA labeled and unlabeled 16-mer duplexes are 5.4, 5.6, 4.9, and 5.0 kcal/mol, respectively. There is only a modest decrease in free energy ($\Delta\Delta G°$) of 0.2 kcal/mol or less for the labeled duplex relative to the unlabeled duplex. The heat capacity traces shown in Figure 2 for the PTZ-T-labeled duplex can also be fit to a two-state model, and the calculated van't Hoff enthalpy (ΔH_v) is 70.4 kcal/mol. This value is similar to the measured enthalpy. These data suggest that a two-state (all-or-none) helix to coil transition occurs in the labeled and

Table 2. Optical and DSC Thermodynamic Data for the PTZ-dT Labeled and Unlabeled Duplexes

	optical data	DSC data				
duplex	T_m °C ± 0.5	T_m °C ± 0.5	ΔH (kcal/mol) ± 1.0	ΔH_v (kcal/mol) ± 1.0	ΔS (cal/mol) ± 3.0	ΔG at 25 °C (kcal/mol) ± 0.1
11·21	49.7	49.6	71.0	70.4	220.1	5.4
16·21	49.6	50.7	70.6	74.6	218.1	5.6
14·24	51.0	48.4	66.8	69.5	207.8	4.9
19·24	49.7	48.6	68.0	70.9	211.4	5.0

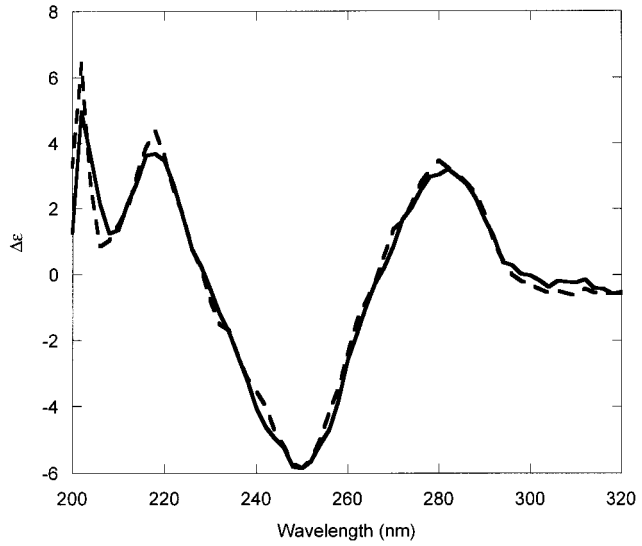

Figure 3. CD spectra of PTZ-dT labeled (**11·21**; solid line) and unlabeled (**16·21**; dashed line) oligodeoxynucleotide duplexes.

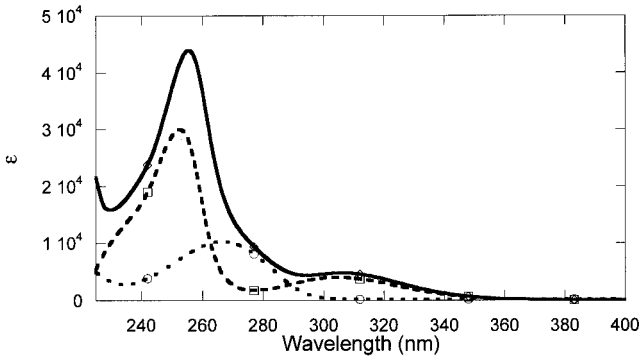

Figure 4. UV-vis spectra of PTZ-acid (**3**, dashed line), thymidine (**4a**, dotted line), and PTZ-thymidine (**8**, solid line).

unlabeled duplexes, and that introduction of PTZ does not generate intermediate states. The formation of a well-defined DNA duplex structure is also supported by circular dichroism (CD) spectroscopy. Figure 3 shows the CD spectra for the unlabeled (**16•21**) and PTZ-thymidine labeled (**11•21**) duplexes. Circular dichroism spectra (*44*) of the unlabeled, PTZ-thymidine labeled, and PTZ-adenosine labeled are similar, and the spectral features for B-DNA are present.

Covalent attachment of PTZ to the 2′-deoxynucleoside or oligodeoxynucleotide does not alter its spectroscopic properties. The UV−vis spectra of PTZ-labeled thymidine (**8a**), phenothiazine (**3**), and thymidine (**4a**) are shown in Figure 4 (1:1 CH_3CN:H_2O). The electronic spectrum of **8a** is a summation of PTZ and thymidine. Specifically the PTZ π-to-π and weak π-to-n absorption are observed at 250 and 306 nm, respectively. The thymidine π-to-n absorption is at 267 nm (Figure 4) (*45*). The PTZ-labeled oligodeoxynucleotide possess an absorption at 260 nm, but the absorption of PTZ at lower energy is masked by the DNA. Excitation of **8a** or **8b** at 315 nm produces an emission centered at 450 nm in 1:1 CH_3CN:H_2O in agreement with the reported literature value (*45*). Likewise, the excitation spectra of ss **14**, and ds **14•24** in phosphate buffer (50 mM NaCl, 5 mM NaH_2PO_4, pH = 7) possess a maximum at 315 nm, and the corresponding emission spectra possess a broad emission centered at 450 nm.

CONCLUSION

The site-specific labeling of oligodeoxynucleotides at a 5′-terminal thymidine or 2′-deoxyadenosine with phenothiazine is reported. The PTZ-labeled oligodeoxynucleotides form stable B-form duplexes with melting temperatures comparable to the unlabeled analogues. Similar results are also observed with oligodeoxynucleotides labeled with PTZ at the nucleobase (*28*) and 5′-terminal phosphate (*30*) indicating that PTZ is amenable to covalent attachment to DNA at different locations. Calorimetric data on the unlabeled and PTZ labeled duplexes reveal only a slight decrease in stability upon labeling with PTZ. The spectroscopic properties of PTZ are retained when the complex is covalently attached to DNA at the 5′-terminal thymidine or 2′-deoxyadenosine position. In summary, these two novel PTZ-modified thymidine and 2′-deoxyadenosine increase the number of well-characterized probes available for study, and the corresponding PTZ-labeled oligodeoxynucleotides are of use for DNA-mediated charge-transfer studies. Photophysical studies are currently underway to monitor the electron-transfer intermediate ($PTZ^{+\bullet}$) in a site-specifically labeled duplex containing PTZ and the inorganic chromophore, $Ru(bpy)_3^{2+}$.

Purity determination by HPLC

The purity of the compounds was determined on a Rainin HPLC instrument system with Adsorbosphere Nucleoside-Nucleotide column (from Alltech, 250 mm × 4.6 mm). Aqueous solution containing 5 mM $N(Bu)_4(H_2PO_4)$ and 60 mM NH_6PO_4 (solvent A), and 5 mM $N(Bu)_4(H_2PO_4)$ in methanol (solvent B) were used as eluting solvents. A flow rate of 1.5 mL/min was used and the concentration of B was increased from 50% to 80% over 30 minutes.

Immobilization of Biomolecules on Polyurethane Membrane Surfaces

Patrick Reichmuth,[†] Hans Sigrist,[‡] Martin Badertscher,[§] Werner E. Morf,[†] Nicolaas F. de Rooij,[†] and Ernö Pretsch*[,§]

Institute of Microtechnology (IMT), University of Neuchâtel, Rue Jaquet-Droz 1, CH-2007 Neuchâtel, Switzerland, Centre Suisse d'Electronique et de Microtechnique SA (CSEM), Rue Jaquet-Droz 1, CH-2007 Neuchâtel, Switzerland, and Swiss Federal Institute of Technology (ETH), Laboratorium für Organische Chemie, Universitätstrasse 16, CH-8092 Zürich, Switzerland. Received May 21, 2001

Lipophilic polymer membranes incorporating binding sites are widely used in various potentiometric, amperometric, and optical sensors. Here, we report on the biofunctional modification of the surface of a Ca^{2+}-selective membrane. A photoactivatable biotin derivative was synthesized and covalently immobilized on a soft polyurethane membrane. The modified polymer was characterized by X-ray photoelectron spectroscopy (XPS) as well as by potentiometric measurements. The selective binding of streptavidin by the photo-cross-linked biotin derivative was demonstrated. The surface coverage obtained with different experimental protocols was analyzed by autoradiography using [^{35}S]-streptavidin. The new approach may significantly extend the scope of applicability of potentiometric sensors.

INTRODUCTION

Lipophilic polymeric membranes incorporating ion-selective ligands (ionophores) and ion exchangers are widely applied in potentiometric sensors (*1*, *2*). The emf response is in most cases governed by the phase boundary potential that is defined by the bulk properties of the membrane and the sample (*1*, *3*). Plasticized poly(vinyl chloride) is the most widely used membrane matrix, but polymers with low glass transition temperatures such as polyurethanes (*4*), silicon rubber (*5*−*8*), and polyacrylates (*9*, *10*) have also been used without plasticizer. Owing to their relatively good biocompatibility, polyurethanes, especially the commercially available Tecoflex, are the best investigated alternatives to PVC (*4*, *11*−*13*). Usually, the ion exchanger and the ionophore are simply dissolved in the polymer matrix, but in other cases they have also been covalently bound to the polymer backbone (*6*, *9*, *10*, *14*−*16*). To improve the biocompatibility, the surface of potentiometric sensor membranes has been modified by covalent attachment of poly(ethylene oxide) (*17*), heparin (*18*), or theophylline (*19*). So far, however, a surface modification of ion-selective electrode membranes with specific, biofunctional binding sites has not yet been reported.

On the other hand, a number of techniques have been used to create selective reaction layers by covalently binding organic compounds to various substrates. One of the most versatile methods is photo-cross-linking using agents that form nitrenes, carbenes, or ketyl radicals upon irradiation (*20*). For example, Yan et al. used functionalized perfluorophenyl azides to pattern the surface of polystyrene (*21*, *22*). Similarly, Hengsakul et al. used an azidobenzene derivative of biotin for protein patterning of polystyrene or nitrocellulose surfaces (*23*). Several biotin derivatives with photosensitive groups have been described in the literature (*24*−*30*). More recently, carbene-generating photobiotins were used for the segregation of micrometer-sized domains of glassy-carbon, quartz, and polymer surfaces (*31*), for the preparation of bioprobes such as a photoaffinity taxoid probe (*32*), or for a photoaffinity labeling system for a glycosyltransferase (*33*).

Here we report on the synthesis of a novel photoactive biotin derivative **5** (Figure 1), its immobilization on the surface of an ion-selective polyurethane membrane (Tecoflex, **6** in Figure 1), and its interaction with streptavidin. The long-term goal of these studies is the development of new sensors to monitor guest molecules that are selectively complexed by host molecules immobilized on the sensor surface. The basic idea is to realize systems that yield a response signal due to the alteration of ion fluxes, similar to the principle used in channel-mimetic sensors (*34*). Instead of using an external current, the response would depend on zero-current transmembrane ion fluxes. The relevance of such fluxes has been demonstrated recently (*35*−*37*). At submicromolar sample activities, flux modulation may have a dramatic effect on the emf response of polymer membrane electrodes (*38*−*41*).

EXPERIMENTAL PROCEDURES

General Methods. Reagents and solvents were reagent-grade and used without further purification, except for THF, which was distilled. Tecoflex SG-80A was purchased from Thermedics Inc. (Woburn, MA). *N*,*N*-Dicyclohexyl-*N*,*N*-dioctadecyl-3-oxapentanediamide (ETH 5234), sodium tetrakis[3,5-bis(trifluoromethyl)phenyl]-borate (NaTFPB), and streptavidin from *Streptomyces avidinii* were obtained from Fluka AG (CH-9471 Buchs, Switzerland). *N*-[3-[3-(trifluoromethyl)diazirine-3-yl]phenyl]-4-maleimidobutyramide (**1**, MAD) was synthesized by

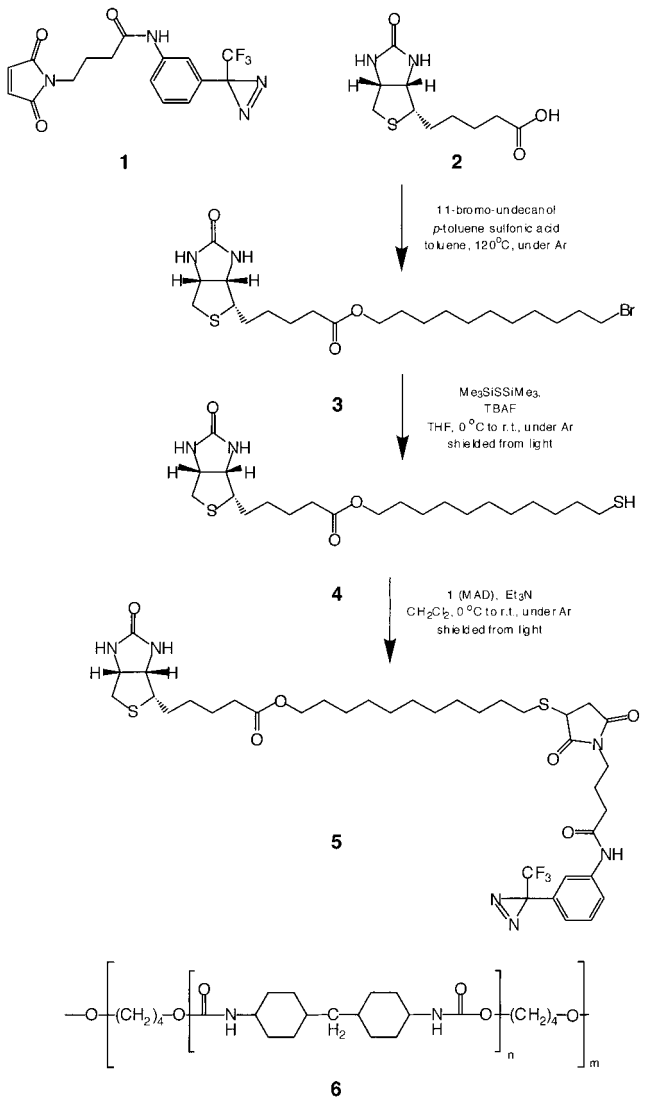

Figure 1. Synthetic pathway to biotin derivative **5**.

Collioud et al. (*42*). [^{35}S]-Streptavidin from Amersham (CH-8600 Dübendorf, Switzerland) had a specific activity of 7.4−74 TBq mmol^{-1}. Gold (99.99%) was obtained from Balzers AG (FL-9496 Balzers, Liechtenstein). Aqueous solutions were prepared with freshly deionized water (18.0 MΩ cm specific resistance) obtained with a NANOpure reagent-grade water system (Barnstead, CH-4009 Basel, Switzerland).

All reactions were performed in standard glassware. Evaporation and concentration in vacuo were done at water aspirator pressure, and compounds were dried at 10^{-2} mbar. Flash column chromatography was made with SiO_2 60 (220−440 mesh, 0.035−0.070 mm) from Fluka, TLC aluminum plates coated with SiO_2 60 F_{254} were from E. Merck, and the substances were visualized by UV light at 254 or 366 nm. TLC glass plates coated with SiO_2 (Silgur-25 UV_{254}) were from Macherey-Nagel (CH-4702 Oensingen, Switzerland). The following instruments were used: melting points, Büchi melting point apparatus (CH-9239 Flawil, Switzerland); IR spectra, 883 infrared spectrophotometer from Perkin-Elmer; UV/vis spectra, Uvikon 940 from Kontron Instruments; EI-MS, VG Tribid instrument, 70 eV; ESI-MS, Finnigan TSQ 7000 instrument; NMR spectra, Varian Gemini 200 (200 MHz) or Bruker AMX-2−500 (500 MHz) spectrometer at 300 K, with solvent peaks as reference.

Syntheses. *Synthesis of (3aS,4S,6aR)-11-Bromoundecyl 5-(Hexahydro-2-oxo-1H-thieno[3,4-d]imidazol-4t-yl)-pentanoate (**3** in Figure 1).* A mixture of biotin (**2**, 1.350 g, 5.5 mmol), 11-bromo-1-undecanol (6.940 g, 27.6 mmol), *p*-toluenesulfonic acid (0.105 g, 0.55 mmol), and toluene (34 mL) was stirred and refluxed at 120 °C for 48 h under argon (*43*). The reaction mixture was cooled to room temperature. Precipitated unreacted biotin was separated by filtration, the solvent was removed in vacuo, and the residue was purified by flash chromatography (MeOH/CH_2Cl_2 5:95) to give **3** as a white solid (1.970 g, 70%). Anal. ($C_{21}H_{37}N_2O_3SBr$) C, H, N, O, S, Br. Mp: 103.5−104.0 °C. IR ν_{max} (cm^{-1}): 3462, 2929, 2853, 1705, 1597. ^{1}H NMR (500 MHz, CD_2Cl_2, δ): 1.28−1.47 (m, 16H), 1.57−1.74 (m, 6H), 1.85 (m, −CH_2CH$_2$Br, 2H), 2.31 (t, J = 7.4 Hz, −CH_2C(O)OCH$_2$−, 2H), 2.71 (d, J = 12.6 Hz, −CHCH_2S−, 1H), 2.90 (dd, J = 12.6 Hz, J = 5.0 Hz, −CHCH_2S−, 1H), 3.17 (m, −SCH−, 1H), 3.42 (t, J = 6.9 Hz, −CH_2Br, 2H), 4.03 (t, J = 6.9 Hz, −OCH_2−, 2H), 4.30 (m, −NHCHCH$_2$−, 1H), 4.48 (m, −NHCH(CH−)$_2$, 1H), 5.43 (s, −NHCH(CH−)$_2$, 1H), 5.73 (s, −NH-CHCH$_2$−, 1H). ^{13}C NMR (125 MHz, CD_2Cl_2, δ): 25.28, 26.33, 28.57, 28.70, 28.78, 29.07, 29.15, 29.65, 29.81, 29.86, 29.88, 33.31 (−CH$_2$CH$_2$Br), 34.31, 34.68, 41.04 (−CH$_2$S−), 55.90 (−SCH−), 60.54 (−NCHCH$_2$), 62.28 (−NCH(CH−)$_2$), 64.82 (−C(O)OCH$_2$−), 163.94 (−NC(O)N−), 173.95 (−C(O)O−). *Synthesis of (3aS,4S,6aR)-11-Sulfanylundecyl 5-(Hexahydro-2-oxo-1H-thieno[3,4-d]imidazol-4t-yl)pentanoate (**4** in Figure 1).* A stirred solution of **3** (1.000 g, 2.09 mmol) in THF was cooled to −10 °C, and hexamethyldisilathiane (2.20 mL, 10.45 mmol) and TBAF (10.5 mL, 1.0 M solution in THF with 5% water, 10.45 mmol) were added (*44*). The resulting reaction mixture was allowed to warm to room temperature while it was stirred. The reaction was carried out under argon and under shielding from ambient light in order to avoid photoinduced side reactions. After 20 min, the reaction mixture was washed with 20 mL of aqueous ammonium chloride (saturated) and 10 mL of CH_2Cl_2. Recrystallization from CH_2Cl_2 and hexane gave **4** as white solid (0.673 g, 75% yield). Anal. ($C_{21}H_{38}N_2O_3S_2$) H, N; C: calcd, 58.57; found, 57.94; S: calcd 14.89; found, 14.31 (the ^{1}H NMR spectrum indicated that some disulfides occurred as impurities in the product). Mp: 99.5−101.0 °C. IR ν_{max} (cm^{-1}): 3462, 2929, 2853, 1705, 1597. UV (CH_2Cl_2) λ_{max} (log ϵ): 219 (0.48). ^{1}H NMR (500 MHz, CD_2Cl_2, δ): 1.28−1.47 (m, 17H), 1.57−1.74 (m, 6H), 1.87 (m, −CH_2CH$_2$SH, 2H), 2.31 (t, J = 7.4 Hz, −CH_2C(O)OCH$_2$−, 2H), 2.50 (q, J = 7.4, −CH_2-SH, 2H), 2.71 (d, J = 12.7 Hz, −CHCH_2S−, 1H), 2.91 (dd, J = 12.7, 5.0 Hz, −CHCH_2S−, 1H), 3.16 (m, −SCH−, 1H), 4.03 (t, J = 6.8 Hz, −OCH_2−, 2H), 4.30 (m, −NHCHCH$_2$−, 1H), 4.48 (m, −NHCH(CH−)$_2$, 1H), 5.44 (s, −NHCH(CH−)$_2$, 1H), 5.71 (s, −NHCHCH$_2$−, 1H). ^{13}C NMR (125 MHz, CD_2Cl_2, δ): 24.96 (−CH$_2$SH), 25.28, 26.33 28.71, 28.78 (2C), 29.08, 29.47, 29.66, 29.90 (3C), 34.32, 34.53, 41.04 (−CH$_2$S−), 55.90 (−SCH−), 60.54 (−NCCH$_2$), 62.27 (−NC(CH−)$_2$), 64.82 (−C(O)OCH$_2$−), 163.91 (−NC(O)N−), 173.95 (−C(O)O−). *Synthesis of (3aS,4S,6aR)-11-[[3-(3-Trifluoromethyl-3H-diaziren-3-yl)phenylamino][1-(4-oxobutyl)pyrrolidine-2,5-dioxo-3-yl]thio]undecyl 5-(Hexahydro-2-oxo-1H-thieno-[3,4-d]imidazol-4t-yl)pentanoate (**5** in Figure 1).* To a solution of **4** (7.32 mg, 17 μmol) in CH_2Cl_2 (3 mL) at 0 °C was added a solution of **1** (6.23 mg, 17 μmol) in 0.2 mL CH_2Cl_2, followed by 5 drops of triethylamine. The mixture

was allowed to reach room temperature and then was stirred for 7 h. The reaction was shielded from light in order to avoid photoinduced side reactions and was carried out under argon. The resulting mixture was concentrated under reduced pressure, and the residue was purified by chromatography on a silica glass plate (hexane/1,2-dichloroethane/acetonitrile/ethanol 40:30:24:6) to give **5** as a diastereoisometric mixture in form of a white solid (11.1 mg, 82% yield). ^{1}H NMR (200 MHz, $CDCl_3$, δ): 1.28−1.49 (m, 16H), 1.57−1.74 (m, 8H), 2.04 (m, $-NCH_2CH_2CH_2CO-$, 2H), 2.33 (m, $-CH_2COOCH_2-$, $-NCH_2CH_2CH_2CO-$, 4H), 2.50 (dd, J = 18.7, 3.3 Hz, $-CH_2CH_2S-$, 2H), 2.69−3.00 (m, $-CHCHS-$, $-SCHCH_2-$CO−, 4H), 3.07−3.24 (m, $-SCHCHNH$, 1H), 3.58−3.76 (m, $-NCH_2-$, $-SCHCO$, 3H), 4.07 (t, J = 6.6 Hz, $-OCH_2-$, 2H), 4.35 (m, $-NHCHCH_2-$, 1H), 4.53 (m, $-NHCH(CH-)_2$, 1H), 4.88 (s, $-NHCH(CH-)_2$, 1H), 5.06 (s, $-NHCHCH_2-$, 1H), 6.94 (d, J = 7.1 Hz, Ar H, 1H), 7.34 (t, J = 7.9 Hz, Ar H, 1H), 7.48 (s, Ar H, 1H), 7.67 (d, J = 7.5 Hz, Ar H, 1H), 8.55 (d, J = 5.4 Hz, −NH-Ar, 1H). ESI-MS m/z: $(M + 1)^+$ 797, $(M + Na)^+$ 819, $(M + K)^+$ 835.

Atomic Force Microscopy (AFM). Glass microscope slides covered with an Au layer were prepared according to a standard procedure for self-assembled monolayers (*45*). Solution aliquots of pure Tecoflex were cast onto the gold substrate (1.0 × 1.0 cm^2) resulting in a membrane of 200 μm thickness. An Autoprobe CP from Park Scientific Instruments was used to image the pure Tecoflex membrane. The images were collected in intermittent-contact mode, in room atmosphere, and at ambient temperature. Commercially available silicon cantilevers with high aspect ratio tips were used.

X-ray Photoelectron Spectroscopy (XPS). The gold substrates covered with pure Tecoflex were washed in ethanol and dried for 1 h at room temperature under high vacuum (10^{-2} mbar). Then 25 μL of a solution of **1** (2.7 mM in ethanol) was deposited. The samples were dried under a vacuum of 20 mbar for 1 h at room temperature. For XPS-studies after photobinding, the samples were irradiated for 20 min using a Stragene UV Stratalinker 350 nm light source with a radiance of 0.95 mW cm^{-2} and washed in hexane and in ethanol (*42*, *46*). Photolyses were done at ambient temperature (20−25 °C). The surface of dry membrane films was analyzed via XPS under an ultrahigh vacuum of 10^{-9} mbar. Spectra were collected with a Perkin-Elmer 5700 spectrometer (Perkin-Elmer, Norwalk, CT) using an Al Kα X-ray source ($h\nu$ = 1486.7 eV) with an emission power of 350 W to stimulate photoelectron emission. A spherical analyzer with an investigation area of 0.80 mm^2 was used, and the hydrocarbon C1s peak was referenced at 285 eV. Samples were analyzed at 45° takeoff angle (the angle between the surface normal and the analyzer lens axes). An average of three measurements was obtained. Data were collected and stored on a Perkin-Elmer computer, which also controlled the spectrometer. Software provided with the instrument was used to interpret the data.

Potentiometry. The ion-selective membranes contained 2.0 wt % (25.0 mmol kg^{-1}), ETH 5234, 1.0 wt % (11.0 mmol kg^{-1}) NaTFPB, and Tecoflex. A membrane of 100 μm thickness was obtained by casting a solution of 316.80 mg of the membrane components, dissolved in 2.5 mL THF, into a glass ring (60 mm i.d.) fixed on a glass plate covered with a Teflon foil. For each ISE, a disk of 7 mm diameter was punched from the membrane and glued to plasticized PVC tubing with THF. The inner filling solution was 0.05 M Na_2EDTA, 10^{-3} M $CaCl_2$, and 0.06 M NaOH (pH 8.9, calculated ion activity $a_{Ca^{2+}}$ = 2.3 × 10^{-12} M). A diaphragm separated the internal filling solutions from the reference half cell (Ag/AgCl in 0.1 M KCl. The ISEs were conditioned for 2 d in a solution of 5 × 10^{-5} M 2-morpholinoethanesulfonic acid (MES) and 5 × 10^{-5} M NaOH (pH 6.5). Measuring solutions were prepared by successive automatic dilution of stock solutions with a Liquino 711 and two Dosino 700 instruments (Metrohm AG, CH-9010 Herisau). Potentials were measured with a 16-channel electrode monitor EMF16 (Lawson Labs Inc., Malvern, PA 19355) at room temperature (20−21 °C) in solutions stirred with a rod stirrer. An Ag/AgCl reference electrode (Metrohm, type 6.0729.100) with a 1 M KCl bridge electrolyte was used. All EMF values were corrected for the liquid-junction potential at the sample/bridge electrolyte interface using the Henderson equation (*3*).

For the preparation of ISEs with immobilized **5**, ISE membranes were washed in deionized water and dried under vacuum (20 mbar) for 1 h at room temperature. Then 40 μL of an acetonitrile (MeCN) solution of **5** (0.28 mM) were deposited on each membrane. The samples were dried for 1 h under a vacuum of 20 mbar at room temperature. For photobinding, the ISEs were irradiated for 20 min using a Stragene UV Stratalinker 350 nm light source with a light intensity of 0.95 mW cm^{-2} and washed in MeCN. Photolyses were done at ambient temperature (20−25 °C). The conditioned ISEs were set, before the streptavidin incubation, into a solution of 0.02% polyoxyethylenesorbitan monolaurate (Tween 20) for 20 min. A 0.1 M MES buffer of pH 6.1 (with NaOH) was used for the streptavidin binding experiments. The concentration of streptavidin in the MES buffer was 42 μg mL^{-1} (0.7 μM), and the reaction of this solution with the surface was allowed to proceed for 1 h. The membranes were rinsed with water in order to remove unbound streptavidin and set back into the conditioning solution for 1 h before the potentiometric measurements.

Radiochemistry. Glass slides (0.8 × 0.8 cm^2) were covered with a membrane which had the same composition as the one used in the potentiometric experiments. All samples were washed in acetonitrile (MeCN) and dried under vacuum (10^{-2} mbar) for 1 h at room temperature. Samples of series A and B: deposition of 25 μL of a solution of **5** (2.3 mM in MeCN), drying for 10 min under high vacuum of 0.05 mbar at room temperature, UV irradiation, washing in MeCN. Samples of series C: deposition of 25 μL of **5** (2.3 mM in MeCN), drying for 20 min under 0.05 mbar at r.t., UV-irradiation, washing in MeCN. Samples of series D, E, and F: deposition of 25 μL **5** (2.3 mM in MeCN), drying for 80 min under 0.05 mbar at rt, UV irradiation, washing in MeCN. Samples of series G: deposition of a pure MeCN drop, drying for 80 min under 0.05 mbar at rt, UV irradiation, washing in MeCN. Samples of series H and I: only washing in MeCN. All photobinding experiments were carried out employing a high-pressure mercury lamp (Osram HBO 350 W) mounted in a SUSS LH 1000 lamp house equipped with a shutter to control exposure times. The samples were irradiated for 200 s with a light intensity of 1.14 W cm^{-2} at 365 nm at ambient temperature (20−25 °C).

After the photoimmobilization, the glass slides with the membrane were conditioned in water for 2 d. A 0.1 M MES buffer of pH 6.1 (with NaOH) was used for the streptavidin binding. The protein concentrations in the MES buffer were 21 μg mL^{-1} (0.35 μM) streptavidin (not radiolabeled) and 3.1 ng mL^{-1} (52 pM) [^{35}S]-streptavidin with an activity of 15.4 × 10^3 Bq mL^{-1}. After being rinsed with water in order to remove unbound streptavidin,

[a] The capital letters correspond to the series described in the Experimental Procedures and Figure 3. [b] The radiolabel densities were quantified by autoradiography. Error bounds correspond to standard deviations obtained from five measurements (four in series F).

the samples were set back into the conditioning solution for 1 h, and dried at room temperature for 15 h. As shown in Table 2, some sample series were set into a solution of 0.02% Tween 20 for 20 min before or after the streptavidin incubation. Autoradiography of the dried glass slides with the membranes was done with storage screens from Molecular Dynamics (Sunnyvale, CA), which were exposed for 12 h. For quantification, a PhosphorImager from Molecular Dynamics and an external one-point calibration ($n = 5$) with [^{35}S]-streptavidin was used. All work with radioactivity was performed in a certified laboratory.

RESULTS AND DISCUSSION

In this work, the surface of an ion-selective polyurethane membrane was modified by photocross-linking of biotin. First, the morphology of a pure Tecoflex membrane without **1** was mapped out using atomic force microscopy (AFM). The surface structure of the Tecoflex membrane was featureless with a root-mean-square roughness of about 0.7 nm. The height differences between the lower and higher spots were around 3 nm. Nurdin et al. (*47*) found for a similar polyurethane surface, after drying it in the vacuum, a peak-to-valley distance of about 15 nm. The plain and homogeneous surface morphology of the investigated polyurethane is well suited for the planned application. In the next step, X-ray photoelectron spectroscopy (XPS) was used to obtain evidence for the cross-linking of **1** to the polyurethane membrane surface. Tecoflex membranes with and without **1** were examined by XPS for providing a qualitative and quantitative analysis of their surface. No fluorine was detected in the case of membranes without **1** (Table 1). There are small differences between the surface concentrations determined from the XPS analysis (Table 1, second row) and the bulk membrane composition found from the elemental analysis (Table 1, first row). This may be the consequence of a phase separation that takes place at the few outermost molecular layers of the polyurethane, where little or no hard segments were found in earlier studies (*48*, *49*). For the membrane with **1**, the detection of fluorine is a clear evidence for the successful photoimmobilization on the membrane surface (*46*).

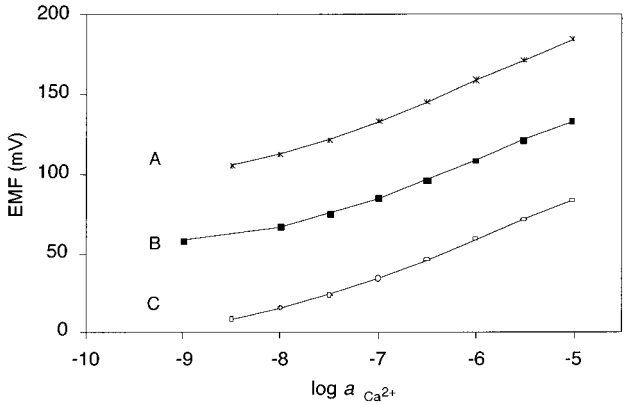

Figure 2. Response of ISEs based on the calcium-selective ionophore ETH 5234, NaTFPB and Tecoflex: A, without B and C with surface modification with **5**; C, after incubation with a streptavidin solution. Inner filling solution: 0.05 M Na_2EDTA, 10^{-3} M $CaCl_2$, and 0.06 M NaOH (pH 8.9). Sample solution: $CaCl_2$ in a buffer of 5×10^{-5} M 2-morpholinoethanesulfonic acid (MES) and 5×10^{-5} M NaOH (pH 6.5). Electrode slopes (mV dec^{-1} in the range 10^{-5} M bis 10^{-7} M): A, 25.8; B, 24.3; C, 25.0.

On the basis of the positive results of the above-described preliminary experiments, a biotin derivative with a covalently attached photo-cross-linking unit was designed and synthesized. The synthetic pathway to the novel photobiotin **5** with the carbene-generating trifluoromethylaryldiazirine group is shown in Figure 1. Brooks et al. demonstrated recently that photo-cross-linking of a related photobiotin (*31*) was more efficient than for the nitrene derivative used in their earlier studies (*31*). The photo-cross-linking unit is a derivative of *N*-[3-[3-(trifluoromethyl)diazirine-3-yl]phenyl]-4-maleimidobutyramide (**1**, MAD), which has been shown to have excellent properties in several earlier studies (*20*). To obtain optimal binding characteristics of streptavidin, a spacer with a carbon chain of 11 CH_2 groups is interposed between the biotin moiety and the photocross-linker (*24*, *25*). The intermediate product **4**, a thiol-bearing biotin derivative was prepared by a simpler procedure and in a higher yield than for similar compounds described previously (*26*−*30*).

The influence of the surface modification on the potentiometric response behavior of membrane-based sensors was investigated for Ca^{2+}-selective electrodes. A complete coverage of the membrane with a dense layer of proteins may be expected to result in a different response signal of the respective ISE. The experiments were performed using calcium-selective electrodes based on Tecoflex membranes. The biotin derivative **5** was photoimmobilized onto the surface of the membranes containing the Ca^{2+}-selective ionophore ETH 5243 and the ion exchanger NaTFPB (see the Experimental Procedures). To achieve detection limits in the nanomolar range (*39*, *50*), the inner filling solution of these ISEs contained a high sodium activity and a low calcium activity established with EDTA as ion-buffering system. The calibration curves of an untreated membrane (A) and one with immobilized biotin (B) were found to be virtually identical (Figure 2). This is even true for membrane B after incubation in a streptavidin solution (curve C). In all cases, it is possible to measure calcium activities down to the nanomolar range. It appears that the surface-immobilized biotin−streptavidin conjugate does not influence the potentiometric response of these sensors.

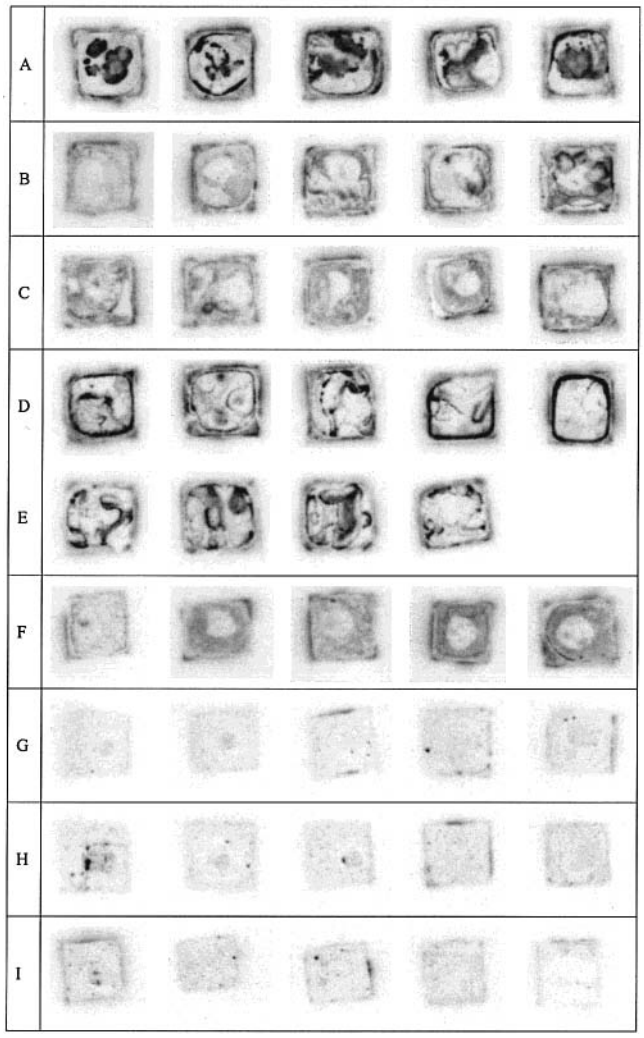

Figure 3. Autoradiographic measurements on Tecoflex films-coated (8 × 8 mm) glass slides, after incubation into a solution of [^{35}S]-streptavidin. The darkness is proportional to the density of bound or adsorbed [^{35}S]-streptavidin. Contact times before photo-cross-linking (in min): A, B, 10; C, 20; D−F, 80; blank samples: GI. Tween 20 was applied before streptavidin for samples B, C, and F and after streptavidin for membranes E. The density values shown in the five columns were determined from repeated experiments under identical conditions.

Evidently, the exchange of calcium ions at the interface between membrane and sample solution is not blocked by the binding of streptavidin. This implies that the streptavidin layer on the membrane surface cannot be very dense. To confirm this hypothesis, the surface coverage is analyzed experimentally in the following section.

The distribution of covalently bound biotin accessible for conjugation with streptavidin was monitored by autoradiography using the soft β-emitter [^{35}S]-streptavidin as radiolabel. The experiments were performed on Tecoflex membranes that had the same composition as the ones used for the ISE measurements. From the data shown in Figure 3 and Table 2, it is evident that the membranes with photoimmobilized biotin (A − F) bind a significantly larger amount of [^{35}S]-streptavidin than the ones without biotin (G and H). Consequently, the cross-linked biotin derivative is able to bind [^{35}S]-streptavidin on the polyurethane surface, and its biological activity is apparently not affected by the photochemical immobilization process. Although some adsorption of streptavidin occurs even for membranes without biotin, the effect is in all cases smaller than for membranes with biotin. While the surface distribution of the labeled streptavidin strongly varies from experiment to experiment (rows in Figure 3), the variation of the total amount within a given series of experiments is much smaller (Table 2, last column). The nonuniform distribution of the labeled streptavidin on membranes A−F must be caused by irregular photoimmobilization of **5**, since the [^{35}S]-streptavidin coverage on membranes G−I without immobilized biotin is found to be much more homogeneous, as shown in Figure 3. The heterogeneity of the coverage by **5** after deposition and vacuum treatment can even be observed with a magnifying glass. Previously, nonuniform immobilization of photobiotin was also reported for the case of solid substrates (*51*). AFM images also indicated that the distribution of streptavidin on biotinylated surfaces is nonuniform, and that the proteins tend to cluster (*52*). More than 80% of the adsorbed proteins were found in clusters of three or more molecules (*28*). Similarly, it was found that only a part of biotin is able to bind avidin if it is immobilized on a surface (*51*).

One of the reasons for the heterogeneous photoimmobilization may be the low photocoupling efficiency. For example, it was found in previous studies that the photocoupling efficiency of MAD-[^{35}S]Cys to polystyrene is only 7% (*42*). In the present system, the diffusion of the biotin derivative **5** into the polyurethane membrane before cross-linking may also have an effect. The diffusion coefficient of organic compounds in such membranes is on the order of 10^{-8} cm^2 s^{-1} (*1*). Assuming that compound **5** is sufficiently soluble in Tecoflex, one would expect a mean diffusion distance of 35 and 49 μm after 10 and 20 min, respectively. The amount of biotin available for the surface reaction would decrease accordingly. The measured dependence of the streptavidin density on the contact time before photo-cross-linking suggests such an influence. Figures 3 A vs D, as well as Figure 3 B and C vs F, indicate that an effect is well observable after contact times of 80 min, but the differences are small between 10 and 20 min.

To reduce nonspecific adsorption of proteins, the corresponding substrates are occasionally treated with a surfactant (*53*). Experiments were done in these lines with the nonionic surfactant Tween 20. If the surfactant is applied before the contact of the biotinylated membrane with [^{35}S]-streptavidin, the surface concentration of bound proteins is heavily reduced (see A vs B and D vs F in Figure 3 and Table 2). However, as demonstrated by the experiments H and I, this decrease is not due to a reduction of the nonspecific adsorption. It might rather be a consequence of an accumulation of Tween 20 at the membrane surface (*54*, *55*) and its competitive binding to the protein (*56*). In striking contrast, a treatment of the membranes after conjugation with [^{35}S]-streptavidin does not affect the surface concentration at all (see D and E in Figure 3 and Table 2).

Before performing the radiochemistry experiments, the membranes were kept 2 d in distilled water. As indicated by control experiments without conditioning (not shown) this did not significantly influence the measured [^{35}S] activity. Thus, once the biotin derivative is bound to the surface, it forms a rather stable layer despite the presence of a soft polymer substrate. Using the density of a two-dimensional crystalline streptavidin (C2,2,2) monolayer (262 ng cm^{-2}) (*30*, *57*) the percentage of the protein bound relative to the amount required for a compact monolayer can be calculated. It is 120% for membrane A and 50−60% for membranes D and E with long contact times before photoimmobilization.

CONCLUSIONS

We demonstrated that biotin can be covalently immobilized on the surface of a soft polyurethane and that the immobilized biotin is capable of binding streptavidin. Films made from Tecoflex, the applied polyurethane, seem to be ideally suited as substrate because of their very plain surface. While the total amount of streptavidin bound to the biotinylated polyurethane is rather close to that required for a compact monolayer, the uniformity varied significantly. Such a variation was also observed earlier with hard substrates (*51*).

ACKNOWLEDGMENT

This work was financially supported by the Swiss National Science Foundation, the National Institutes of Health (Grant No. R01-GM59716), and Orion Research, Inc. (Beverly, MA). We gratefully acknowledge the help of Martin Püntener and André Müller concerning the syntheses, Andrea Rainelli for some preliminary measurements, Prof. Roel Prins for permission to use his AFM instrument, and Prof. Nicholas Spencer for performing the XPS measurements.

An Efficient Binding Chemistry for Glass Polynucleotide Microarrays

Paul H. Lee,[†] Samuel P. Sawan,[‡] Zora Modrusan,[†] Lyle J. Arnold, Jr.,[†] and Mark A. Reynolds*[,†]

Incyte Genomics, Microarray Research and Development, 6519 Dumbarton Circle, Fremont, California 94555 and University of Massachusetts, Department of Chemistry, One University Avenue, Lowell, Massachusetts 01854. Received June 29, 2001; Revised Manuscript Received September 10, 2001

A variety of methods have been described for making synthetic polynucleotide microarrays. These include in situ synthesis directly on the array surface, for example, by photolithography or ink-jet printing technologies, and the application of presynthesized polynucleotides that are derivatized with various nucleophiles or electrophiles. In the latter case, a variety of surface chemistries have been developed, and several are available commercially. These chemistries must be compatible with nanoliter-scale volumes of polynucleotide reagents, which contact the array over a small portion of their surface. We reasoned that a three-dimensional polymer coating could potentially offer greater surface contact and higher binding efficiency. Here we describe a polyethylenimine-based coating chemistry that provides exceptional binding and hybridization characteristics. In our preferred process, size-fractionated polyethylenimine polymers are cross-linked onto an aminopropylsilanated glass surface in the presence of cyanuric chloride. The resulting three-dimensional coating binds polynucleotides through a mixture of covalent and noncovalent interactions as evidenced by comparisons between 5′-aminoalkyl modified and unmodified polynucleotides. Binding and hybridization comparisons are presented including analogous two-dimensional electrophilic and electrostatic chemistries.

INTRODUCTION

Microarray platform development has accelerated in recent years for a variety of biological applications. These include gene and protein expression profiling, where hundreds to thousands of biomolecules are analyzed simultaneously (*1*, *2*). Recent improvements have been driven by an increasing need for sensitivity and precision (*3*), as multivariate analyses and database approaches become more commonly employed (*4*). In the case of microarrays that are prepared by deposition (spotted arrays), a robust binding chemistry is essential for optimal performance. Such chemistry must be capable of binding the deposited target molecules with high efficiency without compromising their ability to bind their intended query molecules. Moreover, reproducible performance between batches is essential for generating data of sufficient quality to be incorporated into a relational database.

Over the past several years we have developed and optimized a commercial cDNA-based microarray platform (LifeArray) for gene expression profiling. This platform utilizes PCR-amplified cDNA clones that are representative of publicly available and proprietary expressed gene sequences. Our standard production process has been described previously (*5*). Briefly, the PCR-amplified products are spotted onto an aminopropylsilanated glass surface (up to 10000 spots over a 12 × 12 mm area). In our standard dual channel format, mRNA samples from two different tissues (for example a reference pool and a diseased or drug-challenged tissue) are labeled with two different fluorescent dyes (cyanine-3 and cyanine-5) by reverse transcription. The resulting cDNA probes are pooled, copurified, and hybridized together on the array. The arrays are then detected with a dual laser scanner and analyzed using GEMTools image analysis software. This process generally yields greater than 2.5 logs dynamic range, has a sensitivity of 1:100000 (about 1 copy per cell), and can detect greater than 1.7-fold differential gene expression at ≥99.5% confidence (*6*).

Recently, our laboratory developed a synthetic polynucleotide microarray platform (Z. Modrusan et al., manuscript in preparation). This platform offers several potential advantages compared to our standard cDNA microarrays, including the ability to generate arrays from sequences for which no cDNA clones are yet available and the possibility of higher gene discrimination by avoiding repetitive and homologous sequences. The development of synthetic polynucleotide microarrays with sensitivity and precision rivaling our commercial cDNA platform proved to be a considerable challenge. For example, a survey of commonly reported and commercially available glass chemistries resulted in sensitivities that were at best about 10-fold lower than cDNA microarrays (M. A. Reynolds and P. H. Lee, data not shown). On the basis of these results, we decided to examine cross-linked polymer chemistries, assuming that this approach might enable a higher density of bound polynucleotide per unit surface area.

Several cross-linked polymer chemistries have already been described for microarray applications. These include polyacrylamide gel pads (*7*, *8*) and mixed dendrimers that are synthesized in situ (*9*). Polyethylenimine has been used successfully for the chromatographic separation of nucleic acids (*10*) and also as a transfection agent for plasmids and antisense oligonucleotides (*11*). It is relatively inexpensive and can be size fractionated and characterized prior to conjugation. We reasoned that this

polymer might also enhance the binding and hybridization of polynucleotides on microarrays, due to its electrostatic character and three-dimensional structure. Here we describe a method of conjugating polyethylenimine onto glass microarray surfaces. The method involves cyanuric chloride, a multifunctional cross-linking agent that provides residual electrophilic activity for reaction with deposited polynucleotides.

MATERIALS AND METHODS

Unless noted otherwise, all glass chemistry was conducted in a particle-free fume hood configured for HEPA filtration (Clean Air Products, Minneapolis, MN). Coated slides were stored desiccated at room temperature until used. Commercial poly-L-lysine coated glass slides were purchased from Sigma (Poly-Prep Slides, St. Louis, MO).

Preparation of Aminopropylsilanated Glass Slides (APS slides). Glass microscope slides (Corning, purchased from VWR Scientific, Part No. 48312-036) were cleaned in an ultrasonic bath (Branson Ultrasonics Corp., Danbury, CT) with 1% SDS followed by 4% aqueous hydrofluoric acid. The slides were then dried in an oven at 110 °C. After cooling to room temperature in the hood, the slides were immersed in a solution of 3-aminopropyltrimethoxysilane (0.05% w/v in 95% ethanol, Aldrich, Milwaukee, WI), rinsed several times with 95% ethanol, and then cured in an oven at 110 °C.

Preparation of Cyanuric Chloride-Activated Slides (CC-slides). Aminopropylsilanated slides were immersed in a stirred slurry of cyanuric chloride (12.7 g, Aldrich, Milwaukee, WI) and sodium carbonate (25 g) in *n*-hexane (1 L) at 4 °C for 1 h. The slides were then rinsed with *n*-hexane in an ultrasonic bath and air-dried.

Reaction of Cyanuric Chloride-Activated Slides with Polyethylenimine (PEI-slides). CC-slides were immersed in a stirred 0.1% aqueous solution of polyethylenimine (Aldrich Lot No. 40.872-7, average M_n ca. 10000 (GPC), average Mw ca. 25000 (LS), branched polymer) at 4 °C for 1 h with ultrasonication. The slides were then rinsed several times in deionized water with ultrasonication and air-dried.

Second Reaction of Polyethylenimine-Coated Slides with Cyanuric Chloride (P-slides). PEI-slides were reacted a second time with cyanuric chloride as described above (CC-slides) to cross-link the polyethylene polymers on the surface and to provide residual electrophiles for reaction with spotted analytes. After rinsing with *n*-hexane, these slides were further rinsed with acetone before air-drying.

FTIR-ATR Spectroscopy. The chemically modified slides were analyzed on a Nexus Model 470 instrument to confirm coating compositions (Nicolet Instrument Corp.).

Dynamic Contact Angle Measurements. Surface wetability and surface roughness were measured using a Model DCA315 dynamic contact angle analyzer (Cahn Instruments, Inc., CA). Each value reported represents the average of six independent measurements over a 2.5-cm × 3.5-cm area with an advancing speed of 80 μm/s. Distilled water and methylene iodide were used as test liquids with a two-parameter surface energy model[12] to isolate the London dispersion (d) and Keesom polar (p) contributions to the solid vapor surface tension, γ_s.

$$\gamma_s = \gamma_s^{\,d} + \gamma_s^{\,p}$$

The method of analyzing contact angle data according to the above surface energy model has been described by Kaelble (*13*).

$$(1 + \cos\theta_1)\gamma_1 = 2\,[(\gamma_1^{\,d}\,\gamma_s^{\,d})^{1/2} + (\gamma_1^{\,p}\,\gamma_s^{\,p})^{1/2}]$$

$$(1 + \cos\theta_2)\gamma_2 = 2[(\gamma_2^{\,d}\,\gamma_s^{\,d})^{1/2} + (\gamma_2^{\,p}\,\gamma_s^{\,p})^{1/2}]$$

In the case of water and methylene iodide, the solid vapor surface tension parameters have already been described: $\gamma_{water}{}^{d} = 22.1$, $\gamma_{water}{}^{p} = 50.7$ erg/cm^2; for methylene iodide $\gamma_{CH_2I_2}{}^{d} = 44.1$, $\gamma_{CH_2I_2}{}^{p} = 6.7$ erg/cm^2 (*14*). The slides were first assayed in distilled water, dried overnight in a dust-free fume hood, and then analyzed in methylene iodide.

Fluorescent Probe for Reactive Cyanuric Chloride Residues. An amino-reactive fluorescent dye was prepared to probe the various glass coatings containing reactive cyanuric chloride residues. FluoroLink Cy3 monofunctional dye (Amersham-Pharmacia Biotech) was reacted with a 5-fold molar excess of 1,7-diaminoheptane (Aldrich Chemical Co., Milwaukee, WI) to generate an amino-reactive fluorescent probe for surface characterization. Slides were reacted with an aqueous solution of the resulting dye mixture (1 μM final concentration of Cy3 dye) for 30 min at room temperature, washed sequentially with 0.1 N NaOH, 0.2% SDS, and deionized water, and then spun dry. Samples of "capped" surfaces containing cyanuric chloride residues were pretreated with 1,7-diaminohexane (1 mM in distilled water overnight at room temperature) before reaction with the fluorescent dye reagent.

Polynucleotide Reagents. Synthetic 59-mer polynucleotides modified with primary alkylamino moieties and/or cyanine dyes were purchased from Operon Technologies (Alameda, CA, YCF115 sequences, see Table 1) and TriLink Biotechnologies (San Diego, CA, YCF3 sequences, see Table 1). Each polynucleotide targets an inter-ORF region of *S. cerevisiae*. The regions selected are approximately 1000 bp in length and contain minimal sequence homology against any known expressed human gene sequence. Polynucleotide concentrations were determined by absorbance spectroscopy using a molar

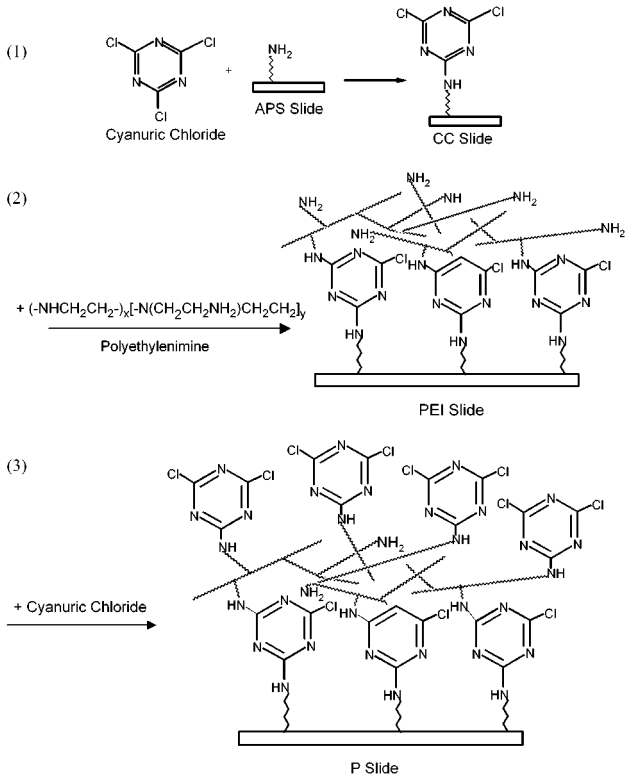

Figure 1. Schemes for the synthesis of APS, CC, PEI, and P glass surface coatings.

extinction coefficient (260 nm) of 5.7×10^5 $M^{-1}cm^{-1}$. Stock solutions were prepared in 2X SSC buffer (300 mM NaCl, 30 mM sodium citrate, pH 7.0).

Microarray Fabrication and Polynucleotide Binding. A dilution series of each polynucleotide (containing 10-mol % of the corresponding Cy3-labeled polynucleotide as an internal standard) was prepared in 4-fold replication in microtiter plates. All dilutions were made in 2X SSC buffer (2.5−20 μM final concentrations). Microarraying was performed in the Incyte Genomics microarray facility (80−100 μm spots at 180-μm spacing, center to center). For postprocessing, the slides were rinsed in 0.2% SDS for 2 min followed by three 1 min rinses in deionized water. Next, they were treated with 0.2% I-Block reagent (Tropix, Bedford, MA) in 1X Dulbecco's phosphate-buffered saline (Life Technologies, Gaithersburg, MD) at 60 °C for 30 min. Finally, they were washed again in 0.2% SDS and water as described above. These microarrays were analyzed for Cy3-dye fluorescence (see below) to determine percent bound polynucleotide = (avg. Cy3 fluorescent counts after washing)/(avg. Cy3 fluorescent counts post-arraying) × 100.

Table 2. Dynamic Contact Angle Measurements for Chemically Modified Glass Slides[a]

surface	θ_{H_2O}	$\theta_{CH_2I_2}$	γ^d(erg/cm^2)	γ^p(erg/cm^2)	γ(erg/cm^2)
APS slides	72.5	40.2	33.7	7.5	41.2
CC slides	87.2	37.7	38.5	1.4	39.9
PEI slides	62.8	32.0	35.7	11.6	47.4
P slides	72.0	37.0	35.2	7.3	42.5

[a] The standard deviations for θ_{H_2O} and $\theta_{CH_2I_2}$ were less than 2° and 1°, respectively.

Preparation of Inter-ORF *S. cerevisiae* RNA Transcripts for Probe Generation. T7 RNA transcripts were generated from PCR-amplified yeast templates by incorporating a T7 promoter sequence in the upstream PCR primer and a polyA sequence in the downstream PCR primer. The resulting in vitro RNA transcripts were then purified, quantified, and included in every probe labeling reaction at specified inputs (see below).

Probe Labeling and Hybridization. Synthetic yeast RNA transcripts corresponding to target polynucleotides (1 ng) were added to complex human placenta mRNA (200 ng, Biochain Institute, Hayward, CA) and then fluorescently labeled by reverse-transcription with cyanine-5 (Cy5) fluorescent dye (GEMbright labeling kit, Incyte Genomics) as previously described (*6*). The resulting Cy5-labeled cDNA probes were purified by size exclusion chromatography (TE-30 column, Clontech, Palo Alto, CA), ethanol-precipitated, and then resuspended in 24 μL of hybridization buffer (5X SSC, 0.2% SDS, 1 mM DTT).

The resuspended fluorescent cDNA probes were applied to the microarrays under 22 × 22 mm glass cover slips, placed in sealed chambers to prevent evaporation, and then incubated at 60 °C for 6 h. After hybridization, the microarrays were washed in 0.1X SSC/1 mM DTT at 45 °C for 10 min.

Scanning and Data Analysis. The microarrays were scanned at 532 nm (cyanine-3) and 635 nm (cyanine-5) using a dual-laser confocal fluorescence scanner (Axon Instruments, Foster City, CA) at 10 μm resolution. These signals were collected with 16-bits-per-pixel resolution. In the case of nonarrayed slides treated with amino-reactive Cy3-dye reagent, the images were analyzed with

GenePix software provided by the manufacturer. To monitor polynucleotide binding (Cy3 channel) and hybridization (Cy5 channel), the images were analyzed with GEMTools image analysis software (Incyte Genomics) to provide corrected signal intensities including local background subtraction. Tab-delineated text files were exported from GEMTools for graphical analysis using Microsoft Excel software. Reported signals are the average of 160 data points (80 spots per slide × 2 slides per assay). Error bars are one standard deviation from the mean.

RESULTS

Synthesis and Characterization of Glass Coatings. Figure 1 summarizes the steps used to prepare the two- and three-dimensional surface coatings described in this study. Each step was monitored by FTIR spectroscopy to confirm chemical modification (Figure 2). FTIR spectra were unchanged before and after treatment of the glass slides with aminopropyltrimethoxysilane, indicating that the thickness of this layer was below the detection limit of the instrument (i.e., less than about 1 μm). However, resonance in the range of ~1260 to 1540 cm^{-1} could be detected after treatment with cyanuric chloride (CC slides), indicative of 1,3,5-triazine ring stretching. Further reaction with polyethylenimine (PEI slides) resulted in a number of new resonances detected, including peaks at 2864 and 2975 cm^{-1} that are indicative of $-CH_2-$ stretching.

Surface wetability, commonly defined as the contact angle resulting when a liquid spot contacts a surface, was measured after each of the treatment steps using dynamic contact angle analysis (see Materials and Methods). The application of two different solvents of widely different known polarities (water and methylene iodide) enabled determinations of surface energy for each surface (Table 2). The observed increase in γ^d and decrease in γ^p after treatment with cyanuric chloride (CC slides) is consistent with a decrease in the polar nature of the surface. After reaction with polyethylenimine (PEI slides), γ^d decreased slightly and γ^p increased dramatically, consistent with an increase in surface polarity. Further

reaction with cyanuric chloride (P slides) decreases γ^p and leaves γ^d essentially unchanged, indicating that a majority of amino moieties exposed to solvent are unreacted with cyanuric chloride.

The availability of reactive electrophiles on each glass coating was probed with an amino-reactive Cy3 fluorescent dye. Capped slides that had been pretreated with 1,7-diaminoheptane were included in this experiment for comparison (see Materials and Methods). Histograms of the resulting fluorescent signals before and after capping are shown in Figures 3a and 3b, respectively. In each case, the fluorescent signals from capped slides were significantly reduced, demonstrating that the capping reaction was greater than 97% efficient. In the absence of capping, CC slides showed considerably less fluorescence than P slides, consistent with their respective two- and three-dimensional surface characteristics. P slides were more fluorescent than PEI slides as expected based on their additional treatment with cyanuric chloride. However, the data indicates that PEI slides retain considerable electrophilic activity (presumably due to residual mono- and bis-functional cyanuric chloride residues at the interface between APS and polyethylenimine layers).

Covalent Contribution to Surface Binding. To assess the contribution of reactive cyanuric chloride residues to polynucleotide binding, samples of CC, PEI, and P slides were pretreated with 1,7-diaminoheptane ("capped") prior to arraying, as described in the previous section. The contribution of covalent reaction chemistry to polynucleotide binding can be inferred by comparing data from uncapped and capped slides, respectively. Polynucleotides with and without alkylamino modification were included in this assessment (see Table 1). The averaged polynucleotide binding signals (Cy3-channel) are summarized in Figure 4. As predicted, the covalent binding contribution was higher for the three-dimensional surfaces (PEI and P) compared to the two-dimensional CC surface. P slides showed the highest covalent contribution, indicating that reactive cyanuric chloride residues are readily accessible to spotted polynucleotides. PEI slides showed a lower covalent contribution, suggesting that cyanuric chloride residues are less accessible on this coating. It is interesting to note that some covalent contribution can also be attributed to the unmodified polynucleotide (i.e., no alkylamino linker). This indicates that other nucleophilic groups of the polynucleotide are also able to react with cyanuric

Table 3. Relative Percentages of Deposited Polynucleotide[a]

10 μM	2.1	12	18	21
20 μM	2.0	9	13	16

[a] Based on averaged Cy3 signals pre- and postwashing.

chloride residues. The data from unmodified polynucleotide bound to the capped surfaces provides a relative measure of noncovalent binding (Figure 4b). In this case, the P and PEI slides performed similarly, and both showed increased binding relative to the CC and APS surfaces. These data indicates that P and PEI slides bind spotted polynucleotides through a combination of covalent and noncovalent interactions. Overall, the relative ranking for polynucleotide binding was P > PEI > CC > APS.

Relationship between Polynucleotide Binding and Hybridization. A two-color format was employed to monitor polynucleotide binding and probe hybridization in Cy3 and Cy5 channels, respectively. In this case, the slides were scanned pre- and postwashing. The percentages of deposited polynucleotide retained on each surface are summarized in Table 3. As in the previous experiment, the relative ranking was P > PEI > CC > APS. In each case, the amounts of bound polynucleotide increased with their prearrayed concentrations. However, the percentages of retained polynucleotide decreased at higher concentrations (Table 3). As observed in the previous experiment, the two-dimensional surfaces (APS and CC) showed lower binding efficiencies over the concentration range investigated, whereas the three-dimensional surfaces (PEI and P) showed higher binding efficiencies (up to 35% in the case of P slides).

The microarrayed slides were then hybridized to a complementary RNA transcript in the presence of a complex RNA background (human placenta mRNA) to provide a relative measure of their binding and hybridization efficiencies. For comparison purposes, commercial poly-L-lysine-coated glass slides were included in this experiment. The averaged binding (Cy3) and hybridization (Cy5) signals are summarized in Figure 5. In general, the hybridization signals showed a good correlation with the binding signals, although they appeared to plateau above 10 μM arrayed polynucleotide in the case of the P surface (Figure 5b).

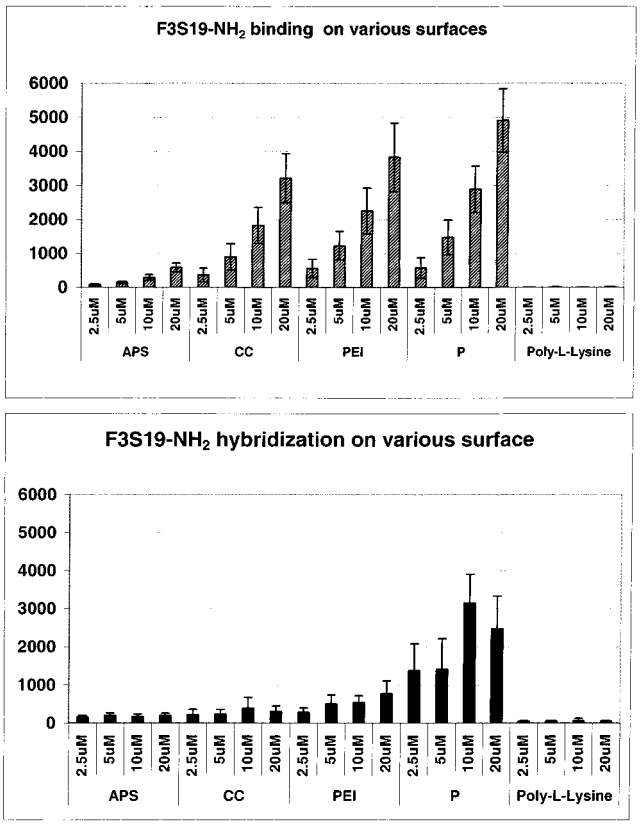

Figure 5. Comparison of averaged binding (Cy3) and hybridization (Cy5) signals for various chemically modified glass slides. Only polynucleotides modified with alkylamino linkers were used in this experiment. These polynucleotides had the sequence designation "YCF3" (see Table 1). (a) Binding signals (Cy3). (b) Hybridization signals (Cy5).

CONCLUSIONS

The results presented in this study demonstrate that glass coatings containing polyethylenimine provide enhanced binding of spotted polynucleotides. In particular, the P coating provided the best overall binding and hybridization performance. A number of other binding chemistries have been investigated in our laboratory, both on two-dimensional APS coatings and three-dimensional polyethylenimine coatings (data now shown). These include surface derivatization with reactive alkyl and aryl esters, aldehydes, and isothiocyanates, as have been described elsewhere (*15*−*17*). In practice, cyanuric chloride has provided the best and most consistent binding results.

The commercial polylysine surface showed low binding and hybridization efficiency according to our experimental conditions. It is possible that alternative conditions could improve the binding performance of this surface (i.e., different array buffers, wash conditions, etc.), but this possibility was not explored in detail.

In summary, a glass coating comprising polyethylenimine and reactive cyanuric chloride residues has been developed for the production of spotted polynucleotide microarrays. This surface binds polynucleotides through a combination of covalent and noncovalent interactions. The application of this surface to the production of polynucleotide microarrays is currently being investigated in our laboratory. Polynucleotide microarrays generated with this coating have discriminated gene transcripts sharing up to about 80% sequence identity (human cytochrome P-450 family, M. A. Reynolds, unpublished results). Preliminary studies with microarrays targeting human gene transcripts demonstrate comparable specificity and sensitivity to our commercial cDNA platform for gene expression profiling (Z. Modrusan, manuscript in preparation).

ACKNOWLEDGMENT

We thank Scott Braxton and Tod Bedilion for early contributions to this work. We also thank Rick Johnston, Scott Winder, and Sang Park for guidance and assistance with surface analyses.

The immobilization of thiol-derivatized DNA on a Au (111) single crystal surface by self-assembly has been investigated by electrochemical scanning tunneling microscopy (EC-STM). Continuous potential-dependent orientation changes of double-stranded oligodeoxynucleotides (ODN) have been observed in a certain potential range from 200 to 600 mV (versus SCE). It is suggested that the DNA duplexes stand straight on the gold surface at potentials negative of the potential of zero charge (pzc) and then lay down on the surface when the potential shifts positively. These results are in agreement with the expectation based on the Coulombic interaction consideration between negatively charged DNA helices and gold surface. As the applied potential shifts positively, the surface charge changes from negative to positive, that is, the Coulombic force between negatively charged DNA helices and gold surfaces changes from repulsion to attraction. However, for the single-stranded oligodeoxynucleotides, no distinct changes in the surface structure were observed with the applied potential.

INTRODUCTION

The immobilization of DNA is of great importance for the investigation of interaction between DNA and other molecules by surface-based methods, as well as for DNA biosensors (including genochips) with potential use in disease diagnosis and genome sequencing. Many researchers have highlighted the immobilization and characterization of DNA on surfaces. Numerous methods, including X-ray photoelectron spectroscopy (XPS) (*1*, *2*), ellipsometry (*1*), electrochemical method (*3*−*5*), neutron reflectivity (*6*), surface plasmon resonance (SPR) (*5*, *7*), Raman spectroscopy (*8*), and STM (*8*) have been used to study this highlighted topic. However various fundamental and underlying problems, such as the relationship between structure and orientation of surface-anchored DNA and their biological affinity, the relation between the microenvironment on the electrode surface, and the behavior of DNA-modified electrodes, still remain as open questions. The imaging of DNA immobilized on the surface, which could provide detailed and direct recognition of the structure and orientation of the immobilized DNA, has explored very little. By using scanning probe microscopy (SPM), this goal can be achieved. Scanning tunneling microscopy (STM) (*9*−*16*) and atom force microscopy (AFM) (*17*−*21*) have been used for investigation of the DNA structure. These techniques can, in principle, reach atomic resolution and can be operated under the natural conditions, for instance, in aqueous solution and at ambient temperature and pressure, under which conditions the biomolecules behave naturally.

Barton and co-workers investigated the applied potential effect on the orientation of self-assembled DNA helices on gold by electrochemical in-situ atom force microscopy (EC-AFM) (*21*). They found that the monolayer height varied with the applied potential, but no clear and detailed image of the DNA monolayer was acquired.

We report herein the immobilization of thiol-derivatized oligodeoxynucleotides (HS-ODN) containing 15 base pairs on gold via self-assembly and the direct EC-STM observation of ODN monolayer on Au (111) surface. It was found that the STM images of double-stranded oligodeoxynucleotides changed with the applied potential, and the results seemed to agree with electrostatic interaction between negatively charged ODN helices and gold surface. However, perhaps due to their poor rigidity, the images of single-stranded oligodeoxynucleotides were not very clear and seemed not to change with applied potential.

EXPERIMENTAL PROCEDURES

Materials. All solutions were prepared with deionized water (≥18MΩ·cm) from a Millipore MilliQ system. Oligodeoxynucleotides were purchased from Shanghai Sangon Biotechnical Co. Ltd. and used without further purification. A sequence of 5′-TGT ACA GTC ATC GGG-3′ had a 6-mercaptohexyl linker at the 5′-terminus, the control sample had the same sequence but no 6-mercaptohexyl linker contained, and the complementary strand was 5′-CCC GAT GAC TGT ACA-3′. All oligodeoxynucleotides were dissolved in 10 mM pH 7.4 Tris-HCl buffer containing 1 mM EDTA (TE buffer). Double-stranded oligodeoxynucleotides were prepared through hybridization before immobilized on gold surfaces. Hybridization

was performed at 37 °C for 120 min in TE buffer (pH 7.4) containing 0.5 M NaCl.

Preparation of the DNA-Modified Gold Electrodes. A flame-annealed Au (111) surface for EC-STM measurements prepared as reported previously (*8*) or a pretreated gold electrode for cyclic voltammetry (CV) had been immersed in 8.1 μM thiol-derivatized oligodeoxynucleotide (pH 7.4 TE buffer, 0.5 M NaCl) (HS-ODN) for 12 h at 4 °C, followed by a thorough rinse with deionized water to remove unbound ODN; thus, an electrode modified with a self-assembled monolayer of ODN obtained. The concentration of oligodeoxynucleotides in XPS

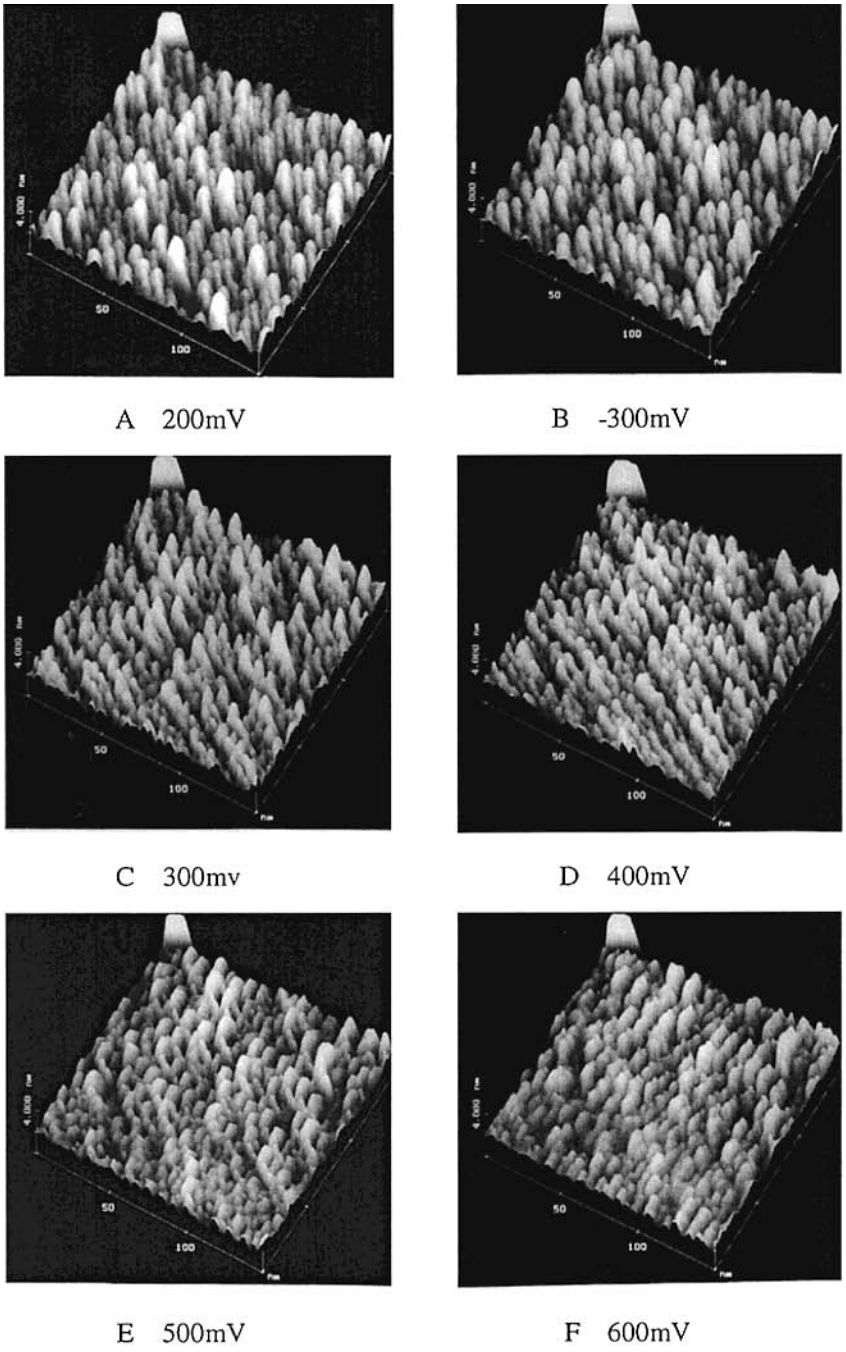

Figure 4. EC-STM 3D images (150 nm × 150 nm) of HS-dsODN on Au (111) recorded in the solution of 10 mM TE buffer containing 10 mM NaCl pH 7.4 at various potentials, (A) 200 mV, (B) −300 mV, (C) 300 mV, (D) 400 mV, (E) 500 mV, (F) 600 mV.

measurements was 2 μM. The preparation of the control electrode followed the same procedure described above except for the control sample of ODN used instead.

Instrumentation. All STM images were acquired on a Naonscope IIIa (Digital Instruments) operated under the constant current mode with an electrochemically etched tungsten tip coated with polymethylstyrene. Monatomic height steps of bare gold surfaces in air were observed clearly under the conditions used. EC-STM images were recorded in the solution of TE buffer containing 10 mM NaCl with a tunneling current of 3 nA over the potential range of −300 to +600 mV (versus SCE). The potential was first decreased with an interval of 100 from 200 to −300 mV and then gradually back to 600 mV.

XPS experiments were conducted on a VG ESCA-LAB MKII spectrometer with Mg radiation. The data were processed with an XPS-AES sampling/processing program (Version 5.0, Tsinghua University). The radiation gun was operated at 11 KV and 20 mA; 25 scans were used, and the PE mode was used for the analyzer with 100 eV pass energy. The sensitivity factors of N and P are 0.42 and 0.39, respectively; all the XPS data discussed below are corrected with these sensitivity factors.

Cyclic voltammograms (CV) were recorded on a CHI 660A electrochemical workstation using a Pt wire and a SCE as the counter and the reference electrode, respectively. $Co(phen)_3^{3+/2+}$ (20 μM) was used as an electrochemical probe for ODN detection on gold. All solutions were deaerated with high purity nitrogen and kept under a nitrogen atmosphere throughout the electrohemical measurements. All reported potentials were against the SCE.

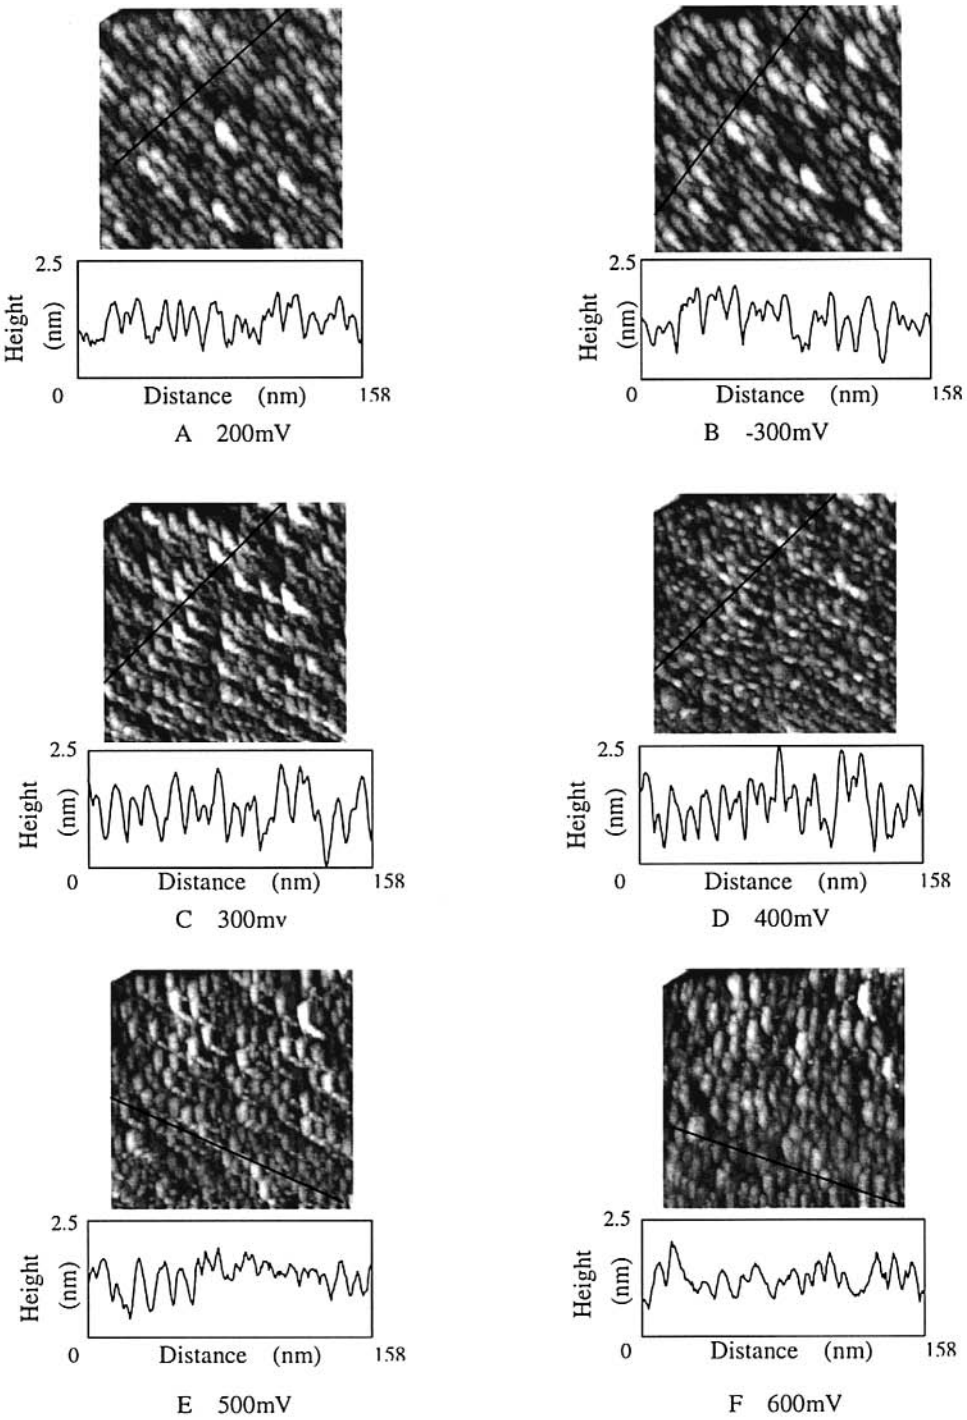

Figure 5. Cross-sectional profiles of dsODN EC-STM images at various potentials (A) 200 mV, (B) −300 mV, (C) 300 mV, (D) 400 mV, (E) 500 mV, (F) 600 mV.

RESULTS AND DISCUSSION

As demonstrated in our previous work (*4*), at the concentration used in the experiments, $Co(phen)_3^{3+/2+}$ had little electrochemical response at the bare gold electrode, but a pair of redox peaks was generated at an ODN-modified gold electrode, which resulted from the enrichment of $Co(phen)_3^{3+/2+}$ at the modified electrode because of the strong interaction between $Co(phen)_3^{3+/2+}$ and ODN (*22*, *23*). Therefore, the redox process can be used to verify whether the oligodeoxynucleotides were anchored on the gold surface or not. The cyclic voltammograms for $Co(phen)_3^{3+/2+}$ at HS-dsODN and HS-ssODN modified electrodes (denoted as HS-dsODN/Au and HS-ssODN/Au, respectively) are given in Figure 1. Evident peaks with a formal potential ($E^{0'}$) of 126 mV at HS-dsODN/Au or 116 mV at HS-ssODN/Au, as shown in Figure 1, suggest that ODNs have been immobilized on the electrode surfaces. The peak current is directly proportional to the scan rate, which is a characteristic of the surface process. The value of peak potential separation, ΔE_p, of 46 mV at HS-dsODN/Au or 53 mV at HS-ssODN at a scan rate of 100 mV/s also characterizes the surface process.

The N 1s (*1*) and P 2p (*8*) peaks in the XPS spectra can provide further reliable evidence for the immobilization of ODNs. The buffer solutions contained no phosphorus element, and there was no XPS-detectable nitrogen from bare gold surfaces exposed to buffer solutions. So we may conclude that any observed N 1s and P 2p

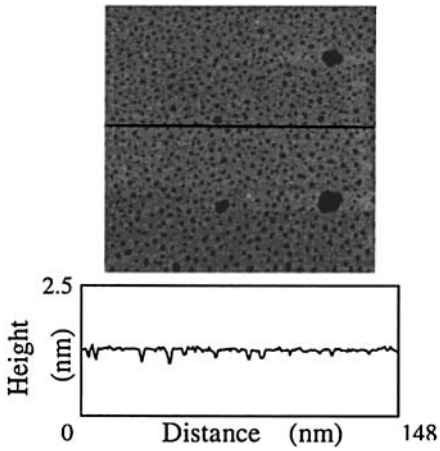

Figure 6. EC-STM image (150 nm × 150 nm) of MCH at potential of 200 mV recorded in the solution of 10 mM TE buffer containing 10 mM NaCl pH 7.4, and the cross-sectional profile. The images at other potential just keep unchanged (see Supporting Information).

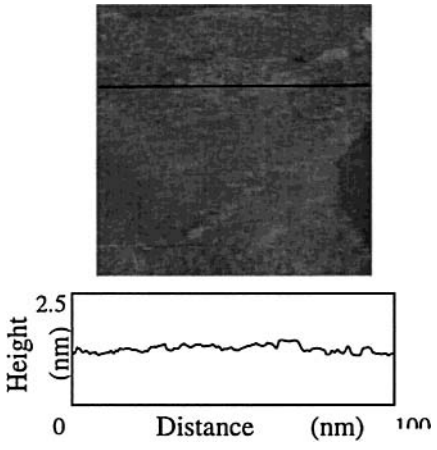

Figure 7. EC-STM image (100 nm × 100 nm) of HS-ssODN at potential of 200 mV recorded in the solution of 10 mMTE buffer containing 10 mMNaCl pH 7.4, and the cross-sectional profile.

signals originate exclusively from the nitrogen-containing bases and phosphate groups of ODN, respectively. In this case, the peak area ratio of N 1s to P 2p should be equal to the molar ratio of nitrogen to phosphorus in DNA. Figure 2 shows the XPS N1s and P2p data of the HS-dsODN/Au and the non-thiol-derivatized dsODN, which support that the HS-dsODN has been attached to the gold surface through the thiol−gold bond by self-assembly. There are very little XPS signals of the control samples, which indicates that nonspecific adsorption of ODN on gold surfaces can be ignored. The peak area ratio of N 1s to P 2p is 3.1, which is close to the value of 3.5 of molar nitrogen-to-phosphorus ratio of HS-dsODN. The XPS N1s and P2p spectra of the HS-ssODN and the non-thiol-derivatized ssODN are shown in Figure 3. The peak area ratio for HS-ssODN is 3.0, which is also close to its molar ratio of nitrogen to phosphorus.

The effect of the applied potential on the surface orientation of ODN was investigated by EC-STM. The image of uniformly and ordered structure of HS-dsODN on Au (111) at 200 mV (Figure 4a) indicates that the HS-dsODN stands straight up on the gold side by side with the thiol-end tethered on the gold and the other end floating in the buffer solution. This ordering may be a result of the electrostatic repulsion between the negatively charged deoxyribose-phosphate backbones of neighboring DNA helices. The cross-sectional profile indicated by a line on this image is shown in Figure 5a. The dsODN rods are measured to be 3 ± 1 nm in diameter, which is similar to that of B-form DNA helix reported by Watson and Crick (*24*). However, the height of dsODN rod measured is smaller than the expected height of 5.1 nm deduced from the 15 base-pair DNA helix structure. The apparent height difference between the measured and the expected is mainly due to the compact character of the dsODN monolayer. The HS-dsODN is perpendicular to the surface, which restricts both the precise measurement of the height of 15-base-pair dsODN and clear imaging of the dsODN helix structure. Moreover, the ends of dsODN helices tethering the surface seem to be interconnected as shown in the cross-sectional profile.

This orientation maintained when potential was decreased from 200 mV to −300 mV as shown in Figures 4a and 4b. To avoid hydrogen evolution, which would destroy the DNA monolayer, further decrease of potential was not attempted. Distinct change of the DNA helix orientation was observed, when potential was reversed to above 200 mV. The DNA helices start to tilt at 300 mV, and the tilted degree increases upon increasing the potential as shown in Figures 4c and 4d. As the applied potential was further increased to 500−600 mV, significant orientation changes were observed as can be seen in Figures 4e and 4f. The DNA helices no longer stand straight on but lie flat on the gold surface in this potential region. The cross-sectional profiles at different potentials are shown in Figure 5. The surface modified with the mercaptohexanol (MCH) exhibits the typical pinhole structure of thioalcohol self-assembly monolayer, instead of the ordered dsODN rod array on HS-dsODN modified gold surface. Moreover the image remained unchanged with varying potential as shown in Figure 6.

This potential dependent orientation change is attributed to the requirement of minimum electrostatic repulsion between the DNA and the gold surface. Both the density and polarity of electric charges on the gold electrode surface will change with the potential if the electrode is driven away from the potential of zero charge (pzc). According to the reference (*25*), the value of pzc on Au (111) is 0.258 V versus SCE. Since the gold surface is negatively charged at the potentials negative of the pzc, as mentioned by Barton (*20*), the negatively charged DNA helices orient themselves vertically to minimize the electrostatic repulsion with the gold surface. Nevertheless, the electrostatic repulsion becomes weaker as the potential shifts positively. It is expected that as the potential is increased across the pzc, the Coulombic interaction between DNA helices and gold surfaces changes from repulsive to attractive, which is favorable for the DNA duplexes leaning toward gold surface. Eventually, the DNA helices tend to lie flat on the surface in virtue of Coulombic attractive forces.

Figure 7 shows EC-STM images of HS-ssODN modified Au (111) at 200 mV. The gold surface exhibits an irregular configuration with the ssODN strands standing on the gold surface in a disorderly fashion. We believe that the difference in rigidity between dsODN and ssODN is mainly responsible for the distinctly different behaviors of the two DNA molecules on the surface. Both the rigidity of double-stranded ODN arising from Watson and Crick helix structure and the electrostatic repulsion between the DNA helices make the contribution in forming the regular arrangement. Since the single-stranded DNA cannot form stable and rigid helix structure, it is not surprising that ssODN does not form the ordered arrangement on the surface. Moreover, for its

poor rigidity, immobilized ssODN might dangle left and right along with the scrape of the tungsten tip. So the image of ssODN was blurred to some extent due to its irregular arrangement on gold surfaces, and no ssODN rod image as clear as dsODN could be obtained. No distinct changes in the surface structure of HS-ssODN were observed with the variation of applied potential, as shown in Supporting Information.

CONCLUSIONS

In summary, EC-STM has been applied to study the behaviors of dsODN and ssODN containing 15 base pairs tethered on Au (111) surface through self-assembly. It is found that dsODN changes its orientation on gold with the applied potential while ssODN does not. The electrostatic interaction between HS-dsODN and gold surface plays an important role for the orientation change of dsODN on gold. The results presented in this paper show that a uniform and compact dsODN monolayer can be formed readily on gold surfaces through self-assembly. The orientation of dsDNA on metal substrates can be controlled by the applied potential. Thus, an appropriate method to acquire desired DNA surface orientation has been developed.

Received July 24, 2001; Revised Manuscript Received October 25, 2001

We have synthesized a bifunctional vinyl sulfone−cysteineamido derivative of DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) that can be conjugated to the sulfhydryls of mildly reduced recombinant antibody (chimeric anti-CEA antibody cT84.66) at pH 7 or to the amino groups of lysine residues at pH 9. The conjugation is sulfhydryl specific at pH 7 (case 1), and amino specific at pH 9 (case 2) as long as the antibody has no free sulhydryl groups. At a molar ratio of 50 BCA (bifunctional chelating agent) to mAb, the number of chelates conjugated is 0.8 for case 1, and 4.6 for case 2. The resulting conjugates can be radiolabeled with ^{111}In to high specific activity (5 mCi/mg) with high efficiency (>95%) at 43 °C in 60 min. The radiolabeled conjugates retained >95% immunoreactivity and are stable in serum containing 1mM DTPA over 3 d. When the radiolabeled conjugates were injected into nude mice bearing LS174T human colon tumor xenografts, over 40% ID/g accumulated in tumors during the period 24−72h. Tumor-to-blood ratios were 4.5, 3.5, and 2.5 for the sulfhydryl coupled conjugate at 24, 48, and 72 h, respectively, and 2.7, 2.5, and 2.3 for the amino-coupled conjugate at the same time points. For other organs the biodistributions were nearly identical whether the conjugates were attached via sulfhydryl or amino groups. These novel BCAs are easy to synthesize, offer versatile conjugation options, and give equivalent biodistributions that result in high tumor uptake and good tumor-to-blood ratios.

INTRODUCTION

Bifunctional chelating agents (BCAs[1]) are routinely conjugated to recombinant antibodies for radiolabeling with radiometals such as ^{111}In for radioimmunoimaging and ^{90}Y for radioimmunotherapy (*1*−*4*). The main advantages of this approach is the ability to radiolabel the conjugate just prior to use and the exceptional stability of the chelated metal, preventing the release of the radionuclide from the conjugate. Starting with BCAs derived from EDTA (*5*, *6*), and then DTPA (*7*−*11*), and more recently DOTA (*12*−*16*), increasingly more stable radiometal−chelate−antibody conjugates have been crafted. Nonetheless, the approach has certain drawbacks inherent in the biodistribution of the antibody which in the case of intact antibody can be deposited in the liver (*17*−*21*), and in the case of antibody fragments, in the kidney (*22*−*25*). High uptake in normal tissues is due to the deposition of free antibody or antibody antigen conjugates in the liver for intact antibody (*21*) and to renal filtering and reabsorption for antibody fragments (*26*). In both cases, the exceptional stability of the radiometal−chelate and the lack of metabolizing enzymes prevents the excretion of these end-products from the lysosomal compartment. While it is assumed that the antibodies are completely degraded in the lysosome, releasing radiometal−chelate, it has only been proven in a few cases (*27*−*31*). In addition, the site of BCA conjugation to the antibody may play a key role in the fate of the radiolabel in both the tumor and normal organs. Furthermore, it is essential that the BCA be conjugated to the antibody without impairment of immunoreactivity. Since a major goal of the field is to reduce normal tissue uptake without decreasing the tumor uptake, we have investigated new BCA derivatives of DOTA that include the possibility of site-specific conjugation and linker specific cleavage. In previous work we showed that a maleimidocysteineamido derivative of DOTA coupled to sulfhydryl groups of mildly reduced intact antibody underwent pH dependent cleavage at the resulting succinimido groups (*32*), lowering blood levels while preserving high tumor uptake (*33*). However, the results were only a marginal improvement over our use of DOTA-active ester conjugated antibody (*34*, *35*). Oxidation of the thioether linker to a sulfone linker further increased the rate of linker bond cleavage, but the rate of blood clearance was too high, preventing good tumor uptake (*33*). Similar approaches utilizing ester linkers for reducing blood levels have been reported, but also suffer from lower blood levels to the point of reducing

tumor uptake (*21*, *36*−*38*). A similar problem is found in using antibody fragments, which clear the blood rapidly, but also give low tumor uptake (*25*). Thus, it is clear that the price of lowering blood levels is the concomitant lowering of tumor uptake, an unacceptable consequence in either radioimmunoimaging or radioimmunotherapy. A possible solution to the problem is the synthesis of BCAs with organ-specific cleavable linkers. Arano and co-workers (*26*, *39*−*41*) have synthesized C-terminal Lys linkers for a radioiodinated hippuric acid−Fab conjugatethat lowered kidney uptake by 50%. Meares and coworkers (*42*−*44*) have synthesized DOTA with cathepsin cleavable linkers for use in lowering liver levels. In the work reported here, we have made new derivatives of DOTA that incorporate a vinyl sulfone-based linker that shows versatility in terms of conjugation to either sulfhydryl or amino groups of antibodies. The BCA is easy to synthesize from readily available chemicals and gives high radiolabeling yields when conjugated to either sulfhydryl or amino groups. The biodistributions in tumor-bearing animals is nearly equivalent, suggesting that the site of conjugation has not affected either the tumor or normal organ uptake. The new BCA may be useful in preventing the impairment of immunoreactivity in cases where coupling through amino groups is problematic.

EXPERIMENTAL PROCEDURES

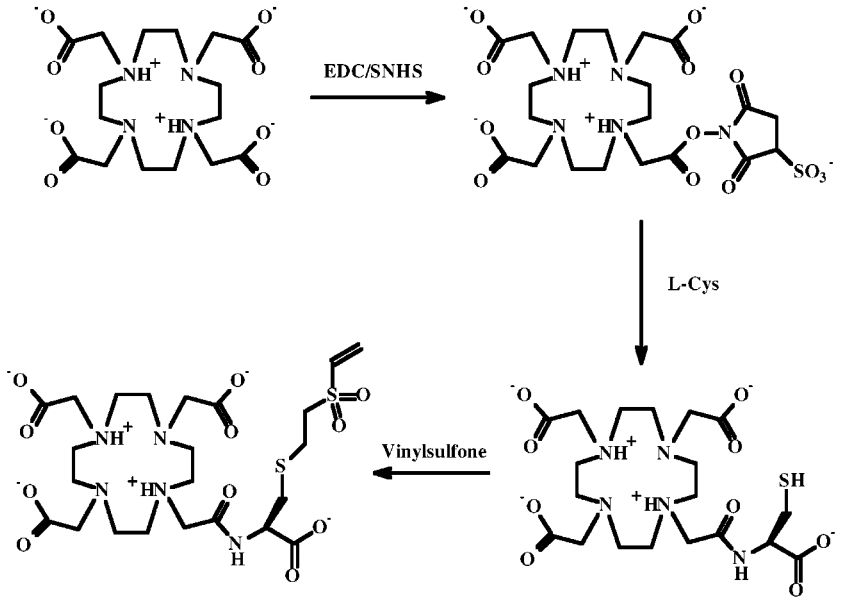
General. DOTA trisodium salt and the free acid were purchased from Parish Chemical Co. (Orem, UT) and Macrocyclics, Inc. (Richardson, TX), respectively. DTPA was obtained from Fluka (Milwaukee, WI), vinyl sulfone from Aldrich (Milwaukee, WI), Chelex 100 from BioRad (Hercules, CA), and L-cysteine from Sigma (St. Louis, MO). Ultrapure water (18 MΩ-cm) was used to make all buffers that were passed over Chelex 100 and pH adjusted if necessary. $^{111}InCl_3$ was obtained from NEN Life Science products, Inc. (Boston, MA). The anti-CEA chT84.66 has been previously described (*35*, *45*). HPLC and TLC were performed as previously described (*32*). Mass spectra were recorded on a Finnigan LCQ ion trap mass spectrometer using a custom nanospray interface. NMR spectra were recorded on a Varian Unity Plus 500 MHz spectrometer. Proton chemical shifts are reported relative to HOD (4.80 ppm). Antibody concentrations were calculated at 280 nm (A_{280}, 1 mg/mL = 1.42). UV spectrophometry was performed on a Shimadzu UV160 instrument using a 1 cm cell. Melting points were recorded on a Thomas-Hoover uni-melt apparatus and are uncorrected. SDS and IEF gel electrophoresis was performed on a Pharmacia PhastGel apparatus according to the manufacturer's instructions.

Vinyl Sulfone−Cysteineamido−DOTA (VSC-DOTA; 2). Cysteineamido-DOTA (**1**) was synthesized as previously reported (*46*). To a solution of 3.24 mg (6.1 μmol) of **1** in 0.6 mL of 50 mM, pH 7.5 potassium phosphate was added 0.06 mL of 0.1 M DTT (6 mmol) and stirred for 0.5 h at RT under Ar. Vinyl sulfone (6.6 μL (64 μmol) in 0.6 mL of DMF was added with continuous stirring for 5 h at RT. A second aliquot was added and the reaction continued for another 22 h (final vol = 1.2 mL, 5.3 mM **1**, 107 mM vinyl sulfone). The excess vinyl sulfone was extracted with ethyl acetate (2 mL, ×3). The aqueous layer was adjusted to pH 8.4, applied to a BioRad Ag1-X4 column (HCO_2^- form, 1 × 10 cm), washed with 30 mL of water, and eluted stepwise with 0.05−2 M HCO_2H (5 mL per step). The product (**2**) was found in fractions 8−13 by ESI/MS. The product was repeatedly lyophilyzed from water to remove excess HCO_2H (yield 3.4 mg). The product had the expected protonated mass by ESI/MS (626.71, expected; 626.73, observed), gave a single spot on TLC, and had a melting point of 140−142 °C. Proton NMR (H_2O): δ 2.92 (m, 2H, $SCH_2CH_2SO_2$), δ 3.10 (m, 2H, $SCH_2CH_2SO_2$), δ 3.10−3.45 [br, 16H, (CH_2-NCH_2) × 4], δ 3.53 (dd, 2H, CH_2SO_2), δ 3.45, 3.70, 3.84 (s, 6H, NCH_2CO_2H), δ 4.39 (m, 1H, $NHCHCO_2H$), δ 6.42 (dd, 2H, SO_2CHCH_2), δ 6.88 (dd, 1H, SO_2CHCH_2), δ 8.20 (d, 1H, CONH−CH).

Preparation of Amino-Conjnugated BCA Antibody (VSC-DOTA-NH-chT84.66). chT84.66 (FW= 150000, 1.0 mg, 6 nmol, at 10 mg/mL, 60 μM) was dialyzed vs 20 mM, pH 7.0 sodium phosphate buffer (three changes, × 1 L, 4 °C) and adjusted to pH 9.0 with 200 mM, pH 10 sodium phosphate (final volume, 0.1 mL). VSC-DOTA (0.1 mL of **2**, FW= 625, 0.7 mg, 1.12 μmol at 1.88 mg/mL, 3.1 mM in 50 mM, pH 9.0 sodium phosphate) was added and the solution rotated at 10 rpm for 4 h at 25 °C. The conjugate was dialyzed vs 250 mM NH_4 acetate (three changes, × 1 L, 4 °C).

Preparation of Sulfhydryl-Conjnugated BCA Antibody (VSC-DOTA-SH-chT84.66). chT84.66 was dialyzed as above and reduced with TCEP (20 μL of 10 mM in 50 mM sodium phosphate, pH 7.0) under argon for 2.5 h at 25 °C. TCEP was removed on a spin column (1 mL of Sephadex G25−50, 1200 rpm, 2 min) under argon. To 1.0 mg (60 nmol) of reduced chT84.66 in 0.1 mL of 50 mM sodium phosphate, pH 7, was added 0.1 mL of 3 mM (300 nmol) of VSC-DOTA (**2**) in the same buffer. The solution was rotated under argon overnight at 25 °C and dialyzed vs NH_4 acetate as described above. In parallel, 1 mg of TCEP reduced chT84.66 in 0.15 mL was reacted with 0.1 mL of 3 mM MC-DOTA and run as a control.

Radiolabeling of VSC-DOTA-chT84.66. The conjugates were radiolabeled with $^{111}InCl_3$ as previously described (*47*). For the animal studies, the conjugates (0.3 mL of 1 mg/mL in 250 mM NH_4 acetate, pH 5.7) were incubated with 0.3 mCi of ^{111}In (0.15 mL of 0.04 M HCl plus 0.03 mL of 250 mM NH_4 acetate, pH 5.7) for 60 min at 43 °C. Excess ^{111}In was chelated with 1 mM DTPA and the radiolabeled product purified on a TosoHaas TSK−Gel G2000SW column (0.75 × 30 cm in saline, 0.5 mL/min, 0.5 mL fractions). The protein peak was mixed with 1 drop of 25% (w/v) of HSA. In other test labelings, 1.0 mCi of ^{111}In was added to 0.2 mg of conjugate and the specific activity determined by ITLC (kit 151−770, Biodex, Medical, New York). Determination of the number of chelates per conjugate and the immunoreactivity was performed as previously described (*5*).



Stability Studies. Aliquots (0.5 mL) of the radiolabeled conjugates in 1% HSA were mixed with 0.05 mL of 10 mM DTPA, stored at 37 °C and injected at various time points onto a Pharmacia Superose 12HR column (as above) to determine the amount of radiolabel in the conjugate and DTPA.

Animal Biodistributions. Groups of five nude mice (Charles River) bearing LS174T human colon tumor xenografts (ave size = 1.5 mg ± 0.5 at t = 0 h) were injected with 2 μCi (2 μg) of radiolabeled conjugate via tail vein. Animals were sacrificed at 0, 12, 24, 48, 72, and 96 h after injection. Major organs, tumor, and blood were weighed, radioactivity was measured, and the results were expressed as mean %ID/g ± SD.

RESULTS

Synthesis and Antibody Conjugation. The synthesis of VSC-DOTA (**2**) is shown in Scheme 1. The product gave the expected proton NMR spectrum and protonated

Scheme 1

mass by ESI/MS and was free of DOTA and the bis-derivative. The reactivity of **2** to free L-cysteine was confirmed by ESI/MS (data not shown). At pH 7, only the mono-derivative was formed, suggesting that the thiol and not the α-amino group of L-cysteine was reactive under these conditions. When VSC-DOTA was incubated for 1−7 d in pH 7 PBS and analyzed by RP-HPLC, there was no evidence of chemical instability (data not shown).

Since VSC-DOTA was expected to react with the ϵ-amino group on the lysines of proteins at pH 9−10, we investigated the reaction of VSC-DOTA with antibody over the pH range of 7−9. The degree of conjugation was determined by IEF gel electrophoresis, wherein conjugation of the acidic BCA to antibody results in a dramatic shift of the antibody to a more acidic pI. The results of the conjugation reaction at pH 7, 8, and 9 shown in Figure 1A, lanes 3−5, demonstrate that little or no reaction occurs at pH 7, while substantial amounts of conjugate are formed at pH 9. The results at pH 8 are intermediate, with <20% product formed. The results at 37 °C, pH 9 demonstrate the expected effect of temperature on the extent of reaction (Figure 1A, lane 6). The products show no change in mobility when run on SDS gel electrophoresis under nonreducing conditions (data not shown). On the basis of these results, we reasoned that sulfhydryl specific conjugation could be performed at pH 7 with little or no conjugation at amino groups, while amino group specific conjugation could be performed at pH 9, as long as no free sulfhydryl groups are present. Since the cysteine residues in most antibodies are engaged in disulfide bonds, this criterion is easily met. In addition, under mild reducing conditions (no denaturing agents), only the hinge disulfides of antibodies are reduced, allowing site-specific conjugation at just these sulfhydryl groups (*48*, *49*). The conjugation of VSC-DOTA to mildly reduced chT84.66 at pH 7 shown in Figure 1B, lane 4, demonstrates that >90% of the antibody is conjugated under these conditions. It should be noted that either DTT or TCEP were successfully used as reducing agents. We prefer TCEP because a lower molar excess is required and since removal of the reducing agent by spin columns is not quantitative, better conjugation yields are routinely obtained.

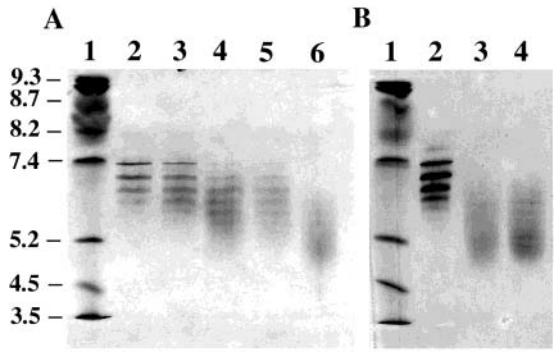


Figure 1. Analysis of VSC-DOTA-mAb conjugates by IEF gel electrophoresis. A: Lane 1: IEF standards; Lane 2: chT84.66 control; Lane 3: 30 μM chT84.66, 1.5 mM VSC-DOTA, pH 7.0, RT, 4h; Lane 4: 30 μM chT84.66, 1.5 mM VSC-DOTA, pH 8.0, RT, 4 h; Lane 5: 30 μM chT84.66, 1.5 mM VSC-DOTA, pH 9.0, RT, 4 h; Lane 6: 30 μM chT84.66, 1.5 mM VSC-DOTA, pH 9.0, 37 °C, 4 h. B: Lane 1: IEF standards; Lane 2: chT84.66 control; Lane 3: 30 μM chT84.66 reduced with 0.5 mM TCEP, the TCEP removed by spin column, and reacted with 1.5 mM MC-DOTA, pH 7.0, RT, 4 h; Lane 4: 30 μM chT84.66, reduced with 0.5 mM TCEP, the TCEP removed by spin column, and reacted with 1.5 mM VSC-DOTA, pH 7.0, RT, 4 h.

The number of chelates per antibody as determined by trace labeling with ^{111}In in a standard solution of $InCl_3$ is shown in Table 1. At pH 7 and with a 50:1 molar ratio of VSC-DOTA to mAb, mildly reduced antibody gave 0.8 chelates/mAb out of a theoretical of 8 for a human IgG1 hinge. At pH 9 with the same molar ratio of VSC-DOTA to mAb, unreduced mAb gave 4.6 chelates/mAb. Radiolabeling of these two conjugates with $^{111}InCl_3$ gave similar percent radiolabeling efficiencies, specific activities, and

Table 1. Radiometal Labeling and Immunoreactivity of VSC-DOTA-mAb[a]

sample	chelates/ mAb	labeling ratio (mCi/mg)	% efficiency	% immuno-reactivity
SH-mAb	0.8	1.0−5.0	>98	>98
NH-mAb	4.5	1.0−5.0	>98	>98

[a] VSC-DOTA was coupled to either SH or NH groups in the mAb as described in the text. The number of chelates per mAb was determined by trace labeling with ^{111}In in a standard solution of $InCl_3$. The labeling ratio was performed with 0.3 mCi of ^{111}In and 0.3 mg of conjugate in 0.3 mL of 0.25 mM ammonium acetate (pH 5.7), or 1.0 mCi of ^{111}In and 0.2 mg of conjugate in 0.2 mL of ammonium actetate (pH 5.7). Immunoreactivity was performed as described in Methods.

immunoreactivities (Table 1). When the radiolabeled conjugates were incubated in 1% HSA and 1 mM DTPA for 1−7d, negligible loss of radioactivity was seen to DTPA (Table 1). In addition, their immunoreactivities were >95% when radiolabeled, bound to excess CEA, and analyzed by gel filtration chromatography. Since their immunoreactivities were similar, we used these conjugates for a direct comparison in animal biodistribution studies.

Comparative Animal Biodistributions of [^{111}In]-VSC-DOTA-SH-chT84.66 and [^{111}In]VSC-DOTA-NH-chT84.66. The two ^{111}In-radiolabeled conjugates were injected into nude mice bearing human colon tumor xenografts and their biodistributions compared (Tables 2 and 3). The overall biodistributions are quite similar, resulting in maximal and sustained tumor uptake of 35−45% ID/g from 24 to 96 h. During the same time period the blood activity drops from about 45% ID/g to 2−3% ID/g. A comparison of tumor to blood curves over the time course suggests that the SH conjugate may be superior to the NH conjugate. Paradoxically, this difference may be due to a slightly slower blood clearance curve for the SH conjugate, resulting in higher uptake. A close analysis of the normal organs reveals nearly identical uptake levels and time courses for the spleen, kidney, and lung, but there are some interesting differences in the liver. The SH conjugate shows lower liver uptake at the earlier time points, suggesting that the NH conjugate accumulates more rapidly in the liver. This result would also account for their observed differences in blood clearance curves.

DISCUSSION

In a search for site-specific BCA derivatives of DOTA we first synthesized a bis-maleimidohexane derivative of cysteineamido-DOTA (*32*). Maleimide is a commonly used reagent that undergoes sulfhydryl specific Michael additions that are thought to be chemically stable (*50*). Although this BCA allowed site-specific conjugation to the sulfhydryl groups of mildly reduced mAb, it proved to be chemically labile, undergoing pH-dependent hydrolysis at its resulting succinimidyl bonds (*32*). Surprisingly, this phenomenon did not prevent good tumor uptake in animal biodistribution studies (*33*). As a result, we proposed that further increasing the chemical lability of the linker may be beneficial, since this would result in lower blood levels. Indeed, oxidation of the thioether bond in the linker to a sulfone increased the chemical lability of the BCA (*32*), but the BCA decomposed too rapidly to allow good tumor uptake. On the basis of these studies, we decided to investigate other Michael addition linkers as candidates for site-specific conjugation to mAbs. We chose vinyl sulfone for its well-documented reaction with sufhydryl groups (*51*). However, we realized from the outset that vinyl sulfone can also react with amino groups (*52*, *53*), and thus we were interested in seeing if this reaction could be controlled by manipulation of the reaction pH.

Vinyl sulfone is a viscous liquid with poor solubility in water, but when dissolved in DMF or acetonitrile reacts well with Michael acceptors in aqueous medium. In the synthesis of the title compound (**2**), we demonstrated a facile reaction between vinyl sulfone and cysteineamido-DOTA. Unlike the maleimido derivatives, the vinyl sulfone derivative of cysteineamido-DOTA is stable in PBS at pH 7. When **2** was reacted with chT84.66 at pH 7, no conjugate was formed unless the mAb was mildly reduced prior to reaction. In addition, we showed that the mAb conjugated with **2** at pH 9 to a greater extent (no. chelates/mAb) as it did to reduced mAb at pH 7 using the same molar ratio of **2** to mAb. Thus, we demonstrated that this BCA can be conjugated to the same mAb via different chemical linkages using pH and reducing agents to convey linkage specificity.

Since the biodistributions of radiolabeled mAbs is highly dependent on the mode of attachment of the radiolabel, it is always interesting to compare BCAs conjugated to the same mAb via different chemical linkages. In most cases, it is difficult to perform this type of comparative study. However, in this study, we have an almost ideal model. In one case, the same BCA is conjugated to sulfhydryl groups, and in the other case, amino groups, but the resulting BCA/mAb ratios are different. Even so, the resulting biodistributions are quite similar. When we compare these results to our previous studies in which DOTA was conjugated to chT84.66 by an active ester derivative of DOTA (*34*, *35*), we find that the uptake curves are similar for both tumor and normal tissues. This suggests that linkage of DOTA based BCAs to mAbs via amides, amine, or sulfhydryl bonds results in similar tissue, including tumor, uptakes, and metabolism. Thus, if one wants to manipulate normal or tumor uptake and metabolism of DOTA-based BCAs, it is necessary to explore other modes of chemical linkage or to insert linkers which have built-in chemical or biological lability. Examples of such linkers have been described by Meares (*21*), Arano (*54*), and ourselves (*32*).

When we examined the comparative biodistributions of the SH and NH BCA-chT84.66 conjugates in more detail, we noticed some intriguing trends. They include

the higher blood levels, higher tumor levels, and lower liver levels for the BCA chT84.66 SH conjugate at early time points 0−24 h. These three "organs" are interdependent in their biodistributions as follows: high tumor uptake is dependent on maintaining high blood levels, especially early in a biodistribution. If the blood is cleared by any mechanism, including rapid liver uptake, then blood and tumor levels will fall together. Thus, the lower liver uptake seen at early time points for the SH conjugate leads to higher blood levels and ultimately to higher tumor uptake which is sustained at later time points. While the biological reasons for these differences are unknown at this time, we can speculate that this mode of conjugation will lead to incremental improvements in the human, where most biodistributions are predicted from the animal model.

In summary, we have prepared a new BCA that allows site-specific conjugation to most mAbs either via sulfhydryl or amino groups by manipulating pH and use of reducing agents. The ^{111}In-radiolabeled versions of these conjugates give more or less equivalent animal biodistributions to previously described ^{111}In-radiolabeled BCA-mAbs, including are own version using the active ester of DOTA (*34*, *35*). This approach should have utility, allowing the investigator to chose one type of chemistry over the other depending on the restrictions implied by a given antibody. Finally, the improvement in tumor to blood and tumor-to-liver ratios seen for the SH-specific conjugate may translate into improved performance in the clinic.

ACKNOWLEDGMENT

High Throughput Magnetic Resonance Imaging for Evaluating Targeted Nanoparticle Probes

Dagmar Högemann, Vasilis Ntziachristos,[§] Lee Josephson,[§] and Ralph Weissleder*

Center for Molecular Imaging Research, Massachusetts General Hospital, Charlestown, Massachusetts 02129.
Received August 21, 2001; Revised Manuscript Received October 26, 2001

The ability to image specific molecular targets in vivo would have significant impact in allowing earlier disease detection and in tailoring molecular therapies. One of the rate-limiting steps in the development of novel compounds as reporter probes has been the lack of cell-based, biologically relevant, high throughput screening methods. Here we describe the development and validation of magnetic resonance imaging (MRI) as a technique to rapidly screen compounds that are potential MR reporter agents for their interaction with specific cellular targets. We show that MR imaging can (1) evaluate thousands of samples simultaneously and rapidly, (2) provide exceedingly accurate measurements, and (3) provide receptor binding/internalization data as validated by radioactive assays. The technique allows the screening of libraries of peptide−nanoparticle conjugates against target cells and the identification of conjugates that may be subsequently used as reporter agents in vivo. The technology should greatly accelerate the development of target-specific or cell-specific MR contrast agents.

INTRODUCTION

The sequencing of the human genome has led to a large number of potential targets for drug development and necessitated ever more efficient strategies for compound synthesis and compound evaluation. Current therapeutic drugs address roughly 500 different molecular targets (45% receptors, 30% enzymes, 25% other targets). Estimates of potential future drug targets are in excess of 5000 to 10000. The large number of potential targets can be contrasted with the handful of specific imaging agents available clinically. One of the clearly identified bottlenecks in drug development generally, and targeted imaging agents in particular, has been the development of efficacy testing methodologies that are both highly relevant to the intended use of the drug and amenable to high throughput screening.

The goal of this study was to develop and validate magnetic resonance imaging (MRI) as a high throughput screening (HTS) modality for examining the interactions between superparamagnetic nanoparticles and cells in the wells of microtiter plates. To accomplish this we used a recently developed technology that allows the attachment of a variety of biological molecules to iron oxide nanoparticles with the retention of biological activity. Proteins such as transferrin (*1*), peptides such as the membrane translocating tat peptide of the HIV tat protein (*2*, *3*), and oligonucleotides of various sequences (*4*) have been attached to an aminated, cross-linked iron oxide nanoparticle (amino-CLIO) and used in a variety of applications.

We first evaluated MR imaging as an analytical method by examining the reproducibility and detectability of nanoparticles in microtiter plates using a clinical MR imaging system. Afterward we used a transferrin−nanoparticle conjugate to validate the method for determining nanoparticle binding and uptake by cells expressing differing levels of the transferrin receptor. Finally, we synthesized a limited library of peptide−nanoparticle conjugates and screened the library using the MR imaging method.

Use of the MR imager permitted up to 1920 samples to be imaged in about 50 min acquiring more than 38000 individual data points in multiecho trains. Using this approach it appears feasible to analyze upward of 20000 experimental samples per day, a number that is currently only limited by the design and availability of better magnetic coils and stronger gradients to achieve higher spatial resolutions. Imaging of large numbers of biological samples in HTS fashion with a clinical MR imager may accelerate the discovery of new targeted MR contrast agents.

MATERIALS AND METHODS

Synthesis of Amino-CLIO Nanoparticles. Monocrystalline iron oxide nanoparticles were prepared through the reaction of iron salts with ammonium hydroxide in the presence of T10 dextrans. The dextrans were then modified in the presence of epichlorohydrin according to previous reports to yield cross-linked iron oxide nanoparticles (CLIO-10). CLIO was finally treated with ammonia to yield amino-CLIO, to obtain reactive groups for the covalent binding of bifunctional linking reagents (*2*, *4*).

Peptide Synthesis. Peptides were synthesized for attachment to the aminated nanoparticle, amino-CLIO. The peptides included the tat peptide of HIV, a well-established membrane translocation signal (GRKKRRQRRRGYK(FITC)C-NH_2), short poly-arginyl peptides which might act as membrane translocating signals (*5*, *6*), and control peptides. Peptides were synthesized on an automatic synthesizer (PS3, Rainin, Woburn, MA) by Fmoc chemistry and underwent reaction with fluorescein isothiocyanate (FITC) to facilitate the determination of the

number of peptides attached per nanoparticle (*2*). Peptides were purified by C18 reversed-phase HPLC and characterized by MALDI-MS. The sequences of the peptides used and values of their molecular weights, as M + 1 (calculated/found), were RRK(FITC)C-NH_2 (951.08/951.47), GRRK(FITC)C-NH_2 (1008.13/1007.97), GRRRRK(FITC)C-NH_2 (1320.51/1321.77), GRRGRRK-(FITC)C-NH_2 (1377.54/1377.55), GRRRRGGGGK(FITC)C-NH_2 (1547.69/1548.66), GRKKRRQRRRGYK(FITC)C-NH_2 (2237.54/2238.54), CGGGPQRYGNQWAVGHLM-NH_2 (1931.13/1391.95), CGVYGWGMGLHGPQRNQA-NH_2 (1931.13/1932.15), and TMG-RRRRRGYK(FITC)-GCG-NH_2 (1689.77/1690.81). TMG stands for tetramethylguanidium and is a capping group on the N-terminal residue of the peptide.

Synthesis of a Limited Library of Peptide−Nanoparticle Conjugates. Peptides were conjugated to amino-CLIO either with long chain *N*-succinimidyl 3-(2-pyridyldithio)propionate (lc-SPDP, Molecular Biosciences, Boulder, CO) or with succinimidyl iodoacetate (SIA, Molecular Biosciences). For the former, 1 mL of amino-CLIO (9.25 mg iron in 5 mM citrate buffer, pH 8), 0.67 mL of PBS (pH 8), and 1.3 mL of 3.4×10^{-2} M (in DMSO) lc-SPDP were incubated for 2 h at room temperature to yield activated CLIO particles. Low molecular weight impurities were removed by filtration through Sephadex G-25 columns equilibrated with PBS, pH 8. Peptides and activated CLIO were mixed at equal molar ratios of peptides and 2-pyridyl disulfide groups in PBS, pH 8, and allowed to react for 18 h at room temperature. Nonreacted peptides were separated from peptide−nanoparticles using magnetic columns (Macs separation columns, Miltenyi Biotec, CA). For the latter, 1.5 mL of amino-CLIO (39 mg iron in 5 mM citrate buffer, pH 8) were reacted with 3 mL of 4.9×10^{-2} M (in DMSO) SIA for 2 h at room temperature. The mixture was separated over Sephadex G25, and the void volume with iron oxide particles was collected. The CLIO particles were mixed with 13 mg of GRKKRRQRRRGYK(FITC)C-NH_2 dissolved in 3 mL of 0.02 M citrate, pH 6.5, and allowed to stand for 3 h at room temperature. The mixture was then applied to the column above to remove nonreacted peptide. Peptide attachment was quantified from absorption of the conjugate (extinction coefficient of 73000 M^{-1} cm^{-1} at 494 nm in 0.1 M phosphate buffer). For non-FITC labeled peptide conjugates, peptide was released by DTT and attachment was determined by HPLC. Standards of the coupled peptide were used whose mass was determined by amino acid analysis. Conjugates had between 2 and 12 mol of peptide per mole of nanoparticles based on 2064 iron atoms per crystal (*7*). Conjugates are denoted as $(\text{peptide sequence})_n$-SS-CLIO or $(\text{peptide sequence})_n$-SC-CLIO where the letters SS or SC indicate disulfide or thioether linking groups, respectively, and n is the number of peptides coupled per particle.

Synthesis of Transferrin−Nanoparticle Conjugate. Transferrin (Tf) was attached to CLIO-NH_2 according to a protocol optimized in an earlier study (*1*). The linker in the current study was SIA (Molecular Biosciences). In brief, 1 mL of amino-CLIO (9.25 mg iron in 5 mM citrate buffer, pH 8), 0.67 mL of PBS (pH 8), and 1.3 mL of 3.4×10^{-2} M (in DMSO) SIA were incubated for 2 h at room temperature to yield activated CLIO particles. Human diferric transferrin was activated through thiolation of primary amine groups (*1*). Tf-SH and iodoacetylated CLIO were mixed at equal molar ratios of transferrin and iodoacetate groups in PBS, pH 8. The mixture was incubated for 18 h at room temperature. Nonreacted Tf-SH was separated from Tf-nanoparticles using Macs separation columns (Miltenyi Biotec). On average each superparamagnetic particle contained one transferrin molecule covalently attached. The transferrin−nanoparticle conjugate is denoted as Tf-SC-CLIO.

Magnetic Resonance Imaging. A 1.5 T superconducting magnet (Signa 5.0; GE Medical Systems, Milwaukee, WI) was used. A standard quadrature extremity coil was chosen to obtain a homogeneous field of view over the well plates. The imaging protocol consisted of a T2-weighted spin−echo sequence (TR 3000 ms, variable TE 15−1200 ms; total of 20−24 echo times). The 1.5 mm imaging slices were carefully placed to avoid partial volume effects. At a field of view (FOV) of 12 × 9 cm and a 256 × 192 imaging matrix, each voxel had a volume of 0.33 mm^3, and image acquisition time was 10.12 min per number of excitation (NEX).

Data Analysis. The MR images obtained at various echo times (TE's) were processed to obtain T2 maps. To automate the calculations a script was written in Matlab (Matlab 6.0; The MathWorks, Natick, MA). In this routine, signal intensities of each voxel were fitted for exponential decay according to the following equation: $SI = A \times e^{(-TE/T2)} + B$; with SI = signal intensity, TE = echo time, A = amplitude, B = offset. Following this calculation, the T2 maps underwent semiautomatic segmentation of the areas of the different wells (IPLab 3.5.2; Scanalytics, Fairfax, VA). The first step was to employ a median filter to change each pixel value to the median value within a neighborhood of 3 × 3 pixels. This filter reduced the noise from isolated pixels without affecting the average T2 values. All regions of interest were simultaneously defined through a one step thresholding function with the threshold set to a value just above the background of the plastic material of the plate. Applying an erode function that computes the minimum value of the pixels within the neighborhood and assigns it to the target pixel made sure that indeed no voxels outside the wells were included into the measurements. The average values of the T2 relaxation times were measured automatically, and the data was exported to a spreadsheet.

Evaluation of Levels of Transferrin Receptor Expression in Different Cell Lines by MR Imaging. 9L gliosarcoma clones, differing in expression of the transferrin receptor (8), were cultivated in Dulbecco's modified Eagle's medium (DMEM, Cellgro, Mediatech, Washington, DC) containing 10% fetal bovine serum (FBS, Cellgro) and were used to validate MR measurements of receptor binding and internalization of transferrin-CLIO. One hundred thousand cells/well of the different clones were grown in 24 well plates (Falcon, Becton Dickinson, Lincoln Park, NJ). The following day the binding and uptake of radioactive labeled transferrin and of Tf-SC-CLIO conjugate were determined. In the radioactive assay different concentrations of unlabeled diferric transferrin (1 nM to 10 μM in DMEM, 10% FBS) were added immediately prior to the addition of ^{125}I-transferrin (0.25 nM in DMEM, 10% FBS) (*1*). After incubation for 2 h at 37 °C, the cells were washed three times with Hanks's Balanced Salt Solution (HBSS, BioWhittaker, Walkersville, MD) and detached with trypsin (0.05% trypsin, 0.53 mM ethylenediaminetetraacetic acid). Cell-associated radioactivity was counted in a gamma-counter (1282 Compugamma CS, LKB Wallac, Sweden). In the MRI assay cells were incubated in the presence of different concentrations of Tf-SC-CLIO (0.018−1.8 mM iron). To control for receptor specificity, cells were also incubated with nonconjugated CLIO (7.2 mM iron)

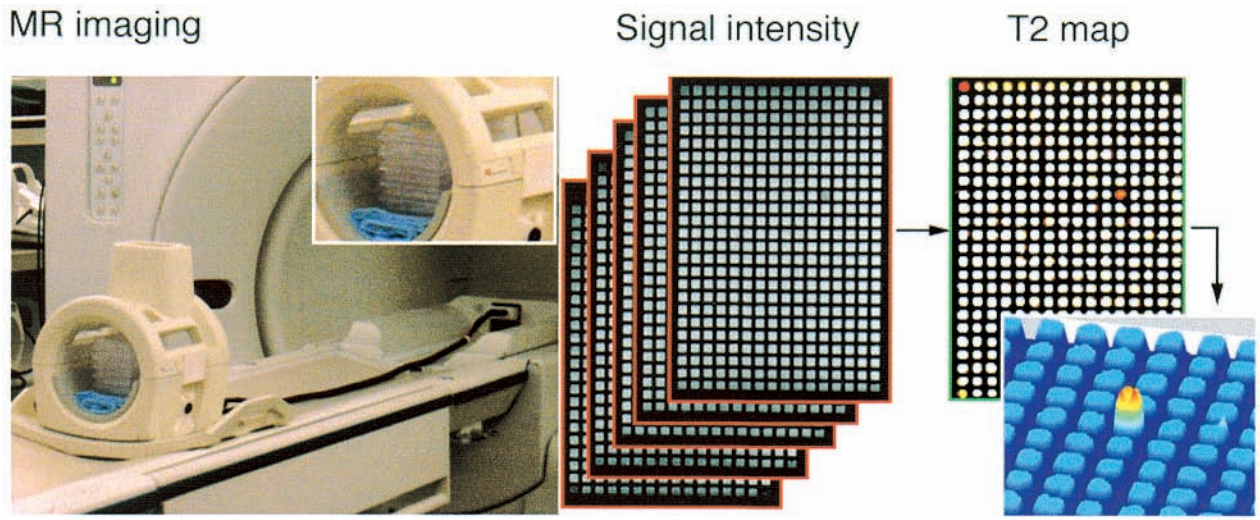

Figure 1. Use of a MR imager for high throughput screening. Microtiter plates were imaged in a quadrature coil with different pulse sequences (variable TE) to yield a series of images for each plate. Signal intensity data were processed to yield a T2 map indicating wells with "hits".

as well as with Tf-SC-CLIO (7.2 mM iron) in the presence of a 100-fold excess of nonconjugated transferrin. Nonspecific binding to the wells was ruled out through the incubation of the culture plates with Tf-SC-CLIO (7.2 mM iron) in the absence of cells. After incubation at 37 °C for 2 h, cells were washed three times with Hanks's Balanced Salt Solution (HBSS, Bio-Whittaker, Walkersville, MD). Cells were lysed in 60 μL of PBS, pH 8, containing 1% Triton X-100 and an aliquot of 5 μL was used to determine the number of cells per well by protein analysis (BCA, Pierce, Rockford, IL). Lysates were transferred to the wells of 384 well plates and centrifuged at 700 rpm for 2 min (Sorvall 7 RT, Kendro Laboratory Products, Newtown, CT) to remove air bubbles. MR imaging and the determination of the T2 values were carried out as described above. The quantification of cell-associated iron concentration was determined from T2 values of nanoparticle standards (1.46 to 29.2 μM iron).

Evaluation of a Limited Library of Peptide−Nanoparticles Conjugates for Cell Uptake by MR Imaging. Peptide−nanoparticle conjugates were evaluated for their cell-association and ability to serve as reagents for cell labeling and tracking (*3*). 9L gliosarcoma cells were cultivated as described above. One hundred thousand cells/well were grown in 24 well plates. The following day 9L gliosarcoma cells were incubated with the various peptide−CLIO conjugates at iron concentrations ranging from 0.0018 to 1.8 mM. After the 1 h incubation at 37 °C, the cells were washed three times with HBSS and lysed in 60 μL of PBS, pH 8, containing 1% Triton X-100. Lysates were transferred to the wells of 384 well plates and centrifuged at 700 rpm for 2 min. MR imaging and the determination of the T2 values were carried out as described above.

RESULTS

We performed three types of experiments to evaluate MR imaging as a HTS method for samples in microtiter plates. They were (a) analysis of signal intensity variation, (b) analysis of T2 variation, and (c) validation of ligand/receptor interaction in a cell based system expressing different levels of receptor. Finally, with the principles of the method established, we used the method to analyze the components of a limited superparamagnetic particle library for uptake into cells. We evaluated two different types of microtiter plates: 384 (60 μL volume per well) and 1536 (10 μL) well plates. All data were obtained with the 384 well configuration except where noted. The general procedure for the MR imaging of iron oxide nanoparticles in microtiter plates is shown in Figure 1.

Analysis of Signal Intensity and T2 Variation. Before utilizing the microtiter plates to screen for nanoparticle interactions with cells by MR imaging, we tested the reproducibility of the measurements of signal intensities and T2 values. Signal intensities were determined for wells over the entire plate at four nanoparticle concentrations. At an echo time of 100 ms an area of 16 × 20 wells provided a 99% confidence interval with individual wells being within 1−2% of the mean signal intensity at all nanoparticle concentrations (Table 1). The reproducibility of the technique was unaffected by stacking plates up to six high during signal acquisition. This enabled data to be obtained simultaneously on 1920 samples of six 384 well plates.

To quantify the changes in signal intensities depending on the different concentrations of nanoparticles, we calculated the changes of the transverse relaxation times (T2). The reproducibility with which T2 could be determined was analyzed for wells over the entire plate (Figure 2A), and the chi-square of the exponential decay curve fit of signal intensities against echo times is shown in Figure 2B. The reproducibility of T2 values determined for 320 wells is shown in Table 2. Again the 99%

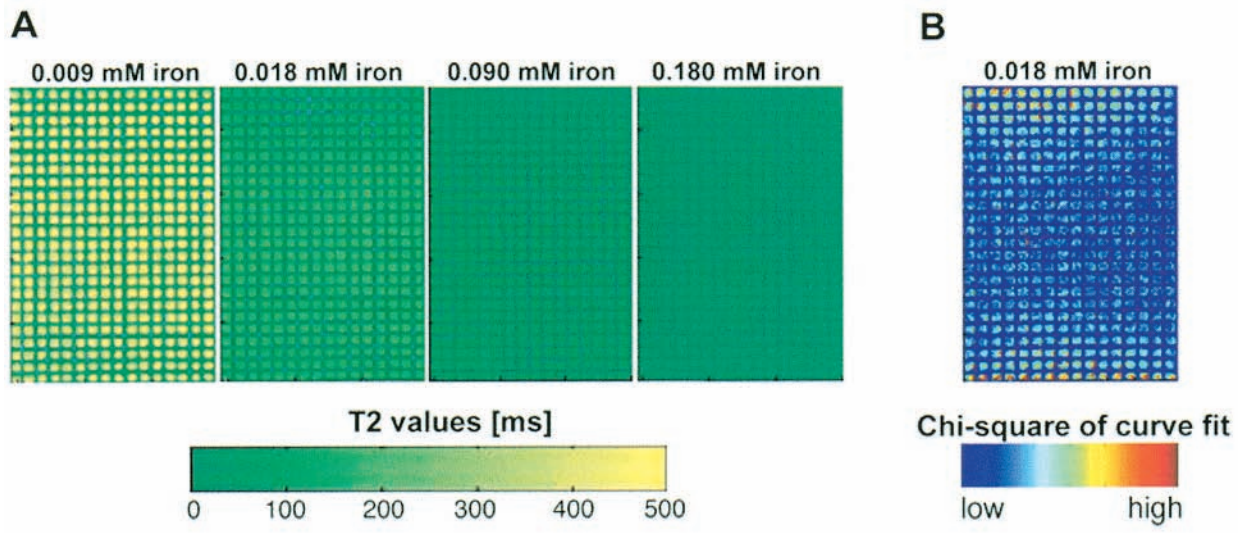

Figure 2. Uniformity of T2 values determined by imaging 384 well microtiter plates. A. Images of plates contained four nanoparticle concentrations. T2 is displayed as a color map from yellow (low nanoparticle concentration, high T2) to green (high nanoparticle concentration, low T2). B. The accuracy of the fitting procedure as a function of plate geometry. Signal intensities were plotted against echo times and T2 values were calculated by curve fitting for exponential decay. The chi-square of each respective curve fit is displayed as a color map from blue (low value of chi-square) to red (high value of chi-square).

Table 2. Reproducibility of T2 Determination at Different Nanoparticle Concentrations (384 well microtiter plate, 16 × 20 Wells, TR/TE = 3000/15−1200)

well no.	0.009 mM	0.018 mM	0.09 mM	0.18 mM
1	485.39	208.59	54.09	30.41
2	494.61	209.93	53.91	29.26

95%	4.22	1.38	0.32	0.07

confidence interval for individual T2 measurements was within 1−2% of the mean.

The reproducibility of T2 determinations was further evaluated over successively smaller areas (fields of view, FOV) for a 384 well plate as shown in Table 3. This experiment, performed to determine the "sweet spot" over which variations would be smallest, evaluated FOV's ranging from 8066 mm^2 (384 wells) to 672 mm^2 (32 wells). The standard deviation ranged from a high of 13.56 ms (mean 233.71 ms), when 384 wells were imaged, to 9.95 ms (mean 235.88 ms), when only the central 32 wells were imaged. Reproducibility of T2 determination is a function of FOV, though values from the entire plate should be sufficiently accurate for most compound or cell line screening experiments.

The data acquisition of 1536 well plates led to similar results as the 384 well format, but required a higher spatial resolution (matrix: 512 × 512) and therefore a two times longer imaging time.

The ability of the imaging method to detect nanoparticles is shown in Figure 3. Figure 3A shows the progressive decrease in T2 values as a colorized map for duplicate samples as the nanoparticle concentration was increased from 0 to 29.2 μM iron. Values of T2 were plotted against iron concentrations as shown in Figure 3B. The relaxivity, R2 was 188.5 $[mM \times s]^{-1}$ with a high coefficient of correlation, $r^2 = 0.999$. Nanoparticle concentrations in the low micromolar range of iron could be distinguished from zero with visual or graphical analyses. Since there are 2064 iron atoms per particle (*7*), iron oxide particle concentrations can be readily detected in the low nanomolar concentration range.

Determining Transferrin Receptor Expression Using a Transferrin−Nanoparticle Conjugate. The expression of the transferrin receptor has been used as a marker gene for imaging transgene expression (*1*, *8*). Five 9L gliosarcoma cell lines differing in transferrin receptor expression were incubated either with the nanoparticle conjugate Tf-SC-CLIO or with ^{125}I labeled Tf under identical conditions. As shown in Figure 4A, which summarizes the imaging results as a colorized T2 map, cell lines were evaluated in duplicate wells after incubation with Tf-SC-CLIO at concentrations ranging from 0.018 mM to 1.8 mM iron. Figure 4B compares the T2 values for duplicate samples of the five cell lines. Three data sets from separate experiments underwent t-test analysis and representative p values are shown. There was no statistically significant difference in T2 between the duplicates of each sample, however, significant differences in transferrin receptor expression were identified among different clones as indicated. ANOVA analysis confirmed the differentiation of five clones by MRI ($p < 0.001$).

The correlation between nanoparticle uptake determined by MR imaging and the cell-associated radioactivity determined with ^{125}I-Tf was examined as shown in Figure 4C. Cell-associated iron was determined from T2 (Figure 4B) using a standard curve of nanoparticles (Figure 3B). The binding and uptake of Tf-SC-CLIO paralleled the binding and uptake of ^{125}I-Tf with a high coefficient of correlation, $r^2 = 0.996$.

Screening a Limited Library of Peptide−Nanoparticle Conjugates for Cell Binding/Uptake. We then employed the HTS MR imaging technique to evaluate a series of peptide−CLIO conjugates for their binding and/or uptake by 9L gliosarcoma cells as shown in Figure 5. Conjugates were evaluated for their ability to become cell-associated and thereby serve as reagents for labeling cells for tracking by MR. Magnetic cell labeling has become an essential tool for tracking stem and progenitor cells in vivo and for isolating homed cells from tissues

[a] Number of wells of 1536 plate in the FOV used for imaging a 384 well plate.

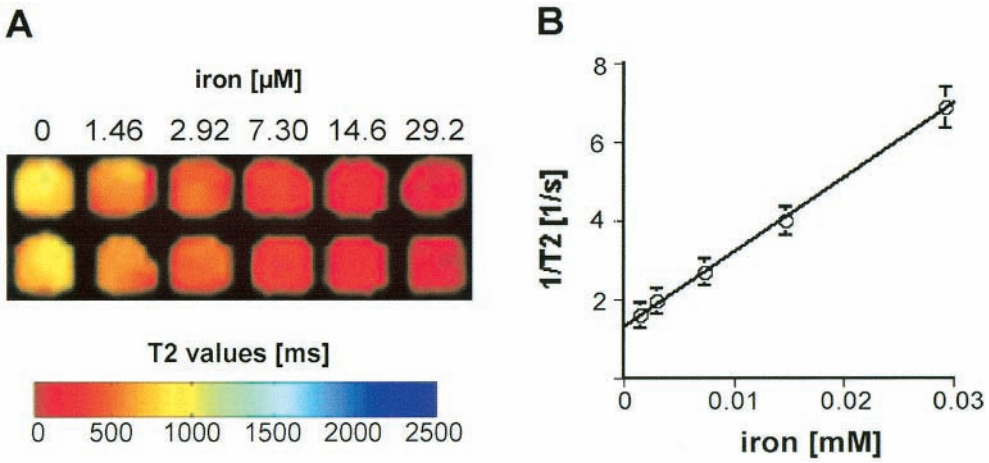

Figure 3. Detection of nanoparticles by MR imaging. A. Duplicate wells with increasing concentrations of nanoparticles were imaged by MR imaging, and the T2 maps were calculated. B. 1/T2 values were plotted versus the iron concentrations to determine the relaxivity R2.

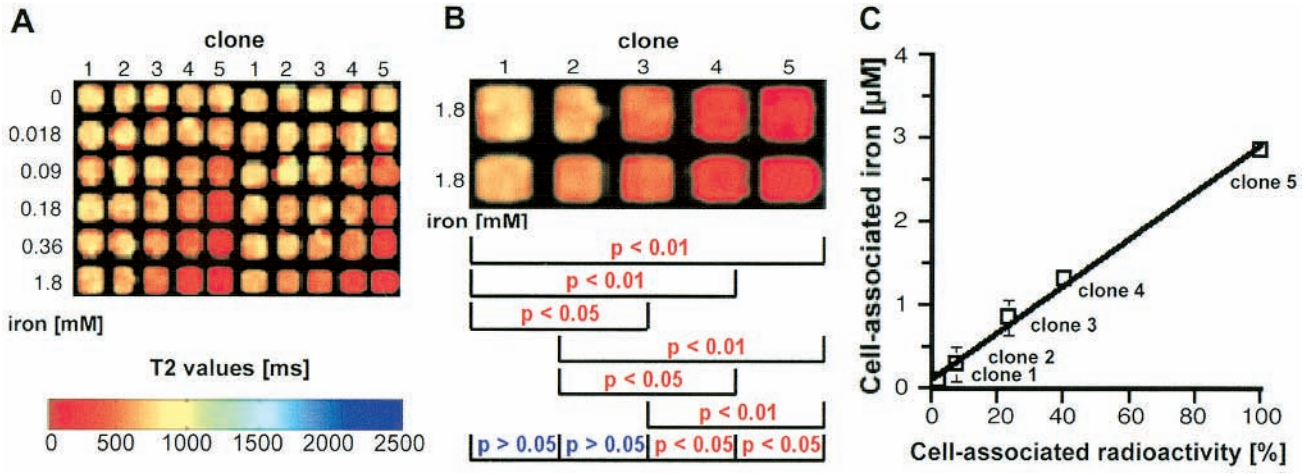

Figure 4. Imaging of transferrin receptor expression. A. Uptake of the nanoparticle conjugate Tf-SC-CLIO by clones 1−5 expressing different levels of the transferrin receptor. Cells were incubated with 0.018 to 1.8 mM iron in Tf-SC-CLIO. Data are expressed as a T2 color map. B. Comparison of T2 values of duplicate wells of clones 1−5 at 1.8 mM Tf-SC-CLIO from Figure 4A. T2's of pairs of clones were evaluated for significance of differences. C. Correlation of receptor expression determined by cell-associated Tf-SC-CLIO (T2 values Figure 4B) or cell-associated ^{125}I-Tf.

(*3*). The highest cellular uptake was observed for the conjugate $(GRKKRRQRRRGYKC\text{-}N)_{11}$-SC-CLIO which led to the lowest T2 values after incubation with 1.8 mM iron (G10) and 0.18 mM iron (B9), with T2 changes still detectable at 0.018 mM iron (D7) (Figure 5). $(GRKKRRQRRRGYKC\text{-}N)_5$-SS-CLIO (1.8 mM iron, D13 and 0.18 mM iron, D5) was the second best conjugate in terms of cell labeling. Finally, $(TMG\text{-}RRRRRGYKGCG\text{-}N)_5$-SS-CLIO also showed some minor efficacy (1.8 mM iron, D12 and 0.18 mM iron, F5) (Figure 5).

DISCUSSION

We used a clinical MR imaging system (1.5 T, 64 MHz) widely available in medical institutions and a conventional send-and-receive quadrature extremity coil to image superparamagnetic nanoparticles in microtiter plates. A major question regarding the use of MR imaging in this fashion is the reproducibility of the data obtained. An imaging protocol where the FOV was <7000 mm^2, corresponding to 320 samples for a 384 well plate, was found to give satisfactory reproducibility. As is apparent from Tables 1 and 2, the reproducibility with which nanoparticle concentrations could be determined was high, with in 99% of the cases the true measurement being within 1−2% of the measured mean. This accuracy is similar to other detection technologies and one of the best for magnetic measurements of small samples (<100 μL).

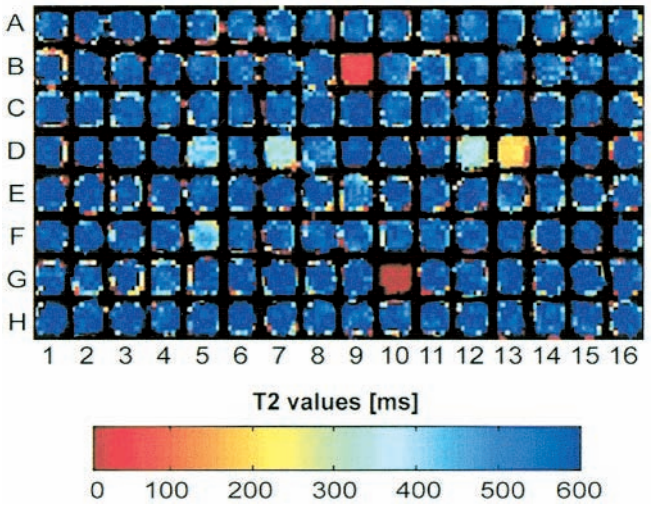

Figure 5. Use of MR imaging to evaluate a limited library of peptide−nanoparticle conjugates. Data are displayed as a T2 color map. The lead candidate was GRKKRRQRRRGYK(FITC)C-$NH_2)_{11}$-SC-CLIO at 1.8 mM iron (G10) and 0.18 mM iron (B9).

To determine how accurate the MR measurements were, we tested a single model compound against a panel of cell lines varying in transferrin receptor expression, which mimics the variable receptor expression seen in different tumors. As shown in Figure 4, based on the comparison of radioactive and superparamagnetic nanoparticle uptake data, measurements by MR imaging were exceedingly accurate.

We then incubated one model cell line with a limited peptide−nanoparticle library of conjugates, to compare their ability to be associated and internalized by cancer cells. Peptide−nanoparticle libraries can be generated by using the linker-chemistry that was developed earlier for the attachment of peptides and proteins to nanoparticles (*1*, *2*). Testing even a limited library of nanoparticle conjugates for cell uptake using conventional, single point relaxometry would have taken days and required sample volumes of 0.5 mL per data point. In contrast, the current assay took less than 4 h for imaging and data analysis and used sample volumes of 60 μL per well. Of the different peptide−nanoparticle conjugates tested a tat-derived peptide with a high valency had the highest uptake. Further studies will employ the HTS MRI technique to systematically screen libraries where peptide sequence, spacer arm chemistry, and valency (number of peptides per particle) will be varied.

The development of high throughput screening methods toward reading equipment capable of ever higher throughputs, lower costs, and higher sensitivities of detection is an ongoing feature of modern drug development. Use of imaging technology (e.g., MR imaging, nuclear imaging, optical imaging) as detection devices for HTS has a number of significant advantages. Imaging modalities have the ability to rapidly obtain signal intensity data of small samples in a field of view comparable to microtiter plates. The capabilities demonstrated here offer a new approach to the discovery of MR imaging reporter agents. The concentrations of labels in individual wells can be determined from signal intensity measurements, and the imaging modality can be used for a variety of tasks such as library deconvolution, determining the pharmacokinetics of internalization, or screening cell lines for the ability to internalize a given ligand. With the approach outlined here, the same imaging modality can be used for compound screening (cell uptake), animal models, and final clinical use. The current approach is well suited to the design of high affinity, targeted ligands for MR imaging and may have a significant impact on the development of new agents that are at the heart of molecular imaging research.

ACKNOWLEDGMENT

The authors thank Dr. Ching H. Tung and Dr. Mark D. Savellano for providing some of the peptides as well as Dr. Ming Zhao and Dr. Nikolay Sergeyev for the preparation and characterization of some of the peptide−CLIO conjugates. We also would like to thank Dr. James P. Basilion and Dr. J. Manuel Perez for the very helpful discussions regarding cell clones and 1536 well plates, respectively. The work was supported by NIH grants RO1 CA 85240, RO1 CA86782, and P50 CA86355. Dr. Dagmar Högemann is a recipient of a fellowship from the Deutsche Forschungsgemeinschaft, Germany.

Magnetic Resonance Imaging of Inducible E-Selectin Expression in Human Endothelial Cell Culture

Hye Won Kang, Lee Josephson, Alexander Petrovsky, Ralph Weissleder, and Alexei Bogdanov, Jr.*

Center for Molecular Imaging Research, Department of Radiology, Massachusetts General Hospital, Harvard Medical School, Building 149, 13th Street, Charlestown, Massachusetts 02129. Received August 28, 2001; Revised Manuscript Received December 3, 2001

Covalent conjugates of the cross-linked iron oxide nanoparticles (CLIO) and high-affinity ($K_d^{app} = 8.5$ nM) anti-human E-selectin (CD62E) F(ab′)$_2$ fragments were prepared and tested in vitro to establish feasibility of endothelial proinflammatory marker magnetic resonance (MR) imaging. The conjugates were obtained by using thiol−disulfide exchange reaction between 3-(2-pyridyl)propionyl-CLIO and *S*-acetylthioacetate-modified F(ab′)$_2$ fragments. The purified CLIO−F(ab′)$_2$ conjugates (average hydrodynamic diameter 40.6 nm) were used in experiments with the live human endothelial umbilical vein cells (HUVEC). Cells treated with IL-1β expressed E-selectin and showed a 100−200 times higher binding of CLIO particles (83−104 ng iron/million cells) than control cells. The binding resulted in a high superparamagnetism of HUVEC with the transverse water proton relaxation time (T2) decrease to 30−40 ms in cell precipitates. Cells did not bind/internalize CLIO−F(ab′)$_2$ conjugates prepared using a control fragment or nonconjugated iron oxide particles before or after treatment with IL-1β. MR imaging of cells showed a highly specific T2-weighted signal darkening associated with cells treated with IL-1β and incubated with anti-E selectin. Demonstration of MR imaging of E-selectin expression justifies further development of MR-targeted agents for monitoring tumor vascular endothelial proliferation, angiogenesis, and atherosclerosis.

INTRODUCTION

Noninvasive imaging of endothelial cell surface marker expression in vivo represents an avenue for identifying early signs of tumor angiogenesis (reviewed in ref 1; *2*) and arthritis and inflammation (*3*, *4*, *5*) as well as atherosclerosis (*6*, *7*). For example, recent research demonstrated feasibility of targeted ^{18}F-labeled peptides (*8*) as well as paramagnetic agents (*2*, *9*) in detecting $\alpha v\beta 3$ integrin expression in endothelial cells lining tumor vessels. Alternatively, several other endothelial cell surface markers or adhesion-promoting molecules including endoglin (*10*) and fibronectin isoform B−FN (*11*) were investigated for imaging endothelial proliferation. There is a significant wealth of evidence suggesting that the expression of E-selectin (CD62E) (*12*), a proinflammatory marker of endothelial cells, is upregulated in proliferating endothelial cells (*13*). E-selectin overexpression was colocalized with dividing microvascular endothelial cells in tissues with active angiogenesis (*14*). In tumors, E-selectin-positive vessels are preferentially found in vascular-rich areas (*15*). In contrast to cell-surface associated E-selectin, levels of cell-shedded soluble E-selectin (sE-selectin) do not usually correlate with primary tumor angiogenesis but are frequently elevated in patients with active metastasis (*16*, *17*). Apart from E-selectin-specific diagnostic probes for angiogenesis, another potentially important application of E-selectin targeted imaging is in detection of early changes in endothelial phenotype linked to atherosclerotic plaque formation (*18*).

The goal of the current study was to develop a MR-detectable reporter with high affinity to E-selectin with an ultimate goal to image E-selectin expression in vivo with high resolution. Since superparamagnetic particles are detectable in tissues at relatively low concentrations of iron oxide (*19*), we chose to couple well-characterized high-affinity anti-human E-selectin antibody fragment (H18/7 (*12*)) to novel cross-linked iron oxide nanoparticles, CLIO[1] (*20*). Here we demonstrate that (1) the antibody−CLIO conjugate retains its specificity for E-selectin; (2) E-selectin expression can be detected by MR imaging in human endothelial cell culture.

MATERIALS AND METHODS

Cross-Linked Iron Oxide (CLIO). Dextran-coated iron oxide cross-linked with epichlorohydrin (cross-linked iron oxide, CLIO) was functionalized as described in (*20*, *21*) and reacted with *N*-succinimidyl-3-(2-pyridyl)dithiopropionate (SPDP) to yield CLIO bearing 3-(2-pyridyl)-propionyl residues (CLIO-SS-2Py). Analysis of CLIO-bound 2-pyridyl disulfide groups was performed by using dithiotrietol (DTT) reduction. Briefly, 50 μL of the CLIO-SS-2Py solution was added to 75 μL of DTT (20 mM) in PBS, pH 7.4 for 30 min. Pyridine-2-thione was separated from CLIO using Microcon 30 concentrators (Amicon, Beverly, MA) and absorbance at 343 nm (ϵ= 8100 M^{-1} cm^{-1}) was measured in the flow-through fraction.

F(ab′)$_2$ fragment of monoclonal anti-human E selectin antibody (H18/7, Vascular Research Division, Department of Pathology, Brigham and Women's Hospital) (90 nmol) was radioiodinated with ^{125}I using IodoGen (Pierce Chemical Co) as described by the manufacturer. Labeled antibody fragment was purified using P-6 gel Minicolumn (Bio-Rad, Hercules CA) equilibrated with PBS pH 7.2. Final specific radioactivity was 1.3−1.5 × 10^6 cpm/μg.

Modification of F(ab′)$_2$ Fragment with *N*-Succinimidyl *S*-Acetylthioacetate. Conjugation of *N*-succinimidyl *S*-acetylthioacetate (*22*) (SATA, Molecular Biosciences, Boulder, CO) to the antibody fragment was accomplished by adding 27 nmol SATA from 0.5 mg/mL stock solution in DMF to 200 μg F(ab′)$_2$ solution (3.5 mg/mL in 0.05 M sodium bicarbonate pH 8.5, containing ^{125}I-F(ab′)$_2$ final specific activity 1·10^5 cpm/μg) and incubating with agitation for 2 h. The 15:1 mol:mol ratio of SATA to mAb was optimal as established in preliminary experiments. The SATA-modified F(ab′)$_2$ fragment was deacetylated by adding an equal volume of 25 mM hydroxylamine, 10 mM EDTA in PBS (pH 7.4) to F(ab′)$_2$−SATA. The excess of free thioacetic acid was removed by passing modified F(ab′)$_2$ through a P-6 gel centrifugation Minicolumn equilibrated with bicarbonate buffer (pH 8.4). Purified thioacetyl-F(ab′)$_2$ was then immediately used for conjugation to CLIO-SS-2Py.

Conjugation of Thioacetyl-F(ab′)$_2$ to CLIO-SS-2Py. An aliquot of CLIO-SS-2Py containing 340 μg Fe was added to 200 μg of thioacetyl-F(ab′)$_2$ in 0.05 M sodium bicarbonate, pH 8.5. The mixture was incubated overnight with mixing at 4 °C. A magnetic separation column (Macs, Miltenyi Biotec, CA) was used to separate the unbound mAb from iron oxide particles. The column was prewashed with 5 mL of degassed buffer (0.05 M sodium bicarbonate, pH 8.5). The reaction mixture was loaded on a column in the presence of external magnetic field. The column was washed twice with 5 mL of degassed buffer to remove nonbound antibody fragment. CLIO−F(ab′)$_2$ conjugate was eluted from the column in the absence of external magnetic field by washing the column with 0.05 M sodium bicarbonate, pH 8.5. The final concentration of iron in purified CLIO−F(ab′)$_2$ was 0.3−0.6 mg/mL. Purified CLIO−F(ab′)$_2$ was kept at 4 °C before use. In control experiments, anti-human IgG mouse monoclonal antibody fragment (control F(ab′)$_2$, Pierce Chemical Co) was conjugated to CLIO-SS-2Py and resultant conjugate was purified using the procedure described above.

Characterization of CLIO−F(ab′)$_2$. Iron concentration was determined as in (*23*). F(ab′)$_2$ concentration was measured by using gamma counting (Compugamma, Wallac, Turku Finland) or determined using BCA kit (Pierce Chemical Co). The size of initial CLIO and conjugates was determined using laser light scattering corrected for scattering properties of particles with different hydrodynamic radii (Zetasizer 3000HS/IHPL; Malvern Instruments Inc.).

Cell Culture Experiments. Human umbilical vein endothelial cells (HUVEC) were provided by Vascular Research Division, Department of Pathology, Brigham and Women's Hospital. HUVEC cells were plated in a gelatin-coated plastic flask containing endothelial cell growth basal medium (EBM) with endothelial growth supplements (Clonetics, BioWhittaker Inc.). Homogeneity of HUVEC culture was checked using flow-cytometry (FACScalibur, Becton-Dickinson) by using rat anti-human CD31 antibody (BD PharmIngen, San Diego CA) followed by anti-rat fluorescein-labeled antibody. To determine apparent dissociation constant (K_D^{app}) for H18/7 F(ab′)$_2$ HUVE cells were plated in 96-well plate and grown to confluency. Cells were treated with human recombinant interleukin-1β (hrIL-1β), freshly prepared by diluting 5μg/mL stock solution 100-fold in sterile HBSS, 10% FBS, 25mM Hepes pH 7.2. Human rIL-1β solution was added to EBM (final concentration −250 pg/mL). Control cells were left untreated. Cells were incubated for 4 h at 37 °C, washed twice with EBM and incubated with ^{125}I-F(ab′)$_2$ that was serially diluted in the medium (1000−1 ng/well) at 4 °C for 30 min. After the extensive washings, cells were solubilized in 1% Igepal/0.1% SDS and radioactivity in lysates was determined using gamma-counting.

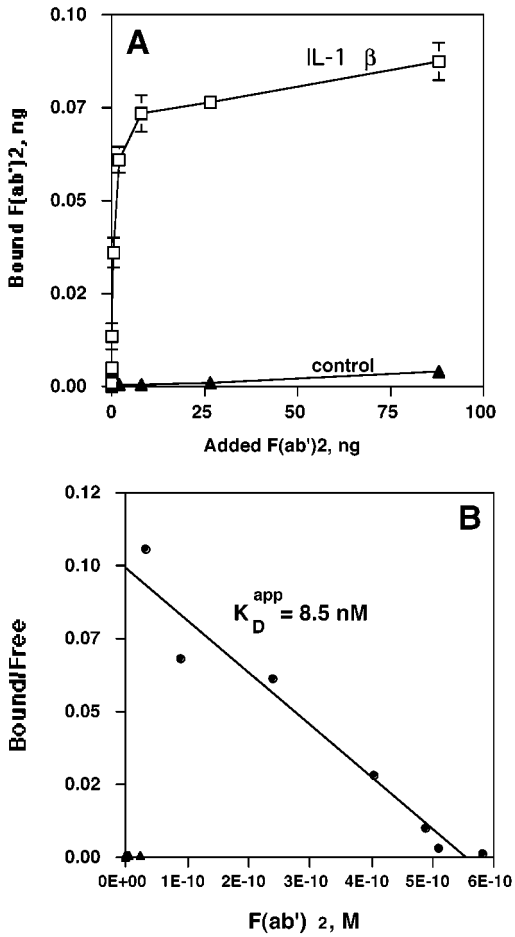

Figure 1. (A) Binding of ^{125}I-labeled H18/7 F(ab′)$_2$ to HUVEC stimulated by IL-1b treatment (squares) and to control HUVEC (triangles). (B) Scatchard plot of binding results presented in A. Circles, IL-1β treated cells; triangles, control cells.

To test the binding of CLIO−F(ab′)$_2$ conjugate to activated or nontreated cells, HUVEC were cultured in 6-well plates until confluence. Expression of E-selectin was induced as described above. Inducible expression of E-selectin on HUVECs after treating cells with IL-1β was verified by FACS after incubating treated and control cells with H18/7 antibody fragment followed by phycoerythrin-labeled goat anti-mouse F(ab′)$_2$ antibody (BD PharmIngen). The medium was replaced with the IL-1β containing EBM, and cells were incubated at 37 °C in 6% CO_2 atmosphere for 2 h. The medium was then replaced with fresh EBM (2 mL/well) containing 20 μL of CLIO−F(ab′)$_2$ conjugate (6.3 μg iron/mL; 400 ng F(ab′)$_2$/mL). Alternatively, an equivalent amount of control, antibody-free CLIO preparation or nonspecific CLIO−F(ab′)$_2$ conjugate were added to each well. The plates were agitated using a rotary incubator for 1 h. The cells were washed three times with HBSS, 10% FBS, 25 mM Hepes pH 7.2, and detached by scraping. Approximately 6.5 ± 0.5 × 10^6 cells were used to prepare samples for MR imaging. Cells were sedimented in 0.25 mL PCR tubes. The total volume of cells and medium was adjusted to 70 μL. The cell layer in the tubes was usually 2.9 ± 0.4 mm high (pellet volume 25 ± 6 μL). Tubes were filled with HBSS, 10% FBS, 25mM Hepes pH 7.2 solution and

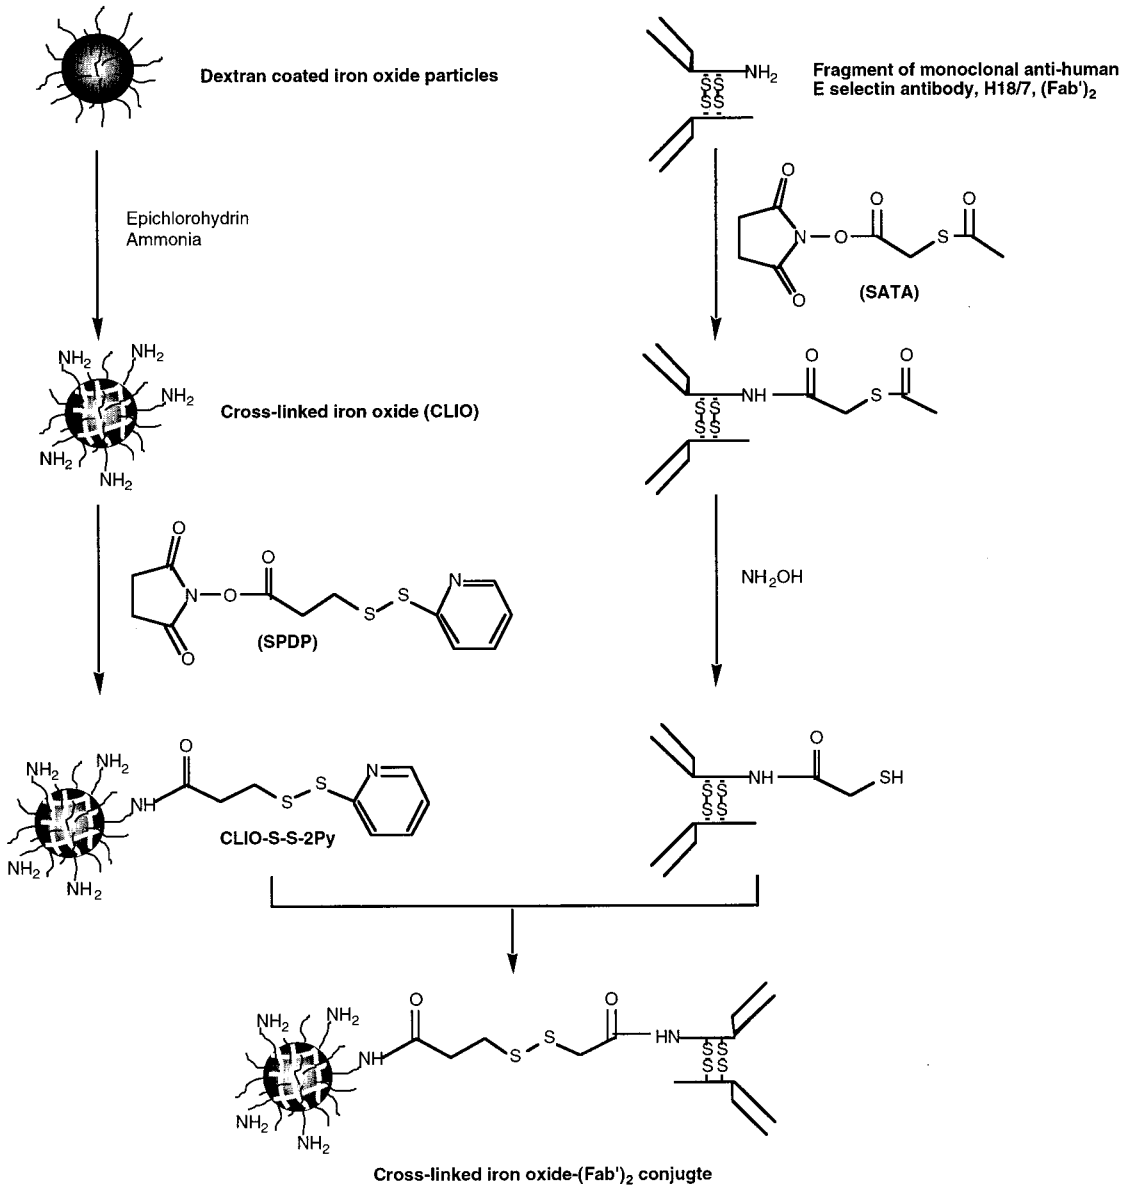

Figure 2. Schema of CLIO−F(ab′)$_2$ synthesis.

subjected to MR imaging. The amount of F(ab′)$_2$ and iron bound to cells was estimated using ^{125}I radioactivity counting (Compugamma, LKB, Gaithersburg, MD) using a previously determined F(ab′)$_2$/Fe ratio in CLIO−F(ab′)$_2$ preparations.

MR Imaging. MRI was performed using a clinical 1.5 T superconducting magnet (Signa 5.0, GE Medical Systems, Milwaukee, WI) and a 3.5 in. surface coil. A T2 weighted spin−echo sequences (TR 3000 ms, variable TE 16−100 ms and 1.0 mm imaging slice) were used for imaging and T2 relaxation time measurements. All sample tubes were placed in water to avoid artifacts during MR imaging. Signal intensity values were measured using IP Lab software (Signal Analytics, Vienna, VA). Relaxation time (T2) values were estimated using monoexponential decay fit as described (*20*) using Prism 2 software (GraphPad Software Inc.).

RESULTS AND DISCUSSION

Previous research suggested that in vivo detection of E-selectin expression by endothelial cells can be of prime importance for tumor angiogenesis imaging and potentially in imaging events preceding the atherosclerotic plaque formation. The expression of E-selectin is transcriptionally upregulated as a result of endothelial cell exposure to several cytokines (e.g., IL-1β and TNFα) and lipopolysaccharide (*24*, *25*, *26*). As demonstrated previously, several monoclonal antibodies to human E-selectin detects inducible E-selectin expression on human endothelial cells with high specificity (*12*, *27*). E-selectin targeted immunoliposomes and anti-E-selectin−hirudin conjugates prepared using H18/7 antibody (*12*) were previously shown to bind to activated human endothelial cells in vitro at the levels exceeding 200-fold those of control cells (*28*, *29*). These findings suggest that the H18/7 antibody or its fragments can potentially serve as excellent targeting ligand for designing imaging probes. In the current research we set forth to chemically link an F(ab′)$_2$ fragment isolated from H18/7 to the surface of cross-linked iron oxide particles (CLIO) and to investigate the utility of resultant CLIO−F(ab′)$_2$ conjugate for MR imaging of inducible E-selectin expression.

Initially, we tested the specificity of H18/7 F(ab′)$_2$ binding to IL-1β-treated cells and determined the apparent K_d. Even at very high antibody/cell ratio (100 ng Fab/10^4 cells) specific binding of antibody fragment was 100-

times higher than the nonspecific uptake (Figure 1A). The apparent dissociation constant of H18/7 F(ab′)$_2$ was estimated as 8.5 nM for IL-1β-treated cells (Figure 1B) suggesting high affinity interaction and potential utility of H18/7 F(ab′)$_2$ for further in vitro and in vivo experiments. To prepare a conjugate of F(ab′)$_2$ with MR imaging probe, cross-linked iron oxide (CLIO) was chosen because of high stability of these particles and controllable chemistry of surface modification. To conjugate antibody fragment to CLIO, the latter was first modified with SPDP to attach pyridyl-disulfide groups to the surface of nanoparticles (*20*) (Figure 2). The resultant preparation contained approximately 27 2-pyridyldithio groups per iron oxide nanoparticle. We then covalently modified F(ab′)$_2$ amino groups with *N*-succinimidyl thioacetate (SATA) to attach protected sulfhydryl groups to F(ab′)$_2$ (*22*) (Figure 2). This conjugation was carried out at the ratio of 1:15 (F(ab′)$_2$:SATA mol/mol). As determined using an IL-1β activation test, modification with SATA resulted in a negligible loss of specificity and was thus used in further experiments as the standard coupling procedure. Our results are in agreement with previous work (*22*) showing that F(ab′)$_2$:SATA ratios 1:10−1:15 are optimal for antibody modification. The next coupling step included deacetylation with hydroxylamine in PBS followed by reacting thioacetyl-F(ab′)$_2$ with CLIO-SS-2Py. The conjugates purified on magnetic columns from the unbound antibody contained 453 ± 145 μg iron and 42.5 ± 1.6 μg F(ab′)$_2$ per mL (4.7 10^{-5} mol F(ab′)$_2$/mol iron). This ratio corresponds to an approximately 10−15% binding yield, assuming that each iron oxide crystal contains approximately 2064 atoms of iron (*23*). One to two molecules F(ab′)$_2$ were conjugated for each 10 nanoparticles. This ratio can be potentially increased by using alternative conjugation strategies or higher initial antibody/iron ratios. However, our results demonstrate that a decrease of Fe/F(ab′)$_2$ ratio does not necessarily result in a dramatic contrast enhancement of E-selectin-positive cells (see Table 1 and Figure 4). Using LALLS we determined that at the chosen ratio of the reactants the hydrodynamic diameter increased 1.6 times from 27.7 nm (nonreacted CLIO) to 40.6 nm (CLIO−F(ab′)$_2$ (polydispersity 0.22−0.28, Figure 3). This was apparently a consequence of F(ab′)$_2$ covalent attachment as the size of conjugates remained constant for almost two months, suggesting a very limited aggregation and sufficient stability of the conjugate. We determined that the further aggregation of CLIO−F(ab′)$_2$ particles was limited to approximately 1% of the total particle number (the size of the aggregates ranged between 150 and 274 nm).

In experiments involving binding of CLIO−F(ab′)$_2$ to HUVEC, either IL-1β activated, or control, we observed a very highly specific binding to activated endothelial cells (Table 1). By using a ^{125}I -labeled CLIO−F(ab′)$_2$ preparation, we determined that on the average, 0.14 ± 0.05% of initially added iron oxide was bound to IL-1β-treated HUVEC if CLIO−F(ab′)$_2$ was added to cells at the concentration of 1.2−2.4 μg iron/mL. In the absence of IL-1β pretreatment only 0.02−0.06% of iron was taken up by the endothelial cells under similar conditions. Thus, our results indicate that CLIO-bound antibody preserved its specificity (approximately 50-fold higher binding to activated than to control cells) and that the HUVECs bind CLIO−F(ab′)$_2$ with the high efficiency (approximately 0.1 pg iron/cell). The shortening of T2 relaxation times of water was clearly dependent on the amount of iron associated with the cells (Table 1). Cells incubated with CLIO−F(ab′)$_2$ conjugate were further subjected to MR imaging to determine whether differential binding of CLIO−F(ab′)$_2$ to nontreated vs IL-1β-treated cells could be verified by MR imaging and MR signal intensity measurements. As shown in Figure 4, T2-weighted MR spin−echo images revealed remarkable differences in signal intensities of IL-1β treated and control cells. Interleukin-treated endothelial cells showed a stronger contrast enhancement in two independent experiments performed using different batches of the conjugate (Table 1). There was no detectable MR signal intensity change observed in pellets of cells incubated with CLIO−F(ab′)$_2$ without pretreatment with IL-1β.

(A**)** MR imaging of HUVEC precipitates **1**, IL-1β-pretreated cells incubated with CLIO−F(ab′)$_2$ #1; **2**, IL-1β-pretreated cells incubated with CLIO−F(ab′)$_2$ #1 in the presence of 10-fold excess of free H18/7 F(ab′)$_2$; **3**, control cells incubated with CLIO−F(ab′)$_2$ #1; **4**, IL-1β-pretreated cells incubated with CLIO-SS-Py; **5**, IL-1β-pretreated cells incubated with MION; **6** and **7,** IL-1β-pretreated cells incubated with CLIO−nsF(ab′)$_2$ (control nonspecific F(ab′)$_2$); **8**, control cells incubated with CLIO-nsF(ab′)$_2$ were incubated for 30 min with 0.5 μg iron/mln cells and washed); **9**−**11**, CLIO−F(ab′) $_2$ standard solutions (0.18 ± 0.01 mg/mL). MR imaging was performed using T2 weighted spin−echo sequence (TE 100/TR 3000), 1.0 mm imaging slice (1.5 T). Field of view, 3 in. (B) Region-of-interest T2-weighted MR signal intensity analysis in samples **1**−**8** (see Figure 4A). The MR signal of water was subtracted from MR signal intensity measurements. Data presented as mean ± SD.

Thus, this result is in agreement with quantitative analysis of CLIO−F(ab′)$_2$ binding to HUVECs (Table 1). However, since an increase of CLIO−F(ab′)$_2$ uptake after IL-1β treatment could be a result of additional cytokine-mediated activation of adsorptive endocytosis or pinocytosis of particles (*30*), we set forth to test this using several control preparations. We compared binding of H18/7 F(ab′)$_2$ conjugated to CLIO with a nonspecific CLIO−F(ab′)$_2$ conjugate as well as unconjugated CLIO or MION (non-cross-linked) iron oxide (*30*). The results of MR imaging (Figure 5 A and B) clearly demonstrate that the profound signal intensity changes detected in IL-1β-activated HUVECs incubated with CLIO−F(ab′)$_2$ do not stem from the augmentation of nonspecific uptake mechanisms since cells incubated in the presence of control nanoparticles did not show any measurable uptake either before or after the IL-1β treatment (Figure 5A, samples 4−8). Interestingly, a 10-fold molar excess of free H18/7 F(ab′)$_2$ over the CLIO-conjugated F(ab′) inhibited binding and uptake by IL-1β treated cells only by 20% on the average. The further increase of free H18/7 F(ab′)$_2$ concentration to the level of 25-fold molar excess in the incubation medium resulted in a 76% of inhibition of the binding and uptake by HUVEC. One of the potential explanations for the observed effect is in that the antibody-conjugated particle has a higher valency, i.e., a higher avidity to the cell surface than F(ab′)$_2$ as a result of multipoint interaction with receptors expressed on the cell surface, the effect well studied in cell-targeted liposome experiments (*28, 31*). In addition, E-selectin is rapidly and constitutively internalized by IL-1β treated HUVEC (*32*) which may result in efficient endocytosis of many E-selectin bound particles by activated endothelial cells.

In conclusion, we demonstrated that H18/7 or control F(ab′)$_2$ fragments can be covalently modified with SATA and attached to superparamagnetic nanoparticles using thiol−disulfide exchange reaction. Anti-E selectin nanoparticles bound with high specificity to IL-1β stimulated HUVECs. We further demonstrated that specific interaction between CLIO−F(ab′)$_2$ and HUVEC can be directly imaged using MRI. This suggests potential in vivo utility of anti-E-selectin targeting for imaging endothelial activation and potentially, angiogenesis. In designing E-selectin-targeted agent we utilized CLIO particles that have a relatively long blood half-life (655 ± 37 min in mice at a dose of 10 mg Fe/kg, P. Wunderbaldinger, personal communication) and the antibody fragment lacking the Fc fragment. Both of these factors can potentially decrease the uptake of anti-E-selectin−CLIO in the liver, the major site of iron oxide elimination from the bloodstream (*30*). Overall, our experiments provide preliminary evidence of the feasibility of E-selectin imaging and justify further development of MR-targeted agents for monitoring proinflammatory markers associated with tumor vascular endothelial proliferation, angiogenesis, and atherosclerosis.

ACKNOWLEDGMENT

The authors acknowledge the help of Jeanne-Marie Kiely for providing H18/7 antibody fragment, Kay Case for assistance with endothelial cell culture, and Dr. Michael Gimbrone, Jr. for useful comments (Vascular Research Division, Department of Pathology, Brigham and Women's Hospital Boston MA). This work has been supported in part by 1P50CA86355-01 (R.W.) and 5RO1 CA74424-01 (AB). A.P. was supported in part by the Russian Department of Education Presidential Award.

Tumor blood vessels can be selectively targeted by RGD-peptides that bind to $\alpha_v\beta_3$ integrin on angiogenic endothelial cells. By inhibiting the binding of these integrins to its natural ligands, RGD-peptides can serve as antiangiogenic therapeutics. We have prepared multivalent derivatives of the cyclic RGD-peptide c(RGDfK) by covalent attachment of the peptide to side chain amino groups of a protein. These RGDpep−protein conjugates inhibited $\alpha_v\beta_3$-mediated endothelial cell adhesion in vitro, while conjugates prepared with a control RAD-peptide showed no activity. Radiobinding and displacement studies with endothelial cells demonstrated an increased affinity of the RGDpep−protein conjugates compared to the free peptide, with IC_{50} values ranging from 23 to 0.6 nM, depending on the amount of coupled RGDpep per protein. Compared to the parental RGD-peptide and the related RGD-peptide ligand c(RGDfV), the RGDpep−protein conjugates showed a considerable increase in affinity (IC_{50} parent RGDpep: 818 nM; IC_{50} c(RGDfV): 158 nM). We conclude that the conjugation of RGD-peptides to a protein, resulting in products that can bind multivalently, is a powerful approach to increase the affinity of peptide ligands for $\alpha_v\beta_3/\alpha_v\beta_5$ integrins.

INTRODUCTION

The formation of new blood vessels is essential for the supply of oxygen and nutrients to proliferating tumor cells. Antitumor therapies that aim at the endothelium of these newly formed tumor blood vessels seem attractive for several reasons. First, the disruption of one blood vessel will result in the killing of a multitude of tumor cells, as shown by inhibiting angiogenesis or by inducing tumor vasculature selective blood coagulation (*1*). Second, endothelial cells of tumor blood vessels are normal, nontransformed cells and therefore less likely to become resistant to antitumor therapy than tumor cells. Last, the endothelium lining the blood vessels is easily accessible for systemically applied therapeutics.

Newly formed blood vessels are characterized by the expression of surface molecules that are not present on resting endothelium (*2*). One of these so-called angiogenic markers is the $\alpha_v\beta_3$ integrin. Cyclic peptides containing a conformationally restrained Arg-Gly-Asp (RGD) sequence have been developed as ligands for $\alpha_v\beta_3$ and the closely related $\alpha_v\beta_5$ integrin (*3*). For instance, the dicyclic peptide CDCRGDCFC (RGD-4C)[1] has been used as a targeting moiety to selectively deliver doxorubicin to angiogenic blood vessels (*4*). A drawback of the RGD-4C peptide is the instability of the two disulfide bridges that maintain the specific three-dimensional structure of the peptide (*5*). A chemically more stable peptide with high affinity for $\alpha_v\beta_3$ integrin and moderate affinity for $\alpha_v\beta_5$ integrin is the cyclic pentapeptide c(RGDfV) (*6, 7*). This peptide consists of a head-to-tail cyclic ring containing one D-amino acid and is currently under investigation for tumor imaging and antitumor radiotherapy (*8*).

The present study describes the development of conjugates of the RGD-peptide c(RGDfK) coupled to the side chain amino groups of a protein backbone (Figure 1). Such conjugates have some favorable characteristics that are not present in the parental peptide. For instance, multiple peptide ligands can be attached covalently to the protein. Theoretically, the resulting multivalency of such a conjugate should result in increased avidity for $\alpha_v\beta_3/\alpha_v\beta_5$ integrins. Furthermore, the larger molecular size of such conjugates often results in longer circulation times in the body (*9*). Finally, our goal is to apply RGDpep−protein conjugates as carrier molecules in drug targeting strategies aiming at angiogenic endothelial cells. The larger size of the RGDpep−protein conjugates allows the attachment of multiple drug molecules, instead of the 1:1 coupling ratio of the RGD-4C-doxorubicin construct mentioned above.

In the current study, a series of conjugates were prepared consisting of different amounts of the RGD-peptide c(RGDfK) and a nonrelevant IgG protein backbone. The binding characteristics of such preparations

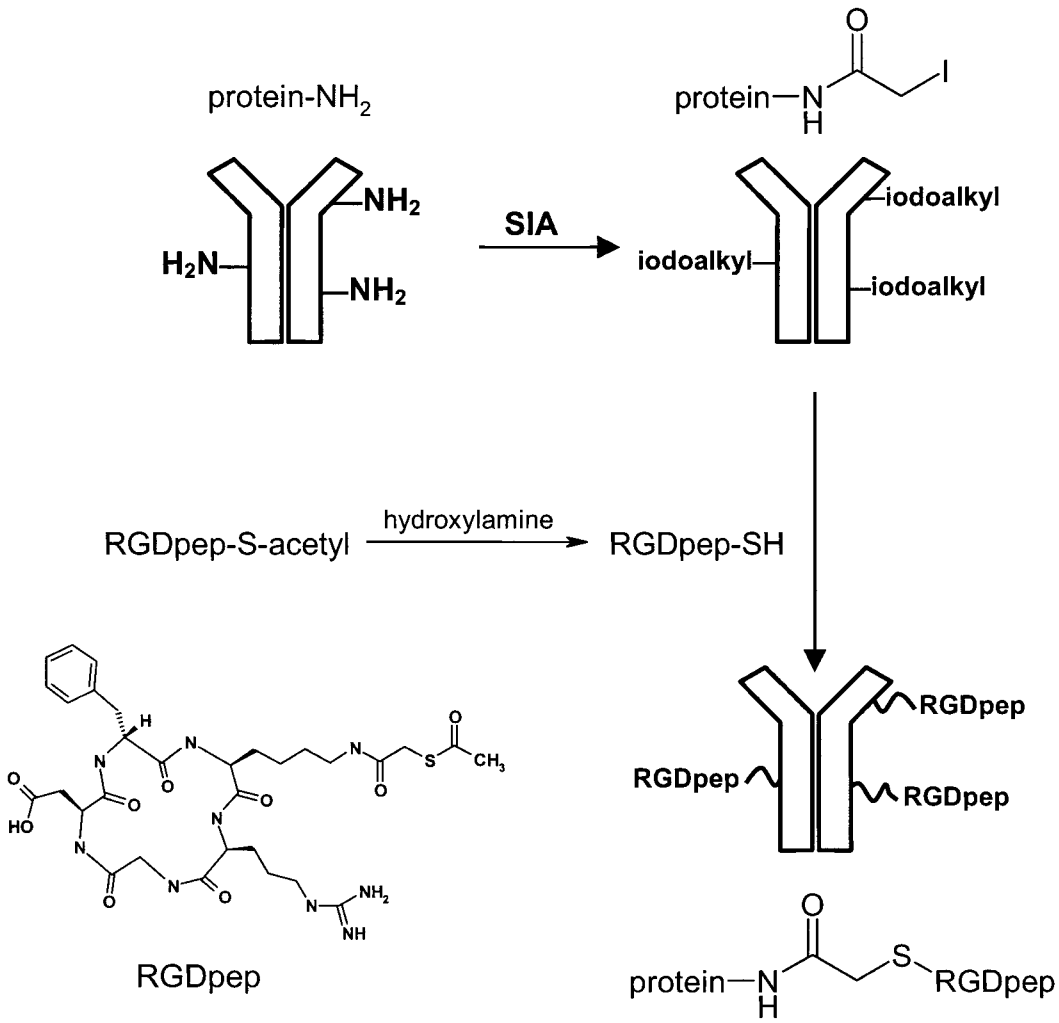

Figure 1. Synthesis of RGDpep−protein conjugates. The iodoacetyl linker (SIA) is coupled to primary amino groups of the protein. After purification by gel filtration, this product is allowed to react in the following reaction. After in situ removal of the protecting thioacetyl group of the peptide with hydroxylamine, RGDpep is coupled via its thiol group with the iodoacetyl group on the protein, resulting in a thioether linkage between RGDpep and protein.

to endothelial cells were studied and compared with those of single monovalent RGD-peptide ligands.

EXPERIMENTAL PROCEDURES

Chemicals and Proteins. All chemicals were used as supplied without further purification. The cyclic RGD-peptide c(RGDf(ϵ-*S*-acetylthioacetyl)K) and the RAD analogue c(RADf(ϵ-*S*-acetylthioacetyl)K), hereafter referred to as RGDpep and RADpep, respectively, were prepared by Ansynth (Roosendaal, The Netherlands). RGD-4C was kindly provided by F. M. H. de Groot (Nijmegen, The Netherlands). c(RGDfV) was obtained from Biomol (Omnilabo International BV, Breda, The Netherlands). HuMab was obtained from the University Hospital Groningen as leftovers from clinical application and consisted of a humanized antibody recognizing an irrelevant human nonendothelial antigen not of interest for our studies. *N*-Succinimidyl iodoacetate (SIA), 3-amino-9-ethyl-carbazole (AEC), *o*-phenylenediamine dihydrochloride tablets (OPD), vitronectin, and crystal violet were obtained from Sigma (St. Louis, MO). 2,2′-Dithiodipyridine (DTDP) was obtained from Fluka (Buchs, Switzerland). L-Cysteine hydrochloride was obtained from Merck (Darmstadt, Germany). Imject Mariculture Keyhole Limpet Hemocyanin (mcKLH), Freund's complete adjuvant, and Freund's incomplete adjuvant were obtained from Pierce (Rockford, IL). Goat-anti-rabbit-peroxidase (GARPO) was obtained from Dako A/S (Glostrup, Denmark). Fibronectin was obtained from Chemicon (Temecula, CA).

Preparation of anti-RGDpep Antiserum. A polyclonal rabbit antiserum was raised against an RGDpep-KLH conjugate in which RGDpep was linked to preactivated mcKLH according to the suppliers protocol. Approximately 600 μg RGDpep-KLH (600 μL) was mixed with an equal volume of Freund's complete adjuvant and injected subcutaneously into a Chinchilla rabbit (Harlan, Zeist, The Netherlands). At 14-day intervals, the immune response was boosted with the injection of RGDpep-KLH emulgated in Freund's incomplete adjuvant (two separate injections of 0.3 mL of emulgate). Blood was collected before immunization and 7 days after immunization. A total of three boosts was needed to obtain adequate anti-RGDpep titers.

Preparation and Characterization of RGDpep−Protein and RADpep−Protein Conjugates. RGDpep or RADpep were coupled in a two-step reaction to the lysine residues in the protein as described below. The iodoacetyl linker molecule SIA was coupled to the primary amino groups of the protein. After purification by size-exclusion chromatography, the SIA-activated proteins were mixed with the peptide and allowed to react after in situ deprotection of the thioacetyl group with hydroxylamine (Figure 1). The peptide:protein ratio of

the conjugate was controlled by varying the amounts of SIA and protein. The peptide was always added in a 2-fold molar excess over the amount of iodoacetyl reagent. To deactivate iodoacetyl groups that had not reacted with the peptide, a final conjugation step was performed with cysteine.

Synthesis of RGDpep−HuMab(I). HuMab (2 mg, 13 nmol) was diluted in PBS to a concentration of 4 mg mL^{-1}. A freshly prepared solution of SIA (19 μg, 67 nmol, 10 mg mL^{-1} in dimethylformamide) was added slowly while the reaction vial was protected from light. The mixture was allowed to react for 1 h at room temperature under gentle mixing. The crude product was purified by sephadex gel filtration (2 serial Hitrap 5 mL desalting columns, Pharmacia Biotech, Roosendaal, The Netherlands) using PBS as eluent at a flow rate of 0.5 mL min^{-1}. The protein-containing fraction was used directly in the following coupling reaction with the peptide. RGDpep (96 μg, 133 nmol), dissolved in an acetonitrile−water mixture (1:4) at a concentration of 10 mg mL^{-1}, was added dropwise to the activated protein. After addition of 100 μL of a freshly prepared hydroxylamine solution (1 M in water), the mixture was allowed to react overnight at room temperature. Remaining iodoacetyl groups were quenched with cysteine (24 μg of hydrochloride salt, 133 nmol, freshly dissolved in water at a concentration of 10 mg mL^{-1}) after which the mixture was reacted for another 1 h. Unreacted reagents were removed by dialysis against PBS at 4 °C. The final product was filtered through a 0.2 μm filter and stored at 4 °C or at −20 °C until further use.

*Synthesis of RGD*pep−Hu*Mab(II)−(IV) and RADpep−HuMab Conjugates.* RGDpep−HuMab and RADpep−HuMab conjugates differing in peptide:protein ratios were prepared according to the same protocol as described above for RGDpep−HuMab(I), using the following amounts of reagents (HuMab/SIA/peptide/cysteine): RGDpep−HuMab(II): 13/133/267/267 nmol; RGDpep−HuMab(III): 13/267/533/533 nmol; RGDpep−HuMab(IV): 13/667/1333/1333; RADpep−HuMab(II): 13/133/267/267 nmol; RADpep−HuMab(IV): 13/667/1333/1333. The amount of hydroxylamine solution (100 μL) was not changed in the various synthesis procedures.

SDS PAGE Analysis and Western Blotting. The covalent coupling of RGDpep or RADpep to the IgG protein in the conjugates was demonstrated by western blotting, followed by immunodetection of coupled peptides in the blotted proteins. For this, the conjugates were subjected to SDS−PAGE analysis performed on a mini-PROTEAN II system (Bio-rad, Veenendaal, The Netherlands) using 7.5% polyacrylamide Tris HCl gels. Samples were prepared for analysis in sample buffer without β-mercaptoethanol (nonreducing conditions) or with β-mercaptoethanol (reducing conditions) to disrupt disulfide bonds between the HuMab IgG subunits. Runned gels were either stained for protein (Coomassie Brilliant Blue staining) or blotted on poly(vinylidene difluoride) membranes (PVDF western blotting membranes, Roche Molecular Biochemicals, Almere, The Netherlands), followed by immunostaining for RGDpep or RADpep using anti-RGDpep polyclonal rabbit antiserum/GARPO/AEC detection. Prestained protein markers (precision prestained molecular weight markers, Bio-rad) were run together with the samples in a separate lane.

Size-Exclusion Chromatography. Molecular size of the prepared conjugates was also analyzed by size-exclusion chromatography under normal conditions, to demonstrate the absence of polymerized IgG or other aggregated proteins due to the conjugation procedures. Separations were performed on a FPLC system equipped with a Superdex 200 HR10/30 column (Pharmacia) and UV detection (214 nm), using PBS at a flow rate of 0.4 mL min^{-1} as mobile phase. HuMab, RGDpep−HuMab(IV), and RADpep−HuMab(IV) conjugates were diluted to a concentration of 100 μg mL^{-1} in PBS, of which 200 μL was injected into the system.

Determination of RGDpep-to-Protein Ratio. The protein content of the conjugates was determined by Lowry (*10*). The number of coupled RGDpep molecules was determined by ELISA using the anti-RGDpep antiserum. Wells were coated with serial dilutions of the RGDpep−protein conjugates for 2 h at 37 °C, washed with 25 mM Tris HCl buffer pH 8 containing 150 mM NaCl and 0.05% Tween 20 and incubated for 1 h with anti-RGDpep antiserum (1:1000 in PBS) at 37 °C, followed by standard detection with GARPO/OPD. The absorbance at 490 nm was measured on a ThermoMax microplate reader (Molecular Devices, Sunnyvale, CA). For each RGDpep−HuMab conjugate, the protein concentration at which 50% of the maximum absorbance was measured (EC_{50}) was calculated by nonlinear regression (Graphpad Prism). The relative RGDpep:protein ratio in each conjugate was calculated by normalization of the EC_{50} to the value of the RGDpep−HuMab(I) conjugate.

An estimate of the absolute RGDpep:protein ratio was obtained by determination of the amount of introduced iodoacetyl groups in the RGDpep−HuMab(IV) conjugate. This number was calculated by reacting the intermediate product SIA−HuMab(IV) with excess cysteine and titration of the remaining amount of free thiol groups with DTDP. In brief, HuMab (13 nmol, 4 mg mL^{-1} in PBS) was reacted with SIA (667 nmol) and purified by gel filtration as described above. To a 1 mL aliquot of the protein-containing fraction were added cysteine (1333 nmol, dissolved in water at a concentration of 10 mg mL^{-1}) and hydroxylamine (100 μL of a freshly prepared 1 M solution in water), and the mixture was stirred for 4 h at room temperature. A 100 μL aliquot was analyzed for thiol content by addition of 900 μL of PBS and 10 μL of DTDP solution (10 mg mL^{-1} in acetone), followed by immediate mixing and measurement of the absorbance at 343 nm. Calibration curves were prepared from a freshly prepared cysteine stock solution. To correct for oxidation of cysteine or consumption of the free thiol other than by reaction with the coupled iodoacetyl groups, a control experiment was performed in which HuMab (13 nmol, 4 mg mL^{-1} in PBS) was *not* reacted with SIA, but otherwise treated similarly as described above. The absolute iodoacetyl:protein ratio of the SIA−HuMab(IV) conjugate was calculated from the decrease in the molar amount of cysteine, corrected for oxidation, and from the protein content of the purified protein.

Cells. Human umbilical vein endothelial cells (HUVEC) were isolated by the method previously described by Mulder (*11*) and cultured on 1% gelatin-precoated plastic tissue culture plates or flasks (Costar Europe, Badhoevedorp, The Netherlands) at 37 °C under 5% CO_2/95% air. The culture medium consisted of RPMI 1640 (BioWittaker, Verviers, Belgium) supplemented with 20% heat-inactivated fetal calf serum (Integro BV, Zaandam, The Netherlands), 2 mM L-glutamine (GIBCO−BRL, Paisley, Scotland), 5 U mL^{-1} heparin (Leo Pharmaceutical Products BV, Weesp, The Netherlands), 100 U mL^{-1} penicillin (Yamanouchi Pharma BV, Leiderdorp, The Netherlands), 100 μg mL^{-1} streptomycin (Radiumfarma-Fisiopharma, Milan, Italy), and 50 μg mL^{-1} endothelial cell growth factor supplement extracted from bovine brain. After attaining confluence, cells were detached

from the surface by trypsin/EDTA (0.5/0.2 mg mL^{-1} in PBS) and split at a 1:3 ratio. HUVEC were used up to passage three.

The H5V mouse endothelioma cell line was kindly provided by Dr. A. Vecchi (Milan, Italy). H5V cells were grown in plastic tissue culture flasks or plates at 37 °C under 5% CO_2/95% air. The culture medium consisted of DMEM supplemented with 10% heat-inactivated FCS, 2 mM L-glutamine, and 300 μg mL^{-1} gentamicin. After attaining confluence, cells were detached from the surface by trypsin/EDTA (0.5/0.2 mg mL^{-1} in PBS) and split at a 1:3 ratio.

Endothelial Cell Adhesion Assay. The functional integrity of the coupled RGDpep was studied in an $\alpha_v\beta_3$-dependent adhesion assay as previously described with minor modifications (*12*). Briefly, flat bottom 96-wells culture plates were coated overnight with vitronectin (500 ng/well in PBS) at 4 °C. Wells were blocked with 1% BSA for 2 h at 37 °C and washed two times with PBS. Trypsinized HUVEC were resuspended in serum-free medium, incubated for 15 min on ice with RGDpep−HuMab or RADpep−HuMab conjugates, and subsequently plated at 2×10^4 cells/well. After incubation at 37 °C for 24 h, unattached cells were removed by rinsing the wells with PBS. Attached cells were fixed in 2% paraformaldehyde, stained with 0.5% crystal violet, and quantified by measuring the absorbance at 575 nm on an Emax microplate reader (Molecular Devices, Sunnyvale, CA). Control experiments included incubations with free RGDpep or RADpep, and adhesion experiments in wells coated with fibronectin, in which case the endothelial cell adhesion is independent of the availability of $\alpha_v\beta_3/\alpha_v\beta_5$ integrins due to adherence via $\alpha_5\beta_1$ integrin. Nonspecific binding of H5V cells was determined by adhesion onto BSA-coated wells.

Radiobinding Assays. The affinity of RGDpep−HuMab conjugates for $\alpha_v\beta_3/\alpha_v\beta_5$ integrin was studied using cells expressing these integrins rather than isolated receptors, to allow cross-linking and possible integrin multimerization in intact cell membranes. RGDpep−HuMab(IV) was radiolabeled with ^{125}I to a specific activity of 0.4 MBq μg^{-1} by a chloramine-T method (*13*). Confluent H5V cell layers in 24-well plates were preincubated for 15 min on ice with binding buffer (50 mM Tris-HCl buffer pH 7.4 supplemented with 150 mM NaCl, 1 mM $CaCl_2$, 1 mM $MgCl_2$, 1mM $MnCl_2$ and 1% BSA). After preincubation, the buffer was replaced by binding buffer containing 70000 cpm of ^{125}I-RGDpep−HuMab(IV) and appropriate dilutions of nonlabeled RGDpep−HuMab conjugates, followed by incubation of the cells for 4 h at 4 °C. After sampling of the supernatant, the cells were washed three times with binding buffer and lysed with 1 M NaOH (30 min at 37 °C). Radioactivity was counted in a LKB multichannel counter (LKB, Bromma, Sweden). Control experiments included competition experiments with RADpep−HuMab conjugates, free RGDpep and RADpep, as well as with c(RGDfV) and RGD-4C.

The K_d of ^{125}I-RGDpep−HuMab(IV) was calculated by nonlinear regression to the Michaelis−Menten equation[2] using the Multifit program (Department of Pharmacokinetics and Drug Delivery, University Centre for Pharmacy, Groningen, The Netherlands). IC_{50} values of RGDpep−HuMab conjugates and RGD-peptides were calculated by nonlinear regression (Graphpad Prism) using a one-site competition model[2].

Statistics. Statistical significance of differences was tested using the two-sided Student's t-test, assuming equal variances.

RESULTS

Preparation and Characterization of Peptide−Protein Conjugates. The peptide RGDpep and its nonbinding counterpart RADpep were coupled covalently to primary amino groups of the HuMab protein after initial derivatization with a iodoacetyl linker (Figure 1). To obtain conjugates with different numbers of coupled peptide, we used ratios of iodoacetyl reagent (SIA) and HuMab of 5:1, 10:1, 20:1, and 50:1 for RGDpep−HuMab-(I) to (IV), respectively. We demonstrated the covalent attachment of RGDpep to HuMab by SDS−PAGE analysis and immunoblotting with a polyclonal anti-RGDpep antiserum (Figure 2). Analysis of samples that were treated with β-mercaptoethanol revealed that the peptide was coupled in both IgG heavy and light chain subunits of the protein. Anti-RGDpep antiserum cross-reacted with RADpep−protein conjugates, but not with conjugates prepared with the iodoacetyl linker and unrelated peptides (data not shown). Therefore, this analysis method could also be applied for the analysis of RADpep−HuMab conjugates.

The covalent conjugation of RGDpep to the HuMab protein was also studied by anti-RGDpep ELISA. This method showed a clear correlation between the RGDpep incorporation and the added equivalents of coupling reagent during the synthesis (Figure 3). From these data, we conclude that we prepared a series of RGDpep−protein conjugates with increasing amounts of coupled RGDpep. In addition, we performed an indirect determination of the number of coupled RGDpep groups for the SIA−HuMab(IV) by reacting the introduced iodoacetyl groups with excess cysteine followed by titration of the remaining free thiol groups with DTDP. This analysis yielded an average of 23 coupled iodoacetyl groups per protein.

Size-exclusion chromatography of the peptide−protein conjugates demonstrated the absence of polymerized protein or other aggregates (Figure 4). A small-increase in molecular size of the conjugates was observed compared to the native IgG protein, both after coupling of RGDpep and RADpep ligands to HuMab.

Endothelial Cell Adhesion Assay. To test the functional integrity of the covalently attached RGDpep, we studied the effect of the RGDpep−HuMab conjugates on the adhesion of endothelial cells on vitronectin-coated surfaces. Figure 5 shows that RGDpep−HuMab conjugates strongly inhibited attachment of HUVEC on vitronectin-coated wells. Similar results were obtained when the adhesion of HUVEC was inhibited by incubation with free RGDpep or with other $\alpha_v\beta_3$ and $\alpha_v\beta_5$ binding peptides such as c(RGDfV) and RGD-4C. In contrast, RADpep−HuMab conjugates had no effect on vitronectin-mediated adhesion. From this, we concluded that the RGDpep−HuMab conjugates functionally interacted with $\alpha_v\beta_3/\alpha_v\beta_5$ in a similar fashion as other RGD-peptide ligands for these integrins. As expected, no inhibition of adhesion by RGDpep−HuMab conjugates was observed in fibronectin-coated wells, which allows HUVEC attachment via both $\alpha_5\beta_1$ and $\alpha_v\beta_3$ integrin (data not shown).

Radiobinding Assays. We studied the binding specificity and affinity of the RGDpep−HuMab conjugates for $\alpha_v\beta_3/\alpha_v\beta_5$-expressing H5V cells with the radioiodinated

[2] One-site binding model: (pmol bound) = $(B_{max})([pM])/(K_d + [pM])$; two-site binding model: (pmol bound) = $(B_{max_1})([pM])/(K_{d_1} + [pM]) + (B_{max_2})([pM])/(K_{d_2} + [pM])$; one-site competition model: % binding = $(100\%)/(1 + 10^{(\log(M) - \log EC_{50})})$.

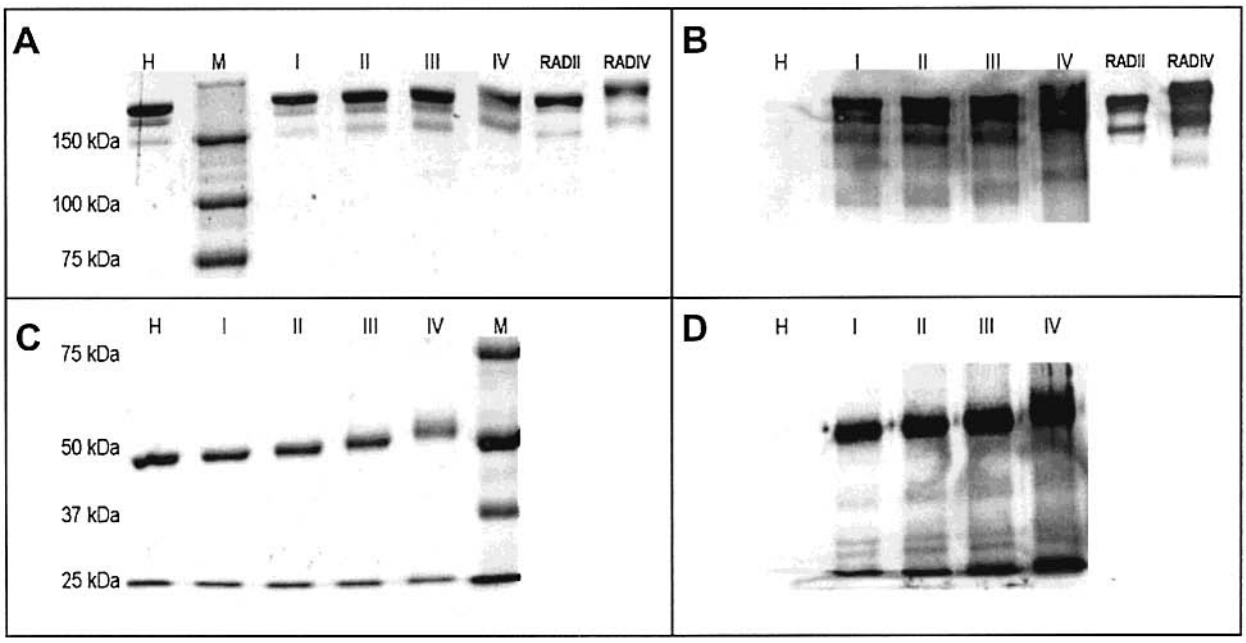

Figure 2. SDS PAGE (A, C) and western blot (B, D) analysis of RGDpep−HuMab conjugates. Panel A: nonreducing conditions, protein staining (Coomassie Brilliant Blue); Panel B: nonreducing conditions, anti-RGDpep immunostaining; Panel C: reducing conditions, protein staining; Panel D: reducing conditions, anti-RGDpep immunostaining. Lanes: (H) HuMab; (M) molecular weight markers; (I to IV) RGDpep−HuMab(I)−(IV); (RADII and -IV) RADpep−HuMab(II) and -(IV).

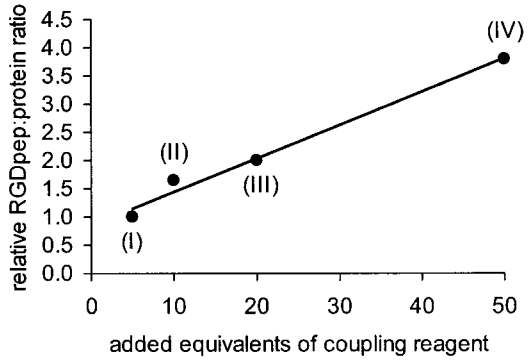

Figure 3. Determination of covalently incorporated RGDpep in RGDpep−HuMab conjugates. Values between parentheses denote the corresponding RGDpep−HuMab conjugate. RGDpep was determined by ELISA using a specific anti-RGDpep antiserum. The relative RGDpep:protein ratio was calculated from the EC_{50} of each conjugate, as determined from the half-maximal OD_{490} absorbance of serial dilutions in the ELISA, and normalized to the value of the RGDpep−HuMab(I) conjugate. See Experimental Procedures for a detailed description of the determination of the relative RGDpep:protein ratio.

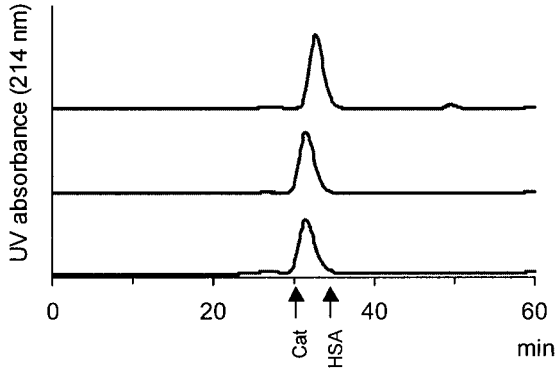

Figure 4. Size-exclusion chromatography of HuMab (upper), RGDpep−HuMab(IV) (middle), and RADpep−HuMab(IV) (bottom). Separations were performed under normal conditions on a Superdex 200 HR10/30 column. Arrows denote the peak elution time of catalase (Cat, 232 kDa) and human serum albumin (HSA, 67 kDa).

RGDpep−HuMab(IV) conjugate. By using whole cells, multivalent binding and clustering of receptors is studied in the natural context of the integrins. The radiobinding experiments were carried out in a Tris binding buffer pH 7.4 supplemented with 1 mM Ca^{2+}, 1mM Mg^{2+}, and 1 mM Mn^{2+}, since these divalent cations are important for the interaction of $\alpha_v\beta_3$ integrin with its ligands (*14*). Experiments in buffers lacking one or more of these cations showed lower absolute binding of ^{125}I-RGDpep−HuMab(IV) (Schraa, A. J., unpublished results).

^{125}I-labeled RGDpep−HuMab(IV) binding could be blocked almost completely by micromolar concentrations of either c(RGDfV) or RGD-4C (Figure 6), indicating that the radiolabeled conjugate bound specifically via its coupled RGDpep groups to the cells. Besides the 50 μM concentration shown in Figure 6, c(RGDfV) at a concentration of 1 M inhibited the binding of ^{125}I-RGDpep−HuMab(IV) to 2.0 ± 0.2% (data not shown).

The specific binding of ^{125}I-RGDpep−HuMab(IV) to the cells was saturable, although maximal binding was not reached at the highest concentration tested (Figure 7). The K_d of RGDpep−HuMab(IV) binding was calculated by nonlinear regression analysis. Assuming two binding sites, which resulted in a better fit of the data than a monovalent model ($p < 0.01$), the analysis yielded binding constants of 0.38 and 22 nM for K1 and K2, respectively (95% confidence intervals: $0.28 < K1 < 0.49$ nM, $0 < K2 < 92$ nM).

We compared the affinities of the RGDpep−HuMab conjugates to the affinity of the parental RGD-peptide by performing competitive displacement studies with the ^{125}I-RGDpep−HuMab(IV) conjugate (Figure 8). All four RGDpep−HuMab conjugates showed a considerable increase in affinity compared to the monovalently binding parental RGD-peptide. Fitting the data with nonlinear regression yielded IC_{50} values presented in Table 1. To compare these data with affinity data of other RGD-peptide ligands, we also determined the IC_{50} of the previously reported c(RGDfV) in our experimental setup

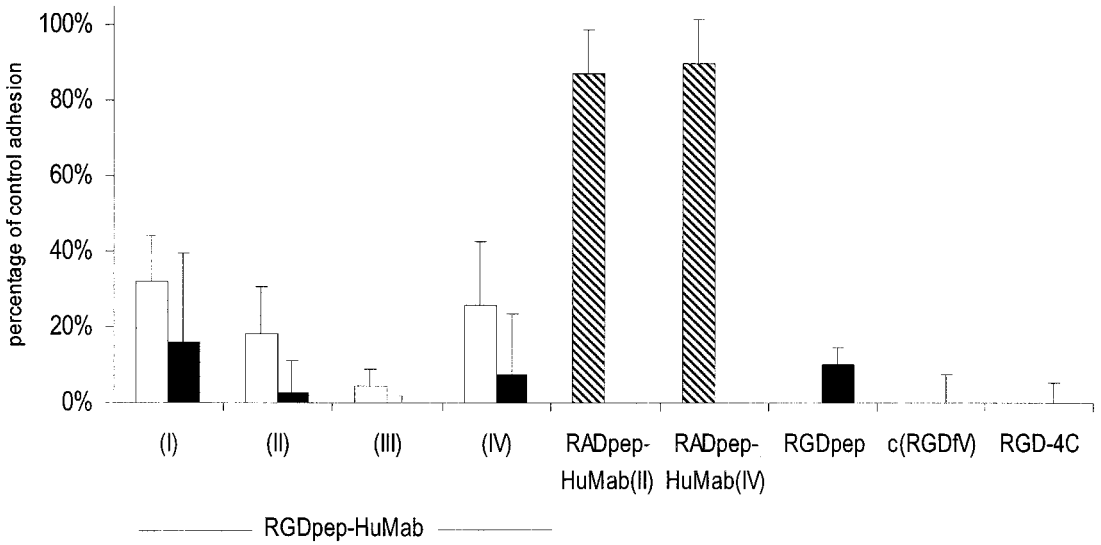

Figure 5. Inhibition of $\alpha_v\beta_3/\alpha_v\beta_5$ mediated adhesion of HUVEC to vitronectin by RGDpep−HuMab conjugates. Adhesion of HUVEC on vitronectin in the absence of inhibitor was set at 100%. Concentration of inhibitors: 500 nM (open bars), 700 nM (hatched bars), 1 μM (closed bars). Values are mean of triplicate assays ± SD. For all RGDpep−HuMab conjugates and RGD-peptides, adhesion of HUVEC significantly differed from control ($p < 0.05$).

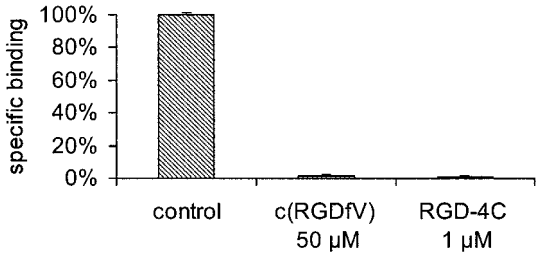

Figure 6. Binding of ^{125}I-RGDpep−HuMab(IV) to H5V endothelial cells. Specific binding of a tracer dose (70000 cpm) of ^{125}I-RGDpep−HuMab(IV) could be inhibited by excess of reported RGD-peptide ligands for $\alpha_v\beta_3/\alpha_v\beta_5$ integrin, c(RGDfV), and RGD-4C. Values are mean of triplicate assays ± SD.

(158 nM). The RGDpep used for preparation of our constructs, c(RGDf(ϵ-*S*-acetylthioacetyl)K), competed at a 5-fold higher IC_{50} than c(RGDfV), likely resulting from the attachment of the acetylthioacetyl linker group.

Competition experiments with RADpep and RADpep−HuMab conjugates showed no inhibition of ^{125}I-RGDpep−HuMab(IV) binding, even at the highest concentration tested. Again, this demonstrates that the binding of ^{125}I-RGDpep−HuMab(IV) is specifically mediated via the coupled RGDpep groups.

DISCUSSION

The present study describes the preparation and characterization of multivalent derivatives of a peptide that binds to $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins via an Arg-Gly-Asp sequence. We coupled this RGDpep chemically to a protein and demonstrated that such RGDpep−protein conjugates bind to endothelial cells with dramatically increased affinity. Since the binding of the RGDpep−protein conjugates can be inhibited by the free RGDpep and other RGD-peptides, but not by similarly prepared RADpep−protein conjugates, we concluded that RGDpep−protein conjugates bind to the cells via the coupled RGDpep groups.

The type of RGD-peptide that was used in the present study binds specifically and with high affinity to $\alpha_v\beta_3$ integrin due to the special constrained conformation of the RGD sequence (*6*). This special RGD conformation is induced by both the unnatural D-amino acid and the head-to-tail cyclization of the pentapeptide. Since such peptide structures cannot be encoded by a recombinant DNA sequence, we have chosen for classical chemical coupling techniques to prepare RGDpep−protein derivatives. In these conjugates, the peptide was coupled via a relatively short linker to amino groups of the HuMab

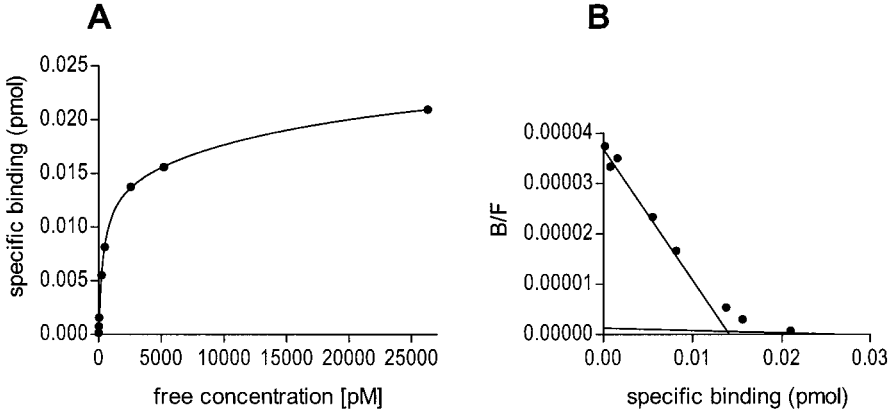

Figure 7. Specific binding of ^{125}I-RGDpep−HuMab(IV) to H5V endothelial cells after incubation for 4 h at 4 °C. Panel A: Specific binding of ^{125}I-RGDpep−HuMab(IV) (pmol/well) plotted against the free concentration of the compound [pM]. Panel B: Scatchard plot of ^{125}I-RGDpep−HuMab(IV) binding. B/F: ratio of specific binding and free concentration (pmol/pM). Fitted lines in both panels were drawn using the K_d and B_{max} values calculated by nonlinear regression analysis.

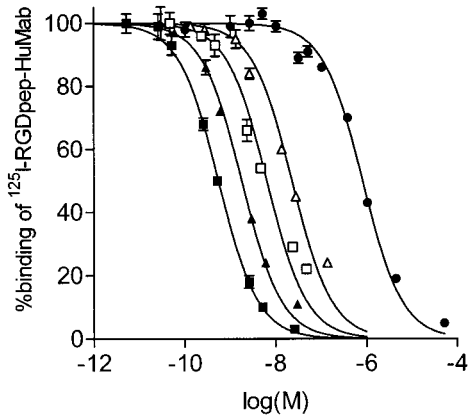

Figure 8. Competitive displacement of ^{125}I-RGDpep−HuMab-(IV) binding by RGDpep−HuMab conjugates and parental RGDpep. H5V cells were incubated with ^{125}I-RGDpep−HuMab-(IV) (tracer dose, 70000 cpm) and appropriate dilutions of nonlabeled compounds. Cell-associated radioactivity in the absence of competitor was set at 100%. Closed circles: RGDpep; open triangles: RGDpep−HuMab(I); open squares: RGDpep−HuMab(II); closed triangles: RGDpep−HuMab(III); closed squares: RGDpep−HuMab(IV). Values are mean of triplicate assays ± SD.

Table 1. Affinity Data of RGDpep−HuMab Conjugates and RGD-Peptides. Competitive Binding Experiments Were Performed on $\alpha_v\beta_3$ Integrin Expressing H5V Cells with Radiolabeled RGDpep−HuMab(IV) Conjugate and the Peptide−Protein Conjugates or Peptides Products Listed below. IC_{50} Values Were Calculated from the Data Presented in Figure 8

product	IC_{50} (nM)	increase in affinity[a]
RADpep	>5000[b]	
RGDpep	818	1
c(RGDfV)	158	5
RGDpep−HuMab(I)	23.2	35
RGDpep−HuMab(II)	6.5	125
RGDpep−HuMab(III)	2.0	410
RGDpep−HuMab(IV)	0.6	1297
RADpep−HuMab(II)	>667[b]	
RADpep−HuMab(IV)	>667[b]	

[a] The increase in affinity was calculated by dividing the IC_{50} of RGDpep by the IC_{50} of the tested product. [b] Highest tested concentration. No inhibition of ^{125}I−RGDpep−HuMab(IV) binding was observed at this concentration.

protein. Since the RGD-binding site of integrins is located in a cleft between the two subunits of the integrin, the pharmacological activity of RGD-peptide could be lost due to steric hindrance of the protein backbone. The spacer in our conjugates accounts for 10 atoms, counted from protein backbone to the ϵ-amino group of the lysine in the c(RGDfK) ring structure. This value fits in the spacer requirements found by Kantlehner and colleagues, who demonstrated that c(RGDfK) coupled via an 8-atom spacer lost its activity, while a 15-atom spacer allowed the peptide to interact freely with its receptor (*15*). Clearly, the binding of our conjugates to endothelial cells and the inhibition of adhesion of HUVEC onto vitronectin-coated wells demonstrate the functional activity of our constructs with $\alpha_v\beta_3$ integrin.

We determined the amount of coupled RGDpep ligands in our conjugates by an anti-RGDpep ELISA, which enabled us to calculate relative RGDpep:protein ratios ranging from 1 to 3.8. In addition, we determined the amount of introduced iodoacetyl groups of the SIA−HuMab(IV) conjugate. From this experiment an absolute RGDpep:protein ratio for the RGDpep−HuMab(IV) conjugate of 23 was established. Since the RGDpep−HuMab-(I) conjugate was prepared using 5 equiv of SIA reagent, the maximal amount of coupled RGDpep molecules in the RGDpep−HuMab(IV) conjugate based on the ELISA would be 19, which is lower than the absolute ratio of 23. Likely, the observed discrepancy results from an underestimation of the relative RGDpep:protein ratio, due to steric hindrance of anti-RGDpep antibody binding in the higher loaded conjugates.

Commonly, the degree of protein modification is calculated indirectly, for instance by TNBS derivatization of remaining primary amino groups (*16*). This approach proved to be inaccurate for our conjugates, due to the low protein concentration of the products. Alternatively, the number of coupled peptides can be derived from the change in apparent molecular weight demonstrated by gel electrophoresis or chromatography (*17*). However, our products showed only small differences compared to the parent protein, probably due to the constrained structure of the RGDpep ligand, although immunostaining clearly demonstrated the presence of the peptide in all conjugates. The large molecular weight of HuMab and the expected heterogeneity of the conjugates would furthermore not allow proper mass spectrometry analysis of the conjugates.

We studied the affinity of our conjugates for cells expressing $\alpha_v\beta_3/\alpha_v\beta_5$ integrins using the radiolabeled RGDpep−HuMab(IV) conjugate, which contained the highest number of coupled RGDpep ligands. ^{125}I-RGDpep−HuMab(IV) bound in a saturable manner to these endothelial cells, although complete saturation of binding was not observed at highest concentration tested. Assuming two binding sites in the fitting model gave better results than a one-binding site model. Whether the conjugate actually binds via two RGDpep-integrin interactions cannot be concluded from our data. More likely, the found binding constants are apparent K_d values.

To compare the binding affinities of the RGDpep−HuMab conjugates with those of free RGDpep and references from the literature, we determined the IC_{50} values of the various RGD-containing compounds (Table 1). The increase in IC_{50} correlated with the number of coupled RGDpep groups for the series of RGDpep−HuMab conjugates. Since the affinity increased to a larger extent than can be accounted for by the number of coupled RGDpep ligands, only cooperative binding due to multivalency can explain these data. Compared to the single RGDpep ligand, an increase in IC_{50} was found of over 3 orders of magnitude for the most potent RGDpep−HuMab conjugate, while about 23 RGDpep ligands have been incorporated in this product. Compared to the reference c(RGDfV), an increase in affinity of up to 250-times was calculated for the RGD-HuMab(IV) product. In comparison, the most potent structure derived from c(RGDfV), c(RGDf(N-Me)V) (EMD121974), binds to $\alpha_v\beta_3$ with an affinity 4.3 times higher than c(RGDfV) (*18*).

To summarize, the coupling of the peptide RGDpep to a protein yielded multivalent conjugates with a strongly increased affinity for $\alpha_v\beta_3$ integrin and/or $\alpha_v\beta_5$ integrin compared the parental peptide. These conjugates were capable of inhibiting the interaction between $\alpha_v\beta_3/\alpha_v\beta_5$ integrins and vitronectin and therefore may display antiangiogenic effects when administered in vivo. In addition, RGDpep-conjugation might be of use for targeting of therapeutic proteins to tumor blood vessels. Candidate proteins for such an approach currently under investigation in our laboratory include truncated Tissue Factor (tTF), that selectively induces blood coagulation in tumor blood vessels when properly bound to receptors on the tumor endothelium (*19*). Initial experiments with RGDpep-tTF conjugates demonstrated that RGDpep-tTF

was still capable of inducing blood coagulation in vitro (Schraa, A. J., unpublished results). Alternatively, RGDpep−protein conjugates can be prepared that induce tumor endothelial cell killing. Examples of proteins that can be used in the latter approach are TNFα and IL-2, both activating the immune system, or glucose oxidase, which generates toxic reactive oxygen species (*20*−*22*). Finally, endothelial delivery of small drug molecules or toxic molecules can be achieved using RGDpep as a targeting device. The validity of such an approach has already been demonstrated with the RGD-4C−doxorubicin prodrug, which displayed a strong antitumor effect (*4*). Preparations based on this approach can either consist of soluble macromolecules, such as proteins or polymeric backbones, or liposomal formulations as recently proposed by Kessler et al. (*23*, *24*).

ACKNOWLEDGMENT

A.D. Berendsen is kindly acknowledged for assisting in the radiobinding experiments, and J.H. Pol from the Department of Nuclear Medicine for radiolabeling of the conjugates. HUVEC and H5V cells were kindly provided by the RuG/AZG Endothelial Cell Facility.

Received June 1, 2001; Revised Manuscript Received October 8, 2001

Neoglycoconjugates were prepared from mannan isolated from yeast *Saccharomyces cerevisiae* and activated by periodate oxidation to create aldehyde groups. Various degrees of oxidation introduced 11−28 aldehyde groups per mannan molecule and simultaneously resulted in a molar mass decrease from 46 to 44.5−31 kDa. The activated mannans were subsequently conjugated with bovine serum albumin forming neoglycoconjugates. Some parameters of these mannan−bovine serum albumin conjugates were characterized: saccharide content 25−30% w/w, molar mass within the range 169−246 kDa, and polydispersion (M_w/M_n) from 2.8 to 3.6. The interaction of these conjugates with lectin concanavalin A was studied using three different methods: (i) quantitative precipitation in solution; (ii) sorption to concanavalin A immobilized on bead cellulose; and (iii) kinetic measurement of the interaction by surface plasmon resonance. Quantitative precipitation assay showed only negligible differences in the precipitation course of original mannan and the corresponding mannan−bovine serum albumin conjugates. Both the sorption method (equilibrium method) and the surface plasmon resonance measurement (kinetic method) demonstrates that the values of dissociation constant K_D of all synthetic neoglycoconjugates were within the range 10^{-7}−10^{-8} mol·L^{-1} (close to $K_D = 10^{-8}$ mol·L^{-1} determined by the sorption method for the original mannan). In conclusion, characterization of synthetic neoglycoconjugates confirmed that the method used for their preparation retained the ability of mannan moiety to interact with concanavalin A.

INTRODUCTION

Carbohydrate moiety in glycoproteins modifies the physicochemical and biological properties of the proteins to which they are attached. By their conjugation with carbohydrate derivatives, the synthetic glycoproteins (neoglycoproteins) can be obtained. Neoglycoconjugates are compounds that in useful ways emulate the behavior of the natural glycoconjugates. Neoglycoproteins can be also prepared from bioactive proteins such as enzymes, immunoglobulins, or growth factors. A variety of strategies have been employed in preparing neoglycoproteins (neoglycoenzymes) using mono-, oligo-, or polysaccharides (Magnusson et al., 1994; Lee and Lee, 1997).

Neoglycoproteins containing mannosylated serum albumin were prepared and used as carriers for selective delivery of drugs to cell membranes. These neoglycoproteins are specifically recognized by membrane lectins of liver (Beljaars et al., 1999; Franssen et al., 1993). Mannosylated bovine serum albumin conjugates were utilized as carriers for receptor-mediated drug delivery to treat macrophage-associated diseases (Chakraborty et al., 1990) and for increase of oligonucleotide internalization in cells (expressing mannose-6-phosphate specific membrane lectins) at inhibition of gene expression (Bonfils et al., 1992). Polysaccharides from certain microorganisms were effectively converted into vaccines by partial hydrolysis and by reductive amination with appropriate protein carriers (Jennings and Sood, 1994).

The biospecific affinity of glycoconjugate to lectins originates from the specific saccharide contained in the protein/enzyme molecule. The immobilization procedures based on binding of glycoenzyme to lectin−matrix (in the case of having a strong affinity to this lectin) are gaining increasing acceptance (Saleemuddin, 1999) in the last years. The synthesis of neoglycoenzymes may therefore serve for preparation of modified enzymes with biospecific affinity to lectins, which could be utilized in such immobilization techniques.

Mannan is a polysaccharide with strong affinity (Jennings and Sood, 1994) to lectin concanavalin A (Con A)[1] and therefore is important for glycoprotein synthesis for their prospective use in lectinology. It was found out that

the polymer carrying multiple specific mannosyl residues exhibited a several times higher affinity toward Con A than methyl α-D-mannopyranoside (α-MMP) considered to be the most interacting monosaccharide (Mortell et al., 1996). This was proved by synthetic multivalent mannosylated clusters (glycodendrimers) which were shown to be high-affinity ligands for mannose specific lectins (Roy et al., 1998). Yeast mannans are extensively branched polymers (Goldstein and Poretz, 1986) where the presence of extended sequences of α-D-(1 → 2)-linked mannose residues in their macromolecules provides sites for interaction with Con A. The interaction of yeast mannan (as a natural multivalent ligand) with Con A is comparable with affinity of 16-mer mannosyl-dendrimer (Pagé et al., 1996). The mannan from *Saccharomyces cerevisiae* (*SC*) was previously used for determination of binding properties of natural and synthetic α-D-mannosyl ligands, e.g., inhibition effect of these ligands on yeast mannan precipitation with Con A was investigated (Goldstein and Hayes, 1978; Pagé et al. 1996). The idea of mannan conjugation with protein, to incorporate the polysaccharide properties into protein molecule, was applied in the last years to preparation of synthetic antigens. The high-molar-mass mannans exhibit immunogenic activity (Young et al., 1998); therefore, the synthetic mannan−protein conjugates (antigens) induce the protective antibody response (Han et al., 1999; Apostolopoulos et al., 2000), but the mannan−protein conjugates have not yet been investigated from the point of view of their interaction with lectins.

The aim of this study was to develop a method to prepare conjugates of *SC* mannan with bovine serum albumin (BSA) with retained lectin-binding affinity of mannan moiety. Three principally different methods to exhaustively investigate mannan−BSA conjugates interaction with Con A were used.

EXPERIMENTAL PROCEDURES

Materials. The mannan isolated from *Saccharomyces cerevisiae* (average molar mass ≈ 46 kDa) was kindly provided by Dr. Šandula (Institute of Chemistry, SAS, Slovak Republic) (Šandula and Vojtková-Lepšíková, 1974). BSA was purchased from IMUNA, Šarišské Michaľany, Slovak Republic, sodium cyanoborohydride ($NaCNBH_3$) was obtained from Fluka Chemie AG, Buchs, Switzerland, and sodium borohydride ($NaBH_4$) and sodium periodate ($NaIO_4$) were the products of Lachema, Brno, Czech Republic. Lectin Con A for precipitation and sorption experiments was obtained from Lectinola, Prague, Czech Republic. α-MMP was purchased from Fluka Chemie AG, Buchs, Germany. Bead cellulose Perlose MT-50 (BC) was supplied by Lovochemie, Lovosice, Czech Republic. Chloro-1,3,5-triazine bead cellulose (CHTBC) was prepared according to the procedure described in our previous work (Mislovičová et al. 1995). The content of 3% w/w of nitrogen and 1.5% w/w of chlorine were determined (10% w/w of chlorotriazine group/dry sorbent).

Con A and *N*-(2-hydroxyethyl)piperazine-*N′*-(2-ethanesulfonic acid) (HEPES) used in the SPR method were purchased from Sigma, St. Louis, USA. The SPR chips CM-5, covered with carboxymethylated dextran and an amine coupling kit, were purchased from BIACORE (Uppsala, Sweden). Other reagents were of the analytical grade.

Preparation of Mannan Conjugates with BSA. 100 mg of *SC* mannan was dissolved in a subsequent volumes of 0.05 mol·L^{-1} aqueous solution of sodium periodate:

1 mL − molar ratio $NaIO_4$/mannosyl unit = 0.054 (sample M1)

2 mL − molar ratio $NaIO_4$/mannosyl unit = 0.135 (sample M2)

3.5 mL − molar ratio $NaIO_4$/mannosyl unit = 0.270 (sample M3)

7 mL − molar ratio $NaIO_4$/mannosyl unit = 0.540 (sample M4)

10 mL − molar ratio $NaIO_4$/mannosyl unit = 0.710 (sample M5).

Reaction mixtures were stirred in the dark at 4 °C during 1 h. Then the reactions were stopped by addition of ethylene glycol (1 mL) and stirred 1 h. Low molecular weight compounds were removed from the mixture by dialysis (Spectra Por dialysis tubing MWCO 6000−8000) against water at 4 °C in the dark. Obtained aqueous solutions of oxidized polysaccharides were lyophilized. The amount of aldehyde groups was determined in lyophilizates by the Park-Johnson method (Park and Johnson, 1949). Mannan dialdehydes M1, M2, and M3 were used for conjugation with bovine serum albumin. The mixtures of each three mannan dialdehydes (M1−M3) in 0.05 mol·L^{-1} phosphate buffer of pH 7 (4 mL, c = 10 mg·mL^{-1}) with a solution of BSA (4 mL, c = 10 mg·mL^{-1} of the same buffer) and a solution of $NaCNBH_3$ (2.5 mL, c = 10 mg·mL^{-1} of the same buffer) were stirred at room temperature. The reaction was stopped after 24 h by addition of $NaBH_4$ in 0.05 mol·L^{-1} borate buffer of pH 9.5 (ca. 50 mol of $NaBH_4$ were added to the determined aldehyde groups, c = 5 mg·mL^{-1}) to reduce the remaining aldehyde groups. The reduction was proceeded by stirring at room temperature for 6 h. The products were adjusted with 4 mol·L^{-1} HCl to pH 6−7 and dialyzed against H_2O. Unreacted mannans and BSA were removed by ultrafiltration (YM 100, Amicon Inc., Beverly, USA), and the resulting water solutions of conjugates were lyophilized. The contents of saccharides (Saha and Brewer, 1994) and proteins (Lowry et al., 1951) in lyophilizates were determined. The content of nitrogen was determined by elemental analysis of conjugates (EA 1108 CHN-O analyzer, Milan, Italy).

Determination of the Molar Mass of the Mannans. M_w of the original as well as of the oxidized mannan samples (after their reduction with $NaBH_4$) (Masárová et al., 2001) were determined by the HPSEC method. HPLC system (Shimadzu, Wien, Austria) was composed of a high-pressure pump LC-10AD, a membrane degasser GT-104, an injector Rheodyne 77251, and a differential refractometer RID-6A. The system was calibrated with a set of pullulans with M_w = 5−100 kDa (Macherey-Nagel, Düren, Germany). The solutions of calibrating pullulans as well as of tested mannans (c = 1 mg·mL^{-1} of water) were applied onto a HEMA BIO 100 column (8 × 250 mm, 10-μm particle size) obtained from Tessek, Prague, Czech Republic, and eluted with 0.02 mol·L^{-1} phosphate buffer at flow rate 0.4 mL·min^{-1} at ambient temperature. The volume of injected sample was 0.02 mL. The chromatographic data were processed by Class-VP-chromatography software (Shimadzu, Wien, Austria).

Determination of the Molar Mass of the Mannan−BSA Conjugates. The molecular characterization of the starting (nonconjugated) mannan and BSA and of the mannan−BSA conjugates was performed by a multidetector size exclusion chromatography (SEC) system. The system consisted of an Alliance 2690 separation module, a 410 differential refractometer from Waters (Milford, MA), a homemade single capillary viscometer (SCV), and an additional multiangle laser light scattering

Table 1. Characteristics of Modified Mannans and Their Interaction with Con A Determined by SPR

(MALS) Dawn DSP-F photometer from Wyatt (Santa Barbara, CA). The SEC-MALS-SCV system was described in detail elsewhere (Wyatt, 1993; Mendichi et al., 1995; Mendichi and Giacometti Schieroni, 1999). The experimental SEC conditions were the following: 0.5 mol·L^{-1} NaCl at 35 °C as mobile phase, 0.8 mL·min^{-1} of flow rate, and 200 μL of injection volume. The column set was composed of two OHpak Shodex columns (KB-806 and KB-805) (8 × 300 mm, 13-μm particle size) from Showa Denko (Tokyo, Japan).

The differential refractive index increment, dn/dc, of the mannan−BSA conjugates with respect to the mobile phase was measured by a KMX-16 differential refractometer from LDC Milton Roy (Riviera Beach, FL).

Quantitative Precipitation Assay. Precipitation of *SC* mannan as well as mannan−BSA conjugates (CM1−CM3) with Con A was assayed in phosphate buffer of pH 7 containing 0.05 mol·L^{-1} sodium phosphate, 0.1 mol·L^{-1} NaCl, 0.1 mmol·L^{-1} $CaCl_2$, and 0.1 mmol·L^{-1} $MnCl_2 \times 4$ H_2O. The total volume of precipitation tests was 1 mL containing 230 μg·mL^{-1} of Con A and various concentrations of mannan (within the range from 20 to 190 μg·mL^{-1}) or conjugate (within the range from 10 to 120 μg·mL^{-1} of the conjugate saccharide). The samples were shaken at 25 °C for 2 h. The precipitates were separated in a microcentrifuge MPW-310 (Mechanika Precyzyjna, Warszawa, Poland) at 10 000 min^{-1} (8400*g*) during 10 min, washed twice with 1 mol·L^{-1} NaCl, centrifuged, and subsequently dissolved in 0.05 mol·L^{-1} phosphate buffer adjusted to pH 10.5 with 1 mol·L^{-1} NaOH. These solutions were analyzed for saccharides (Saha and Brewer, 1994) and proteins (Lowry et al., 1951). In each experiment (at the peak of maximum precipitation), the test was done in parallel in the presence of 0.05 mol·L^{-1} of methyl α-D-mannopyranoside (α-MMP) to confirm the specific interaction.

Sorption Experiments. Con A was bound to the chloro-1,3,5-triazine bead cellulose (CHTBC) matrix by the method described earlier (Mislovičová et al., 1995). The sorption of mannan−BSA (CM1−CM3) conjugates on Con A-TBC matrix (containing 3.61 mg of Con A/g of wet sorbent) was performed in 0.05 mol·L^{-1} phosphate buffer (pH 7) with 0.1 mol·L^{-1} NaCl containing 0.1 mmol·L^{-1} $CaCl_2$ and 0.1 mmol·L^{-1} $MnCl_2 \times 2$ H_2O. Suspensions of Con A-TBC prepared from 0.1 g of sorbent and 1 mL of individual mannan−BSA conjugate solutions (40−200 μg of conjugate or 10−70 μg expressed as the saccharide in the above-mentioned buffer) were shaken slowly at 25 °C for 2 h. At the same time, the blank experiment was performed, where the nonderivatized bead cellulose and maximum amount of pertinent conjugate in suspension was used. Then the supernatants were separated by twice centrifugation at 10 000 min^{-1} (8400*g*). Saccharides and proteins in the obtained supernatants were determined. The amounts of the adsorbed conjugate were calculated as the difference between the contents of saccharides and proteins in supernatants obtained in sorption on BC and on Con-A TBC. The same adsorption experiment was performed with *SC* mannan to compare the behavior of original mannan with mannan−BSA conjugates. Dissociation constants and binding capacities were calculated by rearrangement of the adsorption isotherm equation to the Scatchard plot $Q^* = Q_m - K_D Q^*/C^*$ (Chern et al., 1999), where C^* is the concentration of sorbate in solution in equilibrium, Q^* is the amount of sorbate adsorbed on the sorbent at equilibrium, Q_m is the maximum adsorption capacity of the adsorbent, and K_D is the dissociation constant of sorbate.

Surface Plasmon Resonance Measurement. The SPR measurements were performed with a BIACORE 2000 (Biacore AB, Sweden) operated with a BIAcore Control Software 1.2. All measurements were performed at 25 °C, at a flow rate of 5 μL·min^{-1}. The buffer of pH 7.4 consisted of 0.01 mol·L^{-1} *N′*-(2-hydroxyethyl)piperazine-*N′*-(2-ethanesulfonic acid) (HEPES), 0.15 mol·L^{-1} NaCl, 1 mmol·L^{-1} Ca^{2+}, and 1 mmol·L^{-1} Mn^{2+}. The chip surface was modified by covalently bound Con A using the amine coupling kit. The interaction with Con A was investigated by the injection of 50 μL of sample containing 1 mg·mL^{-1} mannan (RM1−RM5) or mannan−BSA conjugate (CM1−CM3). The chip surface was regenerated by the injection of 20 μL of 5 mg·mL^{-1} *p*-aminophenyl-α-D-mannopyranoside after each measurement. The association (k_a) and dissociation (k_d) rate constants as well as dissociation equilibrium contants (K_D) were calculated (Shinohara et al., 1994).

RESULTS AND DISSCUSION

Oxidized Mannans and their Interaction with Con A. The first step at the conjugation of mannan with BSA was the oxidation of *SC* mannan with periodate to obtain its reactive form. Mannan structure is changed after oxidation, and mannose rings and side chains can be cleaved, which results in a molecular mass decrease. A set of five mannans (M1−M5) oxidized to a different degree (from 11 to 28 of the aldehyde groups per mannan molecule; Table 1, second column) having partially degraded chains (M_p decreases from 46 to 31 kDa; Table 1, third column) and values of polydispersion index within the range from 1.4 to 2.0 (Table 1, fourth column) were prepared. HPSEC chromatograms of these samples are shown in Figure 1.

The oxidation of *SC* mannan was described in more detail in our previous work (Masárová et al., 2001). Quantity of produced aldehyde groups (degree of oxidation) and decrease of M_p of prepared mannan dialdehydes (degree of degradation) were observed. Practically no degradation of polysaccharide chain was observed at the lowest periodate concentration. Degree of degradation was increased with increasing amount of periodate. Samples M4 and M5 were partly insoluble, probably in consequence of the formation of intramolecular hemiac-

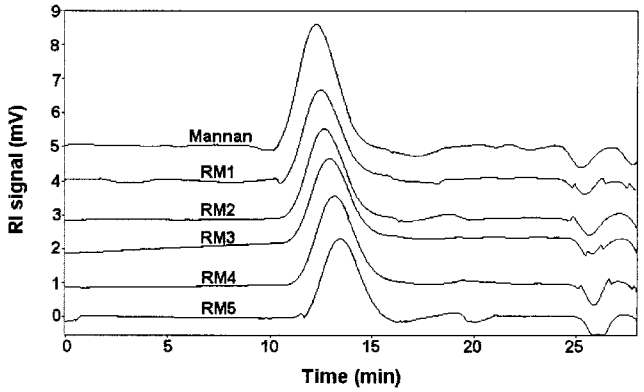

Figure 1. Chromatograms of mannan and oxidized mannan (after reduction) samples obtained by HPSEC chromatography on column HEMA BIO 100. The solutions of calibrating pullulans as well as of tested mannans (c = 1 mg·mL^{-1} of water) were applied onto a HEMA BIO 100 column (8 × 250 mm, 10-μm sorbent of particle size) and eluted with 0.02 mol·L^{-1} phosphate buffer at a flow rate of 0.4 mL·min^{-1} and at ambient temperature. The volume of injected sample was 0.02 mL. The chromatographic data were processed by Class-VP-chromatography software.

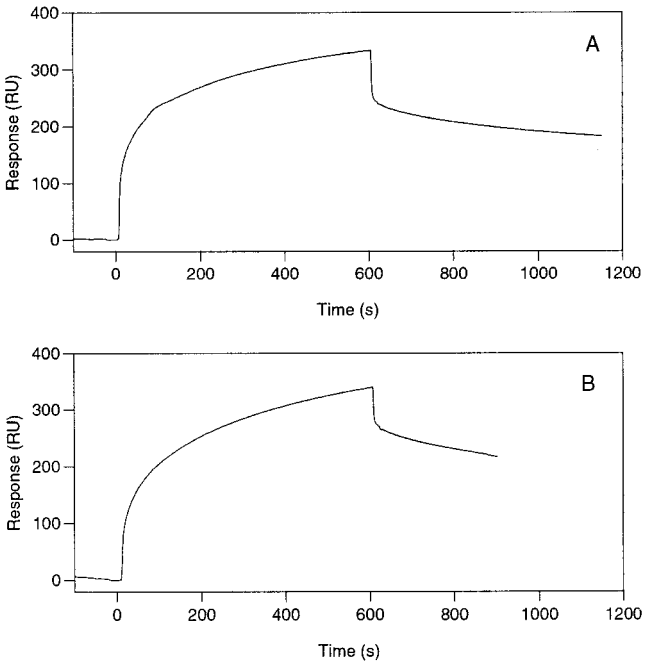

Figure 2. Surface plasmon resonance measurement of the interaction of Con A with mannan. SPR measurements were performed with BIACORE 2000 using the chip with modified surface with covalently bound Con A at a flow rate of 5 μL·min^{-1} with buffer of pH 7.4 consisting of 0.01 mol·L^{-1} HEPES, 0.15 mol·L^{-1} NaCl, 1 mmol·L^{-1} Ca^{2+}, and 1 mmol·L^{-1} Mn^{2+}. The interaction of samples with Con A was investigated by the injection of 50 μL of samples containing 1 mg/mL mannan or mannan-conjugate. Panel A − original mannan; panel B − oxidized mannan M2 after reduction (RM2).

etal bonds. Degree of oxidation and molar mass of these samples therefore could be determined only in the soluble part. By using of higher amount of periodate, higher degradation of polysaccharide chains was going on to the detriment of oxidation.

As it was mentioned above, the activation of mannan has an effect on its structure. The changes of mannan structure has an influence on affinity of mannan samples to lectin Con A. This effect was investigated with mannans that were activated, and subsequently the active groups were reduced. The oxidized mannans were reduced (RM samples) to eliminate chemical reaction of polysaccharide active groups (aldehyde) with amino groups of Con A. The results from precipitation experiments of modified mannans with Con A were presented in a previous paper (Masárová, et al., 2001). Intensive precipitation of mannan and RM1−RM3 samples with Con A was observed. On the other hand, the samples RM4 and RM5 precipitated with Con A weakly. In the present work, the interaction of these modified mannans with Con A was investigated by the SPR method. Figure 2 shows SPR sensorgrams of mannan and the sample RM2 using a chip with surface modified by immobilized Con A. Table 1 shows the calculated kinetic parameters of interactions of original mannan and all the five RM samples with Con A. Gradually reduced mannan affinity to Con A after its modification was observed. There is obvious a correlation of the degree of degradation, and supposed change of mannan structure, with the values of obtained association constants. Surprisingly, the value of k_a of original mannan was not determined to be the highest. We concluded that the oxidized *SC* mannans prepared by mild periodate oxidation (M1−M3) are suitable for the preparation of glycoproteins conjugates. The character (size and valency) of modified mannan in these samples did not change significantly, and therefore they maintained the affinity to Con A.

Preparation and Characterization of Mannan−BSA Conjugates. The three oxidized mannans with the best affinity to Con A (M1, M2, and M3) were used to prepare three BSA conjugates (CM1, CM2, and CM3). The method of reductive amination (described in Experimental Procedures) was used, where the weight ratio mannan/BSA = 1:1 was applied. The content of mannan, M_w, and the polydispersion M_w/M_n in conjugates were determined. The determined characteristics of obtained neoglycoconjugates as well as original mannan and BSA are shown in Table 2.

Table 2. Molecular Characteristics of Mannan, BSA, and Three Mannan−BSA Conjugates

conjugate	content of sacch. [%]	content of prot. [%]	content of N [%]	M_w[a] [kDa]	polydispers. index M_w/M_n
BSA	0	100	14.00	66.7	1.0
mannan	100	0		53.0	1.3
CM1	25	75	10.96	176.2	2.8
CM2	28	72	10.49	246.3	3.2
CM3	30	70	10.33	169.1	3.6

[a] Determined by HPSEC (two Shodex columns) and LS detection.

The conjugation method used produces a mixture of neoglycoconjugates of variable M_w, due to the polydispersion of oxidized mannan, and various stoichiometric mannan to BSA ratios. The polydispersion and modality of the prepared conjugates were estimated by HPSEC experiments on the tandem columns HEMA BIO 1000 + HEMA BIO 100 using UV detection (chromatograms are shown in Figure 3) as well as on the Shodex OH Pak column using LS detector. The high polydispersion of all three samples (≈3) was found. The problems with association of these conjugates caused the difficulties with the determination of their M_w. (It is seen in Figure 3—the first high-molar mass peak shows conjugates in associated form). The conformation of the conjugates was very compact because the gyration radius was low, considering the molecular mass, and the signal of the online viscometer was practically absent. The samples were quite polydisperse, and we can only estimate approximate mannan/BSA ratios (from the determined weight ratio

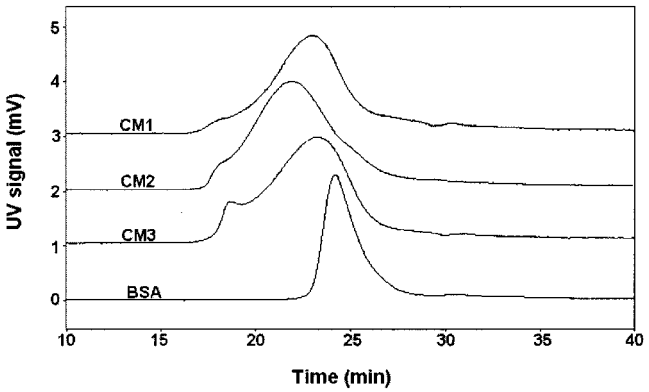

Figure 3. Chromatograms of mannan−BSA conjugates obtained by HPSEC chromatography on two columns HEMA BIO 100 and HEMA BIO 1000. The solutions of tested mannan−BSA conjugates and BSA ($c = 1$ mg·mL^{-1} of water) were applied onto a set of HEMA BIO 100 and HEMA BIO 1000 columns (size of both was 8 × 250 mm with 10-μm particle size of sorbent) and eluted with 0.02 mol·L^{-1} phosphate buffer at a flow rate of 0.5 mL·min^{-1} and at ambient temperature. The volume of injected sample was 0.02 mL. The chromatographic data were processed by Class-VP-chromatography software.

of mannan to BSA in conjugates and M_w of conjugates). We suppose that CM1 contains mainly conjugates with approximately one mannan molecule per two molecules of BSA. The samples CM2 and CM3 are mixtures of 1:1 and 1:2 stoichiometric ratios.

Interaction of Mannan−BSA Conjugates with Con A. The interaction of mannan−BSA conjugates with concanavalin A was studied using three different methods: (i) quantitative precipitation; (ii) sorption method; and (iii) kinetic measurement of the interaction by surface plasmon resonance (SPR).

In the quantitative precipitation method both interacting molecules, neoglycoprotein and Con A, are present in the solution. The measured parameter here is the amount of precipitate obtained at equilibrium. The precipitation profiles of mannan−BSA conjugates with Con A are presented in Figure 4, panel A. The values in precipitation dependence are obtained as the average of two experiments. The similar aggregation course of original mannan and of its conjugates with BSA was determined. Figure 4, panel B, shows dependences of the calculated molar ratios of *SC* mannan and conjugated mannans to Con A in precipitates on the initial concentration of mannan (original or conjugated) in the test. It can be seen that the molar ratio of mannan/Con A in precipitate was achieved to be only 0.5 in the case of original mannan, but the ratios near to 1 were determined for all three conjugates. During precipitation of mannan−BSA conjugates with Con A aggregates with higher content of mannan are formed than in the case of original mannan, what is caused probably by partial association of mannan−BSA conjugates (observed at HPSEC analysis).

The sorption experiments were performed on Con A-TBC MT-50 sorbent with small diameter of pores, to eliminate the sorption of conjugates into pores. Therefore, only the sorption of conjugates on the surface of cellulose beads could be expected. The sorbent with 3.61 mg of Con A/1 g of wet BC was used. The Langmuir isotherm curves (panel A) and the Scatchard plots (panel B) for mannan as well as mannan−BSA samples adsorbed on Con A-bead cellulose are shown in Figure 5. The obtained results are as average of two experiments. Equilibrium concentration of mannan conjugates in solution as well as of their amount adsorbed on Con A-TBC was expressed

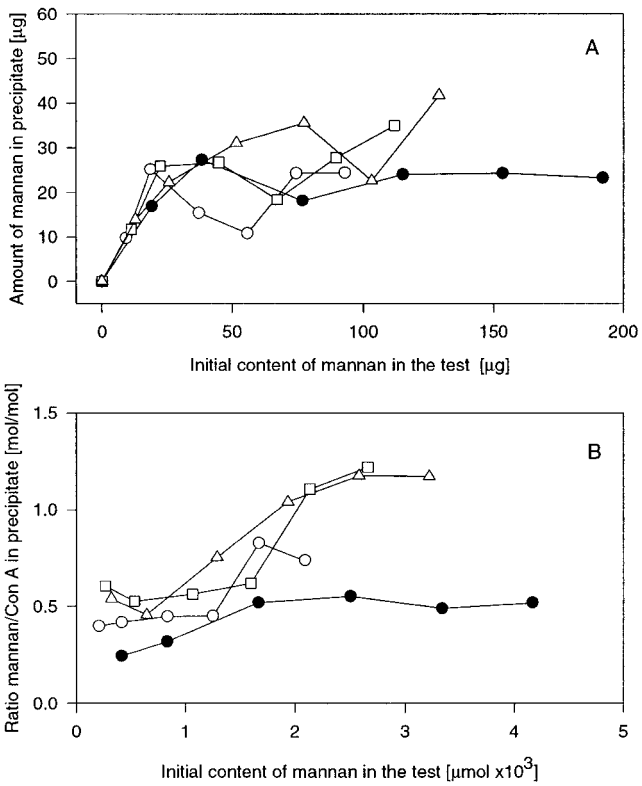

Figure 4. Precipitation of mannan and mannan−BSA conjugates with concanavalin A. Precipitation was performed in 0.05 mol·L^{-1} phosphate buffer of pH 7 containing 0.1 mol·L^{-1} NaCl, 0.1 mmol·L^{-1} Ca^{2+}, and 0.1 mmol·L^{-1} Mn^{2+}. The total volume of precipitation tests was 1 mL containing 230 μg·mL^{-1} Con A and various concentrations of mannan (from 20 to 190 μg·mL^{-1}) or conjugate (from 10 to 120 μg·mL^{-1} of the conjugate saccharide). The samples were shaken at 25 °C for 2 h. The precipitates were centrifugated, washed twice with 1 mol·L^{-1} NaCl, centrifugated, and dissolved in 0.05 mol·L^{-1} phosphate buffer adjusted to pH 10.5. These solutions were analyzed for saccharides and proteins. Panel A, dependences of mannan content (original or in conjugate) in precipitate on the initial content of mannan (original or in conjugate) in the test. Panel B, dependences of the molar ratio mannan (original or in conjugate)/Con A in precipitate on the initial content of mannan (original or in conjugate) in the test. -●- original mannan, -○- CM1, -□- CM2, -△- CM3.

as the mannan concentration. The values of K_D and Q_m estimated from the Scatchard plot and expressed as mannan−BSA conjugates are listed in Table 3. The results obtained by sorption experiments also confirmed that affinity of mannan molecules in conjugates with BSA to Con A was retained. CM2 conjugate showed the highest affinity to immobilized Con A among the three tested conjugates.

Kinetic measurement of the interaction between the neoglycoconjugates and Con A was performed using a biosensor based on surface plasmon resonance. This technique has been previously used for lectin−lipopolysaccharide interaction characterization (Shinohara et al., 1994; Mann et al., 1998; Haselye et al., 1999). SPR uses continuous flow technology and enables one to monitor the interaction in real time in comparison to the sorption method which provides data at equilibrium. In our study, Con A was immobilized on the SPR chip surface, and the interaction of neoglycoconjugates present in solution was monitored. The courses of measurements were similar to that presented in Figure 1; therefore, we present here only the calculated constants summarized in Table 4. The values of dissociation constant K_D are similar to those determined by isothermal adsorption. This demonstrates

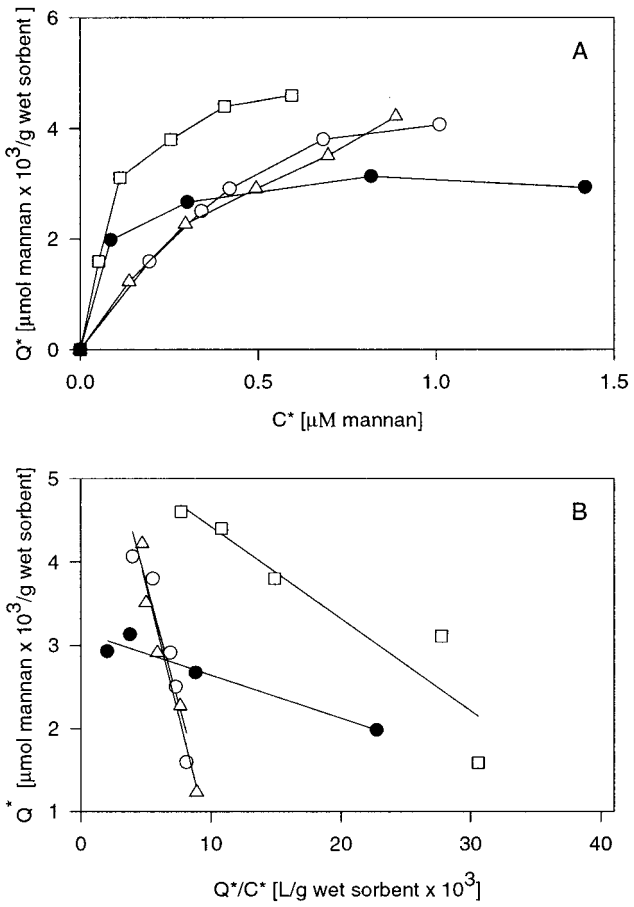

Figure 5. Sorption of mannan−BSA conjugates on Con A-TBC MT-50. The sorption of mannan and mannan−BSA was done in 0.05 mol·L^{-1} phosphate buffer (pH 7) with 0.1 mol·L^{-1} NaCl containing 0.1 mmol·L^{-1} Ca^{2+} and 0.1 mmol·L^{-1} Mn^{2+}. Suspension of Con A-TBC MT-50 (containing 3.61 mg of Con A/g of wet sorbent) prepared from 0.1 g of wet sorbent and 1 mL of individual mannan or mannan−BSA conjugate solutions (from 10 to 70 μg expressed as the saccharide in the above-mentioned buffer) were shaken slowly at 25° C for 2 h. The sorbents were centrifugated, and the saccharide and proteins in supernatants were determined. The amounts of the adsorbed conjugate were calculated as the difference between the contents of saccharides and proteins in supernatants obtained in sorption on blank BC and on Con-A TBC (sorbate is expressed as the content of mannan). Panel A, Langmuir isotherm. Panel B, Scatchard plot; -●- original mannan, -○- CM1, -□- CM2, -△- CM3.

Table 3. Langmuir Parameters for Adsorption of Mannan and Its Conjugates with BSA Determined on Con A Bead Cellulose Sorbent

sorbate	Q_m [μmol of sorbate/ g of wet sorbent]	K_D [mol sorbate·L^{-1}]	R^a
mannan SC	3.16×10^{-3}	5.2×10^{-8}	0.941

CM3	5.71×10^{-3}	2.81×10^{-7}	0.721

[a]Correlation coefficient.

a very good agreement of methods based on measurement at equilibrium (sorption method) and the method based on kinetic measurement (SPR method). We suppose the kinetic behavior of neoglycoconjugates is mainly affected by the two main influences: percentual content of saccharide (Table 2) and modification of mannan which changes kinetic properties of mannan itself (Table 1). The best interaction with Con A was experimentally observed for CM2. CM2 showed the highest kinetic association constant k_a determined by SPR and the lowest equilibrium dissociation constant K_D confirmed by both sorption and SPR method. Another parameter that may influence the interaction of neoglycoproteins are molecular weight and polydispersion. It is interesting that the highest molar mass using HPSEC method was determined for the conjugate CM2.

Table 4. Constants of Mannan−BSA Conjugates Interaction with Con A Determined by SPR

sample	k_a [M^{-1} s^{-1}]	k_d [s^{-1}]	K_D [M][a]
CM1	6.62×10^{2}	3.52×10^{-4}	5.32×10^{-7}
CM2	1.06×10^{3}	3.43×10^{-4}	3.25×10^{-7}
CM3	6.45×10^{2}	3.24×10^{-4}	5.02×10^{-7}

[a]Mol of mannan−BSA conjugate/L.

CONCLUSIONS

Oxidative modification of mannan results in changes in its interaction with Con A and consequently also influences properties of mannan−BSA neoglycoconjugates. Measurement of the interaction of neoglycoconjugates with Con A confirmed that the method used for their preparation retained the ability of the mannan moiety to interact with the lectin concanavalin A. It was observed by both the sorption and the SPR method that binding of mannan moiety of neoglycoprotein is similar as compared to the original mannan; it can be documented by the values of K_D (within the range 10^{-7} and 10^{-8} mol·L^{-1}). The measurements of molar mass and polydispersion suggest that in this conjugation method it is difficult to control structure of prepared conjugates. We suppose that conjugates of various BSA/mannan ratios may be present and also association of conjugates, which influences M_W determination, may occur. Nevertheless, the mannan−BSA conjugates with very similar M_w, polydispersion, composition, and affinity to Con A were obtained at the same condition of their conjugation and separation. This method and obtained experiences may find application in glycosylation of proteins/enzymes, for preparation of biologically active glycoconjugates (e.g., vaccines, markers) or generally as an immobilization technique for glycoproteins.

ACKNOWLEDGMENT

This work was supported by the Slovak Agency for Science VEGA via Grants No. 2/1047/21 and 1/7347/20. J.S. acknowledges support from EC (contract QLK1-CT-1999-51347). We thank D. Žišková for the technical assistance at the interaction experiments.

TECHNICAL NOTES

Synthesis of Novel Glycolipids That Bind HIV-1 Gp120

Rachel Y. LaBell, Neil E. Jacobsen, Jacquelyn Gervay-Hague, and David F. O'Brien*

The University of Arizona, Department of Chemistry, Tucson. Arizona 85721 . Received July 24, 2001

As part of a research effort to design and prepare high affinity ligands for the galactosyl ceramide (GalCer) binding site on the HIV cell surface glycoprotein, gp120, several GalCer analogues have been prepared and characterized. The molecular design of analogues permits independent variations of the carbohydrate, the length of a hydrophilic spacer between the ligand and the lipid, and the composition of the hydrophobic lipid chains. Five different galactosyl analogues were synthesized having hydrophilic spacers of tri-, tetra-, and penta-ethylene glycol separating the carbohydrate from the lipid region which has either oleoyl or stearoyl lipid chains. The synthetic design allows for a convergent synthesis of the three components of the glycolipid conjugate. The structural characterization includes the proton and carbon chemical shifts, which were assigned after analysis of 1D and 2D NMR spectra.

INTRODUCTION

HIV-1 can gain entry into human T-cells by the initial binding of an associated surface glycoprotein (gp120) to the critical domain receptor (CD4) on the T-cell membrane surface. Subsequently, a cascade of events occur leading to HIV-1 replication which ultimately causes impairment of the immune system as HIV infection progresses to AIDS. However, an alternative receptor has been discovered that mediates the infection of CD4 negative cells (*1*−*3*). This galactosyl ceramide (GalCer) receptor is present on the surface of many types of cells including colorectal cells and vaginal epithelial cells (*4*).

GalCer (Figure 1) is a relatively simple glycosphingolipid consisting of a single galactose unit bound via a β-linkage to ceramide. In biological membranes, the galactose portion is displayed very close to the membrane surface. Several laboratories have shown that the length of the spacer group between an antigen and its anchoring lipid can affect the efficiency of binding to antibodies. For example, Ringsdorf et al. found that extending fluorescein away from the membrane surface with a tetraethylene glycol spacer increased the binding of fluorescein to its antibody (*5*). The use of a hydrophilic linker as a spacer group in glycolipids has been reported to enhance the specific interaction of carbohydrates with receptor proteins (*6, 7*). Therefore, we elected to design GalCer analogues with variable length hydrophilic linkers to investigate the effect of spacer group length on the binding of galactosyl lipids with gp120.

The β configuration of galactose is believed to be necessary for effective binding of GalCer to gp120 (*8*). One problem with GalCer is the susceptibility of the anomeric linkage to cleavage by glycosidases. The replacement of the anomeric oxygen with carbon stabilizes the anomeric linkage and is reported to have little effect on the binding of galactose to gp120 (*9, 10*).

The third variable considered in the glycolipid is the nature of the lipid chains. There seems to be conflicting evidence in the literature about whether variation in the lipid chains can influence the binding of GalCer analogues to gp120. Silberger and Bhat provided evidence that variation of the GalCer fatty acid chain length from 16 to 24 carbons showed little effect on binding efficiency when ^{125}I-labeled gp120 was incubated with GalCer doped liposomes (*8*). Other authors reported that varying the GalCer fatty acid chain length from 1 to 14 has a distinct effect on the binding of GalCer analogues to rgp120 in an ELISA-type assay (*9*). Rico-Lattes has reported that a seven-carbon fatty acid chain showed no activity while a ten-carbon chain showed weak activity in binding to SPC3 peptide which mimics the V3 loop of gp120 (*11*). This literature provides evidence that a sufficiently long hydrophobic lipid chain is necessary to effectively anchor the lipid into the membrane, and there is little additional effect on binding efficiency.

The second issue concerning the lipid chains is the presence of unsaturation. GalCer fatty acid is saturated to the extent that it exists in microdomains in biological membranes (*12*). Lipids with an unsaturation in the chains tend to not form domains in biological membranes because they do not pack together well and are more fluidlike. Lipids with saturated chains tend to form domains because the lipid chains pack efficiently and are more solidlike. Whether GalCer analogues that do not form domains will bind to gp120 has not been systematically investigated. Therefore, the design allows for the synthesis of both saturated and unsaturated analogues that will allow evaluation of this variable.

In an effort to design GalCer analogues that could compete with the binding of gp120 to GalCer, a versatile synthetic scheme was developed. The analogue design permits the independent variation of three components that could increase binding: carbohydrate head group, hydrophilic spacer group, and lipid tails. The synthesis of these GalCer analogues is convergent with respect to each component. The hydrophilic spacer is derived from commercially available oligo-ethylene glycols by dif-

ferentiation of the end groups. The carbohydrate head group is derived from β-D-galactose pentaacetate by conversion into the *C*-glycoside using trimethylsilyl cyanide (TMSCN). The lipid chains can be easily obtained by reaction of any long chain alcohol with maleic anhydride to form the maleic diester. Variation of one or more of these components has the potential to affect the binding affinity of the analogue to gp120.

RESULTS

The synthesis started with a commercially available spacer, 2-(2-chloroethoxy)ethoxyethanol (**1a**). The corresponding longer spacers were derived from tetraethylene glycol and pentaethylene glycol by monochlorination with triphenylphosphine and carbon tetrachloride (Scheme 1) (*16*). The statistical mixture of dichloride, monochloride, and diol were separated by silica gel chromatography. In each spacer the remaining alcohol underwent Jones oxidation to give the corresponding monochlorocarboxylic acids **2a**,**b**,**c** (*15*). The synthesis of each spacer is completed by conversion of the ω-chloro carboxylic acid to the ω-thiol by reaction with thiourea, sodium hydroxide, and water **3a**,**b**,**c** (*15*). The literature procedure was modified by addition of 1 equiv of sodium iodide to form the iodide in-situ and improve yields up to 96%. The galactose portion was synthesized from β-D-galactose pentaacetate by displacing the anomeric acetate using TMSCN in the presence of $BF_3 \cdot OEt_2$ **4** (Scheme 2) (*17*). Only the β anomer is formed because of participation of the C-2 acetate (*17*). The peracetylated *C*-galactose was reduced with lithium aluminum hydride in THF to remove all the acetates and convert the cyano group to methylene amine **5** (*18*). There was some acyl migration from the C-2 to the primary amine during the reaction followed by reduction of the amide to give 18% ethylamine as a byproduct.

Two different lipid chains were used to synthesize the five Gal-Cer analogues. The unsaturated series of glycolipids were made using oleoyl alcohol. These analogues were synthesized in order to investigate the effect of non-domain-forming glycolipids on binding affinity. The saturated series was made using stearoyl alcohol. Saturated glycolipids have the propensity to form domains when mixed with dioleoyl phosphatidylcholine (DOPC).

The unsaturated lipid was prepared (Scheme 3) from maleic anhydride and oleoyl alcohol with a catalytic amount of *p*-toluenesulfonic acid in chloroform to give the desired unsaturated diester. The conjugated double bond of the maleic ester provides a site for nucleophilic addition of the ω-thiol carboxylic acid **3a**,**b**,**c**. The product is a lipid-spacer conjugate with a carboxylic acid end group **7a**,**b**,**c** (*19*).

The last step of the synthesis is the formation of an amide bond between the carboxylic acid of the lipid **7a**,**b**,**c** and the *C*-galactoside **6**. The acid was combined with pentafluorophenyl trifluoroacetate to form the activated pentafluoro ester followed by addition of **6** (*20*). Low yields are a result of minimal solubility of the deprotected carbohydrate in DMF. The unsaturated series of glycolipid molecules are named according to the carbohy-

Scheme 3

drate, Gal; the length of the ethylene glycol spacer: 3, 4, or 5; and the nature of the lipid chain: oleoyl (unsat) or stearoyl (sat). Hence the unsaturated series is referred to as Gal-3-Unsat, Gal-4-Unsat, and Gal-5-Unsat.

The saturated series (Scheme 3) was prepared by the same reaction sequence except that the starting alcohol was stearoyl alcohol and the resulting maleic ester has saturated lipid chains **9**. The spacer−lipid conjugate **10a**,**b** and the final glycolipids **11a**,**b** were formed in the same manner as the unsaturated series to give Gal-3-Sat and Gal-4-Sat.

NMR chemical shift assignments were made for Gal-3-Sat, a representative glycolipid analogue (Figure 2). 2D-NMR data (HMQC, HMBC, and COSY) was acquired and analyzed to assign all protons and carbons. NMR chemical shift assignments (Table 1) were obtained by analysis of the HMBC data (Figure 4). The G4 (equatorial) proton signal has small coupling constants and thus can be located in the HSQC spectrum (Figure 3) as a sharp, positive cross-peak. G7 and G6 diastereotopic pairs can also be identified in the HSQC, with the G7 carbon 20 ppm upfield of the G6 carbon since it is bonded to amide nitrogen instead of oxygen. Clear HMBC connectivities allow assignment of the entire *C*-glycoside, with confirmation from the DQF−COSY (data not shown). An HMBC cross-peak from one of the G7 protons to the S1 (carbonyl) carbon verifies the spacer attachment through the amide linkage, and HMBC and COSY connections lead to assignment of the entire spacer. One of the S6 protons shows an HMBC connection through the thioether linkage to the L2 carbon, connecting the spacer to the lipid moiety. The more downfield of the lipid carbonyl

[a] See Figure 2 for numbering system. Lower-case a and b refer to diastereotopic protons in methylene groups which are not stereospecifically assigned. [b] d = doublet, t = triplet, dd = doublet of doublets, dt = doublet of triplets, ddd = double double doublet, m = multiplet. [c] Doublet coupling listed first for all dt. [d] Estimated number of carbons shown in parentheses.

carbons was assigned to L1 due to its proximity to the thioether. HMBC connectivities across the ester linkages in the lipid portion allow unambiguous assignment of the L5 and L5′ (differing in both ^1H and ^{13}C shifts) and the L6 and L6′ (differing in ^1H shifts) positions. Approximately eight carbons from the L8-L19/L8′-L19′ portion of the lipid chains were resolved in the 1D ^{13}C spectrum but could not be assigned (Table 1).

DISCUSSION

Binding of the unsaturated GalCer analogues to gp120 has already been assessed by total internal reflection fluorescence spectroscopy (TIRF) (*21*). Fluorescently tagged recombinant gp120 was allowed to bind to the monolayer surface containing GalCer analogues and an equilibrium measurement of protein bound to the monolayer was accomplished using TIRF. The binding studies investigated the effect of varying the spacer length on binding affinity of GalCer analogues to gp120. The analogues bind cooperatively to gp120 when doped at 5 mol % in a monolayer of DOPC. The binding curves were extrapolated to obtain binding affinity constants (K_a) of 2×10^6. The protein coverage was determined and highest protein coverage was achieved with a spacer group of triethylene glycol. Therefore, a critical spacer arm length has been determined for these GalCer analogues (*21*). A comparative study of the saturated and unsaturated GalCer analogues will be reported elsewhere.

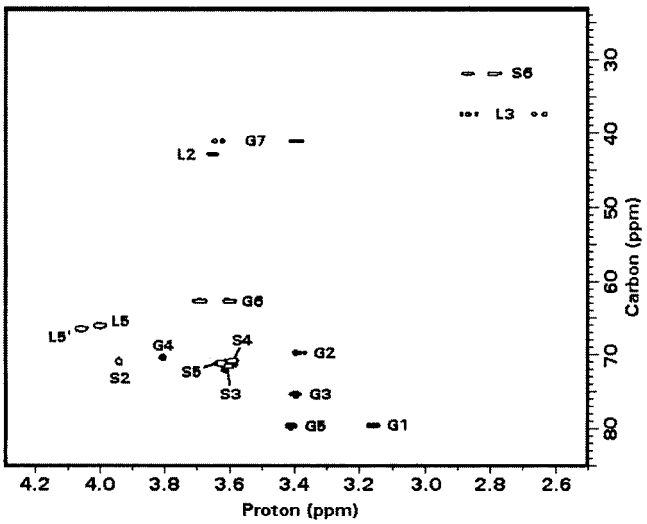

Figure 3. Portion of the edited 2D Gradient-Selected HSQC spectrum of Gal-3-Sat in $CD_3OD/CHCl_3$ (1:1). Data were acquired in TPPI mode with 512 complex pairs in t_2, 750 increments of t_1, and 8 scans per t_1 increment. A skewed, 45°-shifted sinebell was applied in both dimensions with zero-filling to a final real matrix of 2048 (F_2) × 1024 (F_1) data points. Single contours (open) are shown for negative (CH_2) cross-peaks with many contours (filled) for positive (CH_3, CH) cross-peaks.

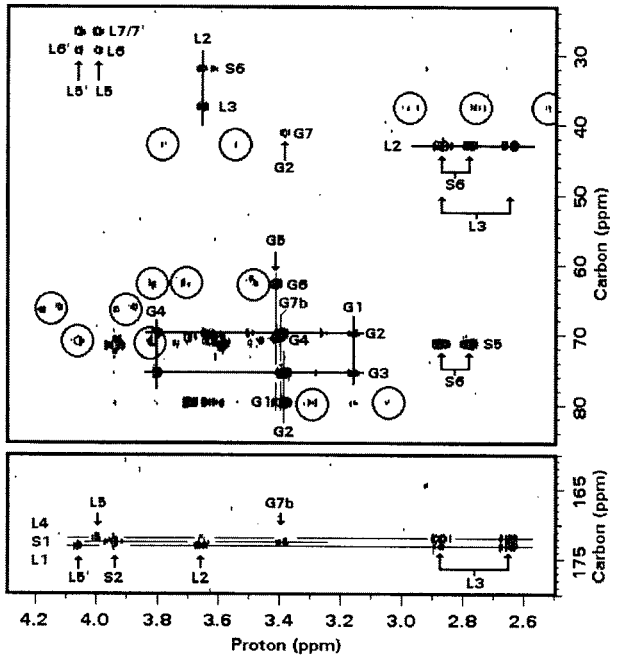

Figure 4. Two portions of the phase-sensitive 2D Gradient-Selective HMBC spectrum of Gal-3-Sat in $CD_3OD/CHCl_3$ (1:1). Data were acquired in echo-antiecho mode with 2048 complex pairs in t_2, 356 increments of t_1, and 16 scans per t_1 increment using a TANGO sequence and a gradient to dephase ^{13}C-bound proton signals before the start of the HMBC (Kover, K. E., personal communication). A 90°-shifted sinebell was applied in both dimensions with zero-filling to a final real matrix of 2048 (F_2) × 1024 (F_1) data points. Single contours (open) are shown for negative cross-peaks with many contours (filled) for positive cross-peaks. Circles indicated one-bond correlations.

This research has led to the development of a versatile synthesis of glycolipids that conjugate a carbohydrate, spacer group, and a lipid. These analogues should improve attempts to design and synthesize new HIV-1 therapies using membrane-tethered receptors for gp120.

EXPERIMENTAL SECTION

General Procedures. All materials were obtained from commercial sources and used without additional purification, unless otherwise noted. 1D ^{1}H and ^{13}C NMR spectra were recorded on Varian Gemini-200, Varian Unity-300 MHz, Bruker DRX-500 or Bruker DRX-600 spectrometers. 1D ^{1}H spectra were referenced to internal tetramethylsilane (0 ppm) and 1D ^{13}C spectra are referenced to the solvent ^{13}C signal, ($CDCl_3$ at 77.0 ppm and CD_3OD at 49.0 ppm). NMR spectra for Gal-3-Sat (^{1}H, ^{13}C, HSQC (*13*), HMBC (*13*), and DQF−COSY (*14*) were acquired on a Bruker DRX-600 spectrometer with a 5 mm Bruker TXI triple-resonance three-axis gradient probe at 25 °C. The sample (30 mg) was dissolved in 0.6 mL of $CDCl_3/CD_3OD$ (1:1). The spectral widths were 4.6 ppm (^{1}H) and 200 ppm (^{13}C) for the 2D spectra. Data were processed and plotted using Felix2000 (Molecular Simulations, San Diego, CA). All 2D spectra were referenced using specific signals in the 1D spectra, which were referenced to internal tetramethylsilane (0 ppm) for ^{1}H and CD_3OD (49.15 ppm) for ^{13}C.

(2-{2-[2-Chloroethoxy]ethoxy}ethoxy)acetic Acid (2b). A mixture of (2-{2-[2-chloroethoxy]ethoxy}ethoxy)-ethanol (3.00 g, 14.2 mmol) in acetone (60 mL) was stirred at room temperature as 6 mL of a 2.67 M Jones reagent (*15*) was added dropwise over 15 min. The reaction was stirred for an additional 30 min followed by addition of 3 drops of 2-propanol. Water (40 mL) was added to the mixture followed by removal of the acetone in vacuo. Saturated NaCl solution (20 mL) was added, and the aqueous mixture was extracted with $CHCl_3$ (7 × 30 mL). The organic layers were combined and dried with anhydrous $MgSO_4$. The product was visualized with bromocresol green on a silica gel TLC plate after elution with 30:5:3 $CHCl_3$/EtOH/HOAc, with an R_f value of 0.5. The solvent was removed in vacuo, and the product was purified by silica gel column chromatography in 30:5:3 $CHCl_3$/EtOH/HOAc to yield 2.63 g of product in 82% yield. ^{1}H NMR (300 MHz, $CDCl_3$) δ 3.50−3.65 (m, 12H), 4.15 (s, 2H), 10.63 (bs, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ 42.5, 68.0, 70.1, 70.2, 70.7, 71.0, 173.8. High-resolution mass spectrum (FAB^+) calcd for $C_8H_{15}O_5Cl$ $(MH)^+$: 227.0686. Found: 227.0680.

(2-{2-[2-(2-Mercaptoethoxy)ethoxy]ethoxy}ethoxy)-acetic Acid (3c). (2-{2-[2-(2-Chloroethoxy)ethoxy]ethoxy}-ethoxy)acetic acid (2.60 g, 9.63 mmol) was combined with thiourea (2.93 g, 38.5 mmol) and sodium iodide (1.45 g, 9.63 mmol) in 40 mL of water, and the reaction mixture was heated at refluxed for 4 h. After addition of 52 mL of 2.5 M, heating was continued for another 4 h. The reaction was cooled to room temperature, and the pH was adjusted to 1 with concentrated HCl. The aqueous mixture was extracted with $CHCl_3$ (7 × 40 mL), and the organic layers were combined and dried with anhydrous $MgSO_4$. The product was visualized with bromocresol green on a silica gel TLC plate after elution with 3:2 $CHCl_3$/EtOH, with an R_f value of 0.30. The solvent was removed in vacuo, and the resulting oil was purified on neutral alumina column chromatograpy using a gradient starting with 6:1 $CHCl_3$/EtOH and ending with 60:40:5 $CHCl_3$/EtOH/HOAc to yield 2.43 g of a colorless oil with a 94% yield. ^{1}H NMR (300 MHz, $CDCl_3$) δ 1.55 (t, J = 8.6 Hz, 1H), 2.64 (q, J = 7.3 Hz, 2H), 3.53−3.73 (m, 14H), 4.14 (s, 2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ 24.0, 68.3, 70.0, 70.3, 70.4, 70.9, 72.7, 174.2. High-resolution mass spectrum (FAB^+) calcd for $C_{10}H_{21}O_6S$ $(MH)^+$: 269.1059. Found: 269.1067.

2-[2-(2-Carboxymethyoxyethoxy)ethylsulfanyl]-succinic Acid dioctadec-9-enyl Ester (7a). Butenedioic acid dioctadec-9-enyl ester (cis) (0.660 g, 1.07 mmol) was dissolved in 40 mL of 2-propanol at 80 °C under an Ar atmosphere. In a separate vial, [2-(2-mercaptoethoxy)-ethoxy]acetic acid (**3a**) (0.193 g, 1.07 mmol) was titrated to pH of 8 with 15% NaOH. The basic solution was added to the reaction mixture followed by a catalytic amount of piperidine (2 drops). The reaction was heated at reflux for 1 h. Solvent was removed in vacuo, and the residue was taken up in water (20 mL). The pH was adjusted to 4 with 10% HCl, and the resulting solution was extracted with ethyl acetate (4 × 80 mL). The organic layers were combined and dried with anhydrous $MgSO_4$, and the solvent was removed in vacuo. The product was visualized by phosphomolybdic acid on a silica gel TLC plate after elution with 9:1 $CHCl_3$/MeOH, giving an R_f of 0.25. The product was purified by silica gel column chromatography using pure $CHCl_3$ to elute the starting ester, followed by 9:1 $CHCl_3$/MeOH to elute the product. A colorless oil (0.50 g) was obtained in 59% yield. ^{1}H NMR (200 MHz, $CDCl_3$) δ 0.85 (t, J = 6.8 Hz, 6H), 1.25 (m, 44H), 1.58 (t, J = 7.6 Hz, 4H), 1.98 (q, J = 5.8 Hz, 8H), 2.57−3.03 (m, 4H), 3.59−3.76 (m, 6H), 4.04 (t, J = 7.0 Hz, 2H), 4.10−4.13 (m, 2H), 5.46 (t, J = 5.2 Hz, 4H). ^{13}C NMR (50 MHz, $CDCl_3$) δ 14.1, 22.6, 25.8, 27.2, 28.5, 29.2, 29.3, 29.4, 29.5, 29.7, 30.8, 31.9, 36.5, 41.7, 65.2, 65.6, 70.0, 70.4, 127.9, 129.9, 170.6, 171.7. Electrospray mass spectrum calcd. for $C_{46}H_{84}O_8S$ $(M)^-$: 796.4. Found: 795.5.

2-{2-[2-(2-Carboxymethoxyethoxy)ethoxy]-ethylsulfanyl}succinic Acid dioctadec-9-enyl Ester (7b). Prepared in a silimar manner to (**7a**). ^{1}H NMR (300 MHz, $CDCl_3$) δ 0.85 (t, J = 7.48 Hz, 6H), 1.17−1.35 (m, 44H), 1.53−1.67 (m, 4H), 1.94−2.02 (m, 8H), 2.55−2.69 (m, 1H), 2.74−2.95 (m, 2H), 3.58−3.71 (m, 12H), 3.99−4.13 (m, 6H), 5.31 (t, J = 5.28 Hz, 4H). ^{13}C NMR (75 MHz, $CDCl_3$) δ 14.0, 21.6, 21.7, 22.6, 25.7, 27.1, 28.4, 29.1, 29.3, 29.4, 29.6, 30.7, 31.8, 36.4, 36.7, 41.7, 65.0, 65.5, 68.4, 68.9, 70.0, 70.2, 129.6, 129.8, 170.6, 171.0, 171.6. Electrospray mass spectrum cald for $C_{48}H_{88}O_9S$ $(M)^-$: 840.0. Found: 839.3.

2-(2-{2-[2-(2-Carboxymethoxyethoxy)ethoxy]-ethoxy}ethylsulfanyl)succinic Acid Dioctadec-9-enyl Ester (7c). Prepared in a silimar manner to (**7a**). ^{1}H NMR (300 MHz, $CDCl_3$) δ 0.86 (t, J = 7.0 Hz, 6H), 1.23−1.30 (m, 44H), 1.51−1.65 (m, 6H), 1.86−2.03 (m, 8H), 2.65 (dd, J = 16.8, 4.4 Hz, 1H), 2.73−3.35 (m, 6H), 3.58−3.70 (m, 10H), 3.96−4.14 (m, 6H), 5.32 (t, J = 5.3 Hz, 4H). ^{13}C NMR (75 MHz, $CDCl_3$) δ 14.1, 22.6, 25.7, 25.8, 27.1, 28.5, 29.2, 29.3, 29.4, 29.5, 29.7, 30.9, 31.8, 36.5, 41.6, 65.1, 65.5, 70.0, 70.2, 129.7, 129.9, 170.6, 171.6. Electrospray mass spectrum calcd. for $C_{50}H_{92}O_{10}S$ $(M)^-$: 884.0. Found: 883.1.

2-[2-(2-Carboxymethoxyethoxy)ethylsulfanyl]-succinic Acid Dioctadecyl Ester (10a). Prepared in a silimar manner to (**7a**). ^{1}H NMR (300 MHz, $CDCl_3$) δ 0.84 (t, J = 6.4 Hz, 6H), 1.21 (m, 60H), 1.58 (p, J = 11.8, 5.9 Hz, 4H), 2.64 (dd, J = 17.0, 11.0 Hz, 1H), 2.74−2.98 (m, 4H), 3.61−3.73 (m, 6H), 4.01−4.13 (m, 6H). ^{13}C NMR (75 MHz, $CDCl_3$) δ 14.1, 22.7, 25.7, 25.8, 28.5, 29.2, 29.3, 29.5, 29.6, 29.7, 30.8, 31.9, 36.5, 41.7, 62.3, 65.2, 65.6, 68.6, 70.1, 70.4, 71.0, 76.6, 78.9, 170.7, 171.7. High-resolution mass spectrum (FAB^+) calcd for $C_{46}H_{89}O_8S$ $(MH)^+$: 801.6278. Found: 801.6289.

2-{2-[2-(2-Carboxymethoxyethoxy)ethoxy]-ethylsulfanyl}succinic Acid Dioctadecyl Ester (10b). Prepared in a silimar manner to (**7a**). ^{1}H NMR (300 MHz, $CDCl_3$) δ 0.88 (t, J = 7.6 Hz, 6H), 1.25 (m, 60H), 1.62 (p, J = 12.7, 6.8 Hz, 4H), 2.68 (dd, J = 17.1, 11.7 Hz, 1H), 2.77−3.01 (m, 4H), 3.61−3.78 (m, 10H), 4.06 (t, J = 7.3 Hz, 2H), 4.10−4.17 (m, 4H). ^{13}C NMR (75 MHz, $CDCl_3$)

δ 14.1, 22.7, 25.8, 28.5, 29.2, 29.4, 29.5, 29.6, 29.7, 31.0, 31.9, 36.6, 41.7, 65.2, 65.6, 70.1, 70.5, 70.6, 170.7, 171.7. Electrospray mass spectrum cald for $C_{48}H_{92}O_9S$ $(M)^-$: 845.3. Found: 845.0.

Gal-3-Unsat (8a). 2-[2-(2-Carboxymethyoxyethoxy)-ethylsulfanyl]succinic acid dioctadec-9-enyl ester (**7a**) (165 mg, 0.21 mmol) was dissolved in 1.0 mL of DMF followed by addition of triethylamine (117 μL, 0.84 mmol) and pentafluorophenyltrifluoroacetate (55 μL, 0.32 mmol) via a Hamilton syringe. The reaction mixture was stirred at room temperature for 2 h to allow formation of the activated pentafluorophenyl ester. The *C*-glycoside amine (**5**) (40 mg, 0.21 mmol) was added, and the reaction was allowed to stir overnight. A solution of 10% $NaHCO_3$ (10 mL) was added directly to the reaction mixture, and then the aqueous layer was extracted with $CHCl_3$ (4 × 10 mL). The organic extracts were combined and dried with anhydrous $MgSO_4$, and the product was visualized with phosphomolybdic acid on a silica gel TLC plate. The R_f was 0.3 when eluted with 9:1 $CHCl_3$/MeOH. The product was purified by silica gel chromatography using a gradient solvent system starting with pure $CHCl_3$ followed by 99:1, 95:1, and 9:1 $CHCl_3$/MeOH. The product (32 mg) was obtained as a colorless, viscous liquid in 17% yield. ^{1}H NMR (600 MHz, CD_3OD) δ 0.80 (t, J = 6.9 Hz, 6H), 1.19 (m, 44H), 1.51−1.57 (m, 4H), 1.94 (m, 8H), 2.65 (d, J = 16.9 Hz, 1H), 2.74−2.88 (m, 3H), 3.21 (m, 8H), 3.30 (q, J = 6.9 Hz, 1H), 3.36 (d, J = 5.9 Hz, 2H), 3.39 (t, J = 6.0 Hz, 1H), 3.55−3.68 (m, 10 H), 3.76 (bs, 1H), 3.92 (s, 2H), 3.98 (q, J = 6.9 Hz, 2H), 4.04 (dt, J = 2.6, 6.5 Hz, 2H), 5.25 (t, J = 4.6 Hz, 4H). ^{13}C NMR (150 MHz, CD_3-OD) δ 14.1, 22.6, 25.8, 27.2, 28.5, 29.2, 29.3, 29.4, 29.5, 29.7, 31.0, 31.9, 36.5, 39.7, 41.7, 50.8, 63.2, 65.3, 69.9, 70.0, 70.1, 70.2, 70.7, 76.4, 76.6, 76.8, 77.8, 78.8, 129.7, 129.9, 170.7, 171.6, 172.4. High-resolution mass spectrum (FAB^+) calcd for $C_{53}H_{97}NO_{12}S$ $(MH)^+$: 972.6810. Found: 972.6815.

Gal-4-Unsat (8b). Prepared in a silimar manner to (**8a**). ^{1}H NMR (600 MHz, $CD_3OD/CDCl_3$) δ 0.86 (t, J = 6.7 Hz, 6H), 1.19−1.34 (m, 44H), 1.50−1.65 (m, 4H), 1.99 (q, J = 12.6, 5.9 Hz, 8H), 2.66 (dd, J = 17.0, 5.5 Hz, 1H), 2.82 (q, J = 6.9 Hz, 1H), 2.88−2.98 (m, 3H), 3.27 (q, J = 8.8 Hz, 1H), 3.37−3.43 (m, 4H), 3.45−3.52 (m, 6H), 3.58−3.70 (m, 10H), 3.73−3.76 (m, 1H), 3.78−3.84 (m, 1H), 3.86−3.91 (m, 1H), 4.02−4.07 (m, 4H), 4.11 (t, J = 6.9 Hz, 2H), 5.33 (p, J = 3.3, 6.9 Hz, 4H. Electrospray ionization mass spectrum (ESI^+) calcd for $C_{55}H_{101}NO_{13}S$ $(MH)^+$: 1016.34. Found: 1016.3.

Gal-5-Unsat (8c). Prepared in a silimar manner to (**8a**). ^{1}H NMR (600 MHz, $CD_3OD/CDCl_3$) δ 0.86 (t, J = 7.1 Hz, 6H), 1.19−1.34 (m, 44H), 1.52−1.65 (m, 4H), 1.99 (q, J = 12.4, 5.9 Hz, 8H), 2.66 (dd, J = 17.0, 5.4 Hz, 1H), 2.82 (q, J = 6.7 Hz, 1H), 2.88−2.98 (m, 3H), 3.23−3.31 (m, 3H), 3.47−3.52 (m, 3H), 3.59−3.70 (m, 14H), 3.78−3.84 (m, 2H), 3.85−3.90 (m, 2H), 3.95−4.06 (m, 7H), 4.11 (*t*, J = 7.1 Hz, 2H), 5.33 (*p*, J = 3.1, 6.3 Hz, 4H). Mass spectrum (FAB^+) calcd for $C_{57}H_{105}NO_{14}S$ $(MH)^+$: 1060.7. Found: 1061.2.

Gal-3-Sat (11a). Prepared in a silimar manner to (**8a**). ^{1}H and ^{13}C assignments: see Table 1. High-resolution mass spectrum (FAB^+) calcd for $C_{53}H_{101}NO_{12}S$ $(MH)^+$: 976.7123. Found: 976.7156.

Gal-4-Sat (11b). Prepared in a silimar manner to (**8a**). ^{1}H NMR (300 MHz, $CDCl_3$) δ 0.87 (t, J = 7.0 Hz, 6H), 1.25 (m, 60H), 1.61 (p, J = 12.0, 5.0 Hz, 4H), 2.67 (dd, J = 16.4, 6.1 Hz, 1H), 2.77−3.01 (m, 4H), 3.25−3.37 (m, 2H), 3.48−3.55 (m, 2H), 3.62−3.72 (m, 14H), 3.85 (t, J = 6.5 Hz, 2H), 4.03−4.15 (m, 10H). ^{13}C NMR (75 MHz, $CDCl_3$) δ 14.1, 22.7, 25.7, 25.8, 28.5, 29.2, 29.3, 29.5, 29.7, 30.8, 31.9, 36.5, 39.7, 41.7, 65.2, 65.7, 67.5, 70.1, 70.2, 70.5, 70.9, 77.4, 170.7, 171.6. Low resolution mass spectrum (FAB^+) calcd for $C_{55}H_{105}NO_{13}S$ $(MH)^+$: 1020.7. Found: 1021.3.

ACKNOWLEDGMENT

Site-Specific Modification of de Novo Designed Coiled-Coil Polypeptides with Inorganic Redox Complexes

Anna Fedorova and Michael Y. Ogawa*

Department of Chemistry and Center for Photochemical Sciences, Bowling Green State University, Bowling Green, Ohio 43403. Received August 9, 2001; Revised Manuscript Received October 26, 2001

A stepwise procedure for preparing of site-specific binuclear metallopeptides is described. The modification procedure involves the alkylation of a cysteine side chain by reaction with $[Ru(bpy)_2(phen\text{-}ClA)]^{2+}$, where bpy = 2,2′-bipyridine and phen-ClA = 5-chloroacetamido-1,10-phenanthroline, followed by the coordination of a ruthenium pentammine complex to a histidine residue located elsewhere along the sequence. The apo and metalated versions of the peptides C10H21(30-mer) and H10C21(30-mer) display circular dichroism spectra having minima at 208 and 222 nm, with $\theta_{222}/\theta_{208} = 1.04$ to indicate that these peptides exist as α-helical coiled-coils in aqueous solution. When the ruthenium polypyridyl complex is attached to C10H21(30-mer), the Δ-*l* and Λ-*l* diastereomers of the resulting metallopeptide can be readily separated from each other by reversed-phase HPLC. However, in the case of the related H10C21(30-mer) metallopeptide, the two diastereomers cannot be chromatographically resolved. These results indicate how the subtle interplay between peptide conformation/sequence and metal complex geometry may alter some of the physical characteristics of metallopeptides.

INTRODUCTION

The incorporation of extrinsic metal centers into proteins and polypeptides has facilitated the study of biological electron-transfer mechanisms (*1, 2*) and, more recently, the de novo design of minimalistic metalloprotein structures (*3*−*9*). Such procedures commonly involve either metal coordination to natural amino acid side chains such as histidine (*4, 8, 10, 11*) or cysteine (*6, 12*−*14*) or the use of non-natural amino acids that contain metal binding sites (*15, 16*). Our group has used previously developed histidine coordination methods to prepare a new series of synthetic metalloproteins (*3, 5*) in which the self-assembled α-helical coiled-coil motif (*17*) is employed as a well-defined protein scaffold upon which metal-based electron donors and acceptors can be attached. Our studies have demonstrated that such systems can undergo either long-range, intraprotein electron-transfer across a well-defined, yet noncovalent, peptide-peptide interface (*5*) or inter-protein electron transfers whose rates can be modulated by electrostatic protein−protein interactions (*3*). In both these cases, the electron-transfer event involved inorganic cofactors that were placed on separate peptide strands of the α-helical coiled-coil. In other situations, it may be desirable to place such cofactors at different positions along the backbone of a single peptide chain. However, the preparation of such peptides presents a special synthetic challenge as coordinatively unsaturated metal complexes can react promiscuously with a variety of potential ligands. Thus, the reaction of inorganic reagents with polypeptides often yields a mixture of difficult-to-separate substitutional isomers. The situation becomes even more complicated when two different metal complexes are to be bound to specific positions along the sequence of a given protein or polypeptide (*18*). In this paper, we present a straightforward solution to this problem in which a thiol-specific metalation reaction is used to attach a coordinatively saturated ruthenium polypyridyl group to a cysteine residue, followed by the coordination of a ruthenium pentammine site to a histidine residue located elsewhere along the sequence. Details of the synthesis, purification, and characterization of these peptides are described here, and their electron-transfer properties will be discussed elsewhere (*19*). It is also reported that the specific placement of a chiral ruthenium polypyridyl complex within the peptide can significantly alter the way the peptide interacts with solid chromatographic supports: one substitutional isomer of the ruthenium polypyridyl-containing metallopeptides, [(Ru-phen)-C10]H21-(30-mer), can be resolved into its two diastereomers by reversed-phase HPLC, whereas the other, H10[(Ru-(phen)-C21](30-mer), cannot. These results indicate that the derivatization of polypeptides with inorganic complexes can subtly alter the physical properties of the macromolecule.

EXPERIMENTAL SECTION

General Methods. UV−vis, electrochemical, and MALDI-TOF mass spectral measurements were performed as previously described (*5*). Electrospray ionization mass spectra (ESI-MS) were obtained on a Bruker Daltonics Esquire LC-MS at the Department of Chemistry of the University of Toledo, Toledo, OH.

All peptide metalation reactions were monitored by HPLC on a semipreparative reversed-phase C_{18} column (Zorbax 300SB-C_{18}, 9.4 × 250 mm, 5 μm particle size, 300 Å pore size) with an AB gradient of 1% B/min for 20 min followed by a gradient of 0.5% B/min. For both gradients, the flow rate was 2 mL/min and solvent A was 0.1% (v/v) HTFA in water and solvent B was 0.1% (v/v) HTFA in acetonitrile. Purification of bulk quantities of the peptides was achieved using a preparative C_{18} column

(Zorbax 300SB-C_{18}, 21.1 mm × 25 cm, 7 μm particle size, 300 Å pore size) using the same gradient as described above but at a flow rate of 5 mL/min.

Peptide Synthesis. Solid-phase techniques were used to prepare the 30-residue polypeptides, C10H21(30-mer): Ac-K-(IEALEGK)(ICALEGK)(IEALEHK)(IEALEGK)-G-amide, and H10C21(30-mer): Ac-K-(IEALEGK)-(IHALEGK)-(IEALECK)(IEALEGK)-G-amide, on an Applied Biosystems model 433A peptide as previously described (*5*). ESI-MS *m/z* (ion): found for C10H21(30-mer) 1088.2 ($[M + 3H^+]^{3+}$), 816.4 ($[M + 4H^+]^{4+}$) 653.4 ($[M + 5H^+]^{5+}$), 544.6 ($[M + 6H^+]^{6+}$; for H10C21(30-mer**)** 1088.1 ($[M + 3H^+]^{3+}$), 816.5 ($[M + 4H^+]^{4+}$), 653.3 ($[M + 5H^+]^{5+}$), 544.6 ($[M + 6H^+]^{6+}$.

Synthesis of $[Ru(bpy)_2(phen\text{-}ClA)](PF_6)_2$. *N,N′*-Dicyclohexylcarbodiimide (DCC) (2.5 g, 1.2 mmol) was added to a solution of chloroacetic acid (2.55 g, 2.7 mmol) dissolved in anhydrous ethyl acetate (75 mL). A white precipitate was seen to form immediately, and the mixture was stirred at ambient temperature for 2 h. The reaction mixture was then filtered, and the volume of the filtrate was reduced by rotary evaporation to yield chloroacetic anhydride as a viscous yellow oil. The oil was dissolved in acetonitrile (30 mL) and added to a solution of $[Ru(bpy)_2(phen\text{-}NH_2)](PF_6)_2$ (2 g, 2 mmol) in acetonitrile (100 mL), where bpy = 2,2′-bipyridine and phen-NH_2 = 5-amino-1,10-phenanthroline. The mixture was stirred overnight, and the acetonitrile was then removed by rotary evaporation. The resulting solid was redissolved in a minimal amount of methanol and precipitated with the addition of saturated NH_4PF_6 (aq). The $Ru(bpy)_2(phen\text{-}ClA)](PF_6)_2$, where phen-ClA = 5-chloroacetamido-1,10-phenanthroline, was collected by vacuum filtration as an orange solid, washed with water followed by diethyl ether, and stored at room temperature in the dark. ESI-MS *m/z* (ion): 830.3 ($[M - PF_6^-]^+$), 684.3 ($[M - 2PF_6^- + e^-]^+$).

Synthesis of $[Ru(bpy)_2(phen\text{-}IA)](PF_6)_2$. This synthesis was performed as outlined above for $[Ru(bpy)_2(phen\text{-}ClA)](PF_6)_2$ except iodoacetic acid was used in place of chloroacetic acid. ESI-MS *m/z* (ion): 922.1 ($[M\text{-}PF_6\text{-}]^+$), 776.2 ($[M\text{-}2PF_6\text{-}+e^-]^+$).

Peptide Labeling with $[Ru(bpy)_2(phen\text{-}ClA)](PF_6)_2$. In a typical procedure, a sample of either C10H21(30-mer) or H10C21(30-mer) (5 mg, 1.28 μmol) was dissolved in 100 mM phosphate buffer (1 mL, pH 7.0), and the resulting solution was purged with argon gas for 15−20 min. To this was added solid tris(2-carboxyethyl)phosphine (ca. 5 mg, 0.017 mmol). After being stirred under an argon atmosphere for ca. 20 min, the solution was neutralized by the dropwise addition of 1 N NaOH (aq). A solution of $[Ru(bpy)_2(phen\text{-}ClA)](PF_6)_2$ (10 mg, 0.01 mmol) dissolved in *N,N*-dimethylformamide (ca. 0.5 mL) was then added to the reaction mixture. After the mixture was stirrred for 4−5 h at room temperature, it was applied directly onto a size-exclusion column (Biogel P-2) that was previously equilibrated with 0.1 N trifluoroacetic acid (HTFA). Elution with the HTFA solution yielded the peptide fraction first followed by the hydrolyzed metal complex. The collected peptide fraction was then analyzed by HPLC and in cases where unreacted apo-peptide was detected, the metalation procedure was repeated using a fresh sample of $[Ru(bpy)_2(phen\text{-}ClA)](PF_6)_2$. ESI-MS *m/z* (ion): found for [(Λ-*l*)(Ru-phen)-C10]H21(30-mer*)* 978. 2 ($[M + 4H^+]^{4+}$), 782.6 ($[M + 5H^+]^{5+}$), 652.4 ($[M + 6H^+]^{6+}$), 559.3 ($[M + 7H^+]^{7+}$; for [(Δ-*l*)(Ru-phen)-C10]H21(30-mer*)* 978. 1 ($[M + 4H^+]^{4+}$), 782.7 ($[M + 5H^+]^{5+}$), 652.5 ($[M + 6H^+]^{6+}$), 559.6 ($[M + 7H^+]^{7+}$; for H10[(Δ-*l* + Λ-*l*)(Ru(phen)-C21](30-mer) 978.

Peptide Labeling with $[Ru(NH_3)_5Cl](TFA)$. The $Ru(bpy)_2(phen)$-labeled peptides [(Λ-*l*)(Ru-phen)-C10]-H21(30-mer*)* and the diastereomeric mixture H10[(Δ-*l* + Λ-*l*)(Ru(phen)-C21](30-mer) were metalated at their histidine side chains by treatment with aquopentammineruthenium(II) as described previously for the metalation of related coiled-coil peptides (*3*, *5*). However, in the present study, the reaction mixtures were treated with 0.1 N HTFA for 2−3 h prior to purification by reversed-phase HPLC. ESI-MS *m/z* (ion): found for [(Δ-*l*)(Ru-phen)-C10][$Ru(NH_3)_5$H21](30-mer*)* 1366.5 ($[M + 3H^+]^{3+}$), 1024.4 ($[M + 4H^+]^{4+}$), 819.9 ($[M + 5H^+]^{5+}$); for [$Ru(NH_3)_5$-H10][(Δ-*l* + Λ-*l*)(Ru(phen)-C21](30-mer) 1366.1 ($[M + 3H^+]^{3+}$), 1024.1 ($[M + 4H^+]^{4+}$), 819.8 ($[M + 5H^+]^{5+}$).

RESULTS AND DISCUSSION

Synthesis of the C10H21(30-mer) and H10C21(30-mer) Apopeptides. Solid-phase techniques were used to prepare the 30-residue polypeptides, C10H21(30-mer): Ac-K-(IEALEGK)(ICALEGK)(IEALEHK)(IEALEGK)-G-amide, and H10C21(30-mer): Ac-K-(IEALEGK)-(IHALEGK)-(IEALECK)(IEALEGK)-G-amide. These sequences are based on a seven residue heptad repeat, $(abcdefg)_n$, in which positions *a* and *d* are occupied by hydrophobic amino acids, positions *b*, *c*, and *f* are occupied by hydrophilic residues, and positions *e* and *g* are occupied by oppositely charged residues. Such sequences have been designed by Hodges and co-workers (*17*) to spontaneously form two-stranded α-helical coiled-coils, which can be described as being an intertwining of 2 α-helices to from a left-handed supercoil. The amino acid sequences of C10H21(30-mer) and H10C21(30-mer) differ from one another only in their placement of the cysteine and histidine residues along the peptide chain (Figure 1). Specifically, cysteine residues were located at either position 10 or 21 of the sequence to allow coupling to a ruthenium tris(bipyridyl) complex. Histidine residues were also placed at either positions 21 or 10 of the sequence to afford the coordination of a pentammineruthenium(II) center along the same peptide chain.

Synthesis of H10[(Ru(phen)-C21] (30-mer). The cysteine side chain of H10C21(30-mer) was alkylated by treatment with $[Ru(bpy)_2(phen\text{-}ClA)](PF_6)_2$, where phen-ClA = 5-chloroacetamido-1,10-phenanthroline and the cysteine residue occupies the most solvent-exposed position *(f)* of the third heptad of the peptide sequence. In this procedure, the ruthenium starting material was

Note that for C10H21(30-mer) two product peaks (**1** and **2**) are seen in the HPLC profile.

prepared by a carbodiimide coupling reaction involving chloroacetic acid and $[Ru(bpy)_2(phen\text{-}NH_2)]$. The alkylation reaction was monitored by reversed-phase HPLC (Figure 2 (top)), which showed that the peak corresponding to the apo-peptide diminished in intensity as a new product peak appeared at a somewhat shorter retention time. Electrospray ionization mass spectrometry showed that the product had a charge-to-mass ratio consistent with that expected for H10[(Ru(bpy)$_2$(phen)-C21](30-mer). The UV−vis spectrum of the product is very similar to that of $[Ru(bpy)_2(phen\text{-}ClA)]^{2+}$, having maxima at 286 and 450 nm, but has a significantly larger absorbance at 210−220 nm due to the presence of the peptide backbone. Additional HPLC experiments showed that metalation of the H10C21(30-mer) occurs in competition with hydrolysis of the $[Ru(bpy)_2(phen\text{-}ClA)]^{2+}$ starting material, as evidenced by the appearance of a new HPLC peak at shorter retention times than that of the ruthenium starting material.

The alkylation of sulfhydryl groups with 5-iodoacetamido-1,10-phenanthroline (phen-IA) has previously been used as a convenient method for attaching metal-binding sites onto the surfaces of proteins, where subsequent treatment of the modified protein with transition metal reagents has led to the creation of specific DNA cleaving agents (*13*, *14*). In related work, luminescent probes (*12*) were attached to the cysteine-containing proteins human serum albumin and human immunoglobulin G, by first reacting $[Ru(bpy)_2Cl_2]$ with phen-IA and then treating the protein with the resulting metal complex. However, in our hands this preparation of the ruthenium reactant gave a mixture of two products as observed by reversed-phase HPLC. The ESI-MS of these products indicated that they were $[Ru(bpy)_2(phen\text{-}IA)]^{2+}$ and $[Ru(bpy)_2(phen\text{-}ClA)]^{2+}$, of which the latter species was likely due to a halogen-exchange involving propitious chloride in solution. HPLC experiments also showed that when the mixture of $[Ru(bpy)_2(phen\text{-}IA)]^{2+}$ and $[Ru(bpy)_2(phen\text{-}ClA)]^{2+}$reactants was treated with H10C21(30-mer), the iodo species hydrolyzed very rapidly and the metalation of the peptide appeared to proceed only from the $[Ru(bpy)_2(phen\text{-}ClA)]^{2+}$ precursor. Indeed, when authentic samples of $[Ru(bpy)_2(phen\text{-}IA)]^{2+}$ and $[Ru(bpy)_2(phen\text{-}ClA)]^{2+}$ were reacted separately with the peptide, it was found that metalation occurred only from the chloro starting material and not the iodo species. This behavior is in contrast to that reported for the metalation of human serum albumin and human immunoglobulin G in which the $[Ru(bpy)_2(phen\text{-}ClA)]^{2+}$ species was observed to be nonreactive (*12*).

Synthesis of [Ru(phen)-C10]H21(30-mer). The cysteine side chain of C10H21(30-mer) was alkylated by treatment with $[Ru(bpy)_2(phen\text{-}ClA)]^{2+}$ as described above. It is noted that the sequence of this peptide places the cysteine residue at position (*b*) of the second heptad repeat. In contrast to the behavior previously described for the metalation of H10C21(30-mer), it was observed that the alkylation of C10H21(30-mer) produced two distinct product peaks (Figure 2 (bottom)). The UV−vis spectra of both species were identical to that of H10[(Ru-(phen)-C21](30-mer), and ESI-MS showed that they both had the charge-to-mass ratio expected for the desired metallopeptide. The circular dichroism spectrum (not shown) of the faster eluting product consists of negative bands appearing at 208 and 222 nm with $[\theta]_{222}/[\theta]_{208} = 1.04$ which indicates that the peptide exists as an α-helical coiled-coil (*17*). These features are also observed in the CD spectrum of the H10C21(30-mer) apopeptide (data not shown). However, the spectrum of the first ruthenated product displays an additional set of features that consists of a strong negative peak at 270 nm, a strong positive peak at 290 nm, a broad negative peak at ca. 420 nm, and a weak positive peak at 470 nm. By analogy to the CD properties of related systems, this latter set of transitions are assigned to the Λ configuration of the octahedral ruthenium polypyridyl complex (*20*, *21*). Thus, the faster eluting product is identified as being the Λ-*l* diastereomer which results from coupling the chiral metal complex to the *l*-polypeptide. The CD spectrum of the slower eluting product is nearly identical to the one described above except that it displays transitions arising from the metal complex corresponding to the Δ configuration. Thus, reaction of C10H21(30-mer) with $[Ru(bpy)_2(phen\text{-}ClA)]^{2+}$ produces the two diastereomers (Λ-*l* and Δ-*l*) of the [(Ru(phen)-C10]H21(30-mer) metallopeptide, which are resolvable by reversed-phase HPLC. It is noted, however, that the two diastereomers of the related H10[(Ru(phen)-C21](30-mer) metallopep-

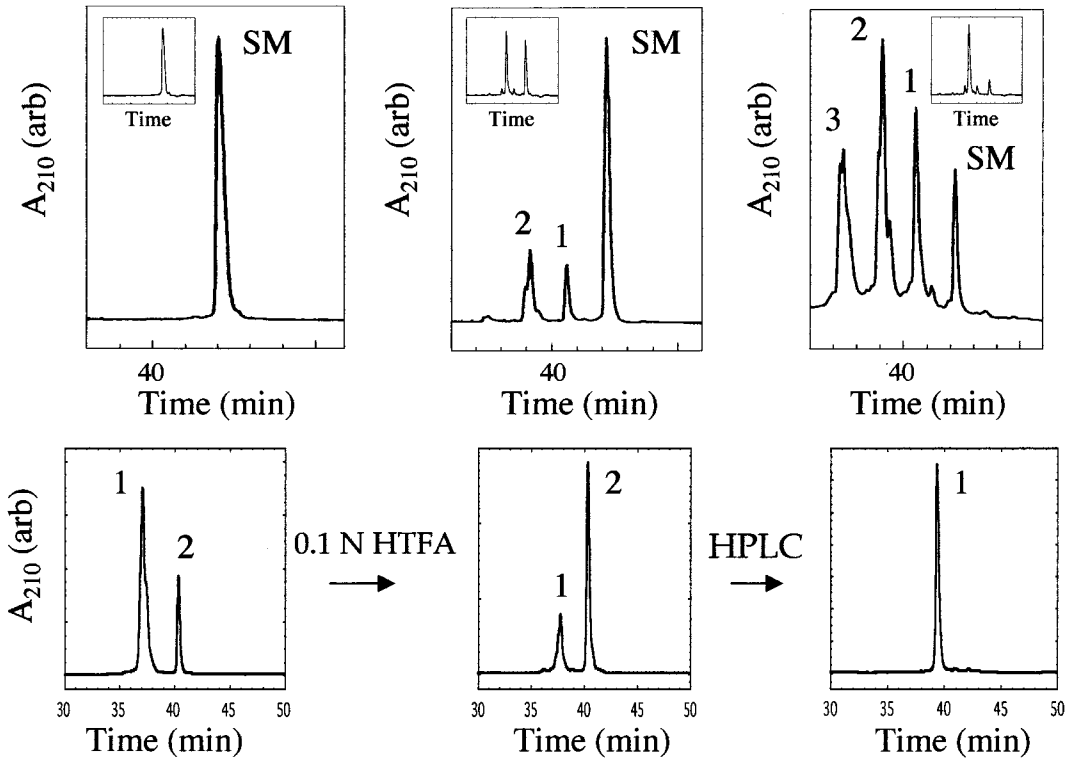

Figure 3. (Top) HPLC profiles showing the progress of the reaction between the H10[(Ru(bpy)$_2$(phen)-C21](30-mer) peptide and $RuA_5(H_2O)^{2+}$ after (a) 0, (b) 1, and (c) 6 h. At longer reaction times, three product peaks are observed (1−3) along with that of the unreacted starting material (SM). The insets show the progress of the corresponding metalation reaction using the related peptide H21(30-mer) (*5*), which undergoes conversion to a single metalated product. (Bottom) HPLC profiles showing that the treatment of product **2** with 0.1 N HTFA results in its conversion to product **1**, which can be separated by HPLC.

tide could not be separated under identical HPLC conditions. Thus, the specific placement of the ruthenium polypyridyl complex within the peptide sequence (i.e., a "b" position on C10H21(30-mer) vs a "f" position on H10C21(30-mer)) sufficiently alters the physical properties of the metallopeptide to yield significantly different HPLC properties of the two sets of metallopeptides.

Synthesis of [Ru(NH$_3$)$_5$-H10][(Δ-l + Λ-l)(Ru(phen)-C21](30-mer). The histidine side chains of the H10[(Ru(phen)-C21](30-mer) metallopeptide were coordinated to a ruthenium pentammine center by treating a diastereomeric mixture (Δ-*l* + Λ-*l*) of the metallopeptide with aquopentammineruthenium(II) made in situ by reducing chloropentammineruthenium(III) chloride with zinc amalgam. Similar procedures have been used to metalate the histidine residues of a variety of native heme proteins (*11*) and synthetic polypeptides (*3*, *5*, *7*). As monitored by reversed-phase HPLC (Figure 3), the reaction of [Ru(NH$_3$)$_5$(H$_2$O)]$^{2+}$ with H10[(Ru(phen)-C21](30-mer), whose two diastereomers appear as a single HPLC peak, results in the appearance of at least three new product peaks, labeled **1**−**3**. This behavior is in contrast to that previously observed for metalation of the related H21(30-mer) polypeptide (*5*) where only a single product peak appeared in the HPLC profile (insets, Figure 3).

The differential pulse polarogram of peak **1** (not shown) consists of a single reduction wave at −0.18 V vs Ag/Ag$^+$ that appears at a similar potential to those of [Ru(NH$_3$)$_5$-H21](30-mer) (*5*), and Ru(NH$_3$)$_5$ bound to His33 of cytochrome *c* (*11*). This peak is therefore assigned to the desired product, [Ru(NH$_3$)$_5$-H10][(Ru(phen)-C21](30-mer). ESI-MS data support this assignment and it is noted that changes in the spectrometer voltage can yield mass spectra that are either consistent with the formulation, [Ru(NH$_3$)$_5$-H10][(Ru(phen)-C21](30-mer), or with the complete loss of the ammonia ligands, as was previously seen in the case of ruthenium ammine labeled cytochrome *c* (*22*).

The polarograms from peaks **2** and **3** each show two reduction waves that appear at −0.18 and −0.32 V vs Ag/Ag$^+$, to suggest the presence of two types of peptide-bound ruthenium pentammine species in these samples. Based on model studies (*23*), the more anodic peak is assigned to the existence of pentamminecarboxylatoruthenium species bound to one or more of the glutamic acid residues in the peptide. However, the ESI-MS of **2** and **3** are identical to that of **1** and it is possible that the carboxylato bound ruthenium complexes dissociate under the MS conditions employed. Thus, to test for the existence of acid-bound ruthenium complexes, products **2** and **3** were isolated by HPLC and dissolved in 0.1 N HTFA for several hours. HPLC analysis (Figure 3) of the resulting solutions showed that this treatment produced the clean conversion of products **2** and **3** into product **1** which suggests the dissociation of carboxylato bound species at low pH.

Synthesis of [(Ru(phen)-C10][(Λ-l)Ru(NH$_3$)$_5$-H21]-(30-mer). The [(Ru(phen)-C10]H21(30-mer) was reacted with aquopentammine ruthenium (II) as described above. However, since the HPLC profile of the starting metallopeptide was complicated by the resolution of its two diastereomers, only the Λ-*l* diastereomer was used in the reaction. The HPLC results again show the presence of multiple product peaks which can be converted to a single peak by treatment with dilute acid.

SUMMARY

A stepwise procedure for the preparation of site-specific, binuclear metallopeptides has been described. The peptide modification proceeds first through the

alkylation of a cysteine side-chain with $[Ru(bpy)_2(phen\text{-}ClA)]^{2+}$, followed by the coordination of a ruthenium pentammine complex to a histidine residue located elsewhere along the sequence. Circular dichroism spectroscopy shows that both the apo and metalated peptides adopt the conformation of an α-helical coiled-coil in aqueous solution. When the ruthenium polypyridyl complex is attached to C10H21(30-mer), the Δ-*l* and Λ-*l* diastereomers of the resulting metallopeptide are readily separated from each another by reversed-phase HPLC. However, when the reaction occurs with H10C21(30-mer), the two peptide diastereomers cannot be chromatograpically resolved. These results demonstrate that the metalation of different positions of the coiled-coil sequence significantly affects the way the resulting peptide interacts with solid supports. An examination of the wheel diagram depicted in Figure 1 shows that the cysteine residue of C10H21(30-mer) is placed at a "b" position of the heptad which is located somewhat close to the peptide-peptide interface. It is speculated that the peptide-bound ruthenium polypyridyl complex may experience a restricted conformational environment that may facilitate its diastereomeric resolution by reversed-phase HPLC. In contrast, the cysteine residue in H10C21-(30-mer) is located at the most highly solvent-exposed position "f" of the heptad repeat, and presumably experiences a significant degree of conformational freedom. These results indicate that the subtle interplay between peptide conformation/sequence and metal complex geometry may be used to control some of the physical characteristics of metallopeptides.

ACKNOWLEDGMENT

We thank Mr. Jedrzej Romanowicz for obtaining the ESI-MS data. This work was supported by the National Institutes of Health through Grant Nos. GM 61171 and GM60258 and the Petroleum Research Fund through Grant No. 34901-AC. A.F. acknowledges predoctoral support from the Harold and Helen McMaster Foundation.

2′-Modified Nucleosides for Site-Specific Labeling of Oligonucleotides

Elizabeth S. Krider, Jeremiah E. Miller, and Thomas J. Meade*

Division of Biology and the Beckman Institute, California Institute of Technology, Pasadena, California 91125.
Received August 16, 2001

We report the synthesis of 2′-modified nucleosides designed specifically for incorporating labels into oligonucleotides. Conversion of these nucleosides to phosphoramidite and solid support-bound derivatives proceeds in good yield. Large-scale synthesis of 11-mer oligonucleotides possessing the 2′-modified nucleosides is achieved using these derivatives. Thermal denaturation studies indicate that the presence of 2′-modified nucleosides in 11-mer duplexes has minimal destabilizing effects on the duplex structure when the nucleosides are placed at the duplex termini. The powerful combination of phosphoramidite and support-bound derivatives of 2′-modified nucleosides affords the large-scale preparation of an entirely new class of oligonucleotides. The ability to synthesize oligonucleotides containing label attachment sites at 3′, intervening, and 5′ locations of a duplex is a significant advance in the development of oligonucleotide conjugates.

INTRODUCTION

Substituents at the 2′-ribose position of nucleosides are important structural and mechanistic probes of nuclease resistance and ribozyme catalysis (*1*). These nucleosides are used in the development of antisense therapeutics (*1b*) and the rapid screening of oligonucleotide sequences displaying high affinity toward protein targets (*2*). Nucleosides containing a primary amine at the 2′ position facilitate the incorporation of several reporter molecules or labels into oligonucleotides (*3*). This is accomplished by (a) introducing the amine-containing nucleoside into an oligonucleotide using standard automated DNA synthesis, (b) purifying the resulting oligonucleotide, (c) reacting the reporter group with the amine-containing oligonucleotide, and (d) isolating the conjugate. Labels such as fluorescent dyes (*3a,c*), aromatic and aliphatic isocyanates (*3b,d*), and transition metal complexes (*3e*) have been successfully incorporated into oligonucleotides using this method.

Our objective is to develop new methods of incorporating labels, namely transition metal complexes, into DNA site-specifically (*4*). To this end we have designed nucleosides containing bidentate amine groups at the 2′-ribose position to which transition metal complexes are chelated (Figure 1). This site on the ribose ring is selected so that both solid support-bound and phosphoramidite forms of the nucleosides can be prepared. The solid support-bound nucleoside is used as the starting material in oligonucleotide synthesis, whereas the phosphoramidite monomer can be introduced at any later position in the oligonucleotide sequence. As a result, labels can be incorporated at the 3′, intervening, or 5′ locations of an oligonucleotide. We report the synthesis of 2′-modified nucleosides as both solid support-bound and phosphoramidite derivatives and their incorporation into oligonucleotides via solid-phase methods. Thermal denaturation studies of the resulting oligonucleotides indicate that the presence of the 2′-modified nucleosides has only a slight destabilizing effect on the duplex structure.

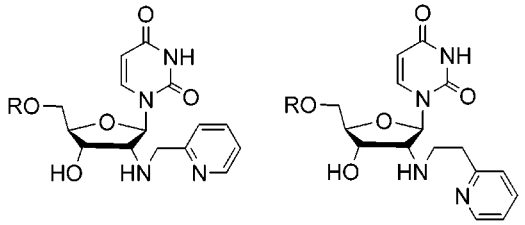

Figure 1. Structure of nucleosides with bidentate ligands at the 2′ ribose position (R = 4,4′-dimethoxytrityl).

EXPERIMENTAL PROCEDURES

General. ^{1}H and ^{31}P spectra were acquired on either Varian 300 or 500 spectrometers. Chemical shifts are reported in parts per million and referenced to the proton chemical shifts of deuterated solvent, trimethylsilane, or 85% H_3PO_4 in H_2O. Reagents and starting materials were used as received from Aldrich. Flash chromatography was performed on EM Science/Merck silica gel 60 (230−400 mesh). Thin-layer chromatography (TLC) was performed on 0.25 mm Merck precoated silica plates (60 F_{254}). Enzymes were purchased from Pharmacia. Mass spectrometry was performed at the Caltech Peptide/Protein Microanalytical Laboratory.

5′-*O*-(4,4′-Dimethoxytrityl)-2,2′-*O*-anhydro-1-(β-D-arabinofuranosyl)uracil, **1.** This compound was prepared from the reaction of 2,2′-*O*-anhydro-1-(β-D-arabinofuranosyl)uracil and 4,4′-dimethoxytrityl chloride as previously described (*5*).

5′-*O*-(4,4′-Dimethoxytrityl)-2′-*N*,3′-*O*-(2-oxooxazolidinyl)-2′-aminomethylpyridyl-2′-deoxyuridine, **2a.** To a solution of **1** (2.2 g, 4.2 mmol) in pyridine (40 mL) was added 1,1′-carbonyldiimidazole (1.01 g, 6.2 mmol). After 30 h of stirring at ambient temperature, the solvent was removed and the residue was resuspended in dichloromethane (40 mL); DIEA (1.1 mL, 6.3 mmol) and AMPy (649 μL, 6.3 mmol) were delivered to the solution. After 60 h of stirring at ambient temperature, the reaction was quenched with 5% citric acid, extracted with fresh dichloromethane, dried over Na_2SO_4, and concentrated

to an oil. The residue was dissolved in tetrahydrofuran (25 mL), DBU (628 μL, 4.2 mmol) was added to the flask, and the solution was refluxed for 46 h. The solvent was removed, and the residue was purified on silica (using 22% EtOAc in dichloromethane containing 1% TEA and 3% methanol) to afford **2a** in 20% yield (548 mg, 828 μmol). ^{1}H NMR ($CDCl_3$, 500 MHz) δ 3.48−3.58 (m, 2H), 3.78 (s, 6H), 4.35−4.40 (m, 1H), 4.54 (d, 1H), 4.75 (dd, 2H), 5.14−5.17 (m, 1H), 5.41 (d, 1H), 6.06 (d, 1H), 6.82 (d, 4H), 7.21−7.30 (m, 9H), 7.33−7.37 (m, 2H), 7.53 (d, 1H), 7.69 (t, 1H), 8.51 (d, 1H), 8.84 (s, 1H). ESI-MS mass calcd for $C_{37}H_{35}N_4O_8$ $(M + H)^+$: 663.24. Found: 663.2.

5′-*O*-(4,4′-Dimethoxytrityl)-2′-*N*,3′-*O*-(2-oxooxazolidinyl)-2′-aminoethylpyridyl-2′-deoxyuridine, **2b.** To a solution of **1** (1.0 g, 1.9 mmol) in pyridine (30 mL) was added 1,1′-carbonyldiimidazole (0.460 g, 2.8 mmol). After 30 h of stirring at ambient temperature, the solvent was removed by rotary evaporation and the residue was resuspended in dichloromethane (30 mL); DIEA (500 μL, 2.85 mmol) and AEPy (340 μL, 2.85 mmol) were delivered to the solution. After 60 h of stirring at ambient temperature, the reaction was worked up as described for **2a**. The residue was dissolved in THF (11 mL), DBU (284 μL, 1.9 mmol) was added to the flask, and the solution was refluxed for 46 h. The solvent was removed by rotary evaporation, and the residue was purified on silica (eluting with 5−15% methanol in EtOAc) to afford **2b** in 10% yield (127 mg, 188 μmol). ^{1}H NMR ($CDCl_3$, 300 MHz) δ 3.07−3.39 (m, 2H), 3.43−3.60 (m, 2H), 3.74−3.77 (m, 6H), 3.93−4.04 (m, 1H), 4.26−4.31 (m, 1H), 4.64 (dd, 2H), 5.09−5.14 (m, 1H), 5.35 (d, 1H), 6.09 (d, 1H), 6.84 (d, 4H), 7.15−7.39 (m, 11H), 7.59−7.69 (m, 2H), 8.57 (d, 1H). ESI-MS mass calcd for $C_{38}H_{37}N_4O_8$ $(M + H)^+$: 677.25. Found: 677.2.

5′-*O*-(4,4′-Dimethoxytrityl)-2′-aminomethylpyridyl-2′-deoxyuridine, **3a.** Compound **2a** (242 mg, 0.36 mmol) was suspended in dioxane (6 mL), 4 M NaOH (4.7 mL), and methanol (4.7 mL), and the mixture was stirred at 50 °C for 36 h. The solvents were removed by rotary evaporation, and the residue was dissolved in dichloromethane (55 mL). The solution was extracted with brine, dried over sodium sulfate, and evaporated to dryness to give **3a** in 92% yield (216 mg, 0.34 mmol). ^{1}H NMR ($CDCl_3$, 300 MHz) δ 3.3 (s(br), 4H), 3.73−3.78 (m, 6H), 3.94−4.02 (m, 1H), 4.1 (d, 1H), 4.2 (s, 1H), 5.3 (d, 1H), 6.1 (d, 1H), 6.7 (dd, 4H), 7.1−7.3 (m, 11H), 7.5−7.6 (m, 2H), 8.4 (s, 1H). ESI-MS mass calcd for $C_{36}H_{37}N_4O_7$ $(M + H)^+$: 637.26. Found: 637.2.

5′-*O*-(4,4′-Dimethoxytrityl)-2′-aminomethylpyridyl-2′-deoxyuridine, **3b.** Compound **2b** (1.7 g, 2.51 mmol) was suspended in dioxane (43 mL), 4 M NaOH (26 mL), and methanol (26 mL), and the mixture was stirred at room temperature for 20 h. The reaction was heated at 60 °C for an additional 2 h, after which the solvents were removed by rotary evaporation. The residue dissolved in dichloromethane, extracted with brine, dried over sodium sulfate, and evaporated to dryness. The material was purified on silica (eluting with 23% ethyl acetate in dichloromethane containing 1% each of methanol and triethylamine) to give **3b** in 88% yield (1.44 g, 2.21 mmol). ^{1}H NMR ($CDCl_3$, 500 MHz) δ 3.03 (t, 2H), 3.12−3.25 (m, 2H), 3.43−3.53 (m, 3H), 3.80 (s, 6H), 4.29 (s, 1H), 4.49 (d, 1H), 5.37 (d, 1H), 5.94 (d, 1H), 6.14 (s(br), 1H), 6.85 (d, 4H), 7.18−7.33 (m, 10H), 7.40 (d, 1H), 7.67 (t, 1H), 7.74 (d, 1H), 8.49 (d, 1H). ESI-MS mass calcd for $C_{37}H_{39}N_4O_7$ $(M + H)^+$: 651.27. Found: 651.2.

5′-*O*-(4,4′-Dimethoxytrityl)-*N*$^{2′}$-trifluoroacetamido-2′-deoxyuridine, **4.** This compound was prepared either from reaction of 2′-amino-5′-*O*-(4,4′-dimethoxytrityl)-2′-deoxyuridine and ethyl trifluoroacetate (*5*) or from reaction *N*$^{2′}$-trifluoroacetyl-2′-amino-2′-deoxyuridine and 4,4′-dimethoxytrityl chloride as previously described (*3a*).

5′-*O*-(4,4′-Dimethoxytrityl)-2′-aminomethylpyridyl −2′-deoxyuridine-3′-*O*-succinate, 5. Compound **3a** (100 mg, 0.157 mmol), DMAP (9.4 mg, 0.5 equiv), and succinic anhydride (17.3 mg, 1.1 equiv) were suspended in dry pyridine (1 mL) and allowed to stir under argon for 2 h, at which time an additional 0.2 equiv of succinic anhydride was added. The reaction proceeded overnight at room temperature, after which the solvent was removed. The residue was dissolved in dichloromethane (20 mL) and stirred with an equal volume of 5% $NaHCO_3$ solution for 2 h. The mixture was partitioned, and the organic phase was extracted with brine. Each phase was back-extracted once. The combined organic phases were washed with cold 5% citric acid and concentrated to a small volume (3−5 mL). The sample was precipitated in stirring hexanes, and the white solid **5** was collected by filtration in 60% yield (69 mg, 0.094 mmol). ^{13}C NMR (75 MHz, CD_3CN) δ 178.82, 174.10, 165.67, 160.11, 158.27, 156.03, 146.0, 145.95, 136.96, 136.76, 136.6, 133.06, 131.32, 129.47, 128.77, 127.74, 122.9, 114.45, 114.0, 102.0, 88.12, 85.33, 73.0, 72.88, 65.04, 56.03, 30.98. ESI-MS mass calcd for $C_{40}H_{39}N_4O_{10}$ $(M - H)^-$: 735.27. Found: 735.2.

5′-*O*-(4,4′-Dimethoxytrityl)-*N*$^{2′}$-trifluoroacetamido-2′-deoxyuridine-3′-*O*-succinate, 6. Compound **4** (100 mg, 0.156 mmol), DMAP (9.4 mg, 0.5 equiv), and succinic anhydride (17.2 mg, 1.1 equiv) were suspended in dry pyridine (2 mL) and stirred under argon for 2 h. An additional 0.2−0.5 equiv of succinic anhydride was added, and the reaction proceeded at room-temperature overnight. The reaction was worked according to the procedure given for **5**. A white powder **7** was isolated in 74% yield (85 mg, 0.115 mmol). ^{13}C NMR (75 MHz, CD_3CN) δ 175.04, 172.80, 163.85, 160.13, 140.71, 131.42, 130.35, 129.32, 128.96, 128.43, 114.60, 114.23, 103.97, 86.30, 84.29, 74.18, 64.77, 56.42, 55.77, 30.49. ESI-MS mass calcd for $C_{36}H_{33}N_3O_{11}$ $(M - H)^-$: 740.21. Found: 740.2.

5′-*O*-(4,4′-Dimethoxytrityl)-2′-aminomethylpyridyl-2′-deoxyuridine-3′-*O*-succinated Support, 7. Compound **7** was prepared by suspending the solid support (controlled pore glass derivatized with long-chain alkylamine, 500 Å pore size, 350 mg) in dry dichloromethane (5 mL) and adding TEA (250 μL) and **5** (180 mg, 245 μmol); HOBT (33 mg, 245 μmol) and BOP (119 mg, 270 μmol) were added to the suspension. The mixture was agitated for 16 h at room temperature, filtered, and washed with dichloromethane (2 × 10 mL). The solid was transferred to a separate flask and suspended in pyridine (7.5 mL). Acetic anhydride (1−2 mL) and *N*-methylimidazole (100 μL) were added to the flask, and the mixture was agitated overnight. The solid was filtered and washed with pyridine (3 × 10 mL), methanol (3 × 10 mL), dichloromethane (3 × 10 mL), and diethyl ether (3 × 10 mL). The white solid **7** was dried in vacuo. The nucleoside loading was determined spectrophotometrically to be 60 μmol/g (*6*).

5′-*O*-(4,4′-Dimethoxytrityl)-*N*$^{2′}$-trifluoroacetamido-2′-deoxyuridine-3′-*O*-succinated Support, 8. Compound **8** was prepared using the same method described for **7**. The nucleoside loading for **8** was 52 μmol/g.

5′-*O*-(4,4′-Dimethoxytrityl)-2′-aminomethylpyridyl-2′-deoxyuridine-3′-*O*-(2-cyanoethyl *N*,*N*-Diisopropylaminophosphoramidite), 9. While under argon **3a** (200 mg, 0.314 mmol) was dissolved in dry dichloromethane (2 mL) containing DIEA (220 μL, 4 equiv). The reaction vessel was degassed several times prior to

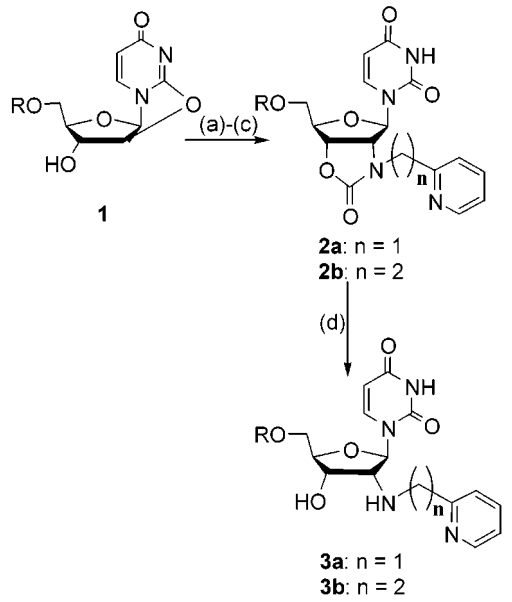
the addition of 2-chlorocyanoethyl *N*,*N*-diisopropylaminophosphoramidite (105 μL, 1.5 equiv) dropwise over 5 min. A positive ninhydrin test indicated formation of the desired product. After 50 min the reaction was diluted with 200 μL of methanol and evaporated to dryness. The residue was applied to silica (eluting with 0−80% dichloromethane in hexane containing 1% TEA) to give an off-white powder **9** in 57% yield (151 mg, 0.180 mmol). ESI-MS mass calcd for $C_{45}H_{52}N_6O_8P$ $(M - H)^-$: 835.37. Found: 835.4.

5′-*O*-(4,4′-Dimethoxytrityl)-*N*$^{2'}$-trifluoroacetamido-2′-deoxyuridine-3′-*O*-(2-cyanoethyl *N*,*N*-diisopropylaminophosphoramidite), **10.** While under argon **4** (100 mg, 0.163 mmol) was dissolved in dry dichloromethane (2 mL) containing DIEA (110 μL, 4 equiv). The reaction vessel was degassed several times prior to the addition of 2-chlorocyanoethyl *N*,*N*-diisopropylaminophosphoramidite (53 μL, 1.5 equiv) dropwise over 5 min. A positive ninhydrin test indicated formation of the desired product. After 90 min the reaction was diluted with ethyl acetate which had been previously washed with cold 10% sodium carbonate. The organic layer was extracted twice with cold 10% sodium carbonate and once with brine. The organic fraction was dried over sodium sulfate and evaporated to an oil. The residue was purified on silica (eluting with 20% hexane in dichloromethane containing 2% methanol and 1% TEA) to yield an off-white powder **10** in 77% yield (105 mg, 0.125 mmol). ^{1}H NMR (CD_3CN, 300 MHz) δ 1.26 (d, 12H), 3.4 (m, 2H), 3.5 (m, 2H), 3.6−3.8 (m, 3H), 3.79 (s, 6H), 4.1 (m, 2H), 4.3 (m, 1H), 4.4 (m, 1H), 4.5 (m, 1H), 4.7 (m, 1H), 4.8 (m, 1H), 5.4 (d, 1H), 5.8 (s, 1H), 6.1 (d, 1H), 6.9 (m, 4H), 7.3 (m, 9H), 7.5 (m, 2H), 7.6 (t, 1H), 7.9 (s, 1H). ^{31}P NMR (CD_3CN, 300 MHz) δ 153.13 and 154.06 ppm observed for the diastereomers. ESI-MS mass calcd for $C_{41}H_{46}F_3N_5O_9P$ $(M - H)^-$: 840.31. Found: 840.2.

Oligonucleotide Synthesis. Protected deoxyribonucleoside phosphoramidites and other reagents required for solid-phase DNA synthesis were purchased from Applied Biosystems, Incorporated (ABI). All oligonucleotides were synthesized on a 1.0 μmole scale. Solid supports (**7**, **8**) were packed in column assemblies purchased from ABI and contained approximately 23 mg of derivatized resin, depending on the nucleoside loading. The initial coupling steps in each synthesis were increased from 30 s to 2 min. The concentration of phosphoramidites (**9**, **10**) typically ranged from 0.1 to 0.18 M in dry acetonitrile. The coupling time for **9** and **10** was 15 min.

Oligonucleotides **11**, **13**, and **14** were synthesized with the terminal dimethoxytrityl (DMT) group retained. Oligonucleotide **12** was prepared with the 5′-DMT group removed prior to cleavage and deprotection. Oligonucleotides **11**−**13** were cleaved from the solid support with concentrated ammonia during the automated synthesis routine and deprotected for either 16 h at 55 °C or 4 h at 65 °C. Oligonucleotide **14** was cleaved manually in 5 mL of concentrated ammonia for 16 h at 55 °C. Oligonucleotides **15**−**18** were prepared by standard trityl-off procedures.

Oligonucleotide Purification. Deprotected oligonucleotides containing a 5′-DMT group were suspended in 20% triethylammonium bicarbonate buffer (1.0 M, pH 8.5) in water and injected onto a reverse phase VYDAC 201HS1022 C18 column. Preparative HPLC was performed with a Waters 600E Controller and 994 Diode Array Detecter, using the following gradient: 0−100% B over 50 min, where A = 0.1 M triethylamine acetate, 2% acetonitrile; B = 0.05 M triethylamine acetate, 50% acetonitrile. The collected peaks were dried in vacuo and further purified using Waters C18 Classic SepPak cartridges. The amount of purified oligonucleotide was determined spectrophotometrically, with ϵ_{260} values given in parentheses: **11** (119800 M^{-1} cm^{-1}), **12** (115150 M^{-1} cm^{-1}), **13** (95900 M^{-1} cm^{-1}), **14** (97250 M^{-1} cm^{-1}).



Oligonucleotides **11**, **13**, and **14** were detritylated according to the procedure outlined by ABI manual and desalted using SepPak cartridges (*7*). The detritylated oligonucleotides were further purified using a weak anion exchange column purchased from SynChroPak (AX-100, analytical, semiprep), using the following gradient: 0−90% B over 35 min, where A = 50 mM sodium phosphate (pH 5.9), 30% methanol; B = 50 mM sodium phosphate (pH 5.9), 30% methanol, 1 M ammonium sulfate. The collected peaks were desalted using SepPak cartridges and assayed as described above.

Oligonucleotide Yield. The overall yield of each modified oligonucleotide, following HPLC purification and workup, ranged from 30 to 40%, based on a 12-μmol synthesis. The detritylated, purified oligonucleotides **11**−**14** were characterized by MALDI-TOF mass spectrometry: **11**, calculated, 3355 [M], found, 3356.24 $[M - H]^-$; **12**, calculated, 3408 [M], found, 3407.17 $[M-H]^-$; **13**, calculated, 3230 [M], found, 3228.38 $[M - H]^-$; **14**, calculated, 3320 [M], found, 3319.43 $[M - H]^-$.

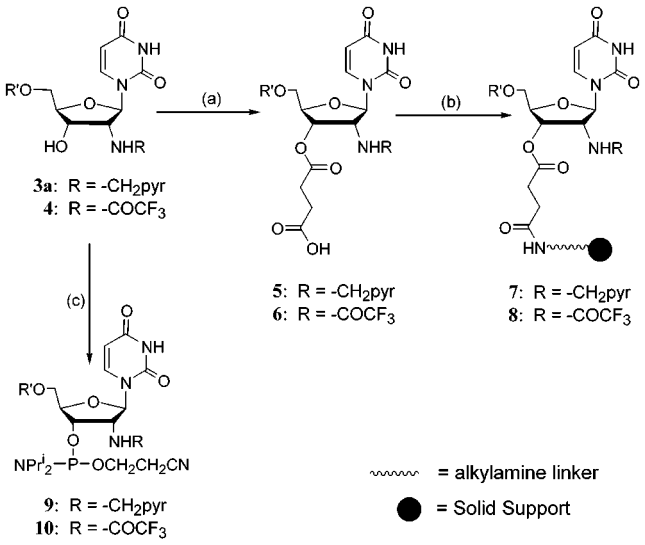
Enzymatic Digestion of Oligonucleotides and HPLC Analysis. Approximately 10−30 nmol of purified oligonucleotide was subjected to enzymatic digestion analysis. The digest cocktail (55 μL/sample) contained bacterial alkaline phosphatase (4 μL, 10 μL/unit) and snake venom phosphodiesterase (2.4 μL, 1 mL/mg), in 1 M $MgCl_2$ (0.8 μL), 0.5 M Tris buffer, pH 7.5 (3.5 μL). The reaction mixture was incubated at 37 °C for 8−16 h. The reaction was stopped by adding 3 M sodium acetate (7 μL) and ethanol (155 μL) to the samples, which were then frozen on dry ice (10 min) and centrifuged (10 min) at 4 °C. The supernatants were removed and transferred to new tubes, each containing 452 μL of ethanol. The samples were frozen and centrifuged; the resulting supernatants were removed and dried in vacuo. The samples were dissolved in water (200 μL) and injected onto a reverse phase Vydac (201HS54 4.6 mm × 25 cm, 5 μm, 90 Å) or Prism (Keystone Scientific, 4.6 × 250 mm, 5 μm, 100 Å) C18 column. The product nucleosides were eluted within 20 min, according to either of the following gradients: (Vydac) 0−30% B over 20 min then 30−100% B over 10 min, where A = 0.1 M triethylamine acetate, 2% acetonitrile, B = 0.05 M triethylamine acetate, 50% acetonitrile; (Prism) 0−17% B over 15 min then 17−75% B over 18 min, where A = 0.1 M triethylamine acetate, pH 7.0, 2% acetonitrile, B = 100% acetonitrile. The resulting peaks were compared against the appropriate set of nucleoside standards for a given oligonucleotide sequence.

Thermal Denaturation Measurements. Individual oligonucleotides were hybridized to their complementary strands in 50 mM NaP_i buffer (pH 7.0), 0.5 M NaCl, to give solutions that were 2.7 μM in each strand. The samples were heated for 20 min at 70 °C and cooled to 4 °C overnight. Thermal denaturation profiles were measured at 260 nm with an Hewlett-Packard diode array UV−vis spectrophotometer equipped with a Peltier temperature controller and interfaced with a personal computer. Samples were equilibrated at 20 °C for 10−20 min prior to data collection. Absorbance values were taken over a temperature range of 20−70 °C, with measurements made every 0.5 °C with an equilibration time of 60 s for each point. Each hybrid went through 2−4

Scheme 1[a]

[a] Reagents: (a) $(imid)_2CO$, pyridine, rt, 30 h; (b) NH_2R (R = CH_2pyr, CH_2CH_2pyr), DIEA, CH_2Cl_2, rt, 60 h; (c) DBU, THF, reflux, 46 h; (d) 6 N NaOH, dioxane, CH_3OH, 50 °C, 36 h. Abbreviation: R = 4,4′-dimethoxytrityl.

separate heat-cool cycles, and the T_m values obtained from these heating and cooling traces were averaged to give the final T_m value. Standard deviations were calculated for each duplex.



RESULTS

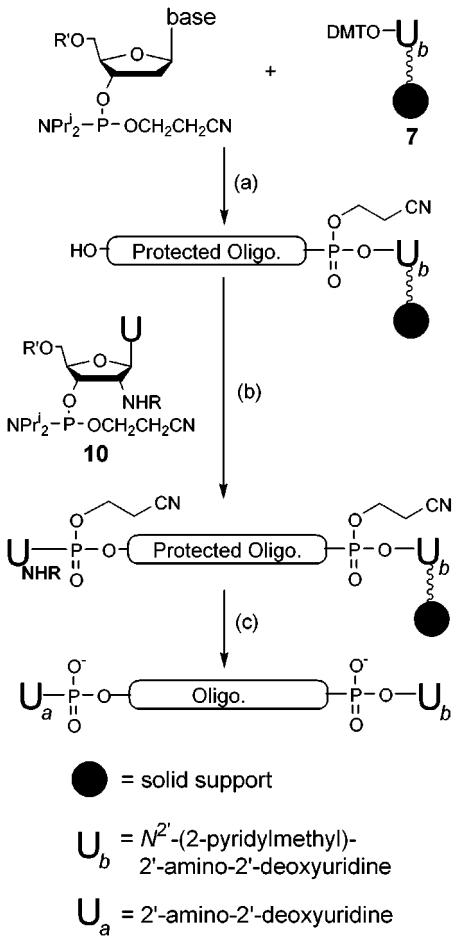
Synthesis of 2′-Modified Nucleosides. Nucleosides with bidentate amine groups such as aminomethylpyridine (AMPy) (*8*) and aminoethylpyridine (AEPy) at the 2′ ribose position were prepared as shown in Scheme 1. This approach was based on methods developed recently for incorporating 2′-*N*-alkylamino substituents into nucleosides (*9*). Nucleoside **1** was converted to the 3′-*N*-alkyl carbamate upon prolonged treatment with carbonyl diimidazole in pyridine; this was followed by the addition of AMPy or AEPy in the presence of DIEA and dichloromethane. Subsequent cyclization in THF using the cyclization agent DBU produced either **2a** or **2b** in yields of 20% and 10%, respectively. Prolonged heating of **2a** and **2b** in a basic dioxane−methanol solution caused deprotection at the 2′,3′-positions, giving **3a** and **3b** in high yield (92% and 88%, respectively).

Derivatization of solid supports with 2′-modified nucleosides was achieved according to Scheme 2. Nucleoside **4** was prepared according to previously published procedures (*3a, 5, 10*). Both **3a** and **4** were treated with succinic anhydride to give the corresponding hemisuccinates **5** and **6** in yields of 60% and 74%, respectively (*6, 11*). Solid supports such as controlled pore glass (CPG) containing long-chain alkylamine groups were derivatized with **6** using *p*-nitrophenol and DCC. This method resulted in solid supports with low nucleoside loading. Subsequent attempts to prepare the nucleoside-modified solid supports employed the coupling agent BOP in the presence of HOBT and TEA (*12*). The unreacted amine groups were treated with acetic anhydride, and the nucleoside loadings of the solid supports **7** and **8** were determined by spectrophotometric assay (60 and 52 μmol/g, respectively) (*6*).

The preparation of phosphoramidite derivatives of nucleosides **3a** and **4** relied on standard methods (*3a, 6, 10*). Nucleosides **3a** and **4** were treated with 2-chlorocyanoethyl *N*,*N*-diisopropylaminophosphoramidite in the presence of DIEA to give **9** and **10** in 57% and 77% yield, respectively (Scheme 2).

Scheme 2[a]

[a] Reagents: (a) succinic anhydride, pyridine, DMAP, rt, 16 h; (b) solid support, TEA, HOBT, BOP, CH_2Cl_2, rt, 16 h; acetic anhydride, *N*-methylimidazole, pyridine, rt, 12 h; (c) amidite, DIEA, CH_2Cl_2, rt, 50 min. Abbreviation: R′ = 4,4′-dimethoxytrityl.



Oligonucleotide Synthesis. A series of oligonucleotides were prepared from the support-bound and phosphoramidite nucleoside derivatives as outlined in Scheme 3 (see Table 1 for sequences). To maximize coupling, the reaction time for the first step was increased from 30 s to 2 min (yield > 95%). The reaction times for **9** and **10** were 15 min in length, leading to coupling yields > 90%.

All oligonucleotides were cleaved from the solid support with concentrated ammonia as a part of the automated synthesis routine, except in the case of **14**, which was manually cleaved. The yield of purified oligonucleotide for **11**−**14** ranged from 30 to 40%, which was comparable to those values observed for **15**−**18**. Results from MALDI-TOF mass spectrometry on **11**−**14** were in excellent agreement with the calculated values. Further characterization of these oligonucleotides was achieved by enzymatic digestion with alkaline phosphatase and phosphodiesterase (Figure 2) (*7*). Analysis of the digestion products showed the expected distribution of nucleosides determined for each oligonucleotide sequence (*13*).

Thermal Denaturation Studies. We investigated the thermal stability of duplexes containing 2′-modified nucleosides. Table 2 shows the transition melting temperatures (T_m) for each duplex prepared in 50 mM sodium phosphate buffer (pH 7.0) containing 0.5 M sodium chloride. The T_m of the 11-mer duplex formed by the unmodified oligonucleotides **15** and **16** was 48 °C. When one 5′-terminal nucleoside from this duplex was substituted with either 2′-amino-2′-deoxyuridine ($\mathbf{U_a}$) or $N^{2'}$-(2-pyridylmethyl)-2′-amino-2′-deoxyuridine ($\mathbf{U_b}$), the T_m value remained unchanged (T_m = 47 °C for duplexes **11**:**15** and **12:16**). When both $\mathbf{U_a}$ and $\mathbf{U_b}$ were incorporated at the 5′ ends of the same duplex (**11:12**), the T_m value decreased to 45 °C.

The small change in the melting profile was similar to the results obtained with duplexes of identical length, GC content, and type of nucleoside modification, but of different sequence. This second set of duplexes contained

5′- TCTCCTACACT	**17**
5′- AGTGTAGGAGA	**18**

[a] The symbol **U$_a$** denotes 2′-amino-2′-deoxyuridine; **U$_b$** denotes $N^{2'}$-(2-pyridylmethyl)-2′-amino-2′-deoxyuridine.

2′-modified nucleosides at both the 3′ and 5′ ends of the same strand. Duplex **13:18** contained **U$_a$** nucleosides at the 5′ and 3′ termini, whereas duplex **14:18** contained **U$_a$** at the 5′ end and **U$_b$** at the 3′ end. The T_m values (46 °C) for duplexes **13:18** and **14:18** decreased slightly in comparison to the value of the unmodified duplex **17:18** (T_m = 48 °C; Figure 3).

DISCUSSION

Synthetic Strategy. Two general methods exist for preparing oligonucleotides containing transition metal complexes. One method involves the synthesis of nucleosides that possess metal-binding ligands, followed by incorporation of these modified nucleosides into oligonucleotides and subsequent metal complexation at the specific attachment sites (*3e, 14*). The second method

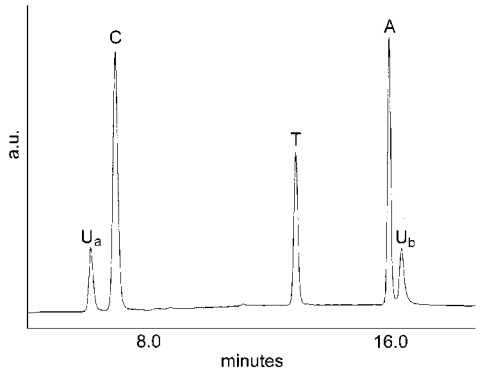

Figure 2. Products of enzymatic digestion of **14** as analyzed by reverse-phase HPLC.

Table 2. Thermal Denaturation Temperatures for Oligonucleotides Containing 2′-Substituted Nucleosides

duplex	T_m[a] (°C)	modification[b]
15:16	48.2 ± 0.5	none
11:15	46.6 ± 0.4	5′ **U$_a$**
12:16	46.7 ± 0.4	5′ **U$_b$**
11:12	45.0 ± 0.5	5′ **U$_a$**, 5′ **U$_b$**
17:18	47.6 ± 0.2	none
13:18	45.8 ± 0.5	5′ **U$_a$**, 3′ **U$_a$**
14:18	46.2 ± 0.5	5′ **U$_a$**, 3′ **U$_b$**

[a] Values determined in 50 mM NaP_i buffer (pH 7.0) containing 0.5 M NaCl. The concentration of each oligomer was 2.7 μM. [b] The symbol **U$_a$** denotes 2′-amino-2′-deoxyuridine; **U$_b$** denotes $N^{2'}$-(2-pyridylmethyl)-2′-amino-2′-deoxyuridine.

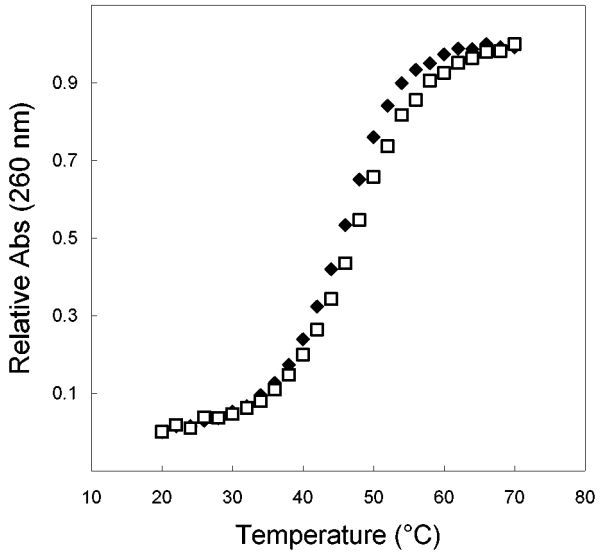

Figure 3. Thermal denaturation curves for the unmodified duplex **17:18** (□) and modified duplex **14:18** (◆).

entails the synthesis of metal-containing nucleosides that are incorporated during solid-phase oligonucleotide synthesis (*4ab, 15*). The 2′-modified nucleosides described in this work can be used in either method, resulting in oligonucleotides site-specifically labeled with metal complexes (*3e, 4*).

The choice of 2′-substituents described here are based on ligands that avidly bind transition metal complexes, such as AMPy and AEPy (*16*). The site-specific labeling of oligonucleotides with metal reagents is of considerable interest for several reasons. Recent experiments involving ruthenium-modified duplexes have shown that DNA can mediate energy and electron transfer reactions (*3e, 15f, 17*). Additionally, metal-modified primers have been used in dideoxy DNA sequencing techniques and elec-

trochemistry-based DNA assays (*18*). Therefore, nucleosides containing metal-binding ligands such as those in Figure 1 can facilitate the use of metal complexes as probes of nucleic acid structure and function (*3e, 4*).

Synthesis of 2′-Modified Nucleosides. The synthesis of nucleosides containing 2′-*N*-alkylamino substituents is an extension of methods developed by Sebesta, McGee, and co-workers (*9*). The yields of isolation determined for **2a** and **2b** are lower than those observed for nucleosides containing similarly bulky substituents and may be attributed to the purification conditions required for DMT-protected vs silyl-protected intermediates (*9a*). The products **3a** and **3b** are isolated in yields comparable to the yields reported by Sebesta for similar 2′-modified nucleosides.

The preparation of solid supports derivatized with 2′-modified nucleosides is complicated by the poor steric accessibility of the 3′ ribose site (*19*). The steric bulk at the 2′ position hinders the reaction of the 3′ hydroxyl with succinic anhydride. Succination of **3a** and **4** proceeds in reasonable yields and demonstrates that both small and large functional groups at the 2′ position can be tolerated in the succination step. High nucleoside loadings for **7** and **8** are achieved using the coupling agent BOP and an excess of nucleoside hemisuccinate in the derivatization step. While the solid support employed here is glass-based, the method is applicable to other supports containing long-chain alkylamine linkers.

Successful derivatization of supports with nucleosides such as **3a** and **4** affords the synthesis of 3′ oligonucleotide conjugates in which the label is incorporated *directly* on the ribose ring. This is a significant advance since the current preparation of 3′ oligonucleotide conjugates is achieved with supports containing either nucleosides with *base-tethered* primary amine groups (*20*) or *nonnucleosidic* amine derivatives (*21*). The ribose is an attractive attachment site since the labels introduced here cause fewer perturbations to the secondary duplex structure than labels attached to the nucleoside base (*4*). Additionally, the absence of a long linker between the attachment site and the incorporated label minimizes disruptions to the hydrogen bonding capacity of the oligonucleotide conjugate.

Oligonucleotide Synthesis with 2′-Modified Nucleosides. The successful large-scale synthesis of several 11-mer oligonucleotides validates the utility of 2′-modified nucleosides as support-bound and phosphoramidite derivatives (Table 1). Oligonucleotide synthesis beginning with **7** or **8** proceeds with minor modification to the automated protocol. The coupling yields of phosphoramidites **9** and **10** are acceptable for routine oligonucleotide preparation, and the purification of the several 11-mer modified oligonucleotides is straightforward. The isolation yields for **11**−**14** are comparable to values determined for oligonucleotides **15**−**18** under identical synthetic and purification conditions, implying that the use of 2′-modified nucleosides does not compromise the overall yield.

Effect of 2′-Modified Nucleosides on Duplex Stability. The presence of nucleosides containing ribose substituents at the 2′ position causes slight destabilization to the modified duplexes, as assessed by thermal denaturation studies. Interestingly, analysis of the transition melting (T_m) temperatures listed in Table 2 suggests that the T_m values are influenced by the number of 2′-modified nucleosides present in a duplex, not the size of the 2′ substituent. For example, thermal denaturation of duplexes **11:15** and **12:16** produces identical T_m values, despite the difference in the size of the 2′ substituent (−NH_2 vs AMPy). The T_m of **11:12** shows the effect of placing two 2′-modified nucleosides at the 5′ ends of the duplex. Similar results are obtained with a second set of duplexes identical in length, GC content, and type of nucleoside modification. The placement of two 2′-modified nucleosides at the 5′ and 3′ ends of the same strand results in duplexes destabilized by 1−2 °C (**13:18** and **14:18** vs **17:18**). We conclude that the extent of duplex destabilization is the same when two 2′-modified nucleosides are introduced at either (1) the 5′ and 3′ ends of a one strand hybridized to its complement, or (2) the 5′ ends of complementary strands.

Compared to 2′-*deoxy*nucleosides, 2′-*amino*nucleosides favor the 2′-endo sugar conformation to a higher degree (*22*). This observation suggests that 2′-aminonucleosides should stabilize DNA/DNA duplexes. However, T_m data for a series of 9-mer duplexes containing a 2′-aminonucleoside in the middle of the sequence indicate that the presence of these modified nucleosides has a destabilizing effect (*3a*). Our work shows that placement of the 2′-amino-modified nucleosides at the ends of the duplexes minimizes the destabilization imposed by the altered sugar conformation.

CONCLUSION

We report the synthesis of 2′-modified nucleosides designed specifically for incorporating reporter molecules into oligonucleotides. Because these nucleosides contain modifications to the ribose ring (as opposed to the nucleobase), they are important contributions to current library of modified nucleosides. The introduction of metal-binding ligands at the 2′ position is achieved after two steps. Conversion of these nucleosides to solid support-bound and phosphoramidite derivatives proceeds in good yield. The powerful combination of these derivatives affords the preparation of an entirely new class of oligonucleotide conjugates—those which contain label attachment sites at 3′, intervening, and 5′ sites of a duplex.

Thermal denaturation studies indicate that the presence of 2′-modified nucleosides in 11-mer duplexes has a slight destabilizing effect on the duplex structure. This effect is limited by the selective placement of these nucleosides at the ends of the duplexes. Interestingly, the size of the metal-binding substituent does not influence the magnitude of the destabilization. This characteristic makes these 2′-modified nucleosides even more attractive for use in the site-specific incorporation of reporter molecules into oligonucleotides.

The methodologies employed here can be extended to other modified nucleosides. Succination yields for nucleosides containing metal-binding ligands at locations other than the 2′ position are expected to be much higher due to the absence of steric constraints. While the solid support is glass-based, the method is applicable to other solid supports containing any long-chain alkylamine linker. The library of solid supports containing modified nucleosides can be significantly expanded with the coupling conditions described here. These nucleoside reagents will enable the incorporation of labels known to be useful probes of nucleic acid structure and function.

ACKNOWLEDGMENT

The authors wish to thank Thomas W. Welch, C. J. Yu, Jeffrey J. Rack, and Natia L. Frank for helpful discussions. This work was supported by NIST (ATP) Award 70NANB5H1031, Jet Propulsion Laboratory (JPL 67192), and the Beckman Institute Biological Imaging Center.

Received September 27, 2001

A high-performance affinity purification technique has been developed for cisplatin (CDDP)-damaged DNA binding proteins directly from crude nuclear extracts of HeLaS3 cell using novel submicron beads synthesized by copolymerization of styrene and glycidyl methacrylate (GMA). The beads dramatically decreased both nonspecific protein adsorption on solid surfaces and elution volume and simplified the handling procedure. Preparation of the beads for purification was carried out by immobilization of telomeric repeats, $(TTAGGG)_n$, on the surface after the reaction with CDDP. At least nine proteins clearly showed higher affinity to CDDP−DNA and were identified by amino acid sequence analysis including HMGB (high mobility group), hUBF (human upstream binding factor), and Ku autoantigen, which were previously reported to be components of CDDP-damaged DNA binding proteins.

INTRODUCTION

Cisplatin (*cis*-diamminedichloroplatinum(II), CDDP) has been widely used as a chemotherapeutic agent in several types of cancer including ovarian, testicular, bladder, small-cell lung, cervical, and head and neck carcinomas. One key step in its mechanism is the binding to DNA, which induces transcriptional interruption (*1*, *2*), cell cycle arrest (*3*), DNA repair (*4*), programmed cell death (apoptosis) via phosphorylation of tumor suppressor protein p53 (*5*), etc. The coordination binding of CDDP unwinds and bends the double helical DNA, especially in the case of intrastrand cross-links to G-rich sequences such as GG and AG (*6*). Various anticancer phenomena based on DNA-damage are attributable to the interactions between CDDP−DNA and some cellular proteins such as HMG-domain proteins acting as triggers (*7*, *8*). Though the purification of proteins binding to CDDP−DNA complexes was performed using affinity chromatography on cellulose (*9*), the efficiency was not

satisfactory because of the low binding ability. To solve this problem, we have developed novel submicron latex beads synthesized by copolymerization of styrene and GMA in a soap-free aqueous solution (*10*), with which drug receptors (*11*) and transcription factors (*12*) were successfully purified with high efficiency. In the present paper, we show for the first time that affinity proteins of CDDP−DNA can be totally analyzed in a very simple way by using whole protein extracts.

The human telomere, a G-rich region as tandem repeats of TTAGGG located at the ends of chromosomes, is important for stabilization of chromosomes, cell aging, and cancer growth (*13*). As the telomere length is known to be shortened by the treatment of CDDP in HeLa cells (*14*, *15*), there is a high possibility that the complex formation of CDDP and telomere is closely related to anticancer activity. Our attention was, therefore, focused on the interaction between the CDDP-telomere and cellular affinity proteins.

RESULTS AND DISCUSSION

Two complementary oligonucleotides, 5′- GGTTAGGGTTAG-3′ and 5′-CCCTAACCCTAA-3′, were chemically synthesized, annealed, 5′-phosphorylated, and ligated to give, on the average, several hundred base pairs of telomeric repeats, followed by gel filtration on Sephadex G-50. The telomeric repeats were reacted with CDDP in 10 mM phosphate buffer in the dark at 37 °C for 1 day according to the ref 15. The platinated DNA showed a gel mobility shift, and the platination reaction was pursued by gel electrophoresis using RI-labeled DNA. The platinum contents were determined by atomic absorption spectroscopy (AA) on a Varian spectrAA-400 spectrophotometer to get the bound drug-to-nucleotide $(D/N)_b$ of 0.079−0.083. A 100 mg amount of the resultant CDDP−DNA complex was reacted with the latex beads through the reaction between the surface epoxy groups and the amino groups of nucleic bases at the extruding ends of the double-strand DNA at 50 °C for 1 day, followed by masking the unreacted epoxy groups with ethanolamine (Figure 1). The yield of CDDP−DNA fixed on the beads (2−3 μg per mg of beads) was calculated from the amount of the unreacted DNA, and those beads showed a minimum amount of nonspecific protein absorption compared with the case of beads with a large amount of DNA on the surface. The DNA-fixed beads without CDDP and the ethanolamine-treated beads without DNA were also prepared as control samples.

Nuclear extracts (NE) and whole cell extracts (WCE) of HeLaS3 cells were prepared according to the methods of Dignam (*16*) and Manley (*17*), respectively. The DNA-fixed beads (2 mg) were suspended in 0.5 mL of NE or WCE including 20 μg of single-strand DNA and 2 μg of poly dI-dC in a 1.5 mL centrifuge tube. After incubation at 0 °C for 1 h, proteins were purified by the salt elution method as follows. The beads were spun down by brief centrifugation and washed three times with 0.1 mL of HEPES buffer containing 20 mM HEPES (pH 7.9), 10% glycerol, 5 mM $MgCl_2$, 0.2 mM EDTA, 0.5 mM dithiothreitol (DTT), and 0.1 M KCl and then washed five times with 0.1 mL of the buffer solution containing 0.4 M KCl. The proteins adsorbed on the beads were eluted three times with 0.1 mL of the buffer solution containing 1.0 M KCl. The proteins in each buffer solution were subjected to electrophoresis by SDS−PAGE, whose separated bands were detected by staining with silver (Figure 2). The affinity of eluted proteins to CDDP−DNA was confirmed by competition experiments in which certain amounts of free CDDP−DNA were added to the protein solution before incubation at 0 °C (Figure 3).

Figure 2 clearly shows the high-performance purification of CDDP−DNA affinity proteins. Compared with CDDP-free DNA beads (lane 2 or lane 4), some bands (especially 26.5, 28, 94, and 97 kDa) were recognized in the eluants from CDDP−DNA beads (lane 3 or lane 5) by silver staining. By using beads without DNA, adsorption of proteins was little observed under these conditions (lane 1). At least nine proteins had higher affinity to CDDP−DNA than to DNA without CDDP. Most of these proteins were identified by amino acid sequence analysis to be HMGB proteins (26.5 and 28 kDa), hUBF (human upstream binding factor, heterodimer of 94 and 97 kDa) proteins, and Ku autoantigen (heterodimer of 70 and 80 kDa), which were reported to interact with both telomeric repeat and CDDP−DNA as a part of DNA-dependent protein kinase (*18*, *19*). We further found mtTF1 (mitochondrial transcription factor 1, 24 kDa) as a new affinity protein and two other proteins whose biological functions are under investigation. Recent papers reported some relationship between telomere and DNA damage by CDDP in telomerase activity (*20*) and p53 dependent apoptosis (*21*), while the telomere is well-known as a transcriptional silent part of the genome.

It should be emphasized that the present technique is exceedingly simple (one-pot purification) and efficient despite using crude whole protein extracts in comparison with the ordinary affinity chromatography on cellulose or agarose that are more laborious procedures. Recently, affinity purification by Sepharose column chromatography was reported for CDDP−DNA (*22*). The new latex beads have the following characteristics superior to the conventional materials. Since the beads can be essentially treated as hard spheres with fairly monodisperse diameter (200 nm on average), chemical and physical reactions are not affected by diffusion-controlled processes inside the beads, which provide a homogeneous environment for binding between DNA and proteins. Subsequent polymerization of GMA after the styrene−GMA copolymerization makes the surface of the beads rather hydrophilic, which significantly reduces nonspecific adsorption of proteins on the beads. Easy removal of proteins from the beads through washing without requiring stringent conditions (e.g., high salt concentration) made it possible to isolate CDDP−DNA affinity proteins with binding constants relatively lower than those of sequence-specific DNA binding proteins. In addition, large surface area per weight (20 m^2 per 1 g) provides sufficient capacity to purify proteins in a milligram scale. Degree of the dilution of eluted proteins depends on the volume of the solution used for elution from the beads. Usually, only 50−100 μL of buffer is used for 1−10 mg of beads. Therefore, a precipitation procedure of the eluted proteins was not necessary to detect them by ordinary staining.

CONCLUSIONS

In the present method, an extensive analysis of binding proteins is generally possible under various conditions even when crude whole protein solutions are used. In addition, this simplified technique for affinity purification may be useful for screening chemical libraries to create new drugs and their receptor library in a short time directly from crude cell extracts.

Formation of a Bioconjugate Composed of Hemin, Smectite, and Quaternary Ammonium Chloride That Is Soluble and Active in Hydrophobic Media

Masaru Kurosawa, Tetsuji Itoh, Yoh Kodera, Ayako Matsushima, Misao Hiroto, Hiroyuki Nishimura, and Yuji Inada*

Toin Human Science and Technology Center, Department of Biomedical Engineering, Toin University of Yokohama, Kurogane-cho, Aoba-ku, Yokohama 225−8502. Received November 2, 2000; Revised Manuscript Received August 27, 2001

Hemin (Fe^{3+}) was adsorbed onto synthetic smectite (clay mineral) intercalated with a quaternary alkenylammonium compound, dioleyldimethylammonium chloride (DOA), to form a hemin−smectite−DOA conjugate. The hemin−smectite−DOA conjugate was soluble in organic solvents such as benzene and toluene to form a transparent colloidal solution with a light yellow color. Its absorption spectrum in benzene showed two bands, 600 and 568 nm, in the visible region and a sharp Soret band at 400 nm with the molar extinction coefficient of 7.5×10^4 M^{-1} cm^{-1}. The formation of the conjugate of smectite and DOA was confirmed by X-ray diffraction analysis: the basal spacing, *d*(001), of hemin−smectite−DOA conjugate was 19 Å which is an expansion of the interlayer space by 5 Å based upon the basal spacing of smectite of 14 Å. Hemin−smectite−DOA conjugate catalyzed the peroxidase-like reaction in organic solvents using benzoyl peroxide as the hydrogen acceptor and leucocrystal violet as the hydrogen donor. The temperature-dependent peroxidase-like activity of the conjugate was compared with peroxidase activity of horseradish peroxidase. The hemin−smectite−DOA conjugate exhibited higher activity as the temperature was increased from 30 to 70 °C, while horseradish peroxidase activity was reduced as the temperature was increased.

INTRODUCTION

Hemin (Fe^{3+}), a prosthetic group of heme-proteins and enzymes, plays an important role by itself in oxido-reductions such as oxidation of a compound with peroxide. Hemin (Fe^{3+}) liberated from holoenzyme is not soluble in neutral aqueous solution and in organic solvents such as benzene and chloroform. However, hemin (Fe^{3+}) itself has a catalytic potential, and several studies have been performed concerning the peroxidase activity (*1*) and catalase activity (*2*) in aqueous solution. It should be noted that hemin molecules tend to aggregate and dimerize in aqueous solutions (*3*), and its catalytic activity is often decreased through dimerization and polymerization (*4*). There are several ways of avoiding the aggregation and dimer formation of hemin (Fe^{3+}) (*5*), and the utilization of detergents was found to be one of the simple but useful techniques (*6*). On the other hand, hemin (Fe^{3+}) has been seldom used as a catalyst in organic media because it is not soluble in organic media.

Chemical modification of proteins with poly(ethylene glycol) (PEG),[1] a nontoxic, nonimmunogenic, and amphipathic polymer, has been extensively studied for the purpose of applying proteins to biomedical and biotechnological processes (*7*, *8*). In the biotechnology field, PEG-modified hydrolases, which are soluble and active in hydrophobic media, catalyze the reverse reactions of hydrolysis, ester synthesis, and ester exchange reactions (*9*, *10*). Along this line of investigations, Takahashi et al. (*11*) prepared PEG-modified hemin (Fe^{3+}) with peroxidase activity in hydrophobic media.

Recently, we have found a clay mineral, smectite, having a catalytic function as seen in a living body, by binding it with bioactive substances. The heme (Fe^{2+})−smectite conjugate, formed by combining smectite with heme (Fe^{2+}), has similar properties to those of hemoglobin or myoglobin in terms of adsorption and desorption of oxygen and carbon monoxide (*12*). Furthermore, chlorophyll *a*−smectite conjugate, smectite conjugated with chlorophyll *a* in place of heme (Fe^{2+}), has proved to be stable in sunlight and to produce hydrogen gas (*13*).

The present study deals with a conjugate of hemin (Fe^{3+}), smectite, and quaternary ammonium compound, dioleoyldimethylammonium chloride (DOA). The layer of smectite was expanded by conjugating with DOA, and consequently the hemin−smectite−DOA conjugate became soluble in organic solvents such as benzene and toluene to form a transparent colloidal solution. Furthermore, the conjugate had a peroxidase-like activity in hydrophobic media.

EXPERIMENTAL PROCEDURES

General. Hemin (crystalline) and horseradish peroxidase (116 purpurogallin units/mg solid) was purchased

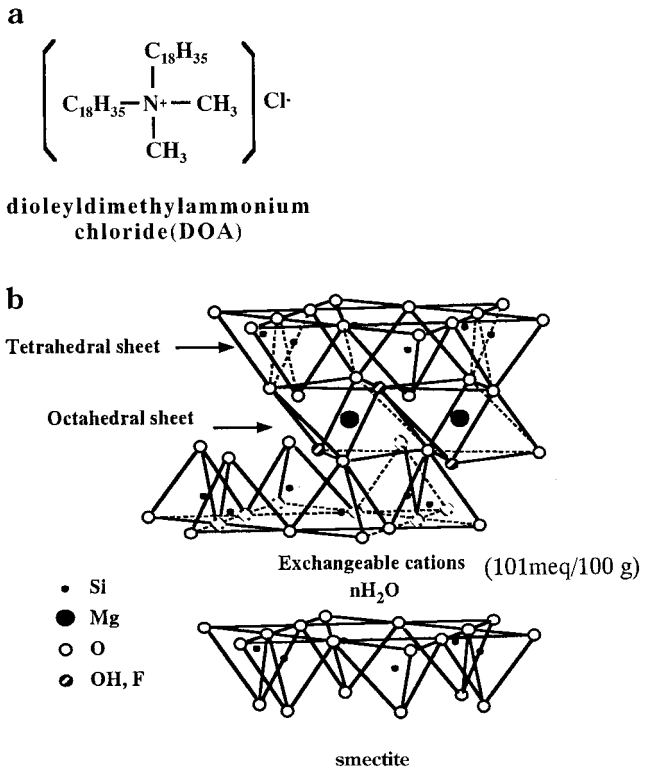

Figure 1. (a) Structure of dioleyldimethylammonium chloride (DOA). (b) The chemical structure of smectite in a crystal state consists of two sheets of linked SiO_4 tetrahedra sandwiching an octahedral cation (Mg) between them, and the interlayer. Elemental composition Si 8.00, Mg 5.65, Li 0.70, Na 1.05; transmittance 95% in 1% aqueous solution at 500 nm; and methylene blue absorption 101 milliequiv per 100 g.

from Sigma Chemical Co. (St. Louis, MO). Dioleoyldimethylammonium chloride (DOA) was kindly provided by Nippon Oil and Fats Co., Ltd. (Tokyo, Japan). Smectite powder (hectorite), which was hydrothermally synthesized by Torii et al. (*14*), was obtained from Co-op Chemical Co., Ltd. (Tokyo, Japan). The chemical structure and property of DOA and smectite were shown in Figure 1. Leucocrystal violet was obtained from Tokyo Kasei Kogyo Co., Ltd. (Tokyo, Japan). Other reagents used were of analytical grade.

Preparation of Hemin−Smectite−DOA Conjugate. The hemin (Fe^{3+})−smectite conjugate was prepared from hemin and smectite by the method of Itoh et al. (*12*). To 36 mL of acetone solution containing hemin (0.9 mg) was added 300 mg of smectite powder. The suspension was shaken for 1 h at 25 °C to establish the adsorption equilibrium between hemin (Fe^{3+}) and smectite. The hemin (Fe^{3+})−smectite conjugate thus formed was collected by centrifugation and was dried under reduced pressure. The amount of hemin (Fe^{3+}) adsorbed onto smectite was spectrophotometrically determined by measuring the absorbance of the supernatant liquid obtained by centrifugation of the sample suspension.

Since smectite[2] has cation-exchange properties of 101 mequiv/100 g of smectite, hemin−smectite conjugate must be bound with quaternary alkenylammonium compound, dioleyldimethylammonium chloride (DOA) (Figure 1a), with ion-exchange reaction. To 20 mL of hemin−smectite conjugate dissolved in water (15 mg/mL) was added 0.68 mL of DOA colloidal solution (70%), and the suspension was then stirred for 7 h at 25 °C to form hemin−smectite−DOA conjugate. The conjugate was collected by centrifugation and was dried under reduced pressure. The absorption spectra of hemin−smectite in water and hemin−smectite−DOA conjugates in organic solvents were measured with a Shimadzu MPS-2000 multipurpose spectrophotometer (Kyoto, Japan). One gram of hemin−smectite−DOA conjugate consists of 2 mg of hemin, 633 mg of smectite, and 365 mg of DOA. X-ray powder diffraction (XRD) analyses were carried out with a Rigaku diffractometer (RTP-300) using monochromatized Cu Kα radiation.

Measurement of Peroxidase Activity of Hemin−Smectite−DOA Conjugate in Organic Solvents. The peroxidase activity of hemin−smectite−DOA conjugate was tested by the modified method of Ajima et al. (*16*). The first series of experiments was conducted by measuring the peroxidase activity of hemin−smectite−DOA conjugate (0−0.32 μM) in an organic solvent, benzene. The reaction system consists of benzoyl peroxide (0−0.66 mM) as a hydrogen acceptor and leucocrystal violet (16.7 mM) as a hydrogen donor. The reaction was carried out for 5 min at 25 °C in the dark. The peroxidase activity of hemin−smectite−DOA conjugate in benzene was spectrophotometrically determined by measuring the amount of oxidized crystal violet using the molar extinction coefficient of $\epsilon_{604\ nm} = 1.2 \times 10^5\ M^{-1}\ cm^{-1}$ (*17*). The second series of experiments was conducted by measuring temperature-dependent peroxidase activity of hemin−smectite−DOA conjugate using benzoyl peroxide and leucocrystal violet as well as horseradish peroxidase using hydrogen peroxide and guaiacol. The peroxidase activity of the conjugate in toluene was spectrophotometrically determined by measuring the absorbance change of oxidized crystal violet at 604 nm/min at temperatures from 30 to 70 °C. As a control experiment, the peroxidase activity of the horseradish peroxidase, instead of hemin−smectite−DOA conjugate, in 0.1 M phosphate buffer (pH 7.4) was determined as follows: the reaction system consisted of horseradish peroxidase in 0.1 M phosphate buffer (pH 7.4), hydrogen peroxide (0.13 mM), and guaiacol (0.28 mM), and its activity was spectrophotometrically determined by measuring the absorbance change of oxidized guaiacol at 460 nm/min at temperatures from 30 to 70 °C.

RESULTS AND DISCUSSION

Absorption Spectra of Hemin−Smectite Conjugate in Water and Hemin−Smectite−DOA Conjugate in Benzene. Hemin, or ferriprotoporphyrin, is practically insoluble in water and in organic solvents except for strong organic bases such as trimethylamine and dimethylaniline. Hemin conjugated with smectite, hemin−smectite conjugate, was soluble in water to form a brownish, transparent colloidal solution. Addition of DOA, quaternary alkenylammonium compound, to hemin−smectite conjugate in water caused the precipitation of hemin−smectite−DOA in which DOA was bound to smectite by a cation-exchange reaction in the interlayer space of hemin−smectite. Then hemin−smectite−DOA conjugate was dissolved in hydrophobic media such as benzene and toluene.

[2] The smectite (hectorite), which was hydrothermally synthesized, had unique physical and chemical properties such as high transparency in water, cation exchange, and the ability to form organic and inorganic interlayer complex (*14*). Expandable phyllosilicates have a structure composed of alternating 2:1 layer, which consists of two sheets of linked SiO_4 tetrahedra sandwiching octahedral cations, Mg, between them (Figure 1 b). The 2:1 layers, which have a net negative charge (layer charge), are loosely tied together by interlayer cations. Water also is present between the layers.

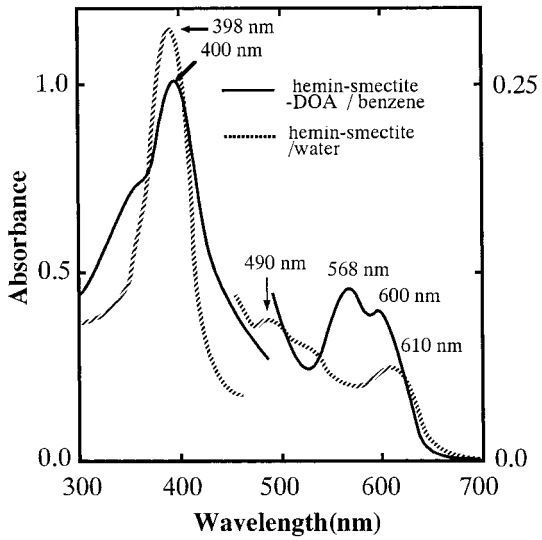

Figure 2. Absorption spectra of hemin–smectite–DOA conjugate and hemin–smectite conjugate. The spectrum of hemin (Fe^{3+})–smectite–DOA conjugate (13 μM) in benzene is shown by a solid line with a sharp Soret band at 400 nm. The spectrum of hemin (Fe^{3+})–smectite conjugate (10 μM) in water is shown by a dotted line with a sharp Soret band at 398 nm.

Figure 2 presents the absorption spectra of hemin–smectite–DOA conjugate in benzene (solid line) and hemin–smectite conjugate in water (dotted line). The absorption spectrum of hemin–smectite–DOA conjugate in benzene has the absorption maxima at 568 nm with a shoulder at 600 nm and Soret band at 400 nm in visible region. The molar extinction coefficient at the Soret band was calculated to be $\epsilon_{400\ nm} = 7.5 \times 10^4\ M^{-1}cm^{-1}$ in benzene (Table 1). On the other hand, the spectrum of hemin–smectite conjugate in water shows two peaks at 610 and 490 nm and the sharp Soret band at 398 nm with $\epsilon_{398\ nm} = 11.6 \times 10^4\ M^{-1}\ cm^{-1}$ in water which is closely in agreement with the molar extinction coefficient of monomeric hematin in water, $12.2 \times 10^4\ M^{-1}\ cm^{-1}$ (*15*). Table 1 summarizes the physicochemical and spectrophotometric properties of hemin–smectite–DOA conjugate together with its compositions. As is clear from the table, the basal spacing of smectite was determined to be 14 Å and that of smectite conjugated with DOA was determined to be 19 Å, indicating an expansion of the interlayer space by 5 Å. Furthermore, the layer of smectite conjugated with hemin was hardly expanded as described above. Therefore, it can be reasonably assumed that hemin is adsorbed onto surface of smectite, and DOA is intercalated in the basal spacing of smectite. Although hemin–smectite conjugate became easily soluble in water to form a transparent colloidal solution with a dark brown color, the conjugate is never soluble in benzene. However, hemin–smectite–DOA conjugate was freely soluble in organic solvents such as benzene and toluene to form a transparent colloidal solution with light yellow color (Figure 2). The solubility of hemin–smectite–DOA conjugate together with its components are shown in Table 1.

Table 1. Physicochemical and Spectrophotometric Properties of Hemin–Smectite–DOA Conjugate Together with Its Compositions

conjugate	*d* (001), Å	Soret band, nm (ϵ_{mM})	solubility[a] water	solubility[a] benzene
DOA[b]	-	-	±	+
hematin	-	398 (122)[c]	±	−
smectite	14	−	+	−
hemin–smectite	14	398 (116)	+	−
hemin–smectite–DOA	19	400 (75)	−	+

[a] +, −, ±: transparent colloidal solution, insoluble, and sparingly soluble, respectively. [b] Dioleyldimethylammonium chloride. [c] Monomeric hematin (*15*).

Peroxidase Activity of Hemin–Smectite–DOA Conjugate in Hydrophobic Media. The finding shown above leads to the study on the peroxidase activity induced by hemin–smectite–DOA conjugate in organic solvents. The first series of experiments was conducted with oxidation of leucocrystal violet (AH) by benzoyl peroxide in the presence of hemin–smectite–DOA conjugate in benzene as shown below (Scheme 1).

Scheme 1

$$\text{Peroxide} + 2\text{AH} \xrightarrow[\text{hemin-smectite-DOA conjugate}]{\text{in benzene}} \text{Reduced peroxide} + 2\text{A}$$

Figure 3a shows the oxidation of leucocrystal violet (AH) with benzoyl peroxide by the catalytic action of hemin–smectite–DOA conjugate with various concentrations (0–0.32 μM) in benzene. The oxidation of leuco-

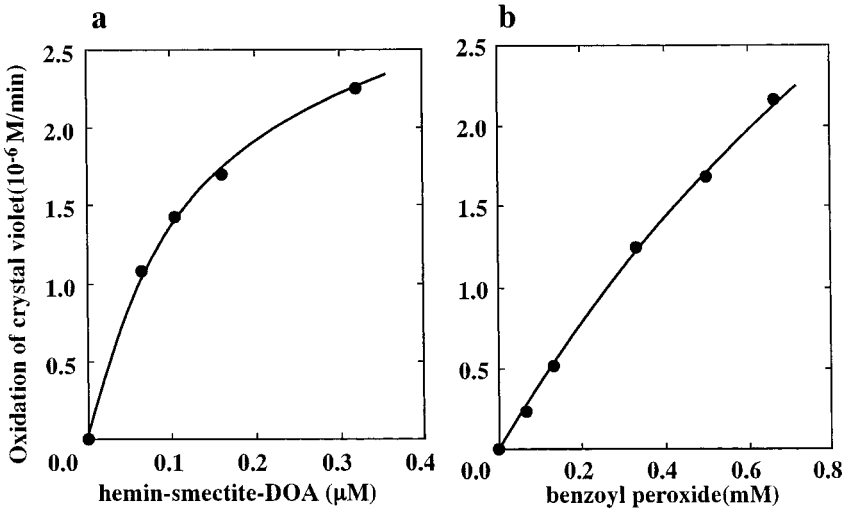

Figure 3. (a) Oxidation of leucocrystal violet (16.7 mM) with benzoyl peroxide (0.66 mM) in benzene by the catalytic action of hemin–smectite–DOA conjugate with various concentrations (0–0.32 μM). (b) Oxidation of leucocrystal violet (16.7 mM) with benzoyl peroxide (0–0.66 mM) in benzene by the catalytic action of hemin–smectite–DOA conjugate (0.32 μM) at 25 °C.

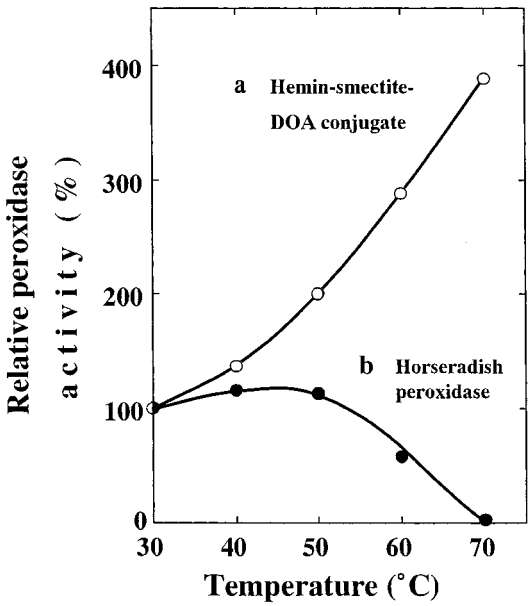

Figure 4. Temperature-dependent peroxidase activity of hemin−smectite−DOA conjugate in hydrophobic media (toluene) and of horseradish peroxidase in hydrophilic media [0.1 M phosphate buffer (pH 7.4)]. Curve a: Oxidation of leucocrystal violet (16.7 mM) with benzoyl peroxide (0.66 mM) by hemin−smectite−DOA conjugate (0.32 μM). Curve b: Oxidation of guaiacol (0.28 mM) with hydrogen peroxide (0.13 mM) by horseradish peroxidase (0.26 purpurogallin units).

crystal violet was linearly enhanced by increasing the amount of the conjugate in the reaction system. No reaction took place in the absence of the conjugate. The similar line of study was conducted by changing the benzoyl peroxide concentration. Figure 3b shows the oxidation of leucocrystal violet by the catalytic action of hemin−smectite−DOA conjugate (0.32 μM) in the presence of benzoyl peroxide (0−0.66 mM) in benzene. Crystal violet in the reduced form was linearly oxidized by the enhancement of benzoyl peroxide concentration in benzene. From the results obtained above, it can be concluded that hemin−smectite−DOA conjugate has peroxidase activity in an organic solvent.

Heat stability of peroxidase activity was tested for hemin−smectite−DOA conjugate and horseradish peroxidase at the temperature range from 30 to 70 °C. Although the absolute activity of horseradish peroxidase is much higher than that of the conjugate at 30 °C, these activities at 30 °C are regarded as 100%. Figure 4 shows the temperature-dependent activity curves of the conjugate and horseradish peroxidase. The peroxidase-like activity of the conjugate is enhanced by increasing the temperature (curve a). On the other hand, the enzymic activity of horseradish peroxidase is lowered by increasing temperature and is completely lost at 70 °C, due to the protein denaturation (curve b). From the result obtained above, the hemin−smectite−DOA conjugate may be available to be catalyst in hydrophobic media at high temperature.

A similar line of studies has been successfully carried out with the conjugate of chlorophyll adsorbed onto clay minerals such as bentonite and smectite which are closely associated with the development of the photochemical function of chlorophylls (*13, 18−20*). Chlorophyll−smectite conjugate becomes soluble in aqueous solution, although chlorophylls are never soluble in water. chlorophyll−poly(vinylpyrrolidone)−smectite conjugate with the absorption maximum at 677 nm was extensively photostable and catalyzed hydrogen gas evolution by the illumination of visible light in aqueous solution.

Along this line of investigations, the organic insolubility of hemin becomes soluble by conjugating with smectite and DOA, and the conjugate exerts peroxidase-like activity in organic media as well.

ACKNOWLEDGMENT

The authors are grateful to Dr. Toshi Tsuzuki and Dr. Hiroaki Kaji, and to Showa Denko K.K. for his basic and technical advice in the X-ray powder diffraction (XRD) analyses.

Electrochemical Detection of Gene Expression in Tumor Samples: Overexpression of Rak Nuclear Tyrosine Kinase

Paul M. Armistead and H. Holden Thorp*

Department of Chemistry and Lineberger Comprehensive Cancer Center, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina 27599-3290. Received December 13, 2000; Revised Manuscript Received March 2, 2001

Absolute quantification of Rak nuclear tyrosine kinase mRNA in breast tissue samples was determined by competitive RT-PCR. The total RNA from the same samples was also chemically amplified through conventional RT-PCR, and the relative amounts of these amplified RT-PCR products were determined by adsorption onto an indium tin oxide (ITO) electrode followed by electrochemical detection. The electrochemical detection was performed using the inorganic metal complex $Ru(bpy)_3^{2+}$ (bpy = 2,2′ bipyridine) to catalyze the oxidation of the guanine residues of the immobilized RT-PCR products. Using the competitive RT-PCR values as standards, it was found that an optimized conventional RT-PCR coupled with electrochemical detection provides a simple method for measuring relative gene expression among a series of mRNA samples from breast tumors. The use of electrochemical detection potentially eliminates the need for gel electrophoresis and fluorescent or radioactive labels in detecting the target genes.

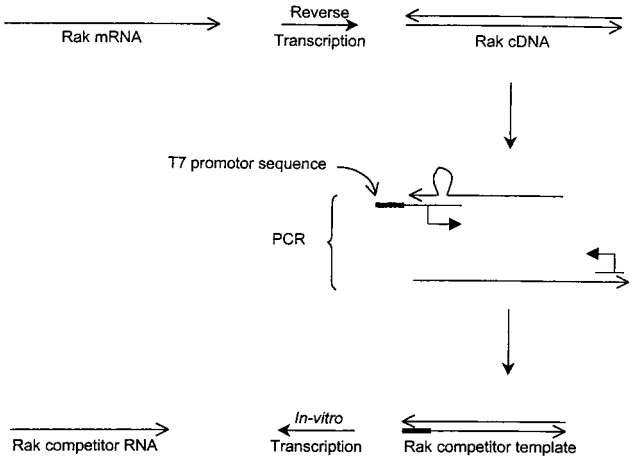
Abnormalities in the expression of specific genes have been linked to a large and increasing number of diseases (*1*−*7*). The identification of overexpressed genes provides a promising framework for identifying diagnostics as well as protein or small molecule drugs; this approach has been particularly successful in studies of HER2-neu in breast cancer (*8*−*10*). Several methods are currently available to quantify mRNA expression in biological samples; these methods typically provide semiquantitative information in some whole genome expression assays and absolute quantification in some single gene assays (*11*−*16*). Easily automated methods for detecting relative gene expression would allow for routine use of gene expression in diagnostics and drug discovery (*17*, *18*).

Our laboratory has developed a method for detecting trace nucleic acids based on electrocatalysis with cyclic voltammetric detection (*19*−*21*). In these experiments, DNA molecules are adsorbed onto indium tin oxide (ITO) electrodes with a surface area of 12.6 mm^2, placed in an electrochemical cell containing 10 μM of the electron-transfer mediator $Ru(bpy)_3^{2+}$ (bpy = 2,2′-bipyridine), and detected via catalytic oxidation of the guanine base according to the following reactions (*22*):

$$Ru(bpy)_3^{2+} \rightarrow Ru(bpy)_3^{3+} + e^- \quad (1)$$

$$Ru(bpy)_3^{3+} + \text{guanine} \rightarrow Ru(bpy)_3^{2+} + \text{guanine}^+ \quad (2)$$

The resulting cyclic voltammmogram shows a dramatic enhancement in the $Ru(bpy)_3^{2+}$ oxidation wave as the generated $Ru(bpy)_3^{3+}$ is recycled to $Ru(bpy)_3^{2+}$ by electrons from the guanine bases. Experiments with model PCR products showed that the sensitivity of this system was 44 amol/mm^2 of electrode area, which translates to a detection limit for the 12.6 mm^2 electrodes of roughly 550 amol (*23*). A number of other electrochemical techniques are under development, and the advantages of electrochemical approaches have been discussed in detail (*24*−*29*). In this application, the electrochemical technique can be used to replace gel electrophoresis performed following the RT-PCR protocol. The electrochemical technique could ultimately be performed in a miniaturized electrode array for analysis in high throughput without fluorescent or radioactive labels.



We report here that our electrochemical technique can be used to determine the mRNA expression level of Rak nuclear tyrosine kinase in a series of breast tissue samples. Rak (also called Frk) is a distant relative in the Src family of tyrosine kinases and is overexpressed in roughly 30% of human epithelial (breast and colon) cancers (*30*). The absolute quantity of Rak mRNA measured by competitive RT-PCR (*14*) ranged from 440 to 2300 zmol/μg of total RNA in breast tissues, which are typical values for the mRNA of signaling molecules (*16*). The same samples were analyzed by conventional RT-PCR with electrochemical detection (*23*), and a strong correlation was observed between the electrochemical current and the absolute quantity of mRNA determined by competitive RT-PCR.

EXPERIMENTAL SECTION

Materials and Reagents. All oligonucleotides were synthesized at the Lineberger Comprehensive Cancer Center Nucleic Acid Core Facility at the University of North Carolina at Chapel Hill. Tissue Samples were from the Tissue Procurement Facility at UNC-CH. Of the seven tissue samples studied, sample 35A was normal tissue, sample 54B was a primary tumor with no signs of invasion through the basal lamina, and the others were invasive breast tumors. Sample 35B was an invasive breast tumor from the same patient as sample 35A. BT-474 cells were a gift from the lab of Dr. Bill Cance. All water used was in-house distilled water that was further purified on a Milli-Q water purification system. Water for use in RNA manipulations was further treated with diethyl pyrocarbonate, DEPC, (Sigma, St. Louis, MO). *N*,*N*-Dimethyl formamide, sodium phosphate, sodium acetate, and sodium chloride were from Mallinckrodt

Scheme 1

(Paris, KY). $Ru(bpy)_3Cl_2$ was purchased from Aldrich (Milwaukee, WI) and purified by recrystallization from acetonitrile. ITO electrodes were purchased from Delta Technologies (Stillwater, MN). Total RNA from both cell culture and tissue samples was purified on Qiagen RNeasy columns according to the manufacturer's directions. All electrochemical measurements were performed in a one-compartment cell on an Princeton Applied Research (Princeton, NJ) model 273A potentiostat that was controlled by a Pentium computer. An Ag/AgCl reference electrode was used (Cypress Systems, Lawrence, KS), and a platinum wire was used as the auxiliary electrode. Fluorescent staining of DNA in agarose was performed using SYBR-green (Molecular Probes, Eugene, OR). Fluorescently stained gels were scanned on a Molecular Dynamics (San Jose, CA) Storm 860 phosphorimager using the blue fluorescence mode. Scanned gels were analyzed using ImageQuaNT software.

Competitive RT-PCR. Synthesis of an appropriate Rak mRNA competitor followed the strategy outlined in Scheme 1 (*15*). A Rak RT-PCR product was produced that contained the T7 promoter sequence as well as a "loop-out" region. The reverse transcription was carried out as follows. A 14-μL reaction mix consisting of 1 μg of total BT-474 RNA, 714 μM dNTPs (Amersham), and 0.4 μg/μL random hexamers (Life Technologies) was prepared. The mix was heated to 75 °C for 3 min and immediately cooled on ice. To the mix was added 4 μL of 5× buffer (Life Technologies), 1 μL of RNasin (Promega), and 1 μL (200 U) of M-MLV reverse transcriptase (Life Technologies). The reaction was allowed to proceed for 1 h at 42 °C and then stopped by heating the mix to 90 °C for 10 min.

A 50-μL PCR was made that contained 5 μL of the reverse transcription mix in 1× buffer, 2.5 mM $MgCl_2$, 125 μM dNTPs, 250 nM forward primer (TAA TAC GAC TCA CTC TAG GGC CTA TCT GGA GTC TCG GAA GCA GAT TTT GGA CTT GCC AGA), 250 nM reverse primer (GGG CAC CTG TCA TAC CAC TGT), and 1 U Taq polymerase (Life Technologies). The reaction was performed with 1 cycle of 95 °C for 5 min followed by 30 cycles of 94 °C for 20 s, 62 °C for 30 s, 72 °C for 40 s, and 1 cycle 72 °C for 5 min. The purity of the product was determined by agarose gel electrophoresis. The gel revealed a single band at the appropriate size (250 bp). The PCR product was purified on Qiagen Qiaquick PCR purification columns.

In vitro transcription was performed by assembling a 20-μL reaction mix that contained 40 mM Tris (pH = 7.5), 10 mM $MgCl_2$, 10 mM DTT, 8 mM NTPs, 50 μg/mL BSA, 170 nM PCR template, and 1× T7 polymerase that was a gift from the lab of Dr. Kevin Weeks. The reaction was allowed to proceed for 7 h at 37 °C. Following the reaction, 1 μL of DNase (Ambion) was added to the reaction and allowed to incubate for 30 min. To the reaction, were added 15 μL of 5 M ammonium acetate, 15 μL of 100 mM sodium EDTA, and 100 μL of DEPC water. The reaction was extracted with acid phenol/chloroform/isoamyl alcohol. The organic phase was back-extracted with 50 μL of DEPC water. The 200 μL of aqueous mix was precipitated with ice cold 2-propanol overnight. The RNA pellet was resuspended in TE buffer and run on a 4% denaturing polyacrylamide gel. The transcription products were visualized by UV shadowing, and the single visible product was cut from the gel using a clean razor blade. The gel fragment was placed into 300 μL of eluting solution containing 500 mM ammonium acetate, 1 mM EDTA, and 0.2% SDS (Ambion). The gel slice was kept in the solution overnight at 4 °C. The eluting solution was transferred from the gel slice, and the eluted RNA was ethanol precipitated overnight revealing a glassy pellet. The pellet was resuspended in TE buffer. The amount of product, 1.8 μg (23 pmol), was determined by UV−vis spectroscopy at 260 nm.

Competitive RT-PCR was performed by preparing 6 reverse transcription mixes for each tissue sample. A 15-μL reaction mix was prepared that contained 0.5 μg of total RNA, a known quantity of the competitor (either 31.3, 62.5, 125, 250, 500, or 1000 zmol), 667 μM dNTPs, and 667 nM reverse primer. The mixes were heated and cooled on ice as described above. To each mix was added 4 μL of 5× buffer and 1 μL (200 U) of M-MLV reverse transcriptase. The reverse transcription and PCR were performed as described above except a different forward primer (GGC CTA TCT GGA GTC TCG GAA) was used. Each reaction mix was run on a 2% agarose gel and stained with SYBR-Green for 20 min. Staining with SYBR-Green was performed after the electrophoresis to minimize measurement errors due to dye migration in the gel. The stained gel was scanned with a Molecular Dynamics Storm 860 phosphorimager in the blue fluorescence mode. The band intensities resulting from both the native Rak mRNA amplification (296 bp) and the competitor RNA amplification (232 bp) were measured, and background fluorescence was subtracted. For each tissue sample, the logarithm of the competitor signal/native signal in each mix was plotted vs the logarithm of the amount of competitor added for each mix. The best linear fit was calculated, and the antilogarithm of x at $y = 0$ was calculated. This value yielded the absolute quantity of Rak mRNA in the tissue sample.

Conventional RT-PCR Amplification of Rak. RT-PCR of Rak was performed on all tissue samples in parallel, except sample 55B, which did not yield enough RNA. Six reverse transcription reactions were assembled (1 for each sample). Each 15-μL reaction contained 0.5 μg of total RNA, 0.4 μg/μL random hexamers, and 667 μM dNTPs. The random hexamers and dNTPs were originally pooled into a master mix and then pipetted into each individual reverse transcription mix. The mixes were heated and cooled as described above. Four microliters of 5× buffer and 1 μL (200 U) of M-MLV were added. These reagents were premixed to ensure that equivalent amounts of enzyme were added to each reverse transcription reaction. The reactions were again performed at 42 °C for 1 h and were stopped by heating to 90 °C for 10 min.

PCR was assembled for each tissue sample as a 100-μL solution that contained 10 μL of reverse transcription

mix, 1× buffer, 2.5 mM $MgCl_2$, 125 μM dNTPs, 250 nM forward primer (GGC CTA TCT GGA GTC TCG GAA), 250 nM reverse primer (GGG CAC CTG TCA TAC CAC TGT), and 2 U Taq polymerase. The reagents were premixed except the reverse transcription mix. Ninety microliters of the master mix was added to 10 μL of the reverse transcription mix. This step again ensured that equivalent amounts of Taq were added to each reaction. The reaction proceeded as follows: 1 cycle of 95 °C for 5 min followed by 28 cycles of 94 °C for 20 s, 62 °C for 30s, 72 °C for 40 s, and 1 cycle 72 °C for 5 min. Five microliters of each product were analyzed by agarose gel electrophoresis.

Purification of Rak RT-PCR Products. After RT-PCR, 90 μL of each PCR were purified on Qiagen Qiaquick PCR purification columns. The purification was performed according to the manufacturer's instructions, except for the final elution step. At this step, each column was treated with 30 μL of 10 mM sodium acetate pH = 8.0 (pH raised by addition of sodium hydroxide). The columns were allowed to sit for one minute and were then centrifuged at 14 000 rpm for 2 min. Again, 5 μL of each product was analyzed by agarose gel electrophoresis. The pre- and post-purification gels were used to confirm that the relative amounts of RT-PCR among samples did not change significantly after purification.

Electrochemical Detection of Rak RT-PCR Products. ITO electrodes were cleaned using the protocol of Willit and Bowden (*31*). The electrodes were cleaned by sonication in 2-propanol for 15 min, and twice in Milli-Q water each time for 15 min. The electrodes were air-dried. For each electrode, 5 μL of purified PCR product were added to 45 μL of DMF. The DMF mixtures were pipetted onto the electrodes, which were placed in a constant humidity chamber for 30 min (*23*). The electrodes were then washed in Milli-Q water for 3 min on a rotary mixer and allowed to air-dry.

The DNA modified electrodes were placed in a one-compartment electrochemical cell. The cell contained 150 μL of 10 μM $Ru(bpy)_3^{2+}$ in 50 mM sodium phosphate buffer at pH = 7.0. Electrochemical detection was performed using cyclic voltammetry at a scan rate of 10 V s^{-1}. The potential range was 0−1300 mV. All measurements were made relative to an Ag/AgCl reference electrode. Because of the large charging currents generated at this fast scan rate, background subtraction was performed. The background scans were taken with no $Ru(bpy)_3^{2+}$ at ITO electrodes that had been treated with a 9:1 DMF/sodium acetate solution (without DNA) and washed as above. The background electrodes were placed in the same electrochemical cell, and cyclic voltammetry was performed only in the presence of 50 mM sodium phosphate. Immobilized DNA was quantitated by comparison of catalytic currents for DNA-modified electrodes scanned with $Ru(bpy)_3^{2+}$ compared to the currents obtained for $Ru(bpy)_3^{2+}$ only on electrodes not modified with DNA.

RESULTS AND DISCUSSION

Absolute Quantification of Rak mRNA in Breast Tissue Samples. Competitive RT-PCR was performed on the seven breast tissue samples and BT-474 cells following a procedure adapted from published protocols (*14*). A typical agarose gel of a competitive RT-PCR is shown in Figure 1 (top). Quantities of amplified material and internal standard were determined by fluorescence and plotted as in Figure 1 (bottom). The linear fits from all of the analyses had an average R-value of 0.99 ± 0.01

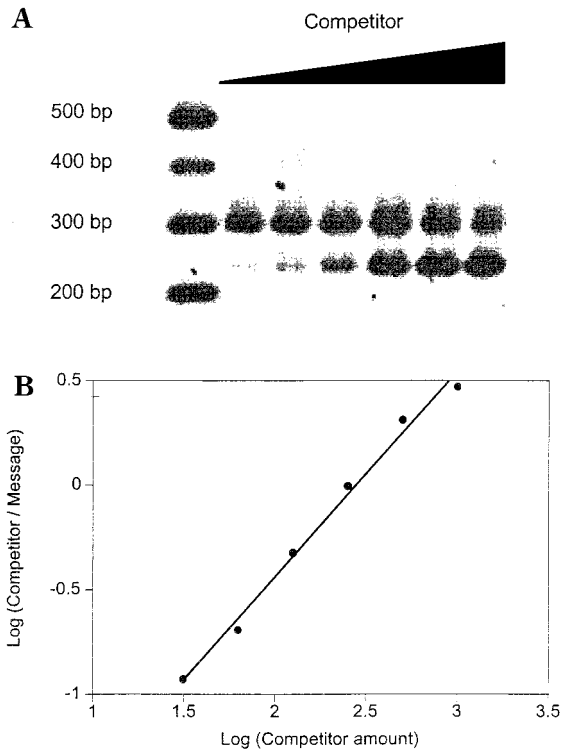

Figure 1. Results of competitive RT-PCR for sample 35B. (A) Agarose gel showing that as the amount of competitor added to each reaction is increased, the ratio of the amount of native RT-PCR product (296 bp) decreases relative to the amount of competitor RT-PCR product (232 bp). (B) The logarithm of the band intensity ratio versus the logarithm of the quantity of competitor.

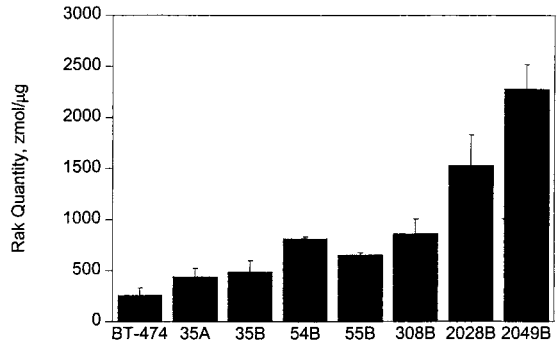

Figure 2. Quantity of Rak mRNA from competitive RT-PCR given as zmol of Rak mRNA per μg of total RNA for the specified sample. Quantities determined for each sample as in Figure 1.

and an average slope of 0.98 ± 0.14. Observation of slopes near unity indicates that the standard RNA is behaving as a proper competitor (*32*).

The competitive RT-PCR results for the seven breast tissues and BT-474 cells are shown in Figure 2. Rak mRNA expression ranged from 440 zmol/μg of total RNA in normal breast tissue (sample 35A) to 2300 zmol/μg of total RNA in sample 2049B. A greater than 2-fold increase in expression (compared to normal sample 35A) was observed in two of the six breast cancer samples, which is consistent with the finding of Cance et al. that Rak is overexpressed in roughly 30% of breast tumors (*30*). The six samples examined here were for the purposes of demonstrating the electrochemical method and not meant to reflect a statistically relevant population; nevertheless, the determined quantities and trends are entirely consistent with the biological expectations. While Rak overexpression is clearly evident, it should be

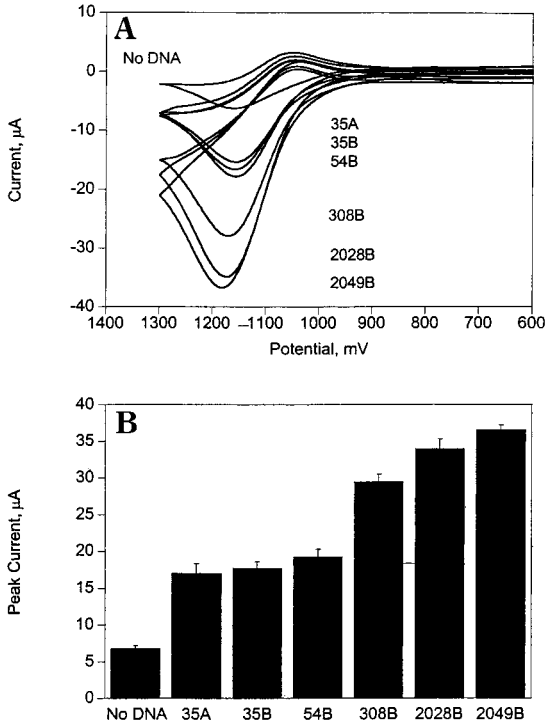

Figure 3. (A) Cyclic voltammograms for ITO electrodes with no DNA or modified with the RT-PCR products from six breast tissue samples at a scan rate of 10 V/s with 10 μM $Ru(bpy)_3^{2+}$ in 50 mM phosphate buffer (pH 7). (B) Peak current for each sample.

noted that the magnitude of overexpression is relatively mild, expecially when compared to other oncogenes such as HER-2, which can vary in expression over 3 orders of magnitude (*16*, *33*).

Electrochemical Quantification of Rak RT-PCR Products. For electrochemical analysis, conventional RT-PCR was performed on each tissue sample, and the resulting PCR reactions were purified to remove the unreacted nucleotides and pyrophosphate, which inhibit adsorption of the DNA onto the electrode (*23*). Agarose gel electrophoresis was performed on all of the samples both before and after the purification step to ensure that purification did not affect the relative quantities of the Rak PCR products. After purification, the PCR products were adsorbed to the electrodes using a procedure similar to that we have published previously (*23*).

Electrochemical detection of the Rak RT-PCR products was performed by cyclic voltammetry in the presence of $Ru(bpy)_3^{2+}$. We have shown previously that the peak currents obtained by this method increase with increasing amounts of adsorbed PCR product (*23*). We have also determined previously that a scan rate of 10 V/s and a 10 μM concentration of $Ru(bpy)_3^{2+}$ provide the optimal sensitivity (*23*). Here we apply this method to clinical samples for the first time. Representative cyclic voltammograms of $Ru(bpy)_3^{2+}$ at unmodified electrodes (no DNA) and at ITO electrodes modified with the Rak RT-PCR products from the breast tissue samples are shown in Figure 3 along with a bar graph giving the peak currents and associated errors.

Figure 4 shows the correlation between the peak currents determined by cyclic voltammetry and the absolute quantity of mRNA applied to the electrode determined by competitive RT-PCR. A good correlation is observed between the expression level and the electrochemical signal. The signal appears to maximize somewhat for the higher expression levels. We have

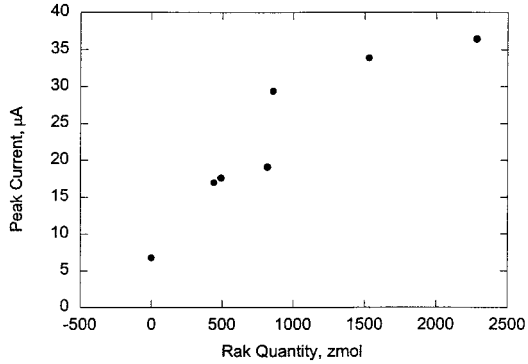

Figure 4. Plot of the absolute quantity of Rak mRNA in the series of breast tumor samples (Figure 2) versus the peak current from the corresponding cyclic voltammograms (Figure 3). Note that the error bars for each axis are given in Figures 2 and 3.

shown previously that the electrochemical method exhibits a high dynamic range for PCR amplicons applied to electrodes and directly quantitated by radiolabeling (*23*); quantities of immobilized PCR products spanning 2 orders of magnitude give distinct electrochemical signals. Thus, the saturation in Figure 4 at high copy numbers is likely due to the reduced dynamic range of the conventional RT-PCR compared to that of competitive RT-PCR (*14*) and not to a lower dynamic range of the electrochemical method as compared to fluorescence detection. The accuracy of the electrochemical method is therefore more than sufficient to distinguish changes in the quantities of conventional RT-PCR products. In particular, the two samples indicating overexpression (2028B and 2049B) were identified using both methods.

CONCLUSIONS

Rak mRNA is expressed in the range of 100−2300 zmol/μg of total RNA in seven breast tissue samples and BT-474 cells as determined by competitive RT-PCR. In this group, 2 of 6 breast tumors expressed Rak at a level more than twice that of normal breast tissue (sample 35A). This result supports the findings of Cance and Liu that Rak is overexpressed in roughly 30% of all invasive breast tumors (*30*). A semiquantitative conventional RT-PCR approach coupled with electrochemical detection led to similar Rak expression data. The two breast tumors with the highest absolute Rak mRNA quantity also gave the largest electrochemical signals (which were also 2× greater than the electrochemical signal from sample 35A). The magnitude of the differences in expression from sample to sample was diminished in the conventional RT-PCR versus the competitive RT-PCR measurements, probably as a result of the reduced dynamic range of the conventional method. Catalytic electrochemical detection of RT-PCR products offers a rapid method for determining the relative amount of a specific mRNA in a series of biological samples. The adsorption of DNA to the ITO electrodes is complete in 30 min, and performing the cyclic voltammogram takes less than 1 s.

Wolfe Street, Baltimore, Maryland 21287. Received July 20, 2001

The development of antisense technology has focused on improving methods for oligonucleotide delivery into cells. In the present work, we describe a novel strategy for oligonucleotide delivery based on a bifunctional peptide composed of a C-terminal protamine-fragment that contains a DNA-binding domain and an N-terminal nuclear localization signal sequence derived from the SV40 large-T antigen (The sequences of two of the peptides are R6WGR6−PKKKRKV [s-protamine-NLS] and R4SR6FGR-6VWR4−PKKKRKV [l-protamine-NLS]). We demonstrated, by intrinsic fluorescence quenching, that peptides of this class form complexes with oligodeoxynucleotides. To evaluate delivery, we used a 20-mer phosphorothioate oligomer (Isis 3521) targeted to the 3′-untranslated region of the PKC-α mRNA and G3139, an 18-mer phosphorothioate targeted to the first six codons of the human bcl-2 open reading frame, and complexed them with either of two peptides (s- or l-protamine-NLS). These peptides bind to and deliver antisense oligonucleotides to the nucleus of T24 bladder and PC3 prostate cancer cells, as demonstrated by confocal microscopy. Furthermore, as shown by Western and Northern blotting, the peptide−oligonucleotide complexes produced excellent downregulation of the expression of the complementary mRNAs, which in turn resulted in downregulation of protein expression. However, under certain circumstances (predominately in PC3 cells), incubation of the cells with chloroquine was required to produce antisense activity. Using this strategy, PKC-α protein and mRNA expression in T24 and PC3 cells and bcl-2 expression in PC3 cells was reduced by approximately 75 ± 10% at a minimum concentration of oligomer of 0.25 μM, in combination with 12−15 μM peptide. On the basis of our results, we conclude that arginine-rich peptides of this class may be potentially useful delivery vehicles for the cellular delivery of antisense oligonucleotides. This new strategy may have several advantages over other methods of oligonucleotide delivery and may complement already existing lipid-based technologies.

INTRODUCTION

Antisense oligonucleotides, especially those containing the phosphorothioate backbone, are currently in clinical trials as potential therapeutic agents and also may be valuable reagents for the validation of gene function. However, at least in tissue culture, antisense oligonucleotides almost invariably must be condensed with a delivery reagent to ensure adequate cellular uptake and release from sequestered sites in the endosomes/lysosomes. The most commonly employed delivery reagents are cationic lipids (e.g., Lipofectin, Lipofectamine), but these reagents may contribute their own cytotoxic effects, which would thus affect the phenotype produced after treatment of the cells with the antisense effector molecule.

Accordingly, a large number of peptide delivery vehicles for antisense oligonucleotides have been devised. Tung and Stein (*1*), in their recent review of covalent peptide−oligonucleotide conjugates, have listed approximately 20 peptides that increase the delivery of oligonucleotides to cells. These include pH sensitive fusogenic peptides (*2*−*5*), Antennapedia-type peptides (*6*, *7*), and the HIV tat C-terminus peptide (*8*, *9*). Other peptides that have been covalently conjugated to oligonucleotides include the ER-retaining peptide YKDEL (*10*) and various nuclear localization signal peptides (including the PKKKRKV sequence derived from the SV40 large-T antigen (*11*−*14*).

Noncovalent peptide oligonucleotide complexes have also been employed to increase cellular delivery (reviewed by (*15*)). Morris et al. (*16*) used a 27-mer peptide, called MPG, which was composed of the N-terminal domain of the HIV gp41 fusion sequence fused to the C-terminal domain derived from the nuclear localization signal derived from the SV40 large-T antigen. Nuclear localization of oligonucleotide in fibroblasts was observed. Pichon et al. (*3*) employed a permeabilizing peptide derived ultimately from an analogue of the N-terminal sequence of the HA2 subunit of the influenza virus hemagglutinin. Permeabilization was successful as judged by the nuclear localization of a fluoresceinated oligonucleotide. This

same group (*17*) subsequently employed histidylated oligolysines to deliver antisense oligonucleotides targeted to ICAM-1, which demonstrated excellent antisense activity.

However, with this exception, in almost all the examples of peptide-mediated delivery given above, it is unclear if any sequence specific downregulation of the expression of a target mRNA was observed. In this work we have produced a bifunctional peptide comprising a C-terminal DNA-binding domain which is a protamine fragment, and an N-terminal nuclear localization signal derived from the SV40 large-T antigen. We demonstrate that peptides of this class both bind to and deliver antisense oligonucleotides to cells, and in addition, permit antisense activity by the oligonucleotide. However, in some cases, nuclear delivery, as well as antisense competency, only occur if the cells are pretreated with the lysosomotropic agent chloroquine, thus highlighting the difficulties that oligonucleotide/peptide complexes have in penetrating the endosomal barrier unassisted.

The antisense oligonucleotides we have employed are the 20-mer phosphorothioate antisense PKC-α, first developed by Dean and colleagues (*18*), which we have recently used to evaluate a novel type of porphyrin carrier (*19*). This oligomer, and G3139, the 18-mer antisense bcl-2 oligonucleotide (*20*) we have also employed in this study, are widely considered to be sequence-specific inhibitors of gene expression. Because of this property, they are both well suited for the evaluation of a novel delivery strategy.

MATERIALS AND METHODS

Peptide Synthesis. The preparation of these peptide sequences required the difficult coupling of multiple positively charged amino acid monomers adjacent to each other. To prepare them in reasonable yields, we used the following monomers, reagents and conditions: Fmoc-Arg-(Pbf)-OH (pentamethyldihydrobenzofuransulfonyl), Fmoc-Ser(tBu)-Opfp (*tert*-butyl), Fmoc-Trp(tBoc)-Opfp (*tert*-butyloxycarbonyl), Fmoc-Lys(tBoc)-Opfp (*tert*-butyloxycarbonyl), Fmoc-Lys(Mtt)-OH (methoxytrityl), Fmoc-Phe-Opfp, Fmoc-Gly-Opfp, Fmoc-Val-Opfp and Fmoc-Val-OH. The resin used was PAC−PEG-PS, (PerSeptive Biosystems, UK). Amino acids, *N*,*N*-dimethylformamide (DMF), 2-(1*H*-benzotriazole-l-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate, DIPEA (diisopropylethylamine), and TFA (triethylsiliane) were purchased from Auspep Australia. HOBt (1-Hydroxybenzotriazole) was purchased from Fluka, TIS (triethylsilane) from Aldrich, and piperidine from Merck.

A 0.05 mmol scale peptide synthesis, using PAC−PEG-PS resin with a loading of 0.19 mmol/g, was carried out on a Rainin PS3 Automated Solid-Phase Peptide Synthesizer. Fmoc-amino acids were used in 5 mol equiv and activated with 5 mol equiv of HOBt or HBTU in 1 M DIPEA (in DMF) for 5 min, followed by a 35 min coupling. HBTU was used for the free alcohols and HOBt for the Opfp esters. Fmoc deprotection was carried out in 20% piperidine in DMF. Cleavage and side chain deprotection involved treating the peptide with a mixture containing 95% TFA, 2.5% TIS, and 2.5% H_2O, for 2 h at room temperature with constant stirring. The peptide was then isolated by ether extraction.

Purification and Characterization of the Peptides. Reverse phase HPLC was carried out using a Vydac 218TP C18 protein and peptide RP 5 μM column (4.6 × 250 mm) on a Waters 996 Photodiode Array Detector. Samples were monitored at 254 nm.

A mobile gradient buffer of 0.1% TFA and HPLC grade acetonitrile (0−60% in 30 min) were employed. The retention times for the peptides (not all of which were employed as delivery agents) are R6WGR6 (18 min), R6WGR6−PKKKRKV (19 min), R6WGR6−PKGKRKV (21min), R6WGR6−KPKRKVK (19 min), R4SR6FGRVWR4 (21.5 min), R4SR6FGR6VWR4−PKKKRKV (25.5 min), R4SR6FGR6VWR4−PKGKRKV (20 min), and R2FGR2VWR2 (19 min).

Matrix assisted laser desorption ionization-time-of-flight mass spectrometry (MALDI-TOF) was carried out on a Bruker Biflex spectrometer, and all data was collected and analyzed using Solaris software. Peptides were analyzed in positive linear mode as 50 ρM in 3:7 acetonitrile/water and 0.1% trifluoroacetic acid.

Cell Culture. Cells were obtained from American Type Culture Collection (12301 Parklawn Drive, Rockville, MD 20852). T24 cells were grown in McCoy's 5A medium (Gibco BRL, Grand Island, NY), containing 10% (v/v) heat-inactivated (56 °C) fetal bovine serum (FBS) (Gibco BRL, Grand Island, NY), supplemented with 25 mM Hepes, 100 units/mL penicillin G sodium, and 100 μg/mL streptomycin sulfate. PC3 cells were grown in RPMI 1640 medium (Gibco BRL), containing 10% (v/v) FBS, to which were added 2 mM glutamine, 1 mM sodium pyruvate, and 0.1 mM nonessential amino acids. Stock cultures were maintained at 37 °C in a humidified 5% CO_2 incubator.

Reagents. The anti-PKC-α mouse monoclonal antibody was purchased from Transduction Laboratories (Lexington, KY). The anti-bcl-2 mouse monoclonal antibody was purchased from Dako (Carpinteria,CA). The anti-mouse horseradish peroxidase conjugated secondary antibody was from Amersham (Arlington Heights, IL).

Synthesis of Oligonucleotides. Phosphorothioate oligonucleotides were synthesized on an Applied Biosystems (Foster City, CA) model 380B DNA. Following cleavage from controlled pore glass support, oligodeoxynucleotides were base-deblocked in ammonium hydroxide at 60 °C for 8 h and purified by reversed phase HPLC [0.1 M triethylammonium bicarbonate (TEAB)/acetonitrile, PRP-1 support]. Oligomers were detritylated in 3% acetic acid and precipitated with 2% lithium perchlorate/acetone, dissolved in sterile water, and reprecipitated as the sodium salt from 1 M NaCl/ethanol. Concentrations were determined by UV spectroscopy.

The sequences of the oligonucleotides used were Isis 3521 (targeted to the 3′ region of the PKC-α mRNA), 5′-GTTCTCGCTGGTGAGTTTCA-3′ (*18*); G3139 (targeted to the first six codons of the human bcl-2 open reading frame), 5′-TCTCCCAGCGTGCGCCAT-3′ (*20*). The sequence of the control, scrambled oligonucleotide (Isis 4559) is 5′-GGTTTTACCATCGGTTCTGG-3′ (*18*).

Treatment of Cells with Oligonucleotide−Peptide Complexes. Cells were grown in six-well plates until 65−75% confluent. The peptides, at the stated peptide/oligonucleotide molar ratios, were diluted in 200 μL of distilled water, and oligonucleotide was then added to the required concentration. The solution was mixed gently and incubated at room temperature for 30 min to allow oligonucleotide−peptide complexes to form. Then, 300 μL of Opti-MEM media was added, and the solution was mixed and overlaid onto the cells, which had been rinsed with Opti-MEM medium and pretreated with 500 μL 50 μM chloroquine for 15 min (the chloroquine with final concentration 25 μM was allowed to remain in solution during incubation with the complexes). The cells were then incubated at 37 °C for 5 h or refed with complete media containing 10% FBS and allowed to

incubate for an additional 19 h (for PKC-α) or 68 h (for bcl-2) before cell lysis and extract preparation.

Fluorescence Titrations. Fluorescence experiments were performed on an Aminco Bowman series 2 luminescence spectrometer (SLM Aminco, Urbana, IL). The intrinsic tryptophan fluorescence of peptide was excited at 290 nm, and the emission spectrum was recorded between 310 and 410 nm with a spectral band-pass of 4 nm. A fixed concentration of protein (0.5 μM) was titrated by increasing the concentration of Isis 3521 (from 0 to 0.35 μM) at room temperature in PBS buffer. Curve fitting was performed with the Grafit program (Excel Software).

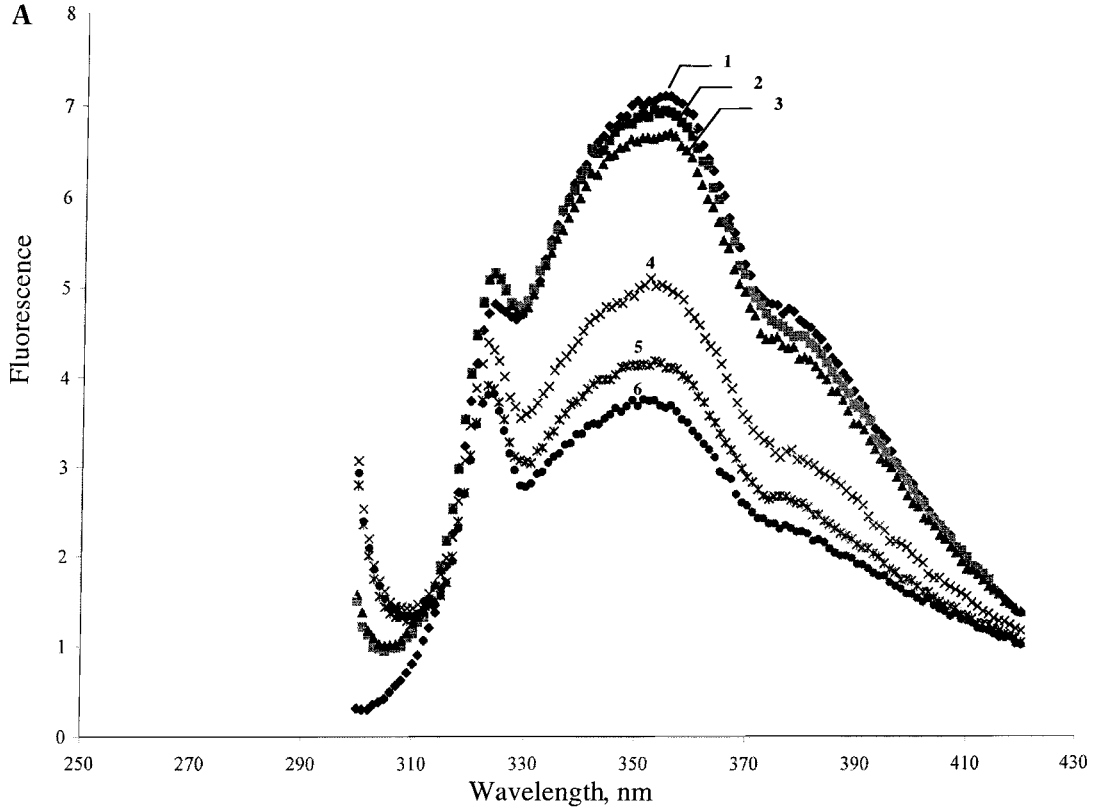
Confocal Microscopy. T24 cells were seeded in glass bottom microwells (MatTec Corp., Ashland, MA) and treated with 5′-fluorescein-Isis 3521 (2 μM) complexed with 15 μM s-protamine-NLS in the presence of 25 μM chloroquine at 37 °C for 5 h. Cellular internalization was examined using an LSM 410 laser scanning confocal microscope (Zeiss, Thornwood, NY) equipped with a krypton/argon laser and attached to a Zeiss Axiovert 100 TV microscope. The 515−540 nm band-pass for fluorescein was used. Z-series were taken of a 1 to 2 micron optical section at 2 μm intervals. For measurements, a maximum projection of all sections was employed. Images were printed using Adobe Photoshop.

Western Blotting. Cells were treated with oligodeoxynucleotide−peptide complexes, scraped, washed with cold PBS, and then extracted in 40−50 μL of lysis buffer [50 mM Tris-HCl, pH 7.5; 1% NP-40; 0.25% sodium deoxycholate; 150 mM NaCl; 1 mM EGTA; 50 μg/mL Pefablock SC; 15 μg/mL aprotinin, leupeptin, chymostatin, and pepstatin A; 1 mM Na_3VO_4; 1 mM NaF] at 4 °C for 1 h. Cell debris was removed by centrifugation at 14000*g* for 20 min at 4 °C. Protein concentrations were determined using the Bio-Rad protein assay system (Bio-Rad Laboratories, Richmond, CA).

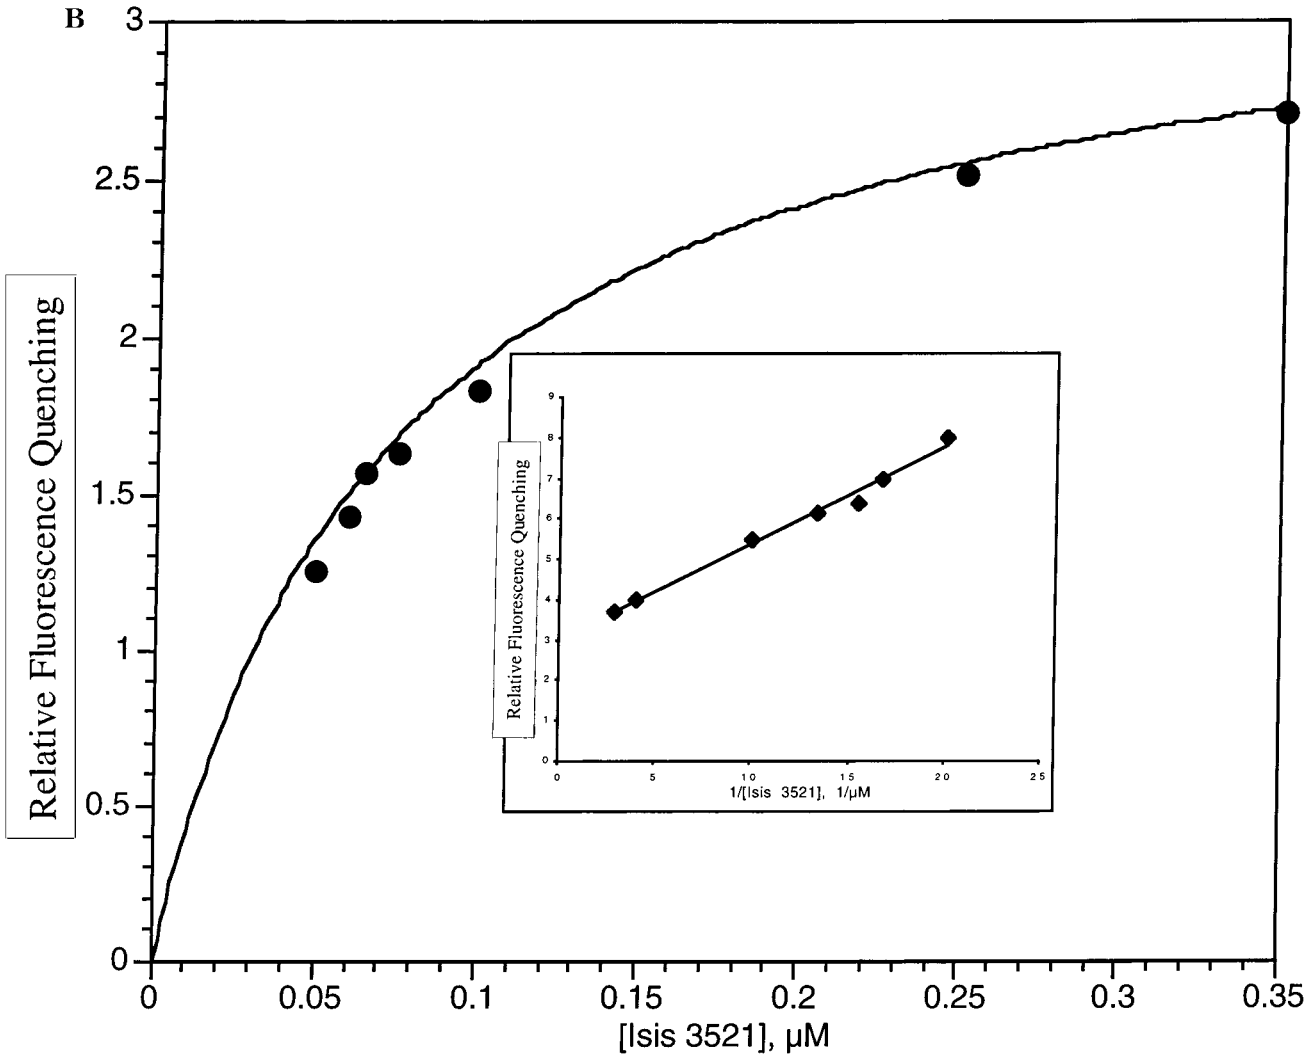
Aliquots of cell extracts containing 20−30 μg of protein were resolved by 10% or 12% SDS−polyacrylamide gel electrophoresis and transferred to Hybond ECL filter paper (Amersham, Arlington Heights, IL). Filters were incubated at room temperature for 1−2 h in Blotto A [5% nonfat milk powder in TBS-T: 10 mM Tris-HCl, pH 8.0, 150 mM NaCl, 0.05% Tween 20 (for PKC-α) and 5% BSA in PBS, 0.5% Tween (for Bcl-2)] and then probed overnight at 4 °C with 1:1000 dilution of anti-PKC-α or 1:500 dilution of anti-Bcl-2 in Blotto A. After washing in TBS-T or PBS-T buffer (3 × 7 min, room temperature), filters were incubated for 1 h at room temperature in 5% milk/TBS-T or 5% milk/PBS-T buffer containing a 1:3000 dilution of peroxidase-conjugated anti-mouse secondary antibody. The filters were then washed (3 × 10 min, room temperature), and ECL was performed according to the manufacturer's instructions.

Northern Blot Analysis. Total cellular RNA was isolated using TRIZOL Reagent (Gibco BRL). 30−40 μg was resolved on 1.2% agarose gel containing 1.1% formaldehyde and transferred to Hybond-N nylon membranes (Amersham). Human PKC-α and bcl-2 cDNA probes were ^{32}P-radiolabeled with [α-^{32}P]dCTP by random primer labeling using a commercially available kit (Promega) according to the manufacturer's instructions. The blots were then hybridized with the cDNA probes in 50% formamide, 5X SSC, 5X Denhardt's solution, 0.5% SDS and 0.1 mg/mL of salmon sperm DNA overnight at 42 °C. The filters were washed at room temperature, twice for 15 min in 2X SSC and 0.1% SDS, once for 20 min in 1X SSC and 0.1% SDS, and finally twice for 15 min in 0.1X SSC and 0.1% SDS at 65 °C. The filters were exposed to Kodak X-ray film for 12−24 h with intensifying screens at −70 °C and then developed.

Cellular Viability Assay. Cells were seeded in 96-well tissue culture plates and treated the next day with oligonucleotide−peptide complexes in the presence of 25 μM chloroquine for 5 h at 37 °C. At the end of this time, the Opti-MEM media was then replaced with complete media containing various concentrations of paclitaxel. After 3 days treatment with paclitaxel (at the indicated concentrations as described in the Results), cellular viability was determined by MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) assay. Briefly, the cells were incubated for 4 h at 37 °C, 5% CO_2 with 0.5 mg/mL MTT in complete media. An equal volume of solubilization solution (10% SDS in 0.01 M HCl) was then added and allowed to incubate overnight at 37 °C. After the formazan crystals were dissolved, the plates were read on a Dynatech MR600 Microplate Reader at 540 nm.



Experiments were performed in quadruplicate and data are expressed as the mean absorbance ± the SD. Statistical analysis of the results was performed using the Analysis ToolPack provided by Microsoft Excel. A Student's two-sample t-test, assuming unequal variances, was used to determine the equality of the means of two samples (* = $p < 0.05$).



RESULTS

Peptides Form Complexes with Oligodeoxynucleotides. The interaction of Isis 3521, a 20-mer phosphorothioate antisense oligonucleotide, with protamine-NLS peptides was evaluated by fluorescence spectroscopy. The peptide contains a single Trp residue, which can be excited at 290 nm and emits fluorescent light at 330 nm. The ability of a bound oligonucleotide to quench this fluorescent emission constitutes a relatively sensitive probe for the monitoring of molecular interactions.

As shown in Figure 1A, the titration of a 0.5 μM solution of l-protamine-NLS with increasing concentrations of Isis 3521, both in PBS and in Opti-MEM (without serum, to mimic our transfection conditions), led to dramatic fluorescence quenching. At low oligonucleotide concentration (relative to l-protamine-NLS peptide) a plot of the decrease in fluorescence (due to quenching) vs oligonucleotide concentration fits an equation of the Michaelis−Menton type (Figure 1B). A Lineweaver−Burke (double reciprocal) plot gives K_d = 80 nM (R^2 = 0.99). However, as oligonucleotide concentration is increased, Trp fluorescence continues to decline, but a similar plot no longer fits a Michaelis−Menton-type equation, and the binding becomes increasingly complex (not shown). Similarly, for the s-peptide-NLS, the binding at relatively low oligonucleotide concentration also fits a single-site model of the Michaelis−Menton type (Figure 1C). A Lineweaver−Burke plot of the data gives K_d = 2 μM. At higher oligonucleotide concentration, the single site binding model also breaks down. For both peptides, these data are somewhat approximate because we could not obtain measurements at lower oligonucleotide concentrations than those indicated.

Protamine-NLS Peptides Deliver Oligonucleotides to the Cell Nucleus. We evaluated the ability of the protamine-NLS peptides to deliver the oligonucleotides into the cell nucleus by confocal microscopy. 5′-Fluorescein-labeled ISIS 3521 (2 μM) was complexed with s-protamine-NLS-peptide (15 μM) and incubated with T24 cells in the presence of chloroquine (25 μM). As shown in Figure 2, the peptide effectively delivered fluoresceinated oligonucleotide to the cell nucleus after

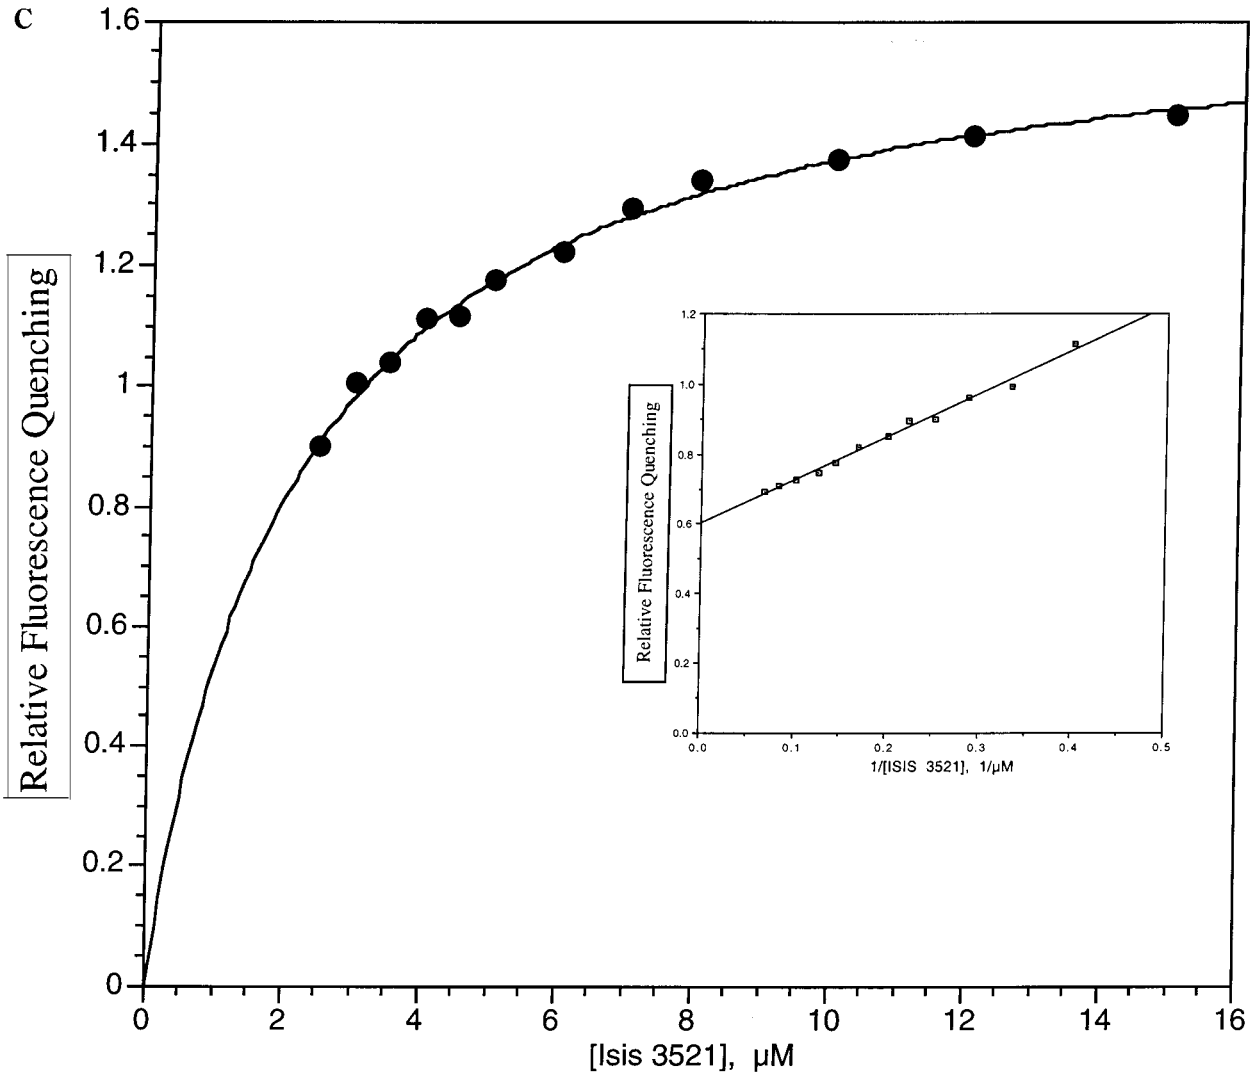

Figure 1. (A) Binding of l-protamine-NLS (0.5 μM) to increasing concentrations of Isis 3521 as monitored by intrinsic fluorescence quenching. The concentrations of Isis 3521 are (traces 1−6, respectively) 0, 0.06, 0.075, 0.1, 0.25, and 0.35 μM. The fluorescence of l-protamine-NLS was excited at 290 nm, and the emission spectrum was recorded between 310 and 410 nm. (B) Relative fluorescence of l-protamine-NLS at 350 nm plotted as a function of the concentration of Isis 3521, with extrapolation to zero concentration. The solid line represents the data plotted as per the Michaelis−Menton equation. The insert depicts a Lineweaver−Burke (double reciprocal) plot of these data. (C) Relative fluorescence of s-protamine-NLS at 350 nm plotted as a function of the concentration of Isis 3521, with extrapolation to zero concentration. The solid line represents the data plotted as per the Michaelis−Menton equation. The insert depicts the Lineweaver−Burke (double reciprocal) plot of these data.

an incubation time of 5 h. In the absence of peptide, oligonucleotides were internalized poorly by the cells, with most of the internalized material accumulating in a punctate pattern, signifying localization in vesicular structures (endosomes/lysosomes; not shown).

Surprisingly, under the same conditions and reagent concentrations, the s-protamine-(scrambled)NLS also promotes the delivery of the oligonucleotide to the nucleus (not shown). However, as described below, when delivered in this fashion, the oligonucleotide does not downregulate the expression of PKC-α protein as determined by Western blotting.

Peptide−Oligodeoxynucleotide Complexes Demonstrate Antisense Activity. *1. s-Protamine-NLS Complexes with Oligonucleotides.* Experiments using the protamine-NLS peptides to deliver antisense oligonucleotides were performed in T24 bladder carcinoma and PC3 prostate carcinoma cells. In addition to the 20-mer ISIS 3521, we also employed the 18-mer phosphorothioate oligonucleotide G3139, which is targeted to the first six codons of the human bcl-2 open reading frame. The

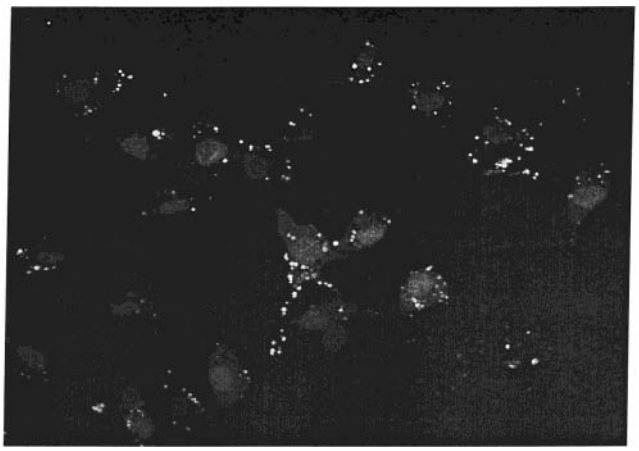

Figure 2. s-Protamine-NLS-mediated delivery of Isis 3521 in T24 bladder carcinoma cells. Cells were treated for 5 h at 37 °C with 5′-fluorescein-labeled Isis 3521 (2 μM) complexed to s-protamine-NLS (15 μM) in the presence of 25 μM chloroquine. Cellular localization was monitored by confocal microscopy, as described in the text.

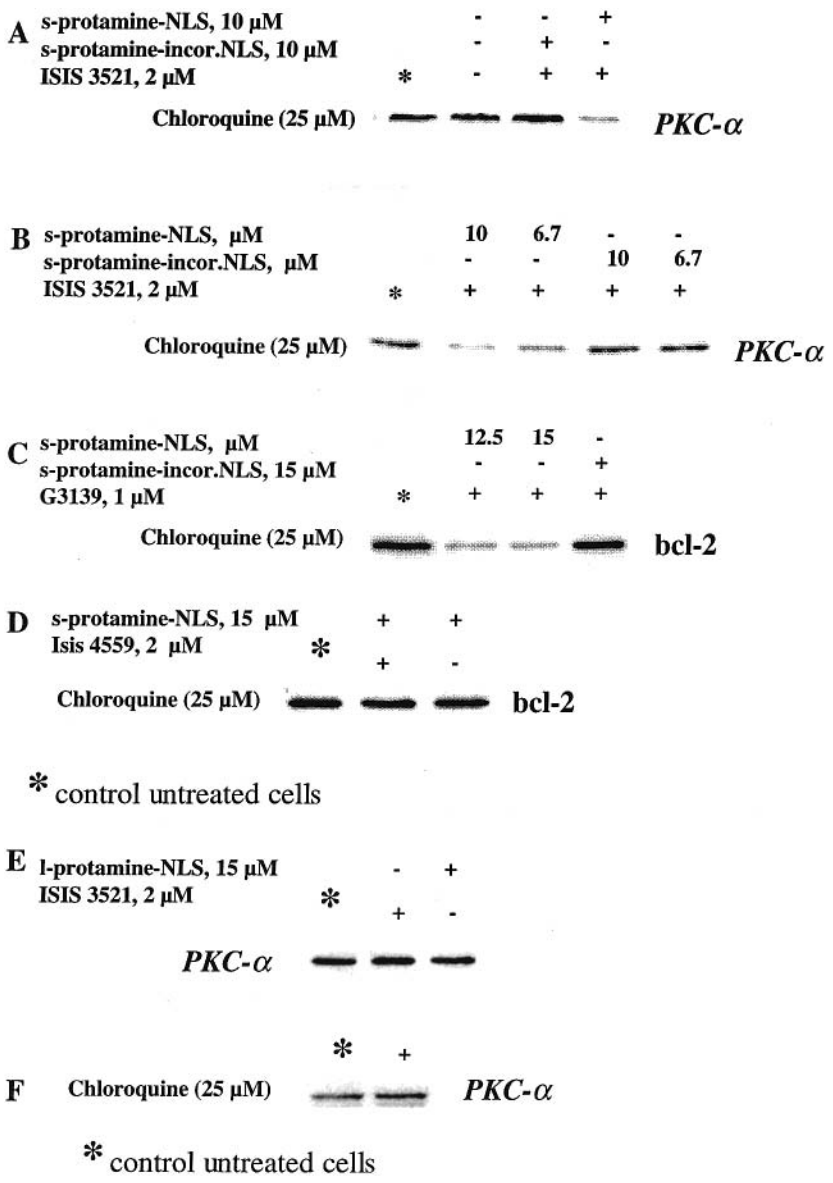

Figure 3. Inhibition of PKC-α protein expression by Isis 3521 (2 μM) (A, B) complexed with s-protamine-NLS (at the stated concentrations) in T24 (A) and PC3 (B) cells. (C) Inhibition of bcl-2 protein expression by G3139 (2 μM) complexed with s-protamine-NLS (15 μM) in PC3 cells. (D) Control oligonucleotide Isis 4559 complexed with s-protamine-NLS has no effect on bcl-2 expression in PC3 cells. (E) Uncomplexed l-protamine-NLS (15 μM) and Isis 3521 oligonucleotide in the presence of 25 μM chloroquine have no effect on PKC-α protein expression in PC3 cells. (F) Chloroquine (25 μM) alone has no effect on PKC-α protein expression in T24 cells. Cells were treated with complexes of Isis 3521 or G3139 oligonucleotides/s-protamine-NLS or control s-protamine-(incorrect)-NLS in the presence of 25 μM chloroquine for 5 h at 37 °C. 19 h (for PKC-α) or 67 h (for bcl-2) later, total protein was harvested, and Western blot analysis (25−30 μg of protein/lane) performed with anti-PKC-α and anti-bcl-2 antibodies as described in the Materials and Methods.

optimum incubation time of the cells with the peptide/oligonucleotide complexes was 5 h for Isis 3521 and G3139, followed by incubation periods of 24 h and 3 days, respectively.

To generate antisense effects, cells treated with s-protamine-NLS complexes with oligonucleotides were also pretreated with 50 μM chloroquine for 15 min. The chloroquine (final concentration = 25 μM) was allowed to remain in solution during incubation with the complexes (i.e., for 5 h). s-Protamine-NLS, when complexed to ISIS 3521 (2 μM), yielded significant antisense activity in both T24 (Figure 3A) and PC-3 cells (Figure 3B). By Western blotting and scanning densitometry, the expression of the PKC-α (T24 and PC3 cells) and Bcl-2 (Figure 3C; PC3 cells only) proteins were all reduced by approximately 70−80%. Naked oligomer (i.e., not complexed with peptide), at the identical concentration (2 μM) + 50 μM chloroquine preincubation and then 25 μM during the incubation period, was completely ineffective (Figure 3E), most likely because of the sequestration of the oligonucleotides in endosomes/lysosomes, as demonstated by confocal microscopy. A control, scrambled phosphorothioate oligonucleotide (Isis 4559; 2 μM)) complexed with the s-protamine-NLS-peptide, and ISIS 3521 complexed with s-protamine-(incorrect)-NLS-peptide under identical conditions (+ 50 μM chloroquine preincubation and then 25 μM during the incubation period), did not produce any reduction in target PKC-α protein levels in either T24 or PC3 cells (Figure 3A and 3B). Furthermore, 25 μM chloroquine alone did not downregulate PKC-α expression (Figure 3F), and neither the l-protamine-NLS alone (15 μM) nor Isis 3521 alone (Figure 3E) were active.

In addition, G3139 when complexed to s-protamine-NLS-peptide was "antisense" active in PC3 cells (Figure

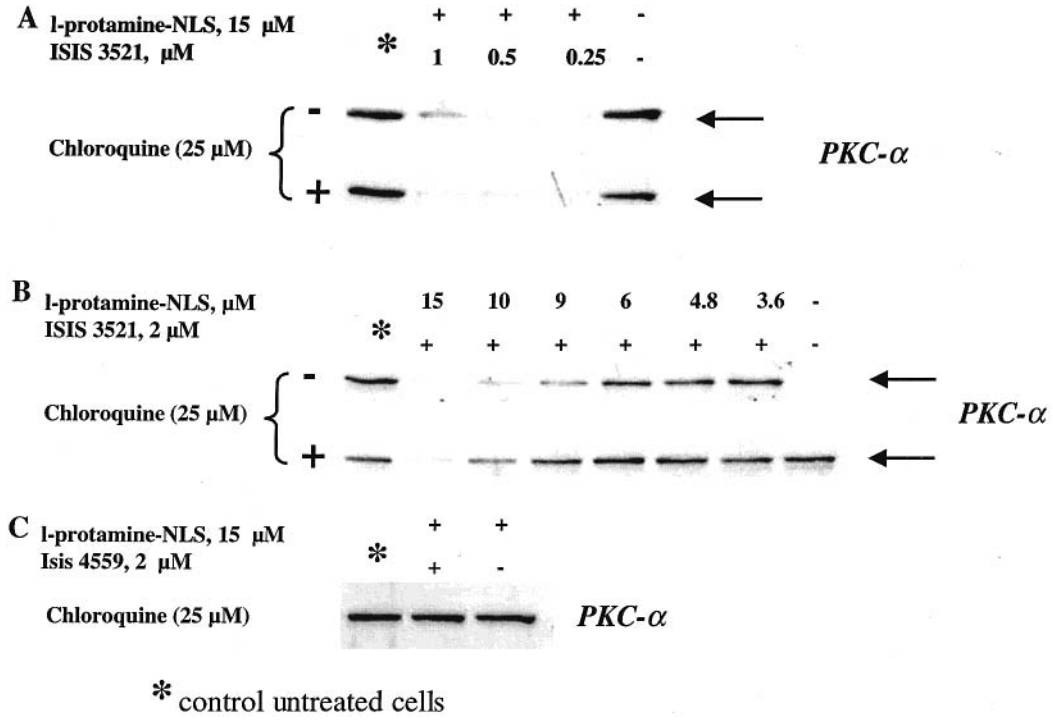

Figure 4. Inhibition of PKC-α protein expression in T24 cells by Isis 3521 (at the stated concentrations) complexed with l-protamine-NLS (15 μM) (A) and Isis 3521 (2 μM)/l-protamine-NLS (at the stated concentrations) (B) in the presence or absence of chloroquine. (C) Control oligonucleotide Isis 4559 (2 μM) complexed with l-protamine-NLS (15 μM), and uncomplexed l-protamine-NLS (15 μM), in the presence of 25 μM chloroquine, have no effect on PKC-α protein expression in T24 cells. Cells were treated with complexes of Isis 3521 or Isis 4559/l-protamine-NLS in the presence or absence of chloroquine for 5 h at 37 °C. 19 h later, total protein was harvested, and Western blot analysis (25−30 μg of protein/lane) was performed as described in the text.

3C). Similar controls as employed above (scrambled oligonucleotide Isis 4559, incorrect NLS sequence (15 μM), chloroquine alone (50 μM pretreatment then 25 μM during incubation; Figure 5C) were all totally inactive. However, we were not able to inhibit the expression of bcl-2 protein expression in T24 cells at any concentration of peptide/oligonucleotide complex.

2. l-Protamine-NLS Complexes with Oligonucleotides. We also evaluated the ability of a longer protamine peptide to diminish PKC-α and Bcl-2 protein expression in T24 and PC3 cells. Complexes of this peptide with the ISIS 3521 or the G3139 oligonucleotides were active over approximately the same concentration range in both cell lines. In T24 cells, as shown in the Western blots in Figure 4A and 4B, pretreatment by 50 μM chloroquine, and then treatment with 25 μM chloroquine during the incubation time was not necessary for the induction of an antisense effect. Instead, at a constant 2 μM concentration of Isis 3521 (Figure 4B), the concentration of peptide required for equivalent downregulation of PKC-α protein expression was slightly, but not dramatically, increased in the absence of chloroquine. At constant l-protamine-NLS concentration (15 μM; Figure 4A), the oligonucleotide concentrations required for maximal downregulation of PKC-α activity were also virtually identical in the presence and absence of chloroquine. However, the l-protamine-NLS (15 μM) complex with a control oligomer, Isis 4559 (2 μM; Figure 4C), did not produce any downregulation of PKC-α expression under the same experimental conditions. Congruent with these observations, the 8.5 kb and 4.0 kb PKC-α mRNA transcripts, as demonstrated by Northern blotting, were downregulated in the absence of chloroquine (Figure 6A).

In contrast, in PC3 prostate cancer cells, chloroquine (50 μM pretreatment + 25 μM during the incubation time) was still required for antisense activity. As shown in Figure 5A, a molar ratio of l-protamine-NLS/Isis 3521 of 7.5 provided maximal downregulation of PKC-α protein expression until a concentration of 1.9/0.25 μM was achieved. However, at a constant concentration of l-protamine-NLS (15 μM), Isis 3521 concentrations as low as 0.25 μM were still active (Figure 5B). Nevertheless, a decrease in peptide concentration to 10 μM virtually eliminated the antisense effect of Isis 3521. Similar to what was observed in the T24 cells, the control oligomer Isis 4559 (2 μM) complexed with 15 μM l-protamine-NLS was equally ineffective in the PC3 cells (Figure 5D). Furthermore, an l-protamine-NLS peptide in which the NLS sequence was mutated from PKKKRKV to PKGK-RKV did downregulate PKC-α protein expression (Figure 5D), but not quite to the same extent as the NLS peptide with the correct sequence.

G3139 (2 μM-0.25 μM) in complex with l-protamine-NLS (15−10 μM; Figure 5C) could effectively downregulate the expression of both bcl-2 protein (after 3 days) and mRNA (after 1 day; Figure 6B), but again only after pretreatment of the PC3 cells with 50 μM chloroquine and then treatment with 25 μM chloroquine during the incubation time. However, at lower peptide concentrations, antisense inhibition was lost (Figure 5C).

Downregulation of PKC-α Increases Sensitivity of T24 Bladder Carcinoma Cells to Paclitaxel. Reductions in cell proliferation was determined by MTT assay. Data are shown in Figure 7A and 7B, as determined after 3 days of drug treatment. This followed 24 h treatment of the T24 cells by complexes of s-protamine-NLS (15 μM)/Isis 3521 (2 μM) complexes and pretreatment of the cells with 50 μM chloroquine and then treatment with 25 μM during the incubation period. Isis 3521, s-protamine-NLS peptide, and 50 μM and then 25 μM chloroquine alone had no effect on cell viability, as assessed by MTT assay. Complexes of s-protamine-NLS

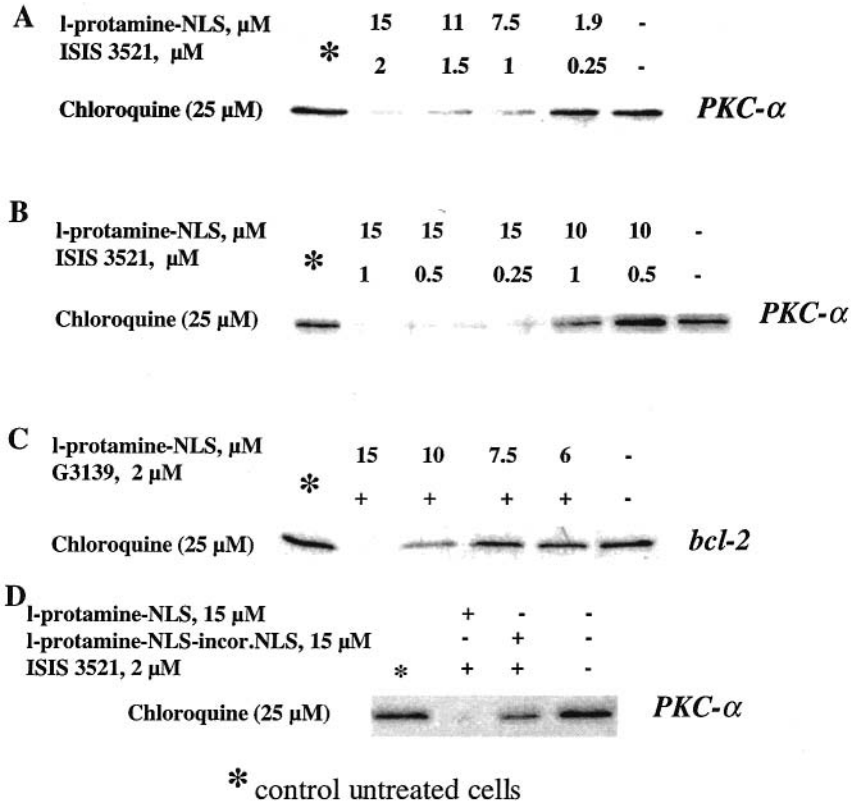

Figure 5. Inhibition of PKC-α protein expression by Isis 3521 (at the stated concentrations) complexed with l-protamine-NLS (at the stated concentrations) in PC3 cells (A, B). (C) Inhibition of bcl-2 protein expression by G3139 (2 μM) complexed with l-protamine-NLS (at the stated concentrations) in PC3 cells. (D) Complexes of Isis 3521/l-protamine-(incorrect)-NLS in the presence of 25 μM chloroquine have a diminished effect on PKC-α protein expression in PC3 cells, while chloroquine alone (25 μM) has no effect. Cells were treated with complexes of Isis 3521 or Isis 4559/l-protamine-NLS or complexes of Isis 3521/l-protamine-(incorrect)-NLS in the presence of 25 μM chloroquine for 5 h at 37 °C. 19 h later, total protein was harvested, and Western blot analysis (25−30 μg of protein/lane) was performed, as described in the text.

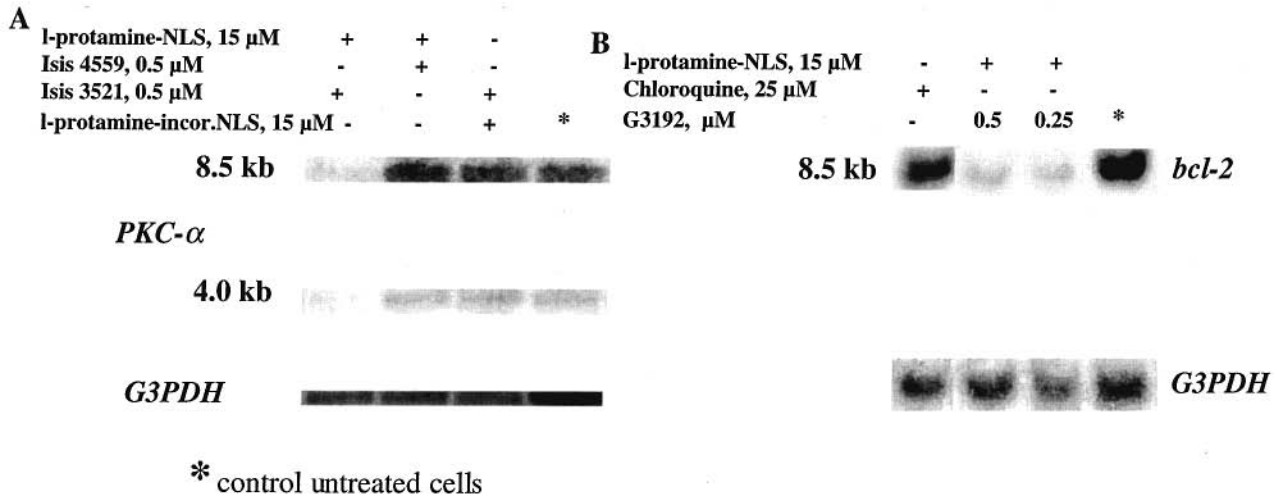

Figure 6. Inhibition of PKC-α mRNA expression by Isis 3521 (0.5 μM) complexed with l-protamine-NLS (15 μM) in T24 cells (A) and bcl-2 mRNA expression by G3139 (0.25 and 0.5 μM) complexed with l-protamine-NLS (15 μM) in PC3 cells (B). Cells were treated with complexes of Isis 3521, G3139 or control oligonucleotide Isis 4559/l-protamine-NLS in the presence of 25 μM chloroquine for 5 h at 37 °C. 19 h later, total mRNA was isolated, and Northern blot analysis was performed as described in the Materials and Methods. 30−40 μg of mRNA was loaded in each lane of the 1.2% denaturing agarose gel, transferred to Hybond-N nylon membranes, and probed with either a PKC-α, bcl-2, or control G3PDH cDNA probe.

(scrambled)-peptide/Isis 3521 reduced cellular viability to a much lesser extent. Only treatment of the cells with s-protamine-NLS/Isis 3521 was able to reduce cellular viability.

DISCUSSION

The peptides in this study were designed in an attempt to satisfy the major requirements for efficient oligonucleotide delivery to the cell nucleus, and, what is of course the ultimate goal, the retention of antisense activity. We believe that these requirements for peptide sequence include (1) the ability to bind to oligodeoxynucleotides, (2) the ability of the peptide−oligonucleotide complexes to penetrate the endosomal/lysosomal membrane, and (3) the ability of the peptide to promote nuclear localization.

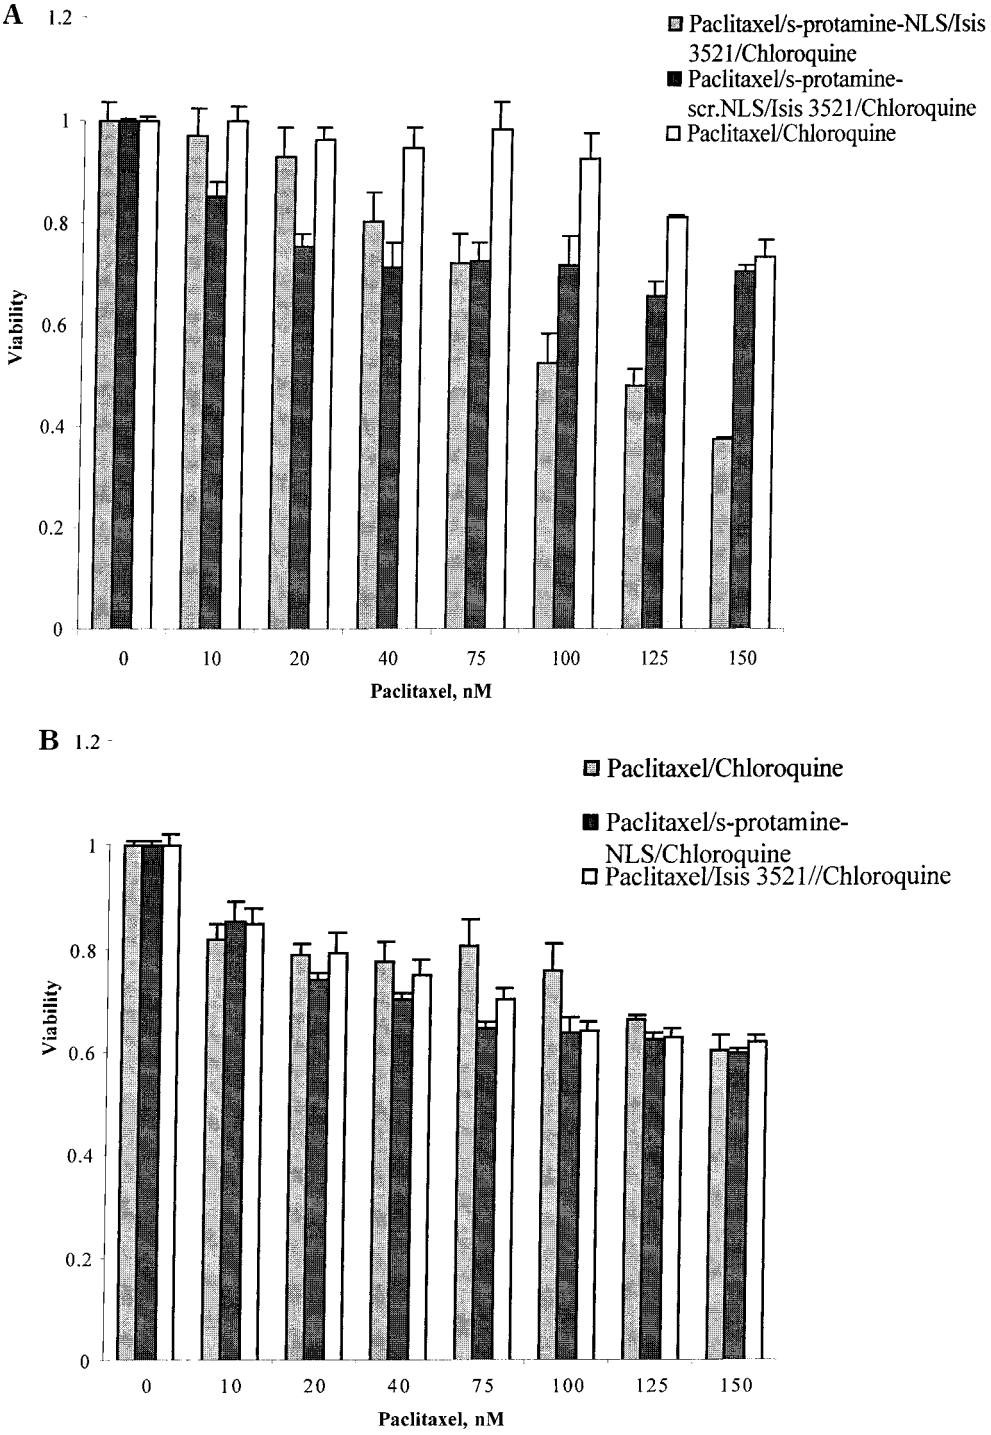

Figure 7. (A) Diminution in T24 cellular viability induced by the Isis 3521/s-protamine-NLS complex in response to increasing concentrations of paclitaxel. Neither control s-protamine-(scrambled)-NLS complexed to Isis 3521 (A), nor s-protamine-NLS or Isis 3521 alone (B) have any significant effect on T24 cellular viability in response to increasing concentrations of paclitaxel. Cells were treated with Isis 3521 complexed to s-protamine-NLS or s-protamine-(scrambled)-NLS or either s-protamine-NLS or Isis 3521 alone in the presence of 25 μM chloroquine for 5 h at 37 °C. The Opti-MEM media was then replaced with complete media containing various concentrations of paclitaxel. After 3 days of incubation, the MTT assay was performed. The absorbance at 540 nm was normalized to the controls to determine cellular viability. Experiments were performed in quaduplicate, and data are expressed as the mean absorbance ± the SD. A Student's two-sample t-test assuming unequal variances was used to determine the equality of the means of two samples (* = p <0.05).

The peptides described in this work satisfy criteria 1 and 3, and with the addition of chloroquine, all of them.

Bull protamine is a 50 amino acid peptide with an arginine rich central domain (ARYRCCLTHSGSRCR-RRRRRRC **RRRRRRFGRRRRRR** VCCRRYTVI.RC-TRQ). The short (s) sequence that we have tested is the central region highlighted in bold, with the exception that we have replaced the phe (F) with a trp (W) amino acid in order to provide an intrinsic fluorescent probe. This region was chosen because it provides the required arginine-rich sequence for oligonucleotide binding, but lacks cysteines which could promote dimerization. The long (l) protamine sequence contains the region in bold above, but the F is retained. Instead, the l-protamine sequence deletes the C and extends the R residues on both the N-and C-termini, as shown in Table 1.

Table 1. Peptides Used in This Work

peptide	sequence	mw	m/z^{+1}
s-protamine	R6WGR6	2134.88	2136.88

l-protamine-NLS	R4SR6FGR6VWR4−PKKKRKV	4580.90	4580.9
l-protamine-(incorrect)NLS	R4SR6FGR6VWR4−PK**G**KRKV	4509.93	4509.9

It is known that the positively charged guanidinium functional groups (pK_a = 12.5) electrostatically interact with the negatively charged phosphate backbone of DNA. These charge based interactions result in an overall charge neutralization leading to condensation of DNA.

In general, studies of protamine interactions have been carried out for double-stranded DNA. These have involved X-ray diffraction, Raman spectra, chemical reaction, and optical detection of magnetic resonance (*21*−*24*). Some of the reports are conflicting, but regardless it is now thought that the interaction of protamine and double-stranded DNA involves binding to the major groove with a β-form DNA and β-conformation for the protamine (*21*, *23*). Unfortunately, the interaction of protamine with single-stranded DNA remains poorly understood. Nevertheless, protamine is known to be an efficient condensing peptide and has been shown to enhance transfection (*25*) and lipid-mediated gene transfer (*26*). In these experiments, the binding of increasing concentrations of oligonucleotide to a much larger concentration of s-protamine-NLS fits a single-site binding model of the Michaelis−Menton type, with K_d as derived from the Lineweaver−Burke analysis equaling 75 nM. The binding of additional molecules of s-protamine-NLS to oligonucleotide is mathematically complex, but on the basis of the spectroscopic measurements, Trp fluorescence is 100% quenched at a peptide/oligomer molar ratio of 4:1 (charge ratio of approximately 3.15:1).

Arginine-rich peptides (e.g., Tat-(48−60) appear to be able to be internalized even at 4 °C by an endocytosis-independent pathway (*27*). Despite this, it seems unlikely that an arginine-rich peptide, when complexed with negatively charged oligonucleotides, will undergo endocytosis-dependent internalization. Experiments with the lysosomotropic agent chloroquine support this idea.

Chloroquine is a weak base (pK_a 10.2 and 8.1) that accumulates in endosomes/lysosomes in a time and concentration-dependent manner. It has been used extensively to improve nuclear delivery of plasmids, but to the best of our knowledge only rarely, if at all, for similar purposes for oligonucleotides (*28*). Intralysosomal concentrations of chloroquine may reach 9 mM, and the compound acts as a buffer to prevent the continuous endosomal acidification process (*29*). This causes a rise in intraendosomal osmolarity and its eventual lysis, releasing peptide/oligonucleotide complexes into the cytoplasm (the "proton sponge" hypothesis (*30*)). It is also possible that, in addition to this mechanism, chloroquine causes some degree of intraendosomal dissociation of the peptide/oligonucleotide complex (*29*). This dissociation may to some extent contribute to the retention of antisense activity (see below), but is probably overshowed in extent by peptide-mediated nuclear delivery.

A large family of nuclear localization signals exists, but the simian virus 40 (SV40 T) large T antigen nuclear localization sequence was chosen because it has resulted in efficient DNA transfer into the nucleus of various cell types, and has enhanced transgene expression (*31*−*34*). The peptide we employed (^{126}PKKKRKV^{132}) consists of a basic stretch of amino acids containing five consecutive positively charged residues, which are necessary for binding to the nuclear import protein karyopherin α (also known as importin α) (*35*). This complex then binds to importin β and, with the assistance of the GTPase Ran, is carried through the nuclear pore by mechanisms that are still poorly defined. Nevertheless, particles as large as 25 nm have been shown to be transported into the nucleus in this fashion (*35*). Since in preliminary experiments the particle size of the complexes is nearly 300 nm, significant intracellular decomposition must be occurring.

Lys-128 appears to be crucial for nuclear import (*36*). In this work, we have mutated Lys-128 to Gly and were unable to detect antisense downregulation of PKC-α protein expression. While these data strongly argue for the importance of the NLS in the generation of an antisense effect, other data suggest its role may be complex. For example, an s-protamine-NLS, in which the NLS has been scrambled, also promoted delivery of oligonucleotides to the nucleus, but did not downregulate the expression of PKC-α protein. This observation may suggest that the binding of the NLS to nuclear elements promotes dissociation of the oligonucleotide/peptide complex that results from particle degradation, thereby increasing the level of free nuclear oligonucleotide. However, this is speculative and other explanations may also be possible.

In summary, we have found a novel, efficient, arginine-peptide (and frequently, chloroquine) dependent way to transfer oligonucleotides into the nucleus of T24 and PC3 cells, where they produce downregulation of protein expression that is consistent with antisense effects. Provided that these substances can be manufactured at reasonable cost, they may be important complements to traditional cationic lipids as transfection vehicles.

Reversible Surface Thiol Immobilization of Carboxyl Group Containing Haptens to a BIAcore Biosensor Chip Enabling Repeated Usage of a Single Sensor Surface

Ulrich Schlecht,† Yoko Nomura, Till Bachmann,† and Isao Karube*

Research Center for Advanced Science and Technology, University of Tokyo, 4-6-1 Komaba, Meguro-ku, Tokyo 153-8904, Japan. Received February 1, 2001

We describe a reversible immobilization method for carboxyl group containing haptens that makes the repeated usage of a BIAcore biosensor chip possible. Haptens which are immobilized according to the surface thiol method can be removed completely from the sensor surface again by a reducing step. In the first part of our study, analogues of the herbicides 2,4-dichlorophenoxyacetic acid and 2,4,5-trichlorophenoxyacetic acid were immobilized in succession to a biosensor surface of a BIAcore surface plasmon resonance instrument according to the thiol coupling method. Direct kinetic analysis of these ligands to a polyclonal *anti*-2,4-dichlorophenoxyacetic acid antibody were performed using these biosensor surfaces. In the second part of the study, different amounts of 2,4-dichlorophenoxyacetic acid were sequentially immobilized onto the same biosensor surface in order to generate a calibration plot for 2,4-dichlorophenoxyacetic acid. Using this plot, the quantitative detection of the herbicide down to a concentration of 0.1 μg/mL, the maximum admissible concentration of pesticides in drinking water, is possible.

INTRODUCTION

2,4-Dichlorophenoxyacetic acid (2,4-D) and 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) are common herbicides used for the control of weeds that can potentially contaminate groundwater and drinking water supplies. It has been reported that exposure of humans to 2,4-D produces acute congestion of all organs and degenerative changes in ganglionic cells of the central nervous system (*1*). 2,4-D is also a carcinogen, causing soft-tissue sarcoma in humans (*2*) and malignant lymphoma in dogs (*3*). Toxicity of 2,4,5-T is mainly based on its contamination by dioxins, such as TCDD and PCDD, during its production (*4*). In the European Community (EC) countries, the maximum admissible concentration for pesticides in drinking water is 0.1 μg/mL for any substance and 0.5 μg/mL for the combined total of pesticides (*5*). Rapid, easy, and economical methods for the detection of these pesticides, most of which are low molecular weight ligands (haptens), are of great importance.

In the past few years, different approaches to the detection of pesticides have been described, for example, capillary gas chromatography with ion trap detection (*6*), piezoelectric biosensors (*7*), fiber-optic immunosensors (*8*), and amperometric cholinesterase biosensors (*9*). Beyond these techniques, the development of the surface plasmon resonance (SPR) technology has opened up a new and elegant way to detect haptens quantitatively. For instance, assays for the detection of the herbicides atrazine (*10*) and simazine (*11*) on the basis of the competition principle have been established. In the present study, we have detected 2,4-D for the first time using the BIAcore SPR technology and, in addition, we describe a new method of detection.

The specific chemistry of 2-(2-pyridinyldithio)ethaneamine hydrochloride (PDEA) that is normally used to perform site-controlled coupling of proteins to biosensor surfaces in the BIAcore system (*12*, *13*) inspired us to develop a reusable biosensor. With the described PDEA-dependent thiol coupling method (*14*), haptens containing a carboxyl group (i.e., 2,4-D) can be immobilized to a biosensor surface and removed again by a reducing step with a dithiothreitol solution. Using one biosensor chip, a calibration plot for the model compound 2,4-D has been generated that makes the quantitative detection of this herbicide down to a concentration of 0.1 μg/mL, the maximum admissible concentration of this pesticide in drinking water, possible.

The BIAcore SPR technology is also a powerful tool for binding affinity studies of haptens to related antibodies. The most common approach involves a competitive study in which an immobilized ligand and a soluble ligand free in solution compete for binding sites on a single analyte (solution competition) (*15*, *16*). The advantage of the solution competition experiment is that a single biosensor surface can be utilized for the determination of equilibrium association and dissociation constants (K_A and K_D, respectively) for a series of related analogues. Unfortunately, the method does not provide apparent association and dissociation rate constants (k_a and k_d, respectively). These constants characterize the association and the dissociation phases of antibodies binding to ligands in particular. They are often more reliable than the equilibrium constants. One way to determine these parameters is by direct kinetic analysis. The analogues are immobilized to the sensor surface, normally according to the amino-coupling method, and the antibody is injected over the surface at different concentrations (*17*). The disadvantage of this method is the necessity of a different sensor surface for each analogue tested (*18*), as the amino-coupling method is irreversible. Sensor chips from BIAcore are of high-quality in terms of a well-defined

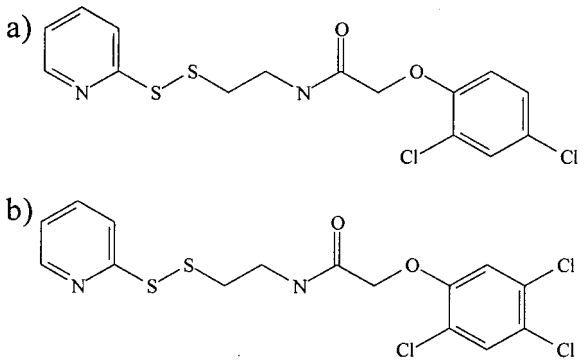
surface chemistry, but they are, at the same time, expensive. It is, therefore, of great interest to establish a fully reversible immobilization method which makes the repeated usage of a biosensor surface possible.

Our novel approach allows for the economical direct kinetic binding studies of several ligands to related antibodies. Different ligands can be reversibly immobilized to the surface. We have carried out direct kinetic analysis of binding parameters of a polyclonal *anti*-2,4-D antibody to 2,4-D and 2,4,5-T analogues using one sensor chip.

MATERIALS



2,4-D, 2,4,5-T, and all other reagents were obtained from Wako Pure Chemical Industries, Ltd. (Tokyo, Japan) unless otherwise noted. Sodium formate and formic acid were obtained from Kanto Chemicals Co., Inc. (Tokyo, Japan). Cystamine hydrochloride was purchased from Tokyo Kasei (Tokyo, Japan). Surface plasmon resonance measurements were carried out on a BIAcore 3000 (BIAcore AB, Uppsala, Sweden) automated system using C1 four-channel sensor chips (BIAcore AB, Uppsala, Sweden). Reagents for the BIAcore instrument consisted of a HBS-EP buffer [10 mM HEPES (pH 7.4), 150 mM NaCl, 3 mM EDTA, and 0.005% polysorbate 20 (v/v)], BIAnormalizing solution [70% (w/w) glycerol], a coupling kit (containing *N*-hydroxysuccinimide (NHS), *N*-ethyl-*N*-[3-(diethylamino)propyl] carbodiimide (EDC) and 1 M ethanolamine hydrochloride (pH 8.5)), and the thiol-coupling reagent 2-(2-pyridinyldithio)ethaneamine hydrochloride (PDEA), all from BIAcore. The polyclonal *anti*-2,4-D antibody was obtained from Guildhay, Ltd. (Guildford, Surrey, U.K.).

METHODS

Immobilization of 2,4-D Analogues to a C1-Sensor Chip. All of the experiments were carried out at 25 °C and with a flow rate of 5 μL/min. Immobilization of 2,4-D to a C1-sensor chip, which has a flat carboxymethylated surface without dextran matrix, was performed according to the surface thiol method described in the BIAapplications Handbook (*14*). Briefly, the biosensor surface was normalized with BIAnormalizing solution and primed with a HBS-EP buffer. It was then activated by a 2 min injection of a solution of 0.2 M EDC and 0.05 M NHS. Cystamine dihydrochloride (40 mM, solved in 100 mM boric acid (pH 8.5)) was then injected (3 min), followed by a 3 min injection of 100 mM dithiothreitol (DTT) reducing solution (solved in 100 mM boric acid (pH 8.5)) to reduce the dithio bridges of the immobilized cystamine. Two flow cells of the biosensor chip were prepared in the described way. In the following experiments, except for the linked reactions control experiment, one was used as the measuring cell and the other as the reference cell.

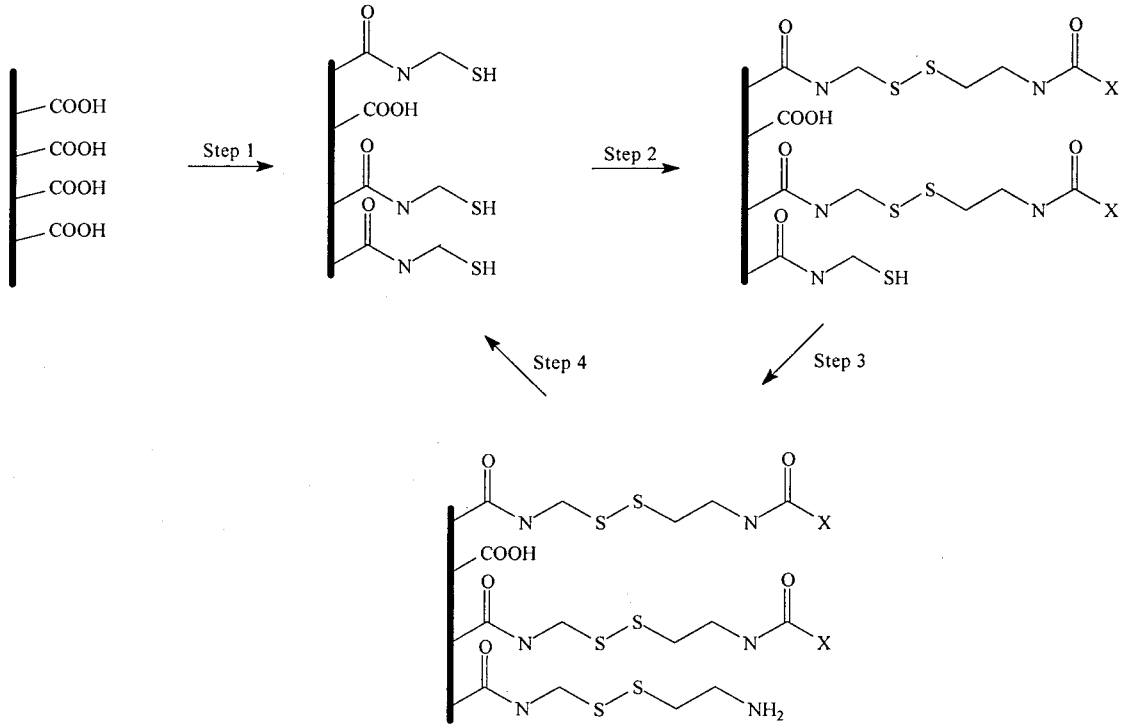
A mixture consisting of 50 μL of 45 mM PDEA (solved in an MES buffer (pH 5.0)), 50 μL of NHS (0.1 M), 50 μL of EDC (0.4 M), and 50 μL of 1.81 mM 2,4-D (solved in a 10 mM PBS buffer (pH 7.4)) was incubated on ice for 1 h to obtain PDEA/2,4-D conjugates (Scheme 1a). The mixture was then injected over the modified biosensor surface of the measuring cell (7 min) in order to immobilize 2,4-D analogues; the thiopyridone leaving group from the PDEA/2,4-D conjugate was set free, and a new dithio bridge between the surface thiol and the thiol of the 2,4-D analogue was formed. A 4 min injection of PDEA/NaCl solution (20 mM PDEA and 1 M NaCl in a 100 mM formate buffer (pH 4.3)) followed to block remaining unreacted active thiol groups in both flow cells.

Scheme 1. PDEA/2,4-D and PDEA/2,4,5-T Conjugates[a]

[a] (a) PDEA/2,4-D conjugate and (b) PDEA/2,4,5-T conjugate, which consist of a thiopyridone ring (leaving group) and the 2,4-D analogue or the 2,4,5-T analogue, respectively. The analogs are bound to the biosensor surface during the immobilization step.

Linked Reactions Control Experiments. For the linked reactions control experiment, 100 nM *anti*-2,4-D antibody solution was injected for 1, 3, and 20 min over the measuring cell of the prepared biosensor surface at a flow rate of 5 μL/min. The biosensor surface was regenerated after each run with a 100 mM hydrochloric acid wash (1 min).

Direct Kinetic Binding Analysis. To determine binding affinity parameters of *anti*-2,4-D antibodies to immobilized 2,4-D analogues, we injected five concentrations of *anti*-2,4-D antibody solution (37.5, 75, 150, 300, and 600 nM) over the biosensor surface. The biosensor surface was regenerated after each run with a 100 mM hydrochloric acid wash (1 min). Sensorgrams for each solution were obtained in duplicate. The fitting of the curves to the bivalent analyte model (*19*) was carried out by the BIAevaluation software (version 3.1).



Removal of 2,4-D Analogues from the C1-Sensor Chip. 2,4-D Analogues were removed from the biosensor surface by injection of a 100 mM DTT reducing solution for 4 min. To ensure that all analogues had been removed, a 600 nM *anti*-2,4-D antibody solution was injected for 2 min.

Scheme 2 shows in an overview the preparation of the C1-sensor chip, the immobilization of carboxyl group containing hapten analogues, the blocking of unreacted thiol groups, and the removal of the analogues from the surface.

Cross-Reactivity Study. A mixture consisting of 50 μL of PDEA (45 mM in an MES buffer (pH 5.0)), 50 μL of NHS (0.1 M), 50 μL of EDC (0.4 M), and 50 μL of 1.57 mM 2,4,5-T (solved in a 10 mM PBS buffer (pH 7.4)) was incubated on ice for 1 h to obtain PDEA/2,4,5-T conjugates (Scheme 1b). The mixture was then injected for 7 min over the biosensor surface of the measuring cell, from which the 2,4-D analogues had been removed before, to immobilize the 2,4,5-T analogues. To determine binding affinity parameters of *anti*-2,4-D antibodies to immobilized 2,4-D analogues, we injected five concentrations of *anti*-2,4-D antibody solution (37.5, 75, 150, 300, and 600 nM) over the biosensor surface. The biosensor surface was regenerated after each run with a 100 mM hydrochloric acid wash (1 min). Sensorgrams for each solution were obtained in duplicate. The fitting of the curves was carried out as described previously.

Creation of a Calibration Plot for 2,4-D Using a C1-Sensor Surface. A second C1-sensor chip was prepared according to the surface thiol method as described previously. Eight mixtures consisting of 50 μL of 45 mM

Scheme 2. Overview of the Preparation of a C1-sensor Chip, the Immobilization of Analogs of Carboxyl Group Containing Haptens, the Blocking of Unreacted Thiol Groups, and the Removal of the Analogs from the Surface[a]

[a] (Step 1) Carboxyl groups on the biosensor surface are activated by the injection of a mixture of 0.2 M EDC and 0.05 M NHS (1:1) for 2 min. A 40 mM cystamine dihydrochloride solution is injected for 3 min. The dithio bridges of the immobilized cystamine are reduced by injection of a 100 mM DTT solution for 3 min. (Step 2) PDEA/*x* conjugates (*x* stands for carboxyl group containing haptens, like 2,4-D or 2,4,5-T) are injected over the sensor surface. The dithio bridges between thiopyridone, the *x* analogue is cleaved, and a new bridge between a thiol group on the sensor surface and the analogue is formed. (Step 3) Unreacted thiol groups on the sensor surface are blocked by injection of a PDEA/NaCl solution. (Step 4) Dithio bridges between the analogues and the thiol groups on the sensor surface are cleaved by a reducing step. After the reducing step, a 600 nM *anti*-2,4-D antibody solution is injected for 2 min in order to ensure that all 2,4-D analogues have been removed.

PDEA (solved in an MES buffer (pH 5.0)), 50 μL of NHS (0.1 M), 50 μL of EDC (0.4 M), and 50 μL of 2,4-D (0, 1.8, 4.5, 13.5, 27, 54, 180, and 450 μM solved in a 10 mM PBS buffer (pH 7.4)) were incubated for 1 h on ice. These mixtures were sequentially injected over the biosensor surface (7 min) of the measuring cell in order to immobilize 2,4-D analogues. A 4 min injection of PDEA/NaCl solution (20 mM PDEA and 1 M NaCl in a 100 mM formate buffer (pH 4.3)) followed to block remaining unreacted active thiol groups in both flow cells.

Immobilized levels of 2,4-D analogues were detected by injecting a 600 nM *anti*-2,4-D antibody solution (2 min) and measuring the shift of the relative response 2 min postinjection in the measuring and the reference cell. The antibody solution was injected 5 to 10 times, depending on how fast a stable relative response level was reached.

The biosensor surfaces were regenerated after each run by washing three times with 100 mM hydrochloric acid (1 min). To remove all 2,4-D analogues from the biosensor surface before the injection of a new 2,4-D/PDEA/NHS/EDC mixture, a DTT reducing solution was injected over the biosensor surface for 4 min. To ensure that all 2,4-D analogues were removed by this reducing step, *anti*-2,4-D antibodies (600 nM) were injected over the biosensor surface (2 min).

RESULTS

Immobilization of 2,4-D Analogues on a C1-Sensor Chip and Linked Reactions Control Experiment. After conjugation of 2,4-D analogues to a C1-sensor chip by the thiol coupling method, an immobilization level of 10 RU was found. Sensorgrams obtained from the linked reactions control experiment are shown in Figure 1. The three sensorgrams show differently shaped association and dissociation profiles for increasing reaction times. This indicates a multistep reaction between the ligands on the biosensor surface and the soluble analyte. Because the analyte is a bivalent antibody, we have assumed that these results reflect its binding to one or two ligands on the surface. Dissociation of the antibody from the surface also occurs in two steps.

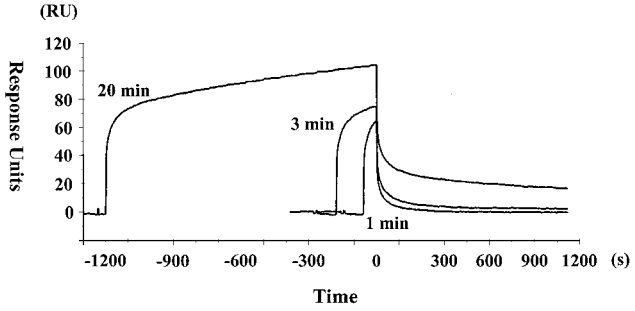


Figure 1. Linked reactions control experiment performed with *anti*-2,4-D antibodies injected over C1-sensor chip with immobilized 2,4-D analogues. A 100 nM *anti*-2,4-D antibody solution was injected for 1, 3, and 20 min over the prepared biosensor surface at a flow rate of 5 μL/min.

Determination of Binding Affinities of *Anti*-2,4-D Antibodies to 2,4-D Analogues. Sensorgrams which were obtained during the binding studies and which were fitted according to the bivalent analyte model are depicted in Figure 2. Binding parameters are shown in Table 1. Binding of the first ligand molecule is described

Table 1. Overview of the Binding Parameters Obtained from Direct Kinetic Analysis

hapten	k_a1 (1/Ms)[a]	k_d1 (1/s)[b]	K_D (1/M)	k_a2 (1/RUs)[c]	k_d2 (1/s)[d]	K_D2 (1/RU)
2,4-D	7.52×10^3	0.024	3.19×10^{-6}	8.09×10^{-5}	2.00×10^{-2}	2.47×10^2
2,4,5-T	6.42×10^3	0.215	3.35×10^{-5}	0.215	0.149	0.693

[a] Association rate constant for A + B = AB. [b] Dissociation rate constant for AB = A + B. [c] Association rate constant for AB + B = AB2. Note that the association rate constants for the second binding are 1/RUs, not 1/Ms. This is because the reaction involves complex (in RU) binding to ligand (in RU). [d] Dissociation rate constant for AB2 = AB + B. (A stands for antibody. B stands for immobilized ligand.)

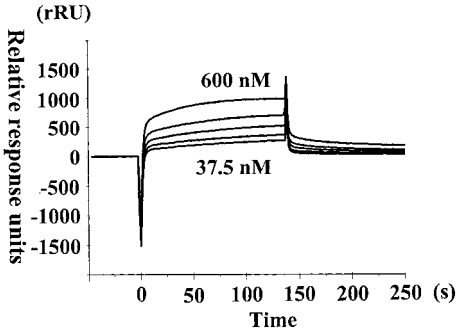

Figure 2. Direct kinetic analysis of binding of *anti*-2,4-D antibodies to 2,4-D analogues immobilized to a C1-sensor chip. Five concentrations of *anti*-2,4-D antibody solution (37.5, 75, 150, 300, and 600 nM) were injected over the biosensor surface for 2 min at a flow rate of 5 μL/min. The biosensor was regenerated after each run with a 100 mM hydrochloric acid wash (1 min).

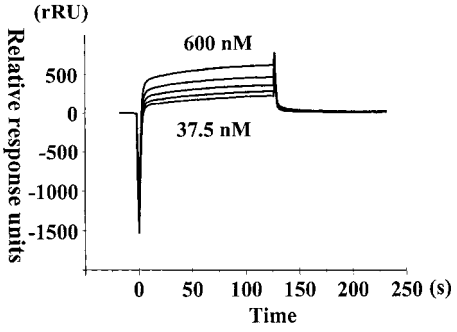

Figure 3. Direct kinetic analysis of binding of *anti*-2,4-D antibodies to 2,4,5-T analogues immobilized to a C1-sensor chip. Five concentrations of *anti*-2,4-D antibody solution (37.5, 75, 150, 300, and 600 nM) were injected over the biosensor surface for 2 min at a flow rate of 5 μL/min. The biosensor was regenerated after each run with a 100 mM hydrochloric acid wash (1 min).

by a single set of rate constants so that the two sites on the analyte are equivalent in the first binding step. Binding of the second ligand molecule is described by a second set of rate constants. The first and the second equilibrium dissociation constant calculated for *anti*-2,4-D antibodies binding to 2,4-D analogues is 3.19×10^{-6} M^{-1} and $2.47 \times 10^{+2}$ RU^{-1}, respectively.

Removal of 2,4-D Analogues from the C1-Sensor Chip. All 2,4-D analogues could be removed from the biosensor surface after reduction with a 100 mM DTT solution. No remaining 2,4-D analogues conjugated to the biosensor surface could be detected by injecting a 600 nM *anti*-2,4-D antibody solution; the relative responses (signal in the measuring cell minus the signal in the reference cell) were always decreased to nearly 0 RU.

Immobilization of 2,4,5-T Analogues on the C1-Sensor Chip and Cross-Reactivity Study. After conjugation of 2,4,5-T analogues to the C1-sensor chip, an immobilization of 8 RU was found. Sensorgrams which were obtained during the binding studies and which were fitted according to the bivalent analyte model are shown in Figure 3. Binding parameters are shown in Table 1. The first and the second equilibrium dissociation constant for *anti*-2,4-D antibodies binding to 2,4,5-T analogues is 3.35×10^{-5} M^{-1} and 6.93×10^{-1} RU^{-1}, respectively. The cross-reactivity of the *anti*-2,4-D antibody to 2,4,5-T is, therefore, 10%.

Creation of a Calibration Curve for 2,4-D. As expected, the relative response level increased with the concentration of 2,4-D in the mixtures and, therefore, with the amount of immobilized 2,4-D analogues. To obtain a calibration curve, the antibody solution was injected 5 to 10 times, depending on how fast a stable relative response level was reached. We have found that the relative response decreases during the first few cycles of detection, as shown in Figure 4, and we think this is due to a removal of only loosely bound 2,4-D analogues from the biosensor surface during the washes with 100 mM hydrochloric acid. Therefore, we have repeated the detection steps until the average of five relative responses had a standard deviation of 10%. The calibration plot of

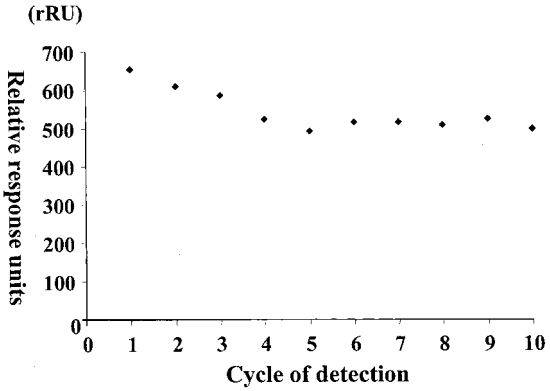

Figure 4. Stability of the relative response levels during detection of 2,4-D analogues. A mixture of PDEA, NHS, EDC, and 450 μM 2,4-D was injected over a C1-sensor chip, which was prepared according to the surface thiol method. Immobilized levels of 2,4-D analogues were detected by injection of a 600 nM *anti*-2,4-D antibody solution. After each detection cycle, the antibodies were washed from the surface by injection of a 100 mM hydrochloride solution (3 times). During the first few cycles, the relative response levels decreased because of the removal of only loosely bound 2,4-D analogues until it became stable.

the average relative responses versus the concentration of 2,4-D in the immobilized mixtures is depicted in Figure 5.

The relative responses after reduction with DTT reducing solution were always decreased to nearly 0 RU. A detection of 2,4-D analogues down to a concentration of 0.1 μg/mL was possible. In this case, the average relative response and standard deviation were 34.6 and 2.4 RU (7%), respectively.

DISCUSSION

The analytical system, BIAcore (*20*), is based on a biosensor that uses surface plasmon resonance to monitor the adsorption of biomolecules on a sensor chip. The SPR phenomenon measures changes in the refractive index in the vicinity of the surface. Such changes are correlated to the change in adsorbed mass (*21*), which makes it

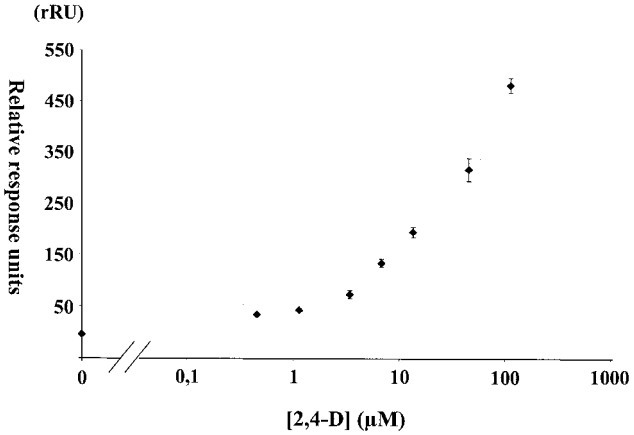

Figure 5. Logarithmic calibration plot for 2,4-D. Mixtures consisting of PDEA, NHS, EDC, and eight different concentrations of 2,4-D (0, 1.8, 4.5, 13.5, 27, 54, 180, and 450 μM) were sequentially injected over a C1-sensor chip, which was prepared according to the surface thiol method. Immobilized 2,4-D analogues were detected by a 600 nM *anti*-2,4-D antibody solution. After each run, the biosensor surface was regenerated with a 100 mM hydrochloric acid wash (1 min). The antibody solution was injected until the average of five relative responses had an SD of 10%. 2,4-D analogues were removed from the biosensor surface by reduction with a 100 mM DTT solution.

suitable for the detection of biomolecules. The larger the mass of the analyte used, the larger the instrumental response; low molecular weight analytes, like herbicides and peptides, only generate a minimal instrument response. An experiment in which the low molecular weight species is conjugated to the biosensor surface is, therefore, advantageous with regard to the generation of an instrument response upon binding of the macromolecular analyte. In this case, the low molecular weight ligand normally is immobilized to the biosensor surface by the amino-coupling method (*18*, *22*, *23*). A big disadvantage of this approach is that it necessitates the production of a different biosensor for each analogue studied, as the amino-coupling method is irreversible. We have, therefore, developed a method by which a hapten can be immobilized to and removed from one single biosensor surface of a BIAcore sensor chip for at least seven times. Considering that a BIAcore biosensor allows for 50−100 analytical cycles, depending on regeneration conditions (*20*), our method makes an even higher frequency of analytical cycles possible to be carried out.

We report, for the first time, a PDEA-dependent conjugation of haptens to a biosensor surface. Every hapten which contains a carboxyl group and which can, therefore, be conjugated to PDEA is suitable for this immobilization method. Because small molecules generally have fewer functional groups available for coupling to biosensor surfaces, in many cases they have to be modified for incorporation of a linker functionality (*18*, *23*), like a carboxyl group, for example. Also, such modified haptens are suitable for the immobilization method described here.

To obtain a calibration curve for the herbicide 2,4-D, seven different amounts of 2,4-D analogues were immobilized to the biosensor surface of a C1-sensor chip. Detection of 2,4-D analogues down to a concentration of 0.1 μg/mL, which is the maximum admissible concentration of pesticides in drinking water, was possible. A drawback with our method is that other haptens bearing carboxyl groups, such as amino acids or carboxyl acids that are present in environmental samples, might interfere with the amount of immobilized 2,4-D analogues.

In comparison to environmental samples, solutions for binding affinitiy studies are well-defined and, therefore, more suitable for our method. In this study, 2,4-D analogues were immobilized on a C1-sensor chip, and direct kinetic analysis was performed. The sensorgrams obtained were fitted according to the bivalent analyte model, which delivered detailed information about the first and the second binding steps of the bivalent analytes to the immobilized haptens. We have used the same biosensor surface to immobilize 2,4,5-T analogues for direct kinetic analysis. This shows that our method allows for easy and economical direct kinetic analysis of binding of several ligands to related antibodies. Cross-reactivity studies can be performed as shown in this paper.

The equilibrium dissociation constants (K_D) calculated for the first (and the second) site binding were 3×10^{-6} M^{-1} ($2.5 \times 10^{+2}$ RU^{-1}) and 3×10^{-5} M^{-1} (7×10^{-1} RU^{-1}) for 2,4-D and 2,4,5-T analogues, respectively, showing a reasonable selectivity of the antibody. The previously published equilibrium dissociation constants for the binding of *anti*-2,4-D antibodies to 2,4-D were 7×10^{-8} M^{-1} and 4×10^{-8} M^{-1} (*6*, *24*). These values showed a tighter binding than those we obtained. This might be due to the fact that we used polyclonal antibodies which were not purified and not due to the immobilization method itself.

CONCLUSION

We describe a reversible immobilization method for low molecular weight ligands containing carboxyl groups to biosensor surfaces of a BIAcore surface plasmon resonance instrument. Our method allowed us to obtain a calibration curve for the detection of the commonly used herbicide 2,4-D and to perform direct kinetic analysis of the binding affinity of a polyclonal *anti*-2,4-D antibody to the analogues of the haptens 2,4-D and 2,4,5-T using only one biosensor surface of a BIAcore sensor chip. There may be drawbacks in the described method of detection, namely, that other substances present in the environmental sample which also carry a carboxyl group might interfere with the level of immobilized 2,4-D. We have proved, however, that our method of immobilization, quantitative detection, and removal of the haptens works in principle. Regarding the kinetic analysis, we have obtained very detailed information. Apparent association and dissociation constants for the first and the second binding step of the bivalent analyte to the immobilized ligands were determined. Calculated equilibrium dissociation constants were smaller as compared to those shown in other publications, but purified monoclonal antibodies or F_{ab} fragments should deliver much better results.

Enzyme-Assisted Synthesis and Structure Characterization of Glucuronide Conjugates of Methyltestosterone (17α-methylandrost-4-en-17*β*-ol-3-one) and Nandrolone (estr-4-en-17*β*-ol-3-one) Metabolites

Box 56, Viikinkaari 5E, FIN-00014 University of Helsinki, Finland, and Laboratory of Toxicokinetics and Metabolism, Department of Industrial Hygiene and Toxicology, Finnish Institute of Occupational Health, FIN-00250 Helsinki, Finland . Received March 15, 2001; Revised Manuscript Received October 5, 2001

A new and useful method based on enzyme-assisted synthesis was developed for producing 3α-*O*-*β*-D-glucuronide conjugates from synthetic phase I metabolites of methyltestosterone and nandrolone. The formed glucuronide conjugates of 17α-methyl-5α-androstane-3α,17*β*-diol (I), 17α-methyl-5*β*-androstane-3α,17*β*-diol (II), 5α-estran-3α-ol-17-one (III), and 5*β*-estran-3α-ol-17-one (IV) are urinary metabolites, indicating the human misuse of the above-mentioned anabolic androgenic steroids (AAS). The common lack of reference material precludes the use and validation of these biomarkers in human doping control. Liver microsomes from Aroclor 1254-induced rats were used as a highly active source of mammalian UDP-glucuronosyltransferases (UGT, EC 2.4.1.17). After purification by protein precipitation, liquid−liquid extraction (dichloromethane), C-18 solid-phase extraction, and lyophilization, the steroid glucuronide structures were characterized by ^{1}H and ^{13}C NMR spectroscopy and tandem mass spectrometry. The enzymatic method was highly stereoselective, producing a single major conjugate from the parent steroids I−IV. The stereochemically pure steroid glucuronide conjugates were recovered in milligram amounts (1.0−2.8 mg, yield 12−29%), which is sufficient for veterinary and human doping control analyses; for pharmaco-, toxico-, and enzyme kinetic studies in the pharmaceutical industry; for clinical laboratories; and for forensic medicine. A new sensitive LC-MS method was developed for controlling the product purity in syntheses, as well as for enzyme kinetic characterization of AAS-metabolizing UGT activities in rat liver toward the aglycones I−IV. In this study, the UGT enzymes responsible for the formation of 3α-O-linked glucuronides from the substrates I, II, III, and IV exhibited the specific enzyme activity values: 25, 124, 48, and 212 nmol/mg microsomal protein in a 2-h incubation, respectively.

INTRODUCTION

Methyltestosterone (17α-methylandrost-4-en-17*β*-ol-3-one) and nandrolone (estr-4-en-17*β*-ol-3-one) are exogenous anabolic androgenic steroids (AAS) and widely misused in human sports. Because of their nonpolar character, AAS are extensively metabolized by routes involving functionalization (phase I) and conjugation (phase II) reactions prior to excretion in urine. AAS molecules with a 3-keto-4-ene structure undergo enzymatic reduction of the C4−C5 double bond in the A-ring as a rate-limiting step, which is catalyzed by 5α- and 5*β*-reductases (Figure 1). As soon as the double bond is reduced, the 3-keto-group is transformed mainly to a 3α-hydroxy structure (*1*, *2*). Phase I reactions thus provide attachment sites for subsequent conjugation reactions mediated by phase II metabolism. For AAS, the main conjugation pathway is glucuronidation (*3*), an S_N2 reaction between the donating coenzyme uridine-5′-

[c] Assayed with liver microsomes from Aroclor 1254 treated rats under conditions essentially the same as in bulk syntheses.

diphospho-α-D-glucuronic acid (UDPGA) and a nucleophilic steroid aglycone, yielding β-D-glucuronides through a configurational inversion of the α-glycosidic bond (*4*). Steroids possessing either a 3α- or 17β-hydroxyl group are predominantly metabolized by the UGT-mediated pathway (*5*), whereas steroids with the 3β-hydroxyl structure are mostly excreted as sulfates (*6, 7*). Studies with isoenzyme preparations of animal and human UGTs, obtained by protein purification or by cDNA-expression techniques, have revealed that members of both the UGT1 and UGT2 families carry out C18 and C19 steroid glucuronidation (*3, 8*−*16*).

The development of a synthesis method for the production of AAS glucuronides is of great interest due to the current lack of commercial reference compounds, especially in the case of exogenous AAS. In addition to veterinary and human doping control analyses, synthetic steroid glucuronides are applicable as reference material for analyses in the pharmaceutical industry, clinical laboratories, and forensic medicine. Regarding recent advances in method development, the adoption of liquid chromatography−mass spectrometry (LC-MS) techniques provides an alternative pathway for direct and straightforward analysis of nonvolatile steroid conjugates, offering a rapid analysis system under the growing pressure of sample input.

Reports of chemical syntheses of steroid glucuronide conjugates have been widely published (*17*−*22*). The problem with the classical synthesis is the possible formation of a racemic mixture of α/β-anomer and additional byproducts (*18*). Enzyme-assisted synthesis may offer an elegant way to produce stereochemically pure steroid glucuronides by virtue of the stereoselectivity encountered in nature for biochemical catalysts, i.e., UGT enzymes (*3*). Methods using rat liver preparations as a source of conjugating enzymes have been described for a structurally diverse group of substrates, e.g., *p*-nitrophenol (*23*); a series of nitrogen-containing antidepressants (*24*); nitrocatechols (*25, 26*); androsterone, androstanediol, dihydrotestosterone (*27*); epitestosterone (*28*); and testosterone (*29*−*31*).

The purpose of the present study was to develop and optimize a synthesis method for enzyme-assisted production of *O*-glucuronide conjugates derived from four AAS metabolites relevant to human metabolism and the abuse of exogenous steroids. The steroid aglycones 17α-methyl-5α-androstane-3α,17β-diol (I), 17α-methyl-5β-androstane-3α,17β-diol (II), 5α-estran-3α-ol-17-one (III), and 5β-estran-3α-ol-17-one (IV) each yielded a major product corresponding to the 3α-*O*-glucuronides referred to as 5α-MTG, 5β-MTG, 5α-NG, and 5β-NG (Figure 1). The synthesized products were characterized by NMR and tandem mass spectrometry and used as reference material for the development of a sensitive LC-MS method suitable for our present and future UGT enzyme kinetic studies.

EXPERIMENTAL SECTION

Chemicals. Steroid aglycones I, III, and IV (see Table 1) were purchased from Steraloids (Wilton, NH). Compound II was synthesized in our laboratory by the synthesis route of Shinohara (*32*), and the structure of the product was confirmed with the GC-EI/MS method against a standard reference of 17α-methyl-5β-androstane-3α,17β-diol. UDPGA was from Boehringer-Mannheim, and D-saccharic acid 1,4-lactone and androsterone glucuronide (internal standard) from Sigma Chemicals (St. Louis, MO). Aroclor 1254 (RCS-088/Analabs, Lot No K040) was from the Foxboro Company (North Haven, CT 06473). Solvents were of HPLC-grade. All other reagents were of analytical grade.

Preparation of Liver Microsomes. Adult female Wistar rats from Helsinki University Breeding Centre (n = 8, weight 224 ± 18 g) were killed on day 8 after administration of Aroclor 1254 (500 mg/4 mL olive oil/kg body weight on day 1, and 125 mg/1 mL/kg on day 6, intraperitoneally). The livers were perfused in situ with saline before being removed and stored at −70 °C. Liver microsomes were prepared by differential centrifugation (*33*), and the protein concentration (37.6 mg/mL) was determined according to the method of Lowry et al. (*34*). The treatment of the animals was approved by the local Ethical Committee for Animal Studies.

Bulk Synthesis. The reaction mixtures for enzyme-assisted synthesis of steroid glucuronides consisted of 1 mM of the lipophilic steroid substrates I, II, III, or IV (dissolved in 2 mL of methanol); 5 mM $MgCl_2$; 5 mM D-saccharic acid 1,4-lactone (a β-glucuronidase inhibitor); and 5 mM UDPGA in 50 mM K−Na-phosphate buffer (pH 7.4) and contained 20 mg of rat liver microsomal protein in a final volume of 20 mL. The concentration of methanol was limited to 10% to avoid protein denaturation. The enzyme reactions (started by UDPGA addition) were carried out at 37 °C (in a water bath) for 24 h in a glass vial with magnet stirring. The synthesis reaction was terminated with 2 mL of water-saturated dichloromethane (*29*), which was added for protein precipitation (15 min in an ice bath) and extraction of the residual steroid aglycone and nonpolar impurities from the synthesis mixture. A clear aqueous phase was separated by

centrifugation (14000 rpm, 10 min). The supernatant obtained was acidified with 4 N perchloric acid to ensure the neutral form of steroid glucuronides for their retention and cleanup by solid-phase extraction (SPE) with a C-18 cartridge (100 mg, International Sorbet Technology). The column was conditioned with 2.5 mL of methanol and then acidified with 2.5 mL of 1 N HCl. After loading of the sample (5 mL per a cartridge), polar impurities were removed with 2.5 mL of water and the final elution was performed with 2.5 mL of methanol. Methanol was evaporated to dryness (N_2, 60 °C), and the dry residue, which was reconstituted to 3 mL with water, was frozen and lyophilized. This step enabled the formation of white crystals of steroid glucuronides.

Mass Spectrometric Characterization. The mass spectra were recorded by Perkin-Elmer Sciex API 300 (Sciex, Concord, Canada) triple quadrupole instrument equipped with electrospray ion source (ESI). Samples were introduced by loop injection, and both positive and negative ion MS and MS/MS spectra were measured. Operation parameters, as well as the MS and MS/MS behavior of the glucuronides studied, have been presented in detail earlier (*35*).

LC-MS Procedure. The LC-MS method was developed for the detection of synthesis impurities and for the enzyme kinetic studies. Liquid chromatography consisted of Perkin-Elmer LC 200 Series micro pump and Series 200 autosampler, and Phenomenex Luna C-18 (150 × 1.0 mm, particle size 5 μm) micro column. The total eluent flow of 100 μL/min was split after the column by a ratio of 1:10 (ICP-04−20, LC-Packings). HPLC eluent A was 15 mM ammonium acetate/formic acid buffer (pH 4.2) in water:acetonitrile (9:1, v/v), and eluent B included the same buffer and acetonitrile but in a reversed ratio (1:9, v/v). The gradient was set as a linear increase of the eluent B content from 10% to 50% in 15 min, corresponding to an actual acetonitrile gradient from 18% to 50%. The column was equilibrated for 11 min after each analysis. The injection volume was 5 μL.

NMR Spectroscopy. Steroid glucuronides were dissolved in 40 μL of acetone-d_6. The NMR experiments were carried out on a Varian Unity 500 spectrometer at 23 °C using a gHX nano-NMR probe. For the DQFCOSY (*36*) experiment (16 scans per t_1 value), a matrix of $2k \times 256$ points was collected and zero-filled to $2k \times 512$. A cosine-bell weighting function was used in both dimensions. For the HMQC (*37*) and HMBC (*38*) spectra (32 and 64 scans per t_1 value, respectively), matrixes of $2k \times 256$ and $2k \times 128$ points were recorded and zero-filled to $2k \times 512$ and $2k \times 256$ points, respectively. A cosine-bell weighing function was used. The average $^1H-^{13}C$ coupling constant was estimated to be 150 Hz and Δ_2 was 60 ms. The ^1H and ^{13}C chemical shifts were referenced to residual acetone, 2.05 and 29.92 ppm, respectively.

Enzyme Activity Studies. The kinetic data obtained for microsomal UGT activity toward the parent steroid aglycones I, II, III, and IV represent mean values of duplicate incubations performed and analyzed all on the same day. In enzyme activity assays the final incubation volume was 100 μL, the microsomal protein content 100 μg, and the test concentration of each substrate 1, 2.5, 5, 10, 25, 50, 100, 250, 500, and 1000 μM. Otherwise, the composition of the reaction mixture was the same as in bulk synthesis. The glucuronidation reaction (preincubated for 11min) was started with the addition of UDPGA, incubated for 2 h at 37 °C before being stopped with 10 μL of 4 N perchloric acid and by chilling the sample tubes for 15 min in an ice bath (protein precipitation). An internal standard, androsterone glucuronide (10 μM), was added prior to centrifugation (14000 rpm, 10 min). The supernatant was cleaned up by the same C-18 SPE procedure as in bulk synthesis, with the exception that the final elution was in 500 μL acetonitrile. The sample was evaporated to dryness (N_2, 60 °C) and diluted in 100 μL of eluent A for LC-MS analysis. The four most concentrated samples of each series (substrate concentration 100−1000 μM) were additionally diluted 10-fold with eluent A to ensure that the measurement was within the dynamic range of ESI-MS. The steroid glucuronide formation was calculated by using the ratio of the peak area of ammonium adduct $[M + NH_4]^+$ of analyte (A_A) and that of the internal standard (A_{ISTD}), i.e., $v = A_A/A_{ISTD}$.

RESULTS AND DISCUSSION

Bulk Synthesis. Figure 1 shows the steroidal 3α-*O*-β-D-glucuronides (5α- and 5β-MTG, 5α- and 5β-NG) formed from 17α-methyl-5α-androstane-3α,17β-diol (I), 17α-methyl-5β-androstane-3α,17β-diol (II), 5α-estran-3α-ol-17-one (III), and 5β-estran-3α-ol-17-one (IV) by means of enzyme-driven syntheses. The compounds I and 5α-MTG can be detected in human urine after dosing with mestanolone, methyltestosterone, or oxymetholone, and the compounds II and 5β-MTG after methandriol, methyltestosterone, or metandione intake (*39*). The compounds III, IV, 5α-NG, and 5β-NG originate from nandrolone metabolism (*39*). Notably, we used liver microsomes from female rats pretreated with a mixture of polychlorinated biphenyls (Aroclor 1254) as the enzyme source. According to human excretion studies, the metabolites synthesized here (Figure 1 and Table 1) are, evidently, also formed in man (*1*, *2*, *39*). The method described in this work is suitable for producing milligram quantities of stereochemically pure steroid glucuronides at reasonable costs. This amount is enough for metabolic in vitro studies as well as for doping control analysis. The concentrations in these analyses are typically below 1 μg/mL, and therefore standard material of 1 mg of steroid glucuronide is enough for more than 1000 analyses.

The data in Table 1 summarize the results for bulk syntheses of the four steroid glucuronides illustrated in Figure 1. We also show the results from the short-term kinetic studies describing the reaction velocities of the present enzyme-driven syntheses. The UGT activities in rat liver microsomes were tested toward the parent steroids I − IV at 10 different substrate concentrations (1−1000 μM) using a reaction time of 2 h and a 5 mM UDPGA concentration. These findings suggested that at a 250−1000 μM substrate concentration the reaction velocity is maintained nearly at maximum for each substrate (I−IV). The efficiency of the rat enzyme source to glucuronidate different steroids exhibited an 8-fold difference. This was revealed by the specific enzyme activities varying from 25 to 212 nmol/mg protein per 2 h (Table 1). Moreover, the 5α-MTG and 5α-NG products were clearly formed at lower specific rates than the 5β-MTG and 5β-NG anomers. Despite careful optimization of the initial reaction conditions (substrate, UDPGA, and microsomal protein), the yields of single syntheses remained lower than expected by the reaction velocities measured for the biosyntheses of 2 h (Table 1). A plausible explanation may lie in the uncertainty of maintaining the optimal reaction conditions throughout an incubation time extended over up to 24 h. Another obvious reason for low yields is the poor solubility of the substrates in aqueous incubation media. This problem could be only partly resolved by addition of methanol,

[a] See nomenclature in Figure 1. [b] n.d. = not detected.

because the amount of organic solvent must be less than 10% to avoid denaturation of enzyme catalysts.

The purity of the synthesis products was characterized with LC-MS. The total ion chromatograms showed only one intense peak corresponding to the steroid glucuronide, and no impurities were detected. Despite a complex incubation matrix containing biological material, a simple procedure based on protein precipitation and liquid−liquid extraction with dichloromethane followed by C-18 SPE was adequate for efficient and rapid cleanup of the syntheses. The chemical stability of aryl and alkyl glucuronides has earlier been reported to be good (*18*). However, during our LC-MS studies it was evident that acid-catalyzed methylation of the glucuronide moiety occurred in standard samples, which were stored in a freezer for more than two weeks in the presence of methanol and at pH 4.2. Stock solutions were therefore prepared in acetonitrile and stored in a freezer for several months without any detectable changes in the steroid glucuronide structure.

Mass Spectrometry. The abundant ammonium adduct ions $[M + NH_4]^+$ and deprotonated molecules $[M - H]^-$ recorded in positive and negative ESI-MS, respectively, indicate the correct molecular weights of the synthesized steroid glucuronides. The product ion spectra of $[M + NH_4]^+$ and $[M - H]^-$ show diagnostic product ions $[M + H - Glu]^+$, $[M + H - Glu - H_2O]^+$, $[M + H - Glu - 2H_2O]^+$ and $[M - H - Glu - 2H]^-$, indicating clearly the presence of the glucuronide moiety (Table 2). These ions also provide strong evidence for the expected *O*-glucuronidation. The product ions $[Glu + H]^+$, $[Glu + H - H_2O]^+$, $[Glu - H]^-$, and $[Glu - H - H_2O]^-$ provide further evidence for the presence of the glucuronide moiety. The isomers 5α-NG and 5β-NG can be distinguished according to the ratio of relative abundances of product ions $[M + H - Glu]^+/[M + H - Glu - H_2O]^+$, which is significantly higher for 5β-NG than for 5α-NG. However, the product ion spectra of 5α-MTG and 5β-MTG pair were strongly analogous and thus without a distinction of isomers. A more detailed discussion about MS and MS/MS behavior of the compounds is presented in our earlier paper (*35*).

NMR Spectroscopy. For structural analysis, the ^1H and ^{13}C spectra of each steroid glucuronide were assigned. The ^1H signals were assigned from DQFCOSY,

[a] See nomenclature in Figure 1. [b] C6−H6,H6′ and C7−H7,H7′ may have to be interchanged. [c] From HMQC. [d] n.d., not determined.

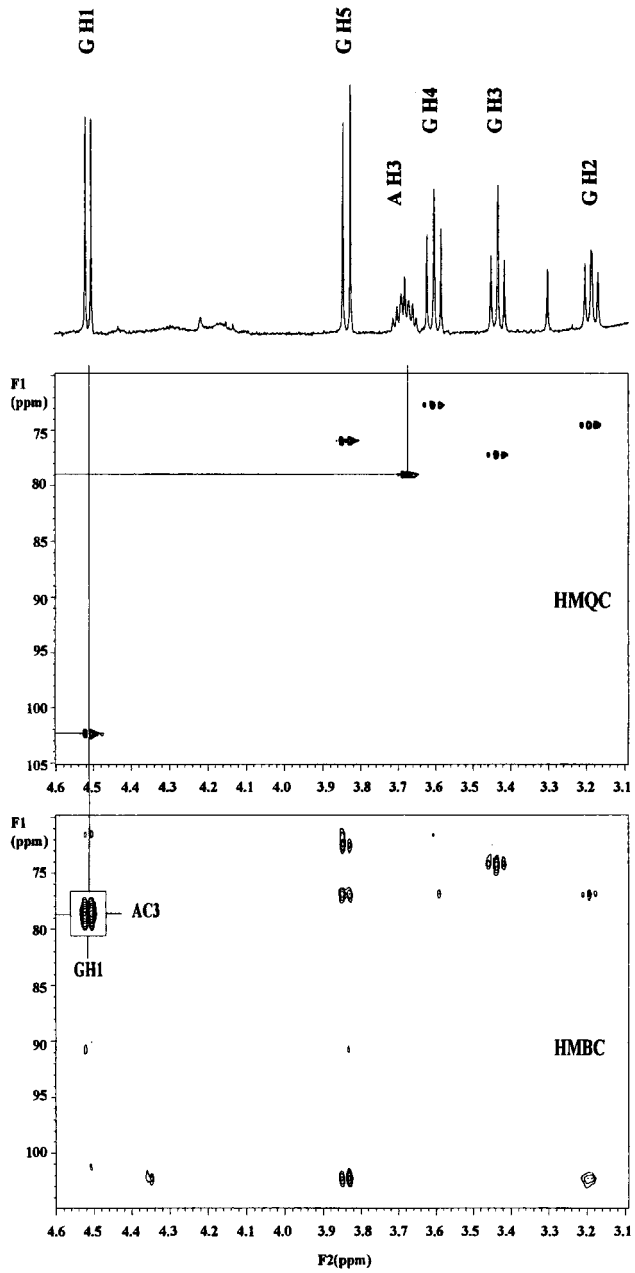

Figure 2. Expansion of 1D, HMQC and HMBC spectra of 5β-NG. In the 1D spectrum, a typical aglycone H3 resonance (AH3) of a H3β−H5β configuration is seen. The solid lines in HMQC and HMBC spectra with $J_{GH1,GH2}$ = 7.7 Hz establish the glycosidic linkage to be β(1→3).

and the corresponding ^{13}C resonances were located from the HMQC spectrum (Table 3). The anomericity of the glucuronide moieties was determined from the vicinal coupling constant $^3J_{GH1,GH2}$. As the measured coupling constants of 7.7−7.8 Hz are typical values between two axial protons (*40*), the β-configuration was confirmed. The aglycone H3 resonance in the ^1H spectra of 5α-MTG and 5α-NG appears as a quintet with a coupling constant of ∼2.5 Hz as expected for the H3β-H5α steroids (*41*). On the other hand, the corresponding H3 resonance in ^1H spectra of 5β-MTG and 5β-NG is a multiplet of seven peaks (Figure 2), which is the typical pattern for the H3β-H5β-configuration (*41*). These results confirm the expected anomericity at H5 for each steroid. Finally, the positions of the glycosidic linkages of each steroid glucuronide were identified from the interglycosidic correlation in the HMBC spectra. In each HMBC spectra the resonance correlating H1 of the glucuronide to C3 of the aglycone was observed (Figure 2).

Liquid Chromatography−Mass Spectrometry. A sensitive LC-MS method was developed for the determination of steroid-glucuronidation activities. Steroid glucuronide structures possess neither chromophores nor fluorophores, and therefore conventional LC methods based on UV or fluorescence detection are not applicable. The method showed a good linearity as indicated by the calibration curves, which were linear over a wide concentration range of 10 to 5000 ng/mL and exhibited correlation coefficients (r^2) between 0.9989 and 0.9993. The quantitation limit of the present method was sufficient for the determination of steroid metabolizing UGT activity in small-volume enzyme assays (100 μL) with a very low aglycone (I, II, III, IV) concentration, starting from 1 μM and upward (Table 1). It is of the utmost importance to work with diluted samples due to the limited dynamic range of ESI-MS. The signal saturation at higher concentrations than 10−50 μM is due to droplet surface saturation in the ESI process (*42*).

Enzyme Kinetics. The velocity of the pathway forming glucuronides linked to the 3α-OH moiety of the parent AAS substrates I−IV was measured in hepatic microsomes from Aroclor-induced rats and with the LC-MS method described above. This UGT activity was readily quantitated even at a substrate concentration as low as 1 μM. The actual reaction rates and their dependence on the aglycone concentrations were measured at a 2 h time point and under the same conditions as used in the bulk syntheses. Because the glucuronidation activities obtained (Table 1) were not fully consistent with the assay conditions required for the determination of enzyme kinetic parameters, no K_m or V_{max} values are given. Our results on enzyme kinetics are in line with reports suggesting that the glucuronidation of hydroxyandrogens shows a high degree of stereo- and regioselectivity (*5*). The 5α-structured steroids, both C18 and C19 steroids, were glucuronidated in all test concentrations (1−1000 μM) at a clearly lower velocity than the corresponding 5β-anomers. It is also noteworthy, that our NMR data supports the assumption that 17α-CH_3 substitution hinders 17β-OH glucuronidation, and the glucuronides detected in the present biosyntheses were linked only to the 3α-hydroxy positions. Yields of the steroid glucuronides 5α-MTG, 5α-NG, and 5β-MTG were reflected by the specific activities assayed at 0.1 to 1 mM substrate concentrations. In this context, 5β-NG was a clear exception.

ACKNOWLEDGMENT

Ms. Leena Luukkanen is gratefully acknowledged for her excellent guidance with enzyme-assisted syntheses, Mr. Antti Leinonen and Dr. Kimmo Kuoppasalmi for scientific support, and the National Technology Agency (TEKES) together with the University Pharmacy (YA) for financial support.

A Homogeneous DNA Hybridization System by Using A New Luminescence Terbium Chelate

Shinji Sueda,[†] Jingli Yuan,[‡] and Kazuko Matsumoto*,[†]

Department of Chemistry, Waseda University, 3-4-1 Okubo, Shinjuku-ku, Tokyo 169-8555, Japan, and Department of Analytical Chemistry, Dalian Institute of Chemical Physics, Chinese Academy of Sciences, Dalian, China. Received April 16, 2001; Revised Manuscript Received December 7, 2001

Homogeneous DNA hybridization assay based on the luminescence resonance energy transfer (LRET) from a new luminescence terbium chelate, *N*,*N*,*N*^{1},*N*^{1}-[2,6-bis(3′-aminomethyl-1′-pyrazolyl)-4-phenylpyridine]tetrakis(acetic acid) (BPTA)-Tb^{3+} (λ_{ex} = 325 nm and λ_{em} = 545 nm) to an organic dye, Cy3 (λ_{ex} = 548 nm and λ_{em} = 565 nm), has been developed. In the system, two DNA probes whose sequences are complementary to the two different consecutive sequences of a target DNA are used; one of the probes is labeled with the Tb^{3+} chelate at the 3′-end, and the other is with Cy3 at the 5′-end. Labeling of the Tb^{3+} chelate is accomplished via the linkage of a biotin-labeled DNA probe with the Tb^{3+} chelate-labeled streptavidin. Strong sensitized emission of Cy3 was observed upon excitation of the Tb^{3+} chelate at 325 nm, when the two probe DNAs were hybridized with the target DNA. The sensitivity of the assay was very high compared with those of the previous homogeneous-format assays using the conventional organic dyes; the detection limit of the present assay is about 30 pM of the target DNA strand.

INTRODUCTION

Several homogeneous DNA hybridization assay systems have been reported (*1*−*4*), in which fluorescence resonance energy transfer (FRET) is used, and the target DNAs can be detected in a homogeneous solution without time-consuming and tedious immobilization of the DNAs or separation of the reaction solution (*5*). In the FRET assay, two DNA probes, each being complementary to the two different consecutive regions of a target DNA, are used. One probe has a donor dye while the other an acceptor dye. The target DNA is detected in a homogeneous manner by monitoring the sensitized emission of the acceptor resulting from the hybridization reaction. In most of the systems developed so far, organic dyes are employed as the donor−acceptor pair. However, the sensitivities of such systems are insufficient for practical use. Such low sensitivity is mostly due to the existence of the substantial background caused by the donor emission and the directly excited acceptor emission.

To circumvent this problem, we have directed our attention to the lanthanide chelates as the energy donor and have already developed a homogeneous DNA hybridization system using the BHHCT-Eu^{3+} chelate as the donor and Cy5 as the acceptor (*6*−*8*). Some of the lanthanide chelates exhibit marked distinct luminescence properties (*9*−*14*): the luminescence emission profiles of the lanthanide chelates are very sharp, usually with the fwhm of ca. 10 nm; the Stokes shift is large, usually in the range of several hundreds of nanometers; the excitation is 300−350 nm and the emission is 615 nm for the Eu^{3+} chelate and 545 nm for the Tb^{3+} chelate. Therefore, the sensitized emission band of the organic dye acceptor can easily be distinguished from the excitation light and the emission of the lanthanide chelate donor. Also, the directly excited acceptor emission is effectively suppressed to almost zero, because the absorption spectra of the acceptor organic dyes hardly overlap on those of the donor lanthanide chelates and therefore the excitation wavelength, owing to the large Stokes shift of the lanthanide chelates. Moreover, the lifetimes of the lanthanide chelates are very long (∼1 ms), and as a result, the sensitized emission of the acceptor also becomes long-lived. Thus, by employing time-resolved luminescence measurement, luminescence of the short-lived species including the directly excited acceptor emission can be eliminated (*11*−*14*).

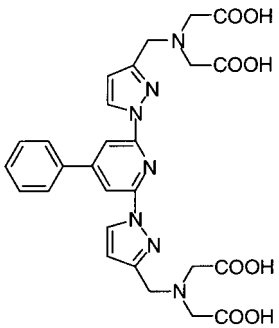

Figure 1. Structure of the BPTA ligand.

Recently, we have developed a new luminescent terbium chelate, *N*,*N*,*N*^{1},*N*^{1}-[2,6-bis(3′-aminomethyl-1′-pyrazolyl)-4-phenylpyridine]tetrakis(acetic acid), (BPTA)-Tb^{3+} (Figure 1). The synthesis and the fluorescence properties of the chelate were detailed in the previous paper (*15*). The Tb^{3+} chelate exhibits strong luminescence characteristic of Tb^{3+} ion at 545 nm by the excitation of the ligand (325 nm), whose lifetime is over 2 ms. In the present manuscript, a homogeneous DNA hybridization assay system based on the luminescence resonance

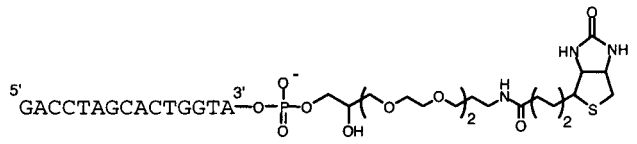
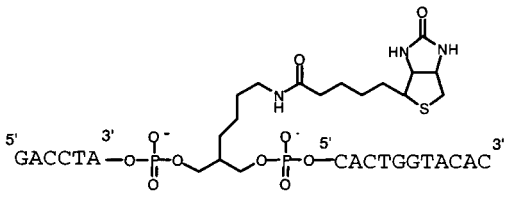
energy transfer (LRET) from the BPTA−Tb^{3+} chelate to an organic dye, Cy3, is reported.

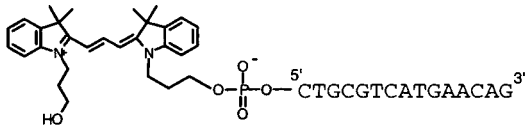
The principle of our method is illustrated in Figure 2. The acceptor Cy3 was directly introduced into the 5′-end of the probe DNA. On the other hand, the donor Tb^{3+} chelate was indirectly introduced into the probe DNA via the biotin−streptavidin bridge: the donor probe DNA was prepared by addition of the Tb^{3+} chelate-labeled streptavidin to the biotin-labeled probe DNA. In the system, the sensitized emission of Cy3 is observed via LRET in the presence of the target DNA, but not in the absence of the target DNA. Therefore, the target DNA can be detected by monitoring the sensitized emission of Cy3, in a homogeneous solution without the conventional immobilization and separation steps. In the present work, two kinds of donor probe DNAs were used, which differ in the biotin labeling position: one has a biotin label at the 3′-end (3′-end donor probe), and the other has in the internal position (internal donor probe). These two donor probe DNAs serve to examine the effect of the distance between the donor and acceptor on the energy transfer efficiency.



EXPERIMENTAL PROCEDURES



The Labeling of Streptavidin with the BPTA−Tb^{3+} Chelate. The synthesis of BPTA was reported in the previous paper (*15*). Streptavidin (SA) was labeled with BPTA by using the succinimidyl monoester of BPTA (NHS−BPTA) according to the procedure slightly modified from that of our previous report (*15*) as follows. Ten milligrams (1.5×10^{-2} mmol) of NHS−BPTA and 5 mg (8.3×10^{-5} mmol) of SA were dissolved in 0.1 M carbonate buffer (pH 9.1) (10 mL). After the solution was stirred for 4 h at room temperature, the solution was dialyzed three times against 3 L of 0.1 M $NaHCO_3$ containing 0.25 g of NaN_3, each time for 24 h at 4 °C. The labeling ratio of BPTA to SA was determined as SA-$(BPTA)_{26}$ by using the absorbance of the labeled SA solution and the molar extinction coefficient of BPTA. The complexation with Tb^{3+} was achieved by dilution of the labeled SA solution (1 mL) with 50 mM Tris-HCl buffer (pH 7.8) (24 mL) containing equimolar amount of $TbCl_3$ and incubation for a few minutes at room temperature. The luminescence of the Tb complex appeared immediately. Dilution of a nonlabeled SA solution with the same $TbCl_3$ buffer solution did not give luminescence, which confirmed that Tb^{3+} binds to BPTA and gives the luminescence. The high stability of the BPTA−Tb^{3+} complex was confirmed by the two experiments: First, the competitive binding assay with EDTA showed that the binding constant of the free BPTA with Tb^{3+} is higher than that of EDTA ($K_a > 10^{18}$). Second, the Tb^{3+} titration with BPTA labeled to SA by monitoring the Tb^{3+} luminescence showed that the chelate formation is stoichiometric in the concentration range less than that of the presence work.



Preparation of the Probe DNAs and the Target DNAs. Figure 3 shows the probe DNAs and the target DNAs used in the present work. The 31mer and 34mer were used as the target DNAs in the 3′-end biotin probe system and the internal biotin probe system, respectively. All DNAs (oligonucleotides) were prepared on a fully automated DNA synthesizer according to the standard phosphoramide coupling method. Biotin was introduced into the 3′-end and the internal position of the oligonucleotides by using biotin TEG CPG and biotin TEG phosphoramidite (Glen Research), respectively, whereas Cy3 was introduced with Cy3 phosphoramidite (Glen Research). The purification of the oligonucleotides was carried out with reversed-phase HPLC.

Hybridization Condition. The target oligonucleotides and probe oligonucleotides were mixed at a desired ratio in the buffer containing 10 mM Tris-HCl (pH 7.8) and 0.5 M NaCl. Oligonucleotides were annealed by heating at 50 °C for 15 min and cooling to room temperature.

Luminescence Energy Transfer Measurement. To a solution of the hybridized oligonucleotides was added the solution of BPTA−Tb^{3+}-labeled SA at an 1:1 molar ratio of SA to the biotinylated DNA. The final concentrations of the probe DNAs and labeled SA were 50 nM or 10 nM. After the solution was incubated for 1 h at room temperature, the luminescence was measured with the excitation at 325 nm. The luminescence was measured

on a LS-50B (Perkin-Elmer) fluorometer equipped with a Xenon flash lamp (10 μs-pulse width and repetition rate of 50 Hz). A 420 nm cut off filter was employed to eliminate the second-order scattering light. The spectra of LRET were measured in two modes. One is a normal luminescence mode, in which all the luminescence was recorded over a gate period of 80 μs after pulse excitation without delay time. The other is the time-resolved luminescence mode, in which luminescence is recorded over a gate period of 500 μs with 40 μs of delay time after pulse excitation. In this time-resolved mode, the luminescence of only the long-lived species can be detected; the fluorescence of the short-lived species are eliminated. Luminescence decay curves were obtained by measuring the luminescence intensity at 565 nm with the gate period of 10 μs gate period after the appropriate delay time. By varying the delay time, the luminescence decay curves were constructed.

RESULTS

Spectral Characteristics of the Donor and Acceptor. The emission spectrum of the BPTA−Tb^{3+} chelate bound to SA, and the emission and absorption spectra of Cy3 bound to the oligonucleotide are shown in Figure 4. The emission peak of the Tb^{3+} chelate overlaps on the absorption spectrum of Cy3, satisfying the requirement for luminescence resonance energy transfer. It should also be noted that the emission intensity of the Tb^{3+} chelate at the Cy3 emission maximum of 565 nm is very weak; the emission intensity of the Tb^{3+} chelate at 565 nm is 250 times lower than that at the Tb^{3+} chelate maximum of 545 nm. Therefore, high signal/background ratio is obtained when the sensitized emission of the acceptor is monitored at 565 nm, resulting in the highly sensitive detection of the target DNA.

Measurement of the Emission Spectra in the Normal Luminescence Mode. Figure 5 shows the

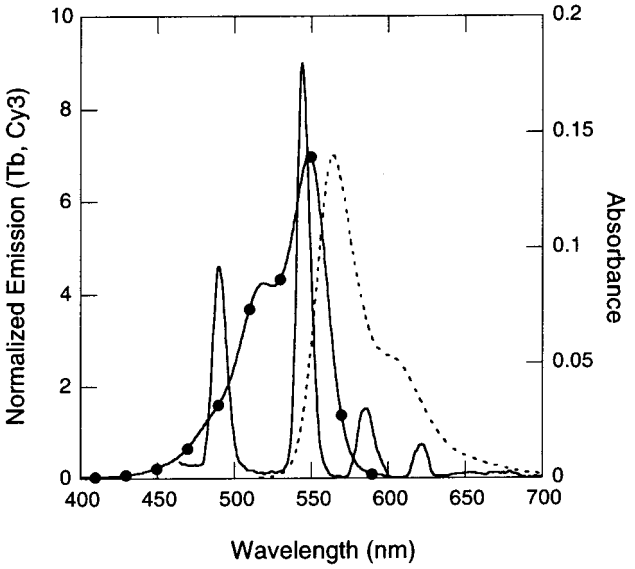

Figure 4. Spectra of the BPTA−Tb^{3+} chelate bound to SA, and Cy3 bound to the oligonucleotide. The solid line is the emission spectrum (λ_{ex} = 325 nm) of the BPTA−Tb^{3+} chelate, and the dashed line and the solid line with dots are the emission spectrum (λ_{ex} = 545 nm) and absorption spectrum of Cy3, respectively.

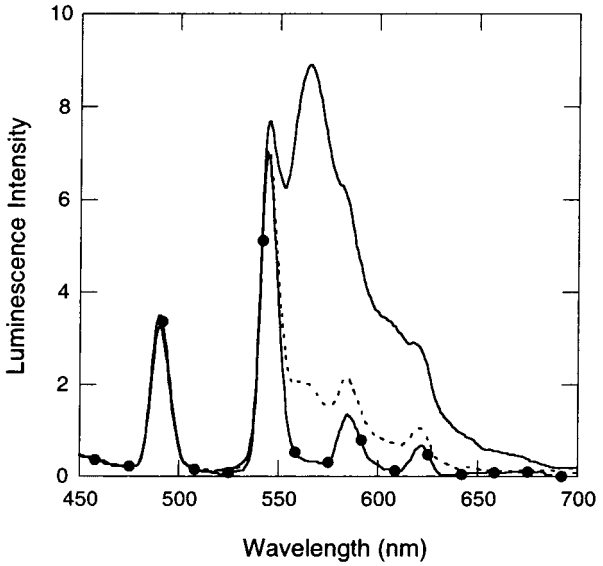

Figure 5. Comparison of the emission spectra obtained in the normal luminescence detection mode. Solid line represents the emission spectrum obtained for the 3′-end donor probe DNAs in the presence of its target DNA (31mer). Dashed line represents the emission spectrum obtained for the internal donor probe DNAs in the presence of its target DNA (34mer). Solid line with dots represents the emission spectrum observed in the absence of the target DNAs. Both of the 3′-end donor system and the internal donor system gave the identical spectrum in the absence of the target DNAs. The concentrations of the probe DNAs, the target DNAs, and SA were 50 nM.

emission spectra obtained in the normal luminescence mode, i.e., the spectra measured without delay time. The comparison of the emission spectra in the presence and absence of the target DNAs shows that the sensitized emission of Cy3 is observed only in the presence of the target DNAs. The sensitized emission is stronger in the 3′-end donor probe system than the internal donor probe system, and this is due to the well-known relation that the energy transfer efficiency decreases with R^{-6}, where R is the distance between the donor and the acceptor (*16*). The biotin is separated from Cy3 by 11 base pairs (ca.

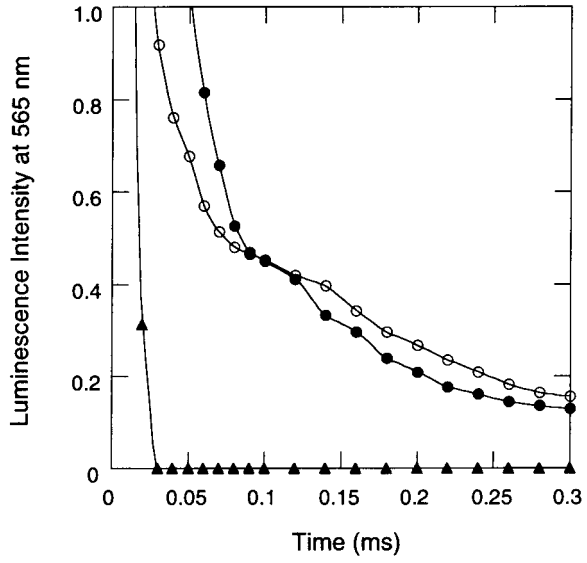

Figure 6. The luminescence decay curves of Cy3 observed at 565 nm. Closed circles are for the 3′-end donor probe DNA, and open circles are for the internal donor probe DNA. Both of the two curves were obtained in the presence of the target DNAs. The curve with triangles was obtained in the absence of the donor probe. The concentrations of the probe DNAs, the target DNAs, and SA were 50 nM.

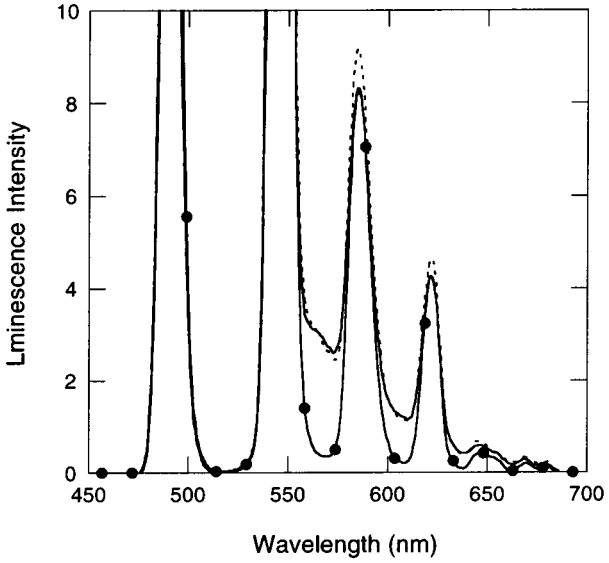

Figure 7. Comparison of the emission spectra observed in the time-resolved luminescence mode. The spectra were obtained with 40 μs delay time and 500 μs gate time. Solid line represents the emission spectrum obtained for the 3′-end donor probe DNA in the presence of its target DNA (31mer). Dashed line represents the emission spectrum obtained for the internal donor probe DNA in the presence of its target DNA (34mer). Solid line with dots represents the emission spectrum observed in the absence of the target DNAs (an identical spectrum was obtained for the both donor probe DNAs systems). The concentrations of the probe DNAs, the target DNAs, and SA were 50 nM.

35 Å) in the internal donor probe system, whereas the separation is only a single base in the 3′-end donor probe system. It is notable that the intensity of the sensitized emission obtained in the 3′-end donor probe system is significantly strong; the signal/background ratio at 565 nm is approximately 30:1 (the signal/background ratio represents the ratio of the emission intensities at 565 nm in the presence and absence of the target DNA).

Measurement of the Luminescence Decay Curves. Since the lifetime of the BPTA−Tb^{3+} chelate is very long (>2 ms), it is expected that the sensitized emission of the acceptor, Cy3, also becomes long-lived. The luminescence decay curves were measured for the sensitized emission by monitoring the intensity at 565 nm (Figure 6). Clearly, the lifetimes of the sensitized emission in both of the donor probe systems are longer-lived than that obtained in the absence of the donor probe DNAs. While exact quantitative determination of the lifetime is not possible in the present LRET, where multiple donor molecules with various distances to the acceptor molecule transfer the energy, the lifetimes were roughly estimated in the range of a few tens to a few hundreds microseconds. This long-lived property clearly demonstrates that the observed emission of Cy3 in the presence of the target DNAs is due to LRET. In Figure 6, while the luminescence intensity is stronger during the initial 0.1 ms for the 3′-end biotin probe system than for the internal biotin probe system, this relation is reversed after 0.1 ms. This means that the lifetime of the sensitized emission of Cy3 becomes longer as the distance between the donor and the acceptor increases. This behavior is explained by the mechanism of LRET as follows: when the distance is short, the efficiency of the energy transfer increases, and the lifetime of the Tb^{3+} chelate becomes short. At the same time, the lifetime of the acceptor, Cy3 decreases, since the donor Tb^{3+} chelate becomes short-lived. Therefore, the lifetime of the sensitized emission is shorter in the 3′-end biotin probe system, in which energy transfer occurs more effectively.

Measurement of the Emission Spectra in the Time-Resolved Luminescence Mode. It was found in the above decay curves that the sensitized emission of Cy3 is moderately long-lived (microsecond order) and therefore can be monitored in the time-resolved luminescence mode. Figure 7 shows the observed time-resolved luminescence spectra in the presence and absence of the target DNAs. In this detection mode, the intensity of the sensitized emission at 565 nm is almost the same in both of the two donor probe DNA systems. As shown in the decay curve experiment, the intensity of the sensitized emission is stronger during the initial 0.1 ms for the 3′-end biotin probe system than for the internal biotin probe system; however, this relation is reversed after 0.1 ms. In this work, the time-resolved spectra were obtained with the gate period of 0.5 ms after 0.04 ms of the delay time. It seems that the intensities of the sensitized emission of the Cy3 happened to be the same in both of the two probe DNA systems under the present condition.

Contrary to our expectation, the signal/background ratio at 565 nm in the time-resolved mode is lower (approximately 10:1) than that in the normal luminescence mode (approximately 30:1). In the present LRET assay, multiple Tb^{3+} chelates labeled to a large streptavidin molecule act as the donor, and the energy transfer occurs between these multiple Tb^{3+} donors and a single Cy3 molecule. The distances of the Tb^{3+} chelates to the Cy3 molecule span a substantial range, since the Tb^{3+} chelates are bound to a large streptavidin molecule. Some of the chelates efficiently transfer the absorbed energy to Cy3, whereas others do not, depending on the distance. Under such circumstances, the lifetime of the Tb^{3+} chelate is still longer than that of Cy3. At 565 nm, the Tb^{3+} chelate has weak emission. This weak emission is really weak compared to the sensitized emission of Cy3 in the normal luminescence measurement, however becomes moderately strong and constitutes the background in the time-resolved measurement, since both of the intensities are collected after 0.04 ms of delay time.

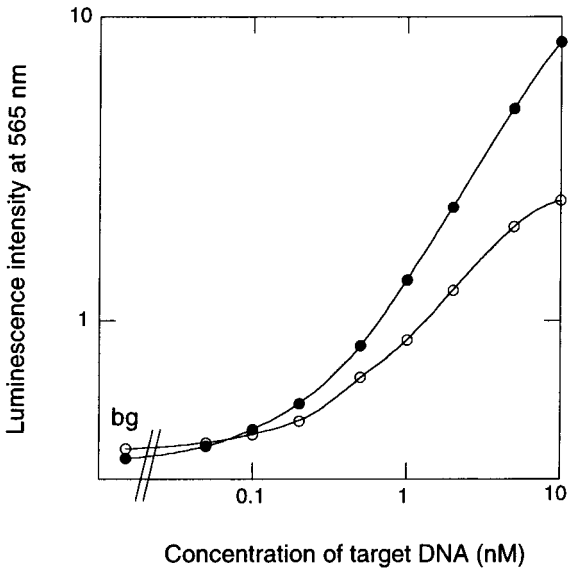

Figure 8. The plot of the Cy3 emission intensity at 565 nm against the concentration of the target DNA (31mer). The plot was obtained for the 3′-end donor probe DNA system. Closed circles are for the normal luminescence mode, and the open circles are for the time-resolved luminescence mode. The concentrations of the probe DNAs and SA were 10 nM.

This is the reason for the low signal/background ratio at 565 nm in Figure 7 than in Figure 5.

The Sensitivities for DNA Detection in the Two Detection Methods. The sensitivity of the present method was examined by using the 3′-end biotin probe system. Figure 8 shows the plot of the Cy3 emission intensity at 565 nm against the concentration of the target DNA. Figure 8 shows both of the normal mode and the time-resolved mode. The detection limit was determined as the concentration corresponding to the twice amount of the background standard deviation. Detection limits in the normal mode and the time-resolved mode are about 30 pM and 50 pM, respectively, when 10 nM of the probe DNA was used. These detection limits are 2 orders of magnitude superior to that obtained with the previous homogeneous hybridization assay (*17*).

DISCUSSION

In the present work, a homogeneous DNA hybridization assay has been developed based on the luminescence resonance energy transfer from the BPTA−Tb^{3+} chelate to Cy3. Two systems differing in the distance between the donor and the acceptor were constructed by using two donor probe DNAs, one having the biotin label at the 3′-end and the other at the internal position. As expected, the emission was more effectively sensitized in the system of the 3′-end biotin probe. By using the 3′-end biotin system, the high signal/background ratio (30:1) was obtained at 565 nm in the normal luminescence mode. Such a high signal/background ratio cannot be achieved in the systems using organic dyes as the donor−acceptor pairs. The emission and absorption peak profiles of the organic dye pairs are broad and overlap to each other to some extent; as a result, the emission of the donor and the directly excited emission of the acceptor cause substantial background to the sensitized emission. However, in our system using the Tb^{3+} chelate as the donor, the emission of the donor hardly interferes with the sensitized emission, because the emission profile of the Tb^{3+} chelate is very sharp and the emission intensity is very weak at the maximum emission wavelength of Cy3. The directly excited emission of the acceptor is also very effectively suppressed, since Cy3 is scarcely excited at the excitation wavelength for the Tb^{3+} chelate, 325 nm (the molar extinction coefficient of Cy3 at 325 nm is about one-eightieth of that at its maximum absorption wavelength, 548 nm).

The detection limit of the present method is excellent, due to the high signal/background ratio and the very effective energy transfer. The Tb^{3+} chelate is multiply labeled onto the probe DNA by using the streptavidin−biotin interaction, and causes strong sensitized emission of Cy3. Such multiple labeling strategy was not effective for enhancing the fluorescence of the acceptor in the conventional donor organic dye system, due to π-stacking and reabsorption of the emitted fluorescence of the donor (*18*). The Tb^{3+} chelate molecules do not stack to each other and do not quench their emission since they have a large Stokes shift.

Under the time-resolved luminescence measurement condition (delay time 40 μs, gate time 500 μs), the intensity of the sensitized emission of the acceptor was almost the same between the 3′-end donor probe system and the internal donor probe system. This behavior is explained by the LRET property that as the distance between the donor and the acceptor increases, the efficiency of the energy transfer is decreased, whereas the lifetime of the sensitized emission is increased. In the time-resolved mode, the signal/background ratio at 565 nm is markedly low, as compared with that in the normal luminescence mode, though the emission in the latter mode contains a considerable contribution from the direct excitation of the Cy3 acceptor. Consequently, the detection limit is better in the normal luminescence mode than in the time-resolved mode. However, the time-resolved detection mode is still attractive, especially for the samples containing many impurities or coexisting materials, since the background emission caused by the short-lived species can be eliminated by the time-resolved mode. Considering these LRET characteristics, the optimal distance between the donor and the acceptor and the optimal measurement conditions must be found, and such parameters are expected to depend on the nature of the samples.

Star Structure of Antibody-Targeted HPMA Copolymer-Bound Doxorubicin: A Novel Type of Polymeric Conjugate for Targeted Drug Delivery with Potent Antitumor Effect

Marek Kovář,[†] Jiří Strohalm,[‡] Tomáš Etrych,[‡] Karel Ulbrich,[‡] and Blanka Říhová*[,†]

Received June 29, 2001; Revised Manuscript Received December 14, 2001

The aim of this study was to compare the properties and antitumor potential of a novel type of antibody-targeted *N*-(2-hydroxypropyl)methacrylamide (HPMA) copolymer-bound doxorubicin conjugates with star structure with those of previously described classic antibody-targeted or lectin-targeted HPMA copolymer-bound doxorubicin conjugates. Classic antibody-targeted conjugates were prepared by aminolytic reaction of the multivalent HPMA copolymer containing side-chains ending in 4-nitrophenyl ester (ONp) reactive groups with primary NH_2 groups of the antibodies. The star structure of antibody-targeted conjugates was prepared using semitelechelic HPMA copolymer chains containing only one reactive *N*-hydroxysuccinimide group at the end of the backbone chain. In both types of conjugates, B1 monoclonal antibody (mAb) was used as a targeting moiety. B1 mAb recognizes the idiotype of surface IgM on BCL1 cells. The star structure of the targeted conjugate had a narrower molecular mass distribution than the classic structure. The peak in the star structure was around 300−350 kDa, while the classic structure conjugate had a peak around 1300 kDa. Doxorubicin was bound to the HPMA copolymer via Gly-Phe(D,L)-Leu-Gly spacer to ensure the controlled intracellular delivery. The release of doxorubicin from polymer conjugates incubated in the presence of cathepsin B was almost twice faster from the star structure of targeted conjugate than from the classic one. The star structure of the targeted conjugate showed a lower binding activity to BCL1 cells in vitro, but the cytostatic activity measured by [^{3}H]thymidine incorporation was three times higher than that seen with the classic conjugate. Cytostatic activity of nontargeted and anti-Thy 1.2 mAb (irrelevant mAb) modified HPMA copolymer-bound doxorubicin was more than hundred times lower as compared to the star structure of B1 mAb targeted conjugate. In vivo, both types of conjugates targeted with B1 mAb bound to BCL1 cells in the spleen with approximately the same intensity. The classic structure of the targeted conjugate bound to BCL1 cells in the blood with a slightly higher intensity than the star structure. Both types of targeted conjugates had a much stronger antitumor effect than nontargeted HPMA copolymer-bound doxorubicin and free doxorubicin. The star structure of targeted conjugate had a remarkably higher antitumor effect than the classic structure: a single intravenous dose of 100 μg of doxorubicin given on day 11 completely cured five out of nine experimental animals whereas the classic structure of targeted conjugate given in the same schedule only prolonged the survival of experimental mice to 138% of control mice. These results show that the star structure of antibody-targeted HPMA copolymer-bound doxorubicin is a suitable conjugate for targeted drug delivery with better characterization, higher cytostatic activity in vitro, and stronger antitumor potential in vivo than classic conjugates.

INTRODUCTION

Cytostatic drugs that are used for conventional chemotherapy of cancer do not show any specific accumulation within the tumor but, due to the higher sensitivity of rapidly dividing cancer cells to these drugs, some preferential killing is achieved. Unfortunately, also tissues containing highly proliferating cells such as bone marrow and epithelia are very often seriously damaged by conventional chemotheraphy, and these toxic side-effects are limiting factors for the chemotherapy dosage. It has been reported that conjugation of the free drug to a polymeric carrier reduces its nonspecific toxicity (*1*, *2*) and markedly prolongs its blood half-life (*3*). A conjugate of a synthetic, water-soluble and biocompatible copolymer based on *N*-(2-hydroxypropyl)methacrylamide (HPMA) and containing doxorubicin bound via the Gly-Phe(D,L)-Leu-Gly spacer, called PK1, is undergoing phase I/II clinical study in UK (*4*), and a conjugate containing doxorubicin and IgG was successfully used in the Czech Republic with a human patient with generalized breast carcinoma (*5*).

The idea of increasing the therapeutic effect and minimizing the side-toxicity of common anticancer drugs is very attractive. This could be achieved by site-specific drug delivery using a targeting moiety specifically recognizing tumor cells. Targeted HPMA copolymer-bound drugs have previously been shown to have antitumor effect in vitro and in vivo (*6*). These conjugates consist

of a HPMA copolymer backbone to which the drug and the targeting moiety are conjugated via a biodegradable spacer Gly-Phe(D,L)-Leu-Gly. This spacer ensures a controlled intracellular release of the bound drug. The targeting moieties to be used can be monoclonal or polyclonal antibodies (*7*), saccharides (*8*), lectins (*9*), and hormones (*10*). The risk of arising of antibodies directed against the targeting moiety after repeated administration, as commonly seen with immunotoxins, is lowered thanks to the decreased immunogenicity of proteins bound to HPMA copolymer (*11*).

Decisive in antibody-targeted drug delivery is the selection of appropriate surface receptor for targeting. In many experimental and preclinical studies, receptors such as carcinoembryonic antigen (*12*), α-fetoprotein (*13*), CD5 (*14*), CD22 (*15*), and many others have been explored. In this study, we have used as a tumor model system murine BCL1 leukemia. It is B-cell derived malignancy and BCL1 cells thus possess surface IgM. We have used the B1 monoclonal antibody (mAb) recognizing the idiotype of surface IgM on BCL1 cells as targeting moiety. Since the idiotype of each clone of B-cells is a unique structure, we have used a strictly tumor-specific marker for drug targeting. Moreover, the surface IgM on B-cells has been shown as a receptor with a high level of expression and rapid internalization after ligand binding (*16, 17*).

Antibody-targeted or lectin-targeted HPMA copolymer-bound doxorubicin conjugates were shown to exhibit binding to target cells, cytostatic activity in vitro, and antitumor effect in vivo (*18*). These conjugates were prepared by an aminolytic reaction of the multivalent HPMA copolymer containing ONp reactive groups with antibody molecules (the IgG molecule contains more than 70 amino groups of lysine residues). Since there are many reactive groups distributed along the both HPMA copolymer and antibody molecule, two or more molecules of the antibody can be joined together to form a high-molecular weight branched structure (classic structure, Figure 1A). Recently, we have introduced a novel type of antibody-targeted HPMA copolymer-bound doxorubicin of a star structure. In this type of conjugate, HPMA copolymer chains containing only one reactive *N*-hydroxysuccinimide group at the end of the molecule react with the amino groups of the only one molecule of antibody (Figure 1B). This means that the star structure of HPMA copolymer-bound doxorubicin targeted with antibody is a more homogeneous and better characterized conjugate than the classic structure.

The purpose of this study was (a) to synthesize and characterize a star conjugate and a classic conjugate of HPMA copolymer-bound doxorubicin targeted with B1 mAb, (b) to compare the binding activity of free B1 mAb, B1mAb in the star conjugate and in classic conjugate, (c) in vitro evaluate cytostatic activity of both types of HPMA copolymer-bound doxorubicin targeted with B1 mAb and compare it to the cytostatic activity of nontargeted and anti-Thy 1.2 mAb containing (irrelevant antibody) conjugate using tumor cell line BCL1, and (d) to determine the binding capacity to target cells and antitumor potential of star and classic structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb in vivo.

MATERIAL AND METHODS

Chemicals. 1-Aminopropan-2-ol, glutathione (GSH), ethylenediaminetetraacetic acid (EDTA), 3-sulfanylpropionic acid (MPA), methacryloyl chloride, glycyl-D,L-phenylalanine, L-leucyl-glycine, 4-nitrophenol, *N*-hydroxysuccinimide, 1-hydroxybenzotriazole, triethylamine (TEA), *N,N′*-dicyclohexylcarbodiimide (DCCI), 2,2′-azobisisobutyronitrile (AIBN), phthalaldehyde (OPA), 5-thio-D-glucose, dimethyl sulfoxide (DMSO), dimethyl formamide (DMF), and doxorubicin hydrochloride (Dox·HCl) were from Fluka AG (Buchs, Switzerland). All other chemicals and solvents were of analytical grade. The solvents were dried and purified by conventional procedures and distilled before use.

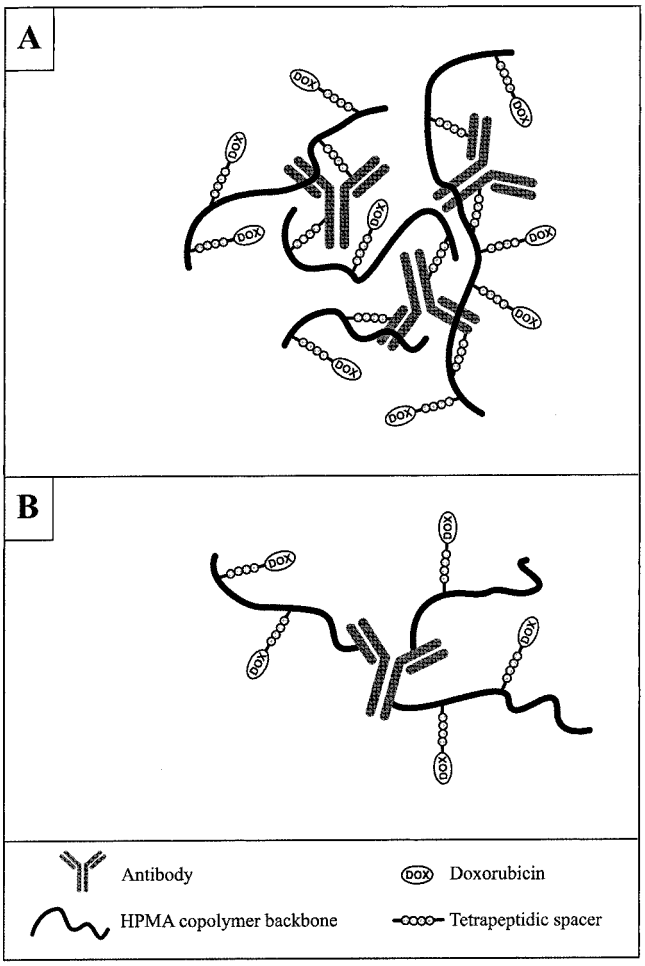

Figure 1. Schematic drawing of the classic structure of antibody-targeted HPMA copolymer-bound doxorubicin conjugate (A) and the star structure of antibody-targeted HPMA copolymer-bound doxorubicin conjugate (B).

Synthesis of Monomers. All monomers were prepared as previously described. Briefly, *N*-(2-hydroxypropyl)methacrylamide (HPMA) was prepared by methacryloylation of 1-aminopropan-2-ol in methylene chloride (*19*), methacryloylglycyl-D,L-phenylalanyl-L-leucylglycine 4-nitrophenyl ester (Ma-Gly-Phe(D,L)-Leu-Gly-ONp) by methacryloylation of Gly-Phe-Leu-Gly tetrapeptide following its synthesis from Boc-GlyPheOH and H-LeuGly-OMe (*20*) (chromatographically pure product, mp = 134−136 °C, amino acid analysis: Gly:L-Phe:D-Phe:L-Leu = 2.04:0.54:0.46:1.00), and methacryloylglycyl-DL-phenylalanyl-L-leucylglycyl doxorubicin amide (Ma-Gly-Phe(D,L)-Leu-Gly-Dox) by the reaction of Ma-Gly-Phe(D,L)-Leu-Gly-ONp with Dox·HCl in DMF in the presence of TEA (*19*) (TLC in chloroform:methanol 8:1 mixture showed two spots at $R_f = 0.46$ and $R_f = 0.4$ corresponding to the D-Phe and L-Phe isomers; HPLC showed a single peak at 18.22 min (UV detection at 230 and 484 nm); amino

acid analysis Gly:L-Phe:D-Phe:L-Leu = 2.04:0.54:0.46:1.00).

Synthesis of Polymer Precursors and Polymer−Doxorubicin Conjugates. Polymer-bound doxorubicin (conjugate 1), classic and star polymer conjugates of doxorubicin with B1mAb antibody (conjugate 2 and conjugate 3), and the classic polymer conjugate of doxorubicin with anti-Thy1,2 antibody (conjugate 4) were prepared from polymer precursors as described (*19*). Briefly, polymer−Dox conjugate 1 was prepared from the polymer precursor I by its reaction with Dox·HCl carried out in the presence of TEA in DMSO. Classic polymer conjugates 2 and 4 were prepared by the reaction of the polymer precursor II with Dox·HCl in the presence of TEA in DMSO, followed by the reaction of such intermediate with the respective antibody in saline solution at controlled pH (7.6 and 8) using pH stat Radiometer Copenhagen. Star conjugate 3 was prepared from the semitelechelic, succinimide group-containing polymer precursor III, by its reaction with the anti-Thy1,2 antibody in phosphate buffer at pH 7.3−7.8. Polymer precursors I and II were prepared by radical precipitation copolymerization of HPMA with Ma-Gly-Phe(D,L)-Leu-Gly-ONp in acetone (initiator AIBN, 0.6 wt %; concentration of monomers 12.5 wt %; molar ratio HPMA: Ma-Gly-Phe(D,L)-Leu-Gly-ONp 5:1 (precursor I) or 10:1 (precursor II); 60 °C; 24 h) as described (*20, 21*). Semitelechelic polymer precursor III was prepared by radical precipitation copolymerization of HPMA with Ma-Gly-DL-Phe-L-Leu-Gly-Dox carried out in acetone and initiated with AIBN in the presence of 3-sulfanylpropionic acid as a chain-transfer agent. Copolymerization was followed by the reaction of the terminal COOH group-containing copolymer with *N*-hydroxysuccinimide in DMF using DCCI method (*19*).

Characterization of Polymer Precursors and Polymer Conjugates. Polymer precursors I and II were characterized by UV spectrophotometry (the content of oligopeptide side chains terminated in 4-nitrophenoxy groups (ONp)) (*20*), by amino acid analysis (LDC Analytical, Riviera Beach, FL, precolumn OPA derivatization) and by liquid chromatography (weight- and number-average molecular weights, M_w and M_n) after aminolysis of reactive groups with 1-aminopropan-2-ol. Polymer−Dox conjugates were characterized and tested for the content of free polymer, free drug, or protein by GPC (Sepharose 4B/6B) or FPLC Pharmacia equipped with Superose 6 column (RI and UV detectors) and by electrophoresis (Pharmacia-LKB Phast System, SDS PAGE, gels with gradient 4−15). Molecular weights of all final conjugates and polymer precursors were determined using liquid chromatograph ÄKTA-Pharmacia equipped with Superose 6 or TSK 5000 PW columns and RI (refractive index) and multiangle light scattering DAWN-DSP−F (Wyatt Technology Corp.) detectors. The protein content in the conjugates was estimated by amino acid analysis (LDC Analytical, Riviera Beach, FL, precolumn OPA derivatization) and Dox content by UV spectrophotometry (*22*). Neither GPC nor electrophoresis showed significant amounts of free protein in the conjugates and the content of free Dox in the conjugate was less than 0.05% of the total Dox content.

Release of Dox from the Conjugates. Release of Dox from polymer conjugates was tested in phosphate buffer pH 6 after their incubation in cathepsin B solution at 37 °C. Incubation medium was 0.1 M sodium phosphate, 0.05 M NaCl, 1 mM EDTA, 5 mM reduced glutathione, and 0.5 μM cathepsin B. The activity of the cysteine proteinase cathepsin B was determined using Bz-Arg-NAp as a substrate (*20*). In all cases, final Dox concentration was 0.5 mM. At predetermined time intervals the samples were tested for the content of free Dox. The amount of Dox released from the polymer conjugate was determined after its extraction from the incubation media into chloroform. A mixture of 0.1 mL of sample solution and 0.3 mL of buffer (0.2 M Na_2CO_3/$NaHCO_3$, pH 9.8) was extracted with 0.6 mL of chloroform. HPLC (Tessek gel C18 column, methanol−water gradient 10−90% methanol, fluorescent detector with excitation at 488 nm and emission at 560 nm) was used to determine the amount of free Dox. The calibration (yield of extraction) was carried out using Dox·HCl. All drug-release data are expressed as the amount of free Dox relative to the total Dox content in the conjugate.

Monoclonal Antibody (mAb). Monoclonal antibody directed against the idiotype of surface IgM of BCL1 cells, clone B1, is of the IgG1 isotype (*23*). For these studies, B1 mAb was purified from Balb/c mouse ascitic fluid by a combination of 45% saturated ammonium sulfate precipitation and protein A affinity chromatography. The concentration was determined by spectrophotometry (λ = 280 nm) and the purity was checked by SDS−PAGE.

Tumor Lines and Tissue Culture Condition. The murine B cell leukemia BCL1 was purchased from the American Type Culture Collection (ATCC, Rockville, MD). It is a well-described cell line that grows rapidly and consistently in immunocompetent Balb/c mice. Routine culture and all in vitro experiments with BCL1 cell line were conducted in RPMI 1640 medium with extra L-glutamine (300 μg/mL), sodium pyruvate (110 μg/mL), 2-mercaptoethanol (5×10^{-5}M), HEPES (10mM), penicillin (100 units/mL), streptomycin (100 μg/mL), and 10% v/v 0.1 μm filtered fetal bovine serum. Cells in exponential growth with viability greater than 95% were used for all experiments. Cultures were maintained at 37 °C in 5% CO_2. The murine B cell lymphoma 38C13 is a cell line with characteristics similar to the BCL1 cell line, and both lines express membrane IgM but do not secrete it. For this reason we decided to use the 38C13 cell line as control cells for in vitro binding studies. Routine culture and all experiments with 38C13 cell line were conducted in the same medium and under the same conditions as with BCL1 cell line.

Mice. Mice of inbred strain Balb/c were obtained from the breeding colony of the Institute of Physiology (Academy of Sciences of the Czech Republic) and kept in standard housing. Animals 9−15 weeks of age and in the 19−22 g weight range were used in in vivo experiments. All experiments were approved by the Animal Welfare Committee of the Institute of Microbiology Academy of Sciences of the Czech Republic.

Biotinylation of Free mAb and Targeted Conjugates Containing mAb. B1 mAb was biotinylated using EZ-Link Sulfo-NHS-LC−Biotin (Pierce). Briefly, 2 mg of B1 mAb in 1 mL of PBS (pH 8.0) was mixed with 100 μL of 1.5 mg/mL Sulfo-NHS-LC−Biotin solution. After a 45-min incubation at room temperature, unreacted biotin was removed by dialysis. The degree of biotinylation was determined using HABA (Pierce), and about 4 biotins per molecule of IgG were found. Conjugates containing B1 mAb as a targeting moiety were biotinylated under the same conditions as free B1 mAb, but the degree of biotinylation was not determined because of the presence of doxorubicin.

Fluorescence-Activated Cell Sorter Analysis (FACS). For in vitro binding studies, BCL1 cells were collected from an exponential growth phase culture. They were centrifuged for 5 min at 300 g, washed twice with PBS

with 1% of calf albumin and 0.1% of sodium azide (FACS solution), resuspended in FACS solution, and counted in trypan blue. Cell density was adjusted to 1×10^7 cells/mL and 0.1 mL of this cell suspension was added to each test tube. From this moment on, all test tubes with cells were maintained on ice (0 °C), and all solutions added were adjusted to this temperature. Cells were again centrifuged for 5 min at 300 g and 100 μL of tested samples in different concentrations was then added. The cells were incubated for 45 min and then washed three times with FACS solution. Streptavidine−FITC conjugate at appropriate dilution was added for 30 min. Finally, the cells were washed three times and then resuspended in 0.5 mL of FACS solution. For in vivo binding studies, Balb/c mice 30 days after intraperitoneal administration of 5×10^5 BCL1 cells were intravenously injected with tested samples (250 μg of B1 mAb). At 45 min after the administration the mice were sacrificed, and spleen and 100 μL of blood from each mouse were placed in precooled test tubes containing 5 IU of heparine. Spleen was homogenized, and both the homogenate and blood were transferred to lysis solution to eliminate erythrocytes. After lysis, splenocytes and peripheral blood leucocytes were washed twice with FACS solution, centrifuged for 5 min at 300 g and streptavidin−FITC conjugate at appropriate dilution was added for 30 min. Finally, the cells were washed three times and resuspended in 0.5 mL of FACS solution. At least 7500 live cells were analyzed for each measurement.

Proliferation Assay in Vitro. BCL1 cells were collected from an exponential growth phase culture. They were centrifuged for 5 min at 300 g, washed, resuspended in fresh culture medium, and counted in trypan blue. Cell density was adjusted to 5×10^4 cells/mL, and 0.2 mL of this cell suspension was loaded by multichannel pipet into each well of Nunc 96-well flat-bottomed plates. The tested samples were then added to the wells to achieve the desired concentrations; the final well volume was 0.25 mL and cell density 1×10^4 cells/well, with five wells for each test condition. The plates were cultured in 5% CO_2 for 72 h at 37 °C, after which 18.5 kBq of [^{3}H]thymidine in 50 μL was added per well, followed by another 6 h incubation. The cells were then collected using a cell harvester (Tomtec, Orange, CT) onto glass fiber filters (filtermat, Wallac, Finland). When the mixture was dried, a sheet of solid scintillator-Meltilex (Wallac) was placed together with a filtermat containing 96 samples in a sample bag and run together through a heat sealer (Microsealer, Wallac). Counting was performed in 1450 MicroBeta TriLux (Wallac).

Treatment of Established BCL1 Leukemia in Vivo. BCL1 cells were collected from an exponential growth phase culture. They were centrifuged for 5 min at 300 g, washed, resuspended in fresh culture medium, and counted in trypan blue. An amount of 5×10^5 BCL1 cells in 0.5 mL culture medium were inoculated intraperitoneally on day 0 to Balb/c mice. Treatment with targeted HPMA copolymer-bound doxorubicin was given intravenously either as a single or as three injections and always began on the 11th day. The second injection was given on the 14th day and the third injection on the 17th day. One dose contained either 50 μg of free doxorubicin or 100 μg of HPMA copolymer-bound doxorubicin. Control mice were injected with only physiological solution. Nine or 10 mice were used for each experimental group.

Statistical Analysis. The Wilcoxon's statistics (multiple comparison method) and Student's *t*-test were used to evaluate the differences among experimental groups. *P* values <0.01 were taken as statistically significant.

Table 1. Characteristics of Polymer Precursors and Antibody-Targeted HPMA Copolymer-Bound Doxorubicin Conjugates

				Content of:		
		M_w		ONp	Dox	mAb
Sample	Structure	(kDa)	M_w/M_n	(mol%)	(wt%)	(wt%)
Conjugate 1	P-GFLG-Dox	26	1.7		6.8	
Conjugate 2	P (GFLG-Dox; GFLG-B1 mAb) (star structure)	320	2.4		3.35	51
Conjugate 3	P (GFLG-Dox; GFLG-B1 mAb) (classic structure)	1300	~5		4.0	25
Conjugate 4	P (GFLG-Dox; GFLG-a-Thy 1.2) (classic structure)	1250	~5		4.54	25
Precursor I	P-GFLG-ONp	23	1.35	5.1		
Precursor II	P-GFLG-ONp	19	1.30	9.0

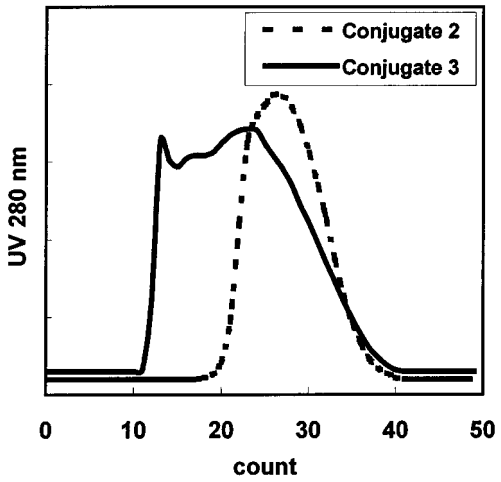

Figure 2. GPC analysis of the classic structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb (Conjugate 3) and the star structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb (Conjugate 2).

RESULTS

Characterization of Synthesized HPMA Copolymer-Bound Doxorubicin Conjugates and Rate of Doxorubicin Release. Conjugates of two structures (Figure 1) consisting of HPMA copolymer, the anticancer drug doxorubicin, and targeting antibody have been synthesized. For characteristics of polymer precursors and polymer conjugates see Table 1. All doxorubicin-bearing conjugates contained <0.1 wt % free doxorubicin (referred to the total doxorubicin content). The molecular mass of the classic structure of antibody-targeted HPMA copolymer-bound doxorubicin was approximately 1300 kDa and polydispersity was broad (Figure 2). The star structure of targeted conjugate exhibited properties of a well-defined and more uniformly characterized conjugate, with molecular mass of 300−350 kDa and low polydispersity. Release profiles of doxorubicin from the HPMA copolymer-bound doxorubicin conjugates after their incubation with cathepsin B are shown in Figure 3. Nontargeted HPMA copolymer-bound doxorubicin conjugate released 49.8% of doxorubicin after 49 h of incubation. The star structure of targeted conjugate showed a lower release rate (38%) and the classic structure of targeted conjugate released only 21.5% of the bound doxorubicin.

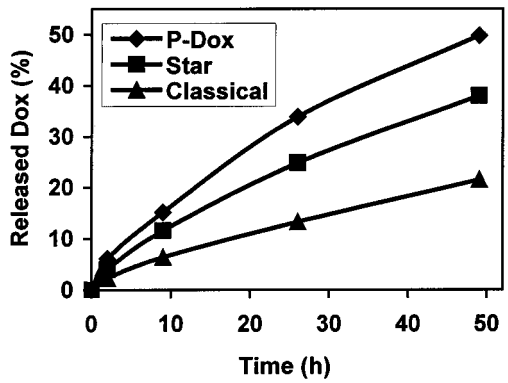

Figure 3. Release profiles of doxorubicin from nontargeted HPMA copolymer-bound doxorubicin (P-Dox), the star structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb (star) and the classical structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb (classical). Release of doxorubicin from polymer conjugates was tested at 37 °C in phosphate buffer pH 6 and in the presence of 0.5 μM cathepsin B.

In Vitro Binding of Free B1 mAb, Classic Structure, and Star Structure of HPMA Copolymer-Bound Doxorubicin Targeted with B1 mAb to Target BCL1 Cells and to 38C13 Cells Used as a Negative Control. Fluorescence activated cell sorter analysis (FACS) was used to evaluate the intensity and specificity of binding of HPMA copolymers containing doxorubicin and targeted with B1 mAb. Free B1 mAb and both types of targeted conjugates were biotinylated to enable the use of FITC-labeled streptavidin for secondary labeling. We tested the intensity of binding at concentrations of 100, 10, and 1 μg/mL of B1 mAb; the corresponding mean fluorescence intensities for free B1 mAb were 2340, 1230, and 220. The classic structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb showed a slightly lower level of binding if compared to the free B1 mAb and the corresponding mean fuorescence intensities were 1700, 708, and 95.4, respectively. The level of binding of the star structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb was considerably lower than that seen with free B1 mAb, with corresponding mean fluorescence intensities of 621, 145, and 25.5, respectively. BCL1 cells treated only with FITC-labeled streptavidin at a concentration equal to that used for secondary labeling showed mean fluorescence intensity of 4.44. Since the conjugate of antibody and synthetic copolymer containing doxorubicin could show nonspecific binding activity, we decided to evaluate the binding of both types of targeted conjugates to control cells. 38C13 cell line was used as appropriate control cells because their characteristics are similar to those of BCL1 cells (see Materials and Methods). Even at a concentration of 100 μg/mL of B1 mAb neither the classic nor the star structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb bound to 38C13 cells (Figure 4).

Cytostatic Activity of Classic and Star Structure of HPMA Copolymer-Bound Doxorubicin Targeted with B1 mAb in Vitro. In Vitro inhibition of cell proliferation of the BCL1 cell line was determined by [^{3}H]-thymidine incorporation. Concentrations of doxorubicin required for 50% inhibiton of cell proliferation (IC_{50}) of the BCL1 cancer cell line are summarized in Table 2. The star structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb showed three times higher cytostatic activity than the classic structure. Both targeted conjugates exhibited a much higher cytostatic activity than nontargeted HPMA copolymer-bound doxorubicin. To prove that higher cytostatic activity of HPMA copolymer-bound doxorubicin targeted with B1 mAb is due to the specific binding of the targeting moiety to the target BCL1 cells, we used HPMA copolymer-bound doxorubicin conjugated with irrelevant anti-Thy 1.2 mAb as control. This conjugate had the same cytostatic activity as nontargeted HPMA copolymer-bound doxorubicin. Furthermore, the cytostatic activity of both classic and star structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb can be strongly reduced (15 and 12 times, respectively) by free B1 mAb. This mAb does not have any effect on the proliferation of BCL1 cells alone (not shown).

In Vivo Binding of Free B1 mAb, Classic and Star Structure of HPMA Copolymer-Bound Doxorubicin Targeted with B1 mAb to Peripheral Blood Leukocytes (PBL) and to Spleen Cells of Balb/c Mouse Bearing BCL1 Leukemia. Fluorescent activated cell sorter analysis (FACS) was used to evaluate the binding capacity of HPMA copolymers containing doxorubicin and targeted with B1 mAb. Biotinylated free B1 mAb and both types of targeted conjugates were intravenously administered (250 μg B1 mAb/dose) to Balb/c mice bearing BCL1 leukemia. Figure 5 demonstrates that 45 min after the application of free B1 mAb and classic structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb these structures bound to the target cells and noticeably separated BCL1 cells in blood from other nonmalignant PBL. The star structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb also bound to BCL1 cells but separation from other PBL was not as significant as that seen with free B1 mAb and the classic structure of targeted conjugate. Binding of free B1 mAb and both types of targeted conjugates to spleen cells of Balb/c mice bearing BCL1 leukemia is shown in Figure 6. In this case, 45 min after intravenous application the classic and the star structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb bound to the target BCL1 cells with comparable binding capacity. Corresponding mean fluorescence intensities were 8.65 and 7.13, respectively. Free B1 mAb showed a higher binding capacity and the corresponding mean fluorescence intensity was 15.3. Mean fluorescence intensities of control spleen cells (no secondary labeling) for free B1 mAb and both types of targeted conjugates were within the range 2.26−2.59.

Treatment of Balb/c Mice with Established BCL1 Leukemia by Classic and Star Structure of HPMA Copolymer-Bound Doxorubicin Targeted with B1 mAb. For the in vivo experiments, 5×10^5 BCL1 tumor cells were administered intraperitoneally to Balb/c mice and the treatment (50 μg of free doxorubicin or 100 μg of HPMA copolymer-bound doxorubicin) was always begun on the 11th day. In the first experiment we tested the effect of three intravenous doses given on the 11th, 14th, and 17th day. As shown in Figure 7, free doxorubicin significantly prolonged the survival of the experimental mice to 143% relative to the control. However, nontargeted HPMA copolymer-bound doxorubicin prolonged the survival of experimental mice to only 112% relative to control mice (not statistically significant). Both the classic and the star structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb strongly prolonged the survival of experimental mice. The result of this experiment would be probably much better than shown in Figure 7 if the experimental mice did not contract systemic staphylococcus infection, which was most probably the reason of their death. We did not find any mice to have splenomegalia, which is the major symptom of

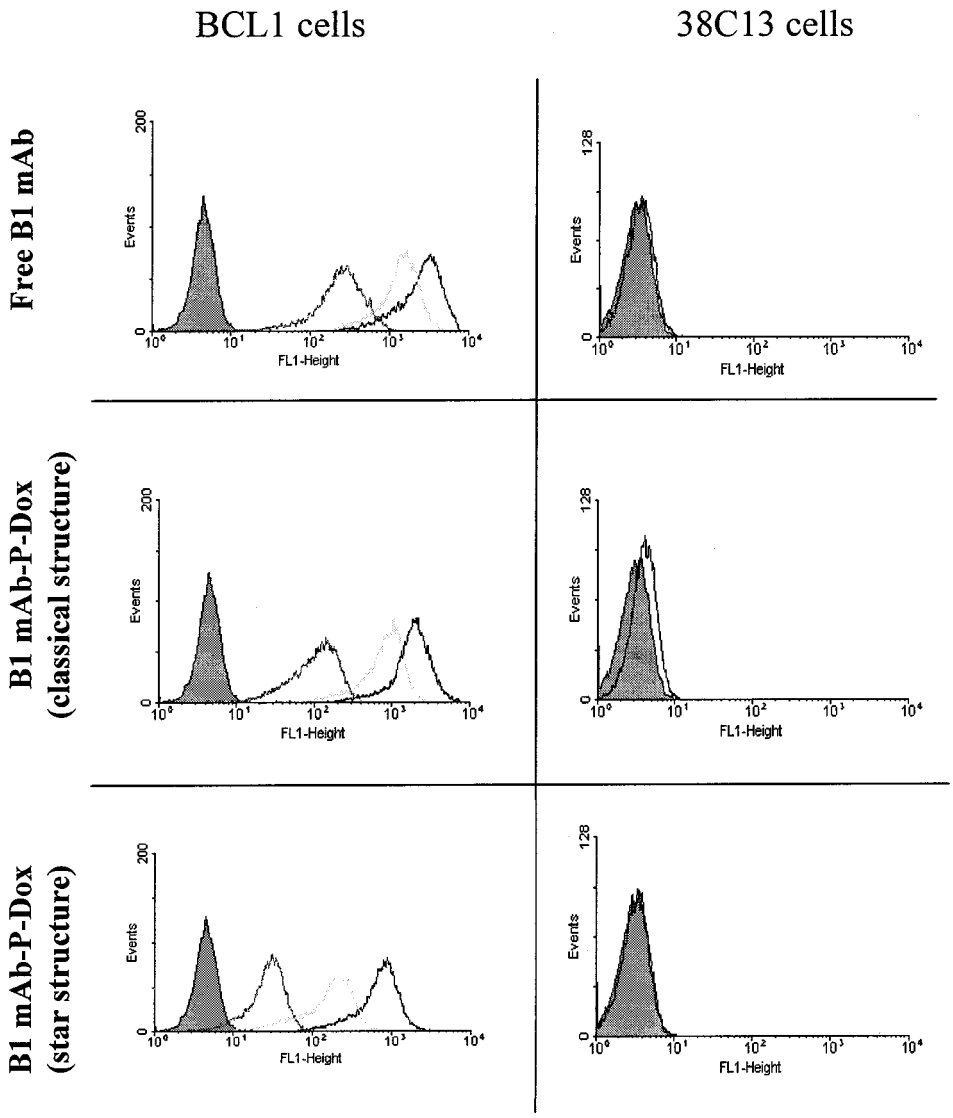

Figure 4. Flow cytometry analysis of biotinylated free B1 mAb, the classical structure and the star structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb (B1 mAb-P-Dox). B1 mAb is anti-idiotype antibody which specifically recognizes the idiotype of surface IgM of BCL1 cells. 38C13 cells also express surface IgM but with a different idiotype. Grey peaks represent the background staining with the secondary FITC-labeled streptavidin alone. BCL1 cells were treated with 100 μg/mL (solid line), 10μg/mL (gray line), and 1 μg/mL (dotted line) of biotinylated B1 mAb.

progression of BCL1 leukemia. In further experiment we decided to use only one dose given on the 11th day. The results of this experiment is shown in Figure 8. As in the previous experiment, treatment with free doxorubicin significantly prolonged the survival of experimental mice (114% relative to control mice) while nontargeted HPMA copolymer-bound doxorubicin prolonged the survival of experimental mice to only 106% relative to control mice (not statistically significant). The classic structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb prolonged the survival of experimental mice to 138% relative to control mice (statistically significant) but did not bring about any total recovery. The star structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb showed an extraordinary effect. It completely cured five out of nine experimental mice and extended the average lifespan of the remaining mice to 258% of that found in the controls. In the last in vivo experiment we tested whether free B1 mAb can block or reduce the strong antitumor effect of the star structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb as it can be seen in vitro. The targeted conjugate was given intravenously on the 11th day in an amount of 75 μg doxorubicin/dose which corresponds to 1.13 mg of B1 mAb. Free B1 mAb was given in two injections (0.4 mg intraperitoneally and 0.8 mg intravenously) separated by 1 h. Figure 9 demonstrates that free B1 mAb did not block the effect of the star structure of HPMA copolymer-bound doxorubicin on the survival of experimental mice. The star structure of targeted conjugate given alone again demonstrated a powerful therapeutic effect, curing completely 7 out of 9 experimental mice. Free B1 mAb did not have any effect on the survival of experimental mice. Moreover, free B1 mAb caused an immediate death of two experimental mice when intravenously injected.

DISCUSSION

Antibody-targeted HPMA copolymer-bound doxorubicin conjugates have been reported in many studies (*24*−*26*) as perspective anticancer drugs. These conjugates were prepared by aminolysis of ONp groups of the HPMA copolymer with the amino group of daunosamine in doxorubicin molecule. It was followed by the reaction of the rest of ONp groups of the HPMA copolymer with

Table 2. IC_{50} Values Determined in Cell Line BCL1 for Different Samples of HPMA Copolymer-Bound Doxorubicin[a]

Sample	IC_{50} concentration (nM Dox) ± SD
P-GFLG-Dox	1450 ± 167
P(GFLG-Dox)(GFLG-a-Thy 1.2 mAb) (classic structure)	1470 ± 179
P(GFLG-Dox)(GFLG-B1 mAb) (classic structure)	32.6 ± 9.2
P(GFLG-Dox)(GFLG-B1 mAb) (star structure)	10.5 ± 3.1
P(GFLG-Dox)(GFLG-B1 mAb) (classic structure) + 20 μg/ml B1 mAb[b]	502 ± 183
P(GFLF-Dox)(GFLG-B1 mAb) (star structure) + 20 μg/ml B1 mAb[b]	121 ± 38
Dox	1.6 ± 0.39

[a] IC_{50} values were evaluated as concentration of doxorubicin which inhibits after 72 h of cultivation (see Material and Methods) the incorporation of [^{3}H]thymidine by BCL1 cells to 50% of the control cell level. The activity of control cells was always higher than 30 000 cpm/well. Experiments were repeated twice with similar results. P-GFLG-Dox: HPMA copolymer-bound doxorubicin, a-Thy 1.2 mAb-GFLG-P-GFLG-Dox: HPMA copolymer-bound doxorubicin targeted with anti-Thy 1.2 mAb, B1 mAb-GFLG-P-Dox: HPMA copolymer-bound doxorubicin targeted with B1 mAb, Dox: free doxorubicin. [b] Free B1 mAb was added to the cells just prior to targeted conjugate.

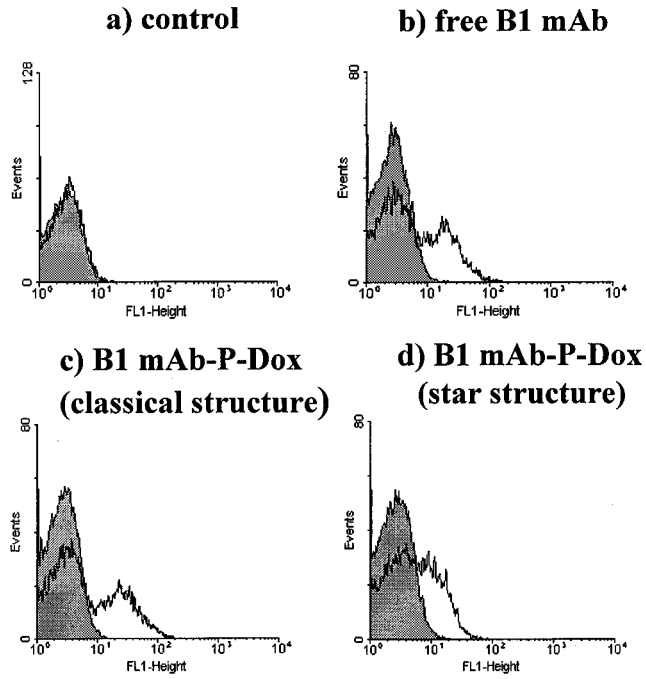

Figure 5. Binding of biotinylated free B1 mAb, the classical structure, and the star structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb (B1 mAb-P-Dox) to peripheral blood leukocytes (PBL) of Balb/c mice bearing BCL1 leukemia after intravenous application of 250 μg of B1 mAb. PBL were isolated 45 min after sample application and secondary labeled by streptavidin-FITC conjugate as described in Material and Methods. Grey peaks represent control (no secondary labeling). Control mouse was injected with physiological solution only.

amino groups of lysine residues in the antibody molecule. Unfortunately, in the reaction of the multivalent polymer precursor with the multivalent antibody, branching reaction cannot be avoided. The effect of branching can be minimized by careful performance and control of pH, ionic strength and temperature of the reaction. Nevertheless, the reaction product is still a mixture of molecules consisting of a single antibody modified with polymer chains, and molecules containing two or more antibody molecules connected by many polymer chains into a branched structure (Figure 1A). Consequently, the molecular weight of such conjugate is high and its polydispersity is fairly broad. This means that the proper characterization of its molecular structure is rather difficult. On the other hand, an advantage of this aminolytic conjugation is the relative ease of performance on a large scale.

With the aim of preparing an antibody-targeted HPMA copolymer-bound doxorubicin conjugate with a better-defined structure, we synthesized a new type of conjugate with a star structure. In this conjugate some of the amino groups (usually 40−45%) of the antibody molecule are modified with HPMA copolymer chains, each of them being attached to the antibody via the polymer end-chain carbonyl group. Analogous to the classic-structure conjugate, the polymers are bearing doxorubicin molecules attached via biodegradable oligopeptide spacers. Similarly, the paper of Wang et al. (*27*) describes the synthesis of starlike *N*-(2-hydroxypropyl)methacrylamide copolymers. The authors of this paper also used semitelechelic HPMA copolymers with terminal COOH, which was activated with *N*-hydroxysuccinimide. In contrast to our paper, Wang et al. conjugated the above-described semitelechelic HPMA copolymers to PAMAM dendrimers. Such conjugate does not possess any targeting moiety and thus cannot be classified as a tumor-specific drug delivery system.

We have used in this study the tetrapeptidic spacer Gly-Phe(D,L)-Leu-Gly which is commonly used as optimal linker between the drug and the HPMA copolymer backbone. In the past we tested the efficacy of conjugates with spacers containing only D-phenylalanine or only L-phenylalanine. In the presence of cathepsin B and after 24 h of incubation, the Gly-Phe(L)-Leu-Gly spacer releases 35% of bound doxorubicin, Gly-Phe(D)-Leu-Gly spacer releases 12% and Gly-Phe(D,L)-Leu-Gly spacer releases 22% of bound doxorubicin.

Surprisingly, using a spacer containing both isomers of phenylalanine gives the best cytostatic activity in vitro and antitumor effect in vivo. No explanation why conjugates with Gly-Phe(D,L)-Leu-Gly spacer show the highest cytostatic activity is available at the moment. Recently, we have also introduced HPMA copolymer-bound doxorubicin conjugates with pH sensitive bond between the drug and the spacer. In this type of conjugates doxorubicin is attached to the spacer through a hydrazone bond. Hydrazone bond is relatively stable at physiological pH 7.4 but it is quickly hydrolyzed at pH 5. So, unlike aminolytically bound doxorubicin, the drug can be released in endosomes since lysosomal proteases are not required and the pH in this cell compartment is favorable. HPMA copolymer conjugates with doxorubicin conjugated through a hydrazone bond exhibit very high cytostatic activity in vitro against a variety of different tumor cell lines including those with a limited content of lysosomes (*28*).

Different release profiles of doxorubicin from HPMA copolymer conjugates after their incubation with cathe-

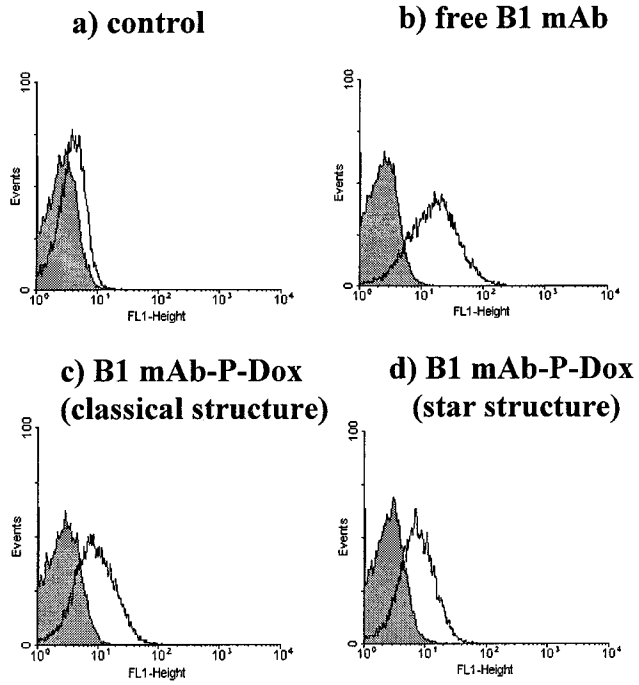

Figure 6. Binding of biotinylated free B1 mAb, the classical structure, and the star structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb (B1 mAb-P-Dox) to spleen cells of Balb/c mice bearing BCL1 leukemia after intravenous application of 250 μg of B1 mAb. Spleen cells were isolated 45 min after sample application and secondary labeled by streptavidin−FITC conjugate as described in Material and Methods. Grey peaks represent control (no secondary labeling). Control mouse was injected with physiological solution only.

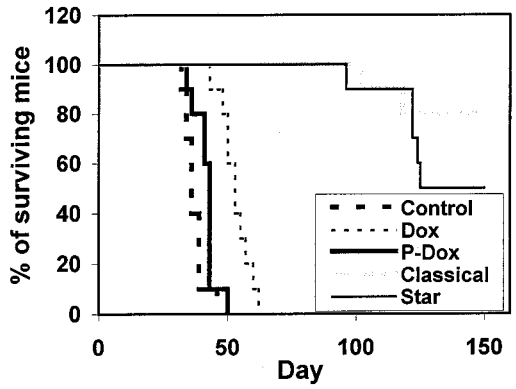

Figure 7. Effect of free doxorubicin (Dox), HPMA copolymer-bound doxorubicin (P-Dox), the classical structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb (Classical), and the star structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb (Star) on the survival of Balb/c mice bearing BCL1 leukemia. The treatment consisted of three intravenous doses given on the 11th, 14th, and 17th day. Each dose contained 50 μg of free doxorubicin or 100 μg of HPMA copolymer-bound doxorubicin. Control mice were injected with the same volume (250 μL) of physiological solution.

psin B are probably due to the different molecular structure of the conjugate and accessibility of the doxorubicin bound to the tetrapeptide spacer. Steric hindrances to the access of the enzyme to the macromolecular substrate could explain the decrease in the rate of doxorubicin release. The steric hindrances are the highest in the branched high molecular-weight conjugate with classic structure. This type of conjugate thus shows the slowest doxorubicin release rate. Steric hindrances are lower in the case of the star structure. The star structure is a conjugate with central antibody molecule surrounded

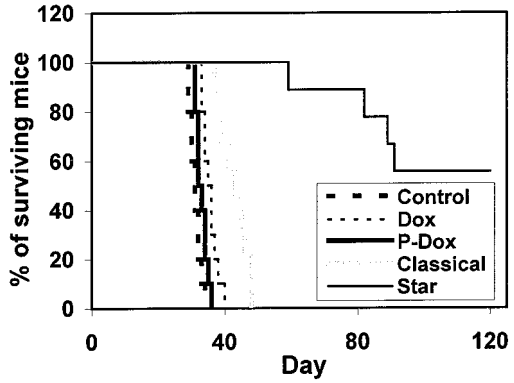

Figure 8. Effect of free doxorubicin (Dox), HPMA copolymer-bound doxorubicin (P-Dox), the classical structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb (Classical), and the star structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb (Star) on the survival of Balb/c mice bearing BCL1 leukemia. The treatment consisted of one intravenous dose given on the 11th day. The dose contained 50 μg of free doxorubicin or 100 μg of HPMA copolymer-bound doxorubicin. Control mice were injected with the same volume (250 μL) of physiological solution.

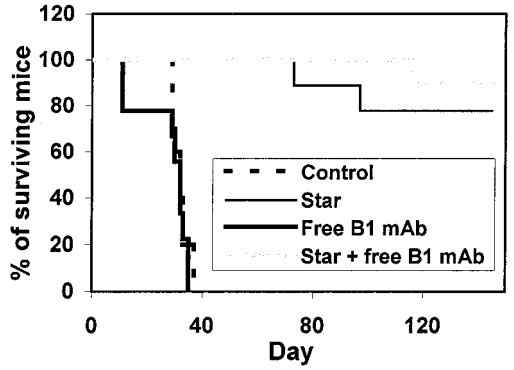

Figure 9. Effect of star structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb (Star), free B1 mAb and a combination of free B1 mAb and the star structure of HPMA copolymer-bound doxorubicin targeted with B1 mAb on the survival of Balb/c mice bearing BCL1 leukemia. Free B1 mAb was given in two injections (125 μL) separated by 1 h (0.4 mg intraperitoneally followed by 0.8 mg intravenously). Targeted conjugate was given in one intravenous injection containing 75 μg of doxorubicin. Combination of free B1 mAb and targeted conjugate was given in two injections (125 μL and 187.5 μL) separated by 1 h (0.4 mg of free B1 mAb intraperitoneally followed by a mixture of 0.8 mg of free B1mAb and targeted conjugate containing 75 μg of doxorubicin intravenously). All treatments were given on the 11th day and control mice were injected intravenously with 187.5 μL of physiological solution.

by the HPMA copolymer chains exposing doxorubicin on the surface. This probably provides faster doxorubicin release. Finally, nontargeted HPMA copolymer-bound doxorubicin is a simple conjugate without antibody showing the fastest doxorubicin release. Differences in the molecular structure of the two antibody-targeted conjugates could also explain the different binding activity to BCL1 cells in vitro. In the star structure where the single antibody molecule is surrounded by the HPMA copolymer chains, the binding site of the antibody could be partially masked and blocked in its binding to its epitope. Moreover, the accessibility of biotins for streptavidine−FITC conjugate on the antibody molecule in the star structure could be lower than the accessibility of biotins in a branched high-molecular-weight antibody-targeted conjugate (classic conjugate).

Our results demonstrate that both antibody-targeted HPMA copolymer-bound doxorubicin conjugates have strong cytostatic activity in vitro. The low cytostatic activity of nontargeted HPMA copolymer-bound doxorubicin reflects the fact that this conjugate has no specific receptor on target cells. It is taken up only by fluid-phase pinocytosis (*29*), which is a slow process and requires a high concentration of the conjugate to produce cytostatic activity. The presence of irrelevant (anti-Thy 1.2) antibody in the conjugate does not enhance its cytostatic activity. This provides an evidence that BCL1 cells take up also this conjugate only by fluid-phase pinocytosis and that other mechanisms such as endocytosis via Fc receptors are not involved. By contrast, HPMA copolymer-bound doxorubicin conjugates targeted with anti-idiotype B1 mAb bind specifically to target BCL1 cells and produce strong cytostatic activity. Anti-idiotype antibodies have been previously used for constructing different immunotoxins (*30, 31*). Here we demonstrate that also a water-soluble polymer-bound drug system based on HPMA copolymer is efficient in anti-idiotype targeting. Direct correlation was reported between the intensity of binding of targeted cytostatic drugs or immunotoxins to target cells and their respective cytotoxicities. Despite this fact, we found that the star structure of HPMA copolymer-bound doxorubicin binds to BCL1 cells with lower activity than the classic structure of targeted conjugate, but it shows a higher cytostatic activity. The discrepancies between the intensity of binding and cytostatic activities may reflect different processing and intracellular release of the targeted drug (*32*). Intracellular release of the bound drug is probably faster within the star structure of the targeted conjugate as documented in vitro (Figure 3). As described for immunotoxins, the cellular internalization rate and intracellular destination are more critical factors in targeted drug efficacy than the number and binding of cell surface receptors (*33*). Nevertheless, our other experimental data shows that the star structure of HPMA copolymer-bound doxorubicin targeted with monoclonal antibody is more effective than the classic structure also in the case of anti-CD71 targeting using B cell lymphoma 38C13 cell line (Kovář, preliminary results) and anti-Thy 1.2 targeting using T cell lymphoma EL4 cell line (*34*).

We have used in our in vivo experiments different doses of free doxorubicin and HPMA copolymer-bound doxorubicin. It was repeatedly shown that conjugation of doxorubicin to HPMA copolymer reduces the cellular toxicity of the drug. For example, the recommended Phase II dose of PK1 is 280 mg/m^2 every 3 weeks in contrast to the free doxorubicin which is given at 60−80 mg/m^2. This means that HPMA copolymer-bound doxorubicin is given at a 3.5−4.6 higher dose than the free drug. We have used only twice higher doses of HPMA copolymer-bound doxorubicin than free doxorubicin. Twice higher doses for HPMA copolymer-bound doxorubicin have already been used in the model of murine T-cell lymphoma EL4 by targeting HPMA copolymer-bound doxorubicin to Thy 1.2 antigen (*35*). The much stronger antitumor effect of the star structure as compared with the classic structure of targeted conjugate against established BCL1 leukemia demonstrates that the molecular design of conjugates for targeted drug delivery is essential for their biological properties. Among the most important factors that influence the activity of such conjugates are the rate of release of the bound drug (*28*), rate of internalization and intracelular pathway, biodistribution and pharmacokinetics. Our preliminary data shows that the star structure of HPMA copolymer-bound doxorubicin targeted with mAb has a prolonged blood-elimination profile if compared to the classic structure. Both types of antibody-targeted conjugates were injected to mice and the blood of these mice was analyzed for the content of the conjugate 24 h after administration. We found less than 5% of administered dose of the conjugate with a classic structure but more than 25% of administered dose of the conjugate with a star structure (*34*). This slower elimination of the star structure of antibody-targeted conjugate is probably a very important feature responsible for its higher antitumor effect.

N-Formyl-methionyl peptides can specifically bind to surface receptors on phagocytic cells. A single copy of *N*-formyl-methionine-leucine-phenylalanine (fMLF) covalently linked to a poly(ethylene glycol)-based polymer displayed reduced binding avidity (K_d = 190 nM) for differentiated HL-60 cells relative to free fMLF (K_d = 28 nM). Increasing the number of fMLF residues (up to eight) attached to a single polymer results in enhanced avidity for these cells (K_d = 0.18 nM), which appears to be independent of whether the polymer backbone is linear or branched. However, no conjugate showed enhanced ability to activate phagocytic cells, relative to the free peptide (EC_{50} = 5 nM), as measured by transient stimulation of release of calcium ions from intracellular stores into the cytoplasm. A polymer bearing four fMLF and four digoxigenin residues showed specific enhancement in binding to differentiated HL-60 cells and mouse peritoneal macrophages in situ relative to a polymer lacking fMLF; no such enhancement was seen in binding to receptor-negative lymphocytic Jurkat cells. These results suggest that multiple fMLF residues linked to a drug-delivery polymer can be used to target appended drugs to phagocytic cells with relatively little toxicity due to cellular activation.

INTRODUCTION

Therapeutic drugs are generally administered via oral or parenteral routes, so that they are widely distributed throughout the body, although only one organ or tissue might be affected by the disease being treated. By targeting a drug to the site of the disease, it should be possible to achieve a higher and more effective dose where needed and a lower and less toxic dose in unaffected tissues. The present study focuses on targeting drugs to macrophages and related phagocytic cells of the reticuloendothelial system, such as monocytes and dendritic cells. Macrophage targeting could be especially useful for therapy of AIDS and tuberculosis, since these cells represent a major reservoir for propagation of the causative virus and bacterium, respectively, as well as for the AIDS-associated opportunistic infection, leishmaniasis, caused by a tropical protozoan. Macrophage targeting has been studied before, examples being the use of nanoparticles for antileishmanial drugs (Venier-Julienne et al., 1995), glycoside-liposomes for antituberculosis drugs (Medda et al., 1995), and mannosylated replacement enzyme for Gaucher's disease (Mistry et al., 1996). To achieve macrophage targeting for AIDS, reverse transcriptase inhibitors have been covalently attached to lipoproteins (Mankertz et al., 1996), noncovalently adsorbed into colloidal nanoparticles (Lobenberg and Kreuter, 1996), and incorporated into erythrocytes (Rossi et al., 1998). In this report, macrophage targeting is based on the chemotactic peptide, *N*-formyl-methionine-leucine-phenylalanine (fMLF),[1] which is indicative of a bacterial infection since all bacterial (but not eukaryotic) proteins are synthesized with *N*-formyl-methionine as their N-terminal amino acid. Monocyte-derived dendritic cells (Randolph et al., 1998), which migrate to lymph nodes and which can be infected by both M-tropic and T-tropic strains of HIV-1, also bind and respond to fMLF (Benelli et al., 1998). The high affinity receptor for fMLF is found on phagocytes and some other cells, while sequence-related low affinity and orphan receptors are more widely distributed (reviewed by Prossnitz and Ye, 1997; Le et al., 2001). Expression of the fMLF receptor has been shown to be sufficient to enable normally receptor nega-

tive cells to specifically bind to fMLF (Prossnitz et al., 1993).

We have developed a novel method of targeting drug delivery to phagocytic cells based on a poly(ethylene glycol) (PEG) carrier possessing multiple sites for covalent attachment of targeting groups and drug moieties (Huang et al., 1998). Whereas the bioreversible disulfide bond had been proposed for reversibly appending the therapeutic agent to the carrier and delivering it to cellular targets (Huang et al., 1998), the present studies used the more stable amide bond for appending the reporter group, digoxigenin, as a surrogate drug substance. To achieve high affinity binding to fMLF receptors, we explored the concept of using multiple copies of this ligand on the carrier polymer. In addition to achieving strong and specific binding to the fMLF receptor, a clinically acceptable targeted drug−carrier conjugate should not activate macrophages, thereby avoiding undesired side effects. A previously proposed solution was to use a receptor antagonist as the targeting group. This could be accomplished by replacing the formyl group on the targeting peptide ligand with a branched carbamate structure, such as the *tert*-butyloxycarbonyl group (tBoc) commonly used as a blocking group in peptide synthesis (Derian et al., 1996). However, this substitution was found to weaken receptor binding 100-fold (K_d increased from 0.033 to 4.5 μM) (Derian et al., 1996). Based on studies using carrier polymers bearing different numbers of fMLF ligands, we now report that we have found a method by which macrophages can be targeted but not activated, by attaching multiple fMLF moieties to a single drug-carrying polymer.

EXPERIMENTAL PROCEDURES

Materials. *N*-Formyl-methionine-leucine-phenylalanine (fMLF) peptide was purchased from Sigma (St. Louis, MO). Radioactive [^{45}Ca]calcium chloride (specific activity 16 mCi/mg) and fML[^{3}H]F (40 Ci/mmol) were from DuPont-NEN Research Products (Boston, MA). The human cells used in this study (HL-60 and Jurkat T-cells) were purchased from the American Type Culture Collection (Manassas, VA). Branched amino-PEGs with three (10 kDa), four (10 kDa), or eight arms (20 kDa) and α,ω-diamino-PEG (3.4 kDa) were purchased from Shearwater Polymers (Huntsville, AL). Dichloromethane (DCM) and *N*,*N*-dimethylformamide (DMF) were purchased from Fisher Scientific (Pittsburgh, PA). Trifluouroacetic acid (TFA), diiosopropylcarbodiimide (DIPC), and *p*-toluenethiosulfonic acid (PTSA) were obtained from Aldrich Chemical (Milwaukee, WI). *N*-Hydroxysuccinimide-digoxigenin (NHS-DIG) was obtained from Boehringer-Mannheim (Indianapolis, IN). Fluorescamine was a gift from S. Udenfriend. Hanks's balanced salt solution (HBSS) and RPMI 1640 tissue culture medium were purchased from GIBCO (Grand Island, NY).

Quantitation of Primary Amino Groups. Fluorescamine (Udenfriend et al., 1972) was used to monitor conversion of primary amines to amides. A fluorescence signal is obtained only by reaction with primary amines and not with amides or with secondary or aromatic amines. To each well of the 96-well plates, 0.1 mL of sample was added. Then 0.05 mL of 0.2 M borate buffer (pH 9.3) was added to each well, and 0.05 mL of fluorescamine (0.5 mg/mL in acetonitrile) was added and mixed immediately. The fluorescence intensity was measured at an excitation wavelength of 390 nm and emission wavelength of 475 nm.

Synthesis of Linear PEG−Aspartate Copolymer. This carrier copolymer was prepared by copolymerization of tBoc-aspartic acid and α,ω-diamino-PEG (3400 Da), using a modification of previous methods (Nathan et al., 1993; Poiani et al., 1994). The tBoc group was removed by treatment with TFA, thereby providing primary amino groups (NH_2) for attachment of fMLF. Copolymer size was determined by size exclusion chromatography using PEG−tyrosine molecular weight standards prepared by us. The molecular weight was estimated to be 29 kDa. The structure of the resulting copolymer ($m \sim 8$, $n \sim 75$) is

$$\text{H-[NHCH}_2\text{CH}_2(\text{OCH}_2\text{CH}_2)_n\text{NHCOCH}_2\text{-CH(NH}_2\text{)CO]}_m\text{-OH}$$

Conjugation of PEG−Aspartate Copolymer with fMLF and DIG. Linear PEG−aspartate (PEG/A) copolymer (about 10 mg) was reacted with 7-fold excess (relative to amino groups) of fMLF peptide, 3.5 molar excess of DIPC, and 0.5 equiv of PTSA and 4-(dimethylamino)-pyridine (4-DMAP) in DMF:DCM (1:1 v/v). The total volume of the reaction was adjusted to 1 mL. The reaction mixture was incubated at room temperature for 24 h with gentle stirring. Then the polymer was precipitated with 10 volumes of ice-cold ethyl ether and dissolved in 90% phosphate-buffered saline (PBS) pH = 7.4, 10% acetonitrile. The unreacted peptide was separated from polymer by ultrafiltration with Microcon 10 (molecular weight cutoff = 10 kDa Amicon/Millipore, Inc., Bedford, MA). The retentate was dried and dissolved in PBS. The extent of peptide conjugated to the polymer was estimated using the fluorescamine assay. Separately, 4 mg of PEG/A or 4 mg of PEG/A−fMLF was reacted with 1 mg of NHS-DIG, dissolved in DMSO, in 0.5 mL of PBS, adjusted with NaOH to pH 8.0, with stirring overnight. The products were precipitated with ether, dissolved in PBS, and separated from the unreacted reagent by ultrafiltration with Microcon 10. The products were PEG/A−$fMLF_4$ and PEG/A−$fMLF_4$−DIG_4, and PEG/A−DIG_8.

Conjugation of fMLF with Branched (B) PEG. Addition of fMLF to the eight-arm branched amino-PEGs was accomplished in a similar manner as above. To achieve a range of molar ratio of fMLF conjugated to the copolymer, three sets of reactions with 14-, 8-, and 2-fold excess fMLF were set up. Fluorescamine assay was used to determine the average extent of conjugation of fMLF on the polymer, which was 8 (100%), 5.5 (68%), and 1.1 (14%) fMLF residues per polymer, respectively, for each reaction. These products are denoted B8-PEG−$fMLF_8$, B8-PEG−$fMLF_{5.5}$, and B8-PEG−$fMLF_{1.1}$, respectively. Similarly, a 14-fold molar excess of fMLF was used for reactions with three-arm and four-arm branched amino-PEGs to achieve100% coupling, yielding B3-PEG−$fMLF_3$ and B4-PEG−$fMLF_4$.

Competitive Receptor Binding Assay. HL-60 cells were propagated in RPMI 1640 supplemented with 2 mM L-glutamine and 10% (v/v) heat-inactivated fetal bovine serum and were subcultured every 3 days at a ratio of 1:4. Cells were grown at 37 °C in an atmosphere of 5% CO_2. Dimethyl sulfoxide (DMSO, 1.3%) was added to the culture (3×10^5 cells/mL) 48 h before the binding assay to initiate cellular differentiation. Differentiated HL-60 cells (2×10^5) were washed with PBS, pH 7.4, and resuspended in 1.77 mM KH_2PO_4, 8.0 mM Na_2HPO_4, 0.117 M NaCl, 0.15 mM $CaCl_2$, 0.5 mM MgCl, and 1% bovine serum albumin (binding buffer) with fML[^{3}H]F (30,000 cpm) and unlabeled fMLF (0.1 nM-200 nM) or conjugate. The cells were incubated for 15 min at 37 °C with gentle shaking. They were collected by centrifuga-

tion at 3000*g* for 5 min at room temperature. The supernatant was removed, and cells were resuspended in 0.1 mL of binding buffer and carefully added to the very top of tubes (Denville Scientific, South Plainfield, NJ, catalog #C19002) that contained 0.3 mL of 10% sucrose. They were centrifuged for 5 min at 12000*g*. The cells settled to the bottom, and any unbound ligand remained in the middle of the tube. The tubes were placed in dry ice for 5 min, and then their bottoms were cut off to collect the cells. Cell-bound and free radioactivity were determined by liquid scintillation counting. The value of K_d for each curve was determined graphically using the Cricket Graph program.

Intracellular Calcium Assay. HL-60 cells (2×10^5 cells/mL) were grown in the presence of 1.3% DMSO for 5 days. For each time course experiment, 2×10^6 cells were resuspended in 5 mL of HBSS containing 2 mCi/mL of $^{45}CaCl_2$ as the sole source of calcium. After 90 min incubation at 37 °C, cells were washed twice as above with cold HBSS. Vesicle-associated and cytoplasmic ^{45}Ca were measured prior to and at 1, 2, 3, 4, 5, and 10 min after the addition of the fMLF or conjugated compounds. The EC_{50} for cellular activation is the concentration of each compound tested resulting in 50% maximal stimulation of calcium efflux by this assay. Cell pellets were treated with 0.5% Triton X-100/0.1 M NaOH and centrifuged in tubes containing 0.3 mL of 10% sucrose, and radioactivity associated with the pellets was measured; this represents vesicle-associated ^{45}Ca. The top portion of the tube, which contained the cytoplasmic ^{45}Ca was also measured. The peak level of transient increase in cytoplasmic calcium and decrease in vesicle-associated calcium represents efflux of calcium from intracellular storage compartments that is stimulated by fMLF interaction with membrane receptors (Montero et al., 1994; Klinker et al., 1996; Azuma et al., 1996; Anderson and Mohamed Goolam, 1997).

Uptake by HL-60, Jurkat and Peritoneal Cells. Human Jurkat T-cell growth conditions were the same as for HL-60 cells, except that the subcultivation ratio was 1:3. Jurkat cells (2×10^5) or fully differentiated HL-60 cells were washed twice with PBS and incubated in binding buffer (see above) with conjugate for 30 min at 37 °C. Each conjugate (1 μg, dissolved at a concentration of 33 nM) was used in these experiments. Cells were lysed, the membranes and cell debris were removed by centrifugation (5 min at 14000*g*), and the enzyme-linked immunosorbant assay (ELISA) for DIG was performed on the supernatant as described below. To study primary peritoneal cells, BALB/c mice were injected in the peritoneal cavity with 5 μg of PEG/A−DIG_4-$fMLF_4$ ($n = 3$ mice), or PEG/A−DIG_8 ($n = 4$ mice). After 1 h, the cavity was flushed with medium, and cells were collected and washed twice with cold PBS, as described above.

Cells were resuspended in 100 μL of PBS, containing 0.6% Tween 20, vortexed briefly, and kept on ice for 30 min. Microscopic examination confirmed complete cell lysis. Uptake of DIG was determined by ELISA of the supernatant. Anti-DIG-Fab fragment and anti-DIG-horseradish peroxidase (POD) were purchased from Boehringer Mannheim. Anti-DIG-Fab (1 mg/mL) was diluted 1:100 and anti-DIG−POD (150 U/mL) was diluted 1:10000. ELISA was performed according to the manufacturer's procedure. DIG content was proportional to the difference in absorbance at 495 and 450 nm. A standard curve for PEG/A−DIG_8 and PEG/A−$fMLF_4$−DIG_4 was included in each assay. To account for the potential different amounts of peritoneal cells from each mouse, the results were normalized to the amount of protein, as measured with the Bradford assay (BioRad, Hercules, CA).

For all cell uptake experiments, statistical significance of the differences between experimental groups was evaluated using the two-sample t-test for independent samples with unequal variance.

RESULTS

Competitive Binding of fMLF Conjugates to Differentiated HL-60 Cells. To determine the effect of different numbers of targeting groups on polymer avidity for differentiated HL-60 cells, conjugates were tested for their binding activity, measured by their ability to compete with fML[H^3]F for cell binding. The HL-60 cells used for these experiments were differentiated for 48 h with DMSO. HL-60 cells treated with DMSO for 5 days yielded similar results (data not shown). However, HL-60 cells that were not subjected to a differentiation-inducing regimen did not bind to fMLF (data not shown). HL-60 cells, which are derived from human promyelocytic leukemia cells, have the capacity to respond to many stimuli to differentiate into many cell types of the monocytic−granulocytic class. The categorization of the differentiated states by the nomenclature for normal cell types is somewhat arbitrary, since the cells tend to have properties that overlap these categories. Although DMSO is considered to induce cells to differentiate along the granulocytic pathway, the final phenotype of these cells is not identical to normal granulocytes (reviewed by Collins, 1987). The functional properties of HL-60 differentiated cells are similar (although not identical) to neutrophils (Dahlgren et al., 1987). They are able to undergo azurophilic granule release and to generate O_2^- (Seifert et al., 1992). Expression of the receptor for fMLF is one of the early events of differentiation of HL-60 cells and its presence is the only requirement for binding of fMLF to these cells (Prossnitz et al.,. 1993). In this work these differentiated HL-60 cells are used as a model cell system; these cells have some properties of both macrophages and neutrophils, but are not identical with either cell type.

Figures 1 and 2 show the result of competitive binding studies. The conjugates tested included PEG/A−$fMLF_4$, PEG/A−$fMLF_4$−DIG_4, PEG/A−DIG_8, B8-PEG−$fMLF_{1.1,5.5,8}$, B4-PEG−$fMLF_4$, and B3-PEG−$fMLF_3$. The amount of fML[H^3]F was kept constant while the concentration of each conjugate was varied. The binding curves (Figures 1 and 2) show that the specific binding is about 75% of the total binding, since about 25% of maximum ligand binding was nonspecific in that it was not subject to competition at any concentration of any competitor. The binding constant (K_d) estimated here for fMLF is 28 nM, which is close to that (33 nM) determined by Derian et al. (1996). As can be seen in Figure 1 and Table 1, the increased K_d of B8-PEG−$fMLF_{1.1}$ (190 nM) relative to the free fMLF peptide (28 nM) indicates that attachment to the polymer reduces the avidity of the peptide for binding to cellular receptors. However, polymers with multiple fMLF moieties attached showed increased avidity for differentiated HL-60 cells, with B8-PEG−$fMLF_8$ showing the lowest K_d (0.18 nM) and the greatest avidity relative to the number of fMLF peptides [$K_d \times$ (no. of fMLF) = 0.18 nM $\times$ 8 = 1.44 nM].

The size or shape of the polymer does not seem to play a major role in avidity of binding, since the linear polymer with four copies of fMLF showed properties similar to its branched counterpart, both displaying a K_d of about

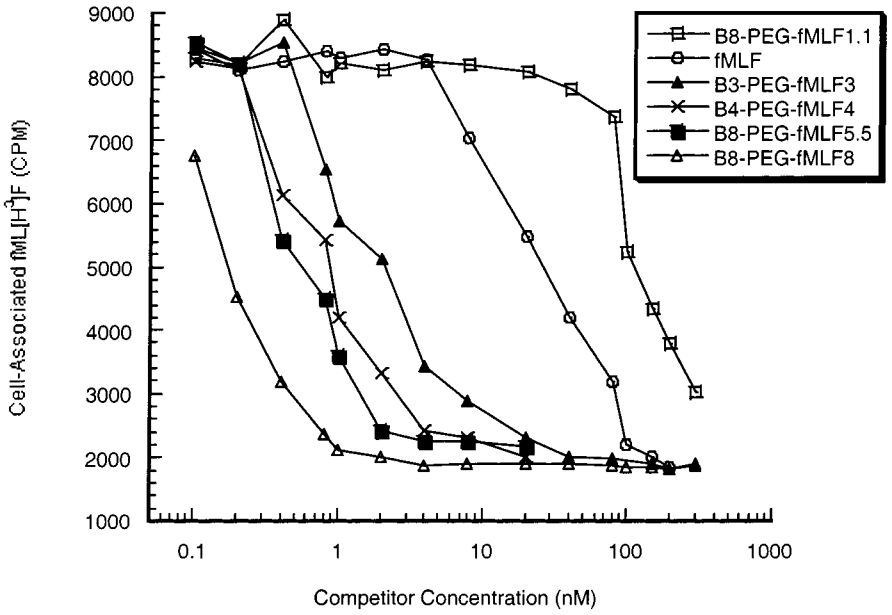

Figure 1. Competition of free and branched polymer-conjugated fMLF for binding to differentiated HL-60 cells. Varying concentrations of the indicated compounds were tested for their ability to compete with fML[^{3}H]F for binding to DMSO-differentiated HL-60 cells, as described in Experimental Procedures. These results are the means of three independent assays; for each data point, the maximal deviation from the mean among these assays was 3%.

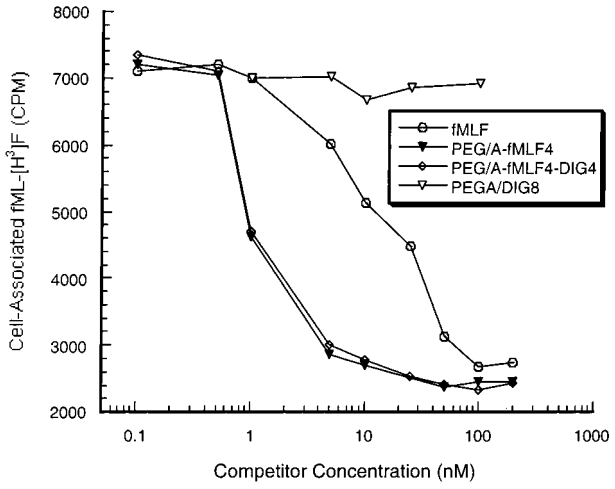

Figure 2. Competition of free and linear polymer-conjugated fMLF for binding to differentiated HL-60 cells. The experiment was performed as in Figure 1. The results shown are the means of three independent assays; the maximal deviation from the mean among these assays was 8%.

1 nM (Table 1). Furthermore, whether the other four potential attachment sites on the linear PEG/A were either unoccupied or were occupied with DIG made little difference in the K_d (Figure 2, Table 1). Thus, additional moieties such as therapeutic drugs could be added to the targeting polymer without compromising the binding avidity.

Cellular Activation of HL-60 Cells. Upon binding of the chemotactic peptide to the G-protein coupled receptor, one of the early events related to cellular activation is the release of Ca^{2+} from membrane-bound intracellular compartments into the cytoplasm (Azuma et al., 1996; Anderson and Mahomed Goolam, 1997; Prossnitz et al., 1999). This assay for cellular activation was used because it is the earliest measurable event after fMLF binding along the complex activation pathway. The release of calcium is rapid, reaching its maximum value in 2−3 min followed by slow recovery to near basal level (Figure 3). Similar kinetics of calcium release were observed in the response of differentiated HL-60 cells to free fMLF and to polymers bearing multiple fMLF moieties (Figure 3 and data not shown). As was the case for binding to these cells, B8-PEG−fMLF$_{1.1}$ showed reduced ability relative to free fMLF to activate differentiated HL-60 cells, with virtually no flux of calcium even at 100 nM polymer. Activation also resembled binding in being enhanced by the presence of multiple fMLF moieties on a polymer, so that three fMLF residues on a polymer yielded readily detectable activation and four fMLF residues on a polymer were about as potent as free fMLF by this assay (Figure 4 and Table 1). However, unlike the binding assay, the Ca^{2+} efflux into the cytoplasm did not further increase as the copy number of fMLF per polymer increased beyond 4 (Figure 4 and Table 1). All of the conjugates with the copy number of fMLF ≥ 4 showed similar half-maximal release of intracellular calcium (EC_{50}, as determined graphically using the Cricket Graph program) of about 5 nM of conjugate, which is approximately the same as the EC_{50} value (4.7 nM) for the free peptide (Table 1). Thus, the presence of multiple ligands (>3) on PEG does not increase the activation potency as much as it increases binding avidity for differentiated HL-60 cells.

Comparison of cellular binding and activation by various conjugates (Table 1) reveals that while no conjugate is more potent in activating differentiated HL-60 cells than is free fMLF, the avidity of conjugate for these cells increases with increasing number of fMLF moieties. This increase is most remarkable when expressed as K_d for the conjugate, but is still evident when a relative avidity is calculated per peptide, by multiplying the K_d of the polymer by the average number of fMLF moieties that it carries. The ratio of avidity ($1/K_d$) to cellular activation ("toxicity") activity ($1/EC_{50}$), measured by EC_{50}/K_d, is 0.168 for free fMLF and increases from 5.05 to 27.8 for conjugates as number of fMLF moieties increases from 3 tof 8. Although the effect of molecular shape was not systematically studied, note that both avidity and cellular activation activity were nearly the same for branched and linear polymers harboring four copies of fMLF.

Table 1. Binding and Cell Activation by Conjugates

competitor	avidity: K_d (nM)	cell activation: EC_{50} (nM)	relative avidity: $K_d \times$ no. of fMLF	avidity/activation: EC_{50}/K_d
fMLF	28	4.7	28	0.168
B8-PEG−$fMLF_{1.1}$	190	–	209	–
B3-PEG−$fMLF_3$	1.9	9.6	5.7	5.05
B4-PEG−$fMLF_4$	0.8	5.0	3.2	6.25
B8-PEG−$fMLF_{5.5}$	0.5	5.3	2.75	10.6
B8-PEG−$fMLF_8$	0.18	5.0	1.44	27.8
PEG/A−$fMLF_4$	1.1	ND	4.4	–
PEG/A−$fMLF_4$−DIG_4	1.2	5.9	4.8	4.92

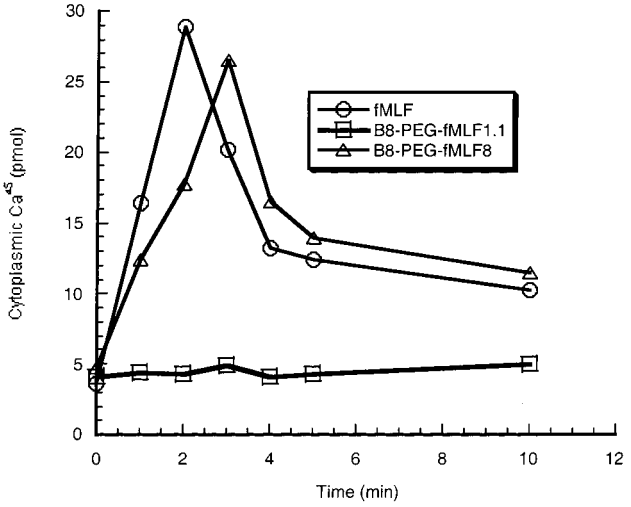

Figure 3. Time course of calcium release from intracellular stores in differentiated HL-60 cells. Release of ^{45}Ca into the cytoplasmic compartment of differentiated HL-60 cells was measured at various times after addition of fMLF or the conjugated polymers. Similar time courses were observed when the added compounds were at concentrations between 1 and 100 nM.

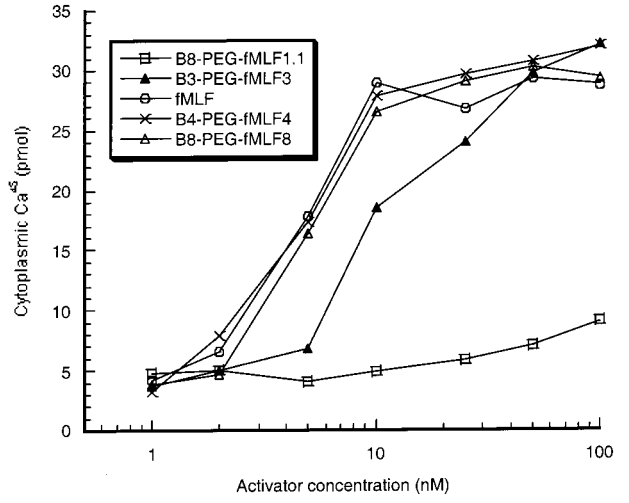

Figure 4. Calcium mobilization in differentiated HL-60 cells by fMLF and polymer-conjugated fMLF. The peak value of calcium release after addition of the indicated fMLF derivatives at various concentrations was measured as shown in Figure 3. Each data point is the mean of at least two independent experiments; for all data points the variation between repeat measurements was less than 8.2%.

Targeting Drugs to Cells. To directly show the accumulation of PEG/A−drug−ligand conjugates, PEG/A−$fMLF_4$−DIG_4 (333 nM) was incubated with differentiated HL-60 cells. The DIG ELISA demonstrated that 18% of this conjugate had been internalized by these cells (Figure 5). When the negative control conjugate, PEG/A−DIG_8, was incubated with HL-60 cells, 4.7% uptake

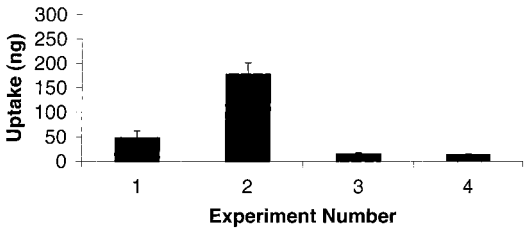

Figure 5. Uptake of PEG/A−$fMLF_4$−DIG_4 and PEG/A−DIG_8 by phagocytic cells. Uptake of the indicated conjugate by cells was measured by ELISA for DIG, as described in Experimental Procedures. Uptake of PEG/A−$fMLF_4$−DIG_4 (experiments 2 and 4) and PEG/A−DIG_8 (experiments 1 and 3) to DMSO-differentiated HL-60 cells (experiments 1 and 2) and Jurkat T-cells (experiments 3 and 4) were measured (n = 3). The total conjugate added to each culture was 1 μg.

was observed. This much lower accumulation ($P < 0.006$) in the absence of fMLF confirmed the importance of this ligand in the interaction of conjugates with differentiated HL-60 cells. Lymphocytic Jurkat cells, which do not express the fMLF receptor, accumulated both PEG/A−DIG_8 (1.5%) and PEG/A−$fMLF_4$−DIG_4 (1.3%) to a much lesser extent than did differentiated HL-60 cells (Figure 5). The difference between uptake of the nontargeted conjugate by differentiated HL-60 cells and Jurkat cells was significant ($P < 0.003$), as was the difference between these two cell types for uptake of the targeted conjugate ($P < 0.004$). Note that for the Jurkat cells, there was no significant difference between the uptake of the two conjugates ($P = 0.80$). These values represent nonspecific cellular binding of polymers. These results indicate the specificity of binding of PEG/A−$fMLF_4$−DIG_4 to differentiated HL-60 cells. The 4.7% accumulation of PEG/A−DIG_8 by differentiated HL-60 cells might reflect the tendency of these cells to bind and phagocytose polymeric PEG/A molecules nonspecifically.

Injection of PEG/A−$fMLF_4$−DIG_4 into the peritoneal cavity of BALB/c mice was used to determine the in vivo properties of this conjugate, in contrast to using the differentiated HL-60 cell line. The mice in this study were not injected with thioglycol, and, therefore, the macrophages in the peritoneal cavity were not activated. These nonactivated peritoneal cells accumulated DIG to about a 5-fold greater extent ($P < 0.0003$) from the targeted conjugate, PEG/A−$fMLF_4$−DIG_4, than from the nontargeted conjugate, PEG/A−DIG_8 (Figure 6). In fact, 17% of the administered PEG/A−$fMLF_4$−DIG_4 was taken up by peritoneal cells, whereas they accumulated only 3.3% of the nontargeted PEG/A−DIG_8. This low level of accumulation of nontargeted DIG is not surprising, since we have shown that in culture there is some nonspecific binding of PEG/A to promyelocytic HL-60 cells (Figure 5). Peritoneal incubation for less than 1 h (15 or 30 min) gave similar results (data not shown). It should be noted that the DIG that was accumulated in cells is expected to remain conjugated to its PEG/A carrier, but this was not confirmed.

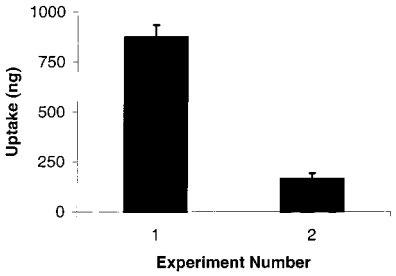

Figure 6. Specific targeting of peritoneal macrophages by fMLF. Each BALB/C mouse was injected intraperitoneally with 5 μg of PEG/A−fMLF$_4$−DIG$_4$ (experiment 1, $n = 3$) or PEG/A−DIG$_8$ (experiment 2, $n = 4$). After 1 h, the peritoneal cavity was flushed, and cells were collected and lysed as described in Experimental Procedures. ELISA was performed to determine intracellular digoxigenin; a standard curve for digoxigenin was included on every assay plate. The results are normalized to the amount of protein in each lysate, to correct for variations in cell number and efficiency of lysis.

DISCUSSION

In this study, we have demonstrated the ability of multiple fMLF moieties to target a polymeric drug delivery molecule (Huang et al., 1998) to phagocytic cells. Such phagocytic cells populate the reticuloendothelial system and play a key role in host defense against bacteria (Seifert and Schultz, 1991). Macrophages recognize bacteria through a specific receptor for peptides containing *N*-formyl-methionine, which is the initiating amino acid in prokaryote protein synthesis. The high affinity formyl methionine receptor (referred to here as the fMLF receptor) is a member of the G-protein coupled receptor family (Gierschik et al., 1991; Prossnitz and Ye, 1997; Le et al., 2001). The binding of fMLF to this receptor initiates a series of cascades, resulting in chemotaxis (Martinet et al., 1994) and cellular activation (Montero et al., 1994). Since this receptor is present on phagocytic cells, such as macrophages and neutrophils (Niedel et al., 1980), it could serve as a targeting ligand for delivering drugs to these cells. Although binding of fMLF initiates the activation process, activation is not required for cellular uptake of fMLF (Prossnitz et al., 1999).

Our approach to drug delivery is based on the use a PEG-based carrier with multiple attachment sites to which drugs or targeting moieties can be linked. By appending drugs via the bioreversible disulfide bond, which can be designed to varying degrees of susceptibility to cleavage by reducing agents (Huang et al., 1998), the circulating time of the carrier can be adjusted, allowing it to reach the targeted cells, before releasing its drug cargo. The multiple attachment sites on the PEG-based carrier can not only provide a high payload of drug, but also can be used for appending one or more moieties for targeting specific cellular receptors or promoting cell uptake of the conjugate. In this study, the enhancement in avidity for the targeted receptor on phagocytic cells by multivalent binding of the fMLF ligand is demonstrated. Thus, a concentration of only 0.18 nM B8-PEG−fMLF$_8$ is needed to get 50% occupancy of the differentiated HL-60 cell surface fMLF receptors, as opposed to 190 nM for B8-PEG−fMLF$_{1.1}$, with only one appended ligand, an increase in avidity of more than 1000-fold (Table 1).

The molecular basis of enhanced avidity by multivalency of ligand attachment to a single polymeric carrier molecule is not obvious. It is possible that such multimeric ligands show their enhanced binding by interacting with multiple cellular receptors. Since a single fMLF moiety bound to a branched PEG polymer shows less avidity for differentiated HL-60 cells than does the free peptide, it seems likely that the bulky carrier group sterically interferes with ligand interaction with its cellular receptor, but this interference is overcome by peptide multivalency on the polymer. This behavior of fMLF conjugated to PEG-based polymers resembles that described for α-sialoside groups, the ligands for the hemagglutinin protein of influenza virus. When a single α-sialoside is linked to a polyacrylamide polymer, the conjugate binds less avidly to the hemagglutinin receptor on the virus than does a low molecular weight form of the ligand (Lees et al., 1994). However polyacrylamides bearing many copies of the ligand show vastly greater binding avidity than the free ligand (Lees et al., 1994; Sigal et al., 1996).

After binding of the free fMLF chemotactic peptide to a phagocytic cell, a rapid receptor-mediated internalization takes place (Niedel et al., 1979). Our results suggest that polymers with multiple fMLF moieties are capable of binding to and/or entering cells in culture and in vivo. In the present study we have not fully defined the possible mechanism of internalization and have only used the model indicator compound digoxigenin stably linked by an amide bond to the carrier polymer rather than an actual therapeutic agent. We are currently studying the subcellular localization of delivered compounds and determining the kinetics of release of a disulfide-linked model drug from the targeted conjugate upon its uptake by phagocytic cells.

A potential cause of adverse effects of targeting fMLF receptors on phagocytes is cellular activation caused by this interaction. Cellular activation is mediated by a complex chain of signal transduction events (reviewed by Prossnitz and Ye, 1997) and can be monitored by the mobilization of calcium from intracellular stores (Camps et al., 1992). This transient increase in intracellular free calcium correlates with acidification and stimulation of superoxide (O^{2-}) release. The level of free fMLF required for half-maximal effect on Ca^{2+} release has been reported to be 2−4 nM (Wenzel-Seifert and Seifert, 1990), in approximate agreement with our determination of 5 nM, while the EC_{50} for superoxide production has been reported to be 15−30 nM fMLF (Klinker et al., 1996). In this study all conjugates with four or more copies of fMLF and free fMLF displayed an EC_{50} value of about 5 nM for calcium release (Table 1 and Figure 4). Therefore, the cooperative effect that was observed in binding is less pronounced for cellular activation. This difference indicates that polymers targeted to phagocytic cells with multiple fMLF moieties should be much more potent as targeting agents than as cellular activators. At a concentration of 1 nM of B8-PEG−fMLF$_8$, nearly 100% of the fMLF receptors were occupied by the targeted drug carrier, whereas little or no cellular activation occurred.

PEG-based copolymers have been found to be biocompatible and are currently being developed for multiple in vivo applications (Poiani et al., 1994). These include the use of biotin targeting moieties to promote sodium-dependent multivitamin transporter (SMVT) mediated transport of molecules across the intestinal epithelium (Ramanathan et al., 2001). In the present study, the high molecular weight (>20 KDa) and inertness of PEG-based conjugate would be expected to confer on appended drugs an extended in vivo half-life and protection from degradative processes and immune system surveillance (Davis et al., 1981). Therefore, we propose that a PEG-based carrier containing multiple copies of fMLF can be used to target drugs to macrophages and other phagocytic cells

without the adverse effects of activation of these cells. Furthermore, the lack of enhancement of cellular activation by polymers carrying multiple targeting fMLF groups might indicate that drugs appended to such polymers would be less likely to be inactivated by the many degradative mechanisms induced by phagocyte activation.

Chemical Synthesis of *Escherichia Coli* ST_h Analogues by Regioselective Disulfide Bond Formation: Biological Evaluation of an ^{111}In-DOTA−Phe^{19}-ST_h Analogue for Specific Targeting of Human Colon Cancers

Hariprasad Gali,[†] Gary L. Sieckman,[§] Timothy J. Hoffman,[†,‡,§] Nellie K. Owen,[†] Dana G. Mazuru,[†] Leonard R. Forte,[§,⊥] and Wynn A. Volkert*[,†,§]

Research Service, Harry S. Truman Memorial Veterans' Administration Hospital, Columbia, Missouri 65201 and Departments of Radiology, Pharmacology and Internal Medicine, University of Missouri−Columbia, Columbia, Missouri 65211. Received July 6, 2001; Revised Manuscript Received October 18, 2001

New human *Escherichia coli* heat-stable peptide (ST_h) analogues containing a DOTA chelating group were synthesized by sequential and selective formation of disulfides bonds in the peptide. This synthetic approach utilizes three orthogonal thiol-protecting groups, Trt, Acm, and t-Bu, to form three disulfide bonds by successive reactions using 2-PDS, iodine, and silyl chloride−sulfoxide systems. The DOTA−ST_h conjugates exhibiting high guanylin/guanylate cyclase-C (GC-C) receptor binding affinities were obtained with >98% purity. In vitro competitive binding assays, employing T-84 human colon cancer cells, demonstrated the IC_{50} values of <2 nM for GC-C receptor binding suggesting that the new synthetic ST_h analogues are biologically active. In vitro stability studies of the ^{111}In-DOTA−Phe^{19}-ST_h conjugate incubated in human serum at 37 °C under 5% CO_2 atmosphere revealed that this conjugate is extremely stable with no observable decomposition at 24 h postincubation. HPLC analysis of mouse urine at 1 h pi of the ^{111}In-DOTA−Phe^{19}-ST_h conjugate showed only about 15% decomposition suggesting that the ^{111}In-DOTA−Phe^{19}-ST_h conjugate is highly stable, even under in vivo conditions. In vivo pharmacokinetic studies of the ^{111}In-DOTA−Phe^{19}-ST_h conjugate in T-84 human colon cancer derived xenografts in SCID mice conducted at 1 h pi showed an initial tumor uptake of 2.04 ± 0.30% ID/g at 1 h pi with efficient clearance from the blood pool (0.23 ± 0.14% ID/g, 1 h pi) by excretion mainly through the renal/urinary pathway (95.8 ± 0.2% ID, 1 h pi). High tumor/blood, tumor/muscle, and tumor/liver ratios of approximately 9:1, 68:1, and 26:1, respectively, were achieved at 1 h pi The specific in vitro and in vivo uptake of the radioactivity by human colonic cancer cells highlights the potential of radiometalated-DOTA−ST_h conjugates as diagnostic/therapeutic radiopharmaceuticals.

INTRODUCTION

Heat-stable (ST) peptides are secreted by several enteric bacteria such as *Escherichia coli*, *Yersinia enterocolitica*, and *Vibrio cholerae non-01* (*1*−*3*). ST peptides bind to guanylin/guanylate cyclase-C (GC-C) receptors that are selectively expressed in apical membranes of intestinal mucosal cells (*4*−*6*). It is reported that functional GC-C receptors are also expressed on human colon cancer cells (*7*−*9*). Considerable efforts have been and are being made to investigate the relationship between structural characteristics of ST peptides and receptor-mediated cellular and physiological response (*5*, *10*−*15*). It has been shown that the GC-C receptor binding domain consists of a sequence of 13 amino acid residues with six cysteines forming three disulfide bonds that are critical for the construction of the three-dimensional tertiary structure (*5*, *11*, *12*). The six cysteines can adopt 15 possible different disulfide arrangements, and only one of them exhibits high GC-C receptor binding affinity and full biological activity (*15*). Thus, in the synthesis of biologically active ST analogues, correct formation of the three disulfide bonds is critical.

The widely used method for the synthesis of ST peptides and their analogues involves simultaneous folding and disulfide bond formation of the fully deprotected peptide by air-oxidation in aqueous solutions (*10*−*12*, *15*−*19*). Reproducible production of the correct conformer is challenging, particularly if there is a large chemical moiety attached to the native peptide sequence that may substantially alter the thermodynamic and steric properties of the system during the folding. To achieve improved synthetic reproducibility, we followed a new synthetic strategy, similar to that described by Akaji et al. (*20*) for synthesizing human insulin, utilizing three well-known orthogonal thiol-protecting groups, Trt, Acm, and t-Bu, to form three disulfide bonds by successive reactions using 2-PDS, iodine, and silyl chloride−sulfoxide system (*20*−*25*). Herein, we report two novel ST_h analogues containing a DOTA chelating agent, synthesized by sequential and selective formation of disulfide bonds. The ST_h analogues synthesized for these studies have the identical structure as the ST peptide

originated from *E. coli* that colonize the human gut (*5*), except that the C-terminal Tyr^{19} residue was replaced by the Phe^{19} residue. This substitution does not alter the biological activity or receptor affinity of the corresponding ST analogue. Utilization of the selective deprotection approach makes it possible to synthesize the entire linear DOTA−ST$_h$ conjugates on the resin prior to S−S bond formation, in contrast to forming the S−S bonds on the binding sequence prior to conjugation with a DOTA moiety (*26*). The in vitro binding of these two ST peptides to GC-C receptors expressed on human colon cancer T-84 cells was measured, and the in vivo stability and pharmacokinetics were assessed in tumor-bearing SCID mice.

EXPERIMENTAL SECTION

All solvents were either ACS certified or HPLC grade. Solvents were obtained from Fisher Scientific and used as received. The fmoc-Phe-Wang resin, Rink Amide MBHA resin, and fmoc-protected amino acids were purchased from Calbiochem-Novabiochem Corp (San Diego, CA) and the other peptide reagents from Applied Biosystems, Inc (Foster City, CA). DOTA-tris(*tert*-butyl ester) was purchased from Macrocyclics (Dallas, TX) and fmoc-6-aminohexanoic acid from Advanced ChemTech (Louisville, KY). All other reagents were purchased from Aldrich Chemical Co. $^{111}InCl_3$ was obtained from Mallinckrodt Medical, Inc (St. Louis, MO) as a 0.05 N HCl solution. ^{125}I-Tyr^5-6-Ahx-Phe^{19}-ST$_h$ and ^{125}I-Tyr^5-Phe^{19}-ST$_h$ were synthesized according to the previously published procedure.[19] Human colon carcinoma T-84 cells were obtained from American Type Culture Collection (ATCC) and maintained and grown for use in these studies in the University of Missouri Cell and Immunology Core facilities. Electrospray mass spectral analyses were performed by Synpep Corporation (Dublin, CA).

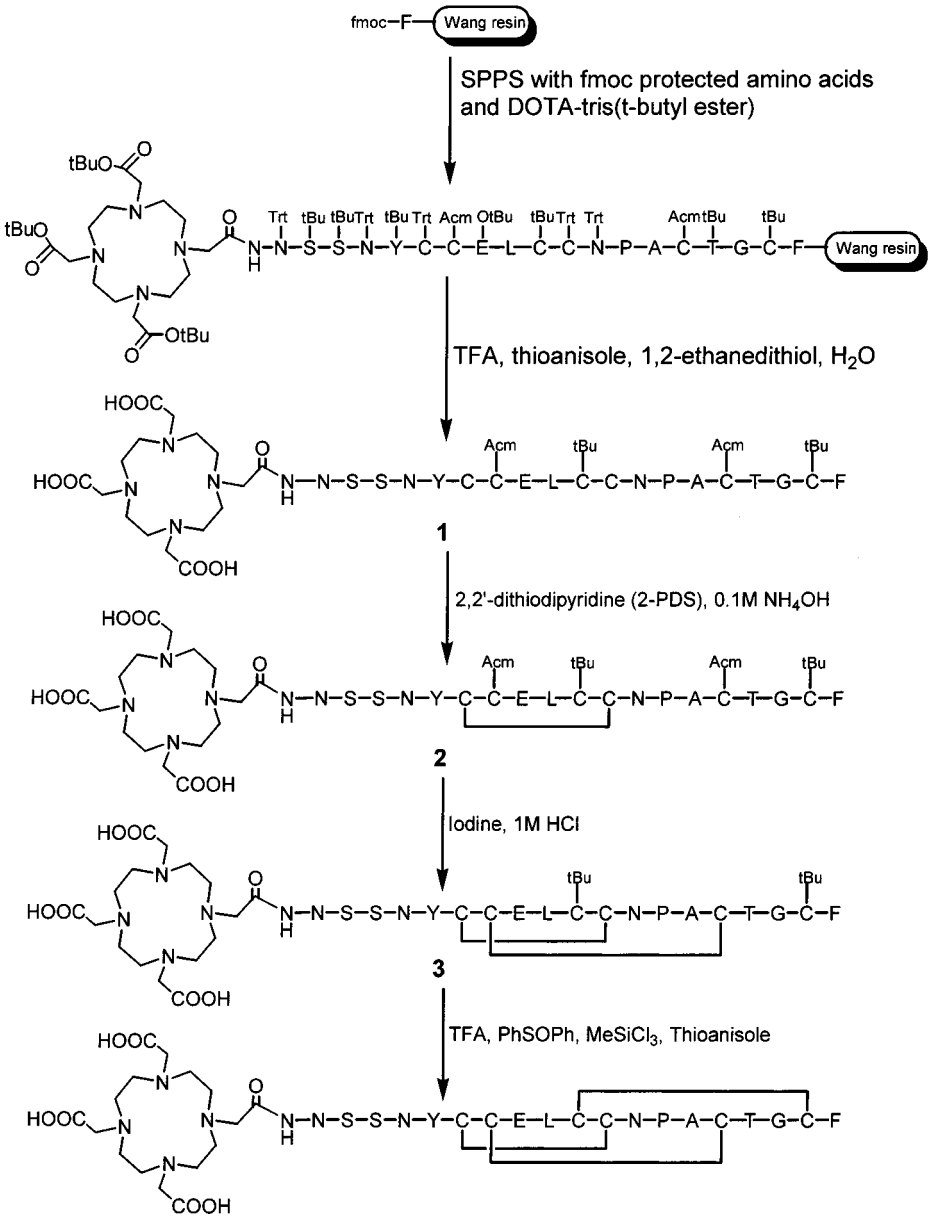
High Performance Liquid Chromatography (HPLC). High performance liquid chromatography (HPLC) analyses were performed on a Waters 600E system equipped with Varian 2550 variable absorption detector, Packard Radiometic 150TR flow scintillation analyzer, sodium iodide crystal radiometric detector, Eppendorf TC-50 column temperature controller, and Hewlett-Packard HP3395 integrators. HPLC solvents consisted of H_2O containing 0.1% trifluoroacetic acid (Solvent A) and acetonitrile containing 0.1% trifluoroacetic acid (Solvent B). Conditions: A Phenomenex Jupiter C-18 (5 μm, 300 Å, 4.6 × 250 mm) column was used with a flow rate of 1.5 mL/min. The column temperature was maintained at 35 °C. Gradient I begins with a solvent composition of 95% A and 5% B followed by a linear gradient to 30% A and 70% B in 25 min, after which the column is reequilibrated. Gradient II begins with a solvent composition of 80% A and 20% B followed by a linear gradient to 70% A and 30% B in 30 min, after which the column is reequilibrated.

DOTA−[Cys^{6,11}, Cys(Acm)^{7,15}, Cys(tBu)^{10,18}]-Phe^{19}-ST$_h$ (1). Linear peptide **1** synthesis was carried out on a Perkin-Elmer Applied Biosystems Model 432 automated peptide synthesizer employing traditional fmoc chemistry with HBTU activation of carboxyl groups on the reactant with the N-terminal amino group on the growing peptide anchored via the C-terminus to the resin. Fmoc-Phe-Wang resin (25 μmol), fmoc-protected amino acid with appropriate side-chain protections (75 μmol), and DOTA-tris(*tert*-butyl ester) (75 μmol) were used for the synthesis. The final product was cleaved by a standard procedure using a cocktail containing thioanisol, water, ethanedithiol, and trifluoroacetic acid in a ratio of 2:1:1:36 and precipitated into methyl *tert*-butyl ether and dried. Yield of the crude peptide was 90% (60 mg).

DOTA−6-Ahx-NSSNY-NH$_2$. The same solid-phase peptide synthetic procedure described to produce linear peptide **1** was used to prepare the DOTA−6-Ahx-NSSNY-NH$_2$ conjugate (this ^{111}In-DOTA−6-Ahx-NSSNY-NH$_2$ conjugate was used as a non-GC-C receptor binding control in in vivo studies) except that Rink Amide MBHA resin replaced the fmoc-Phe-Wang resin, and fmoc-6-aminohexanoic acid added, in the reaction sequence. Electrospray MS calcd *m/z* for $C_{45}H_{71}N_{13}O_{18}$ [M + H]$^+$: 1082.5; found: 1082.7.

DOTA−[Cys(Acm)^{7,15}, Cys(tBu)^{10,18}]-Phe^{19}-ST$_h$ (2). DOTA−[Cys^{6,11}, Cys(Acm)^{7,15}, Cys(tBu)^{10,18}]-Phe^{19}-ST$_h$ **1** (63 mg, 22.6 μmol) was dissolved in water (110 mL), and the pH of the solution was adjusted to 8.6 using 0.1 M NH_4OH (3.5 mL). To this solution was added dropwise 2,2′-dithiodipyridine (2-PDS) (10 mg, 45.5 μmol) in methanol (15 mL) while stirring at room temperature. The stirring was continued for 1 h, and the reaction mixture was concentrated and filtered. The filtrate was purified on the HPLC (t_R = 17.6 min, Gradient I) and lyophilized to give pure DOTA−[Cys(Acm)^{7,15}, Cys(tBu)^{10,18}]-Phe^{19}-ST$_h$ **2** as a white powder in a yield of 29% (18.3 mg). Electrospray MS calcd *m/z* for $C_{109}H_{168}N_{28}O_{38}S_6$ [M + H]$^+$: 2670.0; found: 2670.0.

DOTA−[Cys(tBu)^{10,18}]-Phe^{19}-ST$_h$ (3). DOTA−[Cys(Acm)^{7,15}, Cys(tBu)^{10,18}]-Phe^{19}-ST$_h$ **2** (18 mg, 6.5 μmol) was dissolved in 80% aqueous methanol (7 mL), and 1 M HCl (40 μL, 2.0 equiv) was added. To this solution was added dropwise iodine (40 mg, 157 μmol) dissolved in methanol (0.5 mL) while stirring at room temperature. The stirring was continued for 30 min, and then 1 M ascorbic acid (0.5 mL) was added to reduce the excess iodine. The reaction mixture was concentrated, purified on the HPLC (t_R = 18.6 min, Gradient I) and lyophilized to give pure DOTA−[Cys(tBu)^{10,18}]-Phe^{19}-ST$_h$ **3** as a white powder in a yield of 62% (10.2 mg). Electrospray MS calcd *m/z* for $C_{103}H_{156}N_{26}O_{36}S_6$ [M + H]$^+$: 2526.0; found: 2526.0.



DOTA−Phe^{19}-ST$_h$ (4). To a solution of DOTA−[Cys(tBu)^{10,18}]-Phe^{19}-ST$_h$ **3** (10 mg, 4.0 μmol) in TFA (5 mL) were added PhS(O)Ph (12 mg, 15 equiv) and thioanisole (80 μL, 160 equiv). To this solution was added CH_3SiCl_3 (110 μL, 22 equiv) while stirring at room temperature. The stirring was continued for 45 min, and then the reaction mixture was added to methyl-*tert*-butyl ether (40 mL) and extracted with water (2 × 10 mL). The aqueous solution was neutralized with 10% NH_4OH, concentrated, purified on the HPLC (t_R = 20.0 min, Gradient II), and lyophilized to give pure DOTA−Phe^{19}-ST$_h$ **4** as a white powder in a yield of 6% (0.6 mg). Electrospray MS calcd *m/z* for $C_{95}H_{138}N_{26}O_{36}S_6$ [M + H]$^+$: 2411.8; found: 2412.0.

DOTA−6-Ahx-Phe^{19}-ST$_h$. The same synthetic procedure described to produce DOTA−Phe^{19}-ST$_h$ **4** was used to prepare the DOTA−6-Ahx-Phe^{19}-ST$_h$ analogue except that the fmoc-6-aminohexanoic acid was added in the reaction sequence. Overall yield (starting from resin): 1.5%; electrospray MS calcd *m/z* for $C_{101}H_{149}N_{27}O_{37}S_6$ [M + H]$^+$: 2524.9; found: 2525.0.

Phe^{19}-ST$_h$. The same synthetic procedure described to produce DOTA−Phe^{19}-ST$_h$ **4** was used to prepare the Phe^{19}-ST$_h$ analogue except that the DOTA-tris(*tert*-butyl ester) was deleted from the reaction sequence. Overall yield (starting from resin): 1.6%; electrospray MS calcd *m/z* for $C_{79}H_{112}N_{22}O_{29}S_6$ [M + H]$^+$: 2025.6; found: 2025.6.

In-DOTA−Phe^{19}-ST$_h$. A solution of DOTA−Phe^{19}-ST$_h$ **4** (0.5 mg) in 0.2 M tetramethylammonium acetate (0.5 mL) was added to indium chloride (1.0 mg). The pH of

Scheme 1. Synthesis of DOTA−ST_h Conjugate

the reaction mixture was adjusted to 5.8 (Scheme 2). The reaction mixture was incubated for 1 h at 80 °C. The resultant In-DOTA−Phe^{19}-ST_h conjugate was purified by reversed-phase HPLC (t_R = 17.7 min, Gradient II). Electrospray MS calcd *m*/*z* for $C_{95}H_{135}N_{26}O_{36}S_6In$ $[M + H]^+$: 2523.7; found: 2524.0.

^{111}In Labeling. An aliquot of $^{111}InCl_3$ (0.5−2.5 mCi, 1.85−9.25 MBq, 50 μL) was added to a solution of DOTA−Phe^{19}-ST_h **4** (50 μg) or DOTA−6-Ahx-NSSNY-NH_2 (50 μg) in 0.2 M tetramethylammonium acetate (400 μL). The pH of the reaction mixture was adjusted to 5.8. The reaction mixture was incubated for 1 h at 80 °C. An aliquot of 0.002 M EDTA (50 μL) was added to the reaction mixture to complex the unreacted $^{111}In^{3+}$. The resultant ^{111}In-DOTA−Phe^{19}-ST_h and ^{111}In-DOTA−6-Ahx-NSSNY-NH_2 conjugates were obtained as single products and purified by HPLC. The ^{111}In-DOTA−Phe^{19}-ST_h (t_R = 17.7 min, Gradient II) eluted approximately 2.3 min before the nonmetalated DOTA−Phe^{19}-ST_h conjugate (t_R = 20.0 min, Gradient II) enabling collection of the high-specific activity, NCA ^{111}In-DOTA−Phe^{19}-ST_h conjugate. An isocratic HPLC solvent program of 95% A and 5% B was used to separate ^{111}In-DOTA−6-Ahx-NSSNY-NH_2 (t_R = 5.5 min) from the excess unlabeled DOTA−6-Ahx-NSSNY-NH_2 (t_R = 9.7 min). Both purified ^{111}In-DOTA−Phe^{19}-ST_h and ^{111}In-DOTA−6-Ahx-NSSNY-NH_2 conjugates were concentrated by passing through a 3M Empore C-18 HD high performance extraction disk (7 mm/3 mL) cartridge and eluting with 33% ethanol in 0.1 M NaH_2PO_4 buffer (400 μL). The concentrated fraction was diluted with 0.1 M NaH_2PO_4 buffer (2 0.3 mL, pH 7) to make the final concentration of ethanol in the solution <5%.

In Vitro Competitive Cell Binding Assay. The IC_{50} values of In-DOTA−Phe^{19}-ST_h, DOTA−Phe^{19}-ST_h, DOTA−6-Ahx-Phe^{19}-ST_h, and Phe^{19}-ST_h conjugates were determined in human colon cancer T-84 cells by a competitive displacement cell binding assay using ^{125}I-Tyr^5-6-Ahx-Phe^{19}-ST_h. Briefly, 3×10^6 cells suspended in DMEM/F-12 media containing 14.4 mM MES and 2% BSA, pH-5.5, were incubated at 37 °C for 1 h in the presence of approximately 20000 cpm ^{125}I-Tyr^5-6-Ahx-Phe^{19}-ST_h and

Scheme 2. Indium-111 Labeling of DOTA−ST$_h$ Conjugate

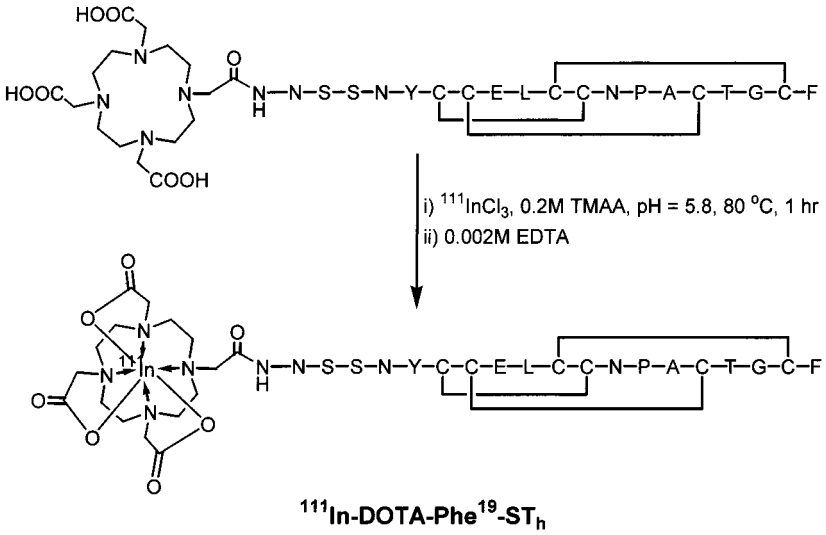


Table 1. In Vitro IC$_{50}$ Values (n = 3 or 4 separate experiments performed in duplicate) Measured from a Competitive Binding Assay with ST$_h$ Analogs vs ^{125}I-Tyr^5-6-Ahx-Phe^{19}-ST$_h$ with Human Colon Cancer T-84 Cells

ST$_h$ analog	IC$_{50}$ (nM)
In-DOTA−Phe^{19}-ST$_h$	3.3 ± 2.0
DOTA−Phe^{19}-ST$_h$	0.6 ± 0.1
DOTA−6-Ahx-Phe^{19}-ST$_h$	1.6 ± 1.2
Phe^{19}-ST$_h$	0.5 ± 0.1

an increasing concentration of ST$_h$ conjugates. After the incubation, the reaction medium was aspirated, and cells were washed three times with media. The radioactivity bound to the cells was counted in a Packard Riastar gamma counting system. The %^{125}I-Tyr^5-6-Ahx-Phe^{19}-ST$_h$ bound to cells was plotted vs increasing concentrations of ST$_h$ conjugate to determine the respective IC$_{50}$ values (Table 1, Figure 1). In-DOTA−6-Ahx-NSSNY-NH$_2$, evaluated using this same system, does not exhibit measurable binding to GC-C receptors (i.e., IC$_{50}$ > 10^5 M). For statistical considerations, three separate in vitro cell binding experiments with each conjugate were performed in duplicate.

Scatchard Analysis. Scatchard analysis was performed in human colon cancer T-84 cells by a receptor-binding assay using ^{125}I-Tyr^5-Phe^{19}-ST$_h$ and Phe^{19}-ST$_h$. Briefly 2.2 × 10^6 cells suspended in DMEM/F-12 media containing 14.4 mM MES and 2% BSA, pH-5.5, were incubated at 37 °C for 1 h in the presence of approximately 27000 cpm ^{125}I-Tyr^5-Phe^{19}-ST$_h$ and an increasing concentration of Phe^{19}-ST$_h$. After the incubation, the reaction medium was aspirated, and cells were washed three times with media. The radioactivity bound to the cells was counted in a Packard Riastar gamma counting system. The experiment was performed in duplicate, and average values were used for the calculations. The total bound peptide (B, both radioactive and nonradioactive) was obtained by multiplying the fraction of bound labeled peptide with the total concentration of peptide (both radioactive and nonradioactive). The total free peptide (F, both radioactive and nonradioactive) was obtained by subtracting the total bound peptide from the total concentration of peptide. The nonspecific binding was neglected in the calculations as it was <3%. The ratio of concentration of total bound and total free peptide (B/F) was plotted vs total bound peptide (B) to determine

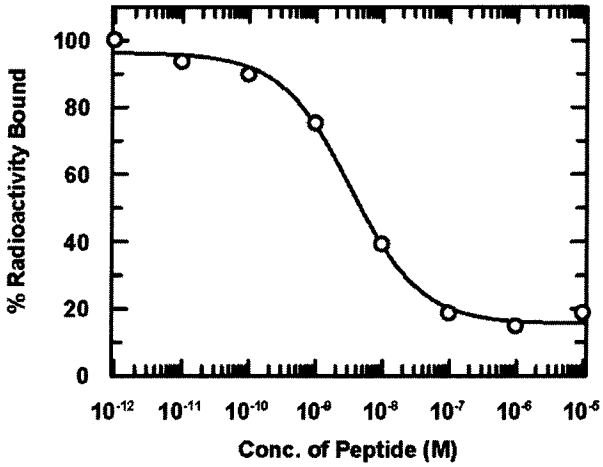

Figure 1. Competitive binding curve of In-DOTA−Phe^{19}-ST$_h$ vs ^{125}I-Tyr^5-6-Ahx-Phe^{19}-ST$_h$ in T-84 cells. IC$_{50}$ of In-DOTA−Phe^{19}-ST$_h$ is 3.3 ± 2.0 nM.

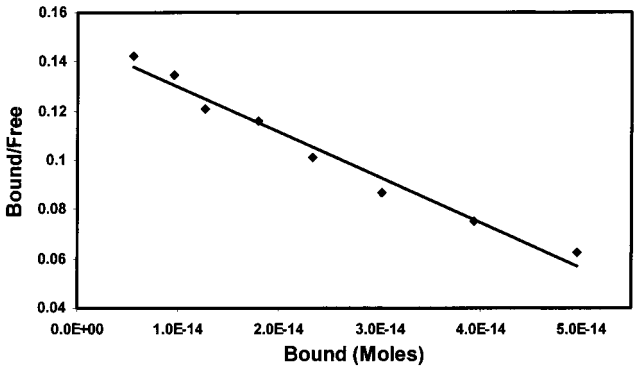

Figure 2. Scatchard plot of ^{125}I-Tyr^5-Phe^{19}-ST$_h$ in T-84 cells. K_d = 1.8 nM and number of receptors per cell at equilibrium (calculated using B_{max} value) = 21715.

the K_d (−1/slope) and B_{max} (X-intercept) values. The number of receptors per cell was calculated from the B_{max} (Figure 2).

In Vitro Stability Studies of ^{111}In-DOTA−Phe^{19}-ST$_h$ in Human Serum. A sample of HPLC purified ^{111}In-DOTA−Phe^{19}-ST$_h$ (100−500 μCi, 3.7−18.5 MBq, 100 μL) was added to 1 mL of human serum in a culture tube and incubated at 37 °C at pH 7.4−7.8 under 5% CO_2 atmosphere. An aliquot of the serum sample (1 μCi, 37

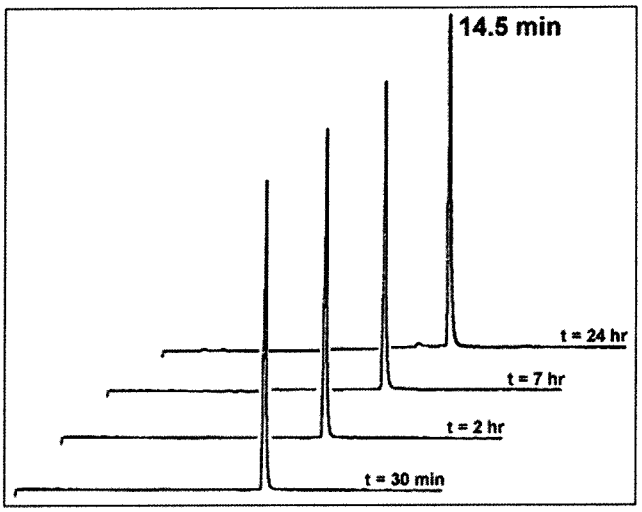

Figure 3. HPLC chromatogram (Gradient I, radiometric detector) of the ^{111}In-DOTA−Phe^{19}-ST$_h$ conjugate incubated in human serum at 37 °C, pH 7.4−7.8, under 5%CO_2 atmosphere. The peaks are normalized to full scale.

KBq, 2−15 μL) was injected into HPLC (Gradient I, radiometric detector) at 30 min, 2, 4, 7 and 24 h to analyze the stability of the ^{111}In-DOTA−ST in human serum (Figure 3). The experiment was performed in duplicate.

In Vivo Pharmacokinetic Studies of ^{111}In-DOTA−Phe^{19}-ST$_h$ in SCID Mice. Four- to five-week old female ICR SCID (severely compromised immunodeficient) outbred mice were obtained from Taconic (Germantown, NY). The mice were housed five animals per cage in sterile microisolator cages in a temperature- and humidity-controlled room with a 12-h light/12-h dark schedule. The animals were fed autoclaved rodent chow (Ralston Purina Company, St. Louis, MO) and water ad libitum. Animals were housed one week prior to inoculation of tumor cells and anesthetized for injections with isoflurane (Baxter Healthcare Corp., Deerfield, IL) at a rate of 2.5% with 0.4 L oxygen through a nonrebreathing anesthesia vaporizer.

Human colon cancer T-84 cells were injected on the bilateral subcutaneous (sc) flank with ~5 × 10^6 cells in a suspension of 100 μL of normal sterile saline per injection site. T-84 cells were allowed to grow in vivo two to three weeks postinoculation, developing tumors ranging in sizes from 0.02 to 1.30 g. The biodistribution and uptake of ^{111}In-DOTA−Phe^{19}-ST$_h$ in tumor-bearing SCID mice was studied. The mice (average weight, 25 g) were injected with aliquots (50−100 μL) of the radiolabeled peptide solution (55−75 kBq) in each animal via the tail vein. Tissues, organs, and tumors were excised from the animals sacrificed at 1 h postinjection (pi). For blocking studies, an access of nonradioactive 6-Ahx-Phe^{19}-ST$_h$ (100 μg) was also injected along with the radiolabeled peptide solution. The radioactivity was measured in a NaI counter and the percent-injected dose per organ and the percent-injected dose per gram tissue were calculated (Table 2). Animal studies were conducted in accordance with the highest standards of care as outlined in the NIH guide for Care and Use of Laboratory Animals and the Policy and Procedures for Animal Research at the Harry S. Truman Memorial Veterans' Hospital and according to approved protocols.

In Vivo Stability Studies of ^{111}In-DOTA−Phe^{19}-ST$_h$ in CF1 Normal Mice. HPLC purified ^{111}In-DOTA−Phe^{19}-ST$_h$ (30−40 μCi, 1.11−1.48 MBq, 100 μL) was injected into normal CF1 mice via the tail vein. The analysis of ^{111}In

[a] Values are expressed as the mean ± SD; $N = 3$. [b] To determine the nonspecific uptake of radioactivity a GC−C-receptor-blocking dose of 6-Ahx-Phe^{19}-ST$_h$ (100 μg) was co-injected intravenously along with the ^{111}In-DOTA−Phe^{19}-ST$_h$.

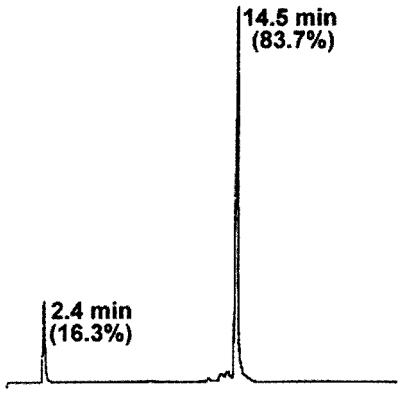

Figure 4. HPLC chromatogram (Gradient I, radiometric detector) of the mouse urine at 1 h pi of the ^{111}In-DOTA−Phe^{19}-ST$_h$.

products excreted into the urine was performed by HPLC using 25 μL aliquots of urine collected from CF1 mice 1 h after iv injection of ^{111}In-DOTA−Phe^{19}-ST$_h$ (Figure 4). At 1 h pi approximately 95% of the injected dose had been excreted into the urine (Table 2).

RESULTS AND DISCUSSION

We recently reported results of studies with an indium-111 labeled DOTA−NCS-6-Ahx-Phe^{19}-ST$_h$ analogue that demonstrated a specific binding affinity for human colon cancer cells both in vitro and in vivo (*26*, *27*). Also we have reported results of studies with another ST$_h$ analogue (DOTA−6-Ahx-Phe^{19}-ST$_h$), in which the chelating framework DOTA−NCS was replaced by DOTA. These data showed that ^{111}In-DOTA−6-Ahx-Phe^{19}-ST$_h$ analogue exhibited increased tumor uptake and reduced kidney retention of the radioactivity producing improved tumor-to-background ratios in T-84 tumor bearing SCID mice when compared to the corresponding DOTA−NCS conjugate (*28*). The DOTA−6-Ahx-Phe^{19}-ST$_h$ analogue was synthesized by random air-oxidation of fully deprotected (reduced) DOTA−6-Ahx-[Cys^{6,7,10,11,15,18}]-Phe^{19}-ST$_h$ in 0.1M NH_4OH (*28*). Although we obtained biologically active DOTA−6-Ahx-Phe^{19}-ST$_h$ analogue with this method, the reproducibility of the generating pure biologically active peptide in consistent yields was poor. Furthermore, when

we tried to synthesize an analogue containing no alkyl chain spacer (DOTA−Phe^{19}-ST$_h$), for studying the effect of alkyl chain spacer on the in vivo biodistribution and pharmacokinetics properties of radiometalated DOTA−ST$_h$ conjugates, using the above method we did not get any product. These results suggested that the attachment of a bulky and polar DOTA group at the amino terminus of the native ST$_h$ peptide impeded proper folding of the peptide. To overcome this problem, we followed a new synthetic strategy, similar to that described by Akaji et al. (*20*) for synthesizing human insulin, using three well-known orthogonal thiol protecting groups to form three regioselective disulfide bonds as required to retain full biological activiy (Scheme 1). The amino acid sequence, of all the ST conjugates reported herein, is identical to the heat-stable enterotoxin ST$_h$ excreted by the human strain of *Escherichia coli* except the C-terminal tyrosine in the 19th position is replaced by phenylalanine (i.e., Phe^{19}).

The first step in the synthesis of DOTA−Phe^{19}-ST$_h$ **4** involves the synthesis of fully protected DOTA−[Cys(Trt)^{6,11}, Cys(Acm)^{7,15}, Cys(tBu)^{10,18}]-Phe^{19}-ST$_h$ on the Wang resin on an automated peptide synthesizer system using traditional fmoc chemistry. Upon cleavage of the fully protected ST$_h$ analogue from the resin using standard TFA cocktail, the crude DOTA−[Cys^{6,11}, Cys(Acm)^{7,15}, Cys(tBu)^{10,18}]-Phe^{19}-ST$_h$ **1** was obtained in a yield of about 90%. The formation of the first disulfide bond was carried out by treating an aqueous solution of **1** with 2,2′-dithiodipyridine (2-PDS) at pH 8.6 (Scheme 1). The 2-PDS reagent selectively reacts only with free thiol group present on the cysteine-containing peptide, forming the S−S-pyridyl derivative of the peptide and 2-thiopyridone. The S−S-pyridyl side chain of cysteine was then attacked by another free thiol group present in the same peptide to form an intramolecular S−S bond (*23*). Thus, the two reduced cysteine residues present on the linear peptide **1** were converted to the oxidized form upon treatment with 2-PDS (*23*). The first folded peptide, DOTA−[Cys(Acm)^{7,15}, Cys(tBu)^{10,18}]-Phe^{19}-ST$_h$ **2**, was obtained in a yield of about 30−40% after HPLC purification using gradient I elution program. The second disulfide bond formation was carried out using a widely employed iodine oxidation method (*20*, *24*, *25*). The two Acm-protected cysteines present in the cyclic peptide **2** were oxidized to form a second S−S bond and the other two tBu protected cysteines remained stable to iodine oxidation. The second folded peptide, DOTA−[Cys-(tBu)^{10,18}]-Phe^{19}-ST$_h$ **3**, was obtained in a yield of about 50−60% after purification on HPLC (Gradient I) (Scheme 1). DOTA−[Cys(tBu)^{10,18}]-Phe^{19}-ST$_h$ **3** exhibited slightly more hydrophobic character than DOTA−[Cys(Acm)^{7,15}, Cys(tBu)^{10,18}]-Phe^{19}-ST$_h$ **2** and eluted about 1 min later during HPLC (Gradient I). The final specific disulfide bond formation was achieved by the treatment of **3** in TFA with methyltrichlorosilane in the presence of diphenyl sulfoxide (Scheme 1). Methyltrichlorosilane in the presence of diphenyl sulfoxide in TFA cleaves the tBu protecting group of the cysteines to form the S−S bond directly by a reduction−oxidation reaction mechanism.[20−22] Pure DOTA−Phe^{19}-ST$_h$ **4** was obtained in yields of about 20−30% after purification on HPLC (Gradient II). The overall yield was about 0.6−1.6% starting from resin with purity >98% as confirmed by HPLC. DOTA−Phe^{19}-ST$_h$ **4** exhibited more hydrophilic character than DOTA−[Cys(tBu)^{10,18}]-Phe^{19}-ST$_h$ **3** and eluted about 4 min earlier on the HPLC (Gradient I). For the purification at the last step of the synthesis, Gradient II was used since the resolution of HPLC peaks (byproducts and other impurities) was optimal. The characterization of product formation at each step was carried out by electrospray mass spectrometry.

Indium-111 labeling as well as the nonradioactive indium metalation of the DOTA−Phe^{19}-ST$_h$ **4** was carried out using $^{111}InCl_3$ (or $InCl_3$) at pH 5.8 and heating at 80 °C for 1 h. The ^{111}In-DOTA−Phe^{19}-ST$_h$ (t_R = 17.7 min, Gradient II) eluted approximately 2.3 min before the nonmetalated DOTA−Phe^{19}-ST$_h$ conjugate (t_R = 20.0 min, Gradient II) enabling collection of the high-specific activity, NCA ^{111}In-DOTA−Phe^{19}-ST$_h$ conjugate. The nonradioactive In-DOTA−Phe^{19}-ST$_h$ conjugate (t_R = 17.7 min, Gradient II) was purified on HPLC and characterized by electrospray mass-spectrometry. The identical HPLC retention times of both radioactive and nonradioactive indium complexes of DOTA−Phe^{19}-ST$_h$ conjugate confirms that the structure at both the micro- and macroscopic level is the same.

The binding affinity of the ST$_h$ analogues, synthesized herein, to GC-C receptors was determined by performing in vitro competitive cell binding assay in human colon cancer T-84 cells. Results from these cell binding assay studies with In-DOTA−Phe^{19}-ST$_h$, DOTA−Phe^{19}-ST$_h$, DOTA−6-Ahx-Phe^{19}-ST$_h$, and Phe^{19}-ST$_h$ analogues vs ^{125}I-Tyr^5-6-Ahx-Phe^{19}-ST$_h$ performed in human colonic cancer T-84 cells demonstrated that all ST$_h$ analogues bind to the GC-C receptors present on these cells with high specificity and affinity (i.e., IC$_{50}$ values measured for the In-DOTA−Phe^{19}-ST$_h$ and DOTA−Phe^{19}-ST$_h$ are 3.3 ± 2.0 and 0.6 ± 0.1 nM, respectively) (Table 1, Figure 1). IC$_{50}$ values measured for metalated and nonmetalated DOTA−6-Ahx-Phe^{19}-ST$_h$ analogues, synthesized by regioselective disulfide bond formation strategy, were found to be identical to those previously synthesized by a random air-oxidation method and similar to those reported earlier for ST peptides (*28*). Interestingly, these values are lower than those reported recently for binding of indium-metalated and nonmetalated DOTA−NCS−ST$_h$ analogues to human colonic cancer cell lines (i.e., T-84, LS-180, and CaCO-2 cells) (*26*, *27*). These in vitro cell binding studies demonstrates that the conformation produced by regioselective disulfide bond formation strategy in the ST$_h$ conjugates, reported herein, is biologically active and binds to GC-C receptors with high affinity. Scatchard analysis of the data obtained from the receptor-binding studies performed in T-84 cells yielded a linear plot with K_d value of 1.8 nM (Figure 2). The number of active receptors per cell at equilibrium (calculated using B_{max} value) was found to be about 21715. These values are in agreement with the results previously reported by Carrithers et al. for low affinity ST receptor binding sites expressed on T-84 cells (*7*).

The in vitro stability studies in human serum shows that no measurable decomposition of the ^{111}In-DOTA−Phe^{19}-ST$_h$ conjugate occurs ≥24 h postincubation at 37 °C (Figure 3). The HPLC (Gradient I) analysis of CF1 normal mice urine at 1 h pi of the ^{111}In-DOTA−Phe^{19}-ST$_h$ shows only about 15% decomposition (Figure 4). These stability studies demonstrate that the three-dimensional structure of the ST provides protection from enzymatic degradation under both in vitro and in vivo conditions and are consistent with previous reports demonstrating that ST-peptides have exceptionally high in vitro and in vivo metabolic stability (*4*, *10*).

In vivo biodistribution studies of the ^{111}In-DOTA−Phe^{19}-ST$_h$ were performed in healthy SCID mice xenografted with human colonic tumors derived from T-84 cells. Table 2 summarizes results of the biodistribution pattern of the ^{111}In-DOTA−Phe^{19}-ST$_h$ in tumor-bearing

SCID mice at 1 h pi. High tumor uptake of 2.04 ± 0.30% ID/g was observed with only 0.23 ± 0.14% ID/g in blood stream at 1 h pi. The radioactivity cleared rapidly from the blood stream with 95.8 ± 0.2% ID found in the urine at 1 h pi. The primary route of clearance of the ^{111}In-DOTA−Phe^{19}-ST$_h$ is via the kidneys into the urine (Table 2). There is only 0.09 ± 0.01% ID, 0.18 ± 0.01% ID, and 1.09 ± 0.04% ID found in the liver, large intestine, and small intestine at 1 h pi, respectively. Thus, a maximum of approximately 1.4% ID that had cleared from circulation and was excreted into the intestines by the hepatobiliary route by 1 h. It is also important to note that there is minimal uptake of the ^{111}In-DOTA−Phe^{19}-ST$_h$ in other organs, other than the kidneys, indicating that these normal tissues and organs exhibit no or minimal GC-C receptor expression, which is consistent with previous reports (*4*−*9*, *27*, *28*). The retention of the radioactivity in the kidneys (Table 2) is reduced substantially when compared to previously reported ^{111}In-DOTA−NCS−ST$_h$ analogue (*27*). The reason for this is not understood but may relate to the lower lipophilicity of the ^{111}In-DOTA−Phe^{19}-ST$_h$ conjugate. The fact that there is minimal accumulation of ^{111}In-DOTA−Phe^{19}-ST$_h$ in the intestines demonstrates that, when this ST-analogue is administered intravenously, it does not have access to the GC-C receptors expressed only on the luminal side of the normal intestinal enterocytes (*7*, *29*−*31*). In contrast, GC-C receptors expressed on colorectal tumor cells are accessible to iv-injected radiolabeled ST analogues (*7*, *29*−*31*). The high tumor to blood, tumor to muscle, and tumor to liver ratios in T-84 tumor-bearing mice of about 9, 68, and 25.5, respectively, at 1 h pi (Table 2) demonstrate the potential of using the ^{111}In-DOTA−Phe^{19}-ST$_h$ as a radiopharmaceutical for imaging colorectal tumors in humans.

To demonstrate that the ^{111}In-DOTA−Phe^{19}-ST$_h$ uptake in T-84 tumors is specific and receptor-mediated, biodistribution studies were performed using a nonspecific peptide, ^{111}In-DOTA−6-Ahx-NSSNY-NH$_2$ (which has similar pharmacokinetic properties to that of ^{111}In-DOTA−Phe^{19}-ST$_h$), in T-84 tumor-bearing SCID mice. An uptake value of 0.36 ± 0.19% ID/g in the tumors was observed at 1 h pi which is representative of nonspecific localization by the normal blood supply in tumors (Table 2). Further verification of tumor specificity is demonstrated by coinjection of an excess (100 μg) of nonradioactive 6-Ahx-Phe^{19}-ST$_h$ along with the ^{111}In-DOTA−Phe^{19}-ST$_h$ in T-84 tumor-bearing SCID mice. In these studies an uptake of 0.81 ± 0.25% ID/g was observed in the tumor at 1 h pi (Table 2), which is about 60% lower uptake than the tumor uptake of ^{111}In-DOTA−Phe^{19}-ST$_h$ when no blocking agent was coinjected (Table 2). The cause of the marked increased degree of ^{111}In-localization in the kidneys (Table 2) with coinjection of excess nonradioactive 6-Ahx-Phe^{19}-ST$_h$ is unknown. Results from these two experiments clearly demonstrates that the ^{111}In-DOTA−Phe^{19}-ST$_h$ binds selectively to the GC-C receptors present on the T-84 tumor cells under in vivo conditions.

CONCLUSION

The synthetic strategy described successfully demonstrates that ST$_h$ analogues containing a DOTA chelating framework that bind with high affinity to GC-C receptors on human colon cancer cells can be produced by regioselective formation of disulfide bonds following SPPS of the linear DOTA-conjugated sequence. The in vitro studies performed in human colon cancer T-84 cells showed that both the metalated and nonmetalated DOTA−ST$_h$ analogues bind to GC-C receptors for guanylin/ST peptides with high specificity and affinity. The in vivo biodistribution of the ^{111}In-DOTA−Phe^{19}-ST$_h$ peptide in SCID mice xenografted with T-84 human colonic tumors showed high uptake of ^{111}In-conjugate in tumors coupled with rapid clearance from the blood stream almost entirely via the renal/urinary pathway. The results from these studies demonstrate that the radiometalated DOTA−ST$_h$ analogues are promising candidates for further development as diagnostic and/or therapeutic radiopharmaceuticals for use in patients with colorectal cancers (*32*−*35*).

Synthesis of Sulfhydryl Cross-Linking Poly(Ethylene Glycol)-Peptides and Glycopeptides as Carriers for Gene Delivery†

Youmie Park, Kai Y. Kwok, Chawki Boukarim, and Kevin G. Rice*

College of Pharmacy, 428 Church Street, University of Michigan, Ann Arbor, Michigan 48109-1065. Received July 16, 2001; Revised Manuscript Received January 7, 2002

Sulfhydryl cross-linking poly(ethylene glycol) (PEG)-peptides and glycopeptides were prepared and tested for spontaneous polymerization by disulfide bond formation when bound to plasmid DNA, resulting in stable PEG-peptide and glycopeptide DNA condensates. A 20 amino acid synthetic peptide possessing a single sulfhydryl group on the N-terminal cysteine, with two or five internal acetamidomethyl (Acm)-protected cysteine residues, was reacted with either PEG vinyl sulfone or iodoacetamide tyrosinamide triantennary *N*-glycan. Following RP-HPLC purification, Acm groups were removed by silver tetrafluoroborate to generate sulfhydryl cross-linking PEG-peptides and glycopeptide that were characterized by either ^{1}H NMR or LC−MS. Sulfhydryl cross-linking PEG-peptides and glycopeptides were found to bind to plasmid DNA and undergo disulfide cross-linking resulting in stable DNA condensates with potential utility for in vivo gene delivery.

INTRODUCTION

Nonviral gene delivery relies upon carrier molecules to bind to plasmid DNA, resulting in the formation of DNA condensates that target to the desired cell-type and mediate transient expression of the encoded gene (*1*). To be therapeutically useful, it is essential to develop sophisticated nonviral gene delivery polymers that can be systematically optimized to mediate high levels of gene expression in vivo (*2*, *3*).

Low molecular weight (LMW)[1] peptide carriers have been substituted for high molecular weight (HMW) polylysine and shown to mediate efficient in vitro gene transfer (*4*, *5*). Even though LMW peptides are potentially less toxic than HMW peptides when used in vivo, LMW peptide DNA condensates are not sufficiently stable in the circulation and target tissue (*6*). Cross-linking strategies have been developed to stabilize LMW peptide DNA condensates during transit in the blood and once inside the target cell (*7*, *8*). Glutaraldehyde is one such cross-linking agent that has been shown to retard LMW peptide DNA condensate metabolism in the liver, thereby affording in vivo gene expression (*6*).

To ensure proper targeting to the desired cell type, poly(ethylene glycol) (PEG) has been attached to LMW peptides and used to form DNA condensates possessing a steric layer that blocks nonspecific binding of serum proteins (*9*, *10*). Likewise, LMW glycopeptides possessing either terminal galactose or mannose residues have been incorporated onto the surface of DNA condensates for the purpose of targeting either the asialoglycoprotein receptor or mannose receptor (*6*, *11*).

More recently, peptides containing multiple cysteine residues that undergo sulfhydryl cross-linking when bound to plasmid DNA have been used to form stable peptide DNA condensates that mediate in vitro gene expression (*12*, *13*). This cross-linking strategy is attractive because, in principle, the degree of stability can be controlled by the number and type of sulfhydryl groups in a peptide and the release of DNA is triggered by the reducing environment of the endosome or cytosol (*14*). This same strategy has been applied to prepare detergents containing sulfhydryl groups that dimerize when bound to DNA to form cationic lipids (*15*−*17*). These lipoplexes are reportedly more homogeneous in particle size and exhibit higher in vitro gene transfer activity because of a triggered release of DNA in the cytosol. Despite progress in the development of sulfhydryl cross-linked gene delivery systems, to date, none of these agents have been tested for in vivo gene delivery. To do this would require derivatization to install a targeting ligand as well as a steric stabilizing agent to form blood-compatible DNA condensates.

In the present study, we have extended the concept of LMW sulfhydryl cross-linking peptides by preparing PEG-peptides and glycopeptides that are able to bind DNA and undergo disulfide bond formation to create stable condensates. The synthesis of these DNA binding molecules represents a significant advance in the design of LMW carriers properly derivatized to test whether sulfhydryl cross-linking peptides will function to mediate in vivo gene expression.

MATERIALS AND METHODS

PEG-vinyl sulfone (PEG-VS, 5 kDa) was purchased from Fluka (Ronkonkoma, NY). Tris(2-carboxyethyl)-phosphine hydrochloride (TCEP) was purchased from Pierce (Rockford, IL). N-terminal Fmoc-protected Boc-Lys, Boc-Trp, and Trt-Cys and 9-hydroxybenzotriazole (HOBt), diisopropylcarbodiimide (DIC), and diisopropyl-

ethylamine (DIPEA) were obtained from Advanced ChemTech (Lexington, KY). Substituted Wang resin for peptide synthesis was obtained from ChemImpex (Wood Dale, IL). N-terminal Fmoc-protected acetamidomethyl (Acm)-protected cysteine was purchased from Novabiochem (La Jolla, CA). *N*,*N*-Dimethylformamide (DMF), trifluoroacetic acid (TFA), acetic anhydride, acetonitrile, acetic acid, ether, and piperidine were purchased from Fisher Scientific (Pittsburgh, PA). CM Sephadex cation-exchange resin and anisole were from Sigma (St. Louis, MO). Silver tetrafluoroborate was from Aldrich (Milwaukee, WI). SYBR-Gold was purchased from Molecular Probes, Inc. (Eugene, OR). Thiazole orange was a gift from Beckton Immunocytometry Systems (San Jose, CA). The 5.6 kb plasmid pCMVL encoding the reporter gene luciferase under the control of the cytomegalovirus promoter was a gift from Dr. M. A. Hickman at the University of California, Davis, CA (*18*). Peptide synthesis was performed on a computer interfaced model 90 Advanced ChemTech solid-phase peptide synthesizer (Lexington, KY). Preparative and analytical HPLC columns were purchased from Vydac (Hesperia, CA). HPLC was performed using a computer-interfaced HPLC and fraction collector from ISCO (Lincoln, NE). Electrospray ionization mass spectrometry (ESI-MS) was performed using a Finnigan LCQ mass spectrometer (San Jose, CA) interfaced with an analytical HPLC from Hitachi (San Jose, CA). ^{1}H NMR was generated on a Bruker 500 MHz spectrometer operated at 23 °C.

Peptide Synthesis and Characterization. CWC(Acm)K_{15}C(Acm)K (**1**) and CW(C(Acm)K_3)$_4$C(Acm)K (**2**) were synthesized using standard Fmoc procedures with HOBt and DIC double couplings followed by N-capping with acetic anhydride after each coupling to avoid deletion sequences. The peptide was cleaved from the resin and side-chain-protecting groups were removed (except for Acm protecting groups on internal cysteines) by reaction with TFA/EDT/water (95/2.5/2.5, v/v/v) for 1 h.

Peptides **1** and **2** were purified to homogeneity by injecting 1 *μ*mol onto a semipreparative RP-HPLC column (2 × 25 cm) eluted at 10 mL/min with 0.1% (v/v) TFA and a gradient of acetonitrile (5−25% over 30 min) while monitoring tryptophan absorbance at 280 nm. The major peak eluting at 15 min for **1** or 22 min for **2** was collected and pooled from multiple injections, concentrated by rotary evaporation, lyophilized, and stored dry at −20 °C. The purified peptides were reconstituted in 0.1% TFA and quantified by tryptophan absorbance ($\epsilon_{280\ nm} = 5600\ M^{-1}\ cm^{-1}$).

Synthesis of PEG-VS-CWCK_{15}CK (5) and PEG-VS-CW(CK_3)$_4$CK (6). PEG-peptides **5** and **6** (Table 1) were synthesized by reacting 1.25 *μ*mol of peptide **1** or **2** with 25 *μ*mol of TCEP and 37 *μ*mol of PEG-VS at room temperature (RT) for 24 h in 4 mL of a 0.1 M sodium phosphate buffer (pH 7.0) (*9*). The reaction was monitored by injecting 5 nmol onto analytical RP-HPLC eluted at 1 mL/min with 0.1% TFA and an acetonitrile gradient of 5−65% over 30 min while detecting by $Abs_{280\ nm}$.

PEG-peptides were purified from unreacted PEG-VS by chromatography on a CM Sephadex cation exchange column (1.5 × 35 cm) eluted with 180 mL of water to remove unreacted PEG-VS and then 180 mL of 2 M sodium chloride while detecting by $Abs_{280\ nm}$. The PEG-peptide peak eluting between 240 and 264 mL was

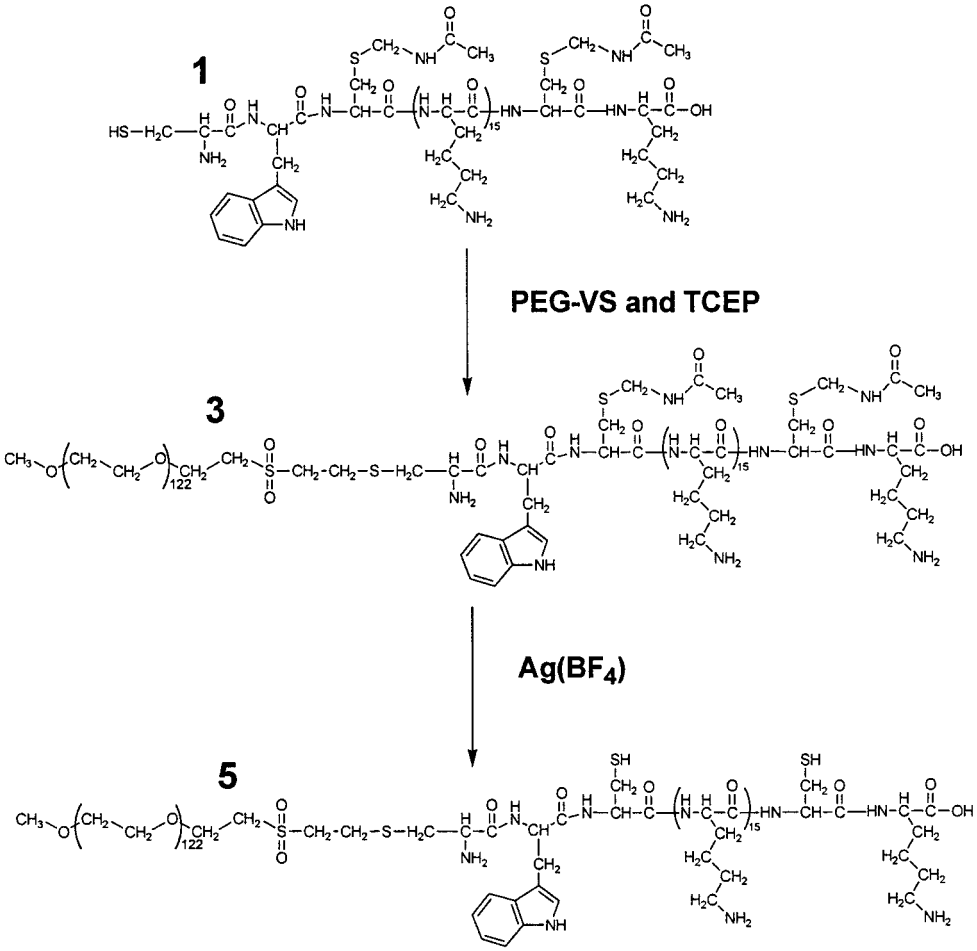

Figure 1. Synthesis of PEG-VS-CWCK$_{15}$CK (**5**). Peptide **1** was reacted with PEG-VS to form PEG-peptide **3** in the presence of TCEP. Acm protecting groups on internal cysteine residues were removed by silver tetrafluoroborate to generate PEG-peptide **5**.

pooled, dialyzed in 1000 MWCO tubing for 12 h against water, and lyophilized. PEG-peptides **3** or **4** were purified by applying 1 μmol onto semipreparative RP-HPLC (2 × 25 cm) eluted at 10 mL/min with 0.1% TFA and a gradient of acetonitrile (5−65% over 30 min) while detecting Abs$_{280\ nm}$.

Final deprotection of PEG-peptides **3** or **4** was accomplished by dissolving 5 μmol in 1 mL of cold TFA followed by the addition of silver tetrafluoroborate (20 equiv/Acm group) and anisol (10 equiv/Acm group) and reaction at 4 °C for 1 h with stirring (*19*). PEG-peptides were recovered as the silver salt by centrifugation of the precipitate formed in 60% (v/v) diethyl ether, then redissolved in 0.1 M acetic acid containing DTT (40 equiv/Acm group), and reacted at RT for 3 h. Following centrifugation to remove insolubles, deprotected PEG-peptides **5** or **6** were purified on semipreparative RP-HPLC eluted as described previously. The isolated product was freeze-dried and reconstituted in 0.1% TFA and reanalyzed by analytical HPLC to determine purity. PEG-peptides **3**−**6** were prepared for ^{1}H NMR by repeated freeze-drying in D_2O followed by dissolving the sample in 0.5 mL of D_2O (99.96%), containing 0.1% acetone as an internal standard, and analyzed on a Bruker 500 MHz NMR spectrometer operating at 23 °C.

Synthesis of Triantennary-CWCK$_{15}$CK (10) and Triantennary-CW(CK$_3$)$_4$CK (11) Glycopeptide. A triantennary *N*-glycan was purified as a Boc tyrosinamide derivative from bovine fetuin (*20*) and converted into the iodoacetamide triantennary *N*-glycan following the removal of Boc as previously reported (*21*). Iodoacetamide

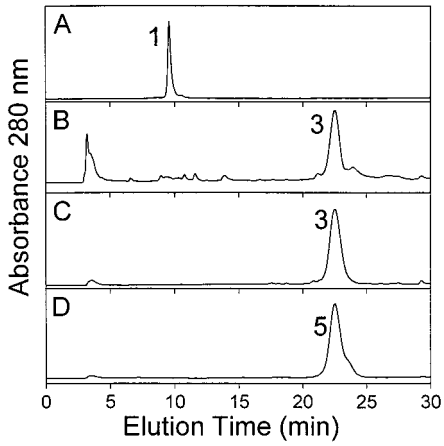

Figure 2. RP-HPLC analysis of PEG-VS-CWCK$_{15}$CK (**5**) synthesis. RP-HPLC analysis of the reaction of peptide **1** and PEG-VS verified the complete consumption of **1** (panel A versus B) with the formation of PEG-peptide **3** (panel B). Purification of **3** via ion-exchange chromatography and RP-HPLC to remove residual PEG-VS resulted in its rechromatograph as single peak (panel C). Following removal of the Acm protecting groups, PEG-peptide **5** chromatographed coincidently with PEG-peptide **3** (panel D). The peaks are numbered according to the nomenclature in Figure 1.

triantennary *N*-glycan **7** (100 nmol) was conjugated to either peptide **1** (125 nmol) or **2** by reaction for 12 h at RT in 400 μL of a 0.2 M Tris buffer (pH 8.0). The resulting glycopeptide was purified by injecting 100 nmol onto a semipreparative RP-HPLC column (2 × 25 cm) eluted at

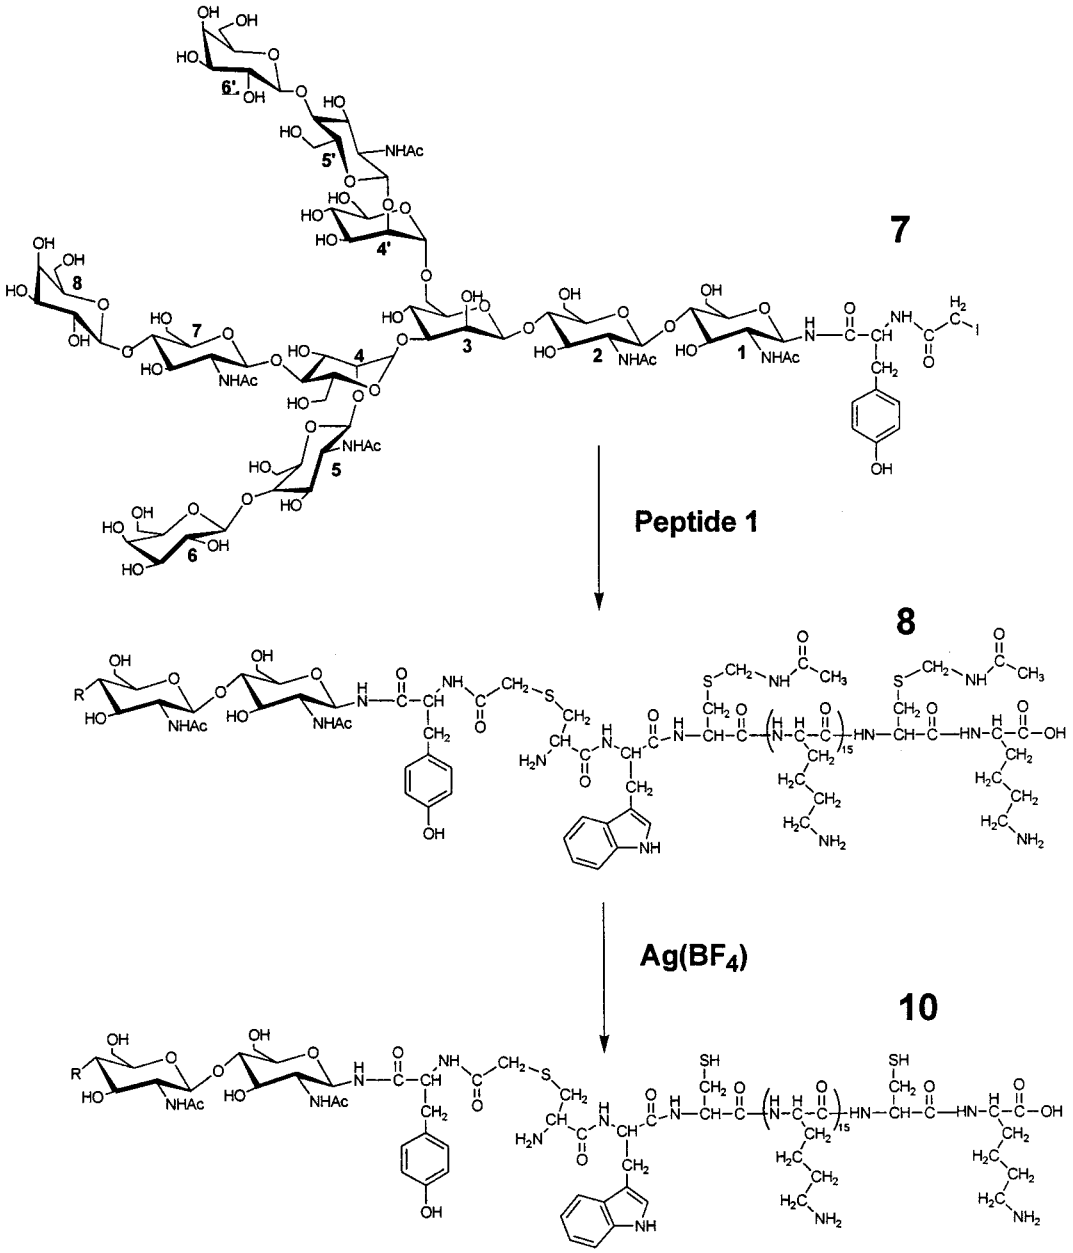

Figure 3. Synthesis of triantennary-CWCK$_{15}$CK (**10**). *N*-iodoacetylated *N*-glycan **7** reacted with peptide **1** to form glycopeptide **8**. Subsequent removal of the Acm protecting groups on internal cysteine residues by silver tetrafluoroborate led to the formation of glycopeptide **10**. R represents the remainder of the triantennary *N*-glycan.

10 mL/min with 0.1% TFA and a gradient of 5−20% acetonitrile over 30 min. The peaks eluting at either 18 or 22 min, representing glycopeptide **8** or **9**, were pooled and lyophilized. Glycopeptides were characterized by ^{1}H NMR, as described previously, and also by LC−MS by injecting 2.5 nmol onto an analytical RP-HPLC column (0.47 × 25 cm) eluted at 1 mL/min with 0.1% acetic acid containing 0.02% (v/v) TFA and an acetonitrile gradient of 1−25% over 30 min. The RP-HPLC eluent was directly infused into the electrospray ionization source of a Finnigan LCQ mass spectrometer, and mass spectral data was obtained in the positive mode. Glycopeptides **8** and **9** were deprotected as described previously, resulting in the generation of final products **10** and **11** that were purified on semipreparative RP-HPLC, reconstituted in 0.1% TFA, quantified by Abs$_{280\ nm}$ ($\epsilon_{280\ nm}$ = 6930 M^{-1} cm^{-1}), and then characterized by LC−MS.

Formulation of Peptide DNA Condensates. PEG-peptide **5** or glycopeptide **10** DNA condensates were prepared by combining 7.5−60 nmol in 750 μL of 5 mM Hepes (pH 7.4) with 75 μg of DNA (pCMVL in 750 μL of Hepes) while vortexing, followed by equilibration at RT for 4 h. Peptide binding to DNA was monitored by a fluorescent dye displacement assay. A 1 μg aliquot of the peptide DNA condensate was diluted to 1 mL in Hepes containing 0.1 μM thiazole orange. The fluorescence of the intercalated dye was measured on an LS50B fluorometer (Perkin-Elmer, U.K.) in a microcuvette by exciting at 500 nm while monitoring emission at 530 nm. Fluorescence blanks were subtracted from all values before data analysis.

The particle size of peptide DNA condensates was analyzed at a DNA concentration of 50 μg/mL in 5 mM Hepes (pH 7.0) at a peptide/DNA charge ratio of 2:1 by quasi-elastic light scattering (QELS). The mean diameter and population distribution were computed from the diffusion coefficient using a multimodal cumulate analysis supplied by the manufacturer. The particle surface

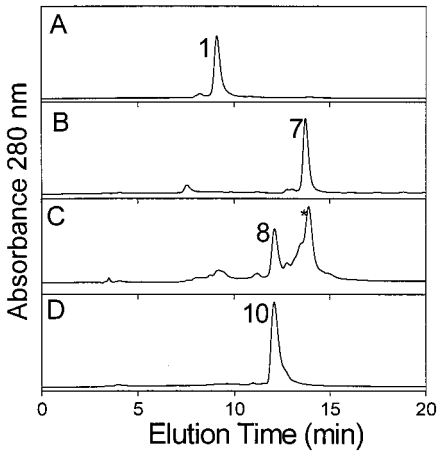

Figure 4. RP-HPLC analysis of triantennary-CWCK$_{15}$CK (**10**)-synthesis. RP-HPLC analysis of the reaction of peptide **1** (panel A) with *N*-glycan **7** (panel B) established the consumption of both starting materials and the formation of glycopeptide **8** and a byproduct (*) determined to be dimeric peptide **1** (panel C). Purification of **8**, followed by the removal of the Acm protecting groups and repurification, yielded glycopeptide **10**, which re-chromatographed as a single peak. The peaks are numbered according to the nomenclature in Figure 3.

charge was determined by ζ potential analysis using a Brookhaven ZetaPlus from Brookhaven Instruments (Worestershire, U.K.).

The kinetics of inter-peptide sulfhydryl cross-linking within peptide DNA condensates was studied indirectly by monitoring the displacement of a SYBR-Gold intercalator dye from DNA condensates as a function of time (*12, 13*). SYBR-Gold was combined with 1 mL of 20 μg/mL peptide DNA condensates prepared at a peptide stoichiometry of 0.4 nmol of peptide/μg of DNA. Immediately after mixing PEG-peptide or glycopeptide and DNA, the fluorescence intensity (E_x, 495 nm; E_m, 537 nm) was continuously monitored for 3 h.

RESULTS

Synthesis and Characterization of Sulfhydryl Cross-Linking Carriers. The synthetic scheme for generating PEG-peptides is illustrated in Figure 1. The individual steps of the reaction were monitored by analytical RP-HPLC (Figure 2). PEG-VS (5 kDa) was reacted with either peptide **1** (Figure 2A) or **2** in the presence of TCEP to generate PEG-peptide **3** (Figure 2B) or **4**. RP-HPLC analysis demonstrated complete consumption of peptide **1** in 12 h to produce PEG-peptide **3** or **4**. Excess PEG-VS was needed to drive the reaction to completion and then removed as a void peak during chromatography on a cation-exchange column. Without this step, PEG-VS and the PEG-peptide coeluted during preparative RP-HPLC. Removal of the Acm protecting groups followed by semipreparative RP-HPLC resulted in a 38% isolated yield of PEG-peptide **5** or **6** that rechromatographed to 96% purity on analytical RP-HPLC (Figure 2D).

Sulfhydryl cross-linking glycopeptides were prepared as illustrated schematically in Figure 3. Monomeric peptide **1** or **2** reacted with iodoacetamide triantennary *N*-glycan **7** (Figure 4B) to generate glycopeptide **8** or **9** and dimeric-peptide as a byproduct. Comparison of the RP-HPLC retention time of peptide **1** (Figure 4A) with that of iodoacetamide triantennary *N*-glycan (Figure 4B) and the crude reaction product (Figure 4C) established the formation of glycopeptide **8** which elutes at 12 min and dimeric peptide **1** as a byproduct eluting at 14 min.

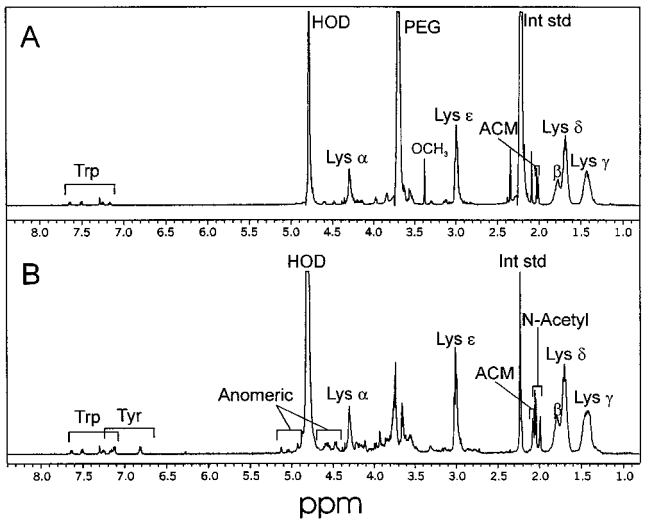

Figure 5. ^{1}H NMR analysis of PEG-peptide **3** and glycopeptide **8**. The ^{1}H NMR spectra of Acm-protected PEG-peptide **3** (panel A) and glycopeptide **8** (panel B) are illustrated. Each spectrum shows characteristic resonances for the peptide lysine side chain α, β, γ, δ, and ϵ protons as well as tryptophan anomeric protons. The PEG methylene resonances at 3.7 ppm (panel A) were integrated relative to lysine ϵ to establish a 1:1 conjugate. Panel B illustrates tyrosine aromatic resonances in addition to Gal (6,6′,8), GlcNAc (1,2,5,5′,7), and Man (4,4′) anomeric resonances as well as GlcNAc *N*-acetyl resonances. Both conjugates possess resonances at 2.019−2.049 ppm arising from the Acm methyl groups.

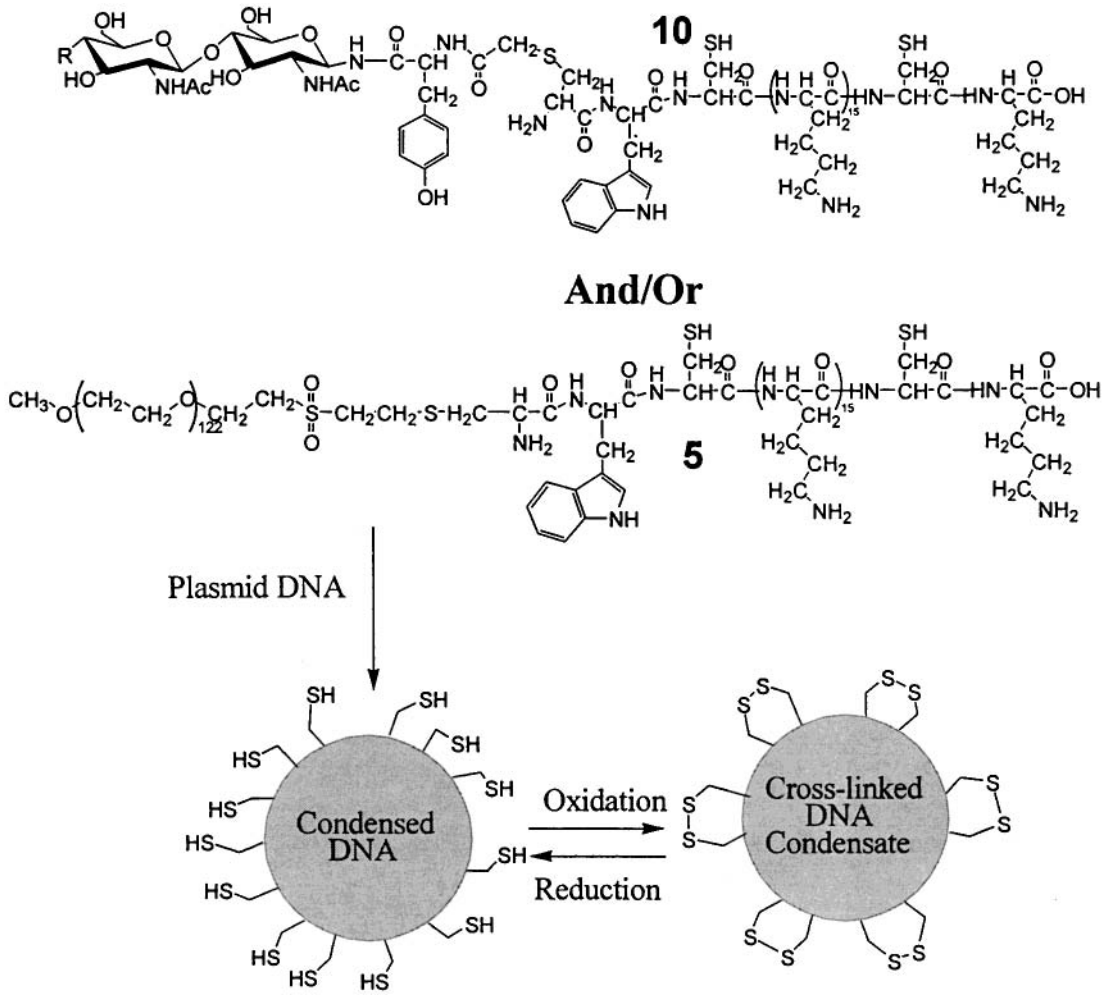

TCEP was omitted from the reaction because it was incompatible with the iodoacetamide *N*-glycan. Excess peptide **1** was used to drive the formation of glycopeptide to completion but also led to the formation of dimeric-peptide **1**. Following RP-HPLC purification of **8**, deprotection afforded glycopeptide **10**, which was isolated in 26% yield at >95%, purity as determined by analytical RP-HPLC (Figure 4D).

^{1}H NMR of PEG-peptide **3** verified the presence of signals arising from both the peptide and PEG (Figure 5A; Table 1) including resonances assigned to lysine as well as the tryptophan aromatic resonances in each spectrum (Figure 5A; Table 1). The integration intensity of the PEG methylene signal at 3.630 ppm relative to the lysine ϵ signal at 2.925 ppm established a 1:1 conjugate of PEG-peptide. Complete deprotection of PEG-peptide **3** to form **5** established the disappearance of methyl resonances of the Acm protecting groups at 1.959 and 1.944, respectively. PEG-peptides were not amendable to LC−MS because of their heterogeneity in PEG.

^{1}H NMR was also used to characterize the structure of glycopeptides **8** and **9** (Figure 5B; Table 1). Each glycopeptide possessed characteristic resonances assigned to the lysine α, β, δ, γ, and ϵ protons, tryptophan and tyrosine protons, anomeric resonances of GlcNAc, Man, and Gal and the GlcNAc *N*-acetyl signals. In contrast to PEG-peptides, LC−MS was successfully applied to characterize the Acm deprotection of glycopeptides **8** and **9**. The observed mass for glycopeptide **8** was *m*/*z*: 4914.9 prior to deprotection which converted to *m*/*z*: 4772.9 for glycopeptide **10** following a loss of two Acm groups. Similarly, glycopeptide **9**, possessing five Acm-protected cysteine residues, had a mass of *m*/*z*: 5053.0, which, upon treatment with silver tetrafluoroborate, converted quantitatively to glycopeptide **11** possessing a mass of *m*/*z*: 4697.5.

Formulation of Sulfhydryl Cross-Linked DNA Condensates. The ability of PEG-peptide **5** or glycopep-

Scheme 1. Formation of Cross-Linked Glycdopeptide and PEG-peptide DNA Condensates[a]

[a] PEG-peptide or glycopeptide DNA condensates are formed instantly through ionic binding of the peptide to the DNA backbone followed by inter-peptide oxidation to form disulfide bonds that reversibly stabilize the DNA condensates.

tide **10** to cross-link upon binding to plasmid DNA, as depicted in Scheme 1, was compared to that of alkylated-CWK_{18} ($AlkCWK_{18}$), which cannot undergo sulfhydryl cross-linking when bound to DNA. The stoichiometry of peptide needed to completely condense DNA was evaluated by monitoring a decrease in fluorescence intensity of thiazole orange while titrating increasing amounts of peptide (Figure 6). The results established that PEG-peptide **5** required a charge ratio of 1.7 to maximally displace fluorophore, whereas glycopeptide **10** and $AlkCWK_{18}$ were nearly equivalent in forming condensates at a charge ratio slightly above 1.

The particle size and ζ potential of DNA condensates formed at a 2:1 charge ratio were compared when using $AlkCWK_{18}$, PEG-peptide **5**, and glycopeptide **10** (Table 2). Each formed DNA condensates that had a major population (90 vol %) of particles that were approximately 60−90 nm in diameter and a minor population of approximately 200−280 nm in diameter. PEG-peptide **5** formed condensates possessing a ζ potential of +6 mV, because of the formation of a steric layer, relative to +32−34 mV determined for glycopeptide **10** or $AlkCWK_{18}$ DNA condensates.

The kinetics of sulfhydryl cross-linking was examined using a fluorescent displacement assay (*12, 13*). In a control experiment, the binding of $AlkCWK_{18}$ to DNA in the presence of SYBR-Gold led to an immediate quench followed by constant fluorescence intensity over time,

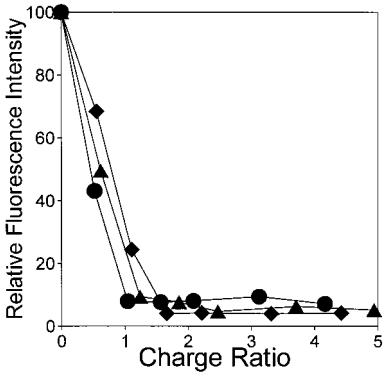

Figure 6. Relative binding affinity of peptides to DNA. The intensity of thiazole orange fluorescence was measured following titration of 7.5−60 pmols of either $AlkCWK_{18}$ (σ), PEG-peptide **5** (υ), or glycopeptide **10** (λ), with 75 ng of a 5.6 kb plasmid in 1 mL of 5 mM Hepes (pH 7.4). The decrease in the fluorescence intensity at a calculated peptide ($R-NH_3^+$) to DNA (PO_4^-) charge ratio of 0−1 results from peptide displacement of the fluororphore from DNA. At a charge ratio of 1 or higher, the asmyptote predicts the stoichiometry at which peptide binding to DNA is saturated.

because this peptide is incapable of forming cross-links (Figure 7). Because of its higher affinity for DNA, HMW polylysine (dp, 1007) displaced fluorophore more efficiently than $AlkCWK_{18}$, resulting in a lower fluorescence intensity that also remains constant with time (not

Table 2. Particle Size and ζ Potential Analysis of DNA Condensates

formulation[a]	particle size[b] (nm)	ζ potential[c] (mV)
$AlkCWK_{18}$ DNA	59 ± 6	34 ± 2
PEG-peptide **5** DNA	91 ± 7	6 ± 1
Glycopeptide **10** DNA	102 ± 18	32 ± 2

[a] DNA condensates prepared at a DNA concentration of 20 μg/mL and peptide to DNA stoichiometry of 0.4 nmol/μg of DNA corresponding to a 2:1 charge ratio in 5 mM Hepes (pH 7.4). [b] Mean and standard deviation of five analyses. [c] Mean and standard deviation of 10 determinations.

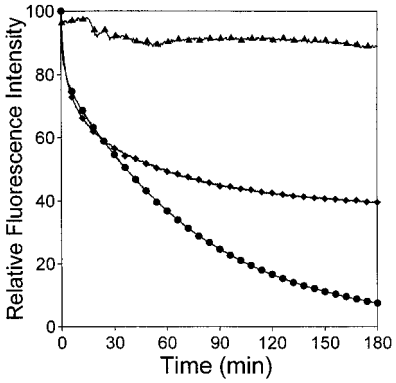

Figure 7. Kinetics of cross-linking. The fluorescence intensity of SYBR-Gold was monitored at (E_x, 495 nm; E_m, 537 nm) over time following formation of peptide DNA condensates prepared by combining 8 nmol of either $AlkCWK_{18}$ (σ), PEG-peptide **5** (υ), or glycopeptide **10** (λ), with 20 μg of DNA in 1 mL of buffer. The decrease in fluorescence intensity over 3 h represents the time course of carrier cross-linking on DNA.

shown) (*12*, *13*). Alternatively, PEG-peptide **5** initially binds to DNA and displaces SYBR-Gold, resulting in comparable fluorescence intensity to that of $AlkCWK_{18}$. However, upon polymerization, the binding affinity increases, leading to a progressive decrease in the fluorescence intensity over time. Comparison of the kinetics of fluorescence decrease determined for PEG-peptide **5** and glycopeptide **10** binding to DNA revealed that the reaction is nearly complete after 3 h but that glycopeptide **10** was more efficient at displacing fluorophore (Figure 7).

DISCUSSION

The ability to synthesize homogeneous LMW carriers provides an important opportunity to systematically change their structure and to determine how single or multiple changes influence the properties of the resulting DNA formulation and gene transfer properties either in vitro or in vivo. This distinct advantage of LMW carriers over HMW carriers provides sufficient justification for their development as gene transfer agents for treating human diseases.

A major challenge when developing LMW nonviral gene delivery carriers is the need for transient stabilization in the circulation, target tissue, and cytosol. One strategy to achieve this is to reversibly cross-link carrier molecules bound to DNA (Scheme 1). This requires the synthesis of homogeneous monomers with precise structures designed to trigger the release of DNA at a strategic location in the cell.

Among the cross-linking strategies under investigation, sulfhydryl cross-linked peptides or cationic lipids have emerged as promising carriers for DNA because the trigger is the reducing environment in the endosome or cytosol (*22*). Consequently, sulfhydryl cross-linked peptide DNA condensates and cationic lipids demonstrate higher levels of transfection in vitro when compared to un-cross-linked DNA condensates (*12*, *13*).

To take the next step toward advancing this concept, a test of their in vivo efficacy is necessary. To do this requires functionalization of a cross-linking peptide with a targeting ligand and PEG chain. Add-mixtures of glycopeptide and PEG-peptide can then be used to create DNA cocondensates that incorporate both carrier molecules in a ratio reflected by the add-mixture ratio (*9*). In previous studies, an add-mixture of carriers was used to systematically optimize DNA targeting to hepatocytes mediated by a triantennary *N*-glycan or to Kupffer cells by a high-mannose *N*-glycan (*11*, *23*).

The difficulty in preparing sulfhydryl cross-linking PEG-peptides and glycopeptides is in accomplishing a site specific coupling to the peptide. We have previously described the synthesis of PEG-Cys-Trp-Lys_{18} and *N*-glycan-Cys-Trp-Lys_{18} based on coupling to a single thiol in the peptide. The methodology described in the present paper extends upon this concept by installing internally masked Acm-protected cysteine residues that are only unmasked following conjugation of PEG or *N*-glycan to an exposed sulfhydryl on cysteine. Silver tetrafluoroborate treatment (*19*) was sufficiently mild to allow for the unmasking of the internal cysteine residues without causing a side reaction with PEG or *N*-glycan, as demonstrated by characterization of the fully deprotected product. ESI-MS was the most convenient method of verifying the complete removal of Acm groups; however, this approach was only amendable to glycopeptides analysis because PEG-peptides (with or without Acm) did not produce ion clusters corresponding to a discrete mass.

The synthesis proved versatile enough to allow for the preparation of glycopeptides and PEG-peptides that contained either two or five cross-linking sulfhydryl groups capable of producing DNA condensates of different reductive stability. In addition, it should be possible to position the trityl protected cysteine at different locations throughout the peptide to determine if the location of a PEG chain or *N*-glycan will influence the physical or biological properties of the resulting cross-linked DNA condensates.

Sulfhydryl cross-linking PEG-peptides and glycopeptides formed small electropositive DNA condensates (102 nm or less in mean diameter) with reduced surface charge when PEG was present as a steric layer. The relative DNA binding affinities of PEG-peptides and glycopeptides were comparable to an underivatized peptide of similar length. Likewise, the kinetics of sulfhydryl cross-linking appears to be complete in approximately 3 h, in close agreement with the rate of cross-linking underivatized sulfhydryl cross-linking peptides (*12*, *13*).

In conclusion, the synthetic methods described have led to the preparation of PEG-peptides and glycopeptides that form cross-linked DNA condensates. A detailed examination of the in vivo properties of these DNA condensates will be reported as part of an ongoing investigation aimed at developing LMW DNA carrier molecules that function in vivo.

Solid-State NMR Investigation of Indomethacin−Cyclodextrin Complexes in PEG 6000 Carrier

Marie Wulff,[†] Maggie Aldén,*[,†] and Jörgen Tegenfeldt[‡]

Department of Physical and Inorganic Pharmaceutical Chemistry, Box 580, Biomedical Center, Uppsala University, SE-751 23 Uppsala, Sweden, and Department of Materials Chemistry, Ångström Laboratory, Box 538, Uppsala University, SE-751 21 Uppsala, Sweden. Received December 13, 2000; Revised Manuscript Received June 18, 2001

Various solid dispersions of α-, *β*- and *γ*-cyclodextrin (CD) in PEG 6000 with and without the addition of 5% w/w indomethacin were prepared by the melting method using the original components. The samples were investigated by solid-state ^{13}C NMR, and the interactions between the drug and the cyclodextrins were evaluated. The indomethacin−*γ*-CD phase with tetragonal symmetry found in a previous X-ray study gave chemical shifts which suggested that this phase is a complex between indomethacin and *γ*-CD. Evidence of an indomethacin−*β*-CD complex were found. A distribution of the chemical shifts for *β*-CD was attributed to the possible formation of different types of complexes between indomethacin and *β*-CD. No complex formation was found in the α-CD system. The degree of relative crystallinity of the samples in the *γ*-CD system was measured by ^{1}H NMR, X-ray powder diffraction (XRD), differential scanning calorimetry (DSC), and modulated-temperature DSC (MTDSC). The results obtained by the NMR, XRD, and DSC techniques showed that the dispersions were less crystalline than the pure polymer carrier, and the dispersion containing the indomethacin−*γ*-CD complex had the lowest degree of crystallinity. By the MTDSC method a deviation was found for the PEG 6000/indomethacin dispersion. This emphasizes that the different techniques give specific information on the crystallinity.

INTRODUCTION

Cyclodextrins (CDs) are cyclic oligosaccharides consisting of six (α-CD), seven (*β*-CD), or eight (*γ*-CD) α-1,4-linked glucose units. These toroidal molecules enclose cavities of approximately 5−8 Å in diameter (*1*) and have, due to their particular conformation, the ability to form inclusion complexes with a variety of guest molecules. Through the inclusion complexation various physicochemical properties of the guest molecules are modified. These complexes can increase the stability and improve the solubility and bioavailability of molecules of pharmaceutical interest (*2*). Inclusion of the nonsteroidal antiinflammatory agent indomethacin in *β*-cyclodextrin has been described to improve the oral administration and limit the gastric irritation and the ulcerative side effects of the drug (*3*).

In aqueous solutions, addition of water-soluble polymers can both enhance and reduce cyclodextrin complexation of a guest molecule (*4*). It has been found (*5*) that α-CD forms complexes with poly(ethylene glycol) (PEG) of various molecular weights to give crystalline complexes in high yields, although *β*-CD did not. On the other hand *β*-CD and *γ*-CD form complexes with other polymers such as polypropylene glycol (PPG) and polyisobutylene (PIB), while α-CD does not form a complex with either of these polymers (*6*).

In a recent study (*7*) the melting method was investigated as a possible method for producing drug/cyclodextrin inclusion compounds dispersed in a polymer, forming a solid dispersion. This type of solid dispersion has tremendous potential in the area of controlled release dosage forms. Moreover, in recent years, the melting method has enjoyed a renaissance in the form of hot melt extrusion (*8*), which should make it possible to overcome problems in scale-up. In the study (*7*), evidence of a complex between indomethacin and *β*-CD and *γ*-CD, respectively, dispersed in PEG 6000 were found, while no complexation of indomethacin with α-CD could be detected. Dissolution tests performed (*7*) showed that the CDs have a delaying effect on the release of indomethacin from PEG 6000 in the order α-CD < *γ*-CD ≤ *β*-CD. In the present work studies on these ternary systems were performed, by solid-state NMR, to elaborate bonding conditions between the components. For investigations of the short-range order in the solid state, ^{13}C NMR was used as a sensitive tool giving information concerning specific interactions in the powder samples.

An essential property of solid dispersions at dissolution and technical handling is the crystallinity of the sample. To determine the degree of crystallinity of polymer-based systems can be a very complex task. In this study the degree of crystallinity of some samples was investigated by three different techniques: ^{1}H NMR, X-ray diffraction, and modulated-temperature DSC (MTDSC). A tentative discussion of the various results that were obtained is presented.

EXPERIMENTAL SECTION

Materials. Indomethacin (IM) (Sigma, St. Louis, MO), a drug with low aqueous solubility, has the formula $C_{19}H_{16}ClNO_4$, M_w = 357.8 g/mol, and mp 162 °C. Poly(ethylene glycol) (PEG) 6000 (Janssen, Geel, Belgium and

Fluka, Buchs, Switzerland) has the formula $HO(C_2H_4O)_nH$, where $n \approx 140$, and the average $M_w = 5600-7000$. Cyclodextrins (CDs): α-CD (Sigma), formula $C_{36}H_{60}O_{30}$, $M_w = 972.9$ g/mol; *β*-CD (Sigma), formula $C_{42}H_{70}O_{35}$, $M_w = 1135$ g/mol; *γ*-CD (Fluka, Switzerland), formula $C_{48}H_{80}O_{40}$, $M_w = 1297$ g/mol.

Methods. *Preparation of Samples.* Various solid dispersions of α-CD, *β*-CD, and *γ*-CD in PEG 6000 with and without the addition of 5% w/w indomethacin were prepared by the melting method in a Carbolite furnace HRF 7/22 with an Eurotherm 818P Programmer at a temperature of 120 °C.

For several reasons the concentration of CD was kept as low as possible and did not exceed 20% w/w in any sample; the viscosity of the melt increases with increased CD concentration and complicates the handling of the samples. It is also desirable that pharmaceutical formulations contain as small an amount of CD as possible since excess cyclodextrin can reduce, for example, drug bioavailability and preservative efficacy (*4*).

The samples were brought to room temperature by fast cooling (50−100 °C/s), and after at least 24 h the dispersions were pulverized in a mortar and sieved to obtain the 300−500 *μ*m fraction. Since a small amount of water may be absorbed by these samples, measures were taken to minimize the water absorption.

Solid-State NMR. The NMR measurements were performed using a Bruker MSL 300 spectrometer equipped with a 7 T magnet. Carbon-13 CPMAS NMR spectra were recorded at room temperature at 75 MHz using 4 mm o.d. zirconium oxide rotors and spinning at about 3−7 kHz. For the spectra presented in this paper, the spinning rate was 7 kHz. The proton and carbon radiofrequency fields used during cross-polarization and decoupling correspond to 4 *μ*s 90° pulses. The cross-polarization contact time was 1 ms. Proton NMR spectra were recorded at 300 MHz and at 25.0 °C. The length of the 90° pulse was 1.5 *μ*s.

X-ray Diffraction (XRD). Phase analysis was made by X-ray powder diffraction using a STOE position sensitive detector (PSD) system (Germany) with Ge monochromatized Cu $K\alpha_1$ radiation. A linear detector covering 7° at 155 mm distance was operated in a scanning mode. Room-temperature runs were performed by rotating the powder attached to a cellulose membrane about the normal to the membrane plane. All phases present could be identified by means of characteristic nonoverlapping peaks (*9*).

Modulated-Temperature Differential Scanning Calorimetry (MTDSC). The samples were analyzed in the temperature range of 10−120 °C using an oscillating Seiko DSC 220 differential scanning calorimeter SSC/5200H (Japan). The samples (4.4−5.4 mg) were kept in aluminum pans in an atmosphere of nitrogen. An amplitude of 2, 4, or 6 °C and a frequency of 0.02 Hz were selected in the oscillating mode together with a heating rate of 2.5 or 5 °C/min. The selected values give both heating and cooling in the temperature cycle and a degree of oscillation (*10*) of 0.96−1.9. The calorimeter was temperature- and heat-calibrated with indium, tin, gallium, and mercury as standards. The three heat of fusion values determined are the reversible c_p-component, ΔH_c, the irreversible kinetic component, ΔH_k, and the conventional component, ΔH. The results are presented as mean values with the standard deviations based on three to five determinations.

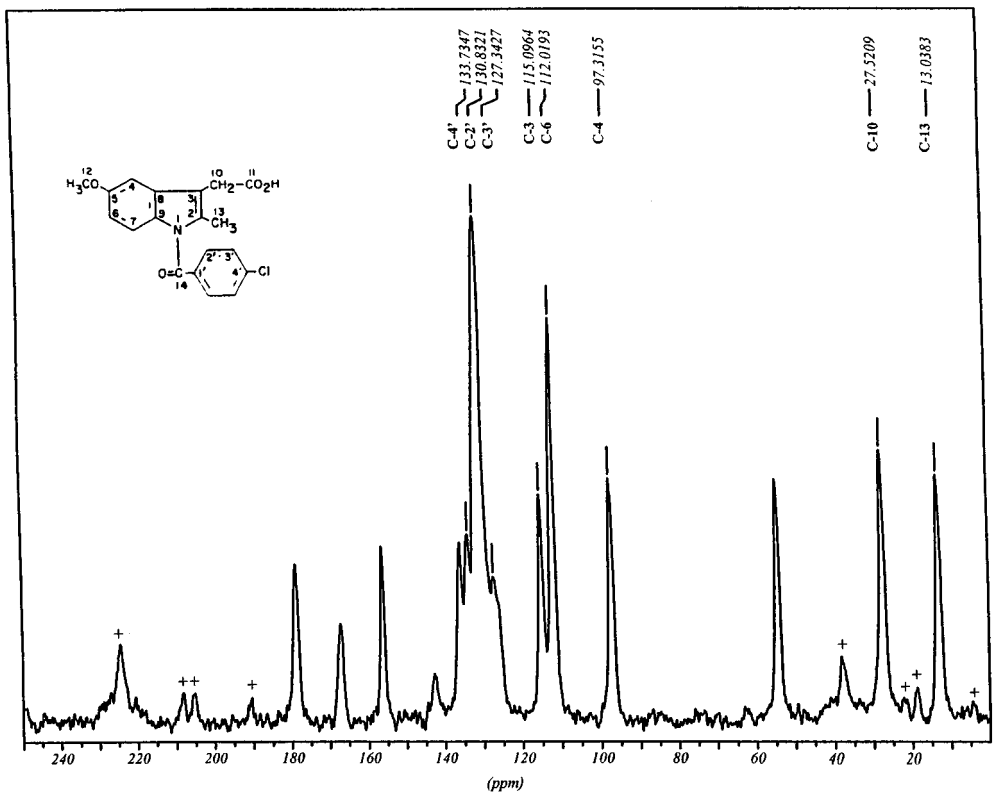
RESULTS AND DISCUSSION

The phase analysis of the samples, by X-ray powder diffraction, was performed in a previous work (*7*). Some of the results are presented in Table 1. In the dispersion of 5% indomethacin in PEG 6000 both indomethacin and PEG were present as pure phases. The dispersions of 10% α-CD and *β*-CD, respectively, in PEG 6000 formed two-phase systems. It should be noted that a small amount of the CDs may be dissolved in the PEG structure, forming a solid solution. This phase can, however, not be distinguished from the pure PEG phase due to the detection limit of the XRD equipment. The notation PEG 6000 in Table 1 thus represents the pure PEG phase or a mixture of the pure phase and the solid solution $(PEG)_{1-y}CD_y$. In the case of *γ*-CD, however, solid solutions were formed in all samples with ≤20% *γ*-CD. In the PEG/α-CD/IM dispersion the three components were all observed as pure phases. Upon addition of 14% *β*-CD to the PEG/IM only two phases were *observed* in the diffraction pattern, one of them PEG and the other *β*-CD. No diffraction lines from pure indomethacin were observed. This fact shows that indomethacin was incorporated in the structure, not as a pure phase though, but possibly as a complex with *β*-CD. In the sample where 19% *γ*-CD was added to the PEG/IM dispersion several new diffraction lines appeared beside the PEG lines. This new well-defined phase was supposed to be an indomethacin−*γ*-CD complex with tetragonal structure that was dispersed in the PEG structure.

Investigation of Inclusion Complexes by Solid-State ^{13}C NMR. In Figure 1 the ^{13}C NMR spectrum of pure indomethacin is shown. The spectra of the dispersions PEG/IM and PEG/CD/IM are presented in Figure 2a−d. The chemical shift data for the carbons in CDs in pure and dispersed states are presented in Table 2.

Indomethacin. The structural formulas of indomethacin is depicted in Figure 1 with the different carbon atoms denoted by appropriate numbers together with the ^{13}C NMR spectrum. The different peaks could be identified by the spectrum presented for indomethacin in liquid solution (*11*). The carbon peaks that are resolved in the spectra of the dispersions are marked. Peaks marked with + are sidebands resulting from the sample spinning.

PEG/Indomethacin. The PEG 6000/IM spectrum is essentially a superposition of the spectra from the two components (Figure 2a). The peak at approximately 72 ppm is the PEG peak while the others arise from indomethacin. This indicates that there is no interaction between the polymer and indomethacin that is changing the short-range order.



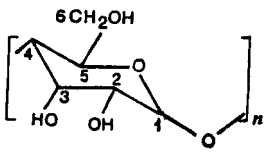


Figure 1. ^{13}C NMR spectrum of pure indomethacin. Peaks marked with + are sidebands resulting from the sample spinning.

Cyclodextrins (CDs). The chemical shift data for the carbons in pure cyclodextrins, presented in Table 2, and the spectra obtained are in agreement with the ^{13}C NMR chemical shifts measured by Furó et al. (*12*) on hydrated and anhydrous cyclodextrins. The C-1 and C-6 peaks were resolved, while the C-4 lines were close to the range of the C-2,3,5 resonances that could not be separated clearly. The structural formulas of the cyclodextrins are also given in Table 2.

PEG/Cyclodextrin. The observed chemical shifts of the carbons of α-, β-, and γ-CD in the PEG/CD and PEG/CD/IM dispersions, respectively, are presented in Table 2. The broad peak at approximately 72 ppm arises from both PEG 6000 and the C-2,3,5 carbons in the cyclodextrins that give chemical shifts at almost the same location due to the similarity in chemical composition. The PEG/α-CD and PEG/β-CD dispersions give spectra which are essentially superpositions of the spectra from the pure phases. All changes in chemical shifts are less than 1 ppm.

In the PEG/γ-CD dispersion, however, the C-1 and C-4 peaks have moved 1−4 ppm downfield, while the C-2,3,5 and C-6 peaks have moved approximately 1 ppm upfield. The large shift seen for C-1 can depend on differences in water content between the treated γ-CD and the dispersions, since the hydrated and anhydrous form of γ-CD have different chemical shifts (*12*). The spectral resolution was somewhat better for the dispersions, and therefore several chemical shift data for C-1, C-4 and C-6 were obtained. Nevertheless, the shifts for these carbons were significant. A structure might be formed where the PEG molecules or their hydroxyl end groups interact with the cyclodextrin, changing the chemical shift in a way similar to that obtained when water is present (*12*).

It has been shown in a recent study (*7*) that up to 20 w/w % γ-CD can dissolve in PEG 6000, forming a solid solution. The single-stranded PEG helix has an average width of 7.6 Å (*13*), and the γ-CD has a cavity diameter of 7.5−8.3 Å (*4*). There is thus a possibility that the PEG helices penetrate the γ-CD cavities forming a solid solution of γ-CD in PEG 6000 where part of the PEG molecules are forming inclusion complexes with γ-CD. A structure similar to this has been found for the complex formed between γ-CD and the water-soluble polymer polyisobutylene (PIB) (*6*).

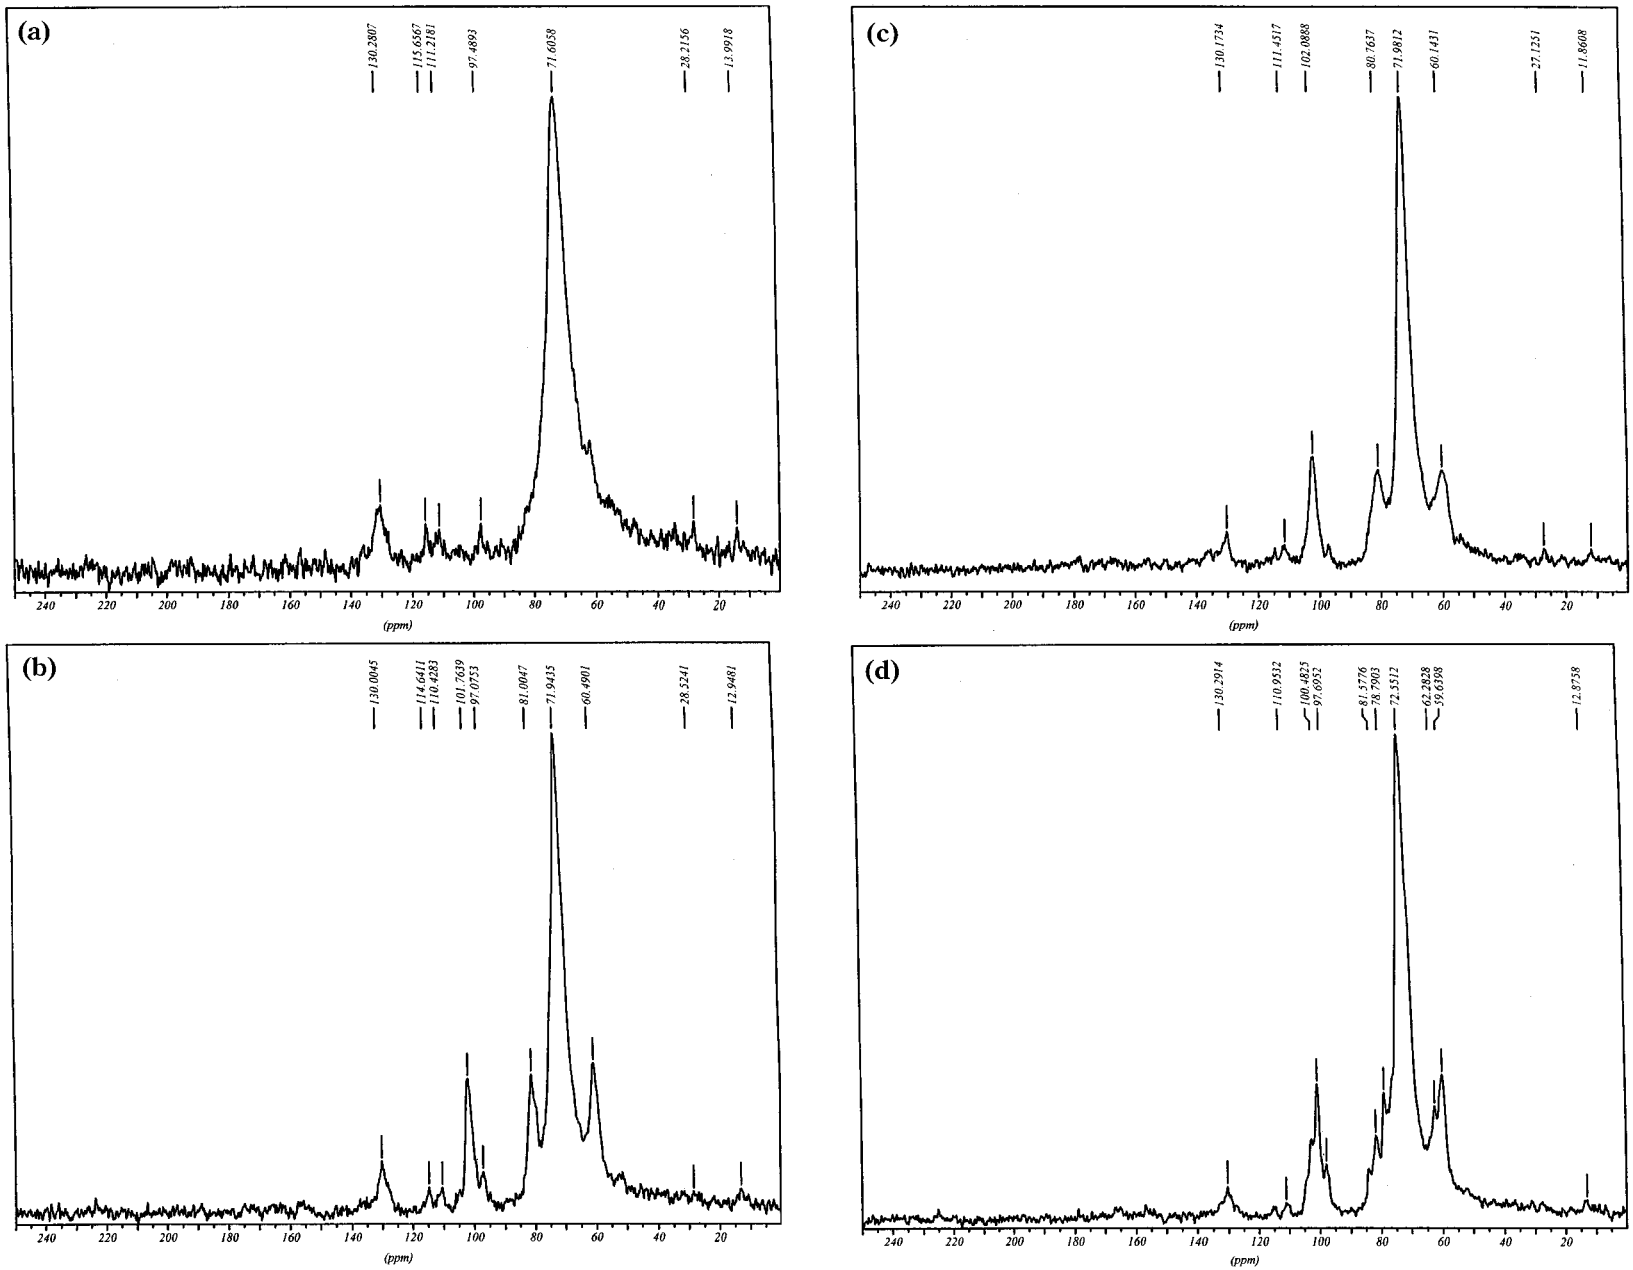

Figure 2. (a) ^{13}C NMR spectrum of PEG 6000 + 5% indomethacin, (b) ^{13}C NMR spectrum of PEG 6000 + 13% α-CD + 5% indomethacin, (c) ^{13}C NMR spectrum of PEG 6000 + 14% β-CD + 5% indomethacin, (d) ^{13}C NMR spectrum of PEG 6000 + 19% γ-CD + 5% indomethacin.

PEG/CD/Indomethacin. In the PEG/IM and PEG/α-CD/IM dispersions (Figure 2a and 2b) the C-2′, C-3, and C-6 peaks of IM at 131, 115, and 111 ppm, respectively, are fully resolved, and the intensity distributions of these are similar. The magnitude of the C-3 and C-6 peaks are almost equal, while the C-2′ peak has twice the intensity of the former. In the PEG/β-CD/IM and PEG/γ-CD/IM samples (Figure 2c and 2d), however, these peaks are much weaker, and a somewhat different intensity distribution was observed. The C-2′, C-3, and C-6 carbons might thus be influenced by the addition of β- or γ-CD.

Indomethacin possesses two different lipophilic parts, namely the phenyl ring and the indole ring, that are able to interact with the nonpolar cavity of CD.

It has been reported (*14*) that the six-membered ring of the indole unit of the indomethacin molecule (carbons C-4 and C-6 in Figure 1) is strongly affected by the formation of the β-CD-indomethacin inclusion complex in aqueous solution. The C-4 peak at 97 ppm is unfortunately not resolved in the CD dispersions in this study due to overlapping with the chemical shift of C-1 in anhydrous cyclodextrins. The results from (*14*) are, however, at variance with the data reported by others (*15*, *16*, *17*) who claim that the *p*-chlorobenzoic part of the indomethacin molecule (carbons C-1′, C-2′, C-3′, and C-4′ in Figure 1) is included in the β-CD channel in aqueous solution. Fronza et al. combined experimental data from 1D NOE and 2D ROESY experiments with theoretical energy calculations, taking into account the existence of two diastereometric forms of indomethacin (*E* and *Z*). The *Z* form is the most thermodynamically stable form and consequently the dominant isomer in solution. However, they found that the complexation selectively stabilizes the *E* isomer with respect to *Z*. One should, however, bear in mind that these results concern the complex in aqueous solution. In the solid state, with a polymer matrix as solvent, the conditions for complex formation may be different, and possibly here both isomers form complex with CD. In the present study the C-1′ peak (130 ppm), which lies very close to the C-2′ peak, is not fully resolved, while the C-3′ and C-4′ peaks at 127 and 134 ppm, respectively, do not appear distinctly in the spectra of the dispersions.

The relation between the C-13 and C-10 peaks at 13 and 28 ppm, respectively, seems also to be affected in the CD dispersions. In the PEG/IM, PEG/α-CD/IM, and PEG/β-CD/IM samples as in pure indomethacin, these two peaks are of the same magnitude, while the C-10 peak has almost disappeared in the γ-CD dispersion. The observations indicate that at least part of the indomethacin molecule experiences a somewhat different surrounding depending on the character of the CD that is added.

Carbon-13 signals from guest molecules are known to be, in many instances, lost or obscured because the amount of the guest molecules is usually low compared with that of the glucose residues. Therefore, the effect of a possible inclusion of indomethacin on the ^{13}C chemical shifts of the CDs were studied, and the results are presented in Table 2. The distinct spectral change on complex formation especially in the C-1, C-4, and C-6 region might arise from a macrocyclic conformational change associated with the inclusion of the guest molecule.

For γ-CD, C-1 and C-4 signals showed a shift 1−4 ppm downfield, while C-2,3,5 signals showed a shift 1 ppm in the opposite direction compared to pure γ-CD. The C-6 carbon located at the exterior of the torus also showed a shift of 2 ppm upfield. These results indicate that indomethacin may interact with γ-CD not only at the interior of the cavity but could also effect, directly or indirectly, the hydrogen bonds at the top of the torus where C-6 is located. In Table 2 the effect of the addition of indomethacin to the PEG/CD dispersion is also calculated. Shifts larger than 1 ppm were only obtained in the γ-CD system, again for the C-1, C-4, and C-6 carbons. A prostaglandin $F_{2\alpha}$−γ-cyclodextrin complex has been reported (*18*) to form a structure similar to the *n*-propyl alcohol−γ-cyclodextrin complex (*19*). These compounds were proposed to have a channel structure with a tetragonal or a hexagonal close packing of the cylinders of γ-CD molecules corresponding to the hydrated and anhydrous form of γ-CD, respectively. In the study by Uekama et al. (*18*) the ^{13}C chemical shifts from the individual carbons of the γ-CD in the prostaglandin $F_{2\alpha}$−γ-cyclodextrin complex were found to be 103.5 ppm (C-1), 81.7 ppm (C-4), 72.6 ppm (C-3,2,5), and 60.0 ppm (C-6), respectively. The shifts observed for the carbons in γ-CD in the indomethacin−γ-CD complex (Table 2) are in good agreement with these values. It is thus probable that the indomethacin−γ-CD complex has a similar bonding between the indomethacin and CD molecules as in the prostaglandin−γ-CD complex. The indomethacin−γ-CD phase found in a previous X-ray experiment (*7*) and appointed a tetragonal symmetry might thus be a complex between indomethacin and γ-CD where the inclusion complex forms a tetragonal packing of cylinders.

For the β-CD system a broadening of the CD peaks compared to the spectrum of the pure CD was observed. This might arise from a distribution of the chemical shift of the carbons or an increased disorder in the surroundings of the β-CD molecules. A recent molecular modeling study of β- and γ-cyclodextrin complexes (20) demonstrates the high capability of deformation of β-CD, which could accommodate several types of ligands. Indomethacin exists in two diastereometric forms (*E* and *Z*) and different parts of the indomethacin molecule has been reported (*14*, *15*, *16*, *17*) to form complex with β-CD, which could explain the distribution of the chemical shift of the β-CD carbons.

For α-CD, the peak at 73 ppm showed a shift approximately 1 ppm upfield both with and without indomethacin. This peak arise from the C-2,3,5 carbons in the cyclodextrin and from the PEG carbons. In the case of α-CD this shift may depend on an interaction with the polymer, α-CD has been reported to form complexes with poly(ethylene glycol) of various molecular weight to give crystalline complexes (*5*). Since C-3-H and C-5-H groups are oriented at the center of the cavity, these carbons may be particularly affected by the shielding due to hydrophobic interactions.

Investigation of Crystallinity. The degree of relative crystallinity of some of the solid dispersions and the solid solutions was investigated using different techniques: ^1H NMR, XRD, and two different DSC methods. We chose to investigate the samples where γ-CD was added to the PEG or the PEG/IM system. In the former a solid solution was formed while in the latter case a new phase could be identified that probably is an inclusion complex (Table 1).

Solid State ^1H NMR. The line-width of a ^1H NMR spectrum is a probe of the strength of interactions between atoms or molecules in a polymer sample, or the molecular flexibility. At room temperature the relaxation rate is faster for protons in crystalline PEG than for those in the amorphous phase (*21*). The two components appear at the same resonance frequency but exhibit different line widths, arising from PEG chain segments with different dynamic properties. In PEG, the rigid, crystalline mate-

[a] $R = \sqrt{\Sigma w(I_o - I_c)^2 / \Sigma w I_o^2}$.

rial gives rise to a broad component with a Gaussian shape, while the signal from the flexible polymer chains in the amorphous phase is a Lorentzian (*21*). The relative area of the broad peak is directly related to the fraction of PEG forming crystalline material in a one-component system. The crystallinity is thus compared with the amorphous part within the same sample. The crystallinity measured as the ratio between the relative area of the broad peak and the total area of the peak is presented in Table 3. When samples contain several components in varying amounts and in different phases, the interpretation is, however, not as straightforward as for a pure polymer sample. The effect of a macroscopic inhomogeneity can influence the response of the sample. Furthermore, the number of protons and relaxation times may differ for indomethacin and the CDs compared to PEG. It is also possible that crystalline regions apart from PEG give rise to narrow peaks with Lorentzian shape.

It can be seen from Table 3 that the ratio for treated PEG 6000 (67%) was decreased to the same extent by addition of indomethacin (43%) and γ-CD (46%), indicating that the PEG structure is somewhat disordered by the distribution of indomethacin and γ-CD, respectively, leading to a decrease in crystallinity. The value obtained for the PEG/γ-CD/IM dispersion (32%) was even lower, indicating a structure of still more amorphous character.

X-ray Diffraction. Most of the X-ray methods for estimating the crystallinity fall into three general categories: separation of the crystalline and amorphous scattering, differential intensity measurements where data are compared with crystalline and amorphous standards, and absolute methods where X-ray scattering equations are used directly (*22*). Crystalline and amorphous scattering are usually separated using some sort of profile-fitting technique. In such analyses the XRD peaks are resolved in Gaussians or Lorentzians or a combination of the two. The curves have three parameters to define the position (x_0), the height (I_0), and the half-width (H) of the peak in the diffractogram.

The shape of the peaks was in this work determined by a profile-fitting program from Siemens (PROFILE, 1996), and the profile function used was the Gaussian split function. When the size of the individual crystals is less than about 0.1 μm (1000 Å), the term "particle size" or crystallite size is usually used. Crystallite sizes can be calculated from the Scherrer formula, eq 1:

$$t = \frac{0.9\lambda}{B \cos \theta} \tag{1}$$

where B = broadening of diffraction line measured at half-maximum intensity and t = diameter of crystal particle (*9*).

Perfect crystallites with long-range order give narrow diffraction lines and thus large particle sizes. Small crystallites giving broad diffraction lines indicate higher short-range order derived from a more amorphous structure. The maximum size measurement by line broadening is close to 2000 Å using a diffractometer (*9*). In a perfect homogeneous material the crystallite sizes that are obtained should be the same, regardless of which reflection that is used for the calculation. This is not the case for the distribution of crystalline and amorphous parts in a polymer. In the crystalline state, PEG, the matrix used here, form lamellae, which can be organized into spherulites. The lamellae built by PEG chains grow in the *z*-direction leaving amorphous areas between them. The spherulites consists of a lamellae layers in the radial direction separated by amorphous parts (*23*). It should thus be emphasized that the same value of the crystallite sizes can hardly be expected from different reflections in a PEG sample. It is, however, possible to compare the values obtained for the same reflection in different PEG samples.

Two different PEG 6000 reflections, with Miller indices *hkl* (011) and *hkl* (210), respectively, were selected, representing a 2θ range with no overlapping from the adjacent, very broad high-intensity peak at 19°. In Table 3 the crystallite sizes calculated from ref 1 are presented together with the *R*-values, and the diffractogram of PEG 6000 together with the peak profile-fitting is shown in Figure 3. In the profile fitting of the peak the measure of agreement between the observed intensity I_o and the calculated intensity I_c is given by the reliability *R*, in this case the weighted *R*-value, defined by eq 2:

$$R = \sqrt{\frac{\sum w(I_o - I_c)^2}{\sum w I_o^2}} \tag{2}$$

where w is a weighing factor that considers the accuracy of the measurement of each peak. A perfect fit gives an *R*-value of 0. A good fit ranges from 1% to 5% depending on the number of data points in the region to fit.

It can be seen from Table 3 that the crystallite sizes are lower in the dispersions than in pure PEG 6000. The particle size in the dispersions PEG/IM and PEG/γ-CD are similar, whereas the ternary dispersion have even smaller crystallite sizes. Our analysis of degree of crystallinity has been made using results from an experiment aimed for phase analysis where a rather short exposure time was used.

Differential Scanning Calorimetry (DSC) and Modulated-Temperature Differential Scanning Calorimetry (MTDSC). The two-phase model (a perfect crystalline and a perfect amorphous phase), although the simplest, is still the most widely used model for defining the degree of crystallinity (*24*). The degree of crystallinity is determined by comparing the heat of fusion value obtained for a sample with a standard defined as 100% crystalline material. In the method the ΔH of the sample is thus compared with the ΔH for an external standard. The difficulty in this method is to find and characterize a 100% crystalline reference. Since PEG 6000 is a semicrystalline polymer and far from 100% crystalline, a comparison between the samples and pure PEG 6000

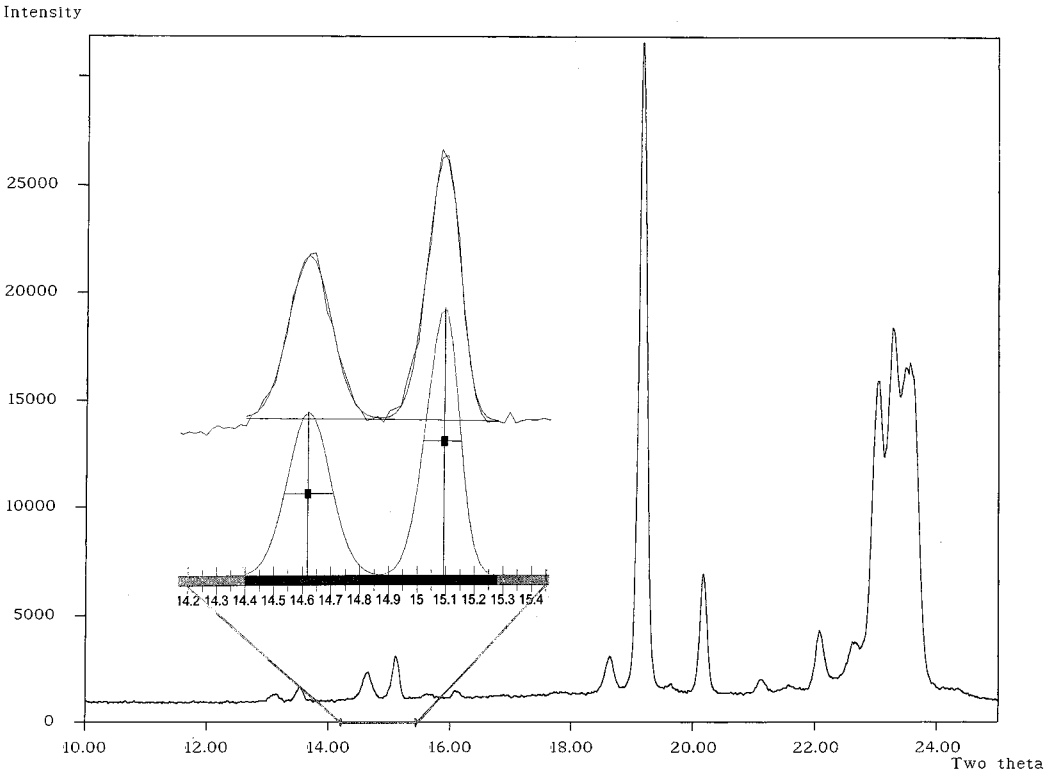

Figure 3. X-ray diffractogram of PEG 6000 (treated) and Gaussian profile-fitted peaks of PEG at $2\theta = 14.62$ and $2\theta = 15.09$, respectively.

only gives a rough estimation if the crystallinity increases or decreases.

The crystallinity values presented in Figure 4a are calculated as the ratio $\Delta H_{\text{sample}}/\Delta H_{\text{PEG 6000}}$ and show lower crystallinity for the dispersions than for pure PEG 6000.

A much more informative method might be offered by the MTDSC method. Three heat of fusion values are obtained with this method: the reversing c_p-component, ΔH_c, the nonreversing kinetic component, ΔH_k, and the conventional component, ΔH. In a previous study it was found that the ratio $\Delta H_c/\Delta H$ might be a possible measure of the degree of crystallinity in a system at certain operational settings defined as degrees of oscillation (*10*). The term degree of oscillation, DO, is a dimension-less quantity defined by a combination of amplitude, frequency, and heating rate giving a certain weight to the c_p component of the total energy. If the DO is selected in such a way that both heating and cooling is obtained in each period, theoretically, both melting and crystallization can occur in each of the modulations. With this technique the transformation energy of the crystalline parts of a sample is compared with the total transformation energy in the same sample. To ensure good reproducibility, there should be at least five modulations under the melting transition, and the sample temperature must follow the modulation during the whole course of the thermal event (*25*). Three DO combinations were selected from a previous study (*10*) that give both heating and cooling in the temperature cycle. A DO ~1−2 was recommended for this particular polymer system for a frequency of 0.02 Hz. A higher DO usually gives better standard deviations but at the cost of less differentiation between the samples. It should be emphasized that only results obtained with the same DO can be compared. The ratio $\Delta H_c/\Delta H$ with standard deviation for the samples obtained with three different degree of oscillation, DO, is presented in Figure 4b. The value 0.96 is the lower limit of DO for this particular system (*10*) which can explain the larger standard deviations obtained for this combination.

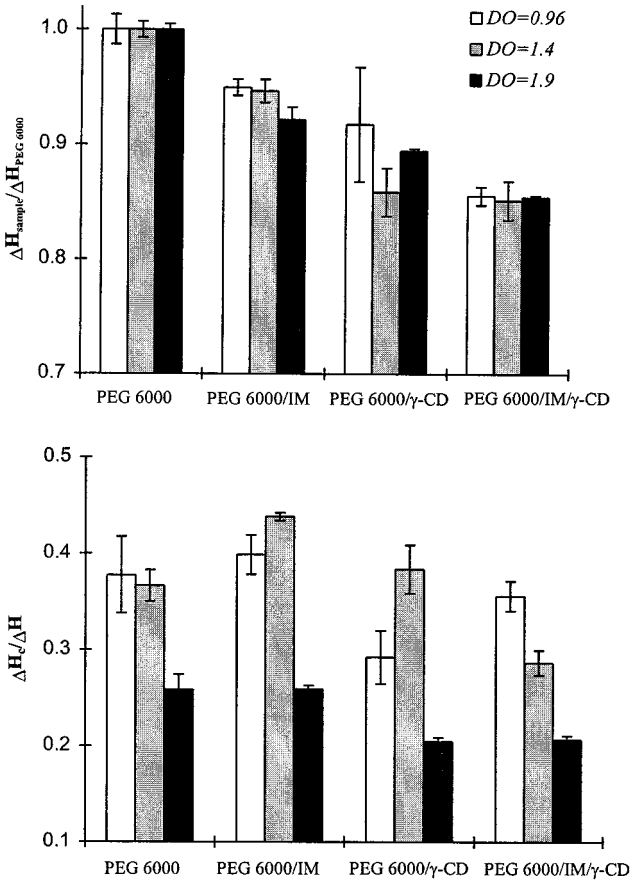

Figure 4. $\Delta H_{\text{sample}}/\Delta H_{\text{PEG 6000}}$ for PEG 6000 dispersions, $\Delta H_c/\Delta H$ for PEG 6000 dispersions.

The ratio $\Delta H_c/\Delta H$ for treated PEG 6000 was not changed or slightly increased by the addition of 5% indomethacin. With an addition of 20% γ-CD to PEG 6000, the ratio was lowered or almost equal for all combinations considering the standard deviations. The dispersion with 5% indomethacin and 19% γ-CD in PEG 6000 had a lower ratio than pure PEG 6000 for all DO, implying a less crystalline structure.

DISCUSSION

On comparison between the methods that were used, it is important to be conscious of what information that is obtained by each technique. In the ^{1}H NMR method the response of all the protons in the samples was measured. These protons are primarily PEG protons, since the polymer is the main component of the dispersions (76−95% w/w), and the carrier also has the highest content of protons per molecule. In the XRD method the crystallite sizes were calculated from two PEG reflections, and the information obtained thus concerned the crystallinity of the PEG matrix. The ΔH method, based on the two-phase model, considered the transformation energy of *all* phases in the sample and compared it with an external reference, namely pure PEG 6000. In the MTDSC method the transformation energy of *all* the crystalline parts of a sample that respond to a cyclic temperature modulation was measured and related to the total transformation energy of the same sample.

The relative crystallinity of the samples predicted by the NMR and the XRD methods are in good accordance with each other. The addition of IM or γ-CD to PEG 6000 decreases the crystallinity of the system. Particles of indomethacin dispersed in the carrier can be expected to distort the PEG structure, and the model proposed above for the solid solution of γ-CD in PEG 6000, where the γ-CD molecules may be thread on the PEG chains or helices, would also lead to a disturbance in the crystalline lamellae structure. However, the DSC and MTDSC methods indicate a difference in crystallinity between the two dispersions PEG 6000/IM and PEG 6000/γ-CD whereas the NMR and XRD methods did not. The results obtained are not necessarily contradictory. The presence of indomethacin particles or γ-cyclodextrin molecules may disturb the PEG matrix to the same extent, but the additives might not respond equally to the cyclic temperature modulation or have the same effect on the total energy of the sample. The ternary dispersion PEG/IM/γ-CD exhibited the lowest degree of crystallinity of the samples as predicted by all methods used. A possible explanation is that the indomethacin−γ-CD complex forms larger particles than pure indomethacin and that the tetragonal packing of the complexes disturbs the host PEG structure to a greater extent than does pure γ-CD.

CONCLUSIONS

The addition of different cyclodextrins to the dispersion of 5% indomethacin in PEG 6000 changed the short-range order in the samples to a varying extent. The NMR spectra of the PEG 6000/IM and PEG 6000/α-CD/IM dispersions were essentially superpositions of the pure components. In the PEG 6000/β-CD/IM dispersion a broadening of the peaks was obtained which was attributed to a distribution of the chemical shifts. Different parts of the indomethacin molecule can bind to β-CD and thereby give several types of complexes. The change in the chemicals shifts of the CD carbons in the PEG 6000/γ-CD/IM dispersion indicated a bond between γ-CD and indomethacin.

The degree of relative crystallinity of the samples in the γ-CD system, obtained by the different methods (^{1}H NMR, XRD, DSC, and MTDSC) showed that the dispersions were less crystalline than the pure polymer and that the dispersion containing the indomethacin−γ-CD complex had the lowest degree of relative crystallinity. Only the MTDSC method deviated, giving differentiation between the PEG 6000/IM and PEG 6000/γ-CD dispersions. Furthermore, equal or higher relative crystallinity for the PEG 6000/IM dispersion than for pure PEG 6000 was obtained, depending on operational parameters. When using different techniques for the determination of relative crystallinity, it is important to be aware of the kind of information that is obtained by the respective experiment.

ACKNOWLEDGMENT

The authors are grateful to MSc Marie Herstedt for assistance in the NMR laboratory, and to Dr Nils-Olov Ersson for skillful help with the XRD profile-fitting procedure. Porphyrin, Chlorin, and Bacteriochlorin Isothiocyanates: Useful Reagents for the Synthesis of Photoactive Bioconjugates†

J. M. Sutton,‡ O. J. Clarke,§ N. Fernandez,‡ and R. W. Boyle*,§

Department of Biological Sciences, University of Essex, Colchester CO4 3SQ, U.K., and Department of Chemistry, University of Hull, Hull HU6 7RX, U.K. Received August 20, 2001; Revised Manuscript Received January 4, 2002

A novel method for conjugating porphyrins and related molecules to proteins has been developed. The method, which involves synthesizing porphyrins, chlorins, and bacteriochlorins bearing a single amine-reactive isothiocyanate group represents a facile system for protein labeling with these photoactive species. Problems associated with the noncovalent binding of porphyrins to proteins are highlighted, and a method for purifying conjugates to yield exclusively covalently bound porphyrin protein species is demonstrated. Biological activity of porphyrin−bovine serum albumin conjugates formed and purified by these methods is demonstrated using laser scanning confocal microscopy.

INTRODUCTION

Porphyrins and their derivatives are of wide general interest because of the range of potential applications associated with these molecules; included among these are photodynamic therapy (PDT) (*1*−*4*) and fluorescence imaging (*5*). Addition reactions at the "exocyclic" double bonds of the porphyrins, which include OsO_4-mediated dihydroxylation reactions (*6*−*10*), leads to the generation of chlorins and bacteriochlorins, which absorb light more efficiently in the red and near-infrared regions of the spectrum. PDT applications, where light penetration through tissue is a limiting factor, are most effective using light in the 600−800 nm range, thus making chlorins and bacteriochlorins particularly suitable on purely photophysical grounds. Furthermore, as porphyrins, chlorins, and bacteriochlorins fluoresce at different wavelengths (*11*) and also have unusually large Stokes shifts (>200 nm), their use in multicolor fluorescence analysis could be envisaged. In both cases, however, the accurate targeting of the chromophore against tissue to be photosensitized or imaged is important.

Porphyrins and their derivatives have been conjugated with several proteins of biological importance, such as human and bovine serum albumins (*12*−*15*), monoclonal antibodies (*16*−*20*), and lipoproteins (*21*, *22*); this has allowed for their use as photosensitizers and imaging agents to be exploited in a more selective and controlled manner than was previously possible. The majority of bioconjugations involving porphyrin derivatives have relied on natural products such as haematoporphyrin (*13*, *16*, *17*) or chlorin e_6 (*15*, *20*, *22*) and have made use of carbodiimide or *N*-hydroxysuccinimide ester (NHS)-based bioconjugation protocols. These porphyin derivatives, however, contain multiple reactive functionalities, which can lead to cross-linking problems. Many bioconjugates of porphyrin and protein formed as previously described also incorporate significant amounts of noncovalently bound (NCB) porphyrin (*13*, *16*, *17*). Some attempts have been made to remove NCB porphyrin derivatives from bioconjugates, but these have usually involved gel permeation chromatography, which is not effective in removing large amounts of strongly NCB material. Hamblin et al. (*15*) successfully removed NCB material using acetone precipitation, which allowed the NCB chlorin e_6, retained in the supernatant, to be removed by successive washes. In PDT applications, the presence of some NCB porphyrin may not negate photosensitization entirely, as a number of NCB complexes or conjugates containing NCB porphyrin derivatives have been used successfully (*13*, *16*, *17*); however, it will decrease the desired selectivity for target tissue. In fluorescence-activated flow cytometry, the fluorophore is usually conjugated directly to a monoclonal antibody (Mab) or indirectly using an avidin−biotin interaction (i.e., biotinylated Mab/avidin−fluorophore conjugate) (*23*). In such applications, NCB porphyrin derivatives can present a major problem, as lipophilic porphyrin molecules can transfer to cell membranes and lead to large errors during flow cytometric analysis.

Recently, bioconjugates of porphyrins with bovine serum albumin (BSA) and a maleylated derivative (mal-BSA) have been successfully used to target particular cell types. BSA and mal-BSA bind selectively to ligands of the macrophage scavenger receptor; then, following cellular internalization by receptor-mediated endocytosis, the porphyrin-derived bioconjugates have been successfully used to image and photosensitize these cells (*13*−*15*, *22*, *23*).

In the study described herein, we have attempted to develop an improved bioconjugation technique for porphyrin derivatives and also to identify structural features which can minimize noncovalent binding (NCB) of porphyrins to protein.

EXPERIMENTAL PROCEDURES

Instrumentation and Materials. Melting points are uncorrected and were recorded on a Kolfer hot-plate microscope. ^1H and ^{13}C NMR spectra were recorded on a JEOL EX270 FT-NMR spectrometer and are referenced

downfield to tetramethylsilane. IR spectra were obtained using a Nicolet series 1600 FTIR spectrophotometer. Nominal mass spectra were obtained using a Kratos Kompact MALDI II spectrometer, EI biotech instrument, or a FAB autospec machine using NOBA matrix. Accurate masses were obtained from EPSRC Mass Spectrometry Service, Swansea, Wales. UV−visible spectra were obtained using Unicam UV-2 or UV-4 spectrometers and were taken in dichloromethane (DCM), unless otherwise stated. Fluorescent measurements were taken using a Perkin-Elmer LS50 spectrophotometer. All commercial chemicals and solvents were of reagent grade or higher and were used as received, unless otherwise specified. TLC analyses were performed on Merck silica-gel 60 plates (F254, 500 μm thickness). Merck silica-gel 60 (230−400 mesh) was used for flash chromatographic purification with all of the crude reaction mixtures being preadsorbed onto silica gel prior to separation, unless otherwise stated. All purified compounds were found to contain only one component by TLC analysis. HeLa cells were obtained in-house.

Chemistry: 5-(4-Methoxyphenyl)dipyrromethane (1). Dipyrromethane **1** was synthesized according to the method of Boyle et al. (*25*). The crude reaction mixture was purified by chromatography, eluting with *n*-hexane/DCM (3:7), to afford the pure product as an off-white solid (4.3 g, 50%); $R_f = 0.33$ (DCM); IR (Nujol, cm^{-1}) ν_{max}: 3382 (br s, NH), 1598 (C═C), 1300, 1050; UV−vis (MeOH) λ_{max} (relative intensity), nm: 224 (1.0); ^{1}H NMR (270 MHz, $CDCl_3$, δ): 7.87 (br s, 2H, *NH*), 7.10 (m, 2H, $J = 8.8$ Hz, *5-m-Ar*), 6.83 (m, 2H, $J = 8.8$ Hz, *5-o-Ar*), 6.66 (m, 2H, *1-H*), 6.14 (m, 2H, *2-H*), 5.89 (m, 2H, *3-H*), 5.40 (s, 1H, *5-H*); MALDI-MS *m/z*: 252.4 (M^+, 100%).

5-(3,4,5-Trismethoxyphenyl)dipyrromethane (2). Dipyrromethane **2** was synthesized according to the method of Boyle et al. (*25*). The reaction mixture was recrystallized from hot ethyl acetate/*n*-hexane and gave the required dipyrromethane as a white solid (5.41 g, 68%); $R_f = 0.44$ (DCM/ethyl acetate, 20:1); IR (Nujol, cm^{-1}) ν_{max}: 3378 (br s, NH), 1594 (C═C), 1233, 1040; UV−vis (MeOH) λ_{max} (relative intensity), nm: 222 (1.0), 280 (0.75); ^{1}H NMR (270 MHz; $CDCl_3$, δ): 8.07 (br s, 2H, *NH*), 7.53 (m, 2H, *1-H*), 6.68 (s, 2H, *5-o-Ar*), 6.37 (m, 2H, *2-H*), 5.93 (m, 2H, *3-H*), 5.38 (s, 1H, *5-H*), 3.80 (s, 3H, *p-OCH$_3$*), 3.73 (s, 6H, *m-OCH$_3$*); ^{13}C (68 MHz; $CDCl_3$, δ): 152.7, 137.3, 136.1, 131.8, 116.7, 107.9, 106.6, 104.9, 60.3, 55.5, 43.7; MALDI-MS *m/z*: 311.2 ($[M - 1]^+$, 100%).

5-(4-Acetamidophenyl)dipyrromethane (3). Dipyrromethane **3** was synthesized according to the method of Boyle et al. (*25*). The crude product was recrystallized from hot ethyl acetate/*n*-hexane and afforded the required dipyrromethane as a white solid (8.0 g, 68%); $R_f = 0.35$ ($CHCl_3$/ethyl acetate, 1:1); IR (Nujol, cm^{-1}) ν_{max}: 3409 (NH, *amide*), 3248 (br s, *NH*), 1650 (*C═O*), 1593 (*C═C*), 1320, 1009; UV−vis (MeOH) λ_{max} (relative intensity), nm: 224 (1.0); ^{1}H NMR (270 MHz, $CDCl_3$, δ): 8.00 (br s, 2H, *NH*), 7.40 (m, 2H, $J = 8.5$ Hz, *5-o-Ar*), 7.30 (br s, 1H, *NH-acetamide*), 7.13 (m, 2H, $J = 8.5$ Hz, *5-m-Ar*), 6.68 (m, 2H, *1-H*), 6.16 (m, 2H, *2-H*), 5.90 (m, 2H, *3-H*), 5.42 (s, 1H, *5-H*), 2.14 (s, 3H, *CH$_3$*); ^{13}C NMR (68 MHz, $CDCl_3$, δ): 168.4, 138.2, 136, 132.4, 128.9, 120.3, 117.2, 108.4, 107.1, 43.4, 24.5; MALDI-MS *m/z*: 279.4 (M^+, 100%).

5-(4-Acetamidophenyl)-15-(4-methoxyphenyl)porphyrin (4). The DPP was synthesized according to the method of Boyle et al. (*25*). The resulting mixture of three porphyrins was chromatographed, eluting initially with DCM to allow for the removal of 5,15-(4-methoxy)-DPP, and then continuing with ethyl acetate/DCM (1:4) to elute the required product as purple crystals (150 mg, 12%); $R_f = 0.40$ (DCM/MeOH, 19:1); mp 305−307 °C (dec); UV−vis (DCM) λ_{max} (relative intensity), nm: 410 (1.0), 502 (0.04), 538 (0.02), 578 (0.015), 630 (0.01); ^{1}H NMR (270 MHz, $CDCl_3$, δ): 10.35 (s, 2H, *10+20-H*), 9.43 (d, 4H, $J = 4.8$ Hz, *β-H*), 9.14 (d, 4H, $J = 4.8$ Hz, *β-H*), 8.65 (m, 2H, $J = 7.2$ Hz, *5-m-Ar*), 8.22−8.12 (m, 4H, (overlapping), $J = 8.1$ Hz, *5+15-o-Ar*), 7.56 (m, 2H, $J = 8.1$ Hz, *15-m-Ar*), 4.14 (s, 3H, *CH$_3$*), −3.00 (br s, 2H, *NH*); MALDI-MS *m/z*: 550.3 (M^+, 100%).

5-(4-Aminophenyl)-15-(4-methoxyphenyl)porphyrin (6) (General Procedure A). 5-(4-Acetamido phenyl)-15-(4-methoxyphenyl)porphyrin **4** (1 equiv, 100 mg, 0.182 mmol) was dissolved in 5 M aqueous HCl (100 mL) and the solution heated for 3 h under reflux. The hot reaction mixture was concentrated in vacuo to yield a crude green solid. The solid was redissolved in a mixture of DCM/triethylamine (9:1) (200 mL) and stirred for 10 min at room temperature. The solution was then washed with water (3 × 200 mL) and saturated brine (200 mL), and the organic layer separated, dried (Na_2SO_4), and then concentrated in vacuo. The crude purple solid was chromatographed, eluting with DCM, and gave the desired porphyrin as a purple crystalline solid (51 mg, 54%), $R_f = 0.30$ (DCM); mp 300 °C (dec); UV−vis (DCM) λ_{max} (relative intensity), nm: 410 (1.0), 503 (0.045), 538-(0.02), 578 (0.015), 630 (0.005); fluorescence (DCM): λ_{max} 634 nm (λ excitation = 410 nm); ^{1}H NMR (270 MHz, $CDCl_3$, δ): 10.30 (s, 2H, *10+20-H*), 9.39 (d, 4H, $J = 4.9$ Hz, *β-H*), 9.17 (d, 2H, $J = 4.9$ Hz, *β-H*), 9.10 (d, 2H, $J = 4.9$ Hz, *β-H*), 8.19 (m, 2H, $J = 8.8$ Hz, *15-o-Ar*), 8.07 (m, 2H, $J = 8.1$ Hz, *5-o-Ar*), 7.35 (m, 2H, $J = 8.8$ Hz, *15-m-Ar*), 7.14 (m, 2H, $J = 8.1$ Hz, *5-m-Ar*), 4.13 (s, 3H, *CH$_3$*), 4.08 (br s, 2H, *NH*), −3.06 (br s, 2H *NH*); MALDI-MS *m/z*: 508.3 ($[M + 1]^+$, 100%). ES-HRMS Anal. Calcd. for $C_{33}H_{26}N_5O$ ($[M + 1]^+$), 508.2137; found, 508.2144.

5-(4-Isothiocyanatophenyl)-15-(4-methoxyphenyl)-porphyrin (8) (General Procedure B). To a stirred solution of **6** (1 equiv, 50 mg, 0.099 mmol) in freshly distilled DCM (20 mL) was added 1,1′-thiocarbonyldi-2(1*H*)-pyridone (2 equiv, 46 mg, 0.198 mmol). The reaction was allowed to stir under argon for 2 h at room temperature, after which the reaction mixture was concentrated in vacuo. The crude residue was chromatographed, eluting with DCM, and afforded the title compound as a purple crystalline solid (45.7 mg, 92%); $R_f = 0.86$ (DCM); mp >350 °C (dec); UV−vis (DCM) λ_{max}, nm: 411, 505, 541, 576, 630; ^{1}H NMR (270 MHz, $CDCl_3$, δ): 10.32 (s, 2H, *10+20-H*), 9.13−9.43 (m, 4H, *β-H*), 9.11 (d, 2H, $J = 5$ Hz, *β-H*), 9.02 (d, 2H, $J = 5$ Hz, *β-H*), 8.27 (m, 2H, $J = 8$ Hz, *5-o-Ar*), 8.19 (m, 2H, $J = 8$ Hz, *15-o-Ar*), 7.69 (m, 2H, $J = 8$ Hz, *5-m-Ar*), 7.36 (m, 2H, $J = 8$ Hz, *15-m-Ar*), 4.13 (s, 3H, *OCH$_3$*), −3.12 (br s, 2H, *NH*). FAB-HRMS Anal. Calcd. for $C_{34}H_{23}N_5OS$ (M^+), 549.1623; found, 549.1604.

5-(4-Acetamidophenyl)-15-(3,4,5-trimethoxyphenyl)porphyrin (5). DPP was synthesized according to the method of Boyle et al. (*25*). The crude porphyrin mixture was chromatographed, eluting with DCM/ethyl acetate (4:1), and afforded the required product as a purple crystalline solid (198 mg, 7.2%); $R_f = 0.37$ (DCM/ethyl acetate, 4:1); mp >350 °C (dec); UV−vis (DCM) λ_{max}, nm: 407, 504, 539, 576, 632; ^{1}H NMR (270 MHz, $CDCl_3$/DMSO-d_6, 1:1, δ): 10.42 (s, 2H, *10+20-H*), 10.27 (br s, 1H, *NH*), 9.50 (d, 4H, $J = 5$ Hz, *β-H*), 9.20 (d, 2H, $J = 5$ Hz, *β-H*), 9.13 (d, 2H, $J = 5$ Hz, *β-H*), 8.18 (m, 2H, $J = 8$

Hz, *5-o-Ar*), 8.12 (d, 2H, $J = 8$ Hz, *5-m-Ar*), 7.54 (s, 2H, *15-o-Ar*), 4.14 (s, 3H, *15-p-OCH$_3$*), 4.02 (s, 6H, *15-m-OCH$_3$*), 2.32 (s, 3H, *CH$_3$*); MALDI-MS *m/z*: 609 (M^+, 100%).

5-(4-Aminophenyl)-15-(3,4,5-trimethoxyphenyl)-porphyrin (7). Porphyrin **5** was converted into the aminoporphyrin **7** following general procedure A. The crude purple solid was chromatographed, eluting with DCM to afford the title compound as a purple crystalline solid (168 mg, 94.8%); $R_f = 0.49$ (DCM/ethyl acetate, 5:1); mp >350 °C (dec); UV−vis (DCM) λ_{max}, nm: 410, 505, 542, 578, 634; ^{1}H NMR (270 MHz, $CDCl_3$, δ): 10.19 (s, 2H, *10+20-H*), 9.28 (d, 4H, $J = 5$ Hz, *β-H*), 9.08 (d, 4H, $J = 5$ Hz, *β-H*), 7.96 (m, 2H, $J = 8$ Hz, *5-o-Ar*), 7.37 (s, 2H, *15-o-Ar*), 7.01 (d, 2H, $J = 8.1$ Hz, *5-m-Ar*), 6.85 (br s, 2H, *NH$_2$*), 3.90 (s, 9H, *15-o/p-OCH$_3$*), −3.18 (br s, 2H, *NH*); ^{13}C NMR (68 MHz, $CDCl_3$, δ): 159.1, 147.6, 147, 146.1, 145.1, 143.3, 136, 131.6, 131.4, 131.3, 131.2, 130.8, 119.9, 118.2, 113.9, 113.8, 105.1, 100, 55.7; MALDI-MS *m/z*: 568 (M^+, 100%).

5-(4-Isothiocyanatophenyl)-15-(3,4,5-trimethoxyphenyl)porphyrin (9). Porphyrin **9** was synthesized from **7** using general procedure B. The crude residue was chromatographed, eluting with DCM to afford the required product as a purple crystalline solid (102 mg, 95.5%); $R_f = 0.72$ (DCM); mp >350 °C (dec); UV−vis (DCM) λ_{max}, nm: 410, 504, 539, 576, 631; ^{1}H NMR (270 MHz, $CDCl_3$, δ): 10.28 (s, 2H, *10+20-H*), 9.35−9.38 (m, 4H, *β-H*), 9.17 (d, 2H, $J = 5$ Hz, *β-H*), 8.98 (d, 2H, $J = 5$ Hz, *β-H*), 8.20 (m, 2H, $J = 8$ Hz, *5-o-Ar*), 7.63 (m, 2H, $J = 8$ Hz, *5-m-Ar*), 7.50 (s, 2H, *15-o-Ar*), 4.20 (s, 3H, *15-p-OCH$_3$*), 3.98 (s, 6H, *15-m-OCH$_3$*), −3.15 (br s, 2H, *NH*); ^{13}C NMR (68 MHz, $CDCl_3$, δ): 151.6, 147.2, 146.7, 145.3, 145.2, 140.6, 137.8, 136.8, 136.4, 135.7, 131.2, 131.9, 131.8, 131.1, 130.4, 124.3, 119.2, 117.2, 112.9, 105.5, 61.3, 56.4. FAB-HRMS Anal. Calcd for $C_{36}H_{27}N_5O_3S$ ([M + H]$^+$), 610.1913; found, 610.1914.

5-(4-Hydroxyphenyl)dipyrromethane (11). The dipyrromethane was synthesized according to the method of Boyle et al. (*25*). The crude dipyrromethame was chromatographed, eluting initially with $CHCl_3$, and then gradient eluting to $CHCl_3$/ethyl acetate (1:1). The required product was obtained as a pale pink crystalline solid (6.36 g, 65%); $R_f = 0.18$ ($CHCl_3$); mp 158−160 °C; IR (Nujol, cm^{-1}) υ_{max}: 3409 (NH), 2968 (OH); ^{1}H NMR (270 MHz, DMSO-d_6, δ): 10.48 (br s, 2H, *NH*); 9.19 (br s, 1H, *OH*), 7.07 (m, 2H, $J = 8.1$ Hz, *5-m-Ar*), 6.90 (m, 2H, $J = 8.1$ Hz, *5-o-Ar*), 6.59 (m, 2H, *1-H*), 5.89 (m, 2H, *2-H*), 5.63 (m, 2H, *3-H*), 5.23 (s, 1H, *5-H*); ^{13}C NMR (68 MHz, DMSO-d_6, δ): 155.6, 134.2, 133.8, 129, 117.4, 116.7, 114.8, 107.2, 106.9, 105.9; MALDI-MS *m/z*: 237 (M^+, 100%).

5-(4-*tert*-Butyldiphenylsilyloxyphenyl)dipyrromethane (12). Imidazole (712 mg, 10 mmol) and *tert*-butylchlorodiphenylsilane (1.3 mL, 5 mmol) were dissolved in anhydrous DMF (2.0 mL, distilled from CaH_2, 0.1 Torr), and the reaction mixture was stirred under argon for 5 min at room temperature. Dipyrromethane **11** (1.0 g, 4.2 mmol) was added, and stirring was continued for a further 17 h under the same conditions. The crude reaction mixture was diluted with ethyl acetate (100 mL) and washed with water (3 × 100 mL) and saturated brine (100 mL). The organic layer was separated and dried (Na_2SO_4) before concentration in vacuo to yield a crude brown oil. The crude product was chromatographed, eluting with DCM, and afforded the title compound as viscous tan oil (1.57 g, 78.8%); $R_f = 0.42$ (DCM); IR (Nujol, cm^{-1}) υ_{max}: 3315 (NH); ^{1}H NMR (270 MHz, $CDCl_3$, δ): 7.52−7.62 (m (overlapping), 4H, *NH* and *Si-o-Ar*); 7.21−7.27 (m, 6H, *Si-m/p-Ar*), 6.75 (m, 2H, $J = 8.6$ Hz, *5-o-Ar*), 6.59 (m, 2H, $J = 8.6$ Hz, *5-m-Ar*), 6.39 (m, 2H, *1-H*), 5.96 (m, 2H, *2-H*), 5.67 (m, 2H, *3-H*), 5.10 (s, 1H, *5-H*), 1.00 (s, 9H, *^{t}Bu*); ^{13}C NMR (68 MHz, $CDCl_3$, δ): 154.9, 135.9, 135.2, 134.9, 133.3, 133.2, 130.3, 130.1, 129.5, 128.2, 120.1, 117.5, 108.6, 107.4, 43.4, 27, 19.9; FAB-MS *m/z*: 474 ([M + H]$^+$, 55%), 410 ([M − C_4H_4N]$^+$, 90%).

5-(4-Acetamidophenyl)-15-(4-*tert*-butyldiphenylsilyloxyphenyl)porphyrin (13). Porphyrin **13** was synthesized according to the method of Boyle et al. (*25*). The porphyrin mixture was chromatographed, eluting with DCM/ethyl acetate (1:1) to give the required product as a purple crystalline solid (317 mg, 42%); $R_f = 0.44$ (DCM/ethyl acetate, 1:1); mp >350 °C (dec); UV−vis (DCM) λ_{max}, nm: 410, 504, 539, 599, 656; ^{1}H NMR (270 MHz, $CDCl_3$, δ): 10.10 (s, 2H, *10+20-H*), 9.26 (d, 2H, $J = 5$ Hz, *β-H*), 9.18 (d, 2H, $J = 5$ Hz, *β-H*), 8.99 (d, 4H, $J = 5$ Hz, *β-H*), 8.61−8.70 (m, 4H, *Si-o-Ar*), 8.21 (br s, 1H, *NH*), 8.10 (m, 2H, $J = 8$ Hz, *5-o-Ar*), 7.93−7.99 (m, 6H, *Si-m/p-Ar*), 7.84 (m, 2H, $J = 8$ Hz, *15-o-Ar*), 7.36 (m, 2H, $J = 8$ Hz, *5-m-Ar*), 7.21 (m, 2H, $J = 8$ Hz, *15-m-Ar*), 2.24 (s, 3H, *CH$_3$*), 1.31 (s, 9H, *^{t}Bu*), −3.11 (br s, 2H, *NH*); FAB-MS *m/z*: 774 ([M + H]$^+$, 100%).

5-(4-Aminophenyl)-15-(4-*tert*-butyldiphenylsilyloxyphenyl)porphyrin (14). Porphyrin **13** was hydrolyzed following general procedure A. The residual crude purple solid was chromatographed, eluting with DCM/ethyl acetate (4:1) to afford the title compound as a purple crystalline solid (90 mg, 97%); $R_f = 0.8$ (DCM/ethyl acetate, 1:1); mp >350 °C (dec); UV−vis (DCM) λ_{max}, nm: 411, 505, 543, 579, 636; ^{1}H NMR (270 MHz, $CDCl_3$, δ): 10.23 (s, 2H, *10+20-H*), 9.24 (m, 4H, *β-H*), 6H, *Si-o-Ar* and *15-o-Ar*), 9.14 (d, 2H, $J = 5$ Hz, *β-H*), 9.00 (d, 2H, $J = 5$ Hz, *β-H*), 7.98 (m, 2H, $J = 8$ Hz, *5-o-Ar*), 7.96 (m (overlapping)), 7.54 m, (6H, *Si-m/p-Ar*), 7.14 (m, 2H, $J = 8$ Hz, *15-m-Ar*), 7.08 (m, 2H, $J = 8$ Hz, *5-m-Ar*), 4.0 (br s, 2H, *NH$_2$*), 1.30 (s, 9H, *^{t}Bu*), −3.11 (br s, 2H, *NH*); ^{13}C NMR (68 MHz, $CDCl_3$, δ): 155.6, 150.5, 147.9, 147.6, 147.3, 146.1, 144.9, 135.9, 135.7, 135.6, 134.1, 133, 131.4, 131.3, 131.1, 130.9, 130.1, 127.9, 120.4, 119.6, 119.3, 118.7, 118.5, 113.7, 105, 26.7, 19.6; FAB-MS *m/z*: 732 (M^+, 50%), 716 ([M − NH_2]$^+$, 9%), 674 ([M − $C(CH_3)_3$]$^+$, 3%).

5-(4-Isothiocyanatophenyl)-15-(4-*tert*-butyldiphenylsilyloxyphenyl)porphyrin (15). Porphyrin **14** was converted into the isothiocyanate using general procedure B. The crude reaction mixture was chromatographed, eluting with DCM which gave the required compound as a purple crystalline solid (133 mg, 97%); $R_f = 0.6$ (DCM/hexane, 1:1); mp >350 °C (dec); UV−vis (DCM) λ_{max}, nm: 410, 504, 539, 576, 631; ^{1}H NMR (270 MHz, $CDCl_3$, δ): 10.27 (s, 2H, *10+20-H*), 9.36 (m, 4H, *β-H*), 9.01 (d, 2H, $J = 5$ Hz, *β-H*), 8.97 (d, 2H, $J = 5$ Hz, *β-H*), 8.21 (m, 2H, $J = 8$ Hz, *5-o-Ar*), 7.95−7.98 (m (overlapping)), 6H, *15-o-Ar* and *Si-o-Ar*), 7.64 (m, 2H, $J = 8$ Hz, *5-m-Ar*), 7.53−7.55 (m, 6H, *Si-m/p-Ar*), 7.20 (m, 2H, $J = 8$ Hz, *15-m-Ar*), 1.30 (s, 9H, *^{t}Bu*), −3.18 (br s, 2H, *NH*); ^{13}C NMR (68 MHz, $CDCl_3$, δ): 155.7, 147.4, 146.6, 145.2, 145, 140.7, 135.8, 135.7, 135.6, 133.9, 133, 131.9, 131.5, 131.2, 131, 130.3, 130.1, 127.9, 124.3, 119.5, 118.5, 116.8, 105.4, 26.7, 19.7; FAB-MS *m/z*: 536 ([M + H]$^+$, 100%).

5-(4-Isothiocyanatophenyl)-15-(4-hydroxyphenyl)-porphyrin (10). To a stirred solution of porphyrin **15** (100 mg, 0.13 mmol) in freshly distilled DCM (20 mL) was added tetrabutylammonium fluoride (40.5 mg, 0.16

mmol). The reaction was allowed to proceed under argon for 1 h at room temperature. The solvent was removed in vacuo to yield a crude purple solid. The crude product was purified by chromatography, eluting with DCM and afforded the title compound as a purple crystalline solid (63.5 mg, 92%); $R_f = 0.67$ (DCM); mp >350 °C (dec); UV−vis (MeOH) λ_{max}, nm: 408, 505, 540, 576, 630; ^{1}H NMR (270 MHz, $CDCl_3$/DMSO-d_6, 1:1, δ): 10.34 (s, 2H, *10+20-H*), 9.43 (m, 4H, *β-H*), 9.16 (m, 2H, *β-H*), 9.02 (m, 2H, *β-H*), 8.25 (m, 2H, *15-o-Ar*), 8.05 (m, 2H, *5-o-Ar*), 7.71 (m, 2H, *15-m-Ar*), 7.30 (m, 2H, *5-m-Ar*), −3.16 (br s, 2H, *NH*); ^{13}C NMR (68 MHz, $CDCl_3$/DMSO-d_6, 1:1, δ): 156.9, 146.9, 146, 144.5, 144.3, 139.9, 135.6, 135.3, 135.1, 131.5, 131.1, 130.8, 130.4, 129.8, 123.8, 119.5, 116.1, 113.7, 104.8. FAB-HRMS (FAB) Anal. Calcd. for $C_{33}H_{21}N_5OS$ ([M + H]$^+$), 536.1545; found, 536.1548.

5-(4-Acetamidophenyl)-10,15,20-tri-(4-methoxyphenyl)porphyrin (18). Porphyrin **18** was synthesized according to the method of Adler et al. (*29*). The crude mixture of porphyrin isomers was purified by chromatography, eluting with DCM/ethyl acetate (4:1) to afford the required product as a purple crystalline solid (1.77 g, 7.5%); $R_f = 0.5$ (DCM/ethyl acetate, 4:1); mp >350 °C (dec); UV−vis (DCM) λ_{max}, nm: 423, 520, 554, 594, 651; ^{1}H NMR (270 MHz, $CDCl_3$, δ): 8.87 (s, 8H, *β-H*), 8.17−8.09 (m, 8H, *5+10+15+20-o-Ar*), 7.91 (m, 2H, $J = 8$ Hz, *5-m-Ar*), 7.78 (br s, 1H, *NH*), 7.29−7.26 (m, 6H, *10+15+20-m-Ar*), 4.09 (s, 9H, CH_3), 2.36 (s, 3H, CH_3), −2.77 (br s, 2H, *NH*); MALDI-MS *m/z*: 762 (M$^+$, 100%).

5-(4-Aminophenyl)-10,15,20-tri-(4-methoxyphenyl)-porphyrin (20). Porphyrin **18** was converted into **20** following general procedure A. The crude purple solid was chromatographed, eluting with DCM/ethyl acetate (4:1), and gave the title compound as a purple crystalline solid (437 mg, 93%); $R_f = 0.84$ (DCM/ethyl acetate, 4:1); mp >350 °C (dec); UV−vis (DCM) λ_{max}, nm: 421, 516, 553, 591, 652; ^{1}H NMR (270 MHz, $CDCl_3$, δ): 8.93−8.86 (m, 8H, *β-H*), 8.13 (m, 6H, $J = 8$ Hz, *10+15+20-o-Ar*), 7.99 (m, 2H, $J = 8$ Hz, *5-o-Ar*), 7.29 (m, 6H, $J = 8$ Hz, *10+15+20-m-Ar*), 7.07 (m, 2H, $J = 8$ Hz, *5-m-Ar*), 4.10 (s, 9H, CH_3), 4.03 (br s, 2H, NH_2), −2.74 (br s, 2H, *NH*); ^{13}C NMR (68 MHz, $CDCl_3$, δ): 159.4, 135.7, 135.6, 134.7, 120.5, 113.5, 112.2, 55.6; MALDI-MS *m/z*: 720 (M$^+$, 100%).

5-(4-Aminophenyl)-10,15,20-tri-(4-hydroxyphenyl)-porphyrin (22) (General Procedure C). To a stirred solution of **20** (1 equiv, 100 mg, 0.139 mmol) in freshly distilled DCM (50 mL) was added boron tribromide (15 equiv, 197 μL, 2.08 mmol). The reaction was allowed to proceed under argon for 17 h at room temperature. The reaction mixture was cooled to 0 °C then treated with water (2.0 mL) and allowed to warm to room temperature for a further 1 h. The reaction was then concentrated in vacuo and redissolved in a (9:1) mixture of DCM/triethylamine (100 mL). The solution was washed with water (3 × 100 mL) and saturated brine (100 mL), the organic layer separated, dried (Na_2SO_4), and then concentrated in vacuo. The crude purple solid was then chromatographed, eluting with DCM/MeOH (5:1) to afford the title compound as a purple crystalline solid (72 mg, 77%); $R_f = 0.48$ (DCM/MeOH, 9:1); mp >350 °C (dec); UV−vis (MeOH) λ_{max}, nm: 423, 517, 554, 592, 651; ^{1}H NMR (270 MHz, DMSO-d_6, δ): 10.00 (br s, 3H, *OH*), 8.91−8.84 (m, 8H *β-H*), 7.99 (m, 6H, $J = 8$ Hz, *10+15+20-o-Ar*), 7.85 (m, 2H, $J = 8$ Hz, *5-o-Ar*), 7.21 (m, 6H, $J = 8$ Hz, *10+15+20-m-Ar*), 7.00 (m, 2H, $J = 8$ Hz, *5-m-Ar*), 5.60 (br s, 2H, *NH*), −2.85 (br s, 2H, *NH*); ^{13}C NMR (67.5 MHz, DMSO-d_6, δ): 157.4, 148.6, 135.4, 131.9, 131.8, 131.6, 131.5, 131.2, 131.1, 131, 130.9, 128.4, 121.2, 119.8, 119.6, 114.9, 113.9, 112.5; MALDI-MS *m/z*: 677 (M$^+$, 100%).

5-(4-Isothiocyanatophenyl)-10,15,20-tri-(4-hydroxyphenyl)porphyrin (16). Porphyrin **22** was converted into isothiocyanate **16** following general procedure B. The solid was chromatographed, eluting with DCM/MeOH (9:1) and gave the required product as a purple crystalline solid (48 mg, 91%); $R_f = 0.4$ (DCM/MeOH, 9:1); mp >350 °C (dec); UV−vis (MeOH) λ_{max}, nm: 422, 519, 556, 590, 651; ^{1}H NMR (270 MHz, DMSO-d_6, δ): 9.99 (br s, 3H, *OH*), 8.89−8.78 (m, 8H, *β-H*), 8.27 (m, 2H, $J = 8$ Hz, *5-o-Ar*), 7.99 (m, 6H, $J = 8$ Hz, *10+15+20-o-Ar*), 7.86 (m, 2H, $J = 8$ Hz, *5-m-Ar*), 7.20 (m, 6H, $J = 8$ Hz, *10+15+20-m-Ar*), −2.91 (br s, 2H, *NH*); ^{13}C NMR (68 MHz, DMSO-d_6, δ): 162.3, 161.2, 158.4, 141.5, 140.9, 137.4, 137.3, 135.8, 135.5, 135.4, 134.4, 131.8, 131.7, 131.3, 129.9, 124.5, 120.6, 120.3, 120, 119.6, 117.6, 114.1, 113.9, 105.7, 104.8. FAB-HRMS Anal. Calcd. for $C_{45}H_{29}N_5O_3S$ ([M + H]$^+$), 720.2069; found, 720.2095.

5-(4-Acetamidophenyl)-10,15,20-tri-(3,5-dimethoxyphenyl)porphyrin (19). Porphyrin **19** was synthesized according to the procedure of Adler et al. (*29*). The crude reaction mixture was purified by chromatography, eluting with DCM/ethyl acetate (4:1) and afforded the title compound as a purple crystalline solid (1.55 g, 9%); $R_f = 0.50$ (DCM/ethyl acetate, 4:1); mp >350 °C (dec); UV−vis (DCM) λ_{max}, nm: 421, 515, 551, 590, 650; ^{1}H NMR (270 MHz, $CDCl_3$, δ): 10.42 (br s, 1H, *NH*), 8.93−8.86 (m, 8H, *β-H*), 7.44 (m, 2H, $J = 8$ Hz, *5-o-Ar*), 7.38 (s, 6H, *10+15+20-o-Ar*), 7.07 (m, 2H, $J = 8$ Hz, *5-m-Ar*), 6.99 (s, 3H, *10+15+20-p-Ar*), 3.93 (s, 18H, *10+15+20-m-OCH_3*), 2.23 (s, 3H, CH_3), −2.96 (br s, 2H, *NH*); ^{13}C NMR (68 MHz, $CDCl_3$, δ): 168.7, 167.9, 160.3, 158.6, 143.1, 139.3, 135.6, 134.5, 131.8, 131.4, 131.3, 131.1, 129, 120, 119.6, 119.4, 119, 117.3, 113.5, 103.9, 23.9, 20.4; MALDI-MS *m/z*: 852 (M$^+$, 100%).

5-(4-Aminophenyl)-10,15,20-tri-(3,5-dimethoxyphenyl)porphyrin (21). Porphyrin **21** was synthesized by hydrolysis of **19** following general procedure A. The crude purple solid was purified by chromatography, eluting with DCM/ethyl acetate (4:1) and gave the desired product as a purple crystalline solid (426 mg, 89.7%); $R_f = 0.89$ (DCM/ethyl acetate, 4:1); mp >350 °C (dec); UV−vis (DCM) λ_{max}, nm: 422, 517, 553, 593, 651; ^{1}H NMR (270 MHz, $CDCl_3$, δ): 8.93 (m, 8H, *β-H*), 7.98 (m, 2H, $J = 8$ Hz, *5-o-Ar*), 7.40 (s, 6H, *10+15+20-o-Ar*), 7.06 (m, 2H, $J = 8$ Hz, *5-m-Ar*), 6.90 (s, 3H, *10+15+20-p-Ar*), 3.96 (s, 18H, *10+15+20-m-OCH_3*), −2.80 (br s, 2H, *NH*); ^{13}C NMR (68 MHz, $CDCl_3$, δ): 159.3; 146.5, 144.6, 144.5, 136.1, 132.7, 131.4, 130.2, 121.4, 120.1, 119.8, 115.7, 114.3, 113.9, 100.6, 20.13; MALDI-MS *m/z*: 809 (M$^+$, 100%).

5-(4-Aminophenyl)-10,15,20-tri-(3,5-dihydroxyphenyl)porphyrin (23). Porphyrin **21** was converted into **23** following general procedure C. The solid residue was chromatographed, eluting with $CHCl_3$/MeOH (9:1) to afford the title compound as a purple crystalline solid (667 mg, 75%); $R_f = 0.19$ ($CHCl_3$/MeOH, 9:1); mp >350 °C (dec); UV−vis (DCM) λ_{max}, nm: 422, 517, 553, 592, 649; ^{1}H NMR (270 MHz, DMSO-d_6, δ): 9.75 (br s, 6H, *10+15+20-m-OH*); 8.94 (s, 8H, *β-H*), 7.87 (m, 2H, $J = 8$ Hz, *5-o-Ar*), 7.06 (s, 6H, *10+15+20-o-Ar*), 7.02 (m, 2H, $J = 8$ Hz, *5-m-Ar*), 6.69 (s, 3H, *10+15+20-p-Ar*), 5.56 (br s, 2H, NH_2), −2.95 (br s, 2H, *NH*); ^{13}C NMR (68 MHz, DMSO-d_6, δ): 156.5, 156.4, 148.6, 142.9, 142.8, 135.5, 130.7−131.3, 128.3, 127.5, 121.5, 119.7, 119.2, 114.1, 113.9, 112.5, 102.3; MALDI-MS *m/z*: 726 (M$^+$, 100%).

5-(4-Isothiocyanatophenyl)-10,15,20-tri-(3,5-dihydroxyphenyl)porphyrin (17). Porphyrin **17** was syn-

thesized from **23** using general procedure B. The solid was purified by chromatography, eluting with $CHCl_3$/MeOH (9:1) which afforded the required product as a purple crystalline solid (67.5 mg, 64%); $R_f = 0.29$ ($CHCl_3$/MeOH, 9:1); mp >350 °C (dec); UV−vis (MeOH) λ_{max}, nm: 422, 516, 552, 592, 648; ^{1}H NMR (270 MHz, 25% CD_3OD in $CDCl_3$, δ): 9.0−8.76 (m, 8H, *β-H*), 8.19 (m, 2H, $J = 8$ Hz, *5-o-Ar*), 7.64 (m, 2H, $J = 8$ Hz, *5-m-Ar*), 7.12 (s, 6H, *10+15+20-o-Ar*), 6.77 (s, 3H, *10+15+20-p-Ar*); ^{13}C NMR (68 MHz, 25% CD_3OD in $CDCl_3$, δ): 155.8, 143.6, 142, 141.2, 136.1, 135.2, 134, 130.9, 123.9, 120.1, 120, 119.9, 117.6, 114.7, 107.1, 101. ES-HRMS Anal. Calcd. for $C_{45}H_{29}N_5O_6S$ ([M + H]$^+$), 768.1914; found, 768.1908.

5-(4-Acetamidophenyl)-10,15,20-tri-(4-pyridyl)porphyrin (25). Porphyrin **25** was synthesized by Adler condensation (*29*). The crude product was chromatographed, eluting with $CHCl_3$/MeOH (19:1), giving the required product as a purple crystalline solid (526 mg, 4%); $R_f = 0.22$ ($CHCl_3$/MeOH, 19:1); mp >350 °C (dec); UV−vis (DCM) λ_{max}, nm: 418, 514, 548, 587, 644; ^{1}H NMR (270 MHz, $CDCl_3$, δ): 10.35 (br s, 1H, *NH*), 9.10−9.15 (m, 6H, *10+15+20-m-Pyr*), 9.06−8.84 (m, 8H, *β-H*), 8.28−8.21 (m, 8H, *5-o-Ar* and *10+15+20-o-Pyr*), 8.07 (m, 2H, $J = 8$ Hz, *5-m-Ar*), 2.49 (s, 3H, CH_3), −2.79 (br s, 2H, *NH*); ^{13}C NMR (68 MHz, $CDCl_3$, δ): 175.2, 150.1, 149.6, 149.4, 149.3, 149, 148.2, 145.1, 142.5, 140.1, 134.7, 123.9, 123.8,123.3, 122.2, 122.1, 121.5, 121.1, 117.9, 110.2, 110.1, 106.9, 26.8; MALDI-MS *m/z*: 675 (M$^+$, 100%).

5-(4-Aminophenyl)-10,15,20-tri-(4-pyridyl)porphyrin (26). Porphyrin **25** was converted into the required product following general procedure A. The crude purple solid was purified by chromatography, eluting with $CHCl_3$/MeOH (20:1), and gave the product as a purple crystalline solid (422 mg, 90%); $R_f = 0.31$ ($CHCl_3$/MeOH, 20:1); mp >350 °C (dec); UV−vis (DCM) λ_{max}, nm: 418, 515, 552, 592, 653; ^{1}H NMR (270 MHz, $CDCl_3$, δ): 9.04 (m, 6H, $J = 5$ Hz, *10+15+20-m-Pyr*), 9.01−8.80 (m, 8H, *β-H*), 8.16 (m, 6H, $J = 5$ Hz, *10+15+20-o-Pyr*), 7.98 (m, 2H, $J = 8$ Hz, *5-o-Ar*), 7.08 (m, 2H, $J = 8$ Hz, *5-m-Ar*), 4.09 (br s, 2H, NH_2), −2.86 (br s, 2H, *NH*); ^{13}C NMR (68 MHz, $CDCl_3$, δ): 150, 149.8, 148.5, 148.4, 2, 146.5, 135.9, 131.7, 129.5, 122.7, 117.9, 117.4, 116.7, 113.6; FAB-MS *m/z*: 633 (M$^+$, 100%).

5-(4-Isothiocyanatophenyl)-10,15,20-tri-(4-pyridyl)-porphyrin (27). Porphyrin **26** was converted to **27** utilizing general procedure B. The crude product was dissolved in a minimum amount of chloroform and chromatographed, eluting with $CHCl_3$/MeOH (49:1) which yielded the title compound as a purple crystalline solid (104 mg, 98%); $R_f = 0.57$ ($CHCl_3$/MeOH, 49:1); mp >350 °C (dec); UV−vis (DCM) λ_{max}, nm: 417, 514, 548, 587, 643; ^{1}H NMR (270 MHz, $CDCl_3$, δ): 9.06 (m, 6H, $J = 5$ Hz, *10+15+20-m-Pyr*), 8.67 (br s, 8H, *β-H*), 8.21−8.15 (m, 8H, *10+15+20-o-Pyr* and *5-o-Ar*), 7.65 (m, 2H, $J = 8$ Hz, *5-m-Ar*), −2.91 (br s, 2H, *NH*); ^{13}C NMR (68 MHz, $CDCl_3$, δ): 149.8, 148.4, 140.6, 136.9, 135.4, 131.6, 129.3, 124.7, 119.7, 117.6, 117.4; FAB-MS *m/z*: 675.7 (M$^+$, 100%). ES-HRMS Anal. Calcd. for $C_{42}H_{26}N_8S$ ([M + H]$^+$), 675.2079; found, 675.2078.

5-(4-Isothiocyanatophenyl)-10,15,20-tri-(4-*N*-methylpyridiniumyl)porphyrin triiodide (24). To a solution of **27** (50 mg, 74 μmol) in anhydrous DMF (10 mL, distilled from CaH_2, 0.1 Torr) was added iodomethane (1 mL, 16 mmol). The reaction was stirred under argon for 3 h at room temperature. Upon completion of the reaction, excess DMF was removed in vacuo (0.1 Torr) at 30−40 °C to yield the title compound as a lustrous purple solid (77 mg, 95%); $R_f = 0.32$ (5 M KNO_3-(aq)/MeCN, 1:4); mp >350 °C (dec); UV−vis (H_2O) λ_{max}, nm: 423, 520, 585; ^{1}H NMR (270 MHz, DMSO-d_6, δ): 9.50 (m, 6H, $J = 6$ Hz, *10+15+20-m-Pyr*), 9.16 (m, 8H, *β-H*), 9.03 (m, 6H, $J = 6$ Hz, *10+15+20-o-Pyr*), 8.32 (m, 2H, $J = 8$ Hz, *5-o-Ar*), 7.96 (m, 2H, $J = 8$ Hz, *5-m-Ar*), 4.74 (br s, 9H, *CH$_3$-pyr*), −3.03 (br s, 2H, *NH*); ^{13}C NMR (67.5 MHz, DMSO-d_6, δ): 156.4, 156.3, 144.1, 139.7, 135.4, 134.7, 132, 130.6, 124.8, 121.1, 115.3, 114.7, 47.9; FAB-MS *m/z*: 719 ([M + H$^+$], 100%), 704 (M − *CH$_3$*, 26%), 689 (M − *2xCH$_3$*, 20%), 674 (M − *3xCH$_3$*, 5%). ES-HRMS Anal. Calcd. for $C_{45}H_{35}N_8S$ ([M + H]$^+$), 719.2705; found, 719.2686.

5-(4-Isothiocyanatophenyl)-10,15,20-tris(4-*N*-methylpyridiniumyl)porphyrin trichloride (28). To a solution of **24** (30 mg, 27 μmol) in anhydrous MeOH (30 mL) was added Amberlite IRA 400 (1.0 g), and the mixture was stirred for 1 h at room temperature. Amberlite IRA 400 resin was filtered under vacuum, and the porphyrin filtrate was recovered, dried (Na_2SO_4), and concentrated in vacuo to yield the required product as a purple crystalline solid (22 mg, 96%). Porphyrins **24** and **28** were distinguished only by their respective solubilities in water.

5-(4-Fluorenylmethylaminophenyl)-15-(4-methoxyphenyl)porphyrin (35). To a stirred solution of porphyrin **6** (28 mg, 55 μmol) in anhydrous 1,4-dioxane (2.5 mL) was added solid sodium hydrogen carbonate (6 equiv, 28 mg, 0.33 mmol). To this mixture was then added a solution of 9-fluorenylmethyl chloroformate (2 equiv, 0.11 mmol, 28.5 mg) in 1,4-dioxane (0.5 mL) under N_2. The reaction flask was covered with aluminum foil to exclude light and stirred at room temperature for a period of 3 h. At this time, the reaction was complete (as monitored by TLC). The 1,4-dioxane was removed in vacuo and the residue partitioned between water (25 mL) and DCM (2 × 25 mL). The combined organic extracts were washed with saturated brine (25 mL), then dried (Na_2SO_4), filtered, and concentrated in vacuo. The required porphyrin was obtained by chromatography, eluting with DCM. The desired porphyrin was obtained as purple crystals (38 mg, 95%); $R_f = 0.39$ (DCM); mp 292−295 °C (dec); UV−vis (DCM) λ_{max} (relative intensity), nm: 410 (1.0), 505 (0.042), 541 (0.02), 578 (0.015), 633 (0.01); fluorescence (DCM): λ_{max} 635 nm (λ excitation = 410 nm); ^{1}H NMR (270 MHz, $CDCl_3$, δ): 10.35 (s, 2H, *10+20-H*), 9.69 (br s, 1H, *NH*), 9.44 (d, 4H, $J = 4.8$ Hz, *β-H*), 9.12 (d, 4H, $J = 4.8$ Hz, *β-H*), 8.20−8.17 (m (overlapping), 4H, $J = 8.1$ Hz, *5+15-o-Ar*), 7.85 (m, 4H, *5+15-m-Ar*), 7.76−7.66 (m, 2H, *fluoreno-Ar*), 7.51−7.30 (m, 6H, *fluoreno-Ar*), 4.69 (d, 2H, $J = 7.2$ Hz, CH_2), 4.30 (t, 1H, $J = 7.2$ Hz, *CH*), 4.13 (s, 3H, CH_3), −3.15 (br. s, 2H, *NH*); MALD-MS *m/z*: 731.5 ([M + H]$^+$, 100%), 508.3 ([M − FMOC + 2]$^+$, 50%). Preparation of Bioconjugates: 2,3-Dihydroxy-5-(4-methoxyphenyl)-15-(4-isothiouridophenyl)chlorin-BSA Bioconjugate (General Procedure D). In a typical bioconjugation procedure, a stock solution of the 2,3-dihydroxy-5-(4-methoxyphenyl)-15-(4-isothiocyanatophenyl)chlorin 29 (higher R_f regioisomer) in anhydrous DMSO (10 mg mL^{-1}) was prepared. To a stirred solution of BSA (1 equiv, 10 mg, 0.15 μmol) in a sodium bicarbonate/sodium carbonate buffer (1 mL, pH 9.2) was added a solution of the isothiocyanate (10 mg mL^{-1} stock solution; 10 equiv, 88 μL, 1.52 μmol). The reaction vessel was protected from light and agitated for a period of 16 h at room temperature. The bioconjugate was purified by gel-filtration using a sodium phosphate buffer (0.5 M, pH 7.0) pre-equilibrated PD-10 gel filtration column, eluting with the same buffer.

BSA-Haematoporphyrin Bioconjugate. Haematoporphyrin (18.0 mg, 30 μmol), *N*-hydroxysuccinimide (6.9 mg, 60 μmol), and DCC (12.5 mg, 60 μmol) in anhydrous DMSO (1.0 mL) were stirred overnight at room temperature to facilitate the formation of the activated NHS-ester(s) of haematoporphyrin. To a solution of BSA (10 mg, 0.15 μmol) in sodium bicarbonate/sodium carbonate buffer (1 mL, pH 9.2) was added, from the stock solution, haemotoporphyrin-NHS (10 equiv, 50 μL, 1.52 μmol). The reaction vessel was protected from light and agitated, at room temperature, for a period of 16 h. The bioconjugate was purified by gel-filtration using a sodium phosphate buffer (0.5 M, pH 7.0) pre-equilibrated PD-10 gel filtration column, eluting with the same buffer.

Characterization of Bioconjugates: Gel Electrophoresis. Bioconjugates were characterized by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE), which were performed for 45 min at 200 V and 400 mA. Stacking gels of 4% were used, and 12% or 15% separating gels were used for BSA and avidin, respectively. The running buffer used was 0.1% (w/v) SDS in a 125 mM Tris-gylcine buffer (pH 8.9). Electrophoresis was performed under nonreducing conditions with samples containing 25% Tris-HCl (125 mM, pH 6.8), 20% (w/v) glycerol 4% (w/v) and 0.03% bromophenol blue. For SDS−PAGE analysis of avidin bioconjugates, the protein solution, in loading buffer, was heated to 95 °C for 1 min. This was undertaken to ensure that all avidin entered the gel (without this, little avidin bioconjugate entered the gel because of the high isoelectric point of avidin, which resulted in extensive aggregation in the loading gel). After electrophoresis, gels were first photographed under 360 nm UV illumination using a Kodak instamatic camera fitted with a 570 nm long pass filter and then silver-stained using the method of Heukenshoven and Dernick (*27*).

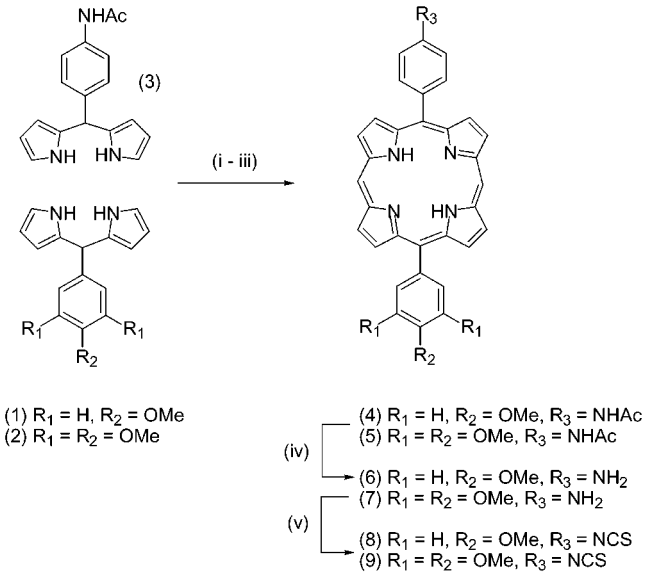
Noncovalent-Binding Studies: Utilizing Chemically Unreactive Fluorescent Probe/Protein Mixtures. To investigate the levels of NCB typical for these potential fluorescent probes, we undertook the synthesis of chlorin **39** and bacteriochlorin **41** examples. The chlorin **39** and bacteriochlorin **41** were then mixed with BSA independently using general procedure D. The colored bands obtained from all PD-10 gel permeation columns were analyzed by UV−vis spectroscopy. Similar mixtures containing unreactive fluorescein and haemotoporphyrin derivative were also analyzed using the same procedure, to establish a comparison of their possible NCB interactions with proteins. SDS−PAGE analysis was used to show that the removal of noncovalently bound fluorescent probes from proteins was possible.

Hela Cell Transfer Experiment Utilizing Crude Bioconjugates and NCB Fluorescent Probe/Protein Mixtures. Further investigation of the potential problems associated with the use of impure bioconjugates, that contain a NCB fluorescent probe, was undertaken with the use of epithelial human carcinoma cell line (HeLa). Products, obtained by mixing capped chlorin **39** and bacteriochlorin **41** with BSA, were purified by gel permeation chromatography (PD-10) and adjusted to varying concentrations (2.5−25 mg mL^{-1}) made up to 3 mL, and their fluorescence intensity was measured. Similar mixtures were then made up to the same final concentration, but to each was added 500 000 HeLa cells. The mixtures were then agitated for 5 min to allow any probe transfer to occur. Each sample was centrifuged at 1000*g* for 3 min, and the fluorescence of the supernatant was remeasured. Finally, the pellets of HeLa cells were resuspended by agitation, and a final fluorescence measurement was taken.

Purification of Bioconjugates: Using SDS−PAGE Electroelution. Following gel permeation chromatography, the BSA bioconjugates were further purified by SDS−PAGE to remove a NCB fluorescent probe. The purified bioconjugates were then recovered using a Millipore centrilutor microelectroeluter (Fisher Life Sciences, U.K.), this device incorporates removable Centricon filter units so as to allow electroeluted proteins to be washed successively with PBS prior to concentration by centrifugation. YM-30 Centricon concentrators were used for BSA bioconjugates. Electroelution was achieved using 200 V (50 mA) and took between 2 and 3 h. The concentrated, purified bioconjugates were then collected in the retentate vials of the filter units by inversion and centrifugation. Sodium azide (2 M, 20 mL) was added, and the bioconjugates were stored at 4 °C.

Using the Acetone Precipitation Method. Initial attempts at the removal of the NCB fluorescent probe were undertaken using the procedure of Hamblin et al. (*15*). Briefly, this involved the slow addition of ACS grade acetone (10*x*) to the crude bioconjugate preparations at 4 °C (approximate concentration of 2.5 mg mL^{-1}). After 6 h, the suspension was centrifuged at 4000*g*, and the supernatant was removed. The pellet was resuspended in the same volume of acetone, and the centrifugation was repeated. After a further three washes, the bioconjugates were redissolved in 1 mL of PBS and exhaustively dialyzed against 2 L of PBS for 2 days to remove all traces of acetone. The semipurified bioconjugates were then analyzed by SDS−PAGE and TLC (1:1 mixture of 10% aqueous ammonium chloride and MeOH).

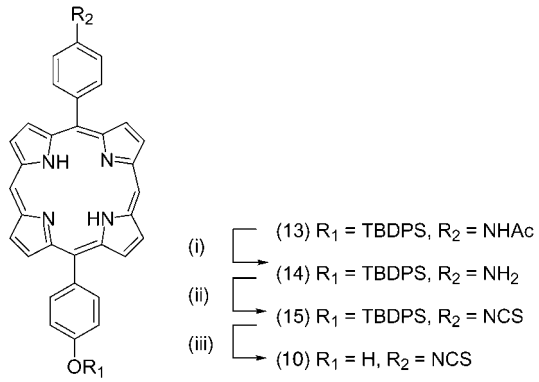
Confocal Laser Scanning Microscope Analysis of BSA Bioconjugates. A preliminary examination of the intracellular localization of BSA bioconjugates was undertaken using fluorescence microscopy. The HeLa cell line was chosen for the microscope studies, and a number of 5 cm culture dishes, with 22 × 22 mm^2 microscope cover slips inside, were seeded with 5×10^5 HeLa and allowed to grow in 5.0 mL media for 2 days until the monolayer of cells generated was about 75% confluent. Further incubation with a range of concentrations of BSA bioconjugates were then undertaken for 30 min prior to cell fixing with 4% formaldehyde and further washings. The cover slips were then placed on histological slides with PBS and fixed along their edges with grease. A Biorad Radiance-2000 confocal laser scanning microscope was then used with argon-ion laser excitation at 514 nm, fluorescent images being collected after passage through a 570 or 640 nm long pass filter.



RESULTS AND DISCUSSION

The majority of attempts at covalently conjugating porphyrin type molecules with biological targeting agents, such as serum albumins (*12*−*15*), monoclonal antibodies (*16*−*20*), and lipoproteins (*21*, *22*), have generally involved the use of carbodiimide or NHS ester-based coupling methodologies. These coupling methods, however, have their drawbacks; carbodiimide-mediated conjugations are slow and invariably lead to extensive loss of porphyrin as the stable *N*-acyl urea derivative; also, both methods can lead to cross-linking when using naturally occurring porphyrins containing multiple carboxyl groups. To overcome these drawbacks, we have become interested in the synthesis and elaboration of a range of synthetic porphyrin derivatives for use in bioconjugation. These derivatives, while still containing the important porphine core, have allowed us to produce fluorescent probes and PDT agents containing a single reactive isothiocyanato (ITC) functionality (*26*, *28*). Although this eliminates the problems associated with cross-linking, another problem has become apparent during our studies. Bioconjugate preparation using tetrapyrrole derivatives invariably result in the formation of noncovalent complexes (*13*, *16*, *17*). For lipophilic derivatives, the level of NCB can significantly exceed that of covalent binding. The NCB complexes formed between lipophilic or amphiphilic porphyrins and proteins are stable and cannot be separated using conventional gel permeation (size exclusion) chromatography. Clearly, the use of such NCB complexes can lead to loss of specificity because of chromophore transfer to serum proteins or cellular membranes. We therefore set out to study, and address, the problem of NCB in the synthesis of photoactive bioconjugates.

Initial Synthetic Studies on Diphenylporphyrin (DPP)-Based Molecular Probes. We have recently been developing DPP's as core structures for the synthesis of imaging agents and PDT photosensitizers. Using methodologies developed within our laboratories (*26*, *28*), we initially synthesized diphenylporphyrin isothiocyanates **8** and **9** bearing different methoxy substitution patterns. This was undertaken in an attempt to induce solubility of the reactive porphyrin isothiocyanate (PITC) in DMSO or DMF "stock" solutions commonly used in protein bioconjugations (most lipophilic porphyrins are almost completely insoluble in DMSO or DMF and completely insoluble in aqueous bioconjugation buffers). Separate acid-catalyzed condensations of the dipyrromethanes **1** and **2** with the *N*-acetyl derivative **3** and trimethyl orthoformate gave the corresponding monoacetamidoporphyrins **4** and **5** (Scheme 1). Hydrolysis of **4** and **5** followed by treatment of the resulting amines **6** and **7** with 1,1′-thiocarbonyldi-2(1*H*)-pyridone (TDP) (*4*, *5*) afforded PITCs **8** and **9**. PITC **8** was found to be completely insoluble in DMSO, DMF, MeOH, and EtOH alike, although PITC **9** was soluble in DMSO. DMSO cosolvent stock solution of **9** was therefore prepared at a standard concentration of 10 mg mL^{-1}, and a 100 μL aliquot of this solution was slowly added to 1 mL of a bicarbonate buffer at pH 9.2, to simulate a typical bioconjugation procedure. Unfortunately, the addition of the cosolvent stock solution to the aqueous buffer resulted in the immediate precipitation of porphyrin. Although PITC **9** was soluble in DMSO and DMF, the inclusion of two extra methoxy groups apparently did not represent a large enough increase in polarity to allow bioconjugation in aqueous media.



As bioconjugations involving the isothiocyanate group are often carried out in carbonate/bicarbonate buffers

Scheme 1[a]

[a] Conditions: (i) trichloroacetic acid, trimethylorthoformate, DCM, RT, 3.5 h; (ii) pyridine, RT, 16 h; (iii) air, RT, 3 h; (iv) 5 M HCl(aq), 80 °C, 3 h; (v) TDP, DCM, RT, 2 h.

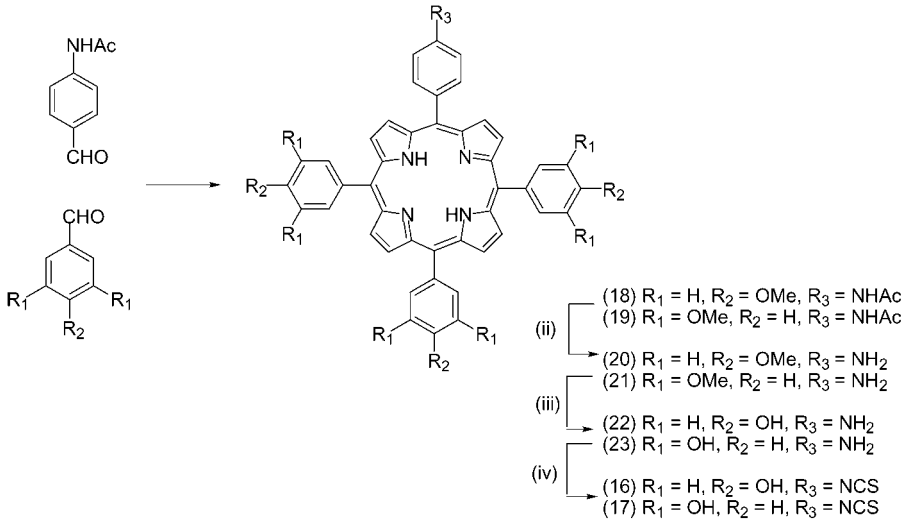
Scheme 2[a]

[a] Conditions: (i) 5 M HCl(aq), 80 °C, 3 h; (ii) TDP, DCM, RT, 5 h; (iii) TBAF, DCM, RT, 1 h.

(typical pH = 9.2), we rationalized that the synthesis of the monophenoxy PITC derivative **10** might give rise to enhanced solubility in basic buffer systems, because of its partial ionization at this pH (pK_a phenol = 10). The condensation of the phenolic dipyrromethane **11** with **3** was carried out in a manner analogous to that in Scheme 1. Yields of unsymmetrically substituted porphyrin from this reaction were low (<1%), and the high polarity of the required acetamidohydroxy-DPP made it difficult to separate chromatographically. We therefore sought an alternative method for the synthesis of this potentially useful DPP (Scheme 2).

The hydroxy group of dipyrromethane **11** was protected with the *tert*-butyldiphenylsilyl (TBDPS) group using standard methodology (TBDPSCl/imidazole in DMF) to afford TBDPSO-dipyrromethane **12**, which was then condensed as previously with dipyrromethane **3**. The resulting unsymmetrically substituted acetamidoporphyrin **13** was formed in unusually high yield (42%), possibly because of the presence of the bulky TBDPS group greatly reducing self-condensation. Regioselective hydrolysis of DPP **13** gave the corresponding amine **14**, with no significant hydrolysis of the TBDPS group, and treatment of **14** with TDP gave the corresponding PITC derivative **15**. Deprotection of **15** was carried out in DCM with tetrabutylammonium fluoride (TBAF) and gave PITC **10** without any degradation of the isothiocyanato functionality. Unfortunately, PITC **10** was found to be insoluble in basic buffer solutions. However, **10** was found to be readily soluble in DMSO and, to a lesser extent, soluble in DMF. When a DMSO cosolvent stock solution of **10** (100 μL, 25.7 mM) was added to a bicarbonate buffer solution, as described for **9**, the porphyrin remained in solution for 2−3 min before visible precipitation commenced. The use of increased quantities of DMSO cosolvent (up to a final concentration of 30% DMSO in buffer) produced no noteworthy increase in the solubility of **10**. Much to our disappointment, the use of 3,4- and 3,5-dihydroxy derivatives of **10** (data not given) also showed no significant improvement upon the solubility observed for **10.** Despite its sparing solubility under aqueous conditions, the bioconjugation of **10** with BSA was investigated and is discussed later.

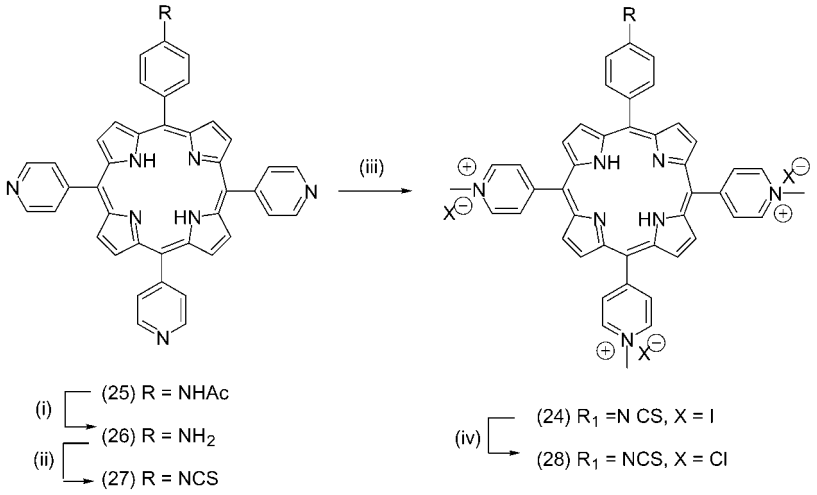
Synthetic Studies Toward Water-Soluble TPP Isothiocyanates. The synthesis of TPP derivatives has been developed over many years and now allows for routine access to multigram quantities of functionalized porphyrins. In our initial studies toward TPP based PITCs, we synthesized a number of hydroxy analogues, which included **16** and **17**, to allow for a direct comparison with hydroxy DPP counterparts under bioconjugation conditions (Scheme 3). PITC **16** was found to be readily soluble in DMSO and DMF but did not retain solubility when added to aqueous buffer, with precipitation detected after only 10 min. Fortunately, hexahydroxy PITC **17** remained completely soluble when dissolved in a typical bioconjugation solution (10% DMSO/pH 9.2 buffer) for 16 h at 4 °C.



Synthesis of Water-Soluble TPP Isothiocyanate. As a logical extension of our search for highly hydrophilic PITCs, we envisaged that combining three water-solubilizing *N*-methylpyridinium cations and a reactive isothiocyanate group, as in PITC **24**, would give full water solubility and allow facile bioconjugation, with a minimum loss of label and reduce, if not eliminate, NCB. The synthetic route to the tri-(*N*-methylpyridiniumyl)-PITCs **24** and **28** is shown in Scheme 4.

Synthetic Studies into the Generation of Wavelength-Shifted Porphyrin Derivatives Suitable for Bioconjugation: Formation of Chlorins and Bacteriochlorins by OsO_4-Mediated Dihydroxylation of Porphyrins. The synthesis of porphyrin derivatives such as chlorins and bacteriochlorins offers easy access to molecules which exhibit favorable optical properties and may be beneficial in PDT and fluorescence imaging applications. Investigations into the use of porphyrin derivatives for conversion to wavelength-shifted dihydroxychlorins and tetrahydroxybacteriochlorins by osmium tetroxide-mediated oxidation were therefore undertaken. Unfortunately, because of the relative inactivity of the TPP β-positions toward OsO_4, presumably because of steric effects, reactions were found to take many weeks using standard conditions (*9*, *10*) and gave very low yields. To overcome these problems, and as a result of recent work within our laboratories (*25*, *26*, *28*), we turned our attention back to DPP derivatives. DPPs were found to undergo facile dihydroxylation (*26*), giving total yields of diphenylchlorin diols (DPCH) and diphenylbacteriochlorin tetrols (DPBC), in many cases above 80%.

Scheme 5 shows the synthetic pathway employed for the preparation of the reactive chlorin- and bacteriochlorin-isothiocyanato derivatives **29** and **30**.



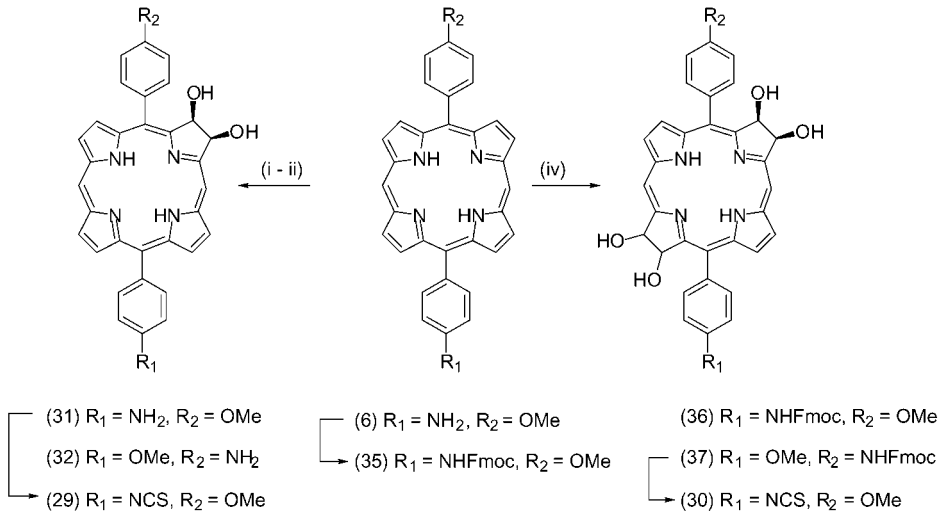
Generation of BSA Bioconjugates Using PITC Derivatives. A comparative bioconjugation study of all

Scheme 3[a]

[a] Conditions: (i) propionic acid, 90 °C, 0.5 h; (ii) 5 M HCl(aq), 80 °C, 3 h; (iii) BBr_3, DCM, 17 h; (iv) TDP, DCM, RT, 2 h.

Scheme 4[a]

[a] Conditions: 5 M HCl(aq), 80 °C, 3 h; (ii) TDP, DCM, RT, 2 h; (iii) MeI, DCM, 3 h; (iv) Amberlite IRA 400, MeOH, RT, 1 h.



PITC derivatives with BSA, as a model protein, was now undertaken. Aliquots, containing 10 equiv of PITCs were taken from 10 mg mL^{-1} stock solutions in DMSO and added dropwise to 10 mg samples of BSA that were predissolved and equilibrated in a carbonate/bicarbonate buffer (pH = 9.2). Final concentrations of DMSO in buffer were approximately 10%. Examination of solubility clearly indicated an encouraging trend, with the PITCs increasing solubility in DMSO and DMF cosolvent (seen from **9**, **10**, **16**, and **17**). The tri-(*N*-methylpyridiniumyl)-Cl-PITC **28** was found to be completely soluble under the bioconjugation conditions used for isothiocyanates. An examination of the solubility characteristics of the chlorin and bacteriochlorin PITCs **29** and **30** during typical bioconjugations has shown that they lie somewhere between that of the tri- and hexa-hydroxy substituted TPPs **16** and **17**. On these occasions, precipitation of the reactive PITC derivatives did not visibly occur for up to 30 min. Therefore, the use of OsO_4-mediated oxidation of DPPs has the double advantage of producing products that contain both favorable solubility and also improved spectroscopic characteristics.

Initial purification of bioconjugates by gel permeation chromatography (PD-10) also indicated that as the polarity, and therefore the hydrophilicity, of the reactive PITC increased, so did the amount of nonbioconjugated material retained at the top of the gel column. This has implications for the use of lipophilic porphyrins in bioconjugation and indicates that resulting bioconjugates will contain significant proportions of NCB porphyrins. For PDT applications, the presence of some NCB porphyrin "complex" does not necessarily negate activity (*13*, *16*, *17*); however, to maximize specificity of the photosensitizer conjugate, it is clearly desirable to minimize this parameter. The preceding argument applies to an even greater extent for fluorescence imaging applications.

Characterization of BSA Bioconjugates. SDS−PAGE analysis of a range of BSA biconjugates, obtained after gel permeation chromatography, has shown that bioconjugations using all but the most water-soluble PITC **28** result in the formation of substantial amounts of PITC/protein NCB complex. Figure 1 shows a typical SDS−PAGE analysis of a conjugate formed from BSA and PITC **17**. Qualitative analysis of image A (lanes 1 and 2) clearly shows the presence of NCB free porphyrin that has not been removed by gel permeation chromatography. A similar scenario was also evident from SDS−PAGE analysis of all other BSA bioconjugation mixtures, in varying degrees, after initial gel permeation.

Investigations of NCB Associated with the Use of Lipophilic PITC in Protein Bioconjugations. To investigate, in more detail, the problems that proteins

Scheme 5[a]

[a] Conditions: (i) 2.5 equiv of OsO_4, 10% pyridine/$CHCl_3$, RT, 72 h; (ii) H_2S(g), RT, 5 min; (iii) TDP, DCM, RT, 2 h; (iv) FmocCl, $NaHCO_3$, 1,4-dioxane, RT, 3 h; (v) 5.0 equiv of OsO_4, 1% pyridine/1,4-dioxane, RT, 72 h; (vi) piperidine, 25% MeOH/DCM, RT, 3 h; (vii) TDP, DCM, RT, 2 h.

with associated lipophilic NCB porphyrin can cause, DPP **4**, DPCH **39**, and DPBC **41** were prepared. These unreactive probes were then mixed with BSA separately under standard bioconjugating conditions and passed through gel permeation columns in order to simulate typical bioconjugation protocols. The colored bands eluted were analyzed by UV−vis spectroscopy and indicated the presence of a NCB probe (DPP 412 nm; DPCH 411 nm; DPBC 376 nm) and protein (282 nm). BSA mixtures contained approximately 2, 1, and 0.6 mol of NCB−DPP, DPCH, and DPBC per mole of protein, respectively. With typical bioconjugations giving degrees of labeling (DOL) of between 2.5 and 5 mol of porphyrin per mole protein in total; this level of NCB represents a significant problem to be overcome. For comparison, haematoporphyrin-NHS ester and fluorescein isothiocyanate (FITC) gave levels of NCB of 0.75 and 0.1 mol of chromophore per mole protein, respectively. It therefore appears that NCB is a much less significant problem for FITC bioconjugates (SDS−PAGE analysis of crude FITC bioconjugates showed almost negligible NCB probe at the gel front). Further investigations of the BSA complexes formed with capped DPP, DPCH, and DPBC indicated that NCB probe actively transfers to cell membranes nonspecifically and rapidly. This was demonstrated by measuring the fluorescence prior to and after mixing of NCB complexes with HeLa cells. Cells were agitated with each complex for 5 min, then the resulting mixtures were centrifuged, and the fluorescence of the supernatant remeasured. BSA mixtures showed marked reductions in fluorescence for the chlorin **39**, with lesser reductions for the bacteriochlorin **41**. More interestingly, the fluorescence of resuspended HeLa cells now showed intense fluorescence corresponding to chlorin and bacteriochlorin, with respective values of 3 and 1, relative to the initial values for these conjugates in solution. Comparison of fluorescence arising from supernatant and cells surprisingly showed greater relative intensity from cells than from the original solution of conjugate prior to mixing with cells. It seems likely that this reflects a lowering of fluorescence quenching in the membrane, as compared to the protein. Experiments repeated with crude bioconjugate mixtures containing NCB and covalently bound porphyrin, chlorin, and bacteriochlorin also showed transfer of fluorophore to the cell membrane but at reduced levels, reflecting the inability of covalently bound fluorophore to transfer to the cell membrane. Reanalysis of supernatants from these experiments by SDS−PAGE, and comparison to gels run before mixing with cells, indicated significant reductions in NCB porphyrin, chlorin, and bacteriochlorin but no reduction in covalently bound material.

To address the problems associated with PITC bioconjugates which contain appreciable amounts of NCB material, we have investigated a number of methods for their removal.

Purification of Porphyrin Chlorin- and Bacteriochlorin-Derived Bioconjugates: Removal of NCB PITC Impurities. To facilitate the removal of the NCB porphyrin, chlorin, and bacteriochlorin from covalent bioconjugates, a number of methods were investigated. We noted from many SDS−PAGE analyses the presence of front running NCB fluorescent probe in bioconjugates purified by gel permeation chromatography (except with water soluble PITC **28**). We therefore decided to recover pure bioconjugates from preparative SDS−PAGE. The procedure involved excising the gel area corresponding to fluorescent labeled protein, followed by electroelution using the same conditions as for the initial SDS−PAGE.

Photographs of the SDS−PAGE gels for a typical bioconjugate (BSA−porphyrin **17**) are shown in Figure 1. Gel A clearly indicates the presence of NCB porphyrin, which can be seen running at the electrophoresis front (bottom of the gel) as a purple stain along with the blue marker dye. Gel B represents the conjugate after purification by electroelution, except for lane 7 which is a control lane of unpurified conjugate for comparison. Gels C and D are the same gels as A and B but have been visualized under UV light, as opposed to white light, to visualize the fluorescent porphyrin. Again, lanes 1−6 in gel D represent conjugate purified by electroelution. Finally, gels E and F are the same gels as A and B and C and D, respectively; however, the gels have now been stained with silver nitrate to visualize protein. Lane 8 shows the visualized molecular weight markers, indicating that the major protein band in gel F corresponds to BSA.

To quantify the levels of NCB material, a number of PITC derivatives were bioconjugated to BSA, using probes of varying lipophilicity (trihydroxy-TPP **16**, DPCH **29**, DPBC **30** and tri-(*N*-methylpyridiumyl)-TPP **28**). An

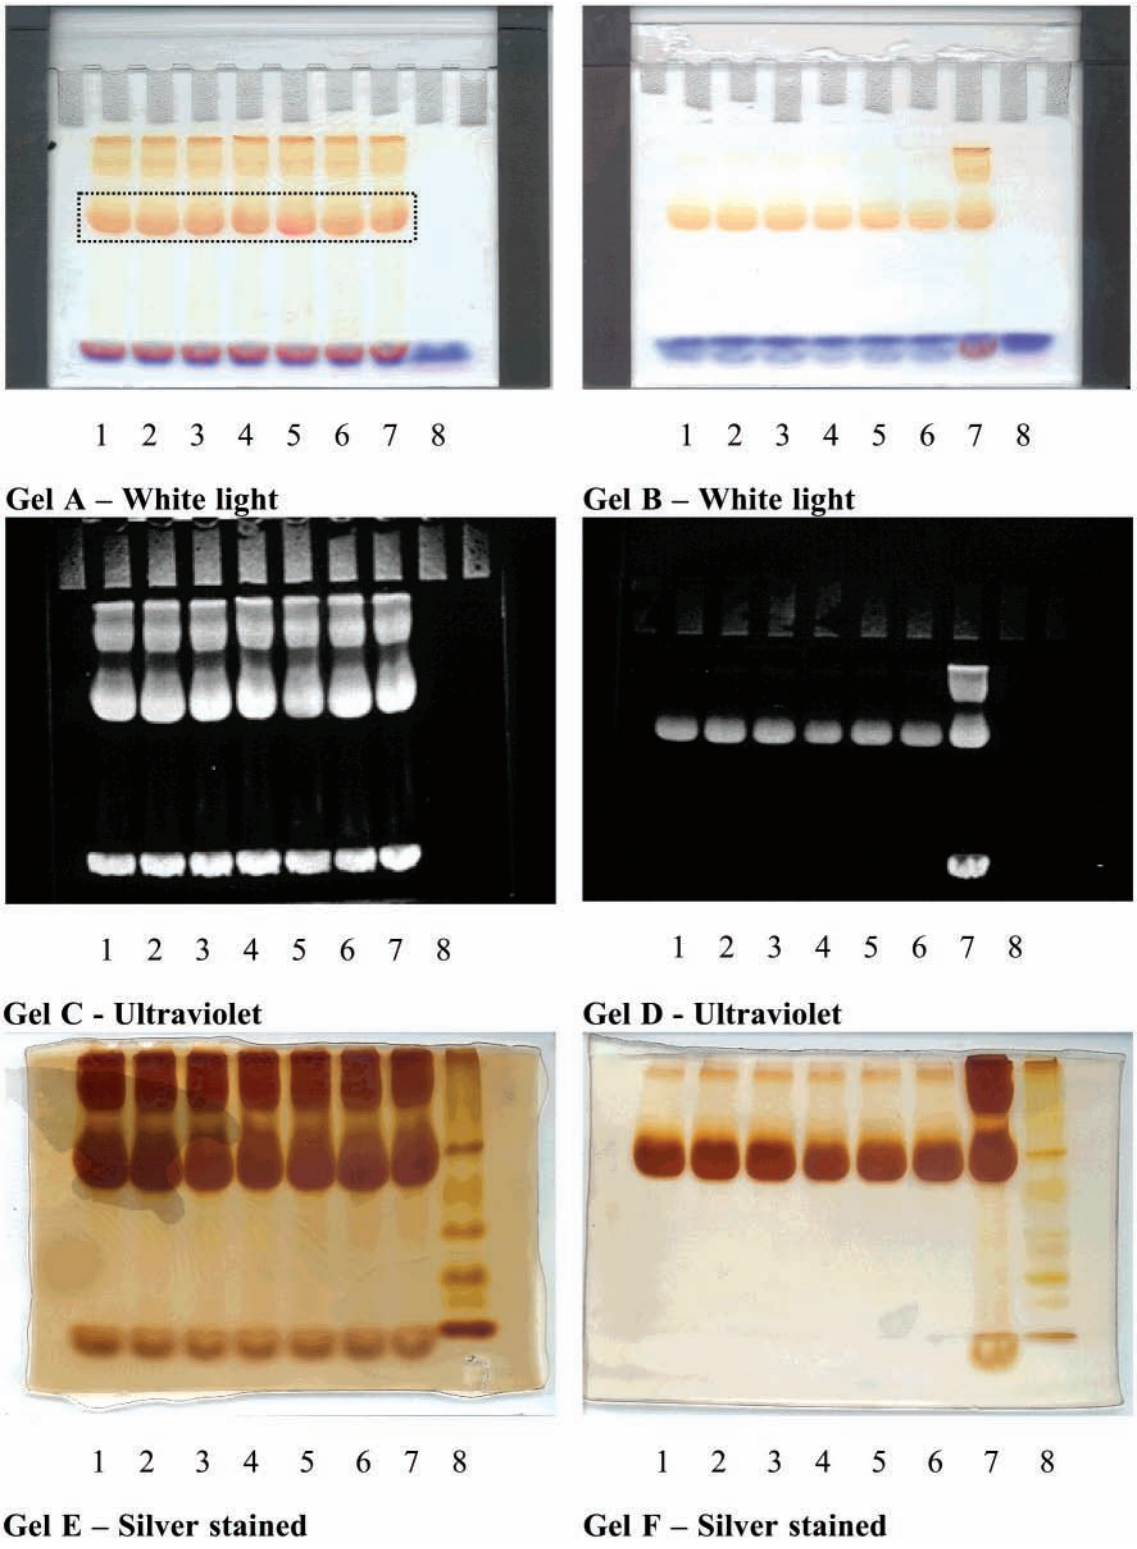


Figure 1. SDS−PAGE gels for BSA−porphyrin (**17**) conjugate before (A, C, E) and after (B, D, F) purification by electroelution.

examination of the proportions of NCB material pre- and post-SDS−PAGE electroelution is given in Table 1. The data clearly indicate that as the PITC derivative increases in polarity, so the level of NCB material drops, with the bioconjugate formed from tri-(*N*-methylpyridium)-PITC **28** having very low levels of NCB, similar to that found for conjugates prepared using commercial FITC. Analysis of DOL data from conjugates pre- and postelectrophoretic purification show interesting trends. Pre-electrophoretic purification, but post-gel permeation chromatography, which has been the usual method for purification of porphyrin conjugates to date, DOL values are inversely proportional to hydrophilicity for the analogous TPP derivatives **16**, **17**, and **28** and also for analogous DPP chlorin and bacteriochlorin **29** and **30**. The same data postelectrophoretic purification, however, reveals a much greater contribution to DOL value for NCB material for the less hydrophilic porphyrin derivatives. Interestingly, we repeated a previously reported NHS ester-mediated conjugation for haematoporphyrin

Table 1. Degree of Labelling for PITC-BSA Conjugates Pre- and Postelectroelution with Percentages of Noncovalent Binding[a]

PITC	degree of labeling electroelution		% NCB
	pre	post	
$TPP(OH)_3$ (**16**)	7:1	2:1	71
$TPP(OH)_6$ (**17**)	6:1	4:1	33
$chlorin(OH)_2$ (**29**)	3:1	2:1	33
$bacteriochlorin(OH)_4$ (**30**)	0.5:1	0.35:1	30
TPP-(methylpyridiniumyl) (**28**)	2:1	1.9:1	5

non-PITC	pre	post	% NCB
haematoporphyrin	4:1	3.4:1	15
fluorescein	3.3:1	3.2:1	3

[a] Haematoporphyrin and fluorescein BSA conjugates are included for comparison.

with BSA (*13*) and analyzed the product for percentage NCB. The result indicated a 15% contribution from NCB haematoporphyrin. It would seem, then, that SDS−PAGE offers the ability to quantify levels of NCB in the conjugation of porphyrins to proteins and can also be used to obtain 100% covalently bound conjugates for study. Although the method used here is obviously suited to small-scale preparations, commercial large-scale preparative electrophoresis apparatus is available, which could be used to produce larger amounts of purified conjugates.

Scanning Confocal Laser Microscopy Studies of BSA PITC Derivatives. The use of protein-photosensitizer (PS) conjugates to obtain specific targeting of a particular cell type may constitute an improvement in PDT. One method, which is becoming increasingly popular, is the generation PS−protein conjugates (usually of BSA, mal-BSA, or LDL) that bind to specific cell surface receptors. Following cellular internalization by receptor-mediated endocytosis, the PS−protein bioconjugate has

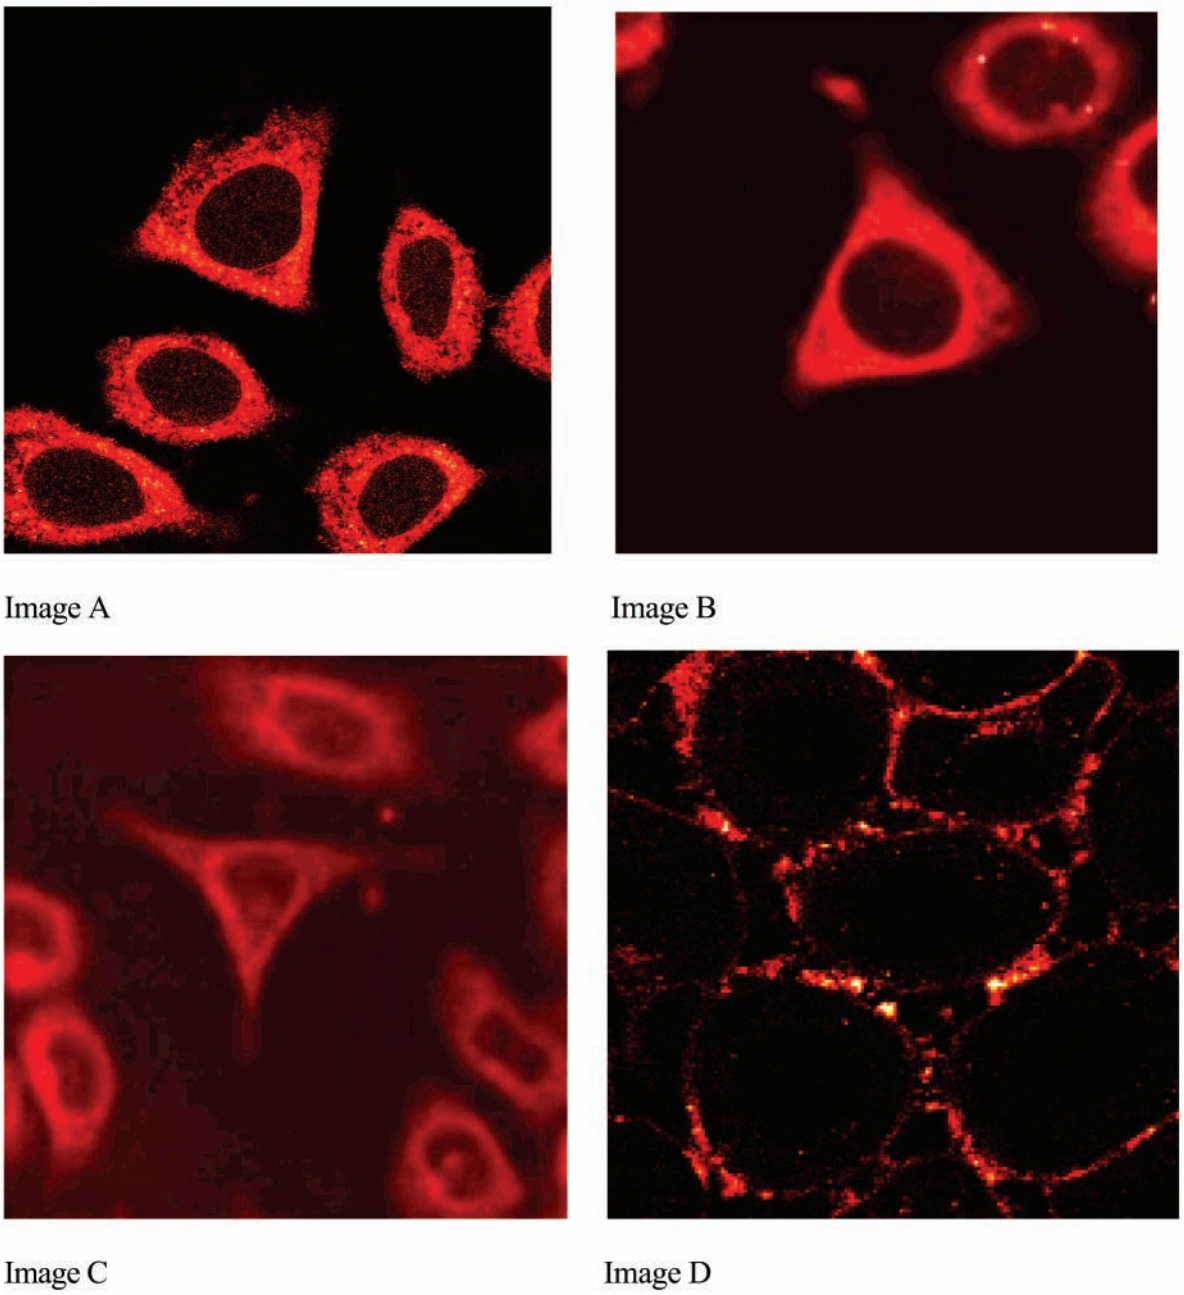

Figure 2. CLSM images of HeLa cells incubated with (A) BSA−porphyrin (**17**) conjugate, (B) BSA−chlorin (**29**) conjugate, (C) BSA−bacteriochlorin (**30**), and (D) Unconjugated porphyrin (**23**).

been successfully used to target destruction of specific cells (*13*−*15*, *22*, *23*).

We therefore undertook a preliminary examination of the intracellular localization of bioconjugates of BSA with a representative porphyrin (**17**), chlorin (**29**), and bacteriochlorin (**30**) using human cultured carcinoma cells (HeLa). HeLa cells overexpress receptors for human serum albumin relative to similar noncarcinoma cells, and as there is a 87% homology between BSA and HSA, it was hoped BSA conjugates would be processed by the HSA receptors. The bioconjugates were first purified vigorously by SDS−PAGE electroelution and then incubated with HeLa cells prior to fixing and imaging by confocal laser scanning microscopy (CLSM). Figure 2 (images A−C) shows CLSM images taken through the center of the cells. Clearly, all BSA conjugates penetrate the cell but are excluded from the nucleus or are subjected to efficient quenching of fluorescence in this cellular region. Images of BSA or PBS controls showed insignificant autofluorescence at the same detector collecting level. However, the control images taken after identical incubation conditions with unconjugated porphyrin (**23**) showed that fluorescence was localized exclusively in the extracellular space (Figure 2, image D), demonstrating that conjugation to the BSA is required in order for probe internalization to occur. Further investigations into the exact mode of cellular entry and intracellular distribution are currently underway within our laboratory.

In conclusion, we have developed methods for the synthesis and bioconjugation of water soluble tri-(*N*-methlpyridiniumyl)porphyrin derivatives typified by PITC **28** with proteins and shown that their increased hydrophilicity minimizes the amount of NCB porphyrin. We have also developed a range of wavelength-shifted chlorin and bacteriochlorin isothiocyanate derivatives **29**/**30** from the OsO_4-mediated oxidation of DPPs, which have been used to generate bioconjugates with BSA. We have highlighted the problem of NCB associated with the use of lipophilic and amphiphilic porphyrin derivatives in bioconjugation and have successfully overcome them by using SDS−PAGE electroelution to obtain bioconjugates of superior quality which retain no NCB material. Furthermore, we have highlighted a potential source of error in using molecular probes containing NCB porphyrins because of the active transfer of NCB porphyrins from protein to cell membranes. This would severely limit the use of these probes in applications such as flow cytometry. Work is currently underway within our laboratory to utilize this technology to generate specific immunoconjugates for use in multicolor FACS analysis and as PDT sensitizers. Finally, we have used the CLSM technique to demonstrate the potential use of purified BSA conjugates as a delivery vehicle for porphyrins, chlorins, and bacteriochlorins.

ACKNOWLEDGMENT

The authors thank EPSRC Mass Spectrometry Service, Swansea, for analysis. The authors also thank Drs. Peter O'Toole and Ian Morrison for their assistance with CLSM and flow cytometric analysis and Huguette Savoie for cell culture support.

Tat Peptide Directs Enhanced Clearance and Hepatic Permeability of Magnetic Nanoparticles

Patrick Wunderbaldinger,[†] Lee Josephson,*[,†] and Ralph Weissleder

From the Center of Molecular Imaging Research, Massachusetts General Hospital, Harvard Medical School, Boston, Massachussets. Received October 5, 2001

Superparamagnetic nanoparticles have a number of important biomedical applications, serving as MR contrast agents for imaging specific molecular targets, as reagents for cell labeling and cell tracking, and for the isolation of specific classes of cells. We have determined the physical and biological properties of MION-47 and amino-CLIO, nanoparticles which serve as precursors for the synthesis of targeted MR contrast agents, and Tat-CLIO, a nanoparticle used as a cell labeling reagent. Blood half-lives for MION-47 and amino-CLIO were 682 ± 34 and 655 ± 37 min, respectively. The attachment of 9.7 tat peptides per crystal to amino-CLIO resulted in a reduction in blood half-life to 47 ± 6 min. MION-47, amino-CLIO, and Tat-CLIO were present in highest concentrations in liver and spleen and lymph nodes, where concentrations for all three nanoparticles ranged from 8.80 to 6.11% of injected dose per gram. Twenty-four hours after the intravenous injection of amino-CLIO, the nanoparticle was concentrated in cells surrounding hepatic blood vessels (endothelial and Kupffer cells), in a fashion similar to that obtained with other nanoparticle preparations. In contrast, Tat-CLIO was present as numerous discrete foci of intense fluorescence throughout the parenchyma. Using the peptide as a component of future nanoparticles, it might be possible to design sensors for the detection of macromolecules present in intracellular compartments.

INTRODUCTION

The ability to induce the internalization of therapeutic agents by attachment to positively charged peptides has suggested a variety of new approaches to drug design including new forms of cyclosporin A (*1*), improved radiotherapy based on the nuclear localization of toxic radioisotopes (*2*), and the enhanced delivery of therapeutic proteins or DNA (*3*−*5*). Peptides with membrane translocating properties include the tat peptide from the HIV tat protein, polyarginyl peptides, and penetrin (the third helix homeodoman of antenapedia) (*1, 6, 7*).

We have shown that the attachment of tat peptides to a superparamagnetic iron oxide known as Tat-CLIO (Tat-cross-linked iron oxide) induces the intracellular accumulation of iron oxide and makes cells highly detectable by magnetic resonance imaging (*8*). Uses of Tat-CLIO include labeling stem cells homing to bone marrow (*9*), labeling T cells homing to the spleen (*10*), labeling neuroprogenitor cells migrating in the developing mouse brain (*11*), and labeling T cells invading diabetic insulitic lesions (*12*) (Table 1). Tat-CLIO uptake is not associated with toxicity (*8*−*10*).

A key question concerning the usefulness of the tat peptide for the delivery of diagnostic and sensing agents involves the fate of tat peptide conjugates after clearance from the vascular compartment. If tat-conjugates move beyond cells bordering the vascular compartment, a new capability to deliver cell impermeable drugs to a wide range of different cell types throughout an organ can be imagined. We therefore chose to examine the in vivo behavior of Tat-CLIO, a nanoparticle developed for cell labeling applications. We examined the physical and biological properties of Tat-CLIO by comparison with two nanoparticles, MION-47 and amino-CLIO, which have served as precursors for the synthesis of Tat-CLIO and targeted nanoparticles generally. Here we report that the attachment of the tat peptide enhances nanoparticle clearance from the vascular compartment and that nanoparticles were found throughout the liver, rather than in cells adjacent to the vascular compartment (endothelial cells/Kupffer cells). This observation opens exciting opportunities for the delivery of intracellular sensing molecules that will allow in vivo molecular imaging.

EXPERIMENTAL PROCEDURES

Synthesis of Magnetic Nanoparticles. The synthesis of nanoparticles used here, MION-47, amino-CLIO, and Tat-CLIO, follows the scheme shown in Figure 1. Amino-CLIO was synthesized by cross-linking MION-47 in strong base with epichlorohydrin followed by reaction with ammonia to provide primary amino groups (*8, 13, 14*). The original synthesis of Tat-CLIO (*8*) was modified to ensure that FITC, used to tract the nanoparticle in fluorescent microscopy studies, could not be cleaved from the nanoparticle in vivo. We used succinimidyl iodoacetate (SIA) as a bifunctional conjugating reagent because it forms a stable thioether linkage between peptide and amino-CLIO. Our earlier synthesis used *N*-succinimidyl 3-(-pyridyldithio)propionate (SPDP), which results in a reducing-environment-sensitive, disulfide linkage between peptide and nanoparticle. Second, our earlier synthesis used GGC*GRKKRRQRRR*K(FITC)-NH_2 as the tat peptide, which features a cysteine residue near the N terminus and a C-terminal lysine modified by FITC. The current study used the peptide *GRKKRRQRRR*GYK-

Tat-CLIO	a cell labeling and cell tracking reagent synthesized from amino-CLIO	9

(FITC)C-NH_2. The C-terminal cysteine side chain is modified by the attachment to the CLIO nanoparticle, while the penultimate lysine is modified by attachment of FITC (Figure 1). Unlike our original Tat-Clio nanoparticle, cleavage of the naturally occurring amino acids providing the membrane translocation sequence will result not result in a separation of FITC from the nanoparticle. To verify the stability of the current Tat-CLIO, the nanoparticle was incubated with 10 μg/mL trypsin, 10 μg/mL chymotrypsin, or 10 mM DTT at 37 °C for 4 h. All treatments failed to separate FITC from the nanoparticle, based on its inability to pass through an ultrafiltration membrane.

*GRKKRRQRRR*GYK(FITC)C$-NH_2$ was synthesized with Fmoc chemistry and labeled with FITC, MALDI-MS $(M+1)^+$: 2237.54 (calc.), 2237.2 (found) as described (*8*). Italicized residues are the membrane translocation sequence of the tat peptide. One and a half milliliters of amino-CLIO (39 mg Fe, 0.70 mmol) in 5 mM sodium citrate, pH 8 was reacted with succinimidyl-iodoacetate or SIA (42 mg, 0.12 mmol) (Molecular Biosciences, Boulder CO) dissolved in DMSO (3 mL). Reaction was for 2 h at room temperature. The mixture was separated on a Sephadex G-25 column (30 × 1.5 cm) and the void volume with iron oxide was collected. To the iron oxide was added 13 mg of peptide dissolved in 3 mL of 0.02 M citrate, pH 6.5 and the mixture was allowed to stand for 3 h at room temperature. The mixture was then applied to the column above to remove unreacted peptide.

Isotopic Labeling of Magnetic Nanoparticles. To prepare indium-labeled MION-47 or indium-labeled amino-CLIO, nanoparticles were dialyzed against 0.01M sodium carbonate, pH 11−11.5. To 0.5 mL of nanoparticle (10 mg Fe, 0.178 mmol) was added diethylenetriaminpentaacetic acid dianhydride (DPTA anhydride, Aldrich, Milwaukee, WI), in 100 μL of DMSO (0.5 mg, 1.4 μmol of DTPA anhydride). The mixture was allowed to stand for 90 min, and the addition of DTPA anhydride was repeated. To remove unreacted DTPA, the mixture was applied to Sephadex G-25 column PD-10 columns equilibrated with 0.02 M citrate, pH 6.5, and the dark void volume was collected. One millicurie of $^{111}InCl_3$ (NEN, Boston MA) was then added and the mixture allowed to stand at room temperature for 4 h. The mixture was added to a Sephadex G-25 PD-10 column equilibrated with the above buffer and which had been spun (4 min × 2000 g) to remove entrapped fluid. The sample was added and the column spun again and the flow through taken.

For indium labeled Tat-CLIO, to 0.6 mL Tat-CLIO (2.1 mg Fe, 0.038 mmol) was added to 0.1 mL of 0.1 M Borate, pH 8.5, and 0.07 mL of 2.8 mM DTPA anhydride (0.20

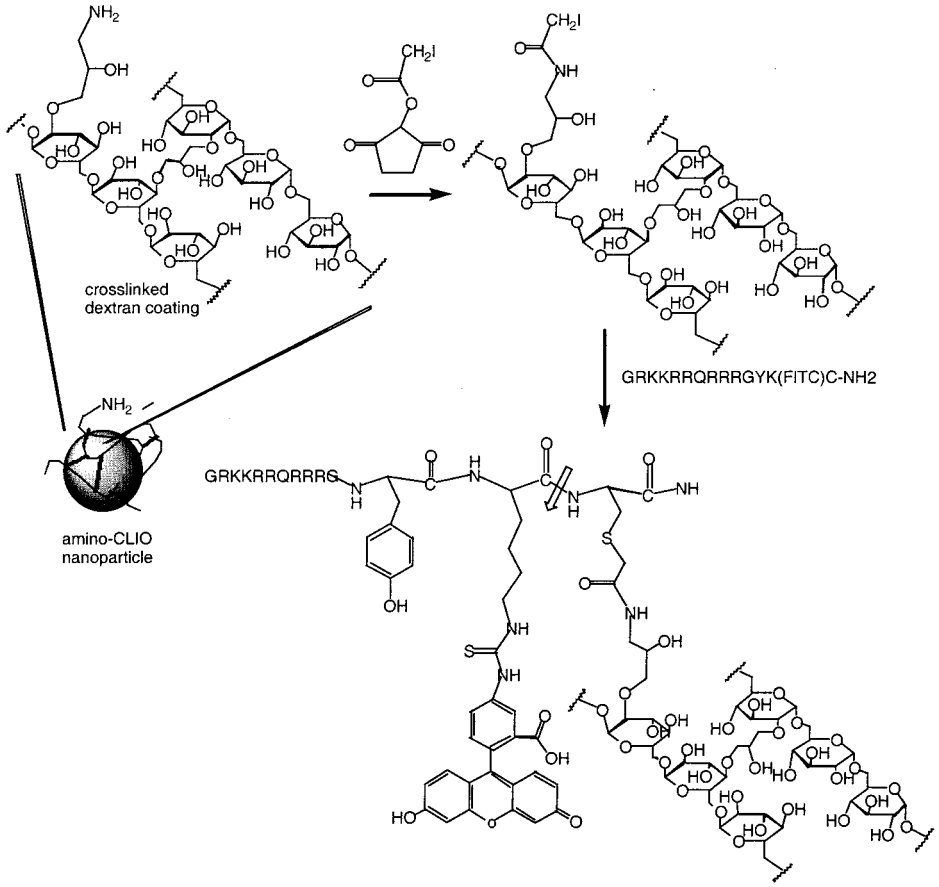

Figure 1. Scheme for the synthesis of Tat-CLIO.

Table 2. Physical and Biological Properties of Magnetic Nanoparticles

agent	size (nm)	R1 ($mM^{-1}\,s^{-1}$)	R2 ($mM^{-1}\,s^{-1}$)	peptides per crystal	blood $T_{1/2}$ (min)
MION-47	27.5 ± 6.8	21.9 ± 3.6	44.6 ± 7.1	NA	682 ± 34
Amino-CLIO	29.8 ± 5.0	23.2 ± 1.9	54.9 ± 15	NA	655 ± 37
Tat-CLIO	65.2 ± 7.3	22.9 ± 1.3	73.4 ± 17.8	11.6 ± 1.7	47 ± 6

μmol) in DMSO. The mixture was allowed to stand 4 h at room temperature and separated on a PD-10 column equilibrated as above. One millicurie of $^{111}InCl_3$ was added and the mixture allowed to stand overnight. Removal of unreacted indium was by centrifugation as above.

To prepare fluorescein isothiocyanate (FITC)-labeled CLIO, 1 mL of amino-CLIO (26 mg Fe, 0.464 mmol) was dialyzed against sodium carbonate as above and 1 mL of 0.01 M FITC (10 μmol) in sodium carbonate was added. The mixture was allowed to stand for 1 h at room temperature and FITC removed with a PD-10 G-25 column in citrate as above.

Characterization of Nanoparticles. Size was determined by laser light scattering using a Coulter N4 particle size analyzer. Relaxivity (R1 and R2) were measured at 0.47 T as described. Iron was measured spectrophotometrically. Details are provided elsewhere (*8, 13*). The number of tat peptides attached was determined from the OD_{493} of a solution of Tat-CLIO of known iron concentration. The OD_{493} of a similar iron concentration of amino-CLIO was subtracted and the peptide concentration calculated from the difference using an extinction coefficient for fluorescein of 73000 $M^{-1}\,cm^{-1}$. Results are expressed as the number of peptides per crystal assuming 2064 iron atoms per crystal (*15*).

Animal Studies. For biodistribution studies, female Balb C mice (six animals per agent) (Charles River Breeding Laboratories, NC) (weight 20−30 g, retired breeders) were used. Mice were anesthetized by an intraperitoneal (IP) injection of ketamine (80 mg(kg) and xylazine (12 mg/kg; Parker-Davis, Morris Plains, NJ/Miles, Shawnee Mission, KS). They were then injected intravenously (iv) through the tail vein with ^{111} In-labeled contrast agents at a dose of 10 mg Fe/kg. Twenty-four hours later animals were sacrificed by an ip injection of pentobarbital (Anpro Pharmaceutical, Arcadia, CA). Brain, heart, intestine, liver, spleen, kidney, muscle, bone, lung, paraaortic and inguinal lymph nodes, and body fluids (blood and urine) were excised, weighed, sealed in test tubes, and counted in a well counter (Wallace, Turku, Finland). Tissue concentration was expressed as percentage of injected dose per gram of tissue (%ID/g).

Blood half-life was calculated from blood radioactivity at various time points after animals were injected. Blood (120 μL) was withdrawn at various known time points between 1 and 24 h postinjection for five animals per agent (MION-47 and amino-CLIO: 1, 5, 8, 12, 18, and 24 h; Tat-CLIO: 1, 2, 4, 8, 12, 18, and 24 h). Half-life was obtained by fitting blood radioactivity to a single-exponential equation use for a one-compartment open pharmacokinetic model:

$$C(t) = C(0)e^{-kt}$$

$C(t)$ is blood radioactivity at time t after injection, $C(0)$ is the concentration of the colloid in the blood at the moment of injection time, k is the decay constant, and t is time after injection. Animal protocols were approved by the Institutional Review Committee on Animal Care and were conducted in accordance with National Animal Welfare guidelines.

All statistical calculations were made using SAS software (SAS Institute, Cary, NC). Results are expressed as mean (±SD).

Fluorescence Microscopy. To visualize the intrahepatic distribution of iron oxides, fluorescence microscopy in the green channel was used (excitation at 485 nm, emission at 530 nm). Mice were injected with FITC labeled amino-CLIO or Tat-CLIO, which has an FITC residue on the tat peptide, at 10 mg/kg and sacrificed 24 h later. Immediately after sacrifice animals were perfused with heparinized 5% glucose to reduce background fluorescence from blood. The liver was then removed, placed in freezing mounting liquid, and frozen in liquid nitrogen. The frozen tissue was cut into 5 μm thick sections for microscopic examination. Fluorescence microscopy on liver tissue was performed on air-dried, unembedded, and unfixed sections. This was done to prevent leaching of Tat-CLIO from the tissue during fixation, bleaching artifacts, and other distortions. HeLa cell images are from ref 8 and were obtained under similar conditions (unfixed, unembedded). Images were collected using a cooled, charge-coupled device (Photometrics, Tucson, AZ) with appropriate filters for excitation and emission (Omega Optics, Brattleboro, VT).

RESULTS AND DISCUSSION

The sizes, magnetic properties and numbers of tat peptides for MION-47 and amino-CLIO and Tat-CLIO are shown in Table 2. Values are the means plus/minus one standard deviation for four lots of MION-47 or amino-CLIO and for three lots of Tat-CLIO. Values are consistent with earlier studies of the physical properties of these materials (*8, 16−18*). Biological data were obtained with one of the three lots of Tat-CLIO that had 9.7 tat peptides attached per crystal.

The blood half-lives of MION-47, amino-CLIO, and Tat-CLIO were determined by sampling blood radioactivity at various time points after injection with results summarized Table 2. Data fit the one compartment model well, with correlation coefficients (r^2 values) of 0.959 for MION-47, 0.997 for amino-CLIO, and 0.98 for Tat-CLIO. Half-lives for MION-47 and amino-CLIO were similar, 682 ± 34 min and 655 ± 37 min, respectively. Thus the cross-linking and amination of the dextran surface of MION-47, to yield amino-CLIO (Figure 1), did not alter the physical properties (size and relaxivity) or the blood half-life. MION has a long blood half-life in rats and humans, i.e., 252 min in rats (*18*) and greater than 24 h in humans (*19*). The attachment of tat peptides resulted in a reduction of blood half-life from 655 ± 37 for amino-CLIO to 47 ± 6 min for Tat-CLIO.

MION-47, amino-CLIO, and Tat-CLIO had similar biodistributions; see Table 3. Each had the highest concentrations in the liver, spleen and lymph nodes, ranging from 8.80 to 6.11% ID/g, which suggests that all three nanoparticles were removed by phagocytes of the reticuloendothelial system. The enhanced clearance of Tat-CLIO is likely due to the enhanced interaction of Tat-CLIO with phagocytes mediated by the tat peptide itself or by enhanced opsonin-mediated phagocytosis.

To compare the distributions of Tat-CLIO and amino-CLIO after clearance, fluorescence microscopy of the liver

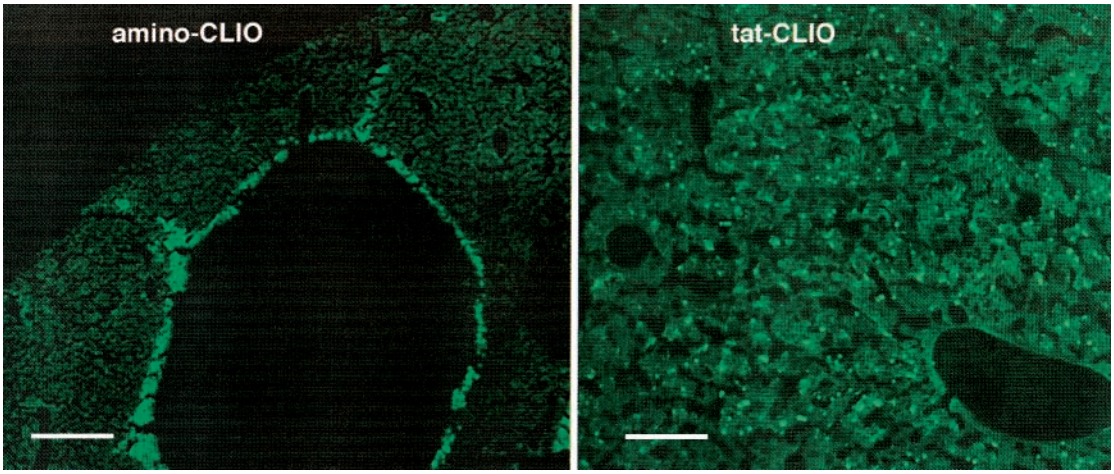

Figure 2. Fluorescence microscopy of livers of mice injected with amino-CLIO or Tat CLIO. Line is a scale marker indicating 50 microns.

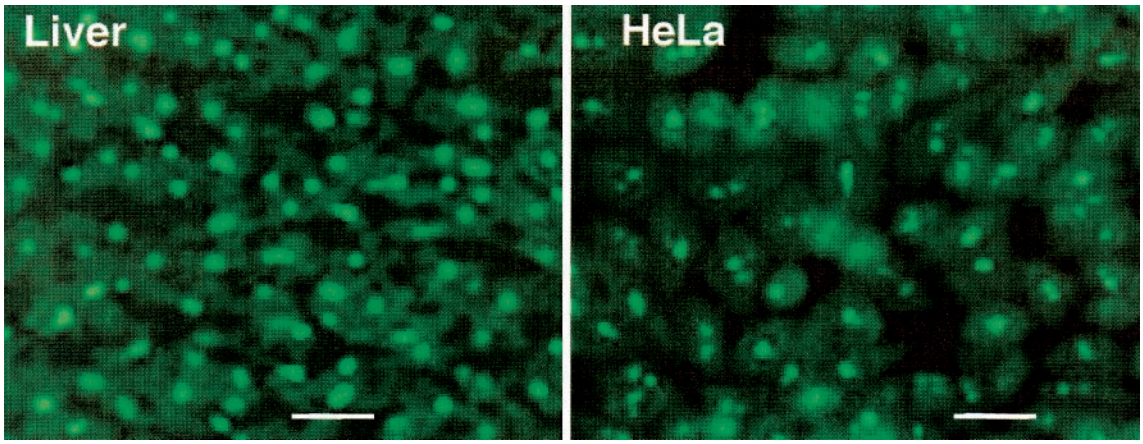

Figure 3. Fluorescence microscopy of livers of mice injected with amino-CLIO and HeLa cells in culture incubated with tat-CLIO. White line indicates 10 microns.

Table 3. Biodistribution of Nanoparticles[a]

organ	MION-47 (%ID/g)	Amino-CLIO (%ID/g)	Tat-CLIO (%ID/g)
liver	8.8 ± 0.27	8.28 ± 0.45	8.53 ± 0.3
lymph node	8.79 ± 0.21	8.75 ± 0.26	6.4 ± 0.1
spleen	6.13 ± 0.21	6.11 ± 0.35	6.27 ± 0.18
kidney	2.94 ± 0.78	2.9 ± 0.51	1.87 ± 0.38
lung	1.82 ± 0.21	1.92 ± 0.27	1.92 ± 0.39
bone	1.69 ± 0.49	1.79 ± 0.25	1.0 ± 0.21
fat	1.84 ± 0.17	1.81 ± 0.41	0.72 ± 0.13
muscle	1.97 ± 0.31	1.91 ± 0.25	0.92 ± 0.19
brain	0.38 ± 0.09	0.17 ± 0.03	0.09 ± 0.02
blood	2.23 ± 0.45	2.2 ± 0.3	0.49 ± 0.19

[a] %ID/g = percent injected dose per gram.

was performed because it achieved high concentrations of Tat-CLIO and because of its well-defined vasculature and large vessel-free regions. Amino-CLIO was concentrated along the hepatic vessels in endothelial cells and/or Kupffer cells as shown in Figure 2, a pattern similar to that seen when MION accumulates in rat liver. MION shows reticuloendothelial uptake, with an absence of iron in hepatocytes (*20*). However, the pattern of hepatic fluorescence obtained after Tat-CLIO administration was quite different, with numerous discrete foci of intense fluorescence throughout the parenchyma and a notable absence of fluorescence surrounding blood vessels. This indicates that Tat-CLIO passes from the vascular compartment, and through cells surrounding blood vessels, to obtain a parenchymal distribution. The distribution of Tat-CLIO fluorescence was analyzed at higher magnification as shown in Figure 3. The distribution of fluorescence appears to be similar to that seen when HeLa cells are incubated with Tat-CLIO, where Tat-CLIO shows a pronounced nuclear accumulation. It appears that attachment of the tat peptide to magnetic nanoparticles reduces blood half-life and leads to a broad parenchymal intrahepatic distribution in the liver, while the organ biodistribution is determined by the nanoparticlate rather than the presence of the tat peptide.

Our results can be compared with studies using protein transduction domains such as the tat peptide to induce enzymes to penetrate tissues after injection. Fusion proteins of the tat protein with β-galactosidase or of the tat peptide with β-glucuronidase have been synthesized and exhibit enhanced tissue penetration after injection (*21, 22*). On the other hand a tat-β-galactosidase, prepared by the conjugation of between one and two peptides per mole of enzyme, concentrated perivascularly after injection (*6*). Schwarze et al. have proposed that protein denaturation plays a role in the cellular uptake of their conjugates.

The label to which the tat peptide is attached here, amino-CLIO, is extremely robust and cannot undergo temperature dependent changes in physical state similar to denaturation. Cross-linked dextran-coated iron oxide (amino-CLIO) can withstand abusive treatments, such as incubation at 121 °C for 30 min, without a change in size, blood half-life, or loss of its dextran coat (Josephson, unpublished observations). Second, the use of Tat-CLIO for cell tracking by MR requires the highly magnetic form

the iron oxide (superparamagnetic iron oxide), which requires preservation of the iron oxide crystals in their original form (greater than 3 nm in diameter with an inverse spinel crystal structure). The magnetic integrity of the iron oxide must be maintained after internalization because of the profound effect that Tat-CLIO loaded cells have on MR images (*9*, *10*). Finally, as explained above, the FITC label of the Tat-CLIO nanoparticle used here cannot be separated from the nanoparticle with the chemistry employed.

Our finding that the tat peptide can affect the delivery of magnetic nanoparticles might provide the basis for the design of new types of magnetic nanoparticle based diagnostic agents. We have recently demonstrated that magnetic nanoparticles can serve as sensitive biosensors for the sequence specific detection of nucleic acids by NMR (*14*). The addition of the tat peptide to such biosensors may provide a signal for their membrane translocation or nuclear localization in vivo. Alternatively, it may be possible to add the tat peptide sequence to direct the intracellular disposition of nanoparticles targeted to cells by antibodies or receptor binding ligands.

The bioluminescent protein aequorin is a sensitive label that has been employed in a number of analytical applications. A mutant of aequorin with enhanced stability produced recombinantly in our laboratory has been employed as a label in the development of an immunoassay for digoxin. Digoxin is a cardiac glycoside used in the treatment of congestive heart failure. This drug has a very narrow therapeutic range of 0.8−2.0 ng/mL (1.0−2.5 nmol/L), thus requiring therapeutic drug monitoring. In this study, a derivative of digoxigenin was chemically conjugated to the mutant aequorin, and the resulting protein−digoxigenin derivative conjugates were characterized in terms of their luminescence properties. A solid-phase immunoassay for digoxin was then developed. The detection limit of the assay for digoxin was 1×10^{-12} M. To demonstrate the use of this mutant aequorin as a label in biological sample analysis without any need for pretreatment of the samples, the assay was tested in serum spiked with digoxin. Interference from digoxin analogues was also evaluated to determine the specificity of the assay.

INTRODUCTION

Aequorin, a calcium-binding photoprotein, was originally isolated from the jellyfish *Aequorea victoria* in Friday Harbor, Washington (*1*). The holoprotein consists of apoaequorin (189 amino acid residues), a chromophore (coelenterazine), and molecular oxygen (*2*). The photoprotein is activated by calcium, which binds to the three EF-hand structures present within the protein molecule (*3*). These EF-hand structures are characteristic of the calcium-binding protein family. Upon addition of calcium, aequorin undergoes a conformational change leading to oxidation of bound coelenterazine to coelenteramide with the subsequent release of CO_2 and a flash of light ($\lambda_{max} = 469$ nm) (*4*).

Aequorin has been employed in a variety of analytical and biological applications. It has been used in the measurement of calcium in various intracellular compartments (*5*). Highly sensitive binding assays and immunoassays have been developed for peptidic and nonpeptidic analytes using aequorin as a label (*6, 7*). A proteolytic bond cleavage assay has also been developed using an aequorin fusion protein (*8*). Since aequorin can be detected down to attomole levels, it has been employed in the determination of biotin in single cells and in picoliter-volume vials (*9*−*11*). In addition, aequorin-labeled probes have been used as an alternative to radiolabels in nucleic acid hybridization assays (*12, 13*).

Several mutational studies have been performed on aequorin to elucidate the effects of various amino acids on the activity of the protein (*14*−*16*). Among them, cysteine-free mutants have shown to increase the protein's luminescence activity. The luminescence activity of the mutant was found to be higher (124%) when compared to that of native protein (100%) (*17, 18*). Although the specific cause for the higher activity is not yet clear, it has been suggested that the cysteines present in the native protein are not essential in the generation of the luminescence activity (*19*). We have postulated that presence of disulfide bonds in the native protein may introduce conformational constraints in the protein structure leading to a reduction in the bioluminescence activity (*19*). In addition to an increased activity, the cysteine-free mutant does not need the addition of a reducing agent to prevent dimerization of the protein, thus increasing the stability of the protein.

The goal of this study was to investigate the performance of this cysteine-free mutant of aequorin constructed previously in our laboratory as a label in immunoassay development. Bioluminescence is a relatively rare phenomenon in nature; thus, when aequorin is used as a label in biological sample analysis it offers the advantage of producing a low background signal (*3*). Therefore, we decided to investigate the detection ability of this mutant of aequorin in the analysis of biological samples and without performing any pretreatment steps.

Digoxin was selected as a model analyte for the study. Digoxin is a cardiac glycoside used in the treatment of congestive heart failure and supraventricular arrhythmias (*20, 21*). It has a narrow therapeutic window of 0.8−2.0 ng/mL with a potential of fatal toxicity. Hence, it frequently needs therapeutic drug monitoring (TDM) (*22*).

For the purpose of this study, a derivative of digoxigenin was employed for its chemical conjugation to the lysine residues of the mutant aequorin. Several mutant aequorin−digoxigenin derivative conjugates with various mole ratios of digoxin to aequorin were prepared and were characterized in terms of their luminescence properties and binding ability to an anti-digoxin antibody. Dose−response curves were generated for digoxin in a sequential binding format. The optimized assay was used

to perform serum analysis with spiked digoxin without any pretreatment of the samples. To determine the specificity of the immunoassay, the assay was also employed to determine the effect of structurally similar compounds to digoxin.

MATERIALS AND METHODS

Reagents. Tris(hydroxymethyl)aminomethane (Tris) free base, ethylenediaminetetraacetic acid (EDTA) sodium salt, glucose, digoxin, monoclonal biotinylated anti-digoxin antibody, digitoxin, bufalin, oleandrin, and human sera were purchased from Sigma (St. Louis, MO). Digoxigenin-3-*O*-methycarbonyl-ϵ-aminocaproic acid *N*-hydroxysuccinimide ester (derivative of digoxigenin) was obtained from Roche Molecular Biochemicals (Indianapolis, IN). Reactibind 96-well neutravidin-coated white polystyrene microtiter plates and biotin-free bovine serum albumin (BSA) were from Pierce (Rockford, IL). Microlite 2 polystyrene microtiter plates were purchased from Dynex (Chantilly, VA). The Bradford protein assay kit was obtained from Bio-Rad Laboratories (Hercules, CA). Coelenterazine was obtained from Biosynth International (Naperville, IL). Luria Bertani (LB) broth was from Gibco-BRL (Gaitherburg, MD). All solutions were prepared using deionized (Milli-Q Water Purification System, Millipore, Bedford, MA) distilled water. All chemicals were reagent grade or better and were used as received.

Apparatus. Ion-exchange chromatography was performed using a BioCAD-SPRINT perfusion chromatography system by Perseptive Biosystems (Cambridge, MA). Fractions containing the mutant aequorin protein were lyophilized using a VirTis Bench Top 3 freeze-dryer (Gardiner, NY). The purity of the aequorin protein was verified by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) on a Phast System by Pharmacia Biotech (Uppsala, Sweden). Absorbance measurements were performed using a HP 8453 UV−Vis spectrophotometer from Hewlett-Packard (Waldbronn, Germany). Bioluminescence measurements were taken on a MLX microtiter plate luminometer from Dynex (Chantilly, VA) using a 100 μL-fixed volume injector. All luminescence intensities reported are the average of a minimum of three replicates and have been corrected for the contribution of the blank.

Expression and Isolation of Mutant Aequorin. *Bacillus subtilis* (*B. subtilis*) cells containing plasmid pSD110 consisting of the gene for mutant apoaequorin were grown in 250 mL of LB broth containing kanamycin (30 μg/mL) for 16 to 18 h. The plasmid pSD110 consists of sequence for signal peptide fused to the gene for mutant apoaequorin. Thus, the expressed protein was secreted out in the culture media. The culture was centrifuged at 13800 × g for 30 min at 4 °C, and the supernatant was collected. The supernatant containing the mutant protein was filtered through 0.2 μm membrane filter to remove any cell debris. The pH of the protein solution was then adjusted to 4.2 by adding glacial acetic acid in order to precipitate the protein. The precipitated protein was collected by centrifugation at 13800 × g for 30 min at 4 °C.

Purification of the Mutant Protein. The precipitate containing the mutant protein was resuspended in 30 mM Tris-HCl, pH 7.0 containing 2 mM EDTA, and it was filtered using 0.2 μm filter. The filtered protein was purified by perfusion anion exchange chromatography using a column consisting of a quarternized polyethyleneimine (HQ) as a stationary phase. A salt gradient from 0.0 to 0.5 M NaCl was employed to elute the protein. Fractions containing the photoprotein were pooled together and lyophilized after adding glucose at a final concentration of 30 mM for protein stability. The lyophilized protein was resuspended in distilled deionized water and immediately dialyzed against 50 mM sodium bicarbonate buffer of pH 8.3 containing 4 mM EDTA to remove excess salt from the protein solution. The purity of the mutant protein was verified by SDS−PAGE using 12.5% polyacrylamide gels, which were developed by silver staining. The protein concentration was determined using the Bradford protein assay, with BSA as the standard.

Preparation of Mutant Apoaequorin−Digoxigenin Derivative Conjugates. To prepare apoaequorin−digoxigenin derivative conjugates, various amounts of derivative of digoxigenin were reacted with a fixed amount of mutant apoaequorin. Five different mole ratios of digoxigenin derivative to mutant apoaequorin, namely, 25/1, 50/1, 100/1, 250/1, and 500/1 were prepared. The digoxgenin derivative in anhydrous dimethyl sulfoxide was added to a solution of mutant apoaequorin in 50 mM sodium bicarbonate, pH 8.3, containing 4 mM EDTA. The reaction was allowed to proceed for 4 h at 4 °C while stirring. After that, a 5-fold molar excess of coelenterazine was added to the reaction mixture, and the solution was incubated for 15 h at 4 °C. After the conjugation reaction was completed, an excess of unconjugated analyte and an excess of coelenterazine were removed by passing the mixture through a Sephadex G-25 size-exclusion column. The concentration of each conjugate was determined using a standard Bradford assay.

Bioluminescence Emission Study. A volume of 100 μL of various conjugates at a concentration of 1.0×10^{-7} M were added to a Microlite 2 polystyrene microtiter plate, and the bioluminescence was measured by injecting 100 μL of luminescence triggering buffer (100 mM Tris-HCl, 100 mM $CaCl_2$, pH 7.5). The bioluminescence signal was collected at 0.1-s interval over a 3-s time period.

Calibration Plot of Mutant Aequorin−Digoxigenin Derivative Conjugates. A stock solution of conjugates (8.0×10^{-7} M) were serially diluted in assay buffer (30 mM Tris-HCl, 4 mM EDTA, 150 mM NaCl, pH 7.5, containing 0.1% (w/v) biotin-free BSA) and the bioluminescence intensity of 100 μL of each dilution was measured after injecting 100 μL of luminescence-triggering buffer.

Binder−Dilution Study. A biotinylated anti-digoxin antibody of differing concentrations were prepared in the dilution buffer (100 mM sodium phosphate, pH 7.4, containing 150 mM NaCl and 0.1% (w/v) biotin-free BSA) and 100 μL of each dilution was immobilized on a neutravidin coated plate with constant shaking for 2 h at room temperature. The plate was then washed three times with wash buffer (30 mM Tris-HCl, 4 mM EDTA, 150 mM NaCl, pH 7.5 containing 0.1% (w/v) biotin-free BSA). Digoxigenin derivative−aequorin conjugate, 50/1 (100 μL, 1×10^{-9} M), in assay buffer was then added to the plate containing immobilized antibody. The plate was incubated for an additional 2 h with shaking at room temperature. The plate was then washed three times with the wash buffer, and the bioluminescence intensity was measured by injecting 100 μL of the luminescence-triggering buffer.

Association−Time Study. For this study, a biotinylated anti-digoxin antibody (100 μL, 2.0 μg/mL) was immobilized on the neutravidin-coated wells of the microtiter plate, as described previously. Next, a volume of

100 μL of the conjugate, 50/1, of concentration 1×10^{-9} M was added to the plate, and the plate was incubated for various time periods with shaking. The plate was then washed three times with the wash buffer, and the luminescence intensity was measured in the presence of 100 μL of luminescence-triggering buffer.

Dose−Response Curves for Digoxin. A stock solution of digoxin of a concentration 1×10^{-3} M was serially diluted in dilution buffer. For the assay, 100 μL of digoxin ranging in concentration from 1×10^{-5} M to 1×10^{-13} M were incubated with immobilized biotinylated anti-digoxin antibody (2 μg/mL) for 2 h at room temperature with shaking. Following this incubation period, the plate was washed three times with wash buffer. A volume of 100 μL of conjugate, 50/1, of concentration 1×10^{-9} M was then added and allowed to incubate with shaking for an additional 2 h at room temperature. After a washing step, the luminescence intensity was measured as described previously. Dose−response curves were also generated in a similar manner for the 25/1 digoxigenin derivative−aequorin conjugate with differing anti-digoxin antibody concentrations. For this, a volume of a 100 μL of a protein conjugate of 5×10^{-11} M concentration was employed, along with 0.5 and 2.0 μg/mL of anti-digoxin antibody, respectively.

Determination of Degree of Conjugation. The degree of conjugation for each conjugate was determined by a simultaneous spectrophotometric assay for two component system by following a previously reported protocol (*23*). For that, absorbance measurement was done at two different wavelengths (λ_1 = 265 nm and λ_2 = 278 nm). Following equations were used to calculate the concentration of the digoxin

$$A_{\lambda 1} = a_{x\lambda 1} b c_x + a_{y\lambda 1} b c_y$$

$$A_{\lambda 2} = a_{x\lambda 2} b c_x + a_{y\lambda 2} b c_y$$

where, $A_{\lambda 1}$ = absorbance at λ_1, b = path length = 1, x = component 1, y = component 2, $a_{x\lambda 1}$ = molar absorptivity of compound 1 at λ_1, c_x = concentration of compound 1.

Recovery Study of Digoxin in Serum. A volume of 100 μL of serum samples were spiked with standard amounts of digoxin. Next, 100 μL of these samples was incubated with immobilized biotinylated anti-digoxin antibody, for 2 h at room temperature followed by a washing step. A volume of 100 μL of the conjugate (25/1) of 5×10^{-10} M concentration was then added to the plate and incubated for 2 h. After a washing step, the luminescence intensity was measured as described previously. Percent recoveries of digoxin in serum samples were determined from the dose−response curve.

Cross-Reactivity Study. A cross-reactivity study was performed in the same way as the studies conducted for digoxin in serum. Various concentrations of compounds structurally similar to digoxin such as bufalin, oleandrin, and digitoxin were spiked in the serum, and the percent cross-reactivity was determined from the dose−response curve generated for digoxin.

RESULTS AND DISCUSSION

Luminescent proteins have become popular reporters due to their ease of handling and inherent sensitivity. Aequorin is one such luminescent protein that has been used as a highly sensitive label in analytical assay systems. Native aequorin contains three cysteine residues in its primary structure, which necessitates the presence of disulfide reducing agents at all times to prevent dimerization of the protein leading to loss in its activity (*14*). Furthermore, the presence of reducing agents can also have a negative effect on the binding capacity of antibodies as they consist of disulfide bonds linking their heavy chains with light chains that together form the binding site for antigens. We have demonstrated that a cysteine-free mutant of aequorin constructed using genetic engineering tools can overcome these problems associated with the native protein. Moreover, this cysteine-free mutant protein has been found to be more active than the wild-type protein (*17*).

Table 1. Characteristics of Aequorin−Digoxin Conjugates.

initial ratio (aequorin:digoxigenin derivative)	degree of conjugation	detection limit (M)	half-life (s)
cysteine-free aequorin	N/A	7.0×10^{-12}	1.22
25/1	1.1	8.0×10^{-12}	1.30
50/1	2.0	5.0×10^{-11}	1.17
100/1	4.0	2.0×10^{-10}	1.27
250/1	4.0	4.0×10^{-10}	1.22
500/1	4.1	1.0×10^{-9}	1.22

In this study, the performance of this mutant aequorin as a label in the development of an immunoassay for the determination of digoxin in biological samples was investigated. As mentioned earlier, patients taking digoxin need to be monitored frequently because of the narrow therapeutic range of this drug. Thus, assays for digoxin that are highly sensitive, rapid, and selective are required. Several immunoassays have been developed for analyzing digoxin and are commercially available. For example, Vitros digoxin immunoassay by Johnson & Johnson Clinical Diagnostics is based on competition between the digoxin and digoxin-peroxidase conjugate for binding to anti-digoxin antibody (*22*). AxSYM Digoxin II is an automated immunoassay for digoxin developed by Abbott Laboratories which uses an alkaline phosphotase conjugate of digoxin in an heterogeneous format (*22*).

The mutant aequorin can be produced using recombinant DNA technique in a highly reproducible manner and in unlimited amounts, thus reducing the reagent cost (*1*). For that, the cysteine-free mutant aequorin was expressed in *B. subtilis* using plasmid pSD110 constructed in our laboratory (*6*). The expressed protein was collected from the culture media by acid precipitation. The crude protein was purified using perfusion anion-exchange chromatography, and the concentration of the protein was determined by Bradford assay. The yield of the protein was found to be 8.38 mg of protein per liter of culture.

Several aequorin−digoxigenin derivative conjugates were prepared by reacting an excess of an *N*-hydroxysuccinimide ester derivative of digoxigenin at various mole ratios with the lysine residues of mutant aequorin as described in the Experimental Section. All the conjugates were characterized in terms of their luminescence properties, detection limits, and half-lives, as shown in Table 1. The detection limit for each conjugate was determined using calibration curves generated by employing varying amounts of conjugates. As it can be seen in Table 1, the detection limit increased with the increasing molar ratios of digoxigenin derivative to aequorin. This can be explained by the fact that an increased molar ratio of digoxigenin derivative to aequorin in the conjugation reaction results in the conjugates with a higher number of digoxigenin derivative bound to the protein. Some of these digoxigenin derivative can bind to the active site of the protein affecting the protein activity, and consequently providing a poor detection limit. However, con-

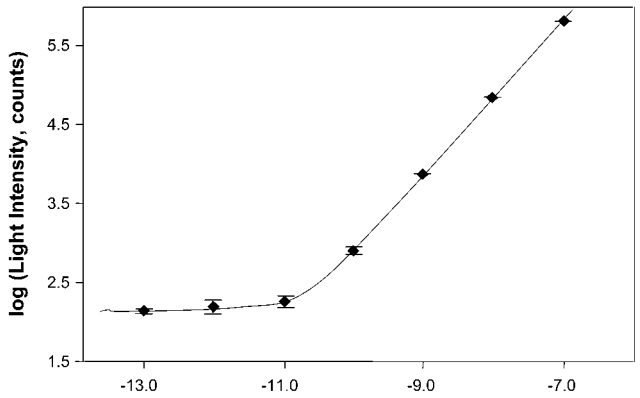

Figure 1. Calibration curve study of the 50/1 aequorin−digoxigenin derivative conjugate. Data are the average plus ± one standard deviation ($n = 3$).

jugates containing approximately one digoxigenin derivative per aequorin molecule were as active as unmodified aequorin. The bioluminescence half-lives of all the conjugates were found to be comparable to the half-life of nonconjugated mutant aequorin. Performance of the conjugates was also evaluated in terms of change in the luminescence activity of aequorin−digoxigenin derivative conjugate in a solution phase in the presence of anti-digoxin antibody. None of the conjugates exhibited any homogeneous change in bioluminescence signal, indicating that the binding event between aequorin-labeled analyte and antibody does not have any effect on the activity of the protein. On the basis of the results obtained above, we decided to use an digoxigenin derivative−aequorin conjugate, 50/1, for further studies. The conjugate 50/1 showed good bioluminescence activity with a low detection limit. The conjugate 25/1 provided a better detection limit than the conjugate 50/1; however, the probability of attachment of digoxigenin derivative to aequorin in a conjugation reaction is higher for the molar ratio of 50/1 of aequorin to digoxin.

A concentration of 1×10^{-9} M of the conjugate 50/1 was selected from the calibration study for further studies as this is a relatively low concentration of protein capable of generating a signal that is well above the background. A typical calibration curve for 50/1 conjugate is presented in Figure 1.

The next step in the study was to determine the amount of antibody to be used in subsequent experiments. For that purpose, a binder−dilution curve was generated (see Figure 2). The biotinylated anti-digoxin antibody was immobilized on a neutravidin-coated plate by taking advantage of the strong binding affinity of neutravidin for biotin. A concentration of antibody of 2 μg/mL was selected from the linear portion of the binder−dilution curve for further studies. This concentration of antibody was chosen in order to achieve a low detection limit while keeping a high signal.

To reduce the total assay time, the optimum time required for binding of the aequorin−digoxigenin derivative conjugate to the antibody was determined by generating an association curve. The association study shown in Figure 3 was performed in the same manner as the binder−dilution study, except that the incubation time for binding the mutant aequorin−digoxigenin derivative conjugate to the antibody was varied. An association time of 2 h was selected since there is no substantial increase in binding after 2 h of incubation.

After evaluating various parameters, such as optimum amount of conjugate, antibody, and time, a dose−

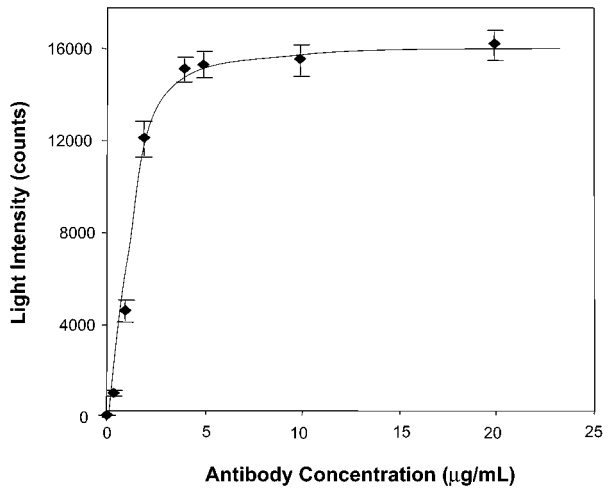

Figure 2. Binder−dilution study conducted using a 100 μL of 1×10^{-9} M 50/1 conjugate with 100 μL of the varying anti-digoxin antibody concentrations. Data are the average plus ± one standard deviation ($n = 3$).

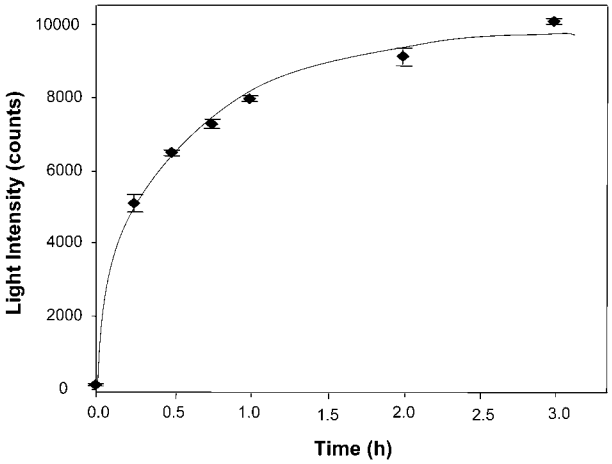

Figure 3. Association time study performed using 100 μL of 1×10^{-9} M 50/1 conjugate, and 100 μL of 2 μg/mL anti-digoxin antibody varying the incubation time period. Data are the average plus ± one standard deviation ($n = 3$).

response curve was generated for digoxin using the conjugate 50/1 in a sequential binding mode. The sequential binding mode has the advantage of producing a lower detection limit compared to the competitive binding mode. When the dose−response curve was generated using the competitive binding mode, a detection limit of 1×10^{-9} M was obtained (data not shown). To generate a dose−response curve in sequential binding format, various concentrations of free digoxin were incubated with the immobilized antibody followed by a washing step. Next, the conjugate was added and the luminescence intensity was measured. The dose−response curve obtained is shown in Figure 4. The study indicated that as expected the luminescence intensity was lower at higher concentrations of free digoxin and that the intensity of the signal increased with decreasing amounts of the digoxin. From this curve, a working range of 4 orders of magnitude was obtained and the detection limit was determined to be 3×10^{-10} M (S/N = 3).

The degree of conjugation was determined for all the conjugates prepared using a spectrophotometric method reported previously (Table 1) (*23*). The results showed that the conjugate 25/1 has 1.1 digoxigenin derivatives per aequorin molecule. Conjugate 50/1 resulted in 2.0 digoxigenin derivatives per aequorin. The other conju-

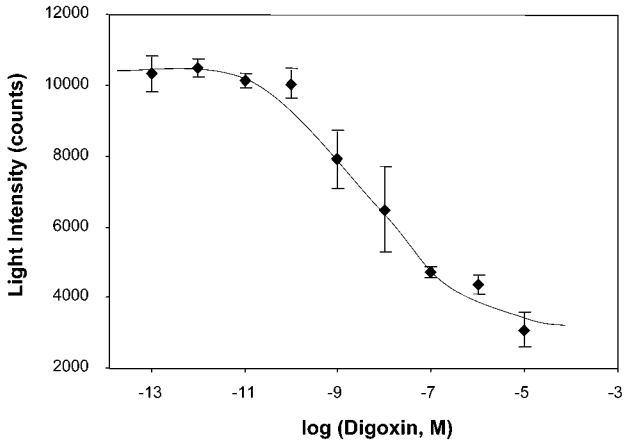

Figure 4. Dose−response curve generated in a sequential binding mode using 100 μL of 1×10^{-9} M 50/1 conjugate and 100 μL of 2 μg/mL anti-digoxin antibody. A stock solution of digoxin was serially diluted and used in the concentration range from 1×10^{-5} to 1×10^{-13} M. Data are the average plus ± one standard deviation ($n = 3$).

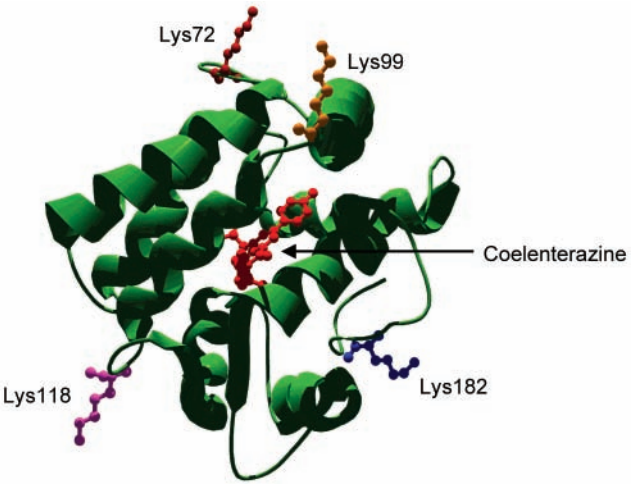

Figure 5. The three-dimensional X-ray crystal structure of aequorin showing the lysine residues 72, 99, 118, and 182. The figure was prepared using Swiss-PdbViewer (*24*) and rendered using POVRAY (*32*).

gates, 100/1, 250/1, and 500/1 had a degree of conjugation of 4.0, 4.0, and 4.1 digoxigenin derivatives per aequorin, respectively. Given these results, it appears that a maximum of four lysine molecules are being conjugated with the digoxigenin derivative employed. An examination of the X-ray crystal structure of aequorin using Swiss-PdbViewer (*24*) revealed that out of the fourteen lysines in the protein, Lys118 and Lys99 are the most accessible to the solvent with ≥62% and 52% accessible surface, respectively (Figure 5). The residues Lys72, Lys182, and Lys88 are also exposed to the solvent but to a lesser degree. The residue Lys72 has ≥43% accessible surface and residues Lys182 and Lys88 have ≥41% accessible surface. Among other lysines, Lys17 and Lys56 have 35% and 31% accessible surface, respectively. The remaining lysine residues, Lys59, 30, 39, 87, 96, 130, and 134 have less than 25% accessible surfaces. We also examined the crystal structure using Swiss-PdbViewer for the possibility of lysine residues forming ionic bonds with nearby aspartate or glutamate residues. We found that Lys30, 56, and 88 are within 3 Å from Glu76, Asp60, and Asp92, respectively. These lysine residues may form ionic bonds and thus may not be available for conjugation. Therefore, on the basis of our conjugation results

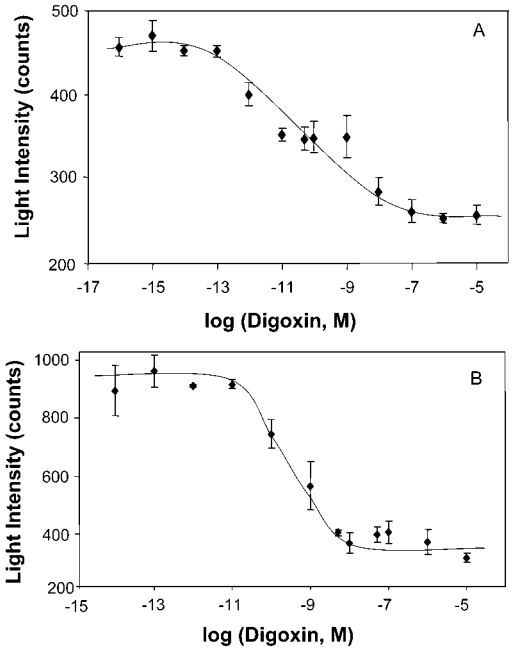

Figure 6. Dose−response curves for digoxin generated using 100 μL of 5×10^{-11} M 25/1 aequorin−digoxigenin derivative conjugate with 100 μL of (A) 0.5 μg/mL and (B) 2 μg/mL anti-digoxin antibody. Data are the average plus ± one standard deviation ($n = 3$).

as well as on the X-ray crystal structure analysis, we postulate that Lys118 and Lys99 are the ones that are most likely conjugated with digoxigenin derivative followed by Lys72 and Lys182.

Since better detection limits will be achieved from the system with only one analyte conjugated per label, digoxigenin derivative−aequorin conjugate 25/1 would provide better detection limit than the conjugate 50/1 (*25*). Thus, dose−response curves were also generated using conjugate 25/1. Two different concentrations of anti-digoxin antibody, 0.5 μg/mL and 2 μg/mL, were employed in the study (Figure 6). When the concentration of anti-digoxin antibody was increased from 0.5 μg/mL to 2 μg/mL, the curve became steeper, and as expected the detection limit for digoxin worsened. This is because as the amount of binder is increased, more free-analyte is required to compete with the labeled analyte. A detection limit of 1.0×10^{-12} M was obtained for digoxin using 0.5 μg/mL of antibody (Figure 6A). The dose−response curve generated using 2 μg/mL of anti-digoxin antibody has a dynamic range of 3 orders of magnitude and a detection limit for digoxin of 1.0×10^{-11} M (Figure 6B). The detection limits were calculated by measuring the signal at three times the standard deviation of the blank. The sensitivity of the assay when calculated in terms of standard deviation at zero dose (σ) (*26*) showed that a lower value of σ was obtained using 2 μg/mL antibody as compared to 0.5 μg/mL of the antibody. Thus, the system is more sensitive when 2 μg/mL of antibody is employed in the study. In general, a better detection limit for digoxin was obtained employing the conjugate 25/1 than when the conjugate 50/1 was used.

The assay developed was employed in the analysis of digoxin spiked in serum samples to determine the effect of the serum matrix on the detection of aequorin. Although this study is not equivalent to real patients sample analysis, it can serve as a good model. It has been found that myocardial digoxin concentration reaches steady state with serum digoxin concentration after several hours of the oral dose (*20*). Thus, digoxin is

Table 2. Percent Recovery of Digoxin in Serum.

spiked concentrations (ng/mL)	percent recovery[a]

routinely monitored in the serum of the patients. The advantage of using aequorin as a label in serum analysis is that the samples do not need any pretreatment due to the absence of background signal. Before performing the serum sample analysis, we investigated the effect of serum on aequorin activity by incubating the aequorin−digoxigenin derivative conjugates in both buffer and in serum. No effect of the serum matrix was observed on the activity of conjugates (data not shown). To mimic digoxin in the real sample, standard amounts of digoxin corresponding to the therapeutic range were spiked into the serum aliquots and employed in the study. Serum sample analyses were performed using the conjugate 25/1. The percent recoveries of digoxin in serum samples were determined from the dose−response curve generated for digoxin standards (Table 2). The results indicated that the matrix in the serum has very little effect on the assay.

In the development of an immunoassay, the specificity of the assay is very important, especially in assays for drugs with narrow therapeutic range. The presence of compounds similar in structure to the target analyte in the sample can provide with erroneous results if the assay is not selective. Since the therapeutic range of digoxin is narrow, its accurate determination in the presence of interferents is essential (*27*). There are several other drugs used in this cardiac treatment that have the structures similar to digoxin. For example, digitoxin, a structurally related cardiac glycoside to digoxin, has been found to decrease the apparent digoxin concentration in the sample (*28*, *29*). Oleandrin, another cardiac glycoside, present in the oleander plant and used in low doses to treat heart diseases competes with digoxin for the binding to the antibody (*28*, *30*). Bufalin is a cardioactive compound found in the venom of the Chinese toad, and it is also known to interfere in the assessment of digoxin concentration (*28*, *31*). These three compounds were tested for their cross-reactivity in our immunoassay. Aliquots of serum were spiked with various concentrations of these compounds in the absence of digoxin. Serum samples were spiked with the therapeutic amount of digitoxin and bufalin. Oleandrin was used in higher concentration than the other two as the micromolar concentration of oleandrin in serum has been found to provide apparent digoxin concentration in nanomolar range. The assay was conducted using aequorin−digoxin conjugate 1:25, and the percent cross-reactivities were determined from the dose−response curve generated for digoxin. None of the three compounds showed any significant cross-reactivity with the digoxin antibody (Table 3).

Stability studies were also performed for the conjugates in terms of retention of the luminescence activity of aequorin over time. All the conjugates were found to be stable for at least four months when stored in liquid form in Tris buffer (30 mM Tris-HCl pH 7.5 containing 2 mM EDTA) at 4 °C.

Table 3. Cross-Reactivity Study.

compounds added in serum	spiked concentrations (ng/mL)	percent cross-reactivity[a]
digitoxin	10.0	3.2 ± 1.3
	50.1	0.7 ± 0.1
	100.2	0.2 ± 0.1
bufalin	10.0	1.1 ± 1.4
	50.3	0.2 ± 0.1
	100.1	0.1 ± 0.1
oleandrin	9976.9	$2.5 \times 10^{-3} \pm 1.9 \times 10^{-3}$
	49884.6	$6.4 \times 10^{-4} \pm 1.0 \times 10^{-4}$
	99769.1	$3.3 \times 10^{-4} \pm 2.0 \times 10^{-4}$

[a] Percent cross-reactivity is calculated as follows: (Concentration obtained from immunoassay)/(Spiked concentration) × 100%.

In conclusion, a highly sensitive assay for digoxin was developed using a cysteine-free mutant of aequorin. We have demonstrated that a cysteine-free mutant of aequorin offers an excellent alternative to native aequorin to use as a label in the development of immunoassays where cysteines in the native protein are undesirable. This mutant of aequorin was found to be as sensitive as the native aequorin. Its performance in the development of immunoassay for digoxin has shown that this mutant can be used as a label in any immunoassays that require sensitive detection and therapeutic drug monitoring. The conjugates prepared retained their bioluminescence activity and had a long shelf life. This study also showed that the mutant aequorin can be effectively used in the assays requiring real sample analysis, and more importantly, no pretreatment of the samples is required, indicating minimal matrix effect. A detection limit for digoxin of 1×10^{-12} M (femtomoles of drug in the sample) was achieved using this cysteine-free mutant of aequorin. Furthermore, no significant cross-reactivity was observed from structurally similar compounds to digoxin.

Received June 9, 2001; Revised Manuscript Received August 15, 2001

The pathological hallmark of Alzheimer's disease (AD) is accumulation in the brain of amyloid composed of the 40-mer peptide Aβ. Many fundamental questions about the biology of (AD) remain unanswered because there is currently no method of quantifying Aβ amyloid in vivo. A noninvasive method of detecting and quantifying Aβ amyloid in vivo would have wide application for the premortem diagnosis of AD and the efficient evaluation of candidate therapeutics aimed at inhibiting the formation and growth of Aβ amyloid. Taking advantage of the extraordinarily high affinity of Aβ for itself, we have synthesized an N′-terminal diethylenetriaminepentaacetic acid (DTPA) derivative of Aβ possessing the kinetic activity and specificity for Aβ amyloid desired of a probe to be used for noninvasive imaging. DTPA-Aβ(3−40) is readily labeled with $^{111}InOAc_3$ to yield a stable probe with exquisite specificity for naturally occurring and synthetic Aβ amyloid in vitro. Moreover, ^{111}In-DTPA-Aβ(3−40), administered intravascularly can specifically deposit onto and label previously injected synthetic Aβ amyloid and be imaged in vivo with a γ camera. The present results demonstrate the design, synthesis, and use of an Aβ amyloid-specific probe and methods for its use as a noninvasive imaging agent. In vivo imaging of Aβ amyloid represents an important step toward the development of biochemically based objective tools for the assessment of progression of AD and efficacy of potential therapeutics.

INTRODUCTION

Approximately 20 human diseases known as amyloidoses have as a common feature the ordered assembly of naturally occurring nonpathogenic peptides and proteins into insoluble fibrillar polymers ("amyloid"), which accumulate and are associated with damage to surrounding tissue (*1*, *2*). The ordered self-assembly of the amyloid forming proteins into β-sheet structures continues to be the focus of research aimed at understanding the pathogenesis of these diseases (*3*) as well as the development of therapeutic interventions (*4*, *5*).

The most common amyloidosis and most common neurodegenerative disease is Alzheimer's disease (AD). Almost a century after its first description (*6*), AD is a major cause of morbidity and mortality among the elderly, affects 40−60% of the population over 85 years of age, and ranks as the third leading cause of death in the elderly population of the developed world behind cardiovascular disease and cancer (*3*). The pathological hallmark of AD is the presence of cerebrovascular and parenchymal amyloid in the brain, concentrated in the hippocampus, amygdala, and cerebral cortex (*3*, *7*−*13*). The major constituent of these amyloid plaques is the human β-amyloid peptide (Aβ), a 39−43 residue peptide (*14*−*16*) of unknown function produced by the proteolytic cleavage of the much larger amyloid precursor protein by two enzymes, β and γ secretase (*17*−*19*). Aβ is expressed constitutively in most tissues as a natural product; its production is not pathogenic, as it is found in similar total concentrations (nM) in both AD positive and negative individuals (*20*−*22*).

Aβ amyloid also exerts a pathological influence peripherally in human skeletal muscle. Inclusion body myositis (IBM) is the most common skeletal muscle disorder in adults, with a typical onset at age 50 or older (*23*, *24*). Both AD and IBM occur as age-dependent, sporadic, or genetically complex familial diseases and share multiple pathologic traits resulting in progressive tissue degeneration. Among a number of features common to AD and IBM, the pathology resulting from the accumulation of Congo red (an amyloid-specific dye) positive fibrillar Aβ deposits continues to be central to investigations aimed at elucidating these diseases (*25*). It is likely that AD and IBM also share pathogenic steps of disease progression given their mutual Aβ amyloid accumulations, and an increased understanding of one of these diseases may provide further details about the other. At present, many questions about the biology of these Aβ amyloidoses remain unanswered because there is currently no method of detecting and quantifying Aβ amyloid in vivo.

Historically, administration of Congo red (sodium diphenyldiazo-bis-α-naphthylamine sulfonate), introduced in 1923 (*26*), had been used to diagnose the presence of systemic amyloidosis by the measurement of the optical density of serum before and after administration and the amount of Congo red excreted in the

patients' urine (*27*). This method proved unreliable because it lacked the sensitivity (high proportion of false negatives), utility, and safety to be used as a diagnostic or research tool. More recently, noninvasive imaging of peripheral amyloid using radiolabeled purified human serum amyloid P (SAP) has been demonstrated and advanced toward clinical use (*28*, *29*).

Attempts at noninvasive detection of Aβ amyloid in vivo have been made using antibodies (*30*), Congo red derivatives (*31*, *32*), and other amyloid-specific dyes (*33*−*35*). Radiolabeled derivatives of Aβ show exquisite sensitivity at detecting Aβ amyloid in brain sections (*36*−*39*) and have been shown to label brain amyloid in vivo in both rodents (*36*) and primates (*38*). Despite these advances, the goal of noninvasive in vivo Aβ amyloid detection has remained elusive because of one or more shortcomings in sensitivity, specificity, kinetics, or accessibility.

Here, we report the design and synthesis of an Aβ derivative in which the two N-terminal amino acid residues have been replaced with the high affinity (K_d = 10^{-29} M) (*40*) ^{111}In chelating moiety diethylenetriaminepentaacetic acid (DTPA). We show that the resulting Aβ derivative, DTPA-Aβ(3−40), can be rapidly and easily labeled with ^{111}In, yielding a radiotracer that closely tracks the kinetic activity and specificity of the previously characterized (*39*, *41*−*43*) ^{125}I-Aβ in vitro. Further, we illustrate that ^{111}In-DTPA-Aβ(3−40), administered intravascularly, can deposit onto peripheral synthetic Aβ amyloid in the biceps femoris muscle of a rat and be imaged noninvasively with a γ camera in vivo. This is, to our knowledge, the first time that Aβ amyloid has been detected and imaged noninvasively in a living animal. This demonstration is a significant step toward the development of an imaging agent with the requisite properties for detection and measurement of Alzheimer's disease Aβ amyloid in vivo.

EXPERIMENTAL PROCEDURES

Synthetic Peptides and Radiolabeling. Aβ(1−40), the major form of Aβ found in human CSF (*14*, *21*), and DTPA-Aβ(3−40), synthesized by fluorenylmethoxycarbonyl (Fmoc) chemistry and purified by HPLC (>98%), were purchased (Quality Controlled Biochemicals, Hopkington, MA) and stored lyophilized at −20 °C. DTPA was added as the dianhydride (Aldrich Chemical Co., Inc., Milwaukee, WI) to the amino terminus of Aβ(3−40) during solid-phase synthesis (Figure 1). The purified peptides were characterized by analytical RP-HPLC (to 98%), amino acid analysis, and matrix-assisted time-of-flight mass spectrometry (Aβ(1−40) = 4329.86; DTPA-Aβ(3−40) = 4520.82).

Aβ(1−40) was radioiodinated (^{125}I at tyrosine-10, methionine-35 as native thioether) with Na^{125}I (Amersham, Arlington Heights, IL) as previously described (*39*) and was purified to a specific activity of 2000 Ci/mmol (10^9 dpm/μg; 1 ^{125}I molecule/Aβ peptide). The labeled peptide was stored at −20 °C in the eluting HPLC mobile phase with 2-mercaptoethanol (0.5%) added to prevent oxidation during storage.

$^{111}InCl_3$ in 40 mM HCl (Nycomed Amersham, Cincinnati, OH) was converted to $^{111}InOAc_3$ by the addition of 0.5 M NaOAc (pH 6) to yield final concentrations of 33 mM HCl and 83 mM NaOAc (*44*). One hundred microliters (1.2 mCi, 26 pmol ^{111}In) of this $^{111}InOAc_3$ stock solution was added to 10 nmol of DTPA-Aβ(3−40) dissolved in 900 μL of ammonium succinate buffer to achieve a final buffer concentration of 50 mM (pH 3). After 60 s

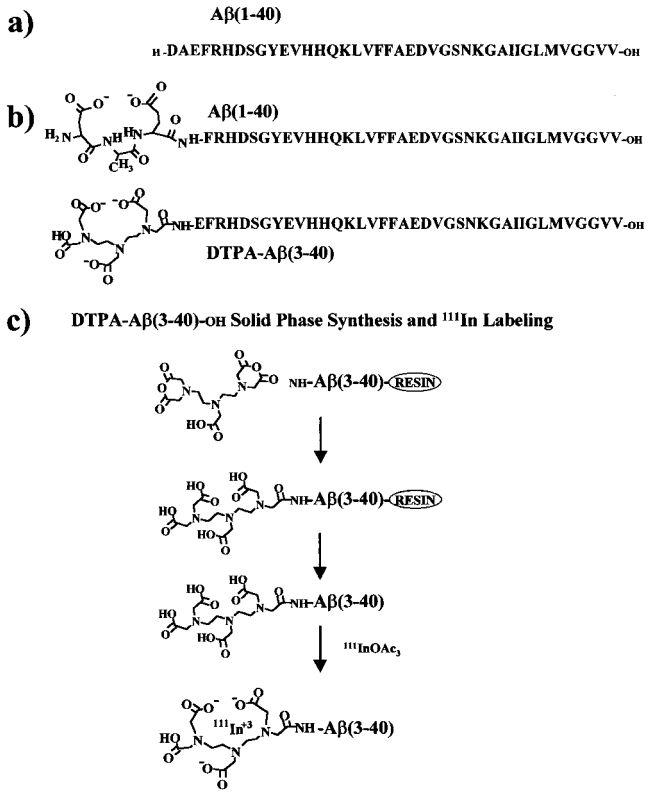

Figure 1. (a) Amino acid sequence of Aβ(1−40) and (b) N′-terminal chemical structure of Aβ(1−40) and DTPA-Aβ(3−40). (c) Solid-phase synthesis of DTPA-Aβ(3−40) using DTPA dianhydride and ^{111}In labeling with $^{111}InOAc_3$.

at room temperature with gentle manual mixing, the reaction was stopped by the addition of 2 mL of 1 mM DTPA free acid in 10 mM aqueous trifluoroacetic acid (TFA) (pH 2). The labeled peptide was purified from the ^{111}In-DTPA using a Sep-Pak Light (Waters Corp., Milford, MA) reversed-phase chromatography cartridge and a stepwise gradient of 0%, 10%, 20%, 40%, 60%, 80%, 90%, 95%, and 100% MeOH/EtOH (50:50) in 10 mM TFA (pH 2) (Figure 2a). Elution fractions 7−9 (200 μL each) were pooled and stored in the eluting mobile phase (approximately 85% MeOH/EtOH in 10 mM aqueous TFA) at room temperature (4 °C for size exclusion stability testing) until used for experiments. Using the 385:1 ratio of DTPA-Aβ(3−40):^{111}In with the conditions described above, ^{111}In labeling of DTPA-Aβ(3−40) is scalable to yield low μCi to high mCi amounts of ^{111}In-DTPA-Aβ(3−40). For in vitro experiments, stock solutions of ^{111}In-DTPA-Aβ(3−40) were diluted to the desired concentrations directly into the assay buffers.

Size exclusion chromatography (SEC) (FPLC; Amersham Pharmacia, Piscataway, NJ) was performed as described (*45*) to characterize the assembly state and stability of the radiotracers. Briefly, ^{125}I-Aβ(1−40) (calculated MW = 4455) or ^{111}In-DTPA-Aβ(3−40) (calculated MW = 4631) were diluted to about 2×10^5 cpm/mL in a 100 mM Tris buffer (0.01% BSA; pH 7.5), centrifuged for 10 min at 14 000*g*, loaded onto a Superdex 75 (10 mm i.d., 30 cm length) column, and eluted with a 100 mM Tris buffer (pH 7.5) at 30 mL/h. Thirty second elution fractions were collected and quantified with a γ counter. The SEC characterization was performed daily for 9 consecutive days using freshly prepared radiotracer (day 1) stored at 4 °C and 20 °C. Standard radiation safety handling precautions and shielding were used to minimize exposure during all experiments which employed the use of ^{111}In or ^{125}I.

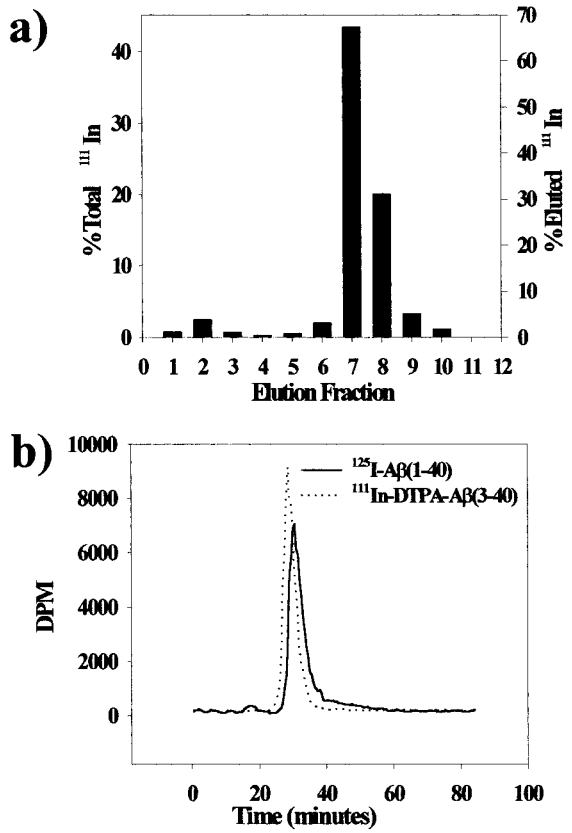

Figure 2. DTPA-Aβ(3−40) efficiently labels with ^{111}In. (a) Approximately 65% of total ^{111}In added to the labeling reaction and greater than 95% of ^{111}In eluted from the labeling reaction are eluted in the peptide fractions. (b) SEC of ^{111}In-DTPA-Aβ-(3−40) and ^{125}I-Aβ(1−40) indicate they are soluble monomers.

Deposition onto AD and Synthetic Aβ Amyloid In Vitro. Synthetic amyloid was prepared as previously described (*46*). Briefly, fibrillar aggregates were prepared from solutions of 10^{-4} Aβ in phosphate-buffered saline (PBS) (pH 7.5). Aβ(1−40) was dissolved in PBS, resulting in a clear solution with no evidence of flocculation or incomplete dissolution. Immediately following dissolution, peptide solutions were incubated under vigorous agitation (Teflon-coated magnetic stir bar at 800 rpm) at room temperature for up to 24 h until visible turbidity no longer increased. After aggregation, the suspensions were frozen on dry ice and stored at −20 °C until used. Synthetic amyloid plates (*46*) were prepared by diluting the aggregated Aβ(1−40) in 0.1% gelatin (60 °C) to yield 10 μg of peptide/mL of final concentration. The resulting suspension was aliquotted onto glass microscope slides for autoradiography or into flexible 96-well assay plates at 1.0 μg of Aβ peptide/well, dried overnight at 60 °C, and stored at room temperature. For deposition assays, the synthetic amyloid plates were preincubated with PBS, (0.1% BSA; pH 7.5) for 30 min. The preincubation buffer was removed, and 100 pM ^{125}I-Aβ(1−40) or 12.5 pM ^{111}In-DTPA-Aβ(3−40) in the PBS buffer was added to each well. After the incubation period (5−240 min), the radiotracer solution was removed, and wells were washed three times with an automated 96-well plate washer (Bio-Tek Instruments, Inc., Winooski, VT), separated, and quantified with a γ counter.

For a test of biological stability, 6.25 pM ^{111}In-DTPA-Aβ(3−40) was used to compare deposition kinetics onto synthetic amyloid in heparinized (250 IU/mL) fresh whole rat blood (collected using cardiac puncture immediately before the experiment) and PBS buffer in parellel. Deposition times of 15, 45, 120, and 1380 min in either buffer or blood were used, and workup was as described previously.

Deposition of ^{125}I-Aβ(1−40) and ^{111}In-DTPA-Aβ(3−40) radiotracers onto immobilized synthetic amyloid and slide-mounted tissue sections for autoradiography was performed as described (*39*, *41*, *46*, *47*). Tissue sections were preincubated at room temperature for 30 min with a PBS deposition buffer (0.1% BSA, 0.004% bacitracin, 0.0002% chymostatin, and 0.0002% leupeptin (pH 7.5)). After preincubation, the buffer was drained from the tissue, and fresh buffer containing the desired concentration of ^{125}I-Aβ(1−40) or ^{111}In-DTPA-Aβ(3−40) was added. After incubation, radiotracer was drained and aspirated from the slides, and the slides were washed three times for 3 min each in PBS (0.1% BSA; pH 7.5) followed by two 5 s rinses in distilled water. Dried slides were placed on film, stored at room temperature for desired exposure, and developed with a Kodak XOMAT film processor.

Immunohistochemical confirmation of Aβ was performed as described (*48*). Sections were washed in Tris-buffered saline (TBS; 140mM NaCl, 2.7 mM KCl, and 24.8 mM Tris, (pH 7.4)) for 20 min followed by 10 min in ethanol/distilled water (1:1). Sections were then washed three times for 10 min each in TBS, washed in blocking solution containing TBS and 10% normal goat serum (NGS) for 30 min, and incubated overnight at 23 °C in TBS containing 1% NGS and polyclonal anti-Aβ (R1282; 1:1500) raised against unaggregated synthetic Aβ(1−40). Three 10 min washes in TBS preceded a 1 h incubation at 23 °C in TBS containing 1% NGS and biotinylated donkey antirabbit IgG (1:500; Jackson ImmunoResearch, West Grove, PA). Sections were washed three times for 10 min each in TBS followed by incubation for 45 min at 23 °C in TBS containing 1% NGS and fluorescein (FITC)-conjugated avidin (1:200; Jackson ImmunoResearch). Sections were again washed three times for 10 min each with TBS and coverslipped using PBS/glycerol (1:1). Immunofluorescence was examined using a MRC-1024 Confocal Imaging System equipped with a krypton/argon ion laser in conjunction with an Olympus BX-75 microscope. Thioflavine S detection of Aβ amyloid was performed by fixing the tissue sections with a 4% paraformaldehyde solution for 30 min followed by a 5 min rinse in each 50% and 80% ethanol. Sections were then incubated in a 1% solution of Thioflavin S for 15 min followed by three 5 min washes in 80% ethanol. Thioflavin S fluorescence was examined using a Zeiss Axioplan microsope imaging system. Labeled sections were imaged using filters appropriate for the specific visualization of either fluorescein or Thioflavin S.

Imaging Synthetic Amyloid In Vivo. All animal experiments were performed under a University of Cincinnati IACUC-approved animal protocol in an AALAC-accredited facility. Five Sprague Dawley rats (100−300 g; Harlan, Indianapolis, IN) were anesthetized with a ketamine (60 mg/mL)/xylazine (12 mg/mL) cocktail. The posterior legs of each animal were clipped and scrubbed, and either synthetic Aβ amyloid (1 μg/μL, 0.9% NaCl) or vehicle was injected into the rat biceps femoris muscle. Animals recovered from anesthesia and were housed individually for one week with food and water ad libitum prior to injection of ^{111}In-DTPA-Aβ(3−40) and in vivo imaging. Pooled elution fractions collected from ^{111}In-DTPA-Aβ(3−40) synthesis were concentrated by evaporation and reconstituted in PBS (pH 6.0; 0.05% Tween 80) prior to injection. Animals were briefly anesthetized using isoflurane, and ^{111}In-DTPA-Aβ(3−40) was injected

(100 μL/min, 2 μCi/μL ^{111}In-DTPA-Aβ(3−40)) into a tail vein. At time intervals from 5 min to 7 days postinjection, animals were anesthetized with isoflurane for in vivo planar γ camera imaging. A Siemens LEM portable γ camera, equipped with both parallel hole and pinhole collimators, was used to image the labeled synthetic amyloid in vivo. After the appropriate survival time, the animals were anesthetized for a final time with a ketamine (60 mg/mL)/xylazine (12 mg/mL) cocktail and then rapidly perfused through the left ventricle with ice cold heparinized (250 IU/mL) saline (0.9% NaCl). After perfusion, the animals were dissected, and the muscle tissue was frozen, blocked, and sectioned with a cryostat microtome onto glass slides for autoradiography and Thioflavin S staining.

RESULTS

Synthesis and ^{111}In Labeling of DTPA-Aβ(3−40). After solid-phase peptide synthesis, DTPA-Aβ(3−40) (Figure 1) was deprotected, cleaved from the resin, and purified. DTPA-Aβ(3−40) has a molecular weight of only 176 Da greater than the naturally occurring Aβ(1−40) and, when labeled with ^{111}In at neutral pH, has an N′-terminal charge difference of only +1. The peptide is efficiently and stably labeled with ^{111}In (Figure 2a). DTPA-Aβ(3−40) can be labeled in high yield in 60 s, and longer incubation under these conditions did not improve the labeling efficiency or total yield of labeled peptide (data not shown). The conditions employed yield ^{111}In-DTPA-Aβ(3−40) with a specific activity of approximately 122 Ci/mmol with 65% ^{111}In incorporation, and scale-up is straightforward. SEC (*45*) (Figure 2b) confirmed that the ^{111}In-DTPA-Aβ(3−40) and ^{125}I-Aβ(1−40) used in these experiments were nonaggregated monomeric solutions. As expected, freshly prepared ^{111}In-DTPA-Aβ(3−40) elutes slightly earlier than monomeric ^{125}I-Aβ(1−40) (Figure 2b). Further, SEC confirmed the stability of ^{111}In-DTPA-Aβ-(3−40) as it remains in monomeric form with no detectable dissociation of ^{111}In for at least three ^{111}In half-lives when stored at either 20 or 4 °C (data not shown).

In Vitro Deposition Activity of ^{111}In-DTPA-Aβ(3−40). Successful in vivo amyloid detection and quantification using a radiolabeled Aβ derivative such as ^{111}In-DTPA-Aβ(3−40) depends on the ability of this derivative to specifically bind to and deposit onto endogenous amyloid plaques. Figures 3 and 4 show that ^{111}In-DTPA-Aβ(3−40) does specifically deposit onto both cerebrovascular and parenchymal Aβ amyloid in human AD brain tissue in vivo. Serial sections (Figure 3a,b) show that the same amyloid deposits labeled by ^{125}I-Aβ(1−40) are labeled by ^{111}In-DTPA-Aβ(3−40). High signal-to-noise exhibited on the human AD tissue sections and negligible signal on age-matched non-AD control serial sections (Figure 3d,e) further demonstrate that these radiolabeled Aβ derivatives are specific for the Aβ amyloid. Moreover, ^{111}In-DTPA-Aβ(3−40) shows significantly improved sensitivity over ^{125}I-Aβ(1−40) (Figure 3a,b), although the ^{125}I-Aβ(1−40) label has a much higher specific activity.

To confirm that ^{111}In-DTPA-Aβ(3−40) is depositing onto and labeling Aβ in the human tissue sections, a human AD tissue section was doubly labeled with ^{111}In-DTPA-Aβ(3−40) and Aβ-specific polyclonal antibody (R1282). ^{111}In-DTPA-Aβ(3−40) exhibits intense and specific labeling of cerebrovascular (CVA) and parenchymal senile plaque (SP) Aβ amyloid (Figure 4). The same CVA and SP (indicated with arrows in Figure 4) that labeled with ^{111}In-DTPA-Aβ(3−40) also labeled with the anti-Aβ antibody. Thioflavin S staining (Figure 4d,e) similarly validates the specificity of ^{111}In-DTPA-Aβ(3−40). ^{111}In-DTPA-Aβ(3−40) labels Aβ amyloid with great sensitivity, and the physical properties (specific activity, half-life, and decay energy) of ^{111}In enable excellent autoradiography resolution, as demonstrated by the ability to resolve the microvasculature lumen containing Aβ amyloid (indicated by arrow in Figure 4b).

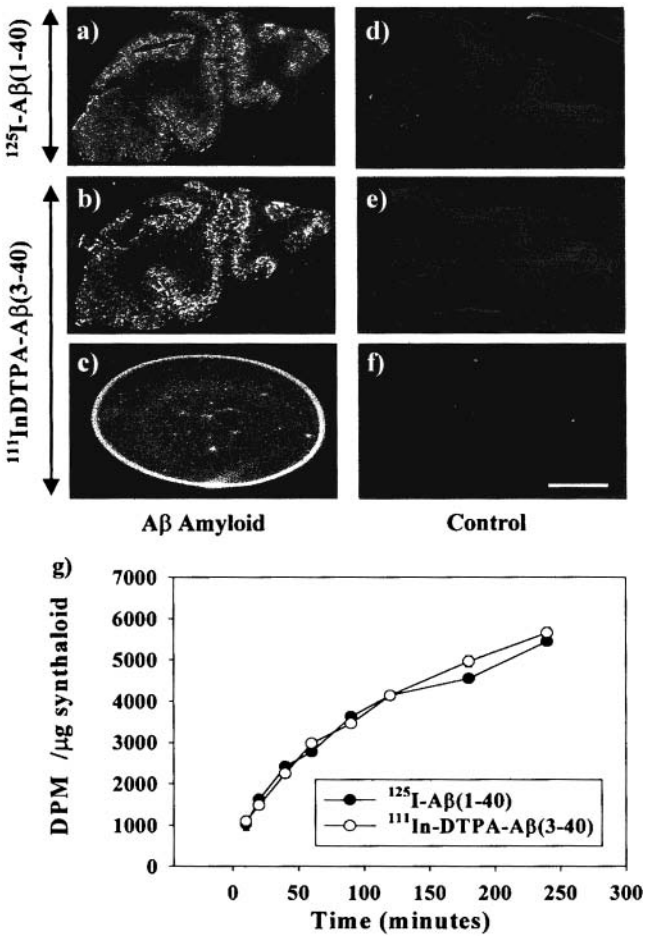

Figure 3. In vitro deposition and Aβ amyloid labeling with ^{111}In-DTPA-Aβ(3−40). Darkfield film autoradiograms of (a, b) 15.5 pM ^{111}In-DTPA-Aβ(3−40) or 125 pM ^{125}I-Aβ(1−40) incubated for 3 h on unfixed human AD cortex tissue sections, (c) immobilized synthetic Aβ amyloid, (d, e) age matched human control tissue sections, and (f) immobilizing polymer control with exposure times of 50 h for ^{111}In-DTPA-Aβ(3−40) (specific activity = 122 Ci/mmol) (for b, e, c, f) and 120 h for ^{125}I-Aβ(1−40) (specific activity = 2000 Ci/mmol) (for a, d) (scalebar = 1 cm). (g) Deposition kinetics of 12.5 pM ^{111}In-DTPA-Aβ(3−40) and 100 pM ^{125}I-Aβ(1−40) deposited onto synthetic Aβ amyloid. Error bars (mostly within symbols) represent mean ± SEM of six replicates.

The ability of ^{111}In-DTPA-Aβ(3−40) to deposit onto and label synthetic amyloid (*46*) was examined. Autoradiography of ^{111}In-DTPA-Aβ(3−40) incubated with synthetic Aβ amyloid immobilized onto a microscope slide versus control (Figure 3c,f) shows that ^{111}In-DTPA-Aβ(3−40) labels synthetic amyloid with high specificity. Comparison of deposition kinetics revealed a similar time course for ^{111}In-DTPA-Aβ(1−40) and ^{125}I-Aβ(1−40) (Figure 3g). Deposition kinetics onto synthetic amyloid in fresh heparinized whole rat blood revealed remarkable stability of ^{111}In-DTPA-Aβ(3−40). After a 23 h incubation, the amount of ^{111}In-DTPA-Aβ(3−40) deposited in the rat blood was 58% of that deposited in the buffer control (Table 1).

Table 1. In-DTPA-Aβ(3−40)Deposition onto Synthetic Amyloid in Fresh Heparinized Whole Rat Blood

time (min)	buffer control (DPM/μg of synthetic amyloid ± SEM)	fresh rat blood (DPM/μg of synthetic amyloid ± SEM)	fresh rat blood (% of buffer control)
15	347 ± 20	385 ± 30	111
45	582 ± 43	730 ± 37	125
120	981 ± 19	1262 ± 75	129
1380	3329 ± 127	1946 ± 115	58

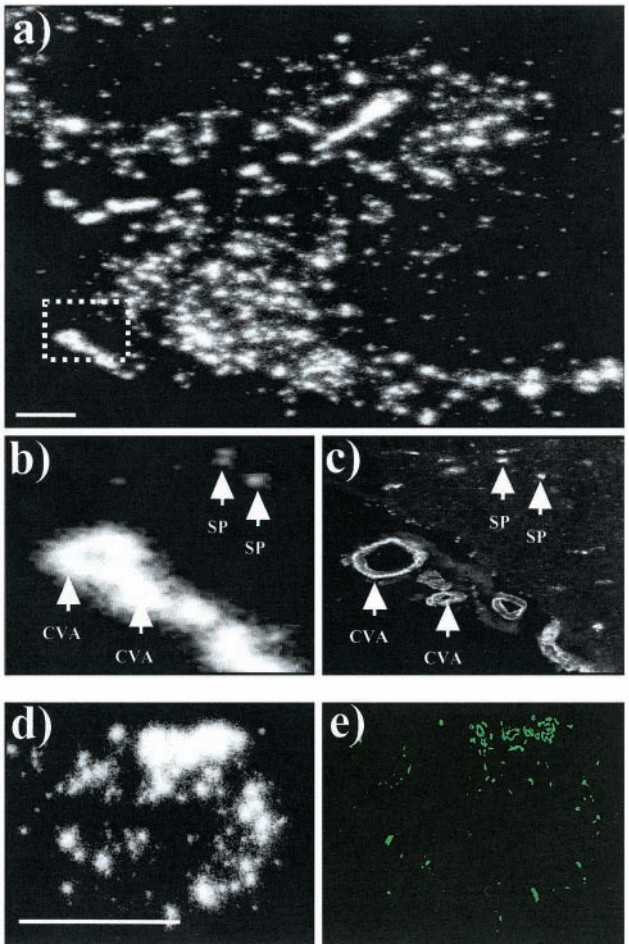

Figure 4. (a) ^{111}In-DTPA-Aβ(3−40) in vitro deposition onto and labeling of Aβ amyloid in unfixed human cortex tissue. Expansion of area indicated by dotted box in (a) is shown in (b) and (c). (b) ^{111}In-DTPA-Aβ(3−40) and (c) polyclonal anti-Aβ antibody R1282 labels showing that ^{111}In-DTPA-Aβ(3−40) deposits onto and labels both cerebrovascular amyloid (CVA) and parenchymal senile plaques (SP) (indicated by arrows). Another human AD cortex section doubly labeled with (d) ^{111}In-DTPA-Aβ(3−40) and (e) Thioflavin S confirms amyloid specificity of ^{111}In-DTPA-Aβ(3−40) (scalebars = 1 mm).

Noninvasive Imaging of Synthetic Amyloid In Vivo with ^{111}In-DTPA-Aβ(3−40). The specificity and sensitivity of ^{111}In-DTPA-Aβ(3−40) at deposition and labeling of naturally occurring and synthetic Aβ amyloid in vitro encouraged us to determine the ability of ^{111}In-DTPA-Aβ(3−40) to deposit onto and label synthetic Aβ amyloid in vivo. ^{111}In-DTPA-Aβ(3−40) injected intravenously (tail vein) deposits onto and labels synthetic Aβ amyloid previously implanted in rat muscle tissue, allowing the Aβ amyloid to be imaged in vivo as shown in Figure 5. The specific labeling of the synthetic Aβ amyloid was imaged with a planar γ camera using high-energy parallel and pinhole collimators and could be detected from 5 min up to 7 days following the injection of ^{111}In-DTPA-Aβ(3−40). Pinhole γ-camera images of rat leg muscle injected with either synthetic Aβ amyloid (Figure 5a) or vehicle (Figure 5b) 1 week earlier demonstrate the

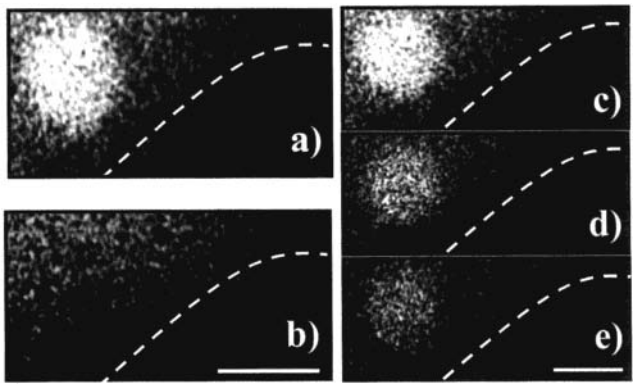

Figure 5. Planar γ-camera images of rat leg in vivo, with biceps femoris muscle containing 150 μg of (a) synthetic Aβ amyloid or (b) an equivalent volume of vehicle (10 min image acquisition time). Images were acquired using a Siemens LEM γ camera with a high-resolution pinhole collimator 97 h postinjection of ^{111}In-DTPA-Aβ(3−40). Signal decay exhibited by images acquired at (c) 97 h, (d) 121 h, and (e) 165 h postinjection of ^{111}In-DTPA-Aβ(3−40). Dashed lines represent the outline of the rat leg (scalebars = 10 mm).

specificity of ^{111}In-DTPA-Aβ(3−40) as an imaging agent for the synthetic Aβ amyloid in vivo. The optimal signal-to-noise ratio for specifically labeled synthetic Aβ amyloid above background radioactivity was attained at approximately 48 h postinjection of ^{111}In-DTPA-Aβ(3−40). Total signal decreased over time with clearance and radioactive decay of the ^{111}In label (Figure 5c−e) and could be compensated for by increasing the image acquisition time (data not shown).

After in vivo imaging, animals were sacrificed and perfused through the left ventricle. Additional γ-camera images acquired postmortem verified the position of the synthetic Aβ amyloid and specificity of the ^{111}In-DTPA-Aβ(3−40) radiotracer. Film autoradiography on tissue sections cut transverse to the synthetic Aβ amyloid injection track confirm that ^{111}In-DTPA-Aβ(3−40) did specifically deposit onto and label the synthetic Aβ amyloid (Figure 6a). Thioflavin S stained the tissue sections in the same region shown to be positive by autoradiography and confirmed that ^{111}In-DTPA-Aβ(3−40) specifically deposited onto and labeled individual synthetic Aβ amyloid aggregates (Figure 6b).

DISCUSSION

The need for a tool to detect and measure Aβ amyloid noninvasively in a living animal or human is well-established. Neuropathological observations in humans (*49*) and animal models (*9*, *33*, *35*, *36*, *38*, *48*, *50*) of AD indicating a direct correlation between disease symptoms and amyloid burden are fundamental to the amyloid hypothesis (*7*, *12*). The characterization of two transgenic animal models of inclusion body myositis, a skeletal muscle Aβ amyloidosis, also imply this relationship (*51*, *52*). To date, a thorough evaluation of this hypothesis has been elusive because there is currently no method of detecting and measuring the salient pathological feature, Aβ amyloid, in vivo.

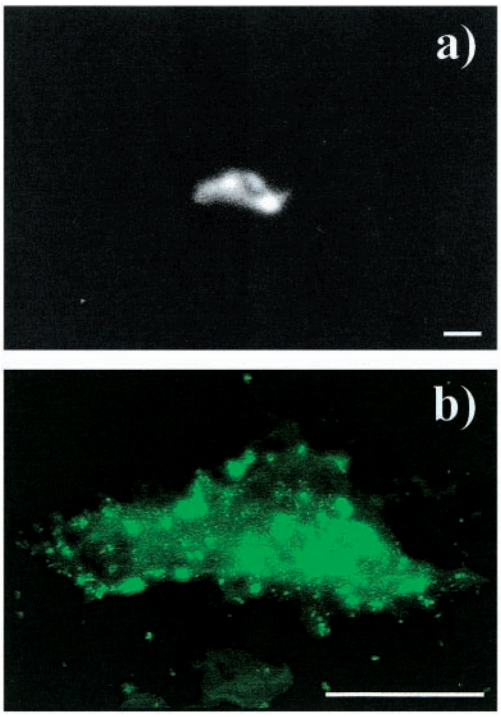

Figure 6. (a) Rat biceps femoris muscle tissue section darkfield film autoradiogram (20 h exposure, scalebar = 2 mm) showing synthetic Aβ amyloid labeled in vivo with ^{111}In-DTPA-Aβ(3−40). (b) Thioflavin S image of the same section confirming the presence of individual synthetic Aβ amyloid aggregates within the tissue area labeled with ^{111}In-DTPA-Aβ(3−40) (scalebars = 250 μm).

The most sensitive and specific method described to date for labeling Aβ amyloid in vitro has been the use of ^{125}I-radiolabeled Aβ peptide (*39*). The specificity results from the extraordinary affinity of Aβ for itself and the sensitivity from the high specific activity of the radiolabeled Aβ (2000 Ci/mmol; 1 ^{125}I molecule/peptide) (*39*, *41*). ^{125}I-Aβ has been shown to accurately track the intrinsic deposition and aggregation activity of unlabeled Aβ in a wide range of experiments in vitro (*39*, *41*, *45*, *46*).

The first significant advance toward the development of a noninvasive in vivo Aβ amyloid imaging agent was the demonstration that ^{125}I-Aβ(1−40), administered intravascularly, crosses the BBB and labels Aβ amyloid in aged primate brain in vivo (*38*). Later studies in transgenic mice using an ^{125}I-Aβ derivative (*36*) or a small fluorescent molecule able to cross the BBB (*35*) are the only known reports of molecules which label brain amyloid in vivo. Antibodies used to label amyloid have the necessary sensitivity and specificity but cannot cross the blood brain barrier (BBB) and, thus, lack accessibility to the lesions of AD (*30*). Several Congo red derivatives (*31*, *32*) or other dye molecules (*35*) have been investigated, and some have successfully overcome the accessibility issue (*35*); but these reagents lack the specificity to label only amyloid and exclude the neurofibrillar pathology found in several other human neurodegerative diseases and the ability to distinguish among amyloidoses derived from different protein precursors. Magnetic resonance imaging techniques have been applied to image Aβ amyloid in tissue samples but have not been advanced to in vivo use (*50*, *53*). Fluorescent microscopy imaging techniques requiring tissue/bone removal for signal detection have had some success at detecting amyloid plaques in the outermost 100 μm of cortex in live transgenic mice (*54*, *55*). However, all of these invasive methods do not facilitate the repetition required to evaluate the amyloid hypothesis or therapeutic efficacy in a single animal.

^{125}I-Aβ crosses the BBB intact in several animals including mice (*56*), rats (*57*), guinea-pigs (*58*), and primates (*59*) and is believed to be carried by a specific transport mechanism (*36*, *58*, *59*). Evidence that BBB permeability can be improved by chemical modification of Aβ (*36*) provides additional support for using radiolabeled Aβ derivatives toward the development of an in vivo Aβ amyloid imaging agent.

Success in detecting and quantifying amyloid by radiochemical imaging in vivo requires an isotope of appropriate energy for nuclear medicine imaging techniques such as planar γ scintigraphy, single photon emission computed tomography (SPECT), or positron emission tomography (PET). The half-life must be long enough to allow sufficient time for radiolabeling, purification to high specific activity, administration, and specific deposition onto the existing endogenous Aβ amyloid. The isotope half-life must also allow background (nonspecifically bound radiotracer) clearance without significantly compromising the intensity of the signal. The intrinsic kinetics (*39*, *43*) of Aβ amyloid deposition fundamental to the use of Aβ derivatives as in vivo imaging agents (Figure 3g) preclude the use of the very short-lived positron-emitting isotopes. A great deal of the signal and specific activity would be lost in the process of labeling and purifying the probes, and multiple half-lives would pass during the deposition process prior to achieving the optimal signal-to-noise ratio for in vivo imaging. The optimal γ decay energy range for SPECT or planar γ scintigraphy is 140−300 keV. Thus, imaging with ^{125}I, a low energy (30 keV) and relatively long half-life isotope, is practical only in tissue sections postmortem. In contrast, ^{123}I has a decay energy (159 keV) suitable for imaging in vivo; however, its relatively short half-life (13.3 h) would prevent its use in Aβ-derivative amyloid imaging agents. A preferable isotope, widely available and used extensively for diagnostic imaging in research and in the clinic, is ^{111}In (γ = 173 and 247 keV, $t_{1/2}$ = 2.8 days) (*40*).

The high affinity trivalent metal chelating moeity diethylenetriaminepentaacetic acid (DTPA) is established (*40*) as a tool for labeling proteins with ^{111}In and has previously been used (*37*) to label Aβ with ^{111}In. In the present study, the two N-teminal residues of Aβ have been replaced with a single DTPA moeity (Figure 1). The conjugation of DTPA to the N terminus of Aβ(3−40) avoids altering the chemical structure of Aβ at Lys16 or Lys28 (*37*) within the Aβ(10−35) sequence shown to be fundamental to the deposition competence of Aβ (*47*). Altering the chemical structure within this key central sequence risks compromising the deposition activity or specificity of the radiotracer. The rapid (60 s) and efficient (Figure 2a) labeling of DTPA-Aβ(3−40) with ^{111}In and purification of ^{111}In-DTPA-Aβ(3−40) produce a radiotracer possessing the specificity and sensitivity desired of an Aβ derivative for use as a noninvasive in vivo Aβ amyloid imaging agent.

As discussed previously, the extraordinary high specific affinity of Aβ for itself confers the specificity of ^{125}I-Aβ(1−40) for Aβ amyloid. Experiments comparing ^{125}I-Aβ(1−40) and ^{111}In-DTPA-Aβ(3−40) demonstrate equally high specificity of ^{111}In-DTPA-Aβ(3−40) for naturally occurring and synthetic Aβ amyloid in vitro (Figure 3). This specificity has been confirmed using two supplemental labels: an Aβ-specific antibody and the amyloid-specific dye Thioflavin S (Figures 3 and 4). As Aβ amyloid peptide probes retain specificity in vivo (*38*), the improved

sensitivity afforded by the physical properties of ^{111}In supported the advancement of ^{111}In-DTPA-Aβ(3−40) to in vivo imaging assays.

As an extension of previous work which showed the ability of ^{125}I-Aβ(1−40) to deposit onto naturally occurring Aβ amyloid plaques in vivo in a primate model of AD (*36*, *38*), we used an in vivo model consisting of peripherally injected synthetic Aβ amyloid to determine whether ^{111}In-DTPA-Aβ(3−40) could be used for noninvasive detection of Aβ amyloid by imaging in a living animal. ^{111}In-DTPA-Aβ(3−40) is able to deposit onto and label synthetic Aβ amyloid in vivo (Figure 5a,b) with specificity comparable to that observed in vitro. The sensitivity evident in vitro is also apparent in vivo and demonstrated by the ability of the γ camera to easily detect, resolve, and image the specifically labeled Aβ amyloid in 10 min (Figure 5). The amount of Aβ amyloid imaged in vivo in Figure 5 is 150 μg, significantly less than that found experimentally (*60*) or theoretically (*61*) in an AD brain. The amount of radiotracer (1.2 mCi) is significantly less than the amount of ^{111}In used in clinical procedures. To the best of our knowledge, the present study is the first report of noninvasive imaging of Aβ amyloid in vivo.

The principle that Aβ amyloid can be imaged noninvasively is established for the first time in the present study. The imaging methods present an example of how these procedures could be adapted to repeated image acquisitions throughout the life of a single animal to monitor the progression of Aβ amyloid burden or the efficacy of potential therapeutics. Furthermore, the sensitivity of γ scintigraphy for detecting the ^{111}In label would allow for efficient screening in multiple animals with little additional time invested relative to the current postmortem methods of detecting and quantifying Aβ amyloid.

The present results describe the development of an Aβ amyloid-specific probe with appropriate kinetics for noninvasive in vivo imaging. We demonstrate the specificity for Aβ amyloid and the sensitivity of imaging with ^{111}In-DTPA-Aβ(3−40) in vitro and in vivo. A desirable property of an AD Aβ amyloid probe, to avoid intrathecal application, is accessibility, the ability of the probe to cross the BBB, and enter the central nervous system. The most desirable method of administration of ^{111}In-DTPA-Aβ(3−40) is intravenous; however, other techniques for delivery to the CNS including injection directly across the BBB into the cerebrospinal fluid, and the use of hyperosmotic mannitol are available and have been effective in animals and humans. The imaging procedures described in the present study would not change following the administration of ^{111}In-DTPA-Aβ(3−40) with either of these methods. The minimal trauma resulting from these administration methods would be transient.

A method for specific in vivo detection and quantification of Aβ amyloid would provide a tool for efficient diagnosis and the capacity to monitor the progression of AD or IBM in an objective, symptom-independent manner. The present study demonstrates a significant step toward the development of such a tool. The ability to evaluate the progression of the disease and the relationship of amyloid burden to symptoms using a single subject over time and the evaluation of candidate therapeutic agents aimed at inhibiting the formation and growth of Aβ amyloid plaques would be a material advance in basic and clinical research related to Alzheimer's Disease.

ACKNOWLEDGMENT

We thank Dr. Dennis Selkoe for his generous gift of antiserum R1282, The University of Cincinnati Hospital Department of Nuclear Medicine for use of the γ camera, Dr. L. C. Washburn for providing $^{111}InCl_3$ and valuable technical advice, and Drs. Randall Sakai and Li Yun Ma for access to their cryostat microtome. This work was supported by NIH (Grant AG12853) and the Alzheimer's Association (Grant ZEN-1842).

Immobilization of Pectin Fragments on Solid Supports: Novel Coupling by Thiazolidine Formation

Fanny Guillaumie,[†,‡] Owen R. T. Thomas,[‡] and Knud J. Jensen*[,†]

Center for Process Biotechnology, Biocentrum-DTU, Building 223, Søltofts Plads, and Department of Chemistry, Building 201, Kemitorvet, Technical University of Denmark, DK-2800 Kgs. Lyngby, Denmark. Received July 26, 2001; Revised Manuscript Received October 18, 2001

As a prerequisite to solid-phase and sequence analyses and for the study of the fine structure of pectin, we have developed oriented and chemoselective methodologies to couple model pectin fragments onto a solid support. Polyethylene glycol polyacrylamide (PEGA) resins were selected due to their excellent swelling properties in a wide range of solvents, including water, and their easy accessibility to enzymes. Following appropriate derivatization of amino-terminated PEGA resins, oligomers of α-D-galacturonic acid (GalA), up to the trimer, were anchored to the support through their reducing end. In addition to reductive amination, the strategies included the formation of an oxime bond, a glycosyl hydrazide, and a pyroglutamyl ring. Further, we developed a new immobilization approach based on the formation of a thiazolidine ring. All methods proved efficient and did not require modification of the GalA oligomers prior to coupling. In addition, very mild conditions and few steps for derivatization of the support were required. Immobilization by thiazolidine ring and oxime bond formation were the preferred methods, given the stability of the linkages formed, their compatibility with aqueous solvents, the few number of steps required, and their potential for application to larger pectin fragments. Thiazolidine and pyroglutamyl anchoring were developed further by the insertion of a disulfide bond which allowed release of the saccharides under mild, selective conditions.

INTRODUCTION

Pectin is a complex polysaccharide that occurs in the primary cell walls and the middle lamella of higher plants (*1*). The main feature of pectin is a linear chain of α-(1→4)-linked D-galacturonic acid units (the so-called 'smooth region') in which varying proportions of the carboxylic acid groups have been converted to methyl esters. The smooth region is interrupted by α-(1→2)-linked L-rhamnose units (the so-called 'hairy region'), carrying further neutral carbohydrate side chains, typically consisting of D-galactose and D-arabinose (*1*). The remarkable gelling properties of pectin have been widely exploited in the food industry for the production of jams, marmalades, and other fruit based products. Pectin has also been used as a stabilizer in dairy products (*2*) and for medical preparations as an antidiarrheal, detoxicant, or in the regulation and the protection of gastrointestinal tract (*1*).

Pectin has been the subject of numerous studies, many of which focused on structure elucidation in pectin (*3*−*9*), binding of pectin with metal ions (*10*−*13*), synthesis of pectin fragments (*14*−*17*), and the development of new analytical methods for pectin structure elucidation (*18*−*20*). However, despite all of these efforts, much still remains to be learned about structure−function relationships in pectin.

Immobilization of pectin fragments on a solid support may prove to be an important technique in the study of fine structure−function relationships in pectin. For example, immobilization would allow solid-phase analysis of the pectin molecule to be carried out and would serve as a prerequisite to sequencing. Moreover, an immobilization strategy could be a useful tool for the determination of the factors influencing the formation of 'egg-box' cavities in pectin. The 'egg-box' model has been proposed for the gelation of low methyl esterified pectin (*21*). It involves the intermolecular binding of two non-esterified segments or two whole pectin chains with interstices in which calcium ions may pack and coordinate.

A number of coupling methods have been developed for the synthesis of glycoconjugates and for the immobilization of oligosaccharides. Reductive amination was one of the first methods to be implemented in the preparation of glycoconjugates (*22*−*24*) and in the coupling of carbohydrates onto solid supports (*25*−*27*). The reactivity toward the reducing end of carbohydrates can be enhanced by substituting amino groups with hydrazide functions. This technique has recently proved to be efficient for the immobilization of simple oligosaccharides on an ELISA plate (*28*). The oxime linkage has also been used to prepare glycoconjugates (*29*) and to immobilize short oligosaccharides on ELISA plates (*28*). Furthermore, small oligosaccharides have been coupled to solid supports (*30*) and glycoconjugates have been prepared (*31*, *32*) by formation of a glycosyl amide linkage. However, none of the above coupling chemistries have so far been applied to the immobilization of polyuronic acids such as pectin or heparin. The formation of a thiazolidine ring has found application in the synthesis of peptide dendrimers (*33*), but has not been applied to the preparation of glycoconjugates nor to the immobilization of oligosaccharides. All of the aforementioned strategies will introduce a stable linkage between the saccha-

ride and the support. Accordingly, in this paper we report on the use of these methodologies for anchoring GalA[1] oligomers onto solid supports. Further, to allow for release of immobilized structures, we have modified the thiazolidine and pyroglutamyl immobilization strategies by including a cleavable disulfide bond. Polyethylene glycol polyacrylamide (PEGA) resin was selected as the solid phase in these studies due to its compatibility with a wide range of solvents, including water, and its accessibility to enzymes with a molecular weight of up to 70 kDa.

MATERIALS AND METHODS

The amino-functionalized PEGA resins (0.4 mmol/g, 150−300 μm, 11.19 wt % in MeOH or 0.2 mmol/g, 300−500 μm, 9.41 wt % in MeOH) used in this study were kindly supplied by Dr. Andrew Coffey of Polymer Laboratories, UK. The PEGA resins were weighed wet, unless stated otherwise. All chemical reagents and solvents were purchased from Sigma-Aldrich Denmark A/S (Vallensbaek Strand, Denmark). All amino acids were of the L-configuration.

General. Melting points were uncorrected. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Varian Mercury 300 instrument equipped with a four-nuclei probe operating at 300.06 and 75.45 MHz, respectively, or on a Varian Unity Inova 500 equipped with a H−C−P probe operating at 499.87 and 125.69 MHz, respectively. FAB-MS analyses were performed on a VG TRIO-2 quadrupole mass spectrometer equipped with a combined electron impact/chemical ionization ion source. The samples were analyzed in the chemical ionization mode with ammonia as reagent gas. ES-MS analyses were conducted on a Micromass LCT mass spectrometer or on a ion trap Esquire-Bruker instrument at Danisco Cultor A/S (Copenhagen, Denmark). Elemental analyses were conducted at the Department of Chemistry, University of Copenhagen. Analytical HPLC was performed with a Waters chromatography system (600E pump, 996 photodiode array (PDA) detector, 717 Plus autosampler, Millenium32 control software) on a 3.0 × 50 mm Waters X-Terra RP_{18} column (3.5 μm particle size), using H_2O (A) and CH_3CN (B) as eluents. The following program was applied: after 0.1 min at 100% A, 0% B, a linear gradient (0−95% B) was applied over the next 5.9 min; the eluent composition was then maintained at 5% A, 95% B for a further 1 min before applying a step change to 100% A, 0% B over 0.1 min to regenerate the column; a flow rate of 1.20 mL/min was employed at all stages. Individual peaks were analyzed by their UV-spectra. All solid-phase reactions were performed in plastic syringes equipped with a polypropylene filter. Before saccharide coupling, all the resins were washed with an increasing concentration of Et_2O in CH_2Cl_2 (0%, 1 × 5 min; 25%, 1 × 5 min; 50%, 1 × 5 min; 75%, 1 × 5 min; 100%, 2 × 5 min) and dried in vacuo for 18 h to give dry PEGA resins suitable for weighing.

Loading Determination by Trityl (Trt) Group Quantitation. The '*indirect method*' was applied to the resins **A**, **B**, **G**, and **H**. Each coupling took place at room temperature and for 1 h. Derivatized resin was washed with CH_2Cl_2−DMF (9:1, 3 × 1 min, 1 × 5 min) and treated with TrtCl (5 equiv) with DIEA (10 equiv) in CH_2Cl_2-DMF (9:1) (*34*). Excess reagents and solvents were removed by filtration, the resin was washed with CH_2Cl_2 (5 × 1 min) and treated with TrtCl (5 equiv) and diisopropylethylamine (DIEA, 10 equiv) in CH_2Cl_2. This coupling step was repeated once. Solvents and unreacted materials were removed by filtration. The resin was then washed with CH_2Cl_2 (3 × 1 min) and treated with TFA−CH_2Cl_2 (1:1) in the presence of Et_3SiH (6 equiv) (*35*). The filtrate was collected, and the resin was washed with two extra portions CH_2Cl_2. The filtrate was evaporated to dryness, redissolved into CH_3CN (1 mL), analyzed by HPLC, and the absorbance of TrtH was read at 226 nm. The amount *n* (mmol) of Trt groups was calculated using a standard curve. The resin was washed with an increasing concentration of Et_2O in CH_2Cl_2 (0%, 1 × 5 min; 25%, 1 × 5 min; 50%, 1 × 5 min; 75%, 1 × 5 min; 100%, 2 × 5 min), dried in vacuo for 18 h, and weighed (*m*). The ratio between *n* and *m* gave the loading of the resin in mmol/g. '*Direct method*': Trt-protected resins **E** and **F** were washed with CH_2Cl_2 (3 × 1 min) and treated with TFA−CH_2Cl_2 (1:1) in the presence of Et_3SiH (6 equiv) (*35*). In each case, the filtrate was collected, and the resin was washed with two extra portions CH_2Cl_2. The filtrate was evaporated to dryness, redissolved into CH_3CN (1 mL), and analyzed by HPLC. The absorbance of TrtH was read at 226 nm and the amount *n* (mmol) of Trt groups was calculated using a standard curve. The resin was washed with an increasing concentration of Et_2O in CH_2Cl_2 (0%, 1 × 5 min; 25%, 1 × 5 min; 50%, 1 × 5 min; 75%, 1 × 5 min; 100%, 2 × 5 min), dried in vacuo for 18 h, and weighed (*m*). The ratio between *n* and *m* gave the loading of the resin in mmol/g.

Determination of Immobilization Efficiency by Anthrone Assay. Resins **A**, **C**, **G**, and **H** prior to immobilization and after immobilization were treated as follows. The resin was washed with an increasing concentration of Et_2O in CH_2Cl_2 (0%, 1 × 5 min; 25%, 1 × 5 min; 50%, 1 × 5 min; 75%, 1 × 5 min; 100%, 2 × 5 min), and dried in vacuo for 18 h. A small portion of the resin (1−5 mg) was weighed in a 1.5 mL safelock plastic vial. Water (0.5 mL) was added, followed by anthrone solution (0.2% in concentrated H_2SO_4, 1 mL) (*36*). The samples were shaken vigorously for 3 min, incubated at 100 °C for 5 min, and cooled in an ice bath for 3 min. A 300 μL amount was transferred to an ELISA plate, and the optical density was read at 570 nm in a microtiter plate reader (Anthos reader 2001, Anthos Labtech Instruments, Salzburg, Austria). The difference in optical density between the pre- and the postimmobilization resins was used as a measure of the amount of GalA units immobilized.

Determination of Immobilization Efficiency by the Ellman Test. Pre- and postimmobilization resins (resins **E** and **F**) were treated as follows. The resin was washed with an increasing concentration of Et_2O in CH_2Cl_2 (0%, 1 × 5 min; 25%, 1 × 5 min; 50%, 1 × 5 min; 75%, 1 × 5 min; 100%, 2 × 5 min), dried in vacuo for 18 h. A small portion of resin (1−4 mg) was treated with a 0.01 M solution of 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB) in aq Na_2HPO_4 buffer (0.1 M, pH 8.5, 400 μL) (*37, 38*). Water (600 μL) was added, and the sample was shaken for 20 min at room temperature and analyzed by reversed-phase HPLC in an isocratic mode using H_2O

[1] Abbrevations: H-Aoa-OH, aminooxy acetic acid; Boc, *tert*-butoxycarbonyl; Cys, cysteine; DIEA, diisopropylethylamine; DMF, dimethylformamide; DTNB, 5,5′-dithiobis(2-nitrobenzoic acid); DTT, dithiothreitol; GalA, α-D-galacturonic acid; $(GalA)_2$, α-D-GalA-(1→4)-D-GalA; $(GalA)_3$, α-D-GalA-(1→4)-α-D-GalA-(1→4)-D-GalA; Glu, glutamic acid; HL, high loading; LL, low loading; PyBOP, (benzotriazol-1-yloxy)tripyrrolidinophosphonium hexafluorophosphate; HBTU, *N*-[(1*H*-benzotriazol-1-yl)-(dimethylamino)methylene]-*N*-methylmethanaminium hexafluorophosphate *N*-oxide; HOBt, 1-hydroxybenzotriazole; PEGA, polyethylene glycol polyacrylamide; Pyr, pyridine; rt, room temperature; Trt, trityl.

as the eluent. The absorbance of the released thiol anion was read at 412 nm, and the amount of resin-bound free thiol groups was determined using a calibration curve with H-Cys-OMe·HCl as a standard.

Preparation of Aminooxy-Terminated Resins (A). Reactions were carried out in a 20 mL syringe, and the washing volumes were 8 mL. Amino PEGA resin (3.8 g, 0.4 mmol/g) was washed with DMF (3 × 1 min), swollen in DMF (1 × 10 min), and washed with 10% DIEA in DMF (3 × 1 min) and DMF (3 × 1 min), respectively. N^{β}-Boc-aminooxy acetic acid (N^{β}-Boc-Aoa-OH, 100 mg, 0.52 mmol), (benzotriazol-1-yloxy)tripyrrolidinophosphonium hexafluorophosphate (PyBOP, 271 mg, 0.52 mmol), and 1-hydroxybenzotriazole (HOBt, 70 mg, 0.52 mmol) were dissolved in DMF (7 mL). DIEA (157 μL, 0.92 mmol) was then added, and the solution was added to the resin. The syringe was shaken at room temperature for 1.2 h, after which a qualitative ninhydrin test was negative. Solvents and unreacted materials were filtered off, and the resin was washed with DMF (4 × 1 min) and CH_2Cl_2 (2 × 1 min, 1 × 5 min and 2 × 1 min). Removal of Boc groups was accomplished by treatment with TFA−CH_2Cl_2 (1:1, 8 mL) for 1 h at room temperature.

Preparation of Carboxylic Acid-Terminated Resins (B). Reactions were performed in a 50 mL syringe, and the washing volumes were 15 mL. Amino PEGA resin (8.94 g, 0.4 mmol/g) was washed and swollen with the same solvents as for **A**. Succinic anhydride (160 mg, 1.6 mmol) and HOBt (162 mg, 1.2 mmol) were dissolved in DMF (13 mL), DIEA (308 μL, 1.8 mmol) was added, and the solution was added to the resin. The syringe was shaken at room temperature for 1.5 h. Excess reagents and solvents were filtered off, and the resin was washed with DMF (4 × 1 min) and MeOH (4 × 1 min). At this point, a ninhydrin test was negative. The resin was stored wet in MeOH at 5 °C until further use.

Preparation of Hydrazide-Terminated Resins (C). A portion of resin **B** (1.98 g, 0.11 mmol) was transferred to a 10 mL syringe. The washing volumes were 4 mL. The resin was washed with DMF (1 × 1 min, 1 × 10 min, and 1 × 1 min). *N*-[(1*H*-Benzotriazol-1-yl)(dimethylamino)methylene]-*N*-methylmethanaminium hexafluorophosphate *N*-oxide (HBTU, 173 mg, 0.46 mmol) and HOBt (62 mg, 0.46 mmol) were dissolved in DMF (3 mL). DIEA (88 μL, 0.51 mmol) was then added, followed by hydrazine monohydrate (28 μL, 0.57 mmol), and the mixture was added to the resin. After 2 h coupling at room temperature, solvents and unreacted compounds were removed by filtration, and the resin was washed with DMF (4 × 1 min) and MeOH (4 × 1 min).

Preparation of Thiol-Terminated Resins (D). Resin **B** (3.30 g, 0.19 mmol) was transferred into a 20 mL syringe. Washing volumes were 6 mL. The resin was washed with DMF (1 × 1 min, 1 × 10 min, and 1 × 1 min). *S*-(2-Pyridylthio)cysteamine hydrochloride (*39*) (212 mg, 0.95 mmol), HBTU (288 mg, 0.76 mmol), and HOBt (103 mg, 0.76 mmol) were dissolved in DMF (6 mL). After addition of DIEA (146 μL, 0.86 mmol), the solution was added to the resin. After shaking for 2 h at room temperature, the resin was washed with DMF (4 × 1 min), H_2O (4 × 1 min), and aq NaOAc buffer (0.1 M, pH 4.8, 2 × 1 min). Pyridine-2-thione was removed from the support by treatment with a solution of dithiothreitol (DTT) (147 mg, 0.95 mmol) in aq NaOAc buffer (7 mL). After 2 h at room temperature, solvents and excess reagents were filtered off, and the resin was washed with H_2O (4 × 1 min) and then with MeOH (3 × 1 min).

Preparation of Cysteine (Cys)-Terminated Resins (E). *Synthesis of Boc-Cys(Trt)-NH-$(CH_2)_2$-S-S-Pyr.* Boc-Cys(Trt)-OH (566 mg, 1.22 mmol) was dissolved in CH_3CN (10 mL). HBTU (512 mg, 1.35 mmol) and NEt_3 (340 μL, 2.44 mmol) were then added, followed by *S*-(2-pyridylthio)cysteamine hydrochloride (*39*) (771 mg, 1.22 mmol). Complete dissolution was accomplished by addition of water (1 mL). After overnight stirring at room temperature, a white precipitate formed. It was isolated by filtration and dried under reduced pressure (1st crop). The filtrate was diluted with EtOAc (40 mL), washed with 1 M aq HCl (3 × 15 mL), saturated aqueous $NaHCO_3$ (3 × 15 mL), and brine (3 × 15 mL), dried over $MgSO_4$, and concentrated to afford white crystals (2nd crop). Fractions 1 and 2 were identified as the title compound (753 mg, 98%), mp 131−134 °C. ^{1}H NMR ($CDCl_3$) δ 1.41 (s, 9 H, CH_3), 2.56 (dd, 1 H, H-β^a (Cys), *J* 5.2 Hz, *J* 12.5 Hz), 2.71 (dd, 1 H, H-β^b (Cys), *J* 7 Hz, *J* 12.5 Hz), 2.86 (m, 2 H, CH_2-S, *J* 1.8 Hz, *J* 5.8 Hz), 3.50 (m, 1 H, CH_2-NH), 4.01 (dd, 1 H, H-α (Cys), *J* 0.8 Hz, *J* 5.4 Hz), 7.06−7.61 (m, 18 H, H arom.), 8.47 (d, 1 H, H-3′ (Pyr), *J* 4.9 Hz). ^{13}C NMR ($CDCl_3$) δ 28.58 (*C*H$_3$, ^{t}Bu), 34.59 (C-β, Cys), 37.62 (*C*H$_2$-S), 38.87 (*C*H$_2$-N), 52.17 (S-*C*Ph$_3$), 67.34 (C-α, Cys), 121.19 (C-6′, Pyr), 121.38 (C-4′, Pyr), 127.07 (Trt), 128.45 (Trt), 129.79 (Trt), 137.15 (C-3′, Pyr), 144.66 (Trt), 150.24 (C-3′, Pyr), 159.22 (*C*O, Boc), 170.64 (*C*O, Cys). ES-MS, calcd. for $C_{34}H_{37}N_3O_3S_3$: 631.20. Found: *m*/*z* 670.11 $[M + K]^+$, 654.13 $[M + Na]^+$, 632.18 $[M + H]^+$, 243.42 $[Trt]^+$. Anal. Calcd for $C_{34}H_{37}N_3O_3S_3$: C, 64.63; H, 5.90; N, 6.65; S,15.22. Found: C, 64.29; H, 5.82; N, 6.65; S, 14.91. Thiol-terminated resin **D** (376 mg, 29 μmol) was weighed in a 10 mL syringe. Washing volumes were 4 mL. Boc-Cys(Trt)-NH-$(CH_2)_2$-S-S-Pyr (72 mg, 0.114 mmol) was dissolved in MeOH (4 mL) and added to the resin. The resin was shaken at room temperature for 2 h and washed with MeOH (4 × 1 min) and CH_2Cl_2 (2 × 1 min, 1 × 5 min, 2 × 1 min). The resin was stored wet at 5 °C and Boc and Trt groups were cleaved with TFA−CH_2Cl_2 (1:1) in the presence of Et_3SiH (15 equiv) prior to coupling.

Preparation of Cys-Terminated Resins (F). '**F** high loading' (**F**-HL): the reactions were performed in a 10 mL syringe, and the washing volumes were 4 mL. Amino-terminated PEGA resin (1.79 g, 0.4 mmol/g) was washed with DMF (3 × 1 min), swollen in DMF (1 × 10 min), and washed with DIEA−DMF (1:9, 3 × 1 min) and DMF (3 × 1 min), respectively. Boc-Cys(Trt)-OH (148 mg, 0.32 mmol) was coupled in the presence of PyBOP (125 mg, 0.24 mmol), HOBt (32 mg, 0.24 mmol), and DIEA (62 μL, 0.36 mmol) in DMF (4 mL) at room temperature. After 1 h, a qualitative ninhydrin test showed complete incorporation of the Cys derivative. The resin was then washed with DMF (3 × 1 min) and CH_2Cl_2 (2 × 1 min, 1 × 5 min, 2 × 1 min) and stored wet at 5 °C. Deprotection of Boc and Trt groups was accomplished with TFA−CH_2Cl_2 (1:1) in the presence of Et_3SiH (15 equiv) immediately prior to sugar immobilization.

'**F** low loading' (**F**-LL): a parallel experiment was conducted using a low loading amino PEGA resin (2.13 g, 0.2 mmol/g) in a 10 mL syringe. Boc-Cys(Trt)-OH (74 mg, 0.16 mmol) was reacted with PyBOP (63 mg, 0.12 mmol), HOBt (16 mg, 0.12 mmol) and DIEA (31 μL, 0.18 mmol) in DMF (4 mL). The coupling was performed at room temperature and was complete within 1 h, according to a qualitative ninhydrin test. Washing conditions were similar to the ones described above. Boc and Trt groups were removed by TFA−CH_2Cl_2 (1:1) in the presence of Et_3SiH (15 equiv) prior to immobilization (see below).

Preparation of Glutamic Acid (Glu)-Terminated Resins (G). *Synthesis of Boc-Glu(O^{t}Bu)-NH-(CH$_2$)$_2$-S-S-Pyr.* A solution of Boc-Glu(O^{t}Bu)-OH (249 mg, 0.82 mmol), HBTU (341 mg, 0.9 mmol), NEt_3 (286 μL, 2.05 mmol), and *S*-(2-pyridylthio)cysteamine hydrochloride (*39*) (200 mg, 0.90 mmol) in CH_3CN (8 mL) was stirred at room temperature. After 15 h, the mixture was diluted with EtOAc (35 mL), washed sequentially with 1 M aq HCl (3 × 12 mL), saturated aqueous $NaHCO_3$ (3 × 12 mL), and brine (3 × 12 mL), dried over $MgSO_4$, and concentrated to a foam identified as the title compound (352 mg, 91%). ^{1}H NMR ($CDCl_3$) δ 1.35 (s, 9 H, CH_3), 1.37 (s, 9 H, CH_3), 1.80 (m, 1 H, H-β^a), 1.97 (m, 1 H, H-β^b), 2.26 (m, 2 H, H-γ), 2.84 (t, 2 H, CH_2-S, *J* 6.1 Hz), 3.46 (m, 2 H, CH_2-NH), 4.03 (dd, 1 H, H-α, *J* 7.1 Hz), 7.08 (m, 1 H, H-4′ Pyr), 7.57 (m, 2 H, H-5′ Pyr, H-6′ Pyr), 7.82 (s, 1 H, N*H*), 8.44 (m, 1H, H-3′ Pyr). ^{13}C NMR (CD_3OD) δ 27.23 (*C*H$_3$, Boc), 27.40 (C-β), 27.57 (*C*H$_3$, ^{t}Bu), 27.69 (C-γ), 31.57 (*C*H$_2$-S), 37.91 (*C*H$_2$-NH), 54.42 (C-α), 79.62 ((CH$_3$)$_3$-*C*, Boc), 80.63 ((CH$_3$)$_3$-*C*, ^{t}Bu), 120.39 (C-6′, Pyr), 121.30 (C-4′, Pyr), 137.85 (C-5′, Pyr), 149.47 (C-3′, Pyr), 159.74 (*C*O, Boc), 172.74 (*C*O, Glu, side chain), 173.55 (*C*O, Glu). ES-MS, calcd. for $C_{21}H_{33}N_3O_5S_2$: 471.19. Found: *m*/*z* 494.29 [M + Na]$^+$, 472.31 [M + H]$^+$, 416.33 [M − ^{t}Bu + 2H]$^+$, 372.37 [M − Boc + 2H]$^+$, 316.35 [M − Boc − ^{t}Bu + 3H]$^+$. Resin **D** (275 mg, 29 μmol) was weighed in a 10 mL syringe. Washing volumes were 4 mL. Boc-Glu(O^{t}Bu)-NH−(CH$_2$)$_2$-S-S-Pyr (54 mg, 0.114 mmol) was dissolved in MeOH (0.7 mL), the volume was adjusted to 4 mL with MeOH, and the solution was added to the resin. During coupling for 2 h at room temperature, a yellow coloration was observed, indicative of the release of pyridine-2-thione. The resin was then washed with MeOH (4 × 1 min) and stored wet at 4 °C until further use.

Preparation of Glu-Terminated Resins (H). Reactions were carried out in a 10 mL syringe. The washing volumes were 4 mL. The initial washing and coupling procedures were identical to the ones described above for the preparation of Cys terminated resins using Boc-Cys-(Trt)-OH. In this case, Boc-Glu(O^{t}Bu)-OH (97 mg, 0.32 mmol) was anchored to amino PEGA resin (1.79 g, 0.4 mmol/g) in the presence of PyBOP (125 mg, 0.24 mmol), HOBt (32 mg, 0.24 mmol), and DIEA (62 μL, 0.36 mmol). According to a qualitative ninhydrin test, coupling was completed within 1 h at room temperature. The resin was then washed with DMF (3 × 1 min) and CH_2Cl_2 (2 × 1 min, 1 × 5 min, 2 × 1 min) and stored wet at 5 °C until deprotection and further derivatization.

Model Reactions in Solution. *Preparation of a Model Glycosyl Hydrazide.* GalA (1.3 g, 6.14 mmol) was dissolved in MeOH (dried over 3 Å molecular sieves, 12 mL), and acetic acid hydrazide (500 mg, 6.75 mmol) (*40*) was added. The mixture was stirred at 65 °C for 7 h. Formation of a precipitate was observed. It was collected by centrifugation and dried under reduced pressure (1st crop). The filtrate was concentrated to a pale yellow solid in vacuo (2nd crop). Fractions 1 and 2 gave 1.53 g (99%) of the acyclic glycosyl hydrazide (*E*/*Z* = 2:1, based on the assumption that δ_Z(H-1) > δ_E(H-1)). ^{1}H NMR (DMSO-d_6) δ 1.85 (s, 1 H, CH_3, *Z*), 2.05 (s, 2 H, CH_3, *E*), 3.45 (d, 1 H, H-3, *J* 9.4 Hz), 3.80 (d, 1 H, H-4, *J* 9.4 Hz), 4.24 (m, 2 H, H-2, H-5), 7.35 (d, 0.66 H, H-1, *E*, *J* 5.7 Hz), 7.46 (d, 0.33 H, H-1, *Z*, *J* 5.9 Hz), 10.84 (s, 0.66 H, N*H*, *E*), 10.99 (s, 0.33 H, N*H*, *Z*). ^{13}C NMR (DMSO-d_6) δ 20.96 (*C*H$_3$, *E*), 21.74 (*C*H$_3$, *Z*), 70.33 (C-2), 70.62 (C-4), 71.98 and 72.06 (C-3), 72.66 and 72.77 (C-5), 149.35 (C-1, *E*), 152.03 (C-1, *Z*), 166.0 (*C*(O), Ac, *Z*), 172.27 (*C*(O), Ac, *E*), 176.04 (C-6). FAB-MS, calcd for $C_8H_{14}N_2O_7$: 250.08. Found: *m*/*z* 170 [M + 3H$_2$O + 2NH$_4$]$^{2+}$, 153 [M + 3H$_2$O + 2H]$^{2+}$.

Preparation of a Model Thiazolidine. H-Cys-OMe.HCl (1 g, 5.8 mmol) (*41*) was dissolved in H_2O (10 mL). K_2CO_3 was added until neutral pH. The solution was extracted with Et_2O (5 × 5 mL), and the combined extracts were dried over $MgSO_4$ and concentrated in vacuo. Residual H-Cys-OMe (100 mg, 0.74 mmol) was dissolved in MeOH (5 mL), and a solution of GalA (157 mg, 0.74 mmol) in MeOH (5 mL) was added. The clear mixture (pH 4) was stirred at room temperature. After 24 h, TLC (eluent CH_2Cl_2−MeOH, 1:1) showed complete disappearance of the starting material. The solvent was then evaporated in vacuo. Purification on a short silica column using MeOH as eluent gave the thiazolidine derivative in 50% yield and as two diastereomers (*R* and *S* configurations at C-1, GalA). ^{13}C NMR (D_2O) δ 35.87 and 36.47 (C-β, Cys), 52.23 and 52.36 (*C*H$_3$, Cys), 64.58 and 65.00 (C-α, Cys), 68.76 and 69.98 (C-1, GalA), 70.97−72.30 (C-2, C-3, C-4, GalA), 76.07 and 76.23 (C-5, GalA), 169.93 (*C*(O), Cys). FAB-MS, calcd for $C_{10}H_{17}NO_8S$: 311.07. Found: *m*/*z* 294 [M + H − H$_2$O]$^+$, 276 [M + H − 2H$_2$O]$^+$.

Immobilization Techniques. *Immobilization via Reductive Amination.* The reaction was performed in a 5 mL syringe, and the washing and reaction volumes were 2 mL. Hydrazide-terminated resin **C** (100 mg dry, 38 μmol) was washed with DMF (2 × 1 min, 1 × 5 min, 2 × 1 min). GalA (40 mg, 0.19 mmol) was dissolved in DMF−AcOH (99:1). The solution was then added to the resin, and following addition of $NaBH_3CN$ (24 mg, 0.38 mmol), the syringe was shaken at room temperature. After 24 h, the solvent and excess reagents were filtered off, and the resin was washed with DMF (4 × 1 min) and stored at 5 °C until quantitation. A similar procedure was applied to immobilize α-D-GalA-(1→4)-D-GalA ((GalA)$_2$, 10 mg, 27 μmol) on resin **C** (14 mg dry, 5 μmol) in the presence of $NaBH_3CN$ (4 mg, 54 μmol). α-D-GalA-(1→4)-α-D-GalA-(1→4)-D-GalA ((GalA)$_3$, 5.9 mg, 11 μmol) was also coupled to resin **C** (6 mg dry, 2 μmol) using $NaBH_3CN$ (7 mg, 11 μmol). In these two cases, 2 mL syringes were used, and the washing and reaction volumes were 1 mL. The anthrone assay was used to determine the coupling efficiencies.

Immobilization via Oxime Formation. The immobilization reaction was performed in a 5 mL syringe, and the washing and reaction volumes were 2 mL. Aminooxy-terminated resin (128 mg dry, 44 μmol) was first washed with DMF−H_2O (1:1, 1 × 1 min, 1 × 5 min, 2 × 1 min) and DMF−0.1 M aq NaOAc, pH 4.76 (1:1, 3 × 1 min). GalA (42 mg, 0.2 mmol) was dissolved in DMF−0.1 M aq NaOAc, pH 4.8 (1:1), and the solution was added to the resin. The syringe was placed in a sand bath at 40 °C for 24 h. The solvents and unreacted compounds were removed by filtration, and the resin was washed with H_2O (4 × 1 min) and stored at 5 °C until quantitation. The same procedure was applied to immobilize (GalA)$_2$ (9.5 mg, 26 μmol) on aminooxy-terminated resins **A** (14 mg dry, 5 μmol) and (GalA)$_3$ (4.4 mg, 8 μmol) on resin **A** (5.6 mg dry, 2 μmol). In these latter cases, 2 mL syringes were used, and the washing and reaction volumes were reduced to 1 mL. Coupling efficiencies were determined by anthrone assay.

Immobilization via Glycosyl Hydrazide Formation. Resin **C** (100 mg dry, 38 μmol) was weighed in a 5 mL syringe. Washing volumes were 2 mL. The resin was washed with MeOH (2 × 1 min, 1 × 5 min, 2 × 1 min). GalA (40 mg, 0.19 mmol) was dissolved in MeOH (2 mL), and the solution was added to the resin. The syringe was placed in a sand bath at 65 °C. After 20 h, the solvents

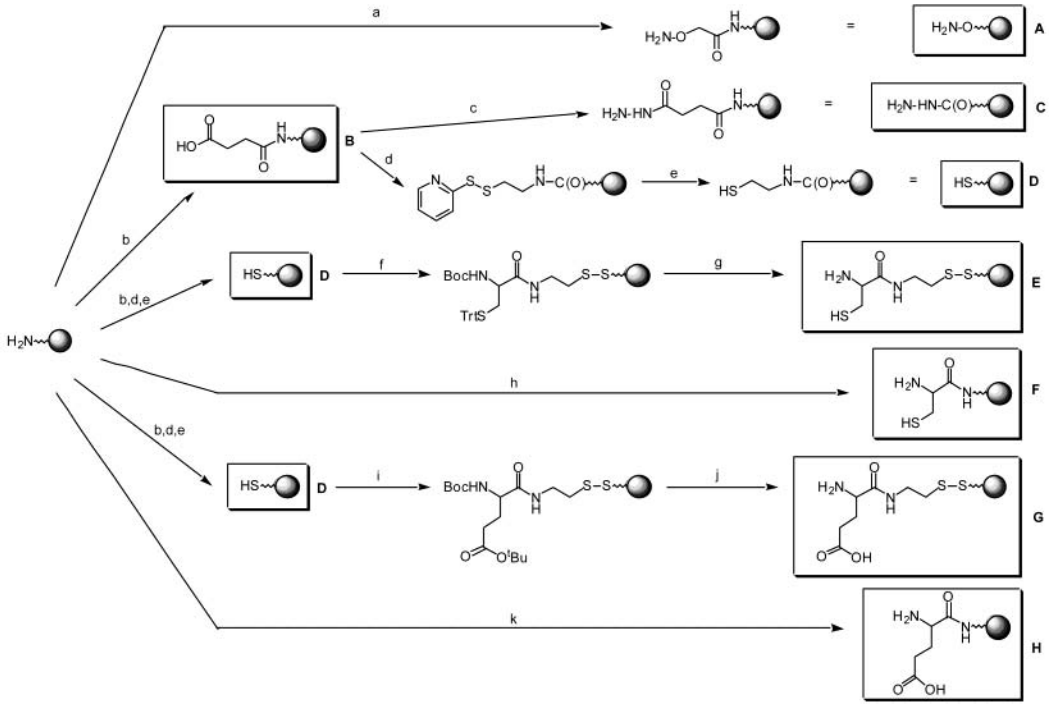
and excess reagents were removed by filtration. The resin was washed with MeOH (4 × 1 min), and stored at 5 °C until quantitation. Similar experiments were conducted in 2 mL syringes (the washing and reaction volumes were 1 mL) to immobilize $(GalA)_2$ (10 mg, 27 μmol) and $(GalA)_3$ (6.2 mg, 11 μmol) on resin **C** (14 mg dry, 5 μmol or 6 mg dry, 2 μmol, respectively). In the latter case, the reaction time was extended to 46 h. The reactions were quantified by the anthrone assay.

Immobilization via Thiazolidine Formation. The coupling reactions were performed in 2 mL syringes, and the washing volumes were 1.5 mL. Resins **E** (20 mg dry, 0.6 μmol) was treated with TFA−CH_2Cl_2 (1:1, 1.5 mL) in the presence of Et_3SiH (2 μL, 12 μmol) for 1 h at room temperature. It was then washed with CH_2Cl_2 (4 × 1 min) and with CH_3CN-H_2O−0.1 M aq NaH_2PO_4 buffer, pH 8.5 (1:1:1, 2 × 1 min). GalA (0.2 mg, 1 μmol) was dissolved into CH_3CN-H_2O−0.1 M aq NaH_2PO_4 buffer, pH 8.5 (1:1:1, 1.5 mL), and the solution (pH 4) was added to the resin. After 48 h at room temperature, the resins were washed with CH_3CN (4 × 1 min) and stored at 5 °C until quantitation. The same procedure was repeated with resin **F**-HL (20 mg dry, 2 μmol) and resin **F**-LL (20 mg dry, 0.8 μmol) with Et_3SiH (5 μL, 31 μmol and 2 μL, 12 μmol, respectively) and GalA (0.6 mg, 3 μmol and 0.2 mg, 1 μmol, respectively). A similar procedure was applied using the same amount of resins **E**, **F**-HL, and **F**-LL and $(GalA)_2$ (0.4 mg, 1 μmol; 1 g, 3 μmol and 0.4 mg, 1 μmol, respectively) as a substrate. Similarly, $(GalA)_3$ (1.4 mg, 3 μmol and 0.5 mg, 1 μmol, respectively) was coupled to Cys-terminated resins **F**-HL (20 mg dry, 2 μmol) and **F**-LL (20 mg dry, 0.8 μmol), respectively. The Ellman test was used to determine the coupling efficiencies.

Immobilization via Pyroglutamyl Formation. Reactions were carried out in 2 mL syringes, and the washing volumes were 1.5 mL. Resin **G** (20 mg dry, 2 μmol) and resin **H** (20 mg dry, 6 μmol) were washed with CH_2Cl_2 (3 × 1 min, 1 × 3 min) and deprotected with TFA−CH_2Cl_2 (1:1, 1.5 mL) and Et_3SiH (5 μL, 30 μmol; 11 μL, 70 μmol, respectively) at room temperature. After 1 h, the solvents and excess reagents were filtered off, and the resin was washed with CH_2Cl_2 (3 × 1 min) and DMF (3 × 1 min, 1 × 3 min). GalA (2 mg, 96 μmol and 5 mg, 23 μmol, respectively) and imidazole (1 mg, 14 μmol and 2.4 mg, 35 μmol, respectively) were dissolved in DMF (1 mL), and the solutions were added to the resins. The syringes were placed in a sand bath at 60 °C for 24 h. After filtration, the resins were washed with DMF (2 × 1 min). Solutions of PyBOP (7 mg, 14 μmol and 18 mg, 35 μmol, respectively) and imidazole (1 mg, 14 μmol and 2.4 mg, 35 μmol, respectively) in DMF (1 mL) were added to the resins. Coupling took place at room temperature for 4 h. Solvents and excess reagents were removed by filtration, and the resins were finally washed with DMF (3 × 1 min), H_2O (2 × 5 min), and DMF (2 × 1 min) and stored at 5 °C until quantitation. In a parallel fashion, $(GalA)_2$ (2 mg, 5 μmol and 4.4 mg, 12 μmol) was coupled to resin **G** (10 mg dry, 1 μmol) and resin **H** (10 mg dry, 3 μmol), respectively, using 2 mL syringes and washing with 1 mL solvent. Quantitation by anthrone assay provided data on the coupling efficiencies.

Cleavage of Immobilized Pectin Fragment from the Support. The cleavage reactions were performed in 2 mL syringes, and the washing volumes were 1 mL. Resins **E** (4.3 mg) and **G** (7 mg), both derivatized with GalA, were washed with H_2O (3 × 1 min) and 50 mM tris(hydroxymethyl)aminomethane buffer (pH 8, 3 × 1 min) and then treated with DTT (1 mg, 6 μmol) in the same buffer (pH 8, 0.8 mL) at room temperature. After 22 h, the filtrates from the cleavage reactions were collected and combined with H_2O washes (2 × 1 min). H_2O (5 mL) was then added to each filtrate, and the samples were freeze-dried. For resin **E**, ES-MS, calcd for $C_{11}H_{20}N_2O_7S_2$: 356.07. Found: *m/z* 395.07 $[M + K]^+$, 379.09 $[M + Na]^+$, 281.20 $[M - C_2H_6NS + H]^+$. For resin **G**, ES-MS, calcd for $C_{13}H_{20}N_2O_8S$: 364.09. Found: *m/z* 363.06 $[M - H]^-$.

RESULTS AND DISCUSSION



In this comprehensive study, we present the development of efficient methodologies for the stable, covalent, and chemoselective anchoring of oligomers of GalA onto a solid support. To ensure that the methods developed could also be used for longer pectin fragments, the oligogalacturonides were *not* derivatized and were immobilized through their reducing end, which provides a unique functionality in the molecule. Several functional groups were installed on amino-terminated PEGA resins by classical solid-phase manipulations prior to immobilization of small GalA oligomers (see Scheme 1). These functionalities included amino, hydrazide, Cys, and Glu moieties. For two of the supports, we also synthesized variants containing a disulfide bridge which, under mild reducing conditions, allows cleavage and release of the immobilized material into solution.

Preparation of Activated Solid Supports. Resin **A** was prepared by coupling N^{β}-Boc-Aoa-OH to amino PEGA resin (0.4 mmol/g). Free aminooxy groups were obtained upon treatment with TFA in CH_2Cl_2. The corresponding loading was determined via an 'indirect method', in which trityl groups were coupled to the aminooxy-terminated groups on the support and subsequently released into solution for quantitation (*34*). Cleavage of the Trt groups with TFA−CH_2Cl_2 (1:1) was optimized by trapping of the released trityl cation with Et_3SiH to form TrtH (*35*). For the loading determination, it was essential to efficiently dry and accurately weigh functionalized PEGA resins. For this purpose, we developed a procedure in which the resin was allowed to collapse gradually using an increasing concentration of Et_2O in CH_2Cl_2 followed by drying in vacuo (*42*). This 'indirect method' was applied to resin **A** and gave a loading of 0.34 mmol/g (Table 1).

The first step in the preparation of a hydrazide support was coupling of succinic anhydride to amino-terminated PEGA resins (0.4 mmol/g, HL and 0.2 mmol/g, LL) using HOBt and DIEA in DMF. The obtained resin **B** (HL) was further derivatized to resin **C** by treatment with hydrazine monohydrate in the presence of standard coupling reagents. The loading of hydrazide resin **C** was 0.38 mmol/g, according to an 'indirect' trityl quantitation as described above (see Table 1).

For the preparation of a thiol-functionalized support, *S*-(2-pyridylthio)cysteamine hydrochloride was synthesized following a literature procedure (*39*) and coupled to **B** (LL) under standard coupling conditions. Subsequent treatment with DTT at pH 4.8 cleaved the disulfide bridge to give free thiol groups of resin **D** (see Scheme 1). A yellow coloration was observed, indicating release of pyridine-2-thione into solution. Resin **D** was then reacted with synthesized Boc-Cys(Trt)-NH-$(CH_2)_2$-S-S-Pyr via a disulfide exchange reaction in MeOH. Final deprotection of the Boc and Trt groups in the presence of Et_3SiH (*35*) afforded Cys-functionalized resin **E**. The release of Trt groups in the last deprotection step was also used to determine the loading of resin **E** ('direct method'). It was found to be 0.03 mmol/g (Table 1). The low value of the loading may be attributed to the large

number of steps from the starting material amino PEGA resins and/or to an incomplete coupling of Boc-Cys(Trt)-NH-$(CH_2)_2$-S-S-Pyr on thiol-functionalized support. Cys-terminated support **F**, with a permanent linkage, was directly obtained from amino PEGA resins (0.4 mmol/g) by standard coupling of Boc-Cys(Trt)-OH followed by acidic treatment under similar conditions as described for **E**. Direct quantitation of the amount of Trt groups released in the last step gave a loading of 0.10 mmol/g (Table 1). Access to resin **F** was faster and easier than to resin **E**, but in the latter case, a cleavable linker was installed through the disulfide bond.

A similar strategy to that used for **E** and **F** was applied to install Glu moieties on solid support. Resin **D** was functionalized with synthesized Boc-Glu(O^tBu)-NH-$(CH_2)_2$-S-S-Pyr and the protecting groups were further removed under acidic conditions to give **G**. The loading was 0.12 mmol/g, according to an 'indirect' trityl quantitation (Table 1). As in **E**, the disulfide bridge introduced a potentially cleavable linkage. Alternatively, Boc-Glu(^{t}Bu)-OH was coupled to amino-terminated PEGA resin (0.4 mmol/g). Subsequent deprotection allowed access to Glu-terminated resin, **H** (loading 0.29 mmol/g, after 'indirect' trityl quantitation; Table 1). Resins **A**, **C**, **E**, **F**, **G**, and **H** were then available for immobilization of pectin fragments.

Methods for the Immobilization of GalA Oligomers. Seppälä and Mäkelä (*22*) reported on the use of hydrazide groups as an alternative to amino groups to enhance, via the α-effect, the reactivity during coupling with various neutral oligosaccharides. In case of solid-supported reductive aminations, coupling conditions were also optimized by careful choice of the solvent and the reagents (*43*). These observations were combined and applied to immobilize model pectin fragments, GalA and $(GalA)_2$, on a hydrazide-terminated resin (see Scheme 2). Typically, the solid-phase reactions were performed in DMF−AcOH (99:1) using 5 equiv of oligogalacturonide and 10 equiv of $NaBH_3CN$ at room temperature for 24 h. For larger pectin fragments, an excess of resin should be used. The immobilization efficiency was determined by the anthrone assay, based on the initial loading of

resin **C**. This colorimetric method was chosen for several reasons. First, it is a general and well-established method for the quantitation of carbohydrates, including uronic acids (*36*). Second, it takes place at very low pH, using concentrated H_2SO_4, and high temperatures are required for the color development of the reagent. Such acidic conditions would cleave the glycosidic linkages along the oligogalacturonide chains, liberating single galacturonic acid units. These could then be quantified by comparison with standards. Furthermore, the harsh conditions were believed to dissolve the PEGA resin, allowing direct analysis of a solution containing oligogalacturonides. Contributions from the support were accounted for by comparing resin samples prior to and after immobilization. Analysis of GalA immobilized resin gave a 93 (±13)% coupling efficiency, which shows that one saccharide unit reacted with anthrone (Table 1). The uncertainty on the coupling efficiency, which takes into account intermediate uncertainties, was calculated using standard methods (Table 1). In case of $(GalA)_2$, the coupling efficiency was 81 (±15)%, when two saccharide units were cleaved and reacted with anthrone. These results prove that reductive amination with hydrazide is an effective method for the immobilization of unprotected GalA oligomers to solid supports. And, whereas conventional methods rely on affinity studies to estimate the degree of coupling (*28, 30*), the quantitation method developed hereby directly estimates the amount of pectin immobilized on the support. However, the data obtained are in contradiction with the literature (*36, 44, 45*). The mechanism for the reaction of anthrone with carbohydrates is complex and not fully elucidated: it involves the formation of strongly colored furfural derivatives when anthrone reacts with the aldehyde group at the reducing end of the carbohydrate. Since solid-phase anchoring of oligogalacturonides onto hydrazide-terminated resin under reducing conditions gives a modified saccharide, the reducing sugar is transformed into an open ring hydrazide. Thus, the anthrone assay was not expected to give a positive response when analyzing GalA-immobilized resin and to show two saccharide units when analyzing $(GalA)_2$ immobilized support.

A second approach which we have implemented for the immobilization of underivatized GalA oligomers was based on the formation of an oxime bond. This type of linkage has recently become a popular method for preparing bioconjugates (*46, 47*), peptide dendrimers (*48*), glycopeptides (*29*), carbopeptides (*49*), and carboproteins (*50*). The efficiency of the method relies on the ease of formation and on the good stability of the oxime linkage up to pH 9. This well-established methodology appears not to have been used for the immobilization of polyuronic acids. Oligogalacturonides, ranging from the monomer to the trimer, were coupled to resin **A** through the aldehyde group at their reducing end. Oxime formation took place under mild conditions, in DMF−H_2O (1:1), at 40 °C and pH 4.8 for 24 h (*33*). Incorporation of GalA oligomers was quantified by the anthrone assay. The coupling efficiencies, based on the initial loading of resin **A**, were 117 (±23)%, 120 (±31)% and 62 (±15)% for immobilized GalA, $(GalA)_2$, and $(GalA)_3$, respectively (Table 1). In each case, the contribution of the pre-immobilization resin was subtracted. In contrast to reductive amination, the sugar structure was preserved after coupling; an equilibrium between the closed ring and open ring forms might occur at the surface of the support. This efficient technique requires few derivatization steps on solid-phase and its compatibility with aqueous solvents makes it very attractive when using larger pectin fragments with limited solubilities.

The direct coupling between the reducing end of various neutral oligosaccharides with hydrazide groups has recently been investigated in carbohydrate recognition studies (*51*) and in the synthesis of surfactants (*52*), demonstrating the stability of the glycosyl hydrazide linkage under neutral to basic conditions. We decided to include this technique in our study, as an alternative to other linkage types. Prior to solid-phase immobilization,

Scheme 3. Solution Synthesis of Glycosylhydrazide and Thiazolidine Derivatives of GalA[a]

[a] (a) MeOH, 65 °C, 7 h; (b) MeOH, rt, 24 h.

a model study was conducted in solution (see Scheme 3). Following the conditions described by Augé and Lubin-Germain (*52*), GalA was coupled to acetic acid hydrazide (*40*) in MeOH at 65 °C for 7 h to give the corresponding glycosyl hydrazide in 99% yield. NMR analysis revealed the presence of two acyclic glycosyl hydrazides, most likely the *E* and *Z* isomers (2:1). These optimized conditions were then applied to the coupling of GalA, as well as its dimer and trimer to hydrazide functionalized resin **C** (Scheme 2). The reaction time was extended to 20 h to compensate for the slower reaction rates generally encountered with solid supports. Quantitation by the anthrone assay showed 117 (±21)%, 89 (±21)% and 75 (±23)% immobilization efficiencies for GalA, $(GalA)_2$, and $(GalA)_3$, respectively (Table 1). The coupling yield decreased with increasing size of the oligogalacturonides. Although an unsaturated hydrazone compound was isolated after solution synthesis, an equilibrium between this form and the closed ring glycosyl hydrazide might occur at the surface of the support. Despite its high coupling efficiency and its ease of preparation, this third approach suffers from poor stability of the linkage at low pH. Acid present in the media could indeed protonate the glycosidic nitrogen at the reducing end and cleave the glycosidic bond.

A well-documented methodology for the covalent linkage of oligosaccharides to other molecules or matrixes is based on the formation of a glycosylamine derivative. The reaction is reversible, and a further acylation step is required to stabilize the glycosylamine (*53*). This latter step can proceed by treatment with acetic anhydride (*30*). Alternatively, a method for the preparation of glycoconjugates has recently been developed by Quétard et al. (*31, 32*) in which various neutral oligosaccharides were reacted with glutamic acid derivatives to form the corresponding glycosylamines. In each case, stabilization of the linkage proceeded via an intramolecular acylation by the activated carboxyl group on the side chain of the glutamyl moiety. The potential of this elegant technique has not been exploited to a large extent, and we wish to report here its application to solid-phase immobilization of model pectin fragments. The designed solid-phase strategy included the introduction of two different spacers with a terminal Glu residue on the resin. Glu-functionalized resin **H** would allow for permanent immobilization, whereas resin **G** contained a linker cleavable in the form of a disulfide bridge. The attachment of GalA and $(GalA)_2$ proceeded according to the conditions described by Quétard et al. (*31, 32*). Typically, the reducing end of the oligomer of GalA was reacted with the amino group of the glutamyl acid in DMF in the presence of imidazole for 24 h to form a glycosylamine (Scheme 2). The reactivity was improved by increasing the temperature to 60 °C. After removal of the excess reagents, the coupling agent PyBOP was added, and the intramolecular acylation of the secondary amine and concomitant pyroglutamyl ring formation was allowed to proceed at room temperature for 4 h. Quantitation of the reaction was performed using the anthrone assay. Immobilization of GalA and $(GalA)_2$ on a short spacer resin (**H**-LL) proceeded with an efficiency of 97 (±18)% and 71 (±14)%, respectively (Table 1). Moreover, GalA and $(GalA)_2$ were immobilized on long spacer resin (**G**-HL) with equally high efficiency: 90 (±7)% and 75 (±12)% respectively (Table 1). In this latter case, an uncertainty of 0.02 mmol/g on the resin loading was assumed. Resin **H**-LL functionalized with GalA was treated with DTT. Subsequent cleavage of the disulfide bond released a pyroglutamyl derivative of GalA as the major compound upon MS analysis.

Finally, both early (*54*) and recent (*55*) studies reported on the formation of a thiazolidine ring when reacting a Cys derivative with an aldehyde. Various thiazolidine compounds have so far been prepared from carbohydrates (*56*−*60*), and the stability of the linkage over a large range of pH (3−9) has recently been illustrated in the synthesis of peptide dendrimers (*33*). However, this very efficient methodology has apparently not been extended to the preparation of larger glycoconjugates nor to immobilization on solid supports. We therefore decided to include the formation of a thiazolidine ring in our general strategy for the solid-phase immobilization of pectin fragments. First, optimization of the available conditions was required, and model reactions were conducted using GalA and Cys methyl ester (H-Cys-OMe, Scheme 3). According to earlier studies, the reaction between an 1,2-aminothiol and an aldehyde proceeds very rapidly at pH 4−5 (*54, 55*). Such acidic conditions were also preferred in order to avoid disulfide formation of the Cys residue. Reaction of GalA with H−Cys-OMe in MeOH gave the expected thiazolidine in 50% yield. These conditions were then modified for immobilization on a solid support. GalA, $(GalA)_2$, or $(GalA)_3$ dissolved in H_2O−CH_3CN (2:1) at pH 4 and were coupled to resins **E** or **F** at room temperature for 24 h (Scheme 2). The anthrone assay was not suitable for on-resin quantitation due to a very high absorbance of the preimmobilization resin. Support bound thiol nucleophiles could theoretically react with the carbonyl group of anthrone. The Ellman test is, however, a well-established assay for the quantitation of free thiol groups (*37, 38, 61*). It was used in our study as an alternative to the anthrone assay for this particular reaction. Conditions for the application of the Ellman test to our system were optimized in terms of sample preparation and analytical technique. Postimmobilization resins were analyzed for their content of free thiol groups, by treatment with the Ellman reagent, DTNB. In all cases, a negative test was obtained, corresponding to a quantitative coupling of the GalA oligomers (see Table 1). Disulfide formation between Cys moieties could in principle also account for a negative test, but this was ruled out by a control experiment on the preimmobiliza-

tion resins, which showed excellent response to the Ellman test. This last strategy therefore proved very efficient for the anchoring of pectin fragments on solid support. In addition, a very stable linkage was installed in a few steps. Finally, this coupling method was validated by conducting a cleavage test on resin **E** functionalized with GalA; reduction of the disulfide linkage with DTT released the corresponding thiazolidine derivative. Extension of this new coupling chemistry to immobilization of other oligosaccharides and the synthesis of glycoconjugates can easily be envisaged.

CONCLUSION

We have prepared new hydrazide, aminooxy, and glutamyl-functionalized PEGA supports designed for chemoselective immobilization of oligomers of GalA by hydrazide, oxime, and pyroglutamyl formation, respectively. As an alternative to these well-established immobilization chemistries, we also prepared Cys-functionalized PEGA resins to immobilize GalA oligomers by *novel* thiazolidine formation. In addition to supports which allow permanent and covalent anchoring of saccharides, we also developed Glu- and Cys-functionalized supports in which a cleavable disulfide linkage was inserted. This strategy allows release of the saccharide derivatives under mild selective conditions. The loading of each functionalized support was determined either by an 'indirect' trityl quantitation, based on a coupling-cleavage strategy, or by a 'direct' trityl quantitation, when trityl groups were part of the synthetic pathway.

All supports allowed for efficient immobilization of oligomers of GalA, i.e., unprotected uronic acids, under mild conditions and without modification of the oligosaccharide prior to immobilization. Most of the coupling chemistries were first validated in solution. The two preferred immobilization methods in this study were oxime formation and formation of a thiazolidine. We anticipate that the novel thiazolidine coupling chemistry may also be applied to the immobilization of other saccharides. These methods are currently being used in our laboratories in the solid-phase analysis and the sequencing of pectin fragments.

ACKNOWLEDGMENT

We wish to thank the following: Dr. Andrew Coffey (Polymer Laboratories, UK) for the gift of PEGA resins; Dr. Tove Christensen (Danisco Cultor, Denmark) for supplying GalA oligomers; Mr. Clive Phipps Walter of Danisco Cultor, Denmark, and Associate Professor Jørgen Øgaard Madsen and Mrs. Anne Hector from the Department of Chemistry, Technical University of Denmark, for performing various MS analyses. Finally, we are grateful to: Dr. Gerrit Limberg for initiating this project, the Danish Technical Science Research Council for financial support through a 'Centerkontrakt' grant, and the Alfred Benzon Foundation for a Bøje Benzon fellowship to K.J.J.

Received August 22, 2001; Revised Manuscript Received November 23, 2001

In this study, we present the design and synthesis of an antisense peptide nucleic acid (asPNA) prodrug, which displays an improved biodistribution profile and an equally improved capacity to reduce the levels of target mRNA. The prodrug, $K(GalNAc)_2$-asPNA, comprised of a 14-mer sequence complementary to the human microsomal triglyceride transfer protein (huMTP) gene, conjugated to a high-affinity tag for the hepatic asialoglycoprotein receptor ($K(GalNAc)_2$). The prodrug was avidly bound and rapidly internalized by HepG2s. After iv injection into mice, $K(GalNAc)_2$-asPNA accumulated in the parenchymal liver cells to a much greater extent than nonconjugated PNA (46% ± 1% vs 3.1% ± 0.5% of the injected dose, respectively). The prodrug was able to reduce MTP mRNA levels in HepG2 cells by 35−40% ($P < 0.02$) at 100 nM in an asialoglycoprotein receptor- and sequence-dependent fashion. In conclusion, hepatocyte-targeted PNA prodrugs combine a greatly improved tropism with an enhanced local intracellular availability and activity, making them attractive therapeutics to lower the expression level of hepatic target genes such as MTP.

INTRODUCTION

Peptide nucleic acids (PNAs)[1] are oligonucleotide analogues in which the entire deoxyribose phosphate has been replaced with an *N*-(2-aminoethyl)glycine pseudopeptide backbone. Unlike conventional phosphorothioate antisense drugs that act by inducing RNase-H-mediated degradation of the target mRNA, PNAs inhibit gene expression by steric hindrance of enzyme/proteins responsible for DNA transcription, RNA splicing, and translation (*1*, *2*). Because of their electrical neutrality, chemo-enzymatic stability (*3*), and avidity of target-strand hybridization (*4*), PNAs hold great promise as antisense or antigene drugs (*1*, *2*). In addition, PNA hybridization is less tolerant toward mismatches, which makes PNAs more specific than conventional antisense drugs (*5*).

Widespread use of PNA-based therapy is, however, still hampered by the fact that PNAs display an even lower tendency to enter cells than phosphodiester or phosphorothioate oligodeoxynucleotides (ODNs) (*6*, *7*). Accordingly, therapeutic PNA activity has been demonstrated in cell free translation/transcription systems (*8*, *9*), in permeable *Escherichia coli* (*9*), and after microinjection into individual cells (*7*, *10*). In a recent study, Faruqui et al. (*11*) described that PNA uptake into fibroblasts could be considerably enhanced by streptolysin-O-mediated permeabilization. Improved delivery to Bowes cells was also observed after the coupling of PNA to intracellular translocation peptides (*12*). In vivo, however, the latter strategy requires the use of invasive local administration protocols. A strategy that exploits the potential of receptor-mediated endocytosis to improve cellular uptake of PNAs will probably be more feasible (*13*−*15*). Illustratively, Basu and Wickstrom demonstrated that the uptake of IGF1 receptor ligand-conjugated PNA by Jurkat cells is 5-fold higher, despite the moderate affinity of the tag (*13*). Successful in vivo delivery of PNAs to the brain could be realized by conjugation to transferrin receptor or OX26-specific antibodies (*14*, *15*). However, the extent of intracerebral penetration of PNA was still modest, and it remains to be established whether the recycling transferrin receptor leans itself for cellular accumulation of PNA drugs.

This study is aimed at devising a PNA-based therapy to down-regulate the expression of the human microso-

mal triglyceride transfer protein (huMTP) (*16*). HuMTP is a rate-limiting key enzyme in the assembly of atherogenic apolipoprotein B100-containing lipoproteins by parenchymal liver cells (*17*, *18*). This makes huMTP an excellent target for therapeutic intervention in patients that suffer from elevated plasma apoB100 levels. We now show in vitro and in vivo that parenchymal liver cell uptake of antisense PNAs can be considerably improved through targeting to the asialoglycoprotein receptor using a high-affinity tag for this receptor. In addition, the efficient target tissue uptake of antisense PNAs was found to be accompanied by a significantly enhanced ability of the PNA to inhibit MTP mRNA levels.

EXPERIMENTAL PROCEDURES

Materials. Tris-saturated biophenol (pH 8) was purchased from Biosolve Ltd., Valkenswaard, The Netherlands. Ribogreen was from Molecular Probes, Eugene, OR. Superscript II reverse transcriptase and RNaseH were obtained from Life Technologies, Frederick, MD. Oligonucleotides and Goldstar DNA polymerase were from Eurogentec, Seraing, Belgium. All other chemicals were of analytical grade. Human orosomucoid was isolated, subsequently desialylated enzymatically, and radioiodinated to yield [^{125}I]-asialoorosomucoid (ASOR), as previously described (*19*). All solvents were of analytical grade. Dry solvents were stored over molecular sieves 4 Å. Merck Kieselgel 60 F_{254} plates were used for TLC analysis. Compounds were visualized by charring with sulfuric acid/ethanol (1/4, v/v) or by dipping in a potassium hydroxide/ethanol/H_2O (v/v/v) solution followed by charring with a 0.3% solution of ninhydrine in acetic acid/*n*-butanol (3/100, v/v). Column chromatography was performed with Kieselgel 60, 230−400 mesh (Merck, Whitehouse Station, NJ). ^{1}H NMR spectra (300 MHz) were recorded with a Bruker WM-300 spectrometer. PEG-PS resin was purchased from Perkin-Elmer (Shelton, CT). Solid-phase synthesis was performed on an ABI 433 synthesizer. Products were analyzed with a Jasco HPLC system using a LiChrospher 100 RP-18 column (Merck; 5 μm, 4.6 × 250 mm). Electrospray mass-spectra were recorded with a Perkin-Elmer SCIEX API 165 single quadrupole LC/MS instrument. Matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry was performed on a Perkin-Elmer/PerSeptive Biosystems Voyager-DE-RP MALDI-TOF mass spectrometer.

Synthesis. *Resin 3.* Resin **3** was prepared manually by shaking amino-PEG-PS resin (2.5 g, 38.4 μmol/g) overnight with a solution of 4-hydroxymethylbenzoic acid (HMBA; 150 mg, 10 eq), *N*,*N*′-dicyclohexylcarbodiimide (DCC), and 4-(dimethylamino)pyridine (DMAP) in *N*,*N*-dimethylformamide (DMF)/dichloromethane (1/1, v/v). The resin was washed three times with DMF, three times with methanol, and finally with ether before drying over P_2O_5. Subsequently, FmocTyr(O*t*Bu)-OH (129 mg, 10 eq) and benzotriazol-1-yl-oxy-tris(dimethylamino)phosphoniumhexafluorophosphate (BOP; 520 mg, 10 eq) were added to a suspension of the resin in DMF/dichloroethane (1/1, v/v). The mixture was shaken for 3 h. Capping was performed with benzoic anhydride (200 mg), after which a small resin sample (15 mg) was taken to determine the loading (33 μmol/g). Finally, the resin was treated with piperidine (10 mL, 20% in DMF) and trifluoroacetic acid (TFA) (10 mL, 95% in H_2O) to deprotect the tyrosine residue. A 14-mer PNA sequence was assembled on resin **3** (30 mg, 1 μmol) using the previously prepared (*20*, *21*) building blocks **4**−**7** in the presence of *N*,*N*-diisopropyl ethylamine (DiPEA) in *N*-methylpyrrolidone. The coupling procedure took approximately 1 h per building block.

*Target Compound (**1**, **2**, and **9**).* For the subsequent preparation of the PNA glycoconjugates (*1*, *2*) and acetylated control PNA (**9**), galactosamine derivative **8** was synthesized starting from galactosamine (Senn chemicals, Dielsdorf, Switzerland), as previously described (*22*). Resin **10** was treated with 25 eq of FmocLys(Fmoc)-OH (15 mg) and 2-(1*H*-9-azabenzotriazole-1-yl)-1,1,3,3-tetramethyluroniumhexafluorophosphate (HATU; 10 mg) using standard solid-phase coupling procedures (30 min), followed by deprotection with piperidine and manual addition of 60 mg of **8** (2 × 25 μmol per free amine), BOP (44 mg, 100 μmol), and DiPEA (100 μmol). The thus obtained resin **12** was washed and suspended in a saturated solution of ammonia in methanol at 55 °C, which resulted in liberation of compound **1** from the resin as well as deprotection of the sugar and PNA residues. The product was purified by reversed-phase HPLC using a 0.1% TFA/H_2O/acetonitrile gradient (5−50%) and eluted at 22% acetonitrile, as was established by LC/MS. After purification, compound **1** was characterized by MALDI-TOF. The scrambled PNA-conjugate **2** (for chemical structure see Figure 1) was prepared analogously, and for acetylated PNA (*9*), resin **11** was treated with piperi-

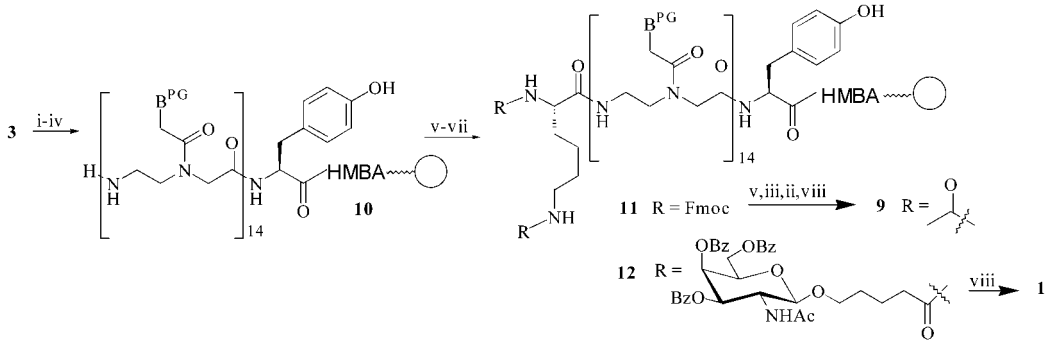
dine and capped with acetic acid anhydride after the coupling of **10** with 25 eq of FmocLys(Fmoc)-OH (15 mg) and HATU (10 mg). Both compounds were purified by reversed-phase HPLC as described for compound **1** and characterized. (Analysis for (**1** and **2**): LC/MS, found 1557 $(M + 3H)^{3+}$; MALDI-TOF, found 4668 $(M + H)^{+}$. Analysis for (**9**): LC/MS, found 1338 $(M + 3H)^{3+}$; MALDI-TOF, found 2073 $(M + 2H)^{2+}$.)

Animals. All animal work was approved by the regulatory authority of Leiden University and carried out in compliance with the guidelines issued by the Dutch government. C57Bl/6 mice were acquired from Charles Rivers (Someren, The Netherlands). The mice were male and 10−12 weeks old at the time of the study. Regular chow diet (Hope Farms, Woerden, The Netherlands) and water were provided ad libitum.

Radioiodination of PNA (Glycoconjugates). $K(GalNAc)_2$-asPNA and asPNA were radiolabeled at the C-terminal tyrosinamide, as previously described (*14*). In short, PNA (1.5 μg, 0.37 nmol), sodium [^{125}I]iodide (0.1 mCi, in 0.1 M NaOH) and chloramine T (2.8 μg) were mixed at a total volume of 40 μL of a phosphate buffer (pH = 7.4). After incubation for 1 min at ambient temperature, the reaction was quenched by adding sodium metabisulfite (11.7 μg), sodium iodide (10 μmol), and TFA (1%, v/v), and the solution was passed over a C18 Sep-Pak extraction cartridge (Waters Corp., Milford, MA). After the column was washed with 0.1% TFA/H_2O (4 mL) and 10% acetonitrile/0.1% TFA/H_2O (4 mL), the radioiodinated product was eluted by washing with 40% acetonitrile/0.1% TFA/H_2O (4 mL). The solvent was removed by lyophilization. The product was checked for purity on 20% SDS−PAGE. PNA associated radioactivity was more than 95%. The specific activity ranged from 1000 to 1200 dpm/ng.

In Vitro Binding and Uptake of K(GalNAc)$_2$-[^{125}I]-asPNA to HepG2 Cells. For uptake studies of $K(GalNAc)_2$-[^{125}I]asPNA, HepG2 cells (grown to confluency in 12-well tissue culture plates) were incubated for 15 min at 37 °C in Dulbecco's modified essential medium (DMEM) + 2% BSA with $K(GalNAc)_2$-[^{125}I]asPNA (0−100 nM), put on ice, washed twice with ice-cold DMEM + 2% (w/v) BSA, and incubated for 10 min at 4 °C with DMEM + 2% (w/v) BSA + EGTA (5 mM) to remove membrane-associated $K(GalNAc)_2$-[^{125}I]asPNA. Subsequently, cells were washed 3 times with Tris-buffered saline (50 mM Tris, 120 mM NaCl (pH 7.4); TBS) + 0.2% (w/v) BSA and once with TBS, and the cell-associated radioactivity was counted and corrected for protein content. Nonspecific uptake was determined in the presence of 100 mM of *N*-acetylgalactosamine. The viability of the cells was not significantly affected by the incubation protocol.

In Vivo Serum Clearance and Liver Association. C57Bl/6 mice were anaesthetised by subcutaneous injection of a cocktail containing ketamine·HCl, fentanyl citrate, droperidol, and fluanisone (75, 0.04, 1.1, and 0.75 mg/kg, respectively). [^{125}I]asPNA or $K(GalNAc)_2$-[^{125}I]asPNA (0.2 μg in 200 μL PBS) was injected into the inferior vena cava, and at the indicated times, the radioactivities in serum and liver were determined as described before (*23*). To assess the involvement of asialoglycoprotein receptors in liver uptake, we have monitored the liver uptake of $K(GalNAc)_2$-[^{125}I]asPNA injected into the vena cava at 1 min after intravenous injection of asialofetuin (15 mg/kg body weight).



Contribution of Liver Cell Types to Hepatic Uptake. C57Bl/6 mice were anaesthetised by subcutaneous injection of a cocktail containing ketamine·HCl, fentanyl citrate, droperidol, and fluanisone (75, 0.04, 1.1, and 0.75 mg/kg, respectively) and subsequently injected with [^{125}I]asPNA or $K(GalNAc)_2$-[^{125}I]asPNA (0.2 μg in 200 μL PBS) as previously described. Ten minutes after injection, the portal vein was cannulated, and the liver was perfused at 4 °C with collagenase (0.01%, w/v) and parenchymal; Kupffer and endothelial liver cells were isolated by differential centrifugation and centrifugal elutriation, as previously described (*23*).

Quantitative Radioactive RT-PCR of Human MTP. The relative abundance of human MTP mRNA was monitored through quantitative RT-PCR with human glyceraldehyde-3-phosphate dehydrogenase (huGAPDH) as an internal standard. Total RNA was isolated from HepG2 cells by lysis in GTC buffer (4 M guanidinium isothiocyanate; 25 mM sodium citrate buffer (pH 7.0); 0.5% *N*-lauroyl sarcosine; and 0.1 M β-mercaptoethanol) according to Chomczynski and Sacchi (*24*). After phenol-chloroform extraction, the total RNA was precipitated by adding 2.5 volumes of ice-cold ethanol, and the pellet was washed twice with 70% ethanol and dissolved in 20 μL of a Tris/EDTA buffer (10 mM Tris-HCl, 1 mM EDTA (pH 8.0)). The RNA concentration in the samples was determined with the RNA-specific fluorescent dye Ribogreen according to the procedure of Jones et al. and using yeast tRNA as calibration standard (yield: 6−18 μg/6 × 10^5 HepG2 cells) (*25*). Total RNA (2 μg) was reverse-transcribed using 100 units of superscript II reverse transcriptase (Life Technologies, Gaithersburg, MD). To minimize reverse transcription reaction variability, all RNA samples were reverse-transcribed simultaneously with a reverse transcription "master mix". cDNAs were amplified for 22 cycles at 54 °C in the presence of [^{32}P]-α-dCTP (0.8 μCi) and Taq polymerase (0.4 units; Eurogentec, Brussels, Belgium) using huMTP primers (forward, 5′-GAA·TCC·TGA·TGG·TGA·TGA·TG; reversed, 5′-GTC·TTG·ATG·AGC·CTG·GTA·GG; 100 ng). Unless otherwise stated, huGAPDH primers (forward, 5′-GGT·GAA·GGT·CGG·AGT·CAA; reversed, 5′-GAG·GGA·TCT·CGC·TCC·TGG; 100 ng) were added after cycle 4. Amplicon formation was monitored through autoradiography using the phosphor-imager as described before (*33*). Formation of huMTP amplicons in the presence or absence of huGAPDH primers was identical. Intra-experimental variation in the huMTP-to-huGAPDH amplicon ratio amounted to 13% and 18%, starting from a single batch of cDNA and mRNA, respectively ($n = 5$).

Effect of (Glycoconjugated) PNA on the huMTP mRNA Level. The PNA effect studies were carried out as follows. Cell cultures of HepG2s were grown to 60−70% confluency in DMEM/Eagles minimal essential medium (1/4, v/v) supplemented with fetal calf serum (10%, v/v), glucose (3.5 mg/mL), nonessential amino acids (20 μM), and biotin (0.2 μg/mL) in a 12-well tissue culture plate. Two days before the experiment, sodium butyrate (2 mM) was added to the medium. Cells were incubated for 6 h at 37 °C in the absence or the presence of asPNA, $K(GalNAc)_2$-asPNA, or $K(GalNAc)_2$-scPNA (100 nM). To establish the involvement of the asialoglycoprotein receptor in PNA uptake, HepG2 cells were also incubated with the PNA (glycoconjugates) in the presence of 10 mM *N*-acetylgalactosamine. After incubation, medium was removed, 0.5 mL medium was added, and the cultures were incubated for 24 h at 37 °C. Cells were lysed in 0.5 mL GTC, after which the total RNAs were isolated and the huMTP-to-huGAPDH amplicon ratio was determined by quantitative radioactive RT-PCR as previously described.

Data Processing. Saturation binding data and substrate curves of initial uptake were analyzed according to a single-site binding model using nonlinear regression

Scheme 1. Assembly of Compound 1 on Solid Support

Reagents: (i) PNA building blocks **4**−**7**, DiPEA; (ii) capping (Ac_2O/HOBt/DiPEA); (iii) piperidine; (iv) repeat (i)−(iii); (v) FmocLys(Fmoc)-OH/HATU/DiPEA; (vi) piperidine; (vii) **8**, BOP/HOBt/DiPEA; (viii) NH_3, MeOH.

(Prism, GraphPAD Software, Inc., San Diego, CA). Displacement studies were analyzed according to a single-site competitive displacement model using nonlinear regression (*19*). Values are expressed as means ± SE. Data variance was analyzed statistically by means of one-way ANOVA with Dunnet's post-testing.

RESULTS

The synthesis on solid support of PNA-glycoconjugate **1** by a Fmoc/benzoyl strategy starts with the preparation of tyrosine-functionalized resin **3**, PNA monomers **4**−**7**, and readily accessible building block **8** (Figure 1). First, commercially available polystyrene resin was equipped with FmocTyr(O*t*Bu)-OH via a hydroxymethylbenzoic acid linker, followed by piperidine and TFA deprotection to give **3** (loading: 33 μmol/g). Then, the active esters of the respective PNA monomers **4**−**7** were prepared from the previously described Fmoc-protected backbone (*20*) and known Bz/*i*Bu-protected base acetic acids (*21*) in 72−80% yield. Finally, galactosamine was extended with a carboxylic acid spacer, as previously described, to afford compound **8** (*22*).

With all of the building blocks in hand, the antisense PNA sequence (asPNA; 5′-CAT·ATA·CAT·TGA·TCT-3′) was assembled on resin **3** (33 mg, 1 μmol) by repetitive coupling cycles using the building blocks **4**−**7** in the presence of DiPEA to give **10** (Scheme 1). Next, immobilized PNA fragment **10** was treated with FmocLys-(Fmoc)-OH in the presence of HATU/DiPEA. Subsequent deprotection of the lysine residue with piperidine allowed for the simultaneous introduction of both galactosamine moieties **8** mediated by BOP, *N*-hydroxybenzotriazole (HOBt), and DiPEA. Treatment of the obtained resin **12** with a saturated solution of ammonia in methanol resulted in cleavage of compound **1** (K(GalNAc)$_2$-asPNA) from the resin and concomitant removal of the nucleobase and sugar protecting groups. The conjugate was then purified by reversed-phase HPLC and characterized by LCMS and MALDI-TOF analysis. Analogously, the 14-mer *scrambled* PNA was conjugated to the divalent galactosamine cluster (**2**, K(GalNAc)$_2$-scPNA; Figure 1). For the synthesis of nonconjugated asPNA (9), resin **11** was treated with piperidine, capped, and subsequently cleaved from the resin, as previously described.

Target-Strand Hybridization. To verify whether the presence of the bulky K(GalNAc)$_2$ group interferes with the hybridization of PNA to the complementary target strand, thermal denaturation studies were performed for duplexes of asPNA or K(GalNAc)$_2$-asPNA and complementary DNA. The two melting curves largely concurred, yielding T_m values of 57.5 and 62.6 °C, respectively.

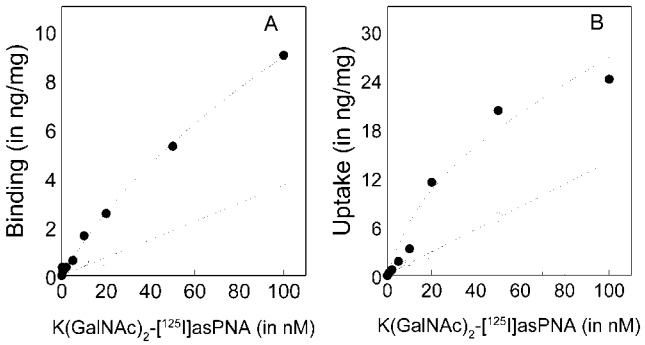


Figure 2. In vitro studies of K(GalNAc)$_2$-[^{125}I]asPNA binding and uptake by HepG2 cells. (A) HepG2s (1−2 × 10^6 cells) were incubated for 2 h at 4 °C in DMEM + 2% (w/v) BSA with 0−100 nM of K(GalNAc)$_2$-[^{125}I]asPNA in the absence (●) or presence (○) of 100 mM *N*-acetylgalactosamine. After incubation, cells were washed thoroughly, and cell binding was determined and corrected for cellular protein content. Total and nonspecific binding is given as mean of a duplicate experiment. (B) HepG2s (1−2 × 10^6 cells) were incubated for 1 h at 37 °C in DMEM + 2% (w/v) BSA with 0−100 nM of K(GalNAc)$_2$-[^{125}I]asPNA in the absence (●) or presence (○) of 100 mM *N*-acetylgalactosamine. After incubation, cells were put on ice and washed thoroughly, and membrane-bound radioactivity was removed by incubation for 5 min with 5 mM EGTA at 4 °C. Cell-associated radioactivity was counted and corrected for cellular protein content.

Apparently, the presence of the K(GalNAc)$_2$ group only slightly impairs PNA hybridization to the target strand.

In Vitro Studies. In vitro binding studies were performed to establish the effect of glycoconjugation on cellular uptake of PNA by HepG2s (Figure 2A). K(GalNAc)$_2$-[^{125}I]asPNA bound to HepG2s in a saturable fashion (B_{max} = 8.5 ng/mg) and with high affinity (K_d = 77 nM). The affinity of the glycoconjugate was only slightly lower than that of the K(GalNAc)$_2$ tag and that of PMEA-K(GalNAc)$_2$ (24 and 46 nM, respectively; *22*, *26*). Equilibrium binding of K(GalNAc)$_2$-[^{125}I]asPNA at 37 °C was rapidly achieved (within 10 min of incubation) (data not shown). Once bound, K(GalNAc)$_2$-[^{125}I]asPNA was efficiently internalized by HepG2 cells at a K_m of 25 nM (Figure 2B). The turn-over-rate of K(GalNAc)$_2$-[^{125}I]asPNA internalization by HepG2 cells as estimated from the B_{max} and V_{max} was approximately 20 min, suggesting that uptake of the glycoconjugate is an efficient process.

In Vivo Fate. Evidently, glycoconjugation has a stimulatory effect on the PNA uptake by HepG2 cells in vitro. A major issue to be addressed is whether the targeting capacity of the K(GalNAc)$_2$ tag is sufficiently high to overcome premature elimination of the PNA by renal clearance or competing uptake routes. Thus, we have compared the tissue distribution profile of the control, [^{125}I]asPNA, after intravenous injection into mice with

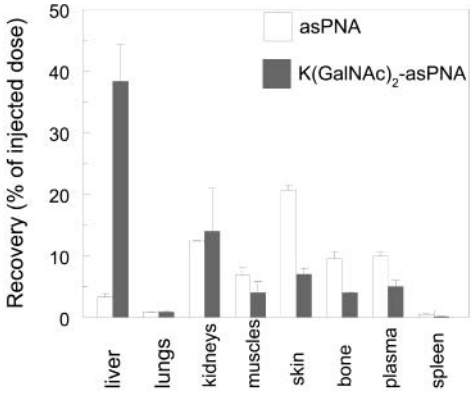

Figure 3. Tissue distribution of PNA (glycoconjugate). [^{125}I]-asPNA (open bars) or K(GalNAc)$_2$-[^{125}I]asPNA (closed bars) (1 μg dissolved in 100 μL PBS) were intravenously injected into mice. After 30 min, mice were sacrificed, and the indicated tissues were analyzed for radioactivity. Tissue recovery was corrected for the radioactivity from entrapped plasma. The recovery of radioactivity in the organs was >80%. Values are means (±SD) of a determination of three experiments.

that of K(GalNAc)$_2$-[^{125}I]asPNA. Preliminary experiments showed that the PNA (glycoconjugates) tended to form aggregates, which accumulated in lung tissue rather than liver (only 20% ± 4% of the injected dose). To avoid aggregate formation, radiolabeled PNA (glycoconjugates) were routinely incubated for 5 min at 96 °C in 50% formamide and subsequently lyophilised before use in further experiments. [^{125}I]asPNA and K(GalNAc)$_2$-[^{125}I]asPNA were equally rapidly cleared from the bloodstream, with a plasma half-life of 0.49 ± 0.08 min and 0.38 ± 0.04 min, respectively. By contrast, the tissue distribution profiles of [^{125}I]asPNA and K(GalNAc)$_2$-[^{125}I]asPNA differed considerably (Figure 3). [^{125}I]asPNA was recovered mainly in skin (20.7% ± 0.7%), kidney (12.4% ± 0.1%), bone (9.5% ± 1.2%), and plasma (10.0% ± 0.6%), whereas the liver appeared to be the major recovery site of K(GalNAc)$_2$-[^{125}I]asPNA (38% ± 6% at 30 min after injection). The accumulation of K(GalNAc)$_2$-[^{125}I]asPNA in skin, plasma, and bone was 2−3-fold lower than that of [^{125}I]asPNA. Hepatic uptake of K(GalNAc)$_2$-[^{125}I]asPNA peaked at 10 min after administration (49% ± 3% as compared to only 4.1% ± 0.3% for control PNA; $P < 0.001$) (Figure 4A). After preinjection of asialofetuin (15 mg/kg) to prevent asialoglycoprotein receptor-mediated uptake, the liver uptake of K(GalNAc)$_2$-[^{125}I]asPNA was significantly reduced to 18.6% ± 4.1% of the injected dose ($P < 0.001$). Of relevance, 97% ± 2% of the liver uptake of K(GalNAc)$_2$-[^{125}I]asPNA could be recovered in the parenchymal liver cells. This implies that 45.8% ± 0.9% of the total injected K(GalNAc)$_2$-[^{125}I]-asPNA reaches the aimed target, as compared to only 3.1% for non-conjugated [^{125}I]-asPNA (Figure 4B). Taken together, the aforementioned data indicate that the 15-fold stimulated hepatic uptake of the glycoconjugated PNA can be attributed almost exclusively to the asialoglycoprotein receptor.

Antisense Effect of Targeted PNAs. From the aforesaid studies, it is apparent that glycoconjugation stimulates the uptake of PNA by the aimed target both in vitro and in vivo. The next issue to be addressed is whether the stimulated cellular uptake is accompanied by an enhanced inhibitory activity of the asPNA. A quantitative radioactive RT-PCR-based assay was set up to measure huMTP mRNA levels. cDNA was amplified for various cycle numbers in the presence of [^{32}P]-α-dCTP and using huMTP and huGAPDH specific primer sets to determine

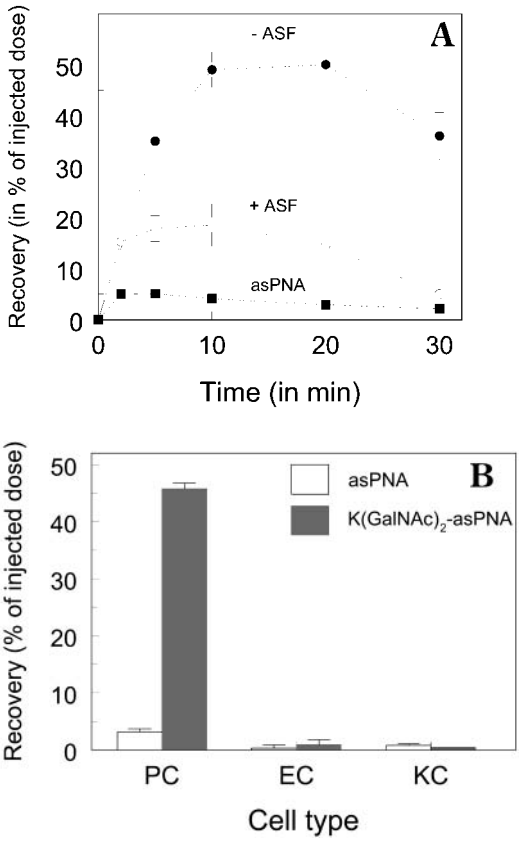

Figure 4. (A) Effect of asialofetuin treatment on the kinetics of liver uptake of PNA (glycoconjugate). [^{125}I]asPNA (1 μg, in 100 μl PBS) (■) or K(GalNAc)$_2$-[^{125}I]asPNA (1 μg in 100 μL PBS) (●, ○) was injected into mice that were injected at 1 min prior to administration of the radiolabel with PBS (100 μl; ●, ■) or PBS containing asialofetuin (15 mg/kg; 100 μl; ○). At the indicated times, radioactivities in the liver were determined. Values are means ± SD of three experiments. (B) Contribution of the various liver cell types to hepatic uptake of PNA (glycoconjugates). [^{125}I]asPNA (open bars) or K(GalNAc)$_2$-[^{125}I]-asPNA (closed bars) was intravenously injected into mice. At 10 min after injection, the liver was excised, and the various liver cell types were isolated by differential centrifugation and centrifugal elutriation. The recovery of radioactivity in the purified cell fractions was determined and corrected for protein content. From the specific recovery, the total contribution of the liver cell types could be calculated assuming the PC, EC, and KC to contribute 92.5%, 2.5%, and 3.1% to the total hepatic cell protein, respectively. Values are means ± SD of three experiments.

the optimal number of cycles (cycle titration). Under optimal conditions (annealing temperature and primer concentration), the logarithmic phase of the PCR amplification ranged from 12 to 21 cycles for huGAPDH and from 15 to 24 cycles for huMTP (Figure 5). For both genes, amplification efficiencies were >90%, both in the absence and presence of a second primer set (correlation coefficients >0.996). Starting from a single batch of cDNA and mRNA, assay variability amounted to 13% and 18% ($n = 5$), respectively, which is sufficiently low to allow for the detection of minor changes in the huMTP-to-huGAPDH mRNA ratio.

Next, we have assessed the effect of the PNA drugs on huMTP mRNA levels in vitro in HepG2 cells. HepG2 cells were incubated for 6 h at 37 °C with 100 nM of asPNA, K(GalNAc)$_2$-asPNA, or scrambled K(GalNAc)$_2$-scPNA and at 24 h after incubation assayed for huMTP and huGAPDH mRNA content. From Figure 6 it can be appreciated that the huMTP-to-huGAPDH amplicon

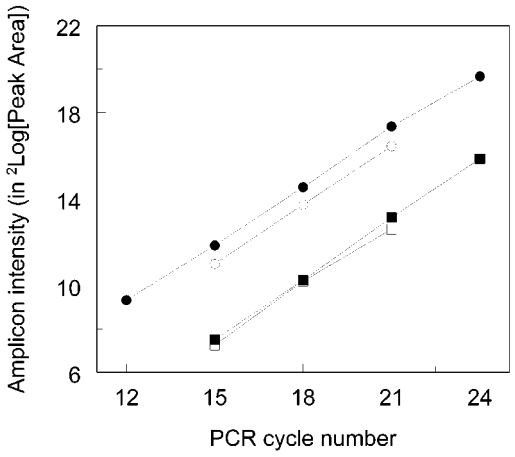

Figure 5. Optimization of the quantitative RT-PCR assay. Total RNA was isolated from HepG2 cells, after which mRNA (2 μg) was reverse-transcribed, and the huMTP cDNA and huGADPH cDNA were amplified for 12−24 cycles in the presence of [^{32}P]-″CTP, as described in the Experimental Procedures section. The PCR products were subjected to gel electrophoresis on 10% polyacrylamide, and the intensity of the [^{32}P]-huMTP and [^{32}P]huGAPDH bands were determined by autoradiography using the Phosphor-Imager. The intensities of the huMTP (■, □) and huGAPDH bands (●, ○) are plotted versus the number of PCR cycles. The PCR reaction was performed in the presence of a single (○, □) or both primer sets for huMTP and huGAPDH (■, ●).

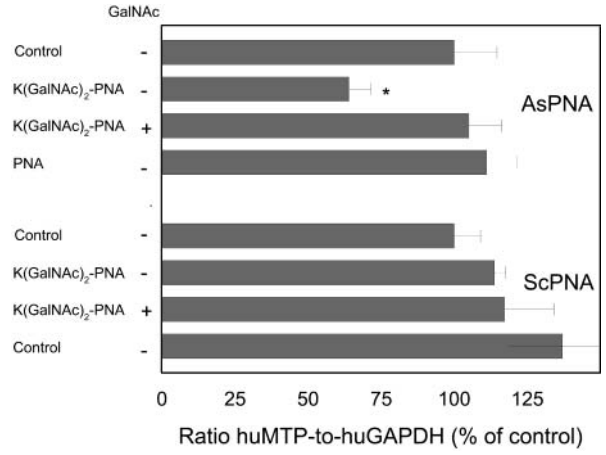

Figure 6. Effect of PNA (glycoconjugates) on MTP mRNA level by HepG2s. HepG2s, grown to 60−70% confluency, were incubated for 6 h at 37 °C without (control) or with PNA (glycoconjugates) (100 nM), washed, and incubated again for 24 h. After incubation, cells were lysed in GTC buffer, after which the total RNA was isolated. The huMTP to huGAPDH mRNA ratios were determined by quantitative radioactive RT-PCR using the Phosphor-Imager. To establish the involvement of the asialoglycoprotein receptor in the antisense effect, the above experiment was also performed in the presence of 10 mM *N*-acetylgalactosamine (GalNAc). Data are means ± SD of an experiment in hexaplo.

ratios were significantly reduced only after incubation with K(GalNAc)$_2$-asPNA (−36%, $P < 0.02$). Essentially similar results were obtained in an initial experiment (39% reduction in the huMTP-to-huGAPDH mRNA ratio after K(GalNAc)$_2$-asPNA treatment; not shown here). Ratios were unaffected after incubation of the HepG2s with nonconjugated asPNA or K(GalNAc)$_2$-scPNA. Importantly, the effect of K(GalNAc)$_2$-asPNA on huMTP-to-huGAPDH ratios was critically dependent on asialoglycoprotein receptor-mediated transport, as ratios were found to be unaffected after co-incubation with *N*-acetylgalactosamine.

DISCUSSION

Because of their electrical neutrality, chemo-enzymatic stability (*3*), and avidity of target-strand hybridization (*4*), PNAs hold great promise as antisense or antigene drugs (*1*, *2*). Nevertheless, they still have not redeemed their initial promise. Partly, this might be attributed to the unfavorable pharmacokinetics of PNAs in vivo (*14*, *15*, *27*) and the inability to enter cells in vitro (*6*, *7*). We (*26*, *29*) and others (*29*−*31*) have recently shown that the therapeutic profile of (oligo)nucleotides can be considerably improved by direct conjugation to a ligand for a receptor that is characteristic for the target tissue or by incorporation into tissue-specific drug carriers. In this study, we show that PNAs may equally benefit from hepatic delivery, as do conventional (oligo)nucleotide drugs. To this end, antisense PNA targeting the human MTP gene was conjugated to K(GalNAc)$_2$, a bivalent *N*-acetylgalactosamine-terminated scaffold with nanomolar affinity for the asialoglycoprotein receptor (*22*). From the thermal denaturation studies, we may conclude that conjugation of the asPNA sequence to K(GalNAc)$_2$ did not significantly affect target-strand hybridization, which is an absolute requisite for antisense drug activity.

The glycoconjugated asPNA was avidly bound to parenchymal liver cells and HepG2 cells at a similar affinity as reported earlier for K(GalNAc)$_2$ conjugated to an antiviral nucleoside (i.e., 46 nM (*26*)). The K(GalNAc)$_2$ tag conferred efficient uptake of PNA by human parenchymal liver as well as by hepatoma cells. A similar increase in PNA uptake by Jurkat cells was recently observed after conjugation to a D-peptide ligand for the IGF1 receptor (*13*).

In agreement with previous studies on the pharmacokinetics of PNAs (*14*, *15*, *27*), PNA displayed a fairly unspecific tissue distribution profile, with kidney, skin muscle, and bone being the major sites of accumulation. The PNA glycoconjugate, however, strongly accumulates in the liver at the dispense of skin, bone, serum, and muscle uptake. The hepatic uptake of the K(GalNAc)$_2$-asPNA could be prevented by prior injection of asialofetuin, indicating that the asialoglycoprotein receptor is responsible for the increased liver uptake. Given the stability of the PNA drug against proteases and nucleotidases (*3*), the observed decrease in liver associated K(GalNAc)$_2$-[^{125}I]asPNA after 20 min probably reflects proteolytic cleavage and subsequent deiodination of the C-terminal [^{125}I]tyrosinamide group rather than degradation of the antisense drug itself. In agreement, PAGE analysis of the liver extract for intact K(GalNAc)$_2$-[^{125}I]asPNA showed a half-life of 16 ± 4 min (data not shown). Intermediate PNA degradation products were not observed, which also points to proteolysis of the radiolabeled tyrosine moiety. Further study of the liver cell distribution profile showed that the parenchymal liver cell uptake increased almost 20-fold after glycoconjugation, which compares well with the targeting efficiencies that were obtained for ODN glycoconjugates (*28*) and for the K(GalNAc)$_2$ conjugate of an antiviral nucleoside (*26*). To date, successful PNA delivery to specific organs has only been reported by Pardridge et al. (*14*) and by Penichet et al. (*15*), showing a 15-fold enhanced brain accumulation of biotinylated anti-HIV asPNA after conjugation to an antibody against the transferrin receptor or Ox-26. However, it is not known whether the improved bioavailability of the PNA drug in the target cells resulted in a similarly enhanced therapeutic activity.

In this study, we demonstrate inhibition of huMTP expression in HepG2 cells after tagging of the asPNA

drug with a high-affinity ligand for the asialoglycoprotein receptor. The antisense PNA used in this study targeted the gene encoding huMTP (*16*), which catalyses a rate-limiting step in the assembly of proatherogenic apolipoprotein-B100-containing lipoproteins (*17*, *18*). Although, recently, a number of potent MTP inhibitors have been devised, these inhibitors also reduce intestinal MTP activity, which may be harmful. The antisense prodrugs, described in this study, may display a more favorable therapeutic profile, as their activity is more liver-specific and possibly, to a lesser extent, dictated by interindividual variations in pharmacodynamics. From secondary RNA structure analysis of the huMTP mRNA using the Zuker algorithm (Mfold, version 3.0), we have selected the nucleotide sequence 3133−3146 as a potential antisense prone site that is probably not involved in hairpin or pseudo-knot formation (*32*).

To enable the detection of minor changes in the relative huMTP level, a sensitive assay for quantification of huMTP mRNA levels in HepG2 cells was set up. Incubation of HepG2 cells with $K(GalNAc)_2$-asPNA led in two independent experiments to a significant reduction of huMTP mRNA levels of 35−40%. This reduction was not observed for scrambled PNA glycoconjugate, establishing the sequence-dependency of PNA induced inhibition of huMTP expression. The antisense effect was neither observed after blockage of the asialoglycoprotein receptor nor observed for the parental asPNA, implying that asialoglycoprotein receptor-mediated uptake is a sine-qua-non requisite for antisense activity of the tagged asPNA. It can be calculated that, under the assay conditions, approximately 15 ng $K(GalNAc)_2$-asPNA/mg cell protein will be taken up by HepG2 cells, corresponding with intracellular concentrations of 700 nM, which apparently is sufficient for antisense activity. Although the asPNA was targeting a sequence on the human MTP gene 3.1 kb downstream from the initiation codon, it was able to interdict transcription or post-transcriptional splicing in HepG2 cells. Homopyrimidine PNAs were reported to be capable of DNA double-strand invasion (*1*, *10*), but the mixed composition of the antisense PNA makes it rather unlikely that its inhibitory activity can be traced down either to duplex formation via Hoogsteen base-pairing or to triplex formation.

In conclusion, PNA glycoconjugates have been synthesized that avidly bind to, and are taken up by, HepG2 cells. The pharmacokinetics of the PNA glycoconjugates are superior to that of PNAs in that parenchymal liver cell uptake is increased by 20-fold, while PNA accumulation in skin, spleen, muscle, bone, and plasma was found to be 2−3-fold lower. The glycoconjugated antisense PNA interfered with the huMTP mRNA levels in HepG2 cells at concentrations as low as 100 nM in a sequence-dependent and receptor-mediated fashion. The aforesaid prodrug strategy for improved and cell-specific PNA delivery thus results in a considerably increased therapeutic activity of the antisense PNA drugs and may be valid also for PNAs directed against other target genes.

Preparation of a Conjugate of 2′,5′-Triadenylate 5′-Triphosphate and Biotinylated Firefly Luciferase and Its Use for Sensitive Bioluminescent Enzyme Immunoassay

Yoshiaki Seto,*[,†,‡] Katsushi Abe,[‡] Masao Itoh,[‡] and Hiroaki Sawai[†]

Department of Chemistry, Faculty of Engineering, Gunma University, 1-5-1 Tenjin-cho, Kiryu, Gunma, 376-8515, Japan and Biochemical Research Laboratory, Eiken Chemical Co., Ltd., 1381−3 Ohtawara, Tochigi, 324-0036, Japan. Received September 6, 2001; Revised Manuscript Received December 11, 2001

A bioluminescent enzyme immunoassay (BLEIA) for 2′,5′-oligoadenylate 5′-triphosphate (pppA2′-p5′A2′Ap5′A, 2-5A) was developed using a conjugate of 2-5A and firefly luciferase as a probe. The conjugate was prepared from a 2-5A derivative bearing a thiol group at the 2′(or 3′) end, and streptavidin (SA) bearing maleimide via a linker-arm and biotinylated luciferase. The thiol group of the 2-5A derivative was relatively stable under aerobic conditions and remained 100% and 56% intact at 25 °C after 1 and 96 h, respectively, without dimerization by aerobic oxidation. The thiol-modified 2-5A was coupled with the SA−maleimide conjugate, followed by complex formation with biotinylated firefly luciferase. BLEIA using this conjugate allowed for the direct analysis of 2-5A in a range of 5−500 fmol (0.1−10 nM in a 50 μL sample) and in a reaction time of 15 min. The measurement of microquantities of 2-5 A from various sources is easy to perform by this BLEIA, because no radioisotope labeled 2-5A was required as a probe.

INTRODUCTION

2′,5′-Oligoadenylate 5′-triphosphate (pppA2′p5′A2′p5′A), referred to as 2-5A, is synthesized from ATP by 2-5A synthetase, which is induced by interferon. The 2-5A binds and activates 2-5A−dependent RNase (RNase L), which degrades messenger and ribosomal RNA at a nanomolar concentration (*1*, *2*). This 2-5A system is implicated not only in interferon's antiviral action but also in cell growth regulation. Therefore, the measurement of nanomolar concentrations of 2-5A is useful for the study of the 2-5A system and for management of interferon therapy and diagnosis for viral diseases. Silvernan et al. and Hersh et al. reported radiobinding and radioimmuno assays for 2-5A using a ^{32}P-labeled 2-5A derivative which was synthesized enzymatically (*3*, *4*). Sawai et al. synthesized the 2-5A conjugate with β-alanyltyrosine and labeled the conjugate with ^{125}I for radioimmunoassay (RIA) (*5*). These methods require a radiolabeled 2-5A derivative as a probe. Recently, RIA methods have been replaced with nonradioisotope immunoassays using enzyme, fluorescence, or chemiluminescence. Nicolas et al. reported enzyme immunoassay for 2-5A using monoclonal antibody and peroxidase-2-5A conjugate, but this method required long reaction time for using a microtiter plate as the solid phase (*16*). Thus, we have explored nonradioisotope, sensitive, and rapid immunoassay to measure subnanomolar concentrations of 2-5A.

The bioluminescent enzyme, firefly luciferase, catalyses the oxidation of D-luciferin in the presence of adenosine 5′-triphosphate(ATP), Mg^{2+}, and molecular oxygen. The exited state oxyluciferin that is produced in the oxidation process generates light, forming a steady state oxyluciferin. This luminescence quantum yield is 0.88 and higher than any other bio- or chemiluminescence (*6*). For this high quantum yield, the firefly luciferase bioluminescent system has been applied to a genetic reporter in molecular biology and in ATP detection in microbiology (*7*, *8*). Tatsumi et al. developed a modified thermostable luciferase genetically and introduced D-biotin (*9*). The biotinylated luciferase can be used as a labeling enzyme for an antibody in an enzyme immunoassay (EIA). Ohkuma and Maeda et al. reported BLEIA for pepsinogen I and II using conjugates constructed from biotinylated luciferase, streptavidin (SA), and a biotinylated antibody (*10*). Recently we developed a BLEIA for thyroid stimulating hormone, in which the antibody was coupled with SA by a cross-linking agent and bound with biotinylated luciferase by a avidin−biotin complex (*11*). These BLEIA give highly sensitive analyses of the target molecules. Thus, we have studied the conjugation of 2-5A and luciferase for use in a BLEIA of 2-5A. For covalently linking 2-5A with SA, we derivatized 2-5A with cysteamine according to the method reported by Torrence et al. (*12*). Contrary to their report that the 2-5A−cysteamine conjugate was unstable because its free thiol group formed a disulfide linkage immediately by aerobic oxidation, we found that thiol-derivatized 2-5A is relatively stable and permitted the conjugation with SA by a bifunctional cross-linking agent bearing maleimide. The resulting 2-5A−SA conjugate was bound with biotinylated luciferase. This report describes the preparation and properties of the conjugates of 2-5A, and a BLEIA for 2-5A using the conjugate and a biotinylated luciferase as a probe.

MATERIALS AND METHODS

Materials. The 2′,5′-oligoadenylate-5′-triphosphate (2-5A) was prepared as described in a previous report (*13*).

ATP and SA were purchased from Sigma (St. Louis, MO). *N*-(11-maleimidoundecanoyloxy)sulfosuccimide, sodium salt (Sulfo-KMUS), *N*-(2-acetamido)iminodiacetic acid (ADA), 2-[4-(2-hydroxyethyl)-1-piperazinyl]ethanesulfonic acid (HEPES), bis(2-hydroxyethyl)iminotris(hydroxymethyl)methane (Bis-Tris), and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide, hydrochloride (EDC or WSC) were obtained from Dojin (Kumamoto, Japan). Anti 2-5A polyclonal antibody was prepared as described previously (*14*). Anti rabbit IgG polyclonal antibody was from Shibayagi (Gunma, Japan). Block Ace was purchased from Dainippon Pharmaceutical (Osaka, Japan). Biotinylated thermostable recombinant firefly luciferase (bL248) was supplied by Kikkoman Corp. (Tokyo, Japan). D-Luciferin was purchased from Biosynth (Staad, Switzerland). Magnetic particle (Immtex MAG1803) was obtained from JSR (Tokyo, Japan).

HPLC. Analytical and fractional HPLC were carried out on a Wakosil DNA column (4.5 mm × 150 mm) using a linear gradient elution of 3−31% of solvent B. Solvent A was 50 mM triethylammonium acetate (TEAA) at pH 7.0 and solvent B was 70% acetonitrile in 50 mM TEAA (pH 7.0).

Preparation of Cystamine Derivative of pppA2′-p5′A2′p5′A (2−5A). To a 50 μL aqueous solution of 2-5A (9.0 ODU at 260 nm, 0.27 μmol) was added 3.8 μL of 0.1 M sodium metaperiodate in distilled water, and the solution was incubated for 25 min on an ice bath. To the reaction mixture, 2.5 μL of 0.1 M cystamine dihydrochloride in water was added and the pH immediately adjusted to 8.5 using 0.1 M NaOH and 1 M NaOH solution. After incubation for 15 min on an ice bath, 5.0 μL of 0.5 M sodium cyanoborohydride in water was added to the reaction mixture, and the pH was adjusted to 6.5 using 0.1 M HCl and 1 M HCl solution immediately. After incubation for 60 min on an ice bath, the product was checked and purified by reverse phase HPLC. Fractions containing 2-5A−cystamine were pooled and lyophilized. The yield was 37% (3.3 ODU at 260 nm, 0.1 μmol). ESI-MS: calculated $[M - H]^-$ *m/z* 1282.1 and $[M - 2H]^{2-}$ *m/z* 640.6, found 1282.2 and 640.6, respectively.

Reduction of 2-5A-Cystamine. To 100 μL of 2-5A−cystamine in distilled water (3.3 ODU at 260 nm, 0.1 μmol) was added 20 μL of 1.0 M dithiothreitol (DTT) in distilled water (DW), and the reaction mixture was incubated at 25 °C for 30 min. The product was checked and purified by reverse phase HPLC. Fractions containing 2-5A−cysteamine were pooled, lyophilized, and stored at −20 °C. The yield was 79% (2.6 ODU at 260 nm, 79 nmol). ESI-MS: calculated $[M - H]^-$ *m/z* 1207.1 and $[M - 2H]^{2-}$ *m/z* 603.1, found 1207.2 and 602.8, respectively.

Conjugation of 2-5A−Cysteamine with Streptavidin (SA). To 100 μL of 40 μM SA in phosphate buffer saline (PBS) was added 6.8 μL of 14.2 mM Sulfo-KMUS in dimethylformamide (DMF), and the solution was incubated at 30 °C for 60 min. The reaction mixture was passed through a PD-10 column using 0.1 M PB containing 5 mM EDTA (pH 7.2) as an elution buffer. The fractions containing SA-KMUS were collected and concentrated by a Centricon-30 centrifuge concentrator (Millipore, MA). The yield of SA-KMUS was 63% based on SA. To 280 μL of 9.0 μM SA-KMUS solution in PBS was added 4.8 μL of 790 μM 2-5A−cysteamine in 0.1 M PB containing 5 mM EDTA (pH 7.2), and the reaction mixture then incubated at 30 °C for 60 min. The product was passed through a PD-10 column using 0.1 M PB containing 5 mM EDTA (pH 7.2) as an elution buffer. Fractions containing 2-5A−cysteamine-SA (2-5A−SA) were collected and pooled. The yield was 20% based on SA-KMUS (0.192 OD at 280 nm, 0.5 nmol). The conjugate showed UV absorption at 280 and 260 nm in a 1 to 0.76 ratio. The numbers of the 2-5A molecule introduced to one molecule of SA was estimated as 1.2 from the ratio of the UV absorption of the conjugate at 260 nm and 280 nm, ascribed to 2-5A and SA, respectively.

Conjugate Formation between Biotinylated Luciferase (bL248) and 2-5A−SA. To 0.5 nmol of the 2-5A−SA solution, 50 nmol 2-mercaptoethanol was added to block the excess maleimide groups in the conjugate, and the mixture incubated at 25 °C for 30 min. Four hundred and seventy microliters of bL248 solution (2.4 mg mL^{-1}) in the storage buffer (0.1 M PB, 2 mM 2-mercaptoethanol, 1 mM EDTA, 10% glycerol) was added to 0.5 nmol 2-5A−SA solution and the mixture incubated at 25 °C for 60 min. The product was purified by Superdex 200HR 10/30 (Pharmacia) column chromatography using 0.1 M PB containing 0.15 M NaCl (pH 7.2) as an elution buffer. Fractions showing high immunological reactivity and enzyme activity were collected. This conjugate solution was diluted to 80 pM (based on enzyme concentration) with conjugate buffer (0.1 M PB containing 2.5 mM EDTA, 0.2% bovine serum albumin, 0.02% casein, and 0.05% NaN_3) and stored at 4 °C.

Immobilization of Anti-Rabbit IgG Polyclonal Antibody to Magnetic Particles. One milliliter of magnetic particle suspension (5 mg mL^{-1}) was washed 3 times with 1 mL of distilled water. The magnetic particles were resuspended with 500 μL of 0.2 M Bis-Tris buffer (pH 5.5), and then 500 μL of 10 mg mL^{-1} EDC in distilled water was added and the mixture stirred at 25 °C for 30 min. The suspension was washed three times with 1 mL of distilled water and with 500 μL of 0.1 M PB(pH 7.2) containing 0.4 M ammonium sulfate. The activated magnetic particles were resuspended with 500 μL of 0.1 M PB(pH 7.2) containing 0.4 M ammonium sulfate and 0.4 mg mL^{-1} anti-rabbit IgG antibody, and the mixture was stirred at 25 °C for 18 h. To the magnetic particles was added 1 mL of blocking buffer (0.05 M PB containing 20% Block Ace, pH 7.2), and the suspension was stirred at 25 °C for 3 h. After blocking buffer was removed from the suspension, 10 mL of stock buffer (0.05 M PB containing 5% Dextran T40, 0.2% bovine serum albumin and 0.1% NaN_3, pH 7.4) was added and stored at 4 °C.

Bioluminescent Enzyme Immunoassay for 2-5A. Immunoassay was carried out by the one-step competitive method. After 50 μL of sample was transferred to a polystyrene test tube (12 × 75 mm), 50 μL of the reaction buffer (0.05 M PB containing 5% Dextran T40, 0.2% bovine serum albumin, and 0.1% NaN_3, pH 7.4), 100 μL of 80 pM 2-5A−Lucferase conjugate solution, a 20 μL suspension of 1 mg mL^{-1} anti-rabbit IgG antibody immobilized on magnetic particles, and 100 μL of anti 2-5A rabbit serum, which was diluted 20,000-fold with the reaction buffer, were added to the test tube and stirred. The mixture was incubated at 25 °C for 15 min and washed with 0.05% Tween 20 in PBS (750 μL × 3). To the magnetic particles was added 100 μL of suspension buffer (50 mM Tris-HCl, pH 8.5), and the mixture stirred for 2 s. The test tube containing the suspension was placed on a luminometer (Lumat LB 9507, EG&G Berthold) and 100 μL of a substrate solution (940 μM luciferin, 2 mM ATP, 40 mM ADA, 16 mM MgSO4, 0.26 mM EDTA, 2 mM potassium pyrophosphate, pH 6.5) added. Luminescence intensity was measured by integrating the emission for 5 s (delay time 0.5 s).

Scheme 1. Preparation of 2−5A-cysteamine

RESULTS AND DISCUSSION

The conjugate of 2-5A used in this BLEIA was bound covalently to SA as shown in Figure 1. We initially prepared a 2-5A derivative bearing biotin and conducted complex formation between biotinylated 2-5A, SA, and biotinylated luciferase. However, simultaneous introduction of biotinylated luciferase and biotinylated 2-5A to SA was difficult to control, because binding of the high molecular weight biotinylated luciferase to SA is suppressed by the preferable binding of the low molecular weight biotinylated 2-5A to SA. Thus, we tried to prepare 2-5A conjugate linked to SA covalently. Several methods can be considered for the covalent conjugation of 2-5A with SA. A homobifunctional cross-linking reagent such as dialdehyde or disuccinmide, which is amine reactive, reacts with SA at both sites forming polymeric structures.

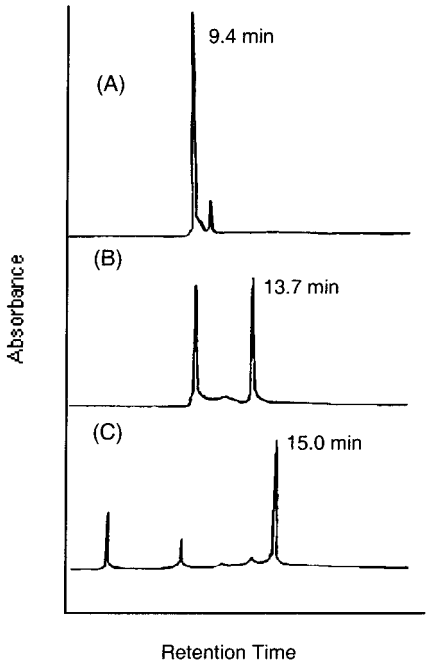

Figure 2. HPLC profiles of 2-5A−cysteamine preparation. (A) The peak at 9.4 min is 2-5A before derivatization. (B) Introduction of cystamine to 2-5A. The peak at 13.7 min is 2-5A−cystamine. (C) Reduction of 2-5A−cystamine with DTT. The peak at 15.0 min is 2-5A−cysteamine. The reaction conditions for the introduction of cystamine to 2-5A and for the reduction of 2-5A−cystamine are in Materials and Methods.

Therefore, we employed a heterobifunctional cross-linking reagent, Sulfo-KMUS, which has an amine reactive *N*-hydroxysuccinimide ester and a thiol reactive maleimide group. Reaction of SA with Sulfo-KMUS yielded SA-KMUS conjugate. No polymerization of SA took place with this cross-linking agent, as SA has no free thiol group. A thiol group has to be introduced into the 2′(or 3′) end of 2-5A for the binding of 2-5A with SA-KMUS, because the 5′-triphosphate moiety of 2-5A is very important in the activation of RNase L and in the binding of the polyclonal antibody to 2-5A used in the BLEIA. We chose cystamine to introduce a thiol group into 2-5A at the 2′(3′) end, as a cystamine moiety of the 2-5A derivative can be reduced easily with DTT to convert a thiol group. The coupling of 2-5A with cystamine was carried out by a modification of a published procedure (*5*, *12*, *14*) as shown in Scheme 1. A dialdehyde group was generated by oxidation of the 2′,3′ terminal diol group of 2-5A with sodium periodate. The dialdehyde group was then reacted with an amino group of cystamine and the resulting unstable Schiff base immediately reduced with sodium cyanoborohydride. The product, 2-5A−cystamine conjugate, was purified by reverse phase HPLC, the profile of which is shown in Figure 2. The peak at 13.7 min is due to 2-5A−cystamine and the other peak at 9.4 min to the unreacted 2-5A. The yield of 2-5A−cystamine after purification by HPLC was 37%. The cystamine moiety of the 2-5A derivative was reduced by 0.1M DTT to convert to 2-5A−cysteamine bearing an active thiol group. This reduction took place almost quantitatively, as shown in Figure 2(C). The purified 2-5A−cysteamine was isolated in 79% yield by HPLC.

Torrence et al. reported that the thiol group in the 2-5A−cysteamine conjugate was unstable and formed disulfide linkage immediately by aerobic oxidation, yielding the dimeric product $(2\text{-}5A\text{−}cysteamine)_2$ (*12*). We checked stability of the thiol group of 2-5A−cysteamine in water at 25 °C. The dimer formation by oxidation of

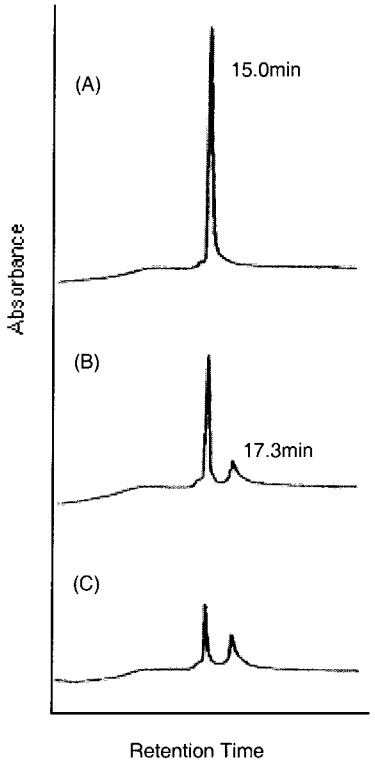

Figure 3. HPLC profiles of oxidation of 2-5A−cysteamine in aqueous solution. The profiles show a decrease of 2-5A−cysteamine (15.0 min) and an increase of its dimer (17.3 min) when 2-5A−cysteamine solution (0.5 mM) was kept at 25 °C for 1 h (A), 52 h (B), and 96 h (C).

2-5A−cysteamine was monitored by HPLC (Figure 3). The monomeric 2-5A−cysteamine remained at 100%, 72.5%, and 56% after 1, 52, and 96 h, respectively, at 25 °C. The identify of the resulting dimer was corroborated by ESI mass spectrometry (calculated $[M\text{-}2H]^{2-}$ *m*/*z* 1206.1 and $[M\text{-}3H]^{3-}$ *m*/*z* 803.7, found 1206.2 and 803.8, respectively). The dimer (peak at 17.3 min) was converted to 2-5A−cysteamine again by reduction with DTT as shown in Figure 4 (B). The thiol group of 2-5A−cysteamine is certainly unstable and was converted to the dimer by oxidation as Torrence et al. mentioned (*12*). However, reaction of 2-5A−cysteamine with the maleimide moiety of SA-KMUS proceeded more quickly than the dimerization. SA-KMUS was obtained from SA and sulfo-KMUS in 63% yield. Conjugate of 2-5A and SA-KMUS was isolated in 20% yield (based on SA-KMUS), as recovered in a small amount during purification by a PD-10 column. The average molar ratio of 2-5A to SA in the resulting 2-5A−SA conjugate was estimated to be 1.2 from the UV absorption at 260 and 280 nm, being the maximal absorption wavelengths of 2-5A and SA, respectively.

Thiol groups in the luciferase play an important role for enzyme activity (*15*). The excess unreacted maleimide groups in the 2-5A−SA conjugate will result in an inactivation of the enzyme by reacting with free thiol groups of the enzyme. Thus, 2-mercaptoethanol was added to the 2-5A−SA conjugate to block excess maleimide groups in the conjugate. The resulting 2-5A−SA conjugate was mixed with biotinylated luciferase to form the complex of 2-5A and luciferase as illustrated in Figure 1. BLEIA for 2-5A was carried out using the 2-5A−luciferase conjugate as a probe and was based on the one step competitive method. Very small amounts of anti-2-5A antibody and labeled 2-5A must be used for the highly sensitive immunoassay of 2-5A. However, the antibody was difficult to immobilize on a solid support in such a

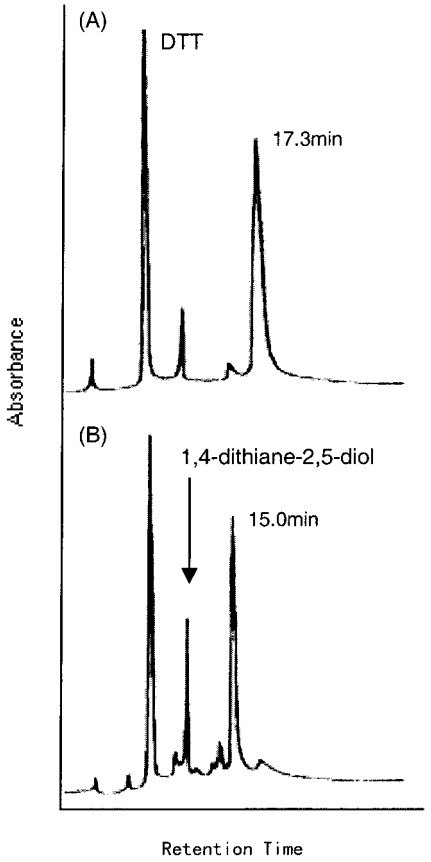

Figure 4. Reduction of the dimer to 2-5A−cysteamine(A) The dimer (0.1 mM) was treated with 0.1 M DTT for 1 min. The dimer was prepared by aerobic oxidation of 2-5A−cysteamine in water by passing O_2 gas at 25 °C for 5 days. The peak at 17.3 min is the dimer of 2-5A−cysteamine. (B) The dimer was treated with 0.1 M DTT for 40 min.

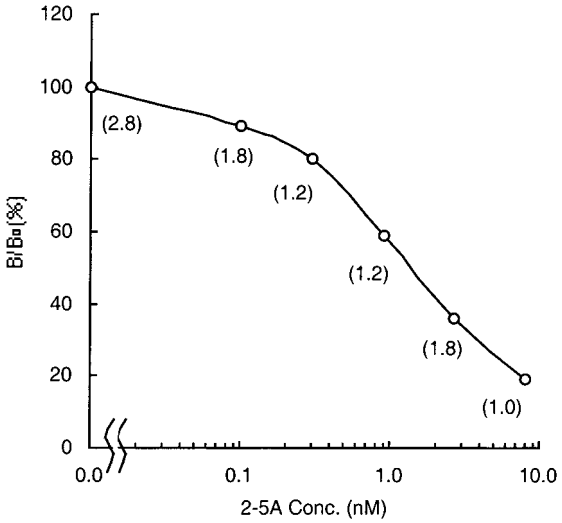

Figure 5. Standard BLEIA curve for 2-5A. Values in parentheses represent the coefficients of variation ($n = 6$). *B* is binding at the 2-5A concentration indicated, and B_0 is the maximum binding of labeled 2-5A in 0 nM 2-5A standard.

small amount. When the anti-2-5A antibody was not bound quantitatively on the solid support, the assay resulted in a low reproductivity. Therefore, we employed a second antibody method for the assay and the anti-rabbit IgG antibody was immobilized on magnetic particles. The second antibody on the magnetic particles bound with the anti-2-5A antibody, which captured the target 2-5A molecule or the probe labeled 2-5A in a

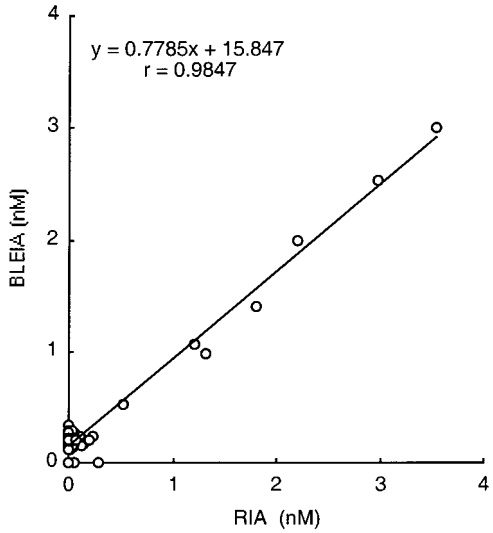

Figure 6. Correlation between this BLEIA and RIA. RIA was carried out by a previously described method (*5*).

sample solution. Magnetic particles could enhance the binding of the target molecule with their vast surface. The 2-5A and labeled 2-5A, captured by the antibody on the magnetic particles, could be separated easily from the unbound ones in the sample mixture by using a strong magnet. After the reaction mixture was removed from the test tube, the remaining magnetic particles were washed three times with a washing solution, and the substrate solution for luminescence was then added to the test tube containing the magnetic particle suspension in 50mM Tris-HCl (pH8.0), followed by luminescence measurement. A typical standard curve for 2-5A is shown in Figure 5. The measurable range of 2-5A was 0.1−10 nM. This range is sufficient in practical use for the assay of 2-5A from various sources, as 2-5A shows its biological activities at nanomolar concentrations. Reproduction of the assay for 2-5A was very good as shown in Figure 5. Variations of the assays at each concentration were 1.0−2.8%. The 2-5A concentrations measured by this BLEIA were compared with those measured by radioimmunoassay (RIA) (*5*) using 60 samples of human plasma. A good correlation between BLEIA and RIA was observed as shown in Figure 6.

CONCLUSIONS

A 2-5A derivative bearing cysteamine at 2′(or 3′) terminal was prepared for conjugation with biotinylated luciferase. The free thiol group of 2-5A−cysteamine was stable during the conjugation process with streptavidin. The 2-5A−SA conjugate formed a strong complex with biotinylated luciferase by biotin−streptavidin bonding. BLEIA for 2-5A using the conjugate of 2-5A and luciferase provides a highly sensitive measurement of 2-5A and is easy to perform compared with other methods, as no radioisotope is required for the assay. BLEIA for 2-5A in human plasma using this conjugate showed good correlation with the previously reported RIA method. Thus, this BLEIA would be useful for study of the 2-5A system and the diagnosis of infectious diseases, as well as for the management of patients undergoing interferon therapy, by measuring the 2-5A produced by 2-5A synthetase induced by interferon.

ACKNOWLEDGMENT

We thank Dr. Hiroki Tatsumi (Kikkoman Corp.) for providing the biotinylated thermostable recombinant

firefly luciferase (bL248) and Mr. Mikio Hikata (JSR Corp.) for providing the magnetic particles (Immtex-MAG1803) used in this study.

Synthesis of New Modified DNAs by Hyperthermophilic DNA Polymerase: Substrate and Template Specificity of Functionalized Thymidine Analogues Bearing an sp3-Hybridized Carbon at the C5 α-Position for Several DNA Polymerases

Hiroki Sawai,* Akiko Ozaki-Nakamura, Masayuki Mine, and Hiroaki Ozaki

Department of Applied Chemistry, Gunma University, Kiryu, Gunma 376-8515, Japan. Received September 12, 2001; Revised Manuscript Received December 31, 2001

Novel thymidine analogue triphosphates, which have an sp3-hybridized carbon at the C5 α-position with amino-linker arms, a methyl ester, or a carboxyl group at the C5 sidearm, were good substrates for primer-extension reactions by DNA polymerase from *Pyrococcus kodakaraensis* (KOD Dash DNA polymerase), yielding exclusively full-length products. The resulting modified DNA was further alllowed to react with a functional molecule such as fluorescein isothiocyanate. By contrast, only truncated products were formed from the thymidine analogue substrate bearing the amino-linker arm or the negatively charged carboxyl group using Taq, Tth DNA polymerase, or DNA polymerase I from *E. coli* (Klenow fragment). The results indicate either that the thymidine analogue was not accepted by the enzymes, or that the polymerases could not extend the products, once the analogue had been incorporated, depending on the type of the analogue. A conventional thymidine analogue bearing an aminopropenyl group at the C5-position was accepted by all enzymes, among which KOD Dash DNA polymerase showed the highest activity for the polymerization with this analogue. Templates bearing the thymidine analogues in place of one thymidine residue were read by KOD Dash, Taq, Tth DNA polymerases, and the Klenow fragment giving the full-length product. KOD Dash DNA polymerase could expand structural diversities of substrates that can be used to prepare modified DNAs.

INTRODUCTION

Modified oligonucleotides with a variety of functional groups are important tools for biological and biochemical studies (*1*−*3*). The C5-position of the pyrimidine ring is an ideal site for the modification, because it is located in the major groove of double-stranded DNA and does not inhibit A:T base pairing. Functional groups such as fluorophores (*3*, *4*), enzymes (*3*, *4*), biotin (*3*, *4*), metal chelators (*6*, *7*), polyamines (*8*), and intercalating agents (*9*, *10*) have been attached to C5 via amino-linker arms. Previously, we reported the synthesis of thymidine analogues, C5-substituted 2′-deoxyuridines bearing amino-linker arms at the C5-position, and their introduction into oligodeoxyribonucleotides (*11*, *12*). Usually, modified DNA is prepared chemically by using a DNA synthesizer.

However, if a DNA polymerase can accept modified nucleotides as substrates, modified DNA can be prepared enzymatically. The resulting modified DNA could be used as a DNA probe by attachment of a reporter group, or as a catalytic DNA by in vitro selection. Thus, nucleotide analogues that are substrates for DNA and RNA polymerases can be powerful tools for biochemical studies. Modified ribonucleoside 5′-triphosphates are substrates for several RNA polymerases, and are used to create various functionalized RNA molecules with catalytic activity or binding activity (*13*−*21*). However, there are a few examples of functionalized DNA molecules prepared using modified deoxynucleoside 5′-triphosphates, because DNA polymerases accept a limited range of molecular structures as a substrate. Some DNA polymerases can use 5′-triphosphates of modified 2′-deoxyuridines with a C5 side chain carrying an (*E*)-propenyl or propynyl group (*22*−*31*). Vent or Taq DNA polymerases can use 2′-deoxyuridine derivatives carrying a triple bond at the C5 α-position, yielding the corresponding modified DNAs (*24*, *26*, *29*). 2′-Deoxyuridine derivatives bearing a propenyl group at the C5 α-position are good substrates for Taq DNA polymerase, but poor substrates for Vent or Pfu DNA polymerase (*25*, *27*, *30*). The Klenow fragment incorporates 2′-deoxyuridine derivatives bearing a propenyl group at the C5-position, but with low efficiency (*22*, *23*). Reduction of the double or triple bond of the C5 propenyl- or alkynyl-substituted 2′-deoxyuridines significantly inhibits their function as a substrate (*30*). These results indicate that an sp- or sp2-hybridized carbon at the C5 α-position of the C5-substituted 2′-deoxyuridine is required as a substrate for some DNA polymerases (*22*−*31*). The differences in reactivity of C5-substituted 2′-deoxyuridines as a substrate may be due to the steric effect of a large side group, or to the ionic effect of a substituent group such as an amino group. The ability of the modified nucleotides as a substrate also depends on the kind of DNA polymerase.

We prepared several triphosphates of thymidine analogues, which have an sp3-hybridized carbon at the C5 α-position with either amino-linker arms or an ester or carboxylic group at the terminus, and have examined for their specificity as a substrate for several DNA polymerases in the primer-extension reaction. We have found that KOD Dash DNA polymerase readily uses the thymidine analogue nucleotides as a substrate and reads a template containing the modified thymidine, but no other DNA polymerase tested, including Taq DNA polymerase,

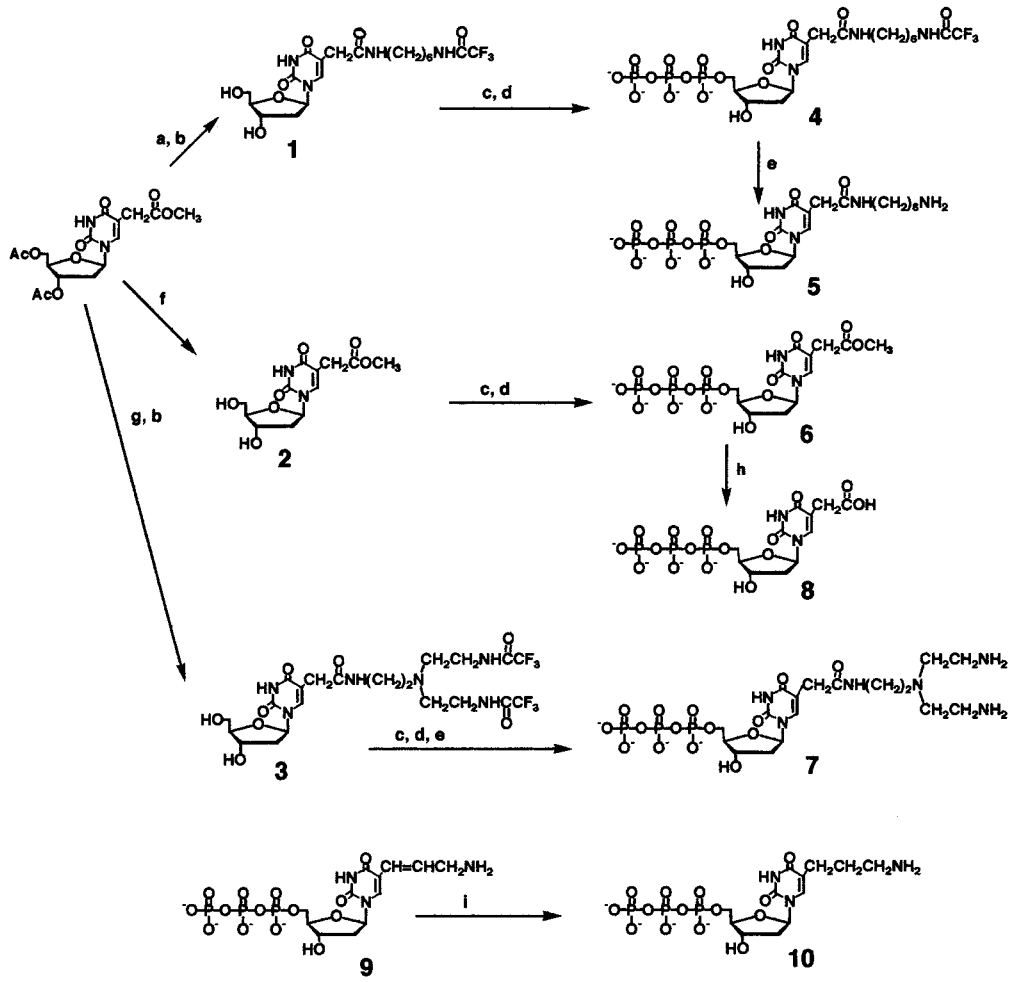
can accept the thymidine analogues as a substrate. KOD Dash DNA polymerase is a hyperthermophilic DNA polymerase and now commercially available. The enzyme was originally isolated from the extremely thermophilic archaeum *Pyrococcus kodakaraensis*, found in a hot spring on Kodakara Island in southern Japan, and is reported to have high DNA polymerization activity with high fidelity (*32*). This is the first report that a thymidine analogue which has an sp3-hybridized carbon at the C5 α-position can function as a substrate. The enzyme also accepts the conventional thymidine analogues bearing an aminopropenyl group more readily than other enzymes. The finding that KOD Dash DNA polymerase has broader substrate specificity than other polymerases may expand the variety of nucleotide analogues that can be used for enzymatic modified DNA synthesis.

MATERIALS AND METHODS

Materials. 2′-Deoxynucleoside 5′-triphosphates (dATP, dGTP, dCTP, and TTP) were purchased from Seikagaku Kogyo. 2′-Deoxyuridine 5′-triphosphate (dUTP) was a gift from Mr. H. Kusakabe of Yamasa Co. Snake venom phosphodiesterase and alkaline phosphatase were from Worthington Biochemicals, and nuclease P1 was from Yamasa Co. Klenow fragment of *E. coli* DNA polymerase I and Taq DNA polymerase were purchased from Takara, and KOD Dash and Tth DNA polymerases were from Toyobo Co. [α-^{32}P]dGTP (800 Ci/mmol) and [α-^{33}P]ddNTP (A, G, C, and T) (1500 Ci/mmol, 450 μCi/mL) were from Amersham. C5-substituted 2′-deoxyuridine derivatives, 5-*N*-(6-trifluoroacetylaminohexyl)carbamoylmethyl-2′-deoxyuridine (**1**), 5-(methoxycarbonylmethyl)-2′-deoxyuridine (**2**), and 5-[*N*-2-[*N*,*N*-bis(2-trifluoroacetylaminoethyl)-amino]ethyl]carbamoylmethyl-2′-deoxyuridine (**3**), were prepared as described previously (*11*, *12*). A radiolabeled DNA marker was prepared from the template and primer DNA using a thermo sequenase radiolabeled terminator cycle sequence kit obtained from USB Co. according to the method of the manufacturer. All other chemicals were reagent grade and were used without further purification.

Oligonucleotides. Oligodeoxyribonulceotides were synthesized on an Applied Biosystems model 381 A DNA synthesizer using deoxyribonucleoside 2-cyanoethyl phosphoramidites. Normal nucleoside phosphoramidites were purchased from Applied Biosystems. Phosphoramidites of the thymidine analogues bearing ethylenediamine, hexamethylenediamine, and tris(2-aminoethyl)amine at the C5-position were prepared as described previously (*12*). Oligodeoxyribonucleotides (37mer) bearing a thymidine analogue in place of one thymidine residue were prepared along with the normal oligodeoxyribonucleotide, and used as the template for DNA polymerase reactions.

Analytical Methods and Gel Electrophoresis. ^{1}H and ^{31}P NMR spectra were obtained with a JEOL α-500. Triphosphates of 2′-deoxyuridine derivatives for NMR measurement were passed through a Dowex 50-WX-8 (Na^+ form) column to convert the triethylammonium salt to the sodium salt. Tetramethylsilane (TMS) and 85% phosphoric acid were used as the internal standards for ^{1}H and ^{31}P NMR, respectively. ESI mass spectra were recorded on a PE Sciex API-100. MALDI TOF mass spectra were taken with a Shimadzu AXIMA-CF. UV spectra were obtained with a Hitachi 3200 spectrometer. High-pressure liquid chromatography (HPLC) on an ODS-silica gel column (4 mm × 250 mm) was carried out with a linear gradient elution (2−40% acetonitrile in 50 mM triethylammonium acetate, pH 7.0) over 30−40 min at a flow rate of 1.0 mL/min. Gel electrophoresis was carried out using 0.5 mm thick denaturing15% polyacrylamide gels containing 7 M urea, and run at 2000 V for 2.5−3 h. The gels were autoradiographed with Kodak BioMax MS film at −70 °C.



Synthesis of 5′-Triphosphates of 2′-Deoxyuridine Derivatives. *(A) 5-N-(6-Trifluoroacetylaminohexyl)carbamoylmethyl-2′-deoxyuridine 5′-Triphosphate (**4**).* 5′-Triphosphorylation of the modified nucleosides was carried out by the method described by Ludwig (*33*) as shown in Scheme 1. To a solution of **1** (143 mg, 0.30 mmol) in trimethyl phosphate (0.75 mL) was added phosphoryl chloride (60 μL, 0.64 mmol) with stirring on ice. After stirring for 2 h at 0 °C, the reaction mixture was added to a solution of 0.5 M tributylammonium pyrophosphate in dry DMF (3 mL) containing 0.3 mL of tributylamine, and the solution was stirred for 30 min at room temperature. The reaction mixture was poured into a 40 mL ether/acetone (1:1) solution containing $NaClO_4$-saturated acetone (2 mL) with stirring. The precipitates were collected, dried under vacuum, and redissolved in a small volume of water, and the products were separated on a column of DEAE-Sephadex A-25 using a linear gradient (0.1−1.0 M) of triethylammonium hydrogen carbonate (pH 7.5) as an eluent. The appropriate fractions containing (**4**) were collected and concentrated under vacuum to give white precipitates, which were further purified by column chromatography on an ODS-silica gel column (30 × 250 mm) with a linear gradient elution of acetonitrile (0−50%) in 50 mM triethylammonium acetate buffer (pH 7.0) to remove inorganic pyrophosphate and lyophilized. The yield of **4** was 13% (346 ODU at 260 nm). UV(H_2O): λ_{max}, 267 nm. ^{31}P NMR(D_2O): δ(ppm), −10.2(d, J = 20 Hz, P_γ), −10.9(d, J = 20 Hz, P_α), −22.6(t, J = 20 Hz, P_β). ^{1}H NMR(D_2O): δ-(ppm), 7.81(s, 1H, H-6), 6.27(t, 1H, H-1′), 4.58(q, 1H, H-3′), 4.15(m, 3H, H-4′+H-5′), 3.28(s, 2H, CH_2CO), 3.24−3.10(m, 4H, NCH_2+CH_2N), 2.34(m, 2H, H-2′), 1.51−1.25-(m, 8H, $(CH_2)_4$). ESI-Mass(negative mode): found 719.2; calcd for $[M-H^+]^-$, 719.1.

*(B) 5-N-(6-Aminohexyl)carbamoylmethyl-2′-deoxyuridine 5′-Triphosphate (**5**).* A portion of **4** (54 ODU at 260 nm) was dissolved in 1 M ammonium hydroxide solution (200 μL) and kept for 3 days at −20 °C to remove the protecting trifluoroacetyl group. The resulting triphosphate of 5-*N*-(6-aminohexyl)carbamoylmethyl-2′-deoxyuridine (**5**) was purified by ODS-silica gel column chromatography as described above and lyophilized. The yield was 24 ODU at 260 nm (44%). UV(H_2O): λ_{max}, 267 nm. ^{31}P NMR(D_2O): δ(ppm), −5.5(d, J = 20 Hz, P_γ), −10.2(d, J = 22 Hz, P_α), −20.9(t, J = 20, 22 Hz, P_β). ^{1}H NMR-(D_2O): δ(ppm), 7.93(s, 1H, H-6), 6.34(t, J = 7.0 Hz, 1H, H-1′), 4.77(m, 1H, H-3′), 4.24−4.17(m, 3H, H-47+H-5′), 3.38(s, 2H, CH_2CO), 3.21(t, J = 6.4 Hz, 2H, CH_2N), 2.96-(t, J = 7.5 Hz, 2H, NCH_2), 2.41(m, 2H, H-2′), 1.67−1.34-(m, 8H, $(CH_2)_4$). ESI-Mass(negative mode): found 623.2; calcd for $[M-H^+]^-$, 623.1.

*(C) 5-[N-2-[N,N-Bis(2-aminoethyl)amino]ethyl]carbamoylmethyl-2′-deoxyuridine 5′-Triphosphate (**7**).* Preparation of 5-[*N*-2-[*N*,*N*-bis(2-aminoethyl)amino]ethyl]carbamoylmethyl-2′-deoxyuridine 5′-triphosphate (**7**) was carried out by a similar procedure to that of **4** from the nucleoside **3** (182 mg, 0.30 mmol). The yield of **7** was 20% from **3** after removing the trifluoroacetyl group by treatment with ammonium hydroxide solution (457 ODU at 260 nm). UV(H_2O): λ_{max}, 267 nm. ^{31}P NMR(D_2O): δ(ppm), −9.6(br, P_γ), −10.9(br, P_α), −22.3(br, P_β). ESI-Mass-(negative mode): found 653.4; calcd for $[M-H^+]^-$, 653.5.

*(D) 5′-Triphosphates of 5-(Methoxycarbonylmethyl)-2′-deoxyuridine (**6**) and of 5-(Carboxymethyl)-2′-deoxyuri-*

Scheme 1. 5-Substituted 2′-Deoxyuridine Triphosphates, 4−10[a]

[a] (a) $H_2N(CH_2)_6NH_2$, MeOH; (b) CF_3COOEt, (dimethylamino)pyridine, MeOH; (c) $POCl_3$, $(MeO)_3PO$; (d) tributylammonium pyrophosphate, DMF; (e) 2 M NH_4OH; (f) triethylamine, MeOH; (g) $N(CH_2CH_2NH_2)_3$, MeOH; (h) 0.2 M NaOH; (i) 5% Pd-C, H_2.

*dine (**8**).* Triphosphorylation of compound **2** (90 mg, 0.3 mmol) was carried out by a similar procedure to that used for **1** as described above. Compound **6** was obtained in 7% yield from **2** (186 ODU at 260 nm). UV(H_2O): λ_{max}, 267 nm. ^{31}P NMR(D_2O): δ(ppm), −5.5(br, P_γ), −10.4(br, P_α), −22.6(br, P_β). ^{1}H NMR(D_2O): δ(ppm), 7.81(s, 1H, H-6), 6.21(dd, J = 6.7 Hz, J = 13.5 Hz, 1H, H-1′), 4.10−4.07(m, 2H, H-3′+H-4′), 4.03(m, 2H, H-5′), 3.60(s, 3H, CH_3), 3.40(s, 2H, CH_2CO), 2.28(m, 2H, H-2′). ESI-Mass(negative mode): found 539.0; calcd for $[M-H^+]^-$, 539.0.

To a solution of **6** (2.4 ODU at 260 nm, 0.27 mmol) in 15 μL of water was added 15 μL of 0.2 M NaOH solution, and the reaction mixture was kept overnight at 4 °C for hydrolysis of the methyl ester. The resulting triphosphate of 5-(carboxymethyl)-2′-deoxyuridine (**8**) was purified by HPLC on ODS-silica gel as described above. The yield was 2.0 ODU at 260 nm (0.23 μmol, 85%). UV(H_2O): λ_{max}, 267 nm. ESI-Mass(negative mode): found 526.2; calcd for $[M-H^+]^-$, 526.0.

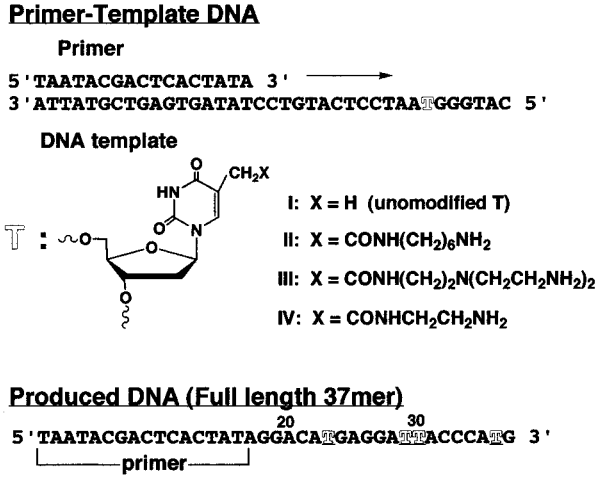
*(E) 5′-Triphosphates of 5-(E)-(Aminopropenyl)-2′-deoxyuridine (**9**) and 5-(Aminopropyl)-2′-deoxyuridine (**10**).* Compound **9** was prepared from dUTP according to the published procedure (*22*). Hydrogenation of **9** (155 ODU at 260 nm) was carried out in the presence of 5% Pd-carbon (8 mg) in 2 mL of methanol/H_2O (9:1) containing 100 μL of 4 M acetic acid for 2 days under an atmospheric pressure of hydrogen. The reaction mixture was filtered through Celite, and the Celite was rinsed with 2 mL of methanol. The filtrate was evaporated under vacuum. The residue was separated by HPLC on ODS-silica gel as described above and lyophilized, giving **10** in 57% yield (88 ODU at 260 nm). UV(H_2O): λ_{max}, 268 nm. ^{31}P NMR(D_2O): δ(ppm), −4.6(br, P_γ), −10.2(br, P_α), −20.4(br, P_β). ^{1}H NMR(D_2O): δ(ppm), 7.86(s, 1H, H-6), 6.38(t, J = 1.1 Hz, 1H, H-1′), 4.69(m, 1H, H-3′), 4.27(br, 2H, H-4′+H-5′), 4.18(br, 1H, H-5′), 3.01(m, 1H, CH), 2.86(m, 1H, CH), 2.48(m, 1H, CH) 2.40(t, J = 5.8 Hz, 2H, H-2′), 2.2(m, 1H, CH), 1.93(m, 2H, CH_2). ESI-Mass(positive mode): found 523.8 and 546.0; calcd for $[M+H^+]^+$ and $[M+Na^+]^+$, 524.2 and 546.2, respectively.

Enzymatic Incorporation of Thymidine Analogues into DNA with KOD Dash, Taq, Tth DNA Polymerase, or DNA Polymerase I (Klenow Fragment). DNA polymerase reactions were performed using a 17mer oligodeoxyribonucleotide, 5′-TAATACGACTCACTATA-3′, as a primer and a 37mer oligodeoxyribonucleotide, 3′-ATTATGCTGAGTGATATCCTGTACTCCTAATGGGTAC-5′, as a template. The primer−template complex was prepared by heating a 1:1 mixture of the primer and the template strands in TE buffer (10 mM Tris-HCl and 0.1 mM EDTA, pH 8.0) to 90 °C for 2 min and then cooling.

KOD Dash DNA polymerase reaction was carried out in a mixture (10 μL) containing 0.5 unit of the enzyme, 0.2 μM primer−template complex, 20 μM substrates (dATP + dCTP + TTP or TTP analogue), 5 μM dGTP, and 1 μCi (800 Ci/mmol) of [α-^{32}P]dGTP in the buffer supplied by the maker or in 120 mM Tris-HCl (pH 8.0),

10 mM KCl, 6 mM $(NH_4)_2SO_4$, 0.1% Triton X-100, 0.01 mg/mL BSA, and 1.0 mM $MgCl_2$. Either unmodified TTP or a thymidine analogue triphosphate (**4**, **5**, **6**, **7**, **8**, **9**, or **10**) was used in each reaction. Control reactions without TTP were carried out under the same conditions. Reaction mixtures were incubated at 50 °C for 5 or 30 min, and quenched by addition of 6 μL of 90% formamide containing 0.1% xylenecyanol, 0.1% bromophenol blue, and 20 mM EDTA (pH 8.0). The solutions were heated for 3 min at 95 °C for denaturation, and then cooled. The reaction products were separated by electrophoresis in a 15% denaturing polyacrylamide gel containing 7 M urea. The gels were visualized by autoradiography.

Taq DNA polymerase reactions were conducted as described above in reaction mixture (10 μL) containing the primer−template complex, the substrates, 0.5 unit of enzyme in 10 mM Tris-HCl (pH 8.3), 50 mM KCl, and 1.5 mM $MgCl_2$ at 50 °C for 5 or 30 min.



Tth DNA polymerase reactions were conducted as described above in reaction mixture (10 μL) containing the primer−template complex, the substrates, 0.5 unit of enzyme in 10 mM Tris-HCl (pH 8.0), 1.5 mM $MgCl_2$, 80 mM KCl, 500 μg/mL of bovine serum albumin, 0.1% sodium cholate, and 0.1% Triton X-100 at 50 °C for 5 or 30 min.

Reactions with the Klenow fragment were performed by a similar method as used for the KOD Dash DNA polymerase except for the reaction conditions. Each reaction mixture (10 μL) contained 0.5 unit of the enzyme, the primer−template complex, the substrates in 10 mM Tris-HCl (pH 8.0), and 5 mM $MgCl_2$. Reaction mixtures were incubated at 37 °C for 30 min.

Preparation of the Modified DNA in Large Quantity from the Thymidine Analogue 5, Its Characterization with a MALDI-TOF Mass Spectrometer, and Reaction with Fluorescein Isothiocyanate. A reaction mixture (1 mL) containing 5 units of KOD Dash DNA polymerase, a 0.1 μM sample of the 37mer DNA template, a 2 μM aliquot of the 17mer primer, 0.2 mM substrates (dATP + dCTP + dGTP + 5), and the buffer supplied by the maker was divided in 10 portions, and each 100 μL solution was transferred in a 0.5 mL tube. The polymerization reaction was carried out with a thermal cycler using the following program: 20 cycles of 20 s at 94 °C, 10 s at 40 °C, 30 s at 60 °C. The resulting 37mer DNA was extracted with PCI solution [phenol saturated with TE buffer/chloroform/isoamyl alcohol (25:24:1) twice, and then with CI solution (chloroform/isoamyl alcohol, 24:1)] and precipitated with ethanol. The product was further purified by HPLC on an ODS-silica gel column, giving 0.28 ODU at 260 nm of the DNA 37mer, whose mass spectrum was taken by a Shimazu AXIMA-CF MALDI-TOF mass spectrometer. Two peaks were present in the mass spectrum. One is due to the template DNA (found 11 370; calcd for $[M+H^+]^+$, 11 368), and the other is due to the modified DNA produced by the polymerization (found 11 937; calcd for $[M+H^+]^+$, 11 932). The DNA 37mer (0.1 ODU) was reacted with fluorescein isothiocyanate (5 mM) in the mixture (50 μL) containing 0.2 M sodium hydrogen carbonate buffer (pH 9.5) and 20% DMF at 37 °C for overnight. The reaction mixture was analyzed by HPLC monitoring by UV (260 nm) and fluorescence (excitation at 490 nm and emission at 520 nm).

Template Activity of Oligodeoxyribonucleotides Containing Thymidine Analogues. DNA polymerase reactions were carried out by the same method as described above using a 37mer modified oligodeoxyribonucleotide template and a 17mer oligodeoxyribonucleotide primer (Scheme 2). Templates contained, at position 31, either normal thymidine or a thymidine analogue bearing hexamethylenediamine, tris(2-aminoethyl)amine, or ethylenediamine at the C5 sidearm (X position). KOD Dash, Taq, and Tth polymerase reactions were performed at 50 °C for 1, 2, 5, or 20 min in reaction mixture (10 μL) containing 0.5 unit of DNA polymerase, 0.2 μM primer−template complex, 20 μM unmodified substrates (dATP, dCTP, and TTP), 5 μM dGTP, and 1 μCi (800 Ci/mmol) of [α-^{32}P]dGTP in the buffer for KOD Dash, Taq, and Tth DNA polymerases described above.

Scheme 2. Sequence of the Primer, the Template, and the Full-Length DNA Product[a]

[a]Templates were Prepared Chemically, and T represents either standard thymidine (I) or one of three modified thymidines (II−IV). In the product, T indicates the positions where the polymerase has to incorporate thymidine residues (modified or unmodified).

The reactions with the Klenow fragment were performed at 37 °C for 5, 10, 30, and 60 min in the reaction mixture (10 μL) containing 0.5 unit of enzyme, 0.2 μM primer−template complex, 20 μM unmodified substrates (dATP, dCTP, and TTP), 5 μM dGTP, and 1 μCi (800 Ci/mmol) of [α-^{32}P]dGTP in 10 mM Tris-HCl (pH 8.0) and 5 mM $MgCl_2$.

The polymerase reactions were stopped by addition of 3 μL of formamide dye, denatured, and analyzed by gel electrophoresis as described above.

RESULTS

A series of C5-substituted 2′-deoxyuridine derivatives were prepared from 3′,5′-di-*O*-acetyl-5-methoxycarbonylmethyl-2′-deoxyuridine, which was synthesized easily according to the method described previously (*11*). The 5′-triphosphorylation of the nucleosides was carried out by the one-pot method described by Ludwig (*32*) with a slight modification as shown in Scheme 1. The terminal amino-protecting trifluoroacetyl group of the triphosphate from **1** or **3** was removed by treatment with concentrated aqueous ammonia quantitatively at low temperature. The resulting terminal amino group can be further modified by reaction with a functional molecule such as fluorescein isothiocyanate. Conventional modified substrates, 5′-triphosphates of 5-(*E*)-(aminopropenyl)-2′-deoxyuridine (**9**) and 5-(aminopropyl)-2′-deoxyuridine (**10**), were also prepared to compare the substrate specificity for the DNA polymerases.

Enzymatic Incorporation of the Thymidine Analogues by DNA Polymerases. Compounds **4**, **5**, **6**, **7**, **8**, **9**, and **10** were tested as substrates for DNA poly-

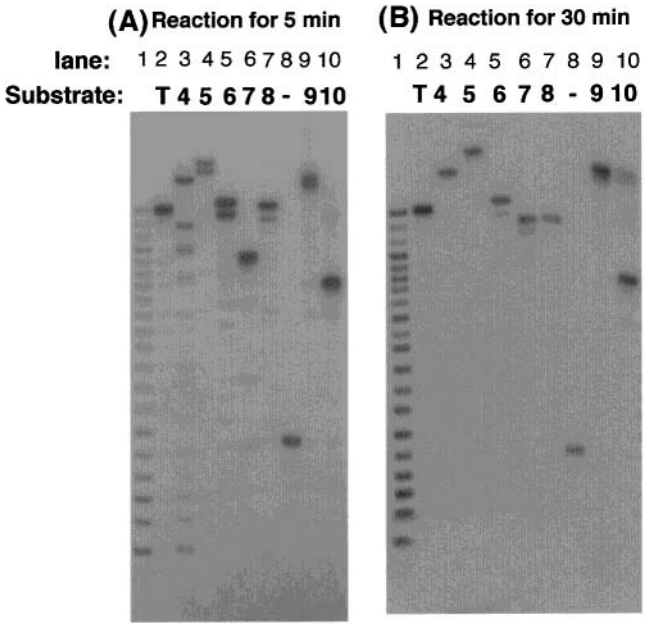


Figure 1. Autoradiogram of the products of primer extension reactions using KOD Dash DNA polymerase, and either normal TTP or modified as substrates. The reactions were done at 50 °C for 5 min (A) or 30 min (B) under the conditions described under Materials and Methods. Lane 1, marker DNA; lane 2, positive control (TTP+dATP+dCTP+dGTP); lane 3, **4**+dATP+dCTP+dGTP; lane 4, **5**+dATP+dCTP+dGTP; lane 5, **6**+dATP+dCTP+dGTP; lane 6, **7**+dATP+dCTP+dGTP; lane 7, **8**+dATP+dCTP+dGTP; lane 8, negative control (dATP+dCTP+dGTP); lane 9, **9**+dATP+dCTP+dGTP; lane 10, **10**+dATP+dCTP+dGTP.

merase I from *E. coli* (Klenow fragment), Taq, Tth, and KOD Dash DNA polymerases using the same amount of standard enzyme activity for comparison of activities against the modified substrate. The polymerization reactions with KOD Dash, Taq, and Tth DNA polymerases were carried out at 50 °C for 5 and 30 min, because the melting temperature of the primer−template complex was estimated to be a little lower than 50 °C under the reaction conditions (*34*). The polymerization reactions in the case of the Klenow fragment were done at 37 °C for 30 min. DNA polymerases extend the primer on the template (Scheme 2). Thus, when unmodified substrates and the same enzyme activities were used, all enzymes formed 37mer full-length DNA at the same rate. However, the ability of the modified thymidine triphosphates to function as a substrate depended on the type of modification, and on the polymerase.

KOD Dash DNA Polymerase Reactions. Figure 1A and Figure 1B show the KOD Dash DNA polymerase reactions for 5 and 30 min, respectively. The 37mer full-length DNA was the major product from the unmodified substrate (lane 2). The result of the control reaction with no TTP is shown in lane 8: the polymerization was completely stopped before the first T position, forming a 22mer DNA. In contrast to the other enzymes, KOD Dash DNA polymerase tolerated the modification, and readily accepted the modified substrates forming the full-length DNA. Thus 37mer DNAs were formed from compounds **4**, **5**, and **6** (lanes 3, 4, and 5) when the polymerization reaction was carried out for 30 min (B), although some short-chained DNAs were observed in the 5 min reaction (A). The 37mer DNA product containing trifluoroacetyl-protected hexamethylenediamine (compound **4**, lane 3) or hexamethylenediamine (compound **5**, lane 4) modified thymidine showed lower electrophoretic mobility than DNA containing unmodified thymidine (lane 2) or methoxycarbonyl-modified thymidine (compound **6**, lane 5). Attachment of a bulky substituent and a cationic protonated amino group presumably retarded the mobility of these modified DNAs. The structure of the modified 37mer obtained from compound **5** was confirmed by MALDI-TOF mass spectroscopy. The observed molecular weight of the modified 37mer, prepared in a large scale and isolated by HPLC, was 11 937, while the calculated mass number $([M+H])^+$ of the enzymatic product was 11 932. The modified DNA from **5** bearing a terminal amino group was further reacted with fluorescein isothiocyanate to furnish the fluorescence-labeled DNA. Treatment of the 37mer obtained from compound **4** with concentrated ammonium hydroxide removed the terminal trifluoroacetyl groups, giving the modified DNA with hexamethylenediamine, whose electrophoretic mobility was the same as the modified DNA obtained from compound **5**. KOD Dash DNA polymerase also accepted as a substrate the highly modified compound **7** (lane 6), which bears a bulky branched polyamine with two cationic protonated amino groups at the C5 sidearm. Incorporation of compound **7** and chain-elongation took place at the first T-23 position. However, the enzyme could not tolerate two successive incorporations of compound **7**, stopping at the T-30 position (lane 6). This enzyme could tolerate the substrate analogue **8** with an anionic carboxyl, yielding the full-length 37mer, although the 36mer was the main product in the case of the long reaction time (lane 7). The enzyme also accepted a conventional modified substrate, **9**, bearing an (*E*)-aminopropenyl group easily giving the corresponding 37mer DNA (lane 9). The analogue **10** bearing an aminopropyl group was partially accepted as a substrate. Small amounts of the full-length 37mer DNA were formed, although the main product was a truncated DNA 30mer in which the chain-elongation stopped at the two successive T positions (lane 10 of Figure 1B). The results indicate that, in contrast to the other DNA polymerases, the KOD Dash DNA polymerase can accept C5-substituted 2′-deoxyuridine with an sp3-hybridized carbon at the α-position as a substrate.

Taq and Tth DNA Polymerase Reactions. Polymerization reactions using Taq and Tth DNA polymerases are shown in Figure 2. Both enzymes showed similar behavior with the modified substrates. The full-length 37mer was exclusively formed after 5 min when the natural substrate TTP was used (Figure 2A, lane 2), while chain-elongation was completely stopped at the first T position, forming 22mer DNA in the control reaction without TTP (Figure 2A, lane 8). Small amounts of 38mer and 23mer DNAs were formed after 30 min due to the terminal transferase activity of the enzymes both with and without TTP, respectively (Figure 2B, lanes 2 and 8). Compounds **4** and **5** slowed elongation, forming mainly the 22mer DNA after 5 min (lanes 3 and 4). However, the enzymes accept compounds **4** and **5** slowly, and extend the polymerization reaction after the first single T position, and a substantial amount of 28mer DNA was formed after 30 min. The incorporation was completely inhibited at the two successive TT positions. The main polymerization product when using compound **6** was 28mer DNA after 5 min (Figure 2A, lane 5). Chain elongation took place after 30 min, forming 29mer and full-length 37mer DNAs (Figure 2B, lane 5). On the other hand, these enzymes could not use compounds **7** and **8**, giving only 22mer and 23mer DNA, although very small amounts of 28mer DNA were formed after 30 min (Figure 2B, lanes 6 and 7). The enzymes use compound **9**, giving full-length 37mer DNA after 30 min in accordance with

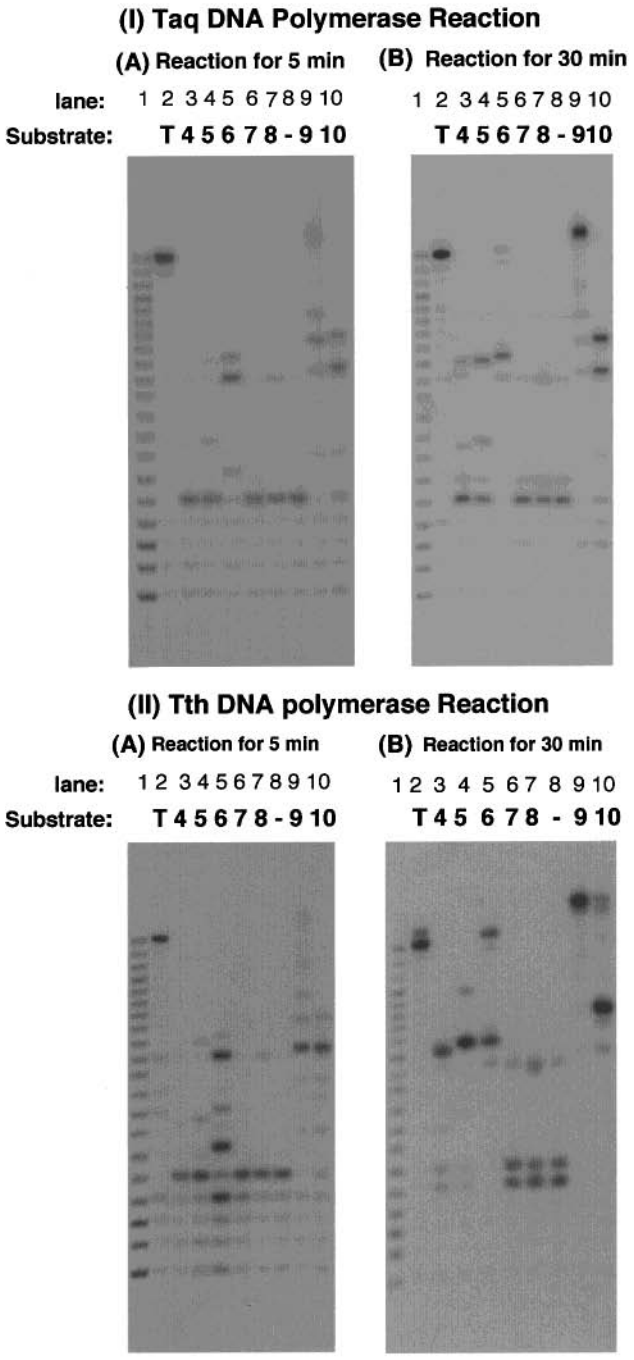

Figure 2. Autoradiogram of the products of primer extension reactions using Taq (I) and Tth (II) DNA polymerase, with various mixtures of nucleoside triphosphates (normal and/or modified). The reactions were done at 50 °C for 5 min (A) or 30 min (B) under the conditions described under Materials and Methods. Lane numbering is identical to that in Figure 1.

previous report (*25*, *30*), although 28mer and 29mer DNAs were the main products in the 5 min reaction (lane 9). Compound **10** was accepted by the enzyme at the first T-23 position, and chain-elongation continued beyond this point, but not at the two successive TT position giving the 28mer and 29mer DNAs (lane 10).

Polymerization Reactions with DNA Polymerase I from *E. coli* (Klenow Fragment). Figure 3 shows results of polymerization reactions with DNA polymerase I from *E. coli* (Klenow fragment). The 37mer full-length DNA was the major polymerization product when the unmodified substrate was used, although small amounts of 38mer and 36mer DNAs were also formed due to the

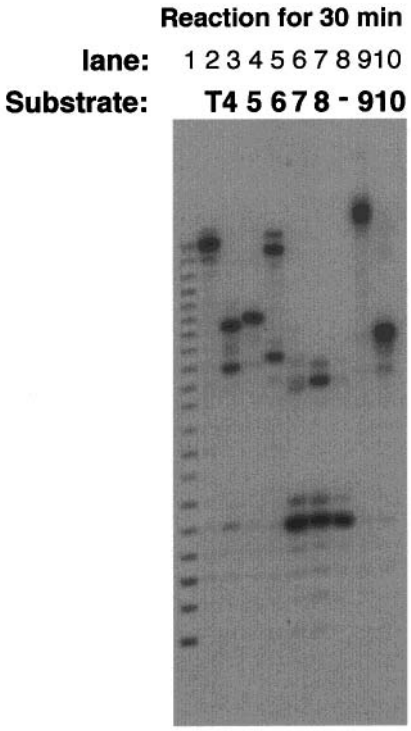

Figure 3. Autoradiogram of the products of primer extension reactions using DNA polymerase I from *E. coli* (Klenow fragment), with various mixtures of nucleoside triphosphates (normal and/or modified). The reactions were done at 37 °C for 30 min under the conditions described under Materials and Methods. Lane numbering is identical to that in Figure 1.

presence of terminal transferase and 3′-5′ exonuclease activities of the enzyme (lane 2). In the control reaction in which TTP was absent (lane 8), polymerization was completely stopped before the first T position, forming 22mer DNA, although small amounts of the 23mer were formed by the terminal transferase activity. Klenow fragment accepted compounds **4** and **5**, and extended the chain elongation at the first T-23 position. The enzyme could tolerate two successive incorporations of **4** or **5** at T-29 and T-30, but further chain-elongation was completely stopped, forming 30mer DNA (lanes 3 and 4). The enzyme also accepted compound **6** producing full-length 37mer DNA, along with substantial amounts of 36mer and 29mer, which were terminated at the T-36 and T-29 positions, respectively (lane 5). Compound **7** completely inhibited the enzyme. Thus, the main product was 22mer DNA which ended before the first T position, although very small amounts of 28mer DNA, in which chain-elongation was stopped before the double T position, were also formed (lane 6). Compound **8** was accepted to some extent by the enzyme, with formation of 28mer DNA, which passed through the T-23 but stopped before the two successive T (lane 7). With the conventional substrate analogue **9**, full-length 37mer DNA was formed as a sole product (lane 9). With compound **10**, only a truncated DNA 30mer was formed (lane 10). The results with compounds **9** and **10** are consistent with the previous report (*22*, *23*) in which the Klenow fragment accepts 2′-deoxyuridine derivatives bearing a propenyl group at the C5-position, but reduction of the double bond inhibits their function as a substrate. The formation of short DNAs with compounds **7** and **8** is due to inhibition of incorporation of the modified substrate. Inhibition of chain-elongation after incorporation results in the formation of the truncated DNA in the cases of compounds **4**, **5**, **6**, and **10**.

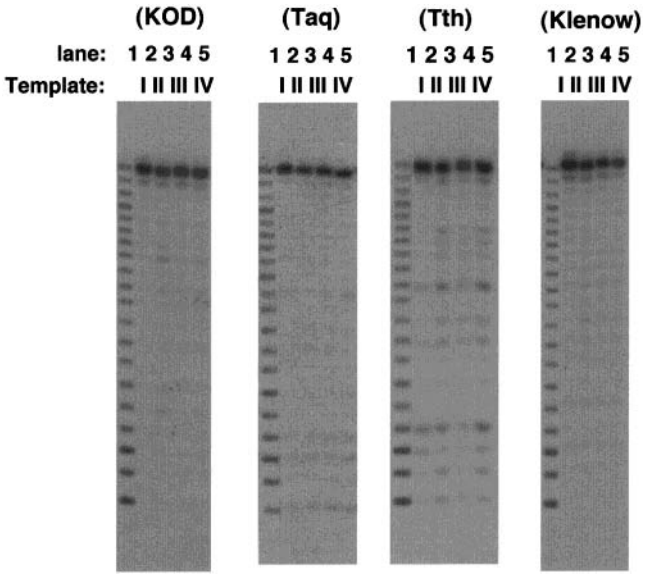

Figure 4. Autoradiogram of the products of primer extension on a DNA template bearing at position 31 either a normal thymidine residue or a C5-substituted 2′-deoxyuridine. The reactions were done at 50 °C for 5 min for Taq, Tth, and KOD Dash DNA polymerases, and at 37 °C for 30 min for Klenow fragment and under the conditions described under Materials and Methods, and unmodified 2′-deoxyribonucleoside triphosphates as substrates (TTP+dATP+dCTP+dGTP). Lane 1, marker DNA; lane 2, positive control (unmodified template I); lane 3, modified template II, bearing hexamethylenediamine at C5; lane 4, modified template III, bearing tris(2-aminoethyl)amine at C5; lane 5, modified template IV, bearing ethylenediamine at C5.

Template Activity of Oligodeoxyribonucleotides Containing Thymidine Analogues. Figure 4 illustrates the results of polymerization of unmodified substrates, dATP, dCTP, dGTP, and TTP, on modified DNA templates by KOD Dash, Taq, and Tth DNA polymerases and the Klenow fragment. The 37mer template DNA contains the thymidine analogue at the 31st position in place of a thymidine residue. All the DNA polymerases examined in this study read through the modified thymidine in the template, and accepted the complementary substrate and continued the chain-elongation until the end of the template, forming the full-length 37mer DNA.

DISCUSSION

We have examined the substrate activity of TTP analogues, **4**, **5**, **6**, **7**, and **8** along with the conventional **9** and **10**, for several DNA polymerases. Compounds **4**−**8** and **10** have an sp3-hybridized carbon at the C5 α-position with or without a bulky sidearm. Compounds **5** and **7** have one or two positively charged amino groups in the sidearm. Compound **8** bears a negatively charged carboxyl group. Compound **6** has a small noncharged substituent. Compound **9**, which has an (*E*)-aminopropenyl group at the C5-positon of 2′-deoxyuridine, is reported to be a good substrate for several DNA polymerases (*22*, *23*, *25*, *27*, *30*). On the other hand, the thymidine analogue **10**, the reduced product of **9**, is reported to be devoid of substrate activity for the enzymes (*27*, *30*). We found that KOD Dash DNA polymerase can accept various TTP analogues, **4**, **5**, **6**, **8**, and **9**, readily as substrates and the corresponding full-length 37mer DNA was formed. The enzyme also accepts compound **10**, although the full-length DNA was formed in modest yield. The enzyme, however, could not tolerate two successive incorporations of compound **7**. KOD Dash DNA polymerase is a hyperthermophilic DNA polymerase from thermophilic archaeum and is now commercially available. The enzyme is reported to have higher DNA polymerization activity with higher fidelity compared with other thermophilic DNA polymerases such as Taq DNA polymerase (*32*).

In contrast, compounds **4**, **5**, **6**, **7**, and **8** were poor substrates for Klenow fragment and Taq and Tth DNA polymerases. Compounds **4** and **5** gave only truncated DNA. A modest to substantial amount of the full-length 37mer DNA was obtained in addition to the truncated one when using compound **6** with these polymerases. The results of the DNA polymerization reaction by the Klenow fragment and Taq and Tth DNA polymerase confirm and extend the results reported previously (*22*−*30*). The 2′-deoxyuridine derivatives bearing a propenyl or propynyl linker at the C5 α-position are reported to function as substrates for several DNA polymerases, but the reduced product does not, indicating the possible requirement for an sp2- or sp-hybridized carbon at the C5 α-position (*22*−*30*). These results demonstrate that the ability of modified thymidine triphosphates to function as a substrate for DNA polymerases depends on the type of modification of the substrate and on the kind of polymerase.

KOD Dash DNA polymerase accepts the thymidine analogues which have an sp3-hybridized carbon at the C5 α-position, while other DNA polymerases cannot accept these analogues. The results are somewhat in contrast to the previous report on modified 2′-deoxyuridines, in which a propenyl or propynyl group at the C5 sidearm is required for the compound to be a substrate for DNA polymerase (*22*−*30*). Thus, this is the first example that C5-substituted 2′-deoxyuridine derivatives bearing an sp3-hybridized carbon at the C5 α-position are incorporated into DNA. All DNA polymerases examined in this study read through the thymidine modification in the template, giving the full-length DNA.

KOD Dash DNA polymerase may expand the range of structural modified substrates for enzymatic synthesis of modified DNAs. The resulting modified DNA can be further functionalized by reaction with a functional molecule such as fluorescein isothiocyanate. KOD Dash DNA polymerase and the thymidine analogues will be useful for preparing large quantities of modified DNA by PCR, and then in vitro selection of the functionalized DNA. The functionalized DNA synthesis by PCR using KOD Dash DNA polymerase and various thymidine analogues will be published elsewhere.

Diethylene triamine pentaacetic acid (DTPA) has been in extensive use as a metal chelator in the development of radiopharmaceuticals and contrast agents. The former application uses DTPA mostly as a bifunctional chelating agent (BCA) conjugated to tumor-targeting vehicles (TTVs) such as monoclonal antibodies (MAbs) and receptor-directed peptides. A new bifunctional DTPA derivative was synthesized by a fully organic scheme. This compound, N^4,N^{α},N^{α},N^{ϵ},N^{ϵ}-[pentakis(carboxymethyl)]-N^4-(carboxymethyl)-2,6-diamino-4-azahexanoic hydrazide (**20**) was prepared by a convergent synthesis strategy using N^{α}-benzyloxycarbonyl-2,3-diaminopropionic acid as the starting compound. This commercially available material was used to build a functionalized triamine which served as the molecular core template for assembling the target molecule. To evaluate the conjugation and radiolabeling capabilities of this new molecule, it was covalently attached to the *anti*-TAG-72 MAb, ΔCH2HuCC49, and the conjugate was radiolabeled in near-quantitative yields with yttrium-90 (^{90}Y) and lutetium-177 (^{177}Lu). Biodistribution of the ^{177}Lu-labeled DTPA−ΔCH2HuCC49 in tumor-bearing nude mice demonstrated preservation of the immunoreactivity of the MAb as indicated by high tumor uptake. In addition to the introduction of a new bifunctional DTPA, this work reports on a novel synthetic approach for preparation of this useful metal chelator and introduces a new conjugation protocol.

INTRODUCTION

Metallic nuclides have found increasingly important applications in diagnostic and therapeutic medicine (*1*−*3*). These, in the main part, include the use of transition metals as contrast agents in magnetic resonance imaging (*4*, *5*) and the development of radiopharmaceuticals, with the latter playing a major role in both diagnosis and therapy of neoplastic disease (*6*−*12*). Targeted delivery of radioactivity to malignant tissue through the application of monoclonal antibodies (MAbs)[1] (*13*) has progressed significantly by the development of MAb derivatives and fragments, and small-molecule peptides (*14*−*20*). In this regard, the design and development of synthetic BCAs for connecting these targeting vehicles to radioactive metals, and improvements in the related conjugation and chelation chemistries, have made significant contributions (*3*, *21*−*25*).

Several classes of BCAs have been reported in radioactive lanthanide and transition metal labeling procedures (*1*−*3*). An important series, the macrocyclic azacarboxylates (MACs), have demonstrated outstanding metal chelation and complex properties with members (DOTA and TETA) already in clinical trials. A large body of radioimmunoconjugate-related data, mainly based on the works of Meares et al., and Gansow and Brechbiel et al., is available for these compounds (*26*−*30*).

Acyclic analogues of MACs, represented by DTPA and EDTA, constitute another major class of BCAs. The iminocarboxylate compound DTPA has been used for the radiolabeling of MAb and peptide TTVs, particularly with the isotopes of yttrium (^{88}Y, ^{90}Y) (*31*−*33*), indium (^{111}In) (*34*−*37*), samarium (^{152}Sm, ^{153}Sm) (*38*, *39*), and lutetium (^{177}Lu) (*40*, *41*). These and other applications of DTPA, such as MRI (*4*, *5*, *42*) and luminescent lanthanide imaging (*43*), confer great importance to this compound. Two major protocols for conjugation of DTPA derivatives to MAbs, peptides, and nucleic acids have been reported, namely, the cyclic dianhydride (*44*, *45*) and isothiocyanate procedures (*46*). While most of the reported work on DTPA conjugation is based on these derivatives, difficulties may sometimes arise. The anhydride coupling may result in conjugation heterogeneity (i.e., mono- versus dicoupling) and is accompanied by the loss of one of the prospective metal chelating carboxyl groups. The latter feature may result in a less stable chelation product with the premature release of the activity in vivo (*47*). The isothiocyanate approach may also show some limited stability of the thiocyanate group and low aqueous solubility of these compounds. Nevertheless, routine

conjugation procedures are being conducted with these compounds.

In this paper, we report through a novel approach, the synthesis of a new bifunctional DTPA containing a hydrazide sidearm for TTV conjugation. The hydrazide function is placed on one of the methylene carbons of the skeletal core, thus leaving all five carboxyl groups available for metal chelation. This feature may lead to significantly better metal complex kinetics and stabilities, which are highly desirable features in diagnosis and therapy procedures. The hydrazide function allows for efficient and group-specific conjugation through a procedure developed in this laboratory for the covalent attachment of unprotected hydroxamate BCAs to Mabs (*22*). In contrast to the cyclic anhydride and isothiocyanate derivatives, the new DTPA hydrazide is stable, both in solid form and in solution, for extended periods of time. This stability is an important feature that may be particularly useful in the development of DTPA kits for clinical applications.

EXPERIMENTAL PROCEDURES

General Procedures. THF was ketyl distilled under argon. All other reagents and solvents were obtained from commercial suppliers and were used as received. ^{1}H NMR spectra were recorded on a Bruker ARX500 FT-NMR spectrometer. The chemical shifts were referenced to internal tetramethylsilane (TMS). ESMS spectra were recorded either on an API VI triple quadruple mass spectrometer (PE-Sciex, Toronto, Ontario) or Micromass Platform LCZ mass spectrometer (Beverly, MA). Thin layer chromatography (TLC) was performed with Whatman glass-backed silica gel plates (2.5 × 7.5 cm, coating thickness 250 μm, detected at 254 nm). Solvents for TLC were mixed on a v/v scale and are defined as follows: (A) chloroform/methanol, 90:10; (E) chloroform/methanol/acetic acid, 77:20:3. RP-HPLC was performed on a BioRad model 5000 Titanium system (BioRad, Richmond, CA) equipped with a model 1806 UV/Vis detector at 254 nm unless otherwise noted. HPLC solvents: H_2O containing 0.1% TFA; 60/40 CH_3CN/H_2O (v/v) containing 0.1% TFA, gradient elution. Analytical HPLC runs were performed on a C_{18} column (4.6 T 250 cm, Vydac, Hesperia, CA). Metal-free purified water (18.2 MΩ) was obtained from a Milli-QF system (Millipore, Bedford, MA). Retention times (t_R's) are reported in minutes at the specified wavelength (nm) with percent area under the peak in parentheses as a measure of compound purity. For analytical SEC−HPLC, a 7.5 mm × 25 cm G3000SW column (TosoHaas, Montgomeryville, PA) was used. A 10 mM PBS containing 10 mM Na_2SO_4 at pH 6.7 was used as solvent. Preparative SEC was carried out using Sephadex G-25 columns (PD-10, Pharmacia Biotech AB, Uppsala, Sweden) eluted with DPBS.

MALDI MS Analyses. Samples were analyzed in the positive mode on a Voyager Elite mass spectrometer with delayed extraction technology (PerSeptive Biosystems, Framingham, MA). The acceleration voltage was set at 25 kV, and 50−100 laser shots were summed. The matrix was Sinapinic acid, dissolved in a 50:50 (v/v) mixture of 0.1% TFA:acetonitrile. A 1 pmol/μL solution of bovine serum albumin was added as an internal standard. Equal volumes of sample and matrix were mixed on a smooth plate, and the average of three measurements were reported. For each reaction, the intact MAb was scanned as the control for evaluation of the following conjugation. The molecular weight increase of the OHA-MAb intermediate was calculated using the unconjugated MAb. The molecular weight of this intermediate then served as the control to measure the increase in the molecular weight of the final product conjugate. Each difference in molecular weight was divided by the molecular weight of the corresponding linker to measure the linker/MAb ratio.

High Resolution Mass Spectroscopy Procedure. The high-resolution liquid secondary ion mass spectra were acquired on a Micromass AutoSpec Magnetic Sector mass spectrometer (Beverly, MA) operated at a resolution of 10 000 (FWHM). All samples were run as approximately 1 μg/mL solutions in *m*-nitrobenzyl alcohol using matrix clusters or added peptides as reference peak.

Methyl N^{α}-(benzyloxy carbonyl)-2,3-diaminopropionate (2). A suspension of N^{α}-(benzyloxy carbonyl)-2,3-diaminopropionic acid (5.0 g, 21 mmol) in methanol (50 mL) was cooled to 0 °C while stirring under argon. A solution of 4 M HCl (40 mL) in dioxane was added dropwise, and the reaction was allowed to gradually warm to ambient temperature over 18 h. The solution was concentrated in vacuo to a white solid. This residue was triturated with diethyl ether (3 × 30 mL) to a fine powder that was dried in vacuo to yield **2** (6.0 g, 99%) as a white crystalline solid in high purity. mp 160−163 °C. R_f (A) 0.03, (E) 0.63. HPLC: t_R 12.97 min (>99%). ^{1}H NMR (500 MHz, DMSO-d_6) d 8.19 (br s, 4H,), 7.95 (br s, 1H), 7.35 (m, 5H), 5.07 (s, 2H), 4.43 (m, 1H), 3.63 (m, 2H), 2.50 (s, 3H). HRMS (FAB$^+$): 253.1195 ($C_{12}H_{16}N_2O_4$ + H requires 253.1188). MS(ES$^+$) 253. Anal. Calcd for $C_{12}H_{17}N_2ClO_4$: C, 49.9; H, 5.9; N, 9.7. Found: C, 50.0; H, 6.0; N, 9.8.

***N*-[1-(2,2-Diethoxy)ethyl]phthalimide (7).** A flask containing a solution of phthalic anhydride (22.2 g, 150 mmol), amino acetaldehyde diethyl acetal (20.0 g, 150 mmol), and DIEA (2.6 mL, 0.15 mmol) in toluene (100 mL) was fitted with a Dean−Stark trap and heated to 100 °C. TLC was used to follow the progress of the reaction. After 20 h, the reaction was complete, and the solution was concentrated in vacuo to a brown oil. The residue was taken up in ethyl acetate (100 mL) treated with charcoal, dried over $MgSO_4$, and filtered. The filtrate was concentrated in vacuo to a yellow-brown solid. The residue was eluted through a silica plug (4 × 6 cm) with chloroform and then recrystallized (2×) from ethyl acetate/hexanes (1:5, v/v) to afford **5** (27.1 g, 69%) as yellow plates in high purity. mp 72−73 °C. R_f (A) 0.89, (E) 0.94. HPLC: t_R 22.33 min (>99%). ^{1}H NMR (500 MHz, $CDCl_3$) d 7.85 (m, 2H), 7.55 (m, 2H), 4.88 (t, J = 5.7 Hz, 2H), 3.82 (d, J = 5.7 Hz, 1H), 3.74 (m, 2H), 3.54 (m, 2H), 1.16 (m, 6H). N^4,N^α,N^α,N^ϵ,N^ϵ-[pentakis(carboxymethyl)]-N^4-(carboxymethyl)-2,6-diamino-4-azahexanoic Hydrazide (20). TFA was added to **19** (0.017 g, 0.03 mmol) and stirred for 35 min. The solution was concentrated in vacuo, the residue was dissolved in methanol (1 mL), and the product was precipitated (4×) from diethyl ether (35 mL). Centrifugation and drying of the collected product in vacuo yielded **20** (0.014 g, 81%) as hygroscopic white microcrystalline TFA salt. mp: 116−119 °C. HPLC (214 nm): t_R 3.0 min (>98%). ^{1}H NMR (500 MHz, D_2O) d 3.32−3.43 (m, 6H), 3.50−3.90 (m, 11H). ^{19}F NMR (564 MHz, D_2O) d −74.3 (s). MS (ES^+) 452.

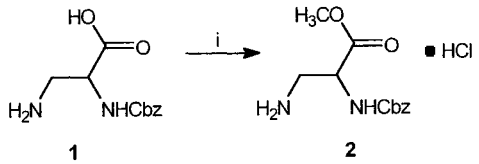
MAb Conjugation. The DTPA hydrazide **20** was conjugated to the MAb ΔCH2HuCC49 through a ketone-hydrazide technique described previously (*22*). Briefly, 6-oxoheptanoic acid was first conjugated to the MAb at pH 8.1. After buffer exchange to 50 mM ammonium acetate (pH 5.5), the BCA was introduced at a molar ratio of 300 relative to the MAb. The solution was stirred at 4 °C for 16 h, and the product was purified by dialysis. Number of DTPAs per antibody (DTPA: MAB) was calculated by MALDI analyses as described before (*22*). This procedure resulted in a DTPA/MAb of 4.

^{90}Y- and ^{177}Lu-Labeling. The same labeling protocol was applied to both isotopes which were supplied (University of Missouri Research Reactor, St. Louis, MO, and NEN, Boston, MA, for ^{90}Y and ^{177}Lu, respectively) as trichloride salts. Briefly, the radiometal in HCl (3 μL) was incubated in 50 μL of acetate buffer (pH 5.5) at ambient temperature for 15 min and was added to the solution of the conjugate (120 μg) in the same buffer (63 μL). Near-quantitative radiolabeling yields (>96%) were obtained with both isotopes as indicated by size-exclusion HPLC, after 1 h incubation at ambient temperature. Under these conditions, a control unconjugated MAb showed about 0.3−4% nonspecific labeling depending on the type of the MAb.[2] Labeled conjugates were purified by gel filtration using PD-10 columns and phosphate-buffered saline as the eluent. One-milliliter fractions were collected with the conjugate eluting in fractions 3 and 4.



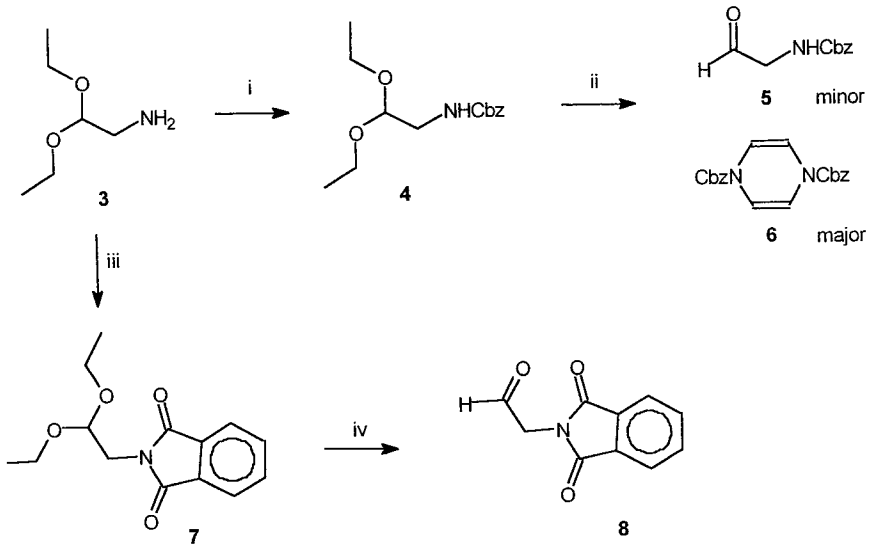
Animal Model. Athymic nude female *nu*/*nu* mice with a BALB/c background, were obtained from the National Cancer Institute Frederick Research Laboratory (Frederick, MD) and were kept under sterile conditions. Procedures to minimize discomfort, pain, and distress were in accord with the Animal Resource Program at the University of Alabama at Birmingham, accredited by the American Association for Accreditation of Laboratory Animal Care. The LS174T human colon cancer cells (American Type Culture Collection, Manassas, VA) were harvested and suspended in sterile PBS at a concentration of 7.5 × 10^8 viable cells/mL. Cell viability was determined by trypan blue dye exclusion. Two groups of animals (6 mice each) were injected i.p. with 10^8 viable cells in PBS. At a tumor diameter of 5−10 mm, 2 μCi of ^{177}Lu-DTPA−ΔCH2HuCC49 was injected i.p. into the mice and the animals were sacrificed 4 and 24 h after administration of the radiopharmaceutical. The radioactivity uptake of the tumor and normal tissues were measured in a gamma-counter, and the counts were used to calculate the percent injected dose per gram of tissue (%ID/g).

RESULTS AND DISCUSSION

Synthesis. In addition to the preparation of a bifunctional DTPA with a new conjugating functionality, a goal of this synthesis was to generate a DTPA precursor with full orthogonal protection of both the *metal-chelating* and the *conjugating* segments. Also, a fully organic phase synthetic strategy, without resorting to biphasic and/or aqueous and buffer-mediated steps, was of interest. All intermediate compounds, formed prior to the deprotected final products, were designed to be compatible with normal-phase silica gel chromatography to exclude any need for ion-exchange or reversed-phase procedures.

The convergent synthetic strategy is illustrated in Schemes 1−3. Commercially available Cbz-diamino propionic acid **1** (Scheme 1) was carboxy-protected, in near

Scheme 1[a]



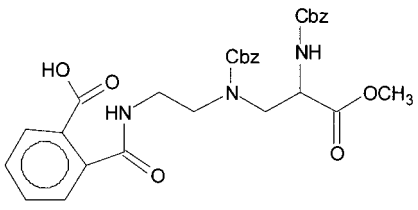
[a] (i) MeOH, HCl/dioxane, 0 °C → rt.

quantitative yields and in a dry methanol/HCl/dioxane solution (*48*), to the methyl ester **2** which served as part of the triamine backbone needed for assembling the molecular scaffold. Since at this stage, establishment of the synthetic protocol, and not the metal chelating features of the ligand, was of interest, the commercially available racemic mixture of diamino propionic acid was used as received. A logical approach to the formation of this triamine was coupling of **2** with a 2-amino ethanol derivative at its C2 position. A number of nucleophilic substitution reactions, between **2** and N-protected amino ethanol tosylates and triflates, were tried under different conditions and without satisfactory results. A second

[2] Radiolabeling of unconjugated mCC49 and HuCC49 resulted in 0.3 and 0.8% nonspecific labeling, respectively.

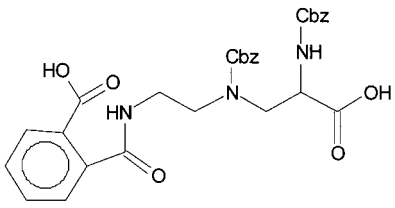
Scheme 2[a]

[a] (i) BCF, DIEA, dioxane; (ii) H^+; (iii) $(Phth)_2O$, DIEA, toluene; (iv) 50% HOAc, 60 °C.



option, coupling of **2** with an N-protected amino acetaldehyde through Schiff base formation was therefore proposed. Of the two possibilities for protection of the amine **3**, i.e., Boc and Cbz, the former was eliminated due to incompatibility with a later step of the synthesis. Specifically, an acid removal of such a Boc group would also remove the *N′*-Boc protection of the hydrazide **16** (Scheme 3).

To test the Cbz option, amino acetaldehyde dimethyl acetal **3** was N-protected by benzyl chloroformate to form **4** (Scheme 2). Deblocking of the aldehyde group of **4** under different standard acidic conditions, and evaluation of the products by electrospray MS, indicated a minor formation of the desired aldehyde and a major product with a molecular weight of 350. Although this byproduct was not isolated, the MW points to the formation of an N^1,N^4-di(benzyloxycarbonyl)-1,4-dihydro pyrazine, **6**, resulting from a head-to-tail condensation of two molecules of the Cbz-aminoaldehyde. This competing reaction appears to have occurred shortly after the aldehyde formation, and due to the high thermodynamic stability of the dihydropyrazine structure. Formation of this compound drastically reduced the yield of the desired aldehyde and complicated the purification.



To circumvent this problem, we postulated that deprotonation of the amide nitrogen in the Cbz-protected amino aldehyde might prevent the formation of the unwanted pyrazine compound by blocking the head-to-tail aminoacetaldehyde condensations. Thus, compound **3** was N-protected by phthalic anhydride in toluene to afford compound **7** in 69% yield after purification (Scheme 2). Indeed, deprotection of compound **7** was a clean reaction affording the desired aldehyde **8** as the major product and with no significant formation of any byproducts. On the other hand, a series of standard acidic conditions to remove the acetal protection of **7** resulted either in low-yield and low-purity reactions or recovery of the starting material with no change. The deprotection, however, worked quite efficiently from both yield and purity standpoints, when aqueous acetic acid was used at elevated temperature. Both compounds **7** and **8** were readily purified by crystallization.

Condensation of the aldehyde **8** with the partially protected amine **2** was carried out, as shown in Scheme 3, in dry THF with in situ reduction of the resulting Schiff base intermediate by sodium acetoxy borohydride. The use of this reagent proved to be superior to $NaCNBH_3$ by affording high-purity products and better yields of recovery. Celite filtration and water/brine wash of the product solution afforded the amine **9** in 86% yield. This procedure provided **9** with sufficient purity for preparative purposes and required no further purification.

To prevent the interference of the secondary amine group of **9** with the coupling reaction used for the construction of the hydrazide conjugating function (see compound **15**), the former was blocked by a Cbz, which was the same as the protection used for the N^{α}-amine; both Cbz groups may now be removed as needed and in the same step. Masking of the secondary amine was carried out by a standard procedure, (*49*) using benzyl chloroformate in dioxane, which formed the fully protected compound **10** in over 88% yield and without needing chromatography.

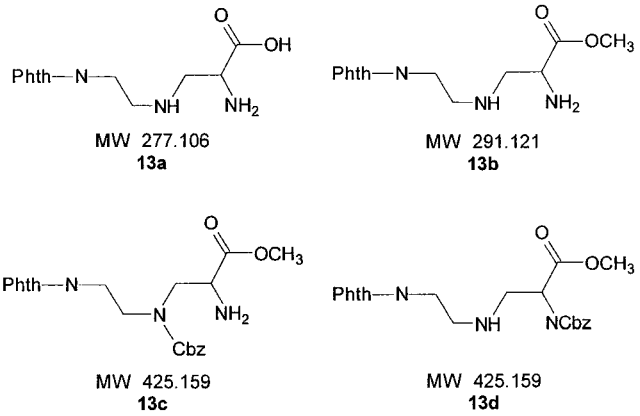
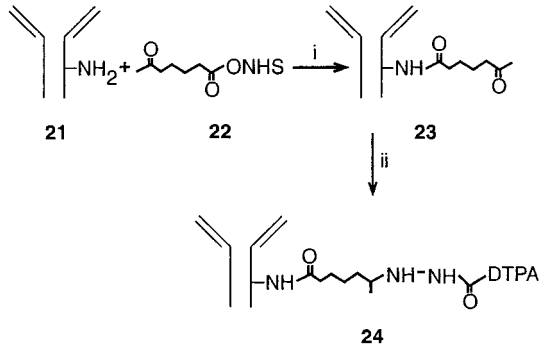
Despite the well-known ease of base hydrolysis of methyl esters, this method could not be applied to the deblocking of the ester **10**. Attempts to remove this ester group by equimolar concentrations of NaOH or KOH in methanol, methanol/water, and THF/water, and also with



Scheme 3[a]



[a] (i) $Na(AcO)_3BH$, THF; (ii) BCF, DIEA, dioxane, 0 °C → rt; (iii) conc HCl, dioxane, 40 °C; (iv) Boc-$NHNH_2$, HOBT, DIEA, DCC, THF; (v) H_2NNH_2, EtOH, 50 °C; (vi) Pd/C (10%) H2, 90% HOAc; (vii) BnO_2CCH_2OTpf; CH_2Cl_2 −78 °C; (viii) Pd/C (10%), MeOH; (ix) TFA.

LiOH in wet methanol or THF/water, resulted mainly in the opening of the phthalimide ring and formation of the corresponding N-substituted phthalamic acid **11**, partially mixed with the demethylated compound, **12**. This was confirmed by the detection of these structures on ESMS as indicated by the *m*/*z* 577 and 563, for structures **11** and **12**, respectively. The same result was obtained when weaker bases such as $NaHCO_3$ and K_2CO_3 were used. A transesterification procedure using anhydrous TFA (*50*) was employed as an alternative route. Over 18 h at 40 °C, this reaction lead to a mixture of products as detected by ESMS. Possible structures based on the MS data are shown in structures **13a**−**d**.

On the basis of the esterification mechanism of the amino acid **1** to form this methyl ester, an acid hydrolysis with concentrated HCl, i.e., reversal of the esterification process was, therefore, proposed. Indeed, treatment of **10** with 25% of concentrated HCl in dioxane at 40 °C selectively removed the methyl ester, without disturbing other protecting groups, to afford the corresponding propionic acid **14** in 67% purified yield. The hydrazide conjugating function was then introduced into this

molecule by a HOBT-promoted carbodiimide reaction, resulting in the formation of **15** in 98% recovery.

To generate the triamine core, the three amine-protecting groups were to be removed in two separate reactions. From the results of the base hydrolysis of the methyl ester **10**, it was expected that the removal of the Cbz groups of **10**, prior to that of the phthalyl, would result in unwanted in situ ring opening reactions caused by the newly formed N^{α}- and N^{4}-amine groups. Therefore, compound **15** was first treated with excess hydrazine to afford the amine **16**, in 69% purified yield. The latter product was hydrogenated catalytically to the triamine **17**, in the form of a diacetate salt and at near quantitative yields.

Assembling the five metal-chelating arms on the amine backbone was carried out under completely organic conditions through a slight modification of the procedure reported by Pickersgill and Rapoport (*51*). Because of the mild conditions, this procedure has the advantage of minimizing the competing lactamization reactions, thereby resulting in an improvement in the yield of recovery of the target product. Thus, reaction of the triamine **17** with the triflate of benzyl glycolate, in dichloromethane and at low temperature, afforded the fully alkylated **18** as the major product.

Since the removal of all protecting groups in the last two steps of this synthesis generates highly polar products, obtaining a highly pure **18** was essential to avoid extensive purification of the polar products **19** and **20**. If performed carefully, both benzyl- and Boc-removal steps could be clean processes, resulting in a final-product BCA with acceptable purity for conjugation protocols.

Removal of the Boc and benzyl groups from compound **18** were carried out in two successive steps starting with catalytic hydrogenation in methanol. The hydrazide-protecting Boc group was then removed by acid treatment of **19** to afford the fully deblocked target molecule **20** in 81% yield. Our attempts to obtain a high-resolution MS on compounds **19** and **20** were not successful probably due to the excessively charged nature of these molecules (*52*). The ^{1}H NMR and ESMS, however, confirm the structure of **20** with a high (>98%) purity as indicated by reversed-phase HPLC. Furthermore, the MALDI-supported antibody conjugation of this compound, and subsequent high-yield radiolabeling reactions with both ^{90}Y and ^{177}Lu, provide indirect evidence for the formation of **20**.

Antibody Conjugation. To test the ability of this new DTPA molecule for conjugation to, e.g., proteins, a model experiment was performed (Scheme 4) using the MAbΔCH2HuCC49 (**21**), a domain-deleted humanized murine immunoglobulin, that binds to TAG-72, a pan-carcinoma antigen (*53*). The ΔCH2HuCC49 is reactive against adenocarcinomas including colorectal, ovarian, gastric, pancreatic, and non-small cell lung cancer.

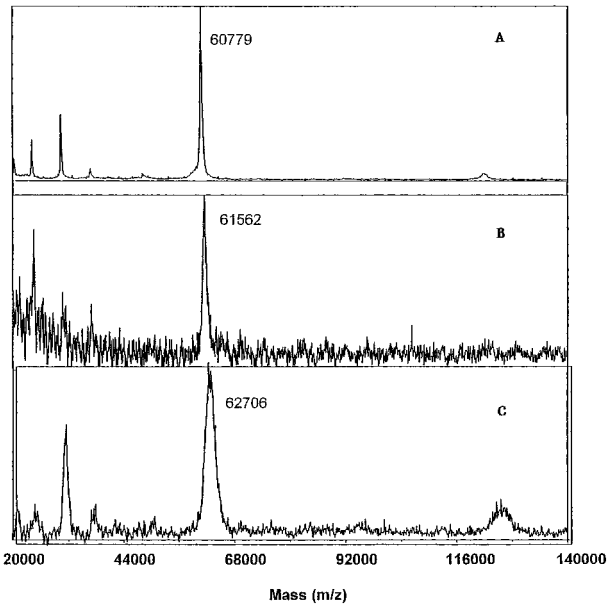

Figure 1. MALDI-TOF mass spectra of the starting MAb ΔCH2HuCC49 (A), the intermediate OHA−ΔCH2HuCC49 (B), and the final product conjugate DTPA−ΔCH2HuCC49 (C). Reaction progress is indicated by the corresponding increases in *m*/*z* values. MWs are shown at half-value from doubly charged species.

We have reported a conjugation procedure for the covalent attachment of unprotected hydroxamic acid BCAs, using a hydrazide conjugating function (*22*). In this procedure, a ketone-derived linker (**22**) is first implanted into the MAb molecule through an activated ester chemistry. With the ketone groups serving as "*hydrazide anchors*" (**23**), the BCA is then conjugated to the MAb, in a group-selective (ketone-directed) manner and with no conflict with the native amine groups of the protein. As compared to the isothiocyanate and cyclic anhydride protocols, this procedure uses a two-step protocol. The addition of an extra step, however, may be compensated by gains in the conjugation outcome as a result of the BCA stability.

Matrix-assisted laser desorption/ionization (MALDI) MS analyses of the conjugation products **23** and **24**, using MWs of the unconjugated starting MAb, the linker, and DTPA **20**, indicated a 4:1 DTPA-to-MAb ratio (Figure 1). Although this ratio is within an acceptable range of BCA-MAb substitution for radiolabeling and in vivo studies of the radiolabeled MAb conjugates, it could be varied by manipulating the conditions for the conjugation sequence of Scheme 4 (*22*).

Radiolabeling. Radiolabeling of the DTPA−ΔCH2-HuCC49 conjugate proceeded efficiently with two therapeutically important radiometals, ^{90}Y and ^{177}Lu. High yields of radiolabeling (>96%) confirmed the ability of the ligand to maintain its metal-chelating properties after conjugation to the MAb. The size-exclusion (SE) HPLC (Figure 2) and Sephadex-25 chromatography (PD-10, Figure 3 for ^{177}Lu only) showed the expected IgG elution patterns. The results of radiolabeling are shown in Table 1 which also demonstrate high specific activities for both ^{90}Y and ^{177}Lu conjugates.

Biodistribution. Tumor and normal tissue uptake of the ^{177}Lu-DTPA−ΔCH2HuCC49 was studied in LS174T-bearing athymic nude mice at two time points as shown

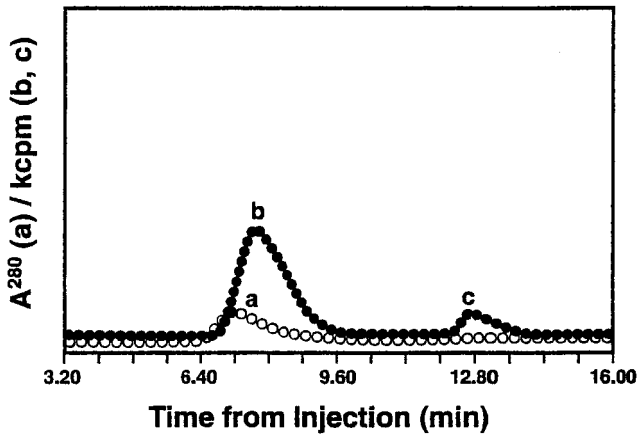

Figure 2. Analytical size-exclusion HPLC profile for ^{177}Lu-DTPA−ΔCH2HuCC49 as determined by UV (○) and radioactive (●) traces. Peaks a and b indicate conjugate elution, while c denotes unbound activity.

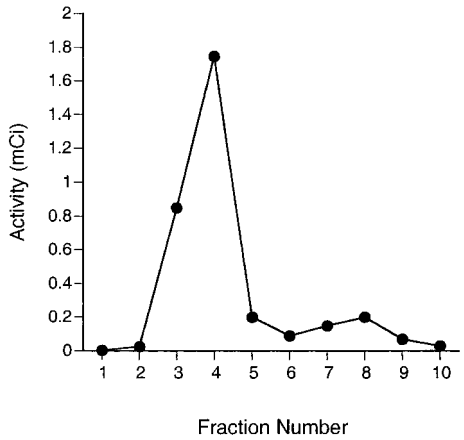

Figure 3. Preparative gel filtration profile for purification of ^{177}Lu-DTPA−ΔCH2HuCC49 on a Sephadex G25 column. Elution of the labeled antibody peaks in fractions 3 and 4 is followed by the later elution of the unbound activity in fractions 7−9.

Table 1. ^{90}Y and ^{177}Lu Labeling of DTPA−ΔCH2HuCC49 Conjugate

isotope	%RY[a]	SA[b]
^{90}Y	96	16
^{177}Lu	98	21

[a] Percent radiolabeling yield calculated from SE HPLC. [b] Specific activity in mCi/mg of conjugate.

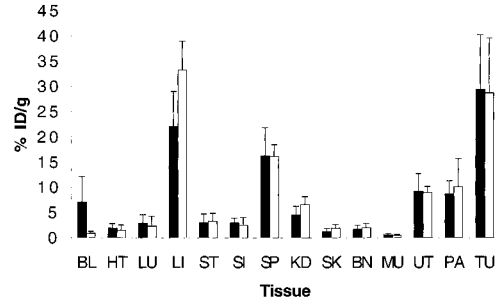

Figure 4. Biodistribution of ^{177}Lu-DTPA−ΔCH2HuCC49 in athymic nude mice bearing i.p. LS174T human colon carcinoma xenografts at 4 h (■) and 24 (□) postinjection as %ID/g for blood (BL), heart (HT), lungs (LU), liver (LI), stomach (ST), small intestine (SI), spleen (SP), kidneys (KD), skin (SK), bone (BN), muscle (MU), uterus (UT), pancreas (PA), and tumor (TU).

in Figure 4. The percent injected radioactivity uptake by unit weight of each tissue (%ID/g) for this conjugate showed a high tumor uptake, indicating that the immunoreactivity of the labeled conjugate was not affected by the conjugation and radiolabeling procedures. The conjugate also showed a blood clearance pattern characteristic of this antibody but had relatively high liver uptake. Work is in progress in this laboratory to evaluate the effect of different BCA-MAb linkers in reducing the liver activity (*54*−*58*). This biodistribution analysis, however, validates the conjugation and radiolabeling protocols used in this work for the production of therapeutically useful radiopharmaceuticals using the new DTPA hydrazide.

CONCLUSION

The metal-chelating agent DTPA has been extensively used for labeling of MAbs and peptides with such radioactive metals as ^{88}Y, ^{90}Y, ^{111}In, ^{152}Sm, ^{153}Sm, and ^{177}Lu, for diagnosis and therapy of malignancies, as well as a contrast agent in MRI and a metal-sequestering agent. Application of organic chelators in metal-tagging of biomolecules requires first the conjugation of the BCA to the latter, a procedure reported with a variety of mechanisms and functional groups. The DTPA-based BCAs used in the reported protocols are mainly either the cyclic dianhydride or isothiocyanate derivatives of this ligand. In this work, we report the synthesis of a novel derivative of this useful metal chelator, the hydrazide DTPA **20**, designed for a new and group-specific conjugation protocol. The synthetic strategy uses a novel approach in building the skeletal backbone of this molecule. This approach enjoys a totally organic route involving diagonally protected nonpolar intermediates, and resulted in the formation of the target DTPA product with a good overall yield and a final-product purity that was suitable for further conjugation procedures. Also, most steps of this synthesis produced, without a need for chromatography, intermediate compounds with purities suitable for preparative applications. The final-product BCA showed a high physical and chemical stability and remained intact over an extended period of time. Furthermore, the conjugation mechanism of this DTPA leaves all five carboxylate groups available for metal chelation, thus resulting in more stable metal complexes.

The ability of the new BCA **20** for covalent attachment to MAbs was tested by conjugation of this molecule to the MAbΔCH2HuCC49. Evaluation of the conjugation products by MALDI MS demonstrated the successful attachment of **20** to this antibody at a BCA/MAb ratio of 4. While the full deprotection of **20** generates a ready-to-conjugate heterobifunctional compound, removal of only the carboxyl group protection may afford a stable metal-chelating DTPA molecule for in vitro and in vivo studies of the corresponding metal complexes.

This new DTPA heterobifunctional chelating agent may serve to improve conjugation of this useful chelating agent to compounds of medical and biological applications, resulting in efficient and controllable protocols and producing reagents with high metal-chelating efficiencies.

ACKNOWLEDGMENT

The authors thank Dr. Michael G. Bartlett (University of Georgia College of Pharmacy) for providing the high resolution mass spectral data and helpful related discussions. Also, we thank Marion Kirk and Lori Coward (UAB Mass Spectroscopy Shared Facility), for running the ESMS and MALDI spectra, respectively, and Soneshia

McMillan for preparing the manuscript. This work was supported by NCI Grants CA62550 and CA78505.

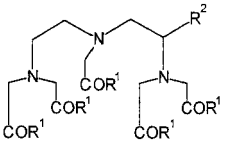
Synthesis of the First Diethylenetriaminepentahydroxamic Acid (DTPH) Bifunctional Chelating Agent†,§



Ahmad Safavy,* Dale C. Smith Jr., Alireza Bazooband,‡ and Donald J. Buchsbaum

Department of Radiation Oncology, University of Alabama at Birmingham, Birmingham, Alabama 35294.
Received October 8, 2001; Revised Manuscript Received January 10, 2002

Synthesis of a new pentahydroxamic acid bifunctional chelating agent (BCA), constructed on the aminoazaalkyl core of diethylenetriaminepentaacetic acid (DTPA), is reported. Rational modifications in the structure of DTPA, which could result in an enhancement of its chelation properties, add to the collection of diagnostic and therapeutic metals bound by this chelator, and might implement significant improvements in the in vivo behavior of this compound, are described. Further improvements in the stability of the ligand−metal complexes of DTPA may improve both diagnostic and therapeutic outcomes such as tumor-to-normal tissue ratios and target-delivered radioactivity. A combination of hydroxamate functions with the azaalkyl backbone of DTPA might be a suitable approach to generate such higher stabilities. This rationale may be justified by the well-known affinity of hydroxamates against different transition metals and favorable properties of DTPA as a versatile chelator. Thus, the N^4,N^α,N^α,N^ϵ,N^ϵ-pentakis[[((*N*-hydroxy-*N*-methyl]carbonyl)methyl]-2, 6-diamino-4-azahexanoic hydrazide (**5**, DTPH) was designed and synthesized through a convergent synthesis and in 40.7% overall yield. Conjugation of this compound to the monoclonal antibody (MAb) ΔCh2HuCC49, used as a model protein, was carried out to evaluate the efficiency of this molecule as a BCA. Radiolabeling of the DTPH−ΔCH2HuCC49 conjugate with lutetium-177 (^{177}Lu) and biodistribution of the labeled conjugate in athymic nude mice, bearing LS174T human colon carcinoma xenografts, are reported.

INTRODUCTION

Diethylenetriaminepentaacetic acid (DTPA[1], **1**, Figure 1) has been widely used as a metal chelating agent in both diagnostic and therapeutic procedures. Although the use of this agent as a single-molecule metal chelator has been reported, its application as a conjugate to TVs, for the transfer of metallic nuclides to the site of the disease, has been more prominent. The latter application includes radiolabeling of MAbs and peptides with different metallic radionuclides such as yttrium (^{88}Y, ^{90}Y) (*1*−*3*), indium (^{111}In) (*4*−*7*), lead (^{203}Pb) (*8*), samarium (^{152}Sm, ^{153}Sm) (*9*, *10*), and lutetium (^{177}Lu) (*11*, *12*). Other applications of DTPA, such as in MRI (*13*−*15*) and luminescent lanthanide imaging (*16*), have also been demonstrated,

1: R^1 = OH; R^2 = H
2: R^1 = OH; R^2 = $CONHNH_2$
3: R^1 = OH; R^2 = CONHNHBoc

which, collectively, point to the importance of this compound in medicine. It may be, therefore, of interest to explore possibilities for the development of more improved derivatives of this molecule. These improvements may be accomplished through either or both of the following approaches: (i) developing a bifunctional DTPA with higher chemical stability, and (ii) designing derivatives that could generate metal complexes of better kinetic/thermodynamic properties. A new bifunctional DTPA hydrazide, using Schiff base formation for MAb conjugation, has been reported by Safavy et al. (*17*). This molecule (**2**) showed a high shelf stability and efficient antibody conjugation under mild conditions, which is expected to be compatible with the structural and immunoreactivity features of most peptides and proteins.

Improvement in the metal complex stability prevents the premature in vivo release of the complex metal, which could, in turn, result in high uptake in normal tissues as well as in low-efficiency treatment protocols. Furthermore, and in the case of immunoconjugates, this metal release is also a function of the BCA-TV bond stability. Readily cleavable covalent bonds, such as carboxylic

esters, may be disrupted in vivo and in the presence of endogenous enzymes. The design of a potential BCA should, therefore, take into account both of these factors for an efficient site-directed delivery of the metal.

Hydroxamic acids have been noted for their favorable metal-chelating features (*18*). This has been the basis for their utilization in nature as iron-solubilizing agents (siderophores) produced by microorganisms (*19*−*23*). In drug development, hydroxamic acids have been the subject of much research in the development of enzyme inhibitors (*24*, *25*), as well as antithalassemic (*26*, *27*), antifungal (*28*), and antibacterial (*29*) agents, while hydroxamate-derived enkephalinase inhibitors have been proposed as nonopioid analgesic drug candidates (*30*−*32*). Furthermore, a trihydroxamate BCA, trisuccin, was reported by Safavy et al. as a radiometal-labeling bifunctional agent (*33*), and the use of this compound in radiolabeling of MAbs and peptides with rhenium-188 (^{188}Re) through a post-conjugation protocol has been reported (*34*). The post-conjugation route of indirect radiolabeling, as opposed to the "preformed chelate approach" (*35*, *36*), is a versatile techniques in preparation of rhenium and technetium radiopharmaceuticals that was not available as a routine procedure prior to the development of trisuccin. Thus, the potential of hydroxamic acids, along with the development of antibody conjugation and rhenium-labeling protocols using trisuccin, warranted studies on the design and synthesis of other hydroxamate BCAs.

In this paper, we report the synthesis of a novel heterobifunctional DTPA pentahydroxamate, DTPH, containing a hydrazide sidearm as the TV-conjugating moiety. In contrast to the cyclic anhydride DTPA, this hydrazide function forms the prospective linkages through one of the core ethylenediamine segments, leaving all five hydroxamate groups available for metal chelation. The hydrazide group is also compatible with free (unprotected) hydroxamate functions and allows for efficient and group-specific antibody conjugation as described before by Safavy et al. (*37*).

EXPERIMENTAL SECTION

General Procedures. Tetrahydrofuran (THF) was ketyl distilled under argon. All other reagents and solvents were obtained from commercial suppliers and were used as received. ^{1}H NMR spectra were recorded on a Bruker ARX500 FT-NMR spectrometer. The chemical shifts were referenced to tetramethylsilane as internal calibrator. Mass spectra in electrospray mode (ESMS) were recorded either on an API VI triple quadruple mass spectrometer (PE-Sciex, Toronto, Ontario) or Micromass Platform LCZ mass spectrometer (Beverly, MA). TLC was performed with Whatman glass-backed silica gel plates (2.5 cm × 7.5 cm, coating thickness 250 μ, 60 A, 254 nm). Solvents for TLC were mixed on a v/v scale and are defined as follows: (A) chloroform/methanol, 90:10; (E) chloroform/methanol/acetic acid, 77:20:3. Metal-free purified water (18.2 MΩ) was obtained from a Milli-QF system (Millipore, Bedford, MA). Melting points were performed in open capillary tubes and are uncorrected. For analytical SE HPLC, a 7.5 mm × 25 cm G3000SW column (TosoHaas, Montgomeryville, PA) was used. A 10 mM PBS containing 10 mM Na_2SO_4 at pH 6.7 was used as solvent. Preparative SE chromatography was carried out using Sephadex G-25 columns (PD-10, Pharmacia Biotech AB, Uppsala, Sweden) eluted with DPBS.

MALDI MS Procedure. Samples were analyzed in the positive mode on a Voyager Elite mass spectrometer with delayed extraction technology (PerSeptive Biosystems, Framingham, MA). The acceleration voltage was set at 25 kV, and 50−100 laser shots were summed. The matrix was sinapinic acid, dissolved in a 50:50 (v/v) mixture of 0.1% TFA/acetonitrile. A 1 pmol/μL solution of bovine serum albumin was added as an internal standard. Equal volumes of sample and matrix were mixed on a smooth plate, and the average of three measurements were reported. For each reaction, the intact MAb was scanned as the control for evaluation of the following conjugation. The molecular weight increase of the OHA-MAb intermediate was calculated using the unconjugated MAb. The molecular weight of this intermediate then served as the control to measure the increase in the molecular weight of the final product conjugate. Each difference in molecular weight was divided by the molecular weight of the corresponding linker to measure the linker/MAb ratio.

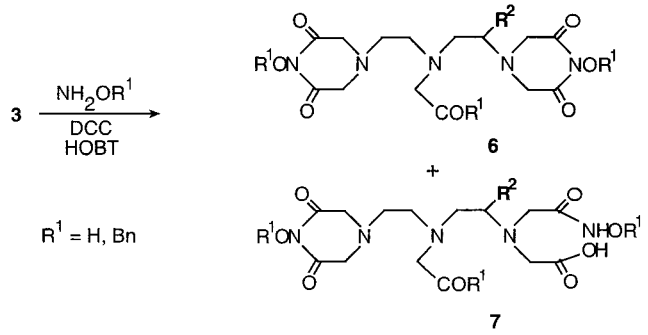
HR MS Procedure. The high-resolution liquid secondary ion mass spectra were acquired on a Micromass AutoSpec Magnetic Sector mass spectrometer (Beverly, MA) operated at a resolution of 10 000 (fwhm). All samples were run as approximately 1 μg/mL solutions in 3-nitrobenzyl alcohol using matrix clusters or added peptides as reference peak.

2-Bromo-*N*-benzyloxy-*N*-methylacetamide (19). A solution of *O*-benzylhydroxylamine·HCl (6.57 g, 41.2 mmol) and K_2CO_3 (17.04 g, 123.5 mmol) in dioxane/water (1:1, 125 mL) was cooled to 0 °C, and a solution of di-*tert*-butyl dicarbonate (9.02 g, 41.3 mmol) in dioxane was added dropwise over 20 min. The reaction was allowed to warm to ambient temperature and stirred vigorously for 20 h. The volatiles were removed in vacuo. The residue was taken up in ethyl acetate (100 mL) and extracted with water (3 × 50 mL), 10% aqueous citric acid (3 × 50 mL), and brine (1 × 20 mL), followed by drying over $MgSO_4$. The filtered solution was concentrated in vacuo to yield *O*-benzyl-*N*-Boc-hydroxylamine (8.93 g, 97.3%) as a colorless oil. R_f 0.86 (A), 0.54 ($CHCl_3$). ^{1}H NMR (500 MHz, $CDCl_3$) d 7.09−7.42 (m, 5H), 4.85 (s, 2H), 1.48 (s, 9H). A solution of *O*-benzyl-*N*-Boc-hydroxylamine (8.75 g, 39.2 mmol), iodomethane (14.5 mL. 235.25 mmol), and K_2CO_3 (5.82 g, 42.1 mmol) in acetone (75 mL) was heated at 50 °C with constant stirring. Reaction was complete after 8 days as monitored by TLC. The reaction mixture was filtered, and the volatiles were removed in vacuo. The oily residue was taken up in diethyl ether (100 mL) and extracted with $NaHCO_3$ (3 × 50 mL) and brine (1 × 50 mL) and dried over $MgSO_4$, and the solution was concentrated in vacuo to yield *O*-benzyl-*N*-Boc-*N*-methylhydroxylamine (9.13 g, 98.2%) as a colorless oil. R_f 0.90 (A), 0.68 ($CHCl_3$). ^{1}H NMR (500 MHz, $CDCl_3$) d 7.34−7.41 (m, 5H), 4.83 (s, 2H), 3.02 (s, 3H), 1.50 (s, 9H).

A flask was charged with the *O*-benzyl-*N*-Boc-*N*-methylhydroxylamine (8.38 g, 35.32 mmol), purged with argon, and cooled to 0 °C. Trifluoroacetic acid (65 mL) was slowly added over 10 min, and the solution was stirred for 1 h (**Caution: highly exothermic reaction**). All volatiles were removed in vacuo to give *O*-benzyl-*N*-methylhydroxylamine·TFA (8.79 g, 93.3%) as an off-white crystalline solid. mp 62−64 °C. R_f 0.65 (A), 0.18 ($CHCl_3$). ^{1}H NMR (500 MHz, $CDCl_3$) d 11.71 (s,1H); 7.32−7.37 (m, 5H), 5.06 (s, 2H), 2.96 (s, 3H). MS(ES+) 138.

A solution of bromoacetyl bromide (0.66 mL, 7.5 mmol) in THF (25 mL) was cooled to −78 °C under an argon purge, and dry K_2CO_3 (0.753 g, 5.52 mmol) was added. The reaction was vigorously stirred, and a solution of DIEA (0.95 mL, 5.1 mmol) and *O*-benzyl-*N*-methylhydroxylamine (1.26 g, 5.02 mmol) in THF (10 mL) was

added over 15 min. The reaction mixture was allowed to warm to 0 °C over 4 h. The reaction mixture was filtered, and the volatiles were removed in vacuo at ambient temperature. The oily residue was taken up in diethyl ether (20 mL), and the solution was extracted with 10% aqueous $NaHCO_3$ (3 × 5 mL) and brine (1 × 5 mL), dried over $MgSO_4$, and filtered. The filtrate was concentrated in vacuo to yield **19** (1.21 g, 93.5%) as a colorless oil. R_f 0.85 (A) 0.24. ^{1}H NMR (500 MHz, $CDCl_3$) d 7.39−7.41 (m, 5H), 4.94 (s, 2H) 3.91 (s, 2H), 3.27 (s, 3H). MS(ES+) 258.0, 260.0.



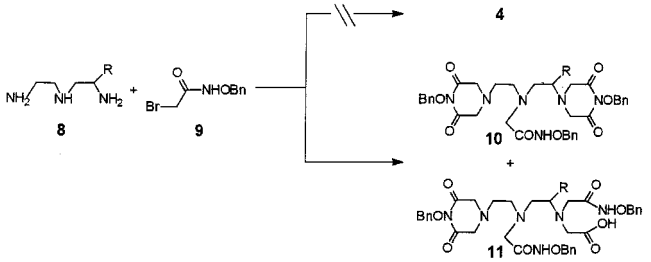
***N′*-BOC-N^4,N^a,N^a,N^e,N^e-pentakis[[((*N*-benzyloxy-*N*-methyl)amino)carbonyl]methyl]-2,6-diamino-4-azahexanoic Hydrazide (20).** A solution of *N′*-Boc-2-amino-3-[[2-(amino)ethyl]amino] propionic hydrazide **8** (0.137 g, 0.311 mmol) (*17*) and DIEA (0.84 mL, 4.67 mmol) was dissolved in DMF (2 mL). A solution of *O*-benzyl-2-bromo-*N*-methylacetohydroxamic acid **19** (1.21 g, 4.67 mmol) dissolved in CH_2Cl_2 was added to the reaction mixture at −50 °C, and the mixture was allowed to warm to ambient temperature over 48 h. The solution was concentrated in vacuo to a yellow-orange oil that was dissolved in ethyl acetate (4 mL). This solution was extracted with 10% aqueous citric acid, 10% aqueous $NaHCO_3$ (2 × 2 mL), and brine (1 × 2 mL) and was dried over $MgSO_4$. Removal of the solvent afforded an oily residue that was triturated with petroleum ether redissolved in ethyl acetate (0.5 mL). The product was then precipitated into a diethyl ether: petroleum ether solution (1:1, 35 mL). The yellow-orange solid was separated by centrifugation and dried in vacuo to yield **20** (0.230 g, 64.5%). mp 93−98 °C. R_f 0.52 (A), 0.86 (E). ^{1}H NMR (500 MHz, $CDCl_3$) d 7.26−7.36 (25H, m); 4.80−4.82 (10H, m); 3.61−3.82 (10H, b); 3.14−3.09 (15H, b); 2.61−2.87 (7H, m); 1.44 (9H, s); HRMS (FAB+) 1147.5748 ($C_{60}H_{79}N_{10}O_{13}$ requires 1147.5828). MS ES+ 1147.2.

***N′*-BOC-N^4,N^a,N^a,N^e,N^e-pentakis[[((*N*-hydroxy-*N*-methyl)amino)carbonyl]methyl]-2,6-diamino-4-azahexanoic Hydrazide (21).** A solution of **20** (0.228 g, 0.199 mmol) in methanol (8 mL) was hydrogenated at ambient temperature over palladium on carbon (10%, 0.046 g) under a hydrogen balloon for 24 h. The catalyst was separated by filtration through a 0.2 μm Acrodisc syringe tip filter (Gelman Sciences, Ann Arbor, MI), and the filtrate was concentrated in vacuo to an off-white oil. The oil was dissolved in methanol (1 mL) and precipitated from diethyl ether (35 mL). The solid was isolated by centrifugation and dried in vacuo to yield **21** (0.112 g, 80.7%) as a hygroscopic yellow-white microcrystalline solid. mp 136−139 °C. ^{1}H NMR (500 MHz, DMSO-d_6) d 3.76−3.82 (b, 15 H), 2.78−3.16 (m, 17 H), 1.48 (s, 9 H). HRMS (FAB+) 697.3489 ($C_{25}H_{49}N_{10}O_{13}$ requires 697.3481). MS ES+ 697.5.

***N^4,N^α,N^α,N^ϵ,N^ϵ*-pentakis[[((*N*-hydroxy-*N*-methyl]-carbonyl)methyl]-2,6-diamino-4-azahexanoic Hydrazide (5).** TFA (5 mL) was added to the Boc-protected **21** (0.154 g, 0.221 mmol), and the homogeneous solution was stirred for 65 min. The solution was concentrated in vacuo and dissolved in methanol (1 mL), and the product was precipitated (×2) from diethyl ether (35 mL). The solid product was separated by centrifugation and dried in vacuo to yield 0.123 g (78.3%) of **5** as a hygroscopic orange-yellow microcrystalline solid. mp 127−133 °C ^{1}H NMR (500 MHz, DMSO-d_6) d 3.76−3.82 (15 H, b); 2.85−3.21 (17 H, m). HRMS (FAB+) 597.2964 ($C_{20}H_{41}N_{10}O_{11}$ requires 597.2956). MS ES+: 597.2.

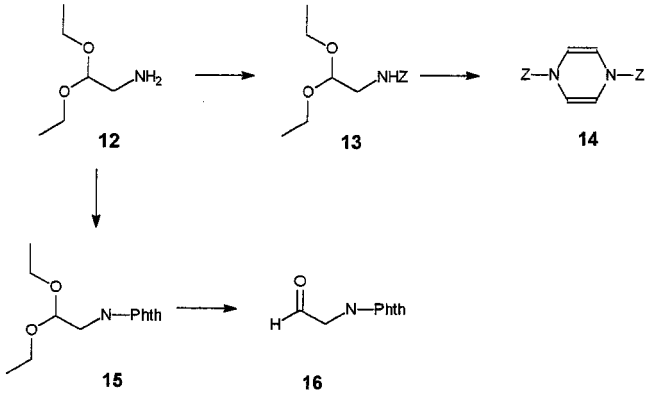
MAb Conjugation. The DTPA hydrazide **5** was conjugated to the MAb ΔCH2HuCC49 using ketone-hydrazide protocol described previously (*37*). Briefly, 6-oxoheptanoic acid was conjugated to the MAb in PBS, pH 8.1. The intermediate conjugate was purified by SE filtration in Centricon-50 against 50 mM ammonium acetate (pH 5.5). Compound **5** was added in the same buffer and at a molar ratio of 300:1 relative to the MAb. The homogeneous solution was stirred at 4 °C for 16 h, and the product conjugate was purified by dialysis. The number of DTPH molecules per antibody (DTPH:MAB) was calculated by MALDI MS as described previously (*37*). This procedure resulted in a DTPH/MAb of 2.2.

Scheme 1



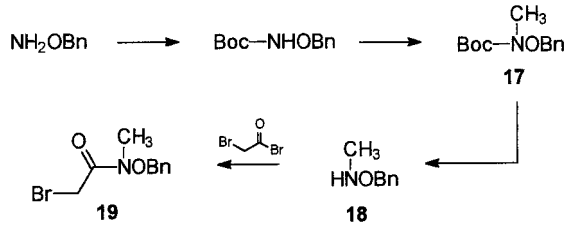
^{177}Lu-Labeling. The radioisotope was supplied (University of Missouri Research Reactor, St. Louis, MO) as lutetium chloride in 0.1 M HCl. The radiometal solution (3 μL) was incubated in 50 μL of acetate buffer (pH 5.5) at ambient temperature for 15 min and was added to the solution of the conjugate (120 μg) in the same buffer (63 μL). Radiolabeling yields (>96%) were assessed by SE HPLC, after 1 h incubation at ambient temperature. A control unconjugated MAb showed negligible nonspecific labeling under these conditions. The labeled conjugate was purified by gel filtration using a PD-10 column and phosphate-buffered saline as the eluant. One-milliliter fractions were collected with the conjugate eluting in fractions 3 and 4.

Animal Model. Athymic nude female *nu/nu* mice with a BALB/c background, obtained from the National Cancer Institute Frederick Research Laboratory (Frederick, MD), kept under sterile conditions, were used. Procedures to minimize discomfort, pain, and distress were in accord with the Animal Resource Program at the University of Alabama at Birmingham, accredited by the American Association for Accreditation of Laboratory Animal Care. The LS174T human colon cancer cells (American Type Culture Collection, Manassas, VA) were harvested and suspended in sterile PBS at 7.5 × 10^8 viable cells/mL. Two groups of animals (6 mice per group) were injected intraperitoneally (i.p.) with 10^8 viable cells in PBS. At a tumor diameter of 5−10 mm, 2 μCi of ^{177}Lu-DTPA-ΔCH2HuCC49 was injected i.p. into the mice, and the animals were dissected 4 and 48 h postinjection. The radioactivity uptake in the tumor, and normal tissues were measured in a gamma-counter and the counts were used to calculate the %ID/g values.

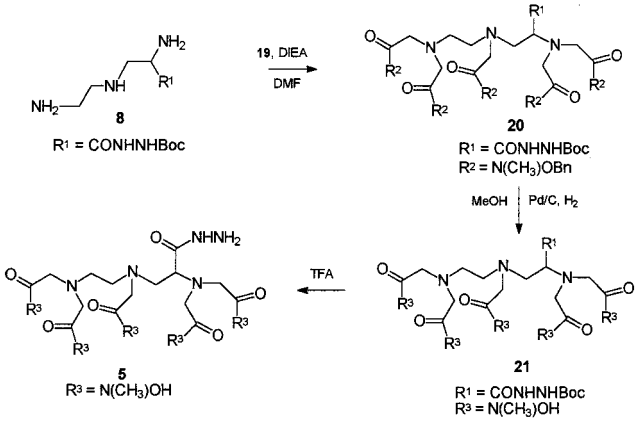


RESULTS AND DISCUSSION

A bifunctional DTPA molecule (**2**, Figure 1), containing a hydrazide function on the methylene backbone, has been recently prepared (*17*). The simplest approach to the synthesis of the target DTPH compound (**5**) seemed to be a direct reaction of the protected pentacarboxylate hydrazide **3**, with an excess of hydroxylamine and in the presence of a coupling reagent. This turned out to be not a simple task as shown in Scheme 1. Reaction of **3** with *O*-benzylhydroxylamine in DCC/HOBT reactions formed



Scheme 2



Scheme 3

Scheme 4

Scheme 5

the cyclized compounds **6** and **7** as the major products and with no or negligible quantities of **4**. Changing the reaction conditions, such as stoichiometry, solvent and temperature, did not improve the results, and longer reaction times converted **7** to **6**.

It was anticipated that a logical solution to this problem would be alkylation of the core diethylene triamine **8** by a reagent already equipped with a protected hydroxamic acid group as shown in Scheme 2. Thus, the functionalized triamine **8** (R = CONHNHBoc) (*17*) was reacted with 2-bromo *N*-benzyloxy acetamide **9** under basic conditions. Again, formation of cyclic products **10** and **11**, and not the desired product **4**, was observed. These results demonstrated the high stabilities of the cyclic structures to the extent of eliminating hydroxylamine and *O*-benzylhydroxylamine as two otherwise poor leaving groups.

In the course of the synthesis of the triamine **8**, formation of a 1,4-disubstituted dihydropyrazine **14**, and not the desired aldehyde, was noted as the major product of the amino aldehyde **13** deprotection as shown in Scheme 3 (17). This occurred only when the protected amine in **13** carried an amide proton. Removal of this proton, using phthalyl as the amine-protecting group (**15**), produced exclusively the target aldehyde **16** and through the same deblocking process.

N-Alkyl hydroxamates have been known to maintain their metal-chelating abilities (*19*, *21*, *27*). The bacterial siderophore, desferrioxamine, as well as some other natural-product siderophores, are potent *N*-alkylated hydroxamic acid chelators (*20*), both in the form of open-chain and cyclic compounds where the hydroxamic nitrogen is incorporated into the ring structure. We anticipated, therefore, that replacing the amide proton of the alkylating agent 2-bromo *N*-bezyloxyacetamide by a small alkyl group should prevent the unwanted cyclizations and still preserve the metal-chelating abilities of the molecule. Thus, 2-bromo-*O*-benzyloxy-*N*-methylacetamide (BNMA, **19**) was prepared by the procedure of Esteves et al. (*38*) with slight modification (Scheme 4). This modification afforded the *O*-benzyl-2-bromo-*N*-methylhydroxylamine in a significantly higher overall yield than reported previously. The improved method involves the N-protection of *O*-benzylhydroxylamine with Boc, instead of 2,2,2-trichloroacetylation, followed by methylation of *N*-Boc-*O*-benzylhydroxylamine with iodomethane at elevated temperature and for 8 days. Additionally, the reaction of *O*-benzyl-*N*-methylhydroxylamine with bromoacetyl bromide was improved by lowering the temperature to −78 °C and carrying out the reaction for 4 h to give the analytically pure product **19** at a higher yield than the one reported previously (93.5 versus 36% reported) (*37*).

Alkylation of the triamine **8** (*17*) with BNMA afforded the product **20** with only minor amounts of the cyclized compounds (Scheme 5). The orthogonally protected **20** was stable and withstood chromatographic purification procedures with no later cyclizations. Removal of the protecting groups by successive hydrogenation/acidolysis proceeded smoothly and with no effect on the structure of the molecule. This synthesis afforded the target product **5** in the form of its TFA salt and at 40.7% overall yield.

MAb Conjugation. A conjugation procedure has been reported for the covalent attachment of unprotected hydroxamic acids to antibodies, using a hydrazide conjugating function (*37*). In this procedure, a ketone-derived linker (6-oxoheptanoic acid) is first implanted into the MAb molecule by an activated ester coupling. With the ketone groups serving as hydrazide anchors, the BCA is then conjugated to the MAb, at a low pH and in a group-selective (ketone-directed) manner, and with no conflict with the native amine groups of the protein. This protocol was used here to conjugate the DTPH hydrazide **5** to the CH2 domain-deleted anti-TAG-72 antibody ΔCH2HuCC49.

MALDI MS analyses of the conjugation products and, using MWs of the unconjugated starting MAb, the linker, and **5**, indicated a DTPH-to-MAb ratio of 2.2 for this conjugation.

Radiolabeling. Radiolabeling of the DTPH-ΔCH2HuCC49 conjugate with ^{177}Lu proceeded at high yields of

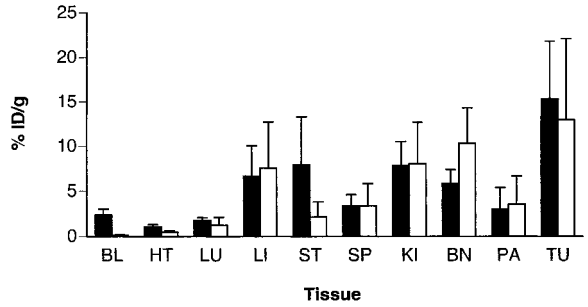


Figure 2. Biodistribution of ^{177}Lu-DTPH−ΔCh2HuCC49 in athymic nude mice bearing i.p. LS174T human colon cancer xenografts at 4 h (■) and 24 h (□) postinjection.

Table 1. Tumor-to-Normal Tissue Ratios for ^{177}Lu-DTPH−Δ*C*H2HuCC49 in LS174T-Bearing Athymic Nude Mice at 4 and 24 h Post-Injection

tissue	4 h	24 h
blood	6.4 ± 1.1	80.9 ± 18.9
heart	14.2 ± 2.7	27.0 ± 4.7
liver	8.5 ± 0.5	10.4 ± 0.3

radiolabeling (>96%) confirming the ability of the ligand to maintain its metal-chelating properties after conjugation to the MAb. The SEC−HPLC and Sephadex-25 (PD-10) showed the expected IgG elution patterns.

Biodistribution. Tumor and normal tissue uptake of the ^{177}Lu-DTPH−ΔCH2HuCC49 were studied in athymic nude mice, implanted i.p. with LS174T human colon carcinoma cells, at two time points as shown in Figure 2. The %ID/g values for this conjugate showed tumor uptake of 15.3 ± 6.5 and 13.0 ± 9.1 at 4 and 24 h time-points, respectively. The respective blood %ID/g values were 2.4 ± 0.7 and 0.16 ± 0.05 at these time-points. The tumor-to-normal tissue ratios (Table 1) indicated positive values for all organs with the tumor-to-blood ratio increasing significantly from the 4-h to the 24-h time points. These results demonstrate that the immunoreactivity of the labeled conjugate was not affected by the conjugation and radiolabeling procedures and the conjugate had a rapid blood clearance pattern characteristic of this antibody. It is important to note, however, that the in vivo stability of the ^{177}Lu complex of DTPH may not be as high as that of its pentacarboxylate counterpart. This is based on the observation that the 24-h bone concentration of ^{177}Lu-DTPH-ΔCH2HuCC49 (Figure 2) is over three times that of a ^{177}Lu-labeled DTPA conjugate (*17*).

Conclusion. In an attempt to evaluate the possibilities of designing derivatives with improved properties, a heterobifunctional pentahydroxamate version of the routinely used chelating agent, DTPA, was synthesized. The rationale was the study of a combination of the azaalkyl backbone of DTPA with the metal-chelating hydroxamic acid functionality. The new DTPH molecule, carrying a hydrazide arm on the core chain, formed a covalent conjugate with the ΔCh2HuCC49 as a model antibody and at a DTPH/MAb ratio of 2.2. The ^{177}Lu-labeled conjugate showed tumor uptake in LS174T-bearing nude mice both at 4 and 24 h postinjection timepoints. This study demonstrates the feasibility of synthesis, antibody conjugation, and radiolabeling of this novel BCA and provides the information needed for moving into the next phase of this investigation, the evaluation of the molecule with other radioactive metals and its comparison with DTPA as a multimetal chelator.

ACKNOWLEDGMENT

The authors thank Dr. Michael G. Bartlett (University of Georgia College of Pharmacy) for high resolution mass spectral measurements and helpful discussions. Also, we thank Marion Kirk and Lori Coward (UAB Comprehensive Cancer Center Mass Spectroscopy Shared Facility) for running the ESMS and MALDI spectra, respectively, and Soneshia McMillan for preparing the manuscript. This work was supported by NCI Grants CA62550 and CA78505.

Synthesis and Cleavage Experiments of Oligonucleotide Conjugates with a Diimidazole-Derived Catalytic Center

Birgit Verbeure, Carl Jeff Lacey, Mattheus Froeyen, Jef Rozenski, and Piet Herdewijn*

Laboratory of Medicinal Chemistry, Rega Institute for Medical Research, Katholieke Universiteit Leuven, Minderbroedersstraat 10, B-3000 Leuven, Belgium. Received October 5, 2001;
Revised Manuscript Received December 11, 2001

Ribonuclease mimics based on diimidazole derived constructs in combination with or without additional amino groups have been synthesized and conjugated to oligonucleotides. The imidazole moiety was used either unprotected, protected with a monomethoxytrityl group or a *tert*-butyloxy carbonyl group. Acylation reactions were carried out using the 3-acyl-1,3-thiazolidine-2-thione activation strategy. The peptides were coupled to the oligonucleotides with a mixture of PyBOP, DIEA an HOBt in DMF on solid support. The conjugates were purified by RP-HPLC and identified using negative ion mode mass spectrometry. Unfortunately, no cleavage of a linear RNA target under physiological conditions could be observed.

INTRODUCTION

The design and synthesis of a small synthetic molecule that mimics the active center of a naturally occurring ribonuclease and that is capable of cleaving RNA molecules is an interesting research subject (*1*). The conjugation of such an artificial ribonuclease to a nucleic acid, i.e., an antisense oligonucleotide, would potentially result in a ribonuclease capable of cleaving its target mRNA in a sequence-specific and RNA-selective manner. The study of these constructs could lead to more profound insights in the biochemical processes of hydrolysis in nature.

Nature has provided us with several examples of enzymes possessing phosphodiesterase activity. Studies to resolve the mechanism of pancreatic ribonuclease, RNase A, revealed the presence of two histidine groups around the catalytic center. The protonated imidazole group of His-119 and free imidazole moiety of His-12 have been shown to act as a general acid and general base catalyst, respectively, and hence promote the hydrolysis of phosphodiester bonds within RNA (*2*). Besides the imidazole moieties present in the enzyme's active center, the side chain amino group of Lys-41 would play an important role in the cleavage reaction as well by stabilization of the phosphorane intermediate. Several small organic molecules designed for cleaving RNA in a hydrolytic manner via an acid−base catalyzed mechanism have been reported in the past, including simple diamine or polyamine constructs, guanidine derivatives, or imidazole conjugates (*1*). Their potential as ribonuclease mimics might be elaborated by metal ion coordination due to the ability of imidazole rings to complex metal ions (*3*, *4*).

Our study on artificial ribonucleases has resulted in the synthesis of diimidazole derived constructs in combination with or without additional amino groups and their DNA conjugates. Monoimidazole conjugates of oligonucleotides have previously been reported to exhibit cleaving activity in the absence (*5*) and presence (*6*) of metal ions. However, the cleavage process of oligonucleotides bearing a histamine at the 3′-end in the presence of Zn^{2+} ions is not very efficient (*6*), i.e., 2−5% of RNA is cleaved in 19 h at room temperature. Since conjugation of an at random diimidazole construct to a strand of DNA does not promise the observance of hydrolytic activity, various backbones bearing juxtaposed functionalities have been used to link the catalytic unit to the oligonucleotide. The amino groups could provide additional charge stabilization on the transition-state or, in its protonated state, improve affinity for the phosphodiester backbone.

Different procedures for covalent derivatization of oligonucleotides have been reviewed recently by C. H. Tung (*7*). In the presented study, the RNase A mimics are to be conjugated to an amino-derivatized oligonucleotide via an amide linkage and are therefore provided by a free carboxy acid.

EXPERIMENTAL PROCEDURES

The ^{1}H NMR and ^{13}C NMR spectra were recorded with a Varian Gemini 200 spectrometer (Varian Inc., Palo Alto, CA). Trimethylsilane (TMS) was used as internal standard for the ^{1}H NMR spectra, $CDCl_3$ (δ = 77.0 ppm), DMSO-d_6 (δ = 39.7 ppm), or CD_3OD (δ = 49.0 ppm) for the ^{13}C NMR spectra (*s* = singlet, d = doublet, t = triplet, m = multiplet, br = broad, dAB = doublet in an AB system). Exact mass measurements were obtained performed on a quadrupole/orthogonal-acceleration time-of-flight (Q/oaTOF) tandem mass spectrometer (qTOF 2, Micromass, Manchester, UK) equipped with a standard electrospray ionization (ESI) interface. Samples were infused in a 2-propanol/water (1:1) mixture at 3 μL/min. Precoated SIL G/UV 254 plates (e.g., Silica gel/TLC-cards, Fluka Chemie, Steinheim, Switserland) were used for thin-layer chromatography (TLC), and products were visualized by UV-light, iodine staining, or ninhydrin and sulfuric acid/anisaldehyde spray. Column chromatography was performed on Acros silica gel (0.060−0.200 mm, Beerse, Belgium). Elemental analyses were performed at the University of Konstanz, Germany. Mixtures of solvents are given on a volume to volume basis (v/v) unless otherwise specified.

For the 5′-amino derivatization of the oligo, the 5′-Amino Modifier 5 from Glen Research Corporation (Sterling, VA) was purchased. HPLC analysis and purification of the oligonucleotide conjugates was done with a Waters Nova-Pak C_{18} column (60 Å, 4 μm) on a Waters 600E instrument using Millenium software for data analysis (Waters Corp., Milford, MA), or with a Merck-Hitachi L-6200A intelligent pump and Pharmacia LKB−Uvicord SII spectrophotometer (Amersham-Pharmacia-Biotech, Freiburg, Germany). The ribooligonucleotides were assembled by Eurogentec (Gent, Belgium). All experiments were conducted in RNase-free water that was prepared by treatment of bi-distilled water with diethyl pyrocarbonate followed by sterilisation.

3-Acetyl-1,3-thiazolidine-2-thione (1). A round-bottom flask, fitted with an addition funnel and equipped with a magnetic stirring bar, was charged with 2-mercaptothiazoline (5.961 g, 50 mmol), 75 mL of dichloromethane (DCM), and triethylamine (Et_3N) (5.060 g, 6.93 mL, 50 mmol). The flask was immersed in an ice bath and stirred. A solution of acetyl chloride (3.925 g, 3.57 mL, 50 mmol) in DCM (65 mL) was placed in the addition funnel and added to the chilled solution dropwise over 45 min. The yellow mixture was stirred at ice bath temperature for an additional 1 h and then at room temperature overnight. The mixture was then extracted successively with 0.2 M citric acid solution and saturated NaCl solution. The organic layer was dried over Na_2SO_4, filtered, and concentrated. The crude material was purified by vacuum distillation: 88−90 °C, 1.0×10^{-1} mbar, 74%, $R_f = 0.60$ (CH_2Cl_2/EtOH 98:2), Upon chilling, the viscous yellow oil crystallized as clear yellow crystals. ^{1}H NMR ($CDCl_3$): δ 2.79 (s, 3H, COC*H*$_3$), 3.30 (t, 2H, ^3J = 7.6 Hz, thiazolidine-C5-*H*$_2$) and 4.589 (t, 2H, ^3J = 7.6 Hz, thiazolidine-C4-*H*$_2$); exact mass (ESI MS, $C_5H_7NOS_2$ + H): calculated 162.0047, found 162.0042.

***N*$^{\alpha}$-Acetyl-L-his-glyOH (3).** To a solution of **1** (161 mg, 1 mmol) in THF (3 mL) was added a solution of Et_3N (101 mg, 139 μL, 1 mmol) and L-his-glyOH (212 mg, 1 mmol) in 3 mL of H_2O. The solution was stirred at room temperature for 16 h, and the solvents were removed on the rotary evaporator. The residue was triturated with THF, the THF drawn off, and the process repeated. The solid was dissolved in 50 mL of boiling methanol. The solution was filtered hot and concentrated, and upon standing at room temperature, the product crystallized. The white product was collected by suction, washed with cold methanol, and dried in a vacuum. Yield: 143 mg, 56%, $R_f = 0.39$ ($CHCl_3$/MeOH/NH_4OH 5:4:1); ^{1}H NMR (DMSO-d_6): δ 1.80 (s, 3H, C*H*$_3$CO), 2.85 (m, 2H, Im-C*H*$_2$), 3.70 (m, 2H, NHC*H*$_2$CO$_2$H), 4.46 (m, 1H, C*H*CO), 6.82 (d, 1H, ^4J = 0.6 Hz, Im-C5-*H*), 7.635 (d, 1H, ^4J = 1 Hz, Im-C2-*H*), 8.01 (d, 1H, ^3J = 8 Hz, AcN*H*) and 8.23 (t, 1H, ^3J = 5.7 Hz, CON*H*CH$_2$); exact mass (ESI MS, $C_{10}H_{14}N_4O_4$, $[M + H]^+$): calculated: 255.1093; found: 255.1078. Elemental analysis: calculated: C 45.62, H 5.74, N 21.23, found: C 45.44, H 5.70, N 21.25.

3-(*O*$^{\gamma}$-Benzyl-*N*$^{\alpha}$-Fmoc-aspartyl)-1,3-thiazolidine-2-thione (5). A mixture of *N*$^{\alpha}$(Fmoc)-*O*^{4}(Bzl)-Asp(OH) (10 mmol, 4.45 g), 1 equiv of DCC (10 mmol, 2.06 g), and 1 equiv of 2-mercaptothiazoline (10 mmol, 1.2 g) in DCM (50 mL) was stirred and cooled on an ice bath. A catalytic amount of DMAP was added to start the reaction. The reaction mixture was stirred at 0 °C for 2 h. The precipitate was removed by filtration and the filtrate evaporated to dryness. The crude product was chromatographed on a silica gel column eluted with 30% ethyl acetate in hexane. Appropriate fractions were pooled and evaporated to dryness, which resulted in yellow foam. R_f = 0.77 (DCM/MeOH 98:2); yield = 90%; ^{1}H NMR ($CDCl_3$): δ 2.9−3.2 (m, 4H, thiazolidine-C$_4$-*H*$_2$, β-C*H*$_2$), 4.1−4.6 (m, 5H, thiazolidine-C$_4$-*H*$_2$, Fmoc-C*H*$_2$C*H*), 5.113 (s, 2H, C*H*$_2$C$_6$H$_5$), 5.964 (d, 1H, ^3J = 7.4 Hz, CON*H*), 6.249 (m, 1H, α-C*H*), 7.2−7.8 (m, 13H, aromatic H benzyl and Fmoc); ^{13}C NMR ($CDCl_3$): δ 28.804 (thiazolidine CH_2N), 36.634 (Asp β-CH_2), 46.953 (Fmoc 9′), 52.234 (Asp α-CH), 56.756 (thiazolidine CH_2S), 66.863 (Bn *C*H$_2$Ph), 67.227 (Fmoc CH_2O), 120.006 (Fmoc 4′/5′), 125.075 (Fmoc 1′/8′), 127.129, 127.746, 128.383, 128.504, 128.626 (Fmoc 2′/7′ and 3′/6′; Bn o and m and p), 135.394 (Bn i), 141.312 (Fmoc 11′/12′), 143.710 (Fmoc 10′/13′), 156.032 (Fmoc OCONH, 170.388 and 172.543 (Asp CONH, COO) 201.315 (thiazolidine N*C*SS); exact mass (ESI MS, $C_{29}H_{26}N_2O_5S_2$, $[M + H]^+$): calculated 547.1361, found 547.1354.

***N*^{1}-(TFA)-*N*^{im}-(Mmtr)-histamine (6a).** A suspension of histamine·2HCl (10 mmol, 1.84 g) in anhydrous pyridine (20 mL) was stirred at room temperature in the presence of a catalytic amount of DMAP. After the addition of 1.2 equiv of trifluoroacetic anhydride (12 mmol, 1.69 mL), the mixture was stirred for an additional 2 h. Subsequently, 1 equiv of monomethoxytrityl chloride (10 mmol, 3.08 g) was added and stirring continued overnight. The solution was concentrated, and 300 mL saturated sodium bicarbonate solution was added. The mixture was extracted three times with DCM (3 × 100 mL), and the combined organic layers were washed with water and brine. The organic layer was dried over Na_2SO_4. After filtration, the solution was evaporated to dryness in a vacuum. Chromatographic purification on a silicagel column (DCM/MeOH 98:2) yielded 4.6 g of a white solid. $R_f = 0.2$ (DCM/MeOH 98:2); yield = 96%; ^{1}H NMR ($CDCl_3$): δ 2.761 (t, 2H, ^3J = 6.2 Hz, Im-C*H*$_2$), 3.6241 (q, 2H, ^3J = 5.8 Hz, NHC*H*$_2$), 3.807 (s, 3H, OC*H*$_3$), 6.621 (s, 1H, Im-C$_5$-*H*), 6.8−7.5 (m, Mmtr, Im-C$_2$-*H*), 8.553 (br t, 1H, TFA-N*H*); ^{13}C NMR ($CDCl_3$): δ 26.194 (Im-*C*H$_2$CH$_2$NH), 39.608 (Im-CH$_2$*C*H$_2$NH), 55.208 (Mmtr, OCH$_3$), 74.967 (Mmtr, CPh$_3$), 113.329 (Mmtr, m′), 118.701 (Im C$_5$), 127.776 (Mmtr p), 128.080 (Mmtr o), 129.597 (Mmtr m), 131.115 (Mmtr o′), 134.301 (Im C$_4$), 138.368 (Im C$_2$), 138.672 (Mmtr i′), 142.557 (Mmtr i), 159.249 (Mmtr p′); exact mass (ESI MS, $C_{27}H_{24}N_3O_2F_3$, $[M + H]^+$): calculated 480.1898, found 480.1873.

***N*^{im}-(Mmtr)-Histamine *O*^{4}-Benzyl-*N*$^{\alpha}$-Fmoc-aspartamide (7).** A NaOH solution (30 mL of a 10% solution) was added to a solution of 9 mmol of (**6a**) in ethanol (30 mL), and the mixture was stirred at room temperature. After 30 min, analysis on TLC indicated complete deprotection of the aliphatic amine. DCM (300 mL) and water (300 mL) were added. The aqueous layer was extracted twice more with DCM. The combined organic layers were washed with brine and dried over anhydrous sodium sulfate. After evaporation of the filtrate to dryness in a vacuum, the residual crude amine (**6b**) was mixed with 9 mmol of **(5)** (9 g) in anhyd THF (50 mL) and stirred at room temperature for an additional 15 min after disappearance of the bright yellow color. After evaporation of the reaction mixture to dryness, the product was purified by silica gel column chromatography (DCM/MeOH 98:2). Appropriate fractions were pooled and evaporated to dryness to yield a white foam. $R_f = 0.88$ (DCM/MeOH 95:5); yield = 80%; ^{1}H NMR ($CDCl_3$): δ 2.678 (t, 2H, ^3J = 6.1 Hz, Im-C*H*$_2$), 2.938 (d AB, 2H, ^2J = 12.4 Hz, ^3J = 5.8 Hz and 4.4 Hz, β-C*H*$_2$), 3.512 (m, 2H, Im-CH$_2$C*H*$_2$), 3.750 (s, 3H, OC*H*$_3$), 4.127 (t, 1H, ^3J = 6.8 Hz, Fmoc-C*H*CH$_2$), 4.354 (d, 2H, ^3J = 7.4 Hz, Fmoc-CHC*H*$_2$), 4.550 (m, 1H, α-C*H*), 5.098 (d, 2H, C*H*$_2$C$_6$H$_5$), 6.050 (d, 1H, ^3J = 8.8 Hz, Fmoc-N*H*), 6.569 (d, 1H, Im-C$_5$-*H*), 6.75−7.8 (aromatic C), 7.720 (d, 1H, Im-C$_2$-*H*); ^{13}C NMR ($CDCl_3$):

δ 27.347 (Im-*C*H_2CH$_2$NH), 36.422 (Asp β-CH$_2$), 39.608 (Im-CH$_2$*C*H$_2$NH), 47.075 (Fmoc 9′), 51.202 (Asp α-CH), 55.148 (Mmtr, OCH$_3$), 66.711 (Fmoc-CH$_2$O), 67.136 (Bn *C*H$_2$Ph), 74.724 (Mmtr, CPh$_3$), 113.208 (Mmtr, m′), 118.519 (Im C$_5$), 119.946 (Fmoc 4′), 125.136 (Fmoc 1′), 127.108, 127.746, 127.989, 128.262, 128.596 (Fmoc 2′/7′ and 3′/6′; Mmtr o and p; Bn i and o and m), 129.627 (Mmtr m), 131.115 (Mmtr o′), 134.453 (Im C$_4$), 135.455 (Bn p), 138.550 (Mmtr i), 138.915 (Im C$_2$), 141.282 (Fmoc 11′/12′), 142.708 (Mmtr i), 143.710 (Fmoc 10′/13′), 156.032 (Fmoc OCONH, 159.098 (Mmtr p′), 169.963 (Asp COO), 171.572 (Asp CONH); exact mass (ESI MS, $C_{51}H_{46}N_2O_6$, $[M + H]^+$): calculated 810.3495, found 810.3519.

***N*^{Im}(Mmtr)-Urocanic Acid (9).** To a suspension of urocanic acid (0.69 g, 5 mmol) in anhydrous pyridine (20 mL) was added 1 equiv of monomethoxytrityl chloride (5 mmol, 1.54 g) and the reaction mixture was stirred overnight at room temperature. After concentration of the reaction mixture under vacuum, chloroform (200 mL) was added. The organic layer was washed twice with a citric acid solution (18% m/v) and once with brine, dried over anhydrous Na_2SO_4 and concentrated under vacuum. The reaction product was precipitated from diethyl ether and isolated as a white solid in 50% yield.

^{1}H NMR ($CDCl_3$): δ 3.816 (s, 3H, −O−C*H*$_3$), 6.5395 (d, 1H, ^3J = 15.4 Hz, HOOC−C*H*=CH-), 6.8−7.4 (m, 15H, aromatic H Mmtr and Im-C$_5$-*H*), 7.563 (d, 1H, ^3J = 15.6 Hz, Im-C*H*=CH-), 7.566 (s, 1H, Im-C$_2$-*H*); ^{13}C NMR ($CDCl_3$): δ 55.269 (Mmtr, −O−CH$_3$), 75.513 (Mmtr, CPh$_3$), 113.511 (Mmtr, m′), 116.334 (Im C$_5$), 124.225 (−CH=*C*H−COOH), 127.897 (Mmtr p), 128.262 (Mmtr o), 129.597 (Mmtr m), 131.145(Mmtr o′), 133.876 (Im C$_4$), 136.760 (Im-*C*H=CH-, 137.276 (Mmtr i′), 140.493 (Im C$_2$), 142.192 (Mmtr i), 159.371 (Mmtr p′), 171.693 (-*C*OOH); exact mass (ESI MS, $C_{26}H_{22}N_2O_3$ $[M-H]^-$): calculated 409.1552, found 409.1546.

***N*^{Im}(Mmtr)-imidazole acetic acid (10).** Imidazole acetic acid·HCl (1.62 g, 10 mmol) was suspended in DCM (40 mL). Subsequently, 3 equiv of triethylamine (30 mmol, 4.16 mL) and a catalytic amount of DMAP were added. After 15 min. stirring at 0 °C, 1 equiv of monomethoxytrityl chloride (3.08 g, 10 mmol) was added. After 1 h of reaction, an additional equiv of monomethoxytrityl chloride was added. After reaction, 50 mL of DCM was added. The solution was extracted with 5% (m/V) citric acid (100 mL), half saturated sodium chloride (100 mL) and two times with brine (75 mL). The organic layer was dried over anhydrous Na_2SO_4 and filtered, and the filtrate was evaporated to dryness in a vacuum. The residue was covered with 13.4 mL of 20% (m/V) potassium hydroxide in methanol and 3.4 mL of water. The mixture was boiled on a steam bath for 5 min and allowed to cool. After addition of 60 mL of water, the aqueous layer was extracted three times with diethyl ether (3 × 100 mL). The aqueous layer was chilled in an ice bath, and glacial acetic acid was added dropwise under stirring till pH 5. The mixture was extracted twice with DCM (200 mL). The combined organic layers were washed with brine, dried over anhydrous Na_2SO_4, and filtered. After evaporation of the solvent in a vacuum, the crude material was triturated in THF/diethyl ether (1:1) and placed in a refrigerator for several hours. The product was collected by filtration and washed with fresh chilled THF/diethyl ether, and the resulting white powder dried in a vacuum over P_2O_5. Yield = 77%; ^{1}H NMR (DMSO-d_6): δ 3.453 (s, 2H, Im-C*H*$_2$COOH), 3.768 (s, 3H, OC*H*$_3$), 6.769 (s, 1H, Im-C5-*H*), 6.95−7.12 and 7.35−7.46 (14H, aromatic H), 7.284 (d, 1H, Im-C2-*H*); ^{13}C NMR ($CDCl_3$): δ 34.289 (Im-*C*H$_2$CO), 55.322 (Mmtr, OCH$_3$), 74.322 (Mmtr, CPh$_3$), 113.687 (Mmtr, m′), 119.333 (Im C$_5$), 127.953, 128.408, 129.349, 130.897 (Mmtr p o m o′), 134.357, 134.812 (Im C$_4$ and Im C$_2$), 137.756 (Mmtr i′), 142.825 (Mmtr i), 158.911 (Mmtr p′), 172.448 (COOH); exact mass (ESI MS, $C_{25}H_{22}N_2O_3$, $[M + H]^+$): calculated: 399.1708; found: 399.1689.

***N*$^{\alpha}$(TFA)-*N*^{Im}(Mmtr)-histidine (11).** Histidine (10 mmol, 1.55 g) was suspended in a mixture of methanol (50 mL) and triethylamine (50 mmol, 7 mL). Five equivalents of ethyl trifluoroacetate (50 mmol, 6 mL) were added over a period of 30 min. After 2 h stirring at room temperature, the reaction mixture was evaporated till dryness in a vacuum. This crude reaction product was coevaporated twice with anhyd pyridine and finally suspended in anhyd pyridine (20 mL). One equivalent of monomethoxytrityl chloride (10 mmol, 3.08 g) was added and the reaction mixture stirred for 2 h at room temperature. EtOAc (300 mL) was added, and this solution was extracted twice with a citric acid solution (18% m/v), washed with brine, and dried over anhydrous sodium sulfate. During evaporation of the solvent under vacuum, the product precipitated as a white solid. Therefore, the mixture was placed in a refrigerator overnight and the product was collected by filtration, washed with freshly chilled EtOAc, and dried in a vacuum over P_2O_5. R_f = 0.25 (DCM/MeOH 95:5); yield = 92%; ^{1}H NMR ($CDCl_3$): δ 3.384 (dAB, 2H, ^2J = 14.6 Hz, ^3J = 3.3 Hz and 5.8 Hz, β-C*H*$_2$ (His)), 3.820 (s, 3H, OC*H*$_3$), 4.499 (m, 1H, α-C*H*), 6.584 (d, 1H, ^4J = 1.6 Hz, Im-C$_5$-*H*), 6.8−7.4 (aromatic H Mmtr), 7.424 (d, 1H, ^3J = 5.2 Hz, TFA-N*H*-), 7.881 (d, 1H, ^4J = 1.6 Hz, Im-C$_2$-*H*); ^{13}C NMR ($CDCl_3$): δ 27.195 (His, β-CH$_2$), 52.841 (His, α-CH$_2$), 55.269 (Mmtr, OCH$_3$), 76.682 (Mmtr, CPh$_3$), 113.724 (Mmtr, m′), 121.190 (Im C$_5$), 128.474 (Mmtr p), 128.656 (Mmtr o), 129.415 (Mmtr m), 131.054 (Mmtr o′), 131.651 (Im C$_4$), 132.845 (Im C$_2$), 137.124, 141.252 (Mmtr i), 159.614 (Mmtr p′), 172.452 (His −COOH); exact mass (ESI MS, $C_{28}H_{24}N_3O_4F_3$, $[M + H]^+$): calculated 524.1797, found 524.1792.

Coupling Procedure for Diimidazole Constructs 12, 13, and 14. The Fmoc-group was removed from compound **7** by treatment for 10 min with 20% piperidine in toluene. After evaporation to dryness in a vacuum, the residue was coevaporated with toluene two times more. The free amine was dissolved in DCM and added to a mixture of the acid **9**, **10**, or **11**, and DIEA in DMF. Consequently, 1 equiv of PyBOP was added to the reaction mixture. After stirring for 3 h at room temperature, the mixture was diluted with DCM and extracted twice with saturated $NaHCO_3$ solution. After washing with brine, the organic phase was dried over anhydrous Na_2SO_4, filtered, and evaporated to dryness in a vacuum. The product was further purified on silica gel column chromatography (DCM/MeOH 98:2).

Benzyl 3-[((2*E*)-3-{1-[(4-Methoxyphenyl)(diphenyl)methyl]-1*H*-imidazol-4-yl}-2-propenoyl)amino]-4-[(2-{1-[(4-methoxyphenyl)(diphenyl)methyl]-1*H*-imidazol-4-yl}ethyl)amino]-4-oxobutanoate (12). Additional extraction of a solution of the product in diethyl ether/ethyl acetate (4:1) with water (four times) was needed for complete purification. The product was isolated as a white foam in 78% yield. R_f = 0.52 (DCM/MeOH 95/5); ^{1}H NMR ($CDCl_3$): δ 2.671 (t, 2H, ^3J = 6.6 Hz, Im-C*H*$_2$CH$_2$), 2.878 (dAB, 2H, ^2J = 17.3 Hz, ^3J = 4.6 and 6.2 Hz, β-C*H*$_2$ (Asp)), 3.490 (m, 2H, Im-CH$_2$C*H*$_2$NH), 3.774 and 3.816 (2 × s, 2 × 3H, OC*H*$_3$), 4.896 (m, 1H, α-C*H* (Asp)), 5.087 (d, 2H, J = 1 Hz, C*H*$_2$C$_6$H$_5$), 6.573 (d, ^3J = 15 Hz, Im-CH=C*H*CO), 6.5−7.5 (aromatic H); ^{13}C NMR ($CDCl_3$): δ 27.620 (Im-*C*H$_2$CH$_2$), 35.845 (Asp

β-CH_2), 39.487 (Im-CH_2CH_2NH), 49.290 (Asp α-CH), 55.208 (Mmtr, OCH_3), 66.711 (Bn CH_2Ph), 74.815 and 75.270 (Mmtr, CPh_3), 113.269 (Mmtr, m′), 118.094 and 118.489 (Im C_5), 123.709 (Im-CH=*C*HCO), 127.928−131.145 (Mmtr p o m o′; Bn o m p), 134.059 and 134.544 (Im C_4), 135.546 (Bn p), 137.215 (Im-*C*H=CH), 138.520 and 138.611 (Mmtr i′), 140.068 (Im C_2), 142.344 and 142.799 (Mmtr i), 159.098 and 159.310 (Mmtr p′), 166.382 (=CH*C*ONH), 170.267, 171.846 (CONH; COO); exact mass (ESI MS, $C_{62}H_{56}N_6O_6$, $[M + H]^+$): calculated 981.4339, found 981.4312.

Benzyl 3-[({1-[(4-Methoxyphenyl)(diphenyl)methyl]-1*H*-imidazol-4-yl}acetyl)amino]-4-[(2-{1-[(4-methoxyphenyl)(diphenyl)methyl]-1*H*-imidazol-4-yl}ethyl)amino]-4-oxobutanoate (13). Complete purification was achieved by silica gel column chromatography using 2% methanol in ethyl acetate as the mobile phase. Appropriate fractions were pooled and evaporated to dryness in a vacuum to yield the product as a white foam. Procedure for Ester Hydrolysis of Compounds 12 and 13. The compound **12** (or **13**) was dissolved in EtOH (5 mL) and a 10% NaOH (m/v) solution (1 mL) was added. After 30 min, DCM (200 mL) was added and the resulting solution was extracted with water and brine. The organic layer was dried over anhydrous sodium sulfate and evaporated in a vacuum. The products were further purified on silica gel column chromatography ($CHCl_3$/MeOH/Et_3N 95/5/0.5). The fractions containing the title compound were pooled and the solvent evaporated. Traces of Et_3N could be removed by extraction of a solution of the product in DCM with a 0.1 M citric acid solution.

3-[(3-{1-[(4-Methoxyphenyl)(diphenyl)methyl]-1*H*-imidazol-4-yl}acryloyl)amino]-4-[(2-{1-[(4-methoxyphenyl)(diphenyl)methyl]-1*H*-imidazol-4-yl}-ethyl)amino]-4-oxobutanoic Acid (15). The product was isolated as a hygroscopic, white solid. $R_f = 0.60$ ($CHCl_3$/MeOH/Et_3N 90/10/0.5); yield = 71%; ^{1}H NMR ($CDCl_3$): δ 2.62−2.84 (m, 4H, Im-CH_2CH$_2$ and β-CH_2 (Asp)), 3.418 (m, 2H, Im-CH_2CH_2NH), 3.787 and 3.809 (2 × s, 2 × 3H, OCH_3), 4.602 (m, 1H, α-C*H* (Asp)), 6.617 (d, $^3J = 15.8$ Hz, Im-CH=*C*HCO), 7.433 (d, $^3J = 15,4$ Hz, Im-CH=*C*HCO), 6.5−7.5 (aromatic H); ^{13}C NMR ($CDCl_3$): δ 26.588 (Im-*C*H_2CH_2), 38.182 (Asp β-CH_2), 39.396 (Im-CH_2*C*H_2NH), 50.504 (Asp α-CH), 55.239 (Mmtr, OCH_3), 75.300 and 75.847 (Mmtr, CPh_3), 113.451 (Mmtr, m′), 119.157 and 119.703 (Im C_5), 123.193 (Im-CH=*C*HCO), 126.987−131.115 (Mmtr p o m o′), 133.512 and 133.937 (Im C_4), 136.699 (Im-*C*H=CH), 137.245 (Mmtr i′), 139.825 (Im C_2), 141.859 and 142.253 (Mmtr i), 159.340 (Mmtr p′), 166.230 (=CH*C*ONH), 171.177, (CONH), 174.455 (COOH); exact mass (ESI MS, $C_{55}H_{50}N_6O_6$, $[M + H]^+$): calculated 891.3869, found 891.3863.

3-({3-{1-[(4-Methoxyphenyl)(diphenyl)methyl]-1*H*-imidazol-4-yl}-2-[(trifluoroacetyl)amino]-propanoyl}amino)-4-[(2-{1-[(4-methoxyphenyl)-(diphenyl)methyl]-1*H*-imidazol-4-yl}ethyl)amino]-4-oxobutanoic Acid (18). Compound **14** (500 mg, 0.45 mmol) was dissolved in 5 mL of EtOH and 1 mL of 10% NaOH solution was added. After 30 min, DCM (200 mL) was added and the solution was extracted with water and brine. The organic layer was dried over anhydrous Na_2SO_4 and evaporated in a vacuum. The residue was treated overnight with 5 equiv (calculated on the starting product, 2.25 mmol, 0.27 mL) of ethyl trifluoroacetate in a mixture of methanol (3 mL) and triethylamine (2.25 mmol, 0.3 mL). The product was isolated by extraction after the addition of 30 mL water with two times 30 mL chloroform. The combined organic layers were washed

twice with brine and dried over anhydrous Na_2SO_4 and filtered, and the filtrate was evaporated in a vacuum. The acid was further purified by silica gel column chromatography ($CHCl_3$/MeOH/Et_3N 95/5/0.5). The positive fractions were pooled, and the solvent was evaporated. The residue was dissolved in DCM and extracted with 0.2 M citric acid and washed with brine. The organic layer was dried over anhydrous Na_2SO_4, filtered, and evaporated in a vacuum to yield the title compound as a hygroscopic, white solid. R_f = 0.51 ($CHCl_3$/MeOH/Et_3N 90/10/0.5); yield = 60%; ^{1}H NMR ($CDCl_3$): δ 2.60−2.78 (m, 4H, Im-CH_2CH$_2$ and β-CH_2 (Asp)), 3.30−3.49 (m, 2H, Im-CH$_2$CH_2), 4.381 (q, 1H, J = 5.87 Hz, α-C*H* (Asp)), 4.664 (br m, 1H, α-C*H* (His)), 6.5−7.4 (aromatic H), 7,471 (t, 1H, OCN*H*CH$_2$), 7.846 (d, 1H, OCN*H*CH (Asp)), 8.795 (br s, 1H, OCN*H*CH (His)); ^{13}C NMR ($CDCl_3$): δ 27.863 (Im-*C*H$_2$CH$_2$NH), 29.654 (His β-CH$_2$), 39.305 (Im-CH$_2$*C*H$_2$-NH and Asp β-CH$_2$), 51.688 (Asp α-CH), 53.721 (His α-CH$_2$), 55.148 (Mmtr, OCH$_3$), 74.724, 113.178 (Mmtr, m′), 118.459 and 119.794 (2 × Im C$_5$), 127.958, 129.567, 131.054 (Mmtr p o m o′), 134.119 and 134.392 (Im C$_4$), 138.308 (Mmtr i′), 138.824 (Im C$_2$), 142.375 and 142.648 (Mmtr i), 159.098 (Mmtr p′), 168.506, 170.874 (2 × CONH), 175.123 (COOH); exact mass (ESI MS, $C_{57}H_{52}N_7O_7F_3$, $[M + H]^+$): calculated 1004.3958, found 1004.3967.

3-{[(9*H*-Fluoren-9-ylmethoxy)carbonyl]amino}-4-[(2-{1-[(4-methoxyphenyl)(diphenyl)methyl]-1*H*-imidazol-4-yl}ethyl)amino]-4-oxobutanoic Acid (20). Compound **7** was subjected to mild hydrolysis by the addition of 5 mL of 20% (m/v) potassium carbonate in water to a solution of 500 mg of the compound in 5 mL of ethanol. The reaction mixture was stirred at room temperature for 30 min. The reaction mixture was concentrated in a vacuum, diluted with 150 mL water, and extracted two times with DCM (2 × 75 mL). The pooled organic layers were washed 0.1 M citric acid and with brine, dried over anhydrous Na_2SO_4, and filtered, and the filtrate was evaporated to dryness in a vacuum. The product was purified by silica gel column chromatography (MeOH/DCM/Et_3N 10:90:0.5). The fractions containing the title compound were pooled and the solvent evaporated. Traces of Et_3N could be removed by extraction of a solution of the product in DCM with 0.1 M citric acid solution. The organic layer was dried over anhydrous Na_2SO_4, filtered, and evaporated in a vacuum to yield the title compound as a white solid. R_f = 0.13 (DCM/MeOH 95/5); yield = 63%; ^{1}H NMR ($CDCl_3$): δ 2.64−2.96 (m, 4H, Im-CH_2CH$_2$ and β-CH_2 (Asp)), 3.455 (m, 2H, Im-CH$_2$CH_2NH), 3.752 (s, 3H, OCH_3), 4.08−4.38 (m, 3H, Fmoc-C*H*CH$_2$ and Fmoc-CHCH_2) 4.470 (br q, 1H, α-C*H* (Asp)), 6.550 (d, 1H, J = 8.5 Hz, N*H* (Asp)), 6.593 (s, 1H, Im-C$_5$-*H*), 6.74−7.56 (aromatic H); ^{13}C NMR ($CDCl_3$): δ 26.710 (Im-*C*H$_2$CH$_2$NH), 38.668 (Asp β-CH$_2$), 39.426 (Im-CH$_2$*C*H$_2$NH), 47.075, 52.325 (Asp α-CH), 55.208 (Mmtr, OCH$_3$), 65.072, 66.833, 75.877 (Mmtr, CPh$_3$), 113.511 (Mmtr, m′), 119.794 ((Im C$_5$), 125.378, 126.987−131.115, 133.452 (Im C$_4$), 136.699, 137.245 (Im C$_2$), 141.221 and 141.798 (Mmtr i), 144.044, 144.196, 156.275, 159.371 (Mmtr p′), 171.086 (CONH), 175.365 (COOH); exact mass (ESI MS, $C_{44}H_{40}N_4O_6$, $[M + H]^+$): calculated 721.3025, found 721.3027.

3-(*N*$^\alpha$-TFA-*N*^{im}-*t*-Boc-L-histidyl)-thiazolidine-2-thione (21). Dicyclohexylcarbodiimide (DCC) (2.063 g, 10 mmol) was weighed into a round-bottom flask, equipped with a stirring bar, followed by thiazolidine-2-thione (MTA) (1.192 g, 10 mmol) and 20 mL (2 mL/mmol) of DCM. Once the DCC had dissolved, the flask was immersed in an ice bath. To the cold mixture was added N^α(TFA)-N^{im}(BOC)-L-histidine (3.513 g, 10 mmol) followed by DMAP (61 mg, 5 mol %). The well-stirred solution was kept at ice bath temperature for 135 min and then overnight at room temperature. The resulting yellow mixture was chilled in a refrigerator for several hours and filtered by suction, and the precipitated urea was washed with several small portions of fresh DCM. The solvent of the filtrate was stripped off, and the oil was taken up in diethyl ether and concentrated. Dissolution in ether and concentration were repeated until the product precipitated or crystallized. After chilling, the yellow crystals were collected by suction and washed with ether. R_f = 0.84 (DCM/MeOH 9:1); yield = 65%; ^{1}H NMR ($CDCl_3$): δ 1.62 (s, 9H, C[CH_3]$_3$), 3.25 (d, 2H, ^3J = 5.2 Hz, β-CH_2), 3.398 (m, 2H, thiazolidine-C$_5$-H_2), 4.581 (m, 2H, thiazolidine-C$_4$-H_2), 6.517 (br q, 1H, ^3J = 5.5 Hz, α-C*H*), 7.179 (d, 1H, ^4J = 0.8 Hz, Im-C4-*H*), 8.004 (d, 1H, ^4J = 1.4 Hz, Im-C2-*H*) and 8.458 (br d, ^3J = 5.2 Hz, TFA-N*H*); exact mass (ESI MS, $C_{16}H_{19}F_3N_4O_4S_2$, $[M + H]^+$): calculated: 453.0878; found: 453.0879. Elemental analysis: calculated: C42.48, H 4.25, N 12.35; found: C 42.56, H 4.38, N 12.41.

***N*$^\alpha$,*N*$^\delta$-bis(*N*$^\alpha$-TFA-*N*^{im}-*t*-Boc-L-histidyl)ornithine (22).** Ornithine·HCl (295 mg, 1.747 mmol) was dissolved in a mixture of MeOH (3.5 mL) and water (42 drops). To the resulting stirred solution was added Et_3N (354 mg, 484 μL, 3.494 mmol) and then a solution of **21** (1.72 g, 1.09 × 3.494 mmol) in 10.5 mL of THF. The mixture was stirred for 24 h. The solution was diluted with more MeOH and concentrated on a rotary evaporator. The residue was diluted with DCM (80 mL) and extracted with 0.2 M citric acid (80 mL). The organic layer was dried over anhydrous Na_2SO_4 and filtered, and the filtrate was concentrated. Purification was done by column chromatography (silica gel, DCM/MeOH 85:15). Appropriate fractions were pooled and evaporated to yield the title compound as clear glassy material. Yield: 34%; ^{13}C NMR (DMSO-d_6): δ 25.435 (γ-CH$_2$ (Orn)), 27.529 (CH$_3$), 27.863 (β-CH$_2$ (Orn)), 29.411 (β-CH$_2$ (His)), under DMSO (δ-CH$_2$ (Orn)), 53.176 (α-CH$_2$ (His)), 58.245 (α-CH$_2$ (Orn)), 85.470 (C[CH$_3$]$_3$), 107.474/113.211/118.978/124.714 (CF$_3$), 114.698 (Im-C5), 137.067 (Im-C4), 139.343 (Im-C2), 146.961 (NHCOO), 155.460/156.188/156.886/157.615 (*C*OCF$_3$), 169.057 and 169.512 (CONH), 174.520 (COOH); exact mass (ESI MS, $C_{31}H_{40}F_6N_8O_{10}$, $[M + H]^+$): calculated: 799.2850; found: 799.2842; elemental analysis: calculated: C 44.60, H 5.31, N 13.43; found C 44.77, H 5.07, N 13.68.

Benzyl *N*$^\alpha$,*N*$^\epsilon$-Bis(*N*$^\alpha$-TFA-*N*^{im}-*t*-Boc-L-histidyl)lysinate (23). Benzyl lysinate·2TsOH (1.161 g, 2 mmol) was covered with THF (10 mL). To the stirred mixture was added Et_3N (304 mg, 416 μL, 3 mmol), followed by dropwise addition of ethanol (approximately 0.5 mL) until a solution obtained. A solution of **21** (1.855 g, 4.1 mmol) in THF (10 mL) was added, followed by an additional 1 equiv of Et_3N. The solution was stirred at room temperature for 3 days. The reaction mixture was concentrated under reduced pressure, diluted with DCM (200 mL), and extracted with cold 0.2 M citric acid (200 mL), H_2O (200 mL), and brine (100 mL). The organic layer was dried over anhydrous Na_2SO_4 and filtered, and the filtrate was concentrated under reduced pressure. The crude material was purified by column chromatography (silica gel, CH_2Cl_2/MeOH 97.5:2.5). Appropriate fractions were pooled, and the solvent was evaporated to yield the title compound as clear glassy material. Yield = 84%, R_f = 0.09 (CH_2Cl_2/MeOH 97.5:2.5); ^{1}H NMR ($CDCl_3$): δ 1.36−1.54 (2 × m, 4H, γ and δ-CH_2 (Lys)), 1.603 (s, 18 H, 6 × CH$_3$), 1.786 (m, 2H, β-CH_2 (Lys)), 2.96−3.1 (m, 4H, 2 × β-CH_2

{Bis[(2-{*N*$^{\alpha}$-TFA-*N*^{im}-*t*-Boc-L-histidyl}amino)propyl]-amino}acetic Acid (30). Compound **28** was hydrogenolyzed as described for compound **29** during 45 h. After filtration and removal of ethanol from the filtrate, the crude material was purified by column chromatography (silica gel, DCM/MeOH/H_2O 8:2:0.1). Appropriate fractions were pooled and evaporated to yield the title compound as gummy material that upon chilling solidifies to a clear glass. R_f = 0.34 (CH_2Cl_2/MeOH/H_2O 8:2:0.1); yield = 60%; ^{13}C NMR ($CDCl_3$): δ 24.342 ($NHCH_2CH_2CH_2N$), 27.650 (CH_3), 29.987 (β-CH_2 (Asp)), 36.573 ($OCNHCH_2CH_2CH_2N$), 52.841 ($OCNHCH_2CH_2$-CH_2N), 53.539 (α-CH (Asp)), 85.832 (C[CH_3]$_3$), 112.935/118.671 (CF_3), 115.120 (Im-C5), 137.094 (Im-C4), 138.095 (Im-C2), 146.745 (NCOO), 157.034/157.762 (*C*OCF$_3$), 170.540 (N*C*OCH); exact mass (ESI MS, $C_{34}H_{47}F_6N_9O_{10}$, $[M + H]^+$): calculated: 856.3428; found: 856.3421. Elemental analysis: calculated: C 46.26, H 5.71, N 14.28; found C 45.67, H 5.79, N 14.16.

Bis(1-methyl-4-piperidinyl)methylamine·3HCl (33). A three-neck round-bottom flask containing a magnetic stirring bar, a reflux condenser, and an addition funnel were dried in an oven, assembled hot, and placed under a positive N_2 pressure. After cooling to room temperature, the flask was charged with Mg (2.072 g, 1.25 × 68.2 mmol). A solution of freshly distilled 4-chloro-1-methylpiperidine (10.937 g, 68.2 mmol) in dry THF (41 mL, 50 mL/0.1 mol of chloride) was transferred via a cannula into the addition funnel. The chloride solution was then added to the flask and the flask immersed in an oil bath preheated to 60 °C. A small crystal of I_2 and a drop of 1,2-dibromoethane were added, and the temperature was increased toward 80 °C. External heating was maintained from the onset of the Grignard reaction so that reflux continued for 6.5 h. A solution of 4-cyano-1-methylpiperidine (8.471 g, 68.2 mmol) in anhyd THF (34.1 mL, 50 mL/0.1 mol of nitrile) was transferred to the addition funnel via a cannula and added dropwise over 30 min to the refluxing Grignard mixture. Reflux was continued for 13.5 h after which time the flask was allowed to cool to room temperature and then immersed in an ice bath. Initial slow dropwise addition of 150 mL of methanol produced a solution which was then poured into 300 mL of chilled methanol, with an additional 50 mL added as a rinsing to the bulk solution. The flask was immersed in an ice bath, and, over a 13-min period, $NaBH_4$ (6.82 g, 1 g/10 mmol of nitrile) was added in portions to the well-stirred solution. The flask was removed from the ice bath and the solution stirred for 1.5 h, until gas evolution ceased. The solvents were stripped off, the residue was covered with a mixture of 150 mL of diethyl ether and 150 mL of THF, and the mixture was allowed to stand at room temperature so that the insoluble material separated. The solid was removed by suction filtration and washed well with Et_2O/THF (1:1). The combined filtrate was concentrated to a viscous oil, which, upon covering with DCM, deposited colorless needles which were removed by filtration and discarded. The filtrate was adjusted with DCM to a volume of 200 mL and extracted with 100 mL of 10% (m/v) NaOH. After the addition of saturated NaCl solution (100 mL), the aqueous layer was extracted with DCM (2 × 100 mL). The combined organic extracts were dried over anhydrous Na_2SO_4 and filtered, and the filtrate concentrated to an oil which was then heated to 55 °C under high vacuum for 2 h (crude yield: 11.25 g). The crude material (11.025 g) was dissolved at ice bath temperature in 50 mL of 6 N HCl. The acid was removed on a rotary evaporator. Dissolution in and removal of water followed by dissolution in and removal of ethanol left a clear gummy material which was crystallized by boiling in isopropyl alcohol and adding methanol in small portions until a solution was obtained. Upon standing at room temperature, fine powder-like crystals deposited from the solution. The flask was kept at 2 °C for 6 days. Due to the degree of hygroscopicity of the product, the supernatant was drawn off, the crystals washed with isopropyl alcohol, and the washing drawn off. The very hygroscopic, white crystals were dried in a vacuum in the presence of P_2O_5. The supernatant and the washing were combined and then concentrated until product appeared. Crystallization overnight at 2 °C produced a second crop, isolated as described above. R_f = 0.19 (DCM/MeOH/NH_4OH 8:2:0.2); yield = 61%; ^{1}H NMR (D_2O) δ 1.50−2.30 (m, 10H, piperidyl C3-*H*$_2$, C4-*H*, and C5−H_2), 2.888 (s, 6H, N−CH_3), 3.078 (br t, 4H, ^3J = 12.2 Hz, piperidyl C2- and C6-H_{ax}), 3.226 (br t, 1H, ^3J = 12.2 Hz, C*H*-NH_2) and 3.55−3.75(br m, 4H, piperidyl C2- and C6-H_{eq}). exact mass (ESI MS, $C_{13}H_{27}N_3$, $[M + H]^+$): calculated: 226.2283; found: 226.2260.

3-Ethoxycarbonyl-1,3-thiazolidine-2-thione (35). 2-Mercaptothiazoline (1,3-thiazolidine-2-thione, 2.38 g, 20 mmol) was placed in a round-bottom flask, equipped with a magnetic stirring bar and fitted with an addition funnel and $CaCl_2$ drying tube, and partially dissolved in anhydrous DCM (20 mL). After addition of Et_3N (2.024 g, 2.77 mL, 20 mmol) to the mixture, the flask was immersed in an ice bath. The addition funnel was charged with a solution of ethyl chloroformate (2.170 g, 1.91 mL, 20 mmol) in DCM (20 mL). The ethyl chloroformate solution was added dropwise to the cold and stirred reaction mixture over 15 min. The reaction mixture was stirred to room-temperature overnight. After being diluted with 100 mL of DCM, the reaction mixture was extracted with 0.2 M citric acid solution (100 mL), H_2O (100 mL), and brine (100 mL). The organic layer was dried over anhydrous Na_2SO_4 and filtered, and the filtrate was concentrated to a yellow oil. Purification was carried out using column chromatography (silica gel, DCM/EtOH 97.5:2.5). Appropriate fractions were pooled and evaporated to yield the title compound as a bright yellow oil. R_f = 0.71 (DCM/EtOH, 97.5:2.5); yield = 89%; ^{1}H NMR ($CDCl_3$): δ 1.372 (t, 3H, ^3J = 7.2 Hz, CH_3), 3.307 (t, 2H, ^3J = 7.5 Hz, thiazolidine-C5-*H*), 4.352 (q, 2H, ^3J = 7.1 Hz, OCH_2CH_3) and 4.528 (t, 2H, ^3J = 7.5 Hz, thiazolidiene-C4-*H*); ^{13}C NMR ($CDCl_3$): δ 13.953 (−CH_3), 28.097 (thiazolidine C5), 55.473 (thiazolidine C4), 63.637 (CH_2O), 151.167 (OCON), 199.728 (NCSS); exact mass (ESI MS, $C_6H_9NO_2S_2$, $[M + H]^+$): calculated: 192.0153; found: 192.0176.

Ethyl Bis(1-methyl-4-piperidinyl)methylcarbamate (36). Compound **33** (3.348 g, 10 mmol) was dissolved in ethanol (40 mL). To this solution were added Et_3N (3.036 g, 4.16 mL, 30 mmol) and a solution of **35** (1.913 g, 10 mmol) in THF (10 mL). The yellow solution was boiled at gentle reflux for 5 days. (Note: Initially, stirring at room temperature for several days produced little product, a result which indicates the steric hindrance associated with this primary amine.) The solvents were stripped off, and the crude residue was taken up in DCM and purified by column chromatography (silica gel, DCM/MeOH/NH_4OH 8:2:0.25). R_f = 0.51 (DCM/MeOH/NH_4OH, 8:2:0.2); yield = 68%; ^{1}H NMR ($CDCl_3$): δ 1.207 (t, 3H, ^3J = 7.1 Hz, CH_2CH_3), 1.28−1.71 (m, 10H, piperidinyl-

C3-H_2, C4-H_2 and C5-*H*), 1.74−1.96 (m, 4H, piperidinyl-C2-H_{ax} and piperidinyl-C6-H_{ax}), 2.871 (br d, 4H, ^2J = 11 Hz, piperidinyl-C2-H_{eq} and piperidinyl-C6-H_{eq}), 3.398 (br s, 1H, C*H*(NH)), 4.070 (q, 2H, ^3J = 7.2 Hz, COOCH_2) and 4.385 (br d, 1H, ^3J = 10.2 Hz, N*H*CO); exact mass (ESI MS, $C_{16}H_{31}N_3O_2$, $[M + H]^+$): calculated: 298.2494; found: 298.2498.

Ethyl Bis(1-ethoxycarbonyl-4-piperidinyl)methylcarbamate (34). Method A. The free base of **33** was prepared by dissolving the trihydrochloride (3.348 g, 10 mmol) in 5 mL of water and 10% (m/V) NaOH (16.1 mL, 1.5 × 30 mmol) and extracting with twice with 50 mL of DCM. The organic layers were pooled and extracted with of brine (40 mL), dried over anhydrous Na_2SO_4, and filtered. The filtrate was concentrated, and solid residue was dried under high vacuum, leaving 2.13 g (95%) of the free base. The triamine was then dissolved in anhydrous DCM in a two-neck 250 mL round-bottom flask equipped with a stirring bar, reflux condenser, addition funnel, and a $CaCl_2$ drying tube. To the solution were added $NaHCO_3$ (924 mg, 11 mmol) and ethyl chloroformate (1 mL, ∼10 mmol) dropwise. After stirring for 5 min, 8.37 mL of ethyl chlorofomate (total = 9.37 mL, 4.4 × 2 × 10 mmol) was added dropwise during 5 min. The mixture was then refluxed for 8 days with chloroformate and/or $NaHCO_3$ being added after 13.5 h (1.87 mL and 840 mg), 4 days (1.67 mL), 6 days (1 mL and 420 mg), and 7 days (1 mL and 420 mg). The mixture was diluted with DCM to a volume of 200 mL and poured onto crushed ice. After the ice had melted, the two layers were separated and the organic layer washed with 0.1 N HCl (200 mL), water (200 mL), and brine (100 mL). The organic layer was dried over anhydrous Na_2SO_4 and filtered, and the filtrate was concentrated to give 3.17 g of very viscous oil. This crude material was used as obtained for the subsequent hydrolysis.

Method B. A 250 mL round-bottom flask equipped with a magnetic stirring bar and reflux condenser was charged with **36** (2.023 g, 6.80 mmol), $NaHCO_3$ (571 mg, 6.80 mmol), and anhydrous DCM (80 mL) and placed under a positive N_2 pressure. To the stirred solution was added ethyl chloroformate (6.495 g, 5.72 mL, 60 mmol), and heating to reflux commenced. Chloroformate and/or $NaHCO_3$ were added after 67.5 h (1.14 mL and 571 mg), 79 h (1.14 mL and 571 mg), 91 h (1 mL and 571 mg), and 100 h (1 mL and 282 mg). Reflux was terminated after 115 h at which time the reaction mixture was diluted with DCM (150 mL) and poured into crushed ice (300 mL). After the ice melted the layers were separated, and the organic layer was washed with 0.1 N HCl (200 mL), water (200 mL), and brine (100 mL). The organic phase was dried over Na_2SO_4 and filtered. The filtrate was concentrated and dried well under vacuum. Upon standing for several days, the hard gum solidified to a white powdery material. Yield = 73%. As in Method A, the crude material can be used for subsequent hydrolysis. R_f = 0.88 (DCM/MeOH/NH_4OH, 8:2:0.2); exact mass (ESI MS, $C_{20}H_{35}N_3O_6$, $[M + H]^+$): calculated: 414.2604; found: 414.2635.

Di(4-piperidinyl)methylamine (37). To **34** was added slowly 26.4 mL of concentrated hydrochloric acid solution (0.88 mL/mmol of amine, based on starting triamine **33**). The mixture was heated at 60 °C. After 5.5 h, 5 mL of concentrated hydrochloric acid solution was added and the reaction mixture was refluxed for an additional 6 h. The cooled reaction mixture was poured into crushed ice, and the aqueous solution was extracted with DCM (2 × 40 mL). The water was stripped off, and the residue was taken up in ethanol and concentrated. This process was repeated several times until a dry glassy product remained. Mass spectral analysis revealed the presence of the desired product along with a monocarbamate species. Because of the difficulty to remove the third carbamate in acidic conditions, basic hydrolysis was carried out by dissolving the crude material in a mixture of 50 mL of ethanol and 30 mL of 50% (m/v) KOH (aq) and refluxing for 23 h. The alcohol was removed on a rotary evaporator, and the aqueous layer was extracted with diethyl ether. Saturated NaCl solution (10 mL) was added and extraction with DCM (4 × 50 mL) performed. The organic extracts were combined, dried over anhydrous Na_2SO_4, and filtered, and the filtrate was concentrated to an oil which crystallized. The proton NMR spectrum showed that the product was quite pure and, because of its tendency to absorb CO_2 readily, it was used immediately in the subsequent condensation step (vide infra). Yield = 1.02 g, R_f = 0.05 ($CHCl_3$/MeOH/NH_4OH 5:4:1). ^{1}H NMR ($CDCl_3/D_2O$): δ 1.10−1.80 (m, 10H, piperidinyl-C3-H_2, -C4-*H*, and -C5-H_2), 2.272 (t, 1H, ^3J = 5.1 Hz, C*H*(NH_2), 2.50−2.70 (m, 4H, piperidinyl-C2-H_{ax} and -C6-H_{ax}) and 3.04−3.20 (m, 4H, piperidinyl-C2-H_{eq} and -C6-H_{eq}). exact mass (ESI MS, $C_{11}H_{23}N_3$, $[M + H]^+$): calculated: 198.1970; found: 198.1979.

1-Triphenylmethyl-5-imidazoleacetic Acid (38). A 50 mL two-neck round-bottom flask equipped with a magnetic stirring bar, reflux condenser, and $CaCl_2$ drying tube was charged with imidazoleacetic acid·HCl (813 mg, 5 mmol), anhydrous DCM (15 mL), and Et_3N (506 mg, 693 μL, 5 mmol). Chlorotrimethylsilane (543 mg, 635 μL, 5 mmol) was added, and the suspension was refluxed for 2 h. The mixture was allowed to cool to room temperature, 5 mmol of Et_3N added, and reflux continued for 5 min. The reaction flask was again cooled to room temperature, a final 5 mmol portion of Et_3N was added followed by a solution of chlorotriphenylmethane (1.39 g, 5 mmol) in anhydrous DCM (15 mL), and the mixture was stirred for 3 h at room temperature. Methanol (500 μL) was added, the solution was stirred for several minutes, and the solvents were removed under reduced pressure. The residue was partitioned between $CHCl_3$ (100 mL) and cold 5% (m/V) citric acid (100 mL) and separated. The organic layer was then extracted once with brine, dried over Na_2SO_4, and filtered, and the filtrate was concentrated. The crude material was recrystallized from $CHCl_3$/hexane at room temperature and was isolated as a white solid by filtration. R_f = 0.27 (CH_2Cl_2/MeOH 9:1); yield = 90%; ^{1}H NMR ($CDCl_3$): δ 3.653 (s, 2H, −CH_2−CO_2H)-, 6.703 (d, 1H, ^4J = 1.6 Hz, Im-C4-*H*), 7.07−7.18 (m, 6H, phenyl-C2-*H* and -C6-*H*), 7.30−7.40 (m, 9H, phenyl-C3-*H*, -C4-*H* and -C5-*H*) and 7.510 (d, 1H, ^1J = 1.4 Hz); exact mass (ESI MS, $C_{24}H_{20}N_2O_2$, $[M + Na]^+$): calculated: 391.1423, found: 391.1443.

Bis(1-{[1-(triphenylmethyl)-1*H*-imidazol-5-yl]-acetyl}4-piperidinyl)methylamine (39). To a stirred suspension of **51** (3.904 g, 2.05x 0.169 mmol) in anhydrous DCM (21 mL, 2 mL/mmol) under N_2 pressure was added carbonyl diimidazole (1.802 g, 2.15 × 5.169 mmol) at once. The solution, resulting after vigorous gas evolution ceased, was stirred for 30 min, and then the reaction flask was immersed in an ice bath. A solution of **37** (1.02 g, 5.169 mmol) in DCM (10 mL) was added dropwise during 3 min. The reaction mixture was stirred at room-temperature overnight (13 h), diluted to 150 mL with DCM, extracted with water (2 × 150 mL) and brine (1 × 100 mL), dried over anhydrous Na_2SO_4, and filtered. The filtrate was concentrated under reduced pressure. Purification was performed using column chromatography (silica gel, DCM/MeOH, first 9:1, then 8:2). Appropriate

fractions were pooled and evaporated to yield the title compound as glassy material. A relatively large amount (1.26 g) of the triacylated material was obtained. R_f = 0.56 (DCM/MeOH 8:2); yield = 36%; exact mass (ESI MS, $C_{59}H_{59}N_7O_2$, $[M + H]^+$): calculated: 898.4808, found: 898.4789.

Bis{1-[2-(1*H*-imidazol-5-yl)ethyl]-4-piperidinyl}-methylamine (40). A two-neck round-bottom flask, reflux condenser and an addition funnel were dried in an oven and then assembled hot and placed under a positive N_2 pressure. Lithium aluminum hydride (254 mg, 3.75 × 1.781 mmol) was added and then covered with anhydrous THF (5 mL). The slurry was stirred and the flask immersed in an oil bath preheated at 65 °C. A sonicated suspension of diamide **39** (1.60 g, 1.781 mmol) in dry THF (15 mL) was transferred to the addition funnel via a cannula. Another 5 mL of anhydrous THF was used for rinsing, and the rinsing was added to the addition funnel in a like manner. The suspension was added dropwise to the slurry of $LiAlH_4$ during 1.33 h. A final 5 mL of anhydrous THF was used to rinse the system and was added to the reaction mixture. Throughout the addition, the temperature was maintained at 65−70 °C, resulting in gentle reflux. As diamide was added, the mixture would initially develop a greenish color, which changed to a reddish color as the reaction proceeded. When more diamide was added, the red color disappeared, giving way again to the green color. Once addition was complete, the temperature was increased to 80 °C and reflux continued for 130 min. during which time the mixture became fairly dark red. After being cooled to room temperature, the reaction was quenched by sequential addition of water (254 μL), 15% (m/v) NaOH (254 μL), and water (762 μL). The mixture was stirred for 1.5 h with intermittent triturating. The solid was removed by suction filtration through a sintered glass filter and washed several times with fresh THF. The filtrate was concentrated on a rotary evaporator, the residue covered with 13 mL of 50% HOAc, and the mixture heated on a boiling steam bath for 15 min. The walls of the flask were rinsed with 1 mL of 50% HOAc, and the mixture was cooled to room temperature, diluted with water (14.5 mL), and chilled in a refrigerator at 2 °C for 5 h. Insoluble trityl-containing byproducts were filtered off and washed several times with water while triturating. The filtrate was concentrated under reduced pressure, the residue redissolved in water, and the water stripped off. The crude material was purified by silica gel column chromatography. For the first column, elution was performed using $CHCl_3$/MeOH/NH_4OH_{concd} 5:4:1 (R_f = 0.75) and for the second MeOH/H_2O/NH_4OH_{concd} 9:0.5:0.5 (R_f = 0.28) was used. The product was dissolved in isopropyl alcohol, and the solution was filtered (0.45 μm filters) and concentrated. The residue was dried under high vacuum to yield the product as a dry, white foam. Yield = 38%; ^{1}H NMR (D_2O): δ 1.20−1.82 (m, 10H, piperidyl-C3-H_2, -C4-*H*, and -C5-H_2), 1.98−2.22 (m, 4H, piperidyl-C2-H_{ax} and -C6-H_{ax}), 2.34−2.44 (m,1H, C*H*(NH_2)), 2.54−2.88 (m, 8H, Im-CH_2CH_2), 2.94−3.14 (m, 4H, piperidinyl-C2-H_{eq} and -C6-H_{eq}), 6.909 (s, 2H, Im-C4-*H*) and 7.660 (d, 2H, ^4J = 1 Hz, Im-C2-*H*); ^{13}C NMR (CD_3OD): δ 25.023 (Im-CH_2), 27.633 and 30.213 (piperidyl-C3 and -C5), 39.288 (piperidyl-C4), 54.858 (piperidyl-C2 and -C6), 59.653 (Im-CH_2*C*H_2), 60.382 (C-[4-piperidyl]$_2$), 117.836 (Im-C5), 136.016 (Im-C4), 136.624 (Im-C2); exact mass (ESI MS, $C_{21}H_{35}N_7$, $[M + H]^+$): calculated: 386.3032, found: 386.3045.

4-[(Bis{1-[2-(1*H*-imidazol-5-yl)ethyl]-4-piperidinyl}-methyl)amino]-4-oxobutanoic acid (41) Primary amine **40** (152 mg, 3.89 × 10^{-4} mol) was placed in a round-bottom flask, equipped with a stirring bar and reflux condenser, and dissolved with heating at 80 °C in a mixture of anhydrous THF (6 mL) and anhydrous DMF (2 mL) while under positive N_2 pressure. After dissolution of the amine was complete, succinic anhydride (39 mg, 3.89 × 10^{-4} mol) was added in one portion and heating and stirring continued for 30 min. After the reaction mixture had cooled to room temperature, a small amount of water was added to dissolve the precipitated product, and the solvents were removed under reduced pressure. The residue was taken up in water and the solution concentrated, and this process was repeated twice with ethanol. The crude product was dissolved in a minimum amount of $CHCl_3$/MeOH/H_2O (5:4:1) and applied to a column of silica gel and eluted with $CHCl_3$/MeOH/NH_4OH_{concd} (5:4:1). The product was dissolved in water, filtered (0.45 μm filters), concentrated, and dried under high vacuum to yield the title compound as a white solid. R_f = 0.50 ($CHCl_3$/MeOH/NH_4OH 5:4:1); yield = 87%; ^{1}H NMR (D_2O): δ 1.22−1.94 (m, 10H, piperidyl-C3-H_2, -C4-*H*, and -C5-H_2), 2.42−2.54 (m, 4H, NHCH_2C$H_2$$CO_2$H), 2.54−2.76 (m, 4H, piperidyl-C2-H_{ax} and -C6-H_{ax}), 2.88−3.16 (m, 8H, Im-CH_2CH_2), 3.30−3.48 (m, 4H, piperidinyl-C2-H_{eq} and -C6-H_{eq}) and 3.653 (br t, 1H, ^3J = 5 Hz, C*H*(NH)); ^{13}C NMR (DMSO-d_6): δ 24.342 (Im-CH_2), 26.861 and 29.198 (piperidyl-C3 and -C5), 30.170 (NHCO*C*$H_2$$CH_2$COOH), 30.564 (NHCOC$H_2$*C*$H_2$COOH), 36.543 (piperidyl-C4), 53.358 (piperidyl-C2 and -C6), 55.574 (C-[4-piperidyl]$_2$), 58.214 (Im-CH_2*C*H_2), 117.490 (Im-C5), 134.700 (Im-C2 and Im-C4), 171.576 (CONH), 174.581 (COOH); exact mass (ESI MS, $C_{25}H_{39}N_7O_3$, $[M + H]^+$): calculated: 486.3192, found: 486.3198.

Oligodeoxynucleotide Synthesis. Assembly was done at a 2 μmol scale on an ABI 392A DNA synthesizer (Applied Biosystems, Perkin-Elmer, Foster City, CA) following standard procedures (*8*). For the 5′-amino modification, the 5′-amino-modifier was dissolved in anhydrous acetonitrile at a concentration of 0.11 M and allowed to react during 180 s. Detritylation was performed manually using 3% trichloroacetic acid (TCA) in DCM until no yellow color was formed upon addition of additional TCA in DCM solution. The internal amino-modifier (**67**) was dissolved in anhydrous acetonitrile (0.12 M) and incorporated in the oligonucleotide on the DNA synthesizer. The coupling procedure was slightly modified as well by increasing the reaction time. The detritylation procedure was extended to 3 × 20 s (from 3 × 12 s) because of the monomethoxytrityl protection of the 5′-OH instead of dimethoxytrityl protection used during standard oligonucleotide synthesis.

Procedure for 5′-Oligonucleotide Conjugation with the RNase A Mimics. After oligonucleotide synthesis at a 2 μM scale and deprotection of the 5′-amino linker, the solid support was transferred to a microtube with sintered glass filter. Twenty equivalents of the RNase A mimics (**3**, **15**, **16**, **18**, **20**, **22**, **24**, **29**, **30**, and **41**) relative to the theoretical amount of oligonucleotide (0.02 mmol) were weighed out in an eppendorf tube, and 100 μL of anhydrous DMF, 3 mg HOBt (0.022 mmol), and 3.5 μL DIEA (0.02 mmol) were added. In the case of **3** and **41** a suspension was formed. Upon addition of PyBOP (10.4 mg, 0.02 mmol) a clear solution was formed in all cases. The reaction mixture was added to the solid-phase-supported oligonucleotide and shaken overnight. Excess reagent was filtered off, and the solid was washed with anhydrous DMF (3 × 500 μL), acetonitrile (3 × 500 μL), and DCM (3 × 500 μL). For the preparation of **43**−**46**, the solid phase was treated with several quanti-

ties of a solution of 3% TCA in DCM until no yellow color formed anymore upon addition of an additional amount of TCA. The support was washed three times with 500 μL of DCM and was dried by passing nitrogen through the tube.

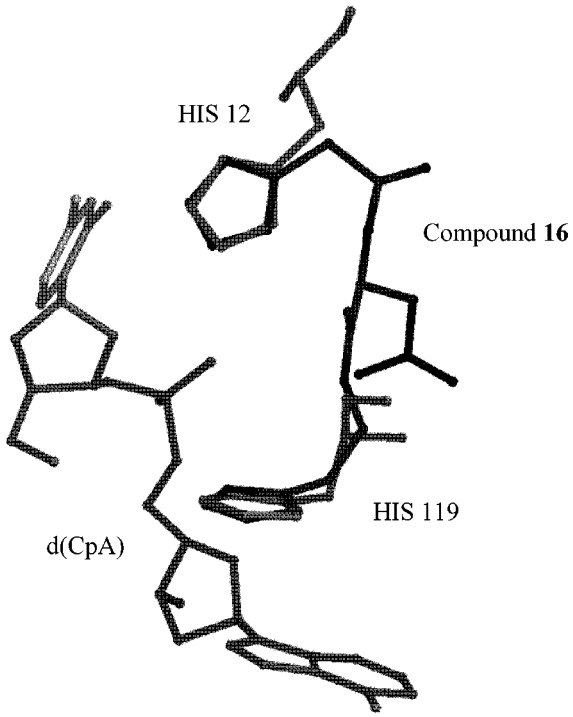
Cleavage and Deprotection with Ammonia/ Methylamine Mixture. The solid supported oligonucleotide conjugates **42**−**46** were transferred into a screw-capped vial, and 1 mL of a mixture of methylamine and 33% aqueous ammonia (1:1) (AMA) was added. The recipient was firmly closed and the mixture vortexed and allowed to react for 2 h at 25 °C. The mixture was vortexed again, and the oligonucleotide conjugates were isolated from the supernatant on a NAP-25 Sephadex column (Pharmacia, Amersham-Pharmacia-Biotech, Freiburg, Germany).

Cleavage and Deprotection with Aqueous Ammonia. The solid-supported oligonucleotide conjugates **47**−**51** were transferred into a screw-capped vial, and 1 mL of 33% aqueous ammonia was added. The recipient was firmly closed and the mixture vortexed and allowed to react for 16 h at 55 °C. The mixture was vortexed again, and the oligonucleotide conjugates were isolated from the supernatant on a NAP-25 Sephadex column.

Analysis and Purification of Conjugates by RP-HPLC. Analysis and purification of the conjugates by RP-HPLC employed buffers A (0.1 M triethylammonium acetate (TEAA), pH 7.0, freshly prepared from 1 M stock solution and filtered prior to use) and B (acetonitrile). For analytical purposes, a linear gradient of 0% to 20% B over 50 min was used. EDTA was added to the sample (final concentration 5 mM) and incubated for 10 min prior to injection. Monitoring was done at 260 nm.

Oligonucleotide Concentration Determination and Thermal Stability Studies. Oligonucleotide concentrations were determined by measuring the absorbance in pure RNase-free water at 260 nm at 80 °C, and the following extinction coefficients were used: adenine nucleotide $\epsilon = 15000$; thymine nucleotides $\epsilon = 8500$; guanine nucleotides $\epsilon = 12500$; cytosine nucleotides $\epsilon = 7500$; uridine nucleotides $\epsilon = 10000$. T_m values were determined in a buffer containing 0.1 M NaCl, 0.02 M potassium phosphate pH=7.5, 0.1 mM EDTA with a 4 μM concentration for each strand. Melting curves were obtained with a Cary 100 Bio spectrophotometer. Cuvettes were maintained at constant temperature by means of water circulation through the cuvette holder. The temperature of the solution was measured with a thermistor directly immersed in one of the cuvettes. Temperature control and data acquisition was done with an IBM-compatible computer using Cary WinUV thermal application software. The samples were heated at a rate of 0.2 °C·min^{-1} starting at 10 °C and heating to 80 °C. Melting temperatures were determined by plotting the first derivative of the absorbance versus temperature curve. Up and down curves showed identical T_m values. (no hysteresis effect observed).

Cleavage Experiments. The ribooligonucleotides were radiolabeled (^{32}P) at the 5′-end using T4 polynucleotide kinase (Gibco BRL) and [γ-^{32}P]adenosine 5′-triphosphate (ATP) (166500 GBq/mmol) by standard procedures (*9*) and purified on a NAP-5 column (Pharmacia). Stock solutions of the radiolabeled RNA target (0.5 μM) and of the oligonucleotide conjugates (2 μM) (**42**−**51**) were prepared. The oligonucleotide conjugate solution, 2.5 μL, was first mixed with 1 μL of EDTA solution (10 mM) and incubated for 10 min. Subsequently, the buffer solution (250 mM Tris·HCl pH 7.5 or 250 mM imidazole pH 7, 10 μL), the sodium and or potassium chloride solutions, and eventually the metal salts were added. The appropriate amount of RNase free water was added to a total volume of 45 μL. Finally, the radiolabeled ribooligonucleotides were added (5 μL, 0.5 μM), and the reaction mixtures were vortexed and centrifuged. The mixtures were incubated at 37 °C. After appropriate time intervals, samples (5 μL) were taken and mixed with an equal volume of stop mix (EDTA 50 mM, Xylene cyanol FF 0.1%, and bromophenol blue 0.1% in formamide). Alkaline hydrolysis ladders were obtained by incubation at 90 °C in 100 mM Na_2CO_3 solution. Samples were taken after 5, 7, 10, and 12 min. Samples were analyzed by denaturing PAGE (20% in the case of the 23-mer RNA substrate, 12% in the case of the 41-mer RNA substrate) containing urea (50%) with TBE buffer at 65 W for 1.5 h. Results were visualized by phosphorimaging (Packard Cyclone, Optiquant Software, Packard Instrument Company, Meriden, CT).



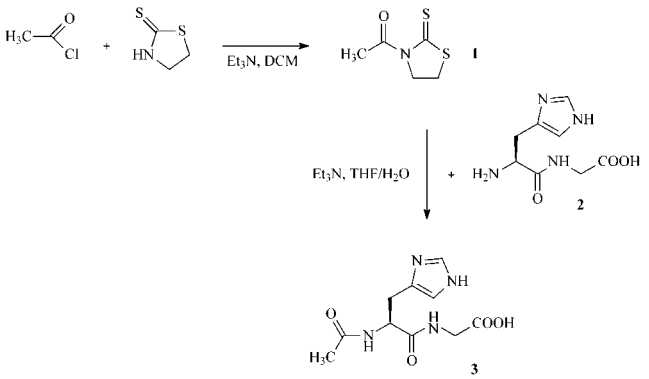


Figure 1. Flexible superposition of compound **16** on the active site histidines of ribonuclease A, shown together with a d(CpA) fragment.

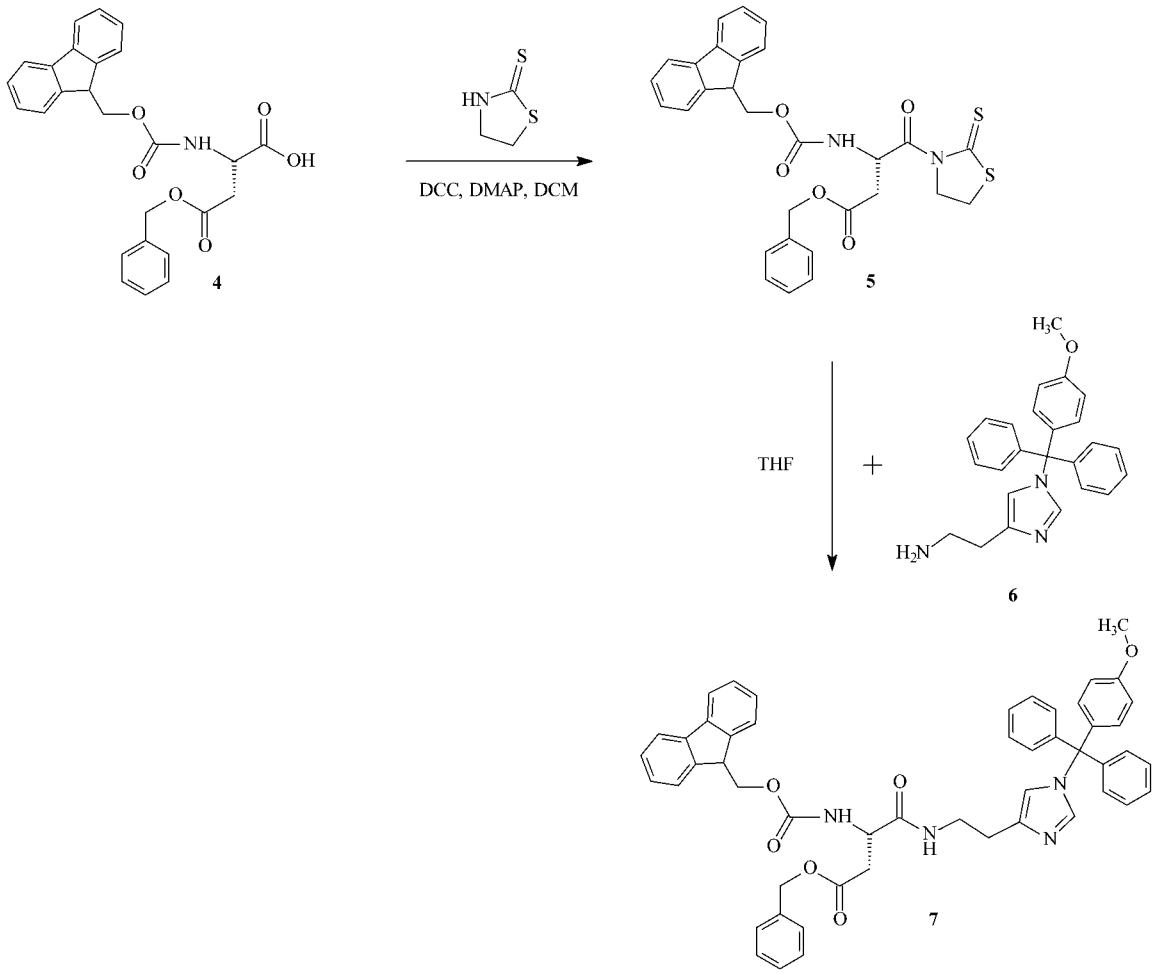
Molecular Modeling Analysis. To preclude the synthesis of RNase A mimics unable to fit in the catalytic ribonuclease system, we did a preliminary check by molecular modeling. Models of structures **16**, **18**, and **24** have been created using Macromodel 5.0 (*10*), and their geometry (one conformation) was optimized in the Amber* force field (*11*) and written out as pdb files. Using a self-made flexible fit program, we investigated if it was possible to match the 2 imidazole functions in our molecules with the two histidines 12 and 119 in the Ribonuclease A enzyme. The X-ray structure of RNase A in complex with dinucleotide d(CpA) from Zegers et al. (*12*) was used as a template. The program varies all possible dihedral angles in the flexible molecule and uses the quaternion fit algorithm (*13*) together with an adaptive simulated annealing minimizer (asa) (*14*) to select the lowest root-mean-square deviation.

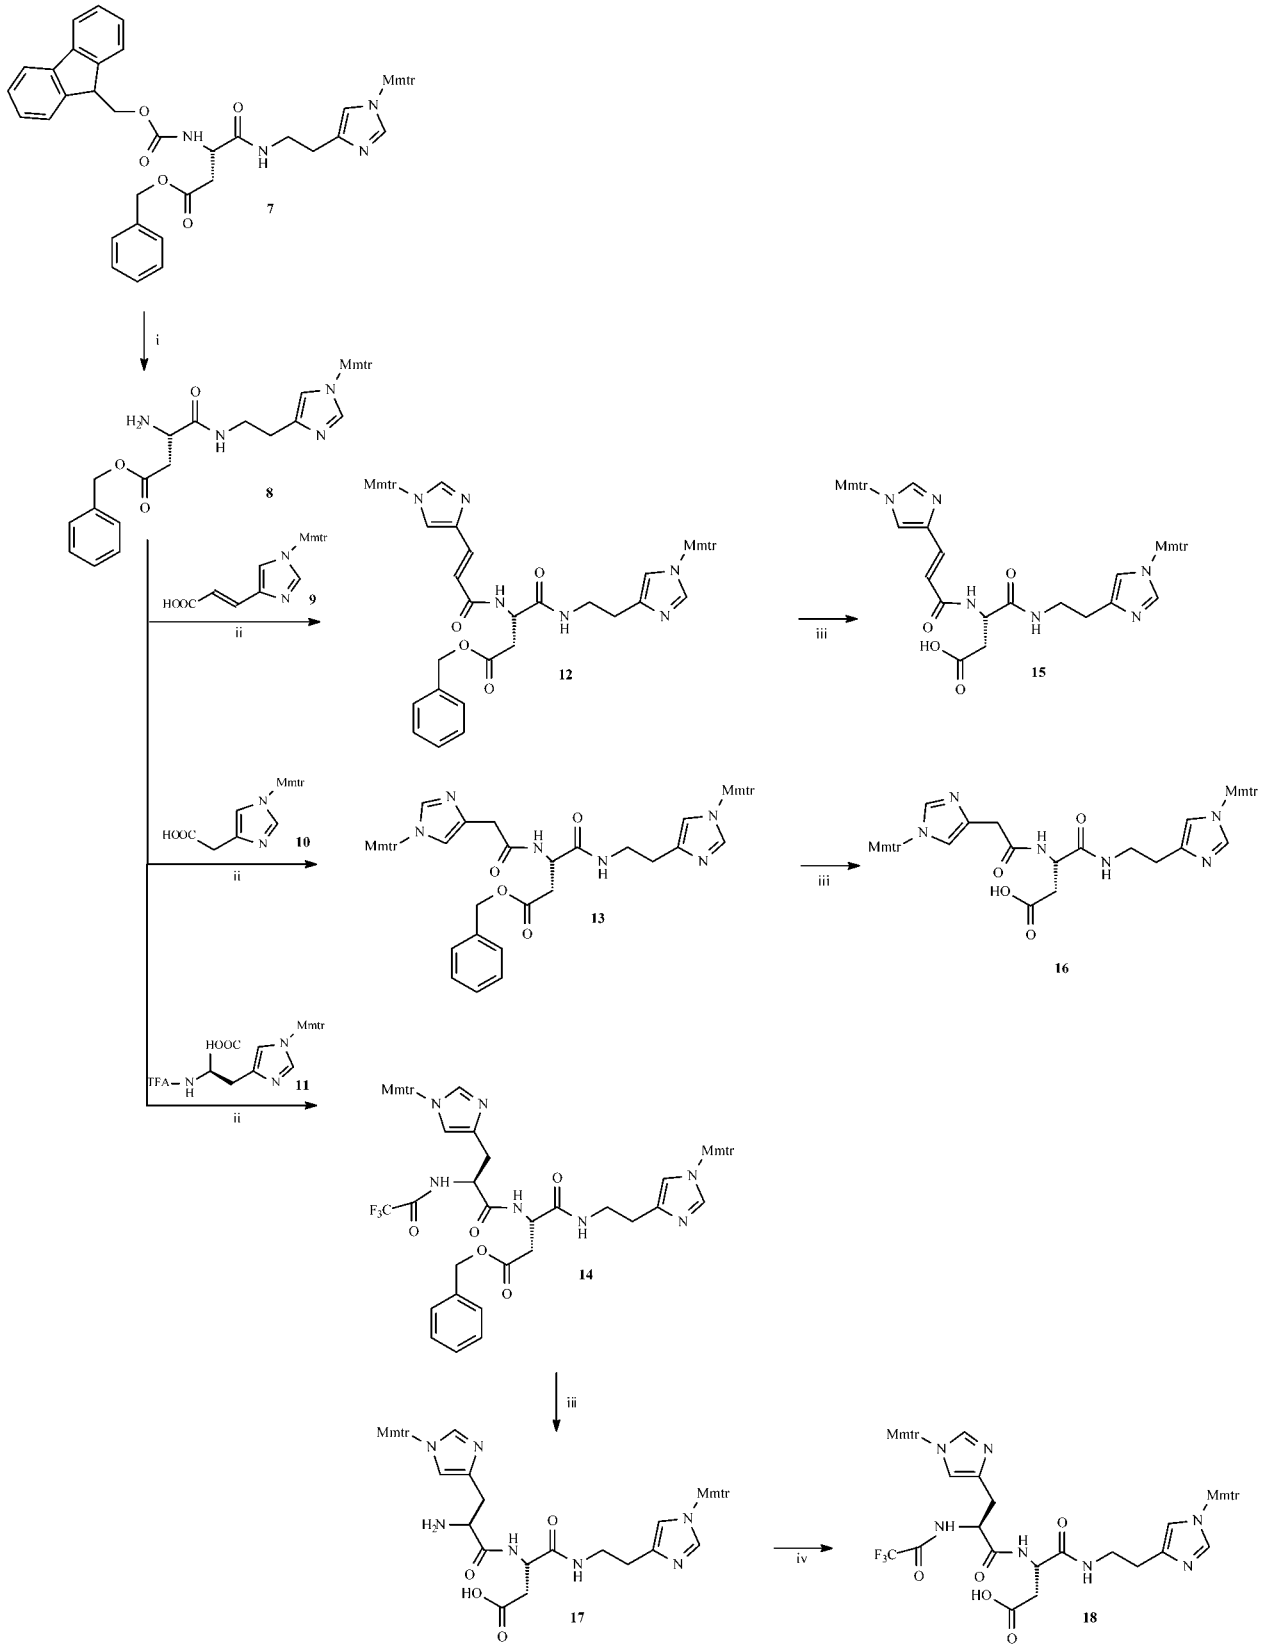
RESULTS AND DISCUSSION

The rationale for the synthesis of the proposed diimidazole conjugates is primarily based on some single

Scheme 1



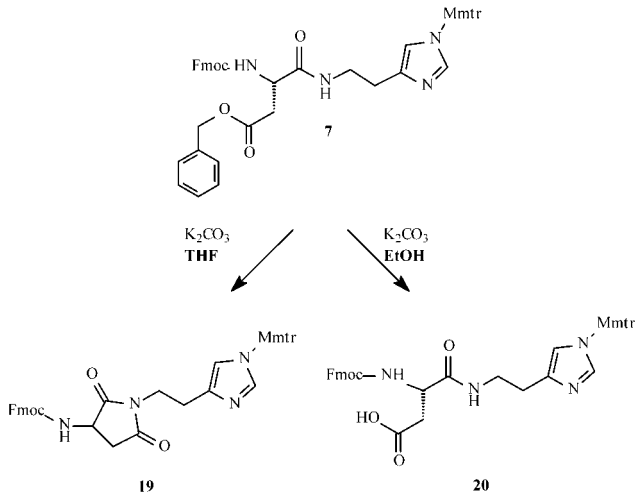
modeling experiments with compounds **16**, **18**, and **24**. The molecular modeling calculations show that there exists at least one conformation of compound **16** where the imidazole functions fit onto his-12 and his-119 of RNase A (Figure 1). The flexible backbone of compound **16** consisting of nine bonds does not hinder approaching the RNA fragment. The same calculations were performed on compounds **18** (10 bonds between the two imidazoles) and **24** (14 bonds) with similar results. These calculations can be extrapolated to the other compounds with similar backbones (**15**: 10 bonds with less flexibility than **18**, due to the presence of the double bond; **22**: 13 bonds; **29**: 14 bonds; **41**: 14 bonds with less flexibility than **24**, due to the presence of the piperidine rings) or longer backbones (**30**: 16 bonds). Moreover, several examples are described of peptide−acridine conjugates (*15*) and of diimidazole intercalator constructs (*16*) that are able to function as mimics of ribonucleases. In those examples, the imidazole groups are bond on a flexible (peptide) linker with 10 to 12 bonds between both imidazole residues.



Synthesis of the RNase A Mimics. Although it has been shown that a free imidazole functionality does not interfere with the conjugation reaction on the oligonucleotide itself, the synthesis of these catalysts as fully protected molecules, with imidazole protection as well as protection of the free α-amino group of the amino acid, appeared very attractive as a useful intermediate from the point of view of solubility and stability. The monomethoxytrityl group (Mmtr) was the first protecting group of choice. The high acid lability of this group allowed its removal after conjugation with the oligonucleotide using the standard detritylation procedure of oligonucleotide chemistry, thereby allowing the evaluation of the coupling reaction. However, for the acylation procedures with an imidazole-containing molecule during the synthesis of the RNase A mimics, where the 3-acyl-1,3-thiazolidine-2-thione activation strategy was applied, the BOC group had to be used for the imidazole protection in order to obtain the desired activated compound. The amino groups were protected as trifluoro acetamides (TFA) or fluorenylmethoxycarbonyl amides (Fmoc).

For the synthesis of the monoimidazole compound, N^{α}-acetyl-L-histidylglycine (**3**), the dipeptide, L-histidylglycine (**2**), was modified by acetylation of the α-amino group

Scheme 2



Scheme 3[a]

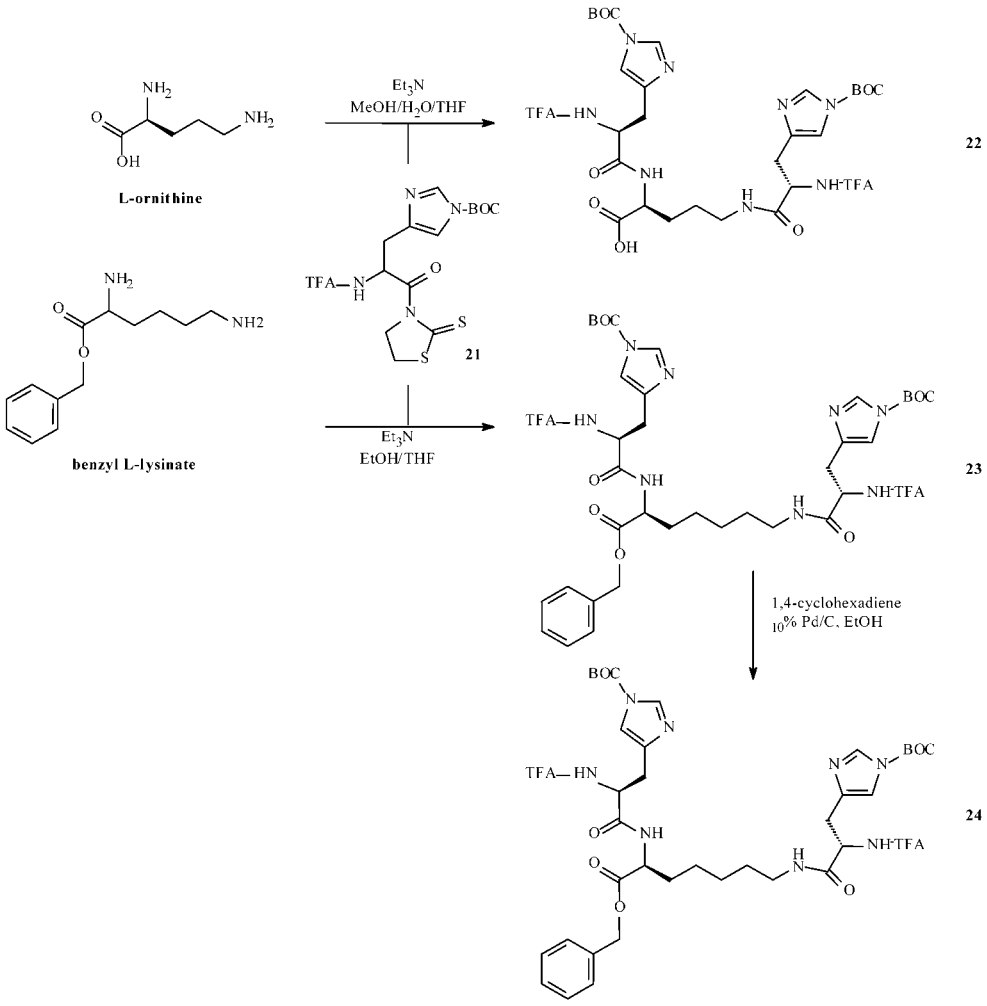
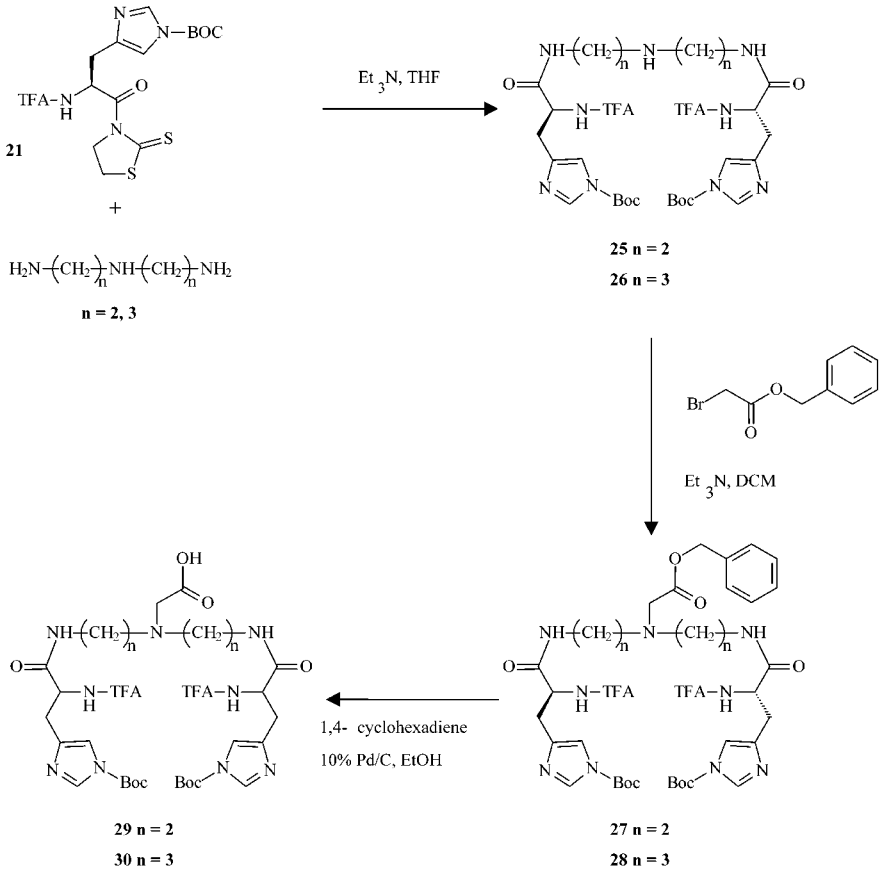
of the histidyl residue (Scheme 1). The acetylation procedure was carried out based on the work of Nagao Y. et al., using a previously unreported reagent (*17*). Hereto, acetic acid was converted into its 3-acyl-1,3-thiazolidine-2-thione derivative (**1**) by the addition of acetyl chloride to a solution of 2-mercaptothiazoline and triethylamine. Of practical importance is the applicability of this strategy in aqueous solution in case the amino-substrate is not soluble in organic solvents (*18*), as it is the case for the acylation of L-histidylglycine.

Scheme 4



In a first series of multifunctional constructs, aspartic acid was used as the brace to attach imidazole groups on one side, providing on the other side a free carboxylic acid function for conjugation onto the oligonucleotide. Starting from O^{γ}-benzyl,N^{α}-[(9*H*-fluoren-9-ylmethoxy)-carbonyl]-L-aspartic acid (**4**) [N^{α}(Fmoc)-L-Asp(OBzl)-OH], the free α-carboxyl group was converted into a 3-acyl-1,3-thiazolidine-2-thione (**5**) (Scheme 2). This enabled the introduction of the first imidazole group by reaction with N^{im}-(Mmtr)-histamine (**6**). To allow introduction of the second imidazole moiety in the molecule (Scheme 3), the α-amino protecting group of protected aspartic acid (**7**) was removed, and the product was used in the following peptide coupling procedure without prior purification of the amine (*19*). The free amine of **8** was reacted with a carboxylic function on three slightly different imidazole containing molecules: N^{im}(Mmtr)-urocanic acid **9**, N^{im}-(Mmtr)-imidazole acetic acid **10**, and N^{α}(TFA)-N^{im}(Mmtr)-histidine **11** (Scheme 3).



For the formation of the amide bond between the free amine of compound **8** and the free acids of **9**, **10**, and **11** respectively (Scheme 3), ByBOP was used as coupling reagent. It was observed that for the chromatographic purification of the reaction products, halogenated solvents are best to be excluded from the mobile phase in order to separate the desired product from tri(1-pyrrolidinyl)phosphine oxide, the product from PyBOP coupling (*20*). Finally, prior to conjugation with the oligonucleotide, the benzyl ester was cleaved by alkaline hydrolysis. Unfortunately, in the case of **14**, the trifluoroacetamide group was cleaved concomitantly. This could easily be restored by treatment of the product (**17**) with methyl trifluoroacetate in methanol.

A candidate molecule for coupling on the oligonucleotide was obtained by immediate benzyl ester hydrolysis of **7** by selective alkaline hydrolysis leaving the α-amino protecting group intact (Scheme 4). The use of an aqueous potassium carbonate solution in combination with THF as the organic solvent resulted in predominant aspartim-

Scheme 5

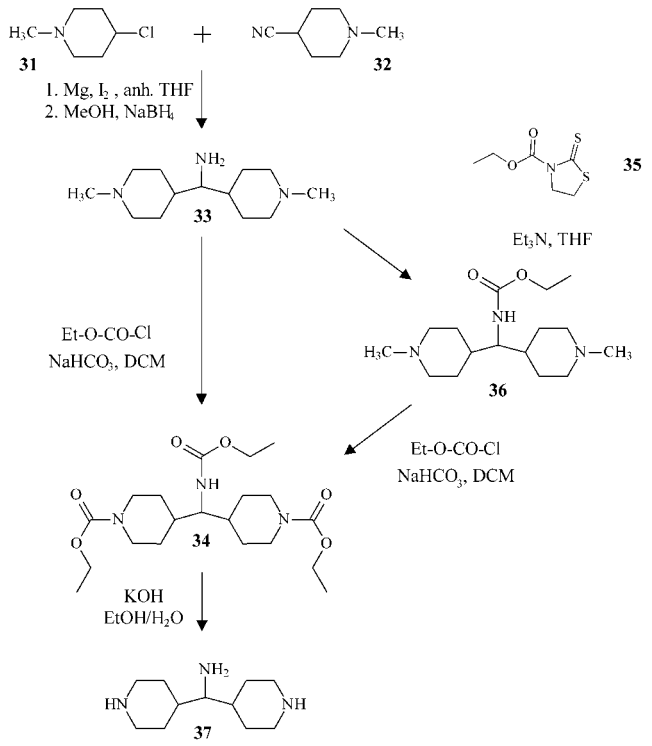
Scheme 6

ide formation (**19**) (*21, 22*). Substituting THF for ethanol resulted in the desired hydrolysis product (**20**).

A different scaffold for the synthesis of RNase A mimic's was found in the natural occurring amino acids lysine and ornithine. Because of the general applicability of the 3-acyl-1,3-thiazolidine-2-thione activation strategy for amide bond formation in polar solvents, acylation of both amines (α- and *δ*-amino (ornithine) and *ϵ*-amino (lysine), respectively) would preferentially be carried out following this procedure because of their solubility properties. The unactivated protected amino acid, N^{α}(TFA)-M^{im}(BOC)-His, was prepared as described by Smith T. H. et al. (*23*) and converted into the 3-acyl-1,3-thiazolidine-2-thione derivative.

For the coupling of **21** with ornithine, the amino acid was used in its free acid form. For the derivatization of lysine, the benzyl ester was used (Scheme 5). Although acylation of the side chain amine proceeds very rapidly, the α-amino group is somewhat less reactive toward 3-acyl-1,3-thiazolidine-2-thione compounds (*24*). The derivatization of ornithine under its free acid form resulted in only half the yield obtained with the benzyl ester of lysine. Subsequent removal of the benzyl group of **23** by catalytic transfer hydrogenation, lowered the total yield of the second approach, and compound **24** was obtained in the same overall yield as compound **22**.

Two other potential catalysts were synthesized by derivatization of dialkyl triamines, i.e., *N*-(2-aminoethyl)-1,2-ethanediamine and *N*-(3-aminopropyl)-1,3-propanediamine (Scheme 6). We observed that it was easily possible to selectively functionalize the primary amines of these triamines in the presence of the secondary amine. In comparison with acylation using thiazolidine-thione, CDI coupling exhibited slightly lower selectivity with these substrates. The diacylated products **25** and **26** appeared quite stable and could easily be alkylated with benzyl bromoacetate under standard conditions. Phase transfer hydrogenolysis of **27** and **28**, with 1,4-cyclohexadiene as the hydrogen source, easily cleaved the ester while leaving the protecting groups intact (*25*).



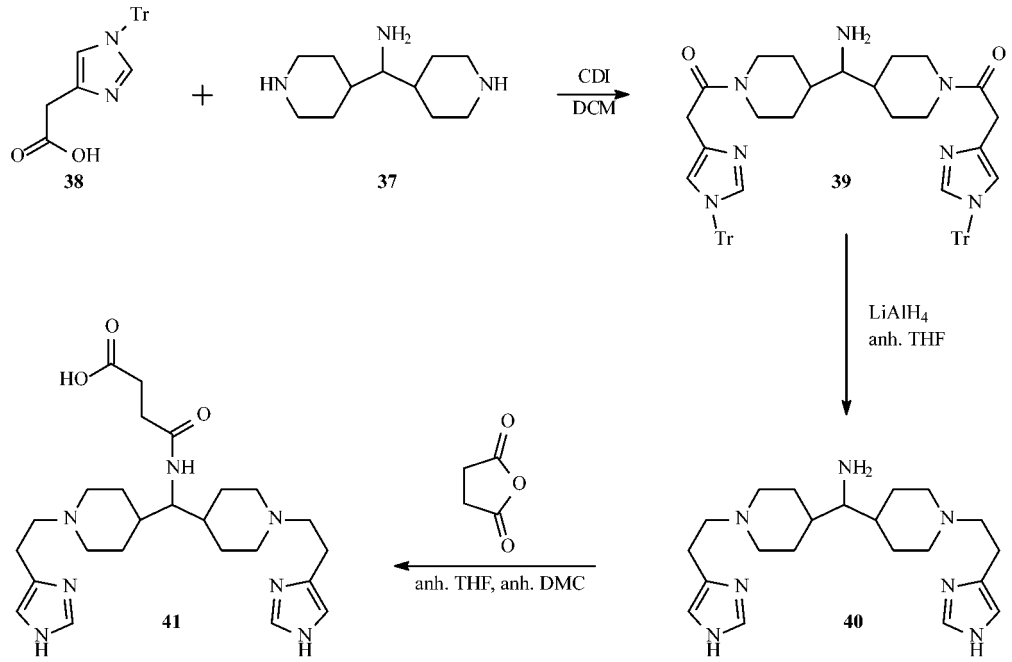
The final RNase A mimic synthesized was based on a bipiperidine moiety. A single amino-functionalized carbon atom was introduced between the two rings in order to be able to link the functionalized bipiperidine to an oligonucleotide.

For the synthesis of the bipiperidine scaffold (Scheme 7), bis(4-piperidinyl)methylamine (**37**), starting from 4-chloro-1-methylpiperidine (**31**) a Grignard reagent was prepared (*26*) that was reacted with 4-cyano-1-methylpiperidine (**32**) (*27*). The resulting imine was immediately reduced using sodium borohydride (*28*). To demethylate the piperidine amino groups, the product was treated with ethyl chloroformate to yield the triethyl carbamate (**34**), which was easily hydrolyzed (*29*). Though the treatment of **33** with ethyl chloroformate yielded the desired compound, a cleaner method was transformation of the primary amine of **33** into its ethyl carbamate (**36**) using 3-(ethyloxycarbonyl)-1,3-thiazolidine-2-thione (**35**)- prior to treatment of the tertiary amines with ethyl chloroformate.

For the introduction of the imidazole moieties (Scheme 8), the secondary amines were first acylated using N^{im}-(trityl)-imidazole acetic acid (**38**). To restore the basicity of the piperidine ring nitrogens, the resulting amide functions were reduced using lithium aluminum hydride. The bis-imidazole compound (**40**) possessing the central primary was succinylated to yield the final product (**41**) ready for conjugation.

Preparation of the Oligonucleotide Conjugates with the RNase A Mimics. For conjugation of the

Scheme 7



oligonucleotide at the 5′-position, the oligonucleotide was first functionalized with an amino group. The amino linker was introduced at the 5′-position by means of a phosphoramidite building block. The monomethoxytrityl group is easily removed using 3% TCA in dichloromethane. Conjugation of the synthesized constructs with the 5′-amino linker on the oligonucleotide was accomplished by activation of the carboxylic acid with PyBOP in the presence of 1 equiv of DIEA and HOBt in DMF. After 4 h of reaction, the beads were washed. In the case of **15**, **16**, **18**, and **20**, the imidazole protecting group, monomethoxytrityl, was removed by washing the solid support with 3% TCA in DCM, prior to the oligonucleotide cleavage and deprotection procedure using a 1/1 mixture of methylamine and ammonia at room temperature during 2 h. In the case of these aspartic acid based RNase A mimic conjugates, cleavage and deprotection using aqueous ammonia overnight at 55 °C lead to loss of the RNase A mimic from the oligonucleotide. The other conjugates with BOC imidazole protection had to be cleaved from solid support and deprotected under standard aqueous ammonia treatment (33%) overnight at 55 °C since no complete removal of the BOC protection was achieved following ammonia/methylamine treatment. The oligonucleotide conjugates were purified by C_{18} reversed phase HPLC. Confirmation of the identity of the oligonucleotide conjugates was obtained by negative ion mode mass spectrometry (Table 1). Direct infusion experiments show −5 to −7 charged molecules (Figure 2). Deconvolution of the spectra gives the molecular mass of the compound the charged species came from. A few spectra contained additional peaks due to sodium or potassium adducts. Capillary reversed phase liquid chromatography coupled experiments in some cases resulted in the appearances of additional peaks or complete shifts

Table 1. Overview of the Yield of the Coupling Reactions of the 5′-Amino-Modified Oligonucleotide with the RNase A Mimics and the Subsequent Result of Mass Spectral Analysis

in the spectra. Apparently, during the process of this capillary liquid chromatography, some of the oligonucleotide conjugates pick up metal ions by complexation from the material of the instruments. The same adducts were observed when comparing direct infusion mass experiments before and after C_{18} RP-HPLC purification. Addition of EDTA during the direct infusion mass experiments did reduce this phenomenon. This observation indicates the tendency of the compounds toward metal complexation and ensures there was no covalent modification of the oligonucleotide conjugates.

RNA Cleavage Experiments. To evaluate the synthesized conjugates on their potential as ribonuclease

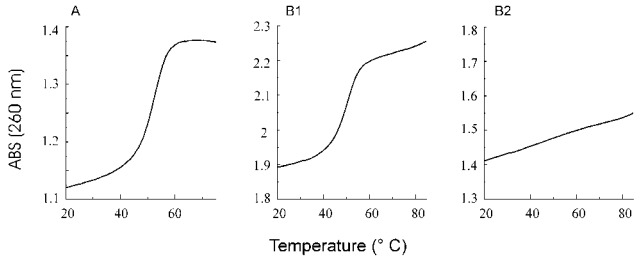

Figure 4. Determination of the melting temperature of duplexes formed between the oligodeoxynucleotide sequence used for the preparation of the oligonucleotide conjugates and (A) the linear RNA target, T_m = 52.3 °C, and (B) the hairpin RNA target. B2 is the curve of the hairpin without oligodeoxynucleotide (no T_m observed), and B1 shows a hyperchromic effect when oligodeoxynucleotide is present, T_m = 50.3 °C.

mimics, two RNA molecules were used as targets. First, a simple linear RNA 23-mer with single strand overhang of nine nucleotides at the 5′-end of the oligonucleotide conjugates (Figure 3A) was used, though the extensive dangling motion allowed in such a target could impede any interaction between the RNA molecule and the ribonuclease mimic. Therefore, a second RNA target was used where, next to the RNA/oligonucleotide−conjugate duplex, the RNA strand is believed to form a hairpin structure (Figure 3B). Some additional unpaired bases are present at the 3′-end, because unpaired (and bulged) regions are cleaved preferentially.

Prior to the cleavage experiments, the melting temperature (T_m value, Figure 4) of the duplex formed between the oligodeoxynucleotide and RNA strands was measured in order to ensure duplex formation at the temperature at which the cleavage experiments are performed. The T_m value for the association of the oligodeoxynucleotide with the linear RNA (Figure 3A) was observed to be 52.3 °C (Figure 4A). In the case of the hairpin RNA, T_m measurements were performed in the presence (Figure 4B1, T_m = 50.3 °C) as well as in the absence (Figure 4B2, no T_m value observed) of the oligodeoxynucleotide used in the oligonucleotide conjugates in order to ascertain the measured T_m value is correlated with the formation of a duplex between the oligodeoxynucleotide and RNA hairpin and that the T_m value is not correlated to the dissociation of the hairpin duplex structure itself. A T_m value for the hairpin structure itself could not be obtained, not even at very low salt concentration. However, the hairpin structure itself was chosen based on previously reported results which indicated the hairpin exhibits extraordinary stability (*30*). Since all exceeded 50 °C, it can be concluded that performing the cleavage tests at 37 °C will not impair association of the oligonucleotide conjugates with their target RNA sequence.

In a first experimental setup, the cleavage tests were performed under the conditions as suggested by Vlassov et al. (*31*) using Tris buffer or imidazole buffer, though

Table 2. Survey of the Conditions Used for Cleavage Experiments

	A	B	C	D	E	F	G	H	I
Tris buffer pH 7.5	50 mM		50 mM	50 mM	50 mM	50 mM	50 mM	50 mM	50 mM
imidazole buffer pH 7		50 mM							
NaCl	150 mM	150 mM	150 mM	75 mM		150 mM	150 mM	150 mM	150 mM
KCl				75 mM	150 mM

metal ion[a]						Zn^{2+}	Mn^{2+}	Cu^{2+}	Pb^{2+}

[a] Final concentration 2 mM.

no specific cuts could be observed. The inclusion of imidazole in the reaction buffer could serve as an exogeneous cleavage catalyst, which seems not to be the case here. Other experiments were performed where the amount of sodium chloride was changed, in combination with or replaced by potassium chloride, albeit without any success. A survey of the different conditions in which the oligonucleotide conjugates were tested is given in Table 2. Because of the tendency of some of the oligonucleotide conjugates to complex metal ions as observed during mass spectral analysis, the experimental setup was complemented with the addition of metal ions in order to cause target degradation. Addition of Mg^{2+}, Zn^{2+}, or Mn^{2+} did not result in any difference. The addition of Cu^{2+} and Pb^{2+} resulted in a complete and specific degradation of the target molecule.

Obviously, more tests can be envisioned in order to elicit hydrolytic RNA degradation. On the other hand, the aim of the project is to develop a method for sequence-specific RNA degradation, preferentially under near physiological conditions. Apparently, the tests performed do not indicate a tendency for successful cleavage under such conditions.

CONCLUSION

The development of organic hydrolytic cleavers occupies a special place in the category of artificial ribonucleases because of their RNA selectivity. Until now, the search for such cleavers was met with limited success because their cleavage capacity is less efficient than that of inorganic cleavers (*33*). The selection of organic functional groups used for this purpose is based on their presence in the active sites of some ribonucleases. We focused on the use of imidazole moieties as derived from RNase A (*32*) and the combination of imidazole and amino groups. The synthesis of the RNase A mimics was based on the proper derivatization with imidazole-containing moieties by amide bond formation of different molecules. These molecules served as linking arm between the imidazole and amino groups and between the cleaver and the oligonucleotide. Therefore, alternative strategies were explored for the selective acylation of polyamine compounds. It was found that thiazolide and imidazolide activation of the carboxy acid function leads to high discrimination for differences in nucleophilicity and sterical environment of the attacking amines. For the coupling of the RNase A mimics with the oligonucleotide, we used peptide bond chemistry. The peptide bond formation with a 5′-amino-functionalized oligonucleotide did work for all RNase A mimics albeit not always in the same extent.

Different conditions were used for the evaluation of the 5′-oligonucleotide conjugates, but no cleavage could be observed. More forcing reaction conditions could be envisioned for these cleavage tests, but the goal of the study was to develop ribonuclease mimics that can be used under physiological or near physiological conditions.

The reason for this failure could be due as well to the structure of the RNase A mimic as to an inappropriate target-selection. The flexibility of the linker between the RNase A mimic and the oligonucleotide as well as the flexibility of the backbone between the two imidazole functions is very high. In the case of the enzyme, RNase A, all participants in the enzymatic reactions are well anchored in the enzyme active site, which favors them entropically compared to the RNase A mimics. From this point of view, the synthesis of RNase mimics with a less flexible linker or the attachment of imidazole groups on a rigid scaffold may be envisaged. Vlassov et al. already emphasized the importance of target selection and structure. Our experiments were mainly carried out on linear nucleic acids while the experiments of Vlassov et al. (*34*) were conducted on $tRNA^{Phe}$. In conclusion, appropriate selection of cleavage agent, target, linker groups, and reaction conditions is needed to obtain a successful RNA-cleaver. It will be very difficult to mimic the in vivo situation by in vitro experiments to make this catalytic RNA-cleaving approach as successful as the natural systems (RNase's and ribozymes).

ACKNOWLEDGMENT

The authors thank K. U. Leuven (GOA 97/11) and F.W.O. for financial support. Dr. J. Lacey is grateful to the K. U. Leuven for a Research Fellowship. We are indebted to G. Schepers and Prof. A. Van Aerschot for the synthesis of the monomethoxytritylated aminoalkoxy derivitized oligonucleotides. We are indebted to C. Biernaux for editorial help. Authors thank the reviewers for helpful comments.

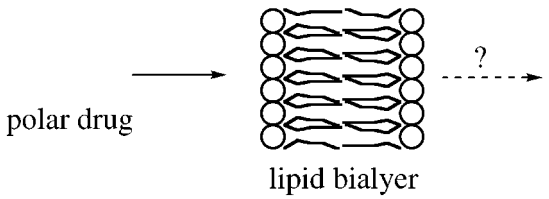
Molecular Umbrella-Assisted Transport of Thiolated AMP and ATP Across Phospholipid Bilayers



Vaclav Janout, Bingwen Jing, and Steven L. Regen*

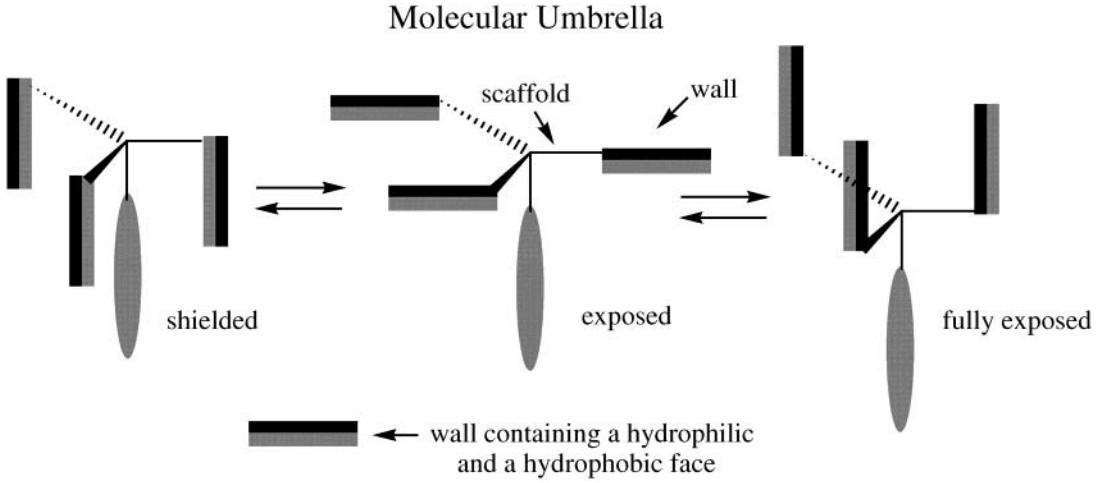
Department of Chemistry, Lehigh University, Bethlehem, Pennsylvania 18015. Received October 9, 2001; Revised Manuscript Received December 4, 2001

Two molecular umbrella-nucleoside conjugates (**1a** and **1b**) have been synthesized via thiolate−disulfide displacement by adenosine 5′-*O*-(3-thiomonophosphate) and adenosine 5′-*O*-(3-thiotriphosphate) on an activated dimer derived from cholic acid, spermidine, and 5,5′-dithiobis-(2-nitrobenzoic acid). Both conjugates readily enter the aqueous compartment of liposomes made from 1-palmitoyl-2-oleyol-*sn*-glycero-3-phosphocholine (POPC) and release the free nucleoside upon reaction with entrapped glutathione. Approximately 50% of the thiolated form of AMP is released within 20 min at 23 °C; 120 min is required for a similar release of the thiolated form of ATP. The facile cleavage of these conjugates by glutathione, together with the fact that mammalian cells contain millimolar concentrations of this tripeptide in their cytoplasm, suggest that such chemistry may be extended to the practical development of prodrugs, e.g., antisense oligonucleotides that can be delivered into cells.

INTRODUCTION

Lipid bilayers play an essential role in cells by serving as barriers for transport (*1*). In particular, they permit the selective passage of those molecules and ions that are necessary for maintaining the living state. Due to their hydrophobic core, the ability of many classes of biologically active agents that have therapeutic potential (e.g., nucleosides, opioid pentapeptides, antisense oligonucleotides, and DNA) to enter cells has been limited (*2*−*15*). Finding ways to improve the bilayer transport of such molecules is a formidable challenge, and one that has important biomedical implications.

With this challenge in mind, we have introduced a unique class of amphiphilic molecules that interconvert between two different morphological states in response to changes in their microenvironment. These "amphomorphic" compounds, in a sense, mimic the structure and function of umbrellas by being able to cover an attached agent and shield it from an incompatible environment (*16*, *17*). Thus, when two or more facially amphiphilic units (i.e., rigid hydrocarbon units that maintain a hydrophobic and a hydrophilic face) are coupled to a suitable scaffold that contains a hydrophilic agent, immersion of such a molecule in an aqueous environment favors an exposed (or fully exposed) conformation, where hydrophobic interactions are maximized and where the hydrophilic faces are hydrated. When immersed in an hydrocarbon environment (e.g., the interior of a lipid bilayer), the umbrella then favors a shielded conformation such that intramolecular dipole−dipole and hydrogen bonding interactions are maximized, and the hydrophobic faces are solvated. A stylized illustration of a molecular umbrella in shielded, exposed, and fully exposed conformations is presented in Scheme 1. Here, each amphiphilic unit appears as a doubly shaded rectangle having a hydrophobic (darkened) and a hydrophilic (lightly shaded) face; the lightly shaded oval corresponds to a hydrophilic agent. Our working hypothesis has been that molecular umbrella conjugates can cross lipid bilayers through the following sequence of events: (i) diffusion to the membrane surface in an exposed or fully exposed state, (ii) insertion into the outer monolayer leaflet by flipping into a shielded state, (iii) diffusion to the inner monolayer leaflet, and (iv) entry into the adjoining aqueous phase via the reversal of steps ii and i (Scheme 2).



In recent studies, we have obtained compelling evidence for an "umbrella" mechanism of permeation for the transport of an umbrella conjugate of glutathione (γ-Glu-Cys-Gly, GSH) across phospholipid bilayers (*18*). Specifically, we found that the ability of this conjugate to cross these bilayers depended more on their facially amphiphilicity than on their hydrophobic/hydrophilic balance. Thus, the permeation of molecular umbrellas across lipid membranes takes place by a mechanism that is different from classic solution-diffusion pathways, where permeation rates are controlled by the permeant's solubility and diffusivity in the hydrocarbon region of the membrane (*3*).

In an effort to expand the scope of molecular umbrellas as membrane transporters, we have begun to turn our attention toward the bilayer transport of antisense oligonucleotides. As a first step in this direction, we sought to demonstrate the feasibility of transporting cleavable forms of adenosine 5′-monophosphate (AMP) and adenosine 5′-triphosphate (ATP) across phospholipid bilayers. Although several studies have been aimed at creating prodrugs of nucleoside 5′monophosphates, reports of membrane transporters of nucleoside 5′-triphosphates are rare. In one recent study, where it was

claimed that a cholesteryloxycarbonyl−ATP conjugate releases of free ATP into the aqueous compartment of liposomes, the transport activity that was observed was only modest; ca. 10% after 9 days at an unspecified temperature (*19*). In this paper, we describe the synthesis of molecular umbrella conjugates of thiolated forms of AMP and ATP. We also show that these conjugates deliver the free nucleosides into liposomes, made from 1-palmitoyl-2-oleoyl-*sn*-glycero-phosphocholine (POPC), with half-lives that are less than 20 and 120 min at 23 °C for the monophosphate and triphosphate, respectively.

MATERIALS AND METHODS

General Methods. Unless stated otherwise, all reagents were obtained from commercial sources and used without further purification. 1-Palmitoyl-2-oleoyl-*sn*-glycero-phosphocholine was obtained from Avanti Polar Lipids (Alabaster, AL). Adenosine 5′-*O*-(3-thiotriphosphate) and adenosine 5′-*O*-(3-thiomonophosphate) were purchased from Fluka and used directly. 5,5′-Dithiobis-(2-nitrobenzoic acid) (Ellman's reagent) was purchased from Aldrich (Milwaukee, WI) and used as obtained. All dialysis experiments were made using a 1.5-mL equilibrium dialysis cell (Fischer Scientific) and SpectraPor #7 dialysis tubing (MWCO 50000). All ^{1}H NMR spectra were recorded on a Bruker 360 MHz instrument; chemical shifts are reported in ppm and are referenced to residual solvent. The buffer that was used in all experiments was composed of 0.1 M H_3BO_3 and 2 mM EDTA, where the pH was adjusted to 7.0 by use of 1 M NaOH. All UV spectra were recorded using a Cary 300 Bio UV/VIS spectrophotometer.

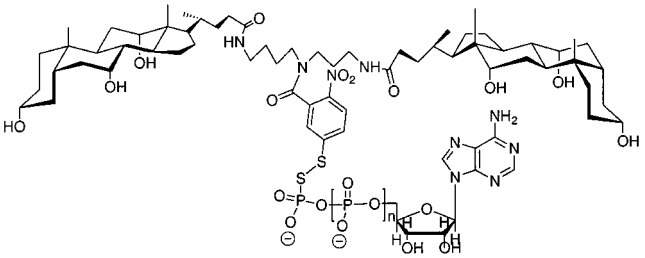
Molecular Umbrella−ATP Conjugate 1b. To a solution of 12.6 mg (5.7 μmol) of **6** in a mixture of 400 μL of CH_3OH and 150 μL of H_2O was added a solution that was made from 3.12 mg (5.7 μmol) of the tetralithium salt of adenosine 5′-*O*-(3-thiotriphosphate) and 150 μL of water. A homogeneous orange-colored solution was produced, and the solution was stirred for a total of 72 h at room temperature. Concentration under reduced pressure, followed by preparative thin-layer chromatography (silica gel, $CHCl_3/CH_3OH/H_2O$, 60/40/10, v/v/v), afforded 2.51 mg (24.9%) of the desired conjugate, **1b**, having R_f 0.45 and ^{1}H NMR (CD_3OD) δ 842 (d, 1 H), 8.19 (s, 1 H), 8.06 (m, 1 H), 7.70 (m, 2 H), 6.05 (m, 1 H), 4.67 (m, 1 H), 4.45 (m, 1 H), 4.25 (m, 3 H), 3.92 (m, 2 H), 3.78 (s, 2 H), 3.35 (m, 6 H), 3.00 (m, 4 H), 0.89−2.20 (m, 66 H), 0.68 (d, 6 H). HRMS for $C_{72}H_{110}N_9O_{24}P_3S_2Na_3$ (MNa^+) Calcd: 1710.6006. Found: 1710.6094.

Molecular Umbrella−AMP Conjugate (1a). Using procedures similar to those used for the synthesis of **1b**, the molecular umbrella−AMP conjugate (**1a**) was ob-

tained in a 53% isolated yield, having R_f 0.41 (silica gel, $CHCl_3/CH_3OH/H_2O$, 65/25/4, v/v/v) and ^1H NMR (CD_3OD) δ 841 (d, 1 H), 8.19 (s, 1 H), 8.03 (m, 1 H), 7.68 (m, 2 H), 6.06 (m, 1 H), 4.66 (m, 1 H), 4.30 (m, 1 H), 4.20 (m, 3 H), 3.92 (m, 2 H), 3.78 (s, 2 H), 3.35 (m, 6 H), 3.00 (m, 4 H), 0.90−2.25 (m, 66 H), 0.69 (d, 6 H). HRMS for $C_{72}H_{109}N_9O_{17}PS_2Na_2$ (MNa^+) Calcd: 1512.6910. Found: 1512.6959.

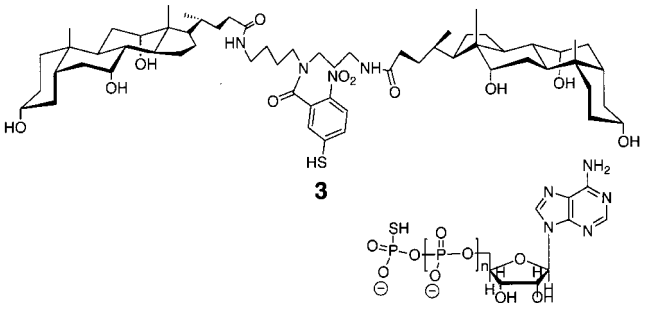
Vesicles for Transport Experiments. Typically, 2.0 mL of a 20 mg/mL solution of POPC in chloroform were transferred to a Pyrex test tube, and the solvent was evaporated by rotating the tube under a stream of nitrogen, resulting in a thin lipid film. The last traces of solvent were removed under reduced pressure (25 °C, 72 h, <0.2 Torr). To the dried film was added 2.20 mL of a 1.2 mM solution of glutathione that was prepared in borate buffer, which had been adjusted to pH 7.0 by addition of a few drops of 1 M NaOH. The mixture was vortexed for 40 s, incubated at room temperature for 5 min, vortexed for another 40 s, and incubated for 25 min at room temperature, while being maintained under an argon atmosphere. The dispersion was then subjected to six freeze/thaw cycles (−196 °C/30 °C), followed by extrusion through a 400 nm Nuclepore membrane (12 times) and a 200 nm Nuclepore membrane (15 times).

Gel Filtration Procedure. All gel filtrations were carried out via minicolumn centrifugation using prepacked Sephadex G-25, PD-10 (Pharmacia Biotech). Prior to use, the Sephadex G-25 was extensively rinsed with borate buffer. Typically, 1.0 mL of the dispersion was gel filtered (two times) using 5.0 g of Sephadex G-25 (fine), by expelling the void volume of the column via centrifugation (3 min). To confirm that all of external glutathione had been removed, an aliquot of the dispersion (400 μL) was dialyzed against 400 μL for 24 h at room temperature, using an equilibrium dialysis cell and SpectraPor #7 dialysis tubing (MWCO 50000). Analysis of the receiving side for thiol content (Ellman's reagent) showed a negligible concentration of glutathione, i.e., <0.1 μM.



Reaction of Vesicle-Entrapped Glutathione with 1b. In a typical experiment, 600 μL of the vesicular dispersion was mixed with 600 μL of a 30 μM solution of **1b** in borate buffer, and half of the mixture was then added to a 0.7 mL UV cuvette. The rate of formation of **3** was then monitored as a function of time (λ_{max} 427 nm) up to 98% conversion. Careful subtraction of apparent absorbances due to light scattering was done in all cases.

In a separate experiment, 600 μL of the original vesicular dispersion was mixed with 600 μL of a 30 μM solution of **1b** in borate buffer, and half of this mixture was then dialyzed against 600 μM of borate buffer for 24 h. A portion of the receiving side (400 μL) was then mixed with 35 μL of 2 mM Ellman's reagent (pH 7.0), and the thiol content was then determined by measuring the absorption at 410 nm. Based on this analysis, the maximum concentration of glutathione that was present outside of the vesicles was determined to be <0.15 μM. Thus, the addition of **1b** does not induce significant leakage of glutathione from the vesicles.

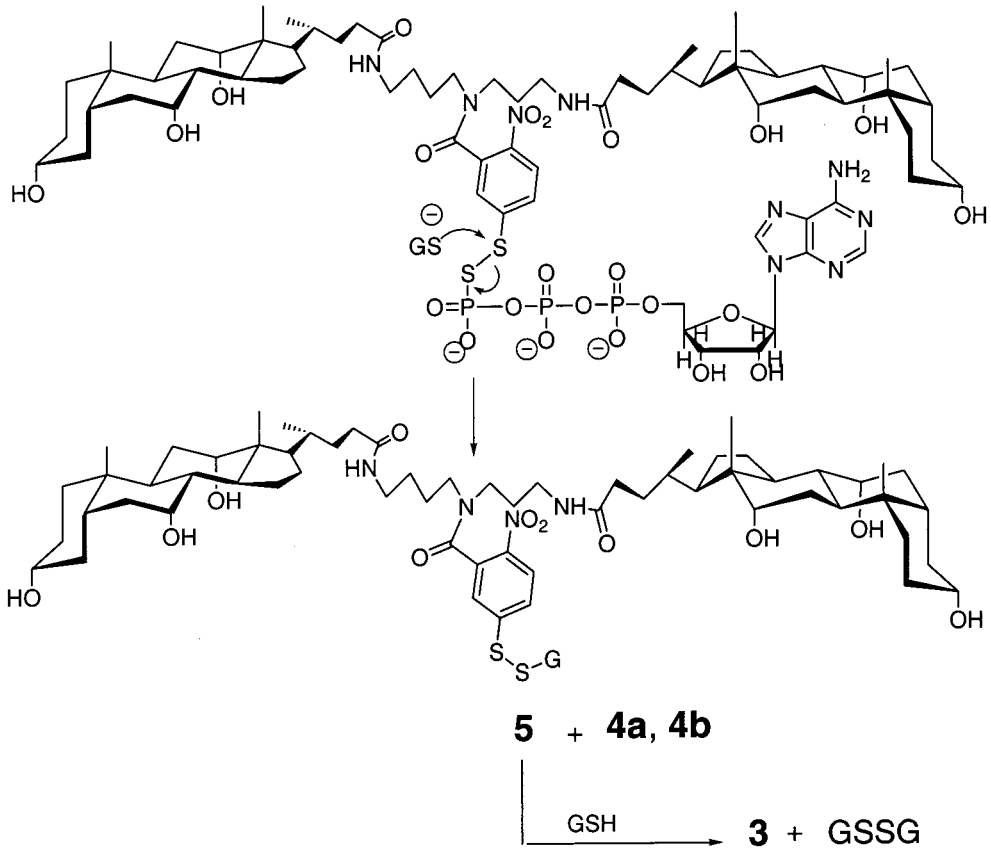


To confirm that the released nucleoside was captured within the vesicles, 400 μL of the disperson (taken from the source side of the dialysis cell after 24 h of reaction) was gel filtered using procedures described above. A 100 μL-aliquot of the void volume was then mixed with 300 μL of ethanol, followed by vortex mixing. The UV spectrum of the homogeneous solution (230−500 nm) was then recorded. After a background subtraction was made, using a similar solution that was devoid of **1b**, the nucleoside content (λ_{max} 260 nm) was determined.

RESULTS AND DISCUSSION

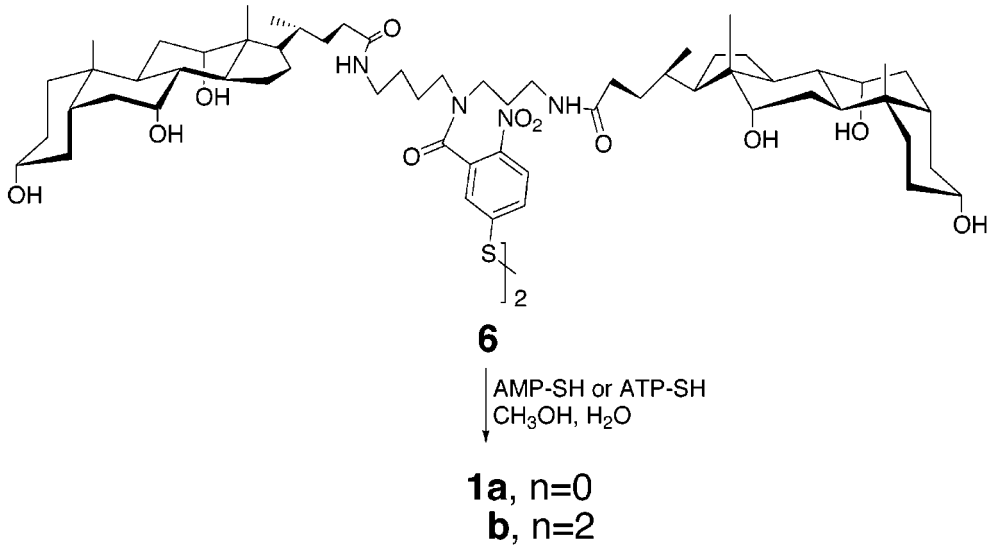
Design and Synthesis of Molecular Umbrella−Nucleoside Conjugates. The molecules that were chosen as synthetic targets for this study were conjugates **1a** and **1b**. Attack by glutathione on the disulfide moiety was expected to result in umbrella−nucleoside cleavage with the formation of **3**, **4a**, and **4b**. In one scenario (pathway A), attack on the disulfide linkage of the umbrella by the thiolate anion of glutathione results in the direct release of the free nucleoside and the formation of **5** (Scheme 3). Subsequent attack by a second glutathione molecule on **5** then liberates **3** plus the oxidized form of glutathione (GSSG). An alternative pathway (pathway B, not shown) is one in which glutathione initially attacks the sulfur atom of the nucleoside, thereby liberating **3**; subsequent attack by a second glutathione molecule on the resulting glutathione−nucleoside conjugate then affords **4a** or **4b** plus GSSG. Given the UV absorbances of **5** (λ_{max} 330 nm; ϵ 5.501 × 10^3 M^{-1} cm^{-1}, borate buffer, pH 7.0) and **3** (λ_{max} 427 nm; ϵ 7.007 × 10^3 M^{-1} cm^{-1}; borate buffer, pH 7.0), one might expect that insight into the preferred reaction pathway could be obtained by following the changes in the UV spectrum with time. An additional basis for the design of these conjugates stems from the fact that mammalian cells contain millimolar concentrations of glutathione. Thus, such conjugates have attractiveness from a prodrug standpoint.

1a, n=0
b, n=2



3

4a, n=0
b, n=2



In Scheme 4 is shown the method by **1a** and **1b** were synthesized. In brief, molecular umbrella dimer, **6**, bearing a labile "Ellman's" moiety (previously described) was reacted with adenosine 5′-*O*-(3-thiotriphosphate) or adenosine 5′-*O*-(3-thiomonophosphate) in an aqueous methanolic solution (*18*, *20*). The desired conjugates were then isolated from the resulting equilibrium mixtures by preparative thin-layer chromatography.

Nature of Molecular Umbrella−Nucleoside Cleavage by Glutathione. To understand how these molecular umbrella−nucleosides are cleaved by glutathione, a solution of **1a** was treated with the peptide in borate

Scheme 3

Scheme 4

buffer. As is evident from Figure 1, the UV absorbance for **1a** (λ_{max} 349 nm; ϵ 7.007 × 10^3 M^{-1} cm^{-1}) disappears almost instantly and is replaced by the UV absorbance of **5** (λ_{max} 330 nm). The latter absorbance then decreases with time and is replaced with the absorbance of **3** (λ_{max} 427 nm). These results clearly indicate that pathway A (Scheme 3) is dominant, where initial attack by glutathione releases the free nucleoside and not **3** (λ_{max} 427 nm). On the basis of the spectral intensity that appeared at 427 nm, after **1a** had fully reacted (i.e., after 30 s of reaction), we estimate that ≥95% of the cleavage occurs via pathway A. Similar results were obtained with **1b**, except that the resolution of the UV absorbances was not as significant (not shown).

Umbrella-Assisted Bilayer Transport of Thiolated AMP and ATP. Large unilamellar vesicles (200 nm diameter) were prepared from 1-palmitoyl-2-oleoyl-*sn*-glycero-phosphocholine (POPC) via extrusion methods in the presence of 1.2 mM of glutathione (*20*). Nonentrapped GSH was then removed by gel filtration. In a typical bilayer transport experiment, a 30 mM POPC liposomal dispersion was mixed with an equal volume of a 28.6 μM solution of **1b** in borate buffer. Subsequent mixing was then carried out in the "source" side of a 1.5-mL equilibrium dialysis cell, which contained an equal volume of borate buffer in the "receiving" side. Agitation of the cell was made by use of a wrist-action shaker. Because of light scattering of the vesicles, the extent of molecular

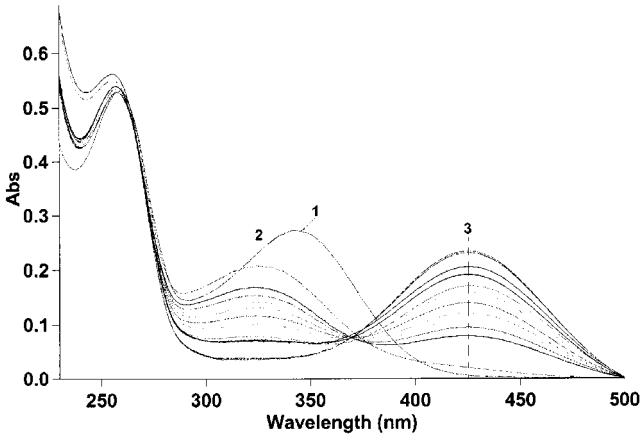


Figure 1. Spectral changes as a function of time for the reaction of 58 μM of **1a** with 220 μM glutathione in borate buffer (pH 7.0) at 25 °C. The λ_{max} for **1a** that appears at 349 nm (#1) was observed at the start of the reaction. After 30 s, a strong peak appeared with a λ_{max} at 330 nm (#2), which decreased in intensity; the lowest absorbance that is shown at this wavelength was observed after 65 min. A gradual "growing in" of the absorbance of **3** was observed at λ_{max} 427 nm (#3).

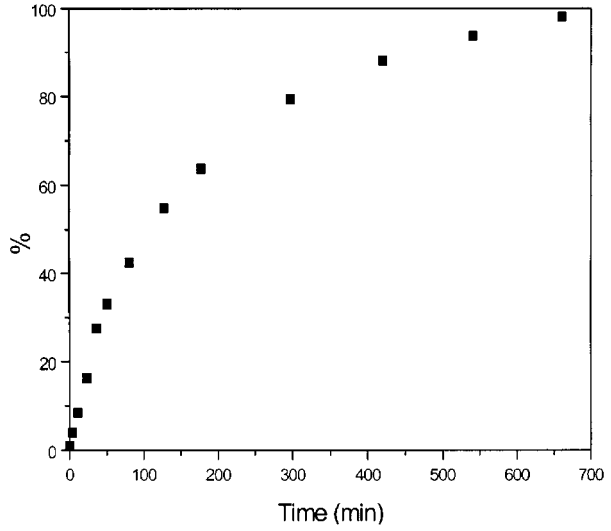

Figure 2. Plot of the percentage of **3** that is formed as a function of time, for the reaction of 15 μM **1a** with 14.3 mM POPC liposomes, containing 1.2 mM entrapped glutathione at 23 °C.

umbrella−nucleoside cleavage was monitored by following the appearance of **3** at 427 nm. A plot of the percent of **3** that is formed as a function of time is shown in Figure 2, which indicates that ca. 120 min is needed for generating ca. 50% of the reduced umbrella. Since the formation of **3** represents a slower second stage of the cleavage reaction (the initial stage being the direct release of the nucleoside), the time that is needed for releasing 50% of the free nucleoside into the aqueous interior of the vesicles must be <120 min. Analysis of the receiving side of the cell after 24 h for thiol content (Ellman's reagent) indicated a maximum glutathione concentration in the external bulk phase to be 0.31 μM. Thus, the extent of leakage that is induced by the presence of **1b** is exceedingly low, if at all.

To confirm that the released nucleoside (**4b**) was captured within the vesicles, a portion of a liposomal dispersion, which had been fully reacted, was mixed with ethanol to destroy the vesicles and then analyzed for **4b** (λ_{max} 260 nm). A second portion of the dispersion was subjected to gel filtration (to remove nonentrapped **4b**) and also analyzed for nucleoside content. Comparison of these two measurements indicate that >90% of **4b** was entrapped within the vesicles; that is <10% of the nucleoside was removed from the dispersion by gel filtration. A control experiment that was carried out, in which an aqueous solution of **4b** was mixed with an equal volume of POPC vesicles (loaded with 1.2 mM glutathione) showed the complete removal of the nucleoside via gel filtration. Analogous transport experiments that were carried out with **1a** gave similar results, except that the rate of appearance of **3** was faster; here, 50% of the conjugate was converted into **3** after 20 min.

CONCLUSIONS

The results reported herein demonstrate the feasibility of conjugating thiolated forms of AMP and ATP to molecular umbrellas and transporting these nucleosides across liposomal membranes. The facile cleavage of such conjugates by entrapped glutathione, together with the fact that mammalian cells contain millimolar concentrations of glutathione in their cytoplasm, suggests that this chemistry may be extended to the practical development of prodrugs, e.g., antisense oligonucleotides, which can be delivered into cells.

Synthesis and Biologic Evaluation of a Radioiodinated Quinazolinone Derivative for Enzyme-Mediated Insolubilization Therapy

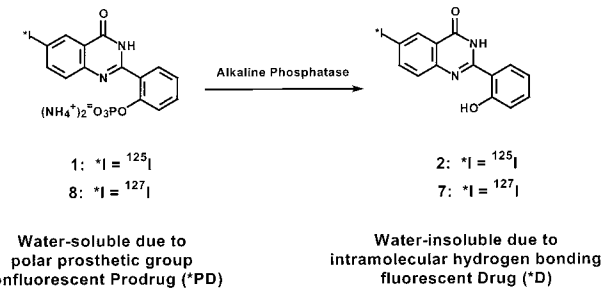
Nan-hui Ho, Ravi S. Harapanhalli, Bassam A. Dahman, Kai Chen, Ketai Wang, S. James Adelstein, and Amin I. Kassis*

Department of Radiology, Harvard Medical School, Goldenson Building B-242, 220 Longwood Avenue, Boston, Massachusetts 02115. Received October 15, 2001; Revised Manuscript Received January 25, 2002

We have developed a new strategy that aims to concentrate therapeutic radionuclides within solid tumors. This approach, which we have named EMIT (enzyme-mediated insolubilization therapy), is a method for enzyme-dependent, site-specific, in vivo precipitation of a radioactive molecule (from a water-soluble precursor) within the extracellular space of solid tumors. The prodrug, ammonium 2-(2′-phosphoryloxyphenyl)-6-iodo-4-(3*H*)-quinazolinone, labeled with iodine-125 (^{125}IPD) and its authentic compound labeled with iodine-127 (IPD) have been synthesized, purified, and characterized. The alkaline phosphatase (ALP)-mediated conversion of these water-soluble nonfluorescent prodrugs to the water-insoluble fluorescent species, iodine-125-labeled 2-(2′-hydroxyphenyl)-6-iodo-4-(3*H*)-quinazolinone (^{125}ID) and its iodine-127-labeled derivative (ID), has been demonstrated in vitro. Biodistribution studies in mice indicate that both ^{125}IPD and ^{125}ID are minimally retained by most tissues and organs. In addition, following its intravenous injection in mice, ^{125}IPD is localized in ALP-rich regions and converted to ^{125}ID, which remains indefinitely within the tissues where it is produced. We believe that EMIT is a strategy that will lead to the active and specific concentration and entrapment of therapeutic radionuclides within solid tumors, the consequent protracted irradiation of tumor cells within the range of the emitted particles, and the effective therapy of solid tumors.

INTRODUCTION

Monoclonal antibodies (mAb)[1] by virtue of their unique in vitro specificity and high affinity for their antigen have been considered particularly attractive as selective carriers of cancer radiotherapeutic atoms/molecules. While most published work on this subject has demonstrated their utility in the diagnosis and treatment of various tumors in *experimental animal models*, the use of radiolabeled mAb to target and treat solid tumors in cancer patients has been for the most part unsuccessful. This failure can be attributed to many causes, including (i) high activity in the whole body, which lowers the maximum tolerated dose (MTD), (ii) limited intratumoral diffusion of the radiolabeled protein molecules and heterogeneity of tumor-associated antigens, both of which lead to nonuniform distribution of the radionuclide within the tumor mass and the consequent sparing of many regions (because either they are outside the range of the emitted particles or they receive a sublethal dose), and (iii) low tumor uptake (∼0.01% injected dose per gram [% ID/g] of tumor in patients versus 5−50% ID/g of tumor in mice). It seems highly probable that the latter point, which is the most distinctive difference between the results obtained from studies in mice and in humans, is the principal factor that has generally led to the therapeutic ineffectiveness of radiolabeled antibodies in man.



In an attempt to bypass some of these limitations, we have been developing a novel strategy that aims to concentrate radioactive molecules within solid tumors. The approach, which we have named EMIT (enzyme-mediated insolubilization therapy), is a method for enzyme-dependent, site-specific, in vivo precipitation of a water-soluble radioactive molecule within the extracellular space of solid tumors. In one of its embodiments, the radiolabeled prodrug is hydrolyzed to its water-insoluble form by a constitutive enzyme present in high concentrations within the tumor. In another embodiment, a mAb−enzyme conjugate is injected into tumor-bearing animals. Following its tumor targeting and partial clearance from normal tissues and organs (i.e., high tumor-to-normal-tissue ratios), a water-soluble radioactive substrate to the preadministered enzyme is injected. Owing to the negatively charged prosthetic group(s) present within the substrate, it is highly hydrophilic and consequently not internalized by mammalian cells. On enzymatic hydrolysis, this water-soluble molecule loses its prosthetic group, and the resulting compound is water insoluble and precipitates. The precipitated molecules are concentrated and trapped within the extracellular space of the targeted solid tumor. For EMIT, the substrate may be radiolabeled with an energetic α- (e.g., ^{211}At, ^{213}Bi) or β- (e.g., ^{131}I, ^{90}Y) particle-emitting radionuclide. Once precipitated and trapped within the tumor, the prolonged

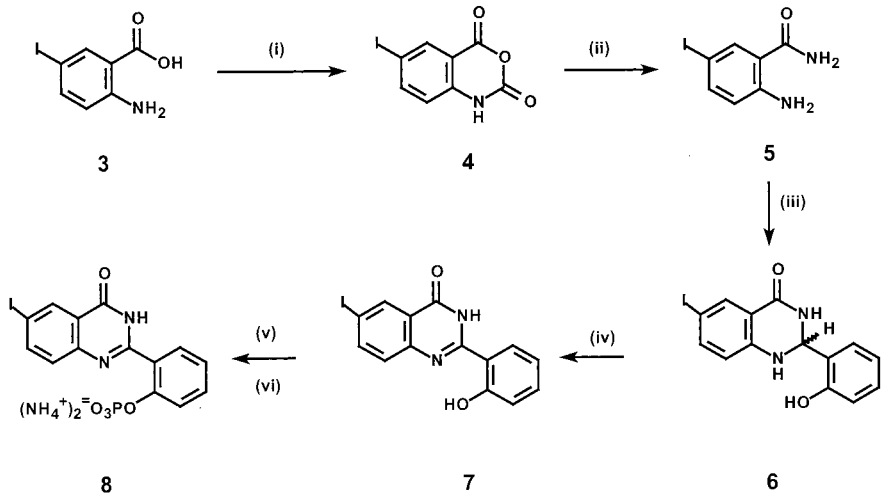
residence time should permit delivery of a high radiation dose to the tumor with a low dose to the rest of the body.

In 1994, Haugland et al. (*1*) described a class of novel substrates made from quinazolinones for the in vitro detection of cell-associated enzyme activity, particularly that of glycosidase, phosphatase, and sulfatase. When the enzyme acts on its weakly fluorescent water-soluble substrate, a highly fluorescent product insoluble in aqueous systems is formed. Using a similar approach, we have synthesized an iodinated (^{127}I/^{125}I) derivative of one of these substrates (Schemes 1−3), ammonium 2-(2′-phosphoryloxyphenyl)-6-iodo-4-(3*H*)-quinazolinone (**1** and **8**). In the presence of alkaline phosphatase (ALP), this water-soluble molecule is hydrolyzed to 2-(2′-hydroxyphenyl)-6-iodo-4-(3*H*)-quinazolinone (**2** and **7**), a water-insoluble alcohol that precipitates in aqueous solution. We plan to localize such molecules, when labeled with therapeutic radionuclides such as ^{131}I or ^{211}At, within solid tumors that are either innately rich in ALP or that have been pretargeted with an antitumor-antibody−ALP conjugate. We believe that the EMIT approach will lead to the active and specific concentration and entrapment of such therapeutic radionuclides in solid tumors, the consequent protracted irradiation of tumor cells within the range of the emitted particles, and effective therapies of solid tumors. To our knowledge, the use of prodrugs radiolabeled with therapeutic radionuclides has not been reported.



EXPERIMENTAL PROCEDURES

General Remarks. The reagents were obtained from Sigma Aldrich Chemical Company and used without further purification. Carrier-free sodium [^{125}I]iodide was obtained from Amersham Corporation. NMR spectroscopy was carried out on either a Varian XL-200 or a Varian XL-500 instrument. Electronspray mass spectra were recorded on a Micromass Platform LCZ mass analyzer. HPLC separations were performed on a reversed-phase Nova-Pak C_{18} column, 3.9 × 30 mm (Waters Corporation), at a flow rate of 1 mL/min. UV absorption (Waters 486 detector, 286 nm) and γ-ray detection were used to analyze the eluates. High-resolution mass spectrometry was performed on a Bruker Daltonics ApexII 3 T Fourier transform mass spectrometer. Elemental analyses were obtained from Oneida Research Services Incorporated, Oneida, NY.

Syntheses. *Iodoisotoic Anhydride (**4**).* 2-Amino-5-iodobenzoic acid (**3**, 2.0 g, 7.6 mmol, Aldrich) and triphosgene (2.26 g, 7.6 mmol) were dissolved in 20 mL of dry THF (freshly distilled from CaH_2) (Scheme 2). The reaction mixture was stirred at room temperature for 1 h. An off-white precipitate was formed, and TLC showed that **3** was consumed. The precipitate was filtered and washed with cold methanol. The crude product was redissolved in hot acetonitrile and crystallized (*2*). After drying in vacuo, **4** was obtained as a white solid (2.0 g, 90%); mp = 235 °C dec. ^{1}H NMR (DMSO-d_6) δ 6.94 (d, 1H, ar), 8.01 (d, 1H, ar), 8.11 (s, 1H, ar). *Iodoanthranilamide (**5**).* A solution of **4** (2.0 g, 6.9 mmol) was suspended in 16 mL of THF. The reaction flask was cooled in an ice-bath. Then 1 mL of 28% aqueous ammonium hydroxide solution was added dropwise to the reaction mixture, accompanied by the evolution of gas. The solution became warm and started to boil. The reaction mixture was stirred for 15 min at 0 °C and 30 min at room temperature. At the end of the reaction, the solution became clear. The solvent was evaporated, and a white solid was obtained. The crude product was filtered to give **5** as a fluffy white solid (1.3 g, 72%). ^{1}H NMR (DMSO-d_6) δ 7.80 (s, 1H, ar), 7.37 (d, J = 8.5 Hz, 1H, ar), 7.13 (bs, 2H, NH_2), 6.69 (bs, 2H, *CO*NH_2), 6.54 (d, J = 8.5 Hz, 1H, ar). *2-(2′-Hydroxyphenyl)-6-iodo-4(3H)-quinazolinone (**7**).* 2-(2′-Hydroxyphenyl)- 6-iodo-2,3-dihydro-4(1*H*)-quinazolinone **6** (1.831 g, 5 mmol) was oxidized by the addition of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (1.816 g, 8 mmol) in 20 mL of methanol. The suspension was refluxed for 2 h and turned a deep-orange color. After being filtered and washed with cold methanol, the light-yellow solid **7** was obtained (1.52 g, 83.5%). ^{1}H NMR (DMSO-d_6) δ 11.3 (s, N−H), 8.39 (s, H-7), 8.17 (d, J = 8.0 Hz), 8.12 (d, H-5, J = 8.75 Hz), 7.56 (d, H-4, J = 8.5 Hz), 7.44 (t, H-4′, J = 7.75 Hz), 6.99 (d, H-6′, J = 7.5 Hz), 6.95 (t, H-5′, J = 7.70 Hz). *2-(2′-Hydroxy)-6-tributylstannyl-4(3H)-quinazolinone (**9**).* To a stirred solution of **7** (0.50 g, 1.49 mmol) in 10 mL of dioxane was added hexa-*n*-butylditin (1.89 g, 3.12 mmol) followed by tetrakis(triphenylphosphine)palladium (17.0 mg, 0.015 mmol) as catalyst (Scheme 3). The solution was cloudy and yellow. The reaction mixture was refluxed for 1.5 h, and progress of the reaction was followed by silica gel TLC with methylene chloride:ethyl acetate (9:1) to test for the formation of a more nonpolar product. The solvent was evaporated, and the crude yellow solid was purified on a silica gel column eluted with a stepwise gradient, starting with hexane followed by hexane: dichloromethane (1:1). The solvent was removed to give a yellow fluorescent solid product **9** (0.4 g, 43%). ^{1}H NMR (DMSO-d_6) δ 8.24−8.6 (m, 2H, H-7, H-3′), 7.88 (d, H-5, ^3J = 7.80 Hz), 7.68 (d, H-4, ^3J = 8.10 Hz), 7.43 (t, H-5′, ^3J = 8.12 Hz), 6.98 (d, H-6′, ^3J = 9.0 Hz), 6.94 (t, H-4′, ^3J = 8.0 Hz), 1.51 (quintet, 6H′, CH_2CH$_2$Sn, ^3J = 7.70 Hz), 1.30 (sextet, 6H′, CH$_3$CH_2, ^3J = 7.30 Hz), 1.09 (dd, with Sn satellites, $^2J_{Sn-CH}$ = 52 Hz, 6H′, CH_2Sn, $^3J_{avg}$ = 8.0 Hz), 0.83 (t, 9H′, CH_3CH$_2$, ^3J = 7.30 Hz). Peak assignment was made using a combination of COSY (2D) and 1D proton NMR spectra. ESI−HRMS calcd for $C_{26}H_{36}N_2O_2$-Sn [M + H]$^+$: 529.1872. Found 529.1878. Anal. Calcd for $C_{26}H_{36}N_2O_2Sn$: C, 59.23; H, 6.88; N, 5.31. Found: C, 59.48; H, 6.75; N, 5.32.

*Ammonium 2-(2′-Phosphoryloxyphenyl)-6-tributylstannyl-4(3H)-quinazolinone (**10**).* To a stirred solution of **9** (54 mg, 0.108 mmol) in 1 mL of dry pyridine cooled to 0 °C was added dropwise phosphorus oxychloride (20 mg, 0.130 mmol) in 1 mL of dry pyridine. The solution turned yellow. The reaction mixture was stirred for 10 min at 0 °C and then quenched by adding 0.2 mL of 28% ammonium hydroxide solution. The solution was slightly basic (pH 9−10) on pH paper. The reaction mixture after quenching was orange-red. The solvent was evaporated, and a mixture of orange-red-yellow solid was obtained. The crude product was redissolved in methanol:acetate (1:1) and purified on a C_{18} column (Waters) using a stepwise gradient, starting with water followed by acetonitrile:water going from 30% to 50% acetonitrile. The solvent was evaporated under reduced pressure (rotary evaporator). An orange-red-yellow nonfluorescent solid (**10**) was obtained (57 mg, 80%). ^{31}P NMR (DMSO-d_6, H_3PO_4 as external reference) δ −17.2. ESI−HRMS calcd for $C_{26}H_{35}N_2O_5PSn$ [M − H]: 605.1228. Found: 605.1226.

*Ammonium 2-(2′-Phosphoryloxyphenyl)-6-iodo-4(3H)-quinazolinone (**8**). Method A.* 2-(2′-Hydroxy)-6-iodo-4-(3*H*)-quinazolinone (**7**, 0.1 g, 0.274 mmol) was added to 1 mL of dried pyridine at 0 °C, followed by phosphorus oxychloride (42 mg, 27 μL, 0.274 mmol) dissolved in 0.2 mL of dried pyridine under nitrogen gas (Scheme 2). The reaction was completed within 2 min as indicated by silica gel TLC (chloroform:ethyl acetate:methanol, 3:1:1). The reaction solution became less cloudy and was neutralized to pH 7.0 by adding 0.4 mL (10 mmol) of 28% ammonium hydroxide in 1.5 mL of water at 0 °C. During neutralization, the solution turned orange-red and then light-yellow. At the end of neutralization, the solution

stayed orange-red and some orange-red precipitate was formed. The solvent was evaporated, and a mixture of orange-red and yellow solid was obtained. The solid product was suspended in 2−3 mL of water. The orange-red solid was filtered. The yellow filtrate was purified by chromatography on a 12 cm^3 Sep-Pak Vac C_{18} cartridge (Waters) eluted with a stepwise gradient, starting with water (8 mL) followed by acetonitrile:water (2:1, 2 mL). A yellow solution containing UV−visible product was collected. The solvent was evaporated under reduced pressure (rotary evaporator). A yellow nonfluorescent solid (**8**) was obtained (80 mg, 62%). ^{1}H NMR (DMSO-d_6) δ 8.36 (d, H-7, ^4J = 3.5 Hz), 8.25 (dd, H-3′, ^3J = 13.5 Hz, ^4J = 2.5 Hz), 8.07 (dd, H-5, ^3J = 14.3 Hz, ^4J = 3.5 Hz), 7.53 (t, H-4′, ^3J = 13.5 Hz), 7.47 (d, H-4, ^3J = 14.5 Hz), 7.22 (t, H-5′, ^3J = 13.0 Hz), 7.08 (d, H-6′, ^3J = 13.5 Hz). ^{31}P NMR (DMSO-d_6, 85% H_3PO_4 as external reference) δ −14.5. ESI−HRMS calcd for $C_{14}H_8IN_2O_5P$ [M − H]: 440.9138. Found: 440.9146.

Method B. Ammonium 2-(2′-phosphoryloxyphenyl)-6-tributylstannyl-4(3*H*)-quinazolinone (**10**, 15 mg, 0.023 mmol) was dissolved in 0.4 mL of methanol (Scheme 3). Sodium iodide (30 mg, 0.2 mmol) in 0.2 mL of water was added, followed by 0.2 mL of diluted hydrogen peroxide (30% solution diluted 500-fold in water). A yellow precipitate formed immediately. The reaction vial was vortex-mixed and incubated for 15 min at 37 °C. Reversed-phase silica gel TLC (RPSF, Analtech) with acetonitrile:water (1:1) showed approximately 50% conversion. An additional 15-min incubation did not improve the conversion. The solvent was evaporated, and the product was purified by chromatography on a Sep-Pak Plus C_{18} cartridge (Waters) eluted with a stepwise gradient, starting with water followed by acetonitrile:water (2:1, 2 mL). A yellow solution containing a UV product was collected, and the solvent was evaporated to yield a yellow nonfluorescent solid. TLC (chloroform:methanol, 1:1) showed the same R_f value (0.6), and proton and ^{31}P NMR gave the same spectra as were obtained with the known compound **8** synthesized by the other route (Scheme 2). Product **8** was spotted on a TLC plate with alkaline phosphatase and Tris buffer. The TLC plate was incubated for 5 min at 37 °C. After developing the TLC with chloroform, a bright fluorescent spot was seen whose R_f value was the same as that of **7** (R_f = 0.33).

*Preparation of Radiolabeled (^{125}I) Ammonium 2-(2′-Phosphoryloxyphenyl)-6-iodo-4(3H)-quinazolinone (**1**).* Three iodobeads (Pierce) were placed in a reaction vial, followed by 20 μL of **10** (1 μg/μL solution) and 30 μL of 0.1 M borate buffer (pH = 8.3) (Scheme 3). The desired quantity of Na^{125}I (800 μCi, 100 μCi/μL in 0.1 M sodium hydroxide) was added. After 20 min at room temperature, an aliquot was removed for HPLC analysis (the reaction was not quenched with sodium bisulfite since we found that **1** was unstable in reducing reagents). The crude reaction mixture was then loaded on a Sep-Pak Plus C_{18} cartridge (Waters) for purification and separation from unreacted organotin precursor (**10**). The column was eluted with 1 mL of water, 2 mL of 10% acetonitrile in water to remove impurities, and finally with 20% acetonitrile in water. The purification was monitored by determining the radioactivity in each tube (Capintec) and analyzing the samples by autoradiography on reversed-phase TLC (acetonitrile:water, 1.5:2). Only the fractions containing a single radioactive spot that had the same R_f as authentic nonradioactive **8** were combined. Approximately 370 μCi of the product (**1**) eluted with the 20% acetonitrile (radiochemical yield, 46%; radiochemical purity, 98%). When **1** was cospotted with nonradioactive **8** on reversed-phase TLC (acetonitrile:water, 1.5:2), a single spot on autoradiograph was obtained that had the same R_f as **8**. Radiolabeled **1** coinjected with **8** into the HPLC showed a single radioactive peak (t_R = 14 min) that matched the t_R value of **8** (Figure 1).

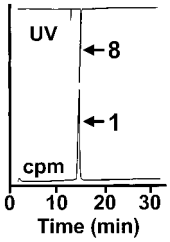

Figure 1. HPLC profile of **1** and **8**.

Biologic Studies. *Enzyme-Dependent Conversion of Prodrug (**8**) to Drug (**7**).* When the water-soluble ^{127}I-labeled **8** is incubated at 37 °C with alkaline phosphatase (ALP), a clearly visible precipitate is formed whose R_f on TLC corresponds to **7**. To assess the kinetics of this enzyme-based hydrolysis (i.e., conversion of **8** to **7**), **8** (60 μM) was mixed with 10 units of ALP in 0.1 M Tris (pH 7.2) containing 50 mM NaCl, 10 mM $MgCl_2$, and 0.1 mM $ZnCl_2$, and the reaction kinetics were followed over time using a Perkin-Elmer LS50B luminescence spectrometer with excitation at 340 nm and emission at 500 nm. The fluorescence intensity at 500 nm was then plotted as a function of time, the linear portions of the data points were fitted, and the slope was used to calculate the half-life ($T_{1/2\alpha}$ and $T_{1/2\beta}$) for the disappearance of **8**.

To assess further the kinetics of this enzyme-based hydrolysis, **8** (2.7 μM) was mixed with 40 units of ALP in buffer (pH 9.8), and the reaction kinetics were followed over time. A plot of reciprocal of the substrate (prodrug **8**) concentration (abscissa) versus reciprocal of reaction velocity (ordinate) furnished a straight Lineweaver−Burk line with a slope equal to K_m/V_{max}; K_m is Michaelis−Menten constant of ALP and V_{max} is maximum velocity.

*Enzyme-Dependent Conversion of Radioiodinated Prodrug (**1**) to Radioiodinated Drug (**2**).* To characterize the radioiodinated prodrug **1**, 5 units of ALP or heat-inactivated (70 °C, 2 h) ALP were incubated (37 °C) for 3 h with **1** (~10 μCi/100 μL of 0.1 M Tris buffer, pH 7.2). Samples were spotted on reversed-phase TLC plates that were then run in acetonitrile:water (1.5:2), and radioactivity was detected by autoradiography.

*Stability of Prodrug **1**.* To assess the chemical nature of the radioactivity in blood post intravenous injection (i.e., determine stability of **1** in blood), mice (n = 5) were injected with ~5 μCi of **1** and bled ~40 min later. The samples were pooled, and ethanol was added to precipitate the cells and proteins. Following centrifugation, the supernatant was spotted on TLC, and the plates were run in acetonitrile:water (1.5:2). Autoradiography was used to visualize the radioactivity on the plates.

*Biodistribution of ^{125}I-Labeled Prodrug (**1**) and Drug (**2**) in Normal Mice.* To determine normal-tissue localization of **1** and **2**, mice (n = 5/group) were injected iv or sc with one of the radioiodinated agents and, at 24 h, the animals were killed. The radioactivity associated with blood, heart, lungs, liver, spleen, kidneys, bladder, urine, stomach, small intestine, large intestine, muscles, skin, skeleton, and thyroid was determined in a gamma counter. Based on the injected activity and the weight of these fluids, tissues, and organs, the percentage injected dose per gram (% ID/g) was then calculated.

*Specific Localization of **1** in Alkaline Phosphatase-Rich Regions.* To demonstrate within an animal the conversion of the water-soluble radioiodinated **1** to the water-insoluble **2**, ALP was dissolved in saline (50, 100, 150, 200, 250, 300, 400 units/10 μL), and10 μL of the enzyme preparations was injected sc, with a 10-μL Hamilton syringe, in the forelimb of Swiss Alpine mice (n = 5/ALP concentration). Five minutes later, 20 μCi of **1** was injected iv (tail vein). The animals were killed 1 h later, and the radioactivity in the forelimbs was measured. As nonspecific controls, mice (n = 5) were injected sc (forelimb) with 200 units of heat-inactivated ALP (56 °C, 30 min) prior to the iv injection of **1**.

*Entrapment of **2** within Tissues.* To demonstrate that the water-insoluble ID is retained within the tissue where it is formed, 100 μCi of **7** and 2.5 mg of **2** were added to 100 μL of DMSO, and the sample was heated. Under these conditions, the water-insoluble iodinated (^{125}I/^{127}I) drug dissolves completely, forms a yellow solution, and remains in solution when the sample is cooled to room temperature. However, when 100 μL of water is added, a visible precipitate forms immediately. Five microliters of **7**−**2**-DMSO solution was injected sc into the right forelimb of Swiss Alpine mice (n = 15) and followed at once by 5 μL of saline (the immediate formation of turbidity was noted through the skin of the mice). For comparison, 5 μCi of **1** in 5 μL of saline was injected sc into the left forelimb of the same mice and followed immediately with 5 μL of DMSO. The animals were killed after 1, 24, and 48 h (n = 5/time point). The radioactivity associated with the forelimbs was measured, and the percentage of radioactivity remaining at the injection site was calculated.

RESULTS

Enzyme-Dependent Conversion of Prodrug (8) to Drug (7). When nonradiolabeled prodrug **8**, a nonfluorescent, water-soluble compound was incubated with alkaline phosphatase and the kinetics of the hydrolysis were followed with a luminescence spectrometer, a rapid increase in fluorescence intensity (excitation at 340 nm; emission at 500 nm) was observed, demonstrating the hydrolysis of **8** and the formation of **7** (Figure 2, top). Analysis of these data indicates the enzyme-dependent disappearance of **8** (or the appearance of **7**) is biphasic with a $T_{1/2\alpha}$ of 31 s and a $T_{1/2\beta}$ of 120 s (Figure 2, bottom). No fluorescence was detected when the enzyme was heat-inactivated prior to its incubation with **8**.

To assess the kinetics of this enzyme-based hydrolysis, the Michaelis−Menten constant of ALP (K_m) and maximum velocity (V_{max}) were determined by a straight Lineweaver−Burk line with a slope equal to K_m/V_{max}, where the y intercept of the line is $1/V_{max}$ and the x intercept is $-1/K_m$. The calculated K_m and V_{max} values, easily determined by extrapolating the straight line to its intercepts on the x and y axes, are 3.07×10^{-6} M and 2.11×10^{-8} M/min.

Enzyme-Dependent Conversion of Radioiodinated Prodrug (1) to Radioiodinated Drug (2). Reversed-phase TLC followed by autoradiography (ARG) was used to characterize the radiolabeled derivative **1** and confirm its ALP-dependent hydrolysis to **2**. When **1** was cospotted with nonradioactive **8**, a single spot was obtained (ARG) that has the same R_f as that of **8** (Figure 3). Furthermore, the incubation of **1** with ALP, but not heat-inactivated ALP, led to its complete conversion to **2** (Figure 3). The incubation of **1** with heat-inactivated ALP did not induce any hydrolysis.

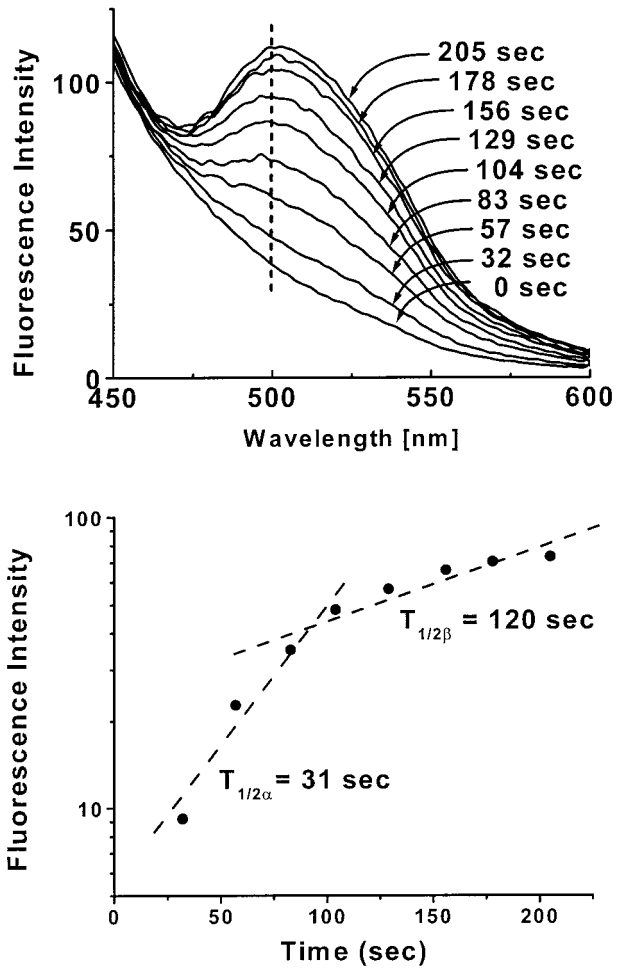

Figure 2. Kinetics of alkaline phosphatase-based hydrolysis of **8** to **7** at 37 °C. Top: change in fluorescence spectra of **8** as function of time. Bottom: change in fluorescence intensity of **8** at 500 nm as function of time. Linear fits were used to calculate the slopes (data points sets 1−4 and 4−9) and the corresponding $T_{1/2\alpha}$ and $T_{1/2\beta}$.

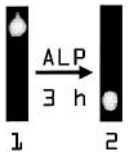

Figure 3. Autoradiograph demonstrating complete conversion of **1** to **2** after incubation in alkaline phosphatase at 37 °C for 3 h.

Stability of Prodrug 1. When the chemical nature of the radioactivity in blood post iv injection in mice was examined, autoradiography demonstrated (i) the presence of a single spot whose R_f is the same as that of **1**, and (ii) no evidence of free iodide.

Biodistribution of ^{125}I-Labeled Prodrug (1) and Drug (2) in Normal Mice. To assess whether ^{125}IPD (**1**) and ^{125}ID (**2**) are taken up and/or retained by normal tissues, the %ID/g was determined in blood and in various organs and tissues in mice injected iv or sc with ~5 μCi of each agent. For ^{125}IPD (Figure 4, top), the data indicate that (i) similar results were obtained regardless of the injection route, (ii) ~10% of the injected dose remained in the body of these animals, (iii) some radioactivity was present in the liver (6% ID/g), the kidneys (7% ID/g), and the thyroid (6−12% ID/g), and (iv) minimal amounts of radioactivity (<2% ID/g) were detected in blood and most organs and tissues. These results suggest

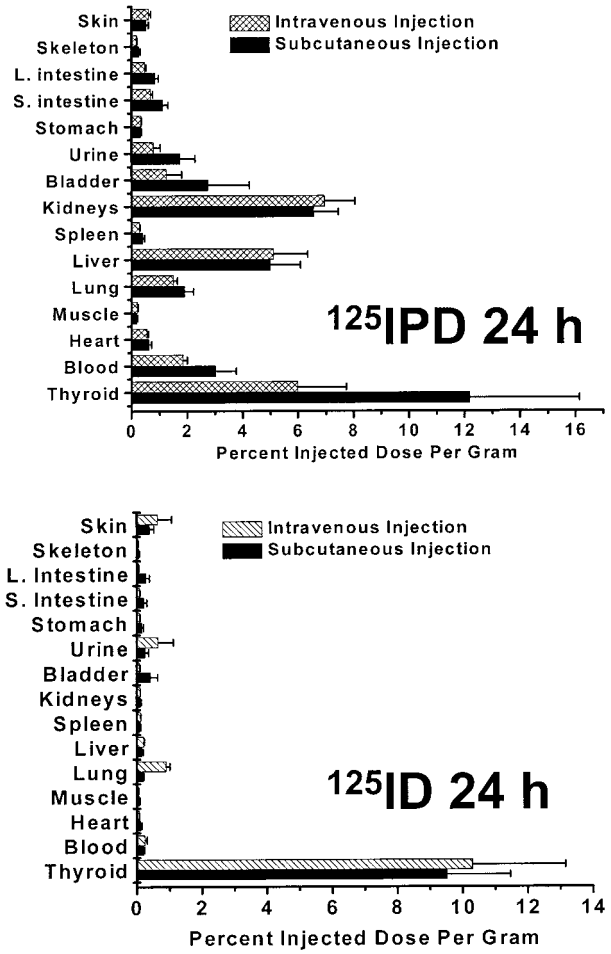

Figure 4. Percentage injected dose per gram of tissues, organs, and fluids 24 h post iv or sc injection of compound in normal mice. Top: **1**. Bottom: **2**.

that (i) **1** and/or its breakdown/hydrolysis product(s) are not taken up, hydrolyzed, or retained by most normal tissues and are rapidly excreted through the urinary system, (ii) some dehalogenation of the compound occurs, as exemplified by the presence of activity within the thyroid, and (iii) the accumulation of radioactivity within the liver and kidneys, which are rich in ALP, may be a result of the hydrolysis of **1** and the consequent formation of precipitated **2**. For ^{125}ID (Figure 4, bottom), minimal radioactivity was observed in all tissues except the thyroid.

Specific Localization of 1 in Alkaline Phosphatase-Rich Regions. To demonstrate the hydrolysis of water-soluble **1** to water-insoluble **2** in ALP-rich regions within an animal, mice were injected sc in the forelimb with ALP (or heat-inactivated ALP) and 5 min later iv (tail vein) with 20 μCi of **1**. The mice were killed 1 h later, and the radioactivity in the forelimb was measured. The data (Figure 5) demonstrate that the radioactive content of the forelimb of animals increased with enzyme dose and plateaued at the highest concentrations. That these increases were due to the enzymatic action of ALP was ascertained in studies that showed no increase in uptake in the forelimb of mice preinjected with heat-inactivated ALP (Figure 5). These results illustrate the specific dose-dependent accumulation of **1** (more accurately **2**) within ALP-containing sites in an animal.

Entrapment of 2 within Tissues. To assess the retention of water-insoluble **2** within the tissue where it is formed, ^{125}ID (**2**) was injected sc into the right forelimb

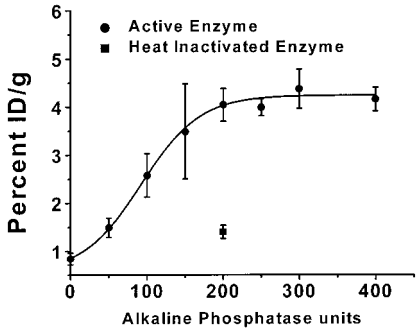

Figure 5. Accumulation of radioactivity in forelimbs of mice after sc injection of alkaline phosphatase followed 5 min later by iv injection of **1**.

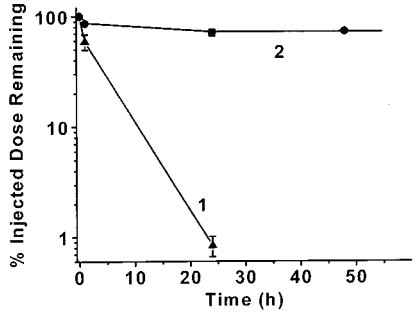

Figure 6. Retention of radioactivity in forelimbs of mice after sc injection of **1** and **2**.

of mice (for comparison, ^{125}IPD (**1**) was injected sc into the left forelimb). The animals were killed at various time periods, and the radioactivity associated with their forelimbs was determined. The data (Figure 6) demonstrate that while >99% of prodrug **1** had seeped from the sc pocket by 24 h, 71 ± 5% of the injected **2** activity remained at the injection site. As presented earlier (Figure 4, bottom), the radioactivity that escaped from sc injected **2** did not localize in any normal tissues within the animal. Finally, the results show no change in the radioactivity in the forelimbs of the animals (~72% injected dose) at 24 and 48 h (Figure 6), indicating that precipitated **2** is permanently and indefinitely trapped within tissues.

DISCUSSION

The treatment of solid tumors with current therapeutic agents continues to be a problem. Over the past two decades, some investigators have proposed two-step and three-step approaches in which a noninternalizing anti-tumor antibody is injected prior to the administration of a low-molecular-weight therapeutic molecule that has an affinity/reactivity with the preinjected antibody molecule. These systems can be categorized into two major classes: antibody-directed radioligand targeting (ADRT), and antibody-directed enzyme prodrug therapy (ADEPT).

The first strategy (ADRT) is based on the pretargeting of a monoclonal antibody (mAb) moiety that has the capacity to bind simultaneously to tumor cells and a radiotherapeutic molecule. For example, bispecific mAb, in which one valency is directed to a tumor-associated antigen while the other is directed to a radiolabeled molecule, have been preadministered into tumor-bearing animals, and after targeting and clearance of unbound material from the blood pool, the animals are injected with the radiolabeled molecule (*3*−*6*). Another system utilizes the high avidity of avidin or streptavidin for biotin ($k_d = \sim 10^{-15}$ M) to bind the radiolabeled molecule

to the pretargeted antibody (*7*−*10*). Both of these systems offer several potential advantages, most prominently (i) rapid blood clearance of the radiopharmaceutical, (ii) short residence of radioactivity in the body, (iii) low radiation doses to normal tissues, and (iv) cross-fire from the emitted long-range particles (α or *β*), negating the need for intracellular localization of the therapeutic agent. A recent report (*11*) that examined the therapeutic efficacy of a ^{90}Y-labeled biotin derivative post-pretargeting with an antitumor mAb−avidin conjugate in tumor-bearing mice showed that 100% of the treated animals were cured of their disease, clearly demonstrating the therapeutic potential of such two-step and three-step approaches.

In ADEPT, which was originally described by Philpott in 1973 (*12*) and later pursued by Bagshawe (*13*, *14*) and Senter (*15*, *16*), a noninternalizing antitumor-antibody−enzyme conjugate is injected into a tumor-bearing animal prior to the administration of a chemotherapeutic agent (prodrug, PD). The enzyme is chosen for its ability to convert the relatively noncytotoxic PD into a highly cytotoxic drug (D). The major advantages offered by ADEPT are (i) low normal tissue toxicity (PD is mildly toxic), (ii) specific conversion of PD in tumors, (iii) high PD-to-D turnover, and (iv) bystander effect (low-molecular-weight D can readily diffuse within the tumor mass and, hence, reach antigen-positive [antibody-targeted] as well as neighboring antigen-negative [antibody nontargeted] tumor cells). However, investigators have realized that, at a minimum, ADEPT has two major limitations: (i) to be therapeutically effective, the cytotoxic agent must be *internalized by each cell* within the tumor mass (*14*, *17*, *18*), and (ii) the toxic agents formed have relatively long biologic half-lives (*19*) and have been shown to escape from within the tumor mass, thereby increasing nonspecific normal tissue toxicity (*14*). Despite these shortcomings, various reports have demonstrated that the injection of prodrugs into tumor-bearing animals preinjected with mAb−enzyme conjugates will lead to tumor regression and delay in tumor growth (*16*, *20*). These findings, as well as those reported for ADRT, clearly demonstrate the credibility of such two- and three-step strategies for the treatment of solid tumors.

In this paper, we describe a novel approach, which we have named EMIT (enzyme-mediated insolubilization therapy), that we believe could fulfill many of the basic requirements for the effective therapy of solid tumors. The strategy combines the major advantages of the above-mentioned two approaches while negating their limitations. As mentioned earlier, EMIT is a method for the site-specific, in vivo conversion of a water-soluble radioactive molecule (**1**) to a water-insoluble radioactive molecule (**2**) by an enzyme present within a solid tumor. Since many tumors (e.g., prostate, osteosarcomas, teratocarcinomas) have been shown to innately express various phosphatases (*21*, *22*), we expect the hydrolysis of **1** (*IPD) within the extracellular spaces of such tumors and the indefinite entrapment of the precipitated radioiodinated **2**. Our current data, which demonstrate that ^{125}IPD concentrates at sites rich in ALP (Figure 5) and that, once formed, the ^{125}ID remains "indefinitely" within the tissue where it is produced (Figure 6), support these expectations. However, for those circumstances where the concentration of the enzyme within a tumor is too low to hydrolyze sufficient amounts of the IPD, the enzyme can be pretargeted to the tumor following its conjugation to a targeting moiety such as a noninternalizing ligand to a tumor-specific receptor or an antitumor antibody, i.e., utilizing the same approaches used in ADEPT. It is important to note that the EMIT approach bypasses the two main limitations reported for ADEPT since (i) the radiolabeled moiety does not need to be internalized (due to the cross-fire irradiation of cells within the range of the emitted α and *β* particles), and (ii) the precipitated molecules formed are trapped within the extracellular spaces of the tumor mass (the biologic half-time within the tumor will in effect equal the physical half-life of the isotope).

For our current studies, we have synthesized (Schemes 2 and 3) a phosporyloxyphenol derivative of a radioiodinated quinazolinone (**1**), a water-soluble molecule that is readily hydrolyzed to water-insoluble **2** when exposed to ALP (Scheme 1). While ALP may seem at first inappropriate for EMIT (it is present in most normal mammalian tissues and fluids), our data demonstrate that except for the liver (∼5% ID/g) and possibly the kidneys (∼6% ID/g), minimal radioactivity is detected and/or retained in all other normal tissues of mice following the injection of **1** (Figure 4, top). These results indicate that **1** is not taken up, concentrated, or hydrolyzed by most tissues. In addition, the choice of ALP is favored since (i) it is present in high concentration within various tumors (*21*, *22*), (ii) it has a very high second-order rate constant ($k_{cat}/K_M = 5 \times 10^7$ M^{-1} s^{-1}), (iii) the availability of its human form should eliminate/reduce its immunogenicity in humans, and (iv) ALP covalently bound to mAb has already been used to activate several chemotherapeutic prodrugs in vitro and to retard tumor growth in vivo (*15*, *16*, *23*−*28*).

We believe that the approach described in this paper should satisfy most of the requirements for an ideal radiotherapeutic agent, namely (i) rapid and efficient concentration by the tumor, (ii) retention by the tumor (i.e., very long effective clearance half-life), (iii) short residence time within normal tissues (i.e., short effective half-life in blood, bone marrow, and whole body), and (iv) high tumor-to-normal-tissue uptake ratios. Since the PD is labeled with an energetic particle emitter, the therapeutic potential of EMIT will depend on (i) attaining an intratumoral distribution that is sufficiently uniform to match the range of the emitted particles (all tumor cells are within the range of the emitted particles), and (ii) achieving an intratumoral concentration that is sufficiently high to deposit a tumoricidal dose in every cell that is within the range of the emitted particles. Experiments that address these issues are currently ongoing.

CONCLUSIONS

We have synthesized and characterized ^{125}I-labeled prodrug (**1**) and its nonradioactive analogue (**8**). The radiochemical yield for no-carrier-added **1** is 46% and the radiochemical purity over 98%. In vitro, water-soluble **8** is rapidly and completely converted to a water-insoluble fluorescent precipitate **7** in the presence of alkaline phosphatase. With the exception of the liver, and possibly the kidneys, the radioiodinated prodrug **1** is not taken up/hydrolyzed by normal tissues in mice. However, in ALP-rich regions in vivo, it is converted to **2**, which is indefinitely retained within the tissue where it is formed.

We believe EMIT to be a technology that will (i) lead to the active and specific concentration of therapeutic radionuclides within solid tumors, (ii) result in the indefinite entrapment of therapeutic radionuclides within solid tumors, (iii) lead to the protracted irradiation of tumor cells that are within the range of the emitted α (50−100 *μ*m) or *β* (0.1 mm−1 cm) particles, and (iv)

negate the limitations of current prodrug approaches and lead to more effective therapies of solid tumors.
