The EAA approach requires that the radiolabeled mAb be biotinylated so that it can be captured on the avidin column. Unfortunately, the chemistry of radiolabeling and conjugation can result in decreased binding of the radiolabeled mAbs with cancer cells. Thus, to generalize and improve the applicability of EAA to a wide variety of radiolabeled mAbs, a standardized method for biotinylation and radiolabeling that minimizes the deleterious effects needs to be developed. This is particularly important as mAbs can vary greatly in sensitivity to conjugation and radiolabeling. Early EAA studies were conducted with the biotinylated and radioiodinated mAbs, L6 and chimeric BR96 (chBR96) (*15*, *16*, *40*, *43*). Generally, direct radioiodination on tyrosine phenols, and conjugation of a biotin on lysine amines, of mAbs is well tolerated. The combination of these two protein modifications might also be expected to be well tolerated when minimal derivatization is done. However, some mAbs are quite sensitive to the oxidizing conditions used in direct radioiodinations, and other mAbs are internalized, which can result in the rapid release of radioiodine. Therefore, the combination of direct radioiodination and biotinylation can lead to undesirable results. In studies comparing direct radioiodination, and radioiodination using an iodobenzoate, of the internalizing mAb chBR96, it was found that the conjugate radioiodination method provided higher tumor concentration (*46*, *47*). Additionally, previous studies with the internalizing mAb chimeric BR96 demonstrated that ^{111}In labeling gave better results than those obtained with direct radioiodination (48). Other metal radionuclides,

including Re-188 (*49*), have been studied, but our choice of radionuclides for this investigation, ^{111}In and ^{90}Y, was based on their favorable emission properties and on the fact that they are widely used in diagnostic and therapeutic procedures.

The studies described herein were undertaken to develop reagents that minimized the effect of conjugating both radionuclide chelation groups and biotin moieties to mAbs. It was envisioned that combining the two functionalities (metal chelation moiety and biotin) on a single molecule for conjugation would minimize the effect of conjugation, as fewer conjugates could be coupled to the mAb. Such a combined functionality molecule could also provide other benefits. Importantly, every mAb that was radiolabeled would also have a biotin moiety present so that it could be removed via the avidin column. Also, minimal derivatization could be undertaken as the mAbs that did not contain at least one conjugate would not radiolabel, and thus would not need to be removed by the avidin column. The design of a combined functionality conjugation molecule requires that it be trifunctional in nature, also incorporating a protein conjugation moiety. Thus, the trifunctional reagent design had to contain a biotin moiety, a chelation moiety that binds In and Y, and a protein reactive moiety for application to radiolabeled monoclonal antibodies for EAA.

Several studies have demonstrated that linkers between biotin and the protein conjugation functionality are sometimes required to obtain maximal binding with avidin or streptavidin (*50*−*53*). Thus, as in our previous studies, 4,7,10-trioxatridecane-1,13-diamine was incorporated as a 19 Å spacer between biotin and the other portion of the conjugation molecule. Additionally, this linker moiety provides increased water solubility of the reagents. Two metal chelation groups were chosen for incorporated into the trifunctional reagents based on previously determined labeling characteristics and in vivo stability with ^{111}In and ^{90}Y. A cyclohexyl modified DTPA derivative, termed CHX-A″ was chosen, as previous studies had shown that it labels under mild conditions and has high stability in vivo (*54*, *55*). The macrocyclic chelate DOTA, was chosen as an alternate to the CHX-A″ because it forms radiometal complexes that are very stable to in vivo demetalation (*56*, *57*). While the highest in vivo stability is sought, radiolabeling DOTA conjugates requires elevated temperatures which may be deleterious to some mAbs. Fortunately, both the isothiocyanatobenzyl-CHX-A″ and isothiocyanatobenzyl-DOTA derivatives were available from either synthesis (*21*) or commercial sources. Although it was not clear that a linker molecule was required between the DTPA or DOTA moiety and the rest of the molecule, it was decided that incorporation of another trioxatridecanediamine moiety might improve their aqueous solubility at physiological pH. To conjugate the metal chelate and biotin to the mAbs, a reactive functionality was required. The isothiocyanate was an obvious choice, as it is readily prepared in the presence of the carboxylates of the DTPA and DOTA moieties. The only other consideration in the design of the trifunctional reagent was that of blocking in vivo degradation by the serum enzyme, biotinidase (*58*, *59*). Because studies in our laboratory with a few biotinylated mAbs demonstrated that biotin was not cleaved by biotinidase when conjugated to mAbs (*60*), the initial trifunctional reagent, **8**, did not incorporate a biotinidase blocking functionality. However, in the two other trifunctional reagents, **12** and **20**, aspartic acid was incorporated adjacent to the biotin moiety to block the action of biotinidase (*61*). The biotinidase blocking group was incorporated, as insufficient data was available to state definitively that it would not be required with some mAbs. Additionally, we wanted to make the reagents generally applicable for other radionuclide carriers, so we felt that it was necessary to incorporate the biotinidase blocking moiety.

Table 2. Stability of Y-90 Labeled mAb When Challenged[a]

mAb conjugate	serum (37 °C)	10 mM EDTA (rt)	10 mM DTPA (rt)
free Y-90	4	2	2
17	92	85	2
12	94	85	2
18	97	93	96
20	91	91	92

[a] Values are percent remaining in Microcon top (e.g., protein bound).

Table 3. Specific and Nonspecific Binding of Conjugates with an Avidin Column

mAb conjugate	specific In-111	nonspecific In-111	specific Y-90	nonspecific Y-90
A6H[a]				
8 (15 equiv)	88	10	89	9
107-1A4	−	−	−	−
12 (10 equiv)	93	1	94	0.3
12 (25 equiv)	98	1	98	1
20 (10 equiv)	98	0.1	98	−
20 (25 equiv)	99	0.1	96	0.2

[a] The radiolabeled antibody was mixed with 0.1% BSA.

The synthesis of the three trifunctional reagents following the routes outlined in Schemes 1−3 was straightforward. The synthetic route outlined in Scheme 3 proved to be the best, as it utilizes a common intermediate, **16**, for addition of either chelation group and resulted in good overall chemical yields. Although not conducted, a similar intermediate can be prepared without the biotinidase blocking aspartate moiety. More importantly, the biotinyl-trifunctional intermediate **16**, and the corresponding reagent without the aspartate, could be used to incorporate other radionuclide binding moieties or other (reporter) functionalities such as chromophores or fluorophores (*62*) into new trifunctional reagents.

The three trifunctional reagents, **8**, **12**, and **20**, were readily conjugated with mAbs. In the studies, varying quantities of reagents were used in the conjugations to determine the ratio of trifunctional reagent to mAb to obtain a desired level of conjugation. While it is expected that both radiolabeling and capture by the avidin column would be improved with higher numbers of conjugates per mAb molecule, the cell binding studies demonstrate that even with the trifunctional reagents, minimal derivatization is best. On the basis of the results, it seems that 2−3 conjugates per mAb would be the maximum that one might want to have, but this should be evaluated for each mAb. Although based on high concentrations of challenging chelate (i.e., 10 mM), the stability difference between the CHX-A″ and DOTA chelates was clearly demonstrated (Table 2). It seems prudent to use the trifuntional reagent containing the DOTA chelate, **20**, unless the mAb is sensitive to the radiolabeling conditions required for that chelate. Most importantly, it was demonstrated that a high percentage of the radiolabeled mAb conjugated with the trifunctional reagents could be bound to an avidin column in one pass.

In Summary. Three trifunctional reagents that contain a metal chelation moiety and a biotin moiety have been prepared for modification of mAbs used in blood

clearance by extracorporeal affinity adsorption. Conjugation of a low number of trifunctional reagents (fewer than three) results in retention of the mAb's cell binding properties. Good radiolabeling yields and high avidin column binding were achieved with the minimally derivatized mAbs. On the basis of the results obtained, testing of mAbs modified with a trifunctional reagent in combination with a device containing an avidin column is planned. The trifunctional reagents may also be useful when conjugated with other cancer-targeting agents.

ACKNOWLEDGMENT

We thank Dr. Robert Vessella (Department of Urology, University of Washington) for supplying the mAbs, A6H, and 107-1A4, used in the studies. Financial support for the majority of the studies was provided by Mitra Medical Technology AB of Lund, Sweden. Funding for portions of the studies was provided by the Department of Energy, Medical Applications and Biophysical Research Division, Office of Health and Environmental Research under Grant Number DE-FG03-98ER62572. We are grateful for the funding from both of these sources.

Supporting Information Available: HPLC chromatograms, NMR spectra, and mass spectra of all new compounds (**5**−**8**, **10**−**12**, **14**, **15**, **19**, and **20**) (33 pages) and scanned SDS−PAGE gels (reducing and nonreducing) of 107-1A4 conjugates (3 pages). This material is available free of charge via the Internet at http://pubs.acs.org.

A Novel 2′-(*N*-Methylpyridinium Acetate) Prodrug of Paclitaxel Induces Superior Antitumor Responses in Preclinical Cancer Models

Wolfgang Wrasidlo,[†] Gerhard Gaedicke,[†] Rodney Kiplin Guy,[‡] Johanne Renaud,[‡] Emmanuel Pitsinos,[‡] Kyriaco C. Nicolaou,[‡] Ralph A. Reisfeld,[§] and Holger N. Lode*[,†]

Charité Children's Hospital, Humboldt University, Berlin, Germany, and The Scripps Research Institute, Departments of Chemistry and Immunology, La Jolla, California 92037. Received April 1, 2002; Revised Manuscript Received July 30, 2002

The development of novel strategies for the treatment of malignancies by successful intervention in advanced stage disease is a major challenge in oncology. We tested the hypothesis that this can be achieved by the rational design of taxoid onium salts modified at C-7 and C-2′ positions. The characterization of these molecules revealed a dramatically improved water solubility and prodrug behavior in plasma. Specifically, all compounds released parental paclitaxel with half-lives ranging from 0.9 to 180 min. In the absence of plasma, only the 2′-(*N*-methylpyridinium acetate) derivative of paclitaxel (2′-MPA-paclitaxel) revealed a complete abrogation of paclitaxel specific microtubule assembly disassembly dynamics and a 3 log reduction in cellular binding, indicating that reversible blockage of the C-2′ position by methylpyridinium acetate yields a true paclitaxel prodrug. Structure/activity profiles of all compounds in tissue culture revealed cytotoxicity effective at picomolar concentrations with a panel of 16 cancer cell lines in contrast to 4 nonmalignant cell lines. Importantly, the decisive cytotoxic potential observed in vitro for all compounds correlated only with in vivo findings for 2′-MPA-paclitaxel. Specifically, the 2′-MPA-paclitaxel prodrug induced regression of primary tumors in three xenograft models of nonsmall cell lung carcinoma, ovarian carcinoma and prostate cancer, in contrast to ineffective C-7 derivatives and parental paclitaxel. At the same time, a reduced systemic toxicity of 2′-MPA-paclitaxel was observed in contrast to a far more toxic parental paclitaxel. Taken together, these findings demonstrate that the 2′-MPA-paclitaxel prodrug is a promising new candidate for cancer therapy.

INTRODUCTION

Paclitaxel is an anticancer agent with established value for clinical application (*1*) including prostate, lung, breast, and ovarian cancer (*2*−*11*). However, limited response rates, significant side effects, and low solubility remain as major obstacles for more effective cancer therapy.

Paclitaxel is a natural product gained from the bark of the pacific yew tree (*Taxus brevifolia*). Its chemical structure was first described by Wani at al. in 1971 (*9*). Unlike other anti-microtubule drugs, such as vinca alkaloids, colchicine, or podophyllotoxin, paclitaxel promotes the irreversible polymerization of tubulin (*12*−*15*). The presence of stable and dysfunctional microtubules causes disruption of the cell division and thus cell death or reversible cell cycle arrest. This arrest in the premitotic G2 and the mitotic phases, the so-called G2M-arrest, enhances the effect of irradiation and possibly the activity of other cytotoxic drugs (*16*). Paclitaxel also enhances the expression of tumor necrosis factor (TNF) α and IL-1 and downregulates TNF receptors, activities which are shared by bacterial lipopolysaccharides. This cytokine stimulatory activity may also contribute to its antitumor properties and seems not to be related to the effect on microtubule assembly (*17*). Paclitaxel also induced internucleosomal DNA fragmentation associated with bcl-2 expression in leukemic cells, suggesting that its action triggers a gene-directed mechanism of programmed cell death (*18*). Toxicity consists mainly of hypersensitivity reactions, hematologic toxicity, and neurotoxicity. Hypersensitivity, despite proper premedication with dexametasone and/or histamine H2 antagonist diphenhydramine, is reported in 1−3% of patients (*19*−*21*).

The clinical application of paclitaxel, which has a limited solubility in water (<0.004 mg/mL), requires formulations as emulsions between alcohol and oils such as Cremophor EL, accounting for vehicle specific hypersensitivity reactions observed following paclitaxel therapy (*22*). It appears that the most critical issue in producing effective water soluble paclitaxel prodrugs involves the pharmacokinetics of prodrug reversion to the natural compound, which requires a balance between in vivo hydrolytic stability, bioavailability, and rate of elimination. We have evaluated paclitaxel analogues containing structural modifications at different locations of the parent molecule, which influence both their chemical and pharmacological properties. Here, we report results with analogues based on oxonium salts of paclitaxel with different structure/activity profiles depending on the nature and position of these substitutions.

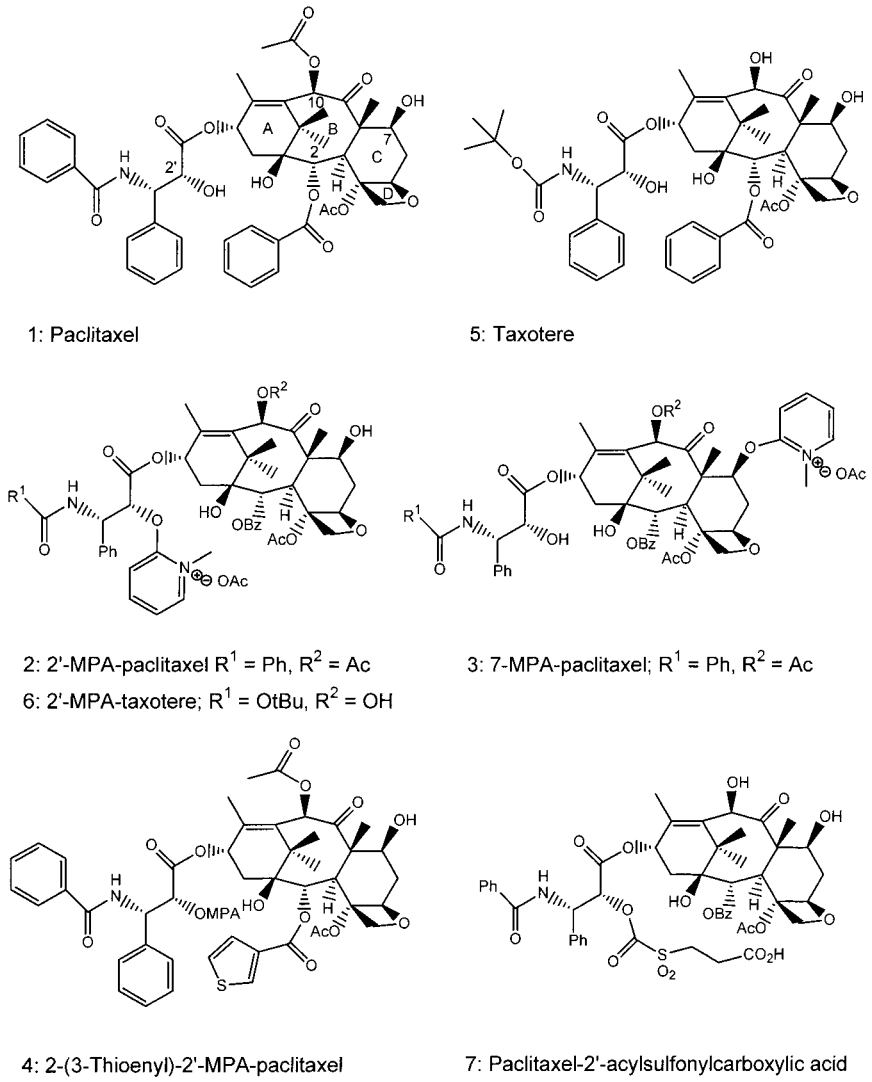

Figure 1. Chemical structures of paclitaxel, taxotere, and C-2′, C-7, and C-2 substituted derivatives.

MATERIALS AND METHODS

Synthesis of Taxoid-Onium Salts. Structures of compounds used in this study are shown in Figure 1. Paclitaxel (**1**) was purchased from the Napro Co. (Boulder, CO). Taxotere (**5**) was synthesized in house from deacetylbacatin III. The C-2′-methyl pyridinium acetate salts (MPA[1]) of paclitaxel (**2**), and taxotere (**6**) and the 2-(3-thienyl)-2′-MPA-paclitaxel analogue (**4**), were synthesized as described previously (*23*, *24*). The synthesis of the 7-MPA-paclitaxel (**3**) was previously described (*25*). Tritiated paclitaxel was obtained from Perkin-Elmer (former New England Nuclear, Boston MA).

Cells. Tumor cell lines (A549, PC-3, Ovcar 3, Molt-4) were obtained from ATCC, Rockville, MD, grown in RPMI, 10% FCS in the presence of 100 IU/mL penicillin/streptomycin (P/S) and propagated under standard tissue culture conditions of 5% CO_2 and 37 °C. Human dermal fibroblasts, peripheral blood lymphoblasts, and mammary epithelial cells were obtained from Clonogenic Corp. (San Diego, CA) and maintained in media provided by the supplier.

Mice. Athymic nude mice were obtained at 8 weeks of age from Harlan−Sprague−Dawley. They were housed in the pathogen-free mouse colony at our institution in groups of eight mice per cage. Mice were fed ad libitum on standard mouse laboratory chow. Animal experiments were performed according to the German guide for the care and use of laboratory animals, i.e., "Tierschutzgesetz".

Cytotoxicity Assays. Cytotoxicity was determined by the XTT tetrazolium/formazan assay as previously described (*26*). Briefly, cells were seeded in 96 flat bottom well plates at a density of 10^4/well in 100 μL of media and exposed to drug concentrations ranging from 10^{-4} to 10^{-12} M. At the indicated time points (72 h), cell viability was assessed by adding 50 μL of XTT-reagent (1 mg/mL in serum free RPMI) activated with 0.2% v/v PMS (1.53 mg/mL in PBS) and incubated at 37 °C for 4 h. Plates were analyzed in a Thermomax (Molecular Devices) micro plate reader at 450 nm. OD values were plotted as a function of drug concentration and the curves were integrated using the softmax software to obtain the IC_{50} concentration values.

Cell Uptake and Competition Assays. Tritiated paclitaxel was reacted with 2-fluoropyridinium tosylate as previously described for the nontritiated analogues (*23*) to yield the 2′-MPA-^{3}H-paclitaxel. Six well plates were incubated with 10^6 Molt-4 cells in 50 mM PBS to which 10^{-9} M of the radiolabeled paclitaxel or paclitaxel onium salt were added together with increasing concentrations of nonradiolabeled compound. After 30 min, the cells were centrifuged and washed with PBS, and 1% SDS

was added. The radioactivity of lysed cells was then determined by means of a LKB Model 1219 scintillation counter.

Microtubule Assembly−Disassembly Assay. Tubulin was isolated from calf brain according to a procedure previously described (*27*). It was stored at a concentration of 5.5 mg/mL in liquid nitrogen. The analysis of tubulin polymerization−depolymerization was accomplished as follows: 96-well microtiter plates were charged with 30 μL of PEM buffer (100 mM PIPES, 1 mM EGTA, 1 mM $MgSO_4$, pH 6.9) and 10 μL of DMSO containing drug. Then 35 μL of tubulin solution (2 mg/mL) and 8 μL of GTP (1 mM) in water were added to initiate tubulin polymerization. The plates were shaken on a titer plate shaker for 10 s and placed into the microplate reader and absorbance determined at 1 min intervals at 340 nm and a plate temperature of 37 °C. After 15 min, 10 μL of calcium chloride (10 mM) was added to initiate tubulin depolymerization, and the determination of the absorbance at 340 nm was continued for another 5 min.

Antitumor Effect in Xenograft Models. Primary tumors were induced by sc injection of 1×10^6 A549 lung adenocarcinoma, Ovcar-3 ovarian carcinoma or PC-3 prostate carcinoma cells in 100 μL of RPMI (pH 7.4) into the skin of the left lateral flank of each nude mouse. Primary tumors in mice ($n = 8$) were treated by intraperitoneal injection of solvent (0.9% saline), paclitaxel (Cremophor EL/ 5% Dextrose in water (D5W), 5/95, v/v), or taxoid-onium salts (0.9% saline) in a total volume of 400 μL. Each mouse received a total of six injections on days 1, 3, 5, 7, 9, and 11 after tumor cell inoculation. Primary tumor size was determined over time by microcaliper measurements, and volumes were calculated according to $^1/_2 \times$ width $\times$ width $\times$ length. Body weight was determined on a standard digital scale.

Statistics. The statistical significance of differential findings between experimental groups of animals was determined by two-tailed Student's t test. Findings were regarded as significant if two-tailed p values were <0.01.

RESULTS

Prodrug Activation. To establish that onium salts of paclitaxel are prodrugs, we determined the release of free paclitaxel in human plasma at 37 °C by ethyl acetate extraction of free compounds, followed by HPLC analysis of concentrates. Due to differences in the retention times under the HPLC conditions used and differing ultraviolet absorption maxima between the prodrug and the drug, the activation could easily be assayed by UV detection. The only products detected were the free taxoids and the pyridinones released by hydrolysis of the taxoid-onium salts. In water, these compounds show stability for up to four weeks at 4 °C (data not shown). The plasma half-lives and fraction of free drug present are listed in Table 1. All three C-2′ substituted MPA derivatives (**2**, **4**, **6**) exhibited relatively short half-lives of less than 14 min while the C-2′ substituted paclitaxel-2′-acylsulfonylcarboxylic acid analogue (**7**) and the C-7 substituted 7-MPA-paclitaxel (**3**) had a half-life of 100 and 180 min, respectively. The fraction of ethyl acetate-extractable material was between 18 and 23% for all onium salts and 95% for the parent compounds. Since the partition coefficients for the organic/water phases for these compounds are greater than 50, the relatively low ethyl acetate extractable values shown in Table 1 are most likely due to a strong affinity of the onium salts for plasma proteins.

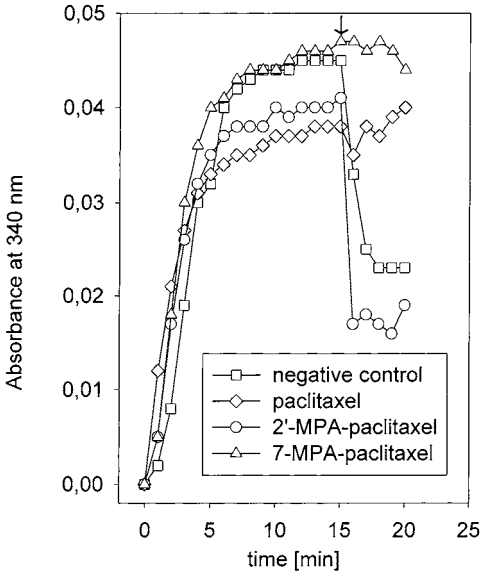

Figure 2. Effect of onium salt derivatives of paclitaxel on tubulin polymerization−depolymerization. GTP-induced tubulin polymerization ($t = 0$ min) and $CaCl_2$-promoted depolymerization (arrow, $t = 15$ min) were determined in the absence (square = negative control) and presence of paclitaxel (diamond), 7-MPA-paclitaxel (triangle), and 2′-MPA-paclitaxel (circle). Each drug was used at 10^{-6} M concentration. Turbidity was determined in a microplate reader at 340 nm. Graphs represent a typical result of three experiments.

Effect of Paclitaxel Derivatives on Microtubule Assembly−Disassembly. In order to determine which derivatives are true prodrugs, abrogation of paclitaxel specific cytotoxic effects, GTP-induced polymerization, and calcium chloride-induced depolymerization of tubulin were evaluated. Results obtained with paclitaxel and the 2′- (**2**) and 7-MPA (**3**) substituted derivatives are shown in Figure 2. The 2′-MPA-paclitaxel (**2**) behaved in this assay similar to the negative control, demonstrating that blockage of the C-2′ hydroxyl group with ′ *N*-methylpyridinium acetate (MPA) is effective in abrogating paclitaxel-specific effects. The GTP controls and 2′-MPA-paclitaxel (**2**) revealed the characteristics of calcium-induced depolymerization profiles, with about 70% reversal to tubulin. This finding was in contrast to those

[a] Structures are depicted in Figure 1. [b] Not performed.

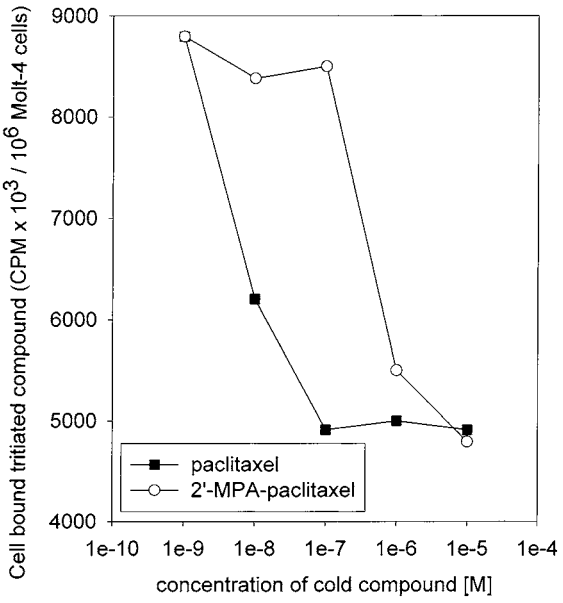

Figure 3. Competition binding of paclitaxel and 2′-MPA-paclitaxel to Molt-3 cells. Binding of tritiated paclitaxel (1×10^{-9}M) (closed square) and 2′-MPA-paclitaxel (1×10^{-9}M) (open circle) to 10^6 Molt-4 cells was determined in the presence of increasing concentrations of the respective cold analogue as described in Materials and Methods. Cell lysates were subjected to scintillation counting in an LKB 1219 counter, and results were plotted as a function of the concentration of added nonradioactive analogue. Graphs represent a typical result of three experiments.

obtained with both paclitaxel and its 7-MPA salts, which induced essentially complete inhibition of depolymerization of microtubules to tubulin. The C-2-substituted 2-(3-thienyl)-2′-MPA-paclitaxel derivative (**4**) inhibited depolymerization similar to paclitaxel (data not shown).

Specific Binding to Intact Cells. Binding to intact cells in PBS was demonstrated using a competition assay comparing 2′-MPA-paclitaxel (**2**) with parental paclitaxel on the suspension cell line Molt-4 (Figure 3). The binding constants were obtained from Scatchard plots and were 5×10^{-9} and 3×10^{-6} for paclitaxel (**1**) and 2′-MPA-paclitaxel (**2**), respectively. Addition of increasing concentrations of cold competitor resulted in saturation kinetics reaching a plateau, which constitutes nonspecific background binding. The kinetics determined with 2′-MPA-paclitaxel were similar to those obtained for paclitaxel; however, the specific binding affinity was 1000-fold lower. These results are consistent with data obtained from the microtubule assay and demonstrate that cellular binding is also reduced by blocking the C-2′ position of paclitaxel.

In summary, the 2′-MPA-paclitaxel derivative shows no paclitaxel specific activity in the absence of plasma but reverts to free paclitaxel in human plasma, clearly documenting its prodrug characteristics.

Cytotoxic Evaluations. The cytotoxic potencies of the six paclitaxel derivatives were determined against a panel of human and murine tumor cell lines and results compared to several nonmalignant cell lines (Table 2). In general, the cytotoxic potencies of these analogues were comparable to their parent compounds generally within 1.5 logs of molar concentrations with median values for tumor cell lines in the nanomolar range.

Cell lines with high resistance against paclitaxel and paclitaxel prodrugs were derived from melanoma (SK-Mel-28), CNS cancer (U2511), and renal cell adenocarcinoma (786−0) with IC_{50} values > 10.0 nM. The cytotoxicity obtained against these cell lines was within the range for nonmalignant cells (CHO, HMEC, NHDF, and RPMI-7666).

For most cell lines, Taxotere (**5**) and 2′-MPA-taxotere (**6**) were about 10-fold more cytotoxic than paclitaxel or its onium salts. Furthermore, 2′-MPA-paclitaxel (**2**) resulted for most cell lines used in about 10-fold higher IC_{50} values than the C-7-isomer 7-MPA-paclitaxel (**3**).

Antitumor Activity and Drug Elimination. The antitumor activity of the onium salts of paclitaxel was assessed in nude mice bearing tumors of human nonsmall cell lung carcinoma (A-549), ovarian carcinoma (Ovcar-3), and prostate carcinoma (PC-3) cells (Figures 4−6). Interestingly, in contrast to cytotoxicity assays in vitro, large differences in antiproliferative activity between the two 2′-substituted pro-paclitaxels were demonstrated in xenograft models. In a nonsmall cell lung carcinoma model (Figure 4), the 2′-MPA-paclitaxel derivative (**2**) completely inhibited tumor growth in contrast to paclitaxel-2′-acylsulfonylcarboxylic acid (**7**) which resulted in

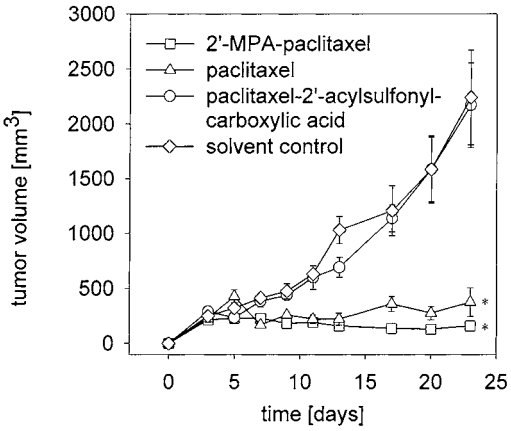

Figure 4. Effect of paclitaxel derivatives in a human lung xenograft model. The antitumor effects of paclitaxel-2′-acylsulfonylcarboxylic acid (circle), paclitaxel (triangle), and 2′-MPA-paclitaxel (square) were determined in a non-small-cell lung carcinoma model and compared to a solvent control (diamond). For this purpose, 10^6 A549 cells were injected sc, and mice were treated by intraperitoneal injections on days 1, 3, 5, 7, 9, and 11. Drugs were provided in a total volume of 0.4 mL of diluted in Cremophor EL/D5W (5/95; v/v) and administered to four experimental groups of mice ($n = 6$). One of each group was treated with Paclitaxel (18 mg/kg) and an equivalent amount of 2′-MPA-paclitaxel (24 mg/kg) and paclitaxel-2′-acylsulfonylcarboxylic acid (26 mg/kg) based on molecular weight. Tumor size was determined by microcaliper measurements as described in Materials and Methods. Graphs represent mean values ± standard error. Differences between paclitaxel/2′-MPA-paclitaxel and solvent/paclitaxel-2′-acylsulfonylcarboxylic acid were statistically significant starting on day 9 (* $p < 0.01$).

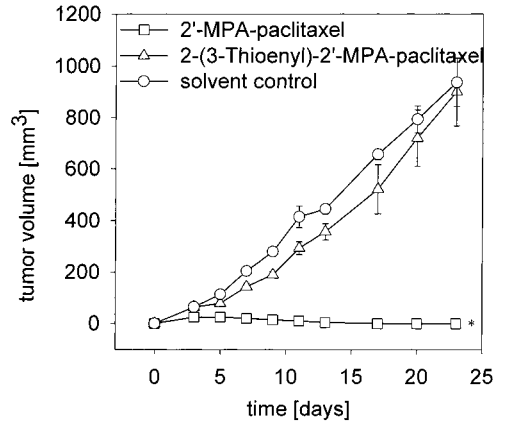

Figure 5. Effect of paclitaxel derivatives on tumor growth in a human ovarian carcinoma xenograft model. The antitumor effects of 2-(3-thienyl)-2′-MPA-paclitaxel (triangle) and 2′-MPA-paclitaxel (square) were determined in an ovarian carcinoma model and compared to a solvent control (circle). Ovcar-3 cells (10^6) were injected sc and mice treated by intraperitoneal injections on days 1, 3, 5, 7, 9, and 11. Drugs were provided in a total volume of 0.4 mL diluted in Cremophor EL/D5W (5/95; v/v) and administered to three experimental groups of mice ($n = 6$). One of each group was treated with 2′-MPA-paclitaxel (24 mg/kg) and an equivalent amount of 2-(3-thienyl)-2′-MPA-paclitaxel (26 mg/kg) based on molecular weight. Tumor size was determined by microcaliper measurements as described. Graphs represent mean values ± standard error. Differences between 2′-MPA-paclitaxel and solvent/2-(3-thienyl)-2′-MPA-paclitaxel were statistically significant starting on day 7 (* $p < 0.01$).

continuous tumor growth similar to that observed with the solvent control. Antiproliferative activities for 2-(3-thienyl)-2′-MPA-paclitaxel (**4**) and 2′-MPA-paclitaxel (**2**) were investigated in the ovarian carcinoma model (Figure 5). Results demonstrated complete inhibition of tumor growth in 100% of animals by the 2′-MPA-paclitaxel (**2**).

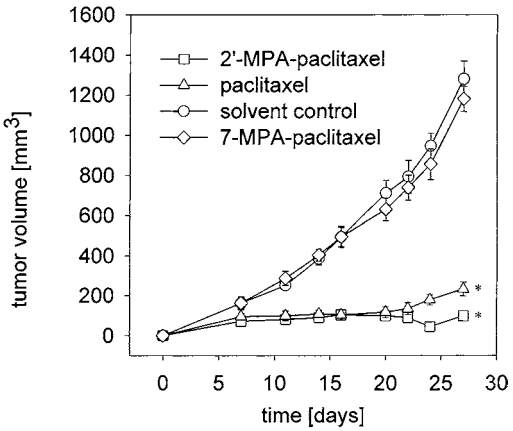

Figure 6. Effect of paclitaxel derivatives on tumor growth in a human prostate cancer xenograft model. The antitumor effects of 7-MPA paclitaxel (diamond), paclitaxel (triangle), and 2′-MPA-paclitaxel (square) were determined in a prostate carcinoma model and compared to a solvent control (circle). For this purpose, 10^6 PC-3 cells were injected sc, and mice were treated by intraperitoneal injections on days 1, 3, 5, 7, 9, and 11. Drugs were provided in a total volume of 0.4 mL diluted in Cremophor EL/D5W (5/95; v/v) and administered to four experimental groups of mice ($n = 6$). One of each group was treated with paclitaxel (18 mg/kg) and an equivalent amount of 2′-MPA-paclitaxel (24 mg/kg) and 7-MPA-paclitaxel (24 mg/kg) based on molecular weight. Tumor size was determined by microcaliper measurements as described in Materials and Methods. Graphs represent mean values ± standard error. Differences between paclitaxel/2′-MPA-paclitaxel and solvent/7-MPA-paclitaxel were statistically significant starting on day 11 (* $p < 0.01$).

In the prostate carcinoma model, paclitaxel was compared with both, the 2′- and 7-substituted oxonium salts (Figure 6). Therapy with the paclitaxel control (**1**) and the 2′-MPA-paclitaxel (**2**) resulted in regression of primary tumors. Significantly, five of eight animals treated with compound **2** remained tumor free for a total of 4 weeks. The 7-MPA isomer (**3**) showed essentially no antitumor activity as indicated by the lack of a significant difference with the solvent controls. Importantly, only three of eight mice survived the paclitaxel treatment, whereas all eight mice survived when treated with either the 2′-MPA-paclitaxel or 7-MPA-paclitaxel.

DISCUSSION

Paclitaxel continues to be extensively investigated because of its well documented clinical utility as an anticancer agent (*28*−*32*). Several distinct cellular response mechanisms induced by paclitaxel were described thus far. For example it has been reported that paclitaxel aids in inducing TNF-α and IL-1 involved in inflammatory responses as well as LPS-like activity by inducing genes such as D3, D7, and IP-10 in macrophages (*33*, *34*). This drug is also capable of inducing hematopoetic growth factor G-CSF, an activity that occurs in B-cells where it is regulated by the cytokine IL-4 (*35*). At very low concentrations, in the nanomolar range, paclitaxel was shown to inhibit mitotic spindle progression without affecting the function of preformed spindles or causing mitotic arrest in tumor cells (*36*), suggesting a mechanism of cytotoxic action other than the general inhibition of microtubule depolymerization.

A generally recognized shortcoming of paclitaxel is its extremely low solubility in the aqueous media normally employed in administering drugs, thus requiring formulation of this compound in mineral oil suspensions which exacerbate undesirable side effects in patients. The main

objective of the current study was to assess the potential of water soluble pyridinium salts of paclitaxel as antitumor leads. In this regard, it was of interest to evaluate the effects of chemical modifications of the parent compounds on in vitro and in vivo activities. The 2′- and 7-hydroxyl groups of paclitaxel and taxotere are most readily amenable to modifications and have been exploited for modification in previous reports (*37* −*40*). All paclitaxel derivatives reported including the prodrugs of this study showed relatively high cytotoxicity profiles for tumor cell lines with IC_{50} values in the nanomolar range, results which did not uniformly correlate with antiproliferative effects observed in various nude mouse tumor models. In fact, the nature of the substituents for a given position as well as the location of a given substituent at different positions in the molecule had profound effects on the antitumor activity of these compounds, which could not be predicted from the in vitro results. For example, the 7-substituted pyridinium salt of paclitaxel 7-MPA-paclitaxel (**3**) was as effective as paclitaxel in inhibiting calcium induced microtubule disassembly and showed cytotoxicities in human tumor cell lines comparable to paclitaxel; however, it completely failed to inhibit the growth of these tumors in nude mice. In contrast, the 2′- substituted paclitaxel-2′-acylsulfonylcarboxylic acid derivative (**7**), which in our previous study exhibited a high cytotoxicity profile in vitro and behaved as a prodrug (*37*), completely failed to demonstrate any antitumor effects in vivo.

Here we report for the first time that 2′-MPA-paclitaxel (**2**) is a prodrug with excellent efficacy in human xenograft models and improved antitumor activity over parental paclitaxel. In fact, in the absence of human plasma, 2′-MPA-paclitaxel showed no tubulin binding and in competition assays with intact cells revealed affinity profiles 3 orders of magnitudes below that of the parent paclitaxel. When tested in vivo, this compound produced tumor regressions with a high percentage of animals remaining tumor free at the end of the experiment. At the same time, this compound was tolerated better than paclitaxel, without detectable toxic side effects and no significant weight loss in tumor bearing nude mice. In contrast, paclitaxel administered on an equimolar basis induced significant weight losses in all animals with a death rate increased to over 50%. However, when paclitaxel was administered at lower doses to avoid toxicity, its efficacy declined dramatically (data not shown), indicating that this drug has a relatively narrow therapeutic window. The higher plasma affinity of the onium salts may be one reason for their improved tolerance in animals.

In summary, we could demonstrate that a C-2′ methylpyridinium acetate derivative of paclitaxel shows prodrug characteristics in vitro and excellent cytotoxic efficacy in the nanomolar range against a panel of cancer cell lines. It also demonstrated superior efficacy in human tumor xenograft models in contrast to parental paclitaxel. At the same time the 2′-MPA-paclitaxel revealed a lower systemic toxicity when applied in doses equimolar with parental paclitaxel. Taken together, these data suggest that 2′-MPA-paclitaxel is a promising new candidate to further improve the success rate of cancer chemotherapy.

Functionalized Congeners of Tyrosine-Based $P2X_7$ Receptor Antagonists: Probing Multiple Sites for Linking and Dimerization

Wangzhong Chen,[†] R. Gnana Ravi,[†] Sylvia B. Kertesy,[‡] George R. Dubyak,[‡] and Kenneth A. Jacobson*,[†]

Molecular Recognition Section, Laboratory of Bioorganic Chemistry, National Institute of Diabetes, Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland 20892-0810, and Department of Physiology and Biophysics, Case Western Reserve University School of Medicine, Cleveland, Ohio 44106. Received April 6, 2002; Revised Manuscript Received July 17, 2002

Chemically funtionalized analogues of antagonists of the $P2X_7$ receptor, an ATP-gated cation channel, were synthesized as tools for biophysical studies of the receptor. These functionalized congeners were intended for use in chemical conjugation with retention of biological potency. The antagonists were L-tyrosine derivatives, related to [*N*-benzyloxycarbonyl-*O*-(4-arylsulfonyl)-L-tyrosyl]benzoylpiperazine (such as MRS2409, **2**). The analogues were demonstrated to be antagonists in an assay of human $P2X_7$ receptor function, consisting of inhibition of ATP-induced K^+ efflux in HEK293 cells expressing the recombinant receptor. The analogues were of the general structure R_1-Tyr(OR_2)-piperazinyl-R_3, in which three positions (R_1-R_3) were systematically varied in structure through introduction of chemically reactive groups. Each of the three positions was designed to incorporate a 3- or 4-nitrophenyl group. The nitro groups were reduced using $NaBH_4$−copper(II) acetylacetonate to amines, which were either converted to the isothiocyanate groups, as potential affinity labels for the receptor, or acylated, as models for conjugation. An alternate route to N^{α}-3-aminobenzyloxycarbonyl functionalization was devised. The various positions of functionalization were compared for effects on biological potency, and the R_2 and R_3 positions were found to be most amenable to derivatization with retention of high potency. Four dimeric permutations of the antagonists were synthesized by coupling each of the isothiocyanate derivatives to either the precursor amine or to other amine congeners. Only dimers linked at the R_2-position were potent antagonists. In concentration−response studies, two derivatives, a 3-nitrobenzyloxycarbonyl derivative **18** and a 4-nitrotoluenesulfonate **26b**, displayed IC_{50} values of roughly 100 nM as antagonists of $P2X_7$ receptor-mediated K^+ flux.

INTRODUCTION

P2X receptors are ligand-gated cation channels activated by ATP (adenosine 5′-triphosphate) and other purine nucleotides. Seven mammalian subtypes of P2X receptors (termed $P2X_1$ through $P2X_7$) have been cloned (*1*, *2*). Each functional ion channel consists of an oligomeric assembly, probably a trimer. Both homo- and heterooligomerization seem to occur commonly; however the $P2X_7$ subtype exists exclusively as a homomer, and the $P2X_6$ subtype always occurs as a homomer. The cationic selectivity of the P2X receptors is Na^+, $K^+ > Ca^{2+}$ (*3*).

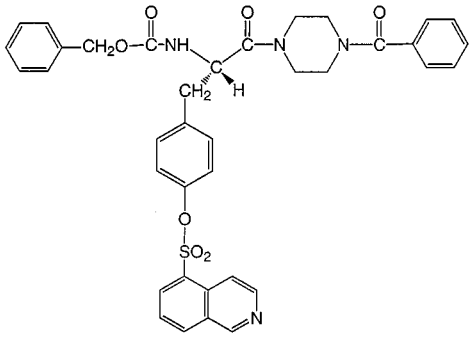
[1] Abbreviations: Bop-Cl, bis(2-oxo-3-oxazolidinyl)phosphinic chloride; Boc, *tert*-butyloxycarbonyl; BSA, bovine serum albumin; Cbz, benzyloxycarbonyl; DMAP, 4-(dimethylamino)pyridine; DMF, dimethylformamide; DMSO, dimethyl sulfoxide; EtOAc, ethyl acetate; FAB, fast atom bombardment; Fmoc, 9-fluorenylmethyloxycarbonyl; HEK, human embryonic kidney; HEPES, *N*-(2-hydroxyethyl)piperazine-*N*′-(2-ethanesulfonic acid); HRMS, high-resolution mass spectrometry; KN-62, 1-[*N*,*O*-bis-(5-isoquinolinesulfonyl)-*N*-methyl-L-tyrosyl]-4-phenylpiperazine; MRS 2409, [*N*-benzyloxycarbonyl-*O*-[4-(isoquinolinylsulfonyl)]-L-tyrosyl]benzoylpiperazine; TFA, trifluoroacetic acid; THF, tetrahydrofuran; TLC, thin-layer chromatography.



The $P2X_7$ receptor (formerly known as the P_{2Z} receptor) is expressed primarily in the immune/inflammatory system (*4*−*9*), i.e., in blood cells (monocytes, macrophages, and lymphocytes) and in the brain on microglial cells, and in the salivary gland (*10*). Its activation is associated with apoptosis in the immune system and release of inflammatory cytokines, such as IL-1β (*8*, *9*, *11*). The $P2X_7$ receptor is distinct from the other P2X subunits in that at high μM concentrations of agonists, it forms or activates a large pore in addition to a cation channel (*12*, *13*). This pore increases permeability indiscriminately to molecules having MW ≤ 900, such as ethidium bromide, which is used as a marker for pore activity. The $P2X_7$ receptor also has a long C-terminal segment which contributes to pore formation (*13*). 2′- and 3′-*O*-(4-benzoylbenzoyl)-ATP (BzATP) is among the most potent agonists at $P2X_7$ receptors, but also has nanomolar potency at $P2X_1$ receptors (*14*). Affinity labeling of the $P2X_7$ receptor in mast cells has been carried out using [^{3}H]-BzATP (*15*).

An objective of the present study was to design antagonist ligand probes based on tyrosine derivatives, to be used for biophysical characterization of the $P2X_7$ receptor. The isoquinoline derivative of tyrosine 1-(*N*,*O*-bis[5-isoquinolinesulfonyl]-*N*-methyl-L-tyrosyl)-4-phenylpiperazine (**1**, KN-62), is a potent noncompetitive antagonist at $P2X_7$ receptors in the submicromolar range (*6*,*7*,*12*). It is also an antagonist of Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) in the micromolar range (*16*). We recently reported a series of potent $P2X_7$ receptor

1, KN-62

2, MRS 2409

antagonists derived from KN-62, of the general structure R_1-Tyr(OR_2)-piperazinyl-R_3, in which three positions (R_1, R_2, and R_3) were systematically varied (*17*). The derivative MRS 2409 ([N-benzyloxycarbonyl-O-[4-(isoquinolinylsulfonyl)]-L-tyrosyl]benzoylpiperazine), **2**, in which R_1 and R_3 differed from the structure of KN-62, was among the most potent analogues prepared (IC_{50} of 200 nM, for release of K^+ stimulated by 3 mM ATP in HEK293 cells expressing the human P2X$_7$ receptor). We now extend the SAR (structure activity relationship) analysis in this series to include more varied functionalization of congeners (*18*−*20*) of MRS 2409, directed toward probing multiple sites on the antagonist molecules for sites of chain attachment that preserve the biological properties. This functionalization is intended for the purpose of cross-linking, either with the receptor and/or with reporter moieties such as fluorescent dyes or radioisotopes. Dimerization of the antagonists through various linkage points has also been carried out in order to explore the spatial relationship between possible multiple binding sites on the large extracellular loop (*13*, *21*) of P2X$_7$ receptor homomers.

MATERIALS AND METHODS

Chemical Synthesis. Protected tyrosine compounds are from Novabiochem (San Diego, CA). Other chemicals are from Aldrich (Milwaukee, WI). ^{1}H NMR spectra were recorded using a Varian Gemini-300 spectrometer. High-resolution FAB (fast atom bombardment) mass spectra were taken with a JEOL SX102 spectrometer using nitrobenzoic acid as matrix. Elemental analysis was performed by Atlantic Microlab Inc. (Norcross, GA).

General Procedure for the Synthesis of 46, 51, 62. A mixture of Fmoc-Tyr-OH or Cbz-Tyr-OH (3.0 mmol), Boc-piperazine, or benzoyl-piperazine (3.0 mmol), Bis(2-oxo-3-oxoazolidinyl)phosphinic chloride (Bop-Cl) (0.77 g, 3.0 mmol), and CH_2Cl_2 (15 mL) was treated with Et_3N (0.96 mL, 6.8 mmol) and stirred at room temperature for 1 h. The solvent was removed in vacuo, and the crude product was purified with silica gel chromatography eluting with methanol−chloroform (5:95) to furnish a white solid foam (yield 75−85%).

*[N-Fmoc-L-tyrosyl]benzoylpiperazine (**46**).* ^{1}H NMR ($CDCl_3$): δ 7.77 (d, J = 7.4 Hz, 2H), 7.59 (d, J = 7.4 Hz, 2H), 7.50−7.28 (m, 5H), 7.05 (d, J = 8.0 Hz, 2H), 6.75 (d, J = 8.0 Hz, 2H), 5.70 (d, J = 8.5 Hz, 1H), 4.84(b, 1H), 4.50−4.25 (m, 2H), 4.25−4.10 (t, J = 7.0 Hz, 1H), 3.80−2.80 (m, 10H).

*[N-Fmoc-L-tyrosyl]-Boc-piperazine (**51**).* ^{1}H NMR ($CDCl_3$): δ 7.77 (d, J = 7.3 Hz, 2H), 7.59 (d, J = 7.3 Hz, 2H), 7.40 (t, J = 7.3 Hz, 2H), 7.31 (t, J = 7.3 Hz, 2H), 7.04 (d, J = 7.7 Hz, 2H), 6.74 (d, J = 7.7 Hz, 2H), 5.88 (s, 1H), 5.72 (d, J = 8.4 Hz, 1H), 4.90−4.78 (m, 1H), 4.44−4.28 (m, 2H), 4.24−4.16 (t, J = 7.0 Hz, 1H), 3.60−2.80 (m, 10 H), 1.45 (s, 9H).

*[N-Benzyloxycarbonyl-O-toluenesulfonyl-L-tyrosyl]piperazine (**62**).* ^{1}H NMR ($CDCl_3$): δ 7.30−7.40 (m, 5H), 7.02 (d, J = 8.2 Hz, 2H), 6.72 (d, J = 8.2 Hz, 2H), 5.65 (d, J = 8.5 Hz, 1H), 5.45 (br s, 1H), 5.14−5.00 (ABq, J = 12.4 Hz, 2H), 4.90−4.75 (m, 1H), 3.60−2.80 (m, 10H), 1.45 (s, 9H).

General Procedure for the Synthesis of 23a, 23b, 47, 52a, 52b, 55. N-Substituted tyrosine (**46**, **51**, or **62**; 2.0 mmol) was dissolved in 10 mL of anhydrous CH_2Cl_2 and cooled to 0 °C. A solution of benzenesulfonyl chloride or related sulfonyl chloride (4.0 mmol), Et_3N (0.3 mL, 2.2 mmol), DMAP (214 mg, 1.7 mmol), and CH_2Cl_2 (5.0 mL) was added dropwise and stirring continued for 30 min at 0 °C. TLC showed the completion of the reaction. The solvent was removed under reduced pressure. Column chromatography (silica gel, CH_3OH:$CHCl_3$ = 5:95) yielded a white solid foam (70−75% yield).

*[N-Benzyloxycarbonyl-O-(3-nitrobenzenesulfonyl)-L-tyrosyl]-Boc-piperazine (**23a**).* ^{1}H NMR ($CDCl_3$): δ 8.71 (t, J = 1.9 Hz, 1H), 8.52 (ddd, J = 1.1, 2.2, 8.2 Hz, 1H), 8.12 (m, 1H), 7.78 (t, J = 8.0 Hz, 1H), 7.40−7.30 (m, 5H), 7.14 (d, J = 8.5 Hz, 1H), 6.93 (m. 1H), 5.58 (d, J = 8.8 Hz, 1H), 5.14−5.00(ABq, J = 12.4 Hz, 2H), 4.88−4.77 (m, 1H), 3.60−2.84 (m, 10H), 1.44 (s, 9H). FAB−HRMS for $C_{32}H_{37}N_4O_{10}S$ (MH^+): calcd 669.2230, found 669.2231. Anal. ($C_{32}H_{36}N_4O_{10}S\cdot0.1H_2O$).

*[N-Benzyloxycarbonyl-O-(4-nitrobenzenesulfonyl)-L-tyrosyl]-Boc-piperazine (**23b**).* ^{1}H NMR ($CDCl_3$): δ 8.39 (d, J = 9.0 Hz, 2H), 8.02 (d, J = 9.1 Hz, 2H), 7.42−7.28 (m, 5H), 7.13 (d, J = 8.5 Hz, 2H), 6.90 (d, J = 8.5 Hz, 2H), 5.60 (d, J = 8.5 Hz, 1H), 5.14−5.00 (ABq, J = 13.7 Hz, 2H), 4.90−4.77 (m, 1H), 3.60−2.78 (m, 10H), 1.45 (s, 9H). FAB-MS: *m*/*z* (relative intensity) 669.1 (M + 1, 6), 613.1 (16), 91 (100). Anal. ($C_{32}H_{36}N_4O_{10}S\cdot0.1H_2O$).

*[N-Fmoc-O-toluenesulfonyl-L-tyrosyl]benzoylpiperazine (**47**).* ^{1}H NMR ($CDCl_3$): δ 7.86−7.64 (m, 4H), 7.60 (d, J = 7.7 Hz, 2H), 7.50−7.28 (m, 11H), 7.13 (d, J = 8.2 Hz, 2H), 6.84−6.88 (d, J = 8.2 Hz, 2H), 5.66 (d, J = 8.2 Hz, 1H), 4.82 (b, 1H), 4.50−4.25 (m, 2H), 4.25−4.10 (m, 1H), 3.8−2.7 (m, 10H), 2.45 (s, 3H).

*[N-Fmoc-O-benzenesulfonyl-L-tyrosyl]-Boc-piperazine (**52a**).* ^{1}H NMR ($CDCl_3$): δ 7.88−7.72 (m, 4H), 7.70−7.60 (m, 2H), 7.46−7.27 (m, 7H), 7.10 (d, J = 8.5 Hz, 2H), 6.90 (d, J = 8.5 Hz, 2H), 5.66 (d, J = 8.2 Hz, 1H), 4.90−4.70 (m, 1H), 4.50−4.30 (m, 2H), 4.25−4.10 (m, 1H), 3.8−2.7 (m, 10H), 1.45 (s, 9H).

*[N-Fmoc-O-(4-nitrobenzenesulfonyl)-L-tyrosyl]-Boc-piperazine (**52b**).* ^{1}H NMR ($CDCl_3$): δ 8.38 (d, J = 8.8 Hz, 2H), 8.02 (d, J = 8.8 Hz, 2H), 7.77 (d, J = 7.7 Hz, 2H), 7.56 (d, J = 7.4 Hz, 2H), 7.47−7.27 (m, 4H), 7.14 (d, J = 7.4 Hz, 2H), 6.91 (d, J = 8.5 Hz, 2H), 5.61 (d, J = 8.5 Hz, 1H), 4.90−4.70 (m, 1H), 4.50−4.28 (m, 2H), 4.26−4.10 (m, 1H), 3.58−2.70 (m. 10H), 1.45 (s, 9H).

*[N-Fmoc-O-toluenesulfonyl-L-tyrosyl]-Boc-piperazine (**55**).* ^{1}H NMR ($CDCl_3$): δ 7.76 (d, J = 7.1 Hz, 2H), 7.70 (d, J = 8.0 Hz, 2H), 7.57 (d, J = 6.9 Hz, 2H), 7.46−7.27 (m, 6H), 7.10 (d, J = 7.9 Hz, 2H), 6.90 (d, J = 7.8 Hz, 2H), 5.65 (d, J = 8.2 Hz, 1H), 4.85−4.70 (m, 1H), 4.50−4.25 (m, 2H), 4.24−4.15 (m, 1H), 3.80−2.70 (m, 10H), 2.43 (s, 3H), 1.45 (s, 9H).

General Procedure for the Synthesis of 17, 19, 20b, 25, 26a, 26b, 28, 31a, 31b, 33, 53a, 53b, 53c, 53d, 57a, 57b. A tyrosine derivative containing a free amine (**20a**, **24**, **27**, **32**, **52a**, **52b**, **56**, **58a**, **58b**, or **63**; 3.0 mmol) was dissolved in CH_2Cl_2 (8.0 mL). DMAP (300 mg) was added, and the solution was cooled to 0 °C. A solution of a benzoyl chloride (4.2 mmol) (alternatively a benzyl chloroformate or acetyl chloride), Et_3N (0.45 mL), and CH_2Cl_2 (5.0 mL) was added dropwise and stirring continued at 0 °C for 40 min. The solvent was removed, and the residue was washed with petroleum ether three times. The resulting crude product was purified by column chromatography (silica gel, CH_3OH:$CHCl_3$ = 5:95) to yield a white solid foam (80−90% yield).

*[N-(4-Nitrobenzyloxycarbonyl)-O-toluenesulfonyl-L-tyrosyl]benzoylpiperazine (**17**).* ^{1}H NMR ($CDCl_3$): δ 8.22 (d, J = 8.8 Hz, 2H), 7.73 (d, J = 8.2 Hz, 2H), 7.60−7.30 (m, 9H), 7.13 (d, J = 8.2 Hz, 2H), 6.93 (d, J = 8.5 Hz, 2H), 5.70 (d, J = 8.5 Hz, 1H), 5.26−5.10 (b, 2H), 4.92−4.70 (b, 1H), 3.90−2.70 (m, 10H), 2.46 (s, 3H). General Procedure for the Synthesis of 3−16. The appropriate tyrosine derivative (**48**, **54a**, **54b**, **54c**, or **54d**; 1.0 mmol), Bop-Cl (1.0 mmol) and appropriate cinnamic acid derivative (1.0 mmol) were dissolved in CH_2Cl_2 (5.0 mL). The solution was treated with Et_3N (2.0 mmol) and stirred at room temperature for 5 h. The solvent was removed, and the residue was purified using silica gel chromatography eluting with methanol−chloroform (5:95) to get a solid foam (40−60% yield).

*[N-(trans-Cinnamoyl)-O-(4-nitrobenzenesulfonyl)-*L*-tyrosyl]-(4-nitrobenzoyl)piperazine (**13**).* ^{1}H NMR ($CDCl_3$): δ 8.43 (d, J = 8.8 Hz, 2H), 8.28 (d, J = 8.2 Hz, 2H), 8.10 (d, J = 8.8 Hz, 2H), 7.70−7.46 (m, 4H), 7.44−7.34 (m, 3H), 7.23 (d, J = 8.5 Hz, 2H), 7.00 (d, J = 8.0 Hz, 2H), 6.49 (d, J = 8.2 Hz, 1H), 6.40 (d, J = 15.7 Hz, 1H), 5.40−5.16 (b, 1H), 3.90−2.80 (m, 10H). FAB-MS: *m/z* (relative intensity) 714.2 (M + 1, 5.5), 119.0 (100). Compound **13** (R_f = 0.56, $CH_3OH/CHCl_3$ = 5: 95) was shown to be pure by TLC.

*[N-(trans-4-Nitrocinnamoyl)-O-(4-nitrobenzenesulfonyl)-*L*-tyrosyl]-(4-nitrobenzoyl)piperazine (**14**).* ^{1}H NMR ($CDCl_3$): δ 8.43 (d, J = 8.8 Hz, 2H), 8.34−8.20(m, 4H), 8.10 (d, J = 8.8 Hz, 2H), 7.78−7.50 (m, 4H), 7.24 (d, J = 8.5 Hz, 2H), 7.01 (d, J = 7.7 Hz, 2H), 6.64 (d, J = 8.2 Hz, 1H), 6.54 (d, J = 15.6 Hz, 1H), 5.40−5.10 (b, 1H), 3.90−2.90 (m, 10H). FAB-MS: *m/z* (relative intensity) 759.2 (M + 1, 1.5), 119.0 (100). Compound **14** (R_f = 0.45, $CH_3OH/CHCl_3$ = 5: 95) was shown to be pure by TLC.

*[N-Benzyloxycarbonyl-O-toluenesulfonyl-*L*-tyrosyl]-benzoylpiperazine (**15**).* ^{1}H NMR ($CDCl_3$): δ 7.72 (d, J = 8.2 Hz, 2H), 7.48−7.28 (m, 12H), 7.12 (d, J = 8.2 Hz, 2H), 6.90 (d, J = 8.2 Hz, 2H), 5.61 (d, J = 8.5 Hz, 1H), 5.16−4.96 (m, 2H), 4.92−4.74 (m, 1H), 3.80−2.60 (m, 10H), 2.45 (s, 3H). Anal. ($C_{35}H_{35}N_3O_7S\cdot 0.1\ H_2O$).

*[N-(2-Chlorobenzyloxycarbonyl)-O-toluenesulfonyl-*L*-tyrosyl]-benzoylpiperazine (**16**).* ^{1}H NMR ($CDCl_3$): δ 7.72 (d, J = 7.7 Hz, 2H), 7.48−7.30 (m, 11H), 7.13 (d, J = 8.2 Hz, 2H), 6.92 (d, J = 8.2 Hz, 2H), 5.56 (d, J = 8.2 Hz, 1H), 5.28−5.10 (ABq, J = 13.1 Hz, 2H), 4.94−4.74 (m, 1H), 3.90−2.70 (m, 10H), 2.46 (s, 3H). Compound **16** (R_f = 0.64, $CH_3OH/CHCl_3$ = 5: 95) was shown to be pure by TLC.

General Procedure for the Synthesis of 20a, 24, 27, 32. To a solution of an aromatic nitro compound (**19**, **23b**, **26b**, or **31b**; 2.0 mmol) in methanol (10 mL), sodium borohydride (10.0 mmol) was added and the solution stirred at room temperature for 5 min. Then copper(II) acetylacetonate was added and stirring continued for 1 h. TLC showed the completion of the reaction. The solvent was removed, and the residue was washed with petroleum ether two times. Then, the crude product was purified using silica gel chromatography eluting with methanol−chloroform (5:95) to provide a white solid foam (80−85% yield).

*[N-(3-Aminobenzyloxycarbonyl)-O-toluenesulfonyl-*L*-tyrosyl]benzoylpiperazine (**20a**).* ^{1}H NMR ($CDCl_3$): δ 7.72 (d, J = 8.5 Hz, 2H), 7.46−7.28 (m, 7H), 7.18−7.06 (m, 3H), 6.92 (d, J = 8.8 Hz, 2H), 6.74−6.58 (m, 3H), 5.57 (d, J = 9.3 Hz, 1H), 5.04−4.92 (m, 2H), 4.88−4.74 (b, 1H), 3.95−2.70 (m, 10H), 2.45 (s, 3H). FAB-MS: *m/z* (relative intensity) 657.3 (M + 1, 45), 658.3 (M + 2, 15), 85 (100). FAB−HRMS for $C_{35}H_{37}N_4O_7S$ [M + H]$^+$: calcd 657.2383, found 657.2385.

*[N-Benzyloxycarbonyl-O-(4-aminobenzenesulfonyl)-*L*-tyrosyl]Boc-piperazine (**24**).* ^{1}H NMR ($CDCl_3$): δ 7.53 (d, J = 8.5 Hz, 2H), 7.40−7.28 (m, 5H), 7.08 (d, J = 8.5 Hz, 2H), 6.92 (d, J = 8.4 Hz, 2H), 6.61 (d, J = 8.8 Hz, 2H), 5.61 (d, J = 8.5 Hz, 1H), 5.02−4.96 (ABq, J = 12.3, 16.0 Hz, 2H), 4.81 (b, 1H), 4.38 (br s, 2H), 3.80−2.60 (m, 10H), 1.45 (s, 9H). FAB-MS (NOBA): *m/z* (relative intensity) 639.3 (M + 1, 1), 661.3 (M + Na, 7), 583.2 (8), 539.3 (10). 91.0 (100). FAB-MS (NOBA/LiCl): *m/z* (relative intensity) 645.3 (M + Li, 15), 687.3 (M + Li$^+_2$Cl, 5).

*[N-Benzyloxycarbonyl-O-(4-aminobenzenesulfonyl)-*L*-tyrosyl]benzoylpiperazine (27).* ^{1}H NMR ($CDCl_3$): δ 7.55 (d, J = 8.5 Hz, 2H), 7.48−7.28 (m, 10H), 7.10 (d, J = 8.0 Hz, 2H), 6.94 (d, J = 8.0 Hz, 2H), 6.64 (d, J = 8.5 Hz, 2H), 5.63 (d, J = 8.8 Hz, 1H), 5.16−5.00 (ABq, J = 12.4, 15.9 Hz, 2H), 4.92−4.70 (b, 1H), 4.50−4.20 (b, 2H), 4.00−2.80 (m, 10H). FAB-MS: *m/z* (relative intensity) 643.4 (M + 1, 24), 391.4 (20), 251.2 (60), 91.1 (100). FAB−HRMS for $C_{34}H_{35}N_4O_7S$ [M + H]$^+$: calcd 643.2226, found 643.2244.

*[N-Benzyloxycarbonyl-O-toluenesulfonyl-*L*-tyrosyl]-(4-aminobenzoyl)piperazine (**32**).* ^{1}H NMR ($CDCl_3$): δ 7.70 (d, J = 8.2 Hz, 2H), 7.40−7.30 (m, 7H), 7.23 (d, J = 8.2 Hz, 2H), 7.12 (d, J = 8.5 Hz, 2H), 6.90 (d, J = 8.5 Hz, 2H), 6.70 (d, J = 8.4 Hz, 2H), 5.61 (d, J = 8.5 Hz, 1H), 5.12−5.02 (ABq, J = 12.3, 15.1 Hz, 2H), 4.88−4.76 (m, 1H), 3.89 (s, 2H), 3.90−2.80 (m, 10H), 2.45 (s, 3H). FAB-MS: *m/z* (relative intensity) 657.2 (M + 1, 95), 679.2 (M+ Na, 25), 120.1 (100), 91.0 (85). FAB−HRMS for $C_{35}H_{37}N_4O_7S$ [M + H]$^+$: calcd 657.2383, found 657.2396. Anal. ($C_{35}H_{36}N_4O_9S\cdot 0.1H_2O$).

General Procedure for the Synthesis of 21, 29, 34. An amine compound (**20a**, **27**, or **32**; 0.08 mmol) was mixed with chloroform (2.0 mL), water (1.0 mL), and sodium bicarbonate (20 mg. 0.24 mmol) and stirred vigorously for 10 min. Thiophosgene (2.0 mmol) was added and stirring continued for 1 h. The solvent was removed, and the residue was washed two times with petroleum ether. The crude product was purified with a preparative TLC plate to provide a white solid foam (70−85% yield).

*[N-(3-Isothiocyanato)benzyloxycarbonyl-O-toluenesulfonyl-*L*-tyrosyl]benzoylpiperazine (**21**).* ^{1}H NMR ($CDCl_3$): δ 7.72 (d, J = 8.8 Hz, 2H), 7.46−7.30 (m, 8H), 7.24−7.08 (m, 5H), 6.92 (d, J = 8.8 Hz, 2H), 5.64 (d, J = 8.5 Hz, 1H), 5.05 (s, 2H), 4.90−4.72 (b, 1H), 4.00−2.70 (m, 10H), 2.45 (s, 3H). FAB−HRMS for $C_{36}H_{35}N_4O_7S_2$ [M + H]$^+$: calcd 699.1947, found 699.1948. Anal. ($C_{36}H_{34}N_4O_7S_2$).

*[N-Benzyloxycarbonyl-O-(4-isothiocyanato)benzenesulfonyl-*L*-tyrosyl]benzoylpiperazine (**29**).* ^{1}H NMR ($CDCl_3$): δ 7.82 (d, J = 8.5 Hz, 2H), 7.48−7.28 (m, 12H), 7.14 (d, J = 8.5 Hz, 2H), 6.92 (d, J = 8.5 Hz, 2H), 5.59 (d, J = 8.5 Hz, 1H), 5.16−5.00 (ABq, J = 12.1, 14.8 Hz, 2H), 4.92−4.72 (b, 1H), 3.80−2.70 (m, 10H). FAB−HRMS for $C_{35}H_{33}N_4O_7S_2$ [M + H]$^+$: calcd 685.1791, found 685.1810.

*[N-Benzyloxycarbonyl-O-toluenesulfonyl-*L*-tyrosyl]-(4-isothiocyanatobenzoyl)piperazine (**34**).* ^{1}H NMR ($CDCl_3$): δ 7.42 (d, J = 8.5 Hz, 2H), 7.40−7.30 (m, 9H), 7.24 (d, J = 8.2 Hz, 2H), 7.14 (d, J = 8.5 Hz, 2H), 6.93 (d, J = 8.5 Hz, 2H), 5.60 (d, J = 8.5 Hz, 1H), 5.16−5.00 (ABq, J = 12.4, 15.4 Hz, 2H), 4.90−4.72 (b, 1H), 3.80−2.60 (m, 10H), 2.47 (s, 3H). [a] All experiments were performed using adherent HEK293 cells stably transfected with cDNA encoding the human P2X$_7$ receptor. Cells were preincubated with antagonists (3 μM final concentration) for 15 min prior to stimulation for 10 min with 3 mM ATP (final concentration). Antagonist function was measured by the percent inhibition of the K^+ release triggered by 3 mM ATP in paired wells in the absence of antagonist. Data points represent the mean ± SD of values obtained. **15**, MRS 2427; **18**, MRS 2464; **26b**, MRS 2447; **30**, MRS 2483; **32**, MRS 2452; **35b**, MRS 2484; **66**, MRS 2454; **67**, MRS 2455.

component (Scheme 7) in dry DMF, and following the same synthetic procedure as for compound **64**, the correspondence dimer was obtained in 5−10% yield.

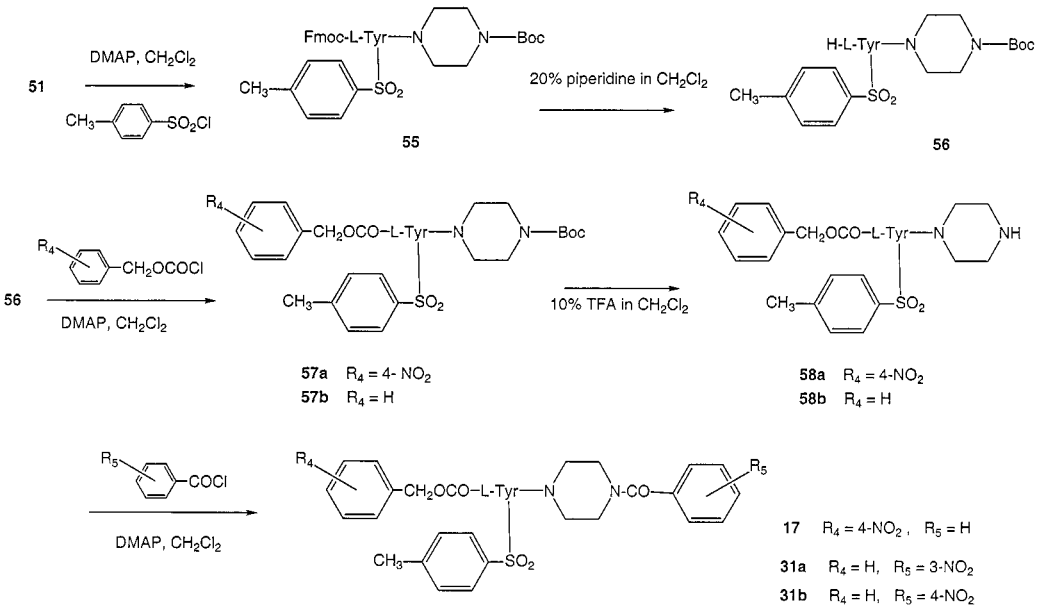
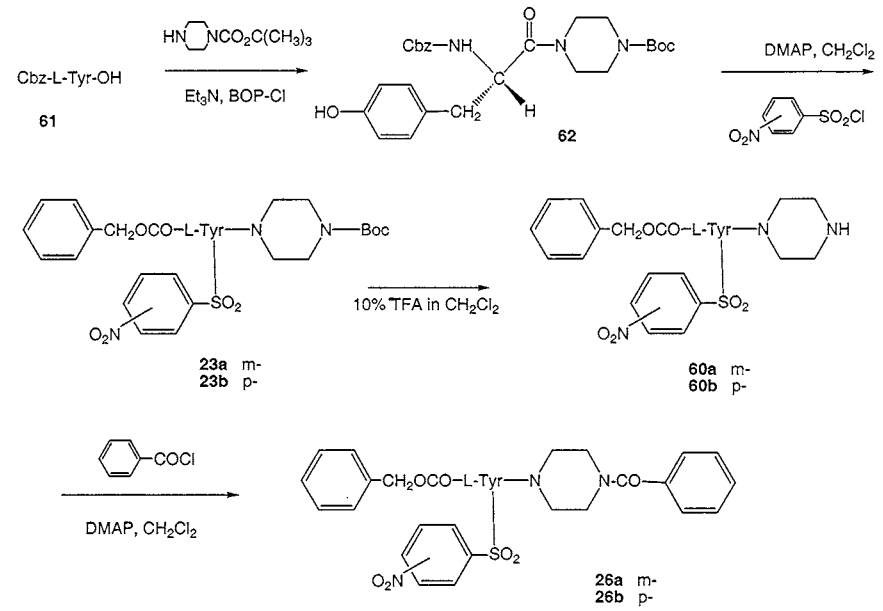
Scheme 2. Synthesis of P2X$_7$ Receptor Antagonists Consisting of L-Tyrosine Derivatives Containing a Nitro Substitution at Either the *N*α-Cinnamoyl Substituent, the Aryl Sulfonate Group Present on the Tyrosyl Side Chain, or the *C*α-Benzoylpiperazine Substituent



Pharmacological Analysis. P2X$_7$ Receptor Channel Activation. All experiments were performed using adherent HEK293 cells stably transfected with cDNA encoding the human P2X$_7$ receptor. Adherent cells on 12-well polylysine-coated plates were incubated at 37 °C in 1 mL of physiological salt solution (125 mM NaCl, 5 mM KCl, 1 mM $MgCl_2$, 1.5 mM $CaCl_2$, 25 mM NaHEPES (pH 7.5), 10 mM D-glucose, 1 mg/mL BSA). Antagonists were added from 1000× stock solutions dissolved in DMSO. Cells were preincubated with antagonists for 15 min prior to stimulation for 10 min with 3 mM ATP (final concentration). Reactions were terminated by rapid aspiration of the extracellular medium in each well. The adherent cells in each well were then extracted overnight with 1 mL 10% HNO_3. K^+ content in these nitric acid extracts was assayed by atomic absorbance spectrophotometry. Duplicate or triplicate wells were run for all test conditions in each separate experiment, and the measured K^+ contents were averaged. Antagonist function was measured by the percent inhibition of the K^+ release triggered by 3 mM ATP in paired wells in the absence of antagonist.



RESULTS

Chemical Synthesis. The analogues consisted of L-tyrosine derivatives, of the general structure R_1-Tyr-(OR_2)-piperazinyl-R_3 (Table 1), in which three variable regions were systematically varied in structure (compounds **3**−**35**) through facile acylation reactions and other procedures. The lead compound MRS 2409 (*17*), **2**, contained an isoquinolinyl sulfonate at the tyrosyl hydroxyl group. For the present study, this group was first substituted with a phenyl sulfonate ester, a structural simplification known to preserve affinity for the receptor (*17*). Each of the three regions (R_1−R_3) was probed systematically for possbile attachment sites, through synthesis alternating with biological evaluation, which consisted of screening at a single concentration (initially

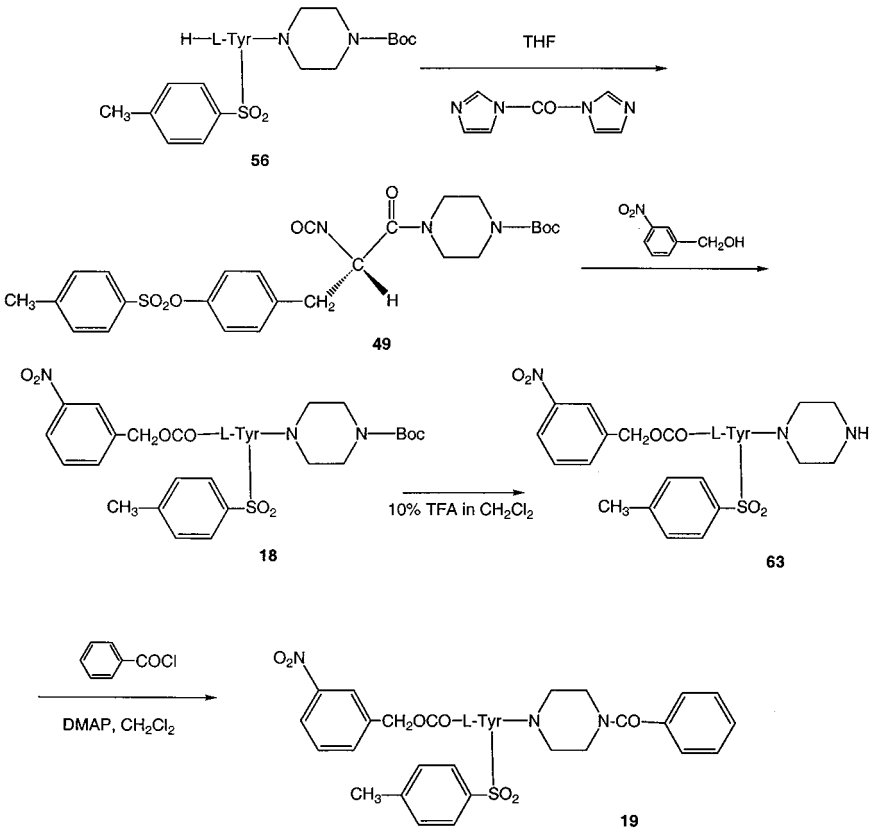
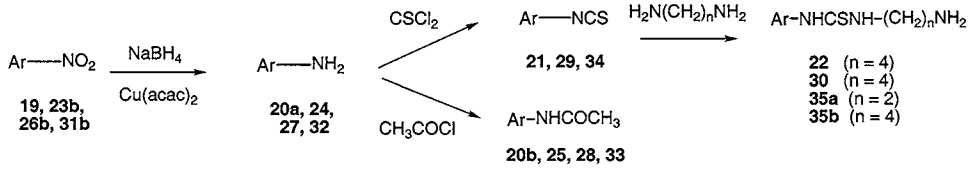
Scheme 4. Synthesis of P2X$_7$ Receptor Antagonists Consisting of L-Tyrosine Derivatives Containing a Nitro Substitution at the Aryl Sulfonate Group Present on the Tyrosyl Side Chain



3 μM). This process led to the identification and partial optimization of potent, functionalized P2X$_7$ antagonists.

The synthetic routes for systematic substitution at three positions on the molecule are shown in Schemes 1−5. Subsequent functional group replacement beginning with nitro groups is shown in Scheme 6. Synthetic yields are listed in Materials and Methods. General probing of the SAR at each position was carried out. Scheme 1 indicates substitutions made at the R_1 position, including both *N*-cinnamoyl (**4**−**7**) and *N*-benzyloxycarbonyl (**15** and **16**) derivatives. Each of the three ring-substitution positions shown in Table 1 (R_1−R_3) was designed for the initial incorporation of a nitro group (at the meta-position for R_1, meta- or para-positions for R_2 and R_3). For a series of *N*-cinnamoyl derivatives (Scheme 2), multiple nitro groups (**11**−**14**) were also included. At R_2 and R_3 the nitro groups were introduced as shown in Schemes 3 and 4.



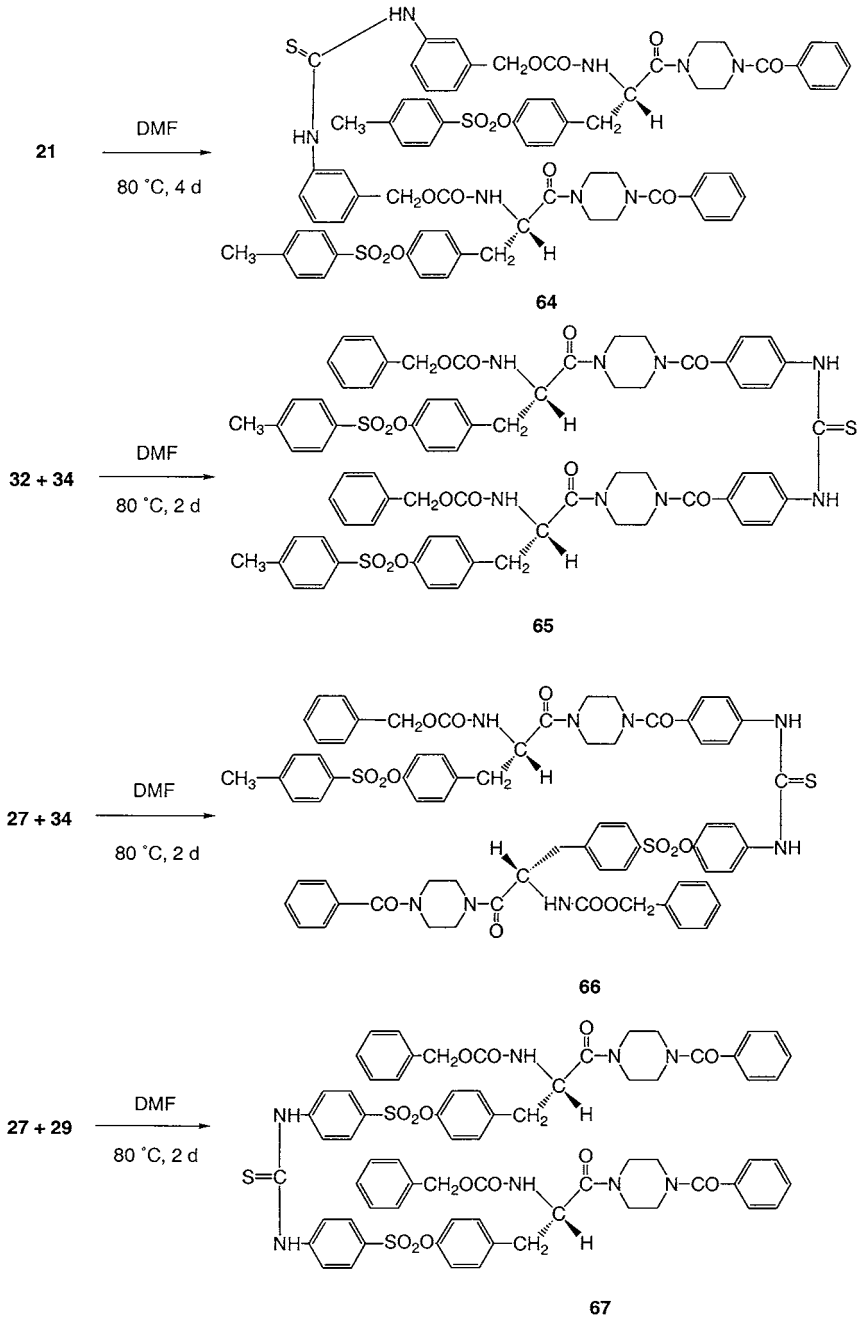
The synthesis of *N*-(nitrobenzyloxycarbonyl)-L-tyrosine derivatives (Scheme 5) required a modification of the original route based on simple reduction of 4-nitro groups. Since the *N*-(4-aminobenzyloxycarbonyl)tyrosine derivative of **17** proved to be unstable, we sought to develop an alternate synthetic method, aimed instead at the 3-nitro derivative, **18**. Usually, benzyl chloroformates are synthesized through the reaction of benzyl alcohol with phosgene (*22*). Here, an interesting alternative for the incorporation of *N*-(3-nitrobenzyloxycarbonyl) into tyrosine was the transformation of the α-amine of the tyrosyl moiety into an isocyanate group first with the aid of 1,1′-carbonyldiimidazole (*23*) to yield **49**, and subsequent addition of the alcohol to yield **18**.

The nitro groups at R_1, R_2, and R_3 were directly reduced to amines (Scheme 6), which were either converted to the isothiocyanate groups, in **21**, **29**, and **34**, as potential affinity labels for the receptor, or acylated, as models for conjugation. The isothiocyanate groups also reacted with alkyl diamines to produce the primary amine congeners **22**, **30**, and **35**. Several methods were compared for

Scheme 5. Synthesis of P2X$_7$ Receptor Antagonists Consisting of L-Tyrosine Derivatives Containing 3-Nitro Substitution at the *N*α-Benzyloxycarbonyl Substituent

Scheme 6. Functional Group Replacement in P2X$_7$ Receptor Antagonists

reduction of the aromatic nitro compounds. Many reducing reagents have been used to reduce aromatic nitro compounds (*24*) with the most classic being zinc, tin, or iron in the presence of an acid. Other reagents include hydrazine, $TiCl_4$−dialkyl telluride and sulfide (*25*). However, most of them lack the desired chemoselectivity over the functional groups that are present in our compounds such as amide, *tert*-butoxycarbonyl (Boc), 9-fluorenylmethoxycarbonyl (Fmoc), and benzyloxycarbonyl (Cbz). Though aromatic nitro compounds are seldom reduced by sodium borohydride in alcoholic solution, we found $NaBH_4$−copper(II) acetylacetonate (*26*) to be the most effective and a mild catalyst for the reduction of nitro groups on these tyrosine derivatives. This reaction occurred nearly quantitatively as judged using TLC.



Four dimer permutations (**64**−**67**) were created by coupling each of the isothiocyanate derivatives to either the precursor amine or to other amine congeners (Scheme 7). These coupling reactions required elevated temperature and were carried out in moderate yield.

Biological Activity. The effects of substitution at R_1, R_2, and R_3 on inhibition of P2X$_7$ receptor-mediated ion flux (Table 1) were compared. Experiments were performed using adherent HEK293 cells stably transfected with cDNA encoding the human P2X$_7$ receptor. Cells were preincubated with each antagonist at a fixed concentration (3 μM) prior to stimulation for 10 min with 3 mM ATP. The percent inhibition of the K^+ release was the parameter used to indicate antagonist function.

The three structural regions for conjugation were compared in their effects on biological potency. Among *N*-cinnamoyl derivatives, more favorable potency was associated with the unsubstituted derivative **9** than with methoxy substitution. Multiple methoxy substitution, e.g., **7**, eliminated the antagonistic effect at the P2X$_7$ receptor. The 4-nitro substitution of the cinnamoyl group also reduced potency (cf. **14** vs **13**). The Cbz derivative **15** was a potent antagonist of the human P2X$_7$ receptor, and 4- or 3-nitro substitution preserved that property, as in **18** and **19**. However, reduction and acetylation of the 3-nitro group, **20a** and **20b**, reduced potency. The corresponding isothiocyanate **21** and amine congener **22** were inactive or weakly potent, respectively.

Nitro subsitution of the tyrosyl side chain (R_2 substituent), at the 3- or 4-position, as in benzoylpiperazine (at R_3) derivatives **26a** and **26b**, respectively, maintained potency at the human P2X$_7$ receptor. There was no difference in biological potency between 3- and 4-nitro derivatives. The corresponding t-Boc derivatives (at the R_3 position, e.g., **23a** and **23b**) similarly antagonized the human P2X$_7$ receptor. This antagonism was preserved when the 4-nitro group was reduced and acetylated (e.g. **24** and **25**; **27** and **28**). A primary amine congener linked at the R_2 4-position, **30**, was a potent antagonist of the

Scheme 7. Dimerization of P2X$_7$ Receptor Antagonists through Formation of Thiourea Linkages

human P2X$_7$ receptor. The corresponding isothiocyanate **29** displayed considerable potency as a P2X$_7$ receptor antagonist and warranted examination as an irreversible receptor inhibitor.

For the R_3 substituent, 3- or 4-nitrobenzoyl subsitution, **31a** and **31b**, respectively, preserved antagonistic properties at the human P2X$_7$ receptor. As for the R_2 substituent, there was no difference in biological potency between 3- and 4-nitro derivatives. The P2X$_7$ receptor antagonism was increased when the 4-nitro group was reduced but diminished upon acetylation (e.g., **32** and **33**). An isothiocyanate **34** only weakly antagonized the effects of ATP at the P2X$_7$ receptor. A primary amine congener containing four methylenes linked at the R_2 4-position, **35b**, was a potent antagonist of the human P2X$_7$ receptor, while a shorter homologue **35a** (two methylenes) antagonized weakly.

Full concentration−response curves provided a more precise means of comparison among some selected, potent compounds, including the 3-nitro-Cbz derivative **18**, a 4-nitrotoluenesulfonate **26b**, a primary amine congener **30**, and 4-aminobenzoyl derivative **32** (Figure 1). Compounds **18** and **26b**, were roughly as potent as **1** as P2X$_7$ receptor antagonists, and appeared to have IC_{50} values in the 0.1 μM range. The other compounds appeared to have IC_{50} values in the 0.3 μM range (**30**) or > 0.3 μM (**32**).

Among antagonist dimers, only the R_2-R_3- and R_2-R_2-linked dimers, **66** and **67**, respectively, displayed significant antagonistic properties at the P2X$_7$ receptor.

DISCUSSION

The binding site for KN-62, **1**, resides within the first 335 residues of the human P2X$_7$ receptor, likely within the large extracellular loop (*13, 21*). While it is not feasible to model this binding interaction, due to lack of a high-resolution template for this ion channel and

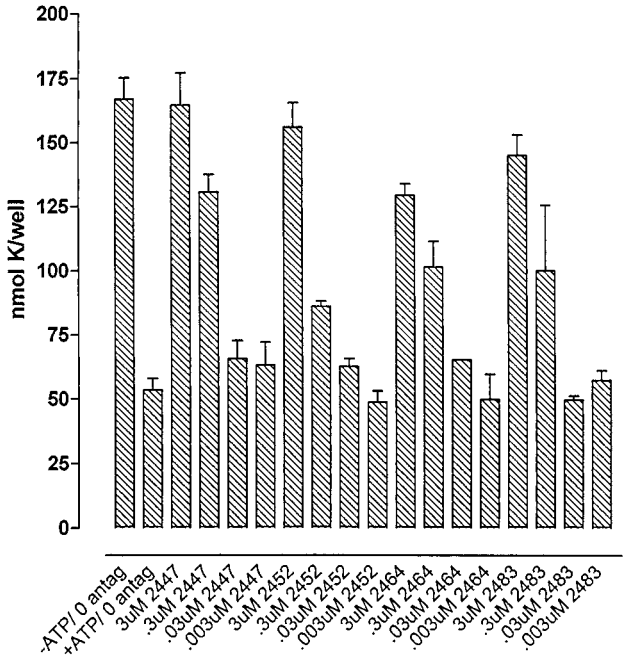


Figure 1. Effects of tyrosyl derivatives on $P2X_7$ receptor-activation in $hP2X_7$−HEK cells. Cells were preincubated with or without the indicated concentrations of selected antagonists (**26b** MRS2447; **32** MRS2452; **18** MRS2464; and **30** MRS2483) prior to stimulation with 3 mM ATP. Data points represent the mean (± SD) K^+ contents from triplicate wells in a single experiment. IC_{50} values mentioned in the text are rough estimates from visual inspection of the concentration−response relationships. Hill coefficients were not determined, since previous studies have shown that the lead compound (KN-62) represses $P2X_7$ receptor function via complex mechanisms that are not readily amenable to standard ligand-binding analyses.

uncertainty about the oligomeric nature of the channel (*27*), chemical probes of the receptor may be very useful in studying the structure. The stoichiometry of association of subunits in P2X receptors has been studied suggesting a trimeric organization (*2*, *27*, *28*), but little is known about the correspondence of antagonist binding sites to the overall oligomeric ion channel structure. By functionalizing derivatives (*17*) of the widely used $P2X_7$ antagonist KN-62 it may be possible to locate the binding site (in conjunction with mutagenesis studies). Mutagenesis studies of the $P2X_7$ receptor aimed at structural and functional elucidation have already been carried out (*29*, *32*). Peptide mapping of receptor digests (*30*) using electrophoretic or mass spectroscopic methods following affinity labeling of the receptor would also be useful in this regard.

Since there may be multiple binding sites on the $P2X_7$ receptor homomer, it may be possible to detect the preferred orientation of covalently linked antagonist dimers that may occupy two distinct binding sites, based on divergent biological potencies for a variety of linkage combinations. Since the dimerization of the antagonists in the present study through the tyrosyl side chain, alone, provided retention of antagonist properties, it is likely that this region of the antagonist occurs in a portion of the binding site that is somewhat relaxed in its steric requirements. Whether the dimers **66** and/or **67** are able to bridge two putative binding sites on the $P2X_7$ homomer will be the object of further studies. The species selectivity of the new functionalized congeners also should be investigated, since differences have been noted for KN-62 (*33*).

Receptor ligands that bridge two subunits of a multimeric receptor may also potentially be of use for tissue selectivity, if there are differences between tissues in the organization of subunits. Such differences have been demonstrated for native $P2X_7$ receptors (*34*), which in peritoneal macrophage and bone marrow cells exist as a strongly bound multimeric complex, and in brain glia and/or astrocytes appear to form only as monomeric subunits.

In conclusion, we have systematically varied substituent groups in a series of tyrosyl analogues, resulting in analogues, among which are antagonists that are equipotent to the lead structure **1** and also contain chemical functional groups for linking purposes. Such functionalized congeners have been used effectively for the structural investigations of other purine receptors (*18*, *19*, *31*), including adenosine A_1, A_{2A}, and A_3 receptors. Suitable sites and chemical approaches to cross-linking these antagonists have been found on the tyrosyl side chain (R_2) and on the Cα-substituent (R_3). The more versatile region for functionalization appears to be the R_2 substituent, since even dimerization through this substituent preserves the receptor binding property. We have prepared several amine functionalized congeners, that may potentially be conjugated to fluorescent probes for receptor characterization, or immobilized on a solid support for isolation of the receptor by affinity chromatography. Among P2X receptors, only the $P2X_1$ subtype has so far been isolated in this manner (*35*).

ACKNOWLEDGMENT

We thank Gilead Sciences (Foster City, CA) for financial support to W. Z. Chen. This work was supported by NIH grant GM36387 to G.D. We thank Mr. Noel Whittaker and Mr. Victor Livengood for determination of mass spectra.

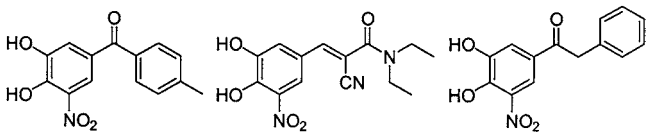
Chemical Synthesis and Characterization of Conjugates of a Novel Catechol-*O*-methyltransferase Inhibitor

David A. Learmonth* and Ana P. Freitas

Laboratory of Chemistry, Department of Research and Development, BIAL, 4745-457 S. Mamede do Coronado, Portugal. Received April 19, 2002; Revised Manuscript Received July 1, 2002



BIA 3-202, 1-(3,4-dihydroxy-5-nitrophenyl)-2-phenylethanone **3**, is a novel, reversible, and tight-binding peripheral inhibitor of the enzyme catechol-*O*-methyltransferase (COMT), which is currently under clinical evaluation for the treatment of Parkinson's disease as an adjunct to current L-Dopa/peripheral decarboxylase inhibitor therapy. Chemically pure, well-characterized reference standards of conjugates of **3** were required for investigation of the routes of metabolism in several animal species (including humans) and for pharmacokinetic studies. The lack of suitable literature precedents for efficient, regioselective synthesis of nitrocatechol conjugate metabolites prompted us to develop efficient and highly selective chemical preparations of *O*-glucuronide and *O*-sulfate conjugates of **3** such that multigram quantities of excellent purity can now be conveniently synthesized. It is anticipated that these procedures could be applied to the synthesis of conjugates of other COMT inhibitors, also based on the 3-nitrocatechol pharmacophore.

INTRODUCTION

Catechol-*O*-methyltransferase is a magnesium-dependent enzyme, widely distributed in mammalian tissues, which is now known to play a fundamental role in the inactivation of endogenous catechols (*1*) and detoxification of xenobiotic catechol-based structures (*2*), namely, by catalyzing the transfer of a methyl group from *S*-adenosyl-L-methionine to a hydroxyl group of the catechol (*3*). Potential inhibitors of COMT have aroused great interest from medicinal chemists, based on the premise that COMT inhibition could enhance the bioavailability and thus prolong the therapeutic effect of L-Dopa (3,4-dihydroxy-L-phenylalanine) in patients suffering from Parkinson's disease (*4*), by preventing O-methylation to 3-*O*-methyldopa (3-OMD).

Of the so-called second-generation COMT inhibitors, structures containing the 3-nitrocatechol motif were discovered to be highly potent. Two of these in particular, tolcapone **1** and entacapone **2** (Figure 1), were found to have inhibition constants (K_i) in the low nanomolar range and which were additionally poor substrates for the enzyme (*5*, *6*). **1** is characterized as an equipotent inhibitor of both central and peripheral COMT, while **2** is a purely peripheral inhibitor. Both have entered into clinical practice, although due to liver toxicity concerns **1** was recently withdrawn. It is thought that peripheral COMT inhibitors may be more effective in the treatment of Parkinson's disease, since L-Dopa undergoes its most extensive metabolic breakdown in the periphery. Due, however, to the very short in vivo half-life of **2**, we were encouraged to investigate the possibility of developing a potent and long-acting inhibitor of peripheral COMT, which eventually led to the discovery of BIA 3-202, **3** (*7*).

The metabolic profile and excretion of **1** have been reported (*8*), but no synthetic details of metabolites were given. Conversely, enzyme-assisted synthesis of 3-*O*-glucuronide conjugates of **2** has been described (*9*), this procedure allowing the production of only small milligram quantities of generally average purity. The lack of literature precedent on nitrocatechol metabolism in general and the synthesis of COMT inhibitor metabolites in particular prompted us to develop efficient chemical methodologies for the regioselective synthesis of highly pure, multigram quantities of conjugates of **3** as standards for identification of metabolic products.

1 **2** **3**

Figure 1. Chemical structures of tolcapone (**1**), entacapone (**2**), and BIA 3-202 (**3**).

EXPERIMENTAL PROCEDURES

Chemistry. Melting points were measured in open capillary tubes on an Electrothermal model 9100 hot stage apparatus and are uncorrected. NMR spectra were recorded on a Bruker Avance DPX (400 MHz) spectrometer with solvent used as an internal standard, and data are reported in the following order: chemical shift (parts per million), multiplicity (s, singlet; d, doublet; t, triplet; m, multiplet; and br, broad), number of protons, approximate coupling constant in hertz, and assignment of a signal. IR spectra were recorded with a Bomem Hartmann & Braun MB Series FTIR spectrometer using KBr tablets. Analytical HPLC was performed on a Gilson system equipped with a model 305 pump, a model 117 UV detector, and LiChrospher 100 RP-18 EcoCART 125-3 Cartridges (Merck) in combination with acetonitrile/water mixtures. Reverse-phase preparative HPLC was carried out on an automated Gilson system equipped with

a model 321 pump, a model 155 UV−vis detector, a model 215 liquid handler, and a Waters SymmetryPrep (RP-18, 7 μm) preparative column (19 mm × 150 mm) in combination with acetonitrile/water mixtures. Analytical TLC was performed on precoated silica gel plates (either Merck 60 Kieselgel F_{254} or Merck RP-18 F_{254s}) and visualized with UV light. Preparative chromatography was carried out on Merck 60 Kieselgel (0.063−0.2 mm). Elemental analyses were performed on a Fisons EA 1110 CHNS instrument, and all analyses are consistent with theoretical values to within ±0.4% unless otherwise indicated. Solvents and reagents were purchased from Aldrich, E. Merck, and Fluka.

1-(3-Hydroxy-4-methoxy-5-nitrophenyl)-2-phenylethanone (5). A red suspension of **3** (1.0 g, 3.66 mmol), potassium carbonate (1.77 g, 12.82 mmol), and dimethyl sulfate (1.38 g, 10.98 mmol) in dimethylformamide (DMF, 10 mL) was stirred at 80 °C for 1 h and then allowed to cool to room temperature. The inorganic material was removed by filtration, and the filter cake was washed with DMF (2 mL). The combined filtrate was poured onto water (50 mL) and extracted with ethyl acetate (3 × 30 mL). The combined organic extracts were washed with water (20 mL) and brine (20 mL), then dried over anhydrous sodium sulfate, and filtered. Evaporation (50 °C, water aspirator pressure) afforded a red oil which was chromatographed on silica gel (2:1 petroleum ether/ethyl acetate) to give the major product as an off-white solid. Recrystallization (dichloromethane/heptane) gave the title product as white crystals (0.26 g, 25%): mp 121−123 °C; IR (KBr) 3361 (OH), 1681 (C═O), 1539 cm^{-1} (NO2); ^{1}H NMR (DMSO-d_6) δ 8.10 (d, 1H, J = 2.1 Hz, H-6), 7.82 (d, 1H, J = 2.1 Hz, H-2), 7.4−7.2 (m, 5H, Ph), 6.26 (br, 1H, 3-OH), 4.25 (s, 2H, CH_2), 4.01 (s, 3H, 4-OCH_3); ^{13}C NMR (DMSO-d_6) δ 195.3, 151.3, 145.4, 142.9, 134.0, 132.7, 129.9, 129.5, 127.9, 120.4, 118.1, 63.2, 46.0. Anal. ($C_{15}H_{13}NO_5$) C, H, N.

1-(3,4-Dimethoxy-5-nitrophenyl)-2-phenylethanone (6). A stirred suspension of **3** (0.50 g, 1.83 mmol), potassium carbonate (0.89 g, 6.41 mmol), and dimethyl sulfate (0.69 g, 5.48 mmol) in acetone (10 mL) was heated at reflux for 2 h and then cooled to room temperature. The inorganic material was removed by filtration and, the filter cake was washed with acetone (3 mL). The combined filtrate was evaporated (40 °C, water aspirator pressure) to leave a yellow oil that solidified on standing. Recrystallization (96% ethanol) afforded pale yellow crystals (0.47 g, 86%): mp 81−82 °C; IR (KBr) 1697 (C═O), 1533 cm^{-1} (NO_2); ^{1}H NMR (DMSO-d_6) δ 8.01 (d, 1H, J = 2.1 Hz, H-6), 7.75 (d, 1H, J = 2.1 Hz, H-2), 7.4−7.25 (m, 5H, Ph), 4.28 (s, 2H, CH_2), 4.05 (s, 3H, 4-OCH_3), 3.96 (s, 3H, 3-OCH_3); ^{13}C NMR (DMSO-d_6) δ 195.3, 154.8, 147.4, 144.8, 134.3, 132.1, 129.9, 129.5, 127.8, 117.8, 115.5, 62.7, 57.2, 45.9. Anal. ($C_{16}H_{15}NO_5$) C, H, N.

1-[3-Hydroxy-5-nitro(4-*O*-2,3,4-triacetyl-β-D-glucuronopyranosidophenyl)]-2-phenylethanone Methyl Ester (8). To a stirred suspension of **3** (1.50 g, 5.49 mmol) and 1α-bromo sugar **7** (1.76 g, 4.63 mmol) in acetonitrile (20 mL) at room temperature was added silver(I) oxide (1.53 g, 6.62 mmol) in one portion. The resulting suspension was stirred in the dark for 1 h, and then filtered through a short Celite pad. The filter cake was washed with ethyl acetate (50 mL), and the combined filtrate was washed with water (3 × 50 mL) and brine (50 mL) and then filtered through Celite again. The organic phase was dried over anhydrous sodium sulfate, filtered, and evaporated (40 °C, water aspirator pressure) to leave a dark brown oil. Chromatography over silica gel (1:1 petroleum ether/ethyl acetate) afforded the major product as a pale orange solid that was recrystallized (MeOH) to give beige crystals (1.44 g, 53%): mp 153−155 °C; IR (KBr) 3400 (OH), 1755 (C═O, ester), 1690 (C═O, ketone), 1544 cm^{-1} (NO_2); ^{1}H NMR (DMSO-d_6) δ 11.1 (vbr, 1H, 3-OH), 7.97 (d, 1H, J = 2.1 Hz, H-6), 7.73 (d, 1H, J = 2.1 Hz, H-2), 7.4−7.2 (m, 5H, Ph), 5.54 (d, 1H, J = 7.9 Hz, H-1′), 5.45 (t, 1H, J = 9.6 Hz, H-3′), 5.03 (dd, 1H, J = 7.9 and 9.6 Hz, H-2′), 5.00 (t, 1H, J = 9.7 Hz, H-4′), 4.48 (d, 1H, J = 9.9 Hz, H-5′), 4.38 (s, 2H, CH_2), 3.60 (s, 3H, OCH_3), 2.03 (s, 3H, $COCH_3$), 1.99 (s, 3H, $COCH_3$), 1.97 (s, 3H, $COCH_3$); ^{13}C NMR (DMSO-d_6) δ 196.4, 170.6, 170.3, 170.0, 167.7, 152.1, 146.6, 139.8, 135.6, 134.2, 130.8, 129.4, 127.7, 120.3, 115.6, 100.8, 71.9, 71.8, 71.8, 69.8, 53.5, 45.5, 21.4, 21.3, 21.2. Anal. ($C_{27}H_{27}NO_{14}$·0.5H_2O) C, H, N.

1-(4-*O*-β-D-Glucuronopyranosido-3-hydroxy-5-nitrophenyl)-2-phenylethanone (9). To a cooled (ice bath) and stirred suspension of the glucuronate **8** (1.40 g, 2.38 mmol) in methanol (30 mL) was added dropwise an aqueous 1 N sodium hydroxide solution (24 mL, 24 mmol). The resulting red mixture was stirred in the cold for 30 min and then left at room temperature for 30 min. A small amount of undissolved material was removed by filtration, and the filtrate was added to cold water containing Amberlyst 15 ion-exchange resin so that the pH reached 2. The mixture was filtered and the resin washed with methanol and water (10 mL, 1:1). The filtrate was evaporated (50 °C, water aspirator pressure) and the residue dried over phosphorus pentoxide at high vacuum to give the title product as an amorphous yellow solid (0.99 g, 93%): mp 84−88 °C; IR (KBr) 3386 (broad, OH), 1733 (C═O, acid), 1693 (C═O, ketone), 1541 cm^{-1} (NO_2); ^{1}H NMR (DMSO-d_6) δ 7.94 (d, 1H, J = 2.1 Hz, H-6), 7.73 (d, 1H, J = 2.1 Hz, H-2), 7.4−7.2 (m, 5H, Ph), 5.2 (vbr, 1H, 3-OH), 5.13 (d, 1H, J = 7.5 Hz, H-1′), 4.38 (s, 2H, CH_2), 3.6 (d, 1H, J = 9.7 Hz, H-5′), 3.5−3.15 (m, 3H, H-2′, H-3′, H-4′); ^{13}C NMR (DMSO-d_6) δ 196.3, 170.7, 152.0, 146.7, 140.7, 135.7, 133.4, 130.8, 129.3, 127.6, 120.4, 115.6, 103.8, 77.0, 76.6, 74.5, 72.2, 45.4. Anal. ($C_{20}H_{19}NO_{11}$·1.5H_2O) C, H, N.

1-[4-Hydroxy-5-nitro(3-*O*-2,3,4-triacetyl-β-D-glucuronopyranosidophenyl)]-2-phenylethanone Methyl Ester (11). To a stirred solution of **3** (3.74 g, 13.7 mmol) and trichloroacetimidate **10** (6.9 g, 14.38 mmol) in dichloromethane (130 mL) at room temperature was added dropwise boron trifluoride diethyl etherate (2.91 g, 20.55 mmol). The resulting mixture was stirred for 2 h and then poured onto water (100 mL). A small amount of unreacted **3** precipitated and was removed by filtration. The organic phase was separated and washed with a cold saturated aqueous sodium bicarbonate solution (3 × 100 mL), water (100 mL), and brine (100 mL), then dried over anhydrous sodium sulfate, filtered, and evaporated (40 °C, water aspirator pressure), leaving a yellow foam. Recrystallization (ethyl acetate/petroleum ether) afforded pale yellow crystals (4.50 g, 56%): mp 181−182 °C; IR (KBr) 3437 (OH), 1752 (C═O, ester), 1678 (C═O, ketone), 1549 cm^{-1} (NO_2); ^{1}H NMR (DMSO-d_6) δ 8.34 (d, 1H, J = 2.1 Hz, H-6), 7.82 (d, 1H, J = 2.1 Hz, H-2), 7.35−7.2 (m, 5H, Ph), 5.78 (d, 1H, J = 7.5 Hz, H-1′), 5.45 (t, 1H, J = 9.6 Hz, H-3′), 5.17 (dd, 1H, J = 7.7 and 9.4 Hz, H-2′), 5.11 (t, 1H, J = 9.7 Hz, H-4′), 4.70 (d, 1H, J = 9.9 Hz, H-5′), 4.36 (d, 1H, J = 15.9 Hz, CH_2), 4.28 (d, 1H, J = 15.9 Hz, CH_2), 3.61 (s, 3H, OCH_3), 1.99 (s, 3H, $COCH_3$), 1.98 (s, 3H, $COCH_3$), 1.96 (s, 3H, $COCH_3$); ^{13}C NMR (DMSO-d_6) δ 195.4, 170.6, 170.4, 170.1, 168.2, 151.5, 148.2, 138.5, 136.1, 130.6, 129.4, 127.6, 124.9, 122.5, 120.5, 99.0, 72.1, 72.1, 71.6, 69.7, 53.6, 45.1, 21.5, 21.3, 21.2. Anal. ($C_{27}H_{27}NO_{14}$·H_2O) C, H, N.

1-(3-*O*-*β*-D-Glucuronopyranosido-4-hydroxy-5-nitrophenyl)-2-phenylethanone (12). Hydrolysis of glucuronate **11** (1.40 g, 2.38 mmol) was carried out as described for preparation of **9** above; the product was obtained as an amorphous yellow solid (1.02 g, 96%): mp 118−122 °C; IR (KBr) 3393 (broad, OH), 1734 (C=O, acid), 1686 (C=O, ketone), 1546 cm^{-1} (NO_2); ^1H NMR (DMSO-d_6) δ 11.1 (vbr, 1H, 4-OH), 8.25 (d, 1H, J = 1.9 Hz, H-6), 7.93 (d, 1H, J = 1.9 Hz, H-2), 7.4−7.1 (m, 5H, Ph), 5.20 (d, 1H, J = 7.3 Hz, H-1′), 4.44 (d, 1H, J = 16.0 Hz, CH_2), 4.29 (d, 1H, J = 16.0 Hz, CH_2), 4.04 (d, 1H, J = 9.7 Hz, H-5′), 3.5−3.3 (m, 3H, H-2′, H-3′, H-4′); ^{13}C NMR (DMSO-d_6) δ 195.8, 171.0, 147.7, 147.3, 138.6, 135.8, 130.7, 129.4, 127.6, 127.6, 120.3, 119.5, 102.5, 76.5, 76.0, 73.8, 72.3, 45.3. Anal. ($C_{20}H_{19}NO_{11}$·1.5H_2O) C, H, N.

1,2-Dioxo-1-[3-hydroxy-5-nitro(4-*O*-2,3,4-triacetyl-*β*-D-glucuronopyranosidophenyl)]-2-phenylethane Methyl Ester (14). A stirred suspension of dione **13** (3.43 g, 11.9 mmol) and 1α-bromo sugar **7** (4.73 g, 11.9 mmol) in acetonitrile (70 mL) at room temperature was treated with silver(I) oxide (2.76 g, 11.9 mmol). The resulting suspension was stirred in the dark, and workup as described for the preparation of **8** above afforded the crude product as a brown foam. Chromatography over silica gel (2:1 to 1:1 petroleum ether/ethyl acetate) gave the major product as a yellow oil that was crystallized from dichloromethane/petroleum ether to give yellowish crystals (3.91 g, 54%): mp 117−119 °C; IR (KBr) 3384 (OH), 1756 (C=O, ester), 1678 (C=O, ketone), 1546 cm^{-1} (NO_2); ^1H NMR (DMSO-d_6) δ 11.39 (br, 1H, 3-OH), 7.96 (d, 2H, *o*-Ph), 7.81 (d, 1H, J = 2.1 Hz, H-6), 7.8 (t, 1H, *p*-Ph), 7.71 (d, 1H, J = 2.1 Hz, H-2), 7.64 (t, 2H, *m*-Ph), 5.64 (d, 1H, J = 8.0 Hz, H-1′), 5.46 (t, 1H, J = 9.7 Hz, H-3′), 5.04 (dd, 1H, J = 7.9 and 9.7 Hz, H-2′), 5.00 (t, 1H, J = 9.9 Hz, H-4′), 4.50 (d, 1H, J = 10.1 Hz, H-5′), 3.60 (s, 3H, OCH_3), 2.02 (s, 3H, $COCH_3$), 1.99 (s, 3H, $COCH_3$), 1.98 (s, 3H, $COCH_3$); ^{13}C NMR (DMSO-d_6) δ 194.1, 192.5, 170.6, 170.3, 170.0, 167.7, 152.6, 146.8, 141.3, 136.7, 132.9, 131.0, 130.4, 129.8, 121.3, 116.8, 100.6, 72.0, 71.8, 71.8, 69.8, 53.5, 21.4, 21.3, 21.2. Anal. ($C_{27}H_{25}NO_{15}$) C, H, N.

1,2-Dioxo-1-[4-hydroxy-5-nitro(3-*O*-2,3,4-triacetyl-*β*-D-glucuronopyranosidophenyl)]-2-phenylethane Methyl Ester (15). To a stirred solution of dione **13** (0.50 g, 1.74 mmol) and trichloroacetimidate **10** (1.25 g, 2.61 mmol) in dichloromethane (20 mL) at room temperature was added dropwise boron trifluoride diethyl etherate (0.37 g, 2.61 mmol). The resulting mixture was stirred for 2 h followed by workup as described for **11** above; recrystallization of the crude product from diethyl ether afforded orange crystals (0.56 g, 53%): mp 181−183 °C; IR (KBr) 3437 (OH), 1756 (C=O, ester), 1675 (C=O, ketone), 1555 cm^{-1} (NO_2); ^1H NMR (DMSO-d_6) δ 7.97 (d, 1H, J = 2.1 Hz, H-6), 7.90 (d, 2H, *o*-Ph), 7.77 (t, 1H, *p*-Ph), 7.61 (t, 2H, *m*-Ph), 7.47 (d, 1H, J = 2.1 Hz, H-2), 5.65 (d, 1H, J = 7.9 Hz, H-1′), 5.45 (t, 1H, J = 9.6 Hz, H-3′), 5.09 (dd, 1H, J = 7.7 and 9.6 Hz, H-2′), 5.06 (t, 1H, J = 9.7 Hz, H-4′), 4.62 (d, 1H, J = 9.7 Hz, H-5′), 3.62 (s, 3H, OCH_3), 2.01 (s, 3H, $COCH_3$), 2.00 (s, 3H, $COCH_3$), 1.99 (s, 3H, $COCH_3$); ^{13}C NMR (DMSO-d_6) δ 196.0, 191.3, 170.5, 170.4, 170.2, 168.3, 138.6, 136.1, 133.9, 130.5, 130.4, 127.9, 118.4, 99.0, 72.1, 72.0, 71.8, 69.9, 53.6, 21.5, 21.4, 21.3. Anal. ($C_{27}H_{25}NO_{15}$·3H_2O) C, H, N.

1-(5-Amino-3,4-dihydroxyphenyl)-2-phenylethanone (16). To a stirred, yellow suspension of **3** (5.0 g, 18.3 mmol) in methanol (100 mL) at room temperature was added 10% palladium on charcoal (0.30 g). Hydrogen gas was bubbled through the mixture for 2 h, leading to formation of a new, gray precipitate. Dimethylformamide (40 mL) was added, and the catalyst was removed by filtration through Celite. The filtrate was evaporated (50 °C, water aspirator pressure) and the residue crystallized from dichloromethane/diethyl ether to give beige crystals (4.07 g, 91%): mp 234−237 °C; IR (KBr) 3364 (OH), 3290 (NH_2), 1669 (C=O, ketone), 1540 cm^{-1} (NO_2); ^1H NMR (DMSO-d_6) δ 9.2 (vbr, 2H, 3-OH, 4-OH), 7.4−7.1 (m, 5H, Ph), 6.94 (d, 1H, J = 2.1 Hz, H-2), 6.84 (d, 1H, J = 2.1 Hz, H-6), 4.8 (vbr, 2H, NH_2), 4.12 (s, 2H, CH_2); ^{13}C NMR (DMSO-d_6) δ 197.2, 145.5, 138.2, 137.9, 136.9, 130.5, 129.2, 128.7, 127.3, 108.4, 106.4, 45.2. Anal. ($C_{14}H_{13}NO_3$) C, H, N.

1-[5-(*N*-Acetylamino)-3,4-dihydroxyphenyl]-2-phenylethanone (17). A stirred suspension of **16** (1.95 g, 8 mmol) in dichloromethane (20 mL) was treated with pyridine (1.90 g, 24 mmol), acetic anhydride (2.44 g, 24 mmol), and 4-(dimethylamino)pyridine (DMAP, 0.01 g). The mildly exothermic reaction subsided after 15 min, and the reaction mixture was washed with cold 2 N HCl (100 mL) and brine (50 mL), then dried over anhydrous sodium sulfate, filtered, and evaporated (40 °C, water aspirator pressure), leaving a beige solid which was recrystallized from dichloromethane/petroleum ether to give off-white crystals (2.40 g, 81%).

This product (2.35 g, 6.36 mmol) was suspended in methanol (35 mL) and cooled in an ice−water bath. An aqueous 1 N sodium hydroxide solution (13 mL, 13 mmol) was added dropwise, and the resulting brown solution was stirred for 30 min and then poured onto ice and 2 N HCl (150 mL). The mixture was extracted with dichloromethane (2 × 150 mL), and the extracts were washed with brine (100 mL), dried over anhydrous sodium sulfate, filtered, and evaporated (40 °C, water aspirator pressure), leaving a beige solid which was recrystallized from petroleum ether/ethyl acetate to give off-white crystals (1.20 g, 66%): mp 150−153 °C; IR (KBr) 3445 (OH), 3322 (NH), 1690 (C=O, acetyl), 1640 (C=O, ketone), 1542 cm^{-1} (NO_2); ^1H NMR ($CDCl_3$) δ 10.95 (br, 1H, 4-OH), 9.16 (br, 1H, NH), 7.55 (d, 1H, J = 2.1 Hz, H-6), 7.49 (d, 1H, J = 2.1 Hz, H-2), 7.4−7.1 (m, 5H, Ph), 6.36 (br, 1H, 3-OH), 4.24 (s, 2H, CH_2), 1.95 (s, 3H, $COCH_3$); ^{13}C NMR ($CDCl_3$) δ 198.8, 172.8, 147.8, 142.1, 134.9, 130.2, 129.3, 129.0, 127.7, 126.7, 115.0, 113.0, 45.8, 23.5. Anal. ($C_{16}H_{15}NO_4$·0.3H_2O) C, H, N.

1-[5-Amino-3-hydroxy(4-*O*-2,3,4-triacetyl-*β*-D-glucuronopyranosidophenyl)]-2-phenylethanone Methyl Ester (20). A stirred semisolution of **8** (0.81 g, 1.38 mmol) in methanol (50 mL) at room temperature was treated with 10% palladium on charcoal (0.25 g), and hydrogen gas was bubbled through the mixture for 1 h. The catalyst was removed by filtration through Celite, and the filtrate was concentrated (40 °C, water aspirator pressure). Chromatography of the residue on silica gel allowed separation of two products. The faster-running component was obtained after recrystallization from dichloromethane/diisopropyl ether as beige crystals (0.5 g, 65%), subsequently identified as the title product: mp 155−157 °C; IR (KBr) 3450 (OH), 3384 (NH_2), 1755 (C=O, ester), 1673 cm^{-1} (C=O, ketone); ^1H NMR (DMSO-d_6) δ 9.63 (br, 1H, 3-OH), 7.35−7.15 (m, 5H, Ph), 6.92 (d, 1H, J = 2.1 Hz, H-6), 6.78 (d, 1H, J = 2.1 Hz, H-2), 5.47 (t, 1H, J = 9.7 Hz, H-3′), 5.26 (d, 1H, J = 7.9 Hz, H-1′), 5.12 (dd, 1H, J = 7.9 and 9.7 Hz, H-2′), 5.02 (m, 1H, H-4′), 4.55 (d, 1H, J = 9.9 Hz, H-5′), 4.17 (s, 2H, CH_2), 3.62 (s, 3H, OCH_3), 2.02 (s, 3H, $COCH_3$), 2.00 (s, 3H, $COCH_3$), 1.99 (s, 3H, $COCH_3$); ^{13}C NMR (DMSO-d_6) δ 197.9, 170.5, 170.4, 170.2, 168.3, 151.0, 144.0, 136.3, 135.6, 134.3,

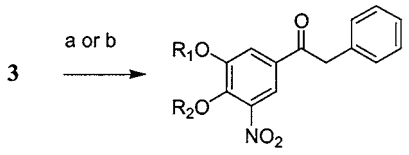
130.6, 129.3, 127.4, 108.2, 105.5, 102.1, 72.0, 71.8, 71.6, 70.0, 53.6, 45.5, 21.6, 21.4, 21.3. Anal. ($C_{27}H_{29}NO_{12}$) C, H, N.

The slower-running component obtained from the column was recrystallized from dichloromethane/petroleum ether to give white crystals (0.15 g, 19%), subsequently identified as 1-[5-amino-3-hydroxy(4-*O*-2,3,4-triacetyl-*β*-D-glucuronopyranosidophenyl)]-1-hydroxy-2-phenylethane methyl ester (**21**): mp 172−174 °C; IR (KBr) 3450 (OH), 3411 (NH_2), 1754 cm^{-1} (C═O, ester); ^1H NMR ($CDCl_3$) δ 7.4−7.15 (m, 5H, Ph), 6.6 (vbr, 1H, 3-OH), 6.43, 6.40 (d, 1H, J = 2.1 Hz, H-2), 6.34, 6.32 (d, 1H, J = 2.1 Hz, H-2), 5.3 (m, 3H, H-2′, H-3′, H-4′), 4.88 (m, 1H, H-1′), 4.69 (m, 1H, C*H*OH), 4.07 (m, 1H, H-5′), 3.9 (vbr, 2H, NH_2), 3.78 (s, 3H, OCH_3), 2.99 (dd, 1H, J = 4.1 and 13.8 Hz, CH_2), 2.90 (dd, 1H, J = 8.9 and 13.8 Hz, CH_2), 2.14 (s, 3H, $COCH_3$), 2.11 (s, 3H, $COCH_3$), 2.06 (s, 3H, $COCH_3$); ^{13}C NMR ($CDCl_3$) δ 170.7, 170.0, 169.7, 167.1, 150.2, 150.1, 143.6, 140.7, 140.6, 138.8, 138.7, 131.4, 131.4, 130.0, 129.1, 127.2, 106.0, 105.9, 105.1, 105.0, 102.7, 75.5, 75.4, 72.7, 72.5, 72.0, 69.3, 53.8, 46.3, 21.3, 21.2, 21.0. Anal. ($C_{27}H_{31}NO_{12}$·1.5H_2O) C, H, N.

1-(5-Amino-4-*O*-*β*-d-glucuronopyranosido-4-hydroxyphenyl)-2-phenylethanone (18). A stirred semisolution of **20** (0.34 g, 0.6 mmol) in methanol (5 mL) was treated dropwise with an aqueous 1 N sodium hydroxide solution (6 mL, 6 mmol) at room temperature. The resulting orange solution was stirred for 2 h and then cooled in an ice−water bath. Acetic acid was added until the pH reached 4, and the solvents were evaporated (60 °C, water aspirator pressure). The residue was purified by reverse-phase preparative HPLC as described above using acetonitrile/water (2:8) as the eluent. Inorganic salt-rich initial fractions were discarded. Homogeneous fractions were combined and evaporated (60 °C, water aspirator pressure) and then dried over phosphorus pentoxide at high vacuum to give the title product as a beige solid (0.2 g, 79%): mp 120−121 °C; IR (KBr) 3431 (broad, OH), 3290 (NH_2), 1682 (C═O, acid), 1640 cm^{-1} (C═O, ketone); ^1H NMR (DMSO-d_6) δ 7.4−7.15 (m, 5H, Ph), 6.88 (d, 1H, J = 2.1 Hz, H-6), 6.78 (d, 1H, J = 2.1 Hz, H-2), 4.52 (d, 1H, J = 8.0 Hz, H-1′), 4.19 (s, 2H, CH_2), 3.64 (d, 1H, J = 9.4 Hz, H-5′), 3.5−3.2 (m, 3H, H-2′, H-3′, H-4′); ^{13}C NMR (DMSO-d_6) δ 198.1, 173.1, 150.9, 143.6, 136.7, 136.5, 134.6, 130.6, 129.3, 127.4, 107.5, 106.6, 106.0, 76.6, 75.9, 74.4, 72.6, 45.5. Anal. ($C_{20}H_{21}NO_9$·1.6H_2O) C, H, N.

1-[5-Amino-4-hydroxy(3-*O*-2,3,4-triacetyl-*β*-D-glucuronopyranosidophenyl)]-2-phenylethanone Methyl Ester (22). To a stirred suspension of **11** (1.10 g, 1.87 mmol) in methanol (50 mL) at room temperature was added 10% palladium on charcoal (0.28 g). Hydrogen gas was bubbled through the reaction mixture for 30 min, and then the catalyst was removed by filtration through Celite. The filtrate was concentrated (40 °C, water aspirator pressure) to leave a foam which was recrystallized from diisopropyl ether to give white crystals (1.01 g, 97%): mp 93−94 °C; IR (KBr) 3445 (broad, OH), 3290 (NH_2), 1755 (C═O, ester), 1670 cm^{-1} (C═O, ketone); ^1H NMR (DMSO-d_6) δ 7.35−7.15 (m, 5H, Ph), 7.14 (d, 1H, J = 2.1 Hz, H-6), 7.11 (d, 1H, J = 2.1 Hz, H-2), 5.70 (d, 1H, J = 7.9 Hz, H-1′), 5.47 (t, 1H, J = 9.6 Hz, H-3′), 5.15 (dd, 1H, J = 7.6 and 9.6 Hz, H-2′), 5.08 (t, 1H, J = 9.6 Hz, H-4′), 4.71 (d, 1H, J = 9.9 Hz, H-5′), 4.20 (d, 1H, J = 14.9 Hz, CH_2), 4.12 (d, 1H, J = 14.9 Hz, CH_2), 3.63 (s, 3H, OCH_3), 2.02 (s, 3H, $COCH_3$), 1.99 (s, 3H, $COCH_3$), 1.95 (s, 3H, $COCH_3$); ^{13}C NMR (DMSO-d_6) δ 197.0, 170.6, 170.4, 170.0, 168.2, 145.0, 139.9, 139.2, 136.7, 130.5, 129.3, 128.6, 127.4, 110.9, 107.0, 99.0, 72.5, 72.0, 71.9, 69.9, 53.6, 45.2, 21.5, 21.4, 21.2. Anal. ($C_{27}H_{29}NO_{12}$) C, H, N.

1-(5-Amino-3-*O*-<bold>d</bold>>*β*-D-glucuronopyranosido-3-hydroxyphenyl)-2-phenylethanone (19). A cooled (ice−water bath) and stirred solution of **22** (0.78 g, 1.39 mmol) in methanol (14 mL) at room temperature was treated dropwise with an aqueous 1 N sodium hydroxide solution (14 mL, 14 mmol). After the mixture had been stirred in the cold for 30 min, acidification, workup, and purification as described for **18** above afforded light brown crystals (0.5 g, 86%): mp 158−163 °C; IR (KBr) 3445 (broad, OH), 3290 (NH_2), 1706 (C═O, acid), 1640 cm^{-1} (C═O, ketone); ^1H NMR (DMSO-d_6) δ 7.3−7.1 (m, 6H, Ph, H-2), 7.04 (d, 1H, J = 2.1 Hz, H-6), 4.49 (d, 1H, J = 7.2 Hz, H-1′), 4.10 (d, 1H, J = 14.9 Hz, CH_2), 4.08 (d, 1H, J = 14.9 Hz, CH_2), 3.38 (d, 1H, J = 9.2 Hz, H-5′), 3.3−3.1 (m, 3H, H-2′, H-3′, H-4′); ^{13}C NMR (DMSO-d_6) δ 196.3, 173.8, 146.5, 145.8, 139.3, 137.2, 130.5, 129.9, 129.2, 127.2, 111.9, 110.3, 105.8, 77.0, 75.0, 74.2, 73.0, 45.1. Anal. ($C_{20}H_{21}NO_9$·1.5H_2O) C, H, N.



1-(3,4-Dihydroxy-5-nitrophenyl)-2-phenylethanone, 3-*O*-Pyridinium Sulfate (23). A stirred solution of **3** (3.0 g, 10.99 mmol) in pyridine (50 mL) at room temperature was treated with the sulfur trioxide−pyridine complex (5.24 g, 32.96 mmol) in portions. The resulting mixture was left stirring for 4 h and then poured slowly onto ice and 2 N HCl (300 mL). After the mixture had been stirred for 30 min, the pale yellow precipitate was filtered off and washed with water (50 mL). Recrystallization (methanol) afforded pale yellow crystals (4.32 g, 91%): mp 143−146 °C; IR (KBr) 3423 (OH), 1688 (C═O), 1550 cm^{-1} (NO_2); ^1H NMR (DMSO-d_6) δ 8.92 (d, 2H, *o*-Pyr), 8.58 (t, 1H, *p*-Pyr), 8.31 (d, 1H, J = 2.2 Hz, H-6), 8.25 (d, 1H, J = 2.2 Hz, H-2), 8.05 (t, 2H, *m*-Pyr), 7.35−7.15 (m, 5H, Ph), 4.35 (s, 2H, CH_2); ^{13}C NMR (DMSO-d_6) δ 195.9, 149.1, 146.8, 144.4, 143.7, 139.0, 135.9, 130.8, 129.3, 128.1, 127.6, 127.3, 125.5, 121.4, 45.2. Anal. ($C_{14}H_{10}NO_8S$·C_5H_6N) C, H, N, S.

1-(5-Amino-3,4-dihydroxyphenyl)-2-phenylethanone, 3-*O*-Pyridinium Sulfate (24). A stirred semisolution of **23** (2.0 g, 4.63 mmol) in methanol (100 mL) at room temperature was treated with 5% palladium on charcoal (0.2 g). Hydrogen gas was passed through the mixture for 3 h, and then the catalyst was removed by filtration through Celite. The filtrate was concentrated (40 °C, water aspirator pressure) to leave a slightly hygroscopic brownish solid (1.78 g, 79%): mp 68−71 °C; IR (KBr) 3423 (OH), 3230 (NH_2), 1671 (C═O), 1550 cm^{-1} (NO_2); ^1H NMR (DMSO-d_6) δ 8.82 (d, 2H, *o*-Pyr), 8.34 (t, 1H, *p*-Pyr), 7.85 (t, 2H, *m*-Pyr), 7.67 (d, 1H, J = 2.1 Hz, H-6), 7.50 (d, 1H, J = 2.1 Hz, H-2), 7.35−7.15 (m, 5H, Ph), 4.21 (s, 2H, CH_2); ^{13}C NMR (DMSO-d_6) δ 196.5, 145.6, 145.5, 144.0, 142.0, 136.3, 130.7, 129.4, 129.3, 128.5, 127.5, 127.2, 118.8, 116.3, 45.3. Anal. ($C_{14}H_{12}NO_6S$·C_5H_6N·H_2O) C, H, N, S.

RESULTS AND DISCUSSION

The major metabolic pathways after oral administration of **3** in several animal species were expected to give rise to three main classes of products: O-methylated catechols and several glucuronide and sulfate conjugates (this work will be published elsewhere). We recently disclosed an efficient synthesis of **3** from commercially available vanillin (*7*) and have developed an improved method (*10*) for the demethylation of the 3-O-methylated derivative **4** (the precursor of **3**). The corresponding 4-*O*-methyl isomer **5** was obtained by regioselective monom-

[a] Reagents: (a) $(CH_3O)_2SO_2$, K_2CO_3, DMF, 80 °C (25%); (b) $(CH_3O)_2SO_2$, K_2CO_3, $(CH_3)_2CO$, Δ (86%). [b]See ref *10*.

ethylation of **3** using potassium carbonate and dimethyl sulfate in warm DMF. Dimethylation to give **6** proceeded without incident in acetone (Scheme 1).

A variety of methods exist for the preparation of glucuronide conjugates of phenolic compounds and have been reviewed (*11*). Often, traditional methods are low-yielding, giving rise to byproducts and/or mixtures of α- and *β*-anomers. Furthermore, regiospecific glucuronidation of substituted catechols has not thus far been reported. In agreement with the 4-O-regioselectivity of methylation above, we found that Koenigs−Knorr coupling of the 1α-bromo sugar **7** with **3** using silver oxide in acetonitrile gave the protected 4-*O*-*β*-glucuronate **8** in acceptable yield (53%, Scheme 2). The ^{1}H NMR spectrum confirmed that only the *β*-anomer was formed, as seen from the coupling constant (J = 7.5 Hz) of the anomeric proton. Hydrolysis of the acetyl protecting groups was achieved using aqueous 1 N sodium hydroxide in methanol. Acidic workup (Amberlyst 15 ion-exchange resin) and evaporation of the solvents afforded the 4-*O*-*β*-glucuronide **9** in good yield (93%) and purity (HPLC, >99%).

An alternative method for enzymatic glucuronidation for direct preparation of the regioisomeric 3-*O*-*β*-glucuronide **10** from **3** was required. This could not be achieved using **7** with heavy metal catalysts (Ag, Cd, and Hg salts). Model studies showed, however, that acetylation of **3**, rather than alkylation, led to exclusive formation of the 3-O-acylated derivative. Further encouraged by a report that the trichloroacetimidate **10** reacts with 4-nitrophenol to afford the corresponding *β*-conjugate in high yield (*12*), we were delighted to discover that reaction of **3** with **10** in the presence of excess boron trifluoride (*13*) afforded exclusively the protected methyl 3-*O*-glucuronate **11** (*β*-anomer only) in reasonable (56%) yield (Scheme 3). The unusually large excess of boron trifluoride (1.5 equiv) was necessary as the reaction proceeded poorly with only catalytic quantities normally utilized in glucuronide synthesis by this procedure, although a similar observation with an unrelated steroidal aglycone has been reported (*14*). The subsequent basic hydrolysis of **11** gave the free glucuronide **12**, again in good yield and excellent chemical purity (HPLC analysis).

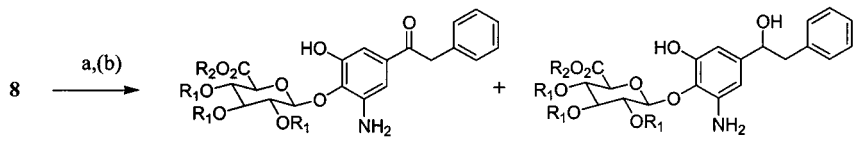
bond (HMQC) and long-range (HMBC) gradient-selected correlation experiments. The HMQC sequence was first employed to determine the direct H−C correlations and to assign the proton-containing carbons. The HMBC technique was then performed to establish the long-range H−C correlations of the quaternary aromatic carbons. COSY and NOESY experiments were also performed and confirmed these assignments.

The strategy for the ^{1}H and ^{13}C signal assignment of these compounds was as follows. For **9** and **12** (Figure 2), both H-2 and H-6 exhibited HMBC three-bond connectivities with the quaternary carbon C-4 and also with C-6 and C-2, respectively. H-2 exhibited for both compounds an HMBC two-bond correlation with C-3 and H-6 an HMBC two-bond correlation with C-5. These results allowed complete ring assignments, which were strictly required to establish the position (3- or 4-*O*-) of the glucuronide substituent.



For compound **12**, H-1′ (δ 5.2) exhibited an HMBC connectivity with C-3 (δ 147.7), confirming the glucuronide substituent on the 3-O-position. For regioisomer **9**, the corresponding connectivity is also seen and there is a further HMBC correlation between the 3-hydroxyl (δ 10.8) and C-4 (δ 140.7) that confirms the glucuronide substituent at the 4-O-position.

The Koenigs−Knorr and Schmidt trichloroacetimidate methods are therefore complementary in that either the 3- or 4-*O*-β-glucuronides of **3** may be preferentially prepared. That this chemistry can be applied to other 3-nitrocatechols can be seen from the same reactions applied to the dione **13**, which gave either the 4-O-β-glucuronide precursor **14** (Koenigs−Knorr) or 3-*O*-β-glucuronide precursor **15** (Schmidt) (Schemes 2 and 3).

Reduction of the nitro moiety is a common metabolic pathway for aromatic nitro compounds (and for **1**), and several potential amino conjugates of **3** were envisaged. **3** was subjected to catalytic hydrogenation at room temperature and atmospheric pressure (Pd/C, H_2, MeOH), undergoing rapid reduction to amino analogue **16** (Scheme 4). Exhaustive acetylation of **16** followed by careful alkaline hydrolysis of the *O*-acetyl residues gave *N*-acetyl derivative **17**. Catalytic hydrogenation (Pd/C, H_2, MeOH) of nitro 4-*O*-β- and 3-*O*-β-glucuronides **9** and **12**, respectively, afforded the corresponding amino 4-*O*-β- and 3-*O*-β-glucuronides **18** and **19**, respectively, as rather impure (80−90%) amorphous solids. Reverse-phase chromatography failed to considerably improve the purity of each. Surprisingly, catalytic hydrogen transfer using cyclohexene, formic acid, or ammonium formate as a hydrogen donor failed to return any **18** or **19**. The suspicion that the major impurity arose from concomitant reduction of the carbonyl group was confirmed on hydrogenation of **8** under the same conditions, which gave on first attempt a separable 2:1 mixture of ketone **20** and alcohol **21**. Careful monitoring of the reaction and a significant reduction in the reaction time (from 6 to 1 h), however, allowed isolation of **20** in 65% yield (Scheme 5). Basic hydrolysis and acidification with acetic acid to pH 4 followed by preparative reverse-phase HPLC to remove inorganic salts gave **18** in good yield and purity (>99%, HPLC). Nitroglucuronate **11** easily underwent hydrogenation to give **22** exclusively (97%), and subsequent basic hydrolysis gave origin to amino-3-*O*-β-glucuronide **19** (>99% purity) under the same conditions previously mentioned (Scheme 6).

Sulfate conjugation catalyzed by sulfotransferase is also a metabolic pathway for phenolic and catecholic substrates in mammals; unsurprisingly, therefore, two sulfate conjugates, of both **3** and amine **16**, were detected. Synthesis of these sulfates proved to be somewhat more complicated than glucuronidation, due to the high lability of the sulfate moiety. Sulfation of **3** with the sulfur trioxide−DMF complex occurred rapidly in a DMF solution, giving a single product (as monitored by HPLC) which, on attempted isolation, reverted back to **3**. The product was, however, stable in solution at room tem-

[a] Reagents: (a) SO_3−pyridine complex, pyridine (91%); (b) 5% Pd/C, CH_3OH, H_2 (79%).

perature. Reaction of **3** with the pyridine−sulfur trioxide complex also gave a single product, which precipitated during the workup (Scheme 7). This was perfectly stable and could be readily isolated and recrystallized (>99% purity). ^1H and ^{13}C NMR showed that the product was exclusively the 3-*O*-pyridinium sulfate **23**; compared to that of **3**, the aromatic proton on C-2 (δ 8.25) of **23** was deshielded by the 3-sulfate ester ($\Delta\delta$ = 0.55 ppm). The ^{13}C spectrum also exhibits a significant deshielding effect on the ortho and para carbon atoms. C-2 has a carbon shift $\Delta\delta$ of 7.3 ppm, C-6 4.0 ppm, and C-4 2.5 ppm. Similar behavior has been reported with dopamine and its 3-*O*- and 4-*O*-sulfates (*15*).

Reduction of the nitro group under catalytic hydrogenation conditions afforded the corresponding hygroscopic amino-3-*O*-sulfate **24** in reasonable yield (78%) and good purity (>98%).

CONCLUSIONS

Efficient chemical methods suitable for the regioselective gram-scale synthesis of highly pure putative *O*-methyl, *O*-glucuronide, and *O*-sulfate metabolic conjugates of BIA 3-202, 1-(3,4-dihydroxy-5-nitrophenyl)-2-phenylethanone **3**, have been developed. These compounds are currently used as standards for the determination of the metabolic profile of **3** in various species, including humans. It is foreseen that these procedures will be useful for the synthesis of conjugates of other COMT inhibitors based on the nitrocatechol pharmacophore.

Development of Annexin V Mutants Suitable for Labeling with Tc(I)-Carbonyl Complex

Jonathan F. Tait,*[,†,‡] Christina Smith,[†] and Donald F. Gibson[†]

Departments of Laboratory Medicine, Medicine (Medical Genetics), and Pathology, University of Washington, Seattle, Washington 98195-7110 . Received May 1, 2002; Revised Manuscript Received July 16, 2002

^{99m}Tc-annexin V can be used to image organs undergoing cell death during cancer chemotherapy and organ transplant rejection. We investigated whether the novel Tc-carbonyl labeling method would be suitable for annexin V. Two mutant molecules of annexin V, called annexin V-122 and annexin V-123, were constructed with N-terminal extensions containing either three or six histidine residues. These molecules were expressed cytoplasmically in *E. coli* and purified with a final yield of 33 mg of protein/L of culture. Analysis by SDS−PAGE, isoelectric focusing, gel filtration chromatography, and mass spectrometry confirmed the purity and homogeneity of the protein preparations. Both mutant proteins retained full binding affinity for cell membranes with exposed phosphatidylserine. Using the Tc-carbonyl reagent, both proteins could be labeled with ^{99m}Tc to specific activities of at least 10−20 μCi/μg with full retention of bioactivity. The radiolabeled proteins were stable when incubated with phosphate-buffered saline or serum in vitro, and there was no transchelation of label to serum proteins during in vitro incubation. In conclusion, annexin V can be modified near its N-terminus to incorporate sequences that form specific chelation sites for ^{99m}Tc-carbonyl without altering its high affinity for cell membranes.

INTRODUCTION

The phospholipid binding protein annexin V can be used to detect the exposure of PS[1] at the extracellular face of the plasma membrane (*1*). Alterations in PS exposure occur in both blood coagulation and apoptosis (*2*, *3*). We have developed annexin V as a means to detect PS exposure in vivo. Annexin V labeled with radioiodine and ^{99m}Tc was used to detect thrombus formation in experimental animals (*4*, *5*). ^{99m}Tc-annexin V was used to detect cell death in vivo in animal models (*6*−*10*). Because of the clinical applicability of this work in monitoring cancer chemotherapy, rejection of transplanted organs (*11*), and mycoardial infarction (*12*), there is interest in developing new annexin V derivatives with improved imaging properties or greater ease of use in the clinical setting.

There have been several methods developed so far for labeling annexin V with technetium. The N_2S_2 preformed chelate method (*13*) was used in the earliest studies (*5*). More recently, annexin V was chemically derivatized with HYNIC (*6*, *7*) or iminomercaptobutylate (*12*). Most recently, we developed novel forms of annexin V that contain genetically engineered sequences that can directly chelate technetium in the +V oxidation state without need for any chemical derivatization with exogenous chelation groups (*14*). Although all these technetium-labeled forms of annexin have certain benefits and uses, none is ideal, and there is still a need to explore additional ways of radiolabeling the protein to provide derivatives with high specific activity and radiostability.

A novel reagent was recently developed for Tc labeling of biomolecules. Alberto et al. (*15*) developed a convenient aqueous synthesis of $[^{99m}Tc(OH_2)_3(CO)_3]^+$ (abbreviated TcCO). Egli et al. (*16*) used this reagent to label peptides to high specific activities, and they showed that among the amino acids histidine formed complexes of highest stability with TcCO. Waibel et al. (*17*) used TcCO to label a recombinant single-chain Fv antibody containing five histidine residues at the C-terminus; this derivative showed high radiochemical stability in vitro and in vivo. Other groups have recently applied this method to label the peptides somatostatin (*18*) and bitistatin (*19*).

In view of the potential advantages of this radiolabeling method, we investigated whether it would be suitable for labeling annexin V. Since histidine is the amino acid likely to form complexes of highest stability with TcCO, and trivalent complexes are the most stable (*20*), we added peptide sequences containing either three or six histidines to annexin V. Although the C-terminal carboxyl group may help to stabilize histidine−TcCO complexes (*17*), we chose to add the histidine residues to the N-terminus of annexin V because alterations in this region are much less likely to affect either membrane binding affinity or protein folding in *E. coli* (*14, 21, 22*). We show that these novel derivatives can be produced in high yield and purity by expression in *E. coli*, and they can be readily labeled with TcCO.

MATERIALS AND METHODS

Materials. Recombinant annexin V was produced in *E. coli* as described (*23*). Fluorescein-annexin V was

prepared as described (*24*). Lyophilized carbonyl reaction mixture was a gift from Mallinckrodt (St. Louis, MO). Erythrocytes with exposed PS (4CPlus Normal Control, part number 7546923) were from Beckman-Coulter (Miami, FL).

Construction and Verification of Plasmids. Two plasmids were constructed to express mutant forms of human annexin V in *E. coli* under control of the phage T7 promoter. Plasmid pJ122 was constructed with oligonucleotides JT-319 (5′-ATGGCCCATCATCATGCACAGGTTCTCAGA-3′) and JT-321 (5′-TTAGTCATCTTCTCCACAGAGCAGCAG-3′); plasmid pJ123 with JT-320 (5′-ATGGCCCATCATCATCATCATCACGCACAGGTTCTCAGA-3′) and JT-321. These oligonucleotides were designed to amplify the entire protein-coding region of wild-type annexin V and add the desired coding sequences to the 5′ end of the gene. PCR of the template pET9a-PAP1, which encodes wild-type annexin V (*25*), was performed with proofreading *Pfu* DNA polymerase (Stratagene) and with annealing steps first at 45 °C for 15 cycles and next at 65 °C for 15 cycles. PCR products were purified by phenol/chloroform extraction and ethanol precipitation; the purified PCR products were amplified again for three cycles with the same primer sets with annealing steps at 65 °C using *Taq* DNA polymerase to add the 3′-dA nucleotide overhangs necessary for ligation. The PCR product was ligated into pETBlue-1 Acceptor Vector (Novagen, Madison, WI), and the ligation mixture was transformed into *E. coli* strain Nova Blue (Novagen) and plated on LB agar containing 50 μg/mL carbenicillin, 70 μg/mL X-gal, and 80 μM IPTG. Plasmid DNA was prepared from white, carbenicillin-resistant colonies and screened by restriction mapping for the presence of the desired insert. Positive clones were subjected to DNA sequence analysis with the Big-Dye kit (Perkin-Elmer) to verify the presence of the desired insertion and the absence of other adventitious mutations.

Expression and Purification of Proteins. Plasmids pJ122 and pJ123 were each transformed into *E. coli* strain Tuner(DE3)pLac I (Novagen) for cytoplasmic expression. Each clone was grown overnight to saturation at 37 °C with shaking in Terrific Broth containing carbenicillin (50 μg/mL). The cells were separated from culture medium by centrifugation for 10 min at 2560*g* and washed in ice-cold buffer (50 mmol/L Tris-HCl, 150 mmol/L NaCl, pH 8.0). Bacteria were disrupted by sonication in ice-cold 50 mmol/L Tris-HCl, pH 7.2, 10 mmol/L $CaCl_2$ and then centrifuged for 20 min at 22530*g* in a Sorvall SS-34 rotor. The supernatant was discarded, and the annexin V bound to bacterial membranes was released by resuspending the pellet in 50 mmol/L Tris-HCl, pH 7.2, 20 mmol/L EDTA. Bacterial membranes were removed by centrifugation for 20 min at 22530*g*; the supernatant containing the annexin V was treated with 10 units/mL Benzonase (Novagen) plus 25 mM $MgCl_2$ for 1 h on ice, to digest DNA and RNA. After centrifugation for 20 min at 4800*g*, the supernatant was filtered with a 0.45 μm filter and then dialyzed against 20 mmol/L Tris-HCl, pH 8.0, at 4 °C.

The dialysand of annexin V-122 was further dialyzed against 20 mmol/L sodium acetate, pH 5.2, filtered through a 0.2 μm filter, applied to a Mono S HR 10/10 column (Pharmacia, Piscataway, NJ), and eluted with a gradient of 0−1 mol/L NaCl in the same buffer. The annexin V-122 eluted at approximately 0.170 mol/L NaCl. The dialysand of annexin V-123 was dialyzed against 20 mmol/L HEPES-Na, pH 7.0, filtered with a 0.2 μm filter, loaded onto a Mono Q HR 10/10 column (Pharmacia), and eluted with 0−1 mol/L NaCl in the same buffer. Annexin V-123 eluted at 0.170 mol/L NaCl. Each purified protein was dialyzed against 20 mmol/L HEPES, pH 7.4, 100 mmol/L NaCl, and stored in aliquots at −70 °C. The final yield of each protein was approximately 33 mg/L of bacterial culture (or 3.3 mg/g wet weight of cell paste), with a purity of ∼98% as judged by SDS−PAGE. Electrophoresis using 10−15% gradient SDS−PAGE and IEF 4−6.5 gels was performed on a PHAST System (Amersham-Pharmacia). Electrospray mass spectrometry was performed on a Micromass Quattro II tandem quadrupole mass spectrometer (Micromass Ltd., Manchester, U.K.) in the Mass Spectrometry Center (Department of Medicinal Chemistry, University of Washington).

Labeling of Proteins with ^{99m}Tc. The ^{99m}TcCO was made by adding 1 mL of TcO_4 (usually 1−10 mCi) in 0.9% deoxygenated NaCl to a 10 mL vial of lyophilized carbonyl reaction mixture (13 mg of L-tartaric acid; 7.6 mg of KBH_4; 20 mg of lactose; borate buffer, pH 11.6; carbon monoxide in headspace). The vial was incubated for 15 min in a boiling water bath, cooled to room temperature, vented with a syringe needle, and neutralized with 0.25 mL of 1 N HCl. Except where noted otherwise, labeling reactions were set up with 100 μL (100 μg) of annexin V-122 or annexin V-123 in 20 mM HEPES-Na, pH 7.4, 100 mM NaCl; 25 μL of 0.5 M HEPES-Na, pH 7.4; 125 μL of ^{99m}TcCO in 0.9% saline and incubated at 37 °C for 1 h. Percent incorporation of ^{99m}Tc was determined by ITLC on oven-dried silica gel plates with PBS as solvent. Radiolabeled proteins were purified by applying the reaction mixture (diluted to 400 μL with PBS) to a Sephadex G-25 column (0.9 × 2.8 cm) previously equilibrated with PBS and eluting the column with 1000 μL of PBS; radiolabeled protein eluted in the last 600 μL. Percent protein-bound radioactivity after gel filtration was determined by ITLC as above. For studies of radiolabel stability in serum, percent protein-bound radioactivity was determined by centrifugal ultrafiltration (3 min at 1860*g*) through a membrane with a 10 000 dalton cutoff (Centricon-10 filter, Amicon, Danvers, MA). Radiolabel stability was also assessed by gel filtration on a Superose-12 column (1 × 30 cm). The column was equilibrated with PBS and eluted at a flow rate of 0.5 mL/min at room temperature; 0.5 mL fractions were collected.

Cell Binding Assays. The affinity of nonradioactive proteins for cell membranes was determined by their ability to compete with fluorescein-annexin V for binding to erythrocytes with exposed phosphatidylserine (*21*). Mutant proteins were added at various concentrations to 1 mL of a solution containing 5 nmol/L fluorescein-annexin V and 8.3×10^6 erythrocytes in a buffer consisting of 10 mmol/L HEPES-Na, pH 7.4, 136 mmol/L NaCl, 2.7 mmol/L KCl, 5 mmol/L glucose, 1 mg/mL BSA (buffer HNKGB) plus 2.5 mmol/L $CaCl_2$. The sample was incubated for 15 min at room temperature. The cells were centrifuged for 3 min at 8300*g*, the supernatant was removed, and the fluorescein-annexin V bound to the pelleted cells was released by resuspension in 980 μL of HNKGB buffer containing 5 mmol/L EDTA. The sample was centrifuged again, the supernatant removed, and the concentration of fluorescein-annexin V in the supernatant determined by fluorometry. The results of this assay are summarized as the concentration of competitor protein that inhibits 50% of the binding of fluorescein-annexin V, abbreviated IC_{50}.

The ability of radiolabeled proteins to bind to cell membranes was determined by incubating them with a large excess of cells in a similar procedure. Radiolabeled protein at 10 nmol/L final concentration was added to

annexin V-123	6 ± 2

[a] Results are given as mean ± SD (n = 3).

duplicate tubes containing a final volume of 1 mL of buffer HNKGB plus 2.5 mmol/L $CaCl_2$. One tube then received 4.2×10^8 erythrocytes in 100 μL; the other tube received an equal volume of buffer. After a 15 min incubation at room temperature, both tubes were centrifuged for 3 min at 8320*g*. Radioactivity was measured in 800 μL of the supernatants. The percentage of radioactivity bound to the cells was calculated from 100 × [1 − (supernatant counts in the presence of cells)/(supernatant counts in absence of cells)].

RESULTS

Protein Production and Characterization. Two mutant proteins were designed to have N-terminal sequences potentially suitable for labeling with TcCO (Figure 1). Annexin V-122 has three adjacent His residues, and annexin V-123 has six. The structures of the expression constructs were verified by DNA sequencing. Both proteins could be expressed cytoplasmically in *E. coli* and purified in reasonable yield (33 mg of pure protein per liter of bacterial culture) under conditions similar to those used to produce wild-type and mutant annexin V (*14*, *23*, *26*). SDS−PAGE analysis (Figure 2) showed that both mutants could be produced in highly pure form. As expected, both mutant proteins (323 and 326 amino acids in length) also migrated with the same apparent molecular weight as wild-type annexin V (319 amino acids). Isoelectric focusing showed that the isoelectric points of the mutant proteins were consistent within 0.1 pH unit with the calculated values given in Figure 1. Gel filtration analysis (described further below) indicated that both proteins were pure and migrated as monomers. Mass spectrometry showed a single major peak at 36 287 (calculated MW 36 288) for annexin V-122, and a single major peak at 36 696 (calculated MW 36 700) for annexin V-123. These results indicate that the initiator methionine was removed from both proteins, and that there were no posttranslational modifications such as N-terminal acetylation. The bioactivity of the mutant proteins was verified by measuring their ability to compete with wild-type annexin V for binding to erythrocyte membranes with exposed PS (Table 1). Both proteins displaced fluorescein-annexin V with the same relative affinity as wild-type annexin V, indicating that attachment of the N-terminal peptide did not interfere with membrane binding.

Table 2. Radiochemical Purity and Bioactivity of Labeled Proteins[a]

protein	labeling yield (%)	radiochemical purity (%)	radioactivity bound to erythrocytes (%)
annexin V-wt	43.0 ± 3.9	91.2 ± 1.7	78.3
annexin V-122	60.6 ± 6.4	96.7 ± 0.9	80.7 ± 0.9
annexin V-123	80.6 ± 0.6	98.4 ± 0.5	85.0 ± 2.8

[a] Labeling was performed with 100 μg of protein and 1 mCi of TcCO for 60 min. Results are given as mean ± SD for two experiments.

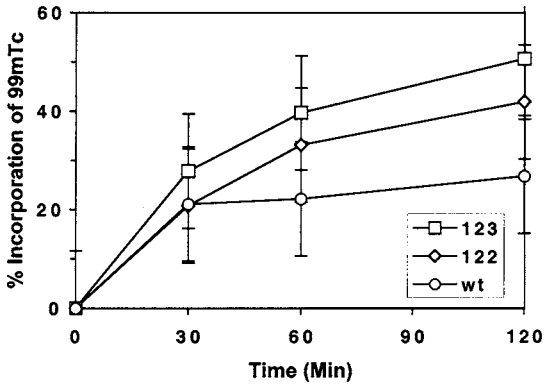

Figure 3. Time course of radiolabeling. Protein (100 μg) was reacted with ^{99m}TcCO (1 mCi) at 37 °C, and ITLC was performed on aliquots taken at the indicated times. Results are mean ± SD for two experiments.

Radiolabeling with ^{99m}Tc. Wild-type and mutant proteins were radiolabeled with TcCO (Table 2). There was some labeling of the wild-type protein, presumably due to its three endogenous histidine residues, but the two mutant proteins incorporated substantially more radioactivity. The radiolabel remained attached to protein after separation from labeling reagents, as indicated by the high radiochemical purity of gel-filtered proteins. To verify that the radiolabeled proteins retained bioactivity, radiolabeled proteins were incubated with erythrocytes in the presence of calcium, and the percentage of radioactivity bound to cells was measured. All proteins showed comparable levels of binding, and this level was comparable to the binding of ^{99m}Tc-HYNIC-annexin V and ^{99m}Tc-annexin V-117 previously tested under the same conditions (*14*). (Even with fully bioactive protein, binding never exceeds about 85% under these assay conditions because of the finite amounts of cells and protein that can be added to the assay.) The time course of labeling was fairly rapid, with most of the Tc being incorporated

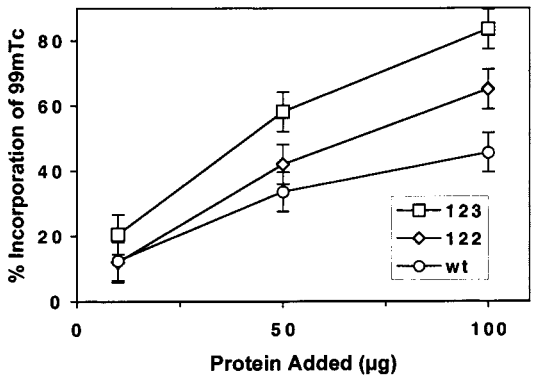

Figure 4. Radiolabeling as a function of technetium/protein ratio. Protein (10−100 μg) was added to TcCO (1 mCi). After 60 min at 37 °C, ITLC was performed on the reaction mixture to determine percent incorporation of technetium into protein. Results are mean ± SD for two experiments.

Table 3. Stability of Radiolabeled Proteins in Vitro[a]

protein	% protein-bound ^{99m}Tc in PBS[b]	% protein-bound ^{99m}Tc in serum[c]
annexin V-122 at 1 h	93.9 ± 0.8	98.4 ± 0.1
annexin V-122 at 4 h	90.1 ± 1.5	98.3 ± 0.6
annexin V-123 at 1 h	96.8 ± 1.4	99.1 ± 0.6
annexin V-123 at 4 h	95.3 ± 2.5	98.8 ± 0.4

[a] Results are given as mean ± SD for two experiments. [b] Determined by ITLC. [c] Determined by centrifugal ultrafiltration.

by 60 min (Figure 3). To determine if proteins could be labeled to higher specific activity, the technetium/protein ratio was varied. As shown in Figure 4, the specific activity could be increased by increasing the ^{99m}TcCO/protein ratio, although at a cost of lower percent incorporation; specific activities of ∼10−20 μCi/μg were readily obtainable for both mutant proteins.

Stability of Radiolabeled Proteins in Vitro. The stability of the radiolabeled protein in vitro was determined after challenge with phosphate-buffered saline and serum. ITLC or ultrafiltration analysis showed that the mutant proteins retained the radiolabel over a period of several hours, indicating that the Tc-protein chelate was of high affinity (Table 3). These results were confirmed by gel filtration chromatography (Figure 5). After incubation of ^{99m}Tc-annexin V-122 or -123 with PBS for 2 h, almost all of the radioactivity eluted in the same position as monomeric annexin V (M_r 36 000); there was no evidence for either multimeric protein aggregates or large-scale release of free Tc. Similarly, gel filtration chromatography of ^{99m}Tc-annexin V-122 or -123 after a 2 h incubation with human serum showed that the radioactivity still eluted in the same position as monomeric annexin V (Figure 5). Thus, there was no evidence for either degradation or transchelation of ^{99m}Tc to other serum proteins over a time period consistent with the normal blood clearance time of annexin V.

DISCUSSION

We have developed and evaluated two mutant forms of annexin V that contain clusters of histidine residues suitable for labeling with TcCO reagent. Both proteins can be produced in good yield and high purity by recombinant-DNA methods. These mutant molecules retain bioactivity both before and after labeling with ^{99m}Tc, as measured by their ability to bind with high affinity to cell membranes with exposed PS. Labeling of these molecules with ^{99m}TcCO is simple, and high specific

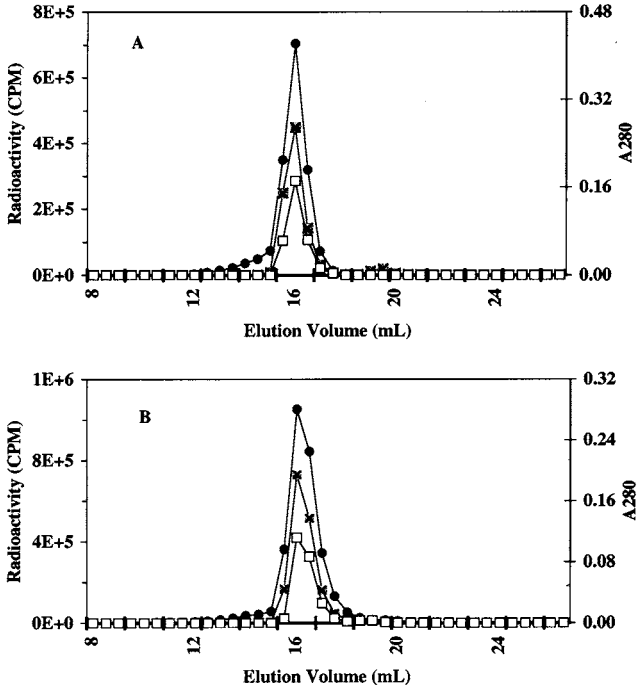

Figure 5. Gel filtration analysis. Labeled protein (50 μg in 300 μL) was mixed with either 300 μL of human serum (circles) or 300 μL of PBS (squares with x), incubated for 2 h at room temperature, and then analyzed on a Superose-12 column as described under Materials and Methods. An aliquot of unlabeled protein (500 μg; open squares) was chromatographed separately to determine the purity and elution position of unlabeled protein. Panel A: ^{99m}Tc-annexin V-122. Panel B: ^{99m}Tc-annexin V-123.

activities can be achieved. The mutant annexins show good radiolabel stability in vitro in PBS and serum, and there is no evidence for transchelation of ^{99m}Tc to other serum proteins during in vitro incubation (Figure 5). Since annexin V does not bind to normal erythrocytes, leukocytes, or platelets in whole blood (*27*), these results imply that TcCO-labeled annexin V will be confined to the plasma fraction of blood in vivo, and it will be stable in this compartment until cleared into other body compartments. Although both proteins are suitable for further development as potential in vivo imaging agents, annexin V-123 may be better than annexin V-122 since it labels to higher specific activity and has slightly higher in vitro radiostability. Presumably, the annexin V-123 mutant labels better than the V-122 mutant because it has six rather than three adjacent histidine residues. Wild-type annexin V labeled less well than either mutant protein, and would thus be the least desirable molecule for further development.

As mentioned in the introduction, there are now several methods available for technetium labeling of annexin V. Each of these methods has certain advantages and disadvantages. Recombinant proteins with endogenous labeling sites are much simpler to produce, since they can be used directly for ^{99m}Tc labeling without the need for attachment of organic Tc chelation groups either during production or at the point of use. The annexin V mutants are also chemically homogeneous, in contrast to the heterogeneous labeling that usually occurs with amine-directed bifunctional organic labeling reagents used on proteins with multiple lysine residues. On the other hand, methods involving derivatization with chemical groups such as N_2S_2 or HYNIC have longer track records to date, which may simplify clinical testing and regulatory approval. The possible immunogenicity of both

chemically modified proteins and recombinant proteins is unknown. The HYNIC-annexin V and annexin V-117 derivatives are the simplest to use in the clinical setting, since both can be labeled with short one-step reactions performed at room temperature or 37 °C; in contrast, the TcCO labeling is a two-step procedure in which the TcCO compound must be first formed in a separate reaction at high temperature, while the N_2S_2 method is a rather complex multistep procedure.

In conclusion, we have shown the feasibility of labeling annexin V with the TcCO reagent, and the novel mutant molecules reported here are promising for future imaging studies of apoptosis, cancer chemotherapy, and myocardial infarction.

ACKNOWLEDGMENT

We thank Alex Pagon for excellent assistance in initial efforts to construct expression vectors; Ross Lawrence of the Department of Medicinal Chemistry for performing mass spectrometry measurements; and Dr. J.-L. Vanderheyden for helpful advice on preparation of the TcCO reagent. This work was supported by a grant from Theseus Medical Imaging, Inc., and by NIH Grant HL-61717.

Received May 14, 2002; Revised Manuscript Received June 27, 2002

A series of five poly[(ethylene imine)-*co*-*N*-(2-hydroxyethyl-ethylene imine)] copolymers with similar molecular weights and different degrees of branching was established to study structure−function relationship with regard to physicochemical and biological properties as gene delivery systems. Copolymers were synthesized by acid-catalyzed ring-opening copolymerization of aziridine and *N*-(2-hydroxyethyl)-aziridine in aqueous solution and characterized by GPC-MALLS, ^{1}H- and ^{13}C NMR, IR, potentiometric titration, and ion exchange chromatography. Complexation of DNA was determined by agarose gel electrophoresis, and complex sizes were quantitated by PCS. Cytotoxicity of the copolymers in fibroblasts was assessed by MTT-assay, LDH-assay, and hemolysis. The transfection efficiency was determined using the reporter plasmid pGL3 in 3T3 mouse fibroblasts. The copolymers obtained by solution polymerization had relatively low molecular weights of about 2000 Da, and the degree of branching increased with increasing ethylene imine ratio. The pK_a as well as the buffer capacity increased proportional to the number of primary and secondary amines. Higher branched polymers showed stronger complexation and condensation of DNA, formed smaller polymer/DNA complexes, and induced the expression of plasmids to a higher extent than less branched polymers. In vitro cytotoxic effects and the hemolysis of erythrocytes decreased with decreased branching. Our results indicate that the basicity and degree of protonation of the polymers depending on their amount of primary and secondary amines seem to be important factors both for their transfection efficiency and for their cytotoxicity in gene transfer.

INTRODUCTION

The polycation polyethylene imine (PEI)[1] is generally regarded as a useful reagent for nonviral delivery of DNA and RNA under both in vitro and in vivo conditions (Remy et al., 1998). PEI, compared to other nonviral vectors, is assumed to affect endosomal escape and the enzymatic protection of DNA and RNA (Behr, 1997). PEI is commercially available with different average molecular weights and degrees of branching. The transfection efficiencies, cytotoxicity, and DNA binding characteristics of PEI have been discussed somewhat controversially in the literature (Fischer et al., 2000; Gebhart and Kabanov, 2001). Systematic studies probing the relationship between the structure of PEI, especially the molecular weight, the degree of branching, the relative ratio of amino functions, and physicochemical and biological effects, are rare.

DNA delivery using PEI was found to depend on the molecular weight of the polymer. Often highly branched PEIs with molecular weights in the range from 25 to 800 kDa were reported to be useful for gene delivery. These PEI/DNA complexes yield high levels of transgene expression in many cell lines and primary cells under in vitro conditions (Boussif et al., 1996; Erbacher et al., 1999), as well as in vivo, e.g., in kidney, lung, and brain (Abdallah et al., 1997; Boletta et al., 1997; Lecocq et al., 2000). Cytotoxic effects, however, limit their utility. Comparing the potential for transgene expression of highly branched PEI with molecular weights in the range from 0.6 to 70 kDa, Godbey et al. (1999) observed an increase in gene expression with increasing molecular weight of the polymers. The transfection efficiency for 1.8 kDa PEI was essentially zero. The inability of PEIs <2 kDa to yield gene expression was also described by others (Baker et al., 1997; Remy et al., 1998). We synthesized a PEI of low molecular weight and a low degree of branching compared to the commercially available PEIs. Despite its relatively low molecular weight, LMW-PEI was efficient and less cytotoxic than 800 kDa

PEI (Fischer et al., 1999). In addition to branched PEI, also linear polymers (22 kDa) have become commercially available (ExGen 500). Linear PEI efficiently transfected lung epithelial cells as well as the central nervous system of mice in vivo without any signs of acute toxicity (Ferrari et al., 1997; Goula et al., 1998).

Both the structure of branched PEI and its buffer capacity were thought to be relevant for the escape mechanism from endosomes, also known as the proton sponge mechanism (Behr, 1997), postulating that endo/lysosomal release of the DNA/PEI-polyplexes occurs after protonation of PEI and subsequent swelling of the polymer. Boletta et al. (1997) reported that branched PEI 25 kDa was superior to linear PEI 22 kDa under in vivo conditions in kidney cells. Also branched PEI appeared to be more effective in condensing DNA at low N/P ratios as compared to the 22 kDa product (Dunlap et al., 1997). However, in other studies linear PEI was found to be superior to the branched form (Ferrari et al., 1997). A dependency of cytotoxicity and transfection of cells on molecular weight and charge density of the linear form was also reported (Jeong et al., 2001). Consequently, we hypothesized that the efficiency and cytotoxicity of PEI as a nonviral vector system may depend not only on the molecular weight, but also on the structure of PEI. The optimal structure of PEI for gene delivery is not yet known with certainty.

We synthesized a series of five PEI derivatives by copolymerization of aziridine and *N*-(2-hydroxyethyl)-aziridine, a reagent which allowed a systematic manipulation of the degree of branching. Homo- and copolymers of comparable molecular weights were then used to determine the influence of polymer structure on in vitro cytotoxicity, DNA-binding characteristics, polyplex formation, and transfection efficiency.

EXPERIMENTAL PROCEDURES

Synthesis of Poly[(ethylene imine)-*co*-*N*-(2-hydroxyethyl-ethylene imine)] Copolymers. Aziridine was prepared from mono-ethanolamine (Fluka, Deisenhofen, Germany) as described by Wenker (1935). Aziridine and *N*-(2-hydroxyethyl)-aziridine (Sigma, Deisenhofen, Germany) monomers were copolymerized in different molar ratios by cationic ring-opening polymerization according to the procedure described earlier (von Harpe et al., 2000). For purification, the reaction mixtures were cooled to room temperature and neutralized with sodium hydroxide, and water was removed under reduced pressure (50 °C, 10 mbar). The crude polymers were redissolved in ethanol and precipitated in diethyl ether. After recovery, the polymers were dried at 50 °C in a vacuum for 3 weeks.

Physicochemical Characterization of the Copolymers. *Molecular weight and distribution* of the copolymers were determined using SEC in combination with multiple angle laser light scattering (MALLS). Formic acid (1%) was used as eluent with a flow rate of 1 mL/min. The column, Novema 100, was purchased from Polymer Standard Service (PSS, Mainz, Germany). The refractive index detector from Merck-Hitachi (RI-71), equipped with an 18 angle light scattering detector, DAWN EOS (Enhanced Optical System) from Wyatt Technology Corp. (Santa Barbara, CA) and in line with the RI detector, allowed the determination of the absolute MW. The weight average MW was determined using a Zimm plot (ASTRA software version 4.73). Refractive index increments, d*n*/d*c*, for the copolymers were calculated with the same software using the data from the RI detector and the polymer concentration.

Infrared spectroscopy was conducted with a Nicolet 510 FT-IR spectrometer and PC/IR v. 3.20 software using potassium bromide disks (Merck, Darmstadt, Germany).

^{1}H NMR and ^{13}C NMR spectra were recorded in deuterium oxide (D_2O, Merck, Darmstadt, Germany) with a LA 500 Eclipse+ Delta FT spectrometer (JEOL, USA) at 500 MHz for ^{1}H and 125 MHz for ^{13}C spectra. To suppress the nuclear Overhauser effect (NOE), all ^{13}C spectra used for quantitative analysis were recorded using inverse gated decoupling pulse sequences. Spectra were evaluated with the NMR data processing program WinNuts 2D (Acorn NMR). Signal intensities of ^{13}C NMR spectra were determined relative to signal 3 (Figure 2).

Buffer capacities of 0.1 mol/L PEI solutions were measured in bidistilled water by potentiometric titration with a Schott CG820 pH meter using 0.1 N HCl (Titrisol, Merck) as the titrant. Each determination was carried out in triplicate at 25 ± 0.1 °C according to Suh et al. (1994). The buffer capacity was calculated as described in Seel (1970).

A CM-Sephadex C50 cation exchanger column (bed volume 6.5 mL, Pharmacia Biotech, Freiburg, Germany), equilibrated with 0.1 M sodium borate, pH 10.0, was used for ion exchange chromatography. Two milligrams of copolymer in 300 μL of distilled water was loaded onto the column and eluted with a gradient of 0.1 M sodium borate, pH 10−13. Fractions were collected and analyzed for polymer content after Cu(II) chelation at 635 nm using UV spectrophotometry as described previously (von Harpe et al., 2000).

DNA-Binding Characteristics and Complex Size. DNA from herring testes (Sigma) was purified by ultrafiltration to remove low molecular weight impurities (cutoff: 300 kDa; Millipore, Eschborn, Germany) and adjusted to a final concentration of 1.0 mg/mL (determined by UV 260/280 nm ratio). Ten micrograms of herring testes DNA and the appropriate amounts of the polymer stock solutions (0.9 mg/mL, pH 7.4) were complexed as described earlier (Fischer et al., 1999). The complex composition was calculated on the basis of PEI nitrogen (N) per DNA phosphate (P) and expressed as the N/P ratio.

Electrophoresis was carried out in 1% agarose gels containing ethidium bromide with a current of 80 V. The DNA localization was visualized by UV transillumination at 254 nm (Fischer et al., 1999). The intensity of the gel bands was determined using Scion Image Beta 4.02 software (Scion Corp., Frederick, MD). An intensity profile of the area at the origin was examined by measuring the size of the peaks corresponding to the individual bands.

Polymer/DNA complexes were prepared as described above using 40 μg of purified DNA from herring testes in a final volume of 500 μL of 50 mM NaCl/3.3% glucose for size measurements. The complexes were measured by photon correlation spectroscopy (PCS) at 25 °C with a Zetasizer 4 (Malvern Instruments, Herrsching, Germany) equipped with a nominal 5 mW helium neon laser and Malvern software version 1.26. Samples were measured in the AZ 110 cell at 633 nm and a scattering angle of 90 °C. The viscosity and refractive index of pure water at 25 °C were used for data analysis.

Cytotoxicity Assays. The MTT assay was performed as described previously (Fischer et al., 1999) using the L929 mouse fibroblast cell line (DSMZ, Braunschweig, Germany).

LDH release was studied in L929 cells (25 000/well) seeded in 6-well multidishes (Gibco, Eggenstein, Germany) and incubated for 48 h. Cell culture medium was

Table 1. Relative Ratio of Primary, Secondary, and Tertiary Amino Groups in the Polymers and Degree of Branching[a]

[a] Calculated from ^{13}C NMR analysis. The molecular weight was determined by GPC as described under Experimental Procedures. An increase in the HEEI content of the copolymers resulted in a decrease of the primary amino groups and reduced the degree of branching. The molecular weights of the copolymers were in a comparable range from Mw 1.925 to 2.291 kDa.

replaced by 2 mL of the polymer solutions, and 100 μL samples were withdrawn after 1, 3, 6, and 11 h of exposure. The LDH content of the samples was measured using a commercial test kit (DG 1340-K, Sigma). Control experiments were performed with 0.1% (w/v) Triton X-100, and the resulting values were set to 100% cytotoxicity.

The hemolytic activity of the polymers was tested according to Parnham and Wetzig (1993). Blood, collected in heparinized tubes from Wistar rats, was centrifuged at 700*g* for 10 min, washed 3 times with cold PBS, pH 7.4, and resuspended in the same buffer. The erythrocyte suspension was freshly prepared for every experiment and used within 24 h. The polymer solutions of different concentrations were mixed with the red blood cell suspension and were incubated at 37 °C for 60 min in a shaking water bath. The release of hemoglobin was investigated after centrifugation (700*g* for 10 min) by spectrophotometric measurement of the absorbance of the supernatant at 540 nm. Complete hemolysis of a control aliquot was achieved with 0.2% (w/v) Triton X-100 and the effect of the polymers expressed as relative percentage of hemoglobin.

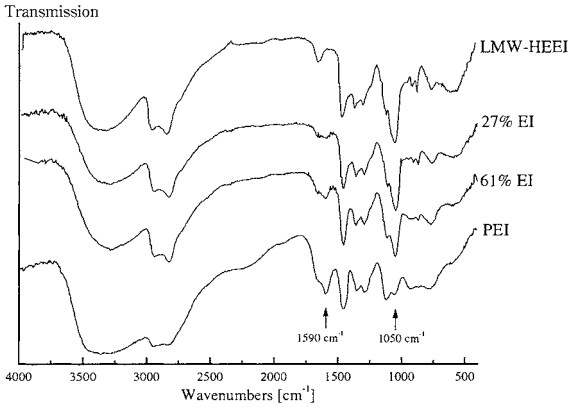
Transfection Experiments under in Vitro Conditions. pGL3-control plasmid from Promega (Mannheim, Germany) was amplified in JM109 competent cells (Promega) and purified using QIAfilter kits (Qiagen, Hilden, Germany) according to the manufacturer's protocol. Transfection experiments were carried out in triplicate in NIH 3T3 cells (Fischer et al., 1999). Luciferase expression was evaluated using a commercial kit (Luciferase Assay System, Promega) and a Berthold Sirius luminometer (Berthold, Pforzheim, Germany). Cells were washed twice with PBS, lysed in cell culture lysis reagent (200 μL/well), transferred into Eppendorf vials, and centrifuged at 18000*g* for 5 min. Then 20 μL of the supernatant was mixed with 100 μL of luciferase assay reagent, and luminescence was determined immediately in relative light units per second as the mean of a 10 s measurement time. RLUs were converted into nanograms of luciferase by creating a calibration curve with recombinant luciferase (Promega). Protein concentrations in the samples were analyzed using a modified BCA assay (Pierce, Rockford, IL) (*25*). Undesired DTT was inactivated with iodoacetamide before the addition of the BCA assay reagent (Hill et al., 1988). Absorption was measured on a Dynatech MR5000 plate reader (Dynatech, Denkendorf, Germany) at 570 nm and compared to a standard curve calibrated with BSA samples of known concentrations.

RESULTS AND DISCUSSION

Synthesis and Structural Characterization of the Copolymers. Homo- and copolymers with a composition of 0, 7, 27, 44, 61, 76, and 100% (w/w) aziridine, respectively, were synthesized by acid-catalyzed polymerization of aziridine with *N*-(2-hydroxyethyl) aziridine in aqueous solutions. The polymerization of aziridine resulted in a branched polymer, in which approximately one-fourth of all nitrogen atoms formed branches (Dick and Ham, 1970). In contrast, the polymerization of PEI and HEEI led to copolymers with a lower degree of branching, since branches originate only from aziridine monomers, due to substitution of HEEI. The synthesis was reproducible with respect to composition and structure (data not shown). All polymers were obtained as free bases and had a colorless, clear, highly viscous appearance. Product yields varied between 54 and 84% (Table 1). The homo- and copolymers were characterized with regard to molecular weight, monomer composition, distribution of the different amino groups, and degree of branching. Table 1 summarizes the characteristics of the polymers used in this investigation.

All polymers showed similar molecular weights (Mn 1500 Da and Mw 2500 Da). Polydispersities were relatively narrow with a polydispersity index (Mw/Mn) of approximately 1.4. Significant differences were only observed for the refractive index increment (d*n*/d*c*), which is a function of the copolymer composition. An increasing amount of ethylene imine repeating units in the copolymer was shown to increase the d*n*/d*c* (Table 1).

As determined by IR and ^1H NMR spectroscopy, the polymer composition corresponded exactly to the monomer composition in the feed. In IR spectra, the C−O stretching absorption at 1050 cm^{-1} increased with increasing content of hydroxyethyl groups, whereas the N−H bending absorption band at 1590 cm^{-1} decreased, due to the increasing number of tertiary amino groups in the molecule. O−H bending absorption at 1400−1200 cm^{-1} was covered by C−N streching (1300−1200 cm^{-1}) and C−H rocking absorption bands at 1450 cm^{-1} (Figure 1). In ^1H NMR spectra, two signals were observed, one at 2.6 ppm for CH_2−N and one at 3.6 ppm for CH_2−O.



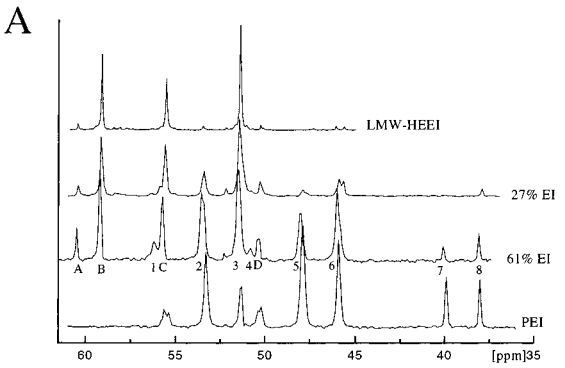


Figure 1. Infrared spectra of selected co- and homopolymers. Absorption bands at 1590 cm^{-1} (N−H, only in EI-containing polymers) and 1050 cm^{-1} (C−O, only in HEEI-containing polymers) are highlighted to show the main differences between the polymers. The polymer composition was found to correspond to the monomer feed.

The ratio of HEEI to EI monomer units in each polymer was calculated from the ratio of these two signals, and again, the results showed that the polymer composition exactly corresponded to monomer feed. Additional signals from residual monomer traces could not be detected in any of the spectra recorded. Since methylene groups adjacent to primary, secondary, or tertiary amino groups could not be distinguished in the ^{1}H NMR spectra, ^{13}C NMR spectroscopy was employed for further structural information. The signals in the ^{13}C NMR spectra appeared between 38 and 61 ppm. Whereas some of the same signals and corresponding structures originated from pure PEI (von Harpe et al., 2000), additional signals appeared for the carbon atoms of the hydroxyethyl side chain and those directly next to a hydroxyethyl-substituted nitrogen. Typical ^{13}C NMR spectra of PEI, PEIHEEI containing 61 and 27 mol % EI, and pure LMW-HEEI are shown in Figure 2A. The signals of the corresponding methylene groups were assigned as indicated (Figure 2B). Results of 2D-INADEQUATE ^{13}C NMR experiments verified the signal assignment proposed here (Figure 3).

The ratio of the different amino groups in the polymers (Table 1) was calculated from signal intensities in ^{13}C NMR spectra as described in von Harpe et al. (2000). The degree of branching increased with increasing ethylene imine content. In pure LMW-HEEI, no branching was observed. The secondary amino groups found in this polymer resulted from the initialization step of the polymerization, during which the addition of a proton formed a secondary amine function. All tertiary amino groups in this polymer were formed by a hydroxyethyl-substituted nitrogen atom and, therefore, did not contribute to branching. In the homopolymer, PEI, on the other hand, all tertiary amino groups can be potential branching points. For the copolymers, signals C and 3 allowed not only the determination of tertiary amino groups, but also the calculation of branching points formed by EI monomer units. Even at values as low as 7 mol % EI branching (6%) occurred, and with increasing EI content, the branching increased up to 23.1% in pure PEI. The content of primary amino groups in the copolymers could be directly correlated to the content of EI monomer ($R = 0.987$). The ratio of the different amino groups and the degree of branching are shown in Table 1.

The commercially available N-substituted aziridine was used to manipulate the three-dimensional structure of PEI since it polymerizes via the same acid-catalyzed

ring-opening polymerization mechanism as ethylene imine and contains a "protective" group generating linear structures. Furthermore, hydroxyethyl groups do not compromise the hydrophilicity of the copolymers. The polymerization of HEEI in various organic solvents has been described earlier (Rivas et al., 1991). The copolymerization of aziridine with HEEI allowed the manipulation of the degrees of branching at similar molecular weights.

Characterization of Basicity and Protonation Behavior. Polymer solutions of equivalent nitrogen concentrations were examined to determine the influence of polymer structure on the protonation behavior. Potentiometric titration with 0.1 N HCl yielded titration curves as shown in Figure 4A. As found in homo-PEI (von Harpe et al., 2000), an area of high buffer capacity is situated above the physiological pH range, namely, between 8 and 10, an area characteristic for polyamines. With an increase of EI monomer, an increase of pK_a and buffer capacity was observed which is mainly due to a lower basicity of the hydroxyethyl-substituted nitrogens. Second, the higher degree of branching with increasing EI content is another important factor due to the higher basicity of the primary and secondary groups compared to the tertiary ones. Between pH 4.5 and 6, a second area of buffer capacity was detected, which was not as distinct as the first one. In this range, our polymers showed comparable basicity.

Analysis of the copolymers by ion exchange chromatography revealed a similar behavior as found in the titration study. The polymers were bound to the ex-

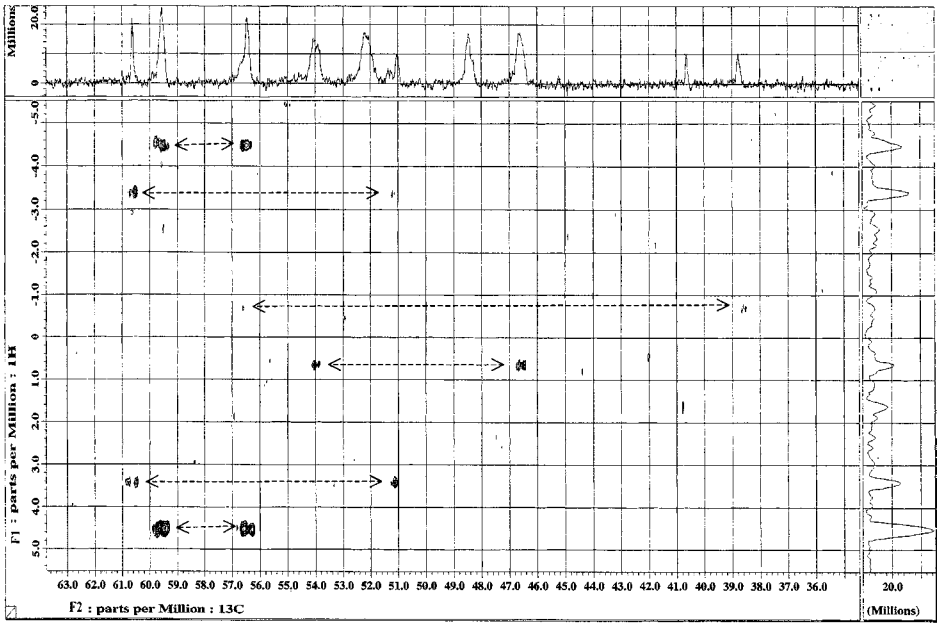

Figure 3. 2D-^{13}C INADEQUATE-NMR spectrum of PEIHEEI copolymer containing 61 mol % EI.

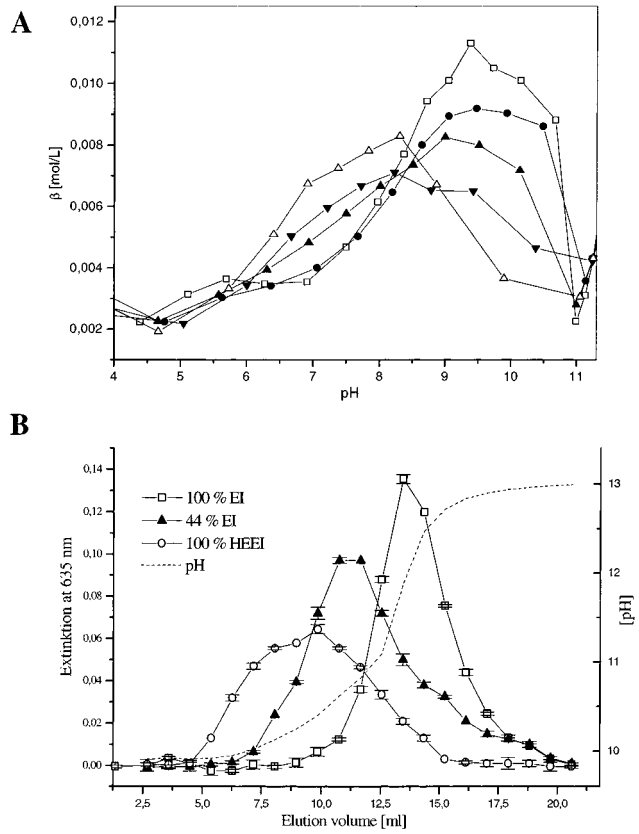

Figure 4. (A) Buffer capacities (β) of PEI and PEIHEEI copolymers in solution as a function of pH (△, LMW-HEEI 0/100; ▼, PEIHEEI 7/93; ▲, PEIHEEI 44/56; ●, PEIHEEI 76/24; - □ -, PEI 100/0). Buffer capacities were calculated from potentiometric titration curves according to Perrine and Landis (1967). The titration analysis showed an increase of pK_a value and buffer capacity with increasing ethylene imine content. (B) Ion exchange chromatography of the polymers on CM-Sephadex G50 cation exchanger. Polymers with high EI content required a higher pH for elution from the column than those with low EI content.

changer resin under loading conditions (pH 10.0). Increasing buffer pH during elution reduced polymer protonation, and the polymer was released from the column. Polymers with high EI content required a higher pH for elution from the column than those with low EI content (Figure 4B), which is consistent with the different pK_a values found by titrations and results in a higher proton affinity with increasing EI content and branching. In accordance to the structural results described above, the fact that all copolymers eluted as one single peak at a pH between the elution pHs of the two homopolymers again demonstrates that copolymers were obtained and not mixtures of homopolymers. Furthermore, the interactions between the ion-exchange resin and the polymers can be used as model for the binding of DNA, which is also driven by electrostatic interactions. Therefore, one would expect stronger interpolyelectrolyte interactions with increasing ethylene imine content of the copolymers. Consequently, the binding of the negatively charged DNA with the cationic polymers was determined by agarose gel electrophoresis.

DNA Binding and Complex Formation. Complexes of all polymers were formed with DNA from herring testes (3−4 kbp) as model DNA at an N/P ratio of 66 (Figure 5A). This ratio was chosen due to the preliminary experiments with LMW-PEI (Fischer et al., 1999). Free DNA (lane 1) gave a broad fluorescent band corresponding to its broad molecular weight distribution. The five PEIHEEI copolymers (lanes 2−6) showed complete retardation of the DNA at the origin, indicating complete complexation of the DNA at this N/P ratio. However, we observed that the fluorescence of the complexes at the origin increased with increasing HEEI content of the copolymers. We interpret the extent of ethidium bromide exclusion from DNA as a reflection of DNA condensation. Higher extents of dye displacement are compatible with a higher fraction of DNA compacted by the polycations. LMW-HEEI completely retained the DNA in the starting position, but showed the highest fluorescence, i.e., the lowest DNA condensation. For HMW-HEEI, we found comparable results indicating a negligible effect of molecular weight. A clear correlation was observed between the integrated intensity of the bands' fluorescence and the HEEI content of the polymers (Figure 5B).

Since condensation of DNA is known to be an important prerequisite for the formation of small polyplexes, the size range of the complexes made with the copolymers

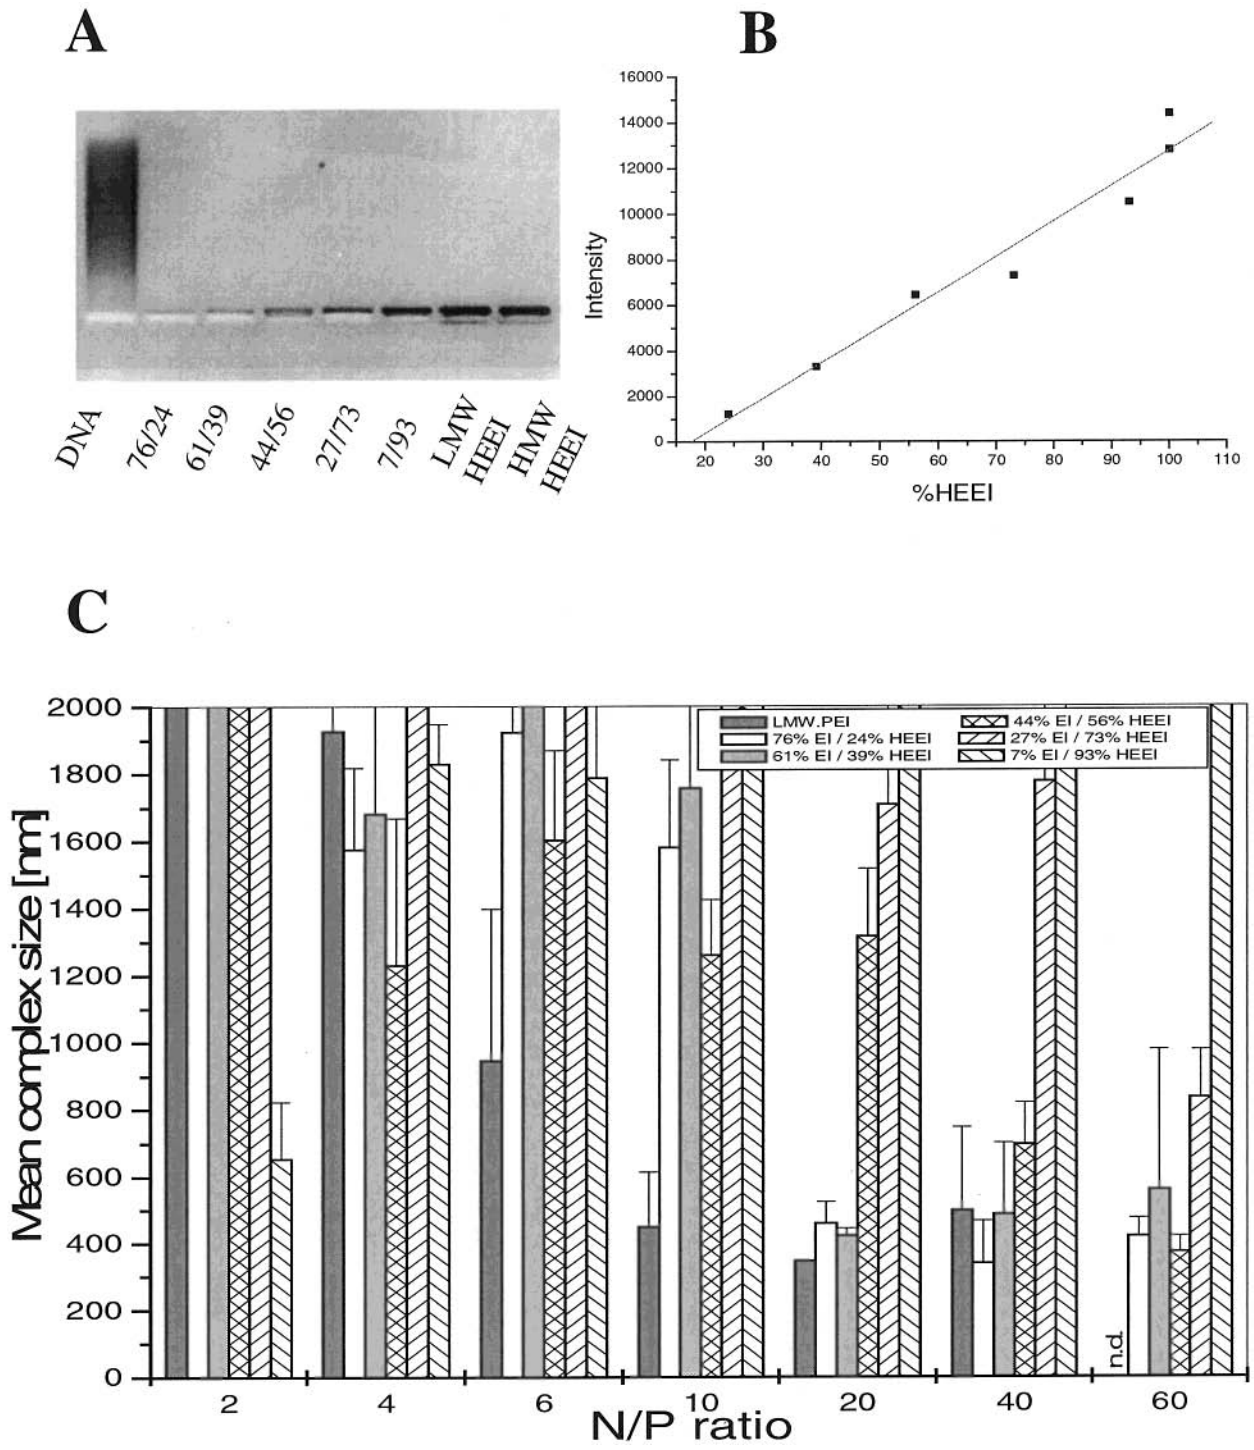

Figure 5. (A) Agarose gel electrophoresis of polymer/herring testes DNA complexes at an N/P ratio of 66. Free DNA (lane 1) was compared with the polymer/DNA complexes of the five copolymers (lanes 2−6), LMW-HEEI (lane 7), and HMW-HEEI (lane 8). All polymers showed complete DNA retardation, but with increasing HEEI content of the polymers the exclusion of the intercalant dye ethidium bromide decreased. (B) The degree of DNA complexation expressed as intensity of the gel bands showed a clear relationship to the HEEI content of the polymers. (C) Mean complex size ± SD of polymer/herring testes DNA complexes at different N/P ratios were measured by photon correlation spectroscopy in 50 mM NaCl/3.3% glucose ($n = 3$).

and herring testes DNA as dependent on the N/P ratio was determined by photon correlation spectroscopy (Figure 5C). At an N/P ratio of 2, all copolymers and PEI formed large aggregates >1 μm with a broad size distribution. One exception was the 7/93 copolymer with only little branching (6%) and a high content of hydroxyethyl substituents, forming complexes of about 650 nm. Increasing the N/P ratio of the complexes, particle sizes were reduced according to the polymer composition. LMW-PEI formed complexes <1 μm at a ratio of 6 and smaller, <500 nm complexes at a ratio of 10 and above. With the PEIHEEIs 76/24 and 6/39, complex sizes <500 nm could be reached at N/P ratios of 20 and higher; with copolymer 44/56, the required ratio was between 40 and 60. Copolymer 27/73 formed larger particles under the chosen conditions, but the size reduction to about 800 nm at N/P 60 indicates that smaller complexes may be formed when higher ratios are used. PEIHEEI 7/93 did not show any tendency to form smaller particles by increasing the N/P ratio. In accordance to the observa-

tions of electrophoresis, LMW-HEEI and HMW-HEEI were not able to form small condensed, measurable particles (data not shown).

The ability of the copolymers to neutralize the charges of DNA sufficiently to form an adequately compacted structure increased with higher N/P ratios and higher EI content of the polymers. The influence of the N/P ratio on complex size has been already described by others (Ogris et al., 1998). Complexation and condensation are expected to occur mainly by electrostatic interactions. According to our observation of a higher pK_a and the stronger binding of the polymers to the exchanger resin with increasing EI content, the interactions with the negatively charged DNA should also increase with a higher content of EI. Since all complexes were formed at pH 7.4, the different basicity of the polymers may result in different numbers and densities of the cationic charges influencing the interaction with DNA. Branched oligocationic peptides bind DNA with affinities that increase with the number of cationic groups (Plank et al., 1999). DNA binding was found to be related to the content of primary amino groups, but for this study polymers of completely different compositions (poly-L-lysine, dendrimers, PEI) were used (Tang and Szoka, 1997). If the content of primary amino groups of our copolymers is reduced to 50%, twice the N/P ratio is needed to form small particles with DNA. Branched 25 kDa PEI condensed DNA to a greater degree compared to a linear 22 kDa PEI (Dunlap et al., 1997). For branched copolymers of histidine and lysine, a reduced particle size of complexes by enhanced condensation compared to linear ones was reported (Chen et al., 2001). Basicity and protonation behavior seem to have a more profound effect than molecular weight, since HMW-HEEI gave results comparable to LMW-HEEI. According to Tang and Szoka (1997), electrostatic interactions dominate over steric and chemical contributions in the primary interactions of the polycations with DNA, resulting in stronger DNA binding with higher proton affinity. Our results are in agreement with these observations.

In Vitro Cytotoxicity Assays. The in vitro cytotoxicity was quantitated by the release of cytosolic enzyme lactate dehydrogenase into cell culture medium, hemolysis of rat red blood cells as markers for membrane activity, and the MTT assay representing the metabolic and mitochondrial activity of the polymer-treated cells. The assays were carried out using cationic polymers not complexed with DNA and at higher concentrations than used for transfection experiments, presenting a worst-case scenario for the interaction of polyplexes with cells. All three assays gave similar results.

LMW-HEEI and PEIHEEI 7/93 did not induce any damage effect in all three assays compared to control cells. For all other polymers, the cytotoxicity was found to increase with longer incubation times, higher polymer concentrations, and higher EI content of the copolymers.

Using concentrations ≤0.1 mg/mL, independent from incubation time, no significant decrease of the mitochondrial activity (80−100%) could be observed for all copolymers (Figure 6A), except for PEIHEEI 76/24 which reduced the cell viability to about 60%. At a 10-fold higher concentration (1 mg/mL) after 3 h again, about 90% viable cells in all cases could be observed (Figure 6B). However, after 12 and 24 h, the viability decreased with increasing EI content of the polymers. This effect was intensified with longer incubation periods from 12 to 24 h. Using 10 mg/mL, generally, the viability decreased about 10%, but the trend of the curves was unchanged

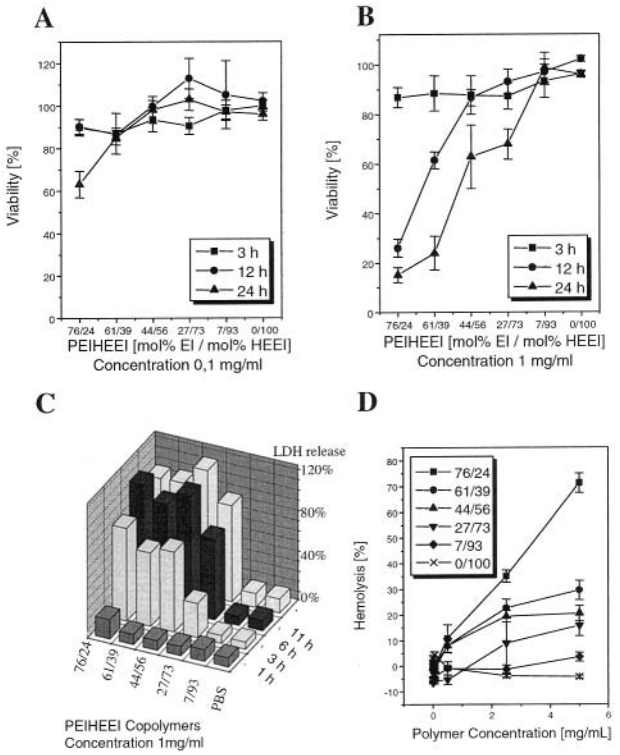

Figure 6. In vitro cytotoxicity testing of the copolymers. The cytotoxic effects as well as hemolysis were reduced with increasing HEEI content in the copolymers. L929 mouse fibroblasts were incubated for 3, 12, and 24 h with (A) 0.1 mg/mL and (B) 1 mg/mL PEIHEEI copolymers of different composition. Cytotoxic effects were quantitated by MTT assay. Each value represents the mean ± SD of seven determinations. (C) The membrane damaging effects were characterized by LDH-release incubating L929 cells with 1 mg/mL polymer solution for 1, 3, 6, and 11 h ($n = 3$). (D) After 1 h incubation, the hemolytic activity of different concentrations of the polymers was determined by UV spectrophotometric measurement of released hemoglobin at 540 nm ($n = 3$).

(data not shown). The homo-PEI showed a cytotoxicity profile comparable to copolymer 76/24 (Fischer et al., 1999).

The LDH assay gave corresponding results. Whereas with the exception of PEIHEEI 76/24 (10.61%), none of the copolymers (1 mg/mL) caused any release of LDH after 1 h, with longer incubation times up to 11 h the level of released enzyme increased with increasing amount of EI of the copolymers. The results of the LDH assay correlated with the changes in cell morphology as observed by phase contrast microscopy. With increasing PEI content in the copolymers, cytotoxic effects could be microscopically detected by the loss of spindle shape and detachment from the dish bottom of the usually adherent, spindle-shaped fibroblasts (data not shown).

Hemolysis of rat red blood cells increased as a function of polymer concentration and composition of the polymers. The hemolytic activity of the PEIHEEI 76/24 increased in a linear manner with higher concentrations up to 70%. Using the polymers with 61, 44, and 27% EI, the relative extent of hemolysis increased significantly from 15% (27/73) to 30% (61/39).

As also discussed for DNA binding, electrostatic interactions between the positive polymer and the negatively charged cell membrane were identified to induce membrane damage and cell death (Choksakulnimitr et al., 1995). The number and density of charges due to the degree of protonation and their arrangement in the three-dimensional polymeric structure were assumed to be

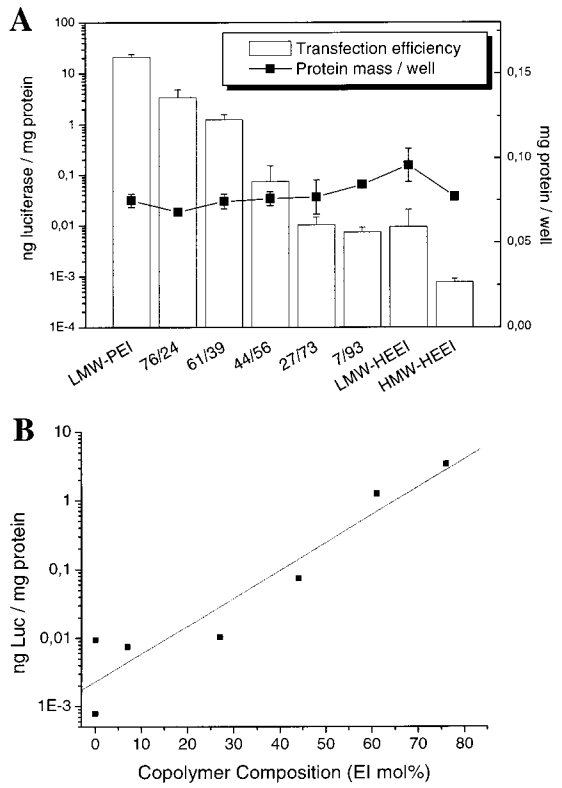

Figure 7. (A) Transfection efficiency in nanograms of luciferase per milligram of protein (black bars) and protein concentration in cell lysates (white bars). Gene expression decreased with increasing HEEI content of the polymers. Protein concentration in cell lysates was very similar for all polymers tested and was not responsible for the differences between the quotients nanograms of luciferase per milligram of protein. (B) Linear regression of log transfection efficiency (in nanograms of luciferase per milligram of protein) versus molar ethylene imine content gave a correlation coefficient of 0.95.

responsible for the different degree of cytotoxicity of polycations. We observed a similar trend: Higher ratios of EI in the copolymers correlated with increasing proton affinity and higher number of primary and secondary amines. This results in a higher degree of protonation, allowing more efficient electrostatic interactions with cell membranes.

The degree of protonation exhibited a greater influence on cytotoxicity than the molecular weight of the polymers. Using HMW-HEEI, only a slightly increased cytotoxicity could be detected compared to LMW-HEEI. Up to 10 mg/mL for LMW-HEEI, no significant cytotoxic effect could be observed over up to 24 h. HMW-HEEI (data not shown) was also nontoxic over 3 and 12 h under the chosen conditions. After 24 h at concentrations $\geq$1 mg/mL, cell viability was reduced (70%) compared to LMW-HEEI, but was still higher compared to all other copolymers.

Transfection Efficiency. If DNA condensation and small complex sizes are essential for transfection, one would predict that at a given N/P ratio the copolymers with high EI contents should perform better than the polymers with high HEEI content in gene delivery experiments. For comparison of the transfection efficiency of our copolymers, a N/P ratio of 66 was chosen because all complexes showed complete DNA complexation at this ratio. In 3T3 cells, the EI content of the copolymers had a clear effect on transfection efficiency in the sense that higher EI content led to higher transfection efficiencies (Figure 7A). While PEIHEEI 76/24 showed a transfection efficiency of 3440 pg of luciferase/mg of protein, PEIHEEI 7/93 showed a transfection efficiency of as low as 7.5 pg of luciferase/mg of protein. Values for the other copolymers lied between those two with decreasing transfection efficiency with decreasing EI content. The two HEEIs showed transfection efficiencies of 0.78 pg of luciferase/mg of protein (HMW-HEEI) and 9.5 pg of luciferase/mg of protein (LMW-HEEI), respectively. Transfection experiments at a N/P ratio of 6.7 showed similar relative results but with much lower values for luciferase expression per protein mass and high standard deviations (data not shown).

We found a strong correlation between the results of the transfection studies and the structure of our polymers. Linear regression of log transfection efficiency (in nanograms of luciferase per milligram of protein) versus molar ethylene imine content gave a satisfactory correlation coefficient (Figure 7B). The observed trends are in line with the physicochemical experiments: As uptake of complexes into cells imposes certain size and stability requirements on the endocytosed material, it is necessary for successful gene transfer that the cation in polyplexes not only bind DNA but also compact it. According to observations reported by Plank et al. (1999) for branched oligocationic peptides, Chen et al. observed that branched histidine/lysine polymers enhanced the transfection efficiency more effectively than the linear derivative and efficiency was positively correlated with the degree of branching (Chen et al., 2001). The linear polymer had little effect on transfection. Dendrimers showed a correlation between transfection efficiency and the degree of polymeric flexibility due to a different degree of branching after heat treatment (Tang et al., 1996). Uptake of particles into cells as well as the diffusion of complexes in the cytoplasm has been described to increase with reduced sizes of the polymer/DNA complexes (Mahato et al., 2000). Since the condensation of DNA is also known to protect the genetic material from enzymatic degradation (Godbey et al., 2000), the decrease of transfection ability of the complexes formed by copolymers with low EI content could therefore be due to instabilities in physiological medium, dissociation, enzymatic degradation, or aggregation. The issue of complex stability requires further studies. Since we used complexes with N/P 66 and therefore an excess of polymer presumably not associated with the DNA, also the cytotoxicity of the polycations should be taken into consideration. However, cytotoxicity-related effects as the reason for the declining transfection efficiencies are unlikely, since the protein concentrations in cell lysates, an indicator for cell growth, treated with the different polymers were very similar (Figure 7A). The role of the excessive polymer in transfection needs further investigation.

According to the "proton sponge" hypothesis, enhanced buffering of endosomal pH by the polymer should be associated with a high transgene expression. Chen et al. (2001, 2002) reported a significant role of the buffering capacity of histidine/lysine-based polymers in augmenting the transfection efficiency. Gene expression was more effectively reduced by the lysosomotropic buffering agent bafilomycin A1 with higher buffering capacity of the polymers. However, in our experiments, the copolymers showed comparable basicity at the pH of the endosomal/lysosomal compartment, suggesting that the ability of the PEIHEEIs to bind the protons should not be a sufficient factor to ensure a high transfection. This was also suggested by Gebhart and Kabanov (2001) comparing the efficiency of polycations of different monomeric struc-

tures. This point needs further investigation. In contrast, Chen et al. (2002) reported that the optimal transfection depends not only on the structure of the polymer but also on the pH of the endocytic vesicles varying in different cell lines and primary cells.

Although we observed a positive correlation between transfection efficiency and branching of our polycations, the high activity of the linear 22 kDa PEI compared to the 25 kDa branched PEI cannot be explained by this effect. Some authors (Wightman et al., 2001) suggested that this could be due to an aggregation and sedimentation behavior of the polyplexes of the linear form different from that of the branched polymer.

CONCLUSION

In this study, we described five new PEI-related copolymers and their chemical and physicochemical characterization and biological effects. By copolymerization with HEEI, we obtained a family of poly[(ethylene imine)-*co*-*N*-(2-hydroxyethyl-ethylene imine)] copolymers with similar molecular weights and different degree of branching. Polymers with a higher EI content and hence higher branching yielded higher reporter gene expression than polymers with more HEEI. The increase in transfection efficiency could be correlated with a higher ability of DNA binding and condensation and the formation of small sized complexes. Since complexation and condensation are mainly based on electrostatic interactions, the degree of protonation of the polymer is an important factor. The binding efficiency correlated with the higher content of primary and secondary amines as well as the higher pK_a values of the polymers.

Many reports suggested that the molecular weight of the polycation is the most critical factor for successful gene delivery. This study with a series of poly[(ethylene imine)-*co*-*N*-(2-hydroxyethyl-ethylene imine)] copolymers suggests that the polymer structure influences basicity and protonation of the copolymers and leads to different DNA binding, complex size, cytotoxicity, and transfection efficiency. Therefore, the structure seems to be of greater importance than the molecular weight of the polymers. Insight into the structure−function relationship may form the basis for rationalization of the development of improved gene delivery systems.

ACKNOWLEDGMENT

We thank the Department of Pharmacology and Toxicology, University of Marburg, for the supply of rat blood. We thank C. Selignow for technical assistance. Support of this work in part by the Deutsche Forschungsgemeinschaft (DFG) is gratefully acknowledged.

We have recently described a new method for attaching padlock oligonucleotides to supercoiled plasmid DNA at specific sequences. A variant of this method has been developed in order to allow the coupling of targeting moieties to plasmids using a convenient strategy. After sequence-specific winding around the double-stranded target DNA sequence by ligand-induced triple helix formation, the extremities of a triplex-forming oligonucleotide hybridize to each other, leaving a dangling single-stranded sequence, which is then ligated to a hairpin oligonucleotide using T4 DNA ligase. Any targeting moiety may be attached to the hairpin oligonucleotide. This strategy was used to attach an NLS peptide to a luciferase-expressing plasmid. Despite the presence of the padlock oligonucleotide, the reporter gene was efficiently expressed after transfection of the plasmid in HeLa or T24 cells, using either cationic lipids or cationic polymers as transfecting agents. However, no increase in gene expression could be observed as a result of peptide attachment. Nevertheless, the coupling strategy described in this paper may find applications as a tool for plasmid functionalization in other targeting experiments, and may lead to the development of improved vectors for gene therapy.

INTRODUCTION

Plasmids are commonly used as expression vectors for gene transfer into eukaryotic cells in vitro and in vivo. They are generally delivered as a complex with chemical and/or biochemical vectors such as cationic lipids or polymers. Such complexes offer several advantages compared to viral vectors, such as a better safety profile, a lower immunogenicity, the possibility of incorporating a larger expression cassette, and an easier large scale production. However, they suffer from a relatively low efficiency of transfection. Although the mechanism of nonviral gene transfer is not perfectly understood, several obstacles to a good efficiency have been reported, including the passage of DNA accross the cellular membrane, the escape from endosomal compartments, the low metabolic stability of plasmids in the cytoplasm, and the inefficient trafficking of genes to the nucleus (*1*). Therefore, the design of new delivery methods has been the focus of intense research efforts in the past years to overcome these limitations.

Exploiting naturally existing biological pathways is a tempting option for improving plasmid targeting and trafficking. Interactions between a ligand on the plasmid/vector complex and an extracellular receptor may enhance cell-specific targeting, whereas the use of signal sequences that are recognized by the intracellular transport machinery may improve intracellular trafficking. The targeting ligand may be coupled to the DNA condensing agent, for example polylysine (*2*) or PEI (*3*). These condensing agents dissociate from the plasmid once inside the cells. Therefore, there is a need for methods that allow for conjugation of functional domains directly to plasmid DNA, especially when the goal is to improve the nuclear localization of the plasmid. These conjugation methods must maintain the activity of the plasmid, i.e., the expression cassette must remain fully functional. This can be achieved using sequence-specific targeting methods. Two different strategies have been reported to date. The first one involves the formation of a covalent triple helix (*4*); the other one is based on the very strong affinity of PNA for locally denatured double-stranded DNA (*5*−*7*). These methods have been used to link NLS (nuclear localization signal) peptides to plasmids in order to increase plasmid uptake into the nucleus, however with limited success (*4*, *5*).

We have developed a new methodology to conjugate a targeting ligand to plasmid DNA without any covalent modification of the DNA backbone. We report here the synthesis and characterization of plasmid-peptide conjugates. The ability of an NLS peptide to enhance gene delivery has been tested in cellular models.

EXPERIMENTAL PROCEDURES

Oligonucleotide and Peptide Synthesis. The following oligonucleotides were synthesized by Eurogentec (Herstal, Belgium): the 63-mer triplex-forming oligonucleotide (TFO) 5′CATCGACCTAGTTCGACGCTAGCTTTTTGTTGGGTTGGTTTGTTTTCACGTGGAGCTACTAGG3′, the nonmodified 32-mer hairpin 5′TCGATGTCCGGATTGGCTTTTGCCAATCCGGA3′, the amino-modified hairpin 5′TCGATGTCCGGATTGGCTTXTGCCAATCCGGA3′ where X is an amino-modifier C6 dT (Glen Research, USA), and the TRAP oligonucleotide 5′CTTTCCTTCTCTCCTTTTTGGAGAGAAGGAAAGTTTTTGTTTGGTTGTGTGG3′. The 32-mers were 5′-phosphorylated during synthesis. All oligonucleotides were ethanol-precipitated, and their concentration was calculated using a nearest-neighbor model for extinction coefficients (*8*). Synthesis of the triplex stabilizing agent BQQ (6-[3-(dimethylamino)propyl]amino-11-methoxybenzo[*f*]quino-[3,4-*b*]quinoxaline) has been described elsewhere (*9*). Peptides containing the wild-type SV40 large T NLS sequence (NLS) (PKKKRKVEDPYC) or a mutated

SV40 large T NLS sequence (mNLS) (PKTKRKVEDPYC) were obtained from Sigma-Genosys (U.K.).

Synthesis of the Oligonucleotide-Peptide Conjugate. SMCC [*N*-succinimidyl 4-(*N*-maleimidomethyl)-cyclohexane-1-carboxylate ester] was obtained from Sigma. The NLS peptide was linked to the hairpin oligonucleotide using a previously described method (*10*, *11*). Briefly, 10 nmol of oligonucleotide was resuspended in 150 μL of 0.1 M Tris−borate, pH 7.0. Then 150 μL of SMCC (0.3 M in DMF) was added, and the mixture was incubated at room temperature for 2 h with gentle agitation. The sample was purified on a nick-spin column (Amersham Pharmacia Biotech) preequilibrated with PBS, to remove the excess SMCC. An equal volume of peptide (2 mg/mL) was then added, and the mixture was left overnight at room temperature with gentle agitation. The conjugate was purified by PAGE.

Formation of Plasmid−Oligonucleotide Complexes. For experiments with radiolabeled molecules, 10 pmol of TFO was incubated in 20 μL of T4 Polynucleotide Kinase (PNK) buffer (New England Biolabs, NEB) with 10 μCi of [γ-^{32}P]ATP (Amersham, >5000 Ci/mmol) and 5 units of T4 PNK (NEB) for 1 h at 37 °C. Unincorporated [γ-^{32}P]ATP was removed using Micro Bio-Spin columns (BIO-RAD). The 5′-labeled TFO (20 nM) was mixed with 50 nM plasmid, 100 nM 32-mer hairpin oligonucleotide, and 20 μM BQQ in T4 DNA ligase buffer. This mixture was heated to 80 °C and slowly cooled to 37 °C. Then, 40 units of T4 DNA ligase (NEB) was added, and the samples were incubated at 37 °C for 1 h. For probing the circular structure of some of the products of the reaction, 0.5 μL (50 units) of Exonuclease III (NEB) was added after heat inactivation of the ligase, and the sample was further incubated for 30 min at 37 °C. Reaction products were analyzed on denaturing 8% polyacrylamide gels. The gels were dried and exposed on phosphorimager screens.

For nonradiolabeled plasmid preparations, 300 pmol of TFO was 5′-phosphorylated using the same protocol as above except that the solution contained 1 mM cold ATP instead of the radioactive label. For attaching the oligonucleotide to the plasmid, the same process as above was also adopted, except that 200 nM plasmid, 400 nM TFO, 600 nM hairpin oligonucleotide, and 133 units of DNA ligase were used. To remove BQQ from the triplex, the sample (10 μL) was first diluted to 50 μL so that the final buffer concentration was 40 mM Tris-HCl, pH 8.0, 80 mM NaCl, 16 mM $MgCl_2$, and the solution contained 5 μM TRAP oligonucleotide. The samples were heated to 80 °C and then slowly cooled to 37 °C. Then, 50 μL of 40 mM spermidine was added, and the samples were left for 30 min at room temperature with frequent vortex-mixing, to allow for plasmid compaction. After centrifugation, the pellet was washed with 200 μL of a solution containing 50% 2-propanol, 10 mM $MgCl_2$, 300 mM NaCl, and 25 mM EDTA as previously described (*12*). Plasmid was resuspended in 20 μL of Tris−EDTA buffer (10 mM Tris, pH 8.0, 0.1 mM EDTA). For larger scale preparations, all these volumes and quantities were increased up to 10-fold.

Gel-Shift Experiments. One microgram of plasmid was diluted in 18 μL of restriction enzyme (RE) buffer containing 10 mM BisTris-propane-HCl, 10 mM $MgCl_2$, 1 mM dithiothreitol (pH 7.0 at 25 °C), and 2 μM BQQ. The samples were heated to 80 °C and slowly cooled to 37 °C. Then, 2 μL of a solution containing 5 units of *Xmn*I, 5 units of *Dra*III, and 1 μg/μL BSA was added to the sample. Digestion was carried out for 2 h at 37 °C. Then, samples were mixed with 5 μL of 50% glycerol and loaded on nondenaturing polyacrylamide gels. The 6% polyacrylamide gel was prepared with a 29:1 acrylamide-to-bisacrylamide ratio. The gel and buffer contained TBM (100 mM Tris/90 mM boric acid, 1 mM EDTA, pH 8.3, 10 mM $MgCl_2$). They were run at 4 °C, then stained for 15 min with SybrGreen (Molecular Probes), washed for an additional 15 min in water, and then imaged by UV transillumination.

Cell Transfection. HeLa cells (ATCC) were grown in modified Eagle's medium (MEM) containing 2.5 mM glucose, supplemented with 2 mM L-glutamine, 10% fetal bovine serum, 100 units/mL penicillin, and 100 μg/mL streptomycin. The T24 cell line was grown in DMEM containing the same supplements. Cells were grown at 37 °C in a 5% CO_2/air incubator. One day before the transfection assay, 24-well culture plates were seeded with 50 000 cells/well.

For transfections using PEI, 75 μL of a solution containing 150 mM NaCl and PEI 25 kDa (Sigma) at a concentration of 1 mM amino groups was prepared from a 10 mM stock solution. The amount of DNA for 3 wells (3 μg) was diluted into 75 μL (final volume) of 150 mM NaCl. Both solutions were left at room temperature for 10 min, vortexing every 5 min. Then, they were mixed together, and incubated at room temperature for 10 min, again vortexing every 5 min. The concentrations that were used correspond to a N/P ratio of 8:1, which was shown to give the best transfection efficiencies. One milliliter of culture medium without serum was then added. Cells were washed with PBS (Gibco BRL), and then transfected with 350 μL of the PEI/DNA mixture. Cells were incubated for 3 h at 37 °C; then the transfection medium was changed to the serum-containing culture medium.

For transfection with Superfect (Qiagen), 3 μg of DNA was diluted to 165 μL in the cell culture medium devoid of serum and of antibiotics, then vortexed briefly. Superfect was then added at a lipid:DNA mass ratio of 5:1. Volume was adjusted to 180 μL with the same medium, and the solution was vortexed. After 10 min incubation at room temperature, 1.05 mL of medium containing serum and antibiotics was added to the lipid−DNA mixture. Cells were washed with PBS, and 390 μL of the DNA solution was added. After 2 h, cells were washed with PBS, and 1 mL of cell culture medium was added.

Luciferase gene expression was measured by a luminescence assay. The cells were washed twice with PBS and lysed with 100 μL of cell culture lysis reagent (Promega) at room temperature for 30 min, with gentle agitation. Samples were then transferred to 96-well plates. Luciferase expression was measured using the Luciferase Assay Reagent (Promega). Light emission was measured by integration over 10 s using a multilabel counter Victor^2 (EG&G Wallac, Evry, France). Light emission was normalized to the protein concentration determined using the Biorad Protein Assay (Biorad). Briefly, 250 μl of a 5 times dilution of the supplied dye reagent concentrate was added to 5 μL of cell lysate or of serial dilutions of a BSA reference solution, and the absorbance at 595 nm was measured in 96-well microtiter plates using the same multilabel counter as above.

RESULTS

Oligonucleotide Design. We designed a new strategy for plasmid modification employing two self-complementary oligonucleotides: a 63-mer TFO with a stem−loop structure, and a 32-mer hairpin oligonucleotide. A sequence made of G and T located in the loop of the TFO

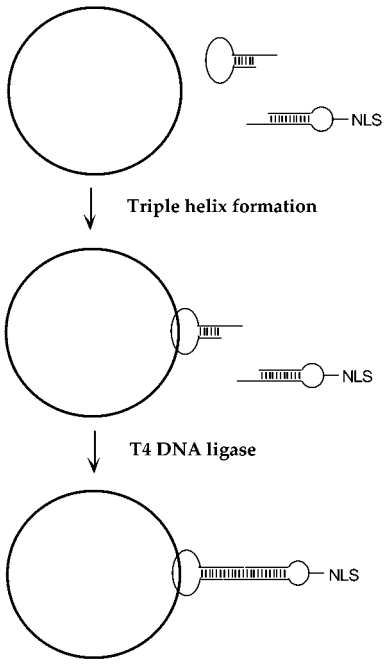

Figure 1. Strategy for the coupling of an NLS peptide to a plasmid. The triplex-forming oligonucleotide binds to an oligopurine·oligopyrimidine sequence in the phage f1 replication origin. This requires a heating step where the oligonucleotide opens and winds around the double-stranded DNA. Then this TFO is ligated to a hairpin oligonucleotide which has previsouly been conjugated to a peptide.

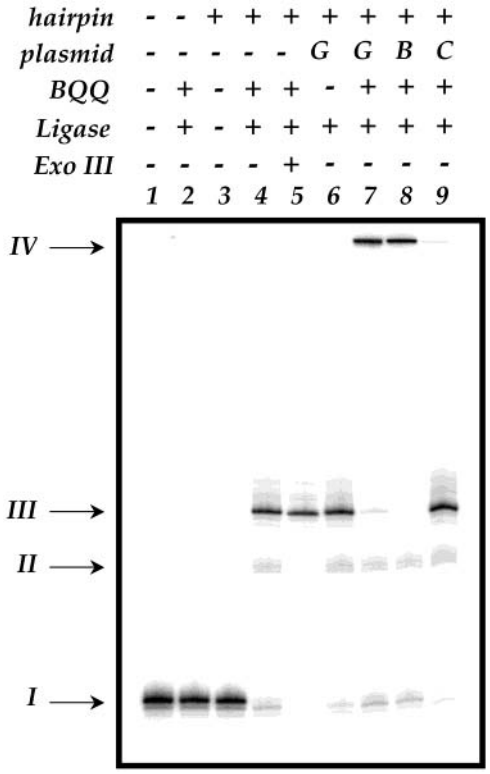

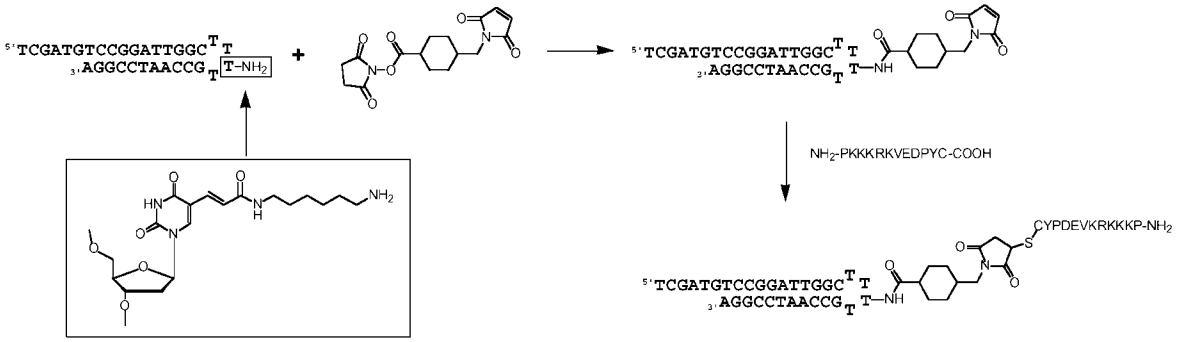

Figure 2. Autoradiogram of a denaturing polyacrylamide gel, showing the attachment of the padlock oligonucleotide to a plasmid. The radiolabeled 63-mer TFO was incubated in the absence or presence of plasmid and treated as described at the top of the gel (see also Experimental Procedures). The different plasmids that have been used are as follows: G, pGL3; B, pBl; C, pBR322. The presence of BQQ, as well as the various enzymatic reactions (ligation and digestion) that were carried out, is also indicated. Band I corresponds to a linear 63-mer oligonucleotide, band II to a linear 95-mer, band III to a circular 95-mer, and band IV to a circular 95-mer catenated to a plasmid.

can form a triple helix in the presence of a triplex-stabilizing agent by binding to a sequence in the phage f1 replication origin, as already described in a previous paper (*13*). This sequence was present on both the pBl (pBluescript SK+, Stratagene) and the pGL3 (pGL3 control, Promega) plasmids. The 3′- and 5′-regions of the TFO can hybridize to each other, thereby forming a short double-stranded stem and leaving a single-stranded dangling 5′-end, which can hybridize to a complementary sequence at the 5′-end of the hairpin oligonucleotide. A length of 6 bp was chosen for the stem so that it can dissociate upon heating, thereby allowing during the cooling step the formation of a triple helix between the loop of the TFO and the target double-stranded sequence on the plasmid, followed by the rehybridization of the complementary sequences of the stem. The length of the complementary single-stranded ends should ensure proper hybridization of the oligonucleotides for the ligation to occur. In the hybridized dumbbell-like structure, ligation of the 5′-end of each oligonucleotide to the 3′-end of the other should result in the formation of a circular 95-mer oligonucleotide (see Figure 1).

Sequence-Specific Formation of a Catenated Plasmid−Oligonucleotide Complex. The radiolabeled 63-mer TFO and the 32-mer hairpin oligonucleotide were incubated in T4 DNA ligase buffer, heated to 80 °C, and slowly cooled to allow for hybridization of the single-stranded ends. T4 DNA ligase was then added, and the sample was incubated at 37 °C for 1 h. This led to the formation of two radiolabeled species with a slower migration rate, the slowest one being the most abundant (Figure 2 , lane 4). To identify these bands, the sample was treated with exonuclease III, which led to the disappearance of the fastest band and of the shorter nonreacted oligonucleotides (lane 5). The fastest band should therefore correspond to a linear 95-mer, whereas the slowest band is a circular 95-mer, as circular oligonucleotides are resistant to digestion by exonuclease III. When the same process was performed in the presence of pGL3 (lane 7) or pBl (lane 8) plasmid and 20 μM BQQ, a band with a very slow migration rate was observed, and the band corresponding to the circular 95-mer almost disappeared. This suggests that the complex formed in this reaction was made of the circular oligonucleotide catenated to the plasmid, as already described in our previous studies (*13, 14*). The catenation was not observed in the absence of the triplex-stabilizing ligand (lane 6), or if plasmid pBR322 was used, which does not contain the phage f1 replication origin recognized by the triplex-forming region of the 63-mer hairpin oligonucleotide (lane 9). Neither was it observed if the ligation reaction was carried out without heating or if the sample was treated with a restriction enzyme which linearizes the plasmid after removal of the triplex-stabilizing agent (data not shown). These results clearly show that the 63-mer and 32-mer oligonucleotides can be assembled into a circular 95-mer oligonucleotide with a dumbbell-like structure catenated to a supercoiled plasmid. Analysis of the sample by agarose gel electrophoresis confirmed that the supercoiled conformation was not affected (data not shown).

Construction and Characterization of Peptide-Plasmid Conjugates. The hairpin oligonucleotide can be modified in order to allow the coupling of a targeting moiety, such as an NLS peptide, for example. A peptide containing the NLS sequence of the wild-type SV40 large T antigen was synthesized and covalently linked to a 32-

Scheme 1. Reaction Scheme for the Synthesis of the Oligonucleotide-NLS Peptide Conjugate

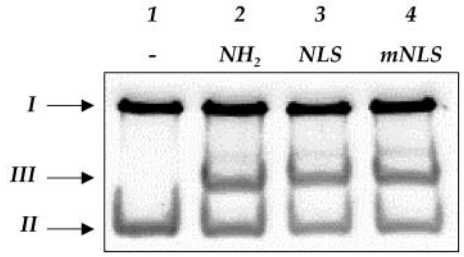

Figure 3. Yield determination by a gel-shift assay. Modified pGL3 plasmids were prepared as indicated under Experimental Procedures, using an excess of 5′-phosphorylated 63-mer TFO and the various 32-mer hairpin oligonucleotides (NH2, carrying an amino group; NLS, carrying an NLS peptide; mNLS, carrying the mutated NLS peptide). After purification by spermidine precipitation, samples were digested by *Xmn*I and *Dra*III to produce a short restriction fragment containing the ORI sequence. Samples were then loaded on a 6% native polyacrylamide gel containing 10 mM $MgCl_2$, stained with Sybr Green I, and imaged with a camera. I and II refer to the restriction fragments of 4704 and 552 bp, respectively. III corresponds to fragment II shifted by the presence of a catenated padlock oligonucleotide.

mer hairpin oligonucleotide containing a thymine with a C(5) amino group in the loop region, using a previously described method (*10, 11*) (see Experimental Procedures). Scheme 1 illustrates the reaction scheme used to prepare the peptide-oligonucleotide conjugates. The yield of conjugate formation was about 50%, which led to an overall yield of 10% after purification, which is in agreement with previous reports.

The pGL3 plasmid, which expresses the firefly luciferase reporter gene, was chosen as a substrate for the reaction, as further experiments were planned to investigate the effects of plasmid modification on transgene expression. Plasmid pGL3 was mixed with the 63-mer TFO, the peptide-oligonucleotide conjugate, and the triplex-stabilizing agent, and the circularization reaction was allowed to proceed as described above. After elimination of both the free oligonucleotides and the triplex-stabilizing agent (see Experimental Procedures and ref *12*), the yield of plasmid modification was measured using the previously described band shift assay (*13*). Briefly, the plasmid was digested in the presence of BQQ by *Xmn*I and *Dra*III to give a 552 bp fragment containing the target sequence, and the samples were analyzed using nondenaturing polyacrylamide gel electrophoresis. When the plasmid was catenated to the circular oligonucleotide, the 552 bp band migrates less far in the gel (Figure 3 , lane 2). Approximately 60% of the fragment was shifted, showing that at least 60% of the plasmids were carrying the circular oligonucleotide at the expected site. In fact, when experiments carried out with radiolabeled oligonucleotides in the presence of an excess of plasmid, only 60% of the labeled oligonucleotide comigrated with the plasmid (see Figure 2). Some truncated oligonucleotides are not circularized, and some are circularized outside of the plasmid. As explained in our previous study (*13*), the yields varied between different oligonucleotide synthesis batches, and were therefore highly influenced by oligonucleotide quality. This parameter is even more important in the present construct as the oligonucleotides have to be ligated to each other at both ends. Importantly, the yield was not affected by the presence of a conjugated peptide on the 32-mer hairpin oligonucleotide (Figure 3, lanes 3 and 4).

Transfection Studies. HeLa and T24 cells can be transfected with the pGL3 plasmid by using a cationic lipid formulation (Superfect) or a polycation, polyethyleneimine (PEI). A series of experiments was undertaken with both cell types and both transfection methods in order to observe the effect of padlock oligonucleotide attachment and peptide grafting on transfection efficiency. Luciferase activity was measured 24 h after transfection. As shown in Figure 4 (A and B), both cell types were efficiently transfected with cationic PEI/DNA complexes (N/P ratio of 8). To check that the protocol used for plasmid modification did not influence transfection efficiency, cells were also transfected using complexes formed with DNA which had been subjected to the treatment used for plasmid modification, but in the absence of oligonucleotides (i.e., the treatment included addition of ligand, heating, addition of ligase, and purification). No significant change in the level of luciferase expression was observed. This was true also for plasmids carrying the amino-substituted oligonucleotide, but no change in transfection efficiency could be observed when the NLS peptide was linked to the plasmid, or when a mutated NLS was used. To check whether using a Lipoplex would lead to different results, T24 cells were also transfected with Superfect as a transfecting agent. Again, no significant change in transfection efficiency could be observed when the plasmids had been submitted to the same treatments and/or modifications as above (Figure 4C).

DISCUSSION

Our goal was to develop a versatile method for attaching a peptide to a plasmid in an irreversible way without affecting the chemical structure of the plasmid. This could have been achieved using the previously described method for padlock oligonucleotide formation, which involves the use of a long TFO (>50 nt) and a short template oligonucleotide for juxtaposition of the 3′- and 5′-ends followed by enzymatic ligation. The peptide may have been linked to the TFO or to the template. However, the synthesis and purification of a peptide-oligonucleotide conjugate is much more difficult with a long oligonucle-

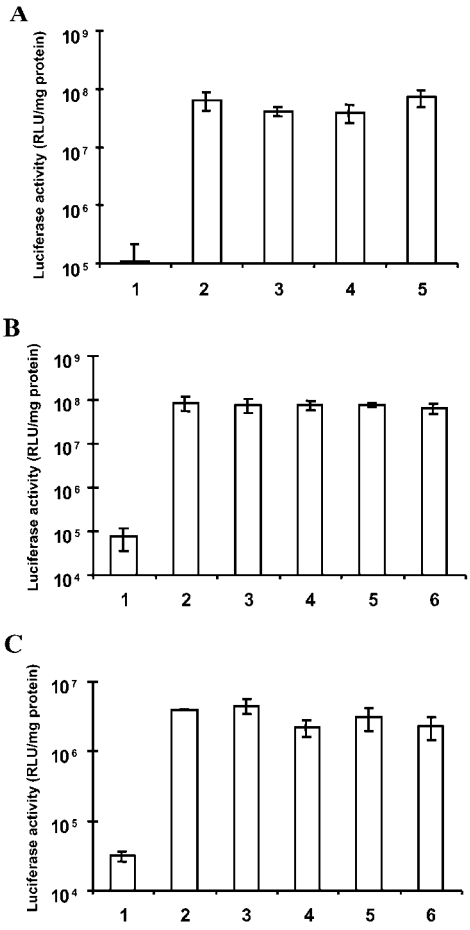

Figure 4. Transgene expression after transfection of plasmid-NLS conjugates. HeLa cells (A and B) and T24 cells (C) were transfected with the nonmodified plasmid and the plasmid which has been submitted to various procedures, using either PEI (A) or Superfect (B and C). Luciferase expression was measured after 24 h and normalized for protein content ($n = 3$ in all cases). (1) No plasmid; (2) nonmodified plasmid; (3) plasmid was treated and purified as for modification, except that the oligonucleotides and the ligase were not added; (4) plasmid carrying an amino-oligonucleotide; (5) plasmid carrying one wild-type NLS peptide; (6) plasmid carrying one mutant NLS peptide.

otide than with a short one, and the template oligonucleotide was linked to the catenated plasmid by Watson−Crick hydrogen bonds, which may be disrupted within cells. Moreover, linking a peptide may have interfered with triplex formation or template hybridization. Therefore, we chose to devise a new approach in which a short oligonucleotide could be used to introduce a chemical modification in an irreversible manner. This method involves the use of two hairpin oligonucleotides which have complementary single-stranded ends and therefore can be ligated to each other using T4 DNA ligase (see Figure 1). One of them can form a triple helix by binding to an oligopurine•oligopyrimidine sequence which is present in the replication origin of phage f1, and therefore in the pGL3 plasmid that we use in gene expression studies. After triple helix formation, the 3′- and 5′-ends of the oligonucleotide reassociate and are ligated to the shorter oligonucleotide. In the resulting complex, the plasmid is catenated to a dumbbell-like circular oligonucleotide. If the short hairpin oligonucleotide has been conjugated to a targeting moiety, this moiety becomes irreversibly linked to the plasmid, although the covalent structure of the plasmid has not been changed. The same conjugated oligonucleotide can be adressed to different double-stranded DNA targets by changing the TFO sequence.

We have used this strategy to construct plasmids carrying a cationic peptide, the NLS from SV40 large T antigen. The synthesis of the oligonucleotide-peptide conjugate was relatively simple. This conjugate was linked to the plasmid with a good efficiency, the yield being solely limited by the quality of the olignucleotides. The use of a peptide-oligonucleotide conjugate did not decrease the yield of plasmid modification when compared to a nonmodified oligonucleotide. This reaction did not alter the supercoiled conformation of the plasmid nor its biological properties as shown by identical transgene expression levels. However, plasmids modified with one single NLS peptide did not display higher transgene expression levels than nonmodified plasmids.

Other groups have attempted to link NLS peptides to DNA. When a single NLS was linked to a plasmid by covalent triple helix formation, no enhancement was observed (*4*). An improvement was observed when the NLS was linked at the end of a linear DNA fragment (*11*), when several peptides were linked using PNAs (*5*), or when the plasmid was condensed with positively charged peptides containing NLS (*15*). The structural context and the mode of attachment that were used in our study were exactly the same as the ones used for the linear DNA study (*11*). Therefore, a single NLS peptide may be sufficient only when the linear DNA can creep inside the nucleus through the nuclear pore. Supercoiled DNA has a modest size which may be compatible with the passage through the nuclear pore. However, the forces, the process, and the folding pathway may be different than with linear DNA. It may be possible that supercoiled DNA requires the presence of several peptides, or even NLS peptides that would differ in the sequence or in the conjugation scheme. The lack of effect of the grafting of a single NLS peptide in our experimental system may also be explained by the fact that luciferase expression was observed after 24 h, and therefore the breakage of the nuclear envelope during cell division may hide the potential benefits that nuclear targeting moieties would provide on nondividing cells.

Other targeting moieties have been linked to plasmids. When a dexamethasone-psoralen conjugate was photocross-linked to a plasmid, an increase of plasmid nuclear uptake was observed (*16*). Binding occurred randomly on the plasmid, and the authors chose conditions that resulted in a mean of one psoralen conjugate per DNA molecule, as more would have resulted in plasmid inactivation. In another study, the protein transferrin was linked to a plasmid using PNA, and these complexes were shown to improve slightly the efficiency of gene delivery into muscle cells (*6*). In this last study, the presence of a conjugated protein in the PNA was shown to decrease its binding efficiency. Both of these approaches may be accommodated with our plasmid modification method, which gives a well-defined product and ensures that gene expression will not be perturbed and that the targeting moiety will not dissociate from the plasmid unless the oligonucleotide or the plasmid is cleaved by a cellular endonuclease or the two molecules are decatenated by an enzymatic process. This is not likely to occur before the plasmid has reached the nucleus.

In conclusion, we have designed a novel versatile method for coupling peptides to plasmid DNA. This technology allows an efficient and well-characterized modification and maintains plasmid integrity and tran-

scriptional activity. The present strategy may be used for coupling other ligands to plasmid DNA, such as cell-targeting antibodies, internalized molecules, or fluorescent reporters. In previously described methods for site-specific incorporation of peptides, for example, using PNA or psoralen-conjugated TFOs, the label is bound to a fixed site on the DNA. Here, the peptide may slide along the plasmid, thereby increasing its accessibility and facilitating interaction with its target. Despite the absence of improvement by attaching one NLS peptide, our strategy may be extended to the use of other targeting agents or the coupling of several peptides. Therefore, the full potential of this strategy still remains to be explored.

ACKNOWLEDGMENT

We thank Dr. Daniel Sherman for helpful discussions, Hélène Walbott for participating in some experimental work, Dr. Jean-Christophe François for advice in cell culture experiments, and Evelyne Charlier for plasmid preparation. T.R. was supported by a Bourse de Docteur Ingénieur from CNRS and a grant from the Association Française contre les Myopathies (AFM). This work was supported by the French Ministery of Research (ACI jeunes chercheurs 2000).

A Trithiolate Tripodal Bifunctional Ligand for the Radiolabeling of Peptides with Gallium(III)

Leonard G. Luyt and John A. Katzenellenbogen*

Department of Chemistry, University of Illinois, Urbana, Illinois 61801. Received May 20, 2002; Revised Manuscript Received July 2, 2002

A tripodal bifunctional chelator for gallium has been prepared with a chelation core consisting of three thiols and a tertiary amine. The synthesis proceeds in 13 steps with an overall yield of 22%. An aromatic amine is available for conjugation to peptides through carbodiimide coupling. Gallium(III) complexes were readily prepared from both the bifunctional chelator and a phenylalanine-conjugated system. These complexes underwent stability evaluation and were found to be stable to ligand exchange and enzymatic hydrolysis. This bifunctional chelator appears to be suitable for conjugation to peptides for the preparation of gallium radiopharmaceuticals.

INTRODUCTION

Gallium-68 ($t_{1/2}$ = 68 min) is considered to be a promising radionuclide for use in positron emission tomography (PET) and has been used in a number of clinical studies. A particular convenience associated with the use of ^{68}Ga is that it can be obtained from a ^{68}Ge/^{68}Ga generator system; thus, PET imaging can be done with this isotope without the need for an on-site cyclotron (*1*). Gallium-67 ($t_{1/2}$ = 3.3 days) is a gallium isotope that has been used for single-photon emission computed tomography (SPECT) for many years, even though its long half-life limits its usefulness as an imaging radionuclide.

Current gallium-based radiopharmaceuticals are, for the most part, simple metal−ligand complexes, such as Ga-citrate.(*2*) Recently, however, a number of gallium radiopharmaceuticals have been successfully developed by the conjugation of a gallium chelation unit to a large biomolecule (*3*−*6*). We are interested in developing methods for radiolabeling large biomolecules, such as peptides and proteins, with gallium for use in receptor-based imaging. Ideally, a chelation unit for labeling biomolecules with gallium for in vivo use should have the following characteristics: (a) it should bind the metal with high kinetic stability, (b) it should have a single site for chelation to facilitate complete spectroscopic characterization of a single product, and (c) and it should have bifunctional character that will allow its conjugation to a variety of biomolecules through a single linking site.

A 4-coordinate tripodal S_3N ligand for gallium(III) was previously described by Koch and co-workers and was found to be stable, neutral, and uniquely, for a gallium(III) complex, able to pass through the blood−brain barrier (*7*−*10*). In contrast to indium and iron complexes with the same chelate system, the gallium(III) complex retains its tetrahedral geometry in the presence of water and DMF. This tripodal ligand appeared to be a suitable candidate for the radiolabeling of peptides with gallium, through a pendant approach as depicted in Figure 1.

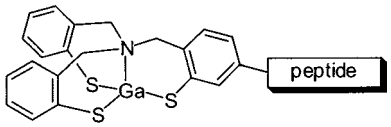

Figure 1. A tripodal gallium(III) bioconjugate.

Herein is a description of the synthesis of this bifunctional chelator, its conjugation to a biomolecule model, and a discussion of the stability of the resultant gallium(III) complexes.

EXPERIMENTAL SECTION

Reagents and solvents were purchased from Acros, Aldrich, Fisher, Strem, or TCI. $[GaCl_4][PPh_4]$ was prepared as previously reported (*11*). Diethyl ether, methylene chloride, and tetrahydrofuran were dried by a solvent delivery system (using activated neutral alumina columns) designed by J. C. Meyer. All air-sensitive reactions were carried out under a nitrogen or argon atmosphere, using flame- or oven-dried glassware. Reaction progress was monitored by analytical thin-layer chromatography (silica). Flash chromatography was performed using Woelm silica gel (0.040−0.063 mm) packing. Hexane for chromatography was distilled prior to use.

^{1}H and ^{13}C NMR spectra were obtained using a Unity 400, Unity 500, or Unity INOVA 500NB Varian FT-NMR spectrometer. Chemical shifts (δ) are reported in parts per million downfield from internal tetramethylsilane and referenced from solvent resonances. NMR coupling constants are reported as absolute values in Hertz. Low-resolution electron impact (EI) mass spectra and high-resolution EI mass spectra (HRMS) were obtained on Micromass 70-VSE, or Micromass 70-SE−4F spectrometers. Both low- and high-resolution fast atom bombardment (FAB) mass spectra were obtained on Micromass ZAB−SE and 70-SE−4F spectrometers, respectively. Melting points were determined on a Thomas-Hoover melting point apparatus and are uncorrected.

HPLC analysis was performed with a ThermoQuest Spectrasystem P4000/AS4000/UV1000, with the UV detector set to 254 nm. A Microsorb-MV C_{18} reversed-phase column (5 μm, 100 Å) was used, with an isocratic eluent of 80% MeOH/20% water at 1.0 mL/min.

(*S*-Benzylthio)salicylic Acid. Thiosalicylic acid (6.33 g, 41.1 mmol) was dissolved in 100 mL of ethanol and 100 mL of 1 M NaOH solution. The solution was cooled to 0 °C; then benzyl bromide (5.13 mL, 43.1 mmol) was added, and the solution was warmed to room temperature and stirred for three h. A 1 M HCl solution was added to acidify the reaction, and the crude product was collected by filtration and then recrystallized from benzene to yield 9.95 g (99%) of off-white needles: mp 186−187 °C. ^{1}H NMR (d_6-acetone): δ 4.21 (s, 2H), 7.20 to 7.53 (m, 8H), 8.01 (m, 1H), 11.33 (br s, 1H). ^{13}C NMR (d_6-acetone): δ 37.24, 124.66, 126.68, 127.98, 128.21, 129.29, 130.00, 132.11, 133.24, 137.64, 143.26, 167.55. MS (EI, 70 eV): *m*/*z* 244 (15.9%, M^+), 91 (100%, SBn).

2-(Benzylthio)benzyl Alcohol (1). A three-necked, flame-dried flask was filled with 30 mL of THF and 16 mL of 1.0 M BH_3·THF and then cooled on an ice-bath (0 °C). To the flask was added (benzylthio)salicylic acid (2.53 g, 7.85 mmol) dissolved in 30 mL of THF, and the reaction was stirred at 0 °C for 1 h and then at RT for 3 h. To this was carefully added 40 mL water, and stirring was continued for 1 h. Solid K_2CO_3 was added until the solution was saturated, and the layers were separated. The organic layer was evaporated to dryness, partioned between ether and water, and extracted into ether (×2). The original aqueous layer was extracted with ether (×2), and all organics were combined, washed with 1 M NaOH, water, and brine, dried over $MgSO_4$, evaporated, and dried under vacuum. The solid product was recrystallized from diethyl ether/petroleum ether (37−54 °C) to give colorless needles (1.77 g, 97%): mp 50 °C (lit. 48.5−49.5 °C) (*10*). ^{1}H NMR ($CDCl_3$): δ 1.97 (br s, 1H, OH), 4.05 (s, 2H, CH_2S), 4.61 (s, 2H, CH_2O), 7.17 to 7.40 (m, 9H). ^{13}C NMR ($CDCl_3$): δ 39.88, 63.58, 127.29, 127.34, 128.27, 128.41, 128.50, 128.75, 131.84, 134.05, 137.36, 141.76. MS (EI, 70 eV): *m*/*z* 230 (7.6%, M^+), 139 (61.9%, M-SBn), 91 (100%, SBn).

2-(Benzylthio)benzyl Bromide (2). A flame-dried flask was charged with benzylic alcohol **1** (1.71 g, 7.43 mmol) dissolved in 100 mL of diethyl ether. After cooling to 0 °C, 0.78 mL of freshly distilled PBr_3 (8.18 mmol) was added, and the reaction was stirred at 0 °C for 15 min. then at RT for 1 h. The reaction was quenched with methanol; then water was added, and the organic layer was washed with sat. $NaHCO_3$, water, brine, dried over $MgSO_4$, evaporated and dried under vacuum yielding 2.12 g (97%) of a clear, colorless oil. ^{1}H NMR ($CDCl_3$): δ 4.14 (s, 2H, CH_2S), 4.61 (s, 2H, CH_2Br), 7.20 to 7.39 (m, 9H). ^{13}C NMR ($CDCl_3$): δ 32.08, 39.65, 127.29, 127.39, 128.48, 128.92, 129.14, 130.58, 132.11, 135.95, 137.09, 138.66. MS (EI, 70 eV): *m*/*z* 294 (5.1%, M^+), 292 (5.0%, M^+), 213 (21.9%, M-Br), 91 (100%, SBn); HRMS calcd $C_{14}H_{13}BrS$, 291.9921, found, 291.9924.

4-Nitro-2-thiocyanatobenzoic Acid (3). This material was prepared from 2-amino-4-nitrobenzoic acid by diazotization followed by treatment with copper thiocyanate, as previously described (yield 86%) (*12*). ^{1}H NMR (CD_3OD): δ 8.29 (dd, 1H, J = 8.4, 1.9 Hz), 8.36 (d, 1H, J = 8.4 Hz), 8.68 (d, 1H, J = 1.9 Hz). ^{13}C NMR (CD_3OD): δ 112.11, 123.13, 123.54, 133.36, 134.26, 134.77, 151.99, 167.95. MS (EI, 70 eV): *m*/*z* 224 (17.9%, M^+), 197 (100%, M − CN); HRMS calcd $C_8H_4N_2O_4S$, 223.9892, found, 223.9888.

2,2′-Dithiobis(4-nitrosalicylic Acid) (4). This material was prepared from **3** as previously described in 86% yield (*12*). ^{1}H NMR (d_6-DMSO): δ 8.14 (dd, 2H, J = 2.4, 8.8 Hz), 8.26 (d, 2H, J = 8.8 Hz), 8.38 (d, 2H, J = 2.4 Hz). ^{13}C NMR (d_6-DMSO): δ 119.94, 121.33, 133.31, 133.61, 140.69, 150.25, 166.56.

4-Nitrothiosalicylic Acid. Disulfide **4** (2.05 g, 5.16 mmol) was dissolved in 150 mL of abs ethanol and heated to 70 °C. Sodium borohydride (0.78 g, 20.6 mmol) was added portionwise. The reaction was heated at reflux for 90 min (TLC, 40% MeOH/60% $CHCl_3$), cooled, poured into 300 mL of water, and acidified with concentrated HCl. The product was extracted into diethyl ether (×3), washed with water, dried over Na_2SO_4, and filtered, the solvent was evaporated, and the product was dried under vacuum to yield 1.91 g (93%) of yellow crystals: mp 267−268 °C. ^{1}H NMR (CD_3OD): δ 7.95 (dd, 1H, J = 2.1, 8.6 Hz), 8.20 (d, 1H, J = 8.6 Hz), 8.33 (d, 1H, J = 2.1 Hz). ^{13}C NMR (CD_3OD): δ 119.74, 126.14, 132.55, 134.00, 142.64, 150.81, 168.20. MS (EI, 70 eV): *m*/*z* 199 (9.1%, M^+), 181 (100%, M-OH_2); HRMS calcd $C_7H_5NO_4S$, 198.9939, found, 198.9937.

2-(Benzylthio)-4-nitrobenzoic Acid (5). To a solution of 4-nitrothiosalicylic acid, prepared above, (1.81 g, 9.08 mmol) in 60 mL of abs ethanol were added 30 mL of 1 M NaOH and 1.1 mL (9.25 mmol) of benzyl bromide. The solution was stirred at 0 °C for 1 h and then at RT for 2 h (TLC, 30% MeOH/70% $CHCl_3$). Water (30 mL) was added, followed by 32 mL of 1 M HCl. The mixture was cooled to 0 °C, and the product, which precipitated, was collected by filtration to yield, after drying, 2.12 g (81%) of a yellow crystalline solid: mp 194−196 °C. ^{1}H NMR (CD_3OD): δ 4.30 (s, 2H), 7.25 (m, 1H), 7.32 (m, 2H), 7.47 (m, 2H), 7.97 (dd, 1H, J = 2.2, 8.5 Hz), 8.12 (d, 1H, J = 8.5 Hz), 8.25 (d, 1H, J = 2.2 Hz). ^{13}C NMR (CD_3OD): δ 37.88, 119.43, 121.66, 128.56, 129.68, 130.26, 133.38, 134.30, 137.17, 145.61, 151.05, 168.03. MS (EI, 70 eV): *m*/*z* 289 (6.3%, M^+), 91 (100%, Bn); HRMS calcd $C_{14}H_{11}NO_4S$, 289.0409, found, 289.0408.

2-(Benzylthio)-4-nitrobenzamide (6). In a flame-dried, N_2-purged flask, a slurry of the nitrobenzoic acid **5** (1.92 g, 6.64 mmol) in 150 mL of CH_2Cl_2 and 2 drops DMF, was cooled to 0 °C. Oxalyl chloride (1.2 mL, 13.3 mmol) was added, the solution was warmed to RT and stirred for 2 h (gas evolution had ceased). The solvent was evaporated, and the resultant yellow solid was dissolved in 100 mL of CH_2Cl_2. Ammonium hydroxide solution (10 mL) was added, and the reaction mixture was stirred at RT for 40 min. The mixture was diluted with water, and the organic layer was separated and washed with sodium bicarbonate, water, and brine. The organic phase was dried over magnesium sulfate and filtered, and the solvent was evaporated to leave 1.81 g (94%) of a yellow solid: mp 171−173 °C. ^{1}H NMR (CD_3OD): δ 4.28 (s, 2H), 7.22 (m, 1H), 7.28 (m, 2H), 7.38 (m, 2H), 7.62 (m, 1H), 8.02 (m, 1H), 8.17 (m, 1H). ^{13}C NMR (CD_3OD): δ 38.12, 120.58, 123.23, 128.19, 129.35, 129.58, 129.96, 137.33, 140.01, 142.46, 149.33, 168.70. MS (EI, 70 eV): *m*/*z* 288 (134%, M^+), 197 (22.3%, M − SBn), 91 (100%, Bn); HRMS calcd $C_{14}H_{12}N_2O_3S$, 288.0569, found, 288.0574.

2-(Benzylthio)-4-nitrobenzylamine (7). A flame-dried flask with attached condenser was charged with 40 mL of THF and 30 mL of 1.0 M BH_3·THF. To this was slowly added nitro amide **6** (1.76 g, 6.11 mmol) dissolved in 60 mL of THF, and the solution was heated at reflux overnight. After cooling to room temperature, 40 mL of 6.0 M HCl was carefully added, the mixture was heated at 50 °C for 90 min and then cooled, and the THF was removed using a rotary evaporator. HCl (1 M) was added to the aqueous solution, followed by ether extraction (×2), with the combined organics being washed with additional 1 M HCl. The combined aqueous layers were basified with solid NaOH, extracted with ether (×3), washed with brine, dried over $MgSO_4$, evaporated, and

dried under vacuum to give a yellow solid (0.96 g, 57%). ^{1}H NMR ($CDCl_3$): δ 3.90 (s, 2H), 4.21 (s, 2H), 7.24 to 7.34 (m, 5H), 7.53 (d, 1H, J = 8.4 Hz), 8.00 (dd, 1H, J = 8.4, 2.3 Hz), 8.16 (d, 1H, J = 2.1 Hz). ^{13}C NMR ($CDCl_3$): δ 38.06, 43.98, 120.85, 122.69, 127.73, 128.01, 128.72, 128.87, 135.73, 137.39, 147.01, 148.86. MS (EI, 70 eV): m/z 274 (1.3%, M^+), 183 (100%, M − SBn); HRMS calcd $C_{14}H_{14}N_2O_2S$, 274.0776, found, 274.0775.

Bis((2-(benzylthio)benzyl)(2-(benzylthio)-4-nitrobenzyl)amine (8). 2 (1.92 g, 6.55 mmol) and the nitrobenzylamine **7** (0.90 g, 3.28 mmol) were dissolved in 100 mL of acetonitrile and then stirred at RT overnight. The solids were removed by filtration, and the solvent was removed using a rotary evaporator to give 2.40 g of crude material. Flash column purification (silica, 1:1/CH_2Cl_2:hexane) yielded the product **8** as a yellow oil (1.73 g, 75%). ^{1}H NMR ($CDCl_3$): δ 3.53 (s, 2H, NCH_2), 3.56 (s, 4H, $N(CH_2)_2$), 4.01 (s, 4H, $S(CH_2)_2$), 4.11 (s, 2H, SCH_2), 7.10 to 7.30 (m, 21H), 7.48 (m, 2H), 7.71 (d, 1H, J = 7.5 Hz), 7.81 (dd, 1H, J = 8.5, 2.2 Hz), 8.04 (d, 1H, J = 2.2 Hz). ^{13}C NMR ($CDCl_3$): δ 38.19, 39.09, 55.34, 56.34, 120.18, 122.04, 126.16, 127.21, 127.49, 127.62, 128.42, 128.66, 128.82, 128.96, 129.53, 129.56, 129.88, 135.81, 136.25, 137.13, 138.20, 138.60, 145.95, 146.78. MS (FAB, +): m/z 699 (100%, $M^+ + H$); HRMS calcd $C_{42}H_{38}N_{22}O_2S_3$, 699.2174, found, 699.2169.

Bis(2-(benzylthio)benzyl)(2-(benzylthio)-4-aminobenzyl)amine (9). The benzylamine **8** (1.72 g, 2.46 mmol) was dissolved in 50 mL of abs ethanol and 50 mL of 1,2-dichloroethane. To this solution was added 0.5 mL of hydrazine hydrate followed by 0.1 mL of 50% Raney nickel slurry. These additions were repeated twice until the reaction was complete by TLC (1 h). The slurry was filtered through Celite, evaporated, and dried under vacuum to yield 1.57 g (95%) of clear, pale yellow viscous oil. ^{1}H NMR ($CDCl_3$): δ 3.53 (s, 2H), 3.61 (s, 4H), 4.02 (s, 2H), 4.05 (s, 4H), 6.49 (dd, 1H, J = 8.1, 2.4 Hz), 6.64 (d, 1H, J = 2.4 Hz), 7.13 to 7.31 (m, 21 H), 7.38 (d, 1H, J = 8.1 Hz), 7.65 (m, 2H). ^{13}C NMR ($CDCl_3$): δ 39.05, 39.09, 55.20, 55.50, 113.48, 115.91, 126.19, 126.94, 127.08 (2 peaks), 128.39 (2 peaks), 128.89, 128.91, 129.25, 129.38, 129.52, 130.62, 135.70, 136.82, 137.31, 137.33, 139.74, 145.28. MS (FAB, +): m/z 669 (100%, $M^+ + H$); HRMS calcd $C_{42}H_{40}N_2S_3$, 669.2432, found, 669.2431.

Bis(2-thio)benzyl-(2-thio-4-aminobenzyl)amine gallium(III) (11). A flame-dried three-necked flask with attached dry ice condenser was cooled to −78 °C and filled with 15 mL of anhydrous ammonia. To this was added the chelate system **9** (143 mg, 0.214 mmol) dissolved in 2 mL of THF, followed by small pieces of sodium. The mixture was warmed to −33 °C to improve solubility and allowed to gently reflux for 45 min. The reaction was quenched with solid NH_4Cl, and the ammonia was evaporated under argon flow, followed by vacuum-drying. The crude trithiol was dissolved in 8 mL of degassed methanol, and $[PPh_4][GaCl_4]$ (118 mg, 0.214 mmol) dissolved in 2 mL of degassed acetonitrile was then added. The pH was adjusted to basic with 0.8 mL of 1 M KOH solution (degassed); the mixture was stirred at room temperature for 30 min, and the solvents were evaporated and dried under vacuum. The crude product was triturated with chloroform, and the solvent was removed by rotary evaporation and dried under vacuum to yield a yellow solid (40 mg, 40%). ^{1}H NMR ($CDCl_3$): δ 3.27 (d, 1H, J = 12.5 Hz to 4.54), 3.32 (d, 1H, J = 12.5 Hz to 4.70), 3.36 (d, 1H, J = 12.5 Hz to 4.59), 3.76 (br s, 2H, NH_2), 4.54 (d, 1H, J = 12.2 Hz), 4.59 (d, 1H, J = 12.2 Hz), 4.70 (d, 1H, J = 12.2 Hz), 6.44 (dd, 1H, J = 2.0, 8.1 Hz), 6.86 (d, 1H, J = 2.2 Hz), 6.94 (d, 1H, J = 8.1 Hz), 7.16 (m, 4H), 7.24 (m, 2H), 7.52 (m, 2H). MS (FAB, +): m/z 467 (11%, ^{71}Ga), 465 (13%, ^{69}Ga); HRMS calcd $C_{21}H_{19}N_2S_3{}^{69}Ga$, 465.0044, found, 465.0043.

Bis(2-(benzylthio)benzyl)(2-(benzylthio)-4-aminobenzyl)amido(*tert*-butoxycarbonyl)phenylalanine (10). The chelate system **9** (213 mg, 0.318 mmol) was combined with *N*-(*tert*-butoxycarbonyloxy)phenylalanine (89 mg, 0.334 mmol), 1,3-dicyclohexylcarbodiimide (66 mg, 0.334 mmol), 1-hydroxybenzotriazole (43 mg, 0.334 mmol), and 111 μL of *N*,*N*-diisopropylethylamine (0.637 mmol) in a flask with 20 mL of methylene chloride. The mixture was stirred at RT for 24 h and then filtered and washed with 0.1 M NaOH, water, and brine. The organic layer was filtered through cotton wool and then evaporated and dried under vacuum. Purification was carried out by flash chromatography (silica, 30% ethyl acetate/70% hexanes) to yield **10** (259 mg, 89%). ^{1}H NMR ($CDCl_3$): δ 1.43 (s, 9H), 3.15 (m, 2H), 3.48 (s, 2H), 3.55 (s, 4H), 4.01 (s, 4H), 4.03 (s, 2H), 4.45 (br, 1H), 5.16 (br, 1H), 7.01 (m, 1H), 7.10 to 7.33 (m, 27H), 7.49 (m, 1H), 7.57 (m, 2H). ^{13}C NMR ($CDCl_3$): δ 28.21, 38.35, 38.67, 39.05, 55.20, 55.62, 56.62, 80.55, 117.45, 119.80, 126.23, 127.06, 127.09, 127.17, 128.38, 128.40, 128.44, 128.81, 128.85, 129.01, 129.26, 129.29, 129.56, 129.67, 134.99, 135.72, 136.16, 136.58, 136.83, 136.94, 137.24, 139.42, 155.77, 169.40. MS (FAB, +): m/z 916 (100%); HRMS calcd $C_{56}H_{57}N_3O_3S_3$, 916.3640, found, 916.3643.

Bis(2-thio)benzyl-(2-thio-4-aminobenzyl)amido-(*tert*-butoxycarbonyl)phenylalanine gallium(III) (12). A flame-dried three-necked flask with attached dry ice condenser was cooled to −78 °C and filled with 15 mL of anhydrous ammonia. To this was added the chelate system **10** (57 mg, 0.062 mmol) dissolved in 1.5 mL of THF, followed by small pieces of sodium until a blue color persisted, and the reaction was stirred at −78 °C for 1 h. The reaction was quenched with solid NH_4Cl, and then the ammonia was evaporated under nitrogen flow, followed by vacuum-drying. The crude trithiol was dissolved in 10 mL of degassed methanol, and then $[GaCl_4][PPh_4]$ (34 mg, 0.062 mmol) was added dissolved in 2 mL of degassed acetonitrile. The pH was adjusted to basic with 0.2 mL of 1 M KOH solution (degassed) and then stirred at room temperature for 35 min, after which the solvents were evaporated and the product was dried under vacuum. The crude material was purified by flash chromatography (silica, 50% ethyl acetate/50% hexanes) to yield 25 mg (57%) of **12** as a colorless solid. ^{1}H NMR ($CDCl_3$): δ 1.41 (s, 9H), 3.12 (m, 2H, CH_2 of Phe), 3.37 (m, 3H, N−CH(H) × 3), 4.42 (m, 1H, CH), 4.55 (d, 1H, J = 12.2 Hz coupled to 3.37 ppm, N−CH(H)), 4.60 (d, 1H, J = 12.4 Hz coupled to 3.37 ppm, N−CH(H)), 4.63 (d, 1H, J = 12.4 Hz coupled to 3.37 ppm, N−CH(H)), 5.08 (m, 1H, NH(BOC)), 7.11 to 7.83 (12H, ar and NH). MS (FAB, +): m/z 714 (3%), 713 (6%), 712 (4%), 711 (6%); HRMS calcd $C_{35}H_{35}N_3O_3S_3{}^{69}Ga$, 711.1175, found, 711.1174.

Histidine and Cysteine Challenge. A conical vial containing a stir bar was charged with 900 μL of test solution (10 mM histidine or cysteine in a buffered saline solution) and 100 μL of substrate (1 mM of **11** or **12** dissolved in methanol). The vial was sealed with a Teflon lined cap and maintained with stirring at 37 °C, with periodic analysis by HPLC.

Enzymatic Hydrolysis. A conical vial containing a stir bar was charged with 800 μL buffered saline solution, 100 μL of substrate solution (1 mM **12** in DMF), 20 μL of Tween solution (1% in water), and 100 μL of α-chymotrypsin solution (approximately 0.7 units in a buffered saline solution). The vial was sealed with a Teflon-lined

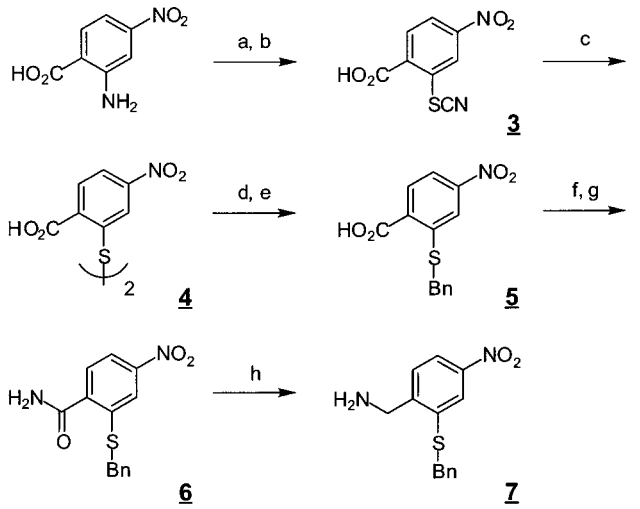
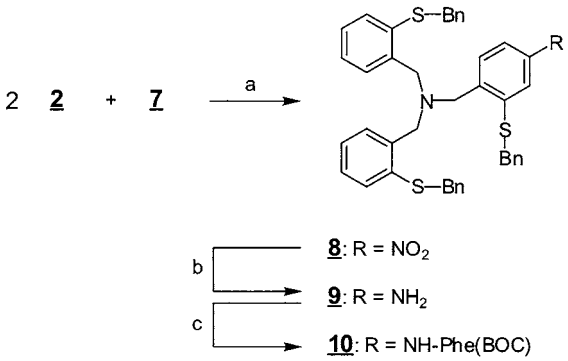
cap and maintained with stirring at 37 °C, with periodic analysis by HPLC (retention time for **11** = 4.4 min, retention time for **12** = 15.5 min). The activity of the α-chymotrypsin was confirmed by the hydrolysis of *N*-benzoyl-L-tyrosine ethyl ester.



RESULTS AND DISCUSSION

The conjugation of the S_3N tripodal chelate system to a peptide (Figure 2, R = peptide) requires a point of attachment on one of the mercaptobenzene groups of the ligand. Since the other two mercaptobenzenes will be identical, this design permits the bifunctional tertiary amine tripodal chelate system to be prepared by a 2 + 1 approach, as depicted in Figure 2. Scheme 1 outlines the preparation of the benzyl bromide derivative **2** starting from thiosalicylic acid, an approach modified from that described earlier for the preparation of the chloride analogue of **2** (*13*). Thiol protection with a benzyl group proceeds in 76% yield, and reduction to the alcohol **1** in 97% yield using borane−THF complex. The benzyl bromide **2** was obtained through reaction with PBr_3 in 97% yield.

The preparation of the benzylamine portion of the tripodal ligand is described in Scheme 2. Prior to developing this route, a more direct approach was taken whereby 4-nitroanthranilic acid was diazotized and then reacted with benzyl mercaptan under basic conditions. Although this produced (benzylthio)nitrobenzoic acid **5** in two steps, the yield was poor (20%) and the chromatographic purification difficult. The improved route proceeds in five steps also starting with 4-nitroanthranilic acid, with the first three steps following a literature precedent (*12*).



Formation of the diazonium salt followed by Sandmeyer-type reaction with copper thiocyanate produced the aryl thiocyanate **3** in 86% yield. Disulfide **4**, prepared by ammonolysis followed by spontaneous oxidation of the thiolate, was rereduced with sodium borohydride, and the resultant thiol was protected with a benzyl group. This five-step transformation to the acid **5** was carried out in 53% yield, a significant improvement over the initial direct approach, with only simple crystallizations required for product recovery. The remaining three steps to the desired benzylamine derivative involve formation

of the acid chloride with oxalyl chloride and subsequent reaction with ammonia to generate benzamide **6** in 94% yield. Reduction with borane−THF complex proceeds in 88% yield giving the benzylamine **7**.

Construction of the tripodal ligand is illustrated in Scheme 3. Initial attempts were carried out using the chloride equivalent of the benzylic bromide **2**, but reaction ceased after formation of the secondary amine and could not be driven further to the tertiary amine. The addition of sodium iodide produced byproducts due to sulfonium salt formation. The benzyl bromide **2** provided the correct reactivity, and with it the tertiary amine **8** could be formed at room temperature in 75% yield. The aromatic nitro substituent was readily reduced with hydrazine/Raney nickel to give the aniline **9** in excellent yield. This amino group is available for attachment of peptides. To model the attachment to peptides, BOC-protected phenylalanine was conjugated via carbodiimide amide formation, to give 89% of **10**.

Deprotection of the thiol groups was carried out using sodium in liquid ammonia, as indicated in Scheme 4. It also proved possible to proceed directly from **8** to the deprotected trithiol, using sodium in liquid ammonia, thus carrying out both the nitro reduction and the thiol deprotection in one step. Due to the air sensitivity of the trithiol compounds, complexation with $[PPh_4][GaCl_4]$ was

cysteine	97	94	91	98	92	44
α-chymotrypsin				97	98	93

[a] Percent of complex remaining at the indicated time. Conditions tested: aqueous medium at room temperature; ligand exchange with histidine; ligand exchange with cysteine; enzymatic hydrolysis with α-chymotrypsin. See Experimental Section for details.

carried out immediately, without purification of the trithiol intermediates. This two-step procedure for the aniline derivative **9** resulted in a 40% yield of the gallium complex **11**. For the phenylalanine conjugate **10**, a 57% yield was achieved in forming the complex **12**.

These four-coordinate gallium complexes have a propeller-type conformation, suggesting that the six benzylic protons (all diastereotopic pairs) would exist as four distinct doublets in the ^1H NMR spectrum. Figure 3 shows the ^1H NMR spectrum of **11**, with an inset COSY ($^1H-^1H$ correlation) for the relevant aliphatic region. The six benzylic protons appear as six distinct doublets, suggesting that in solution complex **11** exists as a twisted propeller, resulting in all six protons being nonequivalent.

To test the applicability of this system for use as an in vivo imaging agent, we analyzed the stability of the gallium complexes **11** and **12** to ligand exchange, as presented in Table 1. In the presence of histidine and cysteine, both complexes appear relatively stable over 24 h. Thus, even with the increased electron density from the free amino group in **11**, there is no significant loss in complex stability at a neutral pH. The decreased stability of the phenylalanine conjugate may be due to the BOC protecting group. However, complex **11** was found to be much less stable under strongly alkaline conditions, as compared to complex **12**. Under neutral conditions, both complexes are stable for long time periods in an aqueous medium.

We were also interested in determining the stability of conjugates with an amide attachment to this gallium core, such as represented by **12**. Thus, the susceptibility of **12** to enzymatic hydrolysis was studied (which would produce **11** as the product), following the hydrolysis by HPLC analysis. With both the phenylalanine substrate specific hydrolase chymotrypsin, and the more general amide hydrolyzing enzyme subtilisin, there was an insignificant level enzymatic hydrolysis of **12**. Thus, the bulky chelate must hinder access of the complex to the active site of these enzymes. This suggests that conjugation of a biomolecule at this location through an amide linkage will provide a complex that will be stable in vivo.

CONCLUSIONS

A tripodal S_3N chelate system has been developed for the radiolabeling of large biomolecules with gallium radioisotopes. The conjugation of this chelator to phenylalanine demonstrates the appropriateness for utilizing this system in the production of gallium-labeled peptides. The bioconjugate complex was found to be stable to ligand exchange and enzymatic hydrolysis, providing initial evidence of its suitability for in vivo use.

ACKNOWLEDGMENT

This research has been supported through a grant from the Department of Energy (DE FG02 86ER60401). NMR spectra were obtained in the Varian Oxford Instrument Center for Excellence in NMR Laboratory. Funding for this instrumentation was provided in part from the W.M. Keck Foundation and the National Science Foundation (NSF CHE 96-10502). Mass spectra were obtained on instruments supported by grants from the National Institute of General Medical Sciences (GM 27029), the National Institute of Health (RR 01575), and the National Science Foundation (PCM 8121494).

New Reagents and Methods for the Synthesis of Internal and 3′-Labeled DNA

Matthew H. Lyttle,* Troy A. Walton, Daren J. Dick, Timothy G. Carter, Jacob H. Beckman, and Ronald M. Cook

Biosearch Technologies, Inc., 81 Digital Drive, Novato, California 94949. Received January 22, 2002

The syntheses of two new nucleoside phosphoramidites containing a hydroxyl functionality masked by a levulinate protecting group are presented; N^4-(2-(ethylene glycol-2-levulinate)ethyl)-5-methyl-5′-(4,4′-dimethoxytrityl)-3′-*O*-(2-cyanoethyldiisopropylphosphoramidite)-2′-deoxycytidine **1** and 5-(*N*-(6-*O*-levulinoyl-1-aminohexyl)-3(*E*)-acrylamido)-5′-(4,4′-dimethoxytrityl)-3′-(2-cyanoethyldiisopropylphosphoramidite)-2′-deoxyuridine **3**. Optimization of solid-phase-supported synthetic parameters for incorporation of these into DNA, removal of the levulinate group by exposure to dilute hydrazine, and subsequent attachment of dye labels is described. Synthesis of the known compound 5-(*N*-(6-trifluoroacetylaminohexyl)-3(*E*)-acrylamido)-5′-(4,4′-dimethoxytrityl)-3′-(2-cyanoethyldiisopropylphosphoramidite)-2′-deoxyuridine **2** (*1*), containing a masked amine at the end of an alkyl chain attached at the 5 position, was also revisited using new techniques developed for **3**.

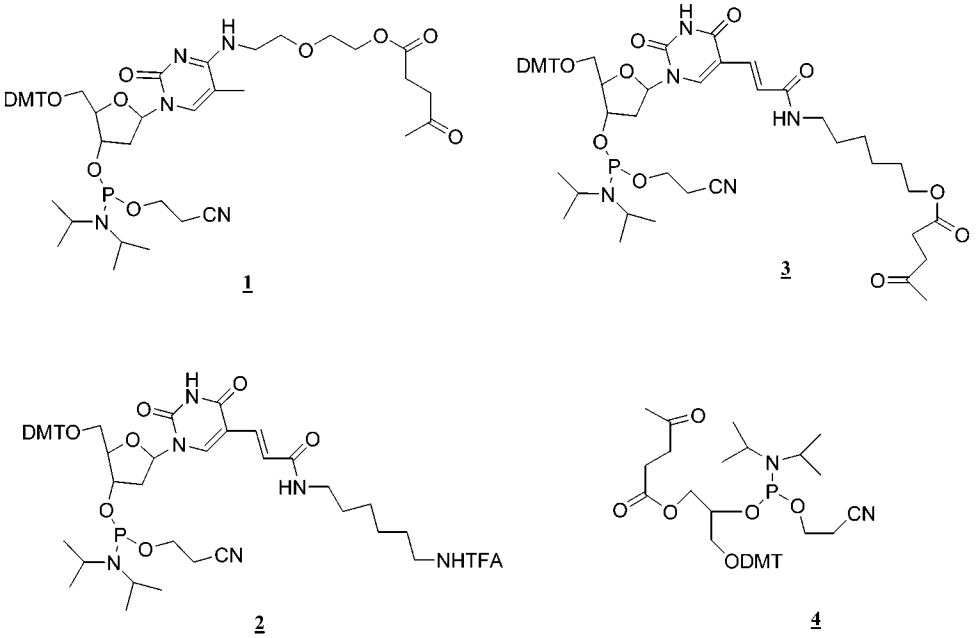
INTRODUCTION

Modern, high-speed synthesis of labeled DNA requires the fewest amount of steps conducted in the shortest possible time. Synthetic methodology (*2*−*4*) has been continuously evolving to meet these challenges. These current trends utilize direct attachment of rapidly reacting reagents to solid-phase-immobilized nascent oligonucleotides, followed by cleavage from the support and purification of the product in precisely the form desired.

While a variety of efficient strategies for solid-phase synthesis of 3′ and 5′ terminal labeled structures are available, there are not many choices for solid-phase-supported internal labeling of DNA. Useful information about the preparation of the needed reagents as well as the performance of the structures produced is limited. Internal labels are usually attached by solution-phase active ester coupling to alkylamines pendant on pyrimadine bases (*5*). These procedures involve multiple purifications and other cumbersome methods not amenable to high throughput synthesis. Label derivatized nucleoside phosphoramidites for internally modified DNA synthesis are commercially available (*6*), but at considerable expense. Furthermore, coupling efficiencies of these have been low in our hands, perhaps due to the high molecular weight and polar nature of some of these compounds. Recently, palladium-assisted coupling of acetylenic compounds to iodinated pyrimidine nucleosides immobilized on solid supports has been reported (*7*). Other current work details solid-phase photolytic deprotection of 2′ amine oligonucleotides and subsequent *on support* attachment of various useful moieties (*8*). Hopefully these methods will achieve widespread application in this area.

We have developed solid-phase-supported methods in which phosphoramidites normally used to functionalize only the 5′ terminus of DNA can also be used to effect labeling internally or at the 3′ terminus of the sequence. Removal of masking groups and the incorporation of labels are done while the DNA is attached to the solid-phase support, which facilitates the separation of tagged DNA products from excess label and deprotection reagents.

Chang, Urdea and Horn (*9*) developed a synthesis of novel branching nucleotide structures in which a hydroxyl functionality, attached via a hydrocarbon chain at N-4 of cytidine, was masked by a levulinate group and then deprotected with a hydrazine cocktail after synthesis of the primary strand. Branching sequences were then added to the oxygen with standard phosphoramidite chemistry. Another phosphoramidite **4** based on 1,2,3-propanetriol containing a similarly masked oxygen is commercially available (*10*). Neither of these structures is desirable for internally labeled DNA which is expected to anneal to a complementary strand at energies (T_ms) close to that of the unmodified DNA sequences. To address this issue we have developed the uridine derivative **3** which has a hydroxyl at the end of a hydrocarbon chain, pendant at C-5, masked by a levulinate group. Groups attached at the C-5 position of uridine would be expected to be less disruptive of double helix formation than at the N-4 of cytidine (*11*). A companion paper (*12*) compares the performance of oligonucleotides made with **1**, **2**, and **3** in practical applications involving annelation to complementary DNA structures.



MATERIALS AND METHODS

Aqueous ammonia, lithium chloride, and concentrated HCl were reagent grade from J. T. Baker. Dichloromethane (DCM), tetrahydrofuran (THF), ethyl acetate (EtOAc), acetonitrile, ethanol, methanol (MeOH), and petroleum ether were Omnisolve grade from VWR. Sodium hydroxide, mercuric acetate, sodium bicarbonate, magnesium sulfate, 6-amino-1-hexanol, 1,6-hexanediamine, acryloyl chloride, methyl trifluoroacetate, levulinic acid, 2-(2-aminoethoxy)ethanol, phosphorus oxychloride, triethylamine, 1,2,4-triazole, iron sulfide, triethylamine, and tetrabutlyammonium fluoride were from Aldrich. Chromatographic silica was from Grace Chemical Co. Deoxyuridine was obtained from Crystal Chem. Co. DMT T, TET and HEX amidites were obtained from

Annovis Corp. Potassium tetrachloropalladate was obtained from Alfa (J. M. Corp.). Controlled pore glass DNA synthesis supports, 6-carboxyfluorescein amidite (6-FAM) and Tamra amidite (*3*), were obtained in house. All other DNA synthesis reagents were as previously described (*13*). Elemental analyses were performed by Desert Analytics (Tucson, AZ), and NMR work was performed by Acorn NMR (Livermore, CA). MALDI Mass spectra were performed in house on a Bruker Biflex MALDI-TOF.

EXPERIMENTAL PROCEDURES

***N*⁴-(2-(Ethylene glycol-2-levulinate)ethyl)-5-methyl-5′-(4,4′-dimethoxytrityl)-3′-*O*-*tert*-butyldimethylsilyl-2′-deoxycytidine, 7.** A solution of 12 mL (20 g, 130 mmol) of phosphorus oxychloride and 40 g (580 mmol) of 1,2,4-triazole in 400 mL of dry CH_3CN was chilled on ice to 0 °C under argon. Triethylamine (90 mL, 90 g, 900 mmol) was added slowly dropwise with stirring over 0.5 h. Next, 31 g (47 mmol) of 5′-(4,4′-dimethoxytrityl)-3′-*O*-*tert*-butyldimethysilylthymidine **5** (*14*) was dissolved in 200 mL of dry CH_3CN and added slowly dropwise over 0.5 h. The solution was stirred and allowed to warm to room temperature overnight. The solution was concentrated to a gum under reduced pressure and dissolved in 500 mL of EtOAc. Saturated aqueous $NaHCO_3$ (300 mL) was added, and the mixture was shaken and separated. The organic phase was washed with another 300 mL portion of satd aqueous $NaHCO_3$ and then dried over $MgSO_4$, filtered, and evaporated to give the N^4-triazolide as a brown foam. This material was dissolved in 150 mL of CH_3CN and added dropwise with stirring to a solution of 30 mL (31.4 g, 300 mmol) of 2-(2-aminoethoxy)ethanol in 300 mL of CH_3CN which had been chilled to 0 °C on ice. The mixture was stirred overnight and allowed to warm to room temperature. The solution was reduced to a tar by rotary evaporation and then redissolved in 300 mL of EtOAc. The solution was washed with 300 mL of satd $NaHCO_3$ and dried over $MgSO_4$. Filtration, followed by reduction to a tar by rotary evaporation and high vacuum overnight, gave 24.3 g of the N^4-(2-(ethylene glycol)ethyl) adduct **6** as a foam. All of this material was dissolved in 300 mL of dry pyridine and 12 mL of *N*-methylimidazole, 12 mL (13.6 g, 117 mmol) levulinic acid was added, and the solution was reduced to an oil by rotary evaporation. Dry CH_3CN, 200 mL, was added along with 12 mL (9.7 g, 77 mmol) diisopropylcarbodiimide. The solution was allowed to stand overnight after thorough mixing. Crystals of *N*,*N*′-diisopropylurea were removed by filtration, and the solution was concentrated to a tar by rotary evaporation. The residue was dissolved in 300 mL of EtOAc, and the organic phase was washed with 150 mL of 1 M citric acid followed by 150 mL of satd $NaHCO_3$ and then dried over $MgSO_4$ and filtered. The product was purified by column chromatography on a 5 × 20 cm bed of activated silica gel eluted with 1% MeOH and 1% pyridine in DCM. Fractions were inspected by TLC in 5% MeOH, 1% pyridine in DCM, and visualized with 10% H_2SO_4 and heat. Once the product (R_f 0.5) began to elute from the column, the MeOH in the column mobile phase was increased to 2%. Fractions containing pure product were pooled and concentrated by rotary evaporation and high vacuum to yield 28 g (70%) of **7** as a white foam. ^{1}H NMR (δ, $CDCl_3$): 7.8 (s, 1H), 7.5−7.2 (m, 11H), 6.8 (d, 4H), 6.4 (t, 1H), 5.4 (t, 1H), 4.5 (q, 1H), 4.2 (dd, 2H), 3.8 (s, 6H), 3.75 (m, 2H), 3.7 (m, 4H), 3.5 (dd, 1H), 3.2 (dd, 1H), 2.8 (t, 2H), 2.6 (t, 2H), 2.4 (m, 1H), 2.2 (m, 1H), 2.1 (s, 3H), 1.5 (s, 3H), 0.8 (s, 9H), 0.0 (d, 6H). Anal. Calcd for $C_{46}H_{61}N_3O_{10}Si\cdot{}^1/_2MeOH$: C, 64.94; H, 7.38. Found: C, 64.59; H, 7.34.

***N*⁴-(2-(Ethylene glycol-2-levulinate)ethyl)-5-methyl-5′-(4,4′-dimethoxytrityl)-2′-deoxycytidine, 8. 7** (24 g, 28 mmol) was dissolved in a solution of 200 mL of THF, 60 mL of 1 N TBAF (in THF), and 10 mL of HOAc. The solution was allowed to stand for 24 h. An aliquot of the solution for TLC was prepared by mixing a few drops of the mixture with 1 mL of EtOAc and 1 mL of satd $NaHCO_3$ in a test tube and spotting the upper phase. The TLC (same mobile phase and visualization as above) showed complete conversion to a new lower spot (R_f 0.15). The reaction mixture was quenched with 20 mL of satd $NaHCO_3$ and most of the THF was removed by rotary evaporation. The residue was dissolved in 300 mL of EtOAc and the organic phase washed with 300 mL of satd $NaHCO_3$ followed by drying with $MgSO_4$ and filtration. The solution was concentrated to a foam by rotary

evaporation, and the product was purified by column chromatography on a 5 × 20 cm bed of activated silica gel eluted with a gradient of 1−6% MeOH over 8 L of mobile phase and 1% pyridine in DCM. Fractions were inspected by TLC as above, and those with pure product were pooled and evaporated to yield 19 g (93%) of **8** as a white foam. ^{1}H NMR (δ, $CDCl_3$): 7.8 (s, 1H), 7.5−7.2 (m, 11H), 6.8 (d, 4H), 6.4 (t, 1H), 5.4 (t, 1H), 4.5 (s, 1H), 4.2 (dd, 2H), 4.1 (s,1H), 3.8 (s, 6H), 3.75 (m, 2H), 3.7 (m, 4H), 3.5 (dd, 1H), 3.4 (m, 2H), 2.7 (t, 2H), 2.6 (m, 3H), 2.25 (m, 1H), 2.2 (s, 3H), 1.5 (s, 3H). Anal. Calcd for $C_{40}H_{47}N_3O_{10}$: C, 65.83; H, 6.49; N, 5.76. Found: C, 65.74; H, 6.68; N, 6.41.

***N*^{4}-(2-(Ethylene glycol-2-levulinate)ethyl)-5-methyl-5′-(4,4′-dimethoxytrityl)-3′-*O*-(2-cyanoethyldiisopropylphosphoramidite)-2′-deoxycytidine, 1. 8** (19 g, 26 mmol) was dried by rotary evaporation from pyridine followed by high vacuum in a 500 mL round-bottom flask. A mixture of 8 g (27 mmol) of 2-cyanoethyl tetraisopropylphosphorodiamidite and 480 mg of tetrazole in 250 mL of CH_3CN was prepared and added to the flask containing the nucleoside **8**. The flask was stoppered and allowed to stand for 2 h after thorough mixing. Inspection of the reaction mixture by TLC as above showed complete conversion to a new product, R_f 0.4. The reaction mixture was concentrated to a tar by rotary evaporation and redissolved in 300 mL of EtOAc. The solution was washed with 200 mL of satd $NaHCO_3$ followed by drying with $MgSO_4$ and filtration. The solution was concentrated to a tar by rotary evaporation and the product purified by column chromatography as above for **8**. Fractions containing pure **1** were pooled and concentrated by rotary evaporation and high vacuum to yield 13.3 g (55%) of **1** as a white foam. ^{31}P NMR (ppm, $CDCl_3$): 149.756, 149.211. Anal. ***N*-Acrylolyl-*N*′-*tert*-butyloxycarbonyl-1,6-hexanediamine, 9.** 1,6-Hexanediamine (100 g, 0.86 mol) was dissolved in 800 mL of THF and chilled in an ice bath. Di-*tert*-butyl dicarbonate, 60 g (0.28 mol) was dissolved in 400 mL of THF and added slowly over 1 h by a dropping funnel. The solution was stirred for 2 h and then filtered. The solid was washed with 200 mL of THF, and the combined filtrates were concentrated by rotary evaporation to 70 g of an oil. The oil was redissolved in 700 mL of $CHCl_3$ and washed three times with 400 mL of water. The solution was concentrated by rotary evaporation and redissolved in 300 mL of THF, and 200 mL of satd Na_2CO_3 was added. The mixture was chilled in an ice bath, and 30 mL (33.4 g, 0.37 mol) of acryloyl chloride was added in 10 mL portions over 2 h. Solid Na_2CO_3 was added, as needed, to keep the pH of the aqueous layer above 8. The mixture was stirred overnight and poured into a separatory funnel. EtOAc, 500 mL, was added, and the lower aqueous layer was removed after the mixture was shaken and allowed to separate. The organic phase was washed with 500 mL of 0.5 M KH_2PO_4 followed by 500 mL of satd $NaHCO_3$ and dried over $MgSO_4$. The solution was filtered and concentrated by rotary evaporation. The material was purified by column chromatography on a 15 × 50 cm bed of activated silica gel eluted with a gradient of 0−4% MeOH over 18 L of mobile phase and 1% pyridine in DCM. Fractions were inspected by TLC (R_f desired product 0.6, UV active, in 2% MeOH, 2% pyridine in DCM), and those with pure product were pooled and evaporated to yield 39 g (52%) of **9** as a white solid. ^{1}H NMR (δ, $CDCl_3$): 6.5−6.0 (m, 3H), 5.9 (d, 1H), 5.8 (d, 1H), 3.3 (m, 2H), 3.0 (m, 2H), 1.5−1.3 (m, 17H). Anal. Calcd for $C_{14}H_{26}N_2O_3$: C, 62.19; H, 9.69; N, 10.36. Found: C, 62.43; H, 9.83; N, 10.42.

5-(*N*-(6-Trifluoroacetylaminohexyl)-3(*E*)-acrylamido-5′-(4,4′dimethoxytrityl)-2′-deoxyuridine, 11. (This reaction must be done in a fume hood because H_2S, which is a toxic and malodorous gas, is used to precipitate metals during workup). Potassium tetrachloropalladate-(II), K_2PdCl_4 (40 g 122 mmol), was added over 1 h in 10 g portions to a gently refluxing solution of LiCl (24 g, 0.6 mol) in 1200 mL of THF. A solution of **9** (33 g, 122 mmol) in 200 mL of THF was added slowly over 10 min. The reaction mixture became dark brown. The solution was stirred and refluxed for 20 min, and then 57 g (123 mmol) of finely powdered 5-chloromercurate-2′-deoxyuridine (*1*) was added in small portions over 15 min. The solution became black and a silver mirror was deposited on the sides of the reaction vessel. Stirring and gentle reflux was continued overnight. The solution was allowed to cool, and H_2S gas was bubbled into the solution. A trap containing Clorox was used to control the odor of the gas. Once the brown precipitate was no longer generated, H_2S delivery was stopped and the solution was filtered to produce a clear yellow solution. The solvent was removed by rotary evaporation and high vacuum overnight to give 75 g of alkylated nucleoside **10** as a beige foam. A small amount of the foam was purified by dissolution in MeOH, addition of water to a cloud point, and chilling. Crystals were obtained, TLC R_f 0.4 (20% MeOH, 2% pyridine in DCM) which was UV (254 nm) active; the spot also fluoresced blue when irradiated with 312 nm UV. The bulk, unpurified material was dissolved in a mixture of 900 mL of DCM and 100 mL of MeOH, and 100 mL of trifluoroacetic acid was added. The solution was refluxed overnight during which a milky precipitate appeared. The suspension was concentrated to a gum by rotary evaporation, and high vacuum was applied to the material for 24 h. The resulting solid was dissolved in 700 mL of MeOH, and 60 mL of TEA was added, followed by 40 mL of methyl trifluroacetate. The solution was mixed and allowed to stand for 6 h and was concentrated to a solid by rotary evaporation. The solid was dried by rotary evaporation with 500 mL of dry pyridine and was then redissolved in 500 mL of dry pyridine. 4,4′-Dimethoxytrityl chloride (25 g, 75 mmol) was added, and the mixture was stirred for 4 h. A drop of the reaction mixture was dissolved in 1 mL of EtOAc and washed with 1 mL of satd $NaHCO_3$. TLC showed the appearance of product (R_f 0.2, 10% MeOH, 2% pyridine in DCM) which had the same UV characteristics as above and also became orange when the plate was sprayed with 10% H_2SO_4 and heated. MeOH (20 mL) was added to quench the reaction, and the brown solution was concentrated to a gum by rotary evaporation. The material was dissolved in 700 mL of DCM and washed with 500 mL of 0.5 KH_2PO_4 solution followed by 500 mL of satd aq $NaHCO_3$. The solution was dried over $MgSO_4$, filtered, concentrated by rotary evaporation, and then purified by column chromatography on a 15 × 150 cm bed of activated silica gel eluted with a gradient of 1−8% MeOH over 18 L of mobile phase and 1% pyridine in DCM. Fractions were inspected by TLC (R_f desired product 0.2, UV active as above, in 10% MeOH, 2% pyridine in DCM), and those with pure product were pooled and evaporated to yield 16.5 g (17%) of **11** as a white foam. ^{1}H NMR (δ, $CDCl_3$): 7.9 (s, 1H), 7.7 (t, 1H), 7.4 (d, 1H), 7.3 (m, 5H), 7.1 (m, 1H), 6.8 (d, 4H), 6.6 (d, 1H), 6.4 (t, 1H), 5.4 (broad s, 1H), 4.5 (s, 1H), 4.1 (s, 1H), 3.75 (s, 6H), 3.5 (dd, 1H), 3.3 (m, 3H), 3.2−3.0 (m, 2H), 2.5 (m, 1H), 2.3 (m, 1H), 1.5 (m, 2H), 1.4−1.2 (m, 6H). ***N*-Acryloyl-*O*-levulinoyl-6-amino-1-hexanol, 12.** 6-Amino-1-hexanol (50 g, 427 mmol) was dissolved in 400 mL of THF, and 200 mL of satd $NaHCO_3$ was added. Acryloyl chloride (caution: lachrymator) (35 mL, 39 g, 430 mmol) was added dropwise over 1 h. Solid $NaHCO_3$ was added, as needed, to maintain a basic pH. The mixture was stirred overnight. EtOAc (600 mL) was added, and the mixture was partitioned. The organic phase was washed with 300 mL of 1 N HCl, and then 300 mL of water followed by 300 mL of satd $NaHCO_3$. The solution was dried over $MgSO_4$, filtered, and evaporated to 53 g of a beige solid. The solid was dissolved in 400 mL of EtOAc with heating and applied to a 15 × 50 cm bed of activated silica gel packed and eluted with EtOAc. Fractions were inspected by TLC (R_f 0.25, 2% pyridine in EtOAc) and visualized with iodine vapor. Fractions containing pure material were pooled and concentrated by rotary evaporation and high vacuum to yield 25.2 g of *N*-acryloyl-6-amino-1-hexanol as a white solid. A portion of this material (10 g, 58 mmol) was dissolved in a mixture of levulinic acid (7 mL, 8 g, 68 mmol), 5 mL of *N*-methylimidazole, and 200 mL of dry pyridine. The solution was concentrated to a tar by rotary evaporation and redissolved in 300 mL of dry CH_3CN. Diisopropylcarbodiimide (10 mL, 8 g, 64 mmol) was added, and the mixture was allowed to stand overnight after mixing. Solids were filtered off, and the solution was concentrated to a tar by rotary evaporation. The material was dissolved in 300 mL of DCM and washed with 200 mL of 1 N citric acid followed by 200 mL of satd $NaHCO_3$ followed by drying with $MgSO_4$ and filtration. The solution was concentrated to a tar by rotary evaporation and the product purified by column chromatography on a 5 × 20 cm bed of activated silica gel eluted with 1:1 petroleum ether: EtOAc. Fractions were inspected by TLC (1:1 petroleum ether: EtOAc) and visualized with iodine vapor. Fractions containing pure **13** (R_f 0.35) were pooled and concentrated by rotary evaporation and high vacuum to yield 6 g (38%) of **12** as a white solid. ^1H NMR (δ, $CDCl_3$): 6.3−6.25 (dd, 1H), 6.2 (broad s, 1H), 6.15−6.05 (dd, 1H), 5.6 (dd, 1H), 4.0 (t, 2H), 3.3 (q, 2H), 2.75 (t, 2H), 2.55 (t, 2H), 2.2 (s, 3H), 1.7−1.5 (m, 4H), 1.4−1.3 (m, 4H). 5-(*N*-(6-*O*-Levulinoyl-1-aminohexyl)-3(*E*)-acrylamido-5′-(4,4′dimethoxytrityl)-3′-(2-cyanoethyldiisopropylphosphoramidite)-2′-deoxyuridine, 3. 14 (6.8 g, 8.5 mmol) was dried by rotary evaporation from 100 mL of dry pyridine followed by high vacuum in a 500 mL round-bottom flask. A mixture of 3.0 g (10 mmol) of

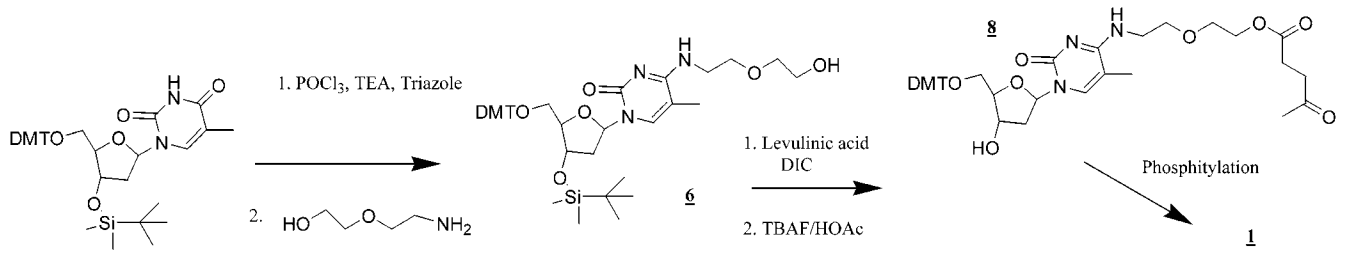
2-cyanoethyl tetraisopropylphosphorodiamidite and 180 mg of tetrazole (2.6 mmol) in 100 mL of dry CH_3CN was prepared and added to the flask containing the nucleoside **14**. The flask was stoppered and allowed to stand for 2 h after thorough mixing. Inspection of the reaction mixture by TLC (2% pyridine/EtOAc) showed complete conversion to a new product, R_f 0.6. The reaction mixture was concentrated to a tar by rotary evaporation and redissolved in 200 mL of EtOAc. The solution was washed with 100 mL of satd $NaHCO_3$ followed by drying with $MgSO_4$ and filtration. The solution was concentrated to a tar by rotary evaporation and the product purified by column chromatography on a 3 × 20 cm bed of activated silica gel eluted with 2% pyridine in EtOAc. Fractions were inspected by TLC (2% pyridine in EtOAc) and visualized with 10% H_2SO_4 and heat. Fractions containing pure **3** were pooled and concentrated by rotary evaporation and high vacuum to yield 5.5 g (81%) of **3** as a white foam. ^{31}P NMR (ppm, $CDCl_3$): 149.677, 149.329. Anal. Calcd for $C_{53}H_{68}N_5O_{12}P$: C, 63.78; H, 6.87; N, 7.02. Found: C, 63.75; H, 6.91; N, 7.13.

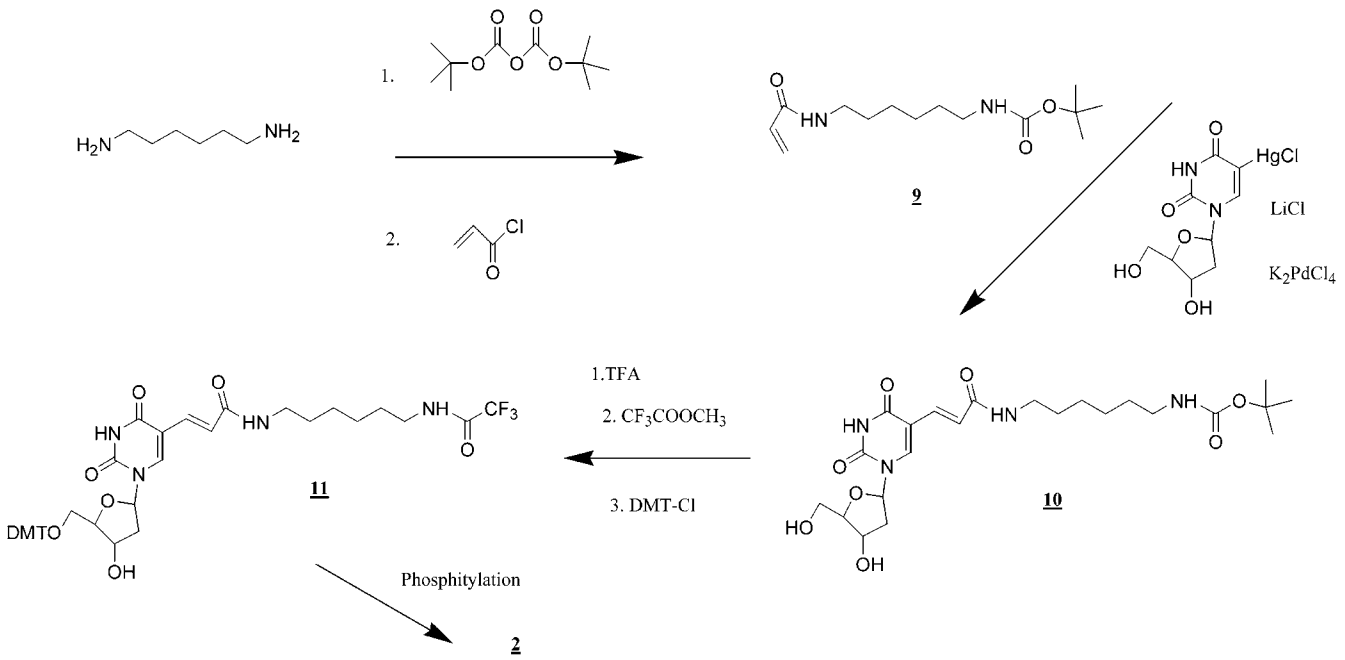
DNA Synthesis. DNA was made on Biosearch 8750 DNA synthesizers with standard conditions as previously described (*13*). Test sequences 5′-CGATCTGA**X**TAGCT**Y**-3′, 5′-TTTT**X**TTTTT-3′ and 5′-TTTTTTTTT**X**-3′where **X** was the nucleotide residue resulting from the use of **1** or **3** and **Y** were different natural bases were made at 1.0 μm and 200 nm synthesis scales. For internal labeling, first a hydrazine solution of 160 μL of hydrazine hydrate (Aldrich, 50 wt % water) in 8 mL of pyridine and 2 mL of HOAc was prepared and well mixed. The DNA sequencer was halted after the base (before **X**) added and the DMT was removed. After thorough washing with CH_3CN, a solution of 200 μL of 100 mg/mL of **1** or **3** in dry acetonitrile and 200 μL of 0.4 M *S*-ethyltetrazole in dry acetonitrile were introduced onto the column by the DNA synthesizer. After 2−3 min, the coupling solution was washed off the column with acetonitrile, and oxidation, followed by capping, was performed. Manual coupling with syringes was also successfully performed (*15*). The hydrazine cocktail above was introduced into the columns; we did this with 200 μL of solution in 1 mL syringes but it can also be done on the instrument. After the support was well wetted with the solution, it was allowed to stand 12−15 min and then was thoroughly washed with CH_3CN. Either TAMRA amidite or 6-FAM was coupled next; the same procedures as above were used. A 10 min coupling time was used for the TAMRA amidite. Oxidation and capping were performed after the coupling solution was washed off the column with acetonitrile. The TAMRA coupling sample was exposed to the capping solution for 5 min. Next, automated DNA synthesis was continued to the 5′ terminus, and the final DMT was removed. The CPG was placed into screw cap eppendorf tubes, and 1 mL of ammonia for the fluorescein DNA and 1 mL of the TAMRA deprotection cocktail for the TAMRA DNA was added to each. The tubes were heated at 55 °C for 18 h and cooled and the solutions evaporated. Yields of labeled DNA at all synthesis scales were close to those without hydrazine treatment, indicating negligible loss of material due to premature cleavage by the hydrazine reagent.

3′-HEX and TET CPG. DMT-*O*-ethylsulfonyl CPG (*16*) (15 g) was placed in a 300 mL coarse frit sintered glass funnel atop a 2 L sidearm flask. 3% Dichloroacetic acid in CH_2Cl_2 (200 mL) was poured in, and the support was agitated briefly with a spatula. The solution became brightly orange. After 2 min, the solution was drained and the step was repeated twice with 200 mL of fresh 3% dichloroacetic acid in CH_2Cl_2. The support was then washed three times with 200 mL of CH_2Cl_2, twice with 100 mL of CH_3CN, and once with 100 mL of pyridine. The support was transferred into a 250 mL round-bottom flask, and 1 g of **1** was added. 40 mL of dry pyridine was added, and the solvent was removed by rotary evaporation. A plug of glass wool was used to keep the CPG from leaving the flask. Once dry, high vacuum was applied to the flask for 18 h. A solution of 150 mL of 0.4 M *S*-ethyltetrazole in dry acetonitrile was prepared, and enough of this was added to the flask containing the CPG to make a slurry. The slurry was allowed to stand for 15 min and was poured into a sintered glass funnel. The support was washed three times with 100 mL of CH_3CN, and then 100 mL of amidite oxidizer solution (*13*) was added. After 5 min, the support was washed twice with 100 mL of CH_3CN. Next, 100 mL of a mixture of acetic anhydride, *N*-methyl imidazole, and THF (1:1:8) was added to the support. After 15 min exposure, the acetylation solution was removed and the support was washed three times with 100 mL of CH_3CN, and a small amount of this was dried. The DMT loading was 18 μm/g (*17*). The hydrazine cocktail above (100 mL) was mixed and added to the support. After 15 min, the support was washed three times with 100 mL of CH_3CN and was divided into two roughly equal portions. HEX and TET Amidite, 0.5 g respectively, were added to each portion, and coupling, oxidation, and capping steps using these amidites proceeded as above. Test sequences 5′-TTTTTTTTTdC(N4-(2-(ethylene glycol)ethyl)-HEX)-3′ and the analogous TET sequence were made; the HEX sample was deprotected with concentrated ammonia for 18 h at room temperature while standard conditions were used for the TET sample.



Anion exchange HPLC analyses were performed as follows: 2−20 μL of the aqueous samples, depending on the concentration, was injected onto a Dionex anion exchange column (4.6 × 250 mm); samples were eluted at 2 mL/min with aqueous buffers of (A) 0.025 M Tris HCl and 0.01 M TRIS, and (B) 0.025 M Tris HCl, 0.01 M TRIS, and 1.0 M NaCl, using a linear gradient of 1:0 to 0:1 over 20 min, with UV detection at 260 nm. Reverse phase HPLC as follows: 20 μL of the aqueous sample was injected onto a HAISIL HL C18 5 μm particle size column (4.6 × 150 mm); samples were eluted at 1 mL/min with buffers of (A) 0.1M TEAA, 5% acetonitrile, (B) acetonitrile, with a linear gradient of 1:0 to 0:1 A:B over 15 min. UV detection at 260 nm. Samples were prepared for MALDI mass spectral analysis as per Bruker.

RESULTS AND DISCUSSION



To develop this technology in an efficient manner, several endeavors had to be successfully completed: (1) Reliable and cost-effective processes for the synthesis of **1** and **3** had to be developed. (2) Easy and efficient solid-phase synthesis methods for incorporation of these compounds into DNA as well as subsequent label attachment had to be established. (3) Finally analytical techniques had to be devised to establish the purity and efficacy of the product DNA in practical applications.

Synthesis of Compounds 1−3. For **1**, commercially available DMT-T was treated with TBDMS-Cl to give **5** (*14*) in 84% yield. **5** was treated with 2-(2-aminoethoxy)-ethanol after activation as per Chang (*9*) to give **6**, which was converted into levulinate ester **7**, obtained as a white foam. The use of the TBDMS group instead of the trimethylsilyl transient protection used in (*9*) afforded certain advantages: the 3′-OTBDMS triazolide was a

Scheme 1. Synthesis of 1

Scheme 2. Synthesis of 2

stable compound which could be prepared in large quantities and stored cold, allowing many different derivatives to be prepared from one preparation of triazolide. Also, the 3′-OTBDMS group lent greater solubility in organic solvents which facilitated extraction and isolation of more polar conjugates containing pendant moieties such as biotin. Removal of the 3′-hydroxyl masking TBDMS group with TBAF gave alcohol **8**, followed by phosphitylation with 2-cyanoethyl tetraisopropylphosphorodiamidite and catalytic tetrazole gave **1**. See Scheme 1. The principal advantage of the use of **1** is cost; a similar derivative without the 5-methyl group can be made starting with more expensive deoxyuridine. This compound should also be accessible from $DMTdC^{(Bz)}$, but more steps would be required (*18*). The primary disadvantage to the use of **1** are anticipated lower T_ms of DNA made with this residue internally than with a natural deoxycytidine in binding to a complimentary DNA strand. A companion paper compares structures made with **1** with those made with **2** and **3** and bears this out. For this reason **1** is primarily used by us as a 3′ labeling tool.

Synthesis of 2. The Heck palladium-assisted coupling of organomercurials to olefins was first applied to nucleoside modification by Bergstrom (*19*). There is a recent paper about palladium-mediated reactions applied to nucleosides also coauthored by Bergstrom (*20*). We attempted first the literature synthesis (*1*) of **2**. Formation of *N*-acryloyl-*N*′-trifluoroacetyl-1,6-hexanediamine by a one-pot mixing of 1,6-hexanediamine, acryloyl chloride, and trifluoroacetic anhydride gave a mixture of products which gave the desired product in low yield. Purification was difficult with the conditions described, owing to close R_f values of products and contaminants. A palladium(II)-mediated coupling reaction with the material and 5-chloromercurated deoxyuridine also gave a mixture of products, which afforded only a few percent overall yield of the desired DMT nucleoside **11** when treated with DMT chloride followed by chromatography. Upon consideration of the low overall yield and high cost of the lithium tetrachloropalladate(II) used, we decided that this was not a cost-effective way to prepare **2**. An alternative scheme was developed, see Scheme 2. 1,6-Hexanediamine was treated with di-*tert*-butyl dicarbonate, and the resulting 6-*tert*-butyloxycarbonamidyl-1-aminohexane was partially purified by extraction. Acryloyl chloride was added to the compound under basic conditions to give 6-acrylolyl-*N*′-*tert*-butyloxycarbonyl-1,6-hexanediamine, **9**, which was obtained in high purity after chromatography. 5-Chloromurcurated deoxyuridine was prepared as per Ruth (*1*), and a palladium(II)-mediated coupling reaction with **9** gave, after several steps, the DMT nucleoside **11** in 24% yield (see Scheme 2). Significant savings in the cost of the palladium reagent was achieved by refluxing a THF solution of potassium tetrachloropalladate with lithium chloride prior to the addition of **9** and the chloromurcurated nucleoside. Recent literature reports that the needed palladium reagent can also be prepared by mixing $PdCl_2$ and LiCl in MeOH for 24 h (*20*) and this also works well, as long as all of the methanol is removed prior to dissolution in THF. **11** was converted into **2** by phosphitylation with

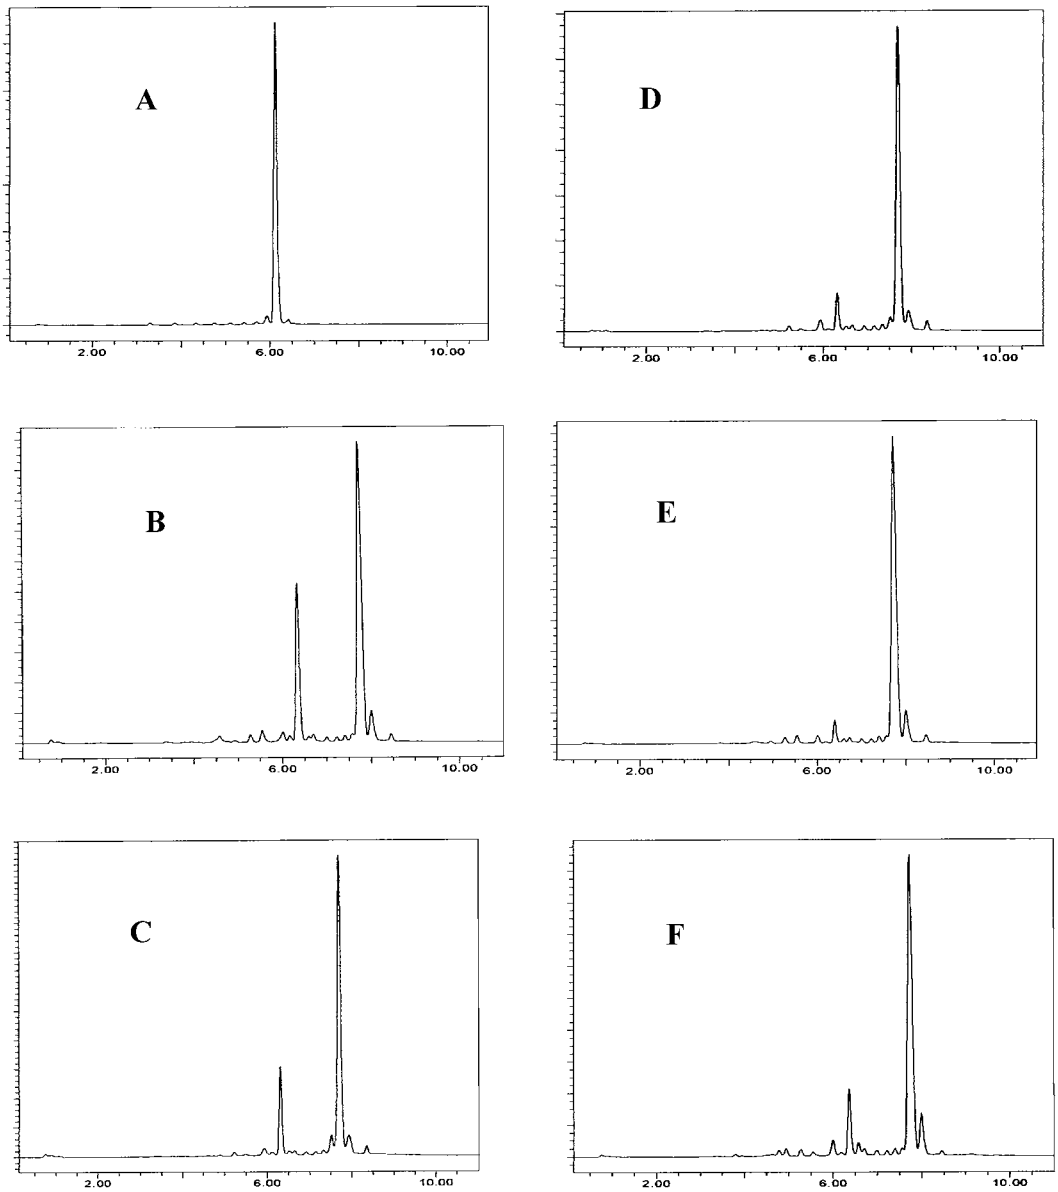


Figure 1. Time course for levulinoyl protecting group removal; A = 5′T_9C(N^4linker-O-lev)-3′ only; B = 2 min hydrazine exposure, then FAM, then T_9 addition; C = 4 min hydrazine, same other conditions; D = 8 min hydrazine, same other conditions; E = 12 min hydrazine, same other conditions; F = FAM after chain assembly with 12 min hydrazine exposure.

2-cyanoethyltetraisopropylphosphorodiamidite and catalytic tetrazole.

Synthesis of 3. A similar strategy to that used for **2** was employed. 6-amino-1-hexanol was first reacted with acryloyl chloride to give 6-acryloylamido-1-hexanol, followed by esterification with levulinic acid to give 6-acryloylamido-1-hexane levulinate **12**, obtained as a white solid after chromatography. **12** was coupled to chloromurcurated deoxyuridine by those methods used for **2** to give **13**, which gave **14** after treatment with DMT chloride. Conversion of **14** into phosphoramidite **3** was accomplished by the same method as for **2**.

Labeled DNA Synthesis. Incorporation of **1** and **3** into DNA was accomplished with standard methods and coupling times (*13*) and removal of levulinate protection was carefully optimized; previously reported conditions (*9*) were too harsh (0.5 M hydrazine in 1:1 pyridine:HOAc for 60 min), resulting in unwanted DMT loss and poor products, in our hands. We found that 0.25 M hydrazine in 4:1 pyridine:HOAc for 12−15 min gave the best results. This mixture and time is closer to the levulinate removal conditions originally described by Van Boom, et al. (*21*) for 5′ deprotection during a phosphate triester DNA oligomerization scheme. For us, the optimum exposure time was determined by an experimental system wherein **1** was first coupled onto sulfonylethyl CPG (*16*) and then subjected to various times of hydrazine exposure (2−12 min). 6-FAM was then coupled onto the deprotected hydroxyl, followed by oxidation and capping, and then extension of the DNA fragment by nine more addition cycles of T amidite. The product 3′-nucleoside fluoresceinated 10 mers were then cleaved with ammonia, and AX HPLC showed that the best results were obtained with 12 min of hydrazine exposure. The composition was confirmed by MALDI mass spectroscopy, calcd 3682, found 3687 amu. Longer exposure times gave more extraneous products. The same conditions using **4** in lieu of **1** did not produce good results (data not shown).

Another question to be addressed was the order of addition. Was it best to build the whole DNA fragment with the internal levulinated base and then deprotect and add the tag? This would be easier than the converse,

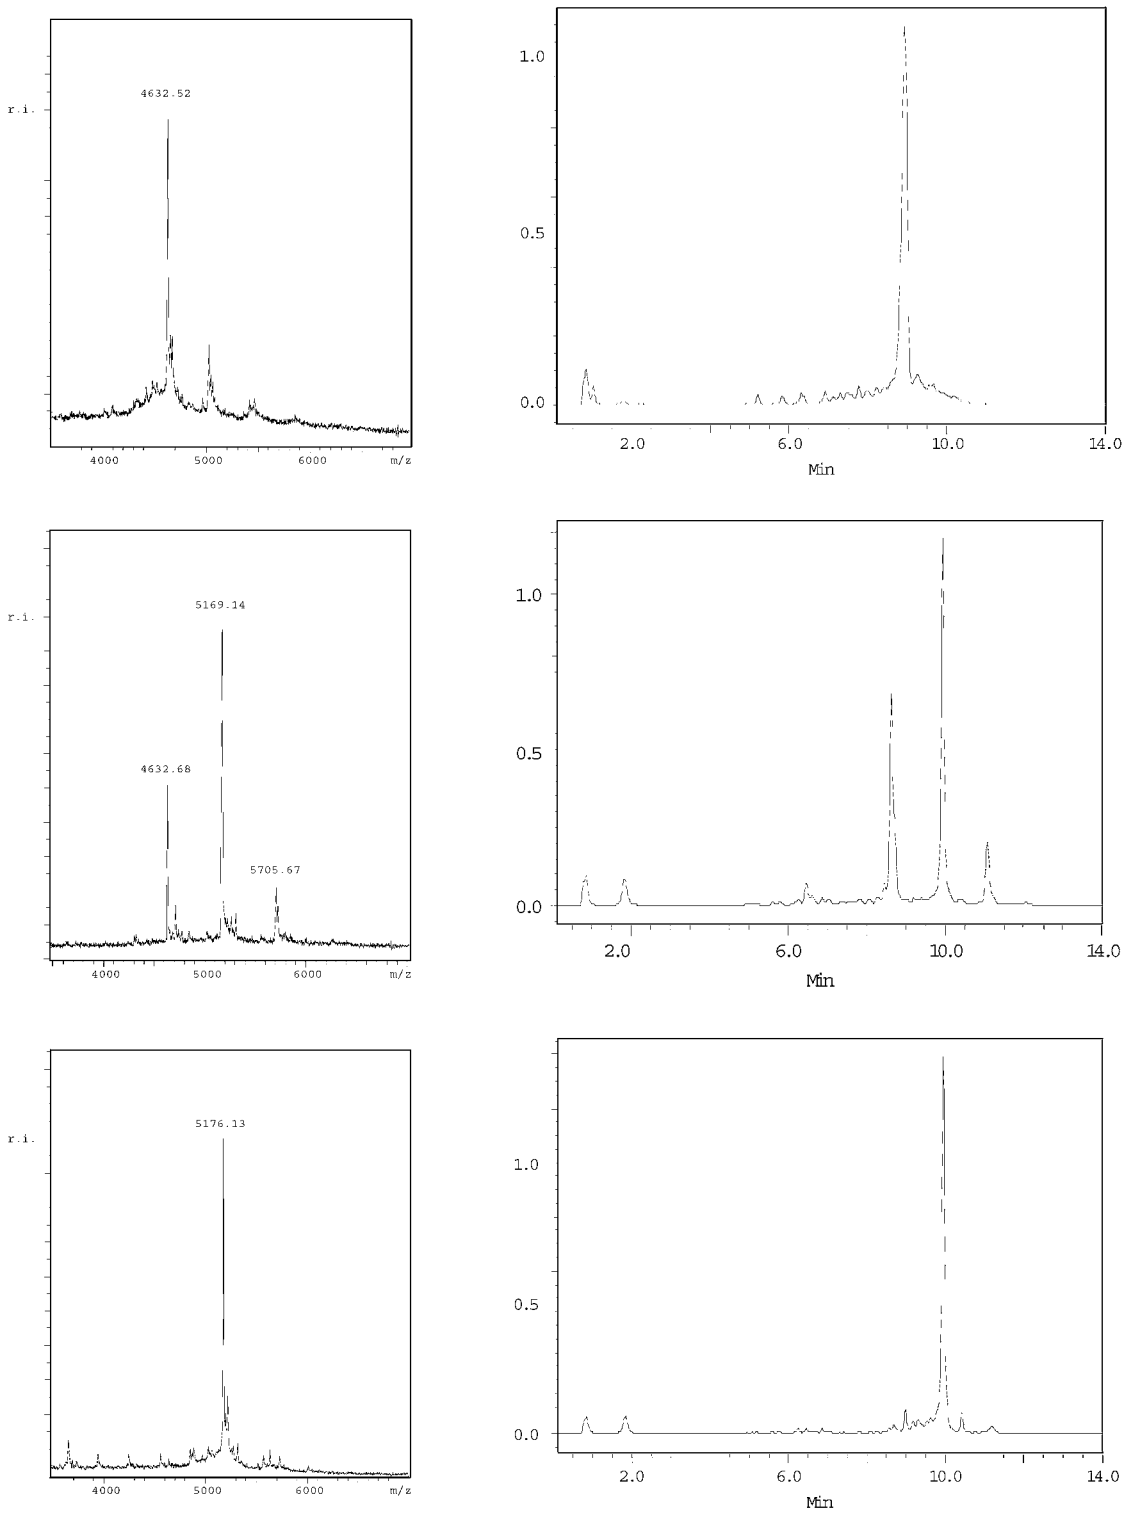

Figure 2. Order of label addition comparison with the synthesis of 5′-CGATCTGAC(N^{4}linker-O−FAM)TAGCTT-3′ by (left) MALDI mass spectra and (right) AX HPLC. Top: No FAM coupling control. Middle: whole fragment synthesis, then OLev removal and FAM addition at the end. Bottom: OLev removal and FAM addition after addition of base 7, then chain completion.

which was to deprotect the levulinated hydroxyl at the position where it was added, add the tag, and then continue the synthesis out to the 5′ terminus. An additional experiment was done with the time course study above, which removed the OLev group with the 12 min (best) conditions after all 10 bases were added and added 6-FAM as the last step. Figure 1 panel F shows clearly a result inferior to addition of fluorescein amidite prior to building the DNA fragment. 3′-HEX and TET CPGs were made with these techniques and gave good results in the synthesis of the analogous 10 mers. See Figures S1 and S2. Another comparison of the order of addition was done with 5′-CGATCTGA**X**TAGCTT-3′ where **X** resulted from the incorporation of **1**; good product purity was seen when addition of FAM occurred after addition of **1** and before chain extension (MALDI *m/e* calcd 5182, found 5176). Addition of fluorescein after the completion of the sequence gave other products in addition to that desired; incomplete FAM addition as well as double FAM addition were seen by mass spectroscopy (see Figure 2) Similar

results were obtained with **3** and FAM. The analogous internally labeled DNA fragment was made with **3** and a TAMRA amidite (*3*) and also gave good results when the TAMRA amidite was added before the rest of the chain, *m*/*e* calcd 5288, found 5275 amu (see Figure S3). Finally, the question of potential base modification by the conditions employed had to be addressed. CPG samples containing DMT-A^{Bz}, -C^{Bz}, -C^{Ac}, -G^{iBu}, -G^{DMF} and -T were subjected to the conditions employed for TAMRA amidite incorporation which includes the hydrazine treatment and a 5 min acetylation step before DMT removal and cleavage with *tert*-butylamine cocktail (18 h, 55 °C). The cleaved nucleosides were analyzed by RP-HPLC, and no extraneous peaks were seen compared to controls (data not shown).

CONCLUSION

Oligonucleotide protecting group chemistry first developed by Van Boom for 5′-hydroxyl protection (*21*) and later applied to side chain branching structures (*9*) has now been extended by us to allow the synthesis of internally dye-labeled DNA. New techniques and novel nucleoside phosphoramidite synthons have been developed which should allow the rapid synthesis of internally labeled structures. Utility of the new methods has been demonstrated with a variety of currently used fluorophores. Significant advantages in speed and simplicity over widely used solution-phase coupling methods, usually of an internally amine-labeled oligonucleotide with an active ester in aqueous solution, should be realized.

TECHNICAL NOTES

Evaluation of New Linkers and Synthetic Methods for Internal Modified Oligonucleotides

Troy A. Walton,* Matthew H. Lyttle, Daren J. Dick, and Ronald M. Cook

Biosearch Technologies, Inc., 81 Digital Drive, Novato, California 94949. Received January 21, 2002; Revised Manuscript Received May 15, 2002

Several fluorescence resonance energy transfer (FRET) oligonucleotide probes were made with different internal linkages between the DNA and the quencher dye. In one example, a 5′-fluorescein β-actin-based 26-mer DNA sequence was synthesized bearing an internal Tamra quencher. Two different versions were prepared using either conventional C5 [*N*-(6-aminohexyl)-3-acrylamido]pyrimidine-modified uridine and solution-phase Tamra active ester coupling or solid-phase addition of a Tamra amidite to a C5 [*N*-(6-hydroxyhexyl)-3-acrylamido]pyrimidine-modified uridine. The products were compared in functional assays. They performed very similarly both in a fluorescence-based melting point assay as well as in quantitative PCR. Another set of β-actin probes were synthesized utilizing N4 [*N*-2-(ethylene glycol ethyl)-5-methyl]cytidine and solid-phase Tamra amidite addition at positions flanking those of the uridine. These versions gave lower T_ms than either uridine-labeled probe and did not work as well in quantitative PCR. A control experiment using oligonucleotides with the same modified residues but without fluorophores attached revealed the same trend as the T_m study of internal Tamra-labeled probes. Experimental details for the synthesis, purification, and testing are presented.

INTRODUCTION

A variety of different FRET oligonucleotide probes require internal modifications, including sunrise (*1*), scorpion (*2*), tandem dye reporters or FRET reporters (*3*), and the invader fluorescent assay (*4*). The maximum FRET effect has been reported with 4−5 nucleotide bases separating reporter and quencher dyes (*5*, *6*), which suggests that the use of internally linked fluorophores (or quenchers) would provide the best performance for longer sequences. Methods for generating internally labeled synthetic oligonucleotides are limited, with solution-phase coupling of active esters to alkylamine internal modifications being prevalent (*3*). Traditionally, solid-phase fluorescent-tagged DNA synthesis is restricted to fluorophore incorporation at the 3′ or 5′ terminus. In recent work, we developed a method using an internal uridine nucleotide modified at C5 with a protected alkyl hydroxyl group to synthesize internally labeled probes on a solid-phase support (*7*). We report here application of this technique to the synthesis of dual-labeled FRET probes and compare the performance of these structures to those synthesized using conventional uridine C5 alkylamine and solution-phase *N*-hydroxysuccinimide (NHS) active ester coupling methods. Probes were also made with a cheaper internal linkage system, utilizing N4-protected alkylhydroxyl functionalized cytidine. Figure 1 shows the structure of the three internal linkages to Tamra. The different probes were compared by a quantitative PCR (qPCR, *3*) assay and melting temperature assays (*8*, *10*). Probes were synthesized with fluorescein on the 5′ end and Tamra internally or with no fluorophore modifications.

MATERIALS AND METHODS

Oligo Synthesis. The probes with sequence 5′-ATGC-C**CTC**CCCCATGCCATCCTGCGT-3′ were targeted for the human β-actin gene (*3*). All oligos were synthesized on Biosearch 8700 DNA synthesizers, using 3′-phosphate controlled pore glass (CPG) (p/n BG5-5000). Modified nucleotide amidites (*7*) and Tamra and fluorescein amidite (FAM) (*9*) were synthesized in-house along with the Tamra NHS ester used for solution-phase coupling. The modified bases were incorporated at the boldface underlined positions shown above. Syntheses were done at a 1 μmol scale. For structure **I** (see Figure 1), also T7-NH-Tamra in Table 1, 5-[*N*-(6-trifluoroacetylaminohexyl)-3-(*E*)-acrylamido]-5′-(4,4′-dimethoxytrityl)-3′-(2-cyanoethyldiisopropylphosphoramidite)-2′-deoxyuridine (*7*) was used in lieu of the T, 7 bases from the 5′ end, and the rest of the bases were added followed by FAM addition (*7*). Workup and Tamra incorporation were done with solution-phase methods as previously reported (*3*). Figure 2A shows an anion exchange (AX) HPLC trace and photodiode array (PDA) spectrum of the purified probe. For the probe containing internal modification **II**, also T7-O-Tamra, automated synthesis was halted after the addition of 5-[*N*-(6-*O*-levulinoyl-1-aminohexyl)-3-(*E*)-acrylamido]-5′-(4,4′-dimethoxytrityl)-3′-(2-cyanoethyldiisopropylphosphoramidite)-2′-deoxyuridine (*7*) at T7, and the CPG was treated with the dilute hydrazine/pyridine/acetic acid (HOAc) cocktail outlined in (*7*). Tamra amidite (*9*) was coupled onto the now unmasked hydroxyl group, followed by oxidation and capping. The rest of the bases were then added by automated synthesis, followed by

FAM addition. Figure 2B shows an AX HPLC trace and PDA spectrum of this purified probe. For the other probes containing modification **III** at the C positions flanking T7, N^4-[2-(ethylene glycol-2-levulinate)ethyl]-5-methyl-5′-(4,4′-dimethoxytrityl)-3′-*O*-(2-cyanoethyldiisopropylphosphoramidite)-2′-deoxycytidine (*7*) was used at the appropriate position to generate either C6-O-Tamra or C8-O-Tamra (Table 1), and the other manipulations were the same as those used to generate **II**. Figure 2C,D has the comparative analysis of these probes. A similar set of probes was synthesized without fluorescent dyes for use as nonlabeled controls in a Sybr Green I melting temperature assay (*10*). These are referred to as T7-OH, C6-OH, C8-OH, and unmodified. After synthesis, Tamra deprotection cocktail (*9*) and 16 h of heating at 60 °C were used to deprotect and remove the probes from the CPG. Volatile components were removed under vacuum, and the crude sample was dissolved in 1 mL of water. Probes were purified using a double-preparative HPLC method consisting of an anion exchange (AX) purification followed by a reversed phase (RP) purification. A Dionex DNA Pac

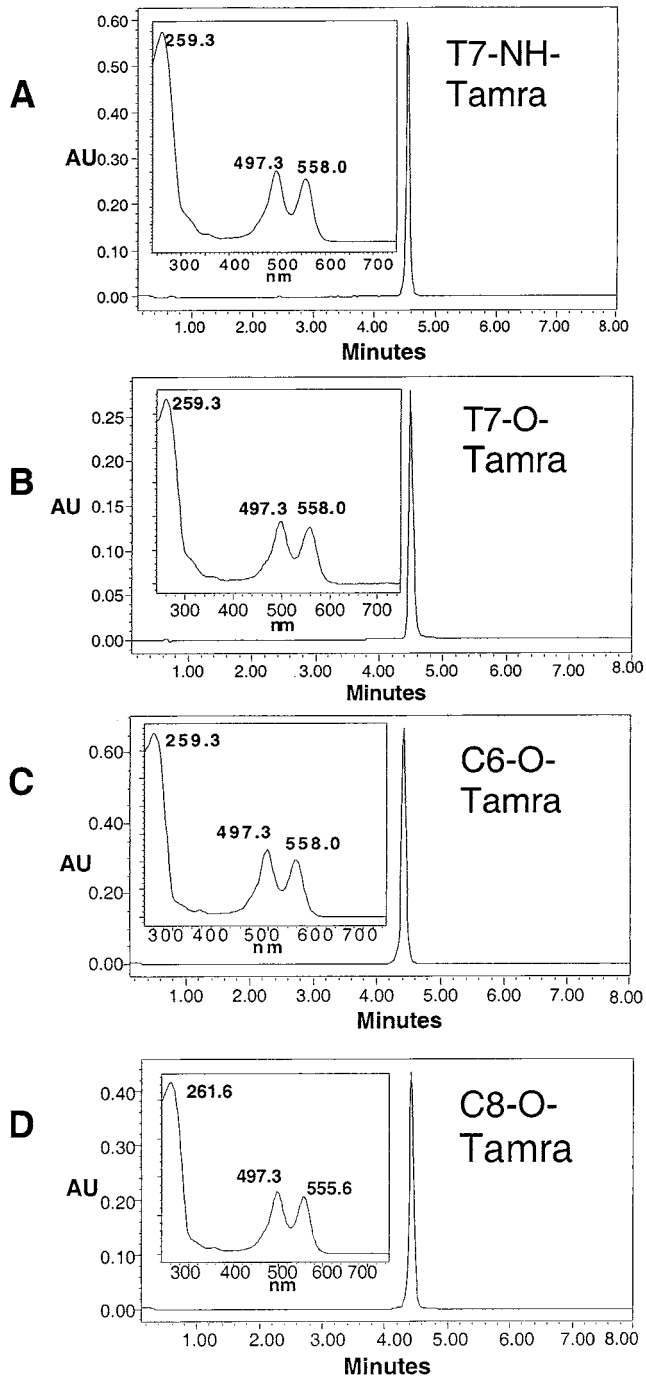

Figure 2. Analytical AX HPLC of internally Tamra-labeled FRET probes. The inset shows the PDA spectrum of each sample. Sequences shown in Table 1.

PA100 9 × 250 mm column was used for AX, and a Hamilton PRP-1 10 × 250 mm 7 μm particle size column was used for RP. A 5 mL injection loop with a 10 mL/min flow rate for AX and a 6 mL/min flow rate for RP were used. The buffers for the AX preparation consisted of 0.038 M Tris at pH 8.0 plus 15% acetonitrile (ACN) for buffer A, and buffer B was buffer A plus 1 M NaBr. The purification gradient was 10−70% B over 12 min. The buffers for the RP purification consisted of 0.1 M TEAA (triethylamine acetate) + 5% ACN for A, and B was ACN. The gradient was 0−75% B over 15 min. A Waters 600 controller and pump with a Waters 490 multiple wavelength detector were used for purification. Intensely colored fractions were inspected by analytical HPLC, and those containing pure material with the

proper spectrum were pooled and evaporated. The yield of purified probes made at this scale was 60−120 nmol.

PCR and Melting Temperature Conditions. The PCR reactions were carried out on an ABI 7700 using 50 μL reaction volumes in Taqman Buffer A (Applied Biosystems). The reactions contained 200 nM primers (Applied Biosystems), 400 nM FRET probe, 100 or 1 ng of sheared human genomic DNA (Clontech), with 4 mM MgCl (Applied Biosystems), 200 μM each dNTP (Sigma), 0.3 unit of *Bst*Xl (Boehringer Mannheim), and 2.5 units of Platinum Taq (Gibco). Thermal cycling conditions were 48 °C for 30 min, then 95 °C for 10 min followed by 40 cycles of 95 °C (25 s) and 60 °C (60 s). The ABI 7700 was set for a single dye (FAM) with Tamra as the quencher. The melting curves were also generated on the 7700 in PCR buffer consisting of 10 mM Tris, pH 8.3, 50 mM KCl, and 3.5 mM $MgCl_2$. The temperature was decreased in 1 °C steps from 90 to 50 °C using the auto increment function with each step lasting 1 min. Probes were suspended at 200 nm, and compliment was suspended at 1 μM. For nonlabeled DNA reactions, Sybr Green I was used at a final 1:40 000 dilution from the stock solution provided by the manufacturer.

RESULTS AND DISCUSSION

Melting Temperature (T_m) Experiments. Instead of conventional T_m measurements using UV absorbance, we chose a system more relevant to the evaluation of FRET probes. Similar buffers and the same instrument were used to generate the T_m data as for qPCR. When the probe hybridizes to exact complement and forms duplex DNA, the fluorescence increases relative to the single-stranded probe free in solution (*3*). Because of this, the T_m can be determined by measuring the fluorescence over a temperature range the same way one would use absorbance measurements at 260 nm (*8*). In the nonlabeled DNA reactions, the intercalating dye Sybr Green I was added to the reaction mix. Sybr Green I increases in fluorescence when it binds to double-stranded DNA. In this melting temperature assay, the change in fluorescence of the Sybr Green I with respect to increasing double-stranded DNA concentration vs temperature reveals melting curves similar to those obtained for the dual dye-labeled oligos (*10*). The data for the dual-labeled probes show that probes containing internal structures **I** and **II** anneal to complement at similar T_ms. In contrast, both of the modified cytidine compounds (structure **III**) give lower T_ms than those given by the modified thymine compounds. They also have a much broader T_m range than the thymine-based probes, suggesting less specificity during the hybridization event (see Figure 3). This same trend is apparent in Figure 4, which shows a similar melting temperature experiment. In this experiment, the same probe structures were synthesized without fluorescent dyes, and the amine modified probe was replaced by a totally unmodified oligo. The conditions for the nonlabeled DNA experiment were the same except that SYBR Green I was used as the reporter. In the Sybr Green I experiment, the melting curves for the unmodified DNA and the hydroxyl-modified thymine oligo (T7-OH in Figure 4) overlap, while the hydroxyl-modified cytidine compounds show a significantly lower melting temperature.

When using either amine- or hydroxyl-modified thymine chemistries, the performance of the dual-labeled probe is virtually unaffected. This same trend has been observed when comparing N4-modified cytidine compounds with hydroxyl functionality and amine functionality (data not shown). We can attribute the difference between the T- and C-labeled probes to the modifications that were used for internal labeling, although other factors might be at play. One plausible explanation is that the thymine residue used has a modification on the methyl group at position C5, while the cytidine residue is modified at N4, and N4 in unmodified cytosine participates in an energetically important G−C base pair. The appendage at position C5 of thymine protrudes out into the major groove of B-DNA and should not affect base pairing. Realistically, we have empirically compared several easily accessible linkages in an important application. Different spacer length and geometry, as well as the presence of a phosphate moiety in some of the linkers, may also be having an effect. Although the linkage differences are more directly compared in the nonlabeled DNA experiment using SYBR Green I, the intercalation itself appears to have some effect on the T_m of these oligos (Figure 4).

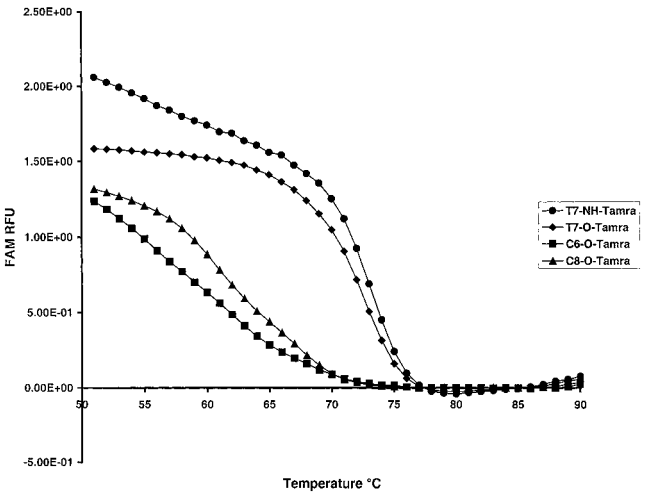

Figure 3. Melting temperature curves of Tamra-quenched probes generated as a function of increasing fluorescein fluorescence on an ABI 7700. RFU = relative fluorescence units.

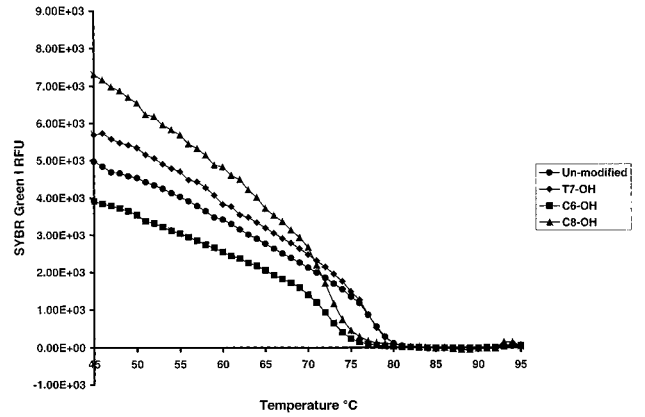

Figure 4. Melting temperature curves of unlabeled probes generated as a function of increasing Sybr Green I fluorescence on an ABI 7700. RFU = relative fluorescence units.

Quantitative PCR Experiments. There are several different chemistries available for qPCR (*11*), including the 5′→3′ exonuclease assay, which was used for this comparison (*12*). In this assay, a dual-labeled fluorescent oligonucleotide is hybridized to the amplicon between the primers and is cleaved by the 5′→3′ nucleolytic activity of Taq polymerase. This cleavage event generates fluorescence because the reporter fluorophore is no longer in close enough proximity to the quencher for efficient

Table 2. Data from qPCR Experiments[a]

	1 ng target		100 ng target	
probe	C_T	std dev	C_T	std dev
T7-NH-TMR	28.85	0.14	21.88	0.13
T7-O-TMR	29.13	0.06	22.2	0.02
C6-O-TMR	31.89	0.13	24.7	0.04
C8-O-TMR	31.09	0.08	24.0	0.02

[a] All reactions were run in triplicate. The average C_T is shown with the standard deviation for each triplicate reaction. Reactions were done for two different input amounts of target human genomic DNA (1 and 100 ng).

energy transfer via the FRET mechanism (*13*). By monitoring the increase in fluoresence produced by this cleavage event over several cycles of PCR, the amount of original target DNA in the reaction mix can be measured (*13*). The cycle in which the fluorescence rises above a certain background level is referred to as threshold cycle (C_T) and is used to calculate the amount of target DNA. Comparison of the oligos from Table 1 in a quantitative PCR assay is summarized in Table 2. While the performance difference, as expressed with the C_T value, is small between the two thymine compounds ($dC_T = 0.28$ for 1 ng target), the difference between the thymine and cytidine compounds is quite dramatic ($dC_T = 2.76$ for 1 ng target, T7-O-Tamra compared with C6-O-Tamra). This same trend is also seen in the 100 ng target samples. The difference in the melting temperature between these probes quite possibly accounts for the difference in performance seen here. The modified cytidine probes have a lower T_m (~62 °C) compared to the modified thymine probes (~73 °C) and therefore would not hybridize as well at the 60 °C extension temperature of the PCR reaction. This difference in hybridization would lead to fewer of the modified cytidine probes being cleaved by the nucleolytic activity of Taq polymerase, thus requiring more cycles of PCR to generate the same fluorescence as the thymine probes. Reprogramming the thermal cycler used for this qPCR experiment with a lower extension temperature would perhaps give improved or equivalent performance, with respect to C_T.

CONCLUSION

Several different ways of attaching Tamra to internal positions of a FRET probe targeting the human β-actin gene have been compared in practical applications. We have supplied useful data, which should be helpful in the design of more effective internally labeled FRET probes. A logical extension of this work would be the preparation of analogous C5-modified cytidine derivatives with a free amine at position N4; this work is in progress.

Our experiments show that when designing an oligonucleotide with an internal label on a modified nucleotide, N4-modified cytidine compounds do not perform the same as C5-modified thymine compounds. The synthetic toolbox for providing these modifications has been expanded, and both C and T are now available with added amine or hydroxyl functions for additional elaboration. The resulting different linker structures do not significantly change the performance of the modified T probes we tested. The solution-phase amine to active ester coupling method requires more synthetic manipulations. Therefore, we prefer the ease and faster throughput of solid-phase synthesis method made possible with the hydroxyl compounds.

A Convenient Method for the Synthesis of Amine-Terminated Poly(ethylene oxide) and Poly(ϵ-caprolactone)

Feng-Zhu Lu,[†] Xiang-Yuan Xiong,[‡] Zi-Chen Li,*[,‡] Fu-Sheng Du,[‡] Bao-Yan Zhang,[†] and Fu-Mian Li[‡]

Department of Polymer Science & Engineering, College of Chemistry, Peking University, Beijing 100871, China, and Department of Chemistry, Northeastern University, Shenyang 110004, China. Received March 19, 2002; Revised Manuscript Received June 25, 2002

A convenient synthetic route to prepare amine-terminated poly(ethylene oxide) (PEO) and poly(ϵ-caprolactone) (PCL) was described. The strategy involved two-step reactions, the condensation of hydroxyl-terminated PEO and PCL with *N*-benzyloxycarbonyl amino acid followed by the catalytic hydrogenation under mild conditions. NMR and GPC measurements indicated that the reactions proceeded nearly quantitatively. Amine-terminated PEO thus prepared was used to initiate the polymerization of α-(*N*$^{\epsilon}$-benzyloxycarbonyl-L-lysine) *N*-carboxy anhydride [lys(Z)-NCA], and the results confirmed that the reactivity of the amino group was high.

INTRODUCTION

Poly(ethylene oxide) (PEO) and poly(ϵ-caprolactone) (PCL) have found many applications as biomedical materials (*1, 2*). Chemical modification, especially end-functionalization, is an important way to expand the applications of these polymers. Amine-terminated polymers are important intermediates for the synthesis of novel polymeric materials. They can react with molecules containing reactive groups such as acid chlorides, sulfonyl chlorides, acid anhydrides, and activated esters to conjugate other bioactive molecules at the end of the polymer chains (*3*). Furthermore, they can also be used as macroinitiators for the ring-opening polymerization of amino acid *N*-carboxy anhydrides (NCAs) to prepare block copolymers containing polypeptide segments (*4*).

The first paper for the synthesis of amine-end capped polyester was reported by Teyssie et al. (*5*). In their report, diethylaluminum 12-bromododecyloxide was used as an initiator of CL, yielding a bromo-terminated PCL, which was then converted into an azide-terminated PCL by the treatment with an excess of sodium azide. An amine-terminated PCL was finally obtained after catalytic hydrogenation. Star-like PCLs with amino end groups have also been reported by this group by using the same approach (*6*). But the synthesis of amine-terminated PLA by this method was demonstrated to be with side reactions (*7*). A similar approach has been reported by Kricheldorf et al. for the synthesis of amine-terminated aliphatic polycarbonates (*8*). The difference is that a nitrophenyl group was introduced to the aluminum alkoxide as an active initiator of trimethylene carbonate (TMC), aminophenyl end-capped poly(TMC), was obtained after catalytic reduction. Other approaches to prepare amine-terminated polyesters are the chain end modification of the polymer precursor under mild conditions. This can be achieved by the in situ reaction of 4-nitrobenzoyl chloride with a macrocyclic PCL, resulting in the formation of a α,ω-diamine-terminated telechelic PCL after reduction (*9*). Recently, Yuan et al. (*10*) prepared an amine-terminated MPEO−PCL diblock polymer from the hydroxyl-terminated polymer through a three-step reaction based on the chemistry as in the case of Teyssie's work.

There have been many reports on the preparation of amine-terminated PEO from hydroxyl-terminated PEO in the literature. The chemistry involved in this synthesis is to convert the hydroxyl groups into bromo, chloro, sulfonic, and aldehyde groups, followed by other chemical reactions leading to the formation of amino groups. For example, Buckmann and Johansson reduced the bromized PEO in alcohol using ammonia and hexadiamine, respectively (*11*). Sulfonic group end-capped PEO was transferred into amine-terminated PEO via a classical Gabriel process (*12*). The aldehyde group precursor of PEO was treated with $NaCNBH_3$ and converted into an amino group (*13*). Besides the above strategies, an approach similar to that for the preparation of amine-terminated PCL was carried out by treating the chloro precursor with NaN_3- and Pd/C-catalyzed hydrogenation successively (*14*). Though amine-terminated PEO can now be commercially available, these methods are still being used for the preparation of amine-terminated PEO of different chain lengths.

We tried another general procedure to obtain amine-terminated PCL and PEO from the hydroxyl-terminated precursors. It involved the condensation of hydroxyl-terminated PEO and PCL with *N*-benzyloxycarbonyl amino acid and subsequent catalytic hydrogenation under mild conditions to liberate the amino groups. The purification procedure was easy. Yet, to the best of our knowledge, only one publication has appeared so far dealing with the synthesis of an amine-terminated PLA by a similar procedure (*4b*). Although the structure of the amino acid used is not the same as the polymer, the short chain length compared with PEO and PCL would not influence the properties of the main chain, but alternate their reactivities. This approach may be a universal synthetic route with a high potential utility for the preparation of amine-end capped polymers from hydroxyl-terminated polymer precursors.

EXPERIMENTAL PROCEDURES

Materials. ϵ-Caprolactone (ϵ-CL) was purchased from Acros, dried over calcium hydride for 48 h at room

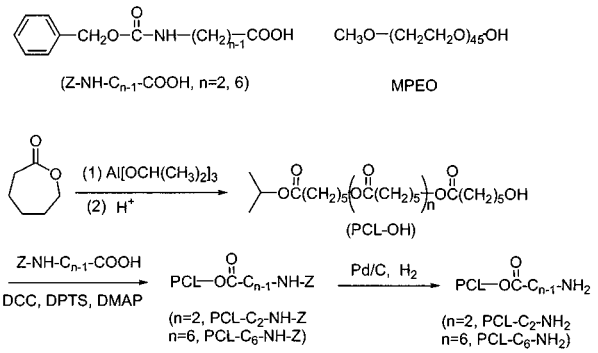
temperature, and then distilled under reduced pressure. $Al(OiPr)_3$ and 10% Pd/C were also from Acros; 10% Pd/C was used as received, and $Al(OiPr)_3$ was distilled under reduced pressure prior to use. Methoxy PEO (MPEO, M_n = 2000) was obtained from Aldrich, and was treated by azeotropic distillation with toluene to get rid of the small amount of water prior to use. *N*-Benzyloxycarbonyl glycine and 6-[(*N*-benzyloxycarbonyl)amino]hexanoic acid were synthesized according to the published procedure (*15*). α-(*N*$^{\epsilon}$-Benzyloxycarbonyl-L-lysine) *N*-carboxy anhydride [lys(Z)-NCA] was synthesized according to the literature method (*16*). (Dimethylamino)pyridine toluenesulfonate (DPTS) was prepared as described previously (*17*). Other regents were commercially available and used as received unless otherwise noted. All solvents were thoroughly dried and distilled before use.

Measurements. ^{1}H NMR spectra were recorded with a Bruker AXR-400 spectrometer operated at 400 MHz, $CDCl_3$ was used as solvent, and tetramethylsilane was used as an internal standard. The average molecular weights and molecular weight distributions were measured on a Waters 410 gel permeation chromatography (GPC) equipped with three Ultrastyragel columns (10^4, 10^3, and 500 Å pore size) at room temperature. The eluent was THF, and polystyrene standards were used as calibrations.

Synthesis of Poly(ϵ-caprolactone) (PCL-OH) (*18*). Dried toluene (40 mL) and 10 mL of ϵ-CL solution in toluene (0.1 mol) were injected through a syringe into a flask which had been dried, purged with nitrogen, and vacuumized several times. Then a solution (0.11 g/mL, 9.27 mL) of $Al(OiPr)_3$ in toluene was introduced at 0 °C to the reactor under nitrogen. The reaction mixture was incubated for 2 h at 0 °C and then diluted with 80 mL of toluene. Afterward, the solution was washed with 0.3 N HCl aqueous solution (3 × 20 mL) and water (3 × 30 mL). The organic phase was obtained and dried over $MgSO_4$. The solution was concentrated to about 10 mL by a rotary evaporator and poured into 100 mL of hexane. The precipitated polymer was obtained by filtration and was redissolved in 10 mL of $CHCl_3$, precipitated again in hexane. The purified product was dried under vacuum at room temperature, yielding 9 g of a white powder. Yield: 90%, M_w/M_n = 1.33, M_n = 4900.

Synthesis of PCL-Cn-NH-Z and MPEO-Cn-NH-Z (*16*). *(1) PCL-Cn-NH-Z.* A 250 mL round-bottomed flask, fitted with a magnetic stir bar, was charged with 4 g of PCL-OH (1.67 mmol), 0.52 g of DCC (4.7 mmol), 0.29 g of DPTS (0.98 mmol), and 100 mL of CH_2Cl_2. To this mixture was added 0.53 g (2 mmol) of 6-[(*N*-benzyloxycarbonyl)amino]hexanoic acid or 0.42 g (2 mmol) of *N*-benzyloxycarbonyl glycine. The reaction mixture was stirred at room temperature for 48 h. After filtration, the solution was reduced in volume to 20 mL by a rotary evaporator, and the polymer was precipitated into cold methanol (400 mL), dissolved in chloroform (30 mL), reprecipitated out by cold methanol (200 mL), and dried under vacuum. PCL-C_6-NH-Z: 65%; PCL-C_2-NH-Z: 53%.



(2) MPEO-Cn-NH-Z. These polymers were prepared from MPEO under the same conditions as in the case of PCL. But the purification procedure is different. The resulting reaction mixture was first precipitated into cold diethyl ether (400 mL), and the products obtained were dissolved in 40 mL of THF. After filtration, the solution was concentrated and precipitated into cold diethyl ether and dried in a vacuum oven. MPEO-C_6-NH-Z: 79%; MPEO-C_2-NH-Z: 85%.

Synthesis of PCL-Cn-NH_2 and MPEO-Cn-NH_2. *(1) PCL-Cn-NH_2.* A suspension of PCL-Cn-NH-Z (2.0 g) in EtOAc/MeOH (v/v, 2:1) (40 mL) and 1.0 g of 10% Pd supported on activated carbon was subjected to hydrogenation under a H_2 blanket at room temperature for 24 h. After filtration over Celite, the solution was concentrated and precipitated into cold methanol. The obtained polymer was reprecipitated from cold methanol by dissolving in chloroform. PCL-C_6-NH_2: 70%, M_n = 4800, M_w/M_n = 1.21; PCL-C_2-NH_2: 60%, M_n = 4200, M_w/M_n = 1.34.

(2) MPEO-Cn-NH_2. The polymers were prepared by using a similar procedure as for PCL-Cn-NH_2, except that the precipitator was cold diethyl ether. MPEO-C_6-NH_2: 87%, M_n = 2100, M_w/M_n = 1.06; MPEO-C_2-NH_2: 80%, M_w/M_n = 2100, M_n = 1.10.

Synthesis of Poly[ethylene oxide-β-(*N*$^{\epsilon}$-benzyloxycarbonyl-L-lysine)] [MPEO-β-P(lys(Z))] (*4e*). A 4.5 g aliquot of α-(*N*$^{\epsilon}$-benzyloxycarbonyl-L-lysine) *N*-carboxy anhydride (15 mmol) was dissolved in 45 mL of DMF. The resultant solution was added to a solution of MPEO-C_2-NH_2 (2 g, 1 mmol) in DMF (70 mL). The reaction mixture was stirred under an inert atmosphere for 72 h at 40 °C and was precipitated into cold diethyl ether, followed by filtration and drying under reduced pressure to give 5.8 g of white powder. Yield: 89%, M_w/M_n = 1.19, M_n = 6000. Elemental analysis was conducted. Assume the average degree of polymerization is 15, Calcd for $C_{303}H_{457}N_{31}O_{92}$ (%): C, 60.61; H, 7.62; N, 7.23. Found: C, 60.51; H, 7.83; N, 7.28.

Scheme 1

RESULTS AND DISCUSSION

The amine-terminated MPEO and PCL were accomplished via a two-step process from hydroxyl-terminated MPEO and PCL as shown in Scheme 1. The hydroxyl-terminated PCL was prepared by the well-known coordination-insertion ring-opening polymerization of ϵ-caprolactone (ϵ-CL) in toluene using $Al(OiPr)_3$ as an initiator (*18*). In our experiment, the reaction temperature was 0 °C, and the polymerization time was 2 h. ^{1}H NMR spectrum of the resulting PCL is shown in Figure 1A. It can be seen that typical signals due to -$\underline{CH_2}$-OH, $(\underline{CH_3})_2$-CHO-, and $(CH_3)_2\underline{CH}$O- are observed at 3.62, 1.22−1.24, and 4.97−5.04 ppm, respectively, and their molar ratio was 2:6:1, confirming the α-hydroxyl ω-isopropyl structure. Based on the integral ratio of -OOC-$\underline{CH_2}$-CH_2- at 2.27−2.36 ppm to $(\underline{CH_3})_2$CHO- at 1.22−1.24 ppm, the average molecular weight of the product was calculated to be 2400. The average molecular weight obtained by GPC measurements shown in Figure 2A is 4900. This value is larger than that derived from ^{1}H NMR, which is normal when PS standards are used for GPC measurements (*9, 20*). The molecular weight distribution is 1.33.

The condensation of hydroxyl-terminated PCL and MPEO with an excess of *N*-benzyloxycarbonyl amino acid was easily done at room temperature according to the literature approach (*19*). To confirm whether the reaction

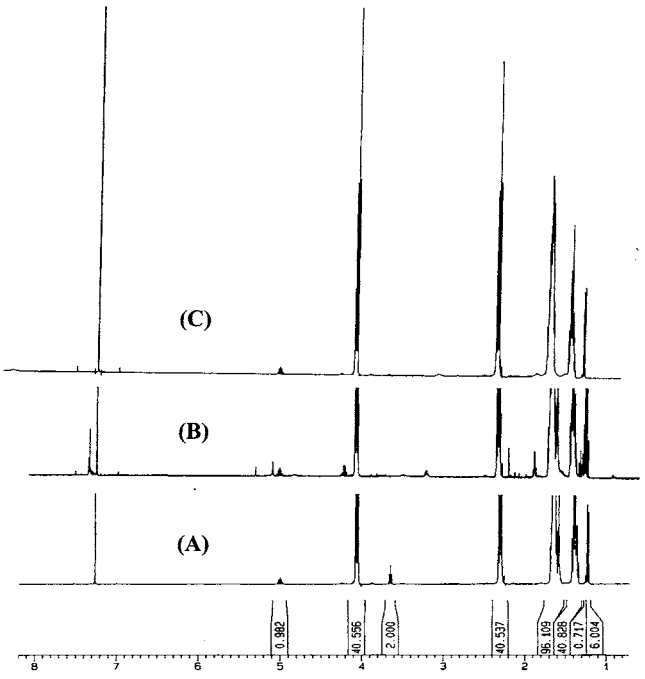


Figure 1. ^{1}H NMR spectra of (A) PCL-OH, (B) PCL-C_6-NH-Z, and (C) PCL-C_6-NH_2.

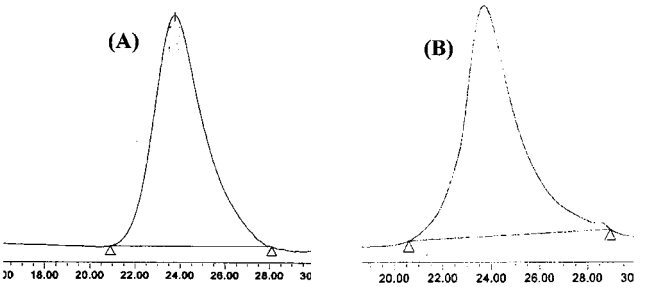

Figure 2. GPC trace of PCL (A) hydroxyl-terminated and (B) amine-terminated.

is applicable for both α-amino acids and α,*ω*-amino acids, two different amino acids, *N*-benzyloxycarbonyl glycine and 6-[(*N*-benzyloxycarbonyl)amino]hexanoic acid, were tested. The reaction conditions were the same. The purification procedure was different for PCL and MPEO. In the case of PCL, purification was easily done by precipitation into cold methanol. Due to the good solubility of DPTS and DCC and the excess of amino acid in methanol, they were easily removed to give pure polymer. But in the case of MPEO-Cn-NH-Z, the solubility of DPTS in cold diethyl ether was not high enough, and the product may contain little DPTS if the final solution was precipitated out directly from diethyl ether. However, DPTS could be eliminated by filtrating the concentrated mixture of DPTS and MPEO-Cn-NH-Z in THF before precipitation into diethyl ether. The ^{1}H NMR spectrum of PCL-C_6-NH-Z is shown in Figure 1B. The emergence of the peaks at 5.10, 7.36 ppm assignable to the benzyloxycarbonyl protons and the disappearance of the peaks at 3.62 ppm belonging to the methylene group near the hydroxyl terminal indicate condensation is taking place. Figure 3 A is the ^{1}H NMR spectrum of MPEO-C_2-NH-Z. The triple peaks at 4.30−4.32 ppm are from the methylene groups adjacent to the newly formed ester bonds (-OCH_2CH_2OOC-). Again, the peaks belonging to protective groups appear at 5.1 and 7.30−7.36 ppm, respectively. Based on the intensity ratio of benzyl or methylene groups adjacent to the ester bond to unchangeable

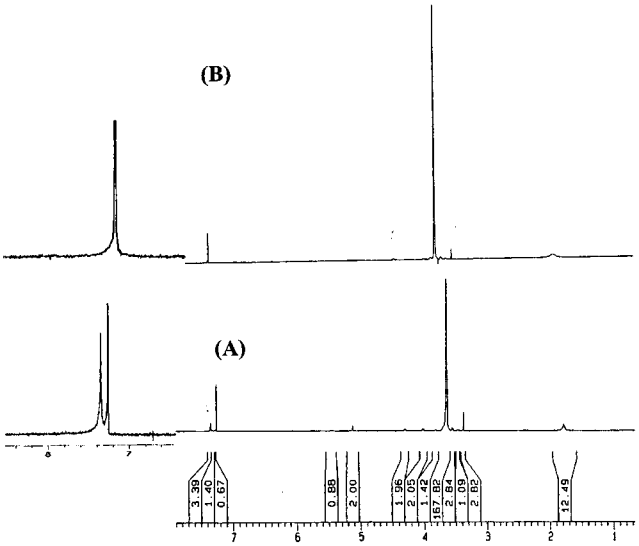

Figure 3. ^{1}H NMR spectra of MPEO. (A) MPEO-C_2-NH-Z. (B) MPEO-C_2-NH_2.

terminal groups [($\underline{CH_3}$)$_2$CH- for PCL-C_6-NH-Z, $\underline{CH_3}$O- for MPEO-C_2-NH-Z], the efficiencies of the end-group functionalization are close to 100%. PCL-C_2-NH-Z and MPEO-C_6-NH-Z gave similar results. The relatively lower yields of the resulting polymers were due to the solubility of polymers in methanol or diethyl ether.

Catalytic hydrogenation is one of the most important methods to liberate the *N*-benzyloxycarbonyl-protected amino group. The catalyst is 10% Pd supported on activated carbon. The reaction condition is mild and is not sensitive to environmental factors such as water moieties. The reaction is known to proceed at the surface of Pd; therefore, once the stirring is gentle enough and H_2 is sufficient, the reaction could proceed smoothly and completely. However, due to the adsorption of the polymer on Celite, the filtration over Celite to remove Pd/C decreases the yields. It can be seen from the ^{1}H NMR spectrum of PCL-C_6-NH_2 as shown in Figure 2C that the signals at 5.10, 7.36 ppm disappear, while the signals at 3.21 ppm assignable to the methylene groups adjacent to amino groups shift to higher field, indicating complete deprotection. In the ^{1}H NMR spectrum of MPEO-C_2-NH_2 (Figure 3B), the disappearance of the peaks belonging to the protective groups at 5.31, 7.30−7.36 ppm indicates that the benzyloxy carbonyl groups have been removed. At the same time, the signals assignable to -$CH_2\underline{CH_2}$-OOC- at 4.3 ppm remain, and the ratio of this peak to the methyl end group is 2:3, so the ester bond of the main chain does not change during the reaction. The structure of PCL-C_6-NH_2 was also confirmed by the ^{13}C NMR spectrum as shown in Figure 4. The signal at 64.08 ppm is the characteristic peak assignable to the methylene close to the amino group, and the peaks due to (CH_3)$_2\underline{C}$H-O- and -$\underline{C}H_2$-OCO- are overlapped with the signals of $CDCl_3$.

The GPC trace of PCL-C_6-NH_2 displays a single and sharp peak as shown in Figure 2B. Compared with the hydroxyl precursor, no obvious change of average molecular weight and molecular weight distributions is observed. It reveals that PCL was stable under the present conditions and little or no transesterification occurred. By increasing of the reaction time to 4 days, a decrease of molecular weight and an increase of molecular weight distributions were found, which might be caused by hydrolysis and transesterification. This phenomenon was reported by Langer et al. in other similar reactions (*21*),

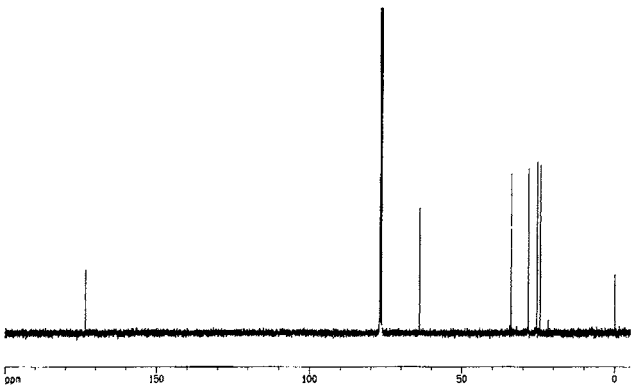

Figure 4. ^{13}C NMR spectrum of PCL-C_6-NH_2.

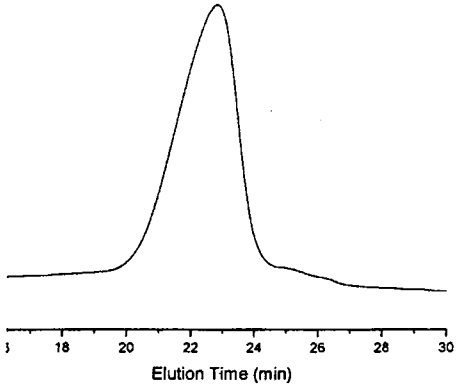

Figure 5. GPC trace of MPEO-β-P[Lys(Z)].

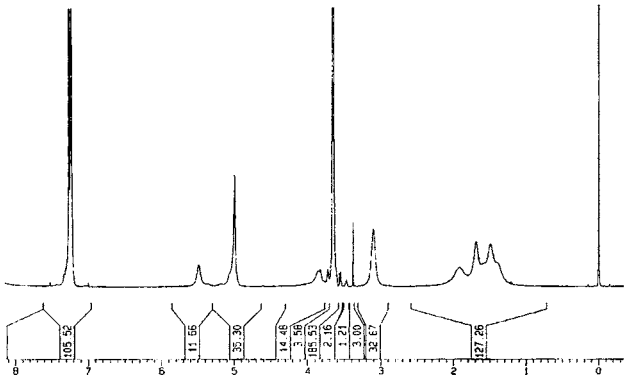

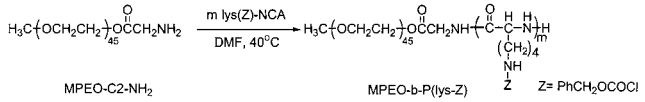

Figure 6. ^1H NMR spectrum of MPEO-β-P[Lys(Z)].

while in the case of MPEO such a side reaction is less possible.

To test the reactivity of the amine-terminated polymers prepared above, MPEO-C_2-NH_2 was used as a macroinitiator to initiate the ring-opening polymerization of a cyclic monomer of lysine, α-(N^ϵ-benzyloxycarbonyl-L-lysine) *N*-carboxy anhydride [lys(Z)-NCA] (Scheme 2). The targeted degree of polymerization of lys(Z)-NCA is designed to be 15. The GPC trace of the resulting copolymer (Figure 5) is a single peak, and the molecular weight distribution of the product is 1.19, showing that the reactivity of MPEO-C_2-NH_2 is high enough and the final product does not contain unreacted MPEO-C_2-NH_2. The ^1H NMR spectrum of MPEO-β-P[lys(Z)] is shown in Figure 6. Besides the signals of the PEO block, new peaks at about 7.26, 1.20−1.90, 5.10, and 5.55 ppm corresponding to the N-protected polypeptide block appeared. From the integral ratio of $\underline{CH_3}$-O- (3.38 ppm) to -$\underline{CH_2}$-NH-Z (3.12 ppm), the average degree of polymerization (DP) of the cyclic monomer is calculated to be 16. Based on the elemental analysis of the final copolymer, the DP is

Scheme 2

15, which confirmed that the initiation reactivity of MPEO-C_2-NH_2 was high.

In conclusion, amine-terminated PCL and MPEO can be prepared conveniently from their hydroxyl-terminated precursors under mild conditions. This method may also be used for the preparation of other kinds of amine-containing polymers from the hydroxyl precursors, and may even be used for α,ω-diamine-terminated polymers.

A General Strategy for Site-Specific Double Labeling of Globular Proteins for Kinetic FRET Studies

V. Ratner, E. Kahana, M. Eichler, and E. Haas*

Faculty of Life Sciences, Bar-Ilan University, Ramat Gan 52900, Israel. Received April 6, 2002; Revised Manuscript Received June 5, 2002

Site-directed mutagenesis provides a straightforward means of creating specific targets for chemical modifications of proteins. This capability enhanced the applications of spectroscopic methods adapted for addressing specific structural questions such as the characterization of partially folded and transient intermediate structures of globular proteins. Some applications such as the steady state or time-resolved fluorescence resonance energy transfer (FRET) detection of the kinetics of protein folding require relatively large quantities (∼10−100 mg) of site-specific doubly labeled protein samples. Engineered cysteine residues are common targets for labeling of proteins. The challenge here is to develop methods for selective modification of one of two reactive sulfhydryl groups in a protein molecule. A general systematic procedure for selective labeling of each of two cysteine residues in a protein molecule was developed, using *Escherichia coli* adenylate kinase (AKe) as a model protein. Potential sites for insertion of cysteine residues were selected by examination of the crystal structure of the protein. A series of single-cysteine mutants was prepared, and the rates of the reaction of each engineered cysteine residue with a reference reagent [5,5′-dithiobis(2-nitrobenzoic acid) (DTNB)] were determined. Two-cysteine mutants were prepared by selection of pairs of sites for which the ratio of this reaction rate constant was high (>80). The conditions for the selective labeling reaction were optimized. In a first cycle of labeling, the more reactive cysteine residue was labeled with a fluorescent probe (donor). The second probe was attached to the less reactive site under unfolding conditions in the second cycle of labeling. The doubly and singly labeled mutants retained full enzymatic activity and the capacity for a reversible folding−unfolding transition. High yields (70−90%) of the preparation of the pure, site-specific doubly labeled AK mutant were obtained. The procedure described herein is a general outline of procedures, which can meet the double challenge of both site specificity and large-scale preparation of doubly labeled proteins.

INTRODUCTION

The folding transition of many globular proteins involves transient intermediate states (Kuwajima, 1989; Ptitsyn, 1995; Miranker and Dobson, 1996; Fersht, 1997). This finding raises the following two research questions: what are the early intermediate steps of the folding process, and what is the order of the events leading to the final native structure? To directly respond to these questions, we propose to characterize transient intermediate structures during fast refolding transitions. The characterization of these structures presents an intricate experimental challenge, and available knowledge of such structures is limited. The main difficulties in characterizing these structures are due to their very short lifetime and the need for new methods of detection.

The determination of intramolecular distances and rates of the fast changes of such distances by time-resolved fluorescence resonance energy transfer (FRET)[1] measurements is a powerful method for the characterization of the structures of partially folded proteins and their transitions. Steady state fluorescence detection of FRET is also a powerful method for monitoring fast changes of the conformations of proteins even with fairly simple instrumentation (Stryer, 1978; Van Der Meer et al., 1994; Haas, 1997). The application of this method is most effective when the dependence of distances between pairs of sites on changes of global or subdomain conformations is maximal. Such cases rarely occur naturally, and therefore, application of this method depends on the development of biochemical methods for site-specific attachment of fluorescent probes by chemical modification of proteins. The most effective design of FRET applications in the present context is achieved when pairs of fluorescent probes are attached at pairs of sites associated with secondary or tertiary structural elements. A major obstacle that hinders a wide range application of this method is the difficulty of preparing suitable protein samples.

Three labeled protein species should be prepared for each well-controlled, time-resolved FRET experiment. These are two singly labeled mutants (one labeled by the donor and the other labeled by the acceptor) and the doubly labeled (by both the donor and acceptor) sample of the protein. The most general and versatile solution to the problem of site-directed labeling is based on site-directed mutagenesis and insertion of cysteine residues at the target sites (Haran et al., 1992; Pennington, 1994; Sinev et al., 1996, 2000; DeSantis et al., 1998; Navon et al., 2001; Ortiz, 2001). Reagents for selective alkylation

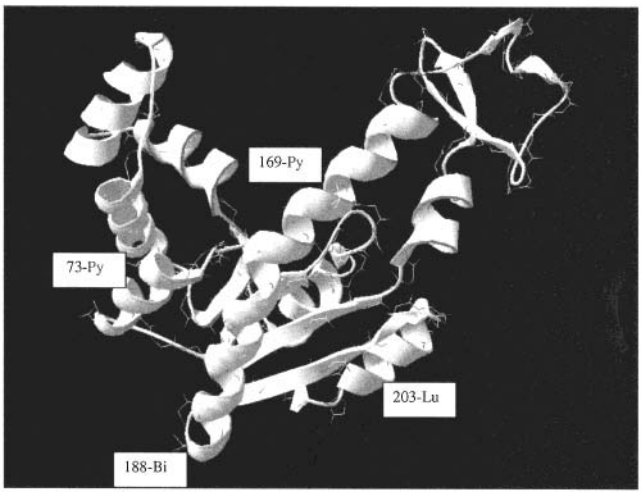

Figure 1. Backbone structure of wt *E. coli* adenylate kinase (AKe) (Schultz et al., 1991). The residues which serve as targets for chemical modifications are marked.

of sulfhydryl residues are available. The challenge here is to develop methods for selective modification of one of the two reactive sulfhydryl groups in the same protein molecule.

Sub-milligram amounts of labeled proteins can suffice for a full set of FRET experiments under equilibrium conditions. Such minute amounts of site-specific doubly labeled protein samples can be prepared, based on high-resolution chromatographic separations. Hundred-fold larger preparations of labeled proteins are needed for flow experiments. In this case, it is desirable to develop methods in which the selectivity is achieved by differential reactivity of selected sites on the protein molecule. The development of a new general systematic procedure for selective labeling of each one of two cysteine residues in a protein molecule is reported here, using *Escherichia coli* adenylate kinase (AKe) as a model protein.

AKe is a ubiquitous enzyme, which catalyzes the phosphoryl transfer reaction ATP + AMP ↔ 2ADP (Noda, 1973). The *E. coli* AKe molecule (Figure 1) consists of a single chain of 214 residues folded in three domains: the large CORE domain (~154 residues) and two smaller domains (~30 residues each) (Schultz, 1990; Müller and Schultz, 1992; Schultz et al., 1997). Residues 161−188 of AKe form a long stretch of helical structure.

Ratner et al. (2000) studied the refolding of fluorescently labeled mutants of AKe by means of fast mixing and time-resolved FRET detection. The starting mutant of AKe used by Ratner et al. (2000) (AK) contained the C77S mutation. The protein was labeled at residue 73 with *N*-(1-pyrenylmethyl)iodoacetamide (I-Py) and residue 203 with lucifer yellow, with a yield of 80%. This experiment showed at least two steps in the refolding kinetics of AK (Ratner et al., 2000). A transient intermediate, formed within 2 ms from the initiation of refolding, was found. The characterization of this intermediate, and the search for possible additional transient intermediate states of the refolding of this protein using FRET detection, requires labeling of additional pairs of sites in 50−100 mg quantities. Residues 169 and 188 were labeled with a donor and an acceptor of excitation energy, respectively. Tens of milligrams of each specifically labeled (>95%) mutant were prepared and characterized.

THEORETICAL BACKGROUND

Calculation of the Maximal Yield of Site-Specific Labeling of Two-Cysteine Mutants. Let [X] be the concentration of the SH groups at the first site, [Y] the concentration of SH groups at the second site, and [D] the concentration of the modifying reagent. All three concentrations decrease during a reaction that modifies cysteine residues in accordance with eqs 1a−c.

$$d[X]/dt = -k_x[X][D] - \sum k_{ix}[A_i][X] \quad (1a)$$

$$d[Y]/dt = -k_y[Y][D] - \sum k_{iy}[A_i][Y] \quad (1b)$$

$$d[D]/dt = -k_x[X][D] - k_y[Y][D] - k_{iD}[D] \quad (1c)$$

where k_{iX} and k_{iY} are the miscellaneous reaction rate constants for various competing reactions of the SH groups, which make the SH groups nonreactive with the modifying reagent. A_i terms represent various solvent additives that can be involved in such reactions. These reactions can be eliminated by the addition of the reducing agent such as tris(2-carboxyethyl)phosphine (TCEP) to the reaction mixture. This reagent maintains the reduced state of the cysteine side chains, and it does not react with alkylating reagents. Thus, the last term in eqs 1a and 1b can be neglected. k_{iD} is the rate constant for reaction of D with solvent components resulting in the deactivation of the reagent.

The division of eq 1a by eq 1b (the last terms are ignored) yields

$$d[X]/d[Y] = (1/R)([X]/[Y]) \quad (2)$$

where $R = k_y/k_x$.

The division of [X] and [Y] by [P], the protein concentration, gives the corresponding fractions of the reactive SH groups, at sites 1 and 2, respectively; $x = [X]/[P]$, and $y = [X]/[P]$. Integration of eq 2 then yields $x = y^R$. The following four species are found in a reaction mixture of any modifying reagent with a protein that carries two reactive cysteine groups at sites 1 and 2: C_1-C_2, D_1-C_2, C_1-D_2, and D_1-D_2 (where C_i and D_i represent the unmodified and modified sites, respectively, in each species). The corresponding fractions are xy, $(1 - x)y$, $x(1 - y)$, and $(1 - x)(1 - y)$. In a case where k_y, the rate constant for the reaction of the sulfhydryl group at site 2, is greater than the rate of reaction of the first site, k_x, i.e., $R > 1$, the goal is to maximize the fraction of the species (C_1-D_2) in the product mixture.

Combining the expressions $x = y^R$ and the fraction of that species, $x(1 - y)$, one obtains

$$[C_1,D_2] = y^R(1-y) \quad (3)$$

This goal can be achieved when y corresponds to the condition $d[C_1-D_2]/dy = 0$. The solution yields

$$y_{opt} = R/(1 + R) \quad (4)$$

At this magnitude of y, the concentration of the desired product is maximal and is provided by eq 5.

$$[C_1-D_2]_{max} = R^R/[(1 + R)^{R+1}] \quad (5)$$

For a given value of R, the control of the yield of the desired product depends on the initial concentrations of the mutant protein ([P]) and the reagent ($[D_o]$) and the ratio k_y/k_{iD}. Practically, two modes of control of the extent

of the reaction are available: either the limitation of the initial concentration of the modifying reagent, $[D_o]$, or the limitation of the time course of the reaction.

In a case where $k_{iD} \ll k_y$, the composition of the product mixture can be controlled by the duration of the reaction. In this case, the link between $[D_o]$ and y is as expected when the calculated extent of labeling of site 2, $(1 - y)$, reaches the optimal value (eq 5). The expected optimal duration of the modification reaction can be determined using the standard kinetics rate law for bimolecular reactions and the rate constants for the reactions of the pairs of single-cysteine mutants and their ratios (R). It was found that for the reaction of iodoacetamidofluorescein, monochlorobimane (Cl-Bi), I-Py, and 4-iodoacetamidosalicylic acid with AK mutants, the competing deactivation reactions can be ignored; i.e., $k_{iD} \ll k_y$.

In the case where $k_{iD} \geq k_y$, i.e., the rate of deactivation of the modifying reagent is greater than the rate of the modification reaction, both modes of control can be used. When the extent of the reaction is controlled by the initial concentration of D ($[D_o]$), the reaction is allowed to proceed to completion, without any time limitation. Under these conditions, the link between $[D_o]$ and y is given by

$$[D_o] = [P](y + y^{1/R}) - (k_{iD}/k_y) \ln(1 - y) \qquad (6)$$

The rate constants (k_x, k_y, and k_{iD}) can be determined for each modification reagent in preliminary experiments using minute amounts of the single-cysteine mutants. Given these rate constants, eq 6 can be applied to calculate the optimal $[D_o]$, which corresponds to the optimal final concentration of the product (C_1−D_2). The commonly used ratio $[D_o]/[P]$ is not valid in this case. A typical example of the fluorescent reagent for which $k_{iD} \gg k_y$ dye is the iodoacetamido derivative of lucifer yellow (Molecular Probes). In an aqueous solution at pH 7.2 and room temperature, this reagent is hydrolyzed in the dark within 15 min.

EXPERIMENTAL PROCEDURES

Procedure for the Systematic Search for Potential Sites for Mutagenesis and Labeling. The task is to prepare a mutant protein with two different organic groups attached to two different sites. These sites were selected according to the needs of a biophysical experiment with minimal perturbation of the native structure and function of the protein. A general procedure for the selection of suitable pairs of sites includes several steps in which the set of residues considered for chemical modification is reduced. (1) Screening for all the residues that could be labeled. The available three-dimensional native structure of the target protein is screened in-search for all the solvent-exposed residues, i.e., those with ≥30% solvent accessibility (algorithms such as the Swiss PDB viewer can be used). The product of this search is a set of residues expected to be accessible to soluble reagents in solution and whose chemical modification is expected to cause minimal perturbation of the global and local structure of the protein. Exposed charged residues are not considered for modification and are eliminated from this set. (2) Producing single-cysteine mutants. Residues included in the reduced set are mutated, one at a time, and single-cysteine mutants are produced and purified. (3) Determining the rate constants for the reaction of the single-cysteine mutants with a reference reagent. A systematic search will be conducted for reaction conditions. These conditions should enhance differences in the reactivity of the selected and purified cysteine mutants with sulfhydryl modification reagents. (4) On the basis of the results of this search, it is possible to select pairs of sites, which show large differences in the reaction rates with the reference reagent, reducing the set by the selection of pairs whose modification is of interest for specific biophysical experiments. These can be pairs of sites where probes can detect changes of conformation according to the goals of the experiment, e.g., secondary or tertiary structural elements, loops, etc. (5) Measurement of the spectroscopic properties (fluorescence lifetimes, spectral shifts, and parameters affecting the Förster critical distance R_o) of the potential probes in situ (at the selected sites) is performed to select the most appropriate probes for each experiment. (6) Optimizing the methods for separation of the protein mutants labeled by a single probe at different sites. (7) Measuring of the kinetics of the reaction of the two single-cysteine mutants with the modification reagents under the optimized conditions. (8) Preparing two-cysteine mutants (cysteine residues inserted at the two sites selected in step 5). (9) Carrying out the reaction of the two-cysteine protein with a chemical modification reagent under the optimized conditions. This reaction produces a mixture of the unlabeled protein and three products: two singly labeled species and the doubly labeled species. Enrichment of the fraction of a selected singly labeled species in the reaction mixture is possible on the basis of knowledge of the ratio of the reaction rate constants of these sites with a modifying reagent.

Expression and Purification of AKe. The expression of cysteine-mutated *E. coli* adenylate kinase and protein purification were performed as described previously (Sinev et al., 1996). The protein was stored in 50% glycerol in 40 mM sodium phosphate buffer (pH 6.5) containing 0.1 M NaCl, 2 mM EDTA, and 2 mM DTT at −18 °C. The starting mutant of *E. coli* adenylate kinase used in this study (AK) contained the C77S mutation.

Small-Scale Labeling of AK Mutants. *Reactivation of Stored Protein Samples.* Samples of the stored protein (3 mg in 0.2 mL) were diluted 5-fold with 100 mM Tris-HCl buffer (pH 8.0) containing 10 mM DTT and 2 mM EDTA (the reactivation buffer). After 30 min, the protein solution was applied to a Sephadex G15 column (1.5 cm × 5 cm for 1 mL protein samples) equilibrated and eluted with 20 mM HEPES buffer (pH 7.2) containing 2 mM EDTA.

Labeling of Single-Cysteine Mutants. The single-cysteine mutants, AK(V169C) and AK(A188C), were labeled with the fluorescent reagent *N*-(1-pyrenylmethyl)iodoacetamide (I-Py) (Molecular Probes). The labeling was performed in 20 mM HEPES (pH 7.2) which contained 2 mM EDTA and 30 μM reducing agent tris(2-carboxyethyl)phosphine (TCEP) (Molecular Probes) (folding buffer). The reaction mixture contained 20 μM protein in this buffer and 75 μM I-Py, which was added in DMSO [the final concentration of DMSO was 10% (v/v)]. The reaction was allowed to proceed at room temperature. Aliquots of the reaction mixture were taken at several time points between 4 and 24 h and analyzed. Excess insoluble pyrene was filtered using a 0.2 μm sterile filter, and the soluble excess of the reagent was removed by gel filtration on a Sephadex G15 column equilibrated with 20 mM Tris-HCl (pH 8). The separation of the labeled protein was performed by anion exchange chromatography. Samples of ∼0.5 mg were applied to a MonoQ column (0.5 cm × 5 cm) (Pharmacia) equilibrated with 20 mM Tris-HCl (pH 8). Proteins were eluted with a linear gradient of NaCl (from 0 to 0.5 M) for 120 min at a flow

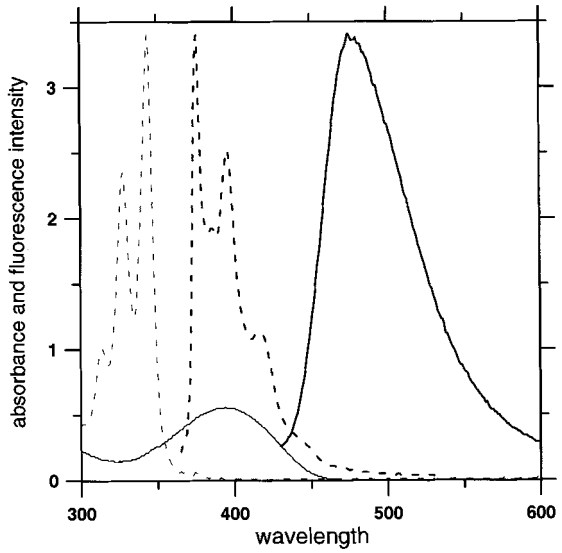

Figure 2. Absorbance and fluorescence spectra of AK(V189C-Py) (donor) (- - -) and AK(A188C-Bi) (acceptor) (—). Emission spectra were recorded by excitation at 345 and 390 nm for Py and Bi, respectively (bandwidth of 3 nm).

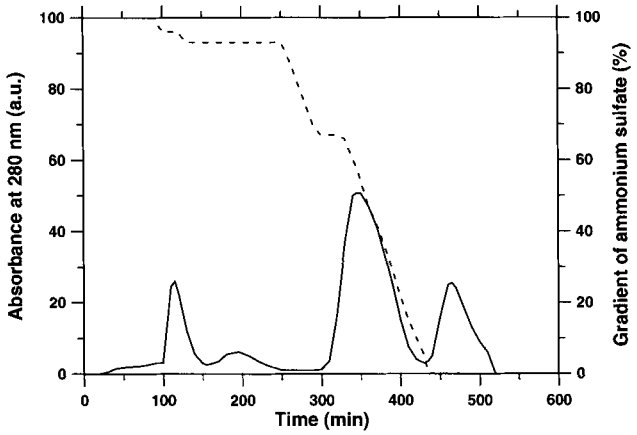

Figure 3. Elution profile (—) of the preparative reaction mixture applied to a Phenyl Sepharose 6 Fast Flow column. Four peaks were resolved. The fractions were as follows: I, unlabeled AK; II, AK(V169C/A188C-Py); III, AK(V169C-Py/A188C); and IV, AK(V169C-Py/A188C-Py) The salt gradient is shown (- - -). The reference preparations for identification of these fractions were the base mutant, AK(V169C-Py), AK-(A188C-Py), and AK(V169C-Py/A188C-Py) labeled in unfolding buffer with excess I-Py.

rate of 0.5 mL/min. The free protein eluted first, at 100−111 mM NaCl; AK(V169C-Py) eluted at 112−119 mM NaCl, and AK(A188C-Py) eluted at 180−190 mM NaCl. The extent of protein labeling was evaluated by determining the area under the peaks, divided by molar extinction coefficients of the unlabeled protein at 280 nm (11 800 M^{-1} cm^{-1}) or the labeled protein at 280 nm (49 200 M^{-1} cm^{-1}).

AK(A188C) (14 μM) was also labeled with monochlorobimane (Molecular Probes) (final concentration of 530 μM), 20 mM HEPES (pH 7.8), 1.8 M GuHCl, 30 μM TCEP, and 2 mM EDTA (unfolding buffer). The concentration of the soluble reagent in the reaction was determined by the absorbance at 390 nm, using a molar extinction coefficients of bimane of 5560 M^{-1} cm^{-1} in HEPES buffer (pH 7.2).

Large-Scale Double Labeling. A quantity of 65 mg of reactivated AK(V169C/A188C) was dialyzed in 20 mM HEPES (pH 7.2) and 2 mM EDTA. Both TCEP (from a 10 mM stock solution in water) and NaCl (from a 4 M stock solution in water) were added to final concentrations of 30 μM and 100 mM, respectively. A solution of 4.6 mg of I-Py in 3.85 mL of DMSO was added in two portions (2.2 and 1.65 mL) at the initiation of the reaction and after 8 h, respectively. The reaction was allowed to proceed for 24 h under slow stirring at room temperature (24 °C) protected from light. The reaction was stopped by the addition of DTT to a final concentration of 50 mM. The excess Py derivatives were removed by filtration through a 0.2 mm filter (acrodisc 32, Gelman Science, Ann Arbor, MI) and by gel filtration on a G15 Sephadex column in Tris buffer (pH 8.0).

The product mixture was resolved by hydrophobic interaction chromatography. NH_4SO_4 was added to a final concentration of 0.8 M, and after 10 min, the solution was applied to a Phenyl Sepharose 6 Fast Flow (low sub) (Pharmacia Biotech) column (2.5 cm × 16 cm), pre-equilibrated with 0.6 M NH_4SO_4 in 20 mM HEPES (pH 7.2). The labeled species were eluted in a linear gradient from 0.6 to 0 NH_4SO_4 in 350 mL at a flow rate of 3 mL/min (Figure 3). The third eluted peak (0.0 M NH_4SO_4, ∼100 mL) was concentrated to ∼10 mL in an ultrafiltration cell with a YM membrane with a 10K cutoff (Amicon) and dialyzed in 20 mM HEPES (pH 7.2) and 2 mM EDTA.

Acceptor Labeling. AK(V169C-Py/A188C) was reactivated and dialyzed against 20 mM HEPES and 2 mM EDTA. GuHCl (8.2 M stock solution in water) and TCEP were added to final concentrations of 1.8 M and 30 μM, respectively. The addition of GuHCl shifted the pH to 7.8. Solid Cl-Bi (Molecular Probes) was added to a final concentration of 500 μM in excess of the protein concentration. The reaction was allowed to proceed for 24 h at room temperature (gently stirring, protected from light) and then terminated by the addition of DTT to a final concentration of 20 mM. The unbound reagent was removed by gel filtration on a Sephadex G15 column (2.5 cm × 24 cm) equilibrated with 1.8 M GndHCl in 20 mM Tris (pH 8.0). Refolding was performed by dialysis in 20 mM Tris-HCl (pH 8). After concentration in a Centriprep-10 ultrafiltration concentrator (Amicon) and being dialyzed in 50 mM imidazole buffer (pH 7.2), all the labeled protein samples were stored in 50 mM imidazole buffer (pH 7.2) containing 50% glycerol at −18 °C.

Large-Scale Preparation of Singly Labeled Mutants. Singly labeled AK(V169C-Py) and AK(A188C-Bi) were prepared from the respective single-cysteine AK mutants. Reactivated AK(V169C) was dialyzed in 20 mM HEPES (pH 7.2) and 2 mM EDTA and labeled in unfolding buffer. The final reaction mixture contained equivalent amounts of protein and dye with an additional portion of 50 μM I-Py in excess of the protein concentration. The total amount of the reagent dissolved in DMSO was added in two equal portions (at the initiation of the reaction and 4 h later). The final DMSO concentration was 15% (v/v), and the reaction was allowed to proceed for 24 h under slow stirring at room temperature (24 °C) protected from light. The reaction was terminated by the addition of DTT to a final concentration of 20 mM. The excess Py derivatives were removed by filtration (0.2 μm) followed by gel filtration on a Sephadex G15 column in 50 mM Tris-HCl (pH 8) containing 1.8 M GuHCl. The unfolded protein was refolded by dialysis in 50 mM Tris-HCl (pH 8.0). The protein was then concentrated and stored in 50 mM imidazole buffer (pH 7.2) containing 50% glycerol at −18 °C.

Table 1. Rate Constants for the Reaction of SH Groups in a Series of AK Mutants with DTNB at pH 7.2 in 20 mM HEPES at Two Temperatures, with and without Salt

	k (mM^{-1} s^{-1})			
	without salt		with 100 mM NaCl	
mutant[a]	22.5 °C	40 °C	22.5 °C	40 °C
AK(V203C)	5.3 ± 0.2	0.84 ± 0.04	10.9 ± 0.3	1.78 ± 0.05
AK(V169C)	1.81 ± 0.09	0.48 ± 0.02	3.58 ± 0.04	0.89 ± 0.05
AK(A55C)	1.13 ± 0.08	0.154 ± 0.013	1.11 ± 0.02	0.16 ± 0.01
AK(V142C)	0.186 ± 0.009	0.059 ± 0.004	0.383 ± 0.008	0.133 ± 0.005
AK(A73C)	0.027 ± 0.002	ND	0.115 ± 0.005	0.050 ± 0.003

[a] *E. coli* adenylate kinase in which cysteine 77 was replaced with serine and one surface-exposed residue was replaced with cysteine.

Reactivated, dialyzed AK(A188C) was labeled with Cl-Bi using the same procedure described for AK(V169C-Py/A188C); it was then concentrated and stored in 50 mM imidazole buffer (pH 7.2) containing 50% glycerol at −18 °C.

The degree of homogeneity of the products AK(V169C-Py/A188C-Bi) and AK(V169C-Py) was analyzed using analytical FPLC ion exchange chromatography.

Spectroscopic Instrumentation. Rate constants for the reaction of AK mutants with DTNB were determined using a homemade stopped-flow device based on a DX17MV mixing unit (Applied Photophysics, Leatherhead, U.K.) (Ratner and Haas, 1998). Reactions were initiated by mixing equal volumes of 12 μM protein and of 0.5−2.0 mM DTNB in 20 mM HEPES and 5 mM EDTA (pH 7.2). The kinetics of the reactions were monitored by recording the absorbance at 440 nm (selected by an interference filter). Rate constants were extracted by curve fitting of the kinetics data using a fitting module prepared by A. Goldin and implemented in MatLab (Ratner and Haas, 1998).

Fluorescence spectra were recorded using an Aviv F105 spectrofluorimeter. Absorbance spectra were recorded using an Aviv 17DS spectrophotometer.

RESULTS

Preparation of Cysteine Mutants of AKe. The single native cysteine residue of Ake(Cys77) was replaced with a serine residue without any perturbation of the folding and activity of the enzyme (Sinev et al., 1996). Ake(C77S) (AK) was the base mutant for all further modifications in this project. Single-cysteine mutants, prepared by the replacement of residues 55, 73, 142, 169, 188, and 203, were produced, expressed, and purified in ∼200 mg quantities (Sinev et al., 1996).

Determination of Reaction Rate Constants with a Reference Reagent. Elman reagent [5,5′-dithiobis-(2-nitrobenzoic acid) (DTNB)] was used as the reference reagent. The rate constants for the reaction of DTNB and each of the single-cysteine mutants were determined in 20 mM HEPES (pH 7.2) and in the same buffer with the addition of 100 mM NaCl at two temperatures. The rate of light absorption change at 440 nm was measured in a stopped-flow device. Table 1 shows that the rate constants for the DTNB−AK reaction varied over a wide range. Pairs of sites for which the ratio of rate constants was nearly 100 were selected for labeling. The first example was the pair AK(V203C) and AK(A73C), which were labeled with lucifer yellow and I-Py, respectively (Ratner et al., 2000). The pair AK(A169C) and AK-(A188C), which had a ratio of rate constants as high as 106, was used in the experiment presented here.

Fluorescent Probes for Labeling Cysteine 169 and 188. The two fluorescent alkylating reagents used in this study were the donor I-Py and Cl-Bi, the acceptor of excitation energy. The alkylation with the pyrene reagent creates a very hydrophobic product, which is a possible source of perturbation of the protein structure or folding. Yet this reagent was used for its favorable spectroscopic properties (very long fluorescence lifetime and high extinction coefficient). The bimane reagent is a comparatively small, uncharged probe.

Preparation of Singly Labeled Mutants. The two single-cysteine mutants, AK(V169C) and AK(A188C) (∼40 μM), were labeled with I-Py (∼100 μM) under reducing−unfolding conditions where every protein sulfhydryl group was accessible to the dye. The solubility of I-Py in folding buffer did not exceed ∼10 μM at 10% DMSO. Therefore, a heterogenic (pseudo-first-order) reaction was used. The insoluble excess of the reagent formed microaggregates, which served as a stock. This stock provided a saturated concentration of the reagent, and was gradually depleted during the reaction.

The reaction was complete (100% labeling) within 4 h at room temperature. The quantum yields of pyrene fluorescence were 0.33 and 0.06 for AK(V169C-Py) and AK(A188C-Py), respectively. Cysteine 169 was chosen as the target for Py conjugation for the planned FRET experiments since it was difficult to find an acceptor probe that has a suitable R_o value when paired with the low-quantum yield pyrene attached to residue 188. Singly labeled AK(A188C-Bi) was obtained by the reaction of 40 μM protein in the unfolding buffer with 550 μM Cl-Bi for 24 h at room temperature. Figure 2 presents the fluorescence spectrum of AK(V169C-Py) and the absorbance spectrum of AK(A188C-Bi). The Förster critical distance, R_o, of the pair *N*-(1-pyrenylmethyl)acetamide (Py) and bimane (Bi) attached to residues 169 and 188, respectively (calculated assuming an orientation factor κ^2 of $^2/_3$), is 26 Å. This length is close to the separation of these two residues in the crystal structure (28.9 Å). The wild-type level of specific enzymatic activity was measured for both singly labeled mutants. This activity is an indication that the above-referenced genetic and chemical modifications did not significantly perturb the native conformation of the protein.

Chromatographic Purification. The search for a method of separating the reaction products was conducted using the singly labeled mutants. Nonlabeled protein and the two singly Py-labeled mutants (at residues 169 and 188) were separated on an analytical MonoQ ion exchange column. Larger-scale preparative separations were performed by hydrophobic chromatography using a Phenyl Sepharose 6 Fast Flow column. The two species of singly Py-labeled AK [AK(V169C-Py) and AK(A188C-Py)], which differed only in the attachment sites of the probe, were resolved with this column. Figure 3 presents the results of the separation of the alkylation reaction products.

Preparation of the Doubly Labeled Mutant. The rate constants for the reaction of the two single-cysteine mutants with I-Py were measured under reducing−folding conditions at room temperature. The following values were obtained: 0.002 and 0.08 h^{-1} for I-Py and cysteine 188 and 169, respectively. These rate constants were used for optimization of the site-directed labeling of the two cysteine residues in AK(V169C/A188C) as outlined above. An ∼40 μM solution of AK(V169C/A188C) was first reacted with I-Py (∼100 μM) in folding buffer at room temperature. Under these conditions, the rate constants obtained for AK(V169C/A188C) matched the rates obtained for single-cysteine mutants AK(V169C) and AK(A188C). The reaction mixture was resolved by ion exchange chromatography on a Mono-Q column.

Large-Scale (∼100 mg) Production of the Doubly Labeled Mutant. With a 10-fold increase in the concentration of the protein in the reaction mixture, the amount of I-Py in this mixture was increased accordingly. Under these conditions, the insoluble excess of I-Py formed large flakes. In addition, the ratio of the reaction rates was reduced due to a cooperative effect, which increased the fraction of AK(V169C-Py/A188C-Py) and reduced the yield of the desired product. Adsorption of protein molecules on the surface of the reagent flakes possibly enhanced the reactivity of the slow-reacting side chain and caused the cooperativity. This undesired cooperative effect was reduced to some extent by the stepwise addition of the reagent (two steps).

The reaction proceeded for 24 h and was terminated by the addition of excess DTT. The resulting product mixture contained ∼70% AK(V169C-Py/A188C) along with smaller fractions of AK(V169C/A188C), AK(V169C/A188C-Py), and AK(V169C-Py/A188C-Py). This mixture was separated by hydrophobic interaction chromatography on a Phenyl Sepharose 6 Fast Flow column (Figure 3).

Second-Site Labeling. The pure AK(V169C-Py/A188C) was reacted with excess Cl-Bi in unfolding buffer. Here, the low reactivity of the side chain of Cys188 was enhanced. After 24 h, the reaction was terminated by the addition of DTT (final concentration of 20 mM). The excess reagent and its products were removed by gel filtration [Sephadex G15 column in 50 mM Tris buffer (pH 8.0) and 1.8 M GndHCl], followed by dialysis against 50 mM Tris buffer. The homogeneity of the final doubly labeled product, AK(V169C-Ph/A188C-Bi), was analyzed by analytical chromatography on a Mono-Q FPLC column. In a control experiment, the base mutant AK (which contains the C77S mutation) was subjected to the same labeling procedure. No trace of fluorescence was detected in the final protein fraction. This finding indicates that only the specific covalent attachment of the probes to the cysteine residues was involved. The chromatography and dialysis steps efficiently removed nonspecifically adsorbed reagents.

Observation of FRET. The bimane fluorescence that was directly excited in AK(A188C-Bi) in the native state was very close to the value obtained for that probe in AK(V169C-Py/A188C-Bi) under those conditions. Under denaturing conditions (in 1.8 M GuHCl), the fluorescence of bimane decreased by ∼10 and ∼70% for AK(A188C-Bi) and AK(V169C-Py/A188C-Bi), respectively, relative to the corresponding values obtained in the native state. The decrease in the fluorescence of bimane in the doubly labeled mutant occurred at the same concentration of GuHCl as the change of the pyrene fluorescence. Figure 4 shows the denaturant concentration dependence of the fluorescence emission intensities of the Py probe in the singly and doubly labeled mutants AK(V169C-Py) and AK(V169C-Py/A188C-Bi). A sharp drop in the emission intensity at ∼0.7−0.8 M GuHCl appears for both mutants. The drop in Py fluorescence intensity in the singly labeled mutant reflects the change in the local environment of the probe. This change affects the Förster critical distance, R_o, which is recalculated for each state of the protein (Table 1). The relative amplitude of the decrease of the donor emission intensity observed for the doubly labeled mutant is greater than that of the singly labeled mutant, due to the enhanced efficiency of the FRET effect upon denaturation. The ratio of the emission intensity of the donor in the doubly and singly labeled mutants (absence and presence of FRET) is used as a measure of the extent of FRET efficiency. The increased ratio found at high GuHCl concentrations indicates enhanced transfer efficiency. Upon unfolding, the extended α-helical conformation (residues 161−188) (Schultz et al., 1991) collapsed to an apparent unordered state, where the apparent mean inter-residue distance between residues 169 and 188 was considerably shorter than in the native state.

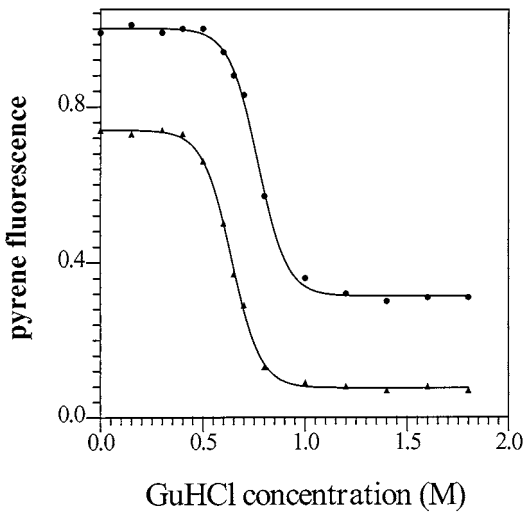

Figure 4. Dependence of pyrene fluorescence in singly (asterisks) and doubly (triangles) labeled AK on GuHCl concentration. The lines show the fits to a two-state model with an m of 8.5 kcal/M and midtransitions at 0.77 and 0.64 M for the singly and doubly labeled mutants, respectively. The FRET parameters for the attached Py-Bi pair were as follows: $R_o = 22$ Å and R_{mean} (apparent mean distance) = 20 Å for the unfolded state and R_o = 25.5 Å and R_{mean} = 32 Å for the folded state of the protein.

The mean FRET efficiencies were calculated for the two equilibrium states (native and denatured). An apparent mean distance between the two probes was calculated for each state. This distance is a rough approximation, because it is obtained by ignoring the effect of the width of the intramolecular distance distributions and the possible contributions to the FRET efficiencies by the fast segmental fluctuations. The distances were calculated under the assumption that distributions of distances were narrow. This is a reasonable approximation for the native state. However, for the denatured states, this approximation is probably somewhat biased toward lower values. Thus, the apparent change in the mean distance from the denatured to the native states may indeed be partially due to a reduction of the distributions.

DISCUSSION

Site-directed mutagenesis provides a straightforward means of creating specific targets for chemical modifica-

tions of proteins. This capability enhanced the applications of spectroscopic methods adapted for addressing specific structural questions. The procedure described herein is a general outline of procedures, which can meet the double challenge of both site specificity and large-scale preparation of doubly labeled proteins.

The selectivity of the labeling reaction can be further enhanced by a local increase or reduction in the reactivity of selected side chains by means of conformational effects. Solvent composition (organic solvents, salt components, and pH) and temperature are the most common variables that can differentially affect the reaction rate constants of selected side chains. Drastic effects can be obtained by ligand binding (substrates, inhibitors, and protein−protein interactions). In this work, the ratio of the reaction rate constants was examined only under a range of temperatures and salt concentrations which yielded satisfactory results for two pairs of sites (residues 73 and 203 and residues 169 and 188).

The level of homogeneity required for spectroscopic measurements makes the chromatographic separation steps indispensable. Separation of the reaction products can be enhanced when one of the reagents is either charged or very hydrophobic. Yet either hydrophobicity or extra electrostatic charges can affect the folding pathway of proteins and can be a disadvantage when the modifications are made for structural studies. Affinity chromatography was also used to separate multiply labeled protein derivatives (Amir et al., 1986; Amir and Haas, 1987). It is also possible to use a mixed disulfide resin for separation of fractions with free cysteine residues in the process of labeling two-cysteine mutants. The excellent separation that was achieved between unlabeled AK and AK labeled with I-Py at either residue 169 or 188 was based on the hydrophobicity of the pyrene moiety.

The procedure described here is based on the preparation of three mutants: two single-cysteine mutants and one two-cysteine mutant. In principle, it is possible to accomplish the FRET experiments without the preparation of the two single-cysteine mutants. The need to prepare two single-cysteine mutants depends on the required quantities of labeled proteins and the availability of analytical procedures for the identification of the labeling sites.

Large-scale preparations can be done either by increasing the volume of the reaction mixture (thus maintaining low protein concentrations) or by increasing the protein concentration. The second procedure was applied in the study presented here since it has two practical advantages: (1) reduction of the waste of precious fluorescent reagents and (2) the prevention of the losses of the labeled protein in the extra concentration step required after a reaction in a large volume. The precipitation of the hydrophobic fluorescent reagent, the ensuing changes of the reaction conditions, and the reduced maximal yield of the labeled protein are the disadvantages of this approach. The optimization of the reaction volume and of the reagent's concentrations in a large-scale labeling reaction depends on the solubility of the protein and the reagents.

FRET Measurements. The reduced quantum yield of the pyrene florescence in the denatured state of the singly labeled mutant AK(V169C-Py) was not due to solvent quenching by the denaturant. This conclusion is evident from the observation that the same probe attached to cysteine 73 exhibited only a minimal reduction of the fluorescence quantum yield under the same conditions (Ratner et al., 2000). A possible source for a specific quenching of pyrene fluorescence in AK(V169C-Py) might be the side chain of one of the neighboring residues. Collision quenching by an adjacent neighbor side chain was restricted by its orientation in the native state helical structure. When this well-defined structure was collapsed by denaturation, the stereochemical restriction was relaxed and collision quenching was made more efficient. Charged side chains, either positive or negative, are possible quenchers found in the vicinity of both residue 73 and residue 169. The phenol side chain of tyrosine is found only near residue 169. Therefore, it is reasonable to speculate that the likely near-neighbor quencher side chain is Tyr171. Incidentally, the donor's specific non-FRET quenching helped to improve the resolution of the distance determination in the experiment described here, since it caused a decrease in the Förster critical distance, R_o, from 26 Å (in the native state) to 21.8 Å. This R_o value is closer to the apparent mean distance between the two residues in the denatured state (Table 2). The mean length of the 20-residue labeled helical segment in the native state (31.7 Å) is close to the theoretically expected value (Cα−Cα separation of 29.3 Å) and the Cγ−Cβ separation in the crystal structure (30.5 Å).

CONCLUSIONS

The preparation of large-scale amounts of site-specific, doubly chemically modified mutant proteins for spectroscopic studies of protein folding and dynamics can be improved. Such improvement can be achieved by following a systematic procedure, which is based on structural and chemical kinetics data. The native three-dimensional structure should be used for the preliminary selection of a set of residues, which can be mutated with minimal structural perturbation, and with a large variation of reactivity of inserted cysteine residues. The determination of individual reaction rate constants of the engineered SH groups and the optimization of reaction conditions allowed high yields (70−90%) of the preparation of the pure, site-specific doubly labeled AK mutant. These high yields make some otherwise difficult experiments, such as the double kinetics time-resolved FRET measurements (Ratner and Haas, 1998; Ratner et al., 2000), feasible. Preliminary FRET measurements show the effectiveness of this experimental approach.

A New Class of RNA-Binding Oligomers: Peptoid Amide and Ester Analogues

Venkitasamy Kesavan,† Natarajan Tamilarasu,† Hong Cao, and Tariq M. Rana*

Chemical Biology Program, Department of Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, 364 Plantation Street, Worcester, Massachusetts 01605-2324. Received June 28, 2002

Replication of human immunodeficiency virus type 1 (HIV-1) requires specific interactions of Tat protein with the *trans*-activation responsive region (TAR) RNA, a 59-base stem-loop structure located at the 5′-end of all HIV mRNAs. Here we report the design, synthesis and in vitro activities of oligopeptoid amide and ester analogues which bind TAR RNA with high affinities. These results show that we have identified a new class of unnatural oligomers for RNA targeting.

RNA−protein interactions are involved in many cellular functions such as transcription, RNA splicing, and translation. Small peptides with unnatural backbones that can bind with high affinity to a specific sequence or structure of nucleic acids and interfere with protein−nucleic acid interactions would provide useful tools in molecular biology and medicine. Successful approaches used thus far include duplex-forming (antisense) (*1*) and triplex-forming (anti-gene) oligonucleotides (*2*−*4*), peptide nucleic acids (PNA) (*5*), and pyrrole-imidazole polyamide oligomers (*6*, *7*). Each class of compounds employs a readout system based on simple rules for recognizing the primary or secondary structure of a linear nucleic acid sequence. Another approach employs carbohydrate-based ligands, calicheamicin oligosaccharides, which interfere with the sequence-specific binding of transcription factors to DNA and inhibit transcription in vivo (*8*, *9*). While antisense oligonucleotides and PNA employ the familiar Watson−Crick base-pairing rules, two others, the triplex-forming oligonucleotides and the pyrrole-imidazole polyamides, take advantage of straightforward rules to read the major and minor grooves, respectively, of the double helix itself.

In addition to its primary structure, RNA has the ability to fold into complex tertiary structures consisting of such local motifs as loops, bulges, pseudoknots, and turns (*10*, *11*). It is not surprising that, when they occur in RNAs that interact with proteins, these local structures are found to play important roles in protein−RNA interactions (*12*). This diversity of local and tertiary structure, however, makes it impossible to design synthetic agents with general, simple-to-use recognition rules analogous to those for the formation of double- and triple-helical nucleic acids. Since RNA−RNA and protein−RNA interactions can be important in viral and microbial disease progression, it would be advantageous to have a general method for rapidly identifying synthetic compounds for targeting specific RNA structures. Figure 1. (A) Secondary structure of TAR RNA used in this study. TAR RNA spans the minimal sequences that are required for Tat responsiveness in vivo (*27*) and for in vitro binding of Tat-derived peptides (*28*). Chemical syntheses were performed on ABI synthesizer Model 392 using standard protocols. TAR RNA was chemically synthesized on a fluorescein-containing CPG 500 support. Synthesis of RNA, deprotection, characterization, and purification were performed as described earlier (*20*, *22*). **(B)** Schematic comparison of peptides and peptoids.

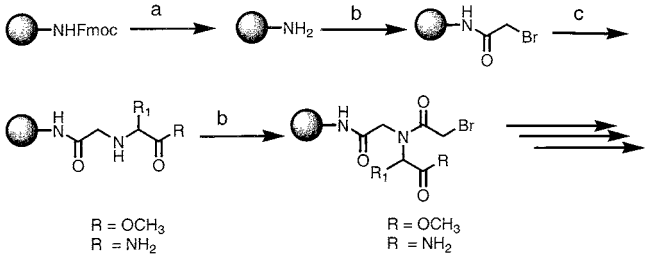
lar protein-binding RNA structure can be considered as a molecular receptor not only for the protein with which it interacts but also for synthetic compounds, which may prove to be antagonists of the protein−RNA interaction.



The mechanism of transactivation of human immunodeficiency virus type 1 (HIV-1) gene expression requires the interaction of Tat protein with the transactivation responsive region (TAR) RNA, a 59-base stem-loop structure located at the 5′-end of all nascent HIV-1 transcripts (*13*). Inhibition of Tat-TAR interactions is a potential approach for anti-HIV therapeutics. Here we report that two oligopeptoids bind TAR RNA with high affinities in vitro.

We have recently begun to examine TAR RNA recognition by unnatural biopolymers containing urea and carbamate backbone structures (*14*, *15*). Small Tat-derived oligocarbamate and oligourea bind TAR RNA specifically with high affinities in vitro (*14*, *15*). TAR RNA-binding oligocarbamate and oligourea are also resistant to protease degradation in vitro (*14*, *15*). While devising oligomers alternative to the natural polymers, the following points should be taken into consideration: (i) Monomers should be straightforward to synthesize in large amounts, (ii) the monomers should have wide variety of functional groups presented as the side chains of the oligomeric backbone, and (iii) the linkage should be resistant to hydrolytic enzymes. To effect the above attributes, we planned to synthesize peptoid analogue oligomers (*16*−*18*).

The schematic comparison of peptides and peptoids (Figure 1B) shows the similarities in the spacing of the side chains and carbonyl groups and the differences in the chirality of two monomers. Similarities between peptides and peptoids should not obscure the important differences in stereochemical and conformational characteristics of the two oligomers. In addition, peptoids are stable to hydrolysis by proteases (*19*). We envisioned that modification of oligopeptoids with ester or amide moieties would change the physical and chemical properties of the oligomers that could result in enhanced bioavailability and in vivo stability.

We synthesized oligopeptoids containing basic arginine-rich region of Tat through solid-phase synthesis (Scheme 1). Rink-amide MBHA resin was treated with piperidine and then coupled with bromoacetic acid in the presence of diisopropylcarbodiimide. Bromide was displaced with ester or amide of the corresponding amino

Scheme 1. The Synthesis of Oligopeptoid Ester and Amide Analogs[a]

[a] (a) 20% piperidine/DMF; (b) bromoacetic acid/diisopropylcarbodiimide, DMF; (c) methyl ester or amide of amino acid, diisopropylethylamine, DMF.

acid in the presence of diisopropylethylamine. These cycles were repeated to synthesize Tat-derived oligopeptoids containing amide or ester groups (Figure 2). For the oligopeptoid ester synthesis, rink amide resin (0.1 mmol) was swelled in dimethylformamide (2 mL) for 15 min. After filtration, 1 M bromoacetic acid in DMF (2 mL) and diisopropylcarbodiimide (400 μL) were added. The resin was filtered after 2 h and washed with DMF (5 × 3 mL). Bromide displacement was effected in the presence of side chain protected amino ester (1 mmol) and triethylamine (1 mmol) in DMF for 12 h. The above procedure was repeated with bromoacetic acid followed by respective amino ester to obtain Tat-derived peptoid ester oligomer. After the completion of synthesis, the resin was cleaved with a mixture of TFA (95%), triisopropylsilane (2.5%), and water (2.5%) and purified by HPLC. The peptoid ester oligomer was characterized by MALDI mass spectrometry (calculated mass for M + H = 2352.5; observed = 2353.8). Similar procedures were used to synthesize the amide analogues of the Tat-derived peptoids.

For dye labeling, MBHA resin containing oligopeptoid amide (14.4 μmol) was treated with 5-(and-6)-carboxytetramethylrhodamine (150 μmol) and diisopropylcarbodiimide (150 μmol) for 3 h. The resin was washed repeatedly with DMF and dichloromethane. Rhodamine-labeled Tat-peptoid was cleaved from the resin by treating with trifluoroacetic acid, water, and phenol (95:2.5:2.5). The product was purified by reverse phase HPLC and characterized by MALDI mass spectrometry (calculated mass = 2378.2; observed = 2376.26).

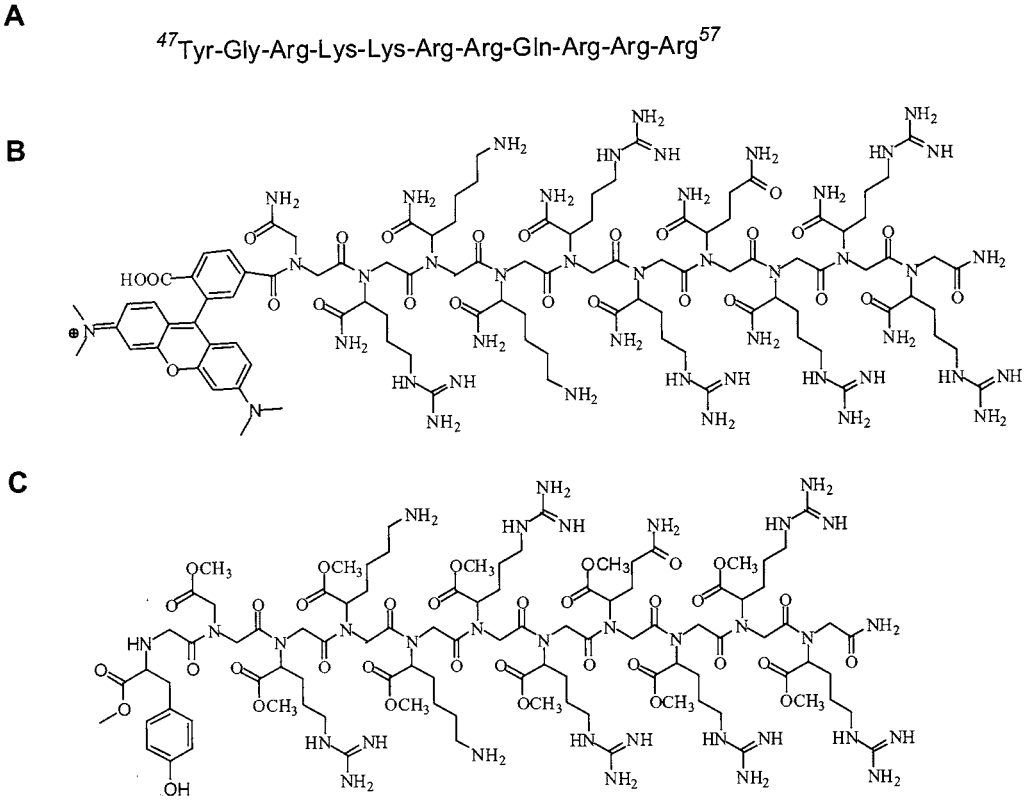


Figure 2. (A) Amino acid sequence of a Tat derived peptide (47−57) that contains RNA-binding region of HIV-1 Tat protein. Structures of the carboxytetramethylrhodamine-labeled oligopeptoid amide **(B)** and the tyrosine containing oligopeptoid ester **(C).** Side chains corresponding to the Tat peptide are shown in **(**A**)**.

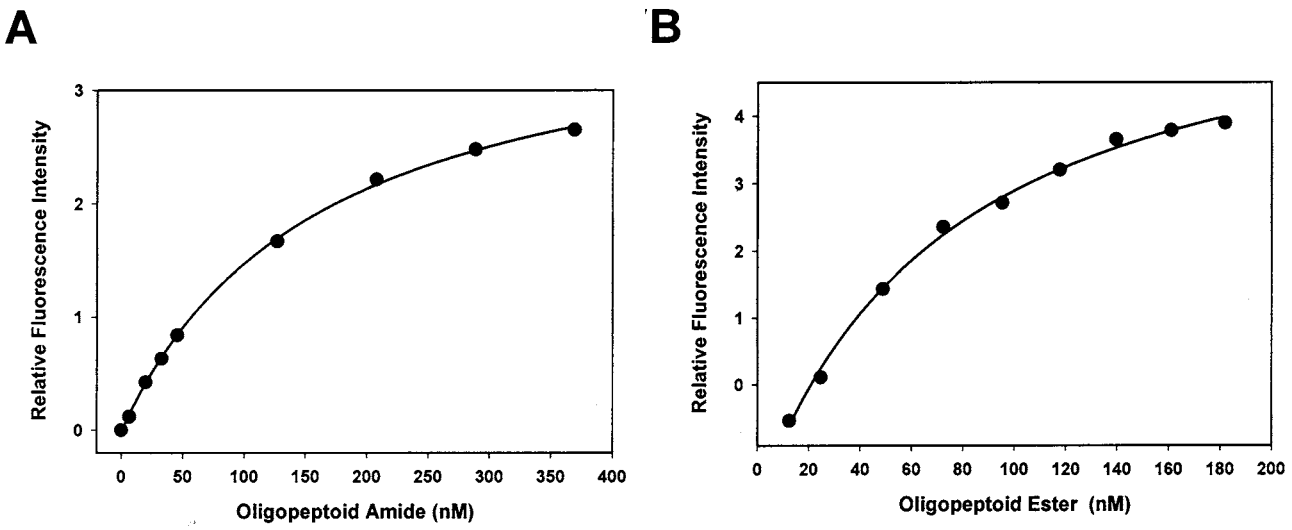

Figure 3. TAR RNA-binding affinities of oligopeptoid amide by FRET **(**A**)** and by fluorescence quenching **(**B**)**. The fluorescence resonance energy transfer (FRET) from fluorescein to rhodamine was measured on PTI (Photon Technology International) fluorescence spectrophotometer. The fluorescein-labeled TAR RNA (Fl-TAR) was excited at 490 nm. The emission spectrum was recorded from 500 to 650 nm for each scan. The slits were set to 4 nm for both excitation and emission lights. All experiments were carried out at room temperature. The initial concentration of Fl-TAR (3′-end fluorescein labeled TAR RNA) was 5.2 nM for all experiments. Each addition of rhodamine-labeled oligopeptoid amide to the Fl-TAR solutions was followed by a 2-min equilibration before the fluorescence spectrum was recorded. For fluorescence quenching experiments, unlabeled oligopeptoid ester was added, the spectra were recorded as described above for the oliogpeptoid amide, and K_D values were determined by fitting data to quadratic eq 3.

To determine the TAR RNA binding activities of Tat-derived oligopeptoids, we employed fluorescence spectroscopy techniques. Modified TAR RNA was synthesized on an Applied Biosystems Model 392 DNA/RNA synthesizer using 2-cyanoethylphosphoramidite chemistry (Figure 1A). All the monomers of (2-cyanoethyl)phosphoramidites were obtained from Glen Research (Sterling, VA). TAR RNA was chemically synthesized on a fluorescein-containing CPG 500 support. RNA (1 μmol) containing fluorescein was deprotected by treatment with NH_3 saturated methanol (2 mL) at 25 °C for 17 h. Product was filtered and dried in SpeedVac. To deprotect 2′-OH silyl groups, the pellet was dissolved in 50% triethylamine trihydrofluoride in dimethyl sulfoxide (0.5 mL) and left at room temperature for 16 h. Deprotected RNA was precipitated by the addition of 2 mL of isopropyl alcohol.

After deprotection, RNA was purified and characterized as described previously (*20*−*22*). This fluorescein-labeled TAR RNA was used to perform fluorescence resonance energy transfer (FRET) and fluorescence quenching experiments.

We carried out FRET experiments to determine the dissociation constant of TAR RNA and peptoid−amide complex. FRET, in which a fluorescent donor molecule transfers energy via a nonradiative dipole−dipole interaction to an acceptor molecule (which is usually also a fluorescent molecule) is a standard spectroscopic technique for measuring distances in the 10−70 Å range (*23*, *24*). The donor's lifetime and intensity are reduced upon energy transfer, and the acceptor fluorescence is increased, or sensitized. Quantification of the efficiency of energy transfer allows determination of the distance between the two fluorophores. We used a well-characterized donor−acceptor dye-pair, fluorescein−rhodamine, for FRET experiments. Rhodamine was incorporated at the terminal amino groups of the oligopeptoid amide during solid-phase synthesis.

The fluorescence resonance energy transfer (FRET) from fluorescein to Rhodamine was measured on PTI (Photon Technology International) fluorescence spectrophotometer. The fluorescein-labeled TAR RNA (Fl-TAR) was excited at 490 nm. The emission spectrum was recorded from 500 to 650 nm for each scan. The slits were set 4 nm for both excitation and emission lights. All experiments were carried out at room temperature. Samples were placed in a plastic microcuvette with a starting volume of 300 μL. The initial concentration of Fl-Tar was around 5.2 nM for all experiments. Each addition of rhodamine-labeled Tat peptoid amide to the Fl-TAR solutions was followed by a 2-min equilibration before the fluorescence spectrum was recorded. The fluorescence intensities were calibrated for the background of buffer (TKT buffer: 50 mM Tris-HCl, pH = 7.4, 20 mM KCl, and 0.02% (w/w) Tween20).

The energy transfer efficiency (E) from the donor to the acceptor was calculated from the decrease of the donor fluorescence intensity at 516 nm according to eq 1:

$$E = (1 - I_{DA}/I_D) \quad (1)$$

where I_{DA} and I_D are the donor fluorescence intensities in the presence and absence of the acceptor, respectively. The distance between the donor and acceptor (R) was calculated according to eq 2:

$$R = R_0(E^{-1} - 1)^{1/6} \quad (2)$$

where $R_0 = 47.6$ Å for fluorescein−rhodamine pair in our system (*25*).

The dissociation constant (K_D) of oligopeptoid amide bound to TAR RNA was obtained by fitting data to quadratic eq 3:

$$F = F_{min} - \{(F_{max} - F_{min})[(e_0 + x + K_D) - ((e_0 + x + K_D)^2 - 4e_0x)^{1/2}]\}/2e_0 \quad (3)$$

where F is the relative fluorescence intensity of the donor (Fl-TAR). F_{min} is the fluorescence intensity at the start of the titration. F_{max} is the fluorescence intensity at saturating concentration of oligopeptoid amide, x. e_0 is the initial concentration of Fl-TAR, 5.2 nM. Results of these experiments are shown in Figure 3A indicating that a high affinity complex between the Tat-derived peptoid amide analogue and TAR RNA was formed ($K_D \approx 155$ nM). The energy transfer efficiency was 47.6%, and a distance of 48.4 Å was calculated between two dyes.

We were unable to incorporate rhodamine at the amino terminal position during the synthesis of Tat-derived oligopeptoid ester analogue due to the formation of a terminal diketopiperazine under basic conditions (diisopropylamine) during rhodamine dye labeling reactions. Therefore, we used fluorescence quenching of fluorescein-TAR RNA by the addition of oligopeptoid ester and determined the binding affinities of Tat-oligopeptoid ester to TAR RNA. As shown in Figure 3B, the oligopeptoid ester was able to bind TAR RNA with high affinity ($K_D \approx 68$ nM). It is interesting that the ester analogue of the Tat-derived oligopeptoid displays a higher affinity to TAR as compared to the amide analogue which contains more functional groups for nucleic acid backbone interactions. Future structural studies may elucidate the differences in RNA recognition by these two oligopeptoids.

Wender et al. recently demonstrated the use of peptoids as molecular transporters (*26*). Peptoid transporters proved to be substantially better than Tat (49−57) peptide. In addition to better uptake performance, these peptoids offer several advantages over Tat peptides including ease of synthesis of analogues and protease stability. These features along with their significant water solubility (>100 mg/mL) indicate that the peptoids could serve as drug candidates, effective transporters for the molecular delivery of drugs and other agents into cells. Our findings reported here show that two analogues of oligopeptoids (ester and amide) derived from Tat sequence binds TAR RNA with high affinities. RNA recognition by an oligopeptoid provides a new tool for the design of drugs and cellular probes which could modulate RNA−protein interactions in vivo. Studies to analyze cellular uptake and in vivo activities of these oligopeptoids are in progress.

ACKNOWLEDGMENT

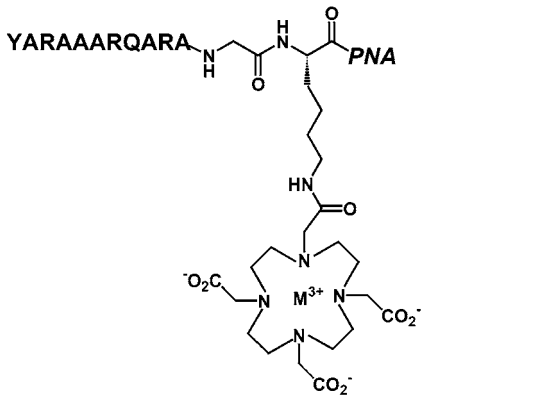
A new antisense peptide−peptide nucleic acid (peptide−PNA) conjugate, designed for targeting *bcl-2* expression, has been radiolabeled, characterized, and evaluated for *bcl-2* mRNA binding in a cell-free system. A PNA complementary to the first six codons of the *bcl-2* gene was synthesized by standard solid-phase Fmoc chemistry and conjugated to a new derivative of 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA) that allows macrocyclic radiometal chelates to be incorporated into any sequence position of a peptide−PNA conjugate. The DOTA−PNA conjugate was then coupled to a membrane-permeating transduction peptide, PTD-4, designed for intracellular delivery of the radiolabeled PNA. The conjugate was characterized by HPLC and ESI-MS and labeled with ^{111}In and ^{90}Y to high specific activities (>1000 Ci/mmol) with high radiochemical purity. Northern blot analysis showed that ^{90}Y-PTD-4−K(DOTA)−anti-*bcl-2*-PNA bound specifically to as little as 50 fmol of *bcl-2* mRNA, a result equivalent to that obtained with the analogous ^{32}P-labeled DNA antisense oligonucleotide. Thus, the mRNA targeting properties of ^{111}In- and ^{90}Y-PTD-4−K(DOTA)−anti-*bcl-2*-PNA demonstrate potential for diagnostic imaging and targeted radiotherapy applications in *bcl-2*-positive cancers.

The processes of carcinogenesis and cancer progression often involve deregulation of proto-oncogenes that confer malignant or aggressive phenotypes to tumor cells. For example, the *B-cell lymphoma/leukemia-2* (*bcl-2*) proto-oncogene (*1*) produces an inhibitor of apoptosis (*2*) that is thought to provide a survival advantage to tumor cells and has been implicated in the development of radiation (*3*−*5*) and chemoresistance (*6*−*8*). *Bcl-2* is overexpressed in non-Hodgkin's lymphoma (NHL) (*9*−*13*) and many other cancers, including breast (*14*), lung (*15, 16*), colon (*17, 18*), prostate (*19, 20*), and neuroendocrine cancers (*21*), malignant melanoma (*22*), acute myeloid leukemia (*23*), and multiple myeloma (*24*).



Response of NHL patients to conventional combination chemotherapy is initially good, with 30−35% achieving long-term survival at 10−15 years follow-up (*25*). Unfortunately, in most cases relapse is inevitable, with transformation to a more aggressive histologic phenotype and development of resistance to radiation and/or chemotherapy. In two large cohort studies of patients with aggressive NHL receiving combination chemotherapy (*26, 27*), multivariate analyses revealed that *bcl-2* overexpression was the only clinical feature that correlated strongly with high relapse rate, reduced disease-free survival, and poor overall survival. Thus *bcl-2* overexpression might be considered a new independent prognostic parameter in NHL, aiding in the identification of patient risk groups. Such patients might respond better to alternative treatments, such as targeted immunotherapy, radioimmunotherapy, or antisense therapy, all of which act through mechanisms that down-regulate *bcl-2*. Therefore, development of new *bcl-2*-targeted diagnostic and therapeutic agents may provide a better understanding of the role this proto-oncogene plays in disease progression and treatment response or failure.

The objective of the present research was to develop *bcl-2* antisense agents labeled with diagnostic and therapeutic radiometals and coupled to a peptide vector for intracellular delivery. Peptide nucleic acid (PNA), developed by Nielsen et al. (*28*), has great potential for antisense applications. PNA is resistant to biological degradation and binds complementary mRNA with affinity, specificity, and stability exceeding those of corresponding DNA:RNA duplexes (*29*). However, studies of antisense properties of PNAs have been limited by their poor cellular uptake. Recent work demonstrated that PNA uptake can be increased substantially (*30, 31*) by conjugation to membrane-permeating peptides such as *Drosophila* antennapedia(43−58) (pAntp) (*32*) or the HIV Tat peptide (*33*). More recently, a synthetic protein transduction domain, PTD-4, was shown to exhibit a 33-fold increase in cellular uptake, compared to the Tat sequence (*34*).

Figure 1. Structures of radiometal-labeled PTD-4−K(DOTA)−anti-*bcl-2*-PNA (**1a**, **1b**) and PTD-4−K(DOTA)−nonsense-PNA (**2a**, **2b**).

We report here the preparation, characterization, and target binding of a PTD-4-antisense PNA conjugate, complementary to the first six codons of *bcl-2* mRNA, and an analogous nonsense PNA conjugate, for which a BLAST database search revealed no homology with any known mammalian gene or DNA sequence. The conjugates were labeled with the diagnostic imaging radiometal ^{111}In ($T_{1/2}$ = 67.4 h; EC 849 keV (100%); γ 173 keV (89%), 247 keV (94%)) and the therapeutic radiometal ^{90}Y ($T_{1/2}$ = 64.0 h; β^- 2.27 MeV (100%)). To provide maximum flexibility in the preparation of radiometal-labeled peptide−PNA conjugates, a bifunctional derivative of 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA), which can be incorporated into any sequence position of a PNA or peptide by standard solid-phase coupling techniques, was synthesized. DOTA chelates a large number of radiometals, including ^{111}In and ^{90}Y, with extremely high in vivo stability. *N*-α-(9-Fluorenylmethoxycarbonyl)-*N*-ϵ-[tris(*tert*-butyl)DOTA]-L-lysine (Fmoc-K(DOTA)), was synthesized by activation of DOTA-tris(*tert*-butyl ester) (Macrocyclics, Dallas, TX) with 2-(1*H*-7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyl uronium hexafluorophosphate (HATU, Applied Biosystems, Foster City, CA) and 1-hydroxy-7-azabenzotriazole (HOAt, Applied Biosystems) in 1-methyl-2-pyrrolidinone and reaction of the resulting active ester with *N*-α-Fmoc-L-lysine (Advanced ChemTech, Louisville, KY). The compound was purified by solvent extraction using ethyl acetate and water, followed by concentration of the organic phase in vacuo and precipitation of the product with cold diethyl ether. Alternatively, Fmoc-K(DOTA) could be purified by semipreparative reversed-phase HPLC. Analytical reversed-phase HPLC, electrospray ionization mass spectrometry (ESI-MS), high-resolution ^1H NMR, and elemental analysis of Fmoc-K(DOTA) were consistent with the structure of the desired product.

Bcl-2 antisense and nonsense PNAs (Figure 1) were synthesized manually on XAL PEG PS resin (Applied Biosystems), using Fmoc-protected PNA monomers (B = T-OH, A(Bhoc)-OH, C(Bhoc)-OH, and G(Bhoc)-OH, Applied Biosystems) and standard solid-phase coupling techniques, followed by manual coupling of Fmoc-K(DOTA) and Fmoc-glycine as a small spacer between the PNA conjugate and PTD-4. Then the fully protected PTD-4 sequence was added to Fmoc-G-K(DOTA)−anti-*bcl-2*-PNA using an automated peptide synthesizer. The PTD-4−K(DOTA)−anti-*bcl-2*-PNA conjugate (**1**) was cleaved and deprotected with trifluoroacetic acid (TFA) containing 2.5% each of triisopropylsilane, *m*-cresol, thioanisole, ethanedithiol, phenol, and H_2O for 4 h at room temperature. Unfortunately, the fully deprotected conjugate coeluted with unmodified PNA at the solvent front when reversed-phase HPLC purification was attempted. Therefore, slightly deprotected PTD-4−K(DOTA)−anti-*bcl-2*-PNA was cleaved from the resin with 25% TFA, 5% triisopropylsilane, 5% *m*-cresol, and 5% H_2O in dichloromethane for two cycles of 15 min at room temperature. Two major slightly deprotected intermediates were purified by semipreparative reversed-phase HPLC. These intermediates were collected separately and fully deprotected as described above, after which **1** was isolated by precipitation with cold diethyl ether and characterized by ESI-MS. Observed molecular ions at *m*/*z* = 2190.0 ($(M + 3H)^{3+}$), 1642.5 ($(M + 4H)^{4+}$), 1314.2 ($(M + 5H)^{5+}$), 1095.1 ($(M + 6H)^{6+}$), and 938.9 ($(M + 7H)^{7+}$) were consistent with the mass of the desired product, 6568 Da. PTD-4−K(DOTA)-nonsense-PNA (**2**) was synthesized and purified using the same procedure, followed by ESI-MS analysis. Molecular ions observed at *m*/*z* = 2211.5 ($(M + 3H)^{3+}$), 1659.1 ($(M + 4H)^{4+}$), 1327.2 ($(M + 5H)^{5+}$), 1106.4 ($(M + 6H)^{6+}$), 948.5 ($(M + 7H)^{7+}$), 830.2 ($(M + 8H)^{8+}$), and 737.8 ($(M + 9H)^{9+}$) were consistent the mass of the desired product, 6629 Da. Synthesis of PTD-4−K(DOTA)-PNA conjugates has been described in brief (*35a*) and will be reported in detail subsequently (*35b*).

Conjugates **1** and **2** were labeled with ^{111}In (**1a**, **2a**) and ^{90}Y (**1b**, **2b**) in 0.2 M ammonium acetate, pH 5.0, containing approximately 1 mg/mL of gentisic acid, for 30 min at 90 °C. The antisense conjugate lacking PTD-4, K(DOTA)−anti-*bcl-2*-PNA (**3**) was labeled with ^{111}In (**3a**) using the same conditions. Diethylenetriaminepentaacetic acid (DTPA) was added to a final concentration of 1 mM, and after 5 min at room temperature the

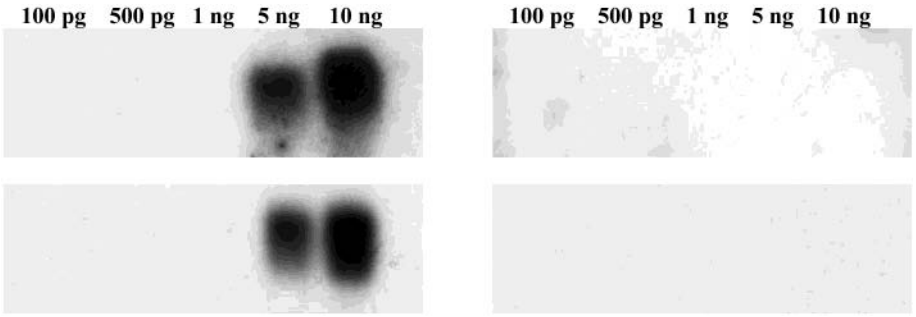

Figure 3. (Top) Northern blot analysis of *bcl-2* mRNA (left) and *luciferase* mRNA (right), using **1b**. (Bottom) Northern blot analysis of *bcl-2* mRNA (left) and *luciferase* mRNA (right), using ^{32}P-anti-*bcl-2*-DNA.

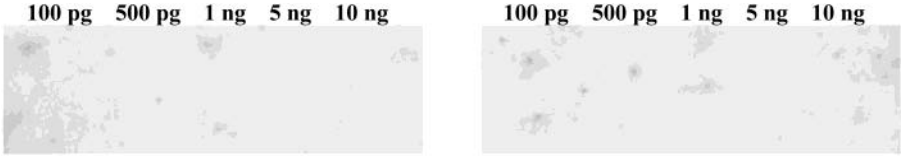

Figure 4. Northern blot analysis of *bcl-2* mRNA (left) and *luciferase* mRNA (right), using **2b**.

reaction mixtures were analyzed by normal-phase TLC and size exclusion HPLC. Both methods showed that ^{111}In and ^{90}Y incorporation into **1** was nearly quantitative at specific activities >1000 Ci/mmol (Table 1), as was ^{111}In labeling of **3**. These specific activities are considerably higher than those employed previously for in vivo imaging of *c-myc* mRNA with ^{111}In-labeled DNA oligonucleotides (*36*) and are also in the range proposed to image mRNA concentrations as low as 1 pM (*37*). Conjugate **2** was also labeled efficiently with ^{111}In and ^{90}Y by the same procedure. Analysis of **1** by size exclusion HPLC (Figure 2) showed that the conjugate had an apparent molecular weight of 5.94 kDa, determined from a calibration curve generated using a Bio-Rad (Hercules, CA) molecular weight standard. This value, lower than the calculated molecular weight, is consistent with the size of an α helix-random coil peptide−PNA conjugate (*38, 39*). Size exclusion HPLC of **1a** (Figure 2) revealed that the radiochemical purity of the compound was 100%.

The kinetic stability of **1a** was evaluated by size exclusion HPLC during incubation in mouse plasma at 37 °C for 168 h (data not shown). No evidence of instability of the ^{111}In-K(DOTA) chelate was seen, and no changes in the chromatographic profile of **1a** were observed for 24 h. At later time points, a reproducible increase of approximately 0.1 min in the retention time of the ^{111}In-labeled conjugate and peak tailing suggested that some proteolytic degradation of PTD-4 may have occurred. However, the *retro-inverso* counterpart of pAntp displays equivalent transduction activity and is much more stable to proteolysis (*30*). Therefore, we intend to synthesize the *retro-inverso*-PTD-4−K(DOTA)−anti-*bcl-2*-PNA analogue and evaluate it in future in vitro and in vivo studies.

A pcDNA3-hygro vector (Invitrogen, Carlsbad, CA) containing the open reading frame of human *bcl-2* was constructed for mRNA synthesis. *Bcl-2* and *luciferase* mRNAs were prepared by in vitro transcription, subjected to electrophoresis through a 1% agarose gel containing 2.2 M formaldehyde (*40*), and immobilized on nylon membranes by capillary transfer (*41*). RNA transfer was determined qualitatively to be complete by ethidium bromide staining of the gel before and after transfer and by methylene blue staining of the membrane. Then 50-μCi aliquots of **1b** and **2b** (5458 Ci/mmol) were incubated with membranes in hybridization solution (CLONTECH, Palo Alto, CA), containing 5% nonfat dry milk, for 1 h at 63.2 °C, after which the membranes were washed according to the manufacturer's instructions. Autoradiography of membranes for 1 h (Figure 3, top) showed that **1b** bound specifically to as little as 5 ng (50 fmol) of the *bcl-2* transcript, while no binding to *luciferase* mRNA was observed. The analogous anti-*bcl-2* DNA oligonucleotide was end-labeled to a specific activity of 6000 Ci/mmol, using γ-[^{32}P]ATP and T4 polynucleotide kinase, and 50 μCi of ^{32}P-anti-*bcl-2*-DNA was hybridized with the immobilized mRNAs under the same conditions, except that nonfat dry milk was not added. Autoradiography with ^{32}P-labeled DNA was carried out for 5.25 h, such that the film was exposed to the same number of radioactive decays as for ^{90}Y-labeled PNA. As shown in Figure 3 (bottom), ^{32}P-anti-*bcl-2*-DNA gave equivalent results to those obtained with **1b**. Analogous control experiments using **2b** showed no binding to either transcript (Figure 4). Thus, the ^{90}Y-labeled antisense peptide−PNA conjugate was qualitatively equal to ^{32}P-labeled antisense DNA in terms of *bcl-2* mRNA detection sensitivity and specificity. However, Northern blot analysis at elevated temperatures demonstrated that **1b** bound to *bcl-2* mRNA with greater thermodynamic stability than ^{32}P-anti-*bcl-2*-DNA (see Supporting Information). Synthetic *bcl-2* and *luciferase* mRNAs were also spiked into a total RNA preparation from 293 human embryonic kidney cells, and the resulting mixtures were analyzed by Northern blotting with **1b** after agarose gel electrophoresis. While some nonspecific binding to cellular RNA was seen (Figure 5), 10 ng (100 fmol) of *bcl-2* mRNA was detected clearly in the presence of a large excess of cellular RNA, and no binding to *luciferase* mRNA was observed.

In conclusion, a new *bcl-2* antisense PNA conjugate, coupled to a membrane-permeating peptide for intracellular delivery, was prepared and labeled to high specific activities with the diagnostic imaging radiometal ^{111}In and the therapeutic radiometal ^{90}Y. Hybridization experiments demonstrated that **1b** was able to bind to immobilized *bcl-2* mRNA with high sensitivity and specificity equivalent to ^{32}P-labeled antisense DNA, yet with greater thermodynamic stability. We are currently evaluating the *bcl-2* targeting properties of **1a** and **1b** in cultured NHL cells and tumor-bearing animal models.

In preliminary studies, uptake of **1a** in Raji cells, which express high levels of *bcl-2* mRNA (*42*), increased significantly ($p < 0.05$) from 6.53% of the total radioactivity added after 30 min at 37 °C to 8.04% at 4 h, while initial

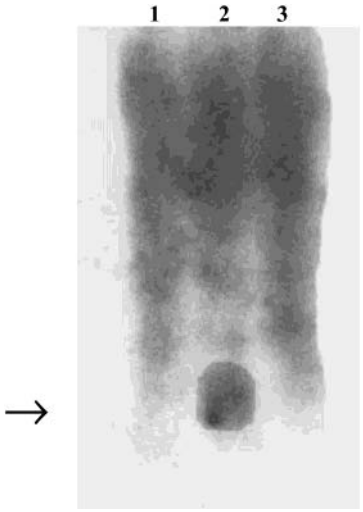

Figure 5. Northern blot analysis of total cellular RNA from 293 cells, using **1b**. Lane 1: total RNA (10 μg); lane 2: total RNA (10 μg), spiked with 10 ng of synthetic *bcl-2* mRNA; lane 3: total RNA (10 μg), spiked with 10 ng of *luciferase* mRNA. The arrow indicates the *bcl-2* transcript, determined to be equal to the theoretical molecular size of 0.754 kb by ethidium bromide staining and comparison with a DNA molecular weight standard (1kb DNA Ladder, Promega, Madison, WI).

uptake of **3a** was approximately 13-fold lower. In U937 cells, which express low levels of *bcl-2* mRNA (*43*), uptake of **1a** decreased significantly ($p < 0.05$) from 4.05% at 30 min to 2.07% at 4 h. At all time points, uptake of **1a** was significantly greater ($p < 0.05$) in Raji cells than in U937 cells. We are currently developing Raji- and U937-bearing mouse models of NHL to evaluate the tumor targeting properties of ^{111}In- and ^{90}Y-*retro-inverso*-PTD-4−K(DOTA)−anti-*bcl-2*-PNA.

ACKNOWLEDGMENT

This work was supported by NIH Grant CA86290 (W. A. Volkert, PI) and a grant from the University of Missouri Research Reactor Research Partnerships Initiative (to M.R.L.). The authors would like to acknowledge the support of the Department of Veterans Affairs and the University of Missouri Research Reactor for purchasing an Advanced ChemTech ACT Model 396 Omega Multiple Biomolecular Synthesizer used in this research.

Received July 22, 2002

A ternary complex of PPI-DAB dendrimer [(1,4-diaminobutane); Gen = *N*; *dendri*-poly(propyleneimine); -[NHC(=O)$CH_2NH_2^+(CH_2)_4NH_3^+$]$_z$], DNA, and cucurbituril (CB) was evaluated as an example of a totally self-assembled gene delivery carrier. The complex was formed in a noncovalent way in which DNA interacts with PPI-DAB electrostatistically and CB with PPI-DAB through multiple noncovalent interactions. Dynamic light scattering data indicated that the diameter and size distributions of the complexes were dependent upon the sequence of mixing of each component with unimodal distribution ranging from 150.8 to 210.2 nm under favorable conditions. Fluorescence studies showed the quantitative binding of CB to PPI-DAB after ternary complex formation. The complex was able to transfect mammalian cells with high efficiency and the cytotoxicity of the PPI-DAB/CB complex was relatively low.

Spontaneously assembled supramacromolecular complexes have been the subject of considerable interest, with the noncovalent self-assembly process between biological macromolecules being mimicked in a chemical approach (*1*−*8*). The study of nonviral gene delivery vectors is one such approach in which virus corelike particles are assembled through electrostatic interactions, e.g., between cationic polymer and negatively charged DNA (*9*). A number of cationic polymers, such as poly-L-lysine (*10*), poly(ethylenimine) (PEI) (*11*), PAMAM dendrimer (*12*), and hyperbranched poly(amino ester) (*13*), were able to compact DNA into submicron-sized water-soluble particles (polyplexes) and carry DNA into the cell nucleus. The polyplexes were made to have specialized functional moieties such as targeting ligands, endosome disruptive functions, and nucleus localization signals by directly (covalently) attaching them to the cationic polymer (*14*−*17*). This covalent strategy has worked well; however, it would be more interesting if we were able to produce similar or even more advanced systems by the use of a noncovalent approach.

The packaging of viruses is also an elaborate multistep noncovalent self-assembly process between the viral genome (DNA or RNA) and a number of proteins (*18*). In this regard, a synthetic functional module that recognizes a specific moiety in the cationic polymer in a noncovalent manner would be useful in the realization of synthetic viruslike particles.

In this paper we report on the development of a noncovalently assembled ternary gene delivery complex based on cationic dendrimer, DNA, and CB reminiscent of virus particles (Scheme 1). CB was regarded as a functional module. CB itself has no biological activity; however, this system can be applied to other noncovalent molecular recognitions, and it would be possible to create a really functional polyplex if the functionalized-CB were synthesized, which we are currently investigating. For example, peptide ligand−CB conjugate could easily be made if amine (NH_2)-, alcohol (OH)-, or sulfhydryl (SH)-functionalized CB was synthesized. The purpose of this work is to evaluate the possibility of generating a three-component gene delivery system consisting of cationic polymer, DNA, and noncovalent ligand equivalent. CB is a large-cage compound composed of glycoluril units interconnected with methylene bridges and is able to form stable pseudorotaxanes with strings derived from diaminoalkanes through multiple noncovalent interactions (*19*, *20*).

The ternary complex was prepared by the sequential treatment of PPI-DAB (G4) with CB and DNA (PPI-DAB/CB/DNA), or DNA and CB (PPI-DAB/DNA/CB). Synthetic details for the preparation of PPI-DAB have been described previously (*21*). The hydrodynamic radii (R_h) of the two preparations were investigated by dynamic light scattering (DLS)[1] as shown in Figure 1. The measured average R_h of PPI-DAB/CB/DNA was 150.8

[1] Light scattering experiments were performed at 25 °C with BI-200SM Goniometer (Brookhaven Instruments Corporation) using a Lexel laser model 95 argon laser (100 mW output power at a wavelength of 514.5 nm). Correlator was PD2000 (Precision Detectors), and the scattering angle was 90°. Data were analyzed using the CONTIN algorithm. The sample was prepared by directly mixing each solution of polymer and DNA in water. The final DNA concentration was adjusted to 5 μg/mL.

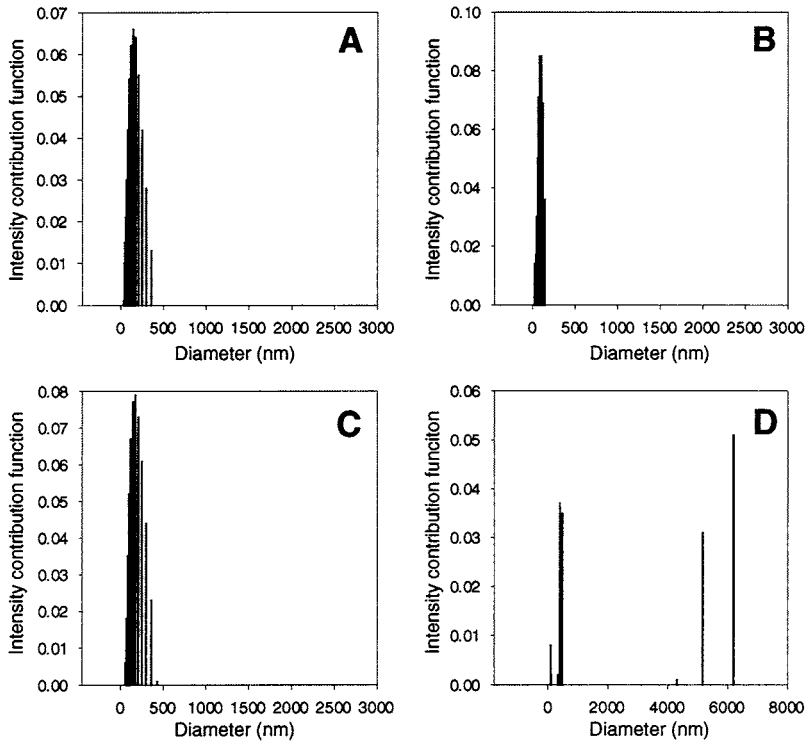

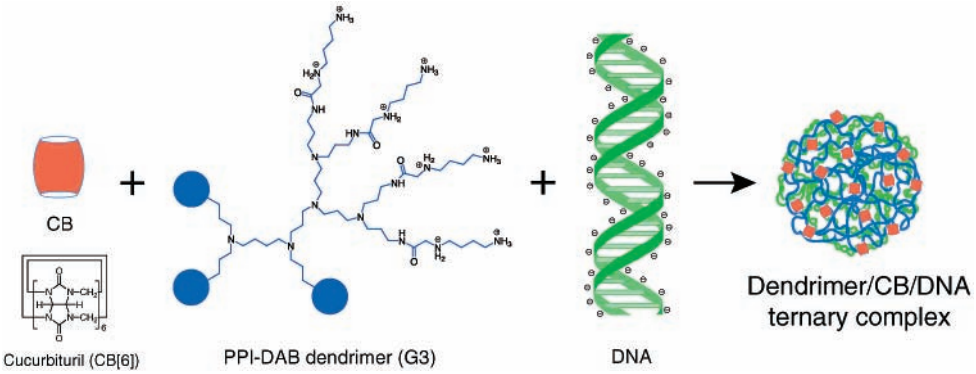

Figure 1. Size distribution of (A) PPI-DAB/CB/DNA (with 100% CB relative to DAB), (B) PPI-DAB/DNA, (C) PPI-DAB/DNA/CB (10% CB), and (D) PPI-DAB/DNA/CB (30% CB) complexes by dynamic light scattering.[1] DNA was pEGFPLuc plasmid DNA.[2] All complexes were formed at a charge ratio (+/−) of 3. Charge ratios were calculated based on the assumption that only primary and secondary amines in DAB are protonated.

Scheme 1. Ternary Complex of PPI-DAB Dendrimer, CB, and DNA

nm. PPI-DAB/CB/DNA was prepared with all the DAB moieties being occupied by CB. The average R_h of PPI-DAB/DNA (83.5 nm) was smaller than that of PPI-DAB/CB/DNA; however, the complex grew larger as CB was added. At 10% and 20% CB concentrations (relative to DAB moieties), the average R_h became 176.2 and 506.1 nm, respectively. Two intensity populations existed above 30% CB concentration, with the smaller sizes presumably due to that of well-defined ternary complexes and the larger sizes probably attributed to aggregates. These results imply differences in tertiary structures between the two preparations. Therefore, further characterization of the ternary complex was conducted with PPI-DAB/CB/DNA for simplification.

The formation of the ternary complex was investigated by observing the shift of DNA electrophoretic migration in agarose gel (Figure 2). All third-generation (G3) polymers and G4 of PPI formed polymer/DNA complexes (polyplexes) at charge ratios (polymer to DNA, +/−) above unity. However, G5 of PPI, G4 and G5 of PPI-DAB, and G4 and G5 of PPI-DAB/CB formed polyplexes at charge ratios above 2. These results indicate that the DNA binding capacity of the three polymers is decreased as the generation number is increased. In addition, the DNA binding capacities were increased in the order, PPI > PPI-DAB ≥ PPI-DAB/CB. Examination of the structural conformations of PPI-DAB and PPI-DAB/CB by molecular dynamic simulation revealed that PPI-DAB/CB adopts a more rigid shell at the exterior than PPI-DAB (*21*). The decreased binding capacity of the higher generation dendrimers and of PPI-DAB/CB and PPI-DAB relative to that of PPI may be related to the formation of a more rigid and compact shell at the exterior where DNA binding amine groups are located, and to the effect of the polymers' different molecular structure and CB on pK_a of amino groups.

To verify the formation of the ternary complex, it was necessary to prove that CB remained associated with PPI-DAB and was not expelled from the polymer in the process of DNA binding. To demonstrate the validity of this assumption, each of CB, PPI-DAB (G4)/CB, and PPI-DAB (G4)/CB/DNA were dialyzed using 3500 M_r cutoff tubing against 0.2 m Na_2SO_4, in which CB dissolves very

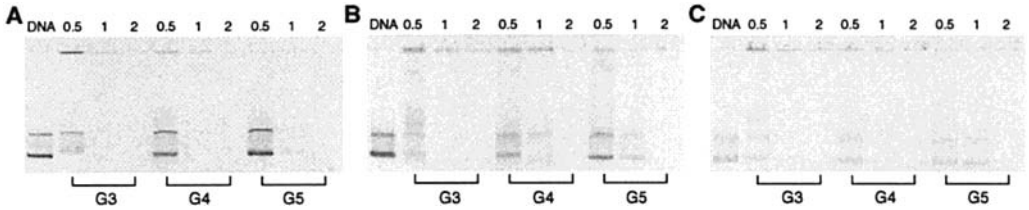

Figure 2. Investigation of polyplex formation by agarose gel band shift assay. Numbers indicate charge ratios (+/−). (A) PPI/DNA polyplex. (B) PPI-DAB/DNA polyplex. (C) PPI-DAB/CB/DNA polyplex. In PPI-DAB/CB/DNA polyplex, all of the DAB moieties are occupied by CB. The original positive image was inverted to make it negative for ease of band discrimination.

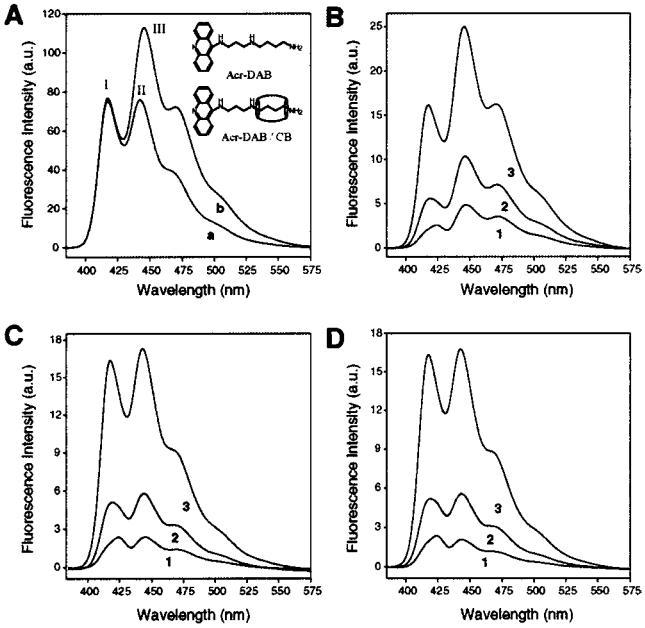

Figure 3. Fluorescence emission spectra of (A) **a**: Acr-DAB; **b**: Acr-DAB/CB and the solution outside the dialysis membrane of (B) CB, (C) PPI-DAB/CB, and (D) PPI-DAB/CB/DNA dialysates after addition of Acr-DAB. **1**: 0.1 μg (1/40 molar equivalent of total CB); **2**: 0.3 μg (3/40); **3**: 1.0 μg (10/40) of Acr-DAB were added to the solution.

well (*20*). In this system, only CB is expected to be freely permeable to the membrane.

The presence of CB in the solution outside the membrane could easily be detected by using DAB-tethered acridine (Acr-DAB) with high sensitivity (Figure 3).[3] The spectrum of Acr-DAB exhibited acridine emission with peaks at 418 (band I) and 442 nm (band II). However, there was a red shift (4 nm) of band II after binding of CB to Acr-DAB with a strong increase in the fluorescence intensity (band III), due to the interaction of CB with the acridine moiety. The shapes of the emission spectra, which were recorded after addition of Acr-DAB to the outside solution of CB dialysate, were identical to that of Acr-DAB/CB (Figure 3B). Varying the amount of added Acr-DAB (1/40, 3/40, and 10/40 molar equivalent of CB) did not influence the shape of the spectrum except in relation to the emission intensity. Identical spectra were obtained in the case where the same amount of Acr-DAB as indicated above was added to an estimated amount of CB, on the assumption that the membrane is freely permeable to CB (data not shown).[4] These results indicate that equilibrium of CB across the membrane had been reached. In contrast, the shape of the emission spectra recorded after addition of varying amounts of Acr-DAB to the outside solution of PPI-DAB/CB or PPI-DAB/CB/DNA dialysate are almost identical to that of Acr-DAB (Figure 3, parts C and D). However, there were slight increases in the fluorescence intensity of band II, indicating that a small amount of CB exists outside the membrane. It has been well established that CB binds tightly to the diaminobutane moiety with high affinity (*19*−*21*). Therefore, the amount of CB present outside the membrane would be minute, and the nearly identically shaped spectra in parts C and D of Figure 3 indicate that there was no change in the CB "beads" threaded on PPI-DAB after the addition of DNA to the PPI-DAB/CB binary complex.

To evaluate the ternary complex as a potential gene delivery vector, the cytotoxicity of the polymers and gene transfer mediated by the complexes were investigated (Figure 4). The results indicated that PPI-DAB/CB polymer had relatively low toxicity with about 50% cells remaining viable even at high concentrations of 100 μg/mL (Figure 4A). Transfection efficiencies (TE) were dependent on the cell type, usually 300−500 times higher in 293 cells than in Vero 76 cells for all polyplexes (PEI, PPI, PPI-DAB, and PPI-DAB/CB polyplexes) tested (Figure 4B). It is well-known that 293 cells are very susceptible to transfection. However, the relative TEs among the polyplexes were similar between the two cell lines. Transfection mediated by PPI-DAB/CB polyplexes was relatively high and was only about 10 times lower than that of PEI, which is one of the most efficient gene carriers hitherto reported (*9*). Szoka and colleagues have shown that fractured PAMAM dendrimers are more efficient in transfection than intact PAMAMs due to the increased flexibility of the fractured dendrimers that enables them to be compact when complexed with DNA and swell when released from DNA (*22*). The lower TEs of PPI, PPI-DAB, and PPI-DAB/CB polyplexes than that of PEI polyplexes may be related to the same mechanism. The TEs of PPI, PPI-DAB, and PPI-DAB/CB polyplexes were increased as the generation number of dendrimers became higher (Figure 4C). Taken together, these results indicated that CB had no negative influence on the TE of polymer/DNA binary complex and the ternary complex is a highly active form of gene delivery vector. This prototype of supramacromolecular ternary complex can

[3] PPI-DAB (G4)/CB or PPI-DAB (G4)/CB/DNA (+/−, 2) each containing 60.4 μg of CB was dissolved in 2 mL of 0.2 M Na_2SO_4. Each of the two solutions and 2 mL of 0.2 M Na_2SO_4 solution containing 60.4 μg of CB were dialyzed against 8 mL of 0.2 M Na_2SO_4 using 3500 molecular weight cutoff tubing (Spectrum Laboratories). After extensive dialysis, 1 mL of the solution outside the tubing was taken. Varying amounts of Acr-DAB (0.1 to 1.0 μg) were added to the solution, and then fluorescence measurements were taken. Fluorescence emission spectra were recorded at room temperature on a Jasco FP-750 spectrofluorometer. The emission bandwidth was set at 5 nm. The excitation wavelength was 370 nm.

[4] For the spectra measurements in Figure 2B, 60.4 μg of CB in 2 mL of 0.2 M Na_2SO_4 was dialyzed against 8 mL of the same solution and 1 mL of the solution outside the membrane was taken for the measurement (final 10-fold dilution). Therefore, 6.04 μg of CB was used for this control.

Class-Selective Drug Detection: Fluorescently-Labeled Calmodulin as the Biorecognition Element for Phenothiazines and Tricyclic Antidepressants

Phillip M. Douglass, Lyndon L. E. Salins, Emre Dikici, and Sylvia Daunert*

Departments of Chemistry and Pharmaceutical Sciences, University of Kentucky, Lexington, Kentucky 40506-0055. Received September 3, 2001; Revised Manuscript Received May 17, 2002

A small-scale, homogeneous, rapid sensing system for phenothiazines and tricyclic antidepressants (TCAs) has been developed by employing fluorescently labeled mutant calmodulin (CaM) as the recognition element. A calmodulin mutant containing a unique cysteine residue at position 109 on the protein was expressed in *Escherichia coli*. Following purification, the environment-sensitive, thiol-specific fluorophores *N*-[2-(1-maleimidyl)ethyl]-7-(diethylamino)coumarin-3-carboxamide (MDCC), 6-acryloyl-2-dimethylaminonaphthalene (acrylodan), and 4-[*N*-(2-(iodoacetoxy)ethyl)-*N*-methylamino]-7-nitrobenz-2-oxa-1,3-diazole (IANBD ester) were coupled to the C109 site of the mutant protein. The response of labeled CaM in the presence of calcium to increasing concentrations of chlorpromazine hydrochloride (CPZ), as well as other phenothiazines and structurally related antipsychotics and antidepressants, was investigated. Fluorescence measurements were performed on benchtop and microtiter plate fluorometers. The responses were characterized as a change in the signal intensity of the labeled protein upon ligand binding, and the stability of the system was monitored over a nine-month period. The assay showed specificity for the phenothiazine and TCA classes of drugs, with limits of detection in the micromolar range. Selectivity studies indicated negligible response of the biosensing system to structurally unrelated compounds. This work represents a proof-of-concept assay for rapid, homogeneous detection of drugs employing binding proteins as the biorecognition element.

INTRODUCTION

The use of fluorescently labeled proteins has recently resulted in a number of biosensing systems for a variety of biomolecules (*1*−*4*). With proteins, one can capitalize on a highly evolved natural sensing system that provides selective and sensitive detection of target ligands and analytes. Such systems have not only been indicated for detection of drugs in a homogeneous-based format as reported herein, but also as a means of studying drug activity in cell-based screens (*2*, *5*).

In high-throughput screening (HTPS) applications, assays are not necessarily required to be highly specific. Screens that are designed to detect classes of drugs versus assays that detect single compounds are more practical and cost-effective in the analysis of combinatorial chemistry products (*6*). "Hits" identified from these preliminary screens need further analysis, and conventional analytical methods are then employed to characterize the nature and level of drug response. Ideal HTPS systems should be homogeneous, facile, and rapid. In addition, they should be amenable for miniaturization and small volume detection of a large number of compounds.

Calmodulin is a 148 amino acid, 17-kDa calcium binding protein. Ubiquitous in nature, CaM plays an important role in intracellular signaling pathways (*7*, *8*). In the presence of calcium, the protein undergoes a conformational change resulting in the exposure of two hydrophobic pockets, one each in the N- and C-termini of the protein. These hydrophobic pockets have a high affinity for enzymes such as phosphodiesterase and myosin light chain kinase, which are activated upon binding to CaM (*9*). The phenothiazines, a family of antipsychotic drugs, bind to the C-terminal hydrophobic pocket of CaM, acting as antagonists of such enzymes (*8*, *10*). In addition, CaM also has affinity for the structurally related tricyclic antidepressants (TCAs). Controversy exists in the literature as to whether the phenothiazines and TCAs also bind to the N-terminal hydrophobic pocket as one might expect, given that the two domains share a 44% residue homology (*9*). Most, however, tend to support the idea of the drugs only binding to the C-terminal with significant affinity (K_d's in the micromolar range). Upon binding to the drug, CaM undergoes a hinge-motion conformational change about its central, 8-turn α-helix, resulting in a collapse of the protein as evident in Figure 1. The crystal structure of CaM bound to trifluoperazine (TFP) has been determined (see Figure 1, at right). Cook et al found that 13 residues form contacts with TFP. Ten of these are hydrophobic; the others are glutamates and interact via van der Waals forces. Only one (Glu11) is in the N-terminal domain of the protein (*11*). The tricyclic ring lies between the side chains of Met124 and Met144; these residues interact directly with the ligand's aromatic rings (*9*, *11*, *12*).

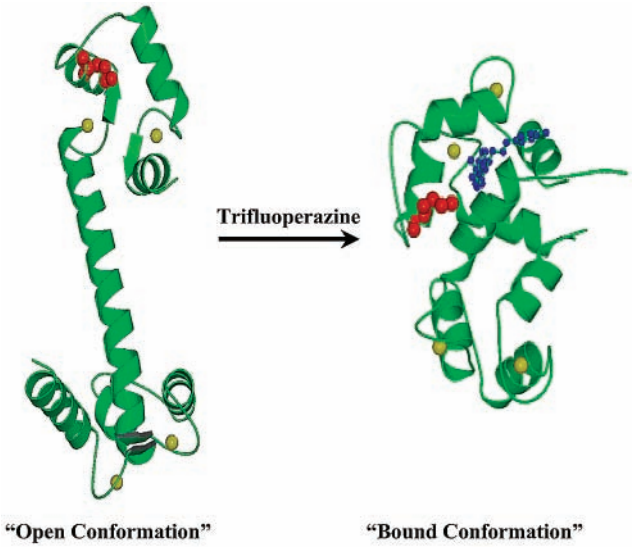

Figure 1. Ribbon diagram of calcium-bound calmodulin in the absence (left) and presence (right) of the phenothiazine trifluoperazine. Calcium is represented by yellow spheres, trifluoperazine is colored blue, and the site of fluorophore conjugation, Cys109, is colored red. Crystal structures were obtained from the Brookhaven Protein Data Bank (files 1CLL and 1CTR) and displayed using Molscript 1.4 (*31*) and Raster3D (*32*) software.

In this work, we report a proof-of-concept approach to drug detection utilizing the changes in conformation that binding proteins undergo upon binding to their ligand. Specifically, the study of fluorescently labeled CaM as a sensing element for the phenothiazine class of drugs and the related TCAs is described. The affinity of CaM for phenothiazines has previously been used in our laboratory as the basis of developing an affinity purification method for the protein and other recombinant proteins fused to CaM (*13*−*15*). Most recently, site-selective fluorescently labeled CaM has been employed in our group as a biosensing system for the detection of calcium (*16*). Given that CaM binds not only to calcium but also to phenothiazines, it is hypothesized that the change in conformation and environment that calcium-bound CaM undergoes upon binding to these drugs will allow the protein to act as a highly sensitive sensing element in their detection (*16*). It has been demonstrated that the location of the fluorophore on the protein highly influences the change in signal observed and thereby the sensitivity and detection limits of the sensing system (*16*). The CaM employed in our studies lacks any native cysteine residues (*17*). A mutant of this CaM has been rationally designed to contain a unique cysteine at a position on the protein that appeared to undergo significant environmental and conformational change upon drug binding (*16*). Utilizing the cysteine's thiol group, mutant CaM was coupled to three different sulfhydro-specific environment-sensitive fluorophores, namely, MDCC, acrylodan, and IANBD ester. The resulting CaM conjugates were then evaluated as biosensing elements for the detection of phenothiazines and related TCAs. Steady-state fluorescence experiments were conducted to verify a difference in fluorescence signal emitted by the fluorescently labeled protein in the presence or absence of analyte. The class-selectivity of the biosensing system toward compounds both structurally related and unrelated to the phenothiazines and TCAs was also evaluated.

EXPERIMENTAL PROCEDURES

Reagents. Luria-Bertani (LB) medium was purchased from GibcoBRL (Gaithersburg, MD). Ethylenebis(oxyethylenenitrilo)tetraacetic acid (EGTA), dithiothreitol (DTT), chlorpromazine hydrochloride (CPZ), trifluoperazine dihydrochloride (TFP), thioridazine hydrochloride, amitryptiline hydrochloride, α-D-glucose, and acetylsalicylic acid were obtained from Aldrich (Milwaukee, WI). Ampicillin, chlorprothixene hydrochloride, and imipramine hydrochloride were obtained from Sigma (St. Louis, MO). Tris(hydroxymethyl)aminomethane (Tris) and 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) were purchased from Research Organics (Cleveland, OH). The fluorophores *N*-[2-(1-maleimidyl)ethyl]-7-(diethylamino)coumarin-3-carboxamide (MDCC), 6-acryloyl-2-dimethylaminonaphthalene (acrylodan), and 4-[*N*-(2-(iodoacetoxy)ethyl)-*N*-methylamino]-7-nitrobenz-2-oxa-1,3-diazole (IANBD ester) were obtained from Molecular Probes (Eugene, OR). Isopropyl β-D-thiogalactopyranoside (IPTG) was purchased from GibcoBRL (Gaithersburg, MD). Fluoronunc white C96 Maxisorp microtiter plates were purchased from VWR (South Plainfield, NJ). The expression plasmid pVUC-1 was kindly provided by Dr. D. M. Watterson (*17*). The phenothiazine 2-(trifluoromethyl)-10*H*-(3′-aminopropyl) phenothiazine hydrochloride (TAPP) was synthesized in our group as previously described (*13*, *15*, *18*). The bicinchoninic acid (BCA) protein microassay reagent kit from Pierce (Rockford, IL) was used to determine the concentration of the purified CaM. Deionized distilled water (Milli-Q water purification system, Millipore, Bedford, MA) was used to prepare all solutions and mobile phases. All chemicals employed were reagent grade or better.

Apparatus. Bacterial colonies were grown on agar plates at 37°C in a Fisher Scientific Incubator (Fair Lawn, NJ). Cell cultures were grown in an Orbital Shaker from Forma Scientific (Marietta, OH) and pelleted using a Beckman J2-MI Centrifuge (Palo Alto, CA). Unpurified protein fractions were filtered with a 0.2 μm filter from Nalgene (Rochester, NY). A BIOCAD SPRINT Perfusion Chromatography System by PE Biosystems (Foster City, CA) was used for protein purification. Protein purity was verified by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS−PAGE) using a PhastSystem from Pharmacia Biotech (Uppsala, Sweden). Purified protein was concentrated via lyophilization using a VirTis Bench Top 3 Freeze-Dryer (Gardiner, NY). Protein was dialyzed against the correct buffer using 10000 MWCO Snakeskin pleated dialysis tubing by Pierce (Rockford, IL). Initial fluorescence studies were performed on a Fluorolog-2 fluorometer, Spex Industries (Edison, NJ) equipped with a 450-W xenon lamp and excitation and emission monochromators. Assay development was carried out on a Cytofluor 4000 fluorescence microtiter plate reader by PE Biosystems (Foster City, CA) equipped with the following filters: 420/50-nm excitation and 490/40-nm emission (for MDCC), 380/20-nm excitation, 490/40-nm emission (for acrylodan), 485/20-nm excitation, 530/25-nm emission (for IANBD ester), 313/55-nm excitation, 460/40-nm emission (for chlorpromazine).

Expression of Calmodulin. The plasmid pVUC-1 (*17*), containing the gene for mutant CaM with a methionine−cysteine mutation at residue 109 (*16*) was transformed into *Escherichia coli* JM109 competent cells and then plated on LB plates containing ampicillin (100 μg/mL). After growing overnight at 37 °C, a colony of transformed cells was picked and incubated overnight in 5 mL of LB media containing 75 μg/mL ampicillin. The culture was transferred into 500 mL of LB and incubated for an additional 7−8 h, until an optical density at 600 nm of 0.6 was obtained. Protein expression was induced

by the addition of 1 mM IPTG. Following 5 h of incubation with IPTG, the cells were harvested by centrifugation, washed in 10 mM HEPES buffer containing 0.5 mM $CaCl_2$, pH 7.5 (Buffer A), and lysed via sonication. The crude extract was boiled for 5 min to precipitate out additional undesired proteins.

Purification of CaM109. A TAPP affinity column was used to purify the mutant CaM following the method of Hentz et al. (*13*). Purified protein was concentrated overnight by lyophilization, and the purity of the protein was confirmed by SDS−PAGE employing silver staining development.

The lyophilized protein was resuspended in 500 μL of deionized water and dialyzed in Buffer A for 24 h to remove any remaining EGTA present from the purification process. Protein concentration was determined by using the BCA protein assay.

Preparation of Fluorescently-Labeled CaM109. A volume of 1 mL of purified CaM109 was dialyzed against Buffer A, containing DTT to eliminate any disulfide linkage formation in preparation for fluorophore conjugation. The protein was then dialyzed to remove any excess DTT. Immediately following DTT removal, a 5-fold molar excess of fluorophore (MDCC, IANBD ester, or acrylodan) was added in the dark. The coupling reactions were allowed to proceed for 4 h with stirring, at which time the samples were loaded onto a Sephadex G-25 size-exclusion column to separate conjugated protein from excess fluorophore. The conjugates were eluted with Buffer A. A SDS−PAGE was run to verify which elution fractions contained the protein conjugate. The fractions containing the conjugate were pooled together, and the final protein concentration was calculated. The purified CaM109 conjugate was stored at 4 °C in the dark until use.

Fluorescence Studies of CaM109-MDCC with CPZ. With the exception of initial optimization studies (where noted), all experiments were performed on the microtiter plate fluorometer with an assay volume of 300 μL, utilizing the CaM109-MDCC conjugate, and CPZ as the analyte. All results reported are the average of a minimum of three replicates, corrected for background, with the blank consisting of Buffer A. Detection limits reported were calculated with S/N = 3.

Chlorpromazine Fluorescence. Solutions of increasing concentrations of CPZ, 1×10^{-7} to 0.1 M, were prepared in Buffer A. Fluorescence measurements were taken on the microtiter plate fluorometer, using the filters previously noted.

MDCC/CPZ Interaction. Aliquots of 25 μL of CPZ solutions ranging in concentration from 1×10^{-7} to 0.1 M were added to 1.5 mL samples of MDCC in Buffer A. Response of the biosensing system to MDCC was measured in the fluorescence microtiter plate reader employing the parameters described above.

Dilution Curve. To determine the optimum concentration of labeled CaM109 to be used in subsequent experiments, the fluorescence emitted by increasing concentrations of each conjugate was measured on the benchtop fluorometer (CaM109-MDCC) or on the fluorescence microtiter plate reader (CaM109-MDCC, CaM109-acrylodan, CaM109-IANBD). Dilutions of labeled CaM109 were prepared ranging from 1×10^{-10} to 1×10^{-5} M. The protein concentration at which an increase in fluorescence signal was considerably larger than that of the background while still being relatively low was chosen as the concentration to be employed in all subsequent experiments.

Time Study of CaM109-MDCC/CPZ Interaction. An experiment was conducted on the benchtop fluorometer to observe the change in fluorescence response of the conjugated CaM109-MDCC to the binding of CPZ at various incubation times. A volume of 1.5 mL of CaM109-MDCC was incubated with 25 μL of 1×10^{-2} M CPZ in Buffer A at RT on a 400 rpm shaker for various periods of time. Average fluorescence quenching values were plotted against the incubation times in minutes. The minimum incubation time allowing for maximal fluorescence response was chosen for all subsequent assays.

Calibration Curves for CaM109-MDCC with Analyte. Aliquots of 25 μL of various concentrations of analytes (phenothiazines, TCAs, structurally related chlorprothixene, and other analytes) were added to a 1.5 mL volume of the labeled protein. The mixture was then incubated on a 400 rpm shaker at RT for 2 min and analyzed in the benchtop fluorometer (CPZ only) or fluorescence microtiter plate reader as previously described. Average fluorescence quenching was plotted against the log of the analyte concentration in the sample. Experiments were also conducted with the additional fluorophores, acrylodan, and IANBD ester following the same procedure.

Stability Studies. The fluorescent response of the CaM109-MDCC conjugate to 1.6×10^{-5} M CPZ was measured on days 3, 14, 21, 99, 151, and 269 of postconjugation in the fluorescence microtiter plate reader following the procedure outlined above.

RESULTS AND DISCUSSION

The detection of phenothiazines and TCAs by the fluorescently labeled mutant CaM described here is based on the calcium-dependent change in conformation of the protein. Calmodulin belongs to a family of binding proteins that contain helix-loop-helix motifs referred to as EF hands. Calmodulin has four such motifs; two are located in both the N- and C-terminal regions of the protein (*8*). Upon binding calcium, CaM undergoes a conformational change about the central α-helix, exposing a hydrophobic region in each domain (*11, 12*). By capitalizing on this change, we have reported herein the development of a class-selective means of drug detection. In addition, employing a biological recognition element, namely the binding protein CaM, takes advantage of nature's highly evolved means of detection and demonstrates the potential application of these binding proteins to current needs of the chemical, pharmaceutical, and biotechnology industries. In particular, our approach provides an alternative solution in the demand for rapid, reliable, and reproducible screening methods in drug discovery programs.

The synthetic CaM employed in our studies (*17*) resembles higher plant CaM with the exception of threonine-26, glycine-96, valine-136, and glutamine-143, which are common to vertebrate CaM. As such, it does not contain any cysteine residues in its structure (*17*). Site-directed mutagenesis on this gene has been performed previously in our group (*16*) to study the structure−activity of certain specific mutations on the protein and to develop a biosensing system for the detection of calcium. On the basis of crystallographic analyses of calcium-bound CaM in both the presence and absence of the phenothiazine trifluoperazine (Figure 1) (*11, 12*), CaM containing a mutation at residue 109 (Met109Cys; CaM109) was chosen as the biosensing element to be employed in the development of the assay for the phenothiazines and TCAs. Located on the surface of the hydrophobic pocket of CaM's C-terminal domain, residue

109's location should allow for efficient conjugation of the fluorophore to the protein (*16*). Studies of these crystal structures have shown that the microenvironment surrounding residue 109 undergoes changes upon the addition of drug, as residue 109 is one of 10 involved in hydrophobic interactions with the phenothiazine class of drugs (*11*, *12*). From the results reported in these studies in addition to previous mutational studies performed with fluorescently labeled CaM (*16*), it was hypothesized that a fluorophore attached at this position would be sensitive to drug binding.

It is important to note, as one can observe from Figure 2, that the phenothiazines and related compounds are naturally fluorescent. Thus, it should be possible to detect them based on their intrinsic fluorescence alone. Having a λ_{ex} of 340 nm and a λ_{em} of 460 nm, CPZ fluorescence could also potentially interfere with the emission wavelength of MDCC, the fluorophore employed in the majority of the studies reported herein. Therefore, detection of a change in CPZ fluorescence as a result of increasing concentrations was evaluated. Figure 3 demonstrates that although CPZ fluorescence can be used in the direct detection of the drug in a sample solution, the detection limit, 6.3×10^{-4} M, may not be sensitive enough for the HTPS of this class of drugs.

The detection of CPZ using CaM109 coupled to three different fluorophores, MDCC, acrylodan, and IANBD ester, was then investigated. The unique cysteine of CaM109 was conjugated with these sulfhydro-specific fluorophores; the concentration of the fluorophore in the reaction mixture was five times that of the protein. Following conjugation, excess fluorophore was separated from the conjugated protein by using size-exclusion chromatography. Fractions of eluant corresponding to CaM109-fluorophore, as determined by SDS−PAGE, were pooled together and employed as the sensing element used in all studies. Initial assay development was performed on a standard benchtop fluorometer, with

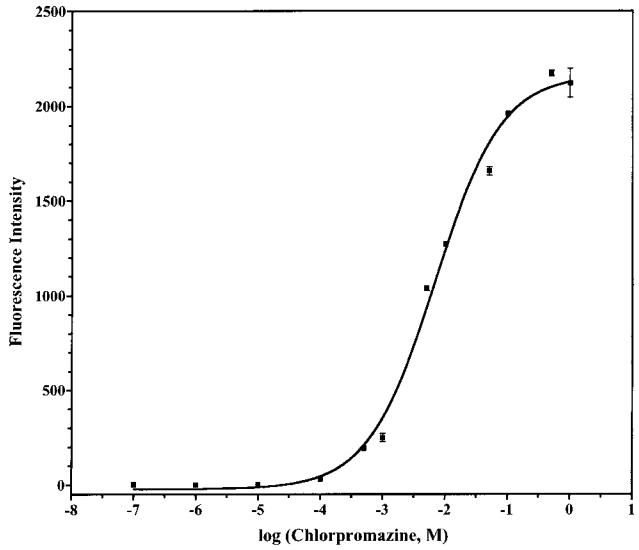

Figure 3. Chlorpromazine fluorescence in the absence of CaM109-MDCC. Error bars not visible are concealed by the points on the graph.

assay volumes of 1.5 mL. To determine the CaM109 concentration that would be used in subsequent experiments, dilution curves were constructed. In these experiments, fluorescence measurements were made employing increasing concentrations of the conjugated protein. For CaM109-MDCC, a concentration of 5×10^{-8} M was chosen. This concentration provided a large enough signal for development of the assay while not consuming a significant amount of reagent.

To determine how long the biosensing element needed to be incubated with the analyte, a time study was performed. From this study, it was determined that an incubation time of 2 min resulted in the generation of maximal sensitivity of the reagent (CaM) to analyte (CPZ) (Figure 4). Such rapid reaction kinetics can provide an advantage for this type of sensing scheme; rapid detection is one of the desired properties of assays employed in the HTPS of drugs and allows for a greater number of compounds to be screened per time.

CaM109 coupled to MDCC has previously been reported by our group as a sensitive biorecognition element

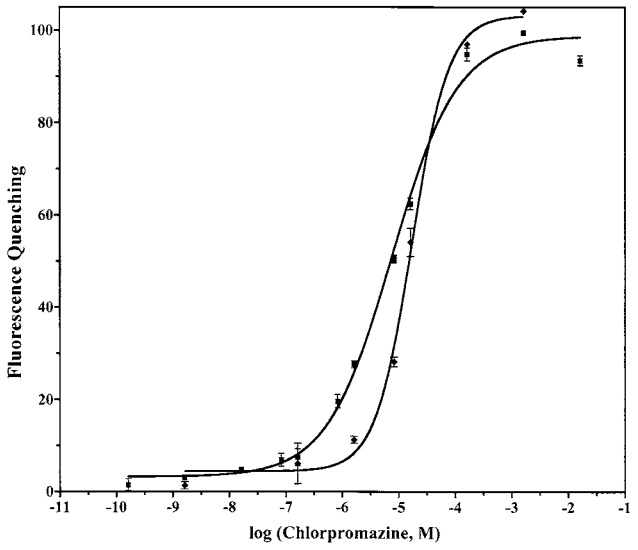

Figure 5. Calibration curve for CPZ employing CaM-MDCC and performed in a benchtop fluorometer (●), with a total assay volume of 1.5 mL, and on a microtiter plate fluorometer (◆), with a total assay volume of 300 μL.

for calcium detection (*16, 19*). As such, we decided to initially focus on this conjugate when designing a sensing scheme for phenothiazines due to their calcium-dependent binding to CaM. MDCC is composed of a reactive maleimide connected to a fluorescent coumarin moiety by a flexible aliphatic spacer arm; MDCC is excited at 425 nm and emits fluorescence at 474 nm. Upon coupling CaM109 with MDCC, a blue shift to 460 nm occurs in the fluorescence emission spectra of the fluorophore (data not shown). We postulate that MDCC is residing in the hydrophobic pocket in the C-terminal domain of the protein in the absence of CPZ. Residues 92, 100, 105, 109, 124, 125, 127, 128, 136, 141, and 144 have been shown to compose this hydrophobic pocket (*11*). As seen in Figure 5, a decrease in the fluorescence quantum yield (quenching) is observed upon binding of the phenothiazine chlorpromazine (CPZ) to the CaM109-MDCC, with a detection limit of 5×10^{-7} M (on the benchtop fluorometer). This quenching could be explained by the change in environment that MDCC experiences upon binding of CPZ to this hydrophobic region. To allow for binding, the flexible spacer arm and the coumarin of the MDCC may be displaced from this region, exposing the fluorophore to a more polar environment. A subsequent red shift in the fluorescence spectra observed upon the addition of increasing concentrations of CPZ supports this idea (data not shown). Red shifts are often, but not always, associated with a decrease in quantum yield (*20*). Also, it is possible that the diethylamino group of the fluorophore is less constrained in the presence of CPZ. Previous work from other groups has shown that coumarins having the lone pair of the amino substituent constrained and not able to interact optimally with the π electrons of the aromatic ring are highly fluorescent (*21*). Studies performed by us and others on the mechanism of response of fluorescently labeled proteins support this theory (*21*−*23*). Although the CPZ native fluorescence spectrum (λ_{ex} and λ_{em} of 340 and 460 nm, respectively) interferes with that of CaM109-MDCC, it does not significantly hinder the sensitivity of our biosensing system. In addition, a steady-state study conducted with MDCC and CPZ indicated that in the absence of CaM the fluorescence signal generated by MDCC is not significantly quenched by the analyte. This observation indicates that the

quenching observed in the CaM-based assays is a result of the changes occurring in the dynamics of the protein−analyte interactions, and not simply due to an interaction between the analyte and the fluorophore itself. An alternative explanation, related to the fact that CaM is being employed as a molecular handle, would be that the fluorophore and analyte are brought into close proximity causing a change in fluorescence as a result of the interaction between the two. To elucidate the exact mechanism by which changes in fluorescently labeled CaM conformation affects the fluorescence emission of the fluorophore, studies involving time-resolved anisotropy measurements need to be performed.

It is important to note that the detection limit of 1.6×10^{-6} M observed for CPZ when measured on the fluorescence microtiter plate reader was higher than that observed in the larger volume format. A shift in the detection limit to higher concentrations when measuring the CPZ levels on the fluorescence microtiter plate reader can in part be explained to a lower collection efficiency of the instrument, and the total amount of reagent present in the 300 μL samples vs the 1 mL samples. Since this assay has been scaled down 10-fold in volume, for optimal sensitivity the concentration of reagent may need to be increased to compensate for this reduction in sample volume. It should be noted that concentrations in primary high-throughput screens can be as high as 10^{-5} M, allowing for the identification of compounds with moderate interaction. There is a need, however, for small volume assays, especially when the supply of new compounds from combinatorial libraries may be limited (*24*−*27*). Reduced consumption as a result of small volume assays allows for synthetic or biological samples to be subjected to a greater number of analyses at these higher concentrations (*28*).

The other two fluorophores, acrylodan and IANBD ester, were similarly evaluated. These CaM109 conjugates were also able to sense increasing levels of CPZ, although with worse detection limits. The acrylodan- and IANBD-labeled CaM each had a shift in detection limits 1 order of magnitude higher (1.6×10^{-5} M), and a reduced maximal fluorescence quenching of 80% at 1×10^{-3} M of CPZ as opposed to 100% for CaM109-MDCC. Nonetheless, CPZ detection using these additional CaM conjugates demonstrates the adaptability of the CaM-based sensing system to fluorophores of differing fluorescence emission profiles.

As previously mentioned, this assay was intended to detect the structurally related TCAs as well, which also are used in the treatment of psychoses and depression. These compounds are also CaM inhibitors (*29*); thus, it was expected the system would elicit a similar response to these drugs. Table 1 includes the response of CaM109-MDCC to the TCAs imipramine and amitriptyline and the structurally related chlorprothixene and compares their response to representative phenothiazines. All phenothiazines and related tricyclic drugs tested had detection limits of 7.4×10^{-6} M or lower, with the phenothiazine trifluoperazine having the lowest detection limit of 1.6×10^{-7} M. Also shown in Table 1 is the response to nine unrelated compounds: acetylsalicylic acid, α-D-glucose, and several nontricyclic antidepressants. Acetylsalicylic acid, dopamine, serotonin, and warfarin were selected as models of structurally unrelated drugs that contain an aromatic ring, and serotonin and dopamine act on the central nervous system. Amantadine and glucose were chosen due to their polarity as compared to TCAs. Tianeptine, amoxapine, and fluoxetine were tested, because they are structurally similar to tricyclic antidepressants but have different activity and mechanism of action. The results showed minimal fluorescence change for all of these compounds, except for fluoxetine. Tianeptine and amoxapine, selective serotonin reuptake inhibitors (SSRI), are structurally similar to tricyclic antidepressants. Their mechanism of action is different, and they do not inhibit calmodulin (*30*). We postulate that tianeptine's long hydrophilic chain and amoxapine's piperazine ring with truncated spacer, prevents them from binding to calmodulin. Fluoxetine, although not a tricyclic antidepressant, showed some response in the assay. This drug has two aromatic rings and contains a hydrophilic side chain with the proper length. We hypothesize that due to its flexibility, fluoxetine can fit into the hydrophobic pocket of calmodulin and the hydrophilic side chain can further stabilize the binding. However, to achieve 30% quenching, as with the TCAs, the concentration required for this was substantially greater. The detection limit for fluoxetine was found to be 5.9×10^{-4} M. This value is above the usual concentration range of drug detection required in high-throughput screening applications. Therefore, CaM provides class-selective detection, more specifically for those drugs belonging to the phenothiazines and TCA families of compounds.

Table 1. Comparison of CaM109-MDCC Response to Phenothiazines, Related Tricyclics, and Other Structurally Unrelated Compounds[c]

compound	max. fluorescence quenching (%)	detection limit (M)
chlorpromazine[a]	97.2	1.6×10^{-6}
trifluoperazine[a]	99.8	1.6×10^{-7}
thioridazine[a]	100.0	1.6×10^{-6}
chlorprothixene[b]	100.0	7.4×10^{-6}
amitriptyline[b]	91.3	1.5×10^{-6}
imipramine[b]	100.0	7.4×10^{-6}
amoxapine[b]	0.5	−
tianeptine[b]	13.7	−
fluoxetine[c]	30.1	5.9×10^{-4}
acetylsalicylic acid[c]	8.7	−
glucose[c]	8.3	−
warfarin[c]	8.3	−
dopamine[c]	13.7	−
amantadine[c]	1.4	−
serotonin[c]	6.9	−

[a] Note: all studies were performed on fluorescence microtiter plate reader. [b] Phenothiazines. [c] Related tricyclics. [d] Structurally unrelated compounds.

A stability study was conducted over a nine-month period to observe the change in fluorescence signal of CaM109-MDCC since initial conjugation (data not shown). The reagent was stored in solution at 4 °C in the dark. These studies were performed to evaluate the long-term storage of the CaM109-MDCC biosensing reagent. Typical calibration curves for CPZ were obtained each time as shown in Figure 5. Results indicated a shift in the detection limit toward higher concentrations; after nine months, the detection limit for CPZ was an order of magnitude higher (1×10^{-5} M) than that observed when fresh CaM109-MDCC was employed.

In conclusion, it has been demonstrated that site-specific fluorescently labeled CaM can be employed as a biosensing reagent in the preliminary screening of certain pharmaceuticals. The CaM-based assay showed to be class-selective toward drugs used in the treatment of psychoses and depression, which contain a phenothiazine/phenothiazine-like structural moiety. The assay developed is reproducible over long periods of time and analyses volumes in the microliter range have shown adequate sensitivity for HTPS. The work presented

herein illustrates a proof-of-concept, model system employing a binding protein (CaM) as the detection element. Given that the assay is homogeneous in nature, this technology is envisioned to offer a valid alternative approach to rapid initial screening of potential new drug candidates in HTPS formats. In addition, not requiring the addition of reagents to generate a signal (i.e., reagentless) provides potential advantages over more conventional means of pharmaceutical analyses. Specifically, this assay offers minimal sample preparation, minimal analyte consumption, and rapid detection kinetics. It is believed that the strategy employed herein could be easily adapted to other binding proteins specific to other classes of ligand/analytes and/or drugs.

Received February 25, 2002; Revised Manuscript Received July 5, 2002

An electrochemical hybridization assay has been devised that enables the rapid analysis of a heterozygous deficiency of the human lipoprotein lipase (LPL) gene. PCR products of 350 base pairs (bp) containing the wild-type sequence, a mutated $G^{818} \rightarrow A$ transition or a G^{916} deletion of the LPL gene were subjected to hybridization with a probe DNA of 13 or 15 bases that represented either the wild-type or the mutated sequence immobilized on a gold electrode. The differential pulse voltammetry of the electrode before and after hybridization was determined in the presence of ferrocenylnaphthalene diimide (FND) at 460 mV. The measured change in peak current, Δi, was defined by $(i - i_o)/i_o \times 100\%$, where i_o and i represent the current before and after hybridization, respectively. Matched combinations of sample and probe gave Δi values of 40−90%, whereas mismatched combinations gave values of 20−35%, enabling the discrimination of matched hybrids from mismatched ones across a slim margin. Because the heterozygote contains both the wild-type and mutated sequences, however, it alone gives large Δi values with both the wild- and mutant-type probes. This system was validated on 10 unknown samples of each of the two types of LPL mutation, which were correctly identified in every case.

INTRODUCTION

The analysis of single nucleotide polymorphisms (SNPs) in genes is important both for diagnosing the risk of common diseases such as hypertension and diabetes and for determining the optimum tailor-made medications (*1, 2*). Each human gene is classified by two identical alleles in homozygotes or two different alleles in heterozygotes. Because the differences in SNPs are so subtle, it is essential that any analytical method for detecting SNPs is sensitive and efficient in order to be practical. Currently, SNP analysis is carried out by one of two techniques that are based on enzymatic reactions (*3, 4*) and mismatch detection on the DNA duplex (*5, 6*). The latter technique is especially useful, as it is an extension of a routine DNA probe method.

Recently, mismatch detection by means of an electrochemical DNA sensor has been reported (*7*−*12*). The advantages of this technique lie in its high analytical sensitivity, speed, and low cost. Two notable variations of this technique have been reported: Willner and co-workers (*9*) carried out heterozygote detection using enzyme amplification, and Marrazza and co-workers (*12*) carried out heterozygote detection using the chronopotentiometric stripping analysis (PSA) developed by Wang (*7*). We have also succeeded in highly sensitive detection of DNA using an electrochemical hybridization assay (*11, 13, 14*). Our breakthrough was the design and synthesis of ferrocenylnaphthalene diimide (FND) as an effective indicator of hybridization. In this paper, we have assessed our electrochemical hybridization assay using two electrodes with different immobilized-DNA probes for the analysis of human lipoprotein lipase (LPL) gene.

Human LPL protein is expressed mainly in adipose tissue and hydrolyzes triglycerides in chylomicrons and in very low-density lipoprotein (VLDL) particles in order to supply the resulting fatty acids and triglycerols to adipose tissue, where they are stored effectively (*15, 16*). A malfunctional form of LPL expressed by homozygotes carrying a mutated LPL gene is known to lead to hypertriglyceridemia with a high probability of pancreatitis (*17*). People with heterozygous LPL deficiency usually manifest with a normolipidemic state, but they can develop type IV hyperlipoproteinemia through the superposition of factors that stimulate triglyceride synthesis, such as high alcohol intake and/or a hyperinsulinemic state (*18*−*22*), which is thought to be a risk for cardiovascular heart disease (*23*). The identification of heterozygous mutations in the LPL gene as an early determination of the etiology underlying type IV hyperlipoproteinemia is therefore important for preventing the progress of hypertriglyceridemia and the subsequent

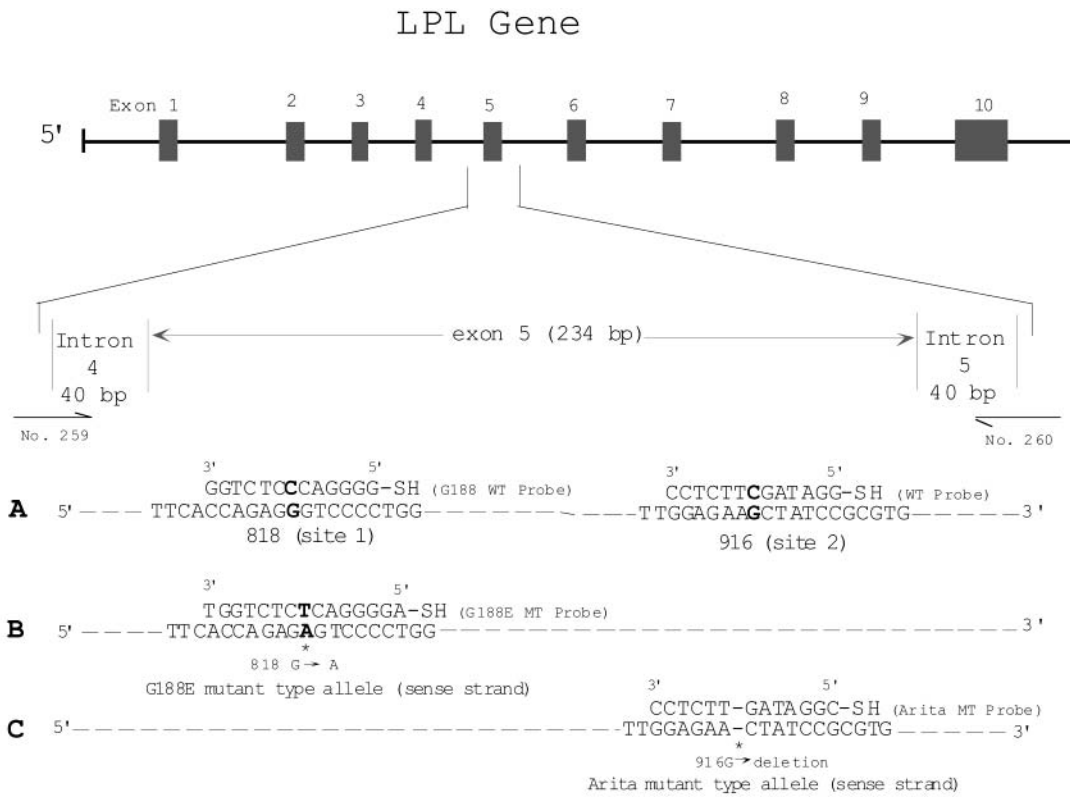

Figure 1. Organization of the human LPL gene with the focus on exon 5, where the two types of mutations studied here are located (sites 1 and 2) (*19*,*24*). The partial nucleotide sequences of the WT for sites 1 and 2 are depicted in (A), together with their complementary probe sequences (13 bases each). The asterisk in (B) indicates the G to A transition at base 818 ($GG^{818}G \rightarrow GAG$), which results in the amino acid substitution $Gly^{188} \rightarrow Glu$ (G188E), together with the G188E mutant type (MT) probe (15 bases). The asterisk in (C) indicates the deletion of G at base 916 ($G^{916}CT$; first position of Ala^{221}), which is designated the Arita mutation, which results in premature termination by a frameshift, together with the Arita MT probe (13 bases).

outbreak of cardiovascular disease (*23*), as the patient can be advised to change to a more healthy life style.

The heterozygous LPL deficiencies studied here are a missense mutation carried on the G188E ($GG^{818}G \rightarrow GAG/Gly^{188} \rightarrow Glu$, site 1) allele (*24*) and a one-base deletion carried on the LPL arita allele ($G^{916} \rightarrow$ deletion, site 2) (*19*), which are both found on exon 5 (Figure 1). We subjected 350-bp PCR products comprising these mutated sites to our electrochemical assay. Because these two mutations are the major forms of mutation in the LPL gene, their successful analysis should lead to the analogous analysis of most other LPL mutations.

RESULTS

Principle of the Electrochemical Hybridization Assay for Heterozygotes. The principles underlying the electrochemical hybridization assay using FND on a gold electrode with a wild-type (WT) probe immobilized for discriminating the WT allele from a mutant-type (MT) allele are illustrated in Figure 2. Before hybridization, the differential pulse voltammetry (DPV) of this electrode is measured at 460 mV, and the current obtained is designated as i_o. The same gold electrode is then allowed to hybridize with the PCR products prepared from a WT/WT homozygote, a WT/MT heterozygote, and an MT/MT homozygote under conditions that have been optimized (e.g., the salt concentration of the hybridization buffer and the temperature) for hybridization of the WT probe with the WT allele. The electrode gives rise to a larger signal, designated as *i*, for PCR products from the WT/WT homozygote and the WT/MT heterozygote, owing to the intercalation of FND into the DNA duplex that forms on it; however, the signal increase is much smaller with PCR products from the MT/MT homozygote because of the one-base mismatch. This signal change is converted into the net increase in current, Δi, which is defined by the equation: $(i - i_o)/i_o \times 100$.

In this assay system, a significant increase in current is observed for a combination of the WT probe and the WT allele from the WT/WT homozygote and the WT/MT heterozygote, but a marginal increase is observed for the WT probe and the MT allele from the MT/MT homozygote. Conversely, a gold electrode with an MT probe immobilized produces a significant increase in current for the MT allele from a WT/MT heterozygote and an MT/MT homozygote, but a marginal increase for the WT allele from a WT/WT homozygote. Thus, only the heterozyote produces a large Δi with both electrodes which allows its identification. If the differences observed are large enough, the WT allele can be discriminated from the MT allele with certainty by this assay system. In other words, a heterozygous genotype can be identified correctly by a significant value of Δi obtained with two electrodes carrying either a WT probe or an MT probe.

Experimentally, a gold electrode carrying a DNA probe was prepared by immobilizing 0.1 pmol of oligonucleotide on a 2 mm^2 gold surface. This electrode gave rise to a current of 1 μA at 460 mV in the presence of 0.05 mM FND (100 pmol), 80% of which seemed to derive from nonspecific binding and/or diffusion of the ligand (unpublished observation). The current increased by 0.3−0.9 μA upon hybridization of 0.2 pmol of a denatured PCR product. An increase in current above 0.3 μA was ascribed to the FND bound to the duplex formed on the electrode, whereas that below 0.3 μA was ascribed to nonspecific binding to the electrode of sample DNA and FND in

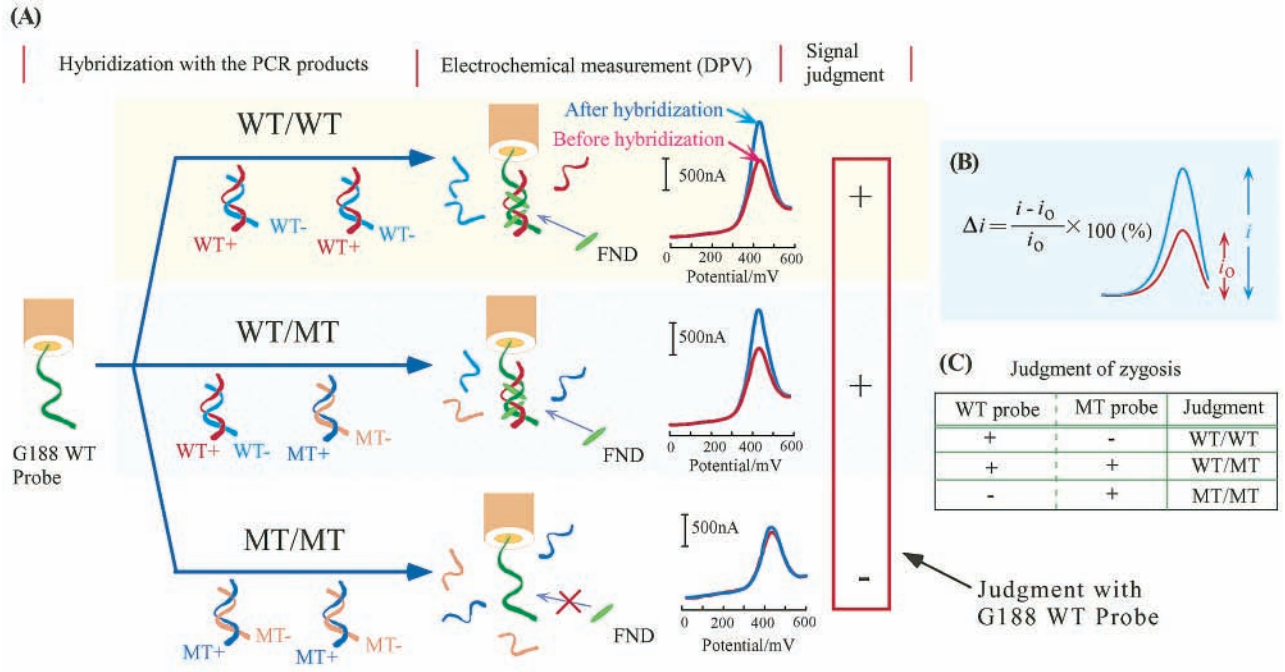

Figure 2. Principles underlying the electrochemical hybridization assay with FND for heterozygotes. (A) An electrode with an immobilized wild-type (WT) probe is allowed to hybridize with PCR products from WT/WT, WT/MT (mutant), or MT/MT genotypes. Differential pulse voltammetry (DPV) of the electrode is measured in the presence of FND at 460 mV before and after hybridization. Samples containing the WT allele (WT/WT and WT/MT) give rise to a large signal increase after hybridization. (B) The peak current due to FND before (i_o) and after hybridization (i) is converted to Δi, which represents a net increase in the current on duplex formation. (C) Identification of the state of zygosis. The same experiment as in (A) is carried out with an electrode carrying an MT probe, which gives a large signal increase with samples containing the MT allele (WT/MT and MT/MT). In other words, only heterozyogous samples give a large Δi with both types of electrode, thereby allowing their identification.

succession (unpublished observation). It thus follows that 3.7 pmol of FND binds to the electrode in a desired fashion, that is, one FND molecule binds to the DNA duplex every five base pairs. Given a large difference in these systems, this estimate is roughly consistent with previous data showing that FND binds to duplex DNA at every other base pair in solution (*14*).

Evaluation of the Electrochemical Hybridization Assay System. To establish optimal conditions for hybridization between the PCR product of exon 5 (350 bp) in the human LPL gene and an allele-specific DNA probe (Figure 1) immobilized on a gold electrode, both the salt concentration of the buffer and the temperature were surveyed for the following four combinations: a site 1 G188 WT probe (13 bases) and a WT allele of exon 5; a G188E MT probe (15 bases) and a G188E allele; a site 2 WT probe (13 bases) and a WT allele; and an Arita MT probe (13 bases) and an Arita allele. The best conditions were found to be 0.25 x SSC (0.3 M sodium citrate and 3 M NaCl) and 35 °C for the G188 WT probe and the WT allele; 0 x SSC and 35 °C for the G188E MT probe and the G188E allele; 0.25 x SSC and 40 °C for the site 2 WT probe and the WT allele; 0 x SSC and 40 °C for the Arita MT probe and the Arita allele after several experiments under the varied salt conditions (0−0.5 × SSC) and temperature (15−60 °C).

Under the best conditions, the PCR products for site 1 of exon 5 (350 bp), prepared from a WT/WT homozygote, a WT/G188E heterozygote and a G188E/G188E homozygote were examined by the electrochemical hybridization assay in the presence of FND on a gold electrode with either the G188 WT probe or the G188E MT probe immobilized. As shown in Figure 3A, the assay with the G188 WT probe gave a Δi (%) of 52 ± 19 (mean ± standard deviation) for WT/WT homozygotes (n = 17), 47 ± 15 for WT/G188E heterozygotes (n = 17), and 17 ± 10 for G188E/G188E homozygotes (n = 17) in 0.25 x SSC at 35 °C. The difference between the G188E/G188E and the WT/WT homozygotes was statistically significant as was the difference between the G188E/G188E homozygote and the WT/G188E heterozygote ($p < 0.0001$ in both cases). These findings demonstrate that the G188 WT probe hybridizes with the G188E allele only weakly because of the one-base mismatch, and that the G188E allele can be identified with certainty under the assay conditions employed. The threshold value that distinguishes the WT allele from the G188E allele was estimated from the Δi values (mean ± SD) of the above three groups as follows: [(52 − 19) + (47 − 15) + (17 + 10)]/3 = 31%.

The electrochemical hybridization assay with the G188E MT probe gave a Δi (%) of 20 ± 13 (mean ± SD) for WT/WT homozygotes (n = 20), 60 ± 15 for WT/G188E heterozygotes (n = 20) and 67 ± 31 for G188E/G188E homozygotes (n = 20) in 0 x SSC at 35 °C (Figure 3B). The differences between the WT/WT homozygote and the G188E/G188E homozygote and those between the WT/WT homozygote and the WT/G188E heterozygote were statistically significant, indicating that the WT allele can also be discriminated by using the G188E MT probe. The threshold value that distinguishes the WT allele from the G188E allele was estimated from the Δi values (mean ± SD) of the above three groups as follows: [(20 + 13) + (60 − 15) + (67 − 31)]/3 = 38%.

Likewise, the electrochemical hybridization assay with the site 2 WT probe gave a Δi (%) of 44 ± 17 (mean ± SD) for WT/WT homozygotes (n = 20), 41 ± 11 for WT/Arita heterozygotes (n = 20), and 16 ± 11 for Arita/Arita homozygotes (n = 20) in 0.25 x SSC at 40 °C, as shown in Figure 3C. The differences between the Arita/Arita homozygote and the WT/WT homozygote and those between the Arita/Arita homozygote and the WT/Arita

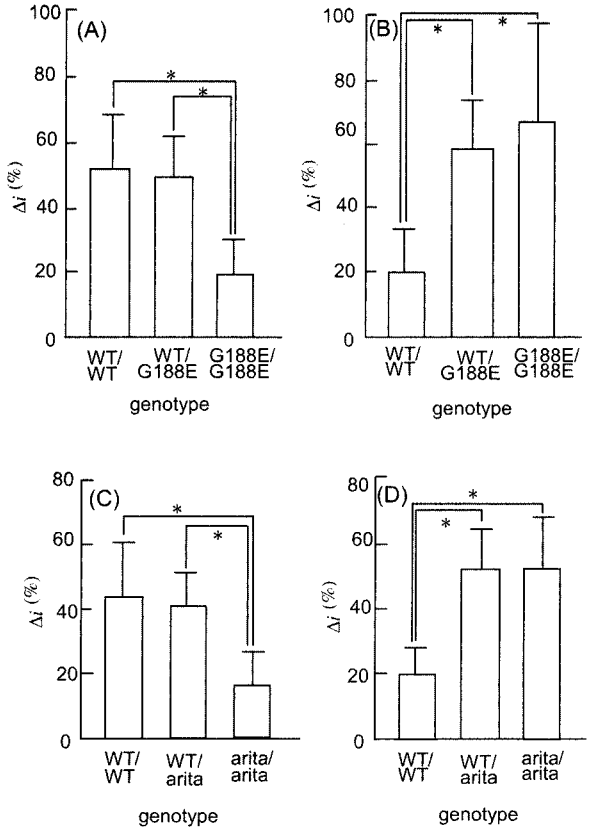

Figure 3. Discrimination between wild-type (WT) and mutant-type (MT) alleles of the human LPL gene by the electrochemical hybridization assay. In A and B, 350-bp PCR products, prepared from a WT/WT homozygote, a WT/G188E heterozygote, and a G188E/G188E homozygote, were analyzed with a gold electrode carrying a G188 WT probe (A) or a G188E MT probe (B) in the presence of 0.05 mM FND. In C and D, 350-bp PCR products, prepared from a WT/WT homozygote, a WT/Arita heterozygote, and an Arita/Arita homozygote, were analyzed with a gold electrode carrying a site 2 WT probe (C) or an Arita MT probe (D) in the presence of 0.05 mM FND. The currents obtained are shown as mean ± standard deviation (SD). The difference between the two combinations marked by the asterisk is statistically significant at $p < 0.0001$.

heterozygote were significant statistically ($p < 0.0001$). The threshold value that distinguishes the WT allele from the Arita MT allele was estimated from the Δi values (mean ± SD) of the above three groups as follows: $[(44 - 17) + (41 - 11) + (16 + 11)]/3 = 28\%$.

The electrochemical hybridization assay with the Arita MT probe gave a Δi (%) of 20 ± 8 (mean ± SD) for WT/WT homozygotes ($n = 20$), 53 ± 13 for WT/Arita heterozygotes ($n = 20$), and 53 ± 16 for Arita /Arita homozygotes ($n = 20$) in 0 x SSC at 40 °C (Figure 3D). Again, the differences between the WT/WT homozygote and the Arita/Arita homozygote and those between the WT/WT homozygote and the WT/Arita heterozygote were significant statistically. These findings indicate that the Arita MT probe hybridizes with the WT allele only weakly because of the one-base mismatch, and that it can discriminate the WT allele with certainty under the conditions employed. The threshold value that distinguishes the WT allele from the Arita allele was estimated from the Δi values (mean ± SD) of the above three groups as follows: $[(20 + 8) + (53 - 13) + (53 - 16)]/3 = 35\%$.

Blind Test of the Electrochemical Hybridization Assay System. The validity of the electrochemical hybridization assay for discriminating between a WT allele and an MT allele was examined in a blind test.

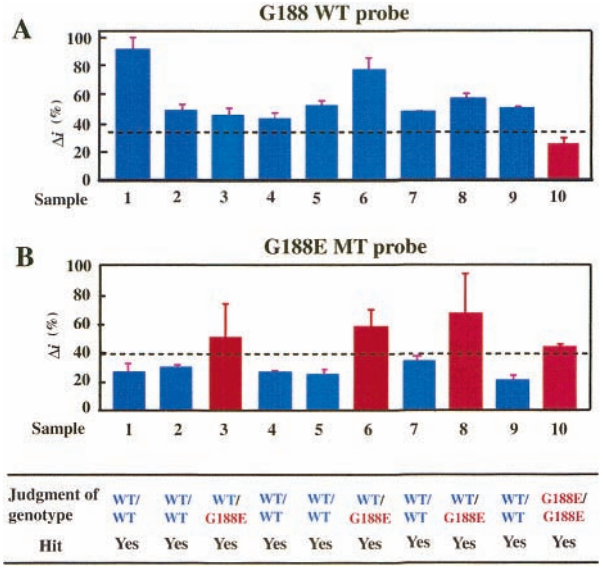

Figure 4. Verification of the electrochemical hybridization assay with FND by testing unknown samples for their LPL genotypes. The 350-bp PCR products, prepared from 10 unknown blood samples, were analyzed with a gold electrode carrying a site 1 G188 WT probe (A) or a G188E MT probe (B) in the presence of 0.05 mM FND. Analysis was carried out for four distinct samples per sample number ($n = 4$), and the currents shown are the mean ± standard error of the mean (SEM). The genotype of each sample was judged on the basis of the threshold values at which the WT allele can be discriminated from the MT allele taken from the data shown in Figures 3A and 3B; that is, 31% for the site 1 G188 WT probe (A) and 38% for the G188E MT probe (B). The threshold values are represented by the dotted horizontal lines in A and B.

PCR products amplified from site 1 of exon 5 (350 bp) in the human LPL gene were prepared from 10 unknown samples and examined by the electrochemical hybridization assay in the presence of FND on a gold electrode with an immobilized G188 WT probe or a G188E MT probe. The data obtained were judged on the basis of the threshold values (31 and 38%) derived from the data shown in Figures 3A and 3B. The genotypes of these samples determined by the hybridization assay were found to be completely consistent with the results from DNA sequencing, as shown in Figure 4. In other words, it appears that this assay system is effective for analyzing unknown or practical samples.

Another blind test was carried out for site 2 of exon 5 of the human LPL gene. PCR products amplified from this site (350 bp) were prepared from 10 unknown samples and analyzed by the electrochemical hybridization assay in the presence of FND on a gold electrode with an immobilized site 2 WT probe or an Arita MT probe. The data obtained were judged on the basis of the threshold values (28 and 35%) derived from the data shown in Figures 3C and 3D. The genotypes of these samples determined by the hybridization assay were completely consistent with results from DNA sequencing, as shown in Figure 5. Again, the usefulness of this assay system was proved by these site 2 samples. In future studies it would be worth investigating this utility of this electrochemical method for the practical analysis of a wider range of genes with known mutations.

DISCUSSION

The analysis of SNPs has become more important since it has been closely associated with the prediction and prevention of various syndromes. Currently, SNPs are analyzed by direct DNA sequencing or new techniques

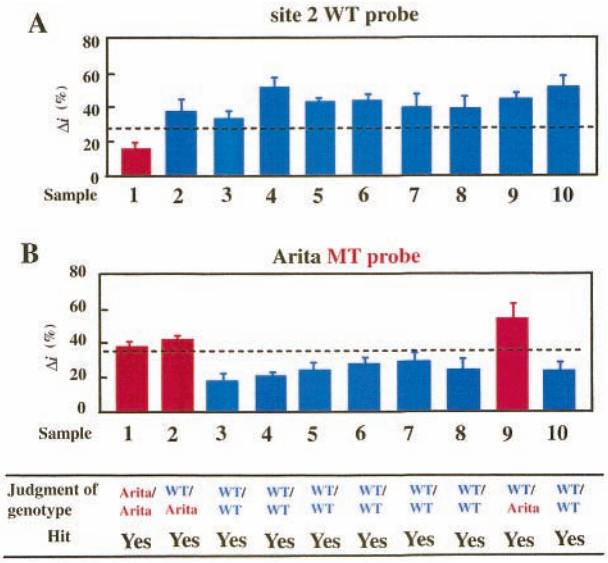

Figure 5. Further verification of the electrochemical hybridization assay with FND by testing unknown samples for their LPL genotypes. The 350-bp PCR products, prepared from 10 unknown blood samples, were analyzed with a gold electrode carrying a site 2 WT probe (A) or an Arita MT probe (B) in the presence of 0.05 mM FND. Analysis was carried out as in Figure 4. The genotype of each sample was judged on the basis of the threshold values at which the WT allele can be distinguished from the MT allele taken from the data shown in Figures 3C and 3D; that is, 28% for the WT probe (A) and 35% for the Arita MT probe (B). The threshol values are represented by the dotted horizontal lines in A and B.

such as dynamic allele-specific hybridization (DASH) (*5*) and template-directed dye-terminator incorporation (TDI) (*3*). The demand for simpler methods never ceases, however, as normally several samples need to be processed at any one time during SNP analysis. An electrochemical method seems to be a promising alternative to the existing fluorescence methods owing to its speed, low operational costs, and amenability to automation. In fact, the highly sensitive detection of gene mutations has been achieved electrochemically by using $Co(phen)_3^{3+}$ or daunomycin as a redox active marker (*9, 12*).

As described above, we have been able to analyze two types of mutations present on exon 5 of the human LPL gene electrochemically with FND. The key to this success lies in the use of two different DNA probes, comprising WT and mutant DNA, immobilized on an electrode. Only heterozygous samples produce a large increase in current with both electrodes, thereby allowing identification of the sample as heterozygous.

Samples containing as little as 0.2 pmol of PCR product can be analyzed by this method, which corresponds to a sensitivity that is 1000-fold higher than that of existing methods. Once the electrodes with the immobilized probes have been prepared, the analysis is straightforward. First, chromosomal DNA is extracted from blood donated by individuals and subjected to PCR. Second, after denaturation, the PCR products are subjected to the electrochemical analysis. This method is based on the fact that the DNA duplex does not form with DNA sequences containing a mismatch(es). Currently, there is only a modest 3−4-fold difference in the value of Δi between the WT and MT alleles. If this difference can be magnified, however, the analysis will become more sensitive, and efforts toward this goal are being made in our laboratories.

Another area that needs future investigation concerns the data values, which fluctuate rather significantly even among given genotypes (ca. 50% of the mean). At present, the exact reason for this fluctuation is not known, but it is possible that material affecting the electrochemical reaction may not have been removed completely by the methods used to isolate the chromosomal DNA. In regard to the background current, its magnitude tends to increase with increasing sizes of DNA; that is, nonspecific adsorption to the electrode becomes marked with DNA larger than 40 bases. Nonspecific binding can be eliminated by warming, but this process can also partially detach the probe DNA from the electrode. A solution to this problem may be the use of other masking agents such as mercaptohexanol instead of 2-mercaptoethanol (unpublished observation).

Despite these limitations, the SNPs of the human LPL gene could be analyzed successfully and practically by our electrochemical hybridization assay with FND. Although only the two types of known mutations were examined in this study, other types of mutations may be analyzed easily if electrodes carrying suitable probes are prepared. Moreover, an electrochemical DNA microarray system based on this technique may be even more useful. Studies are now under way to attain this goal in our laboratories.

EXPERIMENTAL SECTION

Extraction of Chromosomal DNA. Human chromosomal DNA was isolated from whole cells taken from the peripheral blood of a healthy male YI, patient MN (*24*) carrying a heterozygous LPL G188E allele ($GG^{818}G \rightarrow GAG/Gly^{188} \rightarrow Glu$; corresponding to a G-to-A transition at position 818 of exon 5 of the LPL gene), patient EN (*19*) carrying a heterozygous LPLarita allele ($G^{916} \rightarrow$ deletion; corresponding to deletion of G at position 916 on exon 5), and patient TN (*19*) who was homozygous for the LPLarita allele, using a QIAamp DNA Blood kit (QIAGEN GmbH, Germany). With respect to the LPL gene, the genotypes of these individuals were WT/WT, WT/G188E, WT/arita and arita/arita, respectively.

PCR Amplification and Purification of PCR Products. Exon 5 (base numbers 730−963, 234 bp) and its flanking regions (40 bp each side) of the LPL gene were amplified from chromosomal DNA by PCR using the following primer pair: forward (5′-TGT AAA ACG ACG GCC AGT AAA TTT ACA AAT CTG TGT TCC TGC TTT TT-3′, No. 259) and reverse (5′-CAG GAA ACA GCT ATG ACC GAT AAG AGT CAC ATT TAA TTC GCT TCT A-3′, No. 260). Note that each primer contains an extra sequence of 18 bases at their 5′-terminus for direct sequencing, making the size of the PCR product 350 bp. PCR was performed in a 100 μL volume consisting of 1 x PCR buffer containing 1.5 mM $MgCl_2$, 10 pmol of each of the forward and reverse primers, 50 ng of chromosomal DNA, 200 μM dNTPs, and 2.5 U of AmpliTaq Gold (Perkin-Elmer). The PCR reaction protocol was 95 °C for 10 min, 40 cycles of 94 °C for 0.5 min, 55 °C for 1 min, 72 °C for 2 min, and finally an incubation at 72 °C for 7 min in a GeneAmp PCR System 9600 (Perkin-Elmer). Each PCR product was purified by a QIAquick spin column in a QIAquick PCR Purification Kit (QIAGEN), and its integrity was assessed by agarose gel electrophoresis.

In Vitro Preparation of the Homozygote of LPL G188E. Exon 5 and its flanking regions of the LPL gene were amplified from the chromosomal DNA of patient MN carrying a heterozygous LPL G188E allele by PCR using the primer pair described above, and the PCR product (350 bp) was purified with a QIAquick spin

column. After ligation into a pCR2.1 vector, the recombinant was transformed into transfection-competent *E. coli* cells using an Original TA Cloning Kit (Invitrogen, Carlsbad, CA). After verifying the presence of the G188E mutation by Ava II digestion and DNA sequencing, the 350-bp DNA fragment containing the G188E mutation was amplified from this subclone by PCR using the primer pair described above, purified with a QIAquick Spin column, and used for hybridization experiments as a genotype of G188E/G188E.

DNA Probes. DNA probes for site 1 G188 WT and G188E MT, site 2 WT and arita MT with a 5′-thiol moiety (Figure 1) were custom synthesized by Hokkaido System Science Co. Ltd. (Sapporo, Japan), and their concentrations were estimated from their molar absorptivities at 260 nm (*25*): 119 200 cm^{-1} M^{-1}, 142 100 cm^{-1} M^{-1}, 119 000 cm^{-1} M^{-1}, and 120100 cm^{-1} M^{-1}, respectively.

Preparation of Probe DNA-Immobilized Electrodes. *Hybridization of the PCR Product with Immobilized Probe DNA.* A solution of the PCR product in 10 mM Tris HCl buffer (pH 8.5) was mixed with a small volume of 20 x SSC (0.3 M sodium citrate and 3 M NaCl) to bring the final concentration to 0 x SSC or 0.25 x SSC for hybridization. Before hybridization, DNA was denatured in boiling water for 10 min and then cooled quickly on liquid nitrogen. The denatured PCR product was kept at 0 °C until use. One microliter of the denatured PCR product (ca. 0.2 pmol) was placed on the electrode and hybridization with the DNA probe was allowed to proceed for 1 h at 20 °C.

Electrochemical Measurements. Differential pulse voltammetry (DPV) was measured with an ALS model 900 electrochemical analyzer (CH Instruments Inc., Austin, TX), using a normal three-electrode configuration consisting of an Ag/AgCl reference electrode, a Pt counter electrode, and the electrode with the immobilized DNA probe, before and after the hybridization reaction in 2 mL of 0.1 M AcOH−AcOK buffer (pH 5.6) containing 0.1 M KCl and 0.05 mM FND. Measurement temperatures were optimized at 40 °C for the site 1 DNA probes and at 35 °C for site 2 DNA probes. The conditions for DPV measurements were as follows: initial potential, 0 V; final potential, 0.6 V; scan rate, 100 mV/s; pulse amplitude, 0.05 V; sample width, 16.7 ms; pulse period, 0.2 s; pulse width, 0.05 s; quiet time, 2 s; sensitivity, 10^{-6} A/V. Peak currents due to FND were measured at 460 mV before and after hybridization with the sample DNA.

Data Treatment. Data were converted into Δi values, which were defined as $(i - i_o)/i_o \times 100\%$, where i_o and i refer to the current before and after hybridization, respectively. Δi represents a net increase in the current of FND bound to the duplex DNA formed per immobilized DNA probe on the electrode. Nearly 30% of the observed current could be accounted for by the background as noted previously (*26*). The statistical significance of the differences in Δi among three groups was evaluated by Scheffe's *F*-test in a one-factor factorial ANOVA (*27*).

Synthesis and Biological Evaluation of EC20: A New Folate-Derived, ^{99m}Tc-Based Radiopharmaceutical

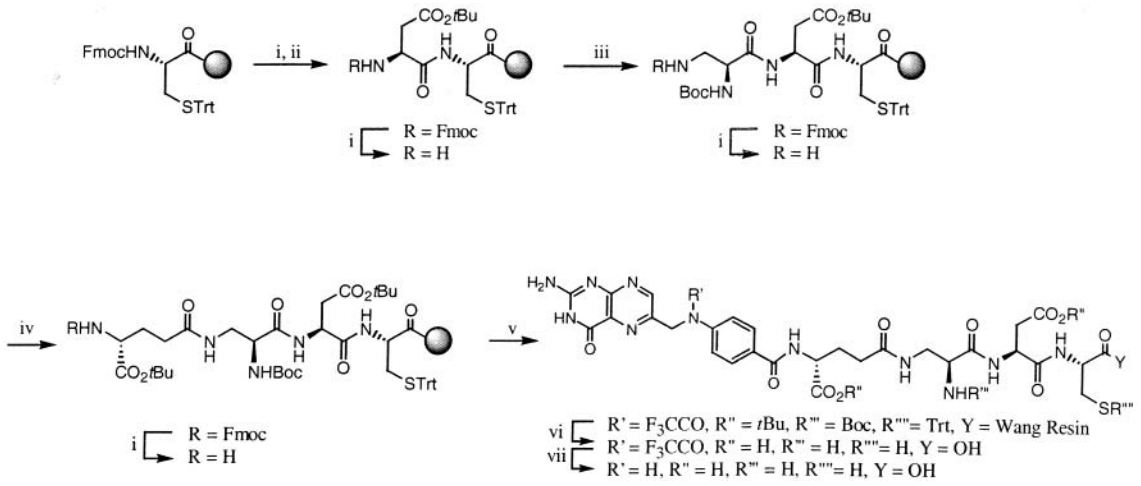
Christopher P. Leamon,* Matthew A. Parker, Iontcho R. Vlahov, Le-Cun Xu, Joseph A. Reddy, Marilynn Vetzel, and Nikki Douglas

Endocyte, Inc., 1205 Kent Avenue, West Lafayette, Indiana 47906. Received June 5, 2002; Revised Manuscript Received August 3, 2002

A new peptide derivative of folic acid was designed to efficiently coordinate ^{99m}Tc. This new chelate, referred to as EC20, was found to bind cultured folate receptor (FR)-positive tumor cells in both a time- and concentration-dependent manner with very high affinity ($K_D \sim 3$ nM). Using an in vitro relative affinity assay, EC20 was also found to effectively compete with ^{3}H-folic acid for cell binding when presented either alone or as a formulated metal chelate. Following intravenous injection into Balb/c mice, ^{99m}Tc-EC20 was rapidly removed from circulation (plasma $t_{1/2} \sim 4$ min) and excreted into the urine in a nonmetabolized form. Data from γ scintigraphic and quantitative biodistribution studies performed in M109 tumor-bearing Balb/c mice confirmed that ^{99m}Tc-EC20 predominantly accumulates in FR-positive tumor and kidney tissues. These results suggest that ^{99m}Tc-EC20 may be clinically useful as a noninvasive radiodiagnostic imaging agent for the detection of FR-positive human cancers.

INTRODUCTION

The field of nuclear medicine has been revitalized with the arrival of tissue-specific radiopharmaceutical targeting technologies. Ligands capable of concentrating at pathological sites have been derivatized with chelator−radionuclide complexes and then used as noninvasive probes for diagnostic imaging purposes. For example, vasoactive intestinal peptide, somatostatin analogues, monoclonal antibodies, vitamin B12, and even folic acid have all been used as ligands to localize radionuclides to tumors (*1*−*10*). Applications with monoclonal antibodies and various fragments thereof initially received the most attention because it was believed that precise, or perhaps superior, tumor-specific targeting might easily be achieved. Unfortunately, this approach was found to be technically challenging and inferior to other methods since (i) antibodies have prolonged circulation times due to their rather large molecular size (an unfavorable trait for imaging purposes), (ii) antibodies are expensive to produce, (iii) antibodies can be immunogenic, forcing their laborious humanization whenever multiple doses would be anticipated, and (iv) tumor to nontarget tissue ratios (T/NT) of antibody-linked radionuclides were essentially sub-optimal (*11*−*13*). Thus, more focus has recently been directed toward the use of smaller tumor-specific ligands that do not suffer from such limitations.



Use of the vitamin folic acid for the targeting of bioactive agents to tumors has been effectively exemplified over the past eleven years (*14*). In fact, folate conjugates of radiopharmaceutical agents (*1*−*6*), MRI contrast agents (*15*), low molecular weight chemotherapeutic agents (*16*), antisense oligonucleotides and ribozymes (*17*−*21*), proteins and protein toxins (*22*−*27*), immunotherapeutic agents (*28*−*31*), liposomes with entrapped drugs (*32*−*36*), and plasmids (*37*−*43*) have all been successfully delivered to FR-expressing cancer cells. Chronologically, the first folic acid "conjugate" described for in vivo tumor imaging was a histamine derivative containing 125-iodine (*44*). Although impressive tumor images were obtained with this conjugate, it was not considered a relevant clinical candidate owing to the long-lived ^{125}I radionuclide component. Subsequent reports described the synthesis and use of a deferoxamine−folate conjugate for tumor targeting (*1*, *2*). Deferoxamine chelates ^{67}Ga, a γ-emitting radionuclide that has a 78 h half-life. Favorable pharmacokinetic biodistribution profiles and high T/NT ratios were obtained with this agent in a tumor-bearing nude mouse model, however partial hepatobiliary clearance was also noted. Thus, further preclinical development was stopped due to anticipated problems in accurately imaging regio-abdominal locations in humans. This obstacle was easily overcome, however, by simply replacing the deferoxamine chelator with diethylenetriamine pentaacetic acid (DTPA), an efficient chelator of ^{111}In (68 h half-life). ^{111}In-DTPA-folate displayed similar tumor-accumulating properties to its deferoxamine predecessor, but its primary route of elimination was confirmed to be through the kidneys (*3*). Thus, ^{111}In-DTPA-folate was selected for development, and phase I/II clinical trials were conducted at several US sites in 1999 and 2000 (*14*).

There were no plans to commercialize ^{111}In-DTPA-folate, mostly because the field of radiodiagnostic imaging had been transitioning toward using ^{99m}Tc-based probes. Nonetheless, clinical evaluation of ^{111}In-DTPA-folate was continued for the purpose of obtaining valuable human biodistribution data while the development of a newer ^{99m}Tc-based folate conjugate was concurrently underway. ^{99m}Tc has been adopted as the preferred radionuclide for diagnostic imaging because (i) the radionuclide is easily obtained in a clinical laboratory from commercially available ^{99}Mo−^{99m}Tc generators, (ii) the cost of producing large amounts of ^{99m}Tc is insignificant compared to the cost of ^{111}In, and (iii) ^{99m}Tc has a much shorter (6 h) half-life, which allows higher radionuclide doses (~25 mCi) to be administered, yielding higher resolution images

without the risk of hazardous radiation exposure to vital organs.

Several folate-based ^{99m}Tc conjugates have already been described in the literature. For example, folate conjugates of ^{99m}Tc-6-hydrazinonicotinamido-hydrazido (HYNIC) (*5*), ^{99m}Tc-12-amino-3,3,9,9-tetramethyl-5-oxa-4,8 diaza-2,10-dodecanedinoe dioxime (OXA) [6], ^{99m}Tc-ethylenedicysteine (*4*), and even ^{99m}Tc-DTPA-folate (*45*), have all shown promising in vivo tumor uptake qualities. The objective of this study, however, was to develop an alternative, proprietary ^{99m}Tc−folate conjugate that would be suitable for clinical development. Thus a new agent, herein referred to as EC20, was prepared and characterized. Detailed analytical and preclinical biological data were collected, and much of the data used to support an Investigational New Drug application is reported below.

EXPERIMENTAL PROCEDURES

Materials. N^{10}-Trifluoroacetylpteroic acid was purchased from Eprova AG, Schaffhausen, Switzerland. Peptide synthesis reagents were purchased from Nova-Biochem and Bachem. ^{99m}Tc Sodium Pertechnetate was supplied by Syncor. $[ReO_2(en)_2]Cl$ was prepared according to Rouschias (*46*). Cellulose plates and DEAE ion exchange plates were purchased from J. T. Baker.

Synthesis, Purification, and Analytical Characterization of EC20. EC20 is a folate-containing peptide consisting in sequence of pteroic acid (Pte), D-Glu, β-L-diaminopropionic acid (βDpr), Asp, and Cys. EC20 was synthesized on an acid-sensitive Wang resin loaded with Fmoc-L-Cys (Trt)-OH, as detailed in Scheme 1. Benzotriazole-1-yl-oxy-tris-pyrrolidino-phosphoniumhexafluorophosphate (PyBOP) was applied as the activating reagent to ensure efficient coupling using low equivalents of amino acids. Fmoc protecting groups were removed after every coupling step under standard conditions (20% piperidine in DMF). After the last assembly step, the peptide was cleaved from the polymeric support by treatment with 92.5% trifluoroacetic acid containing 2.5% ethanedithiol, 2.5% triisopropylsilane, and 2.5% deionized water. This reaction also resulted in simultaneous removal of the t-Bu, Boc and trityl protecting groups. Finally, the trifluoroacetyl moiety was removed in aqueous ammonium hydroxide to give EC20.

The crude EC20 product was purified by HPLC using an Xterra RP18 30 × 300 mm 7 μm column (Waters), mobile phase 32 mM HCl (A) and MeOH (B), and gradient conditions starting with 99% A and 1% B and reaching 89% A and 11% B in 37 min at a flow rate of 20 mL/min. Under these conditions, EC20 monomer typically eluted at 14.4 min, whereas EC20 disulfide dimer (minor contaminant) eluted at 16.8 min.

A 2 mg sample of HPLC-purified EC20 was dissolved in 0.62 mL of D_2O, and a 500 MHz ^{1}H NMR spectrum was collected. Table 1 lists the chemical shifts, signal shapes, and *J* values for all nonexchangeable protons of the EC20 molecule.

EC20 was also analyzed by electrospray-mass spectrometry. Major positive ion peaks (*m*/*z*, relative intensity): 746.1 $(M+H)^+$, 100; 747.1, 44; 556.8, 32; 570.8, 16. Importantly, the calculated molecular weight for the formula $C_{29}H_{35}N_{11}O_{11}S$ is 745.2.

Preparation of the Nonradioactive Reagent Vial. EC20 kits are used for preparation of the ^{99m}Tc-EC20 radioactive drug substance. Each kit contains a sterile, nonpyrogenic lyophilized mixture of 0.1 mg of EC20, 80 mg of sodium α-D-glucoheptonate, 80 mg of tin (II) chloride dihydrate, and sufficient sodium hydroxide or hydrochloric acid to adjust the pH to 6.8 ± 0.2 prior to lyophilization. The lyophilized powder is sealed in a 5 mL vial under an argon atmosphere. The kits are then stored frozen at −20 °C until use or expiration (current shelf life is >2 years). Importantly, the tin (II) component is required to reduce the added ^{99m}Tc-pertechnetate, while the sodium α-D-glucoheptonate component is necessary to stabilize the newly reduced ^{99m}Tc prior to its final chelation to the EC20 compound.

Preparation of ^{99m}Tc-EC20. The procedure for chelating ^{99m}Tc to EC20 consists of the following steps. First, a boiling water bath containing a partially submerged lead vial shield is prepared. The top of an EC20 vial is swabbed with 70% ethanol to sanitize the surface, and it is placed in a suitable shielding container. Using a shielded syringe with 27-gauge needle, 1 mL of Sodium Pertechnetate ^{99m}Tc Injection (<50 mCi) is injected into the shielded vial. Before removal of the syringe from the vial, a volume of gas from the vial equal to the volume of pertechnetate added is withdrawn in order to normalize the pressure inside the vial. The vial is gently swirled for 30 s to ensure complete dissolution of the lyophilized powder. The vial is then placed into the lead shield that is standing in the boiling water bath, heated for ∼18 min,

Table 1. ^{1}H NMR Data for EC20[a]

residue	protons observed	chemical shift (δ)	signals	J values
	H-7	8.76	s

	H-3B	2.89	dd; B of ABX system	

[a] EC20 was dissolved in D_2O, and a 500 MHz spectrum was collected. Chemical shifts (δ) are in ppm. The signal for HOD at $\delta = 4.80$ ppm was used as the reference. pD = 4.78; s = singlet; d = doublet; m = multiplet.

and then cooled to room temperature for a minimum of 15 min. This solution can be stored at room temperature (15−25 °C) protected from light, but it should be used within 6 h of preparation.

The radiochemical stability of the radioactive drug substance was determined by HPLC after storing at room temperature in a lead-shielded container for up to 24 h. Samples of ^{99m}Tc-EC20 solution (20 μL) were analyzed using an HPLC system consisting of a Waters 600E Multisolvent Delivery System and 490 UV detector, a Bioscan FC-3200 radiodetector, Laura v1.5 radiochromatogram software, and a Waters Nova-Pak C18 (3.9 × 150 mm) column. Injected samples were eluted isocratically using an aqueous mobile phase containing 20% methanol and 0.1% trifluoroacetic acid at a flow rate of 1 mL/min. The HPLC analysis was monitored with both the UV detector (280 nm) and the γ radiodetector. Notably, the radiochemical purity of ^{99m}Tc-EC20 remained greater than 90% for at least 24 h in all cases.

Determination of Radiochemical Purity of ^{99m}Tc-EC20 by TLC. The major radiochemical impurities in the preparation of ^{99m}Tc-EC20 are (1) ^{99m}Tc pertechnetate, (2)^{99m}Tc-glucoheptonate (ligand exchange precursor), (3) nonspecific binding ^{99m}Tc (^{99m}Tc bound at a site other than the expected Dap-Asp-Cys chelating moiety of the EC20 molecule), and (4) hydrolyzed ^{99m}Tc. Since ^{99m}Tc-EC20 was being tested for possible clinical use, a three-TLC-based method had been developed to determine the amounts of each impurity and to estimate the overall radiochemical purity of ^{99m}Tc-EC20.

In the first system a cellulose plate is developed with deionized water. ^{99m}Tc-EC20, ^{99m}Tc-glucoheptonate, nonspecific binding ^{99m}Tc, and ^{99m}Tc pertechnetate move to the solvent front (R_f = 1.0), while hydrolyzed ^{99m}Tc remains at the origin (R_f = 0.0). The cellulose plate is cut into two pieces at $R_f = 0.3$, and each piece is counted using a dose calibrator. The percent of hydrolyzed ^{99m}Tc is calculated as follows: A = % hydrolyzed ^{99m}Tc = (μCi in bottom piece/μCi in both pieces) × 100.

In the second system, a cellulose plate is developed with acetone and 0.9% NaCl (7:3,v/v). ^{99m}Tc-pertechnetate moves with $R_f = 0.9$, while ^{99m}Tc-EC20, ^{99m}Tc-glucoheptonate, nonspecific binding ^{99m}Tc, and hydrolyzed ^{99m}Tc remain at the origin (R_f = 0.0). The cellulose/acetone−saline plate is cut into two pieces at $R_f = 0.6$, and each piece is counted using a dose calibrator. The percent of ^{99m}Tc-pertechnetate is calculated as follows: B = % ^{99m}Tc-pertechnetate = (μCi in top piece/μCi in both pieces) × 100.

Finally, in the third system a DEAE ion exchange plate is developed with 0.3 M Na_2SO_4. ^{99m}Tc-glucoheptonate moves to the solvent front ($R_f = 1.0$), nonspecific binding ^{99m}Tc moves with $R_f = 0.6$, and ^{99m}Tc-EC20, hydrolyzed ^{99m}Tc and ^{99m}Tc-pertechnetate remain near the origin (^{99m}Tc-EC20: $R_f = 0.1$; hydrolyzed ^{99m}Tc: $R_f = 0.0$; ^{99m}Tc pertechnetate: $R_f = 0.3$). The cellulose/Na_2SO_4 plate is cut into two pieces at $R_f = 0.5$, and each piece is counted using a dose calibrator. The percent of ^{99m}Tc-glucoheptonate and nonspecific binding ^{99m}Tc are calculated as follows: C = % (^{99m}Tc-Glucoheptonate + nonspecific binding ^{99m}Tc) = (μCi in top piece/μCi in both pieces) × 100. The overall radiochemical purity of ^{99m}Tc-EC20 is then calculated as follows: radiochemical purity = 100 − (A + B + C).

Synthesis of Re-EC20. A 52 mg (0.070 mmol) sample of EC20 and 52 mg (0.14 mmol) of [ReO_2 (en)$_2$]Cl (*46*) was dissolved in 6 mL and 1 mL of argon-purged phosphate buffer (0.05 M, pH 5.8), respectively. The two solutions were combined and heated under an argon atmosphere in a boiling water-bath for 2 h. The reaction mixture was frozen and lyophilized overnight. The crude product was purified by HPLC (Xterra RP18 column, 19 × 150 mm, 10 mM NH_4OAc/CH_3CN, flow rate 10 mL/min; gradient 1−8%). The fractions were collected, lyophilized, and stored at −20 °C until use.

Cell Culture. Cells were grown continuously as a monolayer using folate-free RPMI medium (FFRPMI) containing 10% heat-inactivated fetal calf serum (HIFCS) at 37 °C in a 5% CO_2/95% air-humidified atmosphere with no antibiotics. The HIFCS contained its normal complement of endogenous folates which enabled the cells to sustain growth in this more physiologically relevant medium (*22*). All cell experiments were performed using FFRPMI containing 10% HIFCS (FFRPMI/HIFCS) as the growth medium, except where indicated.

Relative Affinity Assay. The relative affinity of various folate derivatives was determined according to the method described by Westerhoff et al. (*47*) with slight modification. In short, FR-positive KB cells were gently trypsinized in 0.25% trypsin in phosphate-buffered saline (PBS) at room temperature for 3 min and then diluted in FFRPMI/HIFCS. Following a 5 min 800*g* spin and one PBS wash, the final cell pellet was suspended in FFRPMI 1640 (no serum). Cells were incubated for 15 min on ice with 100 nM of ^{3}H-folic acid in the absence and presence of increasing concentrations of folate-containing test articles. Samples were centrifuged at 10 000*g* for 5 min, and cell pellets were suspended in buffer, transferred to

individual vials containing 5 mL of scintillation cocktail, and then counted for radioactivity. Negative control tubes contained only the ^{3}H-folic acid in FFRPMI (no competitor). Positive control tubes contained a final concentration of 1 mM folic acid, and CPMs measured in these samples (representing nonspecific binding of label) were subtracted from all samples. Notably, relative affinities were defined as the inverse molar ratio of compound required to displace 50% of ^{3}H-folic acid bound to FR on KB cells, and the relative affinity of folic acid for the FR was set to 1.

Time-Dependent Cell Uptake. KB cells were seeded in 12-well Falcon plates and allowed to form subconfluent monolayers overnight. Following one rinse with 1 mL of fresh FFRPMI/HIFCS, each well received 1 mL of FFRPMI/HIFCS containing 10 nM ^{99m}Tc-EC20. Cells were incubated for the indicated times at 37 °C and then rinsed four times with 1 mL of ice-cold PBS, pH 7.4. The monolayers were dissolved in 0.5 mL of PBS, pH 7.4, containing 1% sodium dodecyl sulfate for 15 min at room temperature, and then counted for radioactivity using a Packard γ counter. The protein in each sample was next quantitated using a BioRad DC Protein Assay kit, and cellular protein values were converted to cell number using the conversion factor of 2.23×10^{-7} mg protein per cell (*48*). Final tabulated values were expressed in terms of molecules EC20 per cell.

Concentration-Dependent Cell Uptake. KB cells were seeded in 12-well Falcon plates and allowed to form sub-confluent monolayers overnight. Following one rinse with 1 mL of fresh FFRPMI/HIFCS, each well received 1 mL of FFRPMI/HIFCS containing increasing concentrations of ^{99m}Tc-EC20. Cells were incubated for 2 h at 37 °C and then rinsed four times with 1 mL of ice-cold PBS, pH 7.4. The monolayers were dissolved in 0.5 mL of PBS, pH 7.4, containing 1% sodium dodecyl sulfate for 15 min at room temperature and then counted for radioactivity using a Packard γ counter. Protein content was determined as described above, and final tabulated values were expressed in terms of molecules EC20 per cell.

Blood Clearance. Animals used for this study were maintained on a folate-free diet (Harlan #TD-90261) for approximately 3 weeks prior to dose administration. Acclimation to this special diet is essential because regular rodent diets contain large amounts of folic acid (6 mg/kg chow) and promote high serum folate levels in mice (*2*). Furthermore, previous studies have shown that mice placed on a folate-free diet for 3 weeks had maintained a safe serum folate level of 25 ± 7 nM, which is slightly higher than the 9−14 nM concentration measurable in human serum (*5*).

The ^{99m}Tc-EC20 solution was prepared on the day of use and had initially contained 100 μg of EC20 per milliliter. It was further diluted with sterile saline to prepare working stock solutions. The radiochemical purity of the product was estimated to be ≥94% by TLC. Each animal received a dose of 50 μg/kg EC20 (67 nmol/kg) in approximately 0.1 mL volume i.v. via the tail vein during brief diethyl ether anesthesia. At the designated times postinjection, each animal was euthanized by CO_2 asphyxiation, and blood was immediately collected by cardiac puncture.

Tissue Distribution Studies. Four- to five-week-old mice (Balb/c strain) were purchased from Harlan Sprague Dawley, Inc. (Indianapolis, IN) and were maintained on a folate-free diet for a total of 3 weeks prior to the experiment. Syngeneic, FR-positive M109 tumor cells (1×10^{6} per animal) were inoculated in the subcutis of the right axilla two weeks prior to the experiment. All mice were females, and the tumor weights were 54.2 ± 29.8 mg on the day of this experiment. A stock ^{99m}Tc-EC20 solution containing 100 μg of agent per mL was prepared on the day of use, and its radiochemical purity was >96%. Two additional ^{99m}Tc-chelating agents, ^{99m}Tc-EC14 (an EC20 analogue containing 1 additional Glu residue: Pte-D-Glu-D-Glu-βDpr-Asp-Cys) and ^{99m}Tc-EC28 (a non pteridine-containing control: benzoyl-D-Glu-D-Glu-βDpr-Asp-Cys), as well as ^{111}In-DTPA-folate (*3*) were also prepared to >90% radiochemical purity and were coevaluated in this study. All solutions were diluted with either saline alone or a saline solution containing 100 equivalents of folic acid (for competition) such that the final radiopharmaceutical concentration was 10 μmol/mL.

Animals received an approximate 40 μmol/kg i.v. dose of test article in 100 μL volume via a lateral tail vein during brief diethyl ether anesthesia. Four hours after injection, animals were sacrificed by CO_2 asphyxiation and dissected. Selected tissues were removed, weighed, and counted to determine ^{99m}Tc distribution. CPM values were decay-corrected, and results were tabulated as % injected dose per gram of wet weight tissue.

Gamma Scintigraphy. M109 tumor cells (1×10^{6} per animal) were inoculated in the subcutis of the right axilla of Balb/c mice two weeks prior to the experiment. Animals received an approximate 50 μmol/kg i.v. dose of test article in 100 μL volume via a lateral tail vein during brief diethyl ether anesthesia. Four hours after injection, animals were sacrificed by CO_2 asphyxiation and then placed on top of an image acquisition surface. Whole-body image acquisition was performed for 1 min at a count rate of 50−75 000 counts per min using a Technicare Omega 500 Sigma 410 Radioisotope Gamma Camera. All data were analyzed using a Medasys MS-DOS-based computer equipped with Medasys Pinnacle software.

Urinary Excretion and Metabolism. The urinary HPLC speciation profile of ^{99m}Tc-EC20 was obtained using Balb/c mice. Mice (~20 g each) were injected with 1 mCi (6.7 nmol) of ^{99m}Tc-EC20 via a lateral tail vein. Following a 1, 4, or 6 h time period, groups of two mice were euthanized by CO_2 asphyxiation, and urine was collected. After filtration through a GV13 Millex filter, the radiochemical speciation was assessed using an HPLC system equipped with a Nova-Pak C18 3.9 × 150 mm column and a radiochemical detector. The system was isocratically eluted with 20% methanol containing 0.1% TFA at a flow rate of 1 mL/min.

Serum Protein Binding. Fresh rat serum and commercial male human serum (type AB donors, Sigma Chemical Co.) were used to evaluate in vitro binding of ^{99m}Tc-EC20 to serum proteins. One minute after ^{99m}Tc-EC20 was mixed with 1 mL of serum at room temperature, 0.3 mL of the serum solution was transferred to a clean Amicon Centrifree ultrafiltration device (30 000 NMWL) in triplicate. Within one minute of loading the centrifuge with the serum solution, the device was spun at 1000*g* for 20 min at 20 °C. Fifty microliter samples of the original solution, and of the filtrate from each device, were transferred to a clean tube and counted in an automatic γ counter. A control solution of ^{99m}Tc-EC20 mixed with 1 mL of normal saline was ultrafiltered in an identical fashion. The percentage of free ^{99m}Tc was calculated for each of the three samples.

RESULTS

EC20 and Related Structures. The structure of the EC20 molecule is depicted in Figure 1. The folic acid

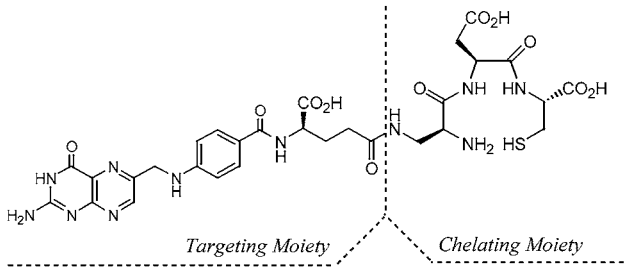

Figure 1. Structure of EC20.

moiety in the EC20 molecule is present to allow its high-affinity binding to cellular FRs. The other part of the molecule consists of a bifunctional peptide-based chelator, which provides the site of ^{99m}Tc coordination. Interestingly, the most successful class of bifunctional technetium chelators to date is represented by similar amine/amide thiolate compounds that coordinate TcO^{3+} via an $(N_{amine/amide})_{4-x}$ $(S_{thiolate})_x$ donor atom set (*49*−*56*).

Radiochemical Characterization. EC20 kits are used for preparation of the ^{99m}Tc-EC20 radioactive drug substance. Each kit contains a sterile, nonpyrogenic lyophilized mixture of EC20, sodium α-D-glucoheptonate, and tin (II) chloride that is sealed under an argon atmosphere. The final ^{99m}Tc-EC20 drug product formulation is then formed by the simple reconstitution of the lyophilized powder with ^{99m}Tc pertechnetate in saline followed by a brief heating step.

As shown in Figure 2, HPLC analysis of the ^{99m}Tc-EC20 formulation shows four radiochemical components, designated as peaks A−D. Peak A was confirmed to be free ^{99m}Tc, and this byproduct is typically present at <1%. Peak B, which was different from that of ^{99m}Tc-glucoheptonate (data not shown), eluted with a retention time of 2.8 min. This component represented about 3% of the mixture and was thought to result from ^{99m}Tc chelating at some other site on the EC20 molecule besides the expected Dap−Asp−Cys moiety (vide infra). Peaks C and D (retention times of 4.8 min and 13.2 min, respectively) account for the majority of the formulated radiochemical activity.

Since no mass spectral facilities were available for analysis of radioactive materials, a nonradioactive rhenium analogue, Re-EC20, was synthesized. Both rhenium and technetium are Group VIIA metals that have significant similarity in physical and chemical properties. They also form similar complexes with organic ligands. This analogous chemical behavior has been frequently used in structure elucidation of new classes of technetium radiopharmaceuticals based on nonradioactive rhenium analogues (*57*−*59*). Interestingly, HPLC analysis of Re-EC20 also showed two major peaks eluting at 5 and 14.2 min, respectively, similar to Peaks C and D for ^{99m}Tc-EC20 (chromatogram not shown). Mass spectral analysis confirmed that these two components were isomers corresponding to the Re-EC20 complex (m/z = 945). In fact, these species were likely diastereomers possessing either a syn or anti configuration of the technetium−oxygen bond in the Dap−Asp−Cys chelating ring, as depicted in Figure 3. Since (i) the two peaks in the Re-EC20 chromatogram represent isomeric complexes and (ii) reports of similar isomerism in technetium complexes exists in the literature, we concluded that components C and D in the ^{99m}Tc-EC20 radiochromatogram are also isomers.

Relative Affinity Assay. EC20 was first evaluated biologically using an in vitro relative affinity assay that measures a ligand's ability to directly compete with folic acid for binding to cell surface FRs. Importantly, a relative affinity value of 1.0 implies that the test article ligand has an affinity equal to that of folic acid for the FR. Likewise, values lower than unity reflect weaker affinity, and values higher than unity reflect stronger affinity.

Cultured KB cells were incubated with 100 nM ^{3}H-folic acid in the presence of increasing concentrations of nonradioactive folic acid, EC20, Rhenium-EC20 (isomer 1; peak C), Rhenium-EC20 (isomer 2; peak D), or a related folate-based radiopharmaceutical, DTPA-folate (*3*). Following a 15 min incubation at 4 °C, cells were rinsed free of unbound material and counted for residual cell-associated radioactivity. The quantity of bound radioactivity was plotted against the concentration of unlabeled ligand, and IC_{50} values (concentration of ligand required to block 50% of ^{3}H-folic acid binding) were estimated. As shown in Figure 4 and Table 2, EC20 was experimentally determined to have an affinity of 0.92 relative to that of folic acid for human FRs. Consequently, both isomers of Rhenium-EC20 displayed relative affinity values that were very similar to, if not better then, the parent EC20 molecule (1.42 and 1.37 for Re-EC20 isomer 1 and isomer 2, respectively). Furthermore, DTPA-folate, an ^{111}In-chelating folate radiopharmaceutical agent, displayed a relative affinity of 0.87 for the folate receptor. Thus, chemical modification of folate with various metal chelating motifs did not disturb the vitamin's intrinsic affinity for the FR.

Time-Dependent Cell Uptake. The kinetics of ^{99m}Tc-EC20 uptake into FR-positive KB cells was quantitatively measured. As shown in Figure 5, steady-state uptake was reached within 2 h at 37 °C, where approximately 3.2 million molecules of EC20 were cell associated. Half-maximal cell association occurred 9 min after mixing 10 nM of this radiopharmaceutical with the cells. Interestingly, the half-maximal saturation point was reached in only 37 s when cells were incubated with a 10-fold higher concentration of ^{99m}Tc-EC20 (100 nM; data not shown).

Concentration-Dependent Cell Uptake. Ligands of the high-affinity FR, including folate conjugates of radiopharmaceuticals and proteins etc., all display dose-dependent cell association (*1, 22, 40, 48, 60*). As shown in Figure 6, the cell uptake of ^{99m}Tc-EC20 was also found to be dependent on the extra-cellular concentration. The particular KB cells maintained in our laboratory were determined to bind a maximum of four million molecules of the folate radiopharmaceutical per cell. Scatchard analysis of the data estimated the dissociation constant (K_D) to be 3.2 nM, a value comparable with the K_D observed for the binding of unmodified folate to these same cells (*61*).

Concentration-Dependent Cell Uptake of Peak B. Although the full identity of the peak B component was not established, UV absorption analysis indicated that it contained a folate moiety (e.g., the absorption spectrum contained folate's signature secondary absorption peak at 363 nm). This HPLC-purified radio-labeled material was collected and then added to cultured KB cells. As shown in Figure 7, the cell uptake of ^{99m}Tc-labeled Peak B component was also found to be dependent on the extra-cellular concentration. Scatchard analysis of the data estimated the K_D of binding to be 1.1 nM. Importantly, the cell association of Peak B was completely blocked when in the presence of excess folic acid, indicating that this minor formulation byproduct is also capable of targeting FR-positive cells for radiodiagnostic purposes.

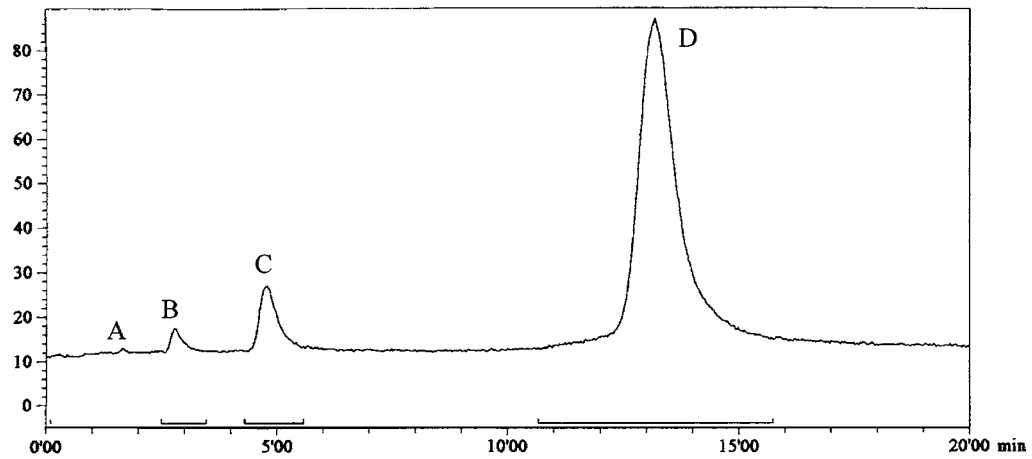

Figure 2. HPLC radiochromatogram of ^{99m}Tc-EC20. Samples of ^{99m}Tc-EC20 were eluted isocratically on a Waters Nova-Pak C18 (3.9 × 150 mm) column using an aqueous mobile phase containing 20% methanol and 0.1% trifluoroacetic acid at a flow rate of 1 mL/min. The HPLC analysis was monitored with both the UV detector (280 nm) and a Bioscan FC-3200 radiodetector. Peak A, free ^{99m}Tc; peak B, a folate-containing chelate of unknown structure; peaks C and D, diastereomers possessing either a syn or anti configuration of the technetium−oxygen bond in the Dap−Asp−Cys chelating ring of EC20.

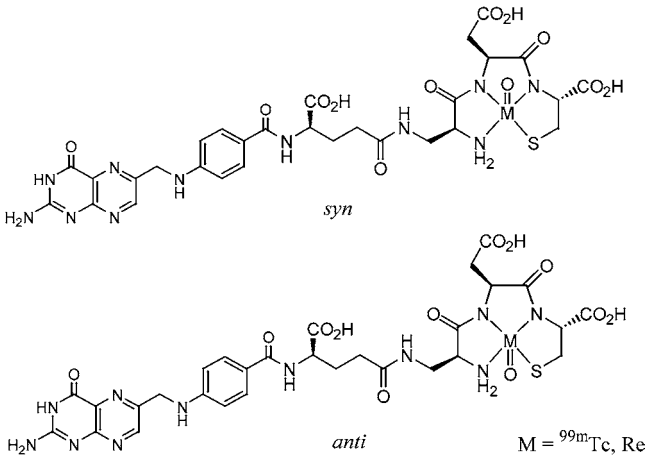

Figure 3. Structures of Re-EC20 and ^{99m}Tc-EC20 isomers (syn or anti position of metal-oxo bond).

Protein Binding. Prior to the onset of tissue distribution studies, we examined the ability of ^{99m}Tc-EC20 to bind proteins in both rat and human sera. Following a 1 min mix of ^{99m}Tc-EC20 with 1 mL of serum at room temperature, samples were ultrafiltered, and the quantity of radioactivity detected in the filtrate was measured to reveal the amount of unbound radiopharmaceutical. While ^{99m}Tc-EC20 exhibited only a minor level of nonspecific binding to the ultra-filtration device (~5%), approximately 70% of it was found to predominantly associate with the >30kDa serum protein fraction in solutions of rat or human serum (69% and 72%, respectively). Importantly, since ^{99m}Tc-EC20 does preferentially accumulate within FR-positive tissues (vide infra), its apparent affinity for serum proteins appears to be inconsequential.

Blood Clearance. We next evaluated the pharmacokinetic blood clearance of the ^{99m}Tc-EC20 formulation. Thus, Balb/c mice received an intravenous dose of 50 μg/kg ^{99m}Tc-EC20, and blood samples were collected at various time intervals thereafter. As shown in Figure 8, ^{99m}Tc-EC20 was rapidly removed from circulation in the Balb/c mouse. The plasma half-life of this radiopharmaceutical was estimated to be ~4 min, and less than 0.2% of the injected ^{99m}Tc-EC20 dose remained in circulation after 4 h (assuming that blood represents 5.5% of the total body mass). These data indicates that folate conjugates are rapidly removed from circulation following intravenous administration and that valuable tissue biodistribution data can be obtained after only a few hours postinjection without the concern for nonspecific tissue uptake due to blood-borne radioactivity.

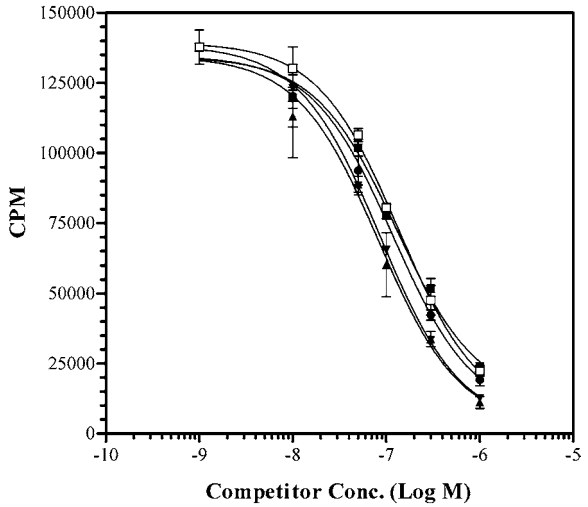

Figure 4. Blocking of ^{3}H-folic acid binding to KB cells with various folate-containing competitors. KB cells were incubated for 15 min on ice with 100 nM ^{3}H-folic acid in the presence and absence of increasing competitor concentrations. (•) Folic acid; (■) EC20; (▲) EC20:Re isomer 1; (▼) EC20:Re isomer 2; (□) DTPA−folate. Error bars represent 1 standard deviation (n = 3).

Table 2. Relative Affinity Estimations[a]

test article	IC_{50} (nM)	S.D.	RA	S.D.
folic acid	118	± 19	1.00	
EC20	128	± 25	0.92	± 0.23
EC20:Re isomer 1	83	± 16	1.42	± 0.36
EC20:Re isomer 2	86	± 3	1.37	± 0.23
DTPA-folate	136	± 12	0.87	± 0.16

[a] Relative affinities (RA) were defined as the inverse molar ratio of compound required to displace 50% of ^{3}H-folic acid bound to FR-positive KB cells. The relative affinity of folic acid was set to 1. Each test article was evaluated in triplicate.

Tissue Biodistribution. The ability of ^{99m}Tc-EC20 to target tumors in vivo was assessed using a FR-positive M109 model (*36*). These tumor cells are syngeneic for the

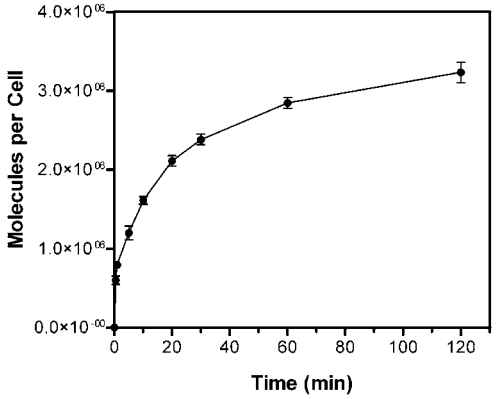

Figure 5. Time-dependent association of ^{99m}Tc-EC20. KB cells were incubated with 10 nM ^{99m}Tc-EC20 for increasing periods of time at 37 °C. Following multiple washes, cells were harvested and counted for associated radioactivity. Error bars represent 1 standard deviation ($n = 3$).

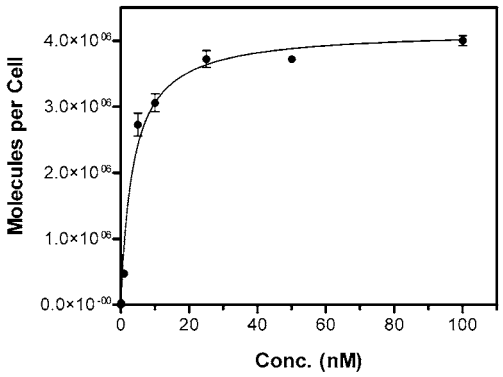

Figure 6. Concentration-dependent association of ^{99m}Tc-EC20. KB cells were incubated for 2 h at 37 °C in the presence of increasing concentrations of ^{99m}Tc-EC20. Following multiple washes, cells were harvested and counted for associated radioactivity. Error bars represent 1 standard deviation ($n = 3$).

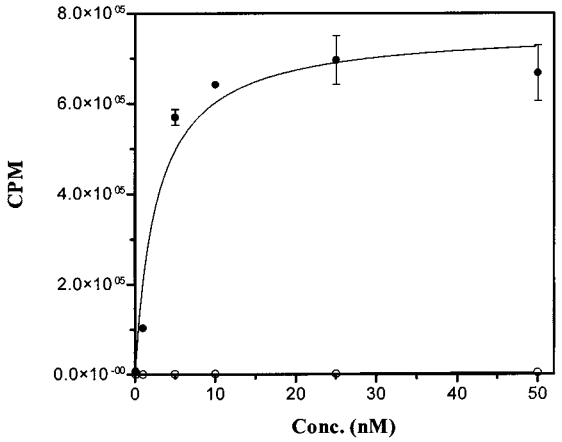

Figure 7. Concentration-dependent association of ^{99m}Tc-EC20 "peak B". KB cells were incubated for 2 h at 37 °C in the presence of increasing concentrations of "peak B" that was chromatographically isolated from the ^{99m}Tc-EC20 formulation. Following multiple washes, cells were harvested and counted for associated radioactivity. Error bars represent 1 standard deviation ($n = 3$). (●) peak B; (○) peak B plus 1 mM folic acid.

Balb/c mouse, and they reproducibly form subcutaneous solid tumors within two weeks post inoculation. ^{99m}Tc-EC14, which is structurally similar to ^{99m}Tc-EC20 except it contains one additional D-Glu residue (i.e., Pte-D-Glu-D-Glu-βDpr-Asp-Cys), ^{99m}Tc-EC28 (a nonpteroate containing control consisting of benzoyl-D-Glu-D-Glu-βDpr-Asp-Cys), and the previously reported ^{111}In-DTPA-folate radiopharmaceutical (*3*) were also evaluated in this bioassay. Importantly, the ^{99m}Tc-EC28 control agent should not bind to cell surface FRs because it lacks an essential pteridine ring moiety.

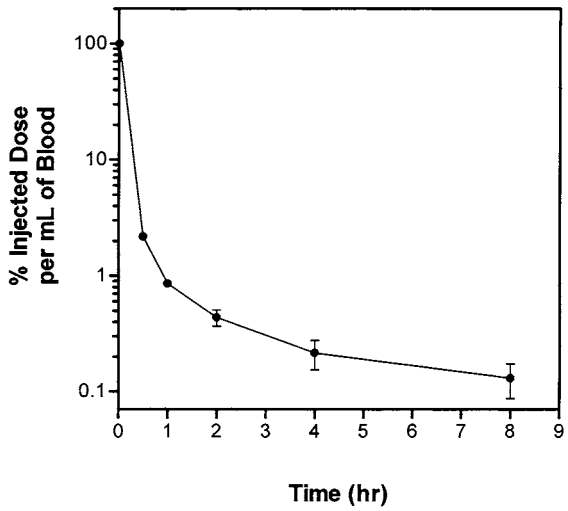

Figure 8. Blood clearance of ^{99m}Tc-EC20 in Balb/c mice. Each animal received an intravenous dose of 50 μg/kg EC20 (67 nmol/kg) in approximately 0.1 mL PBS during brief diethyl ether anesthesia. At the designated times postinjection, each animal was euthanized by CO_2 asphyxiation, and blood was collected and counted for associated radioactivity. Error bars represent 1 standard deviation ($n = 3$ animals).

Four hours after receiving an approximate 40 μmol/kg i.v. dose, animals were euthanized, and selected tissues were removed, weighed, and counted to determine ^{99m}Tc distribution. As shown in Table 3, the three "folate" containing radiopharmaceuticals, ^{99m}Tc-EC14, ^{99m}Tc-EC20, and ^{111}In-DTPA-folate, predominantly accumulated in the FR-positive tumor and kidneys; however, the kidneys concentrated a higher percent injected dose per gram of tissue (%ID/g) than did the tumor. Interestingly, the net tumor accumulation of ^{111}In-DTPA-folate and ^{99m}Tc-EC20 was nearly the same (19% and 17% ID/g, respectively), whereas the tumor uptake of ^{99m}Tc-EC14 was somewhat less at ~10% ID/g. Regardless, all three agents displayed high tumor-to-blood ratios (>30:1).

Folate-specific targeting was further demonstrated by two distinct methods. First, the accumulation of ^{99m}Tc-EC14, ^{99m}Tc-EC20, and ^{111}In-DTPA-folate in the FR-positive tumor and kidneys was effectively blocked (>94%) when these agents were co-administered with a 100-fold excess of folic acid. Second, the ^{99m}Tc-EC28 control agent failed to appreciably accumulate in the kidneys and tumor. Both observations provide evidence that an intact "folate-like" (or pteroate) moiety is required to afford targeted uptake and retention of these radiopharmaceutical agents into FR-positive tissues.

Scintigraphic Imaging. The predominant uptake of ^{99m}Tc-EC20 by the FR-positive M109 tumors and kidneys was further demonstrated using γ scintigraphy. As shown in Figure 9, a ventral image taken of a mouse 4 h after receiving a 50 μmol/kg i.v. dose of ^{99m}Tc-EC20 distinctively localizes the γ radiation to the two kidneys and the M109 tumor mass (shoulder region). No appreciable radiotracer was observed in other body tissues. Importantly, a similar image profile has been reported for the ^{111}In-DTPA-folate radiopharmaceutical (*3*).

Urinary Excretion and Metabolism. It was previously determined that the primary elimination route for ^{111}In-DTPA-folate was via the urine (*3*). Because

[a] Values shown represent the mean ± s.d. of data from three animals per cohort.

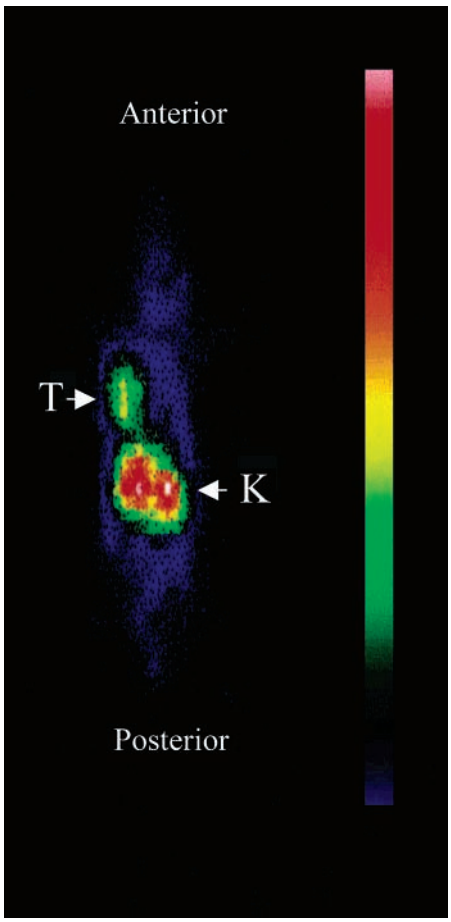

Figure 9. Whole-body γ images (ventral view). Images were obtained 4 h following intravenous administration of ^{99m}Tc-EC20 to a Balb/c mouse bearing a subcutaneous folate receptor-positive M109 tumor. Only the kidneys (K) and tumor (T) exhibit significant accumulation of this radiotracer.

^{99m}Tc-EC20 is a related folate-based radiopharmaceutical, we elected to evaluate its urinary excretion and metabolic profile using a radiochemical HPLC method. Thus, following a 1 mCi injection (6.7 nmol per mouse) of ^{99m}Tc-EC20, mice were euthanized at various time intervals, and urine samples were collected for HPLC analysis.

Similar to the HPLC profile shown in Figure 2, both the ^{99m}Tc-EC20 standard and the urine samples exhibited four radioactive peaks. As shown in Table 4, the radiochemical purity of the standard (sum of peaks C and D presumably corresponding to the syn and anti ^{99m}Tc-EC20) remained constant at ~93% over the 6 h duration of this experiment. The amount of free ^{99m}Tc in the standard (peak A) was ~2%. Importantly, peak B within this radiochemical profile is believed to be EC20 chelated to ^{99m}Tc at an unconventional, less stable position. However, the radioactivity measured in this fraction was not included in the overall radiochemical purity estimation for ^{99m}Tc-EC20. Collectively, these data indicate that the ^{99m}Tc-EC20 formulation remained stable in saline solution throughout this 6 h investigation.

After 1 and 4 h postinjection into Balb/C mice, the radiochemical speciation profile of ^{99m}Tc-EC20 in the mouse urine did not change. The radioactivity present in the urine at 6 h postinjection, however, was too low to accurately assay by HPLC. The proportion of parent drug among radioactive species recovered in urine remained relatively constant at approximately 90% throughout the 4 h during which it could be quantitated. This value is very similar to the ~93% purity of the standard, indicating that ^{99m}Tc-EC20 is predominately excreted into the urine in an un-modified form.

DISCUSSION

The primary goal of this investigation was to identify a folate-based ^{99m}Tc chelator candidate for clinical development. This project required the design, synthesis, analytical, and radiochemical characterization of a new chemical entity, as well as in vitro and in vivo biological evaluations.

We adopted an efficient solid-phase synthetic procedure to produce EC20, a small molecular weight peptide derivative of folate that contains a D-γ-Glu peptide linkage (Figure 1). In its natural form, folate (or pteroylglutamate) has a single glutamyl residue present in an L configuration. However, a D-Glu enantiomer residue was incorporated into the EC20 molecule for the purpose of providing additional metabolic protection against tissue-resident γ-glutamyl hydrolases (*62*). Importantly, similar to EC20, we have found that substitution of the L-Glu residue with a D-Glu residue does not alter folic acid's ability to bind to the high affinity FR (unpublished data).

EC20 was found to efficiently chelate ^{99m}Tc when in the presence of α-D-glucoheptonate and tin (II) chloride. When analyzed by radiochemical HPLC, >95% of the resulting ^{99m}Tc-EC20 formulation consisted of a mixture of syn and anti stereoisomers, each equally capable of binding to FR with high affinity (Figure 3). Approximately 3% of the ^{99m}Tc in the formulation was chelated to EC20 at some other site on the EC20 molecule besides the expected Dap−Asp−Cys moiety. Although this component was not isolated in sufficient quantity for optimal

Table 4. Excretion and Metabolism of ^{99m}Tc-EC20 from the Balb/c Mouse[a]

		area percent

sum C and D		93.5	93.4	93.4	89.2	91.1	85.2	89.8

[a] Mice were injected with 1 mCi (6.7 nmol) of ^{99m}Tc-EC20 via a lateral tail vein. At the indicated times, groups of two mice were euthanized, and urine was collected. The radiochemical speciation was then determined by HPLC. The area percent sum of peaks C and D (syn and anti isomers) is used to calculate the overall purity of intact ^{99m}Tc-EC20.

characterization, it was determined to bind to FR with high affinity (Figure 6). Finally, the remaining ~ 2% of the radioactivity in the ^{99m}Tc-EC20 formulation was attributed to free ^{99m}Tc.

This radiopharmaceutical demonstrated both time- and concentration-dependent association with FR-positive cells, as expected (*22*, *48*). ^{99m}Tc-EC20 was rapidly cleared from the blood ($t_{1/2}$ ~ 4 min), which is a great quality for diagnostic imaging agents, and it preferentially accumulated within FR-positive tumors in large amounts.

The performance of ^{99m}Tc-EC20 was directly compared to that of a similar FR targeting agent, ^{111}In-DTPA-folate, using two different methods. First, both folate-based radiopharmaceuticals were found to equally compete with folic acid for binding to FRs on KB cells (Figure 3 and Table 1). Second, the biodistribution of each agent in tumor-bearing mice was nearly identical (Table 2). High tumor uptake and tumor-to-blood ratios were measured for ^{99m}Tc-EC20 and ^{111}In-DTPA-folate. Taken together, these results suggest that, like ^{111}In-DTPA-folate (*63*), ^{99m}Tc-EC20 has the potential to effectively localize in FR-positive tumors when clinically administered to patients.

Several folate-based ^{99m}Tc conjugates have previously been described in the literature. Limited biodistribution data are available on a ^{99m}Tc-12-amino-3,3,9,9-tetramethyl-5-oxa-4,8 diaza-2,10-dodecanedinoe dioxime (OXA) folate conjugate; however, moderate levels (~7% ID/g) of tracer uptake in a KB tumor was reported (*6*). Studies involving the biodistribution of a ^{99m}Tc-ethylenedicysteine-folate conjugate in mammary tumor-bearing rats were also reported. Unfortunately, the rats in that study were fed a folate-rich diet. Thus, low tumor uptake and low tumor-to-blood ratios were obtained presumably because of competition with endogenous folate ligands (*4*). Last, a ^{99m}Tc-6-hydrazinonicotinamido-hydrazido (HYNIC) folate derivative (HYNIC-folate) was shown to accumulate in large amounts within 24JK-FBP tumors (*5*). Interestingly, ^{99m}Tc-EC20 accumulated within M109 tumors to nearly identical levels as that of HYNIC-folate in 24JK−FBP tumors (~17% ID/g) (*5*; Table 2). These two agents also displayed a roughly 50:1 tumor-to-blood ratio at 4 h post intravenous injection. Thus, folate clearly has the ability to deliver many different types of ^{99m}Tc chelates to FR-positive tumors, and EC20 has proven to be among the best.

The high-affinity FR is expressed at high levels mainly on cancer cells. For example, epithelial cancers of the ovary, mammary gland, colon, lung, nose, throat, and brain have all been reported to express elevated levels of the FR (*64*−*72*). In fact, >90% of all human ovarian tumors are known to express large amounts of this receptor (*66*, *70*, *73*). Overexpression of FR by cancer cells may well be selected for to provide the cells with a growth advantage relative to neighboring normal tissue. Indeed, highly de-differentiated metastatic cancers express considerably more FR than their localized, low-grade counterparts (*71*).

Each year ~26 000 women in the United States are diagnosed with ovarian cancer, and less than 50% of those women survive more than five years. One reason for the low survival rate is the difficulty in diagnosing this form of cancer. Because of the fear of rupturing an unidentified abdominal mass and the potential for spreading cancer throughout the abdominal cavity, fine needle biopsy is not often performed. Rather, the diagnoses and staging of suspicious ovarian masses is typically done through surgical laparotomy, which is an invasive and expensive procedure. Since ^{99m}Tc-EC20 binds tightly to FR which is present in large amounts on ovarian and other cancers, this radiopharmaceutical may provide an inexpensive, noninvasive, but reliable method for the early diagnosis of cancer. Importantly, ^{99m}Tc-EC20 may also help guide the clinical decision process with these patients by making more definitive and earlier diagnoses of recurrent or residual disease.

In summary, a new peptide derivative of folate was created to efficiently chelate ^{99m}Tc. This new compound, referred to as ^{99m}Tc-EC20, avidly binds to FR-positive tumor cells in vitro and in vivo despite its moderately high propensity to bind to serum protein. ^{99m}Tc-EC20 displayed rapid pharmacokinetic distribution out of the blood and into FR-positive tumors and kidney, and it was eliminated via the urine in a nonmetabolized form. These results indicate that ^{99m}Tc-EC20 should be clinically investigated as a noninvasive radiodiagnostic imaging agent for the detection of FR-positive cancers.

ACKNOWLEDGMENT

This work was supported in part by a Phase I and II SBIR grant from the National Institutes of Health. The authors also wish to thank Dr. Mark Green and Carla Mathias for conducting the serum protein binding study and Dr. Philip S. Low for his valuable comments.

To improve gene transfer activity of a new nonviral vector, a polyamidoamine dendrimer (G2) conjugate with α-cyclodextrin (α-CDE conjugate (G2)), we prepared α-CDE conjugates with dendrimer having different generations (G3 and G4), and their gene transfer activities were compared with those of α-CDE conjugate (G2) and TransFast, a novel transfection reagent. α-CDE conjugates (G2, G3, and G4) formed the complexes with pDNA, changing the ζ-potential and particle size of pDNA complexes and the protection of pDNA from DNase I in a charge ratio-dependent manner, although their differences at higher charge ratios (vector/pDNA) were small. The gene transfer activity of α-CDE conjugates (G2, G3, and G4) was higher than that of the corresponding dendrimer alone in NIH3T3 and RAW264.7 cells. Of these CDE conjugates, α-CDE conjugate (G3) had a superior gene transfer activity which was comparable to that of TransFast in NIH3T3 cells. The intracellular distribution of pDNA after application of the pDNA complex with α-CDE conjugate (G3) to NIH3T3 cells was different from that with dendrimer alone (G3), although the cellular association of pDNA was almost comparable among all vectors. α-CDE conjugate (G3) strongly interacted with a fluorescence probe, 2-(*p*-toluidinyl)-naphthalene-6-sulfonate (TNS), suggesting that the conjugate possesses the inclusion ability with biomembrane constituents such as phospholipids after transfection. These results suggest that α-CDE conjugates, particularly the G3 conjugate, could be novel nonviral gene transfer agents.

INTRODUCTION

The promising concept of gene therapy has encouraged the improvement of gene transfer techniques (*1*). At present, the following four methods may be available for gene transfer, i.e., viral vector, nonviral vector and physical (electroporation and gene gun, etc.) methods as well as naked plasmid DNA (pDNA[1]) method without vectors (*2, 3*). Nonvirus vectors have been noticed due to easy preparation of vector/pDNA complexes, low cytotoxicity, and lack of immunogeneity of vectors, but the insufficient gene transfer ability should be improved (*4, 5*). Starburst polyamidoamine (PAMAM) dendrimer (dendrimer) employed in this study is a spherical, highly ordered, dendritic polymer with positively charged primary amino groups on the surface at physiological pH (*6*) and is reported to be useful as nonviral vectors (*7*−*11*). Although the dendrimers with generations higher than 5 (G5) have sufficient gene transfer activity, cytotoxicity increases concomitantly as the generation increases due to higher positive charges (*12*).

Cyclodextrins (CyDs) are cyclic (α-1,4)-linked oligosaccharides of α-D-glucopyranose containing a hydrophobic central cavity and hydrophilic outer surface (*13*−*15*). The most common CyDs are α-, *β*-, and *γ*-CyDs, which consist of six, seven, and eight D-glucopyranose units, respectively. CyDs are known to form inclusion complexes with a variety of guest molecules in solution and in a solid state (*16, 17*). The solubilization of lipophilic compounds by CyDs has many uses in the pharmaceutical field (*18, 19*), while CyDs at higher concentrations induce hemolysis and decrease the integrity of the nasal and intestinal epithelial cells, leading to an increase in the permeability of water-soluble drugs through the membranes (*20*−*22*).

Recently, CyDs have been applied to gene transfer (*23*−*25*) and oligonucleotides delivery (*26*−*29*). Notably, Davis and his colleagues (*30, 31*) reported that of cationic *β*-CyD polymers, a water soluble *β*-CyD polymer with 6^A,6^D-dideoxy-6^A,6^D-di-(2-aminoethanethio)-*β*-CyD and dimethylsuberimidate (*β*CDP6) gave gene transfer activity much higher than Superfect and poly-L-lysine in BHK-21 and CHO-K1 with less cytotoxicity. In addition, most recently they reported that the combination of *β*CDP6 and poly(ethylene glycol) conjugate with adamantane (PEG-AD) forms stable complexes with pDNA through *β*-CyD/adamantane host/guest interactions and the ternary complex of *β*CDP6, galactosylated PEG-AD, and pDNA possesses higher transfection efficiency in hepatoma cells through receptor-mediated endocytosis (*32*).

We reported previously that gene transfer activity was significantly improved when the dendrimer (G2) conjugates with α-CyD, *β*-CyD, and *γ*-CyD were employed as vectors, where the activity was most enhanced by the α-CyD conjugate (α-CDE conjugate) almost 100 times, compared with that of dendrimer (G2) (*30*). Thus, the attachment of a molecule of α-CyD to a terminal amino group of dendrimer (G2) provoked the marked improvement of gene transfer activity, so we expected that the conjugation of α-CyD with dendrimer of higher generation would provide much more gene transfer activity. Therefore, we prepared α-CDE conjugates with dendrimers having different generations (G2, G3, and G4) and

investigated the effects of generation on physicochemical properties such as net charge, ζ-potential, particle size, pDNA degradation by DNase I, gene transfer activity, and cytotoxicity of pDNA complexes with dendrimers (pDNA/dendrimers) and α-CDE conjugates (pDNA/α-CDE conjugates). In addition, the enhancing mechanism of gene transfer activity of α-CDE conjugate (G3) was examined.

MATERIALS AND METHODS

Materials. α-CyD was donated by Nihon Shokuhin Kako (Tokyo) and recrystallized from water. Starburst PAMAM dendrimers (ethylenediamine core, G2, G3, and G4) were purchased from Aldrich Chemical (Tokyo). *p*-Toluenesulfonyl chloride was purchased from Nakarai Tesque (Kyoto, Japan). Fetal calf serum (FCS) was purchased from Nichirei (Tokyo). Dulbecco's modified Eagle's medium and RPMI1640 medium were purchased from Nissui Pharmaceuticals (Tokyo). TransFast transfection reagent, the plasmid pGL3 control vector, which contains the firefly luciferase gene under the control of the SV40 promoter (pDNA) and DNase I were obtained from Promega (Tokyo). 2-(*p*-Toluidinyl)naphthalene-6-sulfonate potassium salt (TNS) was obtained from Research Organics (Cleveland, OH). [α-^{32}P]CTP was obtained from Amersham Pharmacia Biotech (Tokyo). The purification of pDNA amplified in bacteria was carried out using QIAGEN EndoFree plasmid maxi kit (<0.1 EU/μg endotoxin). Other chemicals and solvents were of analytical reagent grade.

Preparation of α-CDE Conjugates. α-CyD was attached to a primary amino residue of dendrimers (G2, G3, and G4) according to the method of Suh et al. (*34*). Monotosyl-α-CyD was prepared according to the method of Melton et al. (*35*). The methanol solution containing dendrimer (2.6×10^{-5} mol) was added to a flask and evaporated under reduced pressure. Monotosyl-α-CyD (25 mg, 2.6×10^{-5} mol) and dimethyl sulfoxide (DMSO, 0.5 mL) were added into the flask. Under nitrogen atmosphere, the mixture was stirred at 60 °C for 24 h. α-CDE conjugates were purified by gel-filtration (TOSOH TSK-Gel HW-40S, Tokyo) and then precipitated with methanol to remove the free dendrimer. ^{1}H NMR spectra of the α-CDE conjugates were measured, and the molar ratio of dendrimer and α-CyD was calculated from the peak areas of anomeric proton of α-CyD and ethylene protons of the dendrimer. These measurements indicated that α-CyD covalently binds to the dendrimer in a molar ratio of 1:1 in α-CDE conjugates (G2, G3, and G4), as shown in Figure 1. The yields of α-CDE conjugate (G2, G3, and G4) were 18%, 15%, and 12%, respectively. α-CDE (G2) conjugate: ^{1}H NMR (500 MHz, D_2O) δ (from TMS) 5.29 and 4.96 (H1, α-CyD), 3.94−3.61 (H3, H5, H6, α-CyD), 3.60−3.33 (H2, H4, α-CyD), 3.33−3.08 (dendrimer methylene), 3.08−2.94 (dendrimer methylene), 2.94−2.60 (dendrimer methylene), 2.60−2.43 (dendrimer methylene), 2.43−2.15 (dendrimer methylene). α-CDE (G3) conjugate: ^{1}H NMR (500 MHz, D_2O) δ (from TMS) 4.93 (H1, α-CyD), 3.85−3.74 (H3, H5, H6, α-CyD), 3.53−3.38 (H2, H4, α-CyD), 3.38−3.13 (dendrimer methylene), 3.10−2.80 (dendrimer methylene), 2.80−2.54 (dendrimer methylene), 2.54−2.38 (dendrimer methylene), 2.38−2.30 (dendrimer methylene). α-CDE (G4) conjugate: ^{1}H NMR (500 MHz, D_2O) δ (from TMS) 4.92 (H1, α-CyD), 3.86−3.72 (H3, H5, H6, α-CyD), 3.52−3.36 (H2, H4, α-CyD), 3.36−3.12 (dendrimer methylene), 3.08−3.02 (dendrimer methylene), 2.95−2.49 (dendrimer methylene), 2.33−2.15 (dendrimer methylene).

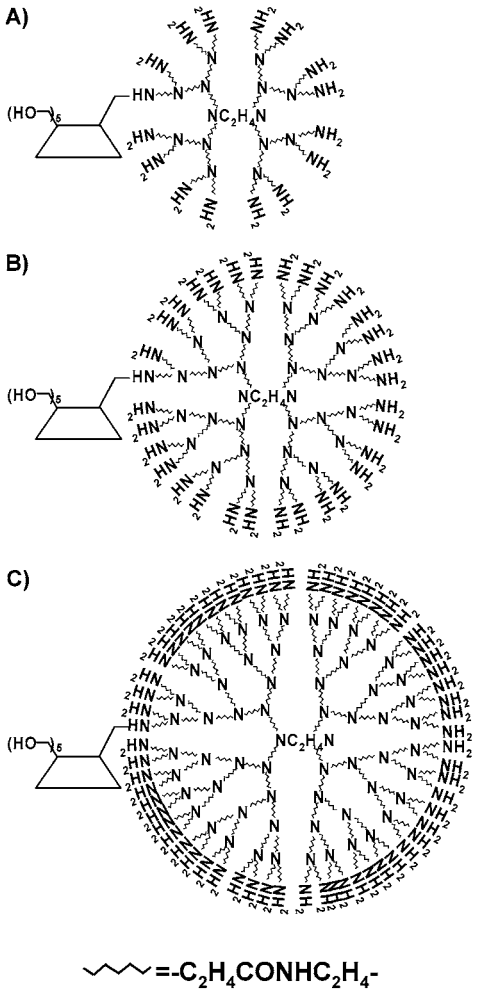

Figure 1. Chemical structures of α-CDE conjugates (G2, G3, and G4). A, α-CDE conjugates (G2); B, α-CDE conjugates (G3); C, α-CDE conjugates (G4).

Gel Electrophoresis. Electrophoretic mobility of the complexes of pDNA/dendrimers or pDNA/α-CDE conjugates was measured using a gel electrophoresis system. Various amounts of dendrimers or α-CDE conjugates were mixed with 0.2 μg of pDNA in Hanks's balanced salt solution (HBSS, pH 7.4). Gel electrophoresis was carried out at room temperature in TBE (45 mM Tris-borate, 1 mM EDTA) buffer (pH 8.0) in 1% (w/v) agarose gel (include 0.1 μg/mL ethidium bromide) using Mupid system (Cosmo Bio, Tokyo) at 100 V for 50 min. pDNA bands were visualized by an UV illuminator.

Measurements of ζ-Potential. To estimate the ζ-potential, the electrophoretic mobility of the complexes of pDNA/dendrimers or pDNA/α-CDE conjugates in HBSS (pH 7.4) was determined by an electrophoretic light scattering spectrophotometer (ELS-800, Otsuka Electronics, Osaka, Japan) at 25 °C. The dendrimers or α-CDE conjugates were added to the pDNA solution (2.5 μg/mL of pDNA) at various charge ratios.

Measurements of Particle Size. Dendrimer- or α-CDE conjugate (G2, G3, or G4)-containing solutions (0.1 mL in HBSS) at various charge ratios were added to pDNA solution (4 μg/1.5 mL in HBSS) and incubated for 15 min. Particle sizes of the complexes of pDNA/dendrimer and pDNA/α-CDE conjugates were determined by quasi-elastic (dynamic) light scattering using a Beckman Coulter N4 Plus machine (Fullerton, CA). The wavelength of the He−Ne laser used was 632.8 nm. The

measurement was carried out at a fixed angle of 62.6°, and the measuring time was 102 s at 25 °C. The measurements were carried out at least in triplicates.

DNase I Protection Assay. The complexes of pDNA (0.2 μg) with dendrimers or α-CDE conjugates were prepared as described above and then incubated for 30 min at 37 °C in the reaction buffer (pH 7.4, 10 mM Tris-HCl, 10 mM NaCl, 10 mM $CaCl_2$, 6 mM $MgCl_2$, and 2 mM DTT, 0.2 μg/mL bovine serum albumin) containing 0.1 unit/μL of DNase I. After the incubation, DNase I was inactivated by heating the solution at 70 °C for 10 min, 1 μL of EDTA (0.5 M), and 10 μL of SDS (10% w/v) were added to each sample and incubated at 37 °C for 60 min to dissociate pDNA from the complexes. After the incubation, gel electrophoresis was carried out in the same manner as described above in the gel electrophoresis section.

Cell Culture. NIH3T3 cells, a mouse fibroblast cell line, and RAW264.7 cells, a mouse macrophage-like cell line, were obtained from the Japan Health Sciences Foundation (Osaka, Japan) and the Riken Cell Bank (Tsukuba, Japan), respectively. NIH3T3 and RAW264.7 cells were grown in Dulbecco's modified Eagle's medium (include 1×10^5 mU/mL of penicillin, 0.1 mg/mL of streptomycin) and RPMI1640 medium (include 4×10^5 mU/mL of penicillin, 0.2 mg/mL of streptomycin), respectively, supplemented with 10% (v/v) FCS at 37 °C in a humidified 5% CO_2 and 95% air atmosphere.

Cytotoxicity. The cell viability was assayed by using a Cell Counting Kit (WST-1 method) from Wako Pure Chemical Industries (Osaka, Japan) (36). This method is a colorimetric assay based on the cleavage of the tetrazolium salt WST-1 by mitochondrial dehydrogenase of viable cells to a water-soluble formazan dye and is similar to MTT assay. In brief, NIH3T3 and RAW264.7 cells were seeded at 2×10^5 cells onto 35-mm dishes (Iwaki, Tokyo) and incubated for 18 h in a humidified atmosphere containing 5% CO_2 and 95% air at 37 °C. Cells were washed twice with serum free medium and then incubated for 1 h with 800 μL of serum-free medium containing pDNA or the complexes with various vectors. The culture medium (1.5 mL) supplemented with 10% (v/v) FCS was added to each well, and the cells were incubated for 24 h in a humidified atmosphere containing 5% CO_2 and 95% air at 37 °C. After washing twice with HBSS (pH 7.4) to remove pDNA and/or various vectors, 0.5 mL of fresh HBSS and 50 μL of WST-1 reagent were added to the plates and incubated for 4 h at 37 °C. The absorbance of aliquot (100 μL) of the solution was measured at 405 nm, with referring the absorbance at 630 nm, with a microplate reader (Bio-Rad Model 550, Tokyo).

Transfection. Transfection of the complexes of pDNA/dendrimers, pDNA/α-CDE conjugates, or pDNA/TransFast was performed utilizing the expression of pDNA encoding firefly luciferase gene under control of SV40 enhancer/promoters. The pDNA (2.0 μg) was mixed with dendrimers at various charge ratios. The pDNA complexes with dendrimers or α-CDE conjugates were then allowed to stand for 15 min at room temperature. The cells (2×10^5 per 35 mm culture dish) were seeded 18 h before transfection and then washed twice with serum-free medium. Eight hundred microliters of serum-free medium containing pDNA or the complexes with various vectors was added to each dish and then incubated for 1 h at 37 °C. The culture medium (1.5 mL) supplemented with 10% (v/v) FCS was added to each dish and then incubated for 24 h (total 25 h) before being harvested for analysis of the expression of the transfected pDNA. Control transfection was performed with TransFast in the same manner as described above. The charge ratio of the complex of pDNA/TransFast was 1/1, at which an optimal transfection activity was obtained under the present experimental conditions.

Measurements of Gene Expression. When pDNA encoding luciferase gene was used, after transfection for 25 h, firefly luciferase content in the cell lysate was quantified using the Promega luciferase assay reagent (Tokyo) and a luminometer (Lumat LB9506, EG&G Berthold Japan, Tokyo). Absolute light emission generated from the luciferase enzyme reaction was determined. It was confirmed that α-CyD and α-CDE conjugates have no influence on the luciferase assay under the experimental conditions. Total protein content of the supernatant was determined by BCA protein assay kit (Pierce, Rockford, IL).

Cellular Association. pDNA was labeled with [α-^{32}P]-CTP using nick translation kit II (Nippon Gene, Toyama, Japan) according to the manufacturer's protocols. [^{32}P]-labeled pDNA ([^{32}P]pDNA) was purified using QIAquick PCR purification Kit (Qiagen, Tokyo). NIH3T3 and RAW264.7 cells were cultured in 35-mm culture dish. The cells were washed twice with 1 mL of culture medium, and [^{32}P]pDNA (1 μg/mL, 5.0×10^4 cpm/μL) with or without dendrimers and α-CDE conjugates were added. After incubation at 37 °C for the indicated time, the cells were washed twice with 0.5 mL of ice-cold PBS and then solubilized with 0.5 mL of 1 N NaOH followed by incubation for 2 h. One-half milliliter of the total solution was added to Hionic-Flour (Packard Japan, Tokyo) and taken for the determination of ^{32}P radioactivity using a liquid scintillation counter (Aloka LSC-5100, Tokyo). Nonspecific binding of labeled pDNA was defined as the binding to the dishes in the absence of cells, and the extent of nonspecific binding was subtracted from that of total binding to calculate the specific binding.

Confocal Microscopic Study. Fluorescein isothiocianate (FITC)-labeled pDNA (FITC-pDNA) was prepared using Mirus label IT fluorescein labeling kit (Madison, WI). FITC-pDNA complexes with dendrimer (G3) or α-CDE conjugate (G3) at a charge ratio of 200/1 (vector/pDNA) were then allowed to stand for 15 min at room temperature. The transfection was performed as described above. After 25 h incubation, the cells were rinsed twice with 2 mL of PBS (pH 7.4) and fixed with 3.7% (v/v) formaldehyde in PBS for 40 min. Then, the cells were washed twice with 2 mL of PBS. The cells were scanned with a confocal fluorescence microscopic system (Olympus FV300−BX, Tokyo) with an argon ion laser (excitation wavelength, 488 nm).

Complexation of α-CDE Conjugates. The fluorescence spectra of TNS were measured by a Hitachi F-4500 spectrofluorometer at 25 °C. The concentration of TNS in 10 mM acetate buffer (pH 5.0) was 0.1 mM and that of dendrimer (G3), α-CyD and α-CDE conjugate (G3) was 1 mM. The excitation wavelength was 333 nm, and the fluorescence spectra were measured in the range of 350−550 nm.

Data Analysis. Data are given as means ± SEM. Statistical significance of mean coefficients was performed by analysis of variance followed by Student's *t*-test. *P* values for significance were set at 0.05.

RESULTS

Physicochemical Properties of pDNA Complexes with α-CDE Conjugates. We first studied the complex-

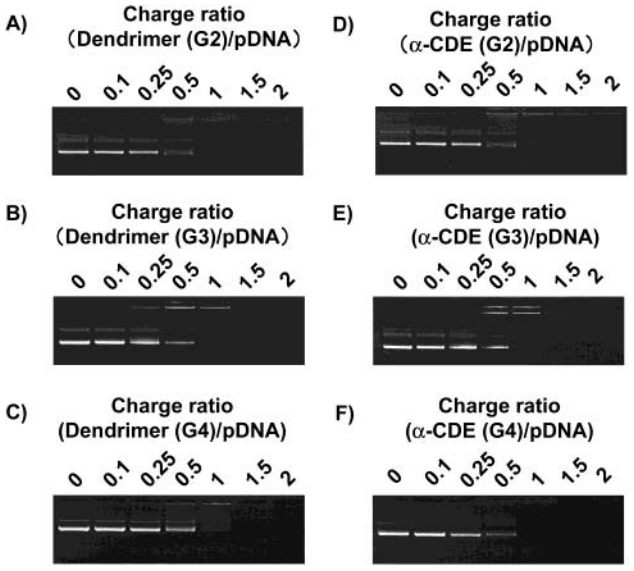

Figure 2. Agarose gel electrophoretic analysis of the complexes of pDNA/dendrimers (G2, G3, and G4) and pDNA/α-CDE conjugates (G2, G3, and G4) using TBE buffer (pH 8.0). The solutions containing the complexes of pDNA/dendrimers or pDNA/α-CDE conjugates were incubated for 15 min at room temperature after slight agitation. The electrophoresis was performed at 100 V for about 50 min. A, dendrimer (G2); B, dendrimer (G3); C, dendrimer (G4); D, α-CDE conjugate (G2); E, α-CDE conjugate (G3); F, α-CDE conjugate (G4).

ation of pDNA with dendrimers or α-CDE conjugates (G2, G3, and G4) using agarose electrophoresis. In the case of the dendrimer (G2) or α-CDE conjugate (G2), the intensity of the band corresponding to pDNA decreased as the charge ratio (vector/pDNA) increased, and the bands disappeared at the charge ratio of 1/1, as shown in Figure 2A and 2D. Similar patterns were observed in the dendrimers (G3 and G4) and α-CDE conjugates (G3 and G4) (Figure 2B, C, E, and F). The addition of parent α-CyD to pDNA solution did not change the electrophoretic band pattern of pDNA (data not shown), suggesting much less interaction of pDNA with α-CyD. These results suggest that α-CDE conjugates (G2, G3, and G4) form the complexes with pDNA in a manner similar to dendrimers (G2, G3, and G4).

ζ-potentials of pDNA complexes with dendrimers and α-CDE conjugates were measured to examine their electric property. The ζ-potential of the pDNA complexes used here increased as the charge ratio (vector/pDNA) increased, and the values were in the range of 14 to 25 mV (Figure 3A). The difference in ζ-potential value between dendrimers and α-CDE conjugates was rather small in each generation. Next, the particle sizes of the complexes of pDNA/dendrimes or pDNA/α-CDE conjugates were measured using quasi-elastic (dynamic) light scattering. As shown in Figure 3B, the particle sizes of the complex of pDNA/dendrimer (G2) or pDNA/α-CDE conjugate (G2) were not significantly affected by the charge ratio, although they decreased slightly at the charge of 1/1. In the G3 and G4 systems, the particle sizes were smallest at the charge ratio of 1/1, which was consistent with the ratio that the band disappeared (Figure 2). These results suggest that α-CDE conjugates (G3 and G4) form the most compact complexes at the charge ratio of 1/1, and at the higher charge ratios the particle sizes of these pDNA/vectors complexes were almost comparable. These results indicate that physicochemical properties of the pDNA complexes were de-

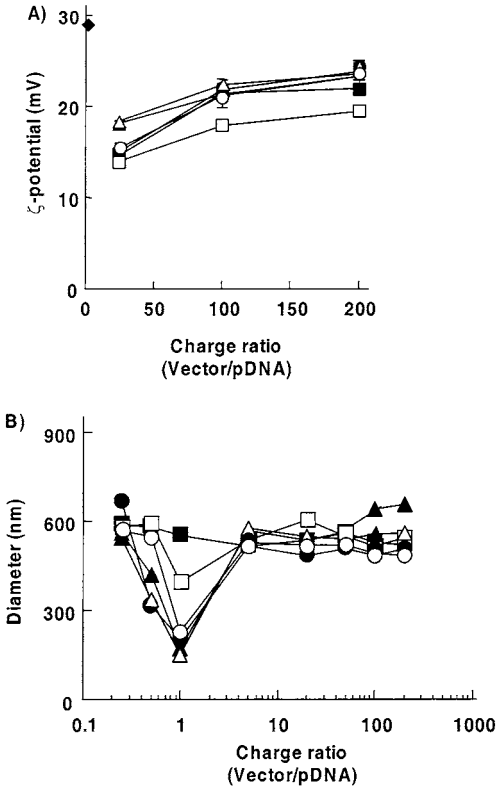

Figure 3. (A) ζ-Potential of the complexes of pDNA/dendrimers (G2, G3, and G4) and pDNA/α-CDE conjugates (G2, G3, and G4). The electrophoretic mobility of the complexes of pDNA/dendrimer or pDNA/α-CDE conjugates in HBSS (pH 7.4) was determined by electrophoretic light scattering spectrophotometer at 25 °C. The dendrimers or α-CDE conjugates were added to the pDNA solution (2.5 μg/mL of pDNA) at various charge ratios. Square, dendrimer (G2) or α-CDE conjugate (G2); circle, dendrimer (G3) or α-CDE conjugate (G3); triangle, dendrimer (G4) or α-CDE conjugate (G4); diamond, TransFast. Open and closed symbols represent dendrimers and α-CDE conjugates, respectively. (B) Particle sizes of the complexes with pDNA/dendrimers (G2, G3, and G4) or pDNA/α-CDE conjugates (G2, G3, and G4). Dendrimer- or α-CDE conjugate (G2, G3 or G4)-containing solutions (0.1 mL in HBSS) at various charge ratios were added to pDNA solution (4 μg/1.5 mL in HBSS) and incubated for 15 min. Particle sizes of the pDNA complexes with dendrimer and α-CDE conjugates were determined by quasi-elastic (dynamic) light scattering. The wavelength of the He−Ne laser used was 632.8 nm. The measurement was carried out at a fixed angle of 62.6°, and the measuring time was 102 s at 25 °C. Square, dendrimer (G2) or α-CDE conjugate (G2); circle, dendrimer (G3) or α-CDE conjugate (G3); triangle, dendrimer (G4) or α-CDE conjugate (G4). Open and closed symbols represent dendrimers and α-CDE conjugates, respectively.

pendent on the generation and the charge ratio, but there is insignificant difference in the property between the complexes of pDNA/dendrimers and pDNA/α-CDE conjugates at higher charge ratios (vector/pDNA).

DNase I Protection Assay. We tested the stabilizing effect of α-CDE conjugates (G2, G3, and G4) on pDNA degradation. The concentration of DNase I was set to 0.1 unit/μL, because the activity in human serum is 2×10^{-4}-8.2×10^{-2} unit/μL (*37*). When pDNA alone was treated with DNase I for 30 min, it degraded into smaller size fractions (data not shown). The addition of dendrimer (G2, G3, and G4) or α-CDE conjugates (G2, G3, and G4) increased the band intensity of pDNA as the charge ratio (vector/pDNA) increased in the region of higher charge ratios (Figure 4A−F). No obvious difference was observed in the protective effect between dendrimers and α-CDE conjugates. Since parent α-CyD alone possessed no protective ability against the DNase I-catalyzed degrada-

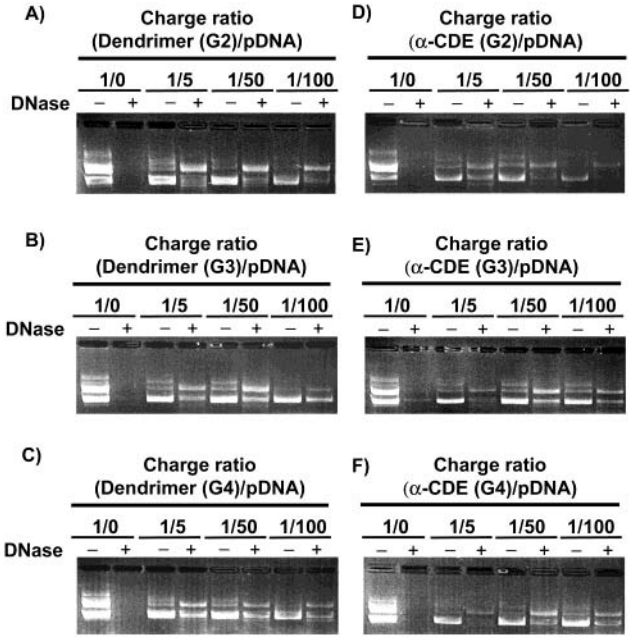

Figure 4. Effects of dendrimers (G2, G3, and G4) and α-CDE conjugates (G2, G3, and G4) on electrophoretic mobility of pDNA treated with DNase I. The complexes of pDNA/dendrimers or pDNA/CDE conjugates were incubated with 0.1 unit/mL of DNase I for 30 min. After DNase I was inactivated at 70 °C for 10 min, 1 mL each of EDTA (0.5 M) and SDS (10% w/v) were added to each sample and incubated at 37 °C for 1 h to dissociate pDNA from the complexes. After incubation, gel electrophoresis was carried out at room temperature in TBE (45 mM Tris-borate and 1 mM EDTA) buffer (pH 8.0) in 1% (w/v) agarose gel (include 0.1 mg/mL of ethidium bromide) using Mupid system at 100 V for 50 min. A, dendrimer (G2); B, dendrimer (G3); C, dendrimer (G4); D, α-CDE conjugate (G2); E, α-CDE conjugate (G3); F, α-CDE conjugate (G4).

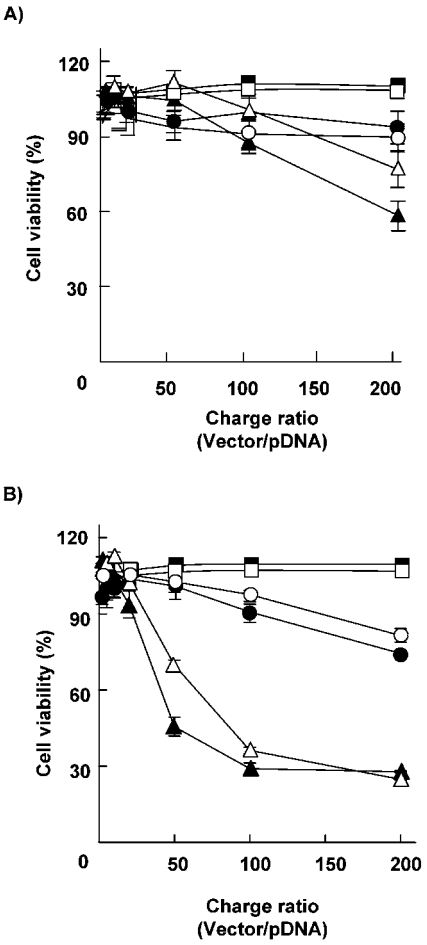

Figure 5. Cytotoxicity of the complexes of pDNA/dendrimers (G2, G3, and G4) or pDNA/α-CDE conjugates (G2, G3, and G4) at various charge ratios in NIH3T3 cells (A) and RAW264.7 cells (B). The cell viability was assayed by WST-1 method. In brief, NIH3T3 and RAW264.7 cells (2×10^5 cells) onto 35-mm dishes were incubated for 1 h after adding 800 μL of serum-free medium containing pDNA or the complexes with various vectors. The culture medium (1.5 mL) supplemented with 10% (v/v) FCS was added to each well, and the cells were incubated for 24 h at 37 °C. After washing, 0.5 mL of fresh HBSS and 50 μL of WST-1 reagent were added to the plates and incubated for 4 h at 37 °C. The absorbance of the solution at 405 nm was measured by referring the absorbance at 630 nm. Square, dendrimer (G2) or α-CDE conjugate (G2); circle, dendrimer (G3) or α-CDE conjugate (G3); triangle, dendrimer (G4) or α-CDE conjugate (G4); diamond, TransFast. Open and closed symbols represent dendrimers and α-CDE conjugates, respectively. Each value represents the mean ± SEM of 4−6 (A) or 4 (B).

tion of pDNA (data not shown), these results suggest that both dendrimers (G2, G3, and G4) and α-CDE conjugates (G2, G3, and G4) are able to protect pDNA against DNase I through the complexation at higher charge ratios (vector/pDNA).

Cytotoxicity. From the safe and potency points of view, cytotoxicity of virus and nonvirus vectors would be evaluated. Cytotoxicity of dendrimers or α-CDE conjugates (G2, G3, and G4) to NIH3T3 and RAW264.7 cells was studied using the WST-1 method (36). As shown in Figure 5A, the cytotoxicity of these vectors in NIH3T3 cells was negligible up to the charge ratio of 100/1 (vector/pDNA), but it increased as the generation increased. Likewise, an increase in the generation resulted in higher cytotoxicity in RAW264.7 cells, especially the complex of pDNA/dendrimer (G4) or pDNA/α-CDE conjugate (G4), provoked significant cytotoxicity in higher charge ratios (vector/pDNA, Figure 5B). These results indicate that the cytotoxicity of α-CDE conjugates (G2 and G3) was moderate in these cells, although α-CDE conjugate (G4) was severe at higher charge ratios (vector/pDNA), presuming that a decrease in the gene transfer activity of α-CDE conjugate (G4) in the cells, especially RAW264.7 cells (Figure 5B).

Transfection. Gene transfer activity of dendrimers (G2, G3, and G4) and α-CDE conjugates (G2, G3, and G4) was examined and compared with that of TransFast, which was employed as a positive control. Figure 6A and 6B show gene transfer activity of dendrimers and α-CDE conjugates at the charge ratio of 200/1 (vector/pDNA) in NIH3T3 cells and RAW264.7 cells, respectively. When pDNA alone was transfected in the absence and presence of α-CyD, no luciferase activity was observed (data not shown). In NIH3T3 cells, the gene transfer activity of the pDNA complexes with α-CDE conjugate (G3) was highest, followed by the activities of the complex with α-CDE conjugate (G4) > dendrimer (G3) > dendrimer (G4) > α-CDE conjugate (G2) ≫ dendrimer (G2) in a deceasing order. In addition, the gene transfer activity of α-CDE conjugate (G3) was higher than approximately 20 and 2 times than that of α-CDE conjugate (G2) and α-CDE conjugate (G4), respectively, and was comparable with that of TransFast in NIH3T3 cells. On the other hand, in RAW264 cells, the greatest gene transfer activity was elicited by the pDNA complexes with α-CDE conjugate (G3), followed in a decreasing order by the complex with α-CDE conjugate (G2) > dendrimer (G3) > dendrimer (G2) > dendrimer (G4) ≥ α-CDE conjugate (G4). These results indicate that of the vectors used here, α-CDE conjugate (G3) possesses highest gene transfer activity

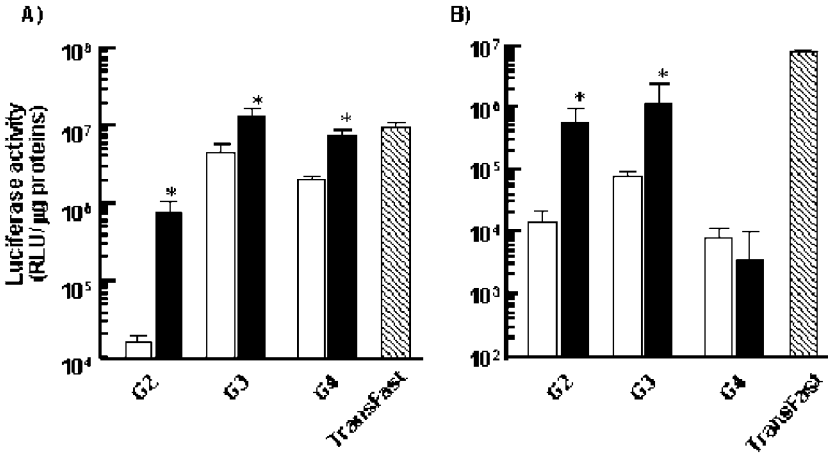

Figure 6. Transfection efficiency of the complexes of pDNA/dendrimers (G2, G3, and G4) or pDNA/α-CDE conjugates (G2, G3, and G4) at the charge ratio of 200/1 (vector/pDNA) in NIH3T3 cells (A) and RAW264.7 cells (B). The luciferase activity in cell lysates was determined 25 h after incubation with pDNA alone or various complexes. The charge ratio of pDNA and TransFast is 1/1. Open, closed and hatched columns represent the complexes of pDNA/dendrimer, pDNA/α-CDE conjugate and pDNA/TransFast. Each value represents the mean ± SEM of 4−6 (A) or 4 (B). *$p < 0.05$, compared with dendrimer alone.

in NIH3T3 and RAW264.7 cells. Figure 7A and 7B show the charge ratios of the complexes on gene transfer activity of dendrimers and α-CDE conjugates in NIH3T3 cells and RAW264.7 cells, respectively. In NIH3T3 cells, the transfection efficiency of all dendrimers and α-CDE conjugates employed increased as the charge ratio (vector/pDNA) increased in the region of lower ratios, and especially α-CDE conjugates possessed higher gene transfer activity than the corresponding dendrimer alone. Thus, α-CDE conjugate (G3) conferred the greatest transfection activity in the charge ratios of 5/1−200/1 (vector/pDNA). As shown in Figure 7B, the transfection efficiency of the complexes of pDNA/α-CDE conjugates (G2 and G3) gradually increased as the charge ratio (vector/pDNA) increased in RAW264.7 cells. The transfection efficiency of the complexes of pDNA/dendrimer (G4) and pDNA/α-CDE conjugate (G4) significantly decreased as the charge ratio increased more than 50/1 (vector/pDNA), although the efficiency of the complex of pDNA/α-CDE conjugate (G4) was higher than that of pDNA/α-CDE conjugates (G2 and G3) at lower charge ratios (vector/pDNA). Thus, low gene transfer activity of the pDNA complexes with dendrimers or α-CDE conjugates may be due to the cytotoxicity to NIH3T3 cells (Figure 5). These results clearly indicate that α-CDE conjugate (G3) possesses preferable gene transfer activity among the dendrimers and α-CDE conjugates used here.

CyDs are known to induce hemolysis and enhance the permeation of water-soluble drugs through biological membranes via the release of membrane components such as phospholipids and cholesterol as described above (*21, 22*). This fact allows us to deduce that α-CyD enhances gene transfer activity through membrane-permeability of pDNA/α-CDE conjugates. To confirm this possibility, we examined the effects of physical mixture of α-CyD and the pDNA complexes with dendrimers (G3 and G4) at various charge ratios in the gene transfer. As a result, there is no difference in the gene transfer activity in NIH3T3 and RAW264.7 cells between the pDNA complex with dendrimer (G3 or G4) and the simple physical mixture of the pDNA/dendrimer complex and α-CyD (data not shown). The same results were conferred in dendrimer (G2) and α-CDE conjugate (G2) (*33*). Therefore, the conjugation of dendrimers with α-CyD is crucial for the gene transfer activity.

Cellular Association of pDNA. We previously reported that the enhancing effect of α-CDE conjugate (G2) relative to dendrimer (G2) could not be attributed to the increased cellular association of pDNA. To test whether α-CDE conjugates (G3 and G4) increase the association of pDNA, we measured the extent of pDNA associating to cells using [^{32}P]pDNA. The association of pDNA to the NIH3T3 (Figure 8A) and RAW264.7 (Figure 8B) cells increased as the charge ratio increased up to 5/1 (vector/pDNA), and above the ratio the association showed a plateau in all of the complexes of pDNA/dendrimers and pDNA/α-CDE conjugates. Here α-CyD showed no influence on the cellular association of pDNA under the present experimental conditions (data not shown), suggesting that α-CyD perturbs the integrity of plasma membrane of cells only very slightly. These results suggest that α-CDE conjugate (G3) may decrease the physical barrier function such as endosomal and nuclear membranes more efficiently than α-CDE conjugate (G2).

Intracellular Distribution of pDNA. Cellular uptake of pDNA and its release from endosomes are necessary for gene expression of pDNA (*38*). Thus, the intracellular distribution of pDNA was observed using FITC-pDNA under confocal laser microscopy. Figure 9A and 9B show the results 25 h after transfection of the complexes of pDNA/dendrimer (G3) and pDNA/α-CDE conjugate (G3) in NIH3T3 cells. The complex of pDNA/α-CDE conjugate (G3) provided higher fluorescence intensity in cytoplasm than that of pDNA/dendrimer (G3), whereas there was no fluorescence in the cells when pDNA alone was applied (data not shown). These results suggest that α-CDE conjugate (G3) changes the distribution of pDNA in the cells, possibly in terms of increase in the release of pDNA from the endosomes into cytoplasm after endocytosis.

Inclusion Ability of α-CDE Conjugate (G3). It is possible that α-CDE conjugate (G3) may interact with membrane constituents. However, the ability of inclusion complexation of α-CDE conjugates still remains unclear. Thus, we examined the ability of inclusion complexation of α-CDE conjugate (G3) spectrophotometrically. Here we used a fluorescent guest molecule, TNS, because the inclusion of TNS into hydrophobic environment such as the α-CyD's cavity is known to induce prominent fluorescence. As shown in Figure 10, the addition of dendrimer (G3) to TNS solution induced fluorescence corresponding to TNS, and the fluorescence intensity was increased by the addition of α-CyD. Importantly, α-CDE conjugate (G3) increased the fluorescent intensity re-

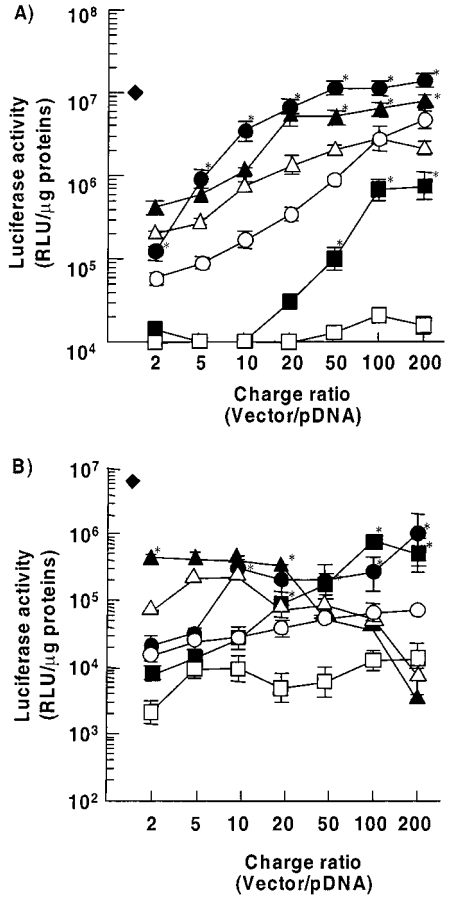

Figure 7. Transfection efficiency of the complexes of pDNA/dendrimers (G2, G3, and G4) or pDNA/α-CDE conjugates (G2, G3, and G4) at the charge ratios of 200/1 (vector/pDNA) in NIH3T3 cells (A) and RAW264.7 cells (B). The luciferase activity in cell lysates was determined 25 h after incubation with pDNA alone or various complexes. The charge ratio of pDNA and TransFast is 1/1. Square, dendrimer (G2) or α-CDE conjugate (G2); circle, dendrimer (G3) or α-CDE conjugate (G3); triangle, dendrimer (G4) or α-CDE conjugate (G4). Open and closed symbols represent the complex of pDNA/dendrimer and the complex of pDNA/α-CDE conjugate, respectively. Each value represents the mean ± SEM of 4−6 (A) or 4 (B). $*p < 0.05$, compared with dendrimer alone.

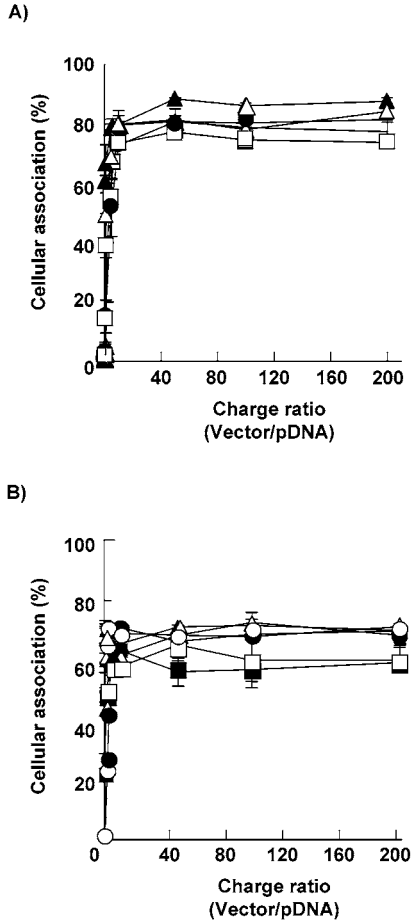

Figure 8. Cellular associations of [α-^{32}P] labeled pDNA at various charge ratios in NIH3T3 cells (A) and RAW264.7 cells (B). Square, dendrimer (G2) or α-CDE conjugate (G2); circle, dendrimer (G3) or α-CDE conjugate (G3); triangle, dendrimer (G4) or α-CDE conjugate (G4). Open and closed symbols represent dendrimer and α-CDE conjugate, respectively. Each value represents the mean ± SEM of 4. $*p < 0.05$, compared with dendrimer alone.

markably, compared with that of the dendrimer (G3) system. These results suggest that α-CDE conjugate (G3) possesses the inclusion ability of guest molecules into the cavity of α-CyD and thus it may interact with constituents of endosomal membranes such as phospholipids after endocytosis.

DISCUSSION

We previously reported that of three CDE conjugates in which α-, β-, and γ-CyD covalently bound to dendrimer (G2) at a molar ratio of 1:1, α-CDE conjugate (G2) possesses the highest transfection activity (33). To improve the efficacy, we prepared three α-CDE conjugates (G2, G3, and G4) with different generation of dendrimers, and their interaction with pDNA, the protective effect of pDNA against DNase I, the gene transfer activity, and the cytotoxicity were examined. Consequently, we clarified that α-CDE conjugate (G3) possesses the greatest gene transfer activity with lower cytotoxicity.

Cationic polymer-mediated transfection should overcome three major barriers for transfection: (1) binding of pDNA to cell surface, (2) endosomal release, and (3) entry of pDNA into the nucleus (*39*). Likewise, the physicochemical properties of polyplex such as net charge and particle size markedly affect these barriers, eventually changing transfection efficiency (*36*). In the present study, the complexes of pDNA/α-CDE conjugates (G2, G3, and G4) showed gel mobility rates (Figure 2) and ζ-potentials (Figure 3A) similar to those of pDNA/dendrimers (G2, G3, and G4) at the higher charge ratios (vector/pDNA). This similarity could be attributed to the two reasons: (1) the structure of α-CDE conjugate and (2) a lack of interaction between α-CyD and pDNA, and α-CyD and the pDNA complexes with dendrimers. The first reason may be explained by the fact that only a molecule of α-CyD binds to an amino group of dendrimers, thereby many intact positively charged amino groups still remains on the surface of these molecules. Second reason may be showed the following data: the addition of α-CyD to the solution containing pDNA or the complex of pDNA/dendrimer (G2, G3, or G4) did not affect their gel mobility rates (data not shown), indicating that α-CyD interacts with pDNA and their complexes only very slightly. Furthermore, a parallel of physicochemical properties between the pDNA complexes with dendrimers and α-CDE conjugate at higher charge ratio may be due to the relatively larger and complicated structure of the complexes because the calculated molar ratio (vector and pDNA) of the pDNA complexes with α-CDE conjugates (G2, G3, and G4) are 701, 339, and 167 in the complexes with α-CDE conjugates (G2, G3, and G4), respectively, even at the charge ratio of 1/1. Therefore, α-CyD changed

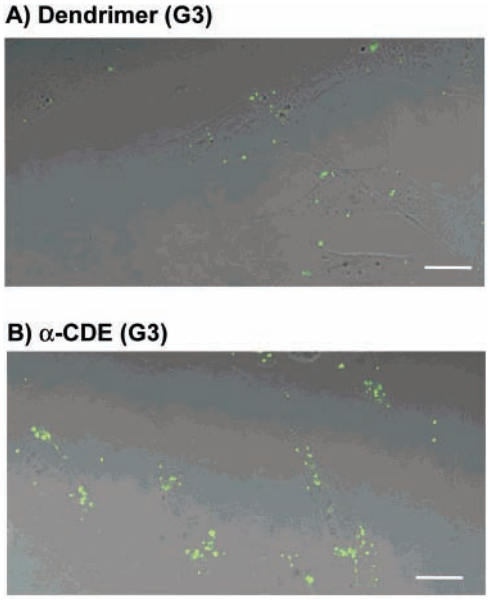

Figure 9. Confocal laser microscopic images for the distribution of FITC-pDNA in NIH3T3 cells after transfection of the complexes of pDNA/dendrimer (G3) (A) and pDNA/α-CDE conjugate (G3) (B). The cells were incubated with the pDNA complexes for 25 h at 37 °C. The charge ratio (vector/pDNA) of the complexes of pDNA/dendrimer (G3) and of pDNA/α-CDE conjugate (G3) was 200/1. Scale bars represent 20 μm. The images shown are typical among similar ones in the several visual fields.

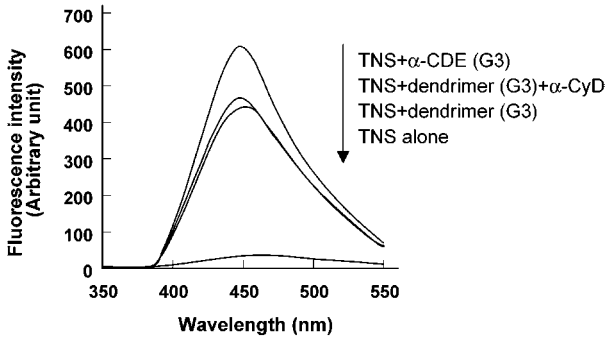

Figure 10. Fluorescence spectra of TNS in the absence and presence of dendrimer (G3) or α-CDE conjugate (G3). The fluorescent spectra of TNS were measured at 25 °C. The concentrations of TNS, dendrimer, α-CyD and α-CDE conjugate (G3) in 10 mM acetate buffer (pH 5.0) were 0.1 mM, 1 mM, 1 mM, and 1 mM, respectively. The excitation wavelength was 333 nm and the fluorescence spectra were measured in the range of 350−550 nm.

the intricate structure of the pDNA complex only very slightly. Thus, physicochemical properties of the pDNA complexes with α-CDE conjugates were changed in the generation-dependent manner, because the number of primary amino groups increases as the generation increases (Figures 2 and 3).

It is evident that the stability against enzymatic degradation of pDNA influences gene transfer activity. The DNase I protection assay demonstrated that pDNA is protected from DNase I by the complexation with dendrimers and α-CDE conjugates, and the protective effects were almost identical between dendrimers and α-CDE conjugates regardless of their generation, up to the charge ratio of 100/1 (vector/pDNA, Figure 4). The stabilizing effect of dendrimers and α-CDE conjugates on pDNA degradation could be concerned with gene transfer into the cells under the experimental conditions. However, the stabilizing effect of dendrimer (G2) and α-CDE conjugate (G2) on the degradation of pDNA in our previous paper (*33*) seems to be somewhat different from the present data: dendrimer (G2) and α-CDE conjugate (G2) prevented the disappearance of the bands by the charge ratio of 20/1 (vector/pDNA), but above the ratios the bands vanished. This inconsistency may be due to difference in the experimental conditions, i.e., the concentration of SDS used for dissociation of pDNA from the vectors in the complexes were 3.8% (w/v) and 4.8% (w/v) in the previous and present studies, respectively. Taken together, the physicochemical properties such as gel mobility shift, ζ-potential, particle size, and enzymatic stability of the complexes of pDNA/dendrimers and pDNA/α-CDE conjugates (G2, G3, and G4) were almost comparable, at least, at the higher charge ratios (vector/pDNA).

Gene transfer activity of dendrimers augmented in the order of G2 < G3 < G4 at the lower charge ratios (Figure 7), probably due to an increase in the proton sponge effect in endosomes (*8*). However, the transfection efficiency of dendrimer (G4) significantly attenuated at the higher charge ratios (vector/pDNA, Figures 6 and 7). This attenuation is certainly due to cytotoxicity (Figure 5), consistent with the results reported by Roberts et al., i.e., the cytotoxicity of dendrimers (G3, G5, and G7) to Chinese hamster lung fibroblasts increased as the generation increased (*40*). The similar patterns of gene transfer activity and cytotoxicity were also observed in the α-CDE conjugate system. The severe cytotoxicity of the pDNA complexes with dendrimer (G4) and α-CDE conjugate (G4) observed in RAW264.7 cells may be due to the distinction in the cellular sensitivity to positively charged amino groups.

It is of importance that of the three α-CDE conjugates used in this study, gene transfer activity of α-CDE conjugate (G3) was the highest. The superior enhancing effect of α-CDE conjugate (G3) to dendrimer (G3) on gene transfer was observed at various times (4, 6, 12, and 25 h) after transfection in NIH3T3 cells. This greatest gene transfer activity could be attributed to the synergistic effects of the proton sponge effect of dendrimer (G3) and the tentative membrane-disrupting effect of α-CyD on endosomal membranes (Figures 9 and 10) because α-CDE conjugate (G3) possesses inclusion ability with a guest molecule, TNS (Figure 10). In addition, the inclusion ability of α-CDE conjugate (G3) with lipids was confirmed by our preliminary experiments: α-CDE conjugate (G3) is able to disrupt liposomal membranes consisting of phospholipids in vitro (data not shown). Thus, it is noteworthy that the introduction of an α-CyD molecule to dendrimer augmented the gene transfer activity of dendrimer (G2 and G3) than the parent dendrimers, showing no increase in cytotoxicity. Moreover, it should be noted that α-CDE conjugate (G3) possessed the comparable gene transfer activity to TransFast in NIH3T3 cells (Figure 6A).

In conclusion, gene transfer activity of α-CDE conjugate (G3) was higher than that of dendrimers (G2, G3, and G4) and α-CDE conjugate (G2), and cytotoxicity of α-CDE conjugate (G3) was lower than that of α-CDE conjugate (G4). Therefore α-CDE conjugate (G3) may be a potent candidate for nonviral vectors. The present data may be useful for design of α-CyD conjugates with other nonviral vectors.

In this study, a novel lipid vector has been developed for targeted delivery of oligodeoxynucleotides (ODN) to tumors that overexpress folate receptor. This is based on a method developed by Semple et al. (*1*), which utilizes an ionizable aminolipid (1,2-dioleoyl-3-(dimethylammonio)propane, DODAP) and an ethanol-containing buffer system for encapsulating large quantities of polyanionic ODN in lipid vesicles. Folate is incorporated into the lipid vesicles via a distearoylphosphatidylethanolamine−poly(ethylene glycol) (DSPE−PEG) spacer. These vesicles are around 100−200 nm in diameter with an ODN entrapment efficiency of 60−80%. Folate mediated efficient delivery of ODN to KB cells that overexpress folate receptor. Uptake of folate-targeted lipidic ODN by KB cells is about 8−10-fold more efficient than that of lipidic ODN without a ligand or free ODN. This formulation is resistant to serum. Thus, targeted delivery of ODN via this novel lipid vector may have potential in treating tumors that overexpress folate receptors.

INTRODUCTION

Functional oligodeoxynucleotides (ODN) such as antisense ODN and DNA enzymes hold promise as new therapeutics for the treatment of various types of diseases such as cancers (*2*, *3*). A number of studies have suggested the existence of ODN receptors on the cell surface (*4*, *5*). However, intracellular delivery of ODN without a delivery vehicle is generally inefficient. Successful application of therapeutic ODN is largely dependent on the development of a vehicle that selectively delivers the ODN into target cells with minimal toxicity. A number of vectors have been developed to improve the intracellular delivery of ODN such as neutral liposomes (*6*) and cationic liposomes (*7*, *8*). ODN can be entrapped inside neutral liposomes. The liposomes can also be designed such that they are long-circulating in the blood and target cell-specific. However, the size of liposomes required for achieving long circulation in the blood and efficient localization is too small for efficient entrapment of ODN. Cationic liposomes readily form complexes with ODN through electrostatic interactions. Almost 100% of ODN can be recovered in complex form. The resulting complexes usually contain slight excess amount of positive charges that allows efficient interaction with the negatively charged cell membrane. A number of cationic liposomes have been developed that significantly enhance the intracellular delivery of ODN. ODN complexed with cationic liposomes exhibit biological activity up to 1000-fold higher than ODN alone (*7*, *8*). However, targeted delivery of ODN to solid tumors via systemic administration remains problematic, although we have shown that cationic liposomes mediate efficient delivery of ODN to pulmonary endothelium (*9*). Recently, a novel lipid formulation has been developed (*1*) that appears to avoid the problems that are associated with each of the formulations discussed above. This formulation is composed of distearoylphosphatidylcholine (DSPC), cholesterol, DODAP, and *N*-palmitoylsphingosine-1-[succinyl(methoxypoly(ethylene glycol))2000] (PEG-CerC_{16}). DODAP is an ionizable cationic lipid that has a p*K* of 6.6 in lipid bilayer systems. At acidic pH values (i.e. pH 4.0), this lipid is positively charged and helps to improve the ODN entrapment via electrostatic interactions. DODAP/ODN complexes can interact with other lipids in an ethanol-containing buffer, and ODN-containing lipid vesicles are formed upon the removal of the ethanol by dialysis. Subsequent adjustment of the external pH to neutral pH values results in a neutral surface charge on the resulting particles. This method led to a significant increase in ODN entrapment efficiency (60−80%) with a final lipid/ODN ratio of 0.15−0.25 (w/w) (*1*). This formulation has also been shown to be long circulating in the blood following systemic administration (*1*). In this study, we have shown that this formulation can be further improved via the incorporation of a targeting ligand, folate. Folate-targeted vesicles are much more efficient than the nontargeted vectors in delivering ODN to KB cells. This improved formulation may have potential for the targeted delivery of therapeutic oligonucleotides to tumors that overexpress folate receptors.

EXPERIMENTAL PROCEDURES

Lipids and Chemicals. Distearoylphosphatidylcholine (DSPC), *N*-palmitoylsphingosine-1-[succinyl(methoxypoly(ethylene glycol))2000] (PEG-CerC_{16}), and 1,2-dioleoyl-3-(dimethylammonio)propane (DODAP) were obtained from Avanti Polar Lipids, Inc. (Alabaster, AL). Folic acid

and cholesterol (CH) were purchased from Sigma-Aldrich. All lipids were >99% pure. Folate-free RPMI 1640 medium, F12 medium, and other tissue culture reagents were purchased from Gibco-BRL (Grand Island, NY). Folate−poly(ethylene glycol) (MW ∼ 3350 or 2000 Da)−distearoyl phosphatidylethanolamine (folate−PEG−DSPE) was synthesized as described previously (10). The final folate−PEG−DSPE product was purified on a column of silica gel (70−200 mesh) using a solvent gradient of 15 to 80% methanol in CH_2Cl_2. Product purity was confirmed by thin-layer chromatography analysis on silica gel GF.

Antisense ODN. All ODN were synthesized with phosphorothioate (PS) backbone chemistry (the Midland Certified Reagent Company, Midland, TX). The sequences of ODN used in this study are shown in Table 1.

Preparation of ODN-Containing Lipid Vesicles. ODN-containing lipid vesicles were prepared according to the method described by Semple et al. (*1*) except that folate−PEG−DSPE was added when preparing the folate-targeted lipid vesicles. Briefly, a lipid solution composed of DSPC, cholesterol, DODAP, and PEG-CerC_{16} in 100% ethanol at indicated molar ratios (Figures 1−7) was prepared. For preparation of folate-targeted lipid vesicles, various amounts of folate−PEG−DSPE were added. To the lipid solution was then added 300 mM citric acid, pH 4.0 to a final ethanol concentration of 40% (v/v). Similarly, ODN were prepared in separate tubes in 300 mM citric acid, pH 4.0, with 40% ethanol. The solutions were prewarmed to 65 °C, and then the lipid solution was slowly added to the ODN with gentle vortexing. The input ratio was 150 μg ODN/μmol lipid. The mixture was passed 10 times through three stacked 100 nm polycarbonate filters. The preparation was dialyzed (12−14 kDa cutoff) against 300 mM citrate buffer, pH 4.0, for approximately 1 h to remove excess ethanol and further dialyzed against HBS (20 mM HEPES, 145 mM NaCl, pH 7.6) for 12−18 h to remove the citrate buffer, neutralize the DODAP, and release any ODN that was associated with the surface of the vesicles. ODN-containing lipid vesicles were finally separated from free ODN via gel filtration on a Sepharose CL-4B column (1 cm × 25 cm).

Cells and Medium. KB human cancer cells, derived from an epidermal carcinoma of the oral cavity, were obtained from American Type Culture Collection (ATCC). The cells were maintained in folate-free RPMI 1640 medium supplemented with 100 units/mL penicillin, 100 g/mL streptomycin, and 10% fetal bovine serum, which provides the only source of folate (the final folate concentration in the serum-supplemented medium was approximately physiological). The cells were cultured as a monolayer in a humidified atmosphere containing 5% CO_2 at 37 °C. CHO cells were obtained from ATCC and cultured in F12 medium supplemented with 10% fetal calf serum.

Uptake of ODN by KB and CHO Cells. Cells were seeded to a 24-well plate at a cell density of 2.5×10^4/well and allowed to grow overnight. ODN, free or encapsulated in lipid vesicles, were added to the cells in various concentrations [determined according to a carbocyanine dye (Cy3)-labeled ODN]. Following incubation at 37 °C for 1 h, cells were washed with PBS (3 × 3 min). Cells were lysed using a lysis buffer (0.1% Triton X in 100 mM Tris, 2 mM EDTA, pH 7.6). The lysed cells were centrifuged at 14000 rpm for 10 min at 4 °C. The amount of Cy3-labeled ODN in the supernatant was determined by examining its fluorescence intensity on a LS50B Perkin-Elmer Luminescence Spectrometer. The protein content of the supernatant was measured with Bio-Rad protein assay system (Bio-Rad, Hercules, CA). The result of ODN uptake was expressed as the pg Cy3-labeled ODN/μg protein.

Fluorescence Microscopic Examination of Cellular Uptake of Folate-Targeted Lipidic ODN. KB cells were seeded at a density of 1×10^5 cells/well in a 4-well Nalge Nunc Lab-Tek chamber slide (Naperville, IL) and kept overnight at 37 °C. ODN, free or formulated in lipid vesicles with or without a folate ligand, were added at a Cy3-ODN concentration of 100 ng/mL. In one well, free folate was added to the folate-targeted lipidic ODN at a final concentration of 1 mM. One hour following the incubation at 37 °C cells were washed three times with PBS. Cells were then fixed with 2% paraformaldehyde at 37 °C for 20 min and further washed three times with PBS. Cellular uptake of Cy3-labeled ODN was examined under a Nikon Eclipse TE 300 fluorescence microscope with a blue filter at 200× magnification.

RESULTS

Preparation and Characterization of Folate-Targeted, ODN-Containing Lipid Vesicles. Cy3-labeled ODN were used as a label for quantification of ODN encapsulation efficiency and for following the cellular uptake of ODN-containing lipid vesicles. Cy3-labeled ODN were mixed with unlabeled ODN at a 1:9 ratio (w/w). ODN were first mixed with a lipid solution composed of DSPC, cholesterol, DODAP, PEG-CerC_{16}, and folate−PEG−DSPE under an acidic condition in the presence of 40% ethanol. DODAP/ODN complexes and other lipids were then self-assembled to form ODN-containing lipid vesicles during the dialysis against 300 mM citrate buffer, pH 4.0, and then against HBS (20 mM HEPES, 145 mM NaCl, pH 7.6). Figure 1 shows the profile of separation of the mixture on Sepharose CL-4B. The lipid-associated ODN were well separated from free ODN. The size of the ODN-containing vesicles ranges from 100 to 200 nm with 60−80% of input ODN being associated with the lipid vectors. These vesicles carry a negative charge surface as confirmed by Zeta potential analysis (data not shown). The ODN that were associated with lipid vesicles were fully protected from degradation by nuclease, suggesting that ODN were encapsulated inside the lipid vesicles (data not shown). These studies were performed with six different ODN ranging from 15 to 23 mer in length (Table 1), and similar results were obtained.

Effect of the Amount of Folate−PEG−DSPE on the Cellular Uptake of Folate-Targeted Lipidic ODN. Figure 2 shows the cellular uptake of lipidic ODN by KB cells with increasing amount of input folate−PEG−DSPE. The total amount of lipid-derivatized PEG (folate−PEG−DSPE plus PEG-CerC_{16}) added is 2 mol %. Increasing the amount of folate from 0.1 to 0.5 mol % resulted in a significant increase in the cellular uptake of ODN. Increasing the input folate beyond 0.5 mol % was not associated with a further increase in the cellular uptake of ODN.

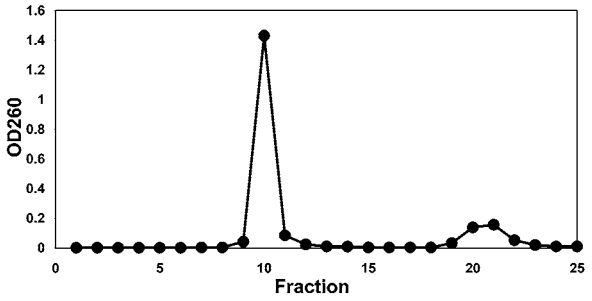

Figure 1. Size-exclusion chromatographic fractionation of ODN-containing lipid vesicles on a Sepharose CL-4B column. DSPC, cholesterol, DODAP, PEG-CerC_{16}, and folate−PEG−DSPE were individually dissolved in ethanol and mixed in a molar ratio of 25/45/25/4/1. To the lipid solution was added 300 mM citric acid, pH 4.0, to a final ethanol concentration of 40% (v/v). Similarly ODN were prepared in separate tubes in 300 mM citric acid, pH 4.0, with 40% ethanol. The solutions were prewarmed to 65 °C, and the lipids were slowly added to the ODN with gentle vortexing. The mixture was passed 10 times through three stacked 100 nm polycarbonate filters. The preparation was dialyzed (12−14 kDa cutoff) against 300 mM citrate buffer, pH 4.0, for approximately 1 h to remove excess ethanol and further dialyzed against HBS (20 mM HEPES, 145 mM NaCl, pH 7.6) for 12−18 h. The dialyzed solution (0.5 mL) was loaded on to a Sepharose CL-4B column (1 cm × 25 cm), which had been equilibrated with HEPES (pH7.6). Lipidic ODN and free ODN were collected with 1 mL in each fraction and examined for their absorbance at 260 nm.

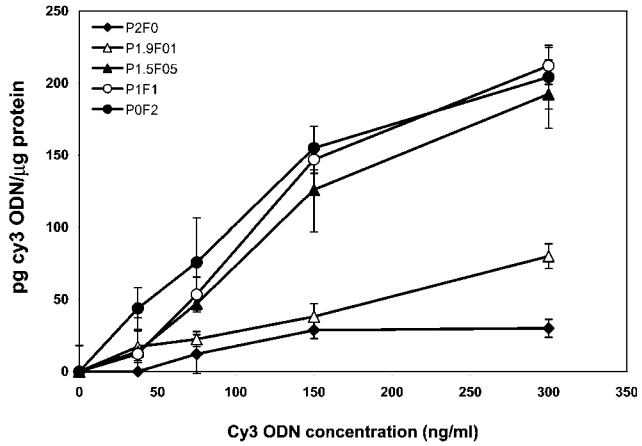

Figure 2. Effect of the amount of folate-PEG-DSPE on the cellular uptake of folate-targeted lipidic ODN. ODN-containing lipid vesicles were prepared as described in the legend to Figure 1 with various amounts of input folate−PEG−DSPE. The total amount of PEG added in the lipid mixture is 2 mol %. KB cells were seeded to a 24-well plate at a cell density of 2.5×10^4/well and allowed to grow overnight. Lipidic ODN were added to the cells in various concentrations (determined according to the Cy3-labeled ODN). Following incubation at 37 °C for 1 h, cells were washed with PBS and then lysed using a lysis buffer. The lysed cells were centrifuged at 14000*g* for 10 min at 4 °C. The amount of Cy3-labeled ODN in the supernatant was determined by examining its fluorescence intensity on a fluorometer. The protein content of the supernatant was measured with Bio-Rad protein assay system. The result of ODN uptake was expressed as the pg Cy3-labeled ODN/μg protein. The *x* and *y* in PxFy (Figures 2, 3, and 5) represent the mol % of PEG-Cer16 and folate−PEG−DSPE in the lipid vesicles, respectively. $n = 3$.

Effect of the Amount of Ceramide-Derivatized PEG on the Cellular Uptake of Folate-Targeted Lipidic ODN. Figure 3 shows the effect of the amount of input ceramide-derivatized PEG on the cellular uptake of folate-targeted lipidic ODN. The amount of input folate−PEG−DSPE is 0.1 (Panel A) or 1 mol % (Panel B). Increasing the amount of ceramide-derivatized PEG from 0 to 10 mol % resulted in a significant decrease in the cellular uptake of ODN when 0.1 mol % of folate−PEG−DSPE was used (Panel A). However, such an inhibitory effect was diminished when the amount of input folate−PEG−DSPE was increased to 1 mol % (Panel B).

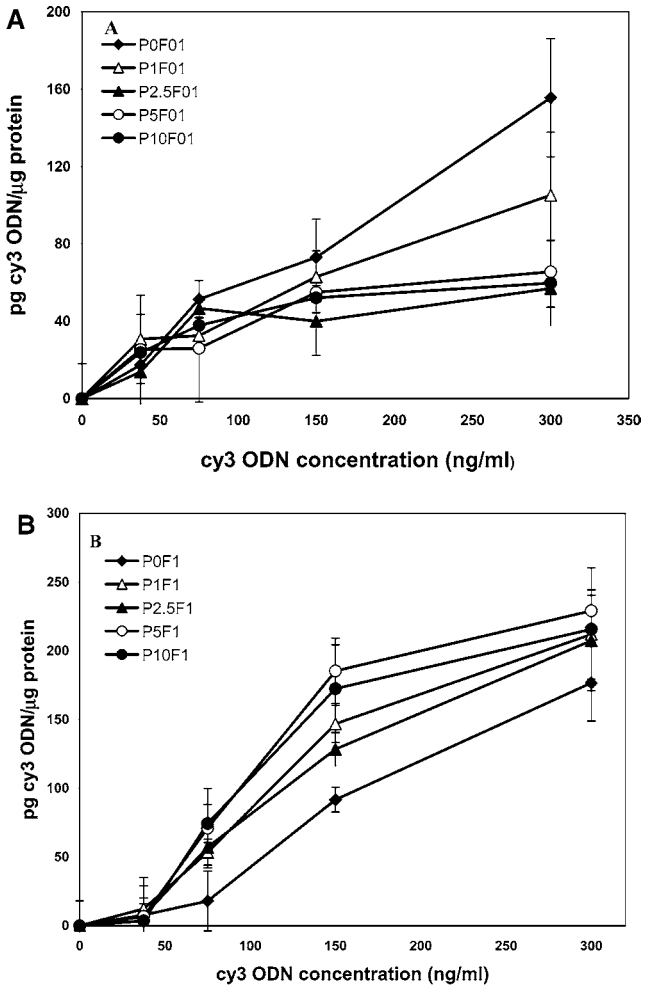

Figure 3. Effect of the amount of ceramide-PEG on the cellular uptake of folate-targeted lipidic ODN. ODN-containing lipid vesicles were prepared as described in the legend to Figure 1 with various amounts of input ceramide-PEG. The amount of input folate−PEG−DSPE was 0.1 mol % (Panel A) or 1 mol % (Panel B). Various amounts of ODN were added to KB cells and the cellular uptake of ODN was evaluated as described in the legend to Figure 2. $n = 3$.

Effect of PEG Length on the Cellular Uptake of Lipidic ODN. Previous studies have shown that folate-mediated targeting of liposomes is affected by the length of PEG spacer between folate and the lipid anchor (such as DSPE in this study) (*10*, *11*). Similar results were observed in this study with ODN targeting using our new lipidic vector (Figure 4). Folate with a PEG of 3500 Da appeared to be more efficient than that with a PEG of 2000 Da in mediating the targeting of ODN to KB cells. This difference became more dramatic with increasing amounts of ceramide−PEG (data not shown).

Cellular Uptake of Folate-Conjugated, Lipidic ODN is Mediated by Folate Receptors. To demonstrate whether the cellular uptake of folate-conjugated, lipidic ODN is mediated by folate receptor, their uptake was also examined on CHO cells, which have a low level of folate receptors (Figure 5). As shown in Panel A, coupling of folate to lipidic ODN led to a significant increase in the cellular uptake by KB cells. The level of ODN uptake was about 8−10-fold higher for folate-

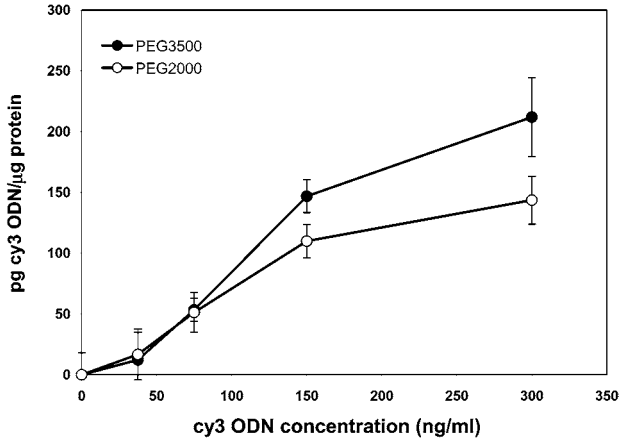

Figure 4. Effect of PEG length on the cellular uptake of lipidic ODN. Lipidic ODN were prepared as described in the legend to Figure 1. The molecular weight of PEG in folate−PEG−DSPE was 2000 or 3500 Da. Various amounts of ODN were added to KB cells and the cellular uptake of ODN was evaluated as described in the legend to Figure 2. $n = 3$.

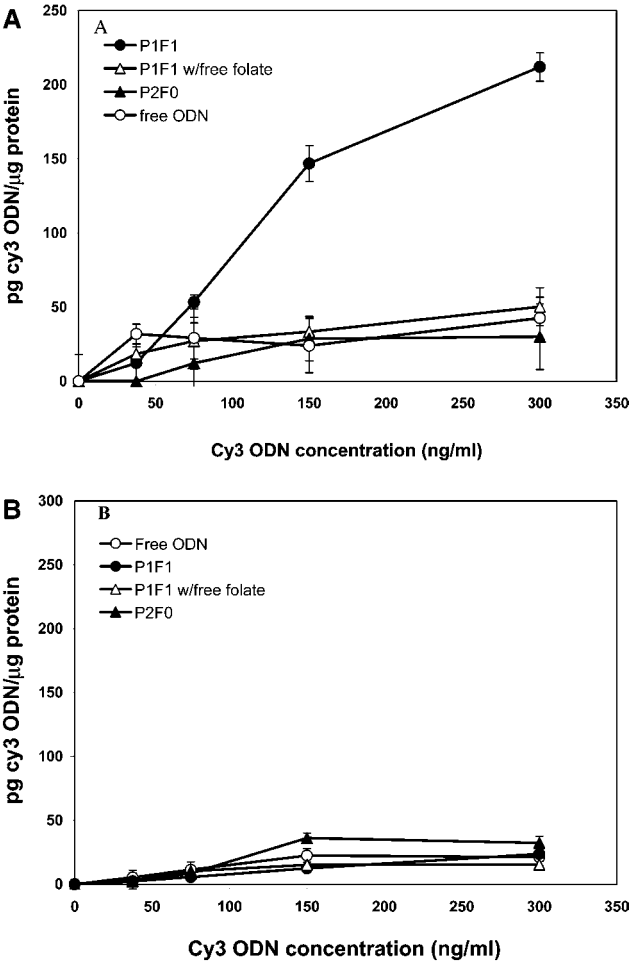

Figure 5. Cell type-specific uptake of folate-targeted lipidic ODN. KB (Panel A) or CHO (Panel B) cells were plated in a 24-well plate. ODN, free or formulated in lipid vesicles with or without a folate ligand, were added to cells in various concentrations. In a separate experiment, free folate was added to folate-targeted lipidic ODN at a final concentration of 1 mM. Cellular uptake of ODN was then evaluated as described in the legend to Figure 2. $n = 3$.

targeted lipidic ODN than that of free ODN or lipidic ODN without a ligand. The improvement in ODN uptake was almost completely blocked by adding excess amount of free folate. There was essentially no difference in the ODN uptake by CHO cells whether ODN were free or formulated in ligand-free lipid vesicles or folate-targeted lipid vesicles (Panel B).

Fluorescence Microscopic Examination of the Cellular Uptake of Folate-Targeted Lipidic ODN. Figure 6 shows the fluorescence images of ODN uptake by KB cells. At 1 h following incubation at 37 °C, folate-targeted ODN were found to be associated with the cell membrane as well as inside the cells (Panel B). In agreement with the quantitative analysis (Figure 5), the level of cell-associated fluorescence intensity is substantially higher with folate-targeted ODN (Panel B) than that with either free ODN (Panel D) or ODN formulated in nontargeted lipid vesicles (Panel A). However, the fluorescence intensity with folate-targeted ODN was decreased to background level by adding excess amounts of free folate (Panel C). These results suggest that the binding and the subsequent internalization of the folate-targeted ODN are mediated by the folate receptors.

Effect of Serum on ODN Uptake by KB Cells. Figure 7 shows the uptake of folate-targeted ODN by KB cells in the presence or absence of 10% FBS. Serum appears to have only a slight effect on the cellular uptake of folate-targeted ODN. Similar phenomenon was observed for free ODN or ODN formulated in nontargeted lipid vesicles (data not shown).

DISCUSSION

An ideal ODN vector should have a large ODN loading capacity and deliver the ODN to target cells in a cell-type-specific manner. Neutral liposomes are suitable for active targeting but suffer from low encapsulation efficiencies and drug-to-lipid ratios. This problem can be resolved via incorporation of cationic lipids into the formulation, but the resulting lipid/nucleic acid complexes are generally unstable and short-lived in blood circulation. Furthermore, substantial amounts of ODN are associated with the positively charged surface of the particles. These ODN may be released from the particles by the highly negatively charged molecules in the blood following systemic administration (*12*). Recently, Stuart and Allen (*13*) described a method by which 80−100% of input ODN were entrapped in a lipid vector that was stable in human plasma. This involves the formation in and extraction of cationic lipid/ODN complex from an organic solvent. The cationic lipid/ODN complex was then mixed with other neutral lipids and ODN-containing lipid vesicles were obtained by a reverse phase evaporation method (*13*). More recently, a much simpler method was developed by Semple and colleagues (*1*), which utilizes an ionizable aminolipid (DODAP) and an ethanol-containing buffer system. A similar level of encapsulation efficiency was achieved (*1*). These ODN-containing lipid vesicles, however, are inefficient in interacting with cells. Furthermore, they lack cell type specificity. In this study we investigated whether a targeting ligand can be incorporated into these vesicles to further improve their efficiency in intracellular delivery of ODN. Folate was chosen as a targeting ligand since folate receptors have been shown to be overexpressed in a number of cancer cells. Folate has been used successfully in targeting to tumors various types of agents including chemotherapeutic drugs (*10*), radionucleotides (*14*, *15*), ODN (*6*, *16*), DNA (*17*, *18*), etc. The advantages of a folate-targeting system include its excellent safety profile and the low immunogenicity. Folate receptors have also been shown to mediate efficient internalization of free folate or the

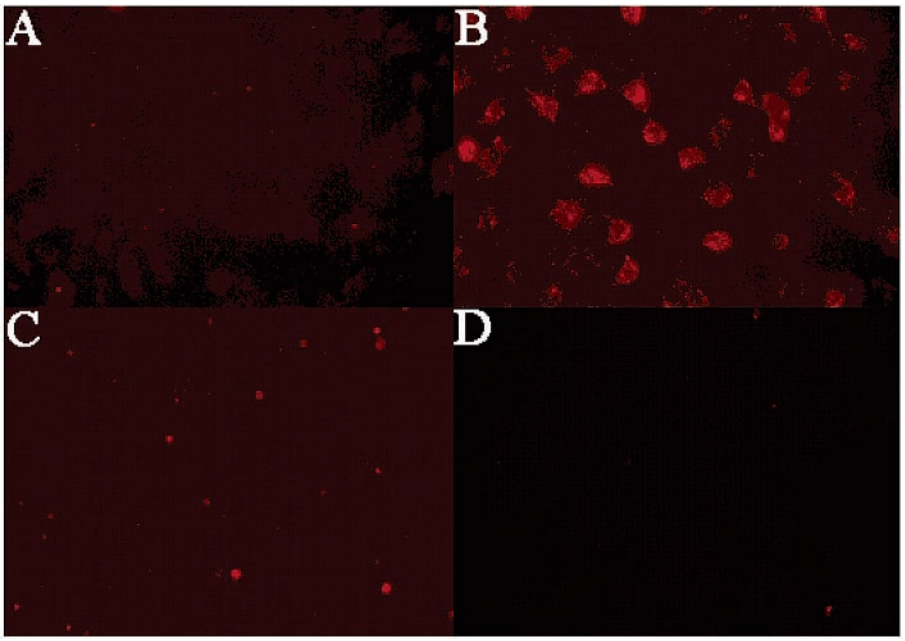

Figure 6. Fluorescence microscopic examination of cellular uptake of folate-targeted lipidic ODN. KB cells were seeded at a density of 1×10^5 cells/well in a 4-well Nalge Nunc Lab-Tek chamber slide (Naperville, IL) and kept overnight at 37 °C. ODN, free or formulated in lipid vesicles with or without a folate ligand, were added at a Cy3-ODN concentration of 100 ng/mL. In one well, free folate was added to the folate-targeted lipidic ODN at a final concentration of 1 mM. One hour following the incubation at 37 °C cells were washed three times with PBS. Cells were then fixed with 2% paraformaldehyde at 37 °C for 20 min and further washed with PBS three times. Cellular uptake of Cy3-labeled ODN was examined under a Nikon fluorescence microscope with a blue filter at 200X magnification. A: Lipidic ODN without a ligand; B: folate-targeted lipidic ODN; C: folate-targeted lipidic ODN + 1 mM free folate; D: free ODN.

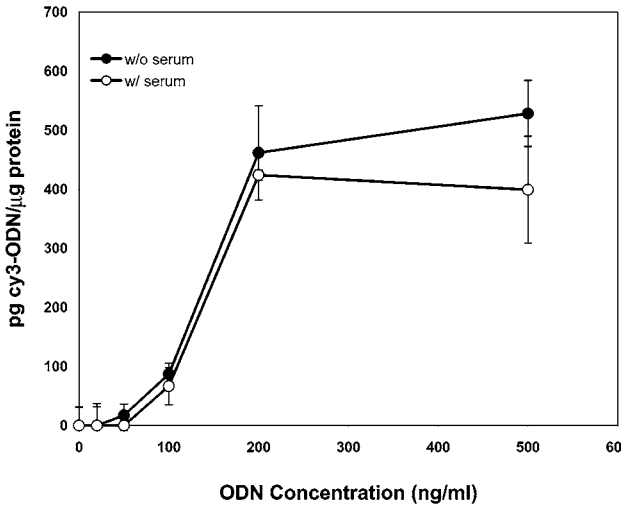

Figure 7. Effect of serum on ODN uptake by KB cells. KB cells were seeded to a 24-well plate at a cell density of 2.5×10^4/well and allowed to grow overnight. Various concentrations of folate-targeted ODN were added to cells in the presence or absence of 10% FBS. Cellular uptake of ODN was then evaluated as described in the legend to Figure 2. $n = 3$.

conjugates, which should facilitate intracellular delivery of the therapeutic agent. Results from this study clearly show that incorporation of folate into the ODN-containing vesicles leads to a significant improvement in delivery of ODN to KB cells that overexpress folate receptors (Figures 5 and 6). The increase in the ODN uptake was almost completely blocked by excess amount of free folate (Figures 5 and 6). Conjugation of folate led to little change in ODN uptake by CHO cells that are negative for folate receptor expression (Figure 5). These studies clearly indicate that targeted delivery of ODN to KB cells via this novel lipid vector is mediated by the folate receptors.

The targeting efficiency of folate-conjugated vesicles is affected by the amount of input folate−PEG−DSPE. Increasing the amount of folate from 0 to 0.5 mol % was associated with a significant increase in ODN uptake. However, increasing the input folate beyond 0.5 mol % was not associated with a further increase in the cellular uptake of ODN (Figure 2). Interestingly, the targeting efficiency of folate-conjugated vesicles is also affected by the amount of input ceramide−PEG (Figure 3). Ceramide−PEG was included for two purposes: (a) to render the resulting particles long-circulating in the blood, and (b) to prevent aggregation during the preparation of ODN-containing lipid vesicles, particularly when the vectors were prepared at high lipid concentrations. However, at a high concentration of ceramide-PEG, substantial amounts of PEG have been shown to be excluded from the lipid vesicles (*1*). Similarly, some of the input folate might be excluded from the vesicles, which may lead to incoporation of less than sufficient amounts of folate needed to achieve efficient targeting when a small amount of input folate−PEG−DSPE is used. This may explain the fact that, at a folate concentration of 0.1 mol %, the efficiency of ODN delivery was decreased dramatically when the ceramide−PEG was increased to above 2.5 mol % (Figure 3A). This problem, however, can be resolved by increasing the amount of input folate−PEG−DSPE. As shown in Figure 3B, increasing the amount of input folate from 0.1 to 1 mol % resulted in a full recovery of targeting efficiency at high concentrations of ceramide−PEG (above 5 mol %). No purification is required to remove the free folate−PEG−DSPE from the folate-conjugated, ODN-containing lipid vesicles.

Similar to liposomal targeting (*10*, *11*), the efficiency of ODN delivery via the new lipid vector is affected by the length of the PEG spacer. This might be due to the fact that the PEG coating imposes steric hindrance for

the folate to interact efficiently with the folate receptors on the cell surface when a short PEG spacer (such as 2000 Da) is used. This interference becomes more pronounced with increasing amounts of ceramide−PEG (data not shown). This problem, however, can be resolved via the use of a longer PEG spacer between the folate and the lipid anchor. As shown in Figure 4, increasing the length of PEG spacer from 2000 to 3500 Da results in a significant improvement in the targeting efficiency. Furthermore, the targeting efficiency of the resulting lipid vectors is not significantly affected by the amount of the input ceramide−PEG (Figure 3B).

In summary, we have developed a novel lipid vector that is highly efficient in delivering ODN to tumor cells that overexpress folate receptor. We have also shown recently that this vector mediates efficient delivery of ODN to mouse lung endothelial cells using an endothelial cell-specific antibody as a ligand (Wilson et al., unpublished data). Currently we are examining the targeting efficiency of this vector in vivo.

Characterization of Novel Histidine-Tagged Tat-Peptide Complexes Dual-Labeled with ^{99m}Tc-Tricarbonyl and Fluorescein for Scintigraphy and Fluorescence Microscopy

Kristin E. Bullok, Mary Dyszlewski, Julie L. Prior, Christina M. Pica, Vijay Sharma, and David Piwnica-Worms*

Molecular Imaging Center, Mallinckrodt Institute of Radiology, Department of Molecular Biology and Pharmacology, Washington University Medical School, St. Louis, Missouri 63110. Received July 12, 2002; Revised Manuscript Received August 15, 2002

To enable concurrent whole body scintigraphy and direct imaging of subcellular localization of permeation peptides, dual-labeled Tat-peptides useful for both radiometric analysis and fluorescence microscopy are desired for molecular imaging applications. Thus, novel dual-labeled D-Tat-peptides comprising Tat-basic domain (hgrkkrrqrrrgc), C-terminus conjugated with fluorescein-5-maleimide (FM) and N-terminus chelated with [^{99m}Tc(CO)$_3$] via histidine coordination, were synthesized and characterized. In human Jurkat cells, radiotracer uptake and washout studies revealed concentration-dependent accumulation of the dual-labeled Tat-peptide within cells. Subcellular localization of Tat-peptide was confirmed by fluorescence microscopy using an analogous [Re(CO)$_3$] dual-labeled Tat-peptide. As seen with C-terminus single-labeled Tat-peptides, localization to the nucleoli was observed with the dual-labeled Tat-peptide, suggesting that the mechanism of Tat-peptide uptake and localization was not dependent on free peptide termini at either end. In Balb/c mice, biodistribution studies performed with the dual-labeled Tat-peptide showed fluorescence intensity by microscopic analysis that visually confirmed and correlated directly with scintigraphic and radiometric data. Of note, following intravenous administration, little brain penetration of these permeation sequences was observed in vivo. His[^{99m}Tc(CO)$_3$]-, DTPA[^{99m}Tc(CO)$_3$]-, and ϵ-lys-gly-cys[^{99m}Tc(O)]-labeled Tat-peptides showed significant pharmacokinetic differences in liver and kidney depending on labeling strategy, indicating that Tat-peptide biodistribution can be impacted by the chelation moiety coordinated with ^{99m}Tc. Thus, we have shown that dual-labeled ^{99m}Tc-tricarbonyl Tat-peptide−FM conjugates can be conveniently synthesized and enable direct comparison of quantitative radiometric and qualitative fluorescence data both in vitro as well as in vivo.

INTRODUCTION

Permeation peptides, including the Tat-peptide basic domain, have been intensely studied recently after early observations demonstrated rapid translocation properties, seemingly independent of receptor-mediated endocytosis, into various cell types. The ability of permeation peptides to cross cell membranes is especially promising for drug delivery, since one major barrier to successful therapies and bioimaging is the need for membrane translocation (*1, 2*). Initial studies of the HIV Tat protein in the late 1980s (*3, 4*) showed the feasibility of utilizing Tat-derived polypeptides for rapid transport of various cargo into cells. Subsequent work with Tat-basic domain and related sequences has shown transport and delivery of polypeptides, immunoreactive epitopes, fluorescent probes, oligonucleotides, and derivatized superparamagnetic iron oxide nanoparticles (*5*−*12*) into various cell types. Tat-peptide has also been pursued as a possible molecular imaging and radiotherapeutic agent via chelation to various radioisotopes, such as ^{99m}Tc (*13*).

^{99m}Tc is a widely used radioisotope in medical imaging because it is readily available through ^{99}Mo/^{99m}Tc generator systems, has an ideal photon energy for imaging applications, and possesses a short half-life (6.02 h) (*14*−*16*). In addition, chelation chemistry for ^{99m}Tc has received much attention because donor cores also enable radiation therapy using chemically analogous ^{186}Re/^{188}Re species (*17*). ^{99m}Tc can be coordinated by a variety of chelators including various tetradentate N or S ligands (N_2S_2, N_3S, etc. donor cores) and diethylenetriaminepentaacetic acid (DTPA) (*1*). Recently, $[M(CO)_3(OH_2)_3]^+$ where (M = ^{99m}Tc or Re) has been incorporated into peptides via facial replacement of water molecules using chelators such as phosphines (*18*) and α-amino moieties of N-terminal histidine (*19*). These ^{99m}Tc triaquo-tricarbonyl species have been shown to be highly stable (*20*−*22*), thereby providing another promising candidate chelation strategy for coordination of [^{99m}Tc(CO)$_3$] to Tat-peptides. We report here the novel use of [^{99m}Tc(CO)$_3$] to radiolabel his-tagged Tat-peptide sequences to yield single-labeled Tat-peptides or in combination with fluorescein-5-maleimide (FM) conjugated to the C-terminus thiol to yield dual-labeled Tat-peptides. Both his[^{99m}Tc(CO)$_3$] and the analogous his[Re(CO)$_3$]-coordinated Tat-peptides were characterized and analyzed in vitro and in vivo. Dual-labeled Tat-peptides were employed to quantitatively measure cellular uptake and tissue biodistribution as well as to qualitatively confirm subcellular localization by fluorescent microscopy.

METHODS

Peptide Synthesis. Peptides **1** (H-his-gly arg-lys-lys-arg-arg-gln-arg-arg-arg-gly cys-NH_2), **2** (H-his-gly arg-lys-lys-arg-arg-gln-arg-arg-arg-NH_2), and **3** (H-gly arg-lys-lys-arg-arg-gln-arg-arg-arg-gly cys-Resin) were prepared by solid-phase peptide synthesis (Tufts University Peptide Synthesis Core Facility, Boston, MA) using all D N-α-Fmoc-protected amino acids and standard BOP/HOBt coupling chemistry. Peptides **1** and **2** were C-terminus amidated and purified (>95%) by C_{18} reversed-phase HPLC at a flow rate of 1 mL/min using as eluent 0.1% trifluoroacetic acid in 5% acetonitrile/95%water [0.1% TFA/(5% CH_3CN/H_2O)] modified with 0.1% trifluoroacetic acid in 90% acetonitrile/10% water [0.1% TFA/(90% CH_3CN/H_2O)] by a linear gradient of 5% to 40% acetonitrile over 40 min. A single HPLC peak was observed (t_R (**1**) = 14.6 min; t_R (**2**) = 13.5 min) and identity of each was confirmed by amino acid analysis (**1**, 13 amino acids: gln 1; his 1; gly 2; cys 1; lys 2, arg 6; **2**, 11 amino acids: gln 1; his 1; gly 1; lys 2, arg 6; **3**, 12 amino acids: gln 1; gly 2; cys 1; lys 2, arg 6; on resin) and electrospray mass spectrometry (EMS) (**1**, *m*/*z*: 1694.0, calcd: $C_{66}H_{125}N_{37}O_{14}S_1$, 1693.0; **2**, *m*/*z*: 1533.9, calcd: $C_{61}H_{117}N_{35}O_{12}$, 1532.8; **3** cleaved from resin, *m*/*z*: 1556.3, calcd: $C_{60}H_{118}N_{34}O_{13}S_1$, 1555.9).

Synthesis of DTPA−Tat-Peptide. To dry tri-*tert*-butyl DTPA (39 mg; 69 μmol) (Mallinckrodt, Inc., St. Louis, MO (*23*)) was added dicyclohexylcarbodiimide (DCC, 17 mg, 1.2 equiv) in anhyd DMF (1.0 mL). Tri-*tert*-butyl DTPA was activated with stirring in DCC for 30−60 min. To 100 mg of dried peptide resin **3**, suspended in 30−35 μL of anhydrous triethylamine, was added the activated tri-*tert*-butyl DTPA solution, and N-terminal coupling was allowed to proceed with stirring overnight. DMF was removed, and resin was washed twice each with DMF followed by acetonitrile and then dried under argon. The peptide was cleaved from resin, and the protecting groups were removed by stirring in TFA stock solution [(TFA (10 mL), phenol (0.75 g), thioanisole (0.5 mL), deionized water (0.5 mL), and ethanedithiol (0.25 mL)] (*24*) at room temp for 3 h. The cleaved and deprotected peptide was then filtered through glass wool to separate from the resin, precipitated in cold ether, pelleted by centrifugation, and the supernatant removed. Finally, pelleted peptide was dissolved in water and lyophilized to obtain dried crude product. Purification was carried out as described above (t_R = 11.6 min; yield ~40%). Purity was assessed by RP-HPLC (>95% pure) and identity by EMS (DTPA-gly-arg-lys-lys-arg-arg-gln-arg-arg-arg-gly-cys-NH_2 (**4**), *m*/*z*: 1932.2, calcd: $C_{74}H_{141}N_{37}O_{23}S_1$, 1932.3).

Synthesis of Tat-Peptide−FM. To **1** or **4** (5 mg) dissolved in PBS (200 μL) was added FM (1.2 mol equiv; Molecular Probes, Eugene, OR) dissolved in DMF (200 μL). The reaction was stirred at ambient temp for 2 h in the dark. Resulting FM-labeled Tat-peptide conjugates were purified by RP-HPLC (>98%; single doublet peak, t_R (**5**) = 25.6, 26.0 min and t_R (**6**) = 24.1, 24.6 min) using the eluent mixture described above and each product was identified by EMS (H-his-gly-arg-lys-lys-arg-arg-gln-arg-arg-arg-gly-cys-FM (**5**), *m*/*z*: 2120.0, calcd: $C_{90}H_{138}N_{38}O_{21}S_1$, 2120.4; DTPA-gly-arg-lys-lys-arg-arg-gln-arg-arg-arg-gly-cys-FM (**6**), *m*/*z*: 2358.0, calcd: $C_{98}H_{154}N_{38}O_{30}S_1$, 2358.6). To further characterize the two closely eluting peaks observed on HPLC chromatograms, the peaks for **5** were separated and analyzed by EMS. Both peaks revealed the same mass, thus confirming that these species were isomers. Because the isomers did not show interconversion for 1 h after purification, the two species were considered as the desired product.

Synthesis of [Re(CO)$_3$]Tat-Peptide−FM. To **5** or **6** (2 mg) in RO water (100 μL) was added $[Re(CO)_3Br_3][NEt_4]_2$ (1 equiv) (*25*) (gift from Roger Schibli, Paul Scherrer Institute, Switzerland) dissolved in water (100 μL). The reaction mixture was stirred at 85 °C − 90 °C for 30 min. For $Re(CO)_3$ coordinated with **5**, RP-HPLC analysis revealed three major doublet peaks (t_R = 27.8, 28.1 min; 28.7, 29.0 min; 30.1, 30.4 min) and two unidentified minor peaks, and for $Re(CO)_3$ coordinated with **6**, a complex spectra, probably due to structural isomers arising from the presence of multiple NO coordination combinations (*26*, *27*). From the $Re(CO)_3$ coordinated with **6**, the main doublet peak was isolated (t_R (**8**) = 26.4, 26.8 min). All product peaks were collected from the $Re(CO)_3$ coordinated with **5**. Purification was performed using the solvent gradient system described above with collection of appropriate fractions. Identity of isolated [Re(CO)$_3$]Tat-peptide complexes was confirmed by EMS ([Re(CO)$_3$]his-gly-arg-lys-lys-arg-arg-gln-arg-arg-arg-gly-cys-FM (**7**), *m*/*z*: 2390.0, calcd: $C_{93}H_{138}N_{38}O_{24}Re_1S_1$, 2390.6; [Re(CO)$_3$]DTPA-gly-arg-lys-lys-arg-arg-gln-arg-arg-arg-gly-cys-FM (**8**), *m*/*z*: 2628.0, calcd: $C_{101}H_{154}N_{38}O_{33}S_1$, 2628.8).

Synthesis of [^{99m}Tc(CO)$_3$]Tat-Peptides. Tat-peptide conjugates were labeled with $[^{99m}Tc(CO)_3]$ using a commercially available tricarbonyl radiopharmaceutical kit ($K_2BO_3CO_2$ (4 mg), $K_2B_4O_7{\cdot}H_2O$ (10 mg), NaK tartrate (10 mg), pH 10; Mallinckrodt, Inc., St. Louis, MO). Kits were reconstituted with Na[$^{99m}TcO_4$] (20−40 mCi) in isotonic saline (1.0 mL), obtained by eluting a commercial radionuclide $^{99}Mo/^{99m}Tc$ generator, and reacted in a 100 °C oil bath for 10−15 min. Following neutralization by 1 N HCl (80 μL), 90 μL of the $[^{99m}Tc(CO)_3(OH_2)_3]^+$ solution was added to 100 μg of **1**, **2**, **4**, **5**, or **6** (10 μL of a 10 mg/mL peptide solution) and reacted for 20−30 min at 85−90 °C. Radiochemical yields (>94%) of $[^{99m}Tc(CO)_3]$-Tat-peptide complexes were determined by TLC using silica gel plates developed with eluent, either methanol:saline:TFA (68:30:2) or H_2O, as indicated, and scanning radiometric detection (Bioscan, Inc., Washington, D.C.). In methanol:saline:TFA, $[^{99m}Tc(CO)_3]$ complexes of **1, 2, 4**, **5**, and **6**, with R_f values between 0.85 and 0.95, were readily distinguished from reduced species such as $[^{99m}Tc]TcO_2$ at the origin. In H_2O, $[^{99m}Tc(CO)_3]$Tat-complexes remained at the origin while $[^{99m}TcO_4]$ moved with the solvent front. Radiochemical purity of aliquots was determined by radiometric RP-HPLC using the solvent gradient system described above. Radiochemical purity of labeled complexes **1**, **2**, and **5** was >94%. Therefore, for complexes **1**, **2**, and **5**, no purification was carried out, and compounds were directly utilized for both in vitro and animal studies. Following radiolabeling, complexes of **4** and **6** were either directly utilized or further purified by RP-HPLC as described to obtain >86% purity with no difference in results. When purified, collected fractions utilized for biodistribution studies were diluted to 35 μCi/mL with phosphate-buffered saline (PBS) to obtain a final pH slightly less than neutral. In contrast, collected fractions utilized for transport assays were spiked with either cold compound **4** or **6** (to simulate the specific activity of nonpurified radiolabeled peptides) for a final peptide concentration of 75 μM. Transport assays were then carried out as described below.

Stability Studies. In vitro and in vivo studies were carried out as previously described (*13*) with slight modifications. Briefly, stability in vitro of $[^{99m}Tc(CO)_3]$-

Tat-peptide complex **5** in aqueous buffers between pH 4 and 9 was evaluated by incubation of the radiolabeled peptide (10 mg/mL) for 1 h at 37 °C in HEPES (10 mM) or Tris base (50 mM) buffer pH adjusted with HCl or NaOH, followed by TLC and scanning radiometric analysis as well as RP-HPLC with UV-radiometric detection. Additional effects of reduced histidine (2.5 mM), cysteine (2.5 mM), or EDTA (2.5 mM) on radiolabeled Tat-peptide stability were evaluated by addition of competing chelator to buffers at each pH. Stability in vitro was further assessed by radio-TLC after incubation of [^{99m}Tc(CO)$_3$]-Tat-peptide of **5** for 1 and 24 h at 37 °C in fetal bovine serum or PBS. Stability in vivo of radiolabeled [^{99m}Tc(CO)$_3$]-Tat-peptide of **5** was characterized by radio-TLC analysis of serum and urine samples 30 min after intravenous administration of 850 μCi of the radiolabeled peptide to FVB mice.

Cell Culture. Monolayers of human epidermoid carcinoma KB 3-1 cells were grown at 37 °C in an atmosphere of 5% CO_2 as previously described (*28, 29*). To attain 60% confluent cell monolayers for experiments, cells were plated 1 day prior to experimentation in 10-cm Petri dishes containing seven 25-mm coverslips and maintained in DMEM (GIBCO, Grand Island, NY) supplemented with L-glutamine (1%), penicillin/streptomycin (0.1%), and heat-inactivated fetal bovine serum (10%). Suspensions of human Jurkat leukemia cells were maintained in RPMI also supplemented with L-glutamine, penicillin/streptomycin, and heat-inactivated fetal bovine serum at 37 °C in an atmosphere of 5% CO_2 (*13*).

Transport Assays. Assays were performed with a minor modification to a previously described procedure (*13*). Briefly, tracer transport assays were carried out with Jurkat cells incubated in modified Earl's balanced salt solution (MEBSS) containing (mM): 145 Na^+, 5.4 K^+, 1.2 Ca^{2+}, 0.8 Mg^{2+}, 152 Cl^-, 0.8 $H_2PO_4^-$, 0.8 SO_4^{2-}, 5.6 dextrose, 4.0 HEPES, and 1% fetal bovine serum (vol/vol), pH 7.4 ± 0.05. Experiments were performed in siliconized microfuge tubes each containing 10 μL of [^{99m}Tc(CO)$_3$]Tat-peptides (with or without purification) and 740 μL of a MEBSS suspension of 10^7 cells. Unless stated otherwise, [^{99m}Tc(CO)$_3$]Tat-peptide complex was added to MEBSS without purifying from the molar excess of unlabeled Tat-peptide as obtained directly from the labeling procedure; final total peptide concentration was typically 1 μM (20−50 nmol/mCi; ∼25 μCi/ml). Tubes were incubated at 37 °C for 20 min with occasional mixing, and the reaction was terminated by spinning two separate 250 μL aliquots from the reaction tubes for 10 s through 800 μL of a mixture (75:25) of silicone oil (density = 1.050; Aldrich) and mineral oil (density = 0.875; Acros). A 50 μL amount of the aqueous phase was obtained to normalize extracellular concentration of the [^{99m}Tc(CO)$_3$]Tat-peptide to cell-associated activity. Remaining aqueous and oil layers were then aspirated, and the cell pellet was extracted in 0.5 mL of 1% SDS, 10 mM sodium borate. For peptide washout experiments, immediately after a 20 min uptake period, cell pellets were collected by rapid spinning and resuspended in 750 μL of peptide-free 4 °C MEBSS buffer. Immediately, another rapid spin was performed and the collected pellet was suspended in 750 μL of fresh 37 °C MEBSS buffer for a 30 min washout period. The experiment was terminated as above, and all cell extracts were assayed for protein by BCA analysis (Pierce Chemical Co.) using bovine serum albumin as the protein standard. Cell extracts, stock solutions, and extracellular buffer samples were assayed for gamma activity in a well-type sodium iodide gamma counter (Cobra II, Beckman; 130−165 keV window). Absolute concentration of total [Tc(CO)$_3$]Tat-peptide complex in solution was determined from the specific activity of ^{99m}Tc, based on equations of ^{99}Mo/^{99m}Tc generator equilibrium (*30*). Transport data are reported as fmol of peptide$_i$ (mg protein)$^{-1}$ (nM$_o$)$^{-1}$, wherein peptide$_i$ represents total peptide (labeled and unlabeled) within the cells and (nM$_o$)$^{-1}$ represents concentration of total peptide in the extracellular buffer (*13, 31*). Data are reported as mean ± SEM.

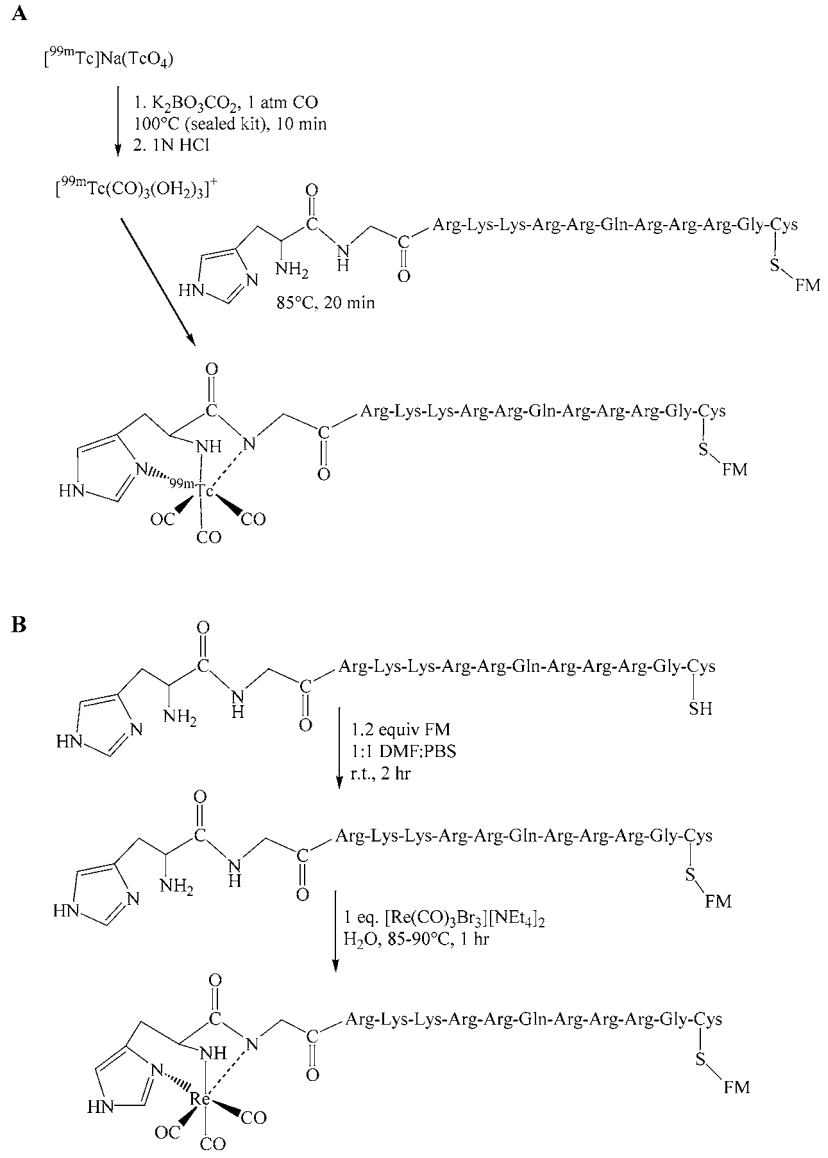
Fluorescence Microscopy. Just prior to the study, 1 mM peptide solutions (freshly made or from stock solutions stored at −20 °C) were diluted in MEBSS buffer (pH = 7.4; 37 °C) to obtain 1 μM peptide solutions, for incubation with KB 3-1 cells, and 10 μM peptide solutions, for incubation with Jurkat cells. For uptake experiments with KB 3-1 cells, coverslips of 60% confluent KB 3-1 cells were removed from incubation and washed briefly in a 37 °C MEBSS buffer bath. After placing a single coverslip in a 35 mm dish, 200 μL of the respective 1 μM peptide conjugates **5**, **6**, **7**, or **8** were added on top of the coverslip. Following a 20 min uptake at 37 °C, the cells were fixed in the presence of peptide solution with 200 μL of 8% paraformaldehyde (4% final PFA) for 10−15 min and washed three times with PBS. For uptake experiments with Jurkat cells, cells were pelleted at 1000 rpm for 5 min. Cells were then resuspended in MEBSS buffer (pH = 7.4; 37 °C) at a concentration of 10^5 cells/90 μL. A 90 μL amount of the cell suspension was directly added to 10 μL of 10 μM peptide solutions of **5** or **7** for a final peptide concentration of 1 μM. Following a 20 min incubation at 37 °C, cells were cytospun onto slides, fixed for 10 min with PFA (4%), and washed three times with PBS. All cells were then mounted with antifading mounting medium according to recommended procedures of the manufacturer (Vector) and analyzed by epifluorescence microscopy on a Zeiss microscope coupled to a Nikon camera equipped with a CCD interfaced to a PC (*32, 33*).

Biodistribution and Imaging Studies. Vertebral animal procedures were approved by the appropriate institutional review committee. Balb/c mice (Taconic, Germantown, NY) were anesthetized by metofane inhalation and injected with [^{99m}Tc(CO)$_3$]Tat-peptide complexes (2 μCi in 50−100 μL of saline) via bolus injection through a tail vein. Animals were sacrificed by cervical dislocation at 5, 30, 60, and 120 min postinjection (n = 2−4). Blood samples were obtained by cardiac puncture and tissues harvested rapidly and weighed. Gamma activity in organ samples was counted for 1 min or until two standard deviations of sampling were below 0.5%. Data are expressed as percent of injected dose (% ID) per organ [(organ μCi) (injected μCi)$^{-1}$ × 100] or % ID per gram of tissue [(tissue μCi) (injected μCi)$^{-1}$ (g tissue)$^{-1}$ × 100].

Fluorescent biodistribution was carried out by injecting mice with conjugate **7** (700 μg/50 μL saline) spiked with [^{99m}Tc(CO)$_3$]Tat-peptide complex of **5** (2 μCi) via bolus injection through a tail vein. Mice were sacrificed 30 min postinjection. Organs were harvested, and half of each organ was weighed and gamma counted as described above. The remaining portions of organs were frozen in O.C.T. (Sakura Finetek, Torrence, CA). Cryosections of frozen tissues were fixed with PFA (4%) and washed three times with PBS. Sections were mounted with antifading mounting media (Vector) and analyzed by epifluorescence microscopy.

For imaging studies, Balb/c mice also were lightly anesthetized with metofane inhalation. [^{99m}Tc(CO)$_3$]Tat-peptide complex of **5** (∼500 μCi in 100 μL of saline) was injected via a tail vein into mice positioned under a

(B) Complex of Tat-peptides **5** and **7**. (C) Complex of Tat-peptide **4**. (D) Complex of Tat-peptides **6** and **8**. Note that many isomers are possible with coordination to DTPA (*26*). Only one isomer is presented.



gamma scintillation camera (Siemens Basicam, Siemens Medical Systems, Iselin, NJ; 5 mm pinhole collimator; 20% energy window centered over 140 keV photopeak of Tc-99m). Sequential posterior images of mice were collected for 5 min each at 3 and 30 min postinjection of the radiotracer with the mouse recovering and being reanesthetized just prior to the 30 min timepoint. A 256 × 256 image matrix with correction for radioactive decay was used on a PC platform and standard image analysis software (ImageJ; National Cancer Institute). No corrections were made for scatter or attenuation. Whole body distribution of the complexes is presented with gray scale images.

RESULTS

Chemistry. Tat-peptides **1**−**4** were synthesized by standard solid-phase methods. Fluorescein-5-maleimide was initially coupled to **1** and **4**, and final synthesis of dual-labeled peptides was accomplished by treating with precursors $[^{99m}Tc(CO)_3(OH_2)_3]^+$ and $[Re(CO)_3Br_3][NEt_4]_2$. Incorporation of the $[M(CO)_3]$ into tridentate ligand systems has been shown to result in facial-type coordination with the tricarbonyl ligands covering one face of the metal and the final three ligands coordinating on the opposite face (*20*, *34*). Aromatic amines have been shown to be the most stable chelation source for tricarbonyl species. One major example is utilization of histidine-type molecules for displacement of water and total coordination of $[Tc/Re(CO)_3]$ (*19*, *21*, *35*). In such systems, metal coordination results in formation of 1 or 2 *fac*-five-membered rings depending on availability of the α-amino group adjacent to histidine for coordination with $[M(CO)_3]$ (referred to as filling the 6th coordination site). With respect to $[^{99m}Tc/Re(CO)_3]$Tat-peptides synthesized and presented here, two putative ligands filling the 4th and 5th coordination sites, were donated from histidine itself, whereas the third putative ligand, filling the 6th coordination site, was donated by the α-amine of the adjacent glycine residue (Figure 1). $[^{99m}Tc(CO)_3]$Tat-peptide complexes were synthesized (Scheme 1A) with radiochemical yields and purity (>94% for histidine coordination; >86% for DTPA coordination) determined by radio-TLC and by radiometric RP-HPLC. Two solvent systems were utilized for TLC development. By developing TLC plates in water, $[^{99m}TcO_4]$ was readily distinguished from $[^{99m}Tc(CO)_3]$Tat-complexes, since pertechnetate moved at or near the solvent front (Figure 2A). A methanol:saline:TFA (68:30:2) solvent system was developed to mobilize $[^{99m}Tc(CO)_3]$-Tat-peptides to near the solvent front for revelation of any reduced $[^{99m}Tc]$ species that may be present at the origin (Figure 2B). By combining these two systems, a more accurate TLC analysis of radiochemical yield of products was obtained.

Coordination of $[Re(CO)_3]$ to Tat-peptides was then carried out (Scheme 1B). RP-HPLC analysis and UV detection of $[Re(CO)_3]$Tat-peptide complex **8** produced a complex chromatogram, while $[Re(CO)_3]$Tat-peptide com-

Scheme 1. Coordination of Tat-Peptides to $^{99m}Tc(CO)_3$ (A) and to $Re(CO)_3$ (B)

plex **7** revealed three major peaks (a, b, and c) each comprising doublets (Figure 3A). Retention times between each doublet were resolved by ~0.5 min, while retention times between peaks a and b and between peaks b and c were 1 and 1.5 min, respectively. Peaks a and b were isolated and kept at 4 °C for 1−2 h until reanalysis for interconversion of isomers by RP-HPLC. Peaks a and b each comprised a majority of the species in their respective vials (~70%) with minor amounts of the other peaks appearing within this time interval (data not shown). When kept at −20 °C for multiple days, purified peaks retained these ratios, suggesting slow interconversion of structural isomers at that temperature. The identity of a and b were confirmed by EMS with both peaks having identical mass (*m*/*z*: 2390). We concluded that each peak represented an isomer of facial coordination of the anticipated metal-tricarbonyl complex **7**. This conclusion is consistent with studies of another planar coordination environment, [^{99m}TcO], that previously established the presence of two isomeric species (*13*). Peak c was not readily isolated but interconverted, mainly into peak b. A series of studies was carried out wherein a mixture of peaks b and c was dissolved in water and acetonitrile/water (0, 10, 30, and 50% acetonitrile) at 40 °C for 15 min. Results indicated peak c gradually increased relative to peak b as acetonitrile percentage increased, suggesting peak c is solvent related and perhaps exchanging into the 6th coordination site. Additionally, when the $Re(CO)_3$ labeling reaction was carried out in a potassium phosphate/sodium hydroxide buffer solution (pH = 6.8), peak c was significantly reduced (data not shown).

The presence of doublets was explained by analyzing compound **5**, synthesized by reacting **1** with fluorescein-5-maleimide. RP-HPLC analysis of **5** revealed a single doublet peak (d and e) resolved by 0.4−0.5 min (Figure 3B). Isolation of each peak and subsequent analysis by mass spectrometry revealed doublets d and e had identical mass (*m*/*z*, 2120; calcd, 2120.03) consistent with two isomeric species. Overall, this suggested d and e were isomers resulting from fluorescein labeling and that these isomers were present in [$Re(CO)_3$] coordination complexes as doublets within peaks.

To study stability of his-tagged Tat-peptide chelate conjugates in vitro, a representative [$^{99m}Tc(CO)_3$] complex of **5** was examined by radio-TLC analysis after incubation in buffered solutions ranging from pH 4−9 (Figure 4). As shown, the [$^{99m}Tc(CO)_3$] complex of **5** was stable to transchelation between pH 4 and pH 7, a physiologically relevant range of pH values encountered in vivo. Percent

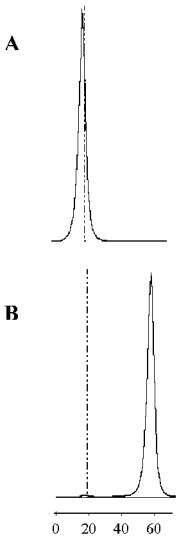


Figure 2. Representative radio-TLC chromatogram of the [^{99m}Tc(CO)$_3$]Tat-peptide complex of **5** in water (A), for identification of remaining pertechnetate, and in methanol:saline:TFA (B), for identification of reduced ^{99m}Tc species. Scale represents millimeters.

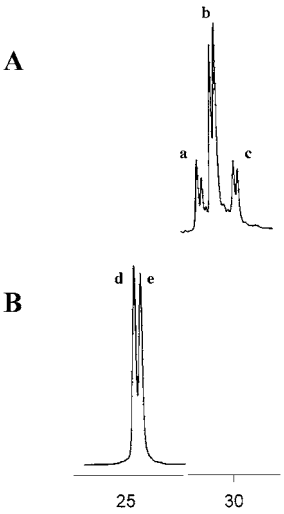

Figure 3. (A) RP-HPLC chromatogram (UV) of [Re(CO)$_3$]Tat-peptide conjugate **7** demonstrating the three major doublet peaks. Peak isolation and mass spectrometry revealed identical masses consistent with the formation of isomers. (B) RP-HPLC chromatogram (UV) of Tat-peptide conjugate **5** demonstrating the single doublet peak. Isolation and mass spectrometry of each peak revealed identical masses consistent with the formation of isomers. Scale represents retention time in min.

intact complex remained >80% over 1 h. The presence of histidine (2.5 mM), a competing physiologic chelator with modest binding affinity, showed only a slight affect below pH 9. Furthermore, the [^{99m}Tc(CO)$_3$] complex of **5** remained >80% intact in the presence of high concentrations of the strong chelator cysteine (2.5 mM), even under alkaline conditions. However, under extreme conditions of alkaline pH (≥9) and highly concentrated EDTA (2.5 mM), only 60% intact complex was observed. Additionally, incubation of the [^{99m}Tc(CO)$_3$] complex of **5** in PBS for 1 and 24 h at 37 °C showed little evidence of transchelation by TLC (data not shown). With incubation for 1 h in fetal bovine serum (FBS), evidence of interaction with serum components began to appear. After a 24 h incubation with FBS, TLC revealed 60% original intact complex present. Overall, these data were generally consistent with published stability studies of aromatic amines coordinated to [^{99m}Tc(CO)$_3$] (*20, 35*).

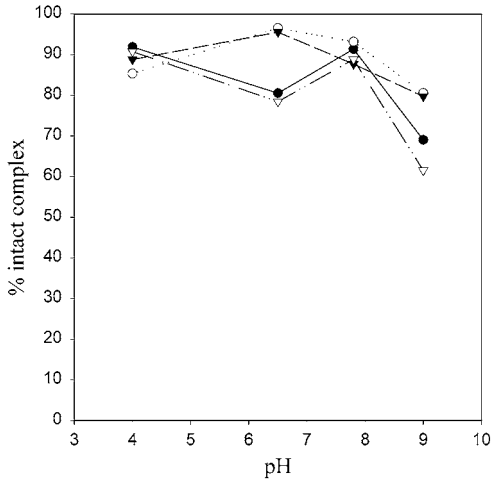

Figure 4. Effect of pH and competing chelation agents on stability of [^{99m}Tc(CO)$_3$]Tat-peptide. Following incubation of [^{99m}Tc(CO)$_3$]Tat-peptide complex **5** for 1 h at 37 °C in HEPES or Tris buffer adjusted to the indicated pH in the absence (●) or presence of cysteine (2.5 mM; ○), histidine (2.5 mM; ▼) or EDTA (2.5 mM; ▽), radiochemical purity (% intact complex) was determined by radio-TLC.

Table 1. Cell Tracer Kinetics of [^{99m}Tc(CO)$_3$]Tat-Peptides with and without Conjugation to FM[a]

peptide	uptake (fmol peptide$_i$ (mg protein)$^{-1}$ (nM$_o$)$^{-1}$)	washout (fmol peptide$_i$ (mg protein)$^{-1}$ (nM$_o$)$^{-1}$)
[Tc(CO)$_3$]**1**	628.0 ± 48.7 (n = 9)	116.0 ± 18.0 (n = 10)
[Tc(CO)$_3$]**5**	93.5 ± 6.8 (n = 14)	35.6 ± 13.8 (n = 11)
[Tc(CO)$_3$]**4**	145.9 ± 14.8 (n = 18)	87.7 ± 7.1 (n = 16)
[Tc(CO)$_3$]**6**	97.7 ± 10.8 (n = 13)	47.7 ± 12.0 (n = 11)

[a] In vitro tracer content following 20 min incubation of Jurkat cells with respective [^{99m}Tc(CO)$_3$]Tat-peptide complexes at 37 °C (uptake) or following 20 min incubation and subsequent 30 min washout in isotope-free MEBSS buffer at 37 °C (washout). Values represent mean ± SEM; n indicates number of determinations.

Additionally, an in vivo stability study was carried out as described. Urine and blood samples at 30 min post-injection indicated that the [^{99m}Tc(CO)$_3$] complex of **5** was >80% intact. However, it was not clear with this analysis whether partial losses of the original complex were a result of conjugate metabolism or coordination of serum components into the 6th coordination site of the [^{99m}Tc(CO)$_3$] complex.

Transport Assay. Using human Jurkat cells, tracer transport studies were performed with [^{99m}Tc(CO)$_3$]Tat-peptide complexes. Both [^{99m}Tc(CO)$_3$]Tat-peptides with fluorescein-5-maleimide conjugated to the C-terminal cysteine (**5**, **6**) and [^{99m}Tc(CO)$_3$]Tat-peptide complexes lacking fluorescein-5-maleimide (**1**, **4**) were compared. All peptides rapidly accumulated into cells over the 20 min uptake period, with Tat-peptides **1** and **4** achieving uptake levels of 628.1 ± 48.7 and 145.9 ± 14.8 fmol (mg protein)$^{-1}$ (nM$_o$)$^{-1}$, respectively, and Tat-peptides **5** and **6** achieving uptake levels of 93.5 ± 6.8 and 97.7 ± 10.8 fmol (mg protein)$^{-1}$ (nM$_o$)$^{-1}$, respectively (Table 1). These levels were compatible with concentration-dependent accumulation of Tat-peptides into cells (*13*). Modest differences were observed between uptake values of single-labeled versus dual-labeled Tat-peptide conjugates in some experiments, while larger differences were observed in others. The cause for uptake variability between experiments was not clearly understood. Nonetheless, these data provided quantitative evidence that

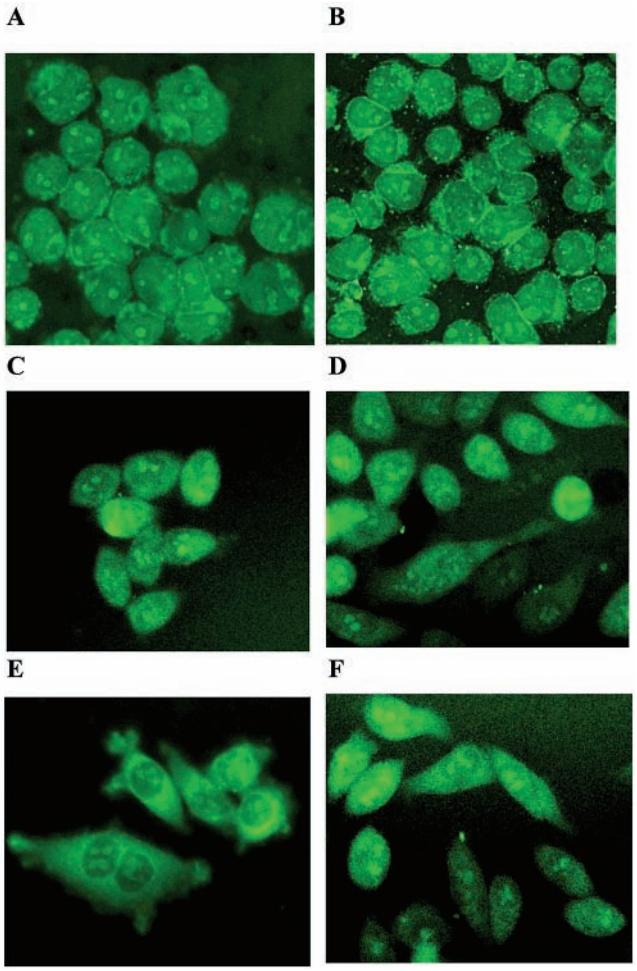

Figure 5. Intracellular localization of Tat-peptide conjugates **5** (A) and **7** (B) in Jurkat cells and conjugates **5**−**8** (C−F, respectively) in KB 3-1 cells. Incubation of cells with Tat-peptide conjugates at 37 °C was carried out for 20 min followed by fixation. Subcellular localization of both single- (A, C, and D) and dual-labeled (B, E, and F) Tat-peptide conjugates was identical both in Jurkat and in KB 3-1 cells.

both single and dual-labeled peptides became similarly cell-associated.

Fluorescence Microscopy. While cell-associated radioactivity was determined in a quantitative manner using radio-tracer experiments, the exact subcellular location of [^{99m}Tc(CO)$_3$]Tat-peptides could not be evaluated by population-based γ-counting techniques. Thus, fluorescein labeled Tat-peptides (**5** and **6**) were used in cell fluorescent uptake experiments to directly determine subcellular localization and thereby prove intracellular translocation of Tat-peptide conjugates. Analogous [Re(CO)$_3$]Tat-peptide chelates (**7** and **8**, respectively) were utilized as isostructural analogues for [^{99m}Tc(CO)$_3$]Tat-peptides to determine the effect of metal coordination on Tat-peptide uptake and subcellular localization. Thus, we hypothesized that these peptides would map the behavior of tracer [^{99m}Tc(CO)$_3$] labeled Tat-peptides inside cells while providing sufficient molar mass to enable direct visualization by fluorescence microscopy. Previous fluorescent cell studies from our laboratory revealed similar translocation efficiency of single-labeled Tat-peptide basic domain into both Jurkat and KB 3−1 cells, resulting in diffuse cytoplasmic fluorescence and focal nucleolar localization (*13*). Thus, both suspension Jurkat and adherent KB 3−1 cells were utilized in the present cell fluorescent study to not only confirm Tat-peptide uptake and localization, but also to determine if qualitative differences could be seen between single-labeled (fluorescein) and dual-labeled (rhenium and fluorescein) Tat-peptide conjugates. No significant differences were observed as both single and dual-labeled peptides exhibited diffuse cytoplasmic and focal nucleolar fluorescence over the entire cell population (Figure 5), similar to analogous Tat-peptides (*13, 36*−*38*). However, perinuclear type staining could also be identified in a subpopulation of KB 3−1 cells that appeared more prominent with dual-labeled Tat-peptide **7** than with single-labeled Tat-peptide **5** (data not shown). It was interesting to note that labeling both ends of Tat-peptide seemed to have little effect on overall peptide uptake and intracellular localization compared to C-terminus labeling with FM alone. Whether single or dual-labeled, Tat-peptide conjugates **1** and **4** localized within cells in a qualitatively similar manner when viewed on the same day and under the same conditions. Overall, fluorescence-staining patterns provided direct evidence for intracellular localization of novel dual-labeled [Re(CO)$_3$]Tat-FM peptide complexes **7** and **8**.

Biodistribution and Imaging. Biodistribution studies were performed to monitor the amount of radioactivity associated with organs or tissues at 5, 30, 60, and 120 min postinjection ($n = 2$−4 each). Results are presented as % ID/organ and % ID/gm (Tables 2−5). For the [^{99m}Tc(CO)$_3$]Tat-peptide-FM complex of **5**, initial uptake was high in liver and kidneys and even continued to accumulate over the 120 min observation period (Figure 6A; Table 2). To confirm that the C-terminal FM was not cleaved, thereby exposing a reduced cysteine and causing prolonged retention through nonspecific binding or conjugation reactions, biodistribution studies were also carried out utilizing [^{99m}Tc(CO)$_3$]Tat-peptide complex of **2**, a conjugate devoid of the C-terminal glycine-cysteine

coordination affected retention, a separate and classical chelation core, DTPA, was N-conjugated in place of the N-terminal histidine to **4**, which contained a free C-terminal thiol, or to **6**, which contained an FM-conjugated C-terminal thiol. After radiolabeling, biodistribution analysis of the [^{99m}Tc(CO)$_3$]Tat-peptide complexes of both **4** and **6** revealed a decrease in liver retention relative to complex of **5**, but persistent accumulation of radioactivity in the kidneys (Figures 6C and 6D; Tables 4 and 5). Brain uptake of all peptide conjugates was consistently low (Tables 2−5). Of note, muscle and bone uptakes of each complex were modestly high. In general, bone clearance of complexes of **2** and **4** (single-labeled Tat-peptides) was minimal whereas clearance of complexes of **5** and **6** (dual-labeled Tat-peptides) was greater. Scintigraphic images, obtained 3 and 30 min post-intravenous injection of [^{99m}Tc(CO)$_3$]Tat-peptide-FM complex of **5** into Balb/c mice, visually confirmed these results (Figure 7).

To further analyze biodistribution results, fluorescent microscopy was used to assess intracellular localization in vivo 30 min after intravenous coinjection of dual-labeled [Re(CO)$_3$]Tat-peptide-FM conjugate **7** spiked with the [^{99m}Tc(CO)$_3$]Tat-peptide−FM complex of **5**. [^{99m}Tc(CO)$_3$]Tat-peptide−FM was coinjected as an internal control to correlate results with radiometric biodistribution data. Fluorescence intensity, as observed by fluorescence microscopy (Figure 8), correlated with γ-counts from the biodistribution studies revealing high intracellular fluorescence in kidneys and liver and no significant fluorescence in brain tissue.

DISCUSSION

Design of Novel Dual-Labeled Tat-Peptides. The ability of permeation sequences such as HIV-1 Tat basic domain peptides to transport various cargo into many

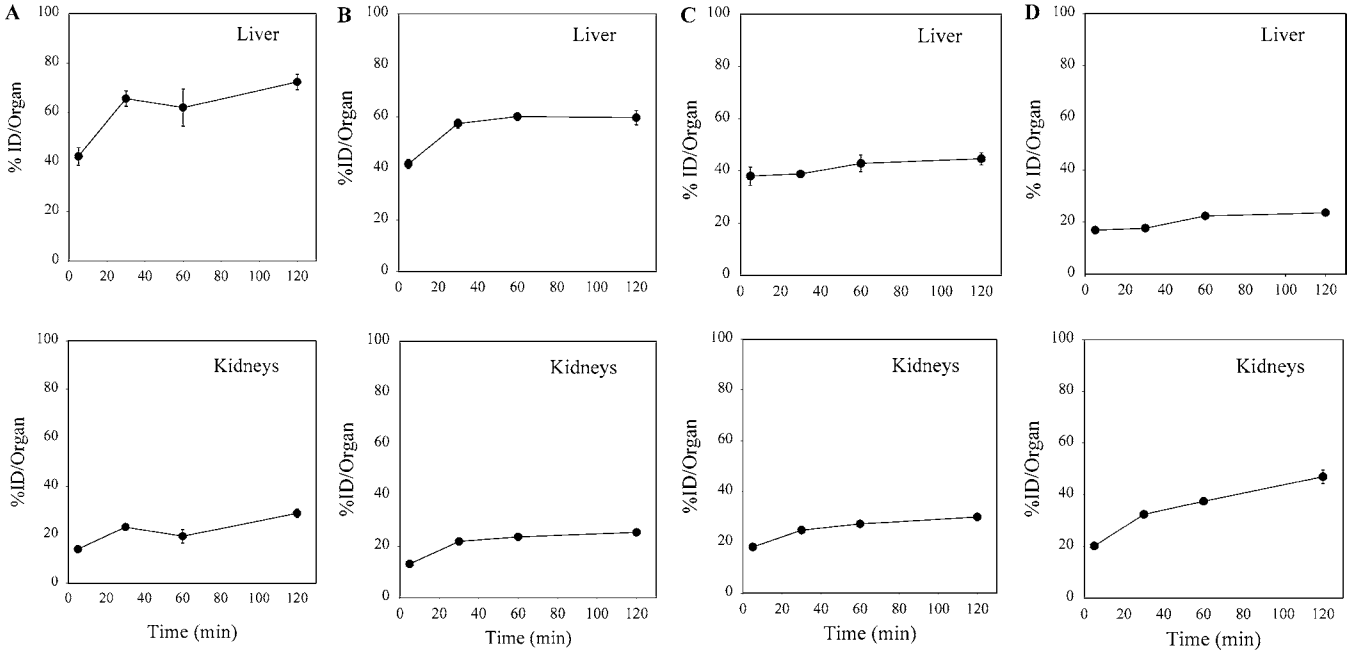

Figure 6. Biodistribution time-activity curves of liver and kidneys showing in vivo uptake of [^{99m}Tc(CO)$_3$]Tat-peptides complexes of **5**, **2**, **4**, and **6** (A−D, respectively). Following bolus intravenous injection, tissues were harvested and counted at 5, 30, 60, and 120 min. Error bars smaller than symbol when not shown.

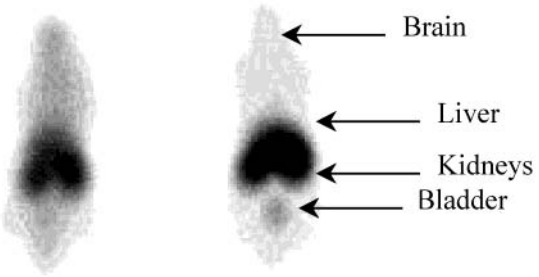

Figure 7. Scintigraphic gray scale images of [^{99m}Tc]Tat-peptide complex of **5** in a Balb/c mouse. Following bolus intravenous injection, posterior images of the mouse were obtained with a gamma scintillation camera. Representative planar images obtained 3 min (left) and 30 min (right) postinjection are shown. Rapid whole body distribution is followed by predominantly hepatic and renal retention of the [^{99m}Tc]Tat-peptide complex and appearance in the urinary bladder.

types of cells has led to wide utilization of permeation peptides in various fields of research (*11, 39, 40*), including exploration of their potential as molecular imaging reagents (*7, 13*). Using [^{99m}Tc/Re(CO)$_3$]-labeled Tat-peptides along with fluorescein-5-maleimide, we have synthesized novel dual-labeled Tat-peptides to quantitatively and qualitatively study cell tracer kinetics, intracellular localization and murine biodistribution. Such a strategy could be applied generally to various N-terminal his-tagged permeation peptide sequences.

[^{99m}Tc(CO)$_3$(OH$_2$)$_3$]$^+$ is an ideal complex for chelation of peptides because simple and relatively facile coordination can be achieved with an N-terminal histidine—an amino acid which is readily added to any peptide during solid-phase synthesis or tagged to polypeptides in common cloning vectors (*19*). Coordination was carried out at atmospheric pressures and reasonable temperatures, a necessity for practical and wide use of radiolabeling (*20, 34*). Additionally, [^{99m}Tc(CO)$_3$(OH$_2$)$_3$]$^+$ has a stable and small donor core (*21*) that is less likely to disrupt secondary structure of the peptide compared to conventional macrocyclic chelators. Further, by utilizing N-terminal histidine-glycine dipeptides for labeling, a less

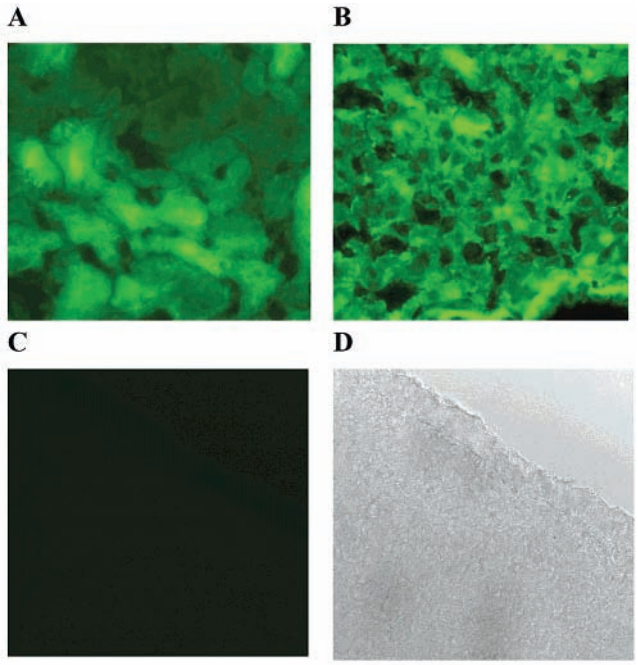

Figure 8. Fluorescence distribution in vivo of [Re(CO)$_3$]Tat-peptide-FM complex **7** spiked with [^{99m}Tc(CO)$_3$]Tat-peptide−FM complex of **5**. Organs were harvested and assayed both by gamma counting and by epifluorescence microscopy. Panels compare fluorescent signal in kidney (A) and liver (B) to brain (C). Panel D represents phase contrast microscopy of the identical brain tissue section as in panel C. Liver and brain fluorescent pictures were obtained at identical magnification and exposure times. The kidney fluorescent picture was taken at an identical magnification as liver and brain, but at a lower exposure time due to intense intracellular fluorescent signal within the tissue.

restricted metal coordination site was established compared to macrocyclic chelators. Thus, Re, a slightly larger metal than ^{99m}Tc, could easily be accommodated by the dipeptide tag and enable a more direct comparison between technetium and rhenium complexes. By examining overall trends, the dual-labeled [^{99m}Tc(CO)$_3$]Tat-

peptide−FM complex of **5** resulted in somewhat lower uptake values than its corresponding single-labeled [^{99m}Tc(CO)$_3$]Tat-peptide; but both complexes retained about the same percentage of radioactivity after a 30 min washout. Reasons for the observed quantitative variations in uptake were not clearly understood, but point to details in cellular mechanisms of translocation requiring further study. However, subcellular localization of the dual-labeled peptides was unaffected by labeling both termini of the peptide. Both Tat-peptides **5** and **7** localized to the nucleus and showed diffuse cytoplasmic fluorescence (Figure 5) as seen previously with single-labeled Tat-peptides. Transport assays and fluorescent cell uptake studies collectively suggested that the mechanism of Tat-peptide translocation is not wholly dependent on the C- or N-termini, although quantitative uptake of dual-labeled [^{99m}Tc(CO)$_3$]Tat-peptide−FM complex of **5** was lower than single-labeled [^{99m}Tc(CO)$_3$]Tat-peptide−FM complex of **1**. Tat-peptide translocation has been suggested to occur via a facial-type interaction wherein the arginine residues associate with the membrane and cause cellular internalization of the entire peptide (*41*). Florescein-5-maleimide, a slightly bulky and hydrophobic moiety, could effect a change in conformation or membrane−peptide interaction that would decrease the efficiency of Tat-peptide basic domain translocation. However, further analysis would be necessary to determine if the reduced quantity of internalized peptide resulted from such an induced conformational change or interaction.

In Vivo Distribution of Dual-Labeled Tat-Peptide. As presented (Figures 6A and 6B), biodistribution utilizing [^{99m}Tc(CO)$_3$]Tat-peptide complexes of **5** and **2** resulted in accumulation of radioactivity in the liver and kidneys. Since the only difference between Tat-peptide complexes of **5** and **2** was the presence of a masked C-terminal cysteine (**5**), retention was not likely due to FM degradation, a reaction that would reveal a free thiol for interaction with other proteins or redox enzymes. Previous [^{99m}Tc(CO)$_3$] studies have indicated that accumulation in liver and kidneys can occur with bidentate coordinated ligands (*34*). Because accumulation of [^{99m}Tc(CO)$_3$]Tat-peptide complexes of **5** and **2** occurred, we hypothesized that the α amine of glycine was coordinated in a weaker fashion to the [^{99m}Tc(CO)$_3$] than the histidine ligands, allowing for exchange with stronger competing ligands. With such a coordination site, biological competitors could potentially compete and coordinate to [^{99m}Tc(CO)$_3$], thus effectively trapping the [^{99m}Tc(CO)$_3$]Tat-peptide in tissues. To test this hypothesis, we coupled DTPA, a chelator with four strong chelating ligands for [^{99m}Tc(CO)$_3$] coordination, to form single-labeled [^{99m}Tc(CO)$_3$]Tat-peptide complexes of **4** and dual-labeled [^{99m}Tc(CO)$_3$]Tat-peptide complexes of **6** for comparative biodistribution with two different chelating groups. Biodistribution of [^{99m}Tc(CO)$_3$]Tat-peptide of **4** revealed a slightly lower initial uptake in the liver that remained constant over time. Initial kidney uptake and accumulation remained similar to complex of **5**. Biodistribution of [^{99m}Tc(CO)$_3$]Tat-peptide of **6** revealed an even more significant reduction (greater than 50%) in initial uptake and retention in the liver compared to [^{99m}Tc(CO)$_3$]Tat-peptide complex of **5**. Instead of accumulation being 72% ID/organ at 120 min, liver radioactivity remained ∼20%. Unexpectedly, radioactivity in the kidney continued to increase throughout the biodistribution time period even though radioactivity in the liver remained consistently lower. These data suggested that Tat-peptide uptake and clearance were strongly influenced by the chelation core, as well as by the coordination of the terminal thiol, rather than being dominated by the permeation peptide itself. Previously published experiments (*13*) utilizing an ϵ-Lys-Gly-Cys [^{99m}TcO]-labeled Tat-peptide lend support to the effect of chelation cores on biodistribution. In those experiments, liver uptake occurred over the first 30 min, similar to the present complexes, with a peak accumulation around 30%. However, in contrast to his[^{99m}Tc(CO)$_3$] coordination, significant clearance from the liver followed peak accumulation, continuing throughout the duration of the experiment for a final % ID/organ of ∼18% at 120 min (*13*). These results are in accord with other observations showing that chelation cores influence pharmacokinetics for a variety of peptide imaging agents (*34, 42−44*). Additionally, these and other studies (*13, 39, 45*) are consistent with our observation that Tat-peptide is characterized by high blood clearance rates, indicating the need for strategies, such as introduction of binding moieties or cleavable domains, that would slow blood clearance rates and increase targeted delivery.

To further determine the utility in vivo of dual-labeled Tat-peptides, fluorescence biodistribution studies were assessed utilizing dual-tagged [Re(CO)$_3$]Tat-peptide−FM complexes. As with radiometric biodistribution and imaging data, the highest fluorescence intensity was observed in liver and kidney tissue with no significant fluorescence intensity in brain tissue. The present results contrast with a previous report suggesting high brain uptake and blood−brain barrier penetration of a similar Tat basic domain fused to β-galactosidase (*9*). In those experiments, β-galactosidase substrate (X-gal) was incubated on brain slices for 16 h and interpreted to indicate high penetration of the blood−brain barrier by the functional fusion protein containing the peptide transduction domain. However, the amount of protein that actually entered the brain parenchyma was not directly measured, and it remains possible that the enzymatically amplified β-galactosidase signal overestimated the quantity of polypeptide penetrating the brain. Other studies (*46, 47*) also have suggested enhanced brain uptake of a biologically active molecule, doxorubicin, when conjugated to permeation peptides. However, these data were obtained mainly utilizing in situ brain perfusion techniques, not intravenous injection as presented here. When intravenous injection was utilized (*46*), the concentration of doxorubicin in the heart and plasma remained significantly greater than in the brain. Additionally, doxorubicin clearance from the brain was slightly greater upon conjugation with the permeation peptide than without. Thus, for delivery of biologically active molecules to the brain utilizing permeation peptides, these and our data suggest that intravenous injection of conjugated permeation peptides may not be an effective method of administration.

CONCLUSION

In summary, we have synthesized and characterized novel dual-labeled Tat-peptides. Evaluation of fluorescein-5-maleimide-labeled [^{99m}Tc(CO)$_3$]Tat-peptide complexes has provided a tool for studying the same peptide both qualitatively by fluorescence microscopy and quantitatively by radiometric analysis in vitro as well as in vivo. As suggested by the radiotracer transport assays indicating concentrative cellular accumulation, a dual-labeled peptide allowed easy confirmation that measured activity was largely due to peptide translocation into the cell interior both in vitro and in vivo. Of significance, following intravenous administration, little brain penetration

of these permeation peptides was observed in mice either by radiometric or fluorescence analyses. These data will assist the design and characterization of permeation sequences, such as the choice of chelation moiety and incorporation of cleavable domains for targeted intracellular drug delivery. The dual-labeled permeation-peptide design also will provide rigor to the study of novel permeation-peptide modifications by the potential to confirm qualitatively and quantitatively the impact of effector moieties on uptake at the target site.

Selective Alkylation and Acylation of α and ϵ Amino Groups with PEG in a Somatostatin Analogue: Tailored Chemistry for Optimized Bioconjugates

Margherita Morpurgo,[†] Cristina Monfardini,[†] Leo J. Hofland,[‡] Mauro Sergi,[†] Paolo Orsolini,[§] Jean M. Dumont,[§] and Francesco M. Veronese*[,‡]

Universitá degli Studi di Padova, Dipartimento Scienze Farmaceutiche, via Marzolo, 5, 35131 Padova, Italy, Department of Internal Medicine, Academic Hospital Dijkzigt, Rotterdam, The Netherlands, and Debio R.P., Martigny, Switzerland. Received April 16, 2001; Revised Manuscript Received November 3, 2001

The effects of the type and location of polymer grafting on the biological activity of different mono-PEG derivatives of the somatostatin analogue RC160 were evaluated. A chemical strategy to obtain mono-PEG alkylation or acylation of the peptide's α-terminal or lysil-ϵ primary amines was devised. Selective BOC protection of the two available primary amines, followed by reaction with two different PEG reagents and removal of the protecting group, was carried out. Chemical characterization, structural studies, and the evaluation of the biological activity of the bioconjugates synthesized allowed the identification of the one having characteristics more suitable for therapeutic application. This corresponds to the mono-ϵ-lysil-pegylated form, obtained by reductive alkylation, where the amine's positive charge is preserved. The results obtained suggest the importance of preliminary studies in the development of new polymer−peptide conjugates with improved pharmacological properties.

INTRODUCTION

Bioconjugation and protein derivatization are fundamental for many biotechnological applications such as, for example, the development of affinity chromatography media, immunoassays, or biosensors (Self and Cook,1996; Yoo, 1976; Wilchek, 1975; Chaiken, 1979). In pharmaceutical sciences, chemical derivatization of bioactive proteins with biocompatible polymers is often used to improve their pharmacokinetic, immunogenic, and antigenic profiles. Polymer-conjugated proteins normally also exhibit higher stability toward harsh environments (high temperature, wide pH range, organic solvents, proteolytic digestion) and are less immunoreactive than their non-modified counterparts (Inada et al., 1986; Nucci et al., 1991; Delgado et al., 1992; Monfardini and Veronese, 1998; Morpurgo and Veronese, 2000; Greenwald et al., 2000; Veronese, 2001).

In bioconjugation, both the choice of the target amino acid in the protein or the type of chemical bond can influence the bioactivity of the final product, and nowadays, several alternative chemical strategies for ligand-to-protein coupling are available to researchers. The most frequent chemical strategy relies on the modification of lysil and/or α-terminal (Kinstler, 1996) primary amines because their acylation often leads to conjugates with desired properties and good residual biological activity. Nevertheless, different approaches may sometimes be necessary, such as, for example, when the integrity of certain lysines is important for the biological activity. Possible alternative targets are the carboxyl functions of aspartic and glutamic acid or the cysteine thiols. The chemistry for the modification of each of these residues has been developed (Zalipsky, 1995; Herman et al., 1995). Nevertheless, loss of biological activity is a complex issue in protein modification and sometimes, as in the case of proteins or peptides with weak structural conformation, it cannot be solved simply by changing the target amino acid. For example, when high molecular weight polymers are used, the polymeric environment can cause protein destabilization with partial to total unfolding, or it may prevent the interaction with the substrate or receptor. In these cases, a tailored chemistry can be of help in minimizing the activity loss: reversible site protection can be carried out to preserve relevant residues during chemical coupling (Caliceti et al., 1993), or alternatively, selective modification of sites that are known to be less important for biorecognition can be tried (Ehrat and Luisi, 1983; Uchio et al., 1999). Besides, the size of the polymer (Veronese et al., 1996 and 1997; Sherman, 1997) and the chemistry for its grafting can be optimized for minimal negative effects. Unfortunately, data about specific residue integrity or steric requirements in biologically active peptides are not always available, and often their importance has to be assessed randomly by using a trial and error approach.

In this work, the principle of tailored chemistry has been applied for the monomethoxypoly(ethylene glycol) (PEG) derivatization of the somatostatin analogue RC-160, (Vapreotide) an octapeptide with potential application as a therapeutic agent (Hofland et al., 1994). Analogues of somatostatin are primarily used for the treatment of patients with growth hormone (GH) secreting adenomas and for the treatment of symptoms related to the hormonal hypersecretion induced by various neuroendocrine tumors. Moreover, the efficacy of vapreotide in the treatment of acute variceal bleeding in cirrhotic patients was recently demonstrated (Calès et al., 2001). However, the administration of this class of molecules is sometimes difficult to optimize. For example, in the case of somatostatin, a continuous intravenous infusion is

Figure 1. Schematic representation of Vapreotide (RC160).

required to reach a suitable blood concentration because single parenteral boosts are not very effective: a large administration dose is responsible for a re-bound effect and several side effects, while low doses are ineffective. New controlled release systems—based on matrixes suitable for polypeptide release (Rothen-Weinhold et al., 1998) or on the conjugation with soluble polymers—that prolong the circulation time without the risk of immunogenicity may therefore offer valuable alternatives in the administration profile of this class of compounds.

From a chemical point of view, RC160 (Figure 1) is an eight-amino acid peptide, and it carries two primary amino groups that offer potential sites for polymer coupling. The first one comes from the peptide's α-amino function (phenylanine), and the other one is the lysine's ϵ-amino residue in position 3. In this work, four mono-PEG derivative of RC160 were synthesized where the α or ϵ amino functions were modified either through an acyl or an alkyl bond. Circular dichroism studies were carried out in order to evaluate the structural conformation of the PEG derivatives, and their biological activity was assessed by measuring their capability to inhibit GH release from rat anterior pituitary cells. On the basis of the results obtained, it has been possible to select the best conjugate for further therapeutic developments.

METHODS

General. RC160 was gently provided by Debiopharm (Lausanne, Switzerland). The native hormone somatostatin (SS-14) was purchased from Sigma (St. Louis, MO); Monomethoxy poly(ethylene glycol)norleucine-N-hydroxysuccinimide (MW 5000) (PEG-Nle-NHS) (Sartore et al., 1991) and PEG-aldehyde (PEG-ALD) (Chamow et al., 1994) were purchased by Shearwater Polymers (Huntsville, AL). High-performance liquid chromatography (HPLC) eluants were of HPLC grade or Microselect (Fluka-Chemie, Amersham, Germany). All other chemicals were of analytical or reagent grade. UV−vis determinations were performed on Perkin-Elmer λ2 and λ5 spectrophotometers; circular dichroism spectra were recorded with a Jasco J-500 spectropolarimeter.

The value of ϵ 280 nm of 12 050 ($A^{1\%}{}_{1\ cm} = 100$) for RC160 was calculated by spectroscopic analysis of weighted samples, and it was used for the determination of protein concentration in all experiments.

All of the RC160 derivatives were characterized by RP-HPLC. Analyses were performed on a Vydac-C4 column, using either CH_3CN/H_2O/0.05%TFA or MeOH/10 mM amonium acetate, pH 6.6, as elution systems. Peaks were detected at 220 or 280 nm. In the CH_3CN/H_2O/TFA elution system, CH_3CN/TFA was linearly increased from 25% to 55% in 15 min; then a 5 min isocratic step at 55% CH_3CN/TFA was applied, followed by a washing step with 95% of the acetonitrile eluant. In the methanol/amonium acetate system, a linear gradient of methanol from 60 to 100% in 15 min was used, followed by a 10 min isocratic step with 100% methanol.

The degree of amino group substitution in the modified RC160 samples was measured by fluorescamine assay (Udenfriend et al., 1972; Stocks et al. 1986): 1 mL of fluorescamine solution (0.3 mg/mL in acetone) was added, while mixing vigorously, to 3 mL of the RC160 sample (10−15 μg) dissolved in 0.1 M phosphate, pH 8.0. After 10 min, the fluorescence (λ exc. 290 nm, λ em.475 nm) was measured.

Matrix-Assisted Laser Desorption Ionization Mass Spectrometry (MALDI-MS) was carried out on the derivatives to confirm the degree of modification on the basis of the increase in molecular weight of the conjugates. Analyses were carried out on a TOF-reflex mass spectrometer (Bruker-Franz Analytik, Brema, Germany). Equal volumes of analyte (100 pmol/mL in milliQ water) and matrix (saturated sinapinic acid in 50% CH_3CN, 50% H_2O) solutions were mixed prior to the analysis, and 2 mL of the final solution was applied on the stainless steel target. Final spectra are the sum of ∼30−60 laser shots, calibrated externally using human insulin.

RC160,α,ϵ-bi-BOC. Di-*tert*-butyl dicarbonate (BOC_2) (0.25 M in THF) was added in a 20-fold excess to RC160, dissolved in ethanol/0.2M borate buffer, pH 8.5, 1/1 (2 mg/mL). The reaction mixture was stirred overnight at room temperature, and the product was analyzed and purified by RP-HPLC and dried by Speed-Vac evaporation

RC160,α-mono-BOC. Di-*tert*-butyl dicarbonate (BOC_2) (0.25 M in THF) was added in 5-fold excess to RC160 dissolved in ethanol/0.1M phosphate buffer, pH 6.0, 1/1 (2 mg/mL), and the mixture was stirred overnight at room temperature. The product was analyzed and purified from the bi-BOC derivative by RP-HPLC and dried by Speed-Vac evaporation.

RC160,ϵ-mono-BOC. Di-*tert*-butyl dicarbonate (BOC_2) (0.25 M in THF) was added in equimolar amounts to RC160 dissolved in ethanol/0.2M borate buffer, pH 8.5, 1/1 (2 mg/mL), and the reaction was stirred overnight at room temperature. The product was analyzed and purified from the bi-BOC-ylated derivative by RP-HPLC and dried by Speed-Vac evaporation.

RC160,α-mono-BOC,ϵ-PEG-Nle (acyl). α-MonoBOC-RC160 was dissolved in ethanol/0.2M borate buffer, pH 8.5, 1/1 (final concentration 2 mg/mL), and a 5-fold excess of PEG-Nle-NHS (M. W. 5000) (Sartore et al., 1991) was added while stirring. The reaction was over after 1 h at room temperature, as confirmed by analytical RP-HPLC. The product was purified by semipreparative HPLC and lyophilized. Total amine substitution was confirmed by fluorescamine assay.

RC160,α-mono-BOC,ϵ-PEG (alkyl). α-MonoBOC-RC160 was dissolved in ethanol/50mM sodium phosphate pH 6.0, 1/1, to a final concentration of 2 mg/mL. Five equivalents of PEG-ALD (M. W.5.000) (Shearwater Pol., Huntsville, AL) and 2 equiv of $NaCNBH_3$ were added to the solution, and the pH was adjusted to 8.0. The reaction, followed by RP-HPLC, was completed in 20 h. The product was purified by RP-HPLC and freeze-dried.

RC160,α-NH_2,ϵ-PEG-Nle (acyl) and RC160,α-NH_2,ϵ-PEG (alkyl). The BOC protective group was removed by acidic treatment (95%TFA, 30 min, room temperature). The acid was neutralized by adding an equimolar amount of triethylamine (TEA) while cooling the solution with an ice bath. After ultrafiltration (Amicon membrane YM1, cutoff 1000), the product was purified by RP-HPLC and freeze-dried.

RC160,α-PEG-Nle (acyl),ϵ-NH_2 and RC160,α-PEG (alkyl),ϵ-NH_2. The same procedures as for the syntheses of RC160-α-NH_2,ϵ-PEG-Nle and RC160-α-NH_2,ϵ-PEG were used. Instead of RC160,α-mono-BOC, RC160,ϵ-mono-BOC was used as the starting compound.

RC160-$TNBS_2$. RC160 (0.5 mg) was dissolved in 400 μL of ethanol/0.2M borate buffer, pH 9.5, 1/1, and trinitrobenzenesulfonic acid (TNBS) (15 mg, 100 equiv.) was added while stirring. After 45 min., 10 mL of

deionized water was added, the product was purified by extensive ultrafiltration (membrane YM1) and freeze-dried. Purity was assessed by RP-HPLC.

RC160,α-TNBS,ϵ-PEG-Nle (acyl). RC160,α-NH_2,ϵ-PEG-Nle was dissolved in 0.1 M borate buffer, pH 9.5 (0.18 mg/100 μL), and TNBS (6.22 mg) was added while stirring. After 1 h., the product was purified by extensive ultrafiltration and freeze-dried. Analysis was carried out by RP-HPLC.

Amino Acid Analysis of unmodified RC160, RC160-$TNBS_2$, RC160,α-TNBS,ϵ-PEG-Nle, and RC160,α-NH_2,ϵ-PEG-Nle was carried out after acidic hydrolysis (24 h, at 110 °C in 6 N HCl, 0.1% phenol). Analysis was carried out by HPLC according to standard protocols (Bidlingmeyer et al., 1984).

Circular Dichroism analyses on unmodified RC160 and its four PEGylated derivatives were carried out in PBS buffer with sample concentration of 0.1 mg/mL.

Biological Activity. The biological activity of RC160, its PEGylated derivatives and of natural somatostatin was measured as previously described (Hofland et al., 1994, Breeman et al., 1994) by assaying their ability to inhibit GH release from anterior pituitary cells obtained from adult male rats. In short, anterior pituitary cells, obtained from rat pituitary glands (Hofland et al., 1994, Breeman et al. 1994) were seeded in 24-well cluster plates (10^5 cells/well) in MEM medium with Earle's salts at pH 7.4, supplemented with nonessential amino acids, sodium pyruvate, 10% fetal calf serum, penicillin, fungizone, L-glutamine, and sodium bicarbonate and incubated in 95% air/ 5% $C0_2$ humidified at 37 °C. After 4−5 days, the medium was refreshed and incubated for 4 h in the presence or absence of several logarithmic dilutions of the RC160 derivatives (10^{-6} to 10^{-14} M), dissolved in the medium above. The native hormone, somatostatin, was tested as positive control. Assays were carried out in quadruplicates.

The amount of GH released in the medium was measured by a commercial radioimmunoassay kit, purchased from Amersham Pharmacia Biotech (Uppsala, Sweden). IC_{50} values for inhibition of growth hormone were calculated from the plots expressing the amount of released GH versus somatostatine analogue concentration, using the computer fitting program of Graphpad (ISI software, Philadelphia, PA). These values reflect the concentration of peptide that allows a level of GH release equal to 50% of the maximal inhibition observed.

RESULTS AND DISCUSSION

In recent years, the use of biocompatible, low molecular weight (5−20 000 Da) polymers to modify peptides or proteins devised for therapy enabled overcoming many of the problems associated with the use of these therapeutically useful molecules. Monomethoxypoly(ethylene glycol) (PEG) is the polymer most commonly used for this purpose because of its high biocompatibilty and its amphiphilic properties. Besides, the monofunctionality of this polymer, which has one single hydroxyl group per molecule, allows a clean chemistry without the risk of cross-linking. In this work, we describe the synthesis and characterization of four mono-PEG derivatives of RC160, a peptide hormone with two reactive amino groups, the α-amino function, and the ϵ function of its unique lysine (Figure 1). Specific modification of each one of its two primary amines with PEG was achieved by selective pH-driven BOC protection of each of them, followed by reaction of the second one with PEG. Two PEG reagents were used, the active succinimidyl ester (NHS) of PEG-norleucine (16) that leads to the formation of an acyl-bond or PEG-ALD, followed by $NaCNBH_3$ treatment, that leads to an alkyl bond where the amine positive charge is maintained (Chamow et al., 1994).

Selective pH-driven BOC protection of each of the two primary amines was carried out by taking advantage of their different acidic and nucleophilic properties that allow modulation of their reactivity according to the reaction pH. In fact, complete primary amine deprotonation occurs at pH above pH 8.0, and in this environment, the reactivity of different amines depends on their nucleophilic properties. Under these conditions, the more nucleophilic lysine ϵ-NH_2 is generally more reactive toward electrophiles than α-amino groups. On the contrary, at a lower pH (6.0), the more acidic α-amino functions are generally more deprotonated than the ϵ-ones, and the order of reactivity is generally inverted.

Selective Reversible Amine Protection with BOC. Figure 2 shows HPLC analysis of the products of BOC reaction carried out at pH 6.0 or 8.5. In both cases, a binary mixture of products was obtained. RP-HPLC (Figure 2), fluorescamine assay and MALDI-MS analysis of each isolated peak (data not shown) confirmed that a mixture of mono- and bi-BOC-ylated RC160 is produced in both cases. However, HPLC co-injection (Figure 2.c) of the two reaction mixtures clearly shows that the mono-BOC adducts obtained at the two pHs are two different products, thus suggesting a different selectivity of the BOC reaction. The α- or ϵ-amino-protected RC160 was then PEGylated at the residual free amino group.

Even though the rationale of the chemical approach could have been enough to allow identification of each one of the mono-BOC-ylated RC160 forms (the α-modified one being obtained at pH 6.0 and the one at the ϵ-lysine obtained at pH 8.5), the identity of the two mono-PEG adducts was confirmed by the following procedure: (1) hypothetical RC160,α-NH_2,ϵ-PEG-Nle was synthesized by coupling PEG-Nle-NHS to the purified mono-BOC-RC160 obtained at pH 6.0, followed by removal of the BOC group by acidic treatment; (2) the free primary amine of this product was derivatized with a trinitrophenyl residue using the TNBS reagent, and similarly, native RC160 was totally modified with TNBS; (3) acidic hydrolysis and amino acid analysis of the four individual products, native RC160, RC160-$TNBS_2$, and the hypothetical RC160,α-NH_2,ϵ-PEG-Nle and RC160,α-TNBS,ϵ-PEG-Nle, was carried out, and the recovery of each amino acid in the samples (Table 1) was evaluated.

It is known from literature (Schiavon et al., 1990) that when a protein is fully trinitrophenylated with TNBS, its lysines cannot be quantified by acidic treatment and amino acid analysis because of the stability of the trinitrophenyl-(TNP)-ϵ amino−lysil bond. On the contrary, the α-amino−TNP bond is less stable to the 6 M HCl treatment, and the α-amino acid of a TNP−protein is almost fully recovered in the amino acid analysis. Furthermore, the PEGϵ−acyl linkage is completely hydrolyzed under the same conditions. This was confirmed when amino acid analysis after acidic treatment was carried out on the RC160−$TNBS_2$ derivative since almost total phenylalanine recovery (80%) was obtained, whereas the amount of lysine was negligible (Table 1). Moreover, when the same analysis was performed on the hypothetical RC160,α-TNBS,ϵ-PEG-Nle and RC160,α-NH_2,ϵ-PEG-Nle, total recovery of both lysine and phenylalanine was obtained in the two samples. These data, added to the fact that 50% of the primary amines in the RC160-NH_2,PEG-Nle could be titrated by the fluorescamine assay, can lead to the conclusion that the lysine in the

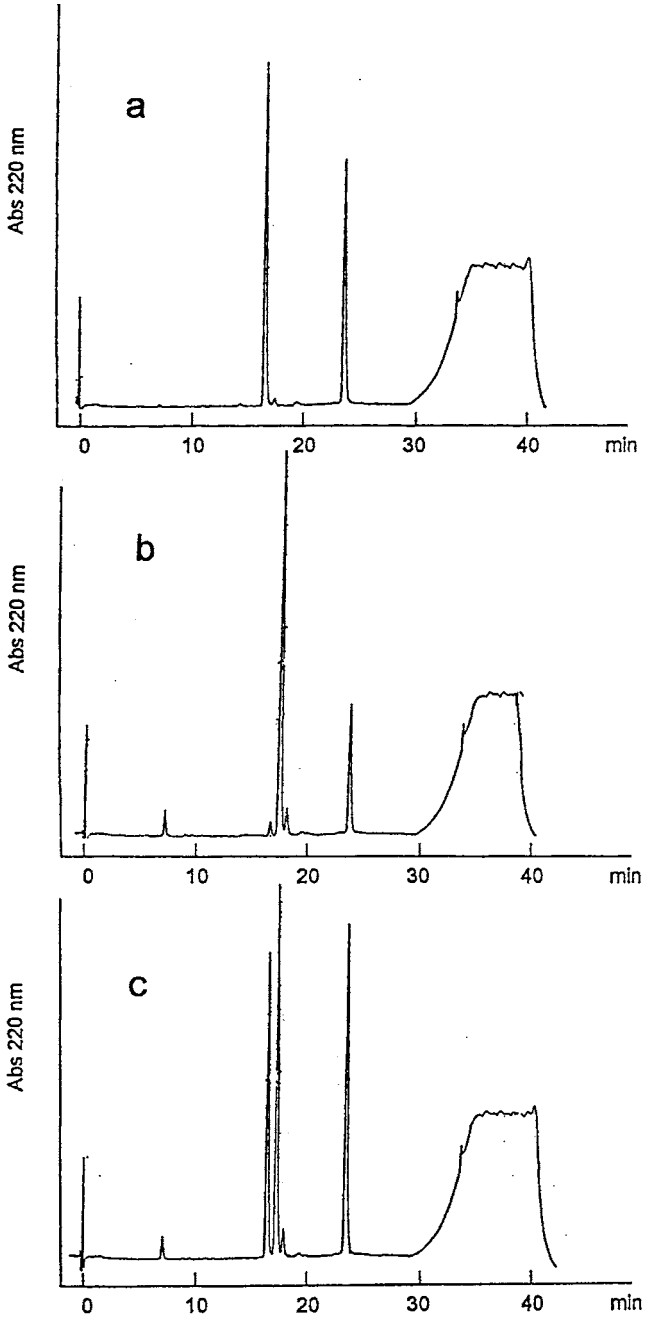

Figure 2. RP-HPLC analysis of the reaction mixtures obtained by reaction RC160 with di-*tert*-butyl dicarbonate at pH 6.0 (a) and 8.5 (b). The reaction mixtures were co-injected (c) to prove the different identity of the mono-modified products (r.t. = 17 and 17.8 min). Analysis was performed on a Vydac C-4 column with water/acetonitrile/ TFA as eluants and a flow of 1 mL/min. Peaks were detected at 220 nm. The compound eluted at 23 min was identified as the bi-BOC-ylated derivative. Unmodified RC160 has a retention time of 7 min, and it is noticeable only as a small peak in the pH 8.5 reaction mixture.

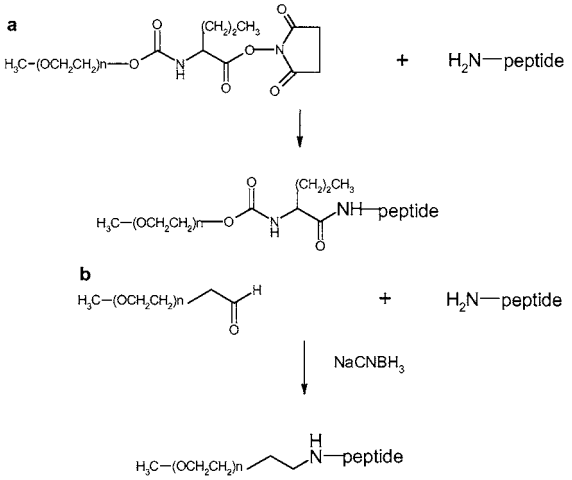
RC160-TNBS,PEG-Nle was linked to PEG and not to the TNBS moiety, thus confirming that the mono-BOC adduct obtained at pH 6.0 is the α-modified one. As a consequence, the product obtained at pH 8.5 was assumed to be the one protected at the ϵ-amino group.



PEGylation of RC160 by Acylation or Alkylation Reaction. Two different chemical approaches were used to "PEGylate" the free amino function of the two mono-BOC-derivatives (Scheme 1). In one approach, the NHS ester of PEG-norleucine (PEG-Nle) was used, this reagent leading to an amide bond. In the second approach, reductive alkylation was carried out by using PEG-aldehyde, followed by $NaCNBH_3$. The advantage of this second approach is that the positive charge in the site of coupling is maintained.

Table 1. Recovery of Phenylalanine (α-NH2) and Lysine (ϵ-NH2) and Nle in the Amino Acid Analysis of Different RC160 Derivatives[a]

	Phe (%)	Lys (%)	Nle (%)
unmodified RC160	100	100	–
RC160-$TNBS_2$	80	9	–
RC160,α-NH_2,ϵ-PEG-Nle	100	100	100
RC160,α-TNBS,ϵ-PEG-Nle	75	100	100

[a] Numbers are reported as percentages and are referred to the recovery of the stable valine in the peptide

Scheme 1. Schematic Representation of Peptide NH_2 Modification: Acylation with PEG-Nle-NHS (a) and Alkylation with PEG-ALD (b)

After PEG coupling, the protective BOC group was removed by acidic treatment to obtain the desired final product. Preparative HPLC was needed for the purification of the final product that was obtained with overall yield of about 65% and 50% for the acyl and alkyl derivatives, respectively. The purity and the identity of the final compounds were then confirmed by RP-HPLC and MALDI-MS spectrometry (Table 2).

Structural Studies by CD Evaluation. The effect of the location of polymer grafting on the peptide's was assayed by circular dichroism. The four mono-PEGylated derivatives were analyzed and compared to the unmodified peptide. The results obtained (Figure 3) demonstrated that modification of the α position causes a stronger perturbation than the one in ϵ: the ϵ-PEGylate alkyl and acyl derivatives maintained about 70% and 50% of the original secondary structure, respectively. On the other hand, the α-modified ones showed more significant loss in their conformation.

On the basis of this result, only the two ϵ-modified peptides were selected for the evaluation of the biological activity.

Biological Activity of RC160 Conjugates on Cell Culture. The biological activity of the unmodified RC160 and the acyl and alkyl ϵ-PEGylated derivatives was assayed in vitro on cultured normal rat anterior pituitary cells measuring the inhibition on GH release. Levels of GH released were normalized against those obtained from cells treated with GRF in the absence of the RC160 derivative. IC_{50} values express the concentration of RC160 derivative that leads to a level of GH release equal to 50% of the maximal inhibitory effect by the compound.

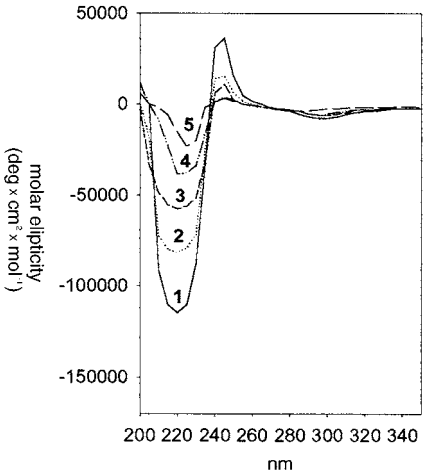

Figure 3. Circular dichroism spectra of unmodified RC160 (**1**) and its four PEG conjugates: RC160,α-NH_2,ϵ-PEG (alkyl) (**2**), RC160,α-NH_2,ϵ-PEGNle (acyl) (**3**), RC160,α-PEG,ϵ-NH_2 (alkyl) (**4**), and RC160,α-PEG-Nle,ϵ-NH_2 (acyl) (**5**). Spectra were recorded in PBS buffer with sample concentration of 0.1 mg/mL.

Table 3. IC50 Values of Inhibition of GH Release by Cultured Rat Anterior Pituitary cells by RC160 Derivatives and Somatostatin (See Methods Section for Experimental Details)

derivative	$IC_{50} \pm SD$
RC160	$(3.15 \pm 4) \times 10^{-13}$ M
RC160,α-NH_2,ϵ-PEG-Nle (acyl)	not active
RC160,α-NH_2,ϵ-PEG (alkyl)	$(4.3 \pm 4.9) \times 10^{-10}$ M
somatostatin	$(1.4 \pm 0.85) \times 10^{-10}$ M

Table 3 shows the mean values of IC50 obtained from two separated sets of experiments, each one carried out in quadruplicates. Only the alkylated derivative showed significant biological activity in the system studied, whereas the acylated compound did not show any effect, thus demonstrating the importance of the lysine's positive charge for the peptide's biological activity.

The ϵ-alkyl PEG derivative is 3 orders of magnitude less active than unmodified RC160. Nevertheless, this bioconjugate is still quite active (for example, its potency is comparable to the one of natural somatostatin in our in vitro test) and might still be useful in therapy. Biological activity of somatostatin analogues depends on both their affinity for the cellular receptor and stability toward enzymatic degradation. For example, natural somatostatin is highly susceptible to degradation, whereas RC160 is more resistant, this property being correlated to the latter's higher potency. In the case of PEGylated RC160, loss of activity might be related to a steric impediment that affects its affinity for the cellular receptor. On the other hand, PEGylation may improve the peptide's bioavailability in vivo thanks to a higher stability and a longer body permanence, as already demonstrated with several PEGylated proteins. Therefore, the real efficacy of this new conjugate as a potential drug will have to be evaluated by further in vivo pharmacological studies.

CONCLUSIONS

In this work, the possibility of using a tailored chemistry for the modification of small peptides with monomethoxy poly(ethylene glycol) has been exploited to prevent total loss of conformation and biological activity.

The problem of preserving the biological potentials of biomolecules after coupling bulky polymers to their surface is particularly important when small peptides are considered. The results here reported confirm this thinking. Four mono-PEGylated derivatives of RC160, an eight-amino acid amino acid analogue of somatostatin, were synthesized by using a tailored chemistry where both the site of polymer grafting and the type of chemical bond were defined. By a combination of chemical, structural, and biological analysis, we could verify that only one of the four synthesized products may be suitable for further therapeutic development. More precisely, circular dichroism analyses demonstrated the importance of the integrity of α-amino function in the peptide, while in vitro biological tests proved that the preservation of lysine's charge is fundamental for the activity.

These result confirm the importance of using a tailored chemistry in the development of polymer-peptide conjugates and, in this specific case, the usefulness of reversible amino acid protection to direct the modification only to the desired residues for the synthesis of bioconjugates with the most favorable properties.

Asymmetrical, Water-Soluble Phthalocyanine Dyes for Covalent Labeling of Oligonucleotides

Robert P. Hammer,* Clyde V. Owens, Seok-Hwan Hwang, Christie M. Sayes, and Steven A. Soper*

Department of Chemistry, Louisiana State University,
Baton Rouge, Louisiana 70803-1804. Received November 30, 2001; Revised Manuscript Received July 31, 2002

Two new water-soluble, porphyrazine (Pz) dyes containing an isothiocyanate function for covalent linking have each been prepared by cross condensation of two different aromatic dinitriles, one containing carboxylates for solubilizing purposes and the other containing a nitro group for conversion into the labeling function. The initial mononitrotricarboxylato Pzs have been purified to homogeneity from the mixture of Pz congeners formed in the condensation reaction by anion exchange chromatography. The phthalocyanine dye **1** has an absorption maxima at 683 nm while the trinaphthoporphyrazine dye **2** has an absorption maxima at 755 nm, due to the increased size of the aromatic system. Both dyes were successfully conjugated to oligonucleotide primers, showing their potential for use in near-infrared-based DNA diagnostic applications.

INTRODUCTION

Most bioanalytical applications using fluorescence as the readout mode for detection typically use labeling reagents that fluoresce in the visible region (400−650 nm) of the electromagnetic spectrum (*1*, *2*). Unfortunately, the spectroscopic range utilized by these fluorophores is susceptible to biological interferences from the sample matrix, which inevitably limits the sensitivity of the measurement. An attractive alternative is the use of near-IR fluorescence (650−1000 nm), which has recently been demonstrated to be a viable detection strategy in many bioanalytical assays, such as liquid chromatography (*3*−*5*), free solution capillary electrophoresis (*6*−*10*), and capillary gel electrophoresis for DNA sequencing and fragment analysis (*11*, *12*). Near-IR fluorescence offers reduced background matrix interferences compared to UV or visible fluorescence resulting primarily from the fact that a limited number of components show intrinsic fluorescence in this region of the electromagnetic spectrum. In addition, lower scattering levels are also observed in the near-IR because of the λ^{-4} dependence of the Raman cross section on the excitation wavelength. Indeed, we have demonstrated improved limits of detection in the near-IR compared to visible excitation for oligonucleotides separated using capillary gel electrophoresis (*11*). Also, near-IR fluorescence allows the use of inexpensive semiconductor devices, such as diode lasers and detectors, significantly simplifying the readout hardware (*13*).

Recently, reports on near-IR water-soluble dyes that can covalently and noncovalently label biomolecules such as amino acids, proteins and oligonucleotides, have been discussed (*14*−*23*). The dyes typically used are the tricarbocyanines, which consist of heteroaromatic structures linked by a polymethine chain containing conjugated carbon/carbon double bonds. These dyes possess large molar absorptivities ($>10^5$ cm^{-1} M^{-1}) and display favorable solubility in aqueous solvents provided by the negatively charged sulfopropyl groups attached to the heteroaromatic rings (*24*). The major limitations associated with these dyes are their poor chemical and photochemical stabilities and low quantum yields in aqueous media, therefore limiting their utility in ultrasensitive applications (*25*, *26*).

An attractive alternative to the cyanine-based near-IR fluorophores is the phthalocyanine [Pc; also know as tetraazaporphyrins or porphyrazines (Pz)] family of compounds. The Pc dyes are chemically and photochemically robust and have large extinction coefficients ($>10^5$ cm^{-1} M^{-1}) as well as favorable quantum yields (*27*). Additionally, absorbance and fluorescence maxima can easily be altered by varying the substituents around the ring or by changing the metal center (Zn, Sn Al, Si, etc.). For example, annulation of benzene rings onto the Pc core will produce the naphthalocyanine (Npc) dyes, which have λ_{max} red-shifted by 50−100 nm compared to the Pc dyes (*28*, *29*). Unfortunately, the Pc and Npc dyes are very hydrophobic and essentially insoluble in water. Functionalization of the periphery of the dye with charged groups (SO_3^-, CO_2^-, PO_3^{2-}, etc.) or attachment of a polar functionality to the metal center (PEG-OSi) does provide water-soluble Pc dyes (*30*). General routes to water-soluble Pc dyes that also contain a labeling function have not been reported to-date because of the need for preparing asymmetrical analogues, which can be very difficult to purify due to statistical formation of isomers during ring assembly.

One way to approach the preparation of labeling water-soluble Pc is to put the reactive group (**L**) in one "quadrant" of the macrocycle (see Figure 1) and then use one or more of the remaining quadrants to incorporate water-solubilizing groups (**S**). Pc and Npc dyes are generally prepared by cyclo-tetramerization of aromatic 1,2-dinitriles (phthalonitriles or naphthalonitriles) using either Lewis base or acid conditions (*31*, *32*). The simplest route to prepare nonsymmetrically substituted Pc dyes as discussed above would use one phthalonitrile that contains the (latent) labeling group **L** and another containing the solubilizing group **S** in a molar ratio of 1:3. This mixed "condensation" route is commonly used to prepare asymmetric Pc and Npc dyes, but as yet has not been applied to dyes containing a mixture of labeling

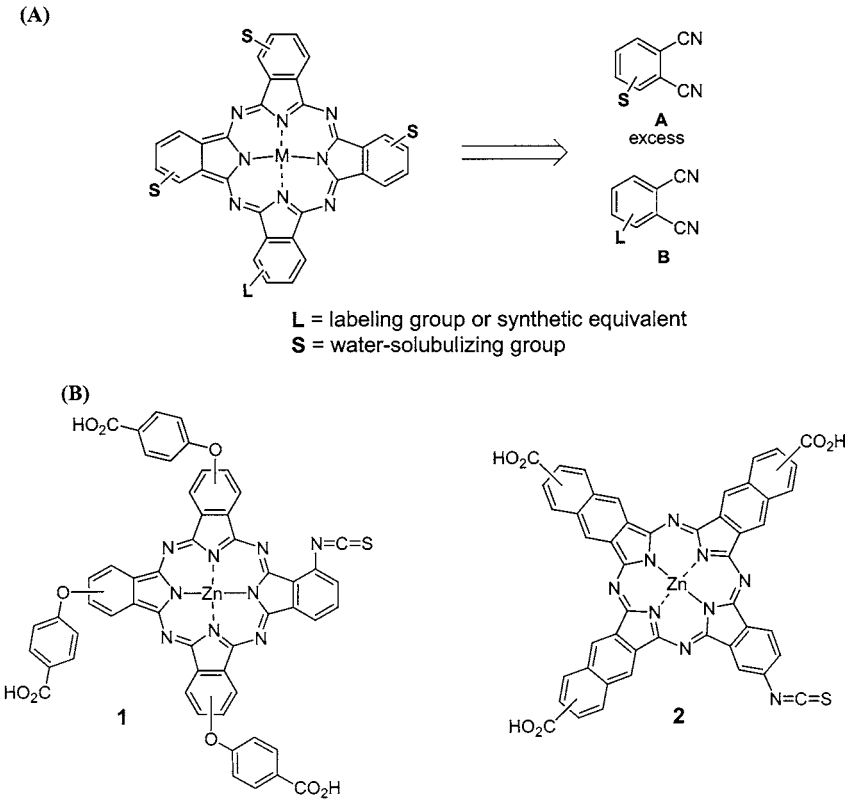

Figure 1. (A) Preparation of labeling, water-soluble Pc dye placing the reactive group (**L**) in one "quadrant" of the macrocycle with one or more of the remaining quadrants used to incorporate water-solubilizing groups (**S**). (B) Structure of water-soluble Pc (**1**) and pseudo-Npc (**2**) dyes containing reactive isothiocyanates for labeling.

and water-solubilizing groups we desire. Herein, we report the synthesis, spectroscopic properties, and labeling reactions of two new water-soluble near-IR dyes, Pc **1** and pseudo-Npc benzotrinaphthoporphyrazine (Tnpz) **2** (Figure 1), both of which contain a reactive isothiocyanate functional group used for covalent labeling of targets containing primary amines.

EXPERIMENTAL SECTION

Reagents. 2,3-Naphthalenedicarbonitrile, 3-nitropthalonitrile, 4-nitropthalonitrile, 1,1′-thiocarbonyldi-2(1*H*)-pyridone, palladium 10% on activated carbon, sodium thiosulfate, fumaronitrile, sodium iodide, carbon tetrachloride, 3,4-dimethylbenzoic acid, and zinc acetate dihydrate were obtained from Aldrich Chemical Co. (Milwaukee, WI). Hydrochloric acid and sulfuric acid were obtained from Fisher Scientific (Houston, TX). Potassium nitrate, sodium carbonate, sodium hydroxide, and urea were obtained from Sigma Chemical Co (St. Louis, MO). All chemicals were used as received. The dinitrile derivatives **3** and **4** used for final ring assembly were synthesized according to Kliesch et al. (*33*).

Chromatographic Purification and Spectroscopic Characterization. The crude reaction mixtures containing the water-soluble macrocycles were assayed by a Rainin HPLC system using a Hamilton PRP-1 analytical column (0.46 × 15 cm; Hamilton, Reno, NV) using a flow rate of 2.0 mL/min and a gradient consisting of 0.1 M triethylammonium acetate/20 mM sodium phosphate buffer (pH = 10.1) and tetrahydrofuran (THF). The absorbance detector (Shimadzu, Columbia, MD) was set at either 680 or 780 nm to monitor elution of the near-IR dyes. For typical analytical analyses, 1 mg of the crude dye mixture was dissolved in 2 mL of 20 mM sodium phosphate buffer. A 20 μL aliquot was injected into the column, which had been equilibrated with 100% 20 mM sodium phosphate buffer. Elution was carried out by a stepwise gradient from 0 to 100% THF over a period of 25 min.

Large-scale separations were carried out on a 2.15 × 25 cm Hamilton PRP-1 preparatory column (Hamilton, Reno, NV) packed with a polymeric reverse phase (C_{18}) that was equilibrated for 10 min with 20 mM sodium phosphate buffer (pH = 10.1). The water-soluble dye mixture (less than 1 g) was dissolved in 10 mL of buffer and injected into the preparatory column. The HPLC stepwise gradient used for analytical separations was slightly modified for preparatory work by extending the gradient step times to compensate for the increased flow rate (5 mL min^{-1}). Dyes were recovered from collected fractions by removing the solvent (HPLC mobile phase) using a rotary evaporator.

The absorption spectra were acquired on a Perkin-Elmer Lambda 3B UV/Vis spectrophotometer. The fluorescence spectra were obtained using a SPEX Fluorolog spectrofluorometer (SPEX, Edison, NJ) equipped with a 75 W xenon lamp. The emission gratings were blazed for 750 nm and the photomultiplier tube was a Hammamatsu R636 red-sensitive tube (Hammamatsu Corporation, Bridgewater, NJ).

Synthesis of Dyes. *[1-Nitro-9(10),16(17),23(24)-tris-(4-carboxyphenoxy)phthalocyanato]zinc(II) (**5**).* 4-(3,4-Dicyanophenoxy)benzoic acid (**3**; 0.425 g, 1.60 mmol) and 3-nitropthalonitrile (0.135 g; 0.81 mmol) were combined with 0.100 g of zinc acetate dihydrate. The reaction mixture was ground together into a fine homogeneous powder and heated at 200 °C for 20 min.

Reactions with the metal salts at 200−210 °C proceeded rapidly. Further heating decreased the yield of the desired metal complex as determined by the loss in

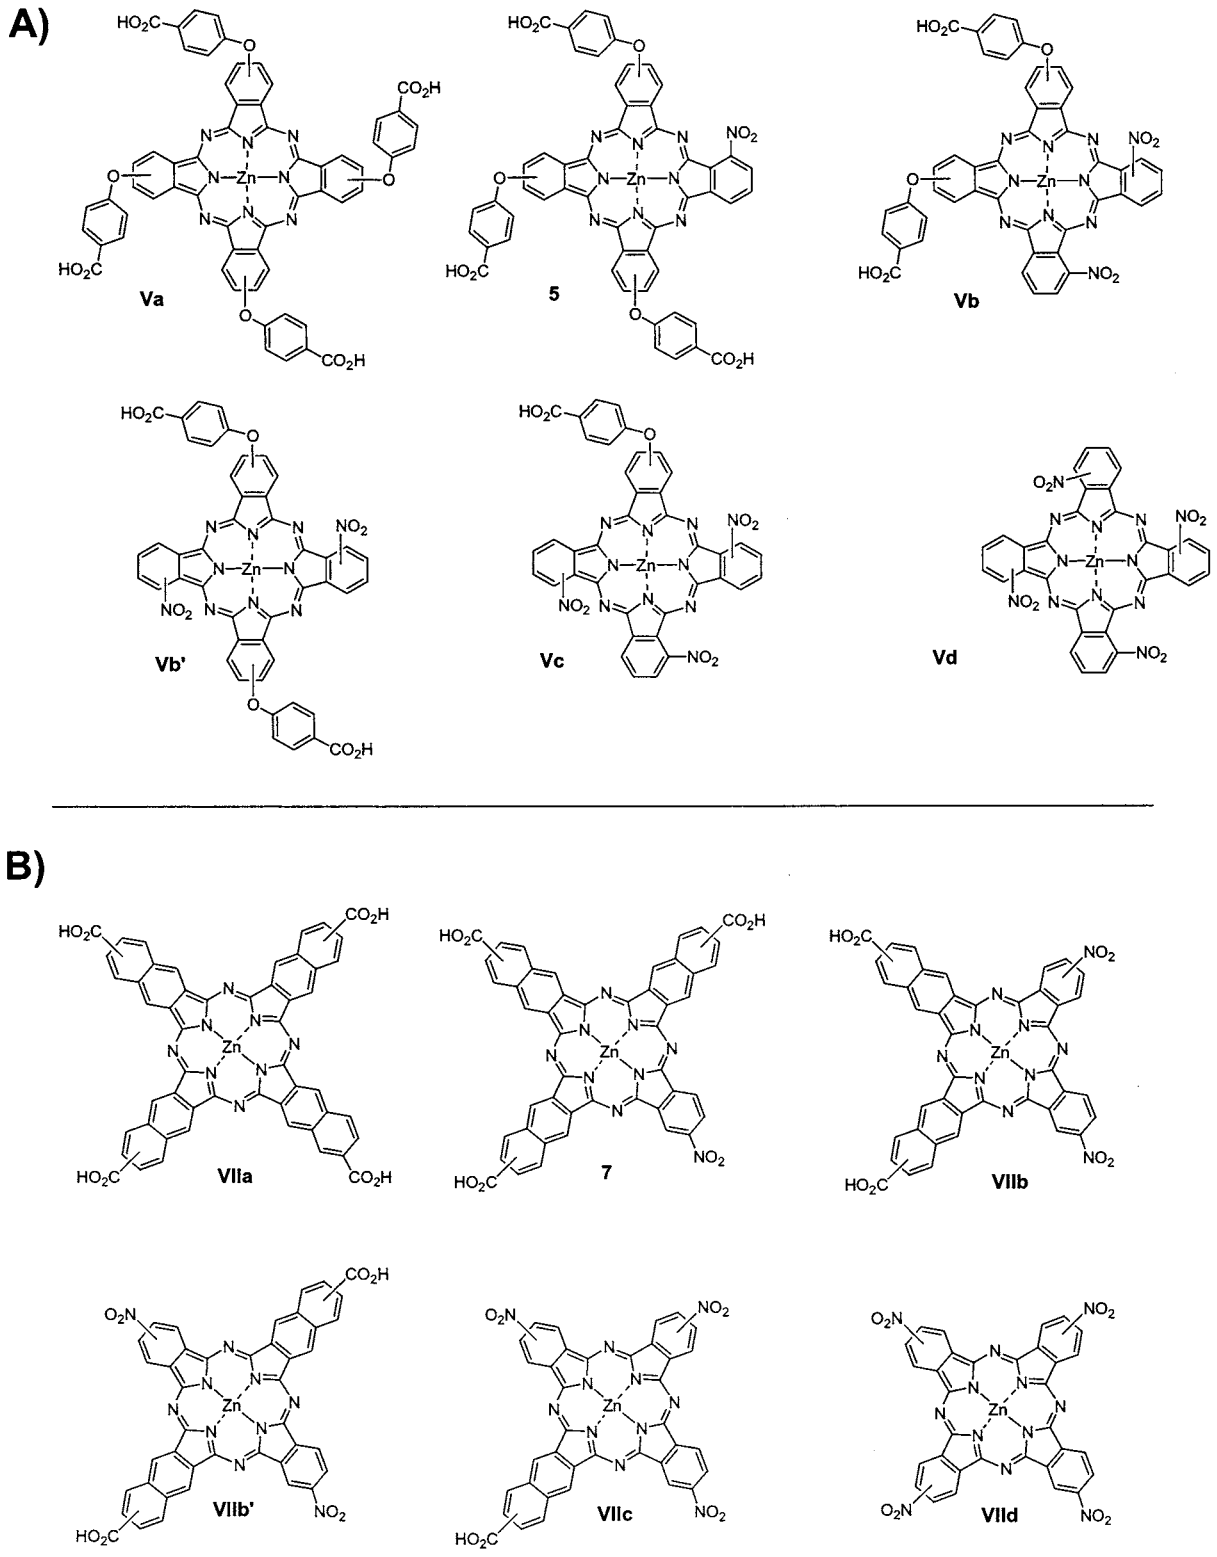

Figure 2. (A) Structures of nitro-Pc congeners (**Va**, **5**, **Vb**, **Vb′**, **Vc**, **Vd**) obtained from the reaction of 3-nitrophthalonitrile with 4-(3,4-dicyanophenoxy)benzoic acid (**3**). (B) Structures of the nitro-Tnpz congeners (**VIIa**, **7**, **VIIb**, **VIIb′**, **VIIc**, **VIId**) obtained from the reaction of 4-nitrophthalonitrile with 6,7-dicyanonaphthalenecarboxylic acid (**4**).

absorption in the near-IR. Lowering the temperature slowed the reaction, but did not increase product yield. The dark green precipitate containing desired Pc **5** and the other Pc congeners **Va-d** was dispersed in boiling 1 M HCl, cooled to room temperature, and collected. The precipitate was dissolved in 1 M NaOH and filtered to remove any insoluble impurities (e.g., tetranitrocongener **Vd**). The filtrate was neutralized with 1 M HCl and rotary-evaporated under vacuum to yield a green solid. This product was a mixture of at least four components, which varied in the number of water soluble groups (**S**) or functional labeling components (**L**) present in the dye (Figures 1 and 2A).

The chromatographic purification/isolation involved injecting 1.0 mg of the water-soluble Pc dye into a polymeric C_{18} column equilibrated with 0.1 M TEAA/20

mM sodium phosphate buffer (pH = 10.1). The components eluted in the following order: tetracarboxylate, tricarboxylate, dicarboxylate, and monocarboxylate, compounds **Va**, **5**, **Vb/b′**, **Vc**, respectively. They were characterized by their electronic absorbance spectra and mass spectra (data not shown). Tetracarboxylate ($4CO_2^-$) Pc **Va**: HPLC t_r = 9.22 min; λ_{max} (DMSO) = 677 nm. Tricarboxylate/mononitro (3 CO_2^-/1 NO_2) Pc **5**: HPLC t_r = 11.11 min; λ_{max} (DMSO) = 672 nm; MALDI (*m*/*z*) 1028 $(M - H)^-$. Dinitro/dicarboxylate (2 CO_2^-/2 NO_2) Pc (**Vb/b′**): HPLC t_r = 12.13 min; MALDI (*m*/*z*) 938 $(M - H)^-$. Trinitro/monocarboxylate (1 CO_2^-/3 NO_2) Pc (**Vc**): HPLC t_r = 17.07 min; MALDI (*m*/*z*) 847 $(M - H)^-$.

The tricarboxylate/mononitro compound **5** is the preferred compound for labeling because of its greater water solubility (3 CO_2^-) and its single nitro group. Crude yield is typically 20% of theory as expected for the isomeric mixture obtained from the reaction. Elemental analysis shows correct C/N ratio for this product: calculated 4.99; found 5.15. MALDI-MS calculated for $C_{53}H_{27}N_9O_{11}Zn$ = 1029, found *m*/*z* 1028 $(M - H)^-$. (λ_{max} (DMSO) = 672 nm).

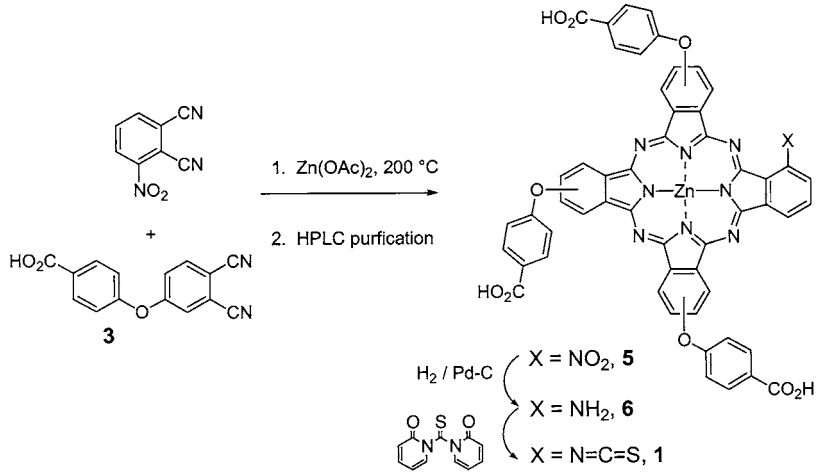
[1-Amino-9(10),16(17),23(24)-tris(4-carboxyphenoxy)-phthalocyanato]zinc(II) (**6**) A large pressure flask containing mononitro-Pc **5** (500 mg; 0.48 mmol) in water (20 mL) and 30 mg of 10% palladium on charcoal was pressurized to 40 psi of hydrogen and was shaken for 3 h at room temperature. The reaction product was filtered to remove the catalyst. The filtrate was concentrated in vacuo and the dark green precipitate dried under vacuum. Crude yield 275 mg (54%). Elemental analysis shows correct C/N ratio for this product: calculated 5.71; found 5.75. MALDI-MS calculated for $C_{53}H_{29}N_9O_9Zn$ = 999, found *m*/*z* 1000 (M + H). (λ_{max} (DMSO) = 702 nm).

[1-(Isothiocyanato)-9(10),16(17),23(24)-tris(4-carboxyphenoxy)phthalocyanato]zinc(II) (**1**). Amino-Pc **6** (350 mg; 0.35 mmol) was added to a solution of 1,1′-thiocarbonyldi-2(1H)-pyridone (250 mg, 1.08 mmol) in DMF (3 mL) and stirred for 2 h. The DMF was removed in vacuo and the dark green product was taken up in HPLC grade H_2O and filtered through a 0.45 μM filter to remove insoluble 1,1′-thiocarbonyldi-2(1*H*)-pyridone products. The filtrate was dried under vacuum to yield 86 mg (27%). Elemental analysis for $C_{54}H_{27}N_9O_9SZn{\cdot}3H_2O$, Calculated (Found): C, 59.33 (59.58); H 3.35 (2.99); N, 11.32 (11.18). MALDI-MS calculated for $C_{54}H_{27}N_9O_9SZn$ = 1041, found *m*/*z* 1040 $(M - H)^-$. (λ_{max} (DMSO) = 686 nm).

[2-Nitro-10(11),19(20),28(29)-tricarboxybenzo[b]trinaphtho[2,3-g:2′,3′−l:2″,3″-q]porphyrazinato]zinc(II) (**7**). In a condensation reaction, 6,7-dicyano-2-naphthalenecarboxylic acid (**4**) (0.474 g; 1.69 mmol) and 4-nitrophthalonitrile (0.135 g; 0.78 mmol) were combined with 0.100 g of zinc acetate dihydrate (see Scheme 2). The reaction mixture was ground together into a fine homogeneous powder and heated to 200 °C for 20 min. The resulting solid black cake (Compound **7**, plus other congeners, **VIIa**, **VIIb**, **VIIb′**, **VIIc**, **VIId;** Figure 2B) was monitored by UV absorbance for the appearance of a near-IR peak.

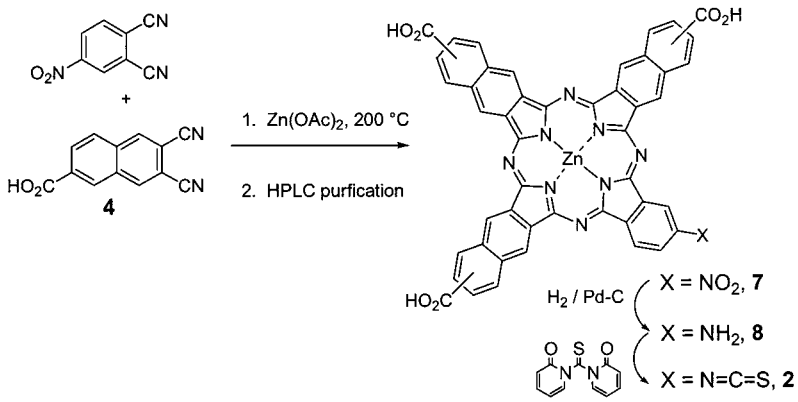
The dark green precipitate was dispersed in boiling 1 M HCl, cooled to room temperature and collected. The precipitate was dissolved in 1 M NaOH and filtered to remove any insoluble impurities (e.g., tetranitrocongener **VIId**). The filtrate was then neutralized with 1 M HCl and rotary-evaporated under vacuum to yield a green solid. This product was a mixture of at least four components, which varied in the number of water soluble groups (**S**) or functional labeling components (**L**) present in the dye (Figure 1 and Figure 2B).

The chromatographic purification/isolation involved injecting 1.0 mg of the water-soluble dye into a polymeric C_{18} column equilibrated with 0.1 M TEAA/20 mM sodium phosphate buffer (pH = 10.1). The components eluted in the following order: tetracarboxylate, tricarboxylate, dicarboxylate, and monocarboxylate, compounds **VIIa**, **7**, **VIIb/b′**, **VIIc**, respectively **(**see Figure 2B) and were characterized by their electronic absorbance spectra and mass spectra. Tetracarboxylate (4 CO_2^-) Npc **VIIa**: HPLC t_r = 5.68 min; λ_{max} (DMSO) = 768 nm; MALDI (*m*/*z*) 952 $(M - H)^-$. Tricarboxylate/mononitro (3 CO_2^-/1 NO_2) Npc (**7**): HPLC t_r = 7.08 min; λ_{max} (DMSO) = 765 nm, 727 nm; MALDI (*m*/*z*) 905 $(M - H)^-$. Dinitro/dicarboxylate (2 CO_2^-/2 NO_2), Npc **VIIb/b′**: HPLC t_r = 16.03 min; λ_{max} (DMSO) = 720 nm, 689 nm; MALDI (*m*/*z*) 856 $(M - H)^-$. Trinitro/monocarboxylate (1 CO_2^-/3 NO_2), Npc **VIIc**: HPLC t_r = 18.82 min; λ_{max} (DMSO) = 684 nm; MALDI (*m*/*z*) 806 $(M - H)^-$.



The tricarboxylate/mononitro compound, **7**, is a preferred compound for labeling because of its high number of water soluble groups (3 CO_2^-) and its single nitro group, which can be converted to a labeling function. The yield of **7** is typically ∼25% of theory as is expected for the mixture of compounds obtained in the initial condensation. IR (KBr) ν = 1645 cm^{-1} (C═O), 1525 cm^{-1} (NO_2), 1350 cm^{-1}(NO_2); MALDI-MS calculated for $C_{47}H_{21}N_9O_8Zn$ = 904, found *m*/*z* 905 $(M + H)^+$. (λ_{max} (DMSO) = 765 nm, 727 nm).

[2-Amino-10(11),19(20),28(29)-tricarboxybenzo[b]trinaphtho[2,3-g:2′,3′−l:2“,3”-q]porphyrazinato]zinc(II) (**8**). In a large pressure flask, the nitro-Tnpz **7 (**0.40 g; 0.44 mmol) was dissolved in water (20 mL) and reduced as described for amino-Pc **6.** Crude yield 210 mg (54%). Elemental analysis shows correct C/N ratio for this product: calculated 4.56; found 4.47. MALDI-MS calculated for $C_{47}H_{23}N_9O_6Zn$ = 873, found *m*/*z* 874 $(M + H)^+$. (λ_{max} (DMSO) = 750 nm).



[2-Isothiocyanato-10(11),19(20),28(29)-tricarboxy-benzo[b]trinaphtho[2,3-g:2′,3′−l:2“,3”-q]porphyrazinato]zinc-(II) (**2**). Amino-Tnpz **8** (300 mg; 0.34 mmol) was added to a solution of 1,1′-thiocarbonyldi-2(1*H*)-pyridone (250 mg, 1.08 mmol) in DMF (3 mL) and stirred for 2 h (Scheme 2). The DMF was removed in vacuo and the dark green product was taken up in HPLC grade H_2O and filtered through a 0.45 μM filter to remove insoluble 1,1′-thiocarbonyldi-2(1*H*)-pyridone products. The yield 60 mg (28%). Elemental analysis for $C_{48}H_{21}N_9SO_6Zn{\cdot}7H_2O$, Calculated (Found): C, 51.8, (51.76); H, 3.2 (2.86); N, 11.3 (11.29). MALDI-MS calculated for $C_{48}H_{21}N_9SO_6Zn$ = 916, found *m*/*z* 917 $(M + H)^+$, (λ_{max} (DMSO) = 756 nm, 723 nm).

Labeling and Purification of DNA Oligonucleotides with Pc and Tnpz Functionalized Dyes. An M13 universal sequencing primer (17mer) containing a 6-carbon alkyl linker terminated with an amino group on the 5′-end was derivatized with the dyes according to procedures outlined by Li−COR (*34*). Briefly, 50 nmol of DNA was added to 25 μL of 40 mM carbonate buffer (pH = 9.1), 25 μL of 2 mM EDTA, and 100 μL of the appropriate dye (2.5 mM) dissolved in DMF. After the reaction was allowed to proceed at room temperature for approximately 4 h, 10 μL of 3 M sodium carbonate and 480 μL of cold EtOH were added to the reaction mixture. The solution was centrifuged for 20 min at 4 °C. The supernatant was discarded and the cold ethanol precipitation step repeated again. The DNA/dye conjugate was then dried and 200 μL of water added to the pellet. The DNA/dye conjugate was finally purified using preparatory HPLC under the following conditions: Column, C_{18}; flow rate, 1.7 mL/min; mobile phase A, 0.1 M triethylammonium acetate, 4% acetonitrile, 96% water; mobile

Scheme 2. Synthesis of [2-Isothiocyanato-10(11),19(20),28(29)-tricarboxy-benzo[*b*]trinaphtho[2,3-*g*:2′,3′−l:2“,3”-*q*]-porphyrazinato]zinc(II) (2)

phase B, 0.1 M triethylammonium acetate, 80% acetonitrile, 20% water. The gradient conditions were 90/10 to 55/45 A/B over 5 min, 55/45 to 0/100 A/B over 20 min, hold 0/100 A/B for 5 min. The collected fractions were pooled and taken to dryness using a centrifugal evaporator and stored in the dark at 0 °C until required for use.

RESULTS AND DISCUSSION

Several different strategies were considered for preparing the water-soluble Pc or Npc dyes containing a labeling moiety. One issue that predicated the selected scheme was the identity of the labeling group on the chromophore. In our case, we selected a labeling group to target primary amines, either an isothiocyanate or succinimide ester. Neither of these reactive groups [Figure 1A, L = NCS, or L = CO(OSu)] would be expected to survive Pc or Npc ring assembly even under the mildest basic or acidic conditions. Therefore, it was decided that the reactive group “L” (Figure 1A) would have to be incorporated following ring assembly from a precursor that was stable to these reaction conditions. We selected isothiocyanates as the final amine-labeling group, since they can be quantitatively prepared from amines using thiophosgene (or synthetic equivalents). However, in our hands the condensation of aminophthalonitriles (L = NH_2) to form the final ring structure was not successful (data not shown). Thus, we chose the *nitro*phthalonitriles (L = NO_2) as masked forms of *amino*phthalonitriles as these were found to be stable under our ring assembly conditions (vide infra, Schemes 1 and 2). Sulfonates are the most commonly used water-solubilizing groups and can be incorporated into the phthalonitrile precursor or added postsynthetically by aromatic sulfonation. In our hands, postassembly sulfonation of nitro-substituted Pc or Npc analogues was unsuccessful due to decomposition of the macrocycle from harsh acidic conditions (*14*). Coassembly of nitrophthalonitriles and sulfonaphthalonitriles did produce near-IR products, but separation of the congeners of these reactions proved impossible either before or after the reduction of the nitro group (data not shown).

We chose to use Zn as the metal center for the Pc and pseudo-Npc dyes as this was both synthetically convenient and provided highly fluorescent dyes (*28*). Metals such as Cu or Co incorporated into the ring center yielded chromophores with only weak fluorescence. Coassembly of the nitrophthalonitrile with the carboxynaphthalonitrile in the presence of zinc acetate provided the most successful synthetic route for preparing our asymmetrical macrocycles (Schemes 1 and 2).

In general, the condensation of two different phthalonitriles, **A** and **B**, with an appropriate metal should produce a mixture of Pcs containing a statistical mixture of products: four **A** or **B** units (**AAAA** or **BBBB**), three **A** units and one **B** unit (**AAAB**), three **B** units and one **A** unit (**BBBA**), or two **A** units and two **B** units (two isomers: **ABAB** and **AABB**). To skew the product mixture toward the desired product having three water-solubilizing groups and one conjugatable group, we used a 3:1 stoichiometric ratio of the two phthalonitrile coupling partners. However, solventless condensation of 3 equiv of 4-(3,4-dicyanophenoxy)benzoic acid (**3**) and

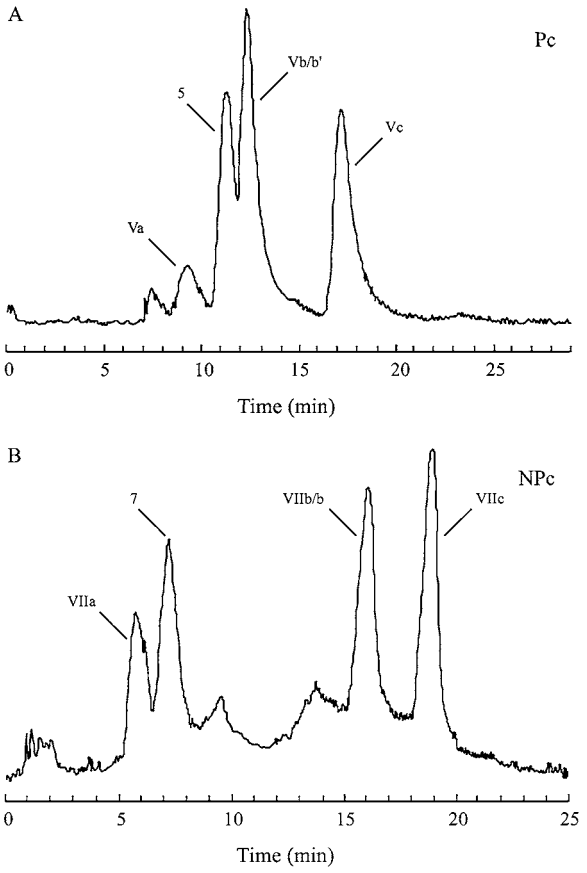

Figure 3. (A) HPLC chromatogram of the crude mixture of Pc congers **Va**, **5**, **Vb**, **Vb′** and **Vc**. HPLC conditions: same as above except detection at 700 nm.

with 1 equiv of 3-nitrophthalonitrile in the presence of zinc acetate still produced a mixture of at least four congeners (as mixtures of constitutional/positional isomers) as shown by HPLC and MS analysis (see Figure 3A). The organic soluble self-condensation product of 3-nitrophthalocyanine was likely removed during extraction of the product. Similar condensation of 3 equiv of 6,7-dicyano-2-naphthalenecarboxylic with 1 equiv of 4-nitrophthalonitrile again produced four major congeners as seen in the chromatograms shown in Figure 3B.

To aid in characterization of the mixtures, the individual precursors, 6,7-dicyano-2-naphthalenecarboxylic acid precursor and nitrophthalonitrile, were reacted separately with zinc acetate and monitored by UV absorbance (see Figure 4). The water-soluble tetracarboxylate zinc Npc **VIIa** was determined to have an absorption maximum at 768 nm, which corresponded to the absorption maximum of the first fraction eluting from the HPLC (t_r = 5.68 min, Figure 3B). The more hydrophobic trinitro zinc Pc **VIIc** was determined to have an absorbance maximum at 684 nm, which also corresponded to the fourth eluting component (t_r = 18.82 min) shown in the chromatogram of Figure 3B.

Following HPLC purification, the isolated product was brought to dryness under reduced pressure and the

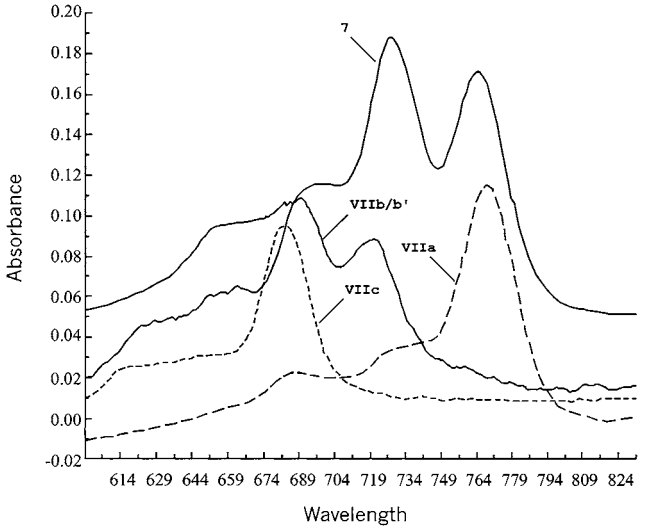

Figure 4. UV absorbance profiles of crude HPLC fractions containing Tnpz congeners (**VIIa**, **7**, **VIIb/b′**, **VIIc**; see Figure 2A) were evaluated after collection from the HPLC (concentrations are unknown).

Column: Reverse Phase-C_{18} 50 × 4.6 mm i.d.; mobile phase: 0.1 M TEAA, pH = 7.0 linear gradient 4 to 80% acetonitrile in 20 min; flow rate: 1.7 mL/min. UV absorbance detection at 254 nm. See Experimental Section for gradient conditions.

water-soluble nitro compound (**5** or **7**) was reduced to the amino group (**6** or **8**) by hydrogenation over palladium/charcoal (Schemes 1 and 2). We originally attempted to reduce the nitro group using Sn(II) chloride in hydrochloric acid. However, the reaction was unsuccessful due to decomposition of the macrocycle and possible exchange of the zinc metal with tin. For conversion of the amino group to the reactive isothiocyanate (**1** or **2**), 1,1′-thiocarbonyldi-2(1*H*)-pyridone was preferred over thiophosgene because of its ease of handling and higher stability, which resulted in higher product yields.

After purification by reverse-phase chromatography, the analysis and structural characterization by mass

Scheme 3. Conjugation of Pc Dyes to an Oligonucleotide

spectrometry (MALDI-MS, negative mode) of the substituted derivatives exhibited the characteristic pseudomolecular ion for Pc **1** and **Tnpz 2**. The infrared spectra demonstrated very strong lines at 1645 cm^{-1} (C═O), 1525 cm^{1} (NO_2), 1350 cm^{-1} (NO_2) for compounds **5** and **7**. Unfortunately, the infrared spectra of the amino (**6**, **8**) and isothiocyanate (**1**, **2**) groups in the target dyes were obscured by other absorbances. The H^1 NMR spectrum provided little information due to substantial aggregation of the samples in the solvents required for NMR, which produced significant broadening in the signal peaks.

The HPLC chromatograms shown in Figure 5 depict the conjugates formed following reaction of an amine-modified DNA 17mer oligonucleotide with the water-soluble Pc (**1**) or Tnpz (**2**) dyes containing the reactive isothiocyanate functional group (Scheme 3) to make DNA−dye conjugates **9** (Figure 5A) and **10** (Figure 5B), respectively. Both dyes demonstrated reasonable conjugation efficiency toward the amine-containing oligonucleotide. In the chromatogram of the Pc **1** conjugation mixture, it is apparent that the conjugation efficiency was slightly better compared to the Tnpz **2** because of the disappearance of unbound DNA in the conjugation reaction. The extinction coefficients for both dyes at 260 nm were found to be small, thereby producing little or no detectable absorbance signal in the chromatogram from free dye. We are not sure of the reason for the slightly poorer conjugation of the Tnpz dye, but it may be due to greater aggregation of the more hydrophobic Tnpz in the conjugation solvent, which lowered its availability for conjugation to the amine of the DNA.

In Figure 6A is shown the absorbance spectrum of the Tnpz dye **2** in methanol/DMF, which displayed two absorption bands at 755 and 725 nm, while the spectrum for this dye in an aqueous buffer solution showed significant broadening, indicative of extensive ground-state aggregation. In the case of the dye−oligonucleotide conjugate, the absorption maximum was found to be 735 nm, with the peak at ~755 nm appearing as only a weak shoulder on the band at 735 nm. The fluorescence emission profile (see Figure 6B) for the Tnpz dye **2** displayed a maximum at ~ 765 nm, while the oligonucleotide conjugate **10** showed a 15 nm red shift (λ_{em} = 780 nm). Using procedures outlined in our previous work for determining the quantum yields of near-IR dyes (*35*), the quantum yield of the conjugate was found to be 0.20 with an extinction coefficient of 1.82×10^5 cm^{-1} M^{-1}.

The dual absorbance bands observed in the electronic spectra of pseudo-Npc **2** most likely resulted from the asymmetrical character of this type of compound. When one of the four naphtho groups along the macrocycle is replaced by a benzo group, it would be expected that only one major absorption band be observed. The presence of a symmetric, single absorption band would suggest that both the molecular asymmetry and the substituents exert a synergistic effect on the electronic properties of the

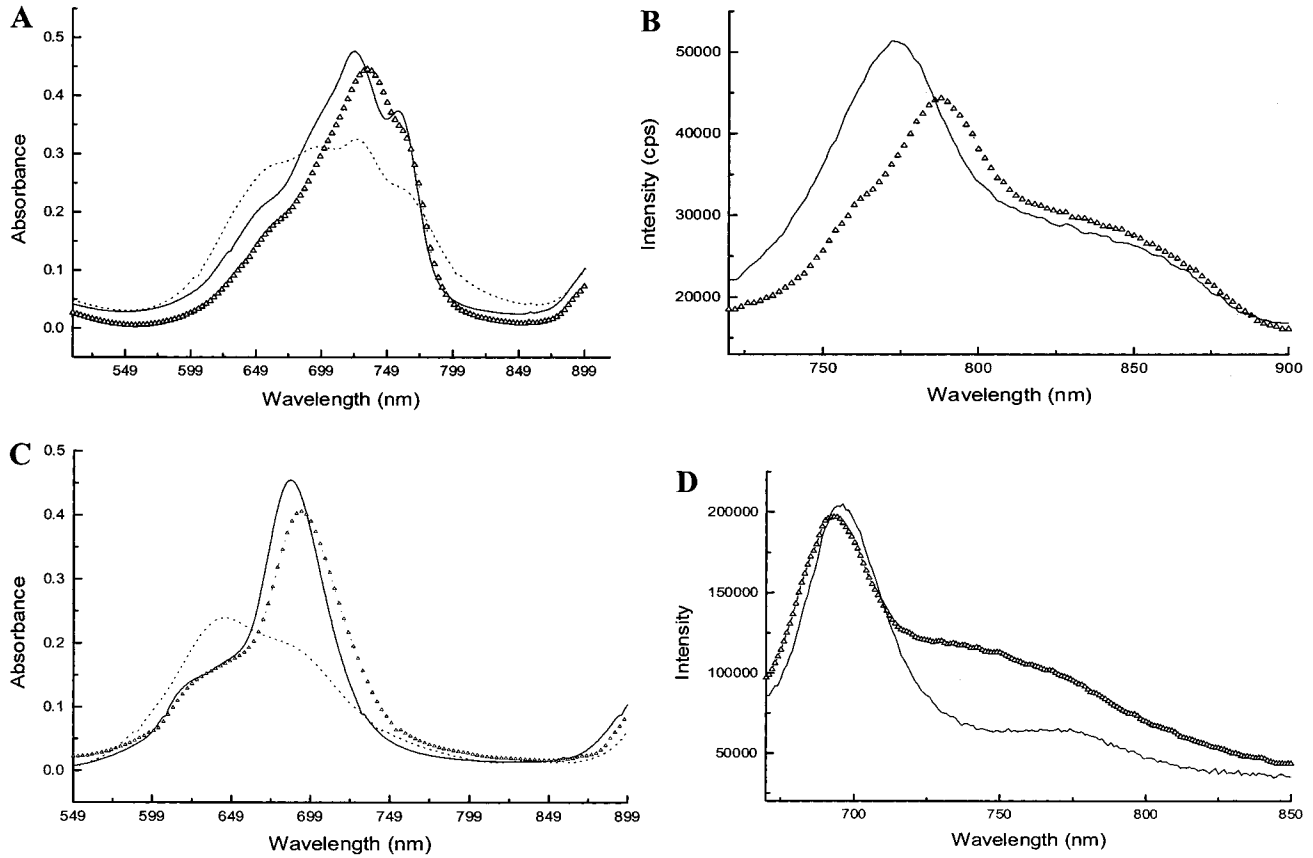

Figure 6. Absorbance (A) and emission (B) spectra of: Tnpz dye **2** in 40 mM borate buffer (- - -); Tnpz dye **2** in 70:30 methanol/DMF (—), and Tnpz-oligonucleotide conjugate **10** in 40 mM borate buffer/30% DMF (△). Absorbance (C) and emission (D) spectra of: Pc dye **1** in 40 mM borate buffer (- - -); Pc dye **1** in 70:30 methanol/DMF (—); and Pc-oligonucleotide conjugate **9** in 40 mM borate buffer/30% DMF (△). The dye concentration for all the experiments was ~2.5×10^{-6} M.

macrocycle derivatives. Instead, we observed two bands in the naphthalocyanine absorption region in organic solvent, which would be expected to be relatively free of aggregation. This observation is in agreement with the 2-fold orbital degeneracy of the excited electronic state of the metallomacrocycle when the group symmetry changes from pseudo-D_{4h} (as in Zn−Pc **1**) to pseudo-C_{2v} (as in Tnpz **2**) (*36*).

The extensive broadening of the absorption spectrum of the free dye in the aqueous buffer solution resulted from extensive ground-state aggregation; however, the dye−oligonucleotide conjugate in this same solvent system displayed predominately the monomeric form, as was evident from the similarity of the electronic spectra for the conjugate in water and free dye in CH_3OH/DMF, where only the monomeric form is expected to be the major component.

The absorption maximum for the Pc **1** dye was found to be 683 nm (see Figure 7C) and the maximum for the **1**−oligonucleotide conjugate was determined to be 694 nm, an 11 nm red shift with respect to the free dye. As with the Tnpz dye in aqueous solvents, Pc dye **1** demonstrated extensive ground state aggregation as is evident from the broad electronic spectrum. However, this aggregation effect was reduced to a large degree when the free dye was conjugated to the highly anionic DNA oligonucleotide. The fluorescence emission profile (see Figure 6D) for the free dye and dye/oligonucleotide conjugate were determined to be 700 and 692 nm, respectively. The extinction coefficient for the conjugate was found to be 1.9×10^5 cm^{-1} M^{-1} with a quantum yield of 0.26.

CONCLUSIONS

We have prepared two near-IR labeling dyes, **1** and **2** (see Figure 1), which are asymmetric Pc and Npc dyes that contain water-solubilizing groups and a labile functional group appropriate for tagging compounds containing primary amines. While most Pc and Npc dyes show poor water solubility, the excellent water solubility demonstrated by these dyes was achieved by insertion of the negatively charged carboxylate groups into the metallomacrocycle. The labeling dyes demonstrated facile conjugation to nucleic acids containing a primary amine group and yielded DNA conjugates that fluoresced strongly in the near-IR. Due to the favorable photophysical properties of these labeling dyes and their superior water solubility, they will make excellent fluorescent tags for genetic assays requiring ultrasensitive fluorescence analysis.

ACKNOWLEDGMENT

The authors would like to thank the NIH (R01-HG01499 and R24-CA84625) for financial support of this work. The authors would also like to express their appreciation to Dr. Tracy McCarley for assistance on obtaining the mass spectrometric measurements and Dr. Frank Zhou for his assistance with the NMR spectrometry.

Fractionation and Characterization of a Conjugate between a Polymeric Drug-Carrier and the Antitumor Drug Camptothecin

R. Mendichi,*,† V. Rizzo,‡ M. Gigli,‡ and A. Giacometti Schieroni†

Istituto per lo Studio delle Macromolecole (CNR), Via E. Bassini 15, 20133 Milan, Italy, and Pharmacia, Viale Pasteur 10, 20014 Nerviano (MI), Italy Received February 26, 2002; Revised Manuscript Received July 12, 2002

A conjugate between the antitumor drug camptothecin and the polymeric drug-carrier poly[*N*-(2-hydroxypropyl)methacrylamide] was synthesized and fractionated. The conjugate samples, both fractionated and unfractionated, were characterized with a multi-detector SEC system using three on-line detectors: a multi-angle light scattering photometer, a viscometer, and a refractometer. The used mobile phase (DMF + 0.01 M LiBr + 0.05 M CH_3COOH) derives from previous experience with similar conjugates. Narrow molar mass distribution fractions of the conjugate obtained by means of a semipreparative LC system were used to derive the coefficients of the Mark−Houwink−Sakurada relationship and to check the universal calibration of the SEC system. This study has demonstrated that the conjugate elutes according to the hydrodynamic volume. Thus, a conventional SEC method that uses only an on-line refractometer detector, commercially available narrow standards, and the universal calibration is adequate for the characterization of the molar mass distribution. Also the size and the conformation of the conjugate were studied by means of the gyration radius−molar mass power law.

INTRODUCTION

The use of synthetic polymers in controlled drug delivery attracts more and more interest (*1*−*5*). It is generally accepted that the success of a polymeric drug delivery system mainly depends on the properties of the used macromolecular carrier (*6*−*8*). Consequently, extensive characterization of the polymeric drug-carrier (both physicochemical and toxicologic) is of paramount relevance. Specifically, in the past few years we have characterized two different conjugates between the polymer poly[*N*-(2-hydroxypropyl)methacrylamide] (PHPMA) and two antitumor drugs. In 1996, we presented the characterization of the conjugate between PHPMA and doxorubicin (DOX) (*9*). In 1998, we presented the characterization of the conjugate between PHPMA and paclitaxel (TAX) (*10*, *11*). Both conjugates underwent phase I clinical studies, and the corresponding results were published (*12*, *13*). Continuing the project, this article presents the characterization of a new conjugate between PHPMA and the antitumor drug camptothecin (CPT). This conjugate and other related analogues have shown very promising results in preclinical models (*14*, *15*). Figure 1 shows a schematic structure of this new PHPMA-CPT conjugate that recently underwent a phase I clinical study.

PHPMA-CPT is water-soluble, and, as with the previous two conjugates, the drug is covalently bound to the carrier via an appropriate spacer. PHPMA is a synthetic polymeric drug-carrier suitable for cancer chemotherapy. PHPMA is biocompatible, water-soluble, nontoxic, and nonimmunogenic, but unfortunately is not biodegradable.

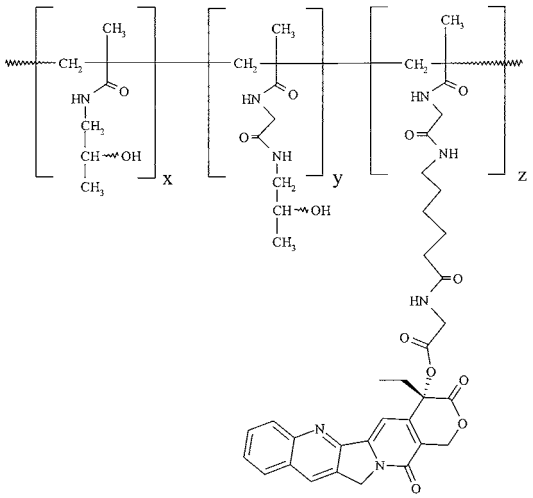

Figure 1. Structure of the PHPMA-CPT conjugate.

Thus, accumulation of the polymer in the body of patients has to be carefully avoided by keeping the whole molar mass distribution (MMD) below the renal excretion threshold (*16*). Moreover, the properties of the whole conjugate have to be studied in detail. Great importance in the biodistribution and excretion patterns of a macromolecular conjugate is attributed to its molecular properties, including MMD and molecular size (*7*, *17*, *18*). However, the conformational properties and the affinity of the macromolecule with the biochemical environment may influence its biodistribution into the organism (*19*).

This study presents the fractionation and the molecular characterization of the PHPMA-CPT conjugate by means of a size exclusion chromatography (SEC) system using three on-line detectors: a multi-angle laser light scattering (MALS) photometer, a single capillary viscometer (SCV), and a differential refractometer as concentration detector. We also report on the determination of the

bound drug content with an appropriate combination of selective hydrolysis and HPLC separation.

MATERIALS AND METHODS

MATERIALS

PHPMA-CPT samples were Pharmacia (Nerviano, Milan, Italy) products. The study was performed using both fractionated and unfractionated PHPMA-CPT samples. Table 1 summarizes the starting broad MMD lots and the narrow MMD fractions of the PHPMA-CPT conjugate. Two laboratory scale lots of PHPMA-CPT, with sizeably different molar mass values, have been used as starting material for the preparation of nine narrow MMD fractions. Lot 1 was obtained by copolymerization of methacryloyl-glycyl-6-NH_2-hexanoyl-glycyl-20-*O*-camptothecin and methacryloyl-2-propanolamide in the presence of α,α′-azo-isobutyro-nitrile in dimethyl sulfoxide at 50 °C for 48 h under stirring. Lot 2 was obtained by coupling a polymeric precursor bearing an activated ester with H_2N-$(CH_2)_5$-CO-Gly camptothecin as described in detail elsewhere (*15*). Two other low molar mass copolymers, lots 3 and 4, were obtained as described for lot 1, with the following changes: solvent was acetonylacetone (80 °C) for fraction 10 and *N*,*N*-dimethylformamide (DMF, 80 °C) for fraction 11, respectively. Lot 5 is a typical laboratory scale preparation as used during the preclinical investigation phase on PHPMA-CPT.

METHODS

Hydrolysis of Bound Camptothecin. A sample of the polymeric conjugate is weighed (about 6 mg), transferred into a screw cap tube, and dissolved under tube shaking with 7.5 mL of methanol and 7.5 mL of borate buffer (50 mM, pH 9.4). The solution is sonicated for 2 min and placed in a thermostat at 30 °C. After 20 h, the reaction is stopped with the addition of 0.1 mL of 42.5% phosphoric acid ($pH_{app} = 3$). After 1 h at room temperature (to allow reestablishment of the camptothecin lactone ring), this solution can be used for HPLC analysis within the next 20 h. A similar procedure has been applied to the bioassay of polymer-bound camptothecin in plasma samples (*20*).

A stock solution of standard camptothecin in methanol is prepared by dissolving a weighed amount (about 5 mg) of camptothecin in 50 mL of methanol. As a reference for total camptothecin assay, 5 mL of the above stock solution is transferred into a screw cap tube and diluted with 2.5 mL of methanol, 0.1 mL of 42.5% phosphoric acid, and 7.5 mL of borate buffer.

Chromatographic Method for the Determination of Bound Camptothecin. The HPLC system was a Hewlett & Packard 1090 equipped with diode array detector. After sample injection (50 μL), separation was obtained on a Waters Symmetry C18 150 × 3.9 mm 100 Å, 5 μm at 1 mL/min flow and 40 °C using 25 mM KH_2PO_4, pH 2.5, and methanol as mobile phase and the gradient program as indicated below. After 4 min of isocratic run at 45% methanol, this was linearly increased to 55% in 1 min and maintained for the next 3 min. A second linear gradient up to 90% methanol was then applied within 1 min, and this methanol content was maintained for the next 5 min. Finally, the methanol content was restored to 45% and the system allowed to reequilibrate for 8 min. Data were collected at 370 nm with a bandwidth of 4 nm (reference wavelength 550 nm, bandwidth 100 nm).

This method was applied to a solution of PHPMA-CPT for the determination of free camptothecin, and subsequently to the hydrolysate for the determination of total (free + bound) camptothecin. The amount of bound drug was obtained from the difference of the two determinations. However, in all cases reported in this paper, the contribution of the free drug was negligible.

SEC Chromatographic System. SEC fractionation and characterization was performed by means of a multidetector system. The SEC system consisted of an Alliance 2690 LC separation module (degasser, pump, and autoinjector), a single-capillary viscometer (SCV), a differential refractometer (DRI) from Waters (Milford, MA), and an additional MALS on-line detector from Wyatt (Santa Barbara, CA). This multi-detector SEC system has been described in detail previously (*21*). The used ternary mobile phase (DMF + 0.01 M LiBr + 0.05 M CH_3COOH) proved already suitable for similar conjugates (*9*−*11*). In general, the column set was composed of two Styragel columns (HR4 and HR3) from Waters. In the characterization of the higher molar mass fractions, we have used also a third Styragel HR5 column. The experimental conditions were the following: 50 °C temperature, 0.8 mL/min flow rate, and 200 μL injection volume.

Light Scattering. The MALS photometer uses a vertically polarized He−Ne laser and simultaneously measures the intensity of the scattered light at 16 angular locations ranging in the mobile phase from 16.5° to 156.9°. The calibration constant was calculated using toluene as standard and assuming a Rayleigh factor of 1.406×10^{-5} cm^{-1}. The normalization of the photodiodes was performed by measuring the scattering intensity of a narrow low molar mass polystyrene standard ($M = 10.9$ kg/mol, $D < 1.03$) in the mobile phase assumed as an isotropic scatterer. Details of the MALS detector have been described elsewhere (*22*) and are not reported herein.

Viscometers. The on-line viscometer was a custom-assembly. Details of this on-line SCV detector have been described elsewhere (*21*). The on-line SCV detector uses the universal calibration (*23*). The universal calibration curve was generated by means of 14 narrow MMD PEO/PEG standards with the molar mass ranging from 106 to 8.5×10^5 g/mol. The off-line viscometer was a classical Ubbelohde capillary viscometer.

d*n*/d*c*. The specific refractive index increment, d*n*/d*c*, with respect to the mobile phase was measured by a Chromatix KMX-16 differential refractometer from LDC Milton Roy (Riviera Beach, FL). The d*n*/d*c* value of the PHPMA-CPT conjugate was 0.128 mL/g.

PHPMA-CPT Fractionation. Fractionation of PHPMA-CPT was performed by semipreparative chromatography on the same type of columns used for SEC analysis, according to molar mass. In particular, lot 1 was loaded at 40 mg/mL on the Styragel HR4 column, whereas lot 2 was chromatographed on a Styragel HR3 column, at the same initial concentration. Fractionation was obtained by diverting the eluate by means of a programmable multi-position valve. The valve switch times had been previously established by injecting a 20 mg/mL sample and by dividing the integrated surface of the peak

(obtained from the refractive index detector) into 4−5 fractions. Fractions 1−5 were obtained from lot 1, fractions 6−9 from lot 2. Fractions 10 and 11 were obtained from the two low molar mass copolymers (lots 3 and 4) without any processing.

For each fraction, the eluate volume (DMF, 0.01 M $LiNO_3$, 0.3% v/v acetic acid) was diluted with 5 volumes of ethyl acetate. The precipitate was isolated either by centrifugation and subsequent filtration on sintered glass, or by direct filtration on Whatman 1.0 μm PTFE membranes. Typically, fractions were redissolved in 5 mL of ethyl alcohol and reprecipitated with 10 volumes of ethyl acetate. Finally, products were dried under vacuum at 30 °C overnight.

RESULTS AND DISCUSSION

The practical goal of this study was a simple, accurate, and reproducible SEC method for the MMD characterization of the production batches of the PHPMA-CPT conjugates. Investigation of the molar mass, size, and intrinsic viscosity distributions is necessary to this scope, but it is also beneficial to understanding the conformational properties of the conjugate. Substantially, we have used the same approach applied to the molecular characterization of the previous PHPMA-DOX and PHPMA-TAX conjugates (*9*−*11*). The true, nonrelative MMD of the polymers can be obtained using suitable SEC methods. For this goal, an on-line light scattering detector is the primary choice because it provides directly the molar mass of the polymer eluting from the SEC columns without calibration of the system. Accordingly, in this study we have used a MALS on-line detector for an accurate characterization of the conjugates. However, the light scattering detector is complex and expensive and is not ideal for the quick quality control of the production batches of the conjugates. As an alternative, the MMD of the polymers can be obtained using a calibrated SEC system. In our case, a direct calibration of the SEC system was not convenient because of the continuous need of well-characterized narrow MMD fractions of the PHPMA-CPT conjugate. Consequently, we have chosen the universal calibration (SEC-UC) method performed with commercially available PEO/PEG standards on a conventional SEC system using only an on-line differential refractometer detector. It is well-known that SEC-UC works if the fractionation of the macromolecules is exclusively steric, i.e., based on the size. Other LC enthalpic interactions (adsorption, partition, ionic inclusion or exclusion, etc.) have to be accurately avoided or at least minimized. Specifically, SEC-UC fractionation is based on the hydrodynamic volume of the macromolecules (*23*). The hydrodynamic volume of a macromolecule is proportional to the product of its molar mass times the intrinsic viscosity ($M\cdot[\eta]$). Hence, in a SEC-UC method, the calibration function is: $\log(M\cdot[\eta]) = f(V)$ where V denotes the elution volume. Usually the universal calibration of the SEC system is approximated with a third-order polynomial function. A convenient method to calculate $[\eta]$ from the molar mass, without the use of an on-line viscometer, is the Mark−Houwink−Sakurada (MHS) relationship. The MHS relationship, $[\eta] = k\cdot M^a$, correlates the intrinsic viscosity to the molar mass. The slope a and the intercept k are valid only for the specific combination of polymer, solvent, and temperature. The SEC-UC method requires the MHS coefficients both for the calibrants and for the PHPMA-CPT conjugate. The MHS constants for PEO and PEG in the mobile phase at 50 °C were determined in previous studies (*9*−*11*): PEO: $k = 2.538 \times 10^{-4}$ ($[\eta]$ in dL/g), $a = 0.709$; PEG: $k = 7.895 \times 10^{-4}$, $a = 0.594$. The MHS constants of the PHPMA-CPT conjugate were determined in this study using the 11 narrow MMD fractions.

Characterization of the PHPMA-CPT Fractions. The 11 narrow MMD fractions of the PHPMA-CPT conjugate were carefully characterized using MALS and SCV detectors on-line to the SEC system. Table 2 reports the most important results obtained with three on-line SEC methods. In short, SEC-MALS denotes the dual-detector system MALS and DRI, SEC-SCV denotes the dual-detector system SCV and DRI, and finally SEC-UC denotes the conventional SEC and universal calibration method using narrow MMD PEO/PEG standards as calibrants. SEC-UC data are reported only for comparison. Table 2 shows the weight-average molar mass, M_w, the dispersity index, $D = M_w/M_n$ (where M_n is the numeric-average molar mass), and the molar mass of the apex of the chromatographic peak, M_p, used in the SEC calibration. In addition, by means of SEC-MALS, we have obtained the z-average of the root-mean square radius, $\langle s^2\rangle_z^{1/2}$ (in short hereafter denoted as gyration radius R_g), and by means of SEC-SCV the intrinsic viscosity, $[\eta]$. There is a very good agreement between SEC-MALS and SEC-SCV molar mass values for fractions 1−9 (Table 2) whereas the molar mass of fractions 10 and 11 as obtained by SEC-MALS was substantially higher than the SEC-SCV values. The low molar mass and the comparatively higher polydispersity of these two fractions may well explain this discrepancy. The lower camptothecin content of fractions 10 and 11 with respect to the other nine fractions may also contribute. At variance with the case of the previous two conjugates, PHPMA-DOX and PHPMA-TAX, the influence of the drug on the dn/dc value for PHPMA-CPT was not negligible. The dn/dc value for a reference PHPMA-CPT conjugate, in the mobile phase at 50 °C, was 0.128 mL/g, and the dn/dc value for PHPMA homopolymer was significantly lower:

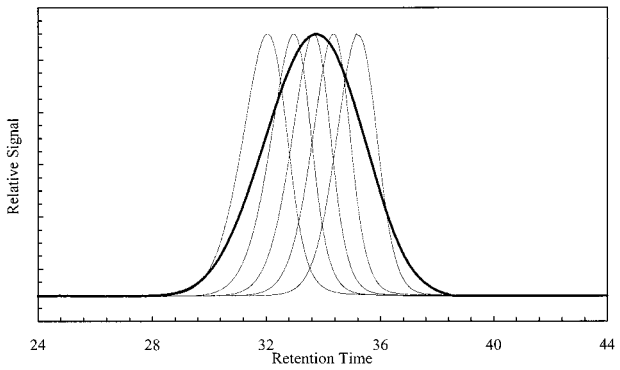

Figure 2. Comparison of the refractometer signals of five narrow MMD fractions (5−9) and of a broad MMD PHPMA-CPT sample (lot 5, boldface line).

0.106 mL/g. This difference is due to the higher drug content of the PHPMA-CPT conjugate, with regard to the former conjugates, and to the relatively high refractive contribution of the camptothecin drug. In view of the problems with the MALS characterization of the two lower molar mass fractions, we have assumed that the molar mass for these two fractions as obtained with the SEC-SCV method was more accurate.

The molar mass range of the 11 PHPMA-CPT fractions is quite large and the MMD very narrow. Figure 2 shows the comparison of the refractometer normalized signals of five narrow MMD fractions (*5*−*9*) and of a broad MMD PHPMA-CPT sample (lot 5). With the exception of the two lower molar mass fractions, the dispersity index D ranges from 1.1 to 1.2, which is adequate for SEC calibration. However, we have to remind ourselves that our final goal was the use of commercially available SEC standards.

For comparison, a selection of the four higher molar mass PHPMA-CPT fractions was characterized also by off-line methods. M_w, the second virial coefficient A_2, and R_g were determined by off-line MALS, that is, using the classical elaboration of a MALS experiment (Zimm-Plot). For each fraction, the use of four concentrations and double extrapolation to infinite dilution and zero-angle led to the three molecular parameters. Furthermore, with a classical Ubbelohde capillary viscometer, we obtained $[\eta]$ of the PHPMA-CPT fractions. The agreement between off-line and on-line M_w and $[\eta]$ results was very good. Finally, M_w, D, and $[\eta]$ values recovered with the conventional SEC-UC method were very close to the corresponding SEC-MALS and SEC-SCV values.

$[\eta] = f(M)$ and $R_g = f(M)$ Power Laws for the PHPMA-CPT Conjugate. The MHS power law for the PHPMA-CPT conjugate is shown in Figure 3. Values of $[\eta]$ and M_w of the 11 narrow MMD PHPMA-CPT fractions, reported in Table 2, were used for the numerical evaluation of "*k*" and "*a*" coefficients of the MHS equation in the SEC mobile phase at 50 °C. The MHS plot is substantially linear with a small discrepancy in the lower molar mass range: approximately $M < 10$ kg/mol. The MHS coefficients as calculated by using nine higher molar mass PHPMA-CPT fractions were $a = 0.64$ and $k = 1.94 \times 10^{-4}$. This result is congruent with the MHS coefficients for the PHPMA homopolymer (*11*).

The MHS coefficients for the PHPMA-CPT conjugate were also estimated using on-line SEC-MALS and SEC-SCV data. The method has been previously described (*11*). The MHS plot is obtained by gathering M and $[\eta]$ data of each slice of the six higher molar mass PHPMA-CPT fractions. Figure 4 shows the MHS plot estimated with on-line M data, from SEC-MALS, and $[\eta]$ data, from

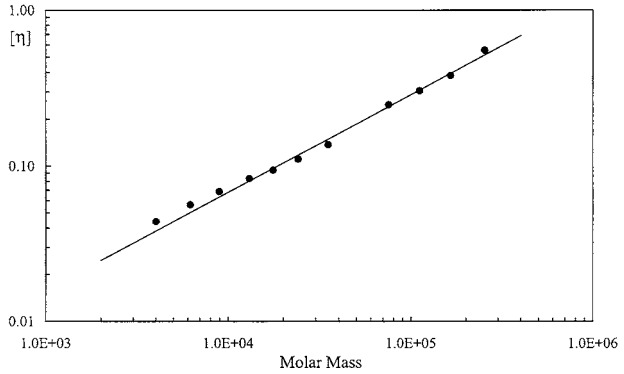

Figure 3. MHS plot for the PHPMA-CPT conjugate from 11 narrow MMD fractions.

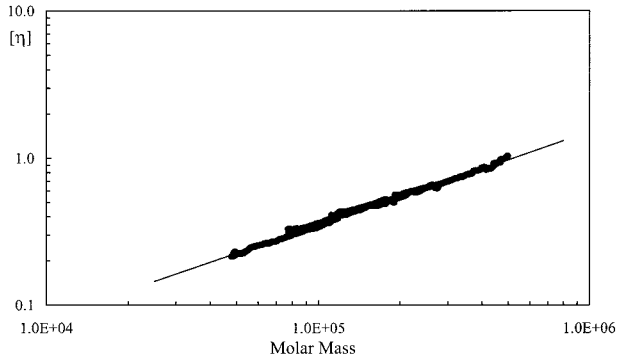

Figure 4. MHS plot for the PHPMA-CPT conjugate from on-line MALS and SCV data.

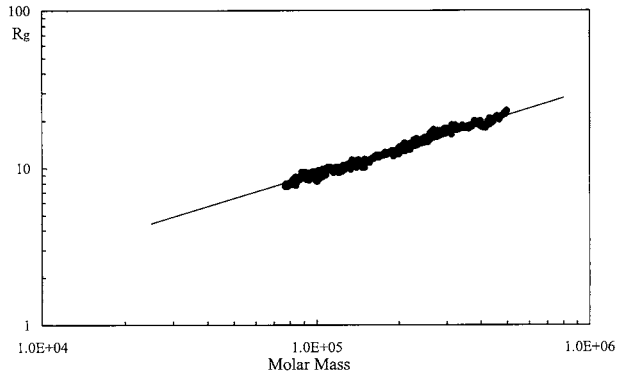

Figure 5. $R_g = f(M)$ power law for the PHPMA-CPT conjugate from on-line MALS data.

SEC-SCV. This approach presents two main advantages: it overcomes the problem of a residual polydispersity of the fractions, and it leads to a derivation of the MHS coefficients from a wide molar mass range. The MHS coefficients derived from on-line measurements were $a = 0.65$ and $k = 1.88 \times 10^{-4}$, with very good agreement between off-line and on-line results. In conclusion, the MHS coefficients obtained with the off-line method have been used in the universal calibration method.

Unfortunately, with the exception of the two higher molar PHPMA-CPT fractions, R_g was too small for an accurate estimation by the MALS detector that uses a He−Ne laser ($\lambda = 633$ nm). However, as for the previously described MHS plot, the $R_g = f(M)$ power law is obtained by gathering M and R_g data for each slice of the four higher molar mass PHPMA-CPT fractions. Figure 5 shows the $R_g = f(M)$ power law evaluated with the SEC-MALS data. The coefficients of the $R_g = K \cdot M^{\alpha}$ power law for the PHPMA-CPT conjugate were intercept $K = 1.7 \times$

Table 3. Comparison of the More Important Results for a Broad MMD PHPMA-CPT Conjugate (Lot 5)

	units	MALS	VISC	SEC-MALS	SEC-SCV	SEC-UC
M_w	g/mol	20000	–	20060	19360	19570
D		–	–	1.46	1.65	1.60
$[\eta]$	dL/g	–	0.100	–	0.100	0.102
A_2	mol·mL·g^{-2}	7.5×10^{-4}	–	–	–	–

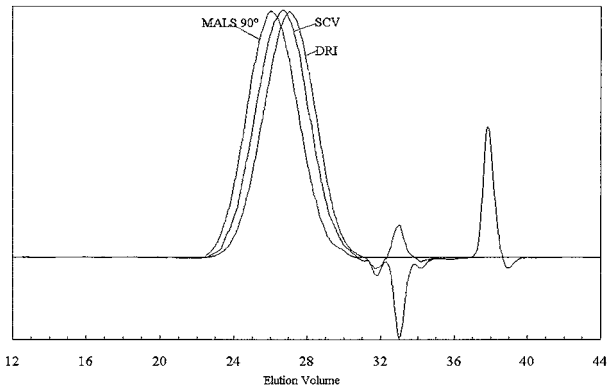

Figure 7. Comparison of the raw signals (MALS 90°, SCV, and DRI) of typical lab-scale batch of PHPMA-CPT conjugate (lot 5).

10^{-2} (R_g in nm) and slope $\alpha = 0.54$. Also these coefficients are congruent with the results obtained for the PHPMA homopolymer (*11*).

Characterization of a Broad MMD PHPMA-CPT Sample. A summary of the more important results for an unfractionated broad MMD PHPMA-CPT conjugate (lot 5) as obtained by five off-line and on-line characterization methods is listed in Table 3. In addition to the on-line SEC methods, Table 3 reports results from two off-line methods denoted in short as MALS and VISC. MALS is the classical static off-line light scattering and VISC the off-line capillary viscometer. Figure 6 shows the Zimm plot of the broad MMD PHPMA-CPT conjugate sample. The M_w of the sample was 20.08 kg/mol, R_g = 5.2 nm, and $A_2 = 7.51 \times 10^{-4}$ mol·mL·g^{-2}. The R_g result is the less accurate, because 5.2 nm is at the lower limit of the MALS measuring range. The large positive A_2 value proves that the used mobile phase was a good solvent for PHPMA-CPT.

A comparison of the raw signals of the three on-line detectors (MALS 90° photodiode, SCV, and DRI), as obtained using the experimental conditions described under Materials and Methods, is shown in Figure 7. As for the previous two PHPMA-DOX and PHPMA-TAX conjugates under identical experimental conditions, the signal-to-noise ratio for all the on-line detectors is quite high, and the polymer is well separated from the low molar mass components with only two SEC columns in series. Also for the broad MMD PHPMA-CPT conjugate sample, the agreement between the different methods was quite good. For the M_w average, the difference between MALS and SEC-MALS results was only 0.3%, between MALS and SEC-SCV 3.2%, between MALS and SEC-UC 2.2%. $[\eta]$ values obtained by off-line and on-line viscometers were identical, and the difference with the SEC-UC value was not significant. Finally, the dispersity index D was 1.50 by the SEC-MALS method, 1.65 by SEC-SCV, and 1.60 by SEC-UC. Because of the low molar mass of the PHPMA-CPT sample, the recovered values from SEC-SCV and SEC-UC are more accurate than the SEC-MALS value.

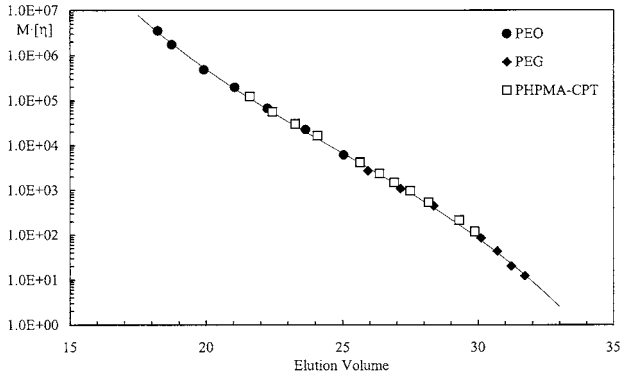

Figure 8. Fitting of the narrow MMD PHPMA-CPT fractions on the universal calibration constructed with PEO and PEG narrow standards.

Use of a Conventional SEC and Universal Calibration Method. In a previous section, we have seen that the recovered M_w, D, and $[\eta]$ values from the SEC-UC method were very close to the absolute values obtained using light scattering and viscometry on-line methods. Obviously, these results are an important confirmation that the SEC-UC method provides a congruent and accurate set of results. However, the fractionation and the accurate characterization of the narrow MMD PHPMA-CPT fractions provide a better test of the universal calibration. The universal calibration holds if the experimental function log (M·[η]) = $f(V)$ is common for calibrants (in our case PEO and PEG) and for the PHPMA-CPT conjugate. Figure 8 shows the experimental data of the above cited narrow MMD standards and the narrow MMD fractions of the PHPMA-CPT conjugate together with a third-order polynomial data fitting. The figure clearly shows that the PHPMA-CPT conjugate fractions follow the universal calibration function and confirms that this polymeric system elutes according to the hydrodynamic volume and therefore can be characterized by a conventional SEC-UC method.

CONCLUSIONS

The PHPMA-CPT conjugate has been fractionated and characterized. Combining multi-angle light scattering and viscometry, the molecular properties of 11 narrow MMD fractions and a typical broad MMD laboratory scale batch have been studied. A complete molecular characterization by means of molar mass, intrinsic viscosity, size, dispersity index, MHS relationship, and gyration radius−molar mass power law has been obtained. Notably, the SEC method used for the previous PHPMA-DOX and PHPMA-TAX conjugates proved suitable also for the new PHPMA-CPT conjugate. It is thus possible to characterize the new conjugate through a conventional SEC and universal calibration method. In essence, the

chromatographic separation of the new PHPMA-CPT conjugate is based on the hydrodynamic volume. This interesting result makes the conventional SEC-UC method suitable for the quality-control of the PHPMA-CPT conjugate samples.

Finally, we can observe that the average molar mass of the typical PHPMA-CPT conjugate sample, $M_w = 20$ kg/mol, is lower than those of the previous two conjugates, PHPMA-DOX and PHPMA-TAX (*9*−*11*). The MMD of this sample is relatively narrow, approximately $D = 1.6$, and compares very well with the results obtained for the conjugates of doxorubicin or paclitaxel. On the basis of the existing clinical experience with the above two conjugates, we can conclude that PHPMA-CPT is suitable for parenteral administration.

Cellular Internalization of Poly(ethylene oxide)-*b*-poly(ϵ-caprolactone) Diblock Copolymer Micelles

Laibin Luo,[†] Joseph Tam,[‡] Dusica Maysinger,*[,‡] and Adi Eisenberg*[,†]

Department of Chemistry, McGill University, 801 Sherbrooke Street West, Montreal, Quebec, H3A 2K6, Canada, and Department of Pharmacology and Therapeutics, McGill University, 3655 Drummond Street, Montreal, Quebec, H3G 1Y6, Canada. Received March 6, 2002; Revised Manuscript Received May 22, 2002

Poly(ethylene oxide)-*b*-poly(ϵ-caprolactone) (PEO-*b*-PCL) block copolymers self-assemble into micelles in aqueous solution. We have examined whether these micelles can internalize into P19 cells in vitro. Fluorescently labeled PEO_{45}-*b*-PCL_{23} block copolymer was prepared by conjugating a tetramethylrhodamine molecule to the end of the hydrophobic PCL block. Dynamic light scattering (DLS) and transmission electron microscopy (TEM) studies yielded 24 ± 2 and 25 ± 2 nm, respectively, for the diameters of the micelles. The studies also showed that chemical labeling did not effect the morphology or size. When the rhodamine-labeled PEO_{45}-*b*-PCL_{23} block copolymer micelles were tested in vitro, time-, concentration-, and pH-dependence of the internalization process suggested that internalization proceeded by endocytosis. The results from these studies provide the first direct evidence for the internalization of PEO_{45}-*b*-PCL_{23} micelles. Future studies will utilize multiple labeling of these micelles, allowing questions to be addressed related to the fate of internalized micelles as drug carriers, the destination of the incorporated drugs or fluorescent probes released from micelles, and the identification of the subcellular localization of the whole drug−carrier system within cells, both in vitro and in vivo.

INTRODUCTION

Recently, the use of block copolymer micelle based delivery systems to improve the therapeutic efficiency of many drugs has received considerable attention (*1*−*3*). Polymeric drug-carrying micelles were first prepared by the group of Ringsdorf (*4*). The drug molecules were attached to the hydrophobic side chains of amphiphilic graft copolymers or to the hydrophobic block of amphiphilic diblock copolymers. Such polymers, in solution, formed nanosized polymeric micelles with hydrophilic shells and drug-modified hydrophobic cores. One system consisted of cyclophosphamide, an alkylating antitumor agent in the core of poly(ethylene oxide)-*b*-poly(L-lysine) (PEO−PLL) micelles. In those studies, cyclophosphamide was conjugated to the poly(L-lysine) block as the sulfido derivative. It was reported that the rate of hydrolysis of cyclophosphamide derivatives in the micellar system varied from minutes to several hours. Recently, the field of polymeric micelles as drug carriers has advanced greatly by the work of the groups of Kabanov and Kataoka, among others (*5*−*21*). Many studies from the group of Kabanov utilized Pluronic copolymers with the poly(ethylene oxide)-poly(propylene oxide)-poly(ethylene oxide) (PEO−PPO−PEO) structure, which can self-assemble into micelles with PPO in the core and PEO in the corona. Such micelles, for expample, enhance the delivery of haloperidol to the brain, resulting in a significant increase in neuroleptic activity of the drug (*5*, *9*). Similarly, Kataoka's group found, for example, that polymeric micelles carrying adriamycin are more effective in vivo than free adriamycin. Micelle-incorporated adriamycin accumulates selectively in a solid tumor, very likely due to the enhanced permeability and retention effect (EPR effect) of the vascular endothelia at the tumor site (*6*, *7*, *10*, *13*, *20*).

Drugs and other agents can be incorporated into the inner core of polymeric micelles both by chemical conjugation and physical entrapment. In fact, many hydrophobic low molecular weight drugs were successfully incorporated into hydrophobic cores (*1*−*21*). Also, cisplatin and poly(ethylene oxide)-poly(α,β-aspartic acid) (PEO−PAA) block copolymers in an aqueous medium can form polymer−metal complex micelles (*22*). The concept has also been extended to polyion complex micelles, in which the block or graft polymers contain ionic and nonionic blocks, and in which a polyion or surfactant with opposite charge interacts with the ionic block to form the core of the complex micelles. Such micelles have been developed to deliver biological macromolecules such as DNA (*23*−*25*).

Polymeric micelles with poly(ethylene oxide) (PEO) as the hydrophilic block forming the corona of the micelles can avoid uptake by the reticuloendothelial system (RES) and thus stay in blood circulation for prolonged times (*1*−*3*). A wide range of polymeric materials has been utilized as the hydrophobic block or the charged block in complexes to form the core of the micelles, the choice depending on the compatibility between the polymers and the incorporated drugs (*2*). In this group, poly(ethylene oxide)-*b*-poly(ϵ-caprolactone) (PEO-*b*-PCL) diblock copolymer micelles have been explored as a drug delivery system (*16*, *17*). PCL is a well-known biodegradable polymer which has been utilized in various biomedical applications because of its excellent biocompatibility and degradability. It has been found that PEO-*b*-PCL micelles

are an effective carrier for lipophilic drugs, such as FK506, L-685,818, and dihydrotestosterone (*16*, *17*).

An understanding of micelle internalization is needed to develop drug delivery systems, especially carriers for subcellular targeting (*26*−*37*). At present, little is known about cellular internalization of polymeric micelles (*31*−*37*). Kabanov's group reported that Pluronic copolymer micelles can be internalized by an endocytotic pathway, and Pluronic copolymers can increase drug absorption by inhibition of the P-glycoprotein (P-gp) drug efflux system in cells (*31*−*34*). Our previous studies suggested cellular internalization of PEO-*b*-PCL into PC12 cells via endocytosis (*36*, *37*). However, since the probes used in these studies were only physically incorporated into micelles, no direct evidence has been provided for the internalization of the polymer micelles themselves. Therefore, we have chemically conjugated a rhodamine molecule to the end of the PCL block, prepared micelles containing these labeled chains, and investigated the internalization of such micelles into P19 cells, a pluripotent embryonic carcinoma cell line (*38*−*40*).

EXPERIMENTAL PROCEDURES

Materials. Poly(ethylene oxide) (number average molecule weight, M_n ca. 2000, Aldrich), tetramethylrhodamine-5-carbonyl azide (T6219) (Molecular Probes), and stannous(II) octoate (SnOct) (Sigma) were used without further purification. ϵ-Caprolactone (Aldrich) was twice dried over CaH_2 at room temperature and distilled under reduced pressure. Tetrahydrofuran (THF) and toluene were distilled just before use.

Synthesis and Characterization of PEO_{45}-*b*-PCL_{23} Block Copolymers and Rhodamine-Conjugated Copolymers. PEO_{45}-*b*-PCL_{23} block copolymers were synthesized as described elsewhere (*41*). A predetermined volume (6.6 mL) of ϵ-caprolactone monomer was placed in a flask containing a preweighed amount (5 g) of PEO under a nitrogen atmosphere. Then a drop of SnOct was added. After cooling to liquid-nitrogen temperature, the flask was evacuated, sealed off, and kept at 130 °C for 24 h. The synthesized polymers were then dissolved in THF, recovered by precipitation into cold hexane, and dried under vacuum at room temperature.

The degree of the polymerization of the PCL and the polydispersity of the polymers were determined by GPC. The degree of polymerization of the PCL was also measured by ^{1}H NMR relative to the degree of polymerization of the PEO.

The rhodamine-conjugated PEO_{45}-*b*-PCL_{23} block copolymers (PEO_{45}-*b*-PCL_{23}-Rh) were synthesized by employing a modified version of an existing procedure (*42*): 20 mg of the dried PEO_{45}-*b*-PCL_{23} block copolymers and 10 mg of tetramethylrhodamine-5-carbonyl azide were dissolved in 10 mL of freshly distilled toluene under a nitrogen atmosphere. After heating at 80 °C for 5 h, the reaction mixture was placed in a dialysis bag (MW = 1000) and dialyzed against DMF for one week to remove unconjugated rhodamine. Both the dialysis bag and the DMF were changed several times. Then the solution was dialyzed against MilliQ water for 3 days to remove any organic solvents. Again, both the dialysis bag and the MilliQ water were changed until no trace of rhodamine in either the external solvent or the dialysis bag in the absence of the internal solution could be detected. The aqueous solution was freeze-dried. The rhodamine-conjugated block copolymers were obtained in 60% yield. ^{1}H NMR was used to determine the amount of rhodamine in the conjugated block copolymers.

Preparation of Unlabeled Micelles (PM). A 20 mg amount of PEO_{45}-*b*-PCL_{23} block copolymers was dissolved in 0.38 g of DMF to yield 0.4 g of solution; the solution was stirred for 4 h. A 1.6 g amount of water was added at a rate of 10 μL every 30 s to induce micellization. The aqueous solution was placed in a dialysis bag (MW 50000) and dialyzed against MilliQ water for 1 day. After dialysis, the solution was diluted to 0.67 wt % of polymer.

Preparation of Labeled Micelles (RhPM). A block copolymer mixture consisting of PEO_{45}-*b*-PCL_{23}/PEO_{45}-*b*-PCL_{23}-Rh (molar ratio: 19/1) was used to prepare the rhodamine-labeled micelles. The polymer mixture was then handled as described above. The polymer and rhodamine concentrations in the solution were 0.67 wt % and 67 μM, respectively.

Preparation of Tetramethylrhodamine-5-carbonyl Azide (T6219) Aqueous Solution. One hundred microliters of 2 mM tetramethylrhodamine-5-carbonyl azide acetone solution was placed in a vial. After acetone was removed under vacuum, 3 mL of MilliQ water was added to dissolve the tetramethylrhodamine-5-carbonyl azide. The concentration of rhodamine in the resulting solution was 67 μM.

Preparation of Nonconjugated Tetramethylrhodamine-5-carbonyl Azide Containing Polymer Micelle Solution (NconRhPM). One hundred microliters of 2 mM tetramethylrhodamine-5-carbonyl azide acetone solution was placed in a vial. After the acetone was removed under vacuum, 3 mL of 0.67 wt % PEO_{45}-*b*-PCL_{23} block copolymers micelle solution was added to dissolve the tetramethylrhodamine-5-carbonyl azide. The total concentration of rhodamine in the micelle solution was 67 μM.

Dynamic Light Scattering (DLS). A Brookhaven laser light scattering instrument with an Uniphase μBlue laser at wavelength of 532 nm was used to determine the size distributions of the micelles at 25 °C. Labeled and unlabeled PEO_{45}-*b*-PCL_{23} block copolymers micelle solutions were filtered through 200 nm filter and used at a concentration of 0.05%.

Electron Microscopy. Transmission electron microscopy (TEM) was carried out on a JEOL microscope with a CCD camera operating at an acceleration voltage of 80 kV. Copper EM grids were precoated with a thin film of Formvar and then coated with carbon. Drops of 0.05 wt % solution of the labeled or unlabeled micelles were deposited on the resulting grids. After being dried in air overnight, the samples were shadowed with palladium/platinum alloy and carbon.

Cell Cultures. P19 mouse embryonal carcinoma cells (European Collection of Cell Cultures), as described by McBurney (*38*−*40*), were cultured in bacteriological Petri dishes (Falcon) for spectrofluorometric analyses or in 16-well chamber glass slides (Nunc) for fluorescent microscopy studies. Cells were grown in RPMI 1640 medium (Gibco-BRL) supplemented with 10% fetal bovine serum (FBS, Gibco-BRL), and serum-free medium was used in all internalization experiments.

Fluorescence Microscopy. Fluorescence microscopy studies were performed to assess the concentration and time dependent internalization of rhodamine-labeled micelles. In the concentration dependent studies, 10, 5, 2.5, or 1 μL PM, RhPM, T6219, or NconRhPM were added to well chambers containing 90 ul RPMI 1640 medium. After a 12 h incubation period, the media were removed and the P19 cells were washed with cold phosphate-buffered saline (PBS), acid solution (0.2 M acetic acid and 0.5 M NaCl aqueous solution), and PBS. In the time course studies, 10 μL of PM, RhPM, T6219, or NconRhPM

were added to chambers containing 90 μL of RMPI 1640 medium. The incubation times were 1, 4, 12, 18, and 24 h. Fluorescent images were captured using an Olympus BX60 system microscope equipped with an Olympus BX-FLA reflected light fluorescence attachment and a Dage-MTI DC-330 color camera coupled to a Compaq Pentium II computer with 128 MB RAM. Magnification was obtained using 20X or 40X objectives. Images were stored in uncompressed tagged image file format (TIFF) at a resolution of 1200 dpi using Image Pro Plus 3.0 image analysis software.

Fluorescence Spectroscopy. To obtain more quantitative data, similar studies were performed using regular fluorescence spectroscopy. For the studies of concentration dependent internalization, cells were grown in 900 μL of RPMI 1640 medium in the Petri dishes and 100, 25, 10, or 5 μL of PM, RhPM, T6219, or NconRhPM solution was added to each dish. After a 12 h incubation period, the media were removed and P19 cells were washed with cold PBS, acid solution, and PBS. Cells were lysed in 300 μL of DMSO. The DMSO solutions were then diluted with 3.7 mL of water. The resulting solutions were used for the determination of the amount of rhodamine using a FluoroMax-2 fluorescence spectrometer: $\lambda_{ex} = 545$ nm, $\lambda_{em} = 578$ nm.

For the studies of time dependent internalization, 100 μL of PM, RhPM, T6219, or NconRhPM solution was added to each dish containing 900 μL of RMPI 1640 medium. After a specific incubation period (30, 24,18, 12, 8, 4, and 1 h, respectively), the P19 cells were treated as described in the experiments of concentration dependent internalization.

Factors Affecting Internalization: Temperature, pH, Ca^{2+}, Drugs. Cells were grown in Petri dishes in the RPM1 1640 medium containing 10% serum. Four hours prior to the start of the experiments, the cells were placed in the serum free RMPI 1640 medium (900 uL) and different agents were added in the following concentrations: calcium (3mM), chlorpromazine (5 μM), FK506 (5 μM), and EGTA (5 mM) (*43*−*48*). The effects of temperature were assessed by incubating the cells at 4 °C and 37 °C (*49*). The pH effect was investigated on cells in a serum-free medium (pH 7.4) and in an acidified medium (pH 5.5) (*50*−*54*). Incubation periods varied, and the details are indicated in the legend to Figure 6.

RESULTS AND DISCUSSION

Synthesis of PEO_{45}-*b*-PCL_{23} Block Copolymers and Rhodamine-Conjugated Copolymers. PEO_{45}-*b*-PCL_{23} block copolymers and rhodamine-conjugated copolymers were synthesized as shown in Scheme 1. The number average molecular weight (M_n) and polydispersity of PEO_{45}-*b*-PCL_{23} block copolymer determined by GPC are 4500 and 1.41, respectively. The block copolymer was also characterized by ^{1}H NMR. An NMR spectrum of the labeled polymer is shown in Figure 1. The methylene protons of ethylene oxide units of the PEO correspond to the singlet at 3.7 ppm (labeled b). The methylene peaks of the caprolactone appear at 4.1, 2.3, 1.63, and 1.37 ppm (e, c, d, and d, respectively) (*41*). The molar ratio of ethylene oxide units to caprolactone units can be calculated based on the ratios of their peak areas. Therefore, the degree of polymerization of caprolactone can be obtained relative to the degree of polymerization of ethylene oxide. In our case, the calculated degree of polymerization of caprolactone is 23. The molecular weight based on the degree of polymerization of caprolactone and ethylene oxide from NMR is 4600 g/mol, which is consistent with the GPC result (4500 g/mol).

Scheme 1. Synthesis of Poly(ethylene glycol)-*b*-poly(ϵ-caprolactone) Diblock Copolymer and Rhodamine-Conjugated Poly(ethylene glycol)-*b*-poly(ϵ-caprolactone) Diblock Copolymer

As shown in Scheme 1, the acyl azide group in tetremethylrhodamine-5-carbonyl azide is rearranged to an isocyanate on heating at 80 °C (*42*). In our PEO_{45}-*b*-PCL_{23} block copolymers, the functional group at the end of PEO chain is methoxy, while the functional group at the end of PCL chain is hydroxy. The hydroxy group can react with the freshly formed isocyanate. Therefore, tetramethylrhodamine can be attached to the end of the PCL chain. The success of the conjugation of tetramethylrhodamine to the block copolymer can be proven by ^{1}H NMR. The signal of methyl protons of tetramethylrhodamine is found at 1.84 ppm (f in Figure 1). The ratios of peak areas of the methyl group in tetramethylrhodamine to those of the methylene groups in PEO or poly(caprolactone) were used to calculate the molar ratio of tetramethylrhodamine to block copolymer chains. The average molar ratio is 0.94, suggesting that 95% of the polymer chains may be functionalized. Despite all the efforts, there may still be an undetectable trace of unconjugated rhodamine. This should lead to only a small

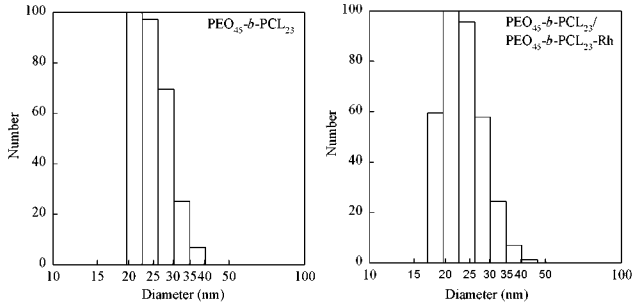

Figure 2. Size distribution of PEO_{45}-*b*-PCL_{23} and PEO_{45}-*b*-PCL_{23}/PEO_{45}-*b*-PCL_{23}-Rh (molar ratio: 19/1) micelles analyzed by DLS.

increase of size of error bar of our results, but should not affect the general conclusions.

Characterization of Labeled and Unlabeled Micelles. Rhodamine-conjugated block copolymer (5%) was mixed with the of the unlabeled block copolymer (95%) to prepare the rhodamine-labeled micelles. Both the labeled and unlabeled micelles were studied by DLS. As shown in Figure 2, the average diameters of unlabeled and labeled micelles are 25 ± 2 and 24 ± 1 nm, respectively. The results suggest that the size distributions of both labeled and unlabeled micelles are narrow, and that there is no significant change on the sizes of micelles after incorporation of rhodamine-conjugated PEO_{45}-*b*-PCL_{23} block copolymer chains.

The sizes and morphologies of labeled and unlabeled micelles were also studied by TEM. As shown in Figure 3, both labeled and unlabeled micelles are generally spheroidal. The sizes (from TEM) for both labeled and unlabeled micelles are identical (25 ± 2 nm and 25 ± 2 nm, respectively) and consistent with the DLS results. It should be noted that in the calculation of average sizes from TEM micrographs, only the spherical units are counted, since some of the elongated aggregates are probably the results of the attachment of two or more micelles during deposition.

Internalization of Micelles into P19 Cells. P19 cells are pluripotent cells, commonly used for in vitro studies, particularly those related to cell differentiation. Some drugs and also DMSO can transform P19 cells into neurons or muscle cells (*38*−*40*). We have grown the cells in the media without drug manipulations to retain them in the nondifferentiated pluripotent state.

We have investigated the rate and the extent of the internalization of rhodamine-labeled micelles, taking unlabeled block copolymer micelles (PM) as a negative control, as well as tetramethylrhodamine-5-carbonyl azide (T6219) and tetramethylrhodamine-5-carbonyl azide incorporated into block copolymer micelles (NconRhPM) as positive controls. Internalization of block copolymer

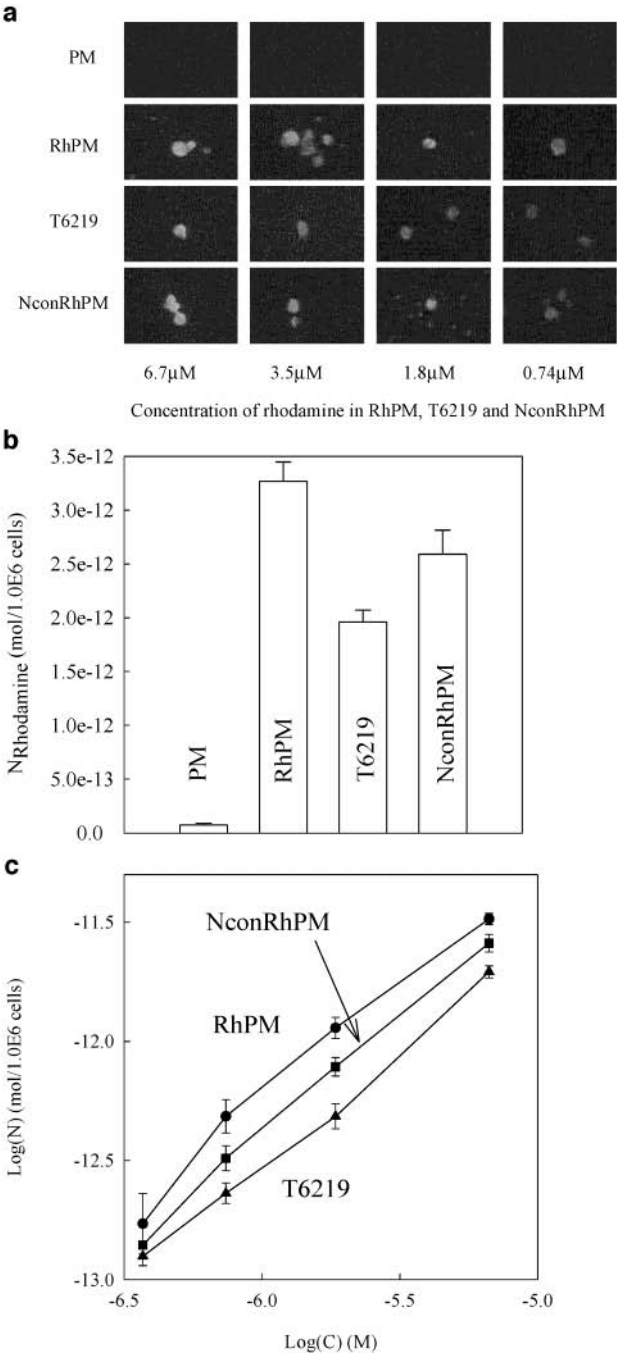

Figure 4. (a) Photographs of fluorescence intensity for rhodamine concentration-dependent internalization with P19 cells in 12 h. The polymer concentrations in RhPM, PM, and NconRhPM are 0.067%, 0.035%, 0.018%, and 0.0074%, respectively. (b) Internalization of PEO_{45}-*b*-PCL_{23} block copolymer micelles and of rhodamine T6219 into P19 cells in 12 h. The concentrations of the polymer in incubation solutions of PM, RhPM and NconRhPM are 0.067 wt %. The rhodamine concentrations of solutions of RhPM, T6219, and NconRhPM are 6.7 μM. (c) Rhodamine concentration-dependent internalization of PEO_{45}-*b*-PCL_{23} block copolymer micelles into P19 cells in 12 h. The polymer concentrations in RhPM and NconRhPM are 0.0037 wt %, 0.0074 wt %, 0.018 and 0.067 wt %, respectively.

micelles into P19 cells is dependent on both polymer concentration (Figure 4−c) and internalization time (Figure 5a,b). The fluorescence intensity of the rhodamine-labeled micelles was very low in low micromolar concentrations and at early time points (between 30 min and 6 h). Therefore, we conducted polymer concentration de-

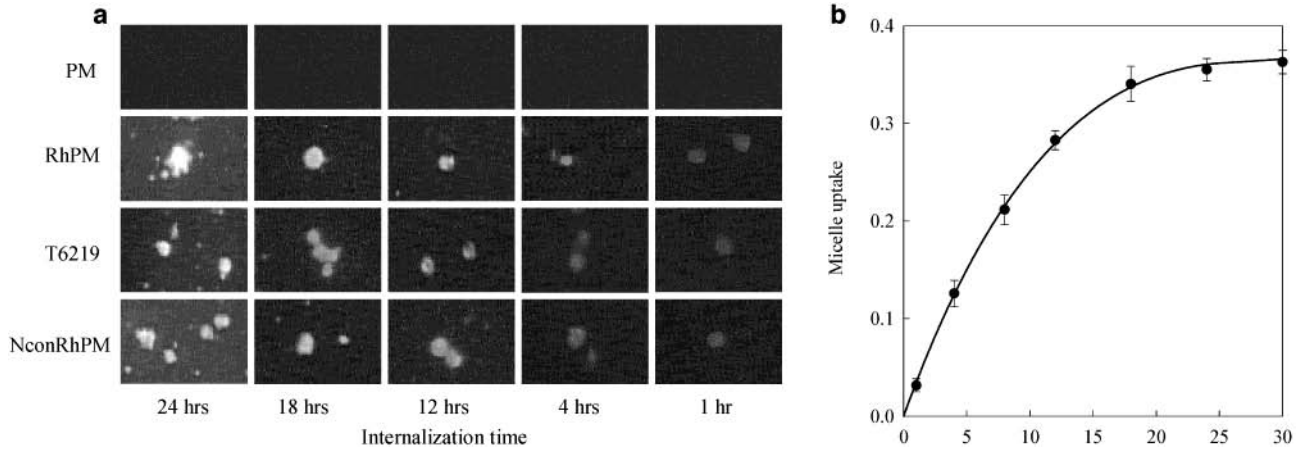

Figure 5. (a) Photographs of time-dependent internalization with P19 cells in 24 h. The polymer concentrations of PM and NconRhPM are 0.067%. The rhodamine concentrations of RhPM and T6219 are 6.7 μM. (b) Time-dependent internalization of RhPM with P19 cells as determined by spectrofluorometry. The polymer concentrations are 0.067%. The rhodamine concentrations are 6.7 μM.

pendent studies employing different concentrations of micelles at fixed 12 h incubation with P19 cells. Fluorescent microscopy studies suggest that fluorescence intensities increase in proportion to the increasing concentrations of rhodamine, and signals in RhPM-treated cells are stronger than those treated with T6219 or NconRhPM. Specrofluorometric measurements corroborate the findings from fluorescent microscopy (Figure 4b). Since the rhodamine molecules in RhPM are chemically linked to the PEO_{45}-*b*-PCL_{23} block copolymers, the results provide direct evidence for internalization of the block copolymer micelles. In addition, the amounts of rhodamine taken up by P19 cells are in the order RhPM > NconRhPM > T6219, suggesting that the block copolymer micelles enhance the accumulation of rhodamine T6219 molecules in the cells.

In most block copolymer solutions, both free unimers and micelles generally coexist. Results from studies with Pluronic P85 block copolymers suggest two different mechanisms of internalization involving free unimers and micelles, respectively (*31*−*35*). In the present case, we can show that it is the micelles which are responsible for the observed internalization. The considerations are as follows:

The polymer concentrations in the experiments described here are 0.067 wt % (150 μM), 0.035 wt % (78 μM), 0.018 wt % (40 μM), and 0.0074 wt % (16 μM), 0.0037% (8 μM), respectively. The CMC of PEO_{44}-*b*-PCL_{21} block copolymers micelles is 1.2 mg/L (unpublished observations); it is reasonable to take the CMC of PEO_{45}-*b*-PCL_{23} block copolymers micelles as also being around 1.2 mg/L, i.e., 0.00012 wt % (0.27 μM). Therefore, the PEO_{45}-*b*-PCL_{23} block copolymers in the solutions of our studies are mainly in the form of micelles, since the concentrations of polymer exceed the CMC by factors of ca. 30 to 600. Therefore, micelles are the primary form in the investigated solutions. Most importantly, free unimer concentrations of the PEO_{45}-*b*-PCL_{23} block copolymer are practically unchanged with changing polymer concentration. If the free unimers were responsible for the internalization, the internalization of RhPM should not be dependent on the total polymer concentration above the CMC. Since the internalization does depend on polymer concentration, we conclude that it is the micelles and not the free unimers of PEO_{45}-*b*-PCL_{23} that are responsible for the transport of PEO_{45}-*b*-PCL_{23} block copolymers into P19 cells.

Time dependent internalization of the block copolymers into P19 cells was confirmed by fluorescence microscopy

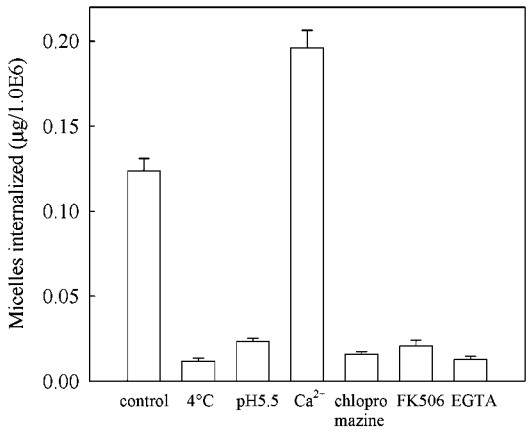

Figure 6. The effect of various pharmacological manipulations on the internalization of P19 cells with RhPM. The polymer concentration of RhPM is 0.067%. The rhodamine concentration is 6.7 μM.

(Figure 5a). As expected, there was no fluorescence in samples with empty PEO_{45}-*b*-PCL_{23} block copolymer micelles. The fluorescence intensities of P19 cells incubated with RhPM, T6219, and NconRhPM increased within 24 h. The amount of internalized PEO_{45}-*b*-PCL_{23} block copolymer micelles increased relatively rapidly initially, and the equilibrium was reached within ca. 24 h (Figure 5b).

If the micelles are internalized by endocytosis, then several basic criteria must be fulfilled (*43*−*54*). For instance, the process is time and energy dependent. Extent of internalization is reduced at low temperature (*49*) and low pH of the medium (*50*−*54*). Moreover, calcium and a number of drugs can significantly alter the extent of the internalization (*43*−*48*). In the present studies, various conditions in the medium significantly alter the extent of internalization of micelles as shown in Figure 6. For example, P19 cells treated with rhodamine-conjugated micelles and incubated at 4 °C, or in an acidified medium (pH 5.5), internalize a significantly smaller amount of micelles than the cells incubated at 37 °C or in the cell culture medium at pH 7.4 (control). Similarly, drug treatment with chlorpromazine or FK506 significantly reduces the amount of internalized micelles. These drugs are often used in internalization studies (*46*−*47*). Endocytosis is a calcium-dependent process. The ion concentrations were manipulated by EGTA (*48*). The internalization of rhodamine-labeled micelles is maximal in the presence of high (3 mM)

calcium concentration. By contrast, chelation of calcium by EGTA, significantly reduces the amount of internalized micelles.

In summary, results from the present studies show that the internalization of PEO_{45}-*b*-PCL_{23} micelles into P19 cells occurs by endocytosis. The influx of the rhodamine derivative used for labeling of the PCL chain appears to be increased when incorporated into PEO_{45}-*b*-PCL_{23} micelles. The studies also show changes in the extent of micelle internalization by pH, temperature, calcium, chlorpromazine, FK506, and ethylene glycol-bis-(*β*-aminoethyl ether)-*N*,*N*′-tetraacetic acid (EGTA) providing additional evidence for endocytosis (Figure 6).

Our earlier studies suggested that PEO-*b*-PCL micelles are internalized into PC12 cells and primary neuron-glia cultures via an endocytotic mechanism. However, in those early studies we did not have available fluorescent block copolymers, and the conclusions were based on studies involving noncovalently incorporated fluorescent or radiolabeled probes within the micelles (*36*, *37*). In agreement with the present findings and those by others (*31*−*37*), we now provide direct evidence for this mode of micelle internalization by employing covalently labeled block copolymers. The availability of these micelles provides a new tool for future studies in other cellular contexts in which the fate of the polymer carrier and incorporated agent can be followed at the subcellular level. Studies employing dual (micelle and probe) and multiple labels (micelle, probe, subcellular compartment) are currently underway in our laboratories to answer questions about the detailed subcellular distributions and in order to devise specific carriers to target different subcellular compartments.

CONCLUSIONS

The tetramethylrhodamine molecule was successfully conjugated to the end of the hydrophobic PCL block of PEO_{45}-*b*-PCL_{23} block copolymers. These fluorescently labeled block copolymers were used to prepare fluorescently labeled PEO_{45}-*b*-PCL_{23} block copolymer micelles. Chemical fluorescent labeling does not affect the spherical morphology or size of such micelles. Utilizing the rhodamine-labeled PEO_{45}-*b*-PCL_{23} block copolymer micelles, we have demonstrated that these micelles can be internalized into P19 cells by endocytosis. The internalization is time and concentration dependent. The results from these studies provide the first direct evidence for internalization of PCL-*b*-PEO micelles. The availability of rhodamine-labeled micelles will allow future studies involving multiple labels (drugs, drug−carrier, and subcellular compartment) to address the questions related to the fate of internalized micelles and the incorporated drugs or fluorescent probes.

Bis-Pyrene-Labeled Oligonucleotides: Sequence Specificity of Excimer and Monomer Fluorescence Changes upon Hybridization with DNA

Kazushige Yamana,* Tatsuya Iwai, Yusuke Ohtani, Sayaka Sato, Mitsunobu Nakamura,† and Hidehiko Nakano

Departments of Applied Chemistry and Engineering Science, Himeji Institute of Technology, 2167 Shosha, Himeji, Hyogo 671-2201, Japan. Received March 18, 2002; Revised Manuscript Received July 23, 2002

The design, synthesis, and properties of a new pyrene excimer-forming probe of DNA have been described. 2,2-(Aminomethyl)propanediol was converted by the reaction with 1-pyrenebutylic acid to bis-pyrene-modified propanediol as a fluorescent non-nucleosidic linker. The bis-pyrene-modified linker can be incorporated via phosphoramidite chemistry into the 5′-terminal or internal positions of oligonucleotides (ODNs). The terminally modified ODNs showed almost similar affinity for complementary DNA when compared with the corresponding unmodified ODNs. The duplexes containing the bis-pyrene in the main chain exhibited higher melting temperatures relative to the corresponding duplexes containing propanediol linker at the same position. The UV and CD spectral studies indicate that the stacking interactions between the pyrene and DNA bases occur in the internally modified duplex and do not in the terminally modified duplex. The bis-pyrene modified linker itself displays excimer (E at 480 nm) and monomer (M at 380 nm) emission in a quantum yield (QY) of 0.17 and the E/M intensity ratio of 15. Incorporation of this linker into the terminal or internal positions of ODNs reduced the QY (0.003−0.009) and the E/M ratio (0.3−0.8). While small changes in the QY and E/M ratio was obtained in binding of the internally labeled ODNs to DNA, up to 27-fold increase in the QY and 17-fold increase in the E/M ratio was observed upon hybridization of the terminally labeled ODNs with DNA. The excimer and monomer fluorescence changes were found to be sensitive to a mismatch base present in the target DNA. The bis-pyrene-modified ODNs thus provide a sequence-sepcific fluorescent probe of DNA.

INTRODUCTION

There is current interest in the design and synthesis of fluorescence-labeled oligonucleotides that display a strongly enhanced signal upon hybrid formation. These types of oligonucleotide probes are attractive, since they can be used for solution-based assays of DNA and RNA. The homogeneous assays have some advantages over heterogeneous ones because of favorable hybridization kinetics and no requirement of washing steps. There have been several approaches to the synthesis of oligonucleotides labeled by fluorophores with useful properties (*1*−*4*). Notable approach has been reported on hairpin-forming oligonucleotides attached to a fluorescent dye at one end and a fluorescence quencher at the other (*5*−*8*). The fluorescence increase upon hybridization to a target DNA has facilitated real-time analysis of DNA sequences being amplified in polymerase chain reaction (PCR) and detection of mutant DNA. The use of fluorescence energy transfer (FRET) between donor and acceptor dyes is another example for solution-based detection of DNA (*9*−*15*). In this approach, changes in fluorescence emission wavelength as well as fluorescence intensity can be used to define a specific sequence in target DNA.

The other example of solution-based assays is the use of pyrene fluorescence (*16*−*29*). Both pyrene monomer and excimer fluorescence has been used as indicator for monitoring hybridization. We have recently disclosed RNA oligonucleotides possessing a pyrenylmethyl group at 2′-position that exhibit significantly enhanced monomer emission upon binding to an RNA segment (*23*). The fluorescence enhancement has been found to be very sensitive to the presence of a base-mismatch in RNA. However, these probes do not emit well upon hybridization with DNA. For detection of DNA in solution, several works have focused on the use of excimer emission (*24*−*29*). Kool et al. have showed that specific DNA sequences can be detected by utilizing oligonucleotides containing pyrene modified C-nucleoside (*28*). Masuko et al. have described a similar strategy that hybridization of two oligonucleotides labeled by a single pyrene group at the terminal ends with complementary DNA results in the excimer formation (*29*). Lewis et al. have indicated that oligonucleotide probes labeled by a bis-pyrenyl group at the 5′-terminus can be used to monitor hybridization with a target DNA (*27*).

Several years ago, we developed a method for single or multiple incorporation of a pyrene-derivatized glycerol linker into the main chain of oligonucleotides (*26*). The oligonucleotide containing two pyrene linkers displayed a strong excimer emission upon duplex formation with a DNA segment. To yield excimer, however, this approach inevitably needs repetitive incorporation of more than two linkers into oligonucleotide chain. We have designed a new excimer forming non-nucleosidic linker that possesses two pyrenyl groups at one backbone. It was expected that the bispyrenyl backbone may be easily

prepared from 2,2-substituted-1,3-propanediol and versatile in labeling at any position of oligonucleotides. In this report, we describe the synthesis, hybridization, and fluorescence of bis-pyrene-labeled olignucleotides. Pyrene excimer and monomer fluorescence was largely altered upon hybridization with a specific sequence of DNA.

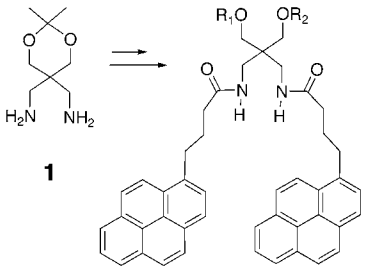
EXPERIMENTAL PROCEDURES

General Methods. ^{1}H NMR spectra were measured on a JEOL EX-270 or Bruker DRX-500 spectrometer, in which chemical shifts (δ, ppm) were determined on the basis of a residual peak of solvent (2.49 for DNSO-d_6). High-performance liquid chromatography (HPLC) was performed on Waters 600 E equipped with UV detector at 260 nm, using a reversed phase Mightysil RP-18 column (4.6 × 150 mm). Column chromatography and thin-layer chromatography (TLC) were carried out Merck silica gel 60 and Merck 60 PF_{254}, respectively. Ultraviolet spectra (UV) spectra were recorded with a Hitachi U-3000 spectrophotometer equipped with a Hitachi SPR-10 thermoelectrically controlled cell holder. Circular dichroism (CD) spectra were obtained on a JASCO CD J-805 spectrophotometer. Steady-state fluorescence emission spectra were measured on a Hitachi F-2500 spectrophotometer using excitaion and emission slits of 5 nm.

Materials and Solvents. 5′-Dimethoxytrityl deoxynucleoside 3′-(2-cyanoethyl)-*N,N′*-diisopropylphosphoramidites, protected propanediol 2-cyanoethyl-*N,N′*-diisopropylphosphoramidite, and nucleoside-loaded controlled pore glass (CPG) supports were purchased from Cruachem. 2-Cyanoethyl-*N,N,N′,N′*-tetraisopropyl phosphorodiamidite was obtained from Aldrich. Oligonucleotides were prepared by phosphoramidite chemistry on ABI 394 DNA/RNA synthesizer. Dichroromethane (CH_2Cl_2) and pyridine were refluxed over CaH_2 for 5 h under nitrogen atmosphere, distilled, and stored over molecular sieves or CaH_2. Dimethylformamide (DMF) was distilled under reduced pressure over ninhydrin and then stored over molecular sieves. All other reagents and solvents were used as received.

Synthesis of 2,2-Bis(aminomethyl)-1,3-(*O*-isopropyridene)-1,3-propanediol (1). The title compound was obtained in two steps from 2,2-bis(bromomethyl)-1,3-propanediol. The starting diol (5 g, 19 mmol) was allowed to react with acetone (50 mL) at reflux conditions in the presence of *p*-toluenesulfonic acid (1.3 g, 7 mmol) as a catalyst to give a protected diol (4 g, 70%). The resulting diol (2.5 g, 5.8 mmol) was treated with potassium phthalimide (3 g, 12 mmol) in DMF (15 mL) and then with excess amount of hydrazine-monohydrate, giving the compound **1** (2 g, 80%). TLC (9:1, CH_2Cl_2-MeOH, v/v) R_f 0.26; ^{1}H NMR (DMSO-d_6): δ = 1.25 (s, 6H, CH_3), 2.65 (s, 4H, CH_2O), 3.55 (s, 4H, CH_2).

Synthesis of 2,2-Bis[(4-pyrenylbutylamide)methyl]-1,3-propanediol (2). Compound **1** (0.75 g, 4.3 mmol) was allowed to react with 1-pyrenebutyric acid (2.5 g, 8.7 mmol) in the presence of DCC (1.9 g, 9.2 mmol) and 1-hydrohybenzotriazole (HOBT)(1.2 g, 8.9 mmol) for 1 day at rt in dry DMF (33 mL). The material was purified with a silica gel column by using CH_2Cl_2 and methanol mixture (20:1, v/v) for elution. The deprotection was done in 0.1 M HCl (16 mL) and THF (140 mL) at reflux conditions for 30 min. The organic solvent was removed in vacuo, and then water (150 mL) was added. The insoluble material was filtered and then dried. Recrystalization from CH_2Cl_2 gave a pale yellow solid (1.2 g, 40%). TLC (9:1, CH_2Cl_2−MeOH, v/v) R_f 0.53; ^{1}H NMR (DMSO-d_6): δ = 1.98−2.03 (m, 4H, CH_2), 2.32 (t, 4H, CH_2-aromatic), 3.04 (d, 4H, CH_2OH), 3.20 (d, 4H, CH_2-NH), 3.30 (t, 4H, CH_2CO), 4.57 (t, 2H, OH), 7.90−8.35 (m, total 20 H, amide and aromatic); EIMS (positive) *m/z* 674.



Synthesis of 2,2-Bis[(4-pyrenylbutylamide)methyl]-1-*O*-mono(dimethoxytrityl)-1,3-propanediol (3). The compound **2** (0.6 g, 0.9 mmol) was dried by coevaporation with dry pyridine three times and then reacted in dry pyridine (18 mL) with 4,4′-dimethoxytrityl chloride (DMT-Cl) (0.27 g, 0.8 mmol) in the presence of 4-(dimethylamino)pyridine (DMAP) (0.022 g, 0.18 mmol) at rt for 1 h. After methanol (1 mL) was added to the mixture, the solvent was removed in vacuo. The resulting material was dissolved in ethyl acetate (150 mL) and then washed with water. The organic layer was dried with Na_2SO_4 and then evaporated to near dryness. The residual material was purified with a silica gel column that was eluted with CH_2Cl_2 containing methanol (15:1, v/v). The appropriate fractions were pooled and then evaporated to near dryness. The residual solution was poured into cold hexane to give a pale yellow powder (0.6 g, 78%). TLC (9:1, CH_2Cl_2−MeOH, v/v) R_f 0.82; ^{1}H NMR (DMSO-d_6): δ = 1.91−1.97 (m, 4H, CH_2), 2.19 (t, 4H, CH_2-pyrene), 2.97 (s, 2H, CH_2-ODMT), 3.05−3.15 (m, total 6H, CH_2-NH and CH_2OH), 3.22 (t, 4H, CH_2CO), 3.60 (s, 6H, CH_3O), 4.62 (t, 1H, OH), 6.73−7.53 (m, total 13 H, DMT), 7.86−8.32 (m, total 20 H, amide and aromatic of pyrene); EIMS (positive) *m/z* 976.

Synthesis of Bis-Pyrene Modified Oligonucleotides. The conversion of **3** to phosphoramidite derivative **4** was carried out in a standard phosphitilation procedure described earlier (*30*). Bispyrene-labeled oligonucleotides were synthesized by phosphoramidite chemistry beginning with 5′-DMT-T (1 μmol) bound to a CPG support. All the coupling of normal nucleoside phosphoramidites (0.1 M in acetonitrile) and the bispyrene amidite **4** (0.15 M in CH_2Cl_2) were performed by a standard protocol of the DNA synthesizer used. With these conditions, all the coupling efficiencies including the modified amidite were 98% based on the dimethoxytrityl cation assay. The CPG-bound oligonucleotides were treated with concentrated ammonium hydroxide in a usual manner. Oligonucleotides modified at the 5′-terminus were purified with reversed phase HPLC. A linear gradient of CH_3CH (0.5%/min) from 10% CH_3CN in 0.05 M triethylammonium acetate (pH 7.0) was used at a flow rate of 1.0 mL/min. Purification of oligonucleotides modified in the main chain was performed by 20% denaturing polyacrylamide gel electrophoresis (DPAGE) as described (*30*). The integrity of oligonucleotide structure was verified with ion-spray MS analysis.

Oligonucleotide Solutions for Physical Measurements. All solutions were prepared using a buffer containing 10 mM sodium phosphate and 100 mM NaCl, adjusted to pH 7.0. Oligonucleotide concentrations were determined by absorbance at 260 nm and the calculated single-strand extinction coefficients based on a nearest neighbor model (*31*).

UV-monitored melting curves of the duplexes were obtained for solutions containing 1:1 strand ratio (2.15×10^{-5} M each) of oligonucleotides with increase in temperature from 0 to 80 °C at a rate of 0.5 °C/min. The solutions were heated at 80 °C, kept there for 5 min, and then gradually cooled before melting experiments. CD spectra were measured for the same solutions used for the UV melting studies at 23 °C. Steady-state fluorescence emission spectra were measured for the same solutions at 23 °C using excitation wavelength of 350 nm. Fluorescence quantum yields were determined by using

quinine sulfate in 0.5 M H_2SO_4 as a standard ($f = 0.55$). Excimer vs monomer fluorescence ratio (E/M ratio) was measured at 23 °C by using the intensity at the wavelength of 480 nm for the excimer (E) and 380 nm for the monomer (M) fluorescence. No attempts were made for eliminating dissolved oxygen in the fluorescence measurements.

RESULTS

Design of Bis-Pyrene Probe. The design of our bispyrene derivative was based on the researches that are concerned with non-nucleoside phosphoramidites derived from 1,3-propanediol for labeling of oligonucleotides at internal position as well as 5′-terminus (*32, 33*). Lewis and Letsinger et al. have shown that bispyrenyl alcohol can be used for 5′-terminal labeling of oligonucleotides and the bis-pyrene probes exhibit significant enhancement of excimer intensity upon hybrid formation with a specific DNA sequence (*27*). To explore the potential of bis-pyrene strategy, we have chosen 2,2-bis-susituted-1,3-propanediol as a building unit that enabled us to incorporate the bis-byrene at any position of oligodeoxynucleotides (ODNs).

Synthesis of Bis-Pyrene-Modified Oligonucleotides. As shown in Scheme 1, the synthesis of bispyrenyl backbone began with conversion of 2,2-bis(bromomethyl)-1,3-propanediol into the protected bisamino derivative **1**. The reaction of **1** with 1-pyrenebutyric acid using DCC/HOBT afforded the desired bis-pyrene derivative **2**. The compound **2** was then converted to the monoprotected diol **3**. The use of small amount of DMT-Cl and DMAP as a catalyst was found to be essential to obtain the desired compound in good yield. The phosphoramidite **4** being obtained in a standard phopshitilating method was used for incorporation of the bispyrenyl group into 5′-terminal (**I**−**IV**) or internal position (**V**−**VII**) of ODNs. The oligomers having the lipophilic residue at the terminus were purified with reversed-phase HPLC. Purification of the internally modified oligomers was carried out with conventional DPAGE. The integrity of each oligomer was verified with ion-spray MS.

The sequences of bis-pyrene labeled ODNs in the present study are shown in Table 1. With covalent attachment of pyrene and bis-pyrene residues into ODNs, both excimer and monomer emission are known to be considerably affected by the nucleobase adjacent to the site of attachment (*23, 29*). The bis-pyrene was therefore placed at the next position of pyrimide (**I**−**III**) or purine (**IV**) in the terminally labeled ODNs. The internally labeled ODNs have the bispyrenyl backbone at the position between purine nucleosides (**V**), pyrimidines (**VI**) and pyrimidine-purine (**VII**).

[a] Duplex melting measurements were carried out at 260 nm for 1:1 mixture of ODNs (2.15×10^{-5} M each) in a buffer containing 10 mM sodium phosphate and 100 mM NaCl, adjusted to pH 7.0. [b] Fluorescence quantum yields (QY) were determined by using quinine sulfate in 0.5 M H_2SO_4 as a standard (QY = 0.55). [c] Excimer vs monomer fluorescence ratio (E/M ratio) was measured at 23 °C by using the intensity at the wavelength of 480 nm for the excimer and 380 nm for the monomer fluorescence. BP and C3 indicate bis-pyrene **2** and propanediol linker, respectively.

Duplexes of Bis-Pyrene Modified Oligonucleotides with DNA. The binding of bis-pyrene modified ODNs to DNA was investigated by UV monitored melting study. Some examples of duplex melting profiles are shown in Figure 1. The melting profiles exhibited sigmoidal curves whose shapes are similar to those of the corresponding unmodified DNA/DNA duplex. All the duplex studied here showed biphasic helix-coil transition. Table 1 summarizes the duplex melting temperatures (T_m) monitored at 260 nm. The terminally modified ODNs **I**−**IV** showed almost similar affinity for complementary DNA when compared with the corresponding unmodified ODN. The duplexes containing the bis-pyrene in the main

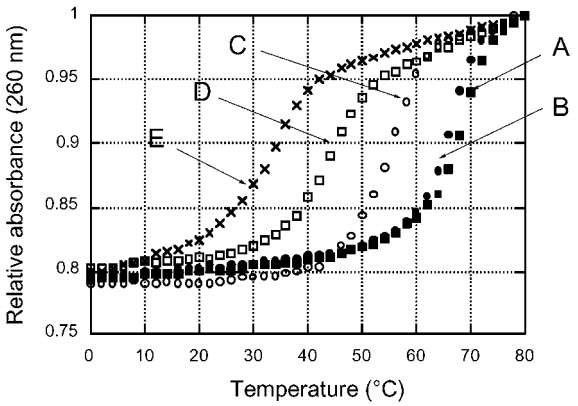

Figure 1. UV melting curves for duplex **I** (curve A), unmodified duplex **I** (curve B), unmodified duplex **IV** (curve C), duplex **VI** (curve D), and C3-modified duplex **VI** (curve E). The measurements were carried out at 260 nm for 1:1 mixture of oligonucleotide (2.15×10^{-5} M each) in a buffer containing 10 mM sodium phosphate and 100 mM NaCl, adjusted to pH 7.0. The sequences of oligomers used in these studies are shown in Table 1.

chain **V**−**VII** had higher melting temperatures when compared with the corresponding duplexes containing propanediol linker at the same position (C3-modifed duplex **V**−**VII**). While the duplex **V** or **VII** showed almost similar T_m to that of the unmodified duplex **IV** or **VII**, the duplex of **VI** had the lower T_m relative to the unmodified duplex **IV**.

The UV spectral changes for the pyrene residues during the duplex melting were shown in Figure 2. At the higher temperature where the duplexes are dissociated to single-stranded oligomers, the absorption maxima at 315, 320, and 345 nm were observed for both the terminally modified duplex **II** and the internally modified duplex **VII**. With decrease in the temperature or upon duplex formation, the red-shift (3−5 nm) of the absorption maxima and the absorption band hypochromism occurs in the internally modified duplex. In contrast, little shifts of the absorption maxima and small increase in the absorption were observed for the terminally modified duplex. Figure 3 indicates the CD spectra for the duplexes **II** and **VII** at ambient temperature. The CD profiles for the terminally modified duplex **II** and the internally modified duplex **VII** exhibit almost the same shapes as those of the corresponding unmodified duplexes, showing that the global conformation of these duplexes is similar to a B-form helix. While little induced CD at around 350 nm was observed in the terminally modified duplex **II**, the positive induced CD bands at this region appear in the internally modified duplex **VII**. These UV and CD spectral observations indicate that the stacking interactions between the pyrene and DNA bases occur in the internally modified duplex and do not in the terminally modified duplex.

Excimer and Monomer Fluorescence Changes upon Binding of Bis-Pyrene Modified Oligonucleotides to DNA. The fluorescence properties of bis-pyrene

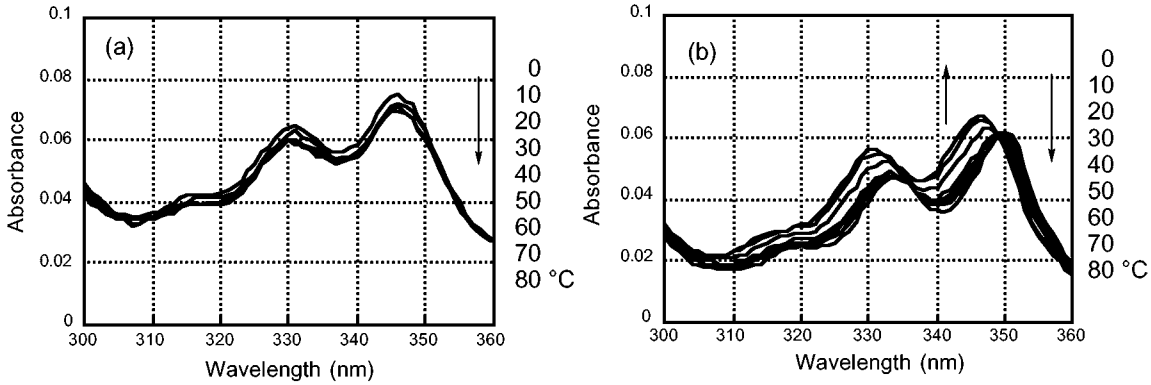

Figure 2. Panel a: UV−vis spectra for duplex **II** at different temperatures (0, 10, 20, 30, 40, 50, 60, 70, 80 °C). Panel b: UV−vis spectra for duplex **VII** at different temperatures (0, 10, 20, 30, 40, 50, 60, 70, 80 °C). UV−vis spectra were recorded under the same conditions described in Figure 1.

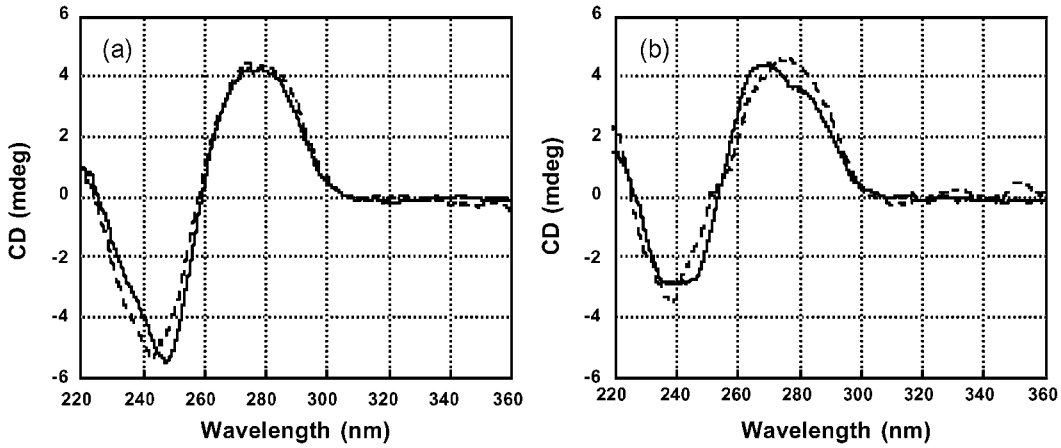

Figure 3. Panel a: CD spectra for duplex **II** (broken line) and unmodified duplex **II** (solid line). Panel b: CD spectra for duplex **VII** (broken line) and unmodified duplex (solid line). The measurements were carried out at 23 °C for the duplexes at total strand concentration of 4.3×10^{-5} M in a buffer containing 10 mM sodium phosphate and 100 mM NaCl, adjusted to pH 7.0. The sequences of oligomers used in these studies are shown in Table 1.

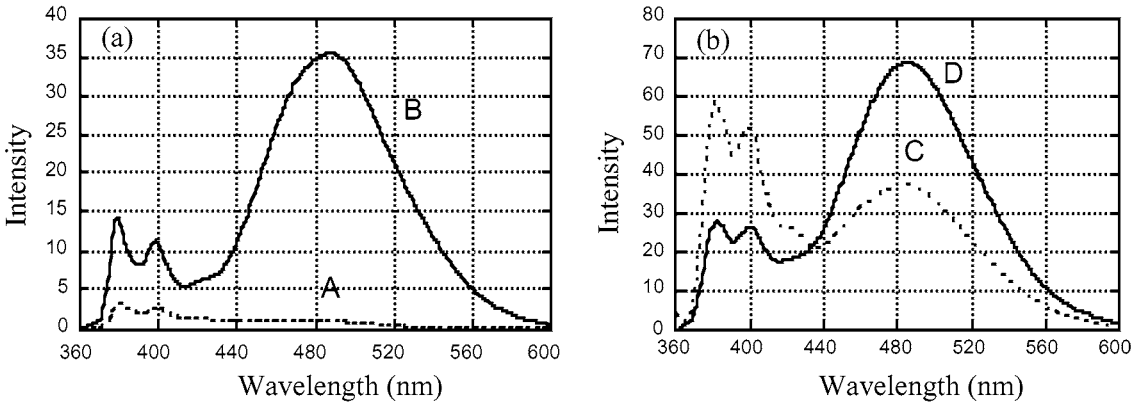

Figure 4. Panel a: Fluorescence spectra for bis-pyrene modified ODN **I** (curve A) and duplex **I** (curve B). Panel b: Fluorescence spectra for bis-pyrene modified ODN **VI** (curve C) and duplex **VI** (curve D). Fluorescence spectra were recorded at 23 °C with an excitation wavelength of 350 nm. The sequences of oligomers used in these studies are shown in Table 1.

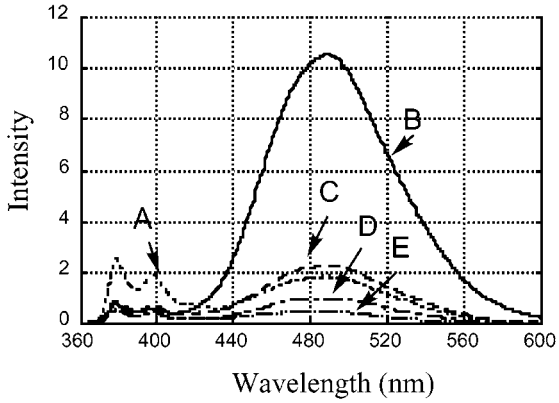
[a] The mismatch base and extra bases in DNA are indicated by the bold font and italic, respectively. [b]Relative flourescence quantum yields were determined at 23 °C based on the single-stranded bis-pyrene-modified ODN II or III. The other conditions were described in Table 1.

modified ODNs (**I**−**VII)** and their duplexes with fully matched DNA are indicated in Table 1. In aqueous solution, compound **2** exhibits excimer emission as major fluorescence in a fluorescence quantum yield of 0.17. The intensity ratio (15) of excimer (E at 480 nm) versus monomer fluorescence (M at 380 nm) was unchanged with dilution, indicating that the intramolecular excimer formation is favorable in aqueous media. Introduction of the bis-pyrene into the terminal or internal positions of oligonucleotides resulted in large decrease in fluorescence quantum yields (0.003−0.009) and switched the E/M ratio to be small (0.3−0.8). The fluorescence spectra for terminal labeled ODNs **I** in the presence or absence of DNA are shown in Figure 4a. Upon binding to fully complementary DNA, the oligomer showed significant enhancement of excimer fluorescence with higher E/M ratio relative to the corresponding single-stranded ODN. All the terminally labeled ODNs **I**−**III** possessing the pyrimidine and **IV** having the purine nucleoside adjacent to the bis-pyrene exhibited strong excimer fluorescence upon hybridization to fully matched DNA. These results indicate that the kind of the adjacent nucleobase appears to have little effect on the excimer formation for the terminally labeled ODNs. Figure 4b shows the fluorescence spectra for oligomer **VI** as an example for internally modified ODNs. Binding of **IV** to DNA with a base facing to the bis-pyrene residue gave higher E/M ratio relative to the single-stranded form that was resulted from increase in the excimer fluorescence and decrease in the monomer emission. The excimer and monomer fluorescence changes for **V** and **VII** were also observed in hybrid formation with DNA, although these changes were smaller relative to **VI**. In hybridization of the internally labeled ODNs, the extent of the fluorescence changes was dependent on the adjacent bases at the bis-pyrene modification.



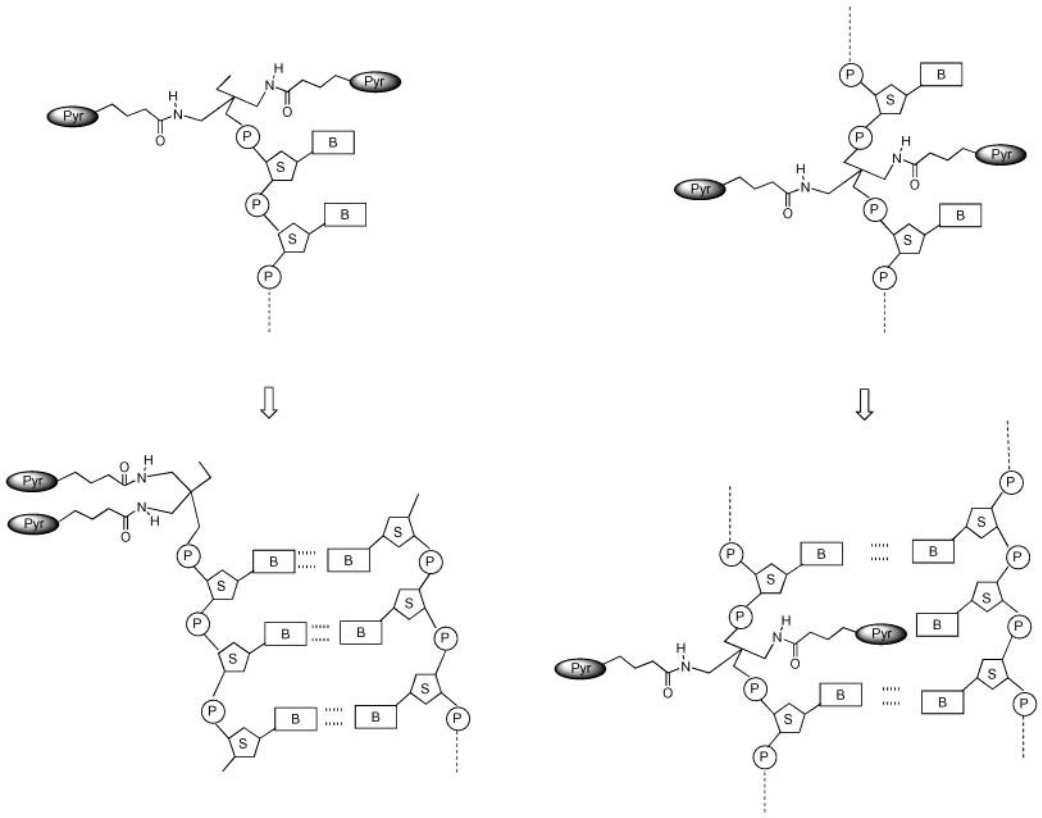


Figure 5. Fluorescence spectra for bis-pyrene modified ODN **II** (curve A), duplex **II** (curve B), and duplexes with DNA containing G−A mismatch (curve C), G−C mismatch (curve D), and G−T mismatch (curve E). Fluorescence spectra were recorded at 23 °C with an excitation wavelength of 350 nm. The sequences of oligomers used in these studies are shown in Tables 1 and 2. (a) The mismatch base and extra bases in DNA are indicated by the bold font and underlined, respectively. (b) Relative fluorescence quantum yields were determined at 23 °C based on the single-stranded bis-pyrene modified ODN **II** or **III**. The other conditions were described in Table 1.

Sequence Specificity of Excimer Fluorescence upon Hybridization. The fluorescence spectra for the duplexes of the bis-pyrene modified ODN **II** with DNA possessing a single base-mismatch are shown Figure 5. The fluorescence and melting data from the mismatch study for ODN **II** and **III** are summarized in Table 2. In hybridization of **II** or **III** with DNA containing a single

Scheme 2. Schematic Representation of Interaction between Bis-Pyrene-Modified ODN and DNA

base-mismatch, much smaller changes of the fluorescence, especially in the G to T mismatch, were observed relative to the hybrids with fully matched DNA. The quenching of the excimer and monomer fluorescence was observed upon binding to DNA possessing fully matched bases to **II** or **III** but extra bases at the 3′-terminus.

DISCUSSION

We have designed and synthesized a new non-nucleosidic backbone containing a bispyrenyl group for labeling of ODNs. Since the propanediol backbone has two pyrenyl residues at 2,2-positions, it can be used for introduction a bis-pyrene group into the terminal or internal position of ODNs by a single synthetic cycle in an automated DNA synthesis. Our approach, therefore, provides an easy and simple method for preparation of a pyrene excimer-forming probe (*24*, *27*, *28*, *29*).

2,2-Bispyrenyl propanediol exhibited strong excimer emission together with small monomer fluorescence in aqueous solution. Excimer versus monomer ratio was not altered with dilution of the solution, indicating that intramolecular excimer formation favorably occurs as expected for bis-pyrene with a 13-atoms linker. Covalent attachment of this backbone into the terminal position of ODNs resulted in large decrease in fluorescence quantum yield and afforded emission spectra of monomer fluorescence as a major component. Similarly, a 7-atoms linker containing bis-pyrene attached at the terminal end of ODNs displays excimer and monomer (almost equal intensity) fluorescence in a lowered quantum yield relative to a free bispyrene alcohol (*27*). Incorporation of our bis-pyrene into the internal position of ODNs also reduced the quantum efficiency of pyrene fluorescence and exhibited emission spectra of monomer fluorescence as a major component.

When the terminal labeled ODNs **I**−**IV** bind to fully complementary DNA sequences, the duplexes formed show almost comparable thermal stability to unmodified duplexes. These results suggest that the interaction of the bis-pyrene group with neighboring nucleobases may not occur with little or no stabilizing energy providing to the duplexes. This is evident from the observations that little shifts of the apsorption maxima and small increase in the absorption occur upon hybridization of the terminally modified duplex. In addition, no induced CD at around the pyrene absorption supports the mode of the pyrene interactions discussed for the terminally modified duplex. Binding of the internally labeled ODNs **V**−**VII** to DNA possessing a base facing at the bis-pyrene provides the duplexes whose stability is considerably higher relative to the duplexes containing the propanediol linker in place of the bis-pyrene (C3-modified duplex **V**−**VII**). The stabilizing energy for the internally labeled duplexes should be originated from the interaction of the pyrenyl residue with the neighboring bases. The stacking interactions occurred between the pyrene and DNA bases in the internally modified duplex were consistent with the spectral observations in the red-shift and hypochromism of the pyrene absorption, and the induced CD appeared at around the pyrene apsorption band.

Based on the bis-pyrene interaction with the nucleobases in the duplexes, the excimer and monomer fluorescence changes upon hybridization may be accounted according to the models as shown in Scheme 2. The model shown at the left is consistent well to the terminally labeled ODNs (**I**−**IV**). In the single stranded form, one (or both) pyrene ring(s) in the bis-pyrene probes has some interaction with neighboring bases, resulting in the low fluorescence quantum yield and disrupting intramolecular excimer formation. As a result of duplex formation, both two pyrene chromophores become relatively free

from the interaction leading to increase in the fluorescence efficiency and formation of the pyrene excimer. This interaction model is likey to explain the observations that the kind of the adjacent base to the bis-pyrene showed little effect on the excimer formation (compare **I**−**III** with **IV**). From the mismatch study, the base-pairing at the terminus adjacent to the bis-pyrene in the labeled duplexes is essential for the observed strong excimer fluorescence. Extra nucleobases present in the target DNA nearby the bis-pyrene in the ODNs disrupt the excimer formation. It is therefore concluded that ODNs modified by the bis-pyrene at the 5′-terminus provide a highly sensitive probe for DNA in a distinctive manner of sequence specificity.

The other model shown at the right is most likely to explain the fluorescence properties of the internally labeled ODNs (**V**−**VII**). In this case, the bis-pyrene backbone serves as an analogue for abasic nucleoside (*34*). The excimer and monomer fluorescence changes were observed upon hybrid formation with DNA containing one base facing to the bis-pyrene and remaining bases fully matched. However, these changes were relatively small when compared with the terminally labeled ODNs (**I**−**IV**) and the extent of the fluorescence changes appeared to be dependent on the probe sequences. The small fluorescence changes dependent on the probe sequences are consistent with the observations that the duplexes of **V**−**VII** are more stable than those for the corresponding C3-modified duplexes. It is therefore strongly suggested that the interaction of the bis-pyrene residue with the neighboring bases occurs in the duplex form as well as in the single-stranded form and is not a favorable factor to form the pyrene excimer. The fluorescence changes of ODN **VI** upon hybridization is larger than those for the ODNs **V** or **VII**, being consistent with the relative stability of the duplex or the extent of the pyrene interaction.

CONCLUSION

In summary, we have demonstrated that oligonucleotides possessing bis-pyrene backbone at the designated position can be easily synthesized by phosphoramidite chemistry. Terminally labeled bis-pyrene probes exhibit strongly enhanced excimer fluorescence upon binding to DNA. The attractive features of our probes are that excimer and monomer fluorescence is sensitive to local base sequences of probe−DNA duplex around the pyrene modification. The pyrene excimer-forming probe would thus be useful in sequence-specific detection of DNA.

ACKNOWLEDGMENT

We are very grateful to Professor Isao Saito for use of his CD spectrometer. We thank Professors Hiroshi Sugiyama, and Kazuhiko Nakatani for mass spectral analysis. This research is supported by Sumitomo Foundation (K.Y.).

Oligonucleotides Incorporating 7-(Aminoalkynyl)-7-deaza-2′-deoxyguanosines: Duplex Stability and Phosphodiester Hydrolysis by Exonucleases†

Helmut Rosemeyer, Natalya Ramzaeva, Eva-Maria Becker, Elisabeth Feiling, and Frank Seela*

Laboratorium für Organische und Bioorganische Chemie, Institut für Chemie, Fachbereich Biologie/Chemie, Universität Osnabrück, Barbarastrasse 7, D-49069 Osnabrück, Germany. Received March 28, 2002; Revised Manuscript Received July 3, 2002

Oligonucleotides containing 7-(ω-aminoalkyn-1-yl)-7-deaza-2′-deoxyguanosines (**1a**−**c**) were investigated regarding their thermal stability (T_m values) as well as their phosphodiester hydrolysis catalyzed by exonucleases. Those derivatives are suitable for the labeling of nucleic acid constituents as well as for the postlabeling of DNA. For this, the phosphoramidites **7a**,**c** (obtained from the nucleoside **1a**,**b**), protected by an isobutyryl group at the 2-amino group and a phthaloyl residue at the side-chain amino function, were synthesized. Using compounds **7a**,**c** together with the phosphoramidite of **1c** in solid-phase synthesis, a series of self-complementary and non-self-complementary oligonucleotides were prepared and characterized by MALDI-TOF mass spectrometry. A comparison of the T_m values of the modified oligomers shows that the thermal stability of the duplexes decreases with the length of the nucleobase 7-(ω-aminoalkyn-1-yl) side chain. Exonucleolytic cleavage of oligonucleotide single strands incorporating either the 7-(3-aminopropyn-1-yl)- or the 7-(4-aminobutyn-1-yl)-substituted nucleosides **1a** or **1b**, respectively, reveals that 3′ → 5′ specific snake venom phosphodiesterase liberates **1a** 5′-monophosphate but not the methylene-extended **1b** 5′-monophosphate. On the contrary, the 5′ → 3′ specific bovine spleen exonuclease is able to cleave off single **1a** and **1b** 3′-monophosphate residues; its action is, however, terminated in the case of oligonucleotides containing two consecutive **1a** or **1b** nucleotide units.

INTRODUCTION

The introduction of aminoalkynyl, aminoalkenyl, and aminoalkyl groups to pyrimidine and purine constituents of DNA has a major impact on its structure and stability. These groups can be used in particular for the conjugation of a DNA with reporter groups (Randolph and Waggoner, 1997; Ramzaeva et al., 2000; Cook et al., 1988; Ramasamy et al., 1994; Takeda et al., 1987; Ono et al., 1994; Haginoya et al., 1997). The incorporation of such cationic groups into a DNA or RNA leads to a partial neutralization of the phosphate negative charge (Hashimoto et al., 1993; Ramzaeva et al., 1997; Seela and Zulauf, 1999; Seela et al., 2001b; Bijapur et al., 1999; Soto et al., 2001). Interestingly, nature has implemented a design of this general type in bacteriophage DNA where half of the thymidine residues are replaced by positively charged α-putrescinylthymidine (= 5-{[(4-aminobutyl)-amino]methyl}thymidine), resulting in one positively charged base for every eight nucleotides on average (Miller Black et al., 1985; Kropinski et al., 1973). On the basis of the proposition of a *neutralization-collaps* model by Manning and Rich (Manning, 1978; Manning et al., 1989), Maher and co-workers showed that the introduction of tethered cationic groups into a DNA in phase with the helical turn leads inevitably to an intrinsic curvature of the nucleic acid (Strauss et al. 1996; Williams and Maher, 2000; Hardwidge, 2001 and literature cited therein). This is due to the partial neutralization of the negatively charged sugar−phosphate backbone leading to an asymmetric decrease in phosphate−phosphate charge repulsions. The latter causes a bias of the opposing but normaly balanced forces of compression (e.g. base stacking, van der Waals contacts) and stretching (e.g. interphosphate Coulombic repulsion) rendering an oligonucleotide to a stiff rod with elastic resilience.

A further impact concerns the incorporation of charge tags into nucleic acids (DNA and RNA) in order to enhance their detectability in MALDI-TOF mass spectrometry. It has been shown that the incorporation of already one charge into a DNA molecule enhances the sensitivity by which it can be detected by a factor of 100 (Wenzel et al., 2001; Gut and Beck, 1995). This result has recently found application in the development of a novel procedure for efficient genotyping of single nucleotide polymorphism ('GOOD' assay) (Sauer et al. 2000).

Apart from that, D. M. Williams and co-workers (Lee et al., 2001, Gorlain et al., 2001) used C(7)-modified 7-deaza-dATP derivatives with pendant 3-aminopropyl, (*Z*)-3-aminopropenyl, and 3-aminopropynyl side chains together with a C(5)-imidazolyl-modified dUTP as substrates for *Taq* polymerase during PCR and demonstrated the simultaneous incorporation of both functionalities into a DNA molecule. Cleavage of the modified oligonucleotide by restriction endonucleases, however, failed.

In this manuscript the synthesis of phosphoramidite building blocks of functionalized 7-deaza-2′-deoxyguanosine derivatives carrying either 7-(3-aminopropyn-1-yl)- or 7-(4-aminobutyn-1-yl) side chains is described. These building blocks are used for the preparation of ami-

noalkynyl-functionalized oligodeoxyribonucleotides. The latters are studied with respect to their thermal stability as well as toward their resistance against phosphodiester hydrolysis by two single strand-specific exonucleases.

EXPERIMENTAL PROCEDURES

General Remarks. All chemicals were purchased from Aldrich, Sigma, or Fluka (Sigma-Aldrich Chemie GmbH, Deisenhofen, Germany). Snake venom phosphodiesterase (from *Crotallus adamanteus*) was purchased from USB Amersham Life Science (Cleveland, OH), bovine spleen phosphodiesterase from Sigma (Sigma-Aldrich Chemie GmbH, Deisenhofen, Germany) and alkaline phosphatase from Roche Diagnostics (Penzberg, Germany). Solvents were of laboratory grade and were distilled before use. Dimethylformamide (DMF) was purified by codistillation with H_2O and benzene before use. Compounds **4a**, **5a**, **6a**, and **7a**,**b** were prepared as described (Ramzaeva et al., 1999; Seela et al. 2001b). Thin-layer chromatography (TLC): aluminum sheets, silica gel 60 F_{254}, 0.2 mm layer (Merck, Germany). Column flash chromatography (FC): silica gel *60* (Merck, Germany) at 0.5 bar (4×10^4 Pa); sample collection with an UltroRac II fractions collector (LKB Instruments, Bromma, Sweden). UV spectra: U-3200 spectrometer (Hitachi, Japan). Elemental analyses were performed by Mikroanalytisches Laboratorium Beller (Göttingen, Germany). NMR Spectra were measured on an AMX-500 spectrometer (Bruker, Germany) operating at a proton resonance frequency of 500.14 MHz (125.1 MHz for ^{13}C and 101.3 MHz for ^{31}P nuclei). Chemical shifts are in ppm relative to tetramethylsilane (TMS) as internal standard or external 85% H_3PO_4. *J* values are given in hertz.

Solid-Phase Synthesis of Oligodeoxyribonucleotides. The synthesis of the oligonucleotides was accomplished on a 1-μmol scale using the 3′-phosphoramidites **7a** and **7c**, respectively, as well as those of the regular 2′-deoxyribonucleosides being commercially available (Sigma, St. Louis, MO). The synthesis followed the regular protocol of the DNA synthesizer (Model 392 B, Applied Biosystems, Weiterstadt, Germany). The oligonucleotides were recovered from the synthesizer as the 5′-dimethoxytritylated derivatives. After treatment with 25% aq NH_3 (12 h, 60 °C) and then with 10% aq methylamine (24 h, room temp) to cleave off the nucleobase protecting groups, the 5′-dimethoxytritylated oligomers were purified by reverse-phase HPLC (see below; RP-18 column, 250 × 4 mm, 7 μm, solvent system I). Detritylation was performed by using 80% HOAc/H_2O for 2 min at room temperature. Detritylated oligomers were again purified by RP-18 HPLC (solvent system II). Oligonucleotides were desalted on a 4 × 25 mm HPLC cartridge (RP-18 silica gel). Inorganic material was eluted with H_2O (10 mL) while the oligomers were eluted with MeOH/H_2O (3:2, v/v). The oligomers were lyophilized on a Speed-Vac evaporator and stored frozen at −23 °C.

The enzymatic hydrolysis of the unmodified oligomers using snake-venom phosphodiesterase (EC 3.1.15.1, *Crotallus adamanteus*) and alkaline phosphatase (EC 3.1.3.1, *E. coli*) was carried out as described (Seela and Lampe, 1991). The reaction mixture was analyzed on reversed-phase HPLC (RP-18, solvent system III). Quantification of the resulting nucleosides was made on the basis of the peak areas which were divided by the extinction coefficients of the nucleoside constituents at $\lambda = 260$ nm: dA 15400, dC 7300, dG 11700, dT 8800 M^{-1} cm^{-1}.

HPLC Separation. HPLC was carried out on a 250 × 4 mm RP-18 column (Merck, Germany) on a Merck-Hitachi HPLC apparatus with one pump (model 655-A-12) connected with a proportioning valve, a variable wavelength monitor (model 655 A), a controller (model L-5000), and an integrator (model D-2000). The solvent gradients, consisting of 0.1 M (Et_3HN)OAc (pH 7.0)/MeCN 95:5 (A) and MeCN (B), were used in the following order: gradient I, 3 min 15% B in A, 7 min 15−40% B in A, flow rate 1 mL/min; gradient II, 20 min 0−20% B in A, flow rate 1 mL/min; solvent system III 20 min 100% A, flow rate 0.6 mL/min.

Melting Experiments. The thermal dissociation/association of the oligomers was measured by temperature-dependent UV melting profiles using a Cary 1E UV/VIS spectrophotometer (Varian, Australia) equipped with a Cary thermoelectrical controller; the actual temperature was measured in the reference cell with a Pt-100 resistor. The thermodynamic data of duplex formation were calculated by curve fitting to a two-state-model using the program *MeltWin* (McDowell and Turner, 1996) or by concentration-dependent T_m measurements.

Mass Spectrometry. MALDI-TOF mass spectra were run on a BIFLEX III instrument (Bruker Saxonia Analytik GmbH, Leipzig, Germany) in the reflector mode. The average power of the nitrogen laser (337.1 nm) at 20 Hz was 3−4 mW (150−200 μJ/pulse) with a delay time of 600 ns. All measurements were performed using the positive detection mode with the following parameters: dwell time: 1.00 ns, delay: 40000 ns, Uis1: 19.00 kV, Uis2: 15.80 kV, Urefl 20.00 kV, Ulens: 9.35 kV. The spectra were obtained by overlaying 500−1000 single pulses with a cutoff mass of 1000 Da. The spectrometer was calibrated using an oligonucleotide calibration standard (Bruker, Part No. 206200) containing a 12-mer (3645.44 Da), a 20-mer (6117.04 Da) and a 30-mer (9191.03 Da).

The sample preparation was performed on Scout MTP MALDI targets (Bruker) as follows: 1 μL of the supernatant of a saturated solution of recrystallized 3-hydroxypicolinic acid in doubly distilled H_2O containing BioRad microbeads AG 50W-X8 (100−200 mesh, NH_4^+-form) was spotted on a target well. A suspension (1 μL) containing 15−20 microbeads in H_2O was added followed by 1 μL of an aq oligonucleotide solution (concentration: 0.1 A_{260} units/10 μL H_2O). The mixture was carefully dried on the target, and the microbeads were removed mechanically with a tip.

Sequencing of Oligonucleotides. The sequencing of oligonucleotides was carried out by time-dependent enzymatic degradation reactions. All reactions were run in H_2O without the addition of salts or buffer. Oligonucleotides were degraded from both ends in separate reactions.

5′ → 3′ Degradation. Two A_{260} units of the oligonucleotide, dissolved in H_2O, was mixed with 1 μL (0.1 U) of an aq solution of bovine spleen phosphodiesterase (BSPDE, EC 3.1.16.1). The mixture was diluted to a total volume of 30 μL with H_2O and then incubated at 37 °C. Aliquots of 1 μL were taken at different time intervals and analyzed as described above.

3′ → 5′ Degradation. As described for the 5′ → 3′ degradation but using 1 μL (0.1 U) of snake venom phosphodiesterase (SVPDE, EC 3.1.15.1).

3-Phthalimido-1-propyne (3a). Compound **3a** was prepared according to Gibson and Benkovic (Gibson and Benkovic, 1987) from 3-amino-1-propyne (20 mL, 0.29 mol) and *N*-ethoxycarbonylphthalimide (64 g, 0.29 mol). Colorless crystals (45 g, 83%); mp 151−153 °C. ^1H NMR (d_6-DMSO): 7.84 (4H, m, phthaloyl); 4.36 (2H, d, ^4J = 2.4, CH_2); 3.25 (1H, t, ^4J = 2.4, CH).

4-Phthalimido-1-butyne (3b) (Meyer, 1994). To an ice-cold solution of triphenylphosphine (6.5 g, 25 mmol)

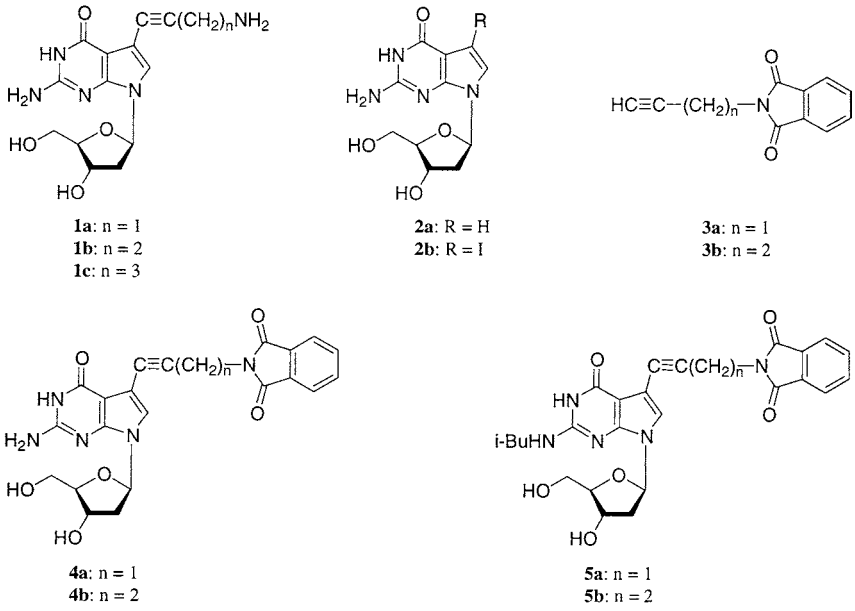
in dioxane (50 mL) was added dropwise diisopropylazidodicarboxylate (5 mL, 22.5 mmol) over a period of 30 min. After the addition has been completed, a solid precipitated. Subsequently, a mixture of phthalimide (3.7 g, 25 mmol) and 3-butyn-1-ol (1.75 g, 25 mmol), dissolved in dioxane (12.5 mL), was added in one portion. After stirring overnight at ambient temperature, the reaction mixture was evaporated and the residue crystallized from CH_2Cl_2 to afford 2.1 g (42%) of **3b** as colorless crystals; mp 134−138 °C. ^{1}H NMR (d_6-DMSO): 7.80 and 7.70 (2 m, 2 × 2H, phthaloyl); 3.84 (t, 2H, CH_2N); 2.55 ('sextett', 2H, CH_2); 1.93 (t, 1H, ^4J = 2.6, CH).

2-Amino-7-(2-deoxy-β-D-erythro-pentofuranosyl)-3,7-dihydro-5-(phthalimido-1-propynyl)-4*H*-pyrrolo-[2,3-*d*]pyrimidin-4-one (4a). Compound **4a** was prepared from **2b** (1.2 g, 3.0 mmol) and 3-phthalimido-1-propyne (**3a**, 1.2 g, 6.5 mmol) as described for compound **4b**. Yield: 1.1 g (80%) of **4a** as a yellowish solid. The crude product was used without additional purification. For elemental analysis the compound was purified by FC (CH_2Cl_2/MeOH, 9:1) R_f 0.44. ^{1}H NMR (d_6-DMSO): 2.07 (1H, m, 2′-H$_\alpha$), 2.29 (1H, m, 2′-H$_\beta$), 3.49 (2H, m, 5′-H), 3.75 (1H, m, 4′-H), 4.27 (1H, m, 3′-H), 4.59 (2H, s, CH_2), 4.87 (1H, t, ^3J = 5.4, 5′-OH), 5.18 (1H, d, ^3J = 3.7, 3′-OH), 6.26 (1H, t, ^3J = 6.0, 1′-H), 6.31 (2H, s, NH_2), 7.26 (1H, s, 6-H), 7.87−7.94 (4H, m, Pht), 10.45 (1H, s, NH). Anal. Calcd for $C_{22}H_{19}N_5O_6$ (449.42): C 58.80, H 4.26, N 15.58. Found: C 58.49, H 4.08, N 15.38.

7-(2-Deoxy-β-D-erythro-pentofuranosyl)-3,7-dihydro-2-(isobutyrylamino)-5- (3-phthalimido-1-propynyl)-4*H*-pyrrolo[2,3-*d*]pyrimidin-4-one (5a). Compound **5a** was prepared from **4a** (1.0 g, 2.2 mmol) as described for **5b**. Chromatographic workup (silica gel, 5−10% MeOH/CH_2Cl_2) gave 765 mg (67%) of **5a** as a colorless solid. TLC (silica gel, CH_2Cl_2/MeOH, 9:1): R_f 0.48. ^{1}H NMR (d_6-DMSO): 1.11 (6H, m, 2 Me), 2.12 (1H, m, 2′-H$_\alpha$), 2.34 (1H, m, 2′-H$_\beta$), 2.73 (1H, m, CH), 3.49 (2H, m, 5′-H), 3.77 (1H, m, 4′-H), 4.29 (1H, m, 3′-H), 4.60 (2H, s, CH_2), 4.88 (1H, t, ^3J = 5.3, 5′-OH), 5.20 (1H, d, ^3J = 3.2, 3′-OH), 6.35 (1H, t, ^3J = 6.2, 1′-H), 7.56 (1H, s, 6-H), 7.86−7.93 (4H, m, Pht), 11.52 (1H, s, NH), 11.78 (1H, s, NH). Anal. Calcd for $C_{26}H_{25}N_5O_7$ (519.15): C 60.11, H 4.85, N 13.48. Found: C 59.82, H 4.95, N 13.31.

7-[2-Deoxy-5-*O*-(4,4′-dimethoxytrityl)-β-D-erythro-pentofuranosyl]-3,7-dihydro-2-(isobutyrylamino)-5-(3-phthalimido-1-propynyl)-4*H*-pyrrolo[2,3-*d*]pyrimidin-4-one (6a). Compound **6a** was prepared from **5a** (519 mg, 1.0 mmol) as described for **6b**. FC (silica gel, 10−20% acetone/CH_2Cl_2) afforded 710 mg (86%) of **6a** as a colorless foam. TLC (silica gel, CH_2Cl_2/acetone, 85:15) R_f 0.30. ^{1}H NMR (d_6-DMSO): 1.12 (6H, m, 2 Me), 2.21 (1H, m, 2′-H$_\alpha$), 2.49 (1H, m, 2′-H$_\beta$), 2.77 (1H, m, CH), 3.12 (2H, m, 5′-H), 3.72 (6H, d, ^3J = 3.0, 2 OMe), 3.91 (1H, m, 4′-H), 4.32 (1H, m, 3′-H), 4.62 (2H, s, CH_2), 5.28 (1H, d, ^3J = 3.7, 3′-OH), 6.37 (1H, t, ^3J = 6.5, 1′-H), 6.82−7.35 (13H, m, arom H), 7.88−7.95 (4H, m, Pht), 11.56 (1H, s, NH), 11.83 (1H, s, NH). Anal. Calcd for $C_{47}H_{43}N_5O_9$ (821.88): C 68.69, H 5.27, N 8.52. Found: C 68.58, H 4.98, N 8.54.

7-[2-Deoxy-5-*O*-(4,4′-dimethoxytrityl)-β-D-erythro-pentofuranosyl]-3,7-dihydro-2-(isobutyrylamino)-5-(3-phthalimido-1-propynyl)-4*H*-pyrrolo[2,3-*d*]pyrimidin-4-one 3′-[(2-Cyanoethyl)-*N*,*N*-(diisopropyl)]-phosphoramidite (7a). Compound **7a** was prepared from **6a** (500 mg, 0.6 mmol) as described for **7b**. FC (silica gel, CH_2Cl_2/EtOAc/Et_3N, 69:30:1) gave a mixture of diastereoisomers **7a** (520 mg, 84%). TLC (silica gel, CH_2Cl_2/acetone, 85:15) R_f 0.8. ^{31}P NMR ($CDCl_3$): 148.17, 148.62.



7-[2-Deoxy-5-*O*-(4,4′-dimethoxytrityl)-β-D-erythro-pentofuranosyl]-3,7-dihydro-2-(isobutyrylamino)-5-(3-phthalimido-1-propynyl)-4*H*-pyrrolo[2,3-*d*]pyrimidin-4-one 3′-(Triethylammonium Phosphonate) (7b). To a solution of PCl_3 (180 μl, 2.0 mmol) and *N*-methylmorpholine (2.2 mL, 20 mmol) in CH_2Cl_2 (15 mL) was added 1*H*-1,2,4-triazole (480 mg, 6.8 mmol). The solution was cooled to 0 °C, **6a** (340 mg, 0.4 mmol) in CH_2Cl_2 (15 mL) was added slowly, and stirring was continued for 30 min at 0 °C. The mixture was poured into 1 M $(Et_3NH)HCO_3$ (TBK, pH 8.5, 30 mL). The aq layer was extracted with CH_2Cl_2 (3 × 40 mL) and the combined organic extract dried (Na_2SO_4) and evaporated. FC (silica gel, CH_2Cl_2/Et_3N, 98:2, then CH_2Cl_2/MeOH/Et_3N, 88:10:2) furnished a main zone which was evaporated. The residue was dissolved in CH_2Cl_2, extracted with aq 0.1 M TBK (6 × 25 mL), dried (Na_2SO_4) and evaporated to give **7b** (270 mg, 69%) as a colorless foam. ^{1}H NMR (d_6-DMSO): δ, 1.14 (15H, m, 5 Me), 2.32 (1H, m, 2′-H$_\alpha$), 2.74 (1H, m, 2′-H$_\beta$), 2.99 (7H, m, 3 CH_2 + CH), 3.20 (2H, m, 5′-H), 3.72 (6H, s, 2 OMe), 4.09 (1H, m, 4′-H), 4.69 (2H, m, CH_2), 4.74 (1H, m, 3′-H), 6.07 (0.5H, s, PH), 6.42 (1H, t, 1′-H), 6.83−7.34 (14.5H, m, arom H + H-6 + PH), 7.89−7.93 (4H, m, Pht), 11.79 (2H, bs, 2 NH). ^{31}P NMR (d_6-DMSO): 0.91 (^1J(P,H) = 581.8; ^3J (P,H) = 8.6). Anal. Calcd for $C_{52}H_{59}N_6O_{11}P$ (975.04): C 64.06, H 6.10, N 8.62. Found: C 63.96, H 6.34, N 8.50.

2-Amino-7-(2-deoxy-β-D-erythro-pentofuranosyl)-3,7-dihydro-5-(4-phthalimido-1-butynyl)-4*H*-pyrrolo-[2,3-*d*]pyrimidine-4-one (4b). A suspension of compound **2b** (1.2 g, 3.1 mmol), [Pd(0)(PPh_3)$_4$] (690 mg, 0.6 mmol), CuI (228 mg, 1.20 mmol), Et_3N (0.6 mL, 4.3 mmol), and 4-phthalimido-1-butyne (**3b**,1.2 g, 6.0 mmol) in anhydrous amine-free DMF (30 mL) was stirred under Ar for 24 h at room temperature. After the reaction was complete, the solvent was evaporated, and the residue precipitated from CH_2Cl_2, filtered, suspended in CH_2Cl_2/MeOH (9:1, v/v), filtered again, and dried. Yield: 1.1 g (78%) of **4b** as a brownish foam. TLC (silica gel, CH_2Cl_2/MeOH, 9:1): R_f 0.45. ^{1}H NMR (d_6-DMSO): 2.10 (1H, m, 2′-H$_\alpha$), 2.26 (1H, m, 2′-H$_\beta$), 2.76 (2H, t, CH_2), 3.52 (2H, m, 5′-H), 3.80 (3H, m, 4′-H + CH_2), 4.30 (1H, m, 3′-H), 4.70 (1H, t, 5′-OH), 5.04 (1H, d, ^3J = 3.0, 3′-OH), 6.14 (2H, s, NH_2), 6.26 (1H, t, ^3J = 6.4, 1′-H), 7.01 (1H, s, 6-H), 7.86−7.88 (4H, m, Pht), 10.25 (1H, s, NH). Anal. Calcd for $C_{23}H_{21}N_5O_6$ (463.44): C, 59.61; H, 4.57; N 15.11. Found: C, 59.88; H, 4.37; N, 14.85.

2-Amino-7-(2-deoxy-β-D-erythro-pentofuranosyl)-3,7-dihydro-5-(1-aminobut-3-ynyl)-4*H*-pyrrolo[2,3-*d*]-pyrimidin-4-one (1b). Compound **4b** (5 mg) was dissolved in concentrated aq ammonia and stirred at 60 °C for 20 h. The reaction mixture was filtered and the filtrate evaporated to dryness yielding a colorless solid. ^{1}H NMR (d_6-DMSO): 2.00 (1H, m, 2′-H$_\alpha$), 2.14 (1H, m, 2′-H$_\beta$), 3.00 (2H, m, CH_2), 3.54 (2H, m, 5′-H), 3.81 (1H, m, 4′-H), 3.88 (2H, m, CH_2), 4.33 (1H, m, 3′-H), 4.98 (1H, br, 5′-OH), 5.23 (1H, br., 3′-OH), 6.20 (2H, br., NH_2), 6.37 (1H, pt, ^3J = 6.7, 1′-H), 7.62 (1H, s, 6-H). RP-18 HPLC (solvent system III): t_R = 12.8 min.

7-(2-Deoxy-β-D-erythro-pentofuranosyl)-3,7-dihydro-2-(isobutyrylamino)-5-(4-phthalimido-1-butynyl)-4*H*-pyrrolo[2,3-*d*]pyrimidine-4-one (5b). Compound **4b** (380 mg, 0.82 mmol) was dried by coevaporation from anhydrous pyridine. The residue was suspended in pyridine (5 mL), and Me_3SiCl (0.53 mL, 4.2 mmol) was added at room temperature. After 15 min of stirring, the solution was treated with isobutyric anhydride (0.67 mL, 4.0 mmol) and maintained at room temperature for 3 h. The mixture was cooled in an ice bath; then H_2O (1 mL)

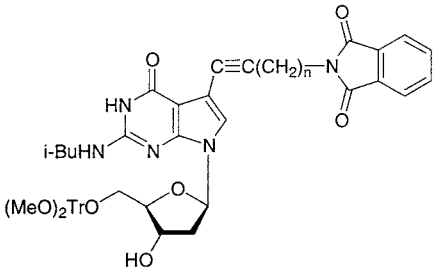
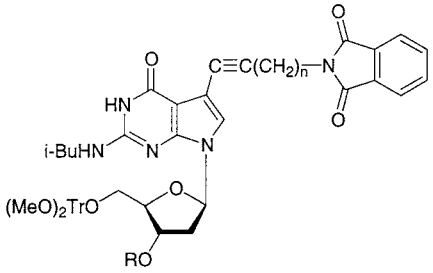
7-[2-Deoxy-5-*O*-(4,4′-dimethoxytrityl)-*β*-D-erythro-pentofuranosyl]-3,7-dihydro-2-(isobutyrylamino)-5-(4-phthalimido-1-butynyl)-4*H*-pyrrolo[2,3-*d*]pyrimidin-4-one (6b). Compound **5b** (510 mg, 0.96 mmol) was dried by repeated coevaporation from anhydrous pyridine and then dissolved in pyridine (20 mL). After addition of 4.4′-dimethoxytrityl chloride (360 mg, 1.06 mmol), the solution was stirred for 4 h at room temperature. Then, MeOH (3 mL) was added, and stirring was continued for 10 min; subsequently, a 5% aq $NaHCO_3$ solution (30 mL) was added, and the aqueous layer was extracted with CH_2Cl_2 (3 × 60 mL) affording, after evaporation of the solvent, 520 mg (65%) of a colorless solid. TLC (silica gel, CH_2Cl_2/acetone, 85:15): R_f 0.3. ^{1}H NMR (d_6-DMSO): 1.13 (6H, d, 2 Me), 2.23 (1H, m, 2′-H$_\alpha$), 2.47 (1H, m, 2′-H$_\beta$), 2.76 (3H, m, CH + CH_2), 3.18 (2H, m, 5′-H), 3.75 (6H, s, 2 OMe), 3.79 (2H, m, CH_2), 3.93 (1H, m, 4′-H), 4.33 (1H, m, 3′-H), 5.32 (1H, d, ^3J = 2.4, 3′-OH), 6.38 (1H, pt, ^3J = 6.2, 1′-H), 6.86−7.39 (14H, m, 6-H + arom H), 7.82−7.85 (4H, m, Pht), 11.54 (1H, s, NH), 11.79 (1H, s, NH). Anal. Calcd for $C_{48}H_{45}N_5O_9$ (835.90): C, 68.97; H, 5.43; N, 8.38. Found: C, 68.67; H, 5.32; N. 8.16.

7-[2-Deoxy-5-*O*-(4,4′-dimethoxytrityl)-*β*-D-erythro-pentofuranosyl]-3,7-dihydro-2-(isobutyrylamino)-5-(4-phthalimido-1-butynyl)-4*H*-pyrrolo[2,3-*d*]pyrimidin-4-one 3′-[(2-Cyanoethyl)-*N*,*N*-(diisopropyl)]-phosphoramidite (7c). To a solution of **6b** (400 mg, 0.48 mmol) in anhydrous CH_2Cl_2 (15 mL) were added (i-Pr)$_2$-EtN (162 μL, 0.93 mmol) and chloro-(2-cyanoethoxy)-(diisopropylamino)phosphine (160 μL, 0.72 mmol). After stirring for 40 min at room temperature, a 5% aq $NaHCO_3$ solution (6 mL) was added, and the mixture was extracted with CH_2Cl_2 (2 × 15 mL). The organic layer was dried (Na_2SO_4), filtered, and evaporated. Flash chromatography (column: 6 × 10 cm, CH_2Cl_2/acetone, 85:15) gave a mixture of diastereoisomers of **7c** (300 mg, 61%). TLC (silica gel, CH_2Cl_2/acetone, 85:15): R_f 0.6. ^{31}P NMR ($CDCl_3$): 148.79, 149.2.



RESULTS AND DISCUSSION

Synthesis of Monomers. The key intermediate for the synthesis of the title compounds is the 7-iodo nucleoside **2b** (Chart 1)which has been described earlier (Ramzaeva and Seela, 1995). Pd(0)-catalyzed cross coupling reaction of compound **2b** with 3-phthalimido-1-propyne (**3a**) (Gibson and Benkovic, 1987) gave **4a** in 80% yield (Ramzaeva et al., 1999; Seela et al., 2001). Analogously, compound **2b** was now reacted with 4-phthalimido-1-butyne (**3b**) (Meyer, 1994) to give **4b** in about the same yield. Cleavage of the phthalimido group is unproblematic in concentrated aqueous ammonia at elevated temperature (60 °C) and leads to compound **1b** (see Experimental Procedures).



Upon the basis of our work on 7-alkynylated 7-deaza-2′-deoxyguanosine derivatives (Ramzaeva et al., 1997), we have chosen the isobutyryl group for the protection of the 2-amino function of compounds **4a** and **4b (**Ti et al., 1982). For comparison, the isobutyryl group of 2-(isobutyrylamino)-7-(hexyn-1-yl)-7-deaza-2′-deoxyguanosine exhibits a half-life value of 80 min (25% aq NH_3, 40 °C) (Ramzaeva et al., 1997). Isobutyrylation of compounds **4a** and **4b** was performed using the protocol of transient protection and furnished compound **5a** (67%) and **5b** (73%).

Subsequently, both compounds were treated with 4,4′-dimethoxytriphenyl-methyl chloride (Schaller et al., 1963) in pyridine to give the 5′-protected derivatives **6a** (86%) and **6b** (65%), respectively (Chart 2). The dimethoxytrityl derivative **6a** was phosphitylated with 2-cyanoethyl diisopropylphosphoramidochloridite (Beaucage and Caruthers, 1981) following a standard protocol to yield the phosphoramidite **7a** (Ramzaeva et al., 1999; Seela et al., 2001 b). Additionally, from compound **6a** the phosphonate **7b** was prepared using PCl_3/*N*-methylmorpholine/1*H*-1,2,4-triazole (Ramzaeva et al., 1999; Seela et al., 2001;

Chart 2

6a: n = 1
6b: n = 2

7a: n = 1, R = $NCCH_2CH_2OPN(i\text{-}Pr)_2$
7b: n = 1, R = $HP(O)O^{\ominus}\ {}^{\oplus}NHEt_3$
7c: n = 2, R = $NCCH_2CH_2OPN(i\text{-}Pr)_2$

Froehler et al., 1986). The 7-(4-aminobutyn-1-yl) derivative **6b** was phosphitylated as described for **6a** to give the phosphoramidite **7c**. It should be mentioned that the 5′-triphosphates of compounds **1b** and **1c** as well as of the phthaloyl-protected **4b** have been prepared earlier and used for dye labeling (Seela et al. 2001a).

Characterization of the Monomers. The newly synthesized derivatives (Charts 1 and 2) were characterized by elemental analysis as well as by ^1H, ^{13}C, and ^{31}P NMR spectroscopy (Tables 1, 2, and Experimental Procedures). Unambiguous assignment of the ^{13}C NMR resonances was made on the basis of gated-decoupled ^{13}C NMR, DEPT-135, and 2D [^1H,^{13}C] HETCORR spectra. As can be seen from Table 1, substitution of the iodo atom of **2b** by an *ω*-aminoalkynyl side chain shifts the *ipso* carbon [C-7] to lower field by about 43 ppm demonstrating the electron-withdrawing effect of the C≡C triple bond. Isobutyrylation of the amino function of **4a** and **4b** results in typical high-field shifts of C-2 ($\Delta\delta = 5.5$ ppm), C-4 ($\Delta\delta = 3$ ppm), and C-6 ($\Delta\delta = 2$ ppm) and in a low-field shift of C-5 ($\Delta\delta = 4$ ppm). Moreover, isobutyrylation affects the chemical shift of the pyrrole carbon C-8: a low-field shift ($\Delta\delta = 2$ ppm) proves an electronic long-range coupling between the exocyclic amino group and the pyrrole ring.

Table 2 summarizes vicinal $^3J(H,H)$ coupling constants of compounds **4a** and **4b** as well as of the parent nucleosides 2′-deoxyguanosine (G_d) and 7-deaza-2′-deoxyguanosine (c^7G_d , **2a**). The data were taken from well-resolved ^1H NMR spectra measured in D_2O. The sugar conformation in solution ($^{3'}T_{2'} \rightleftarrows {}_{3'}T^{2'} \equiv N \rightleftarrows S$) was deduced from the pseudorotational parameters *P* and Ψ_m by application of the PSEUROT program (van Wijk and Altona, 1993). The rotational equilibrium about the C-4′−C5′ bond was calculated according to E. Westhof (Westhof et al., 1975) using the vicinal couplings between H-4′ and H-5′ as well as H-5″. From these data a slight trend can be deduced: The sugar puckering of the 7-(3-aminopropyn-1-yl) derivative **4a** is very similar to that of c^7G_d (28 and 27%, respectively) (Rosemeyer and Seela, 1998). Simultaneously, the three-state equilibrium about the C-4′−C-5′ bond of compounds **4a** and of c^7G_d ($\gamma^{(+)g} \rightleftarrows \gamma^t \rightleftarrows \gamma^{(-)g}$) exhibits very similar populations. On the other hand, the 7-(4-aminobutyn-1-yl) derivative **4b** shows slightly different conformational features: The sugar puckering is shifted toward a higher *N*-type conformer population, and the equilibrium at the C-4′−C-5′ bond is biased away from the $\gamma^{(+)g}$ conformation.

Synthesis and Characterization of Oligonucleotides. Automated solid-phase synthesis of the oligonucleotides **15**−**20** was performed with the phosphoramidites **7a** and **7c** (Froehler, 1993). The oligomer **15** has been also prepared using the phosphonate **7b**. The synthesis followed the standard protocols, and the coupling yields were always higher than 92% for the phosphoramidites and ca. 90% for the phosphonate. Deprotection was performed with 25% aq ammonia (60 °C, overnight) followed by a 24 h-treatment with 10% aq methylamine at room temperature (Seela et al., 2001a) to complete the removal of the phthaloyl residues. The oligonucleotides were detritylated and purified by reversed-phase HPLC (RP-18, see Experimental Procedures). The homogenity of the compounds was established by HPLC (RP-18) as well as by ion-exchange chromatography (NucleoPac-PA-100 column, 4 × 50 mm; Dionex, P/N 043018). The modified oligonucleotides were characterized by MALDI-TOF mass spectra. The detected masses were in good agreement with the calculated values (Table 3).

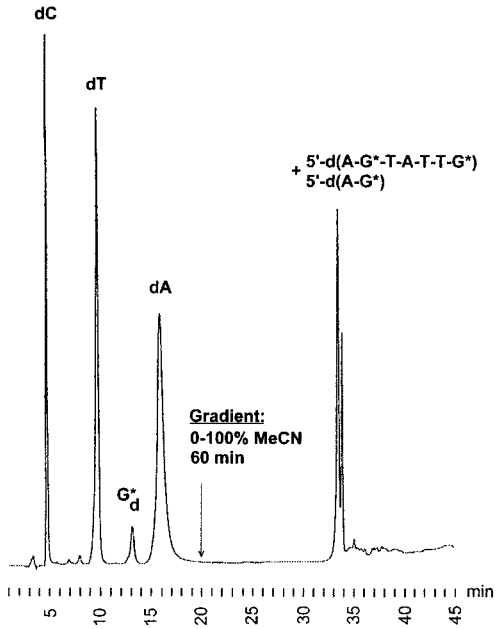


Figure 1. RP-18 HPLC profile of an enzymatic hydrolysis reaction mixture of the oligomer 5′-d(A-G*-T-A-T-T-G*-A-C-C-T-A) after treatment with snake venom phosphodiesterase and alkaline phosphatase (37 °C, 16 h). G^*_d = 7-(4-Aminobutyn-1-yl)-7-deaza-2′-deoxyguanosine. For details see Experimental Procedures.

Attempts to determine the composition of the oligonucleotides **19** and **20** by enzymatic tandem hydrolysis with snake venom phosphodiesterase (SVPDE) and alkaline phosphatase (AP) followed by reversed phase HPLC (RP-18) (Seela and Lampe, 1991) turned out to be problematic. After 16 h of treatment with the above-mentioned enzymes, RP-18 HPLC indicated incomplete cleavage of the modified oligonucleotides (Figure 1).

Only after extension of the total reaction time to 6 d were the oligomers hydrolyzed completely. As it is known that oligonucleotides carrying unsubstituted 7-deaza-2′-deoxyguanosine residues are enzymatically cleaved without problems, it was concluded that the ω-aminoalkynyl side chain of the modified bases causes termination of the phosphodiesterase hydrolysis. In this context it is worth mentioning that it has been reported previously (Seela et al., 1995) that alternating oligonucleotides of the type [5′-d(G*-C)$_4$]$_2$ with G*$_d$ being 7-methylated or iodinated 7-deaza-2′-deoxyguanosine are hydrolyzed at a significantly slower rate by both calf spleen PDE as well as SVPDE. This topic will be taken up below.

Thermal Stability of Oligonucleotides. For all duplexes shown in Table 4, T_m values were measured (10

[a] Measured at 260 nm in 10 mM Na-cacodylate, 10 mM $MgCl_2$, 100 mM NaCl, pH 7, at 5 μM + 5 μM of single strand concentration; ncm: no cooperative melting. [b] Data are within 15% of error.

mM Na-cacodylate, 10 mM $MgCl_2$, 100 mM NaCl, pH 7), and the thermodynamic data of duplex formation were calculated from each individual melting profile according to a two-state model (duplex ⇄ random coil) model with the program *Meltwin* (release version 3.0) (McDowell and Turner, 1996) (Table 4). Replacement of all c^7G_d residues within the alternating oligomer [5′-d(c^7G−C)$_4$]$_2$ (**12·12**) (Ramzaeva et al., 1997) by the (3-aminopropyn-1-yl) − derivative **1a** (→ **15·15**) leads to a significant duplex stabilization compared to the parent **12·12** (ΔT_m = 19 °C; ≅ 5 °C/base pair). This increase of thermal stability is, however, reduced to 2.5 °C/base pair when the ω-aminoalkynyl side chain is extended by one methylene group (**18·18**, T_m = 63°).

Further extension of the side chain to a (5-aminopentyn-1-yl) substituent abolishes duplex formation of the alternating oligomer **21** (Ramzaeva et al., 1999; Seela et al., 2001b).

These surprising results, summarized in Table 5, are apparently related to the positioning of the protonated amino group within the major groove of the B-DNA helix because the corresponding oligomer carrying four uncharged 7-(hexyn-1-yl)-7-deaza-2′-deoxyguanosines (Ramzaeva et al., 1997) shows a T_m value of 59 °C under analogous conditions. It has been demonstrated earlier

[a] Measured at 260 nm in 10 mM Na-cacodylate, 10 mM $MgCl_2$, 100 mM NaCl, pH 7, 10 μM of single strand concentration. [b] CH_3 instead of terminal NH_2 group. G*$_d$ = 7-(ω-aminoalkyn-1-yl)-7-deaza-2′-deoxyguanosine (**1a**−**c**). Distances *d* were calculated using the *Alchemy III* force field (Tripos Co., St. Louis, MO).

that 7-substituents of 7-deazapurine are well accommodated in the major groove of a B-DNA (Seela and Zulauf, 1999; Pullman and Pullman, 1981), the depth of which amounts to 8.5 Å and the width at the periphery to 11.7 Å (Conner et al., 1982). Table 5 shows how the distance between C-7 and the amino group increases with the extension of the ω-aminoalkynyl side chain. A simple reflection reveals that the distance between the protonated amino group of the aminoalkynyl chain and the negatively charged phosphate−sugar backbone of the double helix is minimal for the (5-aminopentyn-1-yl)

[a] Signal intensity is small compared to the preceding and the subsequent ones; ⇒/⇐ termination of the reaction; n.d.: not detected.

residue. Therefore, the Coulomb attraction, being proportional to $1/r^2$, should be maximal in the latter case. Nevertheless, the thermal stability of **21·21** is the lowest one within the series of alternating oligonucleotides. Possibly, the spatial approximation of positively charged nucleobase side chains and the negatively charged backbone leads to a shrinkage or bending of the double helix structure with an obvious penalty in stability as described in the Introduction. In case of the oligonucleotides containing protonated (4-aminobutyn-1-yl) or (3-aminopropyn-1-yl) side chains within the major groove the Coulomb interaction between the ammonium group, and the phosphate backbone is gradually reduced. In these latter cases enhanced stacking interactions of the alkynylated c^7G_d residues compared to unsubstituted c^7G_d are more and more taking effect and overcompensate the Coulomb interaction.

These apparently improved stacking interactions are due to the alkynyl side chain confering (i) a higher molecular polarizability α_m (Rosemeyer and Seela, 2002)[1] and (ii) a higher lipophilicity (expressed in terms of log*P*[1]) to the 7-substituted nucleobase (Table 2) with the consequence of a stabilization of the duplex structure.

Next, compounds **1a** and **1b** were incorporated into non-self-complementary oligonucleotides (Table 4). The oligomers containing the (5-aminopentyn-1-yl) derivative **1c** had already been described earlier (Ramzaeva et al., 1997), but the thermodynamic data of duplex formation are now reevaluated.

[1] Molecular polarizability values (α_m) were calculated from polarizability increments (central atom and neighboring sphere considering the order and aromaticity of bonds) using the program ChemSketch (version 4.55, provided as freeware by Advanced Chemistry Developments Inc., Toronto, Canada; http: www.acdlabs.com). log*P* values were calculated using the program "log*P*" (version 1.0) delivered by the same company; for the log*P* value of G_d see also: Viswanadhan and co-workers (Viswanadhan et al., 1993).

[a] Signal intensity is small compared to the preceding and the subsequent ones; ⟹/⟸ termination of the reaction.

The results of the melting experiments are summarized in Table 4. As can be seen from a comparison of the T_m data of corresponding oligonucleotide duplexes among the different series such as **13·14** (containing **2a**), **16·17** (containing **1a**), **19·20** (containing **1b**), and **22·23** (containing **1c**), the above-described results are confirmed; a clear tendency is followed: the shorter the ω-aminoalkynyl side chain, the higher the duplex stabilization compared with the parent sequence containing unsubstituted 7-deaza-2′-deoxyguanosine. Replacement of c^7G_d–C_d base pairs by **1a**–C_d pairs leads to a T_m enhancement of 12 °C (3 °C/base pair). The same trend holds also for the other corresponding duplexes (e.g., **13·10**, **16·10**, **19·10**, **22·10** etc.). The reason for this behavior is probably the same as described for the alternating, self-complementary oligonucleotides.

Sensitivity of the Base-Modified Oligonucleotides against Exonucleases. As described above the enzymatic hydrolysis of the oligomers **19** and **20** catalyzed by SVPDE was strongly retarded. Therefore, the hydrolysis of the oligomers **16** and **19** by the 5′ → 3′ exonuclease from bovine spleen (BSPDE) and the hydrolysis of **17** and **20** by the 3′ → 5′ exonuclease from snake venom (*Crotallus adamanteus*) was investigated by matrix-assisted laser desorption and ionization mass spectrometry (MALDI-TOF MS) (Karas and Hillenkamp, 1988). From the reaction mixtures aliquots were taken after different time intervals over a total period of up to 7d and analyzed.

For comparison, the hydrolysis of the oligomer 5′-d(C**2a**AACT**2a2a**C**2a**TC) (**24**) containing four 7-deaza-2′-deoxyguanosine residues as well as of the unmodified oligonucleotides **9** and **10** was also studied. MALDI TOF mass spectra showed complete cleavage of the unmodified oligomers by both exonucleases within at least 24 h (data not shown).

Figure 2 displays the mass spectrum of an SVPDE digest of the oligomer **24** after 2d allowing the sequencing of the first eight nucleotide 5′-monophosphates of the oligomer (Pieles et al., 1993; Nordhoff et al., 1995; Schneider and Chait, 1995). Treatment of **24** with BSPDE for 45 min at 37 °C and MALDI-TOF analysis after different time intervals results in a similar MALDI-TOF pattern from which the sequence of the first eight

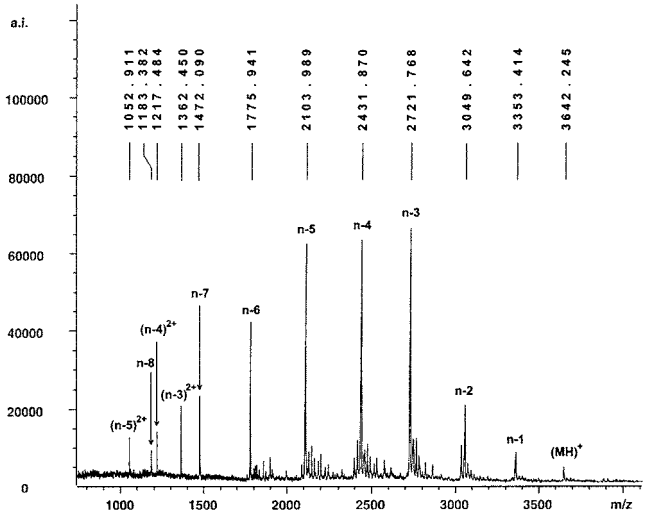

Figure 2. MALDI-TOF mass spectrum of an enzymatic hydrolysis reaction mixture of the oligomer 5′-d(C-G*-A-A-C-T-G*-G*-C-G*-T-C) after treatment with snake venom phosphodiesterase (0.02 units of enzyme/1 μmol of oligomer) in H_2O. G^*_d = 7-Deaza-2′-deoxyguanosine. For details see Experimental Procedures.

nucleoside 3′-monophosphates starting from the 5′-terminus can be read (Table 6).

MALDI-TOF mass spectra of the digestion of the oligomer **17** by SVPDE and of the oligomer **16** by BSPDE (Table 7) imply that the 3′→5′ exonuclease (SVPDE) is able to cleave off the 7-(3-aminopropyn-1-yl)-7-deaza-2′-deoxyguanosine 5′-monophosphate residue (**1a**-MP) being incorporated at position 6 from the 3′-end of **17** (n-6). Even the further signals for the (n-7) and the (n-8) residual oligomers can be detected (Figure 3).

On the other hand, the action of BSPDE on **16** carrying two consecutive **1a** residues is terminated by the modified base: after a reaction time of 24 h, the mass spectrum shows that the 5′ → 3′ exonuclease has cleaved off only the first two nucleotides (dTMP, dAMP) from the 5′-end (Table 7) but not the subsequent **1a**-MP residues. Instead, a digestion from the 3′-terminus occurs, generating the indicated mass peaks. This might be either due to a

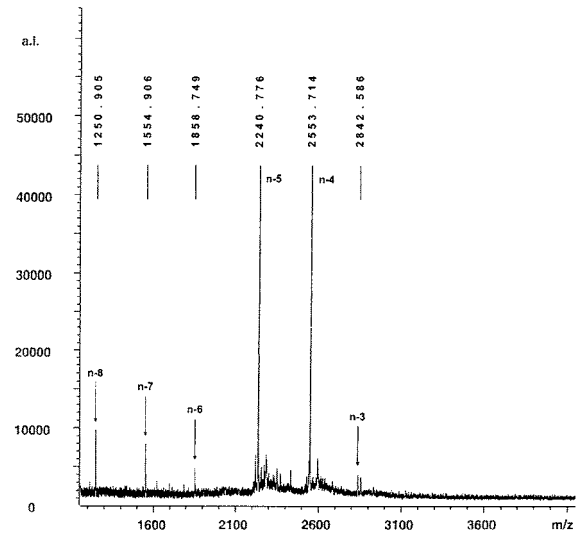

Figure 3. MALDI-TOF mass spectrum of an enzymatic hydrolysis reaction mixture of the oligomer 5′-d(A-G*-T-A-T-T-G*-A-C-C-T-A) after treatment with snake venom phosphodiesterase (0.02 units of enzyme/1 μmol of oligomer) in H_2O. G^*_d = 7-(3-Aminopropyn-1-yl)-7-deaza-2′-deoxyguanosine. For details see Experimental Procedures.

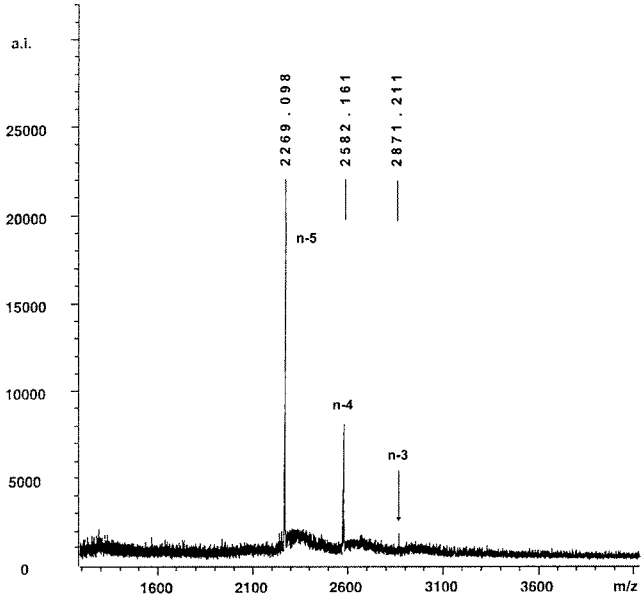

Figure 4. MALDI-TOF mass spectrum of an enzymatic hydrolysis reaction mixture of the oligomer 5′-d(A-G*-T-A-T-T-G*-A-C-C-T-A) after treatment with snake venom phosphodiesterase (0.02 units of enzyme/1 μmol of oligomer) in H_2O. G^*_d = 7-(4-Aminobutyn-1-yl)-7-deaza-2′-deoxyguanosine. For details see Experimental Procedures.

≤1% impurity of the 5′ → 3′ exonuclease by a 3′ → 5′ exonuclease or to a unspecificity of the enzyme with respect to its cleavage direction. The last result is similar to that obtained for the digestion of the oligomer **19**, containing two consecutive (4-aminobutyn-1-yl) derivatives **1b**, by BSPDE (Table 8): also here the mass spectrum, measured after 72 h, indicates a termination of the 5′ → 3′ exonucleolytic activity, but a further digestion of the oligomer from its 3′-end. Interestingly, the SVPDE-digestion of the oligomer **20** with a **1b** residue at position 6 from the 3′-end is completely terminated by **1b**; a further digestion from the 5′-end of **20** cannot be observed (Figure 4, Table 8).

Next, we investigated the BSPDE-mediated cleavage of the oligomers **17** and **20**, both containing isolated **1a** or **1b** residue in positions 2 and 7 from the 5′-terminus. The MALDI-TOF mass spectra (Tables 7, 8) indicate that in both cases the base-modified nucleotides are cleaved off. However, the signals of the residual oligomers from which **1a** or **1b** have just been split off are small compared to the preceding and subsequent peaks; this points to the fact that preferentially dinucleotides (**17**: 5′-d(**1a**-T)p-3′ and 5′-d(**1a**-A)p-3′; **20**: 5′-d(**1b**-T)p-3′ and 5′-d(**1b**-A)p-3′) are released.

CONCLUSION AND PERSPECTIVES

The experiments clearly demonstrate that the incorporation of 7-(ω-aminoalkyn-1-yl)-7-deaza-2′-deoxyguanosine building blocks which differ just in one methylene group within the side chain (**1a** vs **1b**) changes both the rate of hydrolysis of oligonucleotides by exonucleases as well as their propensity of duplex formation. In particular, the results on oligonucleotides carrying the 7-(ω-aminobutyn-1-yl) derivative **1b** opens the possibility to protect an oligonucleotide core against exonucleolytic cleavage. These results are in line with findings reported recently by Matsuda and co-workers (Ueno et al., 2000).

On the other hand, oligonucleotides carrying nucleotide units with primary amino groups can be labeled with various nonradioactive reporter groups such as fluorophores, dyes, biotin, or others by postsynthetic conjugation. With the provision of reactive derivatives (e.g., *N*-hydroxysuccinimide esters) of such reporter molecules this postlabeling technique has almost replaced the former common technique of radioisotope (e.g., ^{32}P) labeling (Agrawal, 1994; Hermanson, 1996). However, care has to be taken concerning (i) the accessibility of the primary amino groups located in the major groove of the functionalized oligonucleotide for the postlabeling reaction, and (ii) the thermal duplex stability of the resulting labeled nucleic acid.

Furthermore, the incorporation of compounds such as **1a**−**c**, mimicing the side chain of basic amino acids, into oligonucleotides may enhance their catalytic repertoire beyond that of ribozymes and aptamers (Burgstaller and Famulok, 1995; Sakhtivel and Barbas, 1998; Santoro et al., 2000; Breaker and Joyce, 1995; Santoro and Joyce, 1997; Carmi et al., 1996; Carmi et al., 1998; Tarasow et al., 1997; Thum et al., 2001).

Synthesis and Photochemical Properties of Nitro-Naphthyl Chromophore and the Corresponding Immunoglobulin Bioconjugate

Anil K. Singh* and Prashant K. Khade

Department of Chemistry, Indian Institute of Technology, Bombay, Powai, Mumbai − 400 076, India Received March 28, 2002

Synthesis, photochemistry, and biomolecular caging properties of a new chromophore namely 3-nitro-2-naphthalenemethanol are described. This chromophore is photoexcitable with photons in 350−400 nm range and in several solvents including aqueous medium. On irradiation, it gives the expected nitroso-aldehyde photoproduct with high quantum yield (0.6−0.8). Further, it can be conveniently coupled to the amino residues of immunoglobulin (IgG) using diphosgene. Irradiation of the resulting IgG−nitronaphthyl chromophore bioconjugate at 380 nm causes photorelease of IgG as evidenced by Protein-A affinity binding studies. The bioconjugate showed low level of binding to Protein-A. However, the binding increases after irradiation and, thus, modifies the Fc site of the IgG. Electrophoresis studies of the irradiated bioconjugate show that IgG does not undergo fragmentation or molecular weight change under the irradiation conditions. Thus, 3-nitro-2-naphthalenemethanol can be used as a photocaging agent under physiological conditions at wavelengths, which does not cause significant damage to the biomolecule. The work provides new directions for the development of organic chromophores for biomolecular caging applications.

INTRODUCTION

Photochemical release of biologically active component from "caged biomolecule" is an important strategy in the study of numerous aspects of structure and dynamics of biochemical and medical significance (*1*−*5*). This is because of the ability of light to control the site, time, and concentration of the released molecule. A caged biomolecule is defined as a biomolecule whose activity or function is lost or altered upon its chemical modification with a photolabile group (i.e., masking of the functional group(s) of the biomolecule by a photocleavable protecting reagent), and irradiation of the caged biomolecule with light results in removal of the protecting group with simultaneous rapid generation of the active or functional biomolecule. Such photochemical deprotection of masked functional groups of biomolecules presents a simple, noninvasive technology to investigate a wide range of cellular activities and gives rise to many practical applications including site directed drug delivery.

Several photocleavable nitroaryl groups have been employed as protecting groups in organic synthesis (*6*). Further, nitroaryl chromophore-based photoactivable caged nucleotides (*7*−*12*) and proteins and peptides (*13*−*23*) have been developed to study intracellular dynamics, metabolism, and enzymatic activities. More recently, applications of photocleavable chromophores have been made in site-directed photocleavage for mapping protein architecture (*24*), synthesis of difficult cyclic peptides by inclusion of photolabile nitrobenzyl auxiliary in a ring contraction strategy (*25*), and selective inhibition, separation, and purification of serine proteases (*26*).

In most cases, caging of the biomolecules has been done with *ortho*-nitrobenzyl chromophoric group, which absorbs mainly in the ultraviolet region, a wavelength that may not be very suitable for biomolecular applications. For practical purposes, it is important to have photocleavable systems, which are useful under physiological conditions and can be photoexcited at a number of wavelength and more importantly at wavelengths which are less damaging to the biological systems.

In this paper are described synthesis, photochemistry, and biomolecular caging properties of a new chromophore, namely, 3-nitro-2-naphthalenemethanol (**7**). It is photoexcitable in 350−400 nm range, and it shows expected photochemical reaction of *ortho*-nitroaryl group giving the nitroso-aldehyde photoproduct. Further, **7** can be conveniently coupled to the amino residues of immunoglobulin (IgG) using diphosgene method via chloroformate **8**. Irradiation of the resulting IgG−**7** biconjugate **9** at 380 nm causes photorelease of IgG, as evidenced by Protein-A affinity binding studies. It has been demonstrated that chromophore **7** can be employed to cage proteins and the conjugated proteins can be photochemically released at wavelengths which are less damaging to the biological matrix in aqueous medium.

EXPERIMENTAL PROCEDURES

Chemicals, Apparatus, and General Methods. Starting materials for synthesis were obtained from M/s. Lancaster and M/s. SRL, India Ltd. Mumbai. Human immunoglobulin (IgG), gel electrophoresis chemicals, and buffers were purchased from M/s. Bangalore Genie, India Ltd. Bangalore. Diphosgene was obtained from the Indian Institute of Chemical Technology, Hyderabad. Protein-A sepharose CL-4B was purchased from Pharmacia Biotech. Synthetic compounds were purified by column chromatography using 60−120 mesh silica gel. Deionized and double distilled water was used for buffer preparation, electrophoresis, and affinity experiments.

Melting points were recorded on Veego melting point apparatus and are uncorrected. UV−vis spectra were

recorded on Shimadzu Uv-260 spectrophotometer. FTIR spectra were measured on Impact Nicolet-400 spectrophotometer. ^{1}H NMR spectra were recorded on Varian 300 MHz NMR spectrometer using TMS as the internal standard. Mass spectra were recorded on GCD 1800A Hewlett-Packard GC-MS spectrometer. Elemental analysis was performed on Theroquest CE instrument-1112 series CHN auto-analyzer. Protein samples were centrifuged at 4 °C in L8M55 Beckman ultracentrifuge equipped with Ti-45 rotor. Electrophoresis experiments were performed on a vertical gel electrophoresis instrument (mini model) from M/s. Bangalore Genie.

Irradiations were done using a 400 W medium pressure mercury lamp (Applied Photophysics Ltd., London, Model R-607), fitted either with a f/3.4 monochromator or with a glass filter to isolate the desired wavelength for irradiation. The organic solvents used for various electronic measurements or photochemical purposes were freshly distilled and thoroughly deoxygenated by bubbling dry nitrogen. The irradiated solutions were analyzed by UV−vis, FTIR, and ^{1}H NMR methods. The relative quantum yield (Φ_{PR}) was determined against potassium ferrioxalate actinometer (*27*).

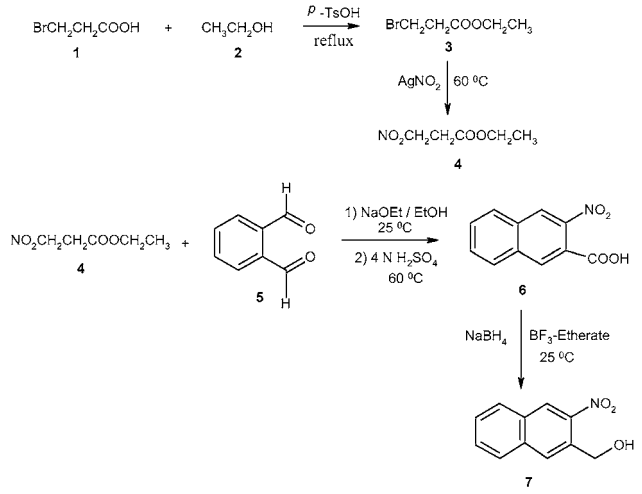
Synthesis of 3-Nitro-2-naphthalenemethanol (7). Compound **7** was synthesized by reacting phthalaldehyde (**5**) with 3-nitropropionic ethyl ester (**4**) in the presence of sodium ethoxide in absolute ethanol as previously described (*28*). Reduction of the resulting 3-nitro-2-naphthoic acid (**6**) with $NaBH_4-BF_3-Et_2O$ in 1,2-dimethoxyethane followed by usual workup and column chromatographic purification yielded the desired alcohol **7**: yield, 40%; mp, 118−19 °C [lit. (*28*) mp 118−19 °C]. UV−vis: λ_{max}, nm (ϵ, mol^{-1} cm^{-1} L) in CH_3CN, 350 (2285). FTIR (KBr): ν_{max} (cm^{-1}) 3458−3372 (OH), 1513, 1331 (NO_2). ^{1}H NMR (DMSO): δ 4.91 (2H, d, J = 5.12 Hz, $-CH_2$), 5.90 (1H, t, −OH), 7.75−7.59 (2H, m, H−C_6 and H−C_7), 8.06 (1H, d, J = 8.24, H−C_8), 8.17 (1H, d, J = 8.05 Hz, H−C_5), 8.24 (1H, s, H−C_1), 8.75 (1H, s, H−C_4). MS *m*/*z* (%): 205 ($M^+ + 2$), 171 (74), 143 (100), 126 (55), 115 (58). Anal. Calcd for $C_{11}H_9NO_3$: C, 65.05; H, 4.47; N, 6.90. Found: C, 65.49; H, 4.33; N, 6.72.

Preparation of 3-Nitro-2-naphthyloxycarbonyl chloride (8). In a typical procedure, 3-nitro-2-naphthalenemethanol (**7**, 0.005 g, 0.25 mmol) was treated with diphosgene (20 μL) and dry pyridine (8 μL) as a catalyst in dried and freshly distilled 1,4-dioxane (150 μL). A yellow precipitate was immediately formed. The reaction mixture was magnetically stirred at ambient temperature for 24 h. The reaction was monitored by TLC using 20% ethyl acetate in petroleum ether (60−80 °C fraction). 1,4-Dioxane, pyridine, and excess of diphosgene were evaporated by using a stream of dry nitrogen. The residue was taken-up in dry 1,4-dioxane (125 μL), and the resulting solution was used for protein conjugation. The chloroformate **8** showed expected IR peaks at 1738 (−OCO) and 1535 and 1377 ($-NO_2$) cm^{-1}.

Coupling of Chloroformate 8 with IgG−Preparation of Bioconjugate 9. In a typical experiment, human immunoglobulin (IgG, 0.004 g) was taken in sodium bicarbonate (4 mL, 0.1 M; pH, 8.3) in a 10 mL round-bottom flask. To this was added 80 μL of chloroformate **8**. The reaction mixture was left overnight for coupling at 4 °C. Subsequently, the mixture was dialyzed twice against 200 mL each of 0.153 M sodium chloride (pH, 6.7). The white insoluble complexes were removed by centrifugation at 15 000*g* for 15 min at 4 °C to obtain bioconjugate **9** as clear solution. To this was added a solution of **9** 4 mL of 0.153 M aq. sodium chloride (pH 6.7), and the resulting solution was used for further study. The bioconjugate thus prepared showed UV−vis band extending up to 410 nm.

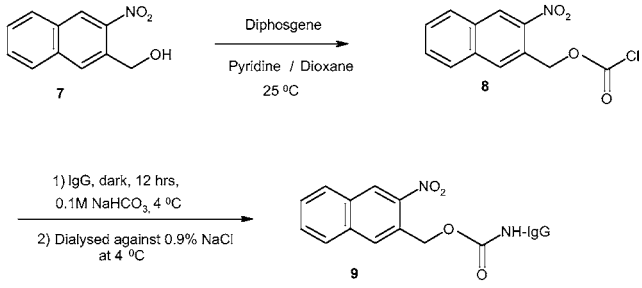
To determine the maximum number of chromophores that bind to IgG, the coupling of IgG to chloroformate **8** was done by using different amounts of **8** (0 μL as the control, and 5,10, and 20 μL aliquots of chloroformates) in 0.001 g of IgG solution in 1 mL of sodium bicarbonate buffer (0.1 M, pH, 8.3). It has been found that 20 μL of 1,4-dioxane solution of chloroformate **8** is sufficient to maximally modify the IgG.

The number of chromophores coupled to the protein was determined as follows. The concentration of chromopohre in bioconjugate was obtained from the absorbance value at the absorption maximum at 350 nm due to the chromophore. The concentration of protein in the bioconjugate was determined by considering its absorbance at 280 nm. However, in bioconjugate there is present absorption contribution by the chromophore also. Therefore, first the absorption contribution of the chromophore at 280 nm was determined from its absorbance at 280 nm in the bioconjugate, followed by subtracting it from the total absorbance of the bioconjugate at 280 nm. In calculating the concentration of chromophore from the absorbances obtained from bioconjugates, the extinction coefficients of chromophore at 280 and 350 nm in ethanol were used. From the concentrations, the number of molecules of IgG and the chromophore were calculated. Thus, the relative number of chromophores attached to the protein was obtained.



Irradiation of Compound 7 and Bioconjugate 9. A solution of **7** in acetonitrile (3 mL of 1.0×10^{-4} M) taken in a quartz cuvette and degassed by passing dry nitrogen was irradiated at 380 nm at ambient temperature. The distance between the sample and the lamp was kept 35 cm. The progress of the photochemical reaction was monitored spectrophotometrically by observing the changes at 350 nm. The photomixture was subsequently analyzed by FTIR and ^{1}H NMR analysis.

The dialyzed solution of bioconjugate **9** (3 mL, 0.153 M NaCl, pH, 6.7) was irradiated at 380 nm under the same conditions as described above. The bioconjugate was also irradiated with light filtered with a glass filter having 47% and 96% transmittance at 370 and 420 nm, respectively. Under this irradiation condition, the distance between the sample and the 400 W medium-pressure mercury lamp was kept 2 cm. The progress of the photolysis was monitored spectrophotometrically.



One aliquot of bioconjugate sample being irradiated was removed time to time and eluted from Protein-A affinity column. In a control experiment, the native IgG solution (3 mL, 0.153 M NaCl, pH 6.7) was subjected to irradiation under conditions identical to the irradiation conditions of conjugate **9**, and its binding affinity to protein-A was also studied.

Affinity Chromatography Studies of Bioconjugate Samples. A 3 cm long and 0.5 cm wide column was packed with Protein-A and equilibrated with 0.05 M Tris-buffer (pH, 7.4). One aliquot (0.5 mL) of irradiated bioconjugate sample was removed time to time and loaded on the affinity column, which was washed with the binding buffer until the absorbance of the eluted solution at 280 nm approached background level. The column was then eluted with 0.05 M glycine buffer (pH, 3.0) to remove the bound IgG protein and washed until the absorbance of elute at 280 nm approached the background level. The fractions collected were neutralized by addition of 100 μL of 1.0 M glycine buffer (pH, 9) in each test tube. Subsequently, the column was washed with 25 mL of binding buffer (0.05 M Tris-buffer, pH 7.4)

Scheme 1

Scheme 2

and equilibrated with it. From the absorbance at 280 nm, the concentration of IgG protein was calculated.

Protein-A binding affinity studies showed that unirradiated protein conjugate **9** binds to Protein-A to the extent of 18%.

Electrophoresis Studies of IgG, Bioconjugate, and Photoreleased IgG. The sample buffer (50 μL, 1.0×10^{-7} M) containing 10% glycerol and SDS, 0.5% bromophenol blue, and 0.5 M Tris-HCl (pH, 6.8) was added separately to irradiated bioconjugate, unirradiated bioconjugate, and unconjugated, native IgG. The mixture was heated to 85 °C for 10 min. The various protein samples, including 50 μL each of irradiated bioconjugate, unirradiated bioconjugate, unconjugated, native IgG, and the marker proteins in 14−200 kD MW range, which contain 5 μL of denaturing buffer were loaded on 10% SDS-polyacrylamide discontinuous gel. The electrophoresis was done in nonreducing conditions by applying 90−120 V and 10 A current. The electrophoresis was stopped when bromophenol blue reached to the bottom of the gel and the gels were stained (brilliant blue G stain, 0.1% w/v brilliant blue G, 25% methanol, 7% acetic acid). The destaining was done by 40% methanol, 10% acetic acid and 50% deionized water.

RESULTS AND DISCUSSION

Synthesis of 3-Nitro-2-naphthalenemethanol (7) and IgG-7 Bioconjugate (9). Synthesis of compound **7** and its IgG-bioconjugate **9** was done by following the steps outlined in Schemes 1 and 2. Esterification of 3-bromopropanoic acid (**1**) with ethanol gave ester **3**, which on reaction with silver nitrate yielded the nitroester **4**. The reaction of nitroester **4** with phthaldehyde **5** in the presence of sodium ethoxide, followed by acidic hydrolysis (of the ester group), resulted in the formation of nitro-naphthoic acid **6**, which on subsequent reduction with sodium borohydride gave the desired compound **7** in an overall yield of 40%. Compound **7** showed a mp identical to the mp reported in the literature (*28*). However, compound **7** was satisfactorily characterized additionally by other physicochemical methods, including electronic absorption, FTIR, ^{1}H NMR, mass, and elemental analysis as described in the Experimental Section.

Table 1. UV−Vis Absorption Spectral[a] and Quantum Yield (Φ_{PR}) Data of 7

solvent	λ/nm	ϵ/M L^{-1} cm^{-1}	Φ_{PR} at 380 nm

	350	1 289	

[a] Absorption coefficient at 280 nm: 6 826 (1,4-dioxane), 5 124 (acetonitrile), 6 200 (ethanol) ,and 2 124 (0.153 M NaCl). At 380 nm: 1 415 (1,4-dioxane), 1 264 (acetonitrile), 1 350 (ethanol), and 809 (0.153 M NaCl).

Bioconjugate **9** could conveniently be prepared via chloroformate **8**. As outlined in Scheme 2, reaction of compound **7** with diphosgene yielded chloroformate **8**, which reacted with the amino residues of IgG to give the desired bioconjugate **9** in about 40% yield. Under the present preparative conditions, about 22 (±2) molecules of **8** coupled to a molecule of IgG. The IgG has a total of 50 lysine units and it is possible that 22 (±2) ϵ-amino groups of lysine in IgG underwent coupling with **8** in the present experimental conditions.

Electronic Absorption and Photochemical Properties of 3-Nitro-2-naphthalenemethanol (7). The UV−vis absorption spectral data and the Φ_{PR} of **7** are summarized in the Table 1. This compound exhibits major absorption bands in 220−250 and 300−350 nm range with tail end absorption extending up to 410 nm for a 1.0×10^{-4} M solution. The longer wavelength absorptions of **7** can be due to the ^1L_a (vertically polarized) transition of the naphthyl group. The molar absorption coefficient of the band in 220−250 range is larger than the band in 300−350 nm range. The UV−vis absorption of **7** remains similar in a variety of solvents including acetonitrile, ethanol, 1,4-dioxane, and 0.153 M aq. NaCl (pH, 6.7). However, the molar absorption coefficient varies with the solvent. An ethanolic solution of **7** shows absorption at 346 nm with molar absorptivity of about 3000 mol^{-1} cm^{-1} L. However, for the same solution, the molar absorptivity is 1350 mol^{-1} cm^{-1} L for absorption at 380 nm. Compound **7** in aq. NaCl medium shows absorption at 350 nm with a molar absorptivity of about 1 289 mol^{-1} cm^{-1} L. Its molar absorptivity at 380 nm is found to be about 809 mol^{-1} cm^{-1} L.

Typical UV−vis absorption changes during 380 nm irradiation of a 1.0×10^{-4} M acetonitrile solution of **7** are shown in Figure 1. The FTIR spectrum of the photomixture is characterized by the presence of bands at 1 532 and 1 341 cm^{-1} due to nitroso group and 1 703

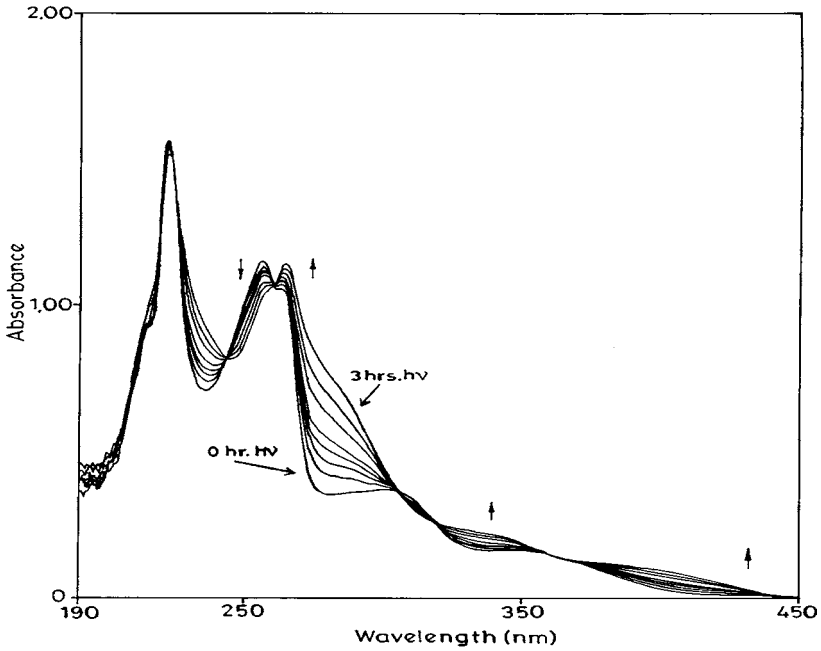

Figure 1. UV−vis absorption spectral changes during 380 nm photolysis of a 1.0×10^{-4} M acetonitrile solution of **7**.

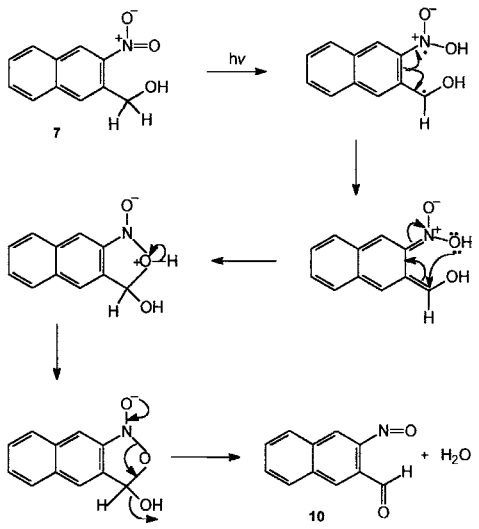
cm^{-1} due to aldehyde group. The alcohol group peak (3 372−3 458 cm^{-1}) that was present in the starting chromophore disappeared after irradiation. The ^{1}H-NMR spectrum of the photomixture showed peak at δ 10.50 due to an aldehyde proton.



Similar photobehavior was observed when **7** was irradiated in protic ethanol, nonpolar 1,4-dioxane, and 0.153 M aq. NaCl solutions, indicating the absence of any solvent effect on the photochemical properties of **7**. Irradiation of **7** at 300, 350, and 400 nm also showed photochemical product profile similar to its irradiation at 380 nm.

The above photochemical and spectroscopic results suggest that compound **7**, on irradiation with photons in 300 to 400 nm range, undergoes the expected light-induced internal oxidation−reduction reaction of aromatic nitro compounds containing a carbon−hydrogen bond ortho to the nitro group (*6*). The primary photochemical process in this reaction is an intramolecular hydrogen abstraction by the nitro group generating free radical species; this is then followed by electron redistribution to the *aci*-nitro form, which subsequently rearranges to the nitroso-aldehyde photoproduct (**10**) (Scheme 3). Thus, it has been possible to develop a chromophore that can be photoexcited with desired photochemistry at wavelengths greater than 350 nm.

Electronic Absorption and Photochemical Properties of Bioconjugate 9. The UV−vis absorption spectrum of bioconjugate **9** in 0.1 M aq. NaCl solution is characterized by absorption bands at 198 and 266 nm, with extended absorption up to 410 nm. The IgG protein peak at 278 nm is masked due to the absorption by chromophoric group of **7** having absorption in 250−300 nm range. The bioconjugate can, however, be photoexcited by taking the advantage of absorption in 350−410 nm, where unconjugated protein has insignificant absorption.

Thus, a 1.0×10^{-5} M solution of bioconjugates **9** in 0.9% (0.153 M) aq. NaCl was irradiated at 380 nm. The irradiation resulted in changes in the absorption at 266 nm (Figure 2). The irradiated bioconjugate samples were analyzed by affinity chromatography on a Protein-A

Scheme 3

sepharose CL4B column, and the extent of binding of photoreleased IgG was determined (Figure 3). The bioconjugate sample irradiated for 3 h showed 70% binding affinity to Protein-A. However, bioconjugate samples irradiated for 5 and 7 h showed binding affinity of only 50% and 40%, respectively, to Protein-A. Thus, the binding affinity was increased from 18% (the extent to which unirradiated IgG binds to Protein-A) to 70% after 3 h of irradiation. However, the binding affinity decreased to 40% after 7 h of irradiation. As control experiments, uncoupled and unirradiated native IgG was irradiated for 0 (control), 3, 5, and 7 h at 380 nm, and the binding affinity for such samples was found to be 100%, 85%, 83%, and 73% respectively.

Further, a sample of bioconjugate **9** irradiated for 40 min using a glass filter having 47% and 96% transmittance at 370 and 420 nm, respectively, showed binding affinity to Protein-A to the extent of 74%. Continued irradiation up to 60 min caused further decrease in binding affinity to 51%. This shows that as the intensity of the photons is increased, the rate of the photoreaction was increased. Thus, photorelease of IgG from the

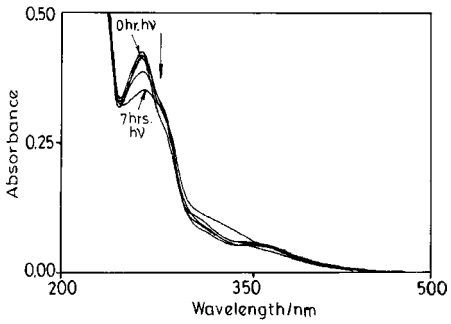


Figure 2. UV−vis absorption spectral changes during 380 nm photolysis of a 1.0×10^{-5} M aq. NaCl (0.153 M) solution of bioconjugate **9**.

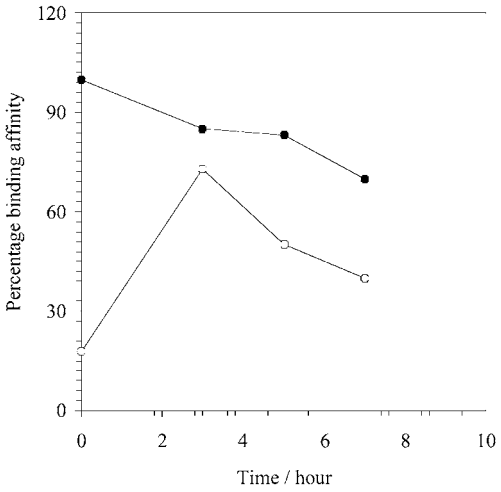

Figure 3. A plot of irradiation time vs percent Protein-A binding affinity. (○) Photo-released IgG (upon irradiation of bioconjugate **9**), and (●) native IgG (which was subjected to irradiation under conditions identical to the irradiation of bioconjugate **9**).

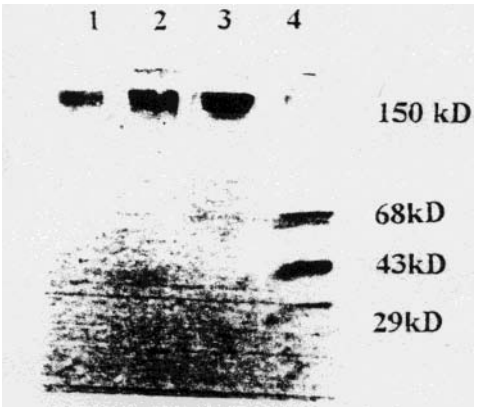
bioconjugate can be effected in much shorter time by use of appropriate light source (e.g. lasers).

It is believed that irradiation of bioconjugate **9** results into the photoconversion of its nitronaphthyl chromophore to nitroso-aldehyde and subsequent release of IgG, as outlined in Scheme 4. The primary photochemical process of bioconjugate **9** is similar to the photochemical process of *ortho*-nitroaryl chromophores having abstractable hydrogen atoms in the vicinity (*6*). Overall, the photochemical reaction of bioconjugate **9** results into release of IgG via the formation of nitroso-aldehyde **10** and carbon dioxide.

The decrease in binding can be due to the artificial irradiation in case of control protein and in case of coupled protein it may be due to the artificial irradiation as well as due to reaction or association of the nitroso-aldehyde photoproduct (**10**) with the photoreleased free protein.

These results further show that the nitro-naphthyl chromophore modifies the F_C site of IgG molecule. The modified protein showed low level of binding, and after irradiation, binding of released protein to Protein-A was increased. This can be due to the fact that irradiation of the conjugate leads to photorelease of the nitro-naphthyl chromophore from the Fc site of IgG, which then becomes available for binding to Protein-A.

Electrophoresis studies of unconjugated native IgG (as control), unirradiated bioconjugate (**9** as the control), and irradiated bioconjugate in discontinuous gel and nonreducing conditions showed that irradiation does not cause



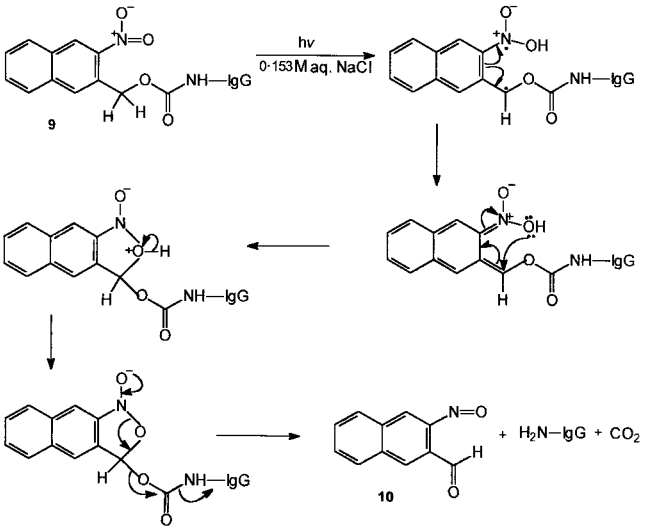


Figure 4. Electrophoresis of various protein samples. (1) Irradiated bioconjugate. (2) Unirradiated bioconjugate. (3) Native IgG. (4) Marker proteins.

Scheme 4

any fragmentation or molecular weight changes in IgG (Figure 4). UV−vis absorption and electrophoresis studies thus indicate IgG protein molecules are not fragmented under the present irradiation conditions.

In conclusion, it can be said that 3-nitro-2-naphthalenemethanol **7** can be used for caging of biomolecules. It can be photoexcited in aqueous solution and at wavelengths that do not cause significant damage to the biomolecules. Further, this chromophore is photoexcitable at many wavelengths in 300−400 nm range. This work provides new directions for the development of organic chromophores for biomolecular caging applications.

ACKNOWLEDGMENT

Polycationic Diblock and Random Polyethylene Glycol- or Tris(hydroxymethyl)methyl-Grafted (Co)telomers for Gene Transfer: Synthesis and Evaluation of Their in Vitro Transfection Efficiency

Bertrand Le Bon,[†] Nathalie Van Craynest,[†] Otmane Boussif,[‡,§] and Pierre Vierling*[,†]

Laboratoire de Chimie Bioorganique, UMR 6001 CNRS, Université de Nice Sophia-Antipolis, Faculté des Sciences, 06108 Nice Cédex 2, France, and Transgène SA, 11 rue de Molsheim, 67082 Strasbourg Cédex, France. Received May 1, 2002; Revised Manuscript Received July 1, 2002

We report on the synthesis of a series of polycationic telomers, polycationic diblock and random polyethylene glycol (PEG)-grafted (co)telomers, and polycationic random tris(hydroxymethyl)methyl (THM) cotelomers, and on their in vitro gene transfer capability. These compounds were obtained by a telomerization process of various amino-, tetraethylene glycol-, or THM-acrylamide taxogens with thiols which might derive from PEG2000. For *N*/*P* ratios [*N* is the number of (co)telomer amine equivalents; *P* is the number of DNA phosphate equivalents] from 0.8 to 10, these (co)telomers condensed DNA, forming (co)teloplexes with mean sizes in the 85−330 nm range, even for an *N*/*P* ratio of 0.8 or 1.25. Some structure−transfection efficiency relationships were established. Among the new polycationic derivatives that were synthesized and investigated for their transfection efficiency, the ^{i}Bu-[NH]$_{75}$ telomers and the diblock polyethylene glycol-conjugated **PEG2000-[NH]$_n$** telomers are very promising candidates for gene transfer purposes.

INTRODUCTION

Introducing a gene into cells with synthetic (nonviral) vectors is a promising alternative for gene therapy. Although viral vectors are useful clinical tools for delivering genes and infect cells, they suffer from several serious drawbacks (*1*−*3*, and references therein). To circumvent these drawbacks, a large number of nonviral vectors, including (poly)cationic lipid- (liposome-) and polymer-based DNA complexes (lipoplexes and polyplexes, respectively) have been evaluated (*3*−*8*, and references therein). Unlike viral vectors, nonviral vectors have advantages in their large scale and easy production, simplicity of use, safety (fewer immunogenic and inflammatory responses, an inability to replicate or to recombine to form an infectious agent, and low integration frequency), and ability to transfer expression cassettes of unlimited size. Although they demonstrated in vitro a real capacity for transfecting culture cells, lipoplexes and polyplexes are not as efficient as viral vectors in achieving successful gene transfer. In addition, nonviral (and viral) gene delivery systems are currently fraught with a number of serious problems when their in vivo use, i.e., after systemic administration for example, is contemplated (*3*, *9*−*12*). To successfully transfect its target cells at a remote site, the gene delivery system must, at least, reach this site while in blood circulation. Unfortunately, clearance of "conventional" DNA carriers from the bloodstream is rapid (*12*). Furthermore, it is very difficult to control their biodistribution and transgene expression in vivo which are not necessarily correlated (*13*, *14*). Gene delivery to a specific target tissue is more challenging and requires strategies that limit nonspecific interactions with the biological environment. For intravenous administrations, formation of large aggregates and interactions with the blood components (e.g., opsonization with plasma proteins) and nontarget cells such as the mononuclear phagocytic system (MPS) are most important obstacles for targeting genes in vivo. Attempts have been made to avoid aggregation of the lipoplexes and polyplexes, to reduce the level of protein binding to the DNA complexes, and to divert them from the MPS by coupling of (i) hydrophilic nonimmunogenic polymers, such as polyethylene glycol (PEG) which provides a "stealth"-like coating, and/or (ii) specific cell-binding ligands (*12*, *15*−*23*).

Recently, as a contribution to this field, some of us have reported on lipoteloplexes and lipo(co)teloplexes, e.g., DNA complexes formulated with lipopolyamine telomers and random cotelomers, respectively, as alternative efficient gene transfer agents (*24*, *25*). These lipopolyamine (co)telomers were obtained from telomerizing one polymerizable acrylamide M monomer or a mixture of polymerizable acrylamide M and M′ monomers comprising a (poly)amine precursor, in the presence of a hydrophobic long chain thiol (L-SH). The lipopolyamine (co)telomers thus obtained, of formula L-S-(M)$_n$-H or random L-S-(M)-*n*-(M′)*n*′-H, exhibited controllable degrees of (co)polymerization (*24*, *25*).

We report herein on the synthesis of new diblock PEG-grafted polycationic telomers and of new random tetraethylene glycol (TEG)- or polyol tris(hydroxymethyl)-methyl (THM)-grafted polycationic cotelomers (Figure 1), on their capabilities of compacting and transferring, in vitro, DNA into a cell, and on their effect on cell viability. These PEG-, TEG-, or THM-grafted polycationic derivatives show a modular structure aimed at modulating the physicochemical and biological properties (e.g., stability with respect to aggregation, biodegradability, cell viability, biodisponibility, and transfection efficacy) of the

teloplexes and coteloplexes they form with DNA. The diblock PEG-grafted polycationic telomers include a long PEG chain (PEG2000) and a variable number (from 4 to 360) of primary or tertiary amine functions. The random cotelomers contain a random combination of primary amine functions and TEG or THM units. The neutral, hydrophilic PEG, TEG, and THM units were selected for improving cell viability (*26*, *27*) and/or reducing the the number of interactions with plasma constituents and opsonization of the DNA complexes (*12*, *15*−*23*). For comparison, we developed and evaluated also the polycationic ^{i}Bu-[NH]$_n$ telomers that were obtained from telogen ^{i}Bu-SH (Figure 1). This telogen was also selected for its diisobutyl group with the aim of facilitating the determination of the average degree of polymerization of the (co)telomers by ^{1}H NMR (*24*, *25*).

EXPERIMENTAL SECTION

General Experimental and Analytical Conditions. All the reactions were performed in anhydrous solvents under dry and oxygen-free nitrogen. The purifications by column chromatography were carried out using silica gel 60 (Merck, 70−230 mesh) and chloroform ($CHCl_3$), dichloromethane (CH_2Cl_2), methanol (MeOH), or mixtures thereof as indicated. The progress of the polymerization reaction was followed by thin-layer chromatography (TLC) on silica plates (SDS 60F254, 60/15 μm). The following developing systems were used: UV light (254 nm), Draggendorff reagents, DTNB [5,5′-dithiobis(2-nitrobenzoic acid)] (Sigma), and ninhydrin reagent (Sigma). The synthesis of taxogen **A**, *N*-{2-[(BOC)aminoethyl]}acrylamide, was performed as reported elsewhere (*24*). Taxogens *N*-[3-(dimethylamino)-propyl]acrylamide (**B**) and *N*-[tris(hydroxymethyl)methyl]-acrylamide (**D**) were purchased from Aldrich and used without further purification.

^{1}H, ^{13}C, and ^{19}F NMR spectra were recorded on a Bruker AC-200 instrument at 200, 50.3, and 188.3 MHz, respectively. Chemical shifts were measured relative to that of $CHCl_3$ (δ 7.27) or CH_3OD (δ 3.35) for ^{1}H, to that of $CDCl_3$ (δ 76.9) for ^{13}C and expressed indirectly in relation to TMS, and to that of CCl_3F as an internal reference for ^{19}F. The following abbreviations are used to describe the signal multiplicities: s (singlet), d (doublet), t (triplet), q (quadruplet), and m (multiplet). Chemical shifts are expressed in parts per million and listed as follows: shift in parts per million (multiplicity, integration, coupling, and attribution). Melting points were measured on an Electrothermal Digital Series 9100 and were not corrected. Mass spectra (MS) were recorded on a Finnigan MAT TSQ 7000 apparatus equipped with an atmospheric-pressure ionization (API) source. Electrospray ionization mass spectrometry (ESI-MS) was used depending on the polar moiety of the molecules to be studied. This method used in the positive mode can give either a M + H$^+$ or a M + Na$^+$ signal.

Scheme 1. Synthesis of Telogen ^{i}Bu-SH and PEG2000-SH[a]

[a] Reagents and conditions: (i) TsCl, NEt_3, DMAP, CH_2Cl_2, 0 °C; (ii) Amberlite IR400 (SH^- form), NaSH in CH_3CN, 50 °C; (iii) EDC, HOBt, THF, CH_2Cl_2, 0 °C, then (^{i}Bu)$_2$NH, NEt_3, THF, 0 °C; (iv) Zn, AcOH.

Synthesis of Taxogen C (2-{2-[2-(2-Methoxyethoxy)ethoxy]ethoxy}ethyl Ester Acrylate). To a solution of 0.6 mL (7.2 mmol) acryloyl chloride (Aldrich) in 10 mL of anhydrous CH_2Cl_2 was added dropwise during 1 h at 0 °C a solution of 0.7 mL (4.8 mmol) of triethylamine and 0.96 mL (4.8 mmol) of 2,5,8,11-tetraoxatridecan-13-ol (tetraethylene glycol monomethyl ether, MeO-TEG, Acros) in 10 mL of anhydrous CH_2Cl_2. After being stirred for 4 h at room temperature, the reaction mixture was concentrated under vacuum, and the residue was chromatographed over a silica column [$CHCl_3$/MeOH eluent, from 100 to 97/3 (v/v)]; 540 mg (2.06 mmol, 43%) of taxogen **C** was obtained as a colorless oil: TLC (98/2 $CHCl_3$/MeOH, UV and Draggendorf) R_f = 0.71; ^{1}H NMR ($CDCl_3$) δ 3.30 (s, 3H, OCH_3), 3.47 (m, 2H, CH_2OCH$_3$), 3.55 (m, 10H, CH_2OCH_2), 3.68 (m, 2H, CH_2CH$_2$OCO), 4.25 (m, 2H, CH_2OCO), 5.78 (dd, 1H, ^3J = 1.7 Hz, ^3J = 10.4 Hz, CH_2CH), 6.08 (dd, 1H, ^3J = 10.4 Hz, ^3J = 17.2 Hz, CH$_2$CH), 6.36 (dd, 1H, ^2J = 1.7 Hz, ^3J = 10.4 Hz, CH_2CH); ^{13}C NMR ($CDCl_3$) δ 59.0 (CH_3O), 63.7 (CH_2-OCO), 69.2 (CH_2CH_2OCO), 70.6 and 70.7 (CH_2OCH_2), 72.0 ($CH_2CH_2OCH_3$), 128.4 (CH_2=CH), 130.9 (CH_2=CH), 166.2 (CO).

Synthesis of the Telogen *N*,*N*-Diisobutyl-3-mercaptopropionamide (^{i}Bu-SH). The synthesis of the telogen ^{i}Bu-SH was carried out in two steps as shown in Scheme 1.

Synthesis of 3-(2-Diisobutylcarbamoylethyldisulfanyl)-*N*,*N*-diisobutylpropionamide. A solution of 250 mg (1.2 mmol) of 3,3′-dithiodipropionic acid (Aldrich) and 480 mg (3.6 mmol) of HOBt (1-hydroxybenzotriazole, Aldrich) in 30 mL of anhydrous THF was added to 680 mg (3.6 mmol) of EDC [1-(3-*N*,*N*-dimethylaminopropyl)-3-ethylcarbodiimide chlorohydrate, Aldrich] in 25 mL of anhydrous CH_2Cl_2 at 0 °C. Then, a solution of 0.5 mL (3.6 mmol) of triethylamine and 0.42 mL (2.4 mmol) of diisobutylamine (Aldrich) in 10 mL of THF was added dropwise at 0 °C, and the resulting reaction mixture was stirred at room temperature for 12 h. The reaction mixture was then concentrated and $CHCl_3$ added. The organic solution was washed with aqueous $NaHCO_3$ (8%) and H_2O until the solution reached neutrality, dried over Na_2SO_4, and filtered. The solution was then concentrated

under vacuum, and the residue was chromatographed over a silica column [hexane/ethyl acetate eluent, from 9/1 to 85/15 (v/v)]; 403 mg (0.93 mmol, 78%) of the title disulfide were obtained as an oil: TLC (9/1 CH_2Cl_2/ethyl acetate, UV) $R_f = 0.61$; ^{1}H NMR ($CDCl_3$) δ 0.79 and 0.85 (d, d, 12H, 12H, $^3J = 6.7$ Hz, CH_3), 1.76−2.02 (m, 4H, CH), 2.69 (m, 4H, CH_2CO), 2.89 (m, 4H, CH_2S), 3.04 and 3.12 (d, d, 4H, 4H, $^3J = 7.5$ Hz, CH_2NCO); ^{13}C NMR ($CDCl_3$) δ 20.0 and 20.1 (CH_3), 26.4 and 27.8 (CH), 33.0 (CH_2S), 33.8 (CH_2CO), 54.3 and 55.5 (CH_2N), 171.0 (CO). The doubling of some signals is due to restricted rotation of the amide bond.

Synthesis of ^{i}Bu-SH. To a solution of 403 mg (0.93 mmol) of the above disulfide in 8 mL of acetic acid was added 600 mg (9.31 mmol) of zinc powder (Aldrich). The solution was stirred under reflux. After completion of the reaction [followed by TLC (UV/DTNB)], the mixture was filtered over Celite 521 (Aldrich). The excess of acetic acid was removed by evaporation in the presence of $CHCl_3$ and cyclohexane. The residue was dissolved in $CHCl_3$ and washed with H_2O until the solution reached neutrality, and the organic phase was then dried over Na_2SO_4, filtered, and concentrated under vacuum; 380 mg (1.75 mmol, 94%) of ^{i}Bu-SH was obtained as a colored oil: TLC (8/2 hexane/ethyl acetate, DTNB) $R_f = 0.56$; ^{1}H NMR ($CDCl_3$) δ 0.89 and 0.87 (d, d, 6H, 6H, $^3J = 6.7$ Hz, CH_3), 1.69 (t, 1H, $^3J = 8.1$ Hz, SH), 1.93 (m, 2H, CH), 2.63 (m, 2H, CH_2CO), 2.77 (m, 2H, CH_2S), 3.05 and 3.16 (d, d, 2H, 2H, $^3J = 7.6$ Hz, CH_2N); ^{13}C NMR ($CDCl_3$) δ 20.0 and 20.1 (CH_3), 20.4 (CH_2SH), 26.4 and 27.8 (CH), 37.7 (CH_2CO), 53.3 and 55.4 (CH_2N), 171.0 (CO); ESI-MS *m*/*z* 218.4 (in agreement with the mass calculated for $C_{11}H_{23}NOS + H^+$).

Synthesis of the Telogen PEG2000-SH. The synthesis of **PEG2000-SH** was carried out in two steps as shown in Scheme 1.

PEG2000-OTs. To a solution of 1.0 g (0.5 mmol) of PEG2000-OH (polyethylene glycol monomethyl ether 2000, Aldrich), 0.21 mL (1.5 mmol) of triethylamine, and 24.5 mg (0.2 mmol) of (dimethylamino)pyridine (DMAP, Aldrich) in 5 mL of anhydrous CH_2Cl_2 was added dropwise 143 mg (0.75 mmol) of tosyl chloride (Fluka) in 2 mL of anhydrous CH_2Cl_2 at 0 °C. The reaction mixture was stirred at room temperature for 1 day and then washed with H_2O. The organic phase was dried over Na_2SO_4, filtered, and concentrated under vacuum. The residue was chromatographed on a silica column [$CHCl_3$/MeOH eluent, from 95/5 to 85/15 (v/v)]; 815 mg (0.37 mmol, 85%) of **PEG2000-OTs** was obtained as a white solid: TLC (8/2 $CHCl_3$/MeOH, Draggendorf) $R_f = 0.77$; mp 50−51 °C; ^{1}H NMR ($CDCl_3$) δ 2.43 (s, 3H, CH_3, Ts), 3.36 (s, 3H, CH_3O), 3.50−3.75 (sl, 178H, CH_2OCH_2), 4.14 (dd, 2H, $^3J = 5.0$ Hz, CH_2OTs), 7.33 (d, 2H, $^3J = 8.3$ Hz, C*H*CH, Ts), 7.78 (d, 2H, $^3J = 8.3$ Hz, CHC*H*, Ts); ^{13}C NMR ($CDCl_3$) δ 21.2 (CH_3, Ts), 59.0 (OCH_3), 68.7 (CH_2OTs), 69.3 (CH_2CH_2OTs), 70.6 (CH_2OCH_2), 128.0 (*C*HC-S, Ts), 129.8 (*C*HC-CH_3, Ts), 134.4 (CH*C*-S, Ts), 144.8 (CH*C*-CH_3, Ts). ESI-MS shows the presence of MeO-$(CH_2CH_2$-$O)_n$-CH_2CH_2OTs compounds with an *n* of 30−56 (*m*/*z* 230.1 + 44*n* + 23), in agreement with the masses calculated for $[C_{10}H_{14}O_4S + n(C_2H_4O) + Na^+]$.

PEG2000-SH. To a solution of 0.5 g (0.23 mmol) of **PEG2000-OTs** in 5 mL of anhydrous acetonitrile (CH_3CN) was added 5 g of anion-exchange resin Amberlite IRA400 (SH^- form) and 130 mg (2.3 mmol) of NaSH (Aldrich). The reaction mixture was stirred at 50 °C. After completion of the reaction (followed by TLC UV, Draggendorf, DTNB), the resin was filtered and washed with CH_2Cl_2. The organic phase was evaporated and concentrated under vacuum. The residue was purified by gel permeation chromatography on a Sephadex LH 20 column (Fluka) ($CHCl_3$/MeOH eluent, 9/1); 367 mg (0.18 mmol, 78%) of **PEG2000-SH** was obtained as a white solid: TLC (9/1 CH_2Cl_2/MeOH, UV, DTNB) $R_f = 0.51$; mp 53−54 °C; ^{1}H NMR (DMSO-d_6) δ 1.82 (m, 1H, SH), 2.60 (m, 2H, CH_2S), 3.22 (s, 3H, OCH_3), 3.40−3.60 (m, 178H, CH_2O); ^{13}C NMR (DMSO-d_6) δ 58.0 (OCH_3), 69.7 (CH_2O) (the CH_2CH_2S resonances could not be detected).

Synthesis of (co)Telomers. *General Procedure for the (Co)telomerization Reactions.* An acetonitrile solution of telogen **PEG2000-SH**, or ^{i}Bu-SH, and taxogen **A**, or **B**, or a mixture of **A** and **C**, or **A** and **D**, at a fixed taxogen/telogen molar ratio, was heated to 50 °C before AIBN was added (0.4 equiv with respect to telogen). The reaction medium was stirred under reflux until the telogen had disappeared (followed by TLC/DTNB) (∼24 h). The solution was concentrated and purified by gel permeation chromatography on a Sephadex LH 20 or LH-60 column (Fluka) with $CHCl_3$ as the eluent. The aDP*n* (=*n*) values were determined by ^{1}H NMR on each collected fraction.

General Procedure for the TFA Deprotection of the BOC-(Co)telomers. The deprotection of telomers **^{i}Bu-[NHBOC]$_n$** and **PEG2000-[NHBOC]$_n$** and cotelomers **^{i}Bu-[TEG]$_m$-[NHBOC]$_n$** and **^{i}Bu-[THM]$_m$-[NHBOC]$_n$** was quantitatively achieved by dissolving and keeping these (co)telomers in a large excess of TFA at room temperature for 2 h. The excess of TFA was removed by evaporation in the presence of CH_2Cl_2 and cyclohexane and by gel permeation on a Sephadex LH-20 or LH-60 column. The respective telomers **^{i}Bu-[NH]$_n$** and **PEG2000-[NH]$_n$** and cotelomers **^{i}Bu-[THM]$_m$-[NH]$_n$**, as their TFA salts, were obtained in the form of white solids, except **^{i}Bu-[TEG]$_m$-[NH]$_n$** which was obtained in the form of resin. The presence of the TFA anions is confirmed by ^{19}F NMR (δ −75.7 in CD_3OD).

Synthesis of Telomers ^{i}Bu-[NH]$_n$. The telomerization protocol applied to (i) 10 mg (46 μmol) or (ii) 1.3 mg (5.8 μmol) of telogen **^{i}Bu-SH** and (i) 197 mg (0.92 mmol) or (ii) 250 mg (1.2 mmol) of taxogen **A** [taxogen/telogen molar ratio of (i) 20 or (ii) 200, respectively] led after gel permeation chromatography to (i) 150 mg of telomers **^{i}Bu-[NHBOC]$_{12}$** or (ii) 276 mg of telomers **^{i}Bu-[NHBOC]$_{75}$**, respectively. The aDP*n* (=*n*) values were determined by ^{1}H NMR: aDP$n = 12H_x/9H_z$ or $12H_y/4H_z$, H_x and H_z being the integration of the signals corresponding to the CH_3 protons of BOC and diisobutyl, respectively, and H_y being the integration of the signal corresponding to the NCH_2 protons. Telomers **^{i}Bu-[NH]$_{12}$** and **^{i}Bu-[NH]$_{75}$** were obtained quantitatively after BOC deprotection of their respective **^{i}Bu-[NHBOC]$_n$** telomers.

***^{i}Bu-[NHBOC]$_{12}$*:** TLC (9/1 CH_2Cl_2/MeOH, UV, ninhydrin) $R_f = 0.56$; ^{1}H NMR ($CDCl_3$) δ 0.80−0.90 (m, 12H, C*H*$_3$CH), 1.00−2.50 [m, (12*n* + 1)H, CH_3 (BOC), C*H*$_2$C*H*, CH_2CO, C*H*CH_3], 2.50−3.50 [m, (4*n* + 10)H, C*H*$_2$C*H*$_2$N, C*H*$_2$SC*H*$_2$, CH_2CO, CH_2N], 5.50−6.50 (m, nH, NHCOO), 6.90−7.90 (m, nH, NHCO), with $n = 12$; ^{13}C NMR ($CDCl_3$) δ 20.1 and 20.2 (*C*H$_3$CH), 26.7 and 27.9 (CHN), 28.5−30.5 (sl, CH_3, BOC, CH*C*H$_2$), 33.8 (CH_2S), 34.9 (*C*H$_2$CO), 40.2−40.4 (m, CH_2CH and *C*H$_2$*C*H$_2$), 53.3 and 55.3 (CH_2N), 79.2−79.4 [*C*(CH$_3$)$_3$], 156.6 (CO, BOC), 177.0 (NHCO) (the NCO resonance could not be detected).

***^{i}Bu-[NH]$_{12}$*:** ^{1}H NMR (CD_3OD) δ 0.85−0.95 (m, 12H, C*H*$_3$CH), 1.00−2.80 [m, (3*n* + 7)H, C*H*$_2$C*H*, C*H*$_2$SC*H*$_2$, C*H*CH$_3$, CH_2CO], 2.80−4.00 [m, (4*n* + 4)H, C*H*$_2$C*H*$_2$N, CH_2N], 6.50−7.40 (m, nH, NHCO) with $n = 12$; ^{13}C NMR (CD_3OD) δ 20.2 and 20.3 (*C*H$_3$CH), 27.7 and 29.1 (CHN), 28.0−30.0 (m, *C*H$_2$CH), 33.8 (CH_2S), 34.9 (CH_2CO), 38.2−

39.0 (m, CH_2NH_3), 40.3−40.5 (m, $NHCH_2$), 43.2−44.5 (m, CH_2CH), 54.7 and 56.8 (CH_2N) (the CO resonances could not be detected).

***^{i}Bu-[NHBOC]$_{75}$*:** TLC (9/1 CH_2Cl_2/MeOH, UV, ninhydrin) R_f = 0.43. The ^{1}H NMR ($CDCl_3$) and ^{13}C NMR ($CDCl_3$) spectra are identical to those of **^{i}Bu-[NHBOC]$_{12}$** but with n = 75.

***^{i}Bu-[NH]$_{75}$*.** The ^{1}H NMR (CD_3OD) and ^{13}C NMR (CD_3OD) spectra are identical to those of **^{i}Bu-[NH]$_{12}$** but with n = 75.

Synthesis of Diblock Telomers PEG2000-[NH]$_n$. The telomerization protocol applied to telogen **PEG2000-SH** [(i) 30 mg or 0.015 mmol, (ii) 30 mg or 0.015 mmol, (iii) 10 mg or 0.005 mmol, and (iv) 10 mg or 0.005 mmol] and taxogen **A** [(i) 160 mg or 0.75 mmol, (ii) 126 mg or 0.6 mmol, (iii) 106 mg or 0.05 mmol, and (iv) 212 mg or 0.09 mmol] at taxogen/telogen molar ratios of (i) 50, (ii) 40, (iii) 100, and (iv) 200 led, after gel permeation chromatography, to telomer (i) **PEG2000-[NHBOC]$_{70}$** (16 mg), (ii) **PEG2000-[NHBOC]$_{125}$** (150 mg), (iii) **PEG2000-[NHBOC]$_{190}$** (87 mg), and (iv) **PEG2000-[NHBOC]$_{260}$** (174 mg), respectively. The aDPn (=n) values were determined by ^{1}H NMR: aDPn = 178H_x/9H_z or 178H_y/4H_z, H_x, H_y, and H_z being the integration of the signals corresponding to the BOC methyl, NCH_2, and OCH_2 groups, respectively. The diblock **PEG2000-[NH]$_n$** telomers were obtained quantitatively after BOC deprotection of their respective **PEG2000-[NHBOC]$_n$** telomers.

PEG2000-[NHBOC]$_{70}$: TLC (7/3/0.4 $CHCl_3$/MeOH/NH_3, UV, ninhydrin) R_f = 0.50; ^{1}H NMR ($CDCl_3$) δ 1.05−2.50 [m, (12n − 1)H, CH_3 (BOC), C*H*CH_2CH, CH_2CO], 2.50−3.50 [m, (4n + 7)H, CH_2CH_2NHBOC, CH_2SCH_2, OCH_3], 3.55−3.65 (m, 178H, CH_2O), 5.40−6.30 (m, nH, NHCOO), 6.80−7.80 (m, nH, NHCO) with n = 70; ^{13}C NMR ($CDCl_3$) δ 27−30 (CH*C*H$_2$CH), 28.6 (CH_3, BOC), 38.0−45.0 (m, NCH_2, CH_2CH), 58.4 (OCH_3), 70.6 (CH_2O), 77.5−81.0 (m, *C*CH$_3$), 155.0−157.0 (m, CO, BOC) (the CH_2S and CONH resonances could not be detected).

***PEG2000-[NHBOC]$_n$** with n = 125, 190, or 260*: TLC (7/3/0.4 $CHCl_3$/MeOH/NH_3, UV, ninhydrin) R_f = 0.83 for n = 125; TLC (85/15 CH_2Cl_2/MeOH, UV, ninhydrin) R_f = 0.4 and 0.63 for n = 190 and 260, respectively. The ^{1}H and ^{13}C NMR ($CDCl_3$) spectra are identical to those of telomer **PEG2000-[NHBOC]$_{70}$** but with n = 125, 190, or 260.

PEG2000-[NH]$_{70}$: ^{1}H NMR (CD_3OD) δ 1.05−3.05 [m, (3n + 3)H, CH_2SCH_2, CH_2C*H*, CH_2CO], 3.05−3.60 [m, (4n + 3)H, CH_2NH$_3$, OCH_3], 3.60−3.70 (m, 178H, CH_2O), 6.80−7.80 (m, nH, N*H*CO) with n = 70; ^{13}C NMR (CD_3OD) δ 26.6−28.2 (m, *C*H$_2$CH), 38.2−39.2 (m, CH_2NH_3), 40.5−40.9 (m, $NHCH_2$), 43.5−44.1 (m, CH_2CH), 59.3 (OCH_3), 71.5 (CH_2O), 178.2−178.6 (m, NHCO) (the CH_2S resonances could not be detected).

***PEG2000-[NH]$_n$** with n = 125, 190, or 260*. The ^{1}H NMR (CD_3OD) and ^{13}C NMR (CD_3OD) spectra are identical to those of **PEG2000-[NH]$_{70}$** but with n = 125, 190, or 260.

Synthesis of Diblock Telomers PEG2000-[CH$_2$-NMe$_2$]$_n$. The telomerization protocol applied to telogen **PEG2000-SH** [(i) 30 mg or 15 μmol and (ii) 50 mg or 25 μmol] and taxogen **B** [(i) 92 mg or 0.6 mmol and (ii) 190 mg or 1.23 mmol] at a taxogen/telogen molar ratio of (i) 40 or (ii) 50 led, after gel permeation chromatography, to diblock telomers (i) **PEG2000-[CH$_2$NMe$_2$]$_4$** (19 mg) and **PEG2000-[CH$_2$NMe$_2$]$_{35}$** (134 mg) and (ii) **PEG2000-[CH$_2$NMe$_2$]$_{360}$** (50 mg), respectively. The aDPn values (=n) were determined by ^{1}H NMR: aDPn = 178H_w/2H_z, 178H_x/2H_z, or 178H_y/8H_z, with H_w, H_x, and H_z being the integration of the signals corresponding to CONHCH$_2$, CH_2NMe_2, and CH_2O methylenes, respectively, and H_y being the integration of the signal corresponding to the CONHCH$_2$CH_2 methylenes and NMe_2 groups.

***PEG2000-[CH$_2$NMe$_2$]$_n$** with n = 4, 35, or 360*: ^{1}H NMR (D_2O) δ 1.05−2.80 [m, (13n + 3)H, $CH_2CH_2CH_2N$, CH_2C*H*, N(CH_3)$_2$, CH_2CO, CH_2SCH_2], 2.80−3.50 [m, (2n + 3)H, CH_3O, NHCH_2], 3.63 (s, 178H, CH_2O), 7.20−8.10 (m, nH, NHCO) with n = 4, 35, or 360; ^{13}C NMR ($CDCl_3$) δ 24.7−24.9 (m, $CH_2CH_2CH_2N$), 40.4−40.5 (m, CH*C*H$_2$), 41.7−41.8 (m, $NHCH_2$), 43.3−43.6 (m, NCH_3, CH_2CH), 55.6−55.8 (m, CH_2N), 69.9 (CH_2O) (the CH_2S, OCH_3, and NHCO resonances could not be detected).

Synthesis of Random Cotelomers ^{i}Bu-[TEG]$_m$-[NH]$_n$. *^{i}Bu-[TEG]$_m$-[NHBOC]$_n$ with m = 12 and n = 20*. The telomerization protocol applied to 20 mg (0.09 mmol) of telogen **^{i}Bu-SH** and a mixture of 241 mg (0.9 mmol) of taxogen **A** and 197 mg (0.9 mmol) **of** taxogen **C** led, after gel permeation chromatography, to 214 mg of random cotelomer **^{i}Bu-[TEG]$_{12}$-[NHBOC]$_{20}$**. The aDP-m,n values of TEG and NHBOC units were determined by ^{1}H NMR. The average number of NHBOC units (n) is equal to 12H_x/9H_z or to 12H_y/4H_z, H_x, H_y, and H_z being the integration of the signals corresponding to the BOC, NCH_2, and CH_3 (diisobutyl group) protons, respectively. The average number of TEG units (n) is equal to 12H_x'/14H_z, H_x' being the integration of the signal corresponding to the OCH_2 group.

^{i}Bu-[TEG]$_{12}$-[NHBOC]$_{20}$: TLC (9/1 CH_2Cl_2/MeOH, UV, ninhydrin) R_f = 0.54; ^{1}H NMR ($CDCl_3$) δ 0.85−0.90 (m, 12H, CH_3CH), 1.00−2.90 [m, (12n + 3m + 7)H, CH_3 (BOC), CH_2C*H*, CH_2SCH_2, CH_3C*H*, CH_2CO], 2.90−4.00 [m, (3n + 19m + 4)H, CH_2N, OCH_3, OCH_2], 5.50−6.20 (m, nH, NHCOO), 6.40−7.30 (m, nH, NHCO) with m = 12 and n = 20; ^{13}C NMR ($CDCl_3$) δ 28.6−29.5 [m, CH_3 (BOC), *C*H$_2$CH], 40.2−40.5 (m, NCH_2CH_2, CH_2CH), 59.1 (CH_3O), 68.5−68.8 (CH_2OCO), 70.1−70.6 [m, $(CH_2O)_4$, $COOCH_2CH_2$], 71.8−72.1 (CH_2OCH_3), 75.6−79.1 [*C*(CH$_3$)$_3$], 156.5−156.7 (m, NHCOO), 173.2 (COO), 175.5−175.8 (NHCO) (the $CHCH_3$, CH_2N, CH_2CO, CH_2S, and CO resonances could not be detected).

***^{i}Bu-[TEG]$_m$-[NHBOC]$_n$** with m = 7 and n = 25*. The telomerization protocol applied to 10.2 mg (47 μmol) of telogen **^{i}Bu-SH** and a mixture of 300 mg (1.4 mmol) of taxogen **A** and 123 mg (0.47 mmol) of taxogen **C** led, after gel permeation chromatography, to 256 mg of random cotelomer **^{i}Bu-[TEG]$_m$-[NHBOC]$_n$** with m = 7 and n = 25. The aDPm,n values of TEG and NHBOC units were determined as described for **^{i}Bu-[TEG]$_{12}$-[NHBOC]$_{20}$**.

^{i}Bu-[TEG]$_7$-[NHBOC]$_{25}$: TLC (85/15 CH_2Cl_2/MeOH, UV, ninhydrin) R_f = 0.6. The ^{1}H NMR ($CDCl_3$) and ^{13}C NMR ($CDCl_3$) spectra are identical to those of cotelomer **^{i}Bu-[TEG]$_{12}$-[NHBOC]$_{20}$** but with m = 7 and n = 25.

***^{i}Bu-[TEG]$_m$-[NH]$_n$** with m = 12 and n = 20, and m = 7 and n = 25*. Cotelomers **^{i}Bu-[TEG]$_m$-[NH]$_n$** were obtained quantitatively after BOC deprotection of their respective cotelomers **^{i}Bu-[TEG]$_m$-[NHBOC]$_n$**.

^{i}Bu-[TEG]$_{12}$-[NH]$_{20}$: ^{1}H NMR (CD_3OD) δ 0.85−0.90 (m, 12H, CH_3CH), 1.00−2.80 [m, (3n + 3m + 7)H, CH_2C*H*, CH_2SCH_2, CH_2CO, CH_3C*H*], 2.80−4.00 [m, (4n + 17m + 4)H, CH_2N, OCH_2, OCH_3], 4.00−4.50 (m, 2nH, CH_2OCO), 6.40−7.30 (m, nH, NHCO) with m = 12 and n = 20; ^{13}C NMR (CD_3OD) δ 38.1−38.4 (m, CH_2NH_3), 40.6−40.8 (m, CH_2NH), 43.1−43.7 (m, CH_2CH), 59.1 (CH_3O), 70.0−70.2 (m, $COOCH_2$), 70.4−70.7 [m, $(CH_2O)_4$, $COOCH_2CH_2$], 71.1−71.4 (CH_2OCH_3), 177.3−177.5 (NHCO) (the CH_2S, CH_2N, CH_2CO, $CHCH_3$, and CO resonances could not be detected).

^{i}Bu-[TEG]$_7$-[NH]$_{25}$. The ^{1}H NMR (CD_3OD) and ^{13}C NMR (CD_3OD) spectra are identical to those of cotelomer **^{i}Bu-[TEG]$_{12}$-[NH]$_{20}$** but with $m = 7$ and $n = 25$.

Synthesis of Random Cotelomers ^{i}Bu-[THM]$_m$-[NH]$_n$. Telogen **^{i}Bu-SH** (20 mg, 0.09 mmol), taxogen **A** (236 mg, 1 mmol), and taxogen **D** (192 mg, 1 mmol) led after gel permeation chromatography to random cotelomers **^{i}Bu-[THM]$_{50}$-[NHBOC]$_{50}$** (224 mg) and **^{i}Bu-[THM]$_{30}$-[NHBOC]$_{100}$** (69 mg). The aDPn ($=n$) corresponding to the number of NHBOC units, determined by ^{1}H NMR, is equal to $12H_x/9H_z$ or to $12H_y/4H_z$, H_x, H_y, and H_z being the integration of the signals corresponding to the BOC methyl, NCH_2, and isobutyl methyl groups, respectively. The aDPm ($=m$) corresponding to the number of THM functions, determined by ^{1}H NMR, is equal to $12H_x'/6H_z$, H_x' being the integration of the signal corresponding to the $HOCH_2$ methylenes. Cotelomers **^{i}Bu-[THM]$_{50}$-[NH]$_{50}$** and **^{i}Bu-[THM]$_{30}$-[NHB]$_{100}$** were obtained quantitatively after BOC deprotection of cotelomers **^{i}Bu-[THM]$_{50}$-[NHBOC]$_{50}$** and **^{i}Bu-[THM]$_{30}$-[NHBOC]$_{100}$**, respectively.

^{i}Bu-[THM]$_{50}$-[NHBOC]$_{50}$: TLC (9/1 CH_2Cl_2/MeOH, UV, ninhydrin) $R_f = 0.25$; ^{1}H NMR ($CDCl_3$) δ 0.85−0.90 (m, 12H, C*H*$_3$CH), 1.00−2.80 [m, (12n + 3m + 7)H, CH_3 (BOC), C*H*$_2$C*H*, NCH, C*H*$_2$SC*H*$_2$, CH_2CO], 2.90−3.50 [m, (4n + 4)H, $NHCH_2$, CH_2N], 3.50−4.00 (m, 6mH, C*H*$_2$OH), 6.50−7.20 (m, nH, NHCOO), 7.80−8.20 (m, nH, NHCO) with $m = 50$ and $n = 50$; ^{13}C NMR ($CDCl_3$) δ 28.4−28.9 [m, CH_3 (BOC), *C*H$_2$CH], 40.1−40.8 (m, NCH_2, *C*HCH$_2$), 59.2−59.8 (m, CH_2OH) (the CH_2S, CH_2CO, NCH_2, CH_3-CH, NHCO, and CO resonances could not be detected).

^{i}Bu-[THM]$_{30}$-[NHBOC]$_{100}$: TLC (8/2 $CHCl_3$/MeOH, UV, ninhydrin) $R_f = 0.4$. The ^{1}H and ^{13}C NMR spectra are identical to those of **^{i}Bu-[THM]$_{50}$-[NHBOC]$_{50}$** but with $m = 30$ and $n = 100$.

^{i}Bu-[THM]$_{50}$-[NH]$_{50}$: ^{1}H NMR (CD_3OD) δ 0.85−0.90 (m, 12H, C*H*$_3$CH), 1.00−2.80 {m, [3(n + m) + 7], C*H*$_2$C*H*, CH, C*H*$_2$SC*H*$_2$, CH_2CO}, 2.90−4.00 [m, (4n + 6m + 4)H, NHC*H*$_2$, C*H*$_2$OH, CH_2N], 7.50−8.10 (m, nH, NHCO) with $m = 50$ and $n = 50$; ^{13}C NMR (CD_3OD) δ 38.0−38.5 (m, $CH_2NH_3^+$), 40.3−40.6 (m, NCH_2), 42.9−43.5 (m, CH_2CH), 59.6 (CH_2OH) (the CH_2S, CH_2CO, NCH_2, CH_3CH, NHCO, and CO resonances could not be detected).

^{i}Bu-[THM]$_{30}$-[NH]$_{100}$. The ^{1}H and ^{13}C NMR spectra are identical to those of **^{i}Bu-[THM]$_{50}$-[NH]$_{50}$** but with $m = 30$ and $n = 100$.

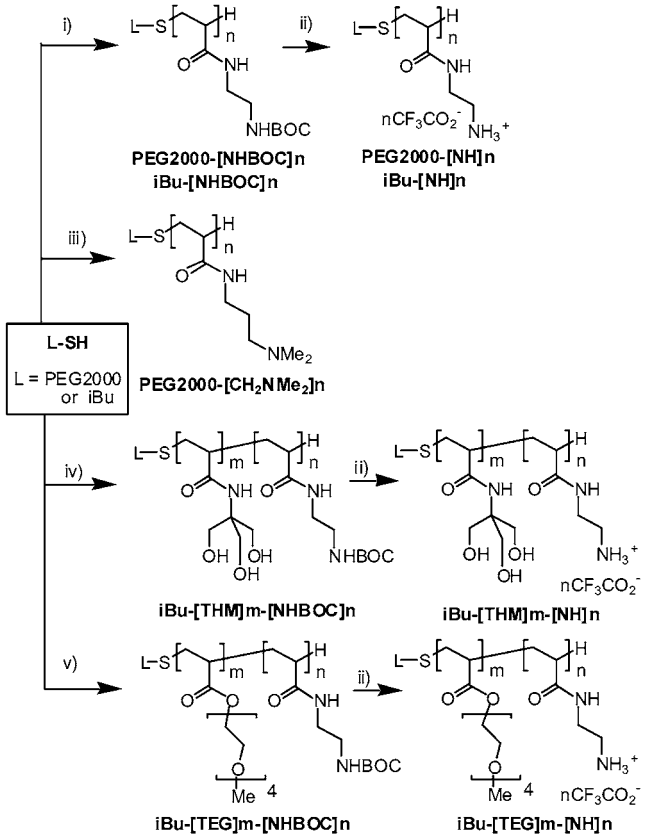
Preparation of Complexes Composed of the Polyamine Telomer Compounds and Plasmid pTG11236. The plasmid pTG11236 was produced by Transgène SA. The endotoxin content of the plasmid preparation was checked using a Limulus Amebocyte Lysat kit (Biogenic, Maurin, France). This value was <1 endotoxin unit/mg of plasmid, hence below the 5 eu/mg of DNA recommended for in vivo protocols. The quantities of compound used were calculated according to the desired DNA concentration of 0.1 mg/mL, the *N*/*P* ratio, the molar weight, and the number of potential positive charges in the selected (co)telomer. The polyamine (co)telomer−DNA complex is formulated by adding a desired volume of (co)telomer preparation at a concentration of 10 mg/mL (in 5% glucose) to the desired volume of a DNA solution to reach the desired DNA concentration (for example, 0.1 mg/mL), as described in refs *8*, *24*, and *25*. This preparation was vortexed for 10 s and was used within 24 h for the particle size measurements and the in vitro transfection experiments.

Measurement of the Size of the (Co)teloplexes. The average sizes were measured by photon correlation spectroscopy using a Coulter N4Plus particle size analyzer. The analyses were performed at 25 °C, after equilibrating the sample at 25 °C for 20 min. The sample was diluted with 5% glucose in the measurement tube and homogenized. These analyses were carried out on complexes having a DNA concentration of 10 μg/mL. The formulations and analyses were reproduced twice.

Agarose Gel Electrophoresis. Each sample (0.5 μg of plasmid) was analyzed by electrophoresis for ∼30 min under 75 V/cm, through a 0.8% agarose gel in 1× TAE (Tris-acetate-EDTA) buffer. The DNA was visualized in 400 mL of TAE buffer containing 40 μL of ethidium bromide (10 mg/mL, Sigma, Saint Quentin Fallavier, France). The plasmid integrity in each sample (0.25 μg) was confirmed by electrophoresis after decomplexing the lipoplexes (10 μL of a plasmid, 0.05 mg/mL) with sodium dodecyl sulfate (10 μL, 80 g/L).

In Vitro Transfection of A549 Cells. Twenty-four hours before transfection, A549 cells (epithelial cells derived from human pulmonary carcinoma) were grown in Dulbecco's modified Eagle's medium (DMEM) (Invitrogen, Life Technologies, Cergy Pontoise, France), containing 1% glutamine (200 mM, Sigma), 0.4% gentamicine (10 μg/mL, Sigma), and 10% fetal calf serum (Sigma), in 96-well plates (2×10^4 cells per well), in a wet (37 °C) and 5% CO_2/95% air atmosphere. The volume of the DNA−polyamine telomer complex (10 μL of DNA and 5 μL of telomer, respectively) was diluted to 100 μL in DMEM supplemented with 10% FCS to obtain various amounts of DNA (1 and 0.5 μg per well, respectively) in the preparation. The culture medium was removed and replaced with 100 μL of DMEM supplemented with 10% FCS and containing the desired amount of DNA. After 4 and 24 h, 50 and 100 μL of DMEM supplemented with 30 and 10% FCS, respectively, were added, respectively.

Forty-eight hours after transfection, the culture medium was discarded and the cells were washed with 100 μL of PBS and then lysed with 50 μL of lysis buffer (Promega, Charbonnières, France). The lysates were frozen at −32 °C, awaiting analysis of luciferase activity. This measurement was taken for 10 s on 10 μL of the lysis mixture in a Berthold LB96P luminometer in dynamic mode, using the "Luciferase" determination system (Promega) in 96-well plates. The total protein concentration per well was determined using conventional techniques (BCA test, Pierce, Montluçon, France). For cells grown in the absence of DNA complexes, a well contains ∼30−50 μg of proteins. Each (co)telomer−DNA complex was formulated twice, and each formulation was tested in triplicate.



Statistical Analyses. Statistical tests were performed with STATGRAPHICS Plus5.0 software. Analysis of variance (Anova) was run on the logarithmic transformation of luciferase expression levels [log(femtograms of luciferase per milligram of protein)] to fit normal distributions of the data.

Three factors, i.e., the chemical nature of the product, the amount of DNA per well (0.5 and 1 μg/well), and the *N*/*P* ratio (10, 5, and 2.5), were analyzed as sources of the variation of the logarithmic transformation of the transfection levels, using a multiple-comparison procedure. Tukey's honestly significant difference (HSD) method was used to discriminate among the means of the logarithmic transformation of luciferase expression levels.

RESULTS AND DISCUSSION

Telogen and Taxogen Synthesis. Telomerization and cotelomerization reactions were performed with telogen **PEG2000-SH** or **^{i}Bu-SH** (the syntheses of which are outlined in Scheme 1).

Scheme 2. Synthesis of ^{i}Bu-[NH]$_n$ Telomers, PEG2000-[NH]$_n$ and PEG2000-[CH$_2$NMe$_2$]$_n$ Diblock Telomers, and of ^{i}Bu-[THM]$_m$-[NH]$_n$ and ^{i}Bu-[TEG]$_m$-[NH]$_n$ Random Cotelomers[a]

[a] Reagents and conditions: (i) CH_2=CHC(O)NH$(CH_2)_2$NHBOC (**A**), AIBN, Δ in CH_3CN; (ii) TFA; (iii) CH_2=CHC(O)NH$(CH_2)_3$-NMe_2 (**B**), AIBN, Δ in CH_3CN; (iv) **A**, CH_2=CHC(O)NH-[$C(CH_2OH)_3$] (**D**), AIBN, Δ in CH_3CN with a 1/1 **A**/**D** molar ratio; (v) **A**, CH_2=CHC(O)O[$(CH_2CH_2O)_4$]Me (**C**), AIBN, Δ in CH_3CN with a 1/1 **A**/**C** molar ratio for $m = 12$ and $n = 20$ or with a 3/1 **A**/**C** molar ratio for $m = 7$ and $n = 25$.

Thiol **PEG2000-SH** was obtained in two steps from commercially available **PEG2000-OH.** The free hydroxyl was first replaced with a tosyl group by the action of tosyl chloride (85%). The resulting tosylate was then converted into the corresponding thiol using an anion-exchange resin (SH^- form) (78%). Thiol **^{i}Bu-SH** was obtained in two steps by coupling 3,3′-dithiodipropionic acid with diisobutylamine using HOBt and EDC as coupling reagents, followed by reduction of the disulfide bond with Zn and AcOH (75% overall yields).

The synthesis of taxogen **C** was performed from acryloyl chloride and tetraethylene glycol monomethyl ether, using the procedure described for that of the NHBOC-containing taxogen **A** (*24*). The NMe_2- and THM-containing taxogens **B** and **D** are commercially available.

Telomer and Cotelomer Synthesis. All (co)telomerization reactions (Scheme 2) were performed under nitrogen by refluxing in acetonitrile and (i) taxogen **A** or **B**, or a mixture of taxogens **A** and **C**, or **A** and **D**, (ii) the thiols **PEG2000-SH**, or **^{i}Bu-SH** in a fixed taxogen/telogen concentration ratio, and (iii) AIBN. At the end of the reaction, the solvent was evaporated under reduced pressure. The random cotelomers were purified and fractionated by gel permeation chromatography on a Sephadex LH20 or LH60 column. This allows separation of the (co)telomers from AIBN and residual disulfide which has formed during telomerization. The diblock PEG2000-grafted BOC-protected telomers were purified after BOC deprotection. The *N*-BOC-telomers and cotelomers obtained from taxogen **A** were deprotected in excess TFA at room temperature. The (poly)cationic telomers and random cotelomers thus obtained were isolated as TFA salts by evaporation of excess reagent in the presence of cyclohexane followed by lyophilization. The diblock PEG-grafted telomers were further purified from residual PEG disulfide by washing with CH_2Cl_2 in which they are not soluble. Quantitative deprotection was confirmed by ^{1}H NMR (the absence of the signal corresponding to the BOC protons). For each telogen and taxogen(s), the different (co)telomers that were isolated and their code names are reported in Table 1. Oxygen- and peroxide-free solvents were used throughout these experimental procedures to avoid oxidation of sulfur into sulfoxide in the (co)telomers (*24*, *25*).

[a] *N* equals the number of (co)telomer amine equivalents; *P* equals the number of plasmid phosphate equivalents. [b] Precipitate. [c] Large.

The average degrees of polymerization, aDP*n* (=*n*), of the PEG-grafted diblock telomers resulting from taxogen **A** or **B** were determined by ^{1}H NMR on the protected **PEG2000-[NHBOC]$_n$** or **PEG2000-[CH$_2$NMe$_2$]$_n$** telomers, respectively. These aDP*n* values were calculated by comparing the integration of the BOC and NCH_2 or NMe signals, respectively, with that of the PEG2000 OCH_2 protons. For the telomers resulting from taxogen **A** and telogen **^{i}Bu-SH** and for all random cotelomers resulting from a mixture of taxogens **A** and **C**, or **A** and **D**, the average degrees of (co)polymerization corresponding to the number of NHBOC, TEG, and THM units were also determined by ^{1}H NMR on the BOC-protected (co)telomers. The number of NHBOC units was calculated by comparing the integration of the NCH_2CH_2NHBOC signals with that of the isobutyl methyl protons. The number of TEG and THM units was calculated by comparing the integration of the TEG (OCH_2 and OCH_3) or THM ($C\underline{H}_2OH$) signals with that of the isobutyl methyl and $NCH_2\underline{C}H_2NHBOC$ resonances.

Formation and Characterization of the DNA Complexes. The capability of the polycationic (co)telomers to condense DNA and to form (co)teloplexes was analyzed with plasmid pTG11236, which was also used for the in vitro transfection assays described in the next section. The sizes of the DNA complexes [size being an important parameter to control when in vivo uses are contemplated or when their in vitro transfection efficiency is evaluated (*28*)] were analyzed by light scattering spectroscopy. The preparation of the (co)teloplexes was performed by mixing a (co)telomer solution with the plasmid in 5% glucose using *N*/*P* ratios of 10, 5, 2.5, 1.25, and 0.8 [*N* equals the number of amine functions of the (co)telomer; *P* equals the number of DNA phosphates]. Table 1 collects the mean particle diameters measured for the different (co)teloplexes. These measurements were performed after 24−48 h of aging at 25 °C.

These formulations were also analyzed by gel electrophoresis which showed the presence of a fully complexed plasmid (not accessible to ethidium bromide) for all *N*/*P* = 10−2.5 formulations and for most *N*/*P* = 1.25 ones. DNA that is complexed, but accessible to ethidium bromide, was however detected for the **PEG2000-[NH]$_{260}$** and **^{i}Bu-[THM]$_{30}$-[NH]$_{100}$** *N*/*P* = 1.25 formulations, and for all the *N*/*P* = 0.8 formulations that were investigated (data not shown). When gel electrophoresis of the (co)teloplexes was performed in the presence of detergent (sodium dodecyl sulfate), dissociation of the complexes was observed in all cases.

In terms of telomer impact on teloplex size and stability (with respect to aggregation), the behavior of the diblock PEG-grafted and random TEG or THM (co)telomers is worth noting. Indeed, these polycationic derivatives led often to stable formulations with a polydispersed population of small-sized teloplexes (85−330 nm), even for *N*/*P* ratios of 1.25 and 0.8, while precipitates were most frequently detected for complexes with *N*/*P* ratios close to 1 (*24*, *25*, *29*).

In Vitro Transfection. The transfection potency of the (co)teloplexes formulated with the luciferase reporter plasmid pTG11236 was assayed in vitro on lung epithelial A549 cells. Although transfection efficiencies with DNA complexes are generally impaired by the presence of serum components, these experiments were nevertheless run in a culture medium containing 10% fetal calf serum. The transfection efficiency of the (co)teloplexes (expressed in femtograms of luciferase per milligram of protein) was evaluated for a DNA dose of 0.5 and 1 μg per well, as compared to naked DNA and to control lipoplexes based on a pcTG90−DOPE *N*/*P* = 5 complex (1/1 molar ratio). These lipoplexes proved to be among the most efficient nonviral formulations for transfecting A549 cells (*8*, *24*). Cells treated with naked DNA under equivalent conditions exhibited expression levels of $\sim 10^2-10^3$ fg of luciferase/mg of protein. The effect on cell viability of the (co)teloplexes was also checked by determining the total amount of protein per well of the transfected cells relative to that measured for untreated cells (for which the total protein amount per well is in a 30−50 μg/well range).

The transfection and cell viability results are illustrated in Figure 2. These data indicate that the (co)teloplexes formulated with telomer **^{i}Bu-[NH]$_{75}$**, diblock **PEG2000-[NH]$_n$** (*n* = 70, 125, 190, or 260), random **^{i}Bu-[THM]$_m$-[NH]$_n$** (*m* = *n* = 50, or *m* = 30 and *n* = 100), and **^{i}Bu-[TEG]$_7$-[NH]$_{25}$** cotelomers do allow transfection of the plasmid into the A549 cells with a much higher efficiency than with naked DNA; luciferase expression levels in the 10^5-10^8 fg of luciferase/mg of protein range were indeed measured for most of these formulations and for *N*/*P* ratios of 5. In contrast, for *N*/*P* ratios of 0.8 and 1.25 (data not shown) and for the NMe_2 diblock **PEG2000-[CH$_2$NMe$_2$]$_n$** and random **^{i}Bu-[TEG]$_{12}$-[NH]$_{20}$** teloplexes, whatever the value of their *N*/*P* ratios, much lower transgene expression levels (10^3-10^4 fg of luciferase/mg of protein) were detected.

As most frequently observed for lipoplexes and polyplexes, the level of luciferase expression of the (co)teloplexes increased when the DNA dose was increased from 0.5 to 1 μg/well and when their *N*/*P* ratios were progressively increased from 0.8−1.25 to 10 (statistical analysis data not shown). These results are likely related to an increase in their level of binding, through electrostatic interactions, to the anionic proteoglycans expressed at the cellular surface and, consequently, of their cellular uptake by endocytosis (*30*−*32*). Concomitantly, a small decrease in their cell tolerance (Figure 2) was seen. It remained, however, very high even for a DNA dose of 1 μg/well for which 80% of the 39 formulations that were investigated displayed a percentage of cell viability within a range of 80−120%. It is therefore noticeable that high transfection levels were attained that were further compatible with high levels of cell survival.

When compared with the control pcTG90−DOPE lipids which display a high transfection efficiency (10^7-10^9 fg of luciferase/mg of protein), none of the new polycationic (co)telomers was found to be as efficient in mediating DNA transfer and expression. This is illustrated in Figure 3 which compares, irrespective of the *N*/*P* ratio and of the amount of DNA per well, the means of luciferase expression obtained with the control pcTG90−DOPE lipoplexes and with the (co)teloplexes. A more detailed analysis (Figure 4) shows that, for *N*/*P* ratios of 2.5 and 5, significantly higher luciferase levels (1−2 orders of magnitude) were obtained with the pcTG90−DOPE lipoplexes than with the most efficient **^{i}Bu-[NH]$_{75}$** or **PEG2000-[NH]$_{190}$** formulations found in this study (see the next section). However, for an *N*/*P* ratio of 10, these latter formulations displayed luciferase levels comparable to those of the control. One should further underline that the **^{i}Bu-[NH]$_{75}$** or **PEG2000-[NH]$_{190}$** formulations displayed a higher cell viability than the control lipoplexes, e.g., 60−120% of cell survival for the **^{i}Bu-[NH]$_{75}$** or **PEG2000-[NH]$_{190}$** formulations versus 40 to ~70% of cell survival for the controls for a DNA dose of 0.5 μg/well (Figure 2B).

Structure−Transfection Efficiency Relationships. One of the objectives of this study was aimed at deter-

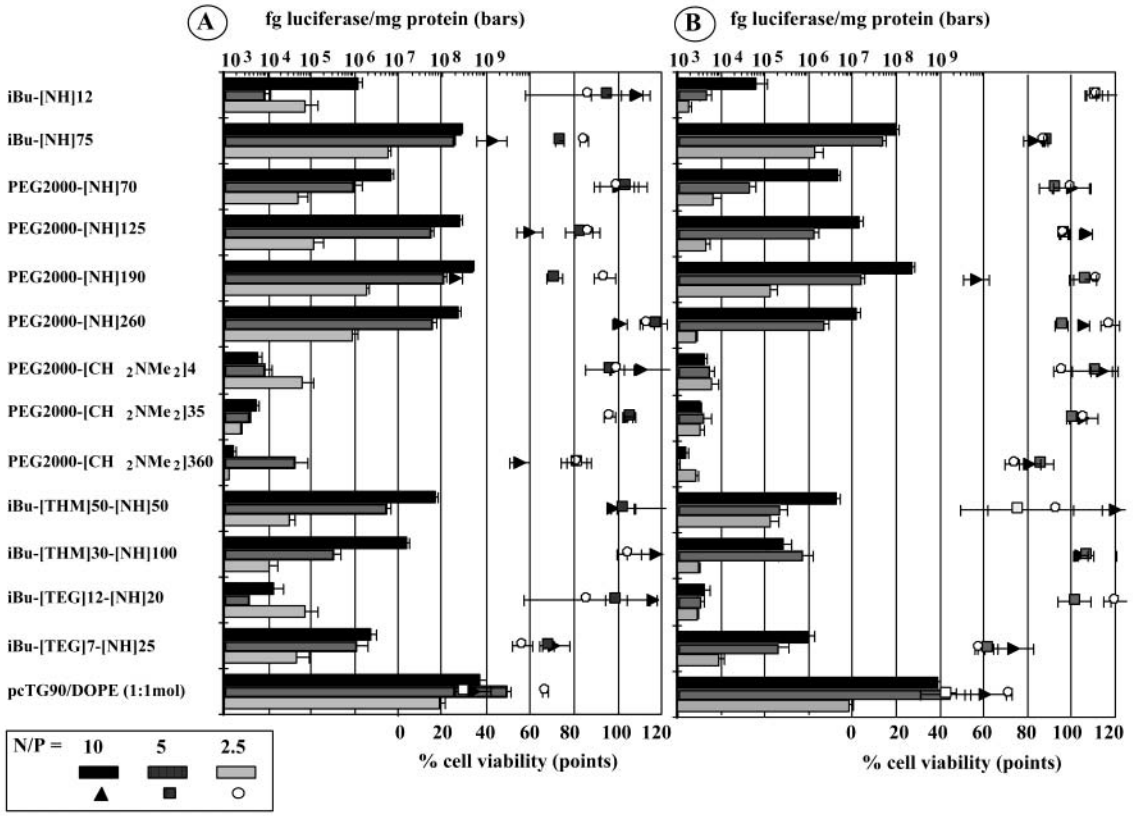

Figure 2. Luciferase expression (bars) and cell viability (points) of the pTG11236 complexes made with **^{i}Bu-[NH]$_n$** telomers, **PEG2000-[NH]$_n$** and **PEG2000-[CH$_2$NMe$_2$]$_n$** diblock telomers, and **^{i}Bu-[TEG]$_m$-[NH]$_n$** and **^{i}Bu-[THM]$_m$-[NH]$_n$** random cotelomers as compared to control pcTG90−DOPE (1/1 molar ratio) lipoplexes in A549 cells. Transfection was performed in the presence of 10% fetal calf serum. Data represent means ± SEM (standard error of the mean) from two independent experiments, each performed in triplicate (for more details, see Experimental Section): DNA doses of 1 (A) and 0.5 μg/well (B).

mining the effects of structural elements of the polyamine (co)telomers on their transfection potential and on cell survival. The structural modifications that were investigated here concern (i) the number of amine functions, (ii) the nature of the polyamine polar head [aminoethyl vs (*N*,*N*-dimethylamino)propyl], (iii) the presence of a block PEG2000 moiety connected to a block polyamine unit of variable length, and (iv) a random combination of primary amines with short tetraethylene glycol (TEG) or THM residues.

One can observe, irrespective of the *N*/*P* value and of the DNA dose, that increasing the average number of primary amine functions from 12 to 75 in the **^{i}Bu-[NH]$_n$** telomer series (hence, its degree of polymerization) induced a substantial (2- to 4-orders of magnitude) transgene expression increase (see Figure 3) and, concomitantly, a slight cell toxicity increase (Figure 2). In the di-block **PEG2000-[NH]n** series, transgene expression rose also but to a much lesser extent when the average number of amine functions was increased from 70 to 125 then to 190. Figure 3 demonstrates further that, in this series, the dependence of the luciferase expression means with the polyamine unit length (n) had a bell-shaped character, an optimum of transfection being attained for $n = 190$. The multiple comparison procedure using the Tukey's HSD method indicated that five of the six different **PEG2000-[NH]n/PEG2000-[NH]n′** pairs of means show statistically significant differences at the 95.0% confidence level, the exception being the **PEG2000-[NH]125/PEG2000-[NH]260** pair. In the di-block **PEG2000-[NH]n** series, increasing the average degree of polymerization did not impair cell survival (Figure 2).

Where the impact on transfection of replacement of the ethyl-NH_3^+ functions (as in **PEG2000-[NH]$_n$**) with propyl-$NHMe_2^+$ ones (as in **PEG2000-[CH$_2$NMe$_2$]$_n$**) is concerned, the level of transgene expression was drastically decreased (see Figures 2 and 3). This result differs substantially from a previous study from this laboratory where it was found that the random replacement of part of NH_3^+ with $NHMe_2^+$ units had no effect on transfection (*25*). However, this result concerned aminoethyl acrylate-deriving cotelomers. The low transfection efficiency of the diblock aminopropyl acrylate **PEG2000-[CH$_2$NMe$_2$]$_n$** cotelomers as compared to that of their aminoethyl acrylate analogues is more likely attributable to the ethyl−propyl backbone replacement rather than to the NH_3^+−$NHMe_2^+$ substitution. Indeed, it was shown that polymers derived from 2-(dimethylamino)propyl methacrylate were less effective gene transfer agents than polymers derived from 2-(dimethylamino)ethyl methacrylate (*33*). This was attributed to the higher pK_a values of the propyl polymers and, consequently, to their lower capacity of buffering endosomes and of their DNA complexes to escape from these endosomes (*33*).

With regard to the impact of the block PEG2000 moiety on transfection, its presence was found to decrease the level of transgene expression. As illustrated in Figure 3, the DNA complexes made with the diblock **PEG2000-[NH]$_{70}$** telomers led to much lower transgene expression levels than those formulated with **^{i}Bu-[NH]$_{75}$** which possesses a polyamine backbone with a comparable degree of polymerization. To compensate in part this transfection efficiency decrease, the length of the polyamine block in **PEG2000-[NH]$_n$** must be increased to up

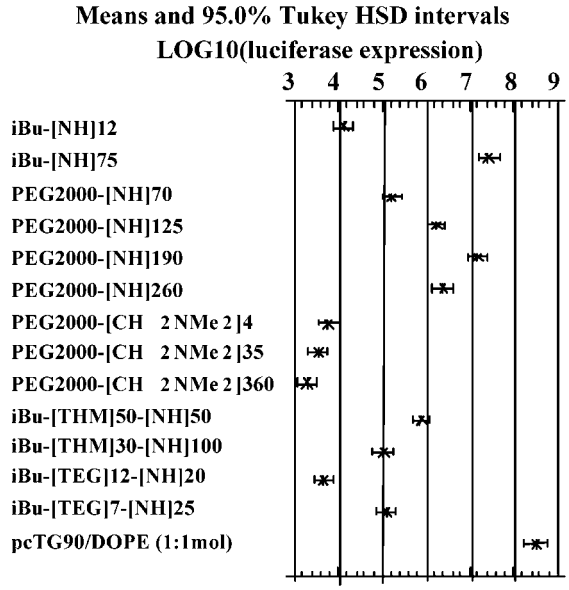

Figure 3. Means and 95.0% Tukey HSD intervals of the logarithmic transformation of luciferase expression levels [log-(femtograms of luciferase per milligram of protein)] for the pTG11236 complexes made with ^{i}**Bu-[NH]**$_n$ telomers, **PEG2000-[NH]**$_n$ and **PEG2000-[CH$_2$NMe$_2$]**$_n$ diblock telomers, or ^{i}**Bu-[TEG]**$_m$**-[NH]**$_n$ and ^{i}**Bu-[THM]**$_m$**-[NH]**$_n$ random cotelomers or with control pcTG90−DOPE (1/1 molar ratio) lipids, irrespective of the DNA dose and of the *N*/*P* ratio. Statistical tests were performed with STATGRAPHICS Plus5.0 software. This comparison was performed using the multiple-sample comparison procedure, and the method used to discriminate among the means of the logarithmic transformation of luciferase expression levels was Tukey's honestly significant difference (HSD) procedure.

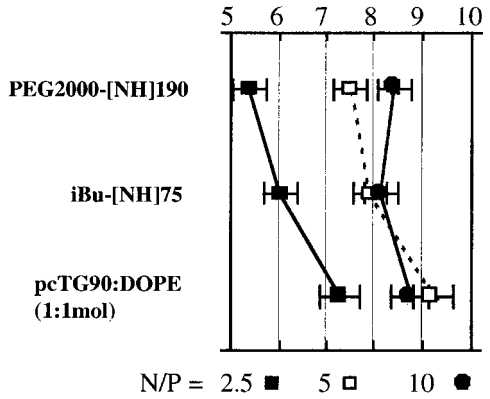

Figure 4. Means and 95.0% Tukey HSD intervals of the logarithmic transformation of luciferase expression levels [log-(femtograms of luciferase per milligram of protein)] for the pTG11236 complexes made with ^{i}**Bu-[NH]**$_{75}$ telomers, **PEG2000-[NH]**$_{190}$ diblock telomers, or control pcTG90−DOPE (1/1 molar ratio) lipids, as a function of the *N*/*P* ratios of the complexes.

to an average number of amine units of 190, as in **PEG2000-[NH]**$_{190}$.

A decrease in the level of transgene expression was also observed upon random replacement of part of primary amine functions with tetraethylene glycol (TEG) residues. Among the coteloplexes formulated with random ^{i}**Bu-[TEG]**$_{12}$**-[NH]**$_{20}$ or ^{i}**Bu-[TEG]**$_7$**-[NH]**$_{25}$, it appears that the most efficient ones were those formulated with the random cotelomers which contain the smallest number of TEG units (see Figure 3). Comparable results were also noticed in the literature for random copolymers derived from 2-(dimethylamino)ethyl methacrylate and ethoxytriethylene glycol methacrylate (*26*).

In a previous study from this laboratory concerning the effect on transfection of replacing randomly part of the primary amine functions by polyol THM residues in lipotelomers, transgene expression was shown to be unaffected while cell viability was seen to be improved to some extent (*25*). Similar results were also noticed in the literature for polylysines and polyallylamines after partial glycosylation (*27*). In contrast, we found here, as illustrated in Figure 3, that the random replacement of part of primary amine functions in ^{i}**Bu-[NH]**$_{75}$ with THM residues, as in ^{i}**Bu-[THM]**$_{30}$**-[NH]**$_{100}$ or ^{i}**Bu-[THM]**$_{50}$**-[NH]**$_{50}$, induced a substantial (10−500-fold) decrease in the transfection efficiency of their corresponding DNA complexes.

Altogether, these results showing a transfection potential decrease induced by the presence either of a block long polyethylene glycol residue (PEG2000) or of a random combination of primary amines with tetraethylene glycol (TEG) or THM residues were in fact to be expected. These residues provide a shielding effect, reducing the strength of electrostatic interactions between the cationic DNA complexes and the anionic cell proteoglycans, and consequently reducing their level of cellular uptake.

CONCLUSION

This work suggests that, among the new polycationic derivatives synthesized and investigated for their transfection efficiency, the ^{i}**Bu-[NH]**$_{75}$ telomers and the diblock polyethylene glycol-conjugated **PEG2000-[NH]**$_n$ telomers are very promising candidates for gene transfer purposes. The variation of structure parameters allowed the establishment of some structure−activity relationships, and the optimization of (co)teloplex formulations, where both high transfection levels and cell viability were achieved. Moreover, these in vitro findings do not prejudge all of their in vitro and in vivo behaviors which remain worthy of investigation.

ACKNOWLEDGMENT

We thank Transgène SA for financial support and Dr. B. Cavallini (Transgène SA) for supplying with plasmid. We also thank Drs. D. Heissler and A. Nazih (ULP Strasbourg) for supplying pcTG90. Thanks to Drs. H. V. J. Kolbe, S. Braun, and O. Meyer (Transgène SA) for their interest in this project and for helpful discussions.

Effect of Hb-Encapsulation with Vesicles on H_2O_2 Reaction and Lipid Peroxidation

Shinji Takeoka, Yuji Teramura, Tomoyasu Atoji, and Eishun Tsuchida*

Advanced Research Institute for Science and Engineering, Waseda University, Tokyo 169-8555, Japan. Received May 1, 2002; Revised Manuscript Received September 26, 2002

We encapsulated a purified and concentrated hemoglobin (Hb) solution with a phospholipid bilayer membrane to form Hb vesicles (particle diameter, ca. 250 nm) for the development of artificial oxygen carriers. Reaction of Hb inside the vesicle with hydrogen peroxide (H_2O_2) is one of the important safety issues to be clarified and compared with a free Hb solution. During the reaction of the Hb solution with H_2O_2, metHb (Fe^{III}) and ferrylHb (Fe^{IV}=O) are produced, and H_2O_2 is decomposed by the catalase-like reaction of Hb. The aggregation of discolored Hb products due to heme degradation is accompanied by the release of iron (ferric ion). On the other hand, the concentrated Hb within the Hb vesicle reacts with H_2O_2 that permeated through the bilayer membrane, and the same products as the Hb solution are formed inside the vesicle. However, there is no turbidity change, no particle diameter change of the Hb vesicles, and no peroxidation of lipids comprising the vesicles after the reaction with H_2O_2. Furthermore, no free iron is detected outside the vesicle, though ferric ion is released from the denatured Hb inside the vesicle, indicating the barrier effect of the bilayer membrane against the permeation of ferric ion. When vesicles composed of egg york lecithin (EYL) as unsaturated lipids are added to the mixture of Hb and H_2O_2, the lipid peroxidation is caused by ferrylHb and hydroxyl radical generated from reaction of the ferric iron with H_2O_2, whereas no lipid peroxidation is observed in the case of the Hb vesicle dispersion because the saturated lipid membrane of the Hb vesicle should prevent the interaction of the ferrylHb or ferric iron with the EYL.

INTRODUCTION

Enormous efforts have been made to develop red blood cell substitutes for clinical applications in recent years (*1*−*3*). Potential benefits of red blood cell substitutes are their infusion in emergency situations without concern for blood type, virus infections, and long-term storage. Hemoglobin (Hb)-based oxygen carriers (HBOCs), which have been developed so far, are generally classified into two types: one is the acellular-type modified Hb molecules such as intramolecularly cross-linked Hb (*4*), recombinant cross-linked Hb (*5*), polymerized Hb (*6*), and intramolecularly polymer-conjugated Hb (*7*). Some of these Hb modifications are currently in the final stage of clinical trials. However, clinical trials have revealed some side effects such as hypertension relating to vasoconstriction, which have been extensively reported in vivo and in vitro (*8*, *9*). Another is the cellular-type Hb such as Hb vesicles which are being developed by our group (*10*) or liposome-encapsulating Hb (*11*). They have a vesicular structure in which concentrated Hb molecules are encapsulated, like red blood cells. Though the Hb vesicles have not yet been clinically studied, their safety and efficacy have been confirmed in comparison with Hb modifications in order to insist on the benefits of the cellular structure (*12*−*17*). From safety tests involving microvascular responses (*12*, *13*) and heme detoxification in liver (*17*), we have clarified the sufficient oxygen-transporting ability comparable with red blood cells in 40% hemorrhage shock (*14*) and 90% exchange transfusion (*16*).

Recently, after the administration of the Hb modifications, it has been noted that heme-mediated reactions such as ligand coordinations and redox reactions could cause organ dysfunction and/or tissue damage (*18*, *19*). Especially, redox reactions may affect the physiological protection against reactive oxygen species (*20*). The oxidation of oxyHb by H_2O_2 is known to generate ferrylHb and metHb accompanied by heme degradation and the release of free iron (*21*). Furthermore, during the autoxidation of oxyHb to metHb, reactive oxygen species such as superoxide, hydrogen peroxide, and the hydroxyl radical are generated to damage not only the remaining oxyHb but also living cells and organs (*22*−*24*). Especially, ferrylHb is known to be a potent oxidant which catalyzes the peroxidation of lipids comprising the biomembrane and other biomaterials (*25*, *26*). In normal human plasma, the concentration of H_2O_2 is 4−5 μM (*27*) and elevates to 100−600 μM under inflammatory (*28*) or ischemia/reperfusion conditions (*29*), in fact, ferrylHb can be found both in the red blood cells (*30*) and in the endothelial cells model after hypoxia reoxygenation (*31*, *32*). Several in vitro studies suggest that free radicals or degradation products catalyzed by ferrylHb could damage the endothelial cells in the presence of acellular-type Hb modifications. Hb-mediated cytotoxicity via ferrylHb is one of the important safety issues of HBOCs (*20*, *33*−*36*). On the other hand, in the cellular-type Hb vesicles (*37*), reactive oxygen species generated within the Hb vesicles during metHb formation were completely consumed by Hb (unpublished data). Though such a reaction leads to Hb oxidation, no reactive oxygen species have been detected outside the vesicles.

Here, we describe the chemical reactions between H_2O_2 and Hb (acellular type), or H_2O_2 and Hb vesicle (cellular type) and demonstrate the influence of the resulting ferrylHb on the peroxidation of unsaturated lipids, which were added to the system as egg york lecithin vesicles to clarify the advantage of Hb vesicle over acellular-type Hb concerning heme-mediated cytotoxicity via ferrylHb.

MATERIALS AND METHODS

(1) Purification of an Hb Solution from Red Blood Cells (*38*). Hb was purified from outdated human red blood cells provided by Japanese Red Cross. The red blood cells were washed three times with saline by centrifugation (2000*g*, 10 min) and concentrated by the removal of the supernatant. They were hemolyzed by the addition of the equal volume of the water for injection, and stromata were removed by ultrafiltration (cutoff M_w 1000 kDa, Biomax-1000V, Millipore Co., Ltd., Bedford). The ligand exchange from O_2 to CO was carried out for the stroma-free Hb solution by CO gas flowing. The proteins other than HbCO were denatured by heat treatment at 60 °C for 12 h and removed as precipitates. The HbCO solution was fractionated using ultrafiltration filters of which cutoff molecular weight were between 1000 kDa and 8 kDa (Biomax-8V, Millipore) followed by concentration with the same 8 kDa ultrafilter.

(2) Preparation of an Hb Vesicle Dispersion (*37*). Pyridoxal 5′-phosphate (PLP, Merck, Whitehouse Station) as an allosteric effector was added to the HbCO solution (40 g/dL) at a 3/1 molar ratio of PLP to Hb. Presome PPG-I [1,2-dipalmitoyl-*sn*-glycero-3-phosphatidylchorine (DPPC)/cholesterol/1,2-dipalmitoyl-*sn*-glycero-3-phosphatidylglycerol (DPPG), Nippon Fine Chemical, Osaka] powder was mixed with the HbCO solution, and the mixture was stirred at 4 °C for 12 h. The resulting dispersion of multilamellar vesicles was extruded through membrane filters (Fuji Film Co., Tokyo) with a Remolino (Millipore). The Hb vesicles with an average diameter of 250 ± 20 nm were obtained after extrusion through the membrane filter with 0.22 μm pore size. After the separation of unencapsulated Hb by ultracentrifugation (10000*g*, 60 min), the precipitate of the Hb vesicles was redispersed into saline. 1,2-Distearoyl-*sn*-glycero-3-phosphatidylethanolamine-*N*-PEG (PEG molecular weight was 5000, Sunbright DSPE−50H, H-form, NOF Co., Tokyo) was added to the dispersion of the Hb vesicles until its concentration to the membrane components became 0.3 mol %. The mixture was incubated at 37 °C for 2 h for the surface modification with PEG-DSPE. Finally, unincorporated DSPE−50H was removed by ultracentrifugation (10000*g*, 60 min) as a supernatant.

(3) Analyses of Hb Samples (Hb Solution or Hb Vesicle Dispersion). After the decarbonylation of HbCO (HbCO→HbO_2) by the irradiation of visible light to the liquid film, the oxyHb solution and the oxyHb vesicle dispersion containing 1.6 mM deferoxamine mesylate (DFO, Sigma, St. Louis, MO) were used as Hb samples. Reaction of the Hb samples ([heme] = 20 μM) with H_2O_2 at various ratios in phosphate buffer (pH7.4, at 37 °C) was assessed by repetitive scanning of a visible region from 450 to 700 nm at 2 min intervals by using an UV−vis spectrophotometer (V-570, Jasco, Tokyo). Under a nitrogen atmosphere, deoxyHb or metHb was rapidly mixed with the H_2O_2 solution using a rapid scan apparatus (model TSP-601, UNISOKU, Osaka), and the repetitive scanned spectra were recorded to calculate the reaction rate.

After the reaction of the Hb samples with H_2O_2, the bottom of the vials was carefully observed to confirm whether precipitates formed. The turbidity change was measured as ΔOD at 700 nm. The particle size of the Hb vesicles was measured by a dynamic light-scattering method (Coulter particle analyzer N4SD, Coulter Co., FL).

(4) Quantitative Analyses of H_2O_2 and Ferric Ion. The concentration of H_2O_2 was measured spectrofluorometrically by the formation of 6,6′-dihydroxy-[1,1′-biphenyl]-3,3′-diacetic acid (DBDA, E_x: 317 nm, E_m: 405 nm) during horseradish peroxidase (HRP)-catalyzed reaction of *p*-hydroxyphenylacetic acid (HPA) with H_2O_2 (*39*). To the reaction mixtures of H_2O_2 and the Hb samples were added HRP and HPA to be 4 μM and 6mM, respectively, to determine the remaining amount of H_2O_2 during the reaction of H_2O_2 with the Hb samples. The amount of produced DBDA was calculated after separating the Hb samples by centrifugal filtration (cutoff 10 kDa, Ultrafree-MC, Millipore) and measured with a fluorescence spectrophotometer (F-4500. Hitachi, Tokyo).

After the reaction of the Hb samples with H_2O_2 in different periods at 37 °C, the aqueous phase was separated by centrifugal filtration. Ferric ion in the filtrate was measured by an ICP emission spectroscopy (SPS-7000, Seiko Instruments Inc., Chiba).

(5) Lipid Analysis of Hb Vesicle by Liquid Chromatography−Mass Spectroscopy. The Hb vesicles were lyophilized after reaction with H_2O_2 and dissolved in chloroform and filtered through PTFE membrane filters with the pore size of 0.22 μm. The mixed lipid components were analyzed with a liquid chromatography−mass spectrometry system (LCQ-DECA, Thermo Quest, Tokyo), equipped with an apparatus of atmospheric pressure chemical ionization (ACPI) and a gel permeation chromatographic column (TSK gel Silica 60, 7.6 mm o.d. × 300 mm h, TOSOH, Tokyo). Two micro liter of the sample solutions was injected and developed with a mixed solvent (chloroform/acetone/methanol/acetic acid/water = 10/4/2/2/1, by vol ratio). The flow rate was 1.0 mL/min, and the temperature was maintained at 40 °C with a column oven. In the mass spectroscopic system, the gas flow rate, the applied voltage, and the CDL temperature were 0.5 mL/min, 2.5 kV, and 250 °C, respectively.

(6) Lipid Peroxidation of Egg York Lecithin Vesicles. The powder of egg york lecithin (EYL) was dispersed into pure water (40 mM) and hydrated at 4 °C for 2 h under an argon atmosphere. The resulting multilamellar vesicles were extruded through the membrane filters with the final pore size of 0.22 μm to prepare the vesicles of which average diameter is 270 ± 50 nm. The Hb samples were mixed with the EYL vesicles (37 mM) and reacted with H_2O_2 at 37 °C for 30 min, and trichloroacetic acid (42 mM) was added to precipitate the Hb samples. The supernatant separated from the Hb samples by centrifugation (12000*g*, 30 min) was mixed with thiobarbituric acid (TBA, 28 mM) and heated for 30 min at 100 °C. Resulting thiobarbituric acid-reacted substance in the solution was measured with a fluorescence spectrophotometer (E_x: 532 nm, E_m: 553 nm).

RESULTS AND DISCUSSION

Figure 1 shows the spectral change in the Hb solution (A) and the Hb vesicle dispersion (B), both of which have a heme concentration of 20 μM, after the addition of H_2O_2 of three different concentrations: (a) 20 μM, (b) 200 μM, and (c) 2 mM. In Figure 1A (a), the two peaks (540 and 575 nm) in the Q-band region of oxyHb gradually decreased after the addition of 20 μM H_2O_2 accompanied

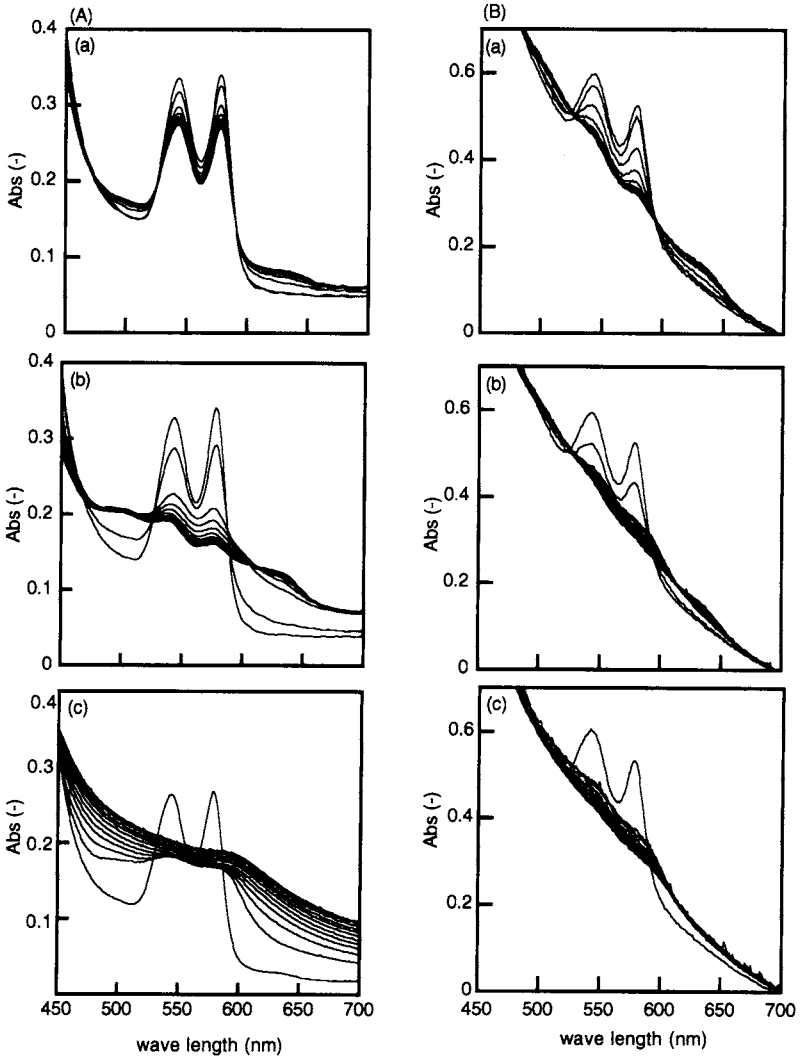

Figure 1. Spectral changes of (A) the Hb solution and (B) the Hb vesicle dispersion ([heme] = 20 μM) during the reaction with H_2O_2 at 37 °C ((a) 20 μM, (b) 200 μM, and (c) 2 mM). The repeatative sacanning was started at a 2 min interval, immediately after the addition of a solution of H_2O_2 to Hb sample solutions.

by the appearance of a small peak at 630 nm showing an isosbestic point at 586 nm. It is considered that oxyHb was gradually oxidized to metHb by H_2O_2 and stopped when H_2O_2 was consumed before the completion of the metHb formation. In the dispersion of Hb vesicles in which a purified Hb solution was encapsulated with a phospholipid bilayer membrane (particle diameter, 250 nm, Figure 1B (a)), the large decline in the baseline from the lower wavelength typically shows the turbidity of the vesicles. The oxyHb in the Hb vesicle was converted to metHb after reaction with 20 μM H_2O_2, and the degree of metHb conversion was greater than that of the oxyHb solution.

When the added amount of H_2O_2 was increased to 200 μM, a completely different feature in the spectral change was observed as shown in Figure 1AB (b). Namely, in the Hb solution, the decrease in the two peaks attributed to oxyHb was accompanied by the total increase in the absorbance from 478 nm to over 700 nm, which can be identified as ferrylHb. The following growth of the peak at 630 nm then had an isosbestic point at 612 nm, indicating the conversion of ferrylHb to metHb. A similar trend was observed for the Hb vesicles except for the baseline change as shown in Figure 1B(b). It is noted that the ratio of metHb in both Hb samples was significantly small after the reaction with 200 μM H_2O_2, in comparison with the metHb spectra of the Hb samples ([heme] = 20 μM) completely converted by the reaction with excess $NaNO_2$, suggesting the existence of discolored Hb products (degraded heme) (*21*).

When 2 mM of H_2O_2 was added to the Hb solution, the transient formation of ferrylHb with the subsequent conversion to the discolored products was confirmed from the baseline increase with no isosbestic points as shown in Figure 1A (c). We also confirmed the white aggregates at the bottom of the flask. A similar trend was also seen in the Hb vesicles but with no aggregation (Figure 1B (c)).

The composition changes of oxyHb, metHb, ferrylHb, and discolored products after the addition of H_2O_2 are summarized in Figure 2. These curves were obtained by a curve fitting technique using computer-simulated spectra from those Hb elements measured one by one.

Figure 2A (a) shows the conversion of the oxyHb solution, of which the heme concentration was 20 μM, to the other Hb products after the reaction with 20 μM H_2O_2. The oxyHb was reduced to 66% within 8 min accompanied by the formation of 29% metHb. The release of ferric ion and the generation of discolored products were slightly detected. The amount of H_2O_2 was below the detectable level (ca. 1 μM) within 7 min, thus showing the catalytic decomposition of H_2O_2 in this system. The direct conversion of oxyHb to metHb induced by a stoichiometric amount of H_2O_2 was also reported in

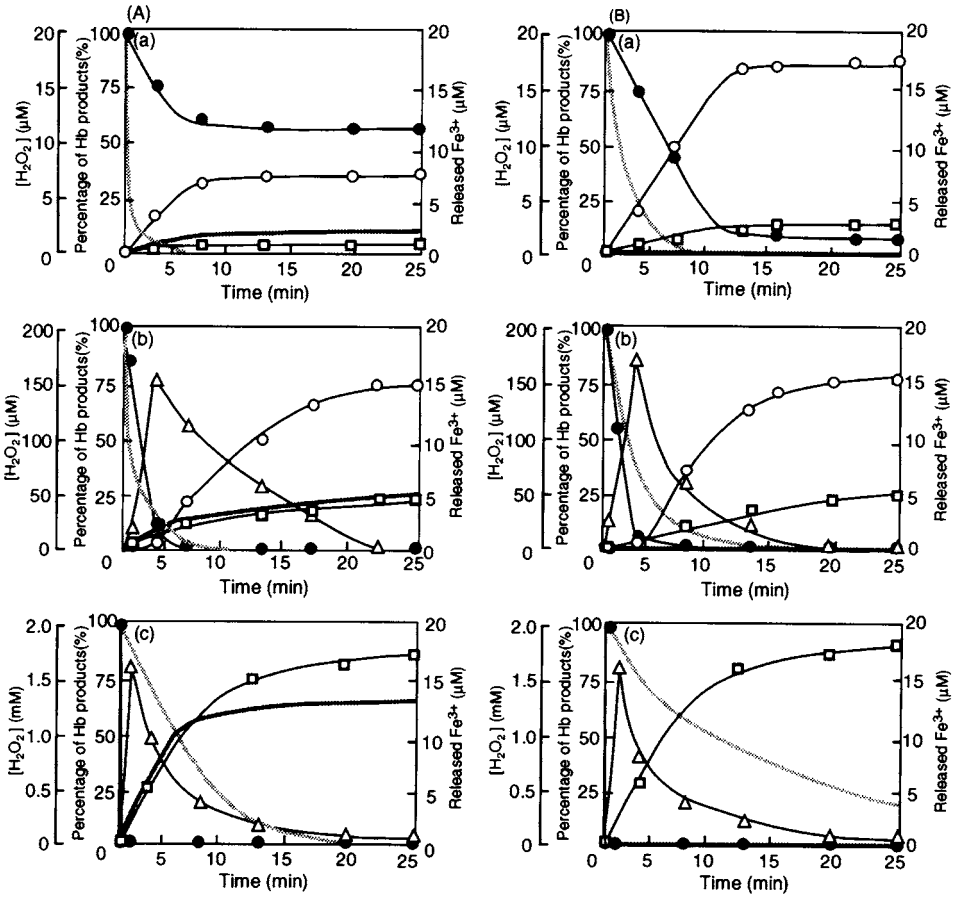

Figure 2. Changes of Hb components and the concentrations of H_2O_2 and Fe^{3+} in (A) the Hb solution and (B) the Hb vesicle dispersion during the reaction with H_2O_2 at 37 °C. Hb or Hb vesicle ([heme] = 20 μM) were reacted with H_2O_2 ((a) 20 μM, (b) 200 μM and (c) 2 mM, respectively). Each Hb component in the vesicle ratio was calculated from the repetative UV−vis spectral changes. ●: oxyHb, ○: metHb, △: ferrylHb, □: discolorated products. black line: Released Fe^{3+} measured by an ICP emission spectroscopy, grey line: H_2O_2 concentration determined with HRP and HPA.

some papers (*40*, *41*) and explained in terms of "comproportionation" between ferrylHb and oxyHb to two metHbs by Giulivi and Davies (*41*). On the other hand, to the dispersion of oxyHb vesicles having the heme concentration of 20 μM, the same concentration of H_2O_2 was added as shown in Figure 2A (b). The oxyHb was reduced to 5% within 13 min accompanied by the formation of 85% metHb and 10% discolored products. No ferric ion was detected during our observation period (30 min). The main difference between these two samples is that the conversion of metHb from the oxyHb solution remained at 29%, whereas that from the oxyHb vesicle dispersion was over 85%. This can be explained as follows. Initially, oxyHb would react with H_2O_2 to convert metHb via comproportionation of ferrylHb with a large amount of oxyHb. The resulting metHb would show more effective catalase-like reactivity than oxyHb (*21*, *30*). In the Hb solution, 20 μM H_2O_2 was completely decomposed by only 6 μM heme. In the case of the Hb vesicle dispersion, the rate-determining stage would be the reaction between oxyHb molecules that are located the vicinity of the bilayer membrane inside the vesicle and H_2O_2 that had just permeated through the bilayer membrane. The resulting metHb would diffuse toward the core of the vesicle and exchange with unreacted oxyHb, and then the oxyHb would react with H_2O_2 to convert metHb. This would result in the higher metHb conversion and ristriction of the catalase-like reaction of metHb. In fact, as shown in Figure 2 AB (a), the half-lives of the H_2O_2 decomposition in the Hb solution and in the Hb vesicle dispersion were 12 s and 115 s, respectively.

The reaction between 10-fold (200 μM) H_2O_2 and oxyHb (20 μM) in the solution state or within a vesicle as a dispersion is shown in Figure 2AB (b) as the conversion of each Hb product. The concentrations of H_2O_2 and ferric ion are also included in these figures. OxyHb completely disappeared within 7 min after the addition of H_2O_2. It was transiently converted to ferrylHb with a maximum at 4 min, followed by the conversion of metHb from the ferrylHb. Furthermore, discolored products were gradually generated from the beginning of the reaction. It is noted that the release of ferric ion was accompanied by the generation of the discolored products in the oxyHb solution. However, no ferric ion was observed in the outer aqueous phase of the oxyHb vesicle dispersion. The half-lives of 200 μM H_2O_2 in the 20 μM oxyHb solution and the vesicle dispersion were 21 s and 200 s, respectively. When compared with those in Figure 2AB (a), only twice the time was needed to decompose the 10-fold H_2O_2. It is indicated that the catalase-like activity that cycles between metHb and ferrylHb (globin) radical, which is one oxidizing equivalent above ferrylHb, remained during the reaction. As described above, once metHb formed by the reaction of oxyHb with H_2O_2 via ferrylHb, the resulting metHb should be rapidly oxidized by H_2O_2 to the ferrylHb radical. The ferryl Hb radical is considered to act like the so-called compound I of catalase, which converts H_2O_2 to H_2O and O_2, and back to metHb (*30*). Since the latter reaction would be slow in comparison with the ferrylHb formation, the ferrylHb from oxyHb and ferrylHb radical from metHb are apparently the main products during the reaction with H_2O_2. These

ferrylHbs gradually returned to metHb after the extinction of H_2O_2 because of its instability.

The discolored products should be degraded to heme fragments and apo-protein during the redox cylcle between oxyHb and ferrylHb, because we confirmed that metHb showed a more stable equilibrium state between metHb and the ferrylHb radical during reaction with H_2O_2 (data not shown). A recent report described that heme degradation was caused by superoxide generated from the reaction of ferrylHb with H_2O_2 (*21*). It is easy to understand that heme degradation triggered the release of ferric ion, and the resulting apo-proteins were so unstable that they aggregated as white precipitates. The generation of such discolored products indicates the nonperfect catalase-like activity of Hb against H_2O_2.

When 1000-fold H_2O_2 was added to the Hb sample solutions, oxyHb in both cases instantly disappeared to convert ferrylHb as an intermediate, and interestingly, the final product was not metHb but discolored products. This indicates that the comproportionation of ferrylHb with oxyHb did not occur because almost all of the oxyHb was instantly converted to ferrylHb, and heme degradation should occur due to the reaction of ferrylHb with the large amount of H_2O_2.

The decomposition of H_2O_2 could also be recognized even if no ferrylHb and metHb existed. The half-lives of H_2O_2 in the oxyHb solution and the oxyHb vesicle dispersion were 390 s and 760 s, respectively. H_2O_2 was hardly decomposed if H_2O_2 was added to the discolored Hb products in the presence of DFO, indicating that the discolored products should have no catalase activity, but H_2O_2 should be decomposed by a Fenton reaction caused by ferric ion released from the degraded heme. For the Hb vesicles, we did not observe the ferric ion in the outer aqueous phase; therefore, H_2O_2 should be decomposed by ferric ion in the inner aqueous phase of the Hb vesicle.

Figure 3 shows the turbidity changes monitored at 700 nm for the six samples depicted in Figure 2 and two samples, i.e., the Hb solution and the Hb vesicle dispersion without the addition of H_2O_2, as references. The turbidity of the Hb solution gradually increases during the reaction with H_2O_2 (Figure 3a). The slope of the turbidity change increases with the increasing amount of H_2O_2. This clearly indicates that the turbidity increase is caused by the reaction of Hb with H_2O_2. We observed the white precipitates at the bottom of the vial soon after finishing the experiments, suggesting the formation of apo-protein, from which degraded heme molecules are lost. On the other hand, there were no changes in the turbidity and the diameter for all the Hb vesicle samples after the reaction with H_2O_2 as shown in Figure 3b. Of course, no white precipitate was observed. We could confirm the encapsulation of all the Hb products such as ferrylHb, metHb, and discolored products within the vesicle after the separation of the vesicles by ultracentrifugation.

Next, the free iron (ferric ion) was determined by ICP emission spectroscopy in the reaction system between H_2O_2 and the Hb samples after 24 h (Figure 4). With the addition of 20 μM, 200 μM, and 2 mM H_2O_2 to the Hb solution, 5.1 μM, 7.2 μM, and 19.8 μM ferric ion were released, respectively. These values respectively correspond to 26, 36, and 99 mol % Hb denaturation. On the other hand, for the Hb vesicle despersion, even with the addition of 2 mM H_2O_2, only 2.0 μM ferric ion was detected in the outer aqueous phase of the vesicles after 24 h. However, when the Hb vesicles after the reaction with H_2O_2 for 24 h was solubilized by 5 mM polyoxyethylene 10 lauryl ether ($C_{12}E_{10}$), which is a good surfactant

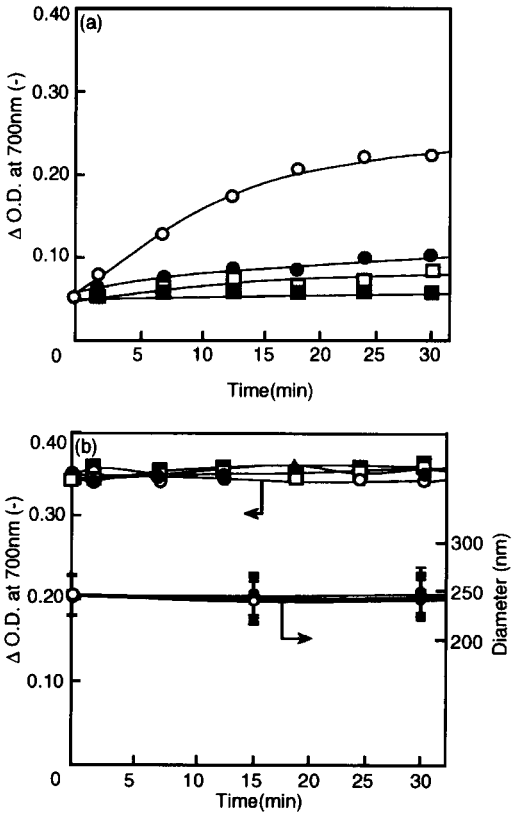

Figure 3. Changes in (a) the solution state of Hb and in (b) the dispersion state of Hb vesicles during the reaction with H_2O_2 at 37 °C. Hb or Hb vesicle ([heme] = 20 μM) were reacted with H_2O_2 (20 μM (□), 200 μM (●), and 2 mM (○), respectively). (■): the Hb solution or the Hb vesicle dispersion without the addition of H_2O_2. The turbidities of the Hb solution and the Hb vesicle dispersion were monitored as ΔOD at 700 nm. The particle diameter was determined by a dynamic light scattering method.

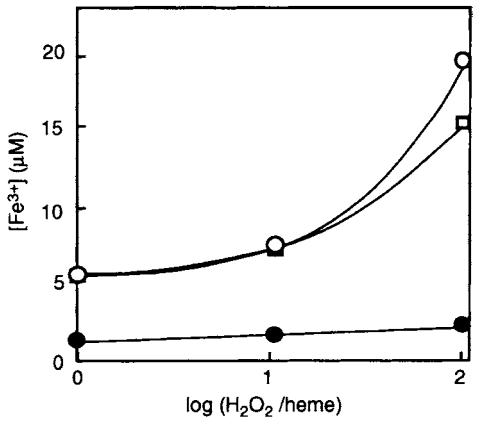

Figure 4. Released Fe^{3+} from Hb (○), Hb vesicle (●), or Hb vesicle solubilized with lauryl ether (□) after the reaction with H_2O_2 and incubation at 37 °C for 24 h. All samples have the same heme concentration of 20 μM.

for the solubilization of the vesicles and does not cause Hb denaturation, the amount of ferric ion similar to that in the Hb solution system was detected. The amount of ferric ion increased corresponding to the added amount of H_2O_2 as shown in Figure 4. Therefore, it was confirmed that ferric ion was also released from the denatured Hb inside the vesicle, but the ferric ion was hard to permeate through the bilayer membrane because of the high resistance of the membrane to ferric ion and the high integrity of the membrane.

Besides the physical integrity of the Hb vesicles, we analyzed the chemical stability of the bilayer membrane

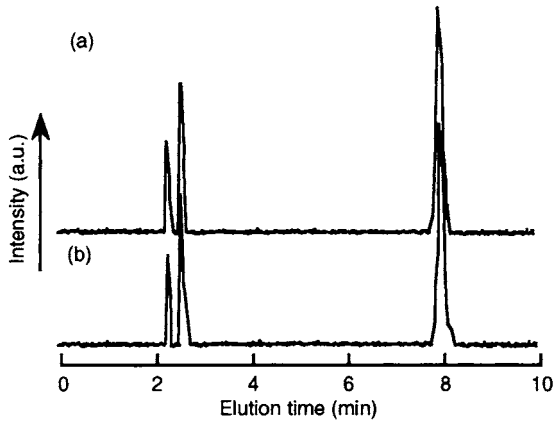

Figure 5. The LC-MS elution profiles of the lipid components of Hb vesicles ([heme] = 20 μM) (a) before and (b) after the reaction with 2 mM H_2O_2. The peaks at around 2.2, 2.5, and 7.9 min correspond to DPPG, cholesterol, and DPPC, respectively.

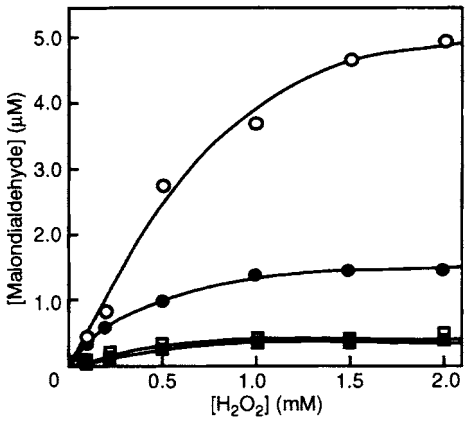

Figure 6. Lipid peroxidation of the EYL vesicles catalyzed by the Hb samples during the reaction with H_2O_2 in the presence or absence of DFO. The 37 mM EYL vesicle was dispersed in the Hb solution or the Hb vesicle dispersion ([heme] = 20 μM) and reacted with H_2O_2 at 37 °C for 30 min. ○: Hb, ●: Hb + DFO, □: Hb vesicle, ■: Hb vesicle + DFO

by liquid chromatography−mass spectroscopy (LC-MS). The membrane components were extracted from the freeze-dried powder of the Hb vesicles after reaction with 2 mM H_2O_2. In the elution profiles, the three peaks were detected at 2.2, 2.5, and 7.9 min, corresponding to DPPG, cholesterol, and DPPC, respectively, as shown in Figure 5. From the mass spectrum of each elution peak and the peak position, we could not confirm any new products and degraded fragments of the lipids after the reaction with even 100-fold H_2O_2 to Hb in the vesicles. Therefore, it was clarified that the saturated phospholipids and cholesterol were stable against H_2O_2, the active products from the reaction of H_2O_2 with Hb, such as ferrylHb and reactive oxygen species.

In the reaction with egg york lecithin (EYL), we could not confirm that either Hb or H_2O_2 had peroxidized the EYL comprising vesicles. However, EYL was surely peroxidized when H_2O_2 was added to the EYL vesicle dispersion in the presence of 20 μM ferric ion, indicating that the hydroxyl radical produced from the Fenton reaction between ferric ion and H_2O_2 should cause lipid peroxidation. Such lipid peroxidation was inhibited by the addition of 1.6 mM DFO as a chelator of ferric ion. To the mixture of 37 mM EYL vesicles, 20 μM Hb, and 1.6 mM DFO were added various concentrations of H_2O_2, and the lipid peroxidation value was measured by a TBA method after incubation for 30 min at 37 °C. The closed circle plots in Figure 6 show evidence of the lipid peroxidation in the triadic reaction system of EYL, Hb, and H_2O_2. No concentration dependence of H_2O_2 was seen above the H_2O_2 concentration of more than 1.0 mM. This suggests that the rate-determining process would be the reaction of Hb with EYL because both concentrations were constant. Therefore, we looked at the relationship between the concentration of ferrylHb and the concentration of malondialdehyde. The linear relationship proves that the ferrylHb converts EYL to the peroxidized lipid (data not shown here).

To study the influence of the ferric ion released from denatured Hb, the same experiment was carried out in the absence of DFO. The open circle plots in Figure 6 clearly demonstrate that the ferric ion significantly contributes to the lipid peroxidation through the Fenton reaction. The proportional relationship between the ferric ion concentration from $FeCl_3$ artificially added to the solution instead of Hb and the concentration of the resulting malondialdehyde suggests that the reaction of H_2O_2 and ferric ion released from the Hb denatured by H_2O_2 should produce the hydroxyl radical which results in the lipid peroxidation. On the other hand, in the Hb vesicle dispersion, the small increase in malondialdehyde despite the absence of DFO is due to the encapsulation

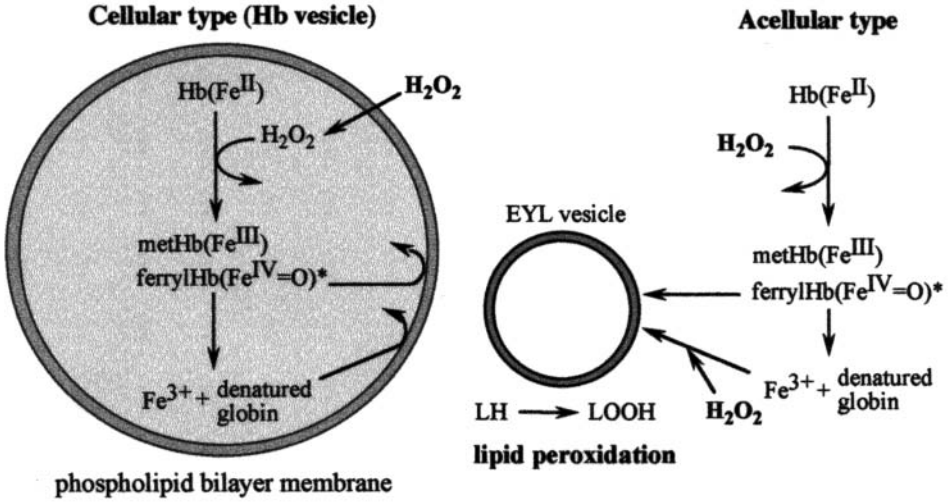

Figure 7. Interaction of acellular-type Hb and cellular-type Hb vesicle with H_2O_2, and their effects on lipid peroxidation of EYL.

effect of Hb and ferric ion with the saturated phospholipid bilayer membrane. This suggests the low cytotoxicity of the endotherial cells in the Hb vesicles in comparison with Hb modifications under oxidative stress (*33*). We are now studying the effect of the Hb samples reacted with H_2O_2 on the endotherial cells.

Figure 7 concludes our experimental results. H_2O_2 reacts with the acellular-type Hb solution to produce metHb and ferrylHb. The ferrylHb and ferric ion from those unstable Hb products facilitates the lipid peroxidation of the EYL vesicles, which represents the cytotoxicity of the reaction series. On the other hand, for the celullar Hb vesicle dispersion, those products are also generated by the reaction of Hb with H_2O_2 permeated through the bilayer membrane of the vesicle. However, they are stably encapsulated within the vesicle and do not cause the lipid peroxidation due to the separation from the EYL vesicles. These results indicate the high safety of the Hb vesicles which enclose the reactive Hb products in the reaction with H_2O_2.

ACKNOWLEDGMENT

Glycosaminoglycan-Mimetic Biomaterials. 3. Glycopolymers Prepared from Alkene-Derivatized Mono- and Disaccharide-Based Glycomonomers

Subramanian Baskaran,[‡] Daniel Grande,[‡] Xue-Long Sun,[‡] Avner Yayon,[§] and Elliot L. Chaikof*[,†,‡]

Laboratory for Biomolecular Materials Research, Department of Surgery and Biomedical Engineering, Emory University, Atlanta, Georgia 30322, School of Chemical Engineering, Georgia Institute of Technology, Atlanta, Georgia 30332, and Weizmann Institute of Science, Rehovot, Israel. Received May 3, 2002; Revised Manuscript Received August 11, 2002

Mono- and disaccharide-containing glycopolymers were synthesized by two different free-radical processes, and their ability to act as heparan sulfate glycomimetics in promoting the binding of Fibroblast Growth Factor-2 (FGF-2) to its receptor (FGFR-1) was evaluated using an in vitro cell-based assay. Cyanoxyl (•OC≡N)-mediated polymerization of acrylamide with alkene-derivatized mono- and disaccharides including sulfated or nonsulfated *N*-acetyl-D-glucosamine is described. The results of this approach are compared to those obtained via the classical ammonium peroxodisulfate (APS)/*N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA) initiating system and confirm the capacity of cyanoxyl-mediated polymerization to generate a variety of glycopolymers with high saccharide contents and low polydispersity indexes. In vitro assays demonstrate that specific glycopolymers can potentiate FGF-2/FGFR-1 binding interactions.

INTRODUCTION

Heparan sulfates (HS) are a large family of polydisperse anionic polysaccharides encountered both in the extracellular matrix and on cell surfaces that bind numerous proteins of biological interest. For example, fibroblast growth factor-2 (FGF-2) binds to heparan sulfate, which stabilizes and protects it against inactivation and facilitates its binding to the FGF receptor-1 (FGFR-1) (*1*). Moreover, heparan sulfates are required for the oligomerization of the FGF-2/FGFR-1 complex that is necessary for effective transmembrane signaling and a biological response (*2*). As a consequence of modulating the FGF-2/FGFR-1 signaling pathway, heparan sulfates have a significant functional role in a wide array of physiological processes, including cell proliferation and migration, as well as angiogenesis, wound healing, and inflammatory responses (*3*−*5*). Thus, the development of synthetic biopolymers that incorporate some of the biological functionality of heparan sulfate, particularly with respect to FGF-2, carries potential significance in a variety of areas, including drug delivery and tissue engineering (*6*).

Heparan sulfates are structurally complex and consist on average of 20 or more repeating disaccharides units composed of a hexauronic acid (D-glucuronic or L-iduronic acid) attached in 1→4 fashion to *N*-acetyl-D-glucosamine with varying patterns of sulfation (*7*). While smaller oligosaccharide sequences have been identified that are responsible for some of the unique biological activities of heparan sulfate (*8*, *9*), optimal binding of FGF-2 to FGFR-1 requires heparan sulfate-derived oligosaccharides containing eight or more sugar residues (*10*). Thus, the generation of heparan sulfate-mimetic compounds that modulate FGF-2-dependent responses remains a challenging endeavor, despite reported advances in solution- and solid-phase methods of carbohydrate synthesis. As an alternative approach, efforts in our group have been recently directed at the investigation of 'glycopolymer'-based strategies in which pendant saccharides are incorporated into a polymer backbone. The observation of enhanced protein binding affinity derived from multivalent oligosaccharide ligands suggested that monomers carrying this or other related saccharides as pendant groups could be used to generate glycopolymers with FGF-2-related bioactivity.

Optimization of glycopolymer properties requires the generation of biomolecular architectures that exhibit low fluctuations both in polymer size and in composition. As a consequence, we are currently examining the applicability of cyanoxyl (•OC≡N)-mediated free-radical polymerization in the synthesis of model glycopolymers from unprotected glycomonomers. Notably, this polymerization technique can be conducted in aqueous solution, is tolerant of a broad range of functional groups (OH, NH_2, COOH, etc.), and can be applied to the synthesis of block and graft copolymers with reported polydispersities below 1.5 (*11*, *12*). In this report, we describe the preparation of alkene-derivatized mono- and disaccharide glycomonomers. Cyanoxyl-mediated and classical free-radical polymerization techniques were then exploited to create a wide variety of water-soluble glycopolymers with high monosaccharide contents and low polydispersity indexes. Finally, the ability of test glycopolymers to potentiate the binding of FGF-2 to FGFR-1 is examined in preliminary bioactivity studies.

EXPERIMENTAL SECTION

Materials. All solvents and reagents were purchased from commercial sources and were used as received, unless otherwise noted. Heparin was obtained from Hepar Industries and is polydisperse with a range of molecular weight between 5 and 30 kD (Franklin, OH). Deionized water with a resistivity of 18 MΩ·cm was used as solvent in all polymerization reactions.

Methods. All reactions were performed in flame-dried glassware under an atmosphere of dry argon. The reaction medium solutions were evaporated under reduced pressure with a rotary evaporator, and the residue was chromatographed on a silica gel (230−400 mesh) column. Analytical thin-layer chromatography (TLC) was performed on Whatman silica gel aluminum-backed plates of 250 μm thickness on which spots were visualized with UV light or charring the plate before and/or after dipping in a H_2SO_4−EtOH mixture. Melting point (mp) measurements were performed with a Thomas-Hoover melting point apparatus in open capillary tubes and were uncorrected. Mass spectra (MS/FAB) were obtained at an ionizing voltage of 70 eV. Optical rotations were determined with a Perkin-Elmer-2 GIMC polarimeter. ^{1}H and ^{13}C NMR spectra were recorded at room temperature with a Varian INOVA 400 spectrometer (magnetic field strengths of 400 and 100 MHz for ^{1}H and ^{13}C NMR analyses, respectively). In all cases, the sample concentration was 10 mg/mL, and the appropriate deuterated solvent was used as the internal standard.

Size-exclusion chromatography (SEC) equipment was comprised of a Waters model 510 HPLC pump, a Waters Ultrahydrogel 250 column, and a Wyatt Technology Optilab 903 refractometer. The eluent consisted of a 0.1 mol/L $NaNO_3$ deionized water solution containing 0.05 wt % sodium azide at a flow rate of 0.7 mL/min. The actual molar masses of the glycopolymer samples were determined from the response of the DAWN F (Wyatt Technology) multiangle laser light-scattering (LLS) detector that was connected to the outlet of the SEC apparatus.

Synthesis of Alkene-Derivatized Glycomonomers with Pendant Monosaccharides. Synthesis and detailed characterization of *n*-pentenyl 2-acetamido-2-deoxy-α-D-glucopyranoside (**1**(C-3)), *ω*-undecenyl 2-acetamido-2-deoxy-α-D-glucopyranoside (**1**(C-9)), and sulfated derivatives thereof (**2**(C-3) and **2**(C-9), respectively) have been reported in detail elsewhere (Figure 1).[13]

Synthesis of Alkene-Derivatized Glycomonomers Bearing Lactose. *n*-Pentenyl *O*-(*β*-D-galactopyranosyl)-(1→4)-*β*-D-glucopyranoside, 3. To a mixture of D-lactose (10 g) and 4-penten-1-ol (large excess, ∼125−175 mL) was added a catalytic amount of 10-camphorsulfonic acid (CSA) (∼400 mg), and the mixture was refluxed at 110 °C for 7 h. The reaction mixture was then cooled and neutralized with triethylamine (E_3N), and the excess of alcohol was removed under vacuum. The solid mass was subsequently rinsed with hot petroleum ether to remove the remaining alkenyl alcohol. The residue was purified by column chromatography using a chloroform/methanol (97/3) mixture to afford the expected product, **3**. Yield: 45%; $[\alpha]^{20}_D = +20.6°$ (*c* 1.8, CH_3OH). ^{1}H NMR (CD_3OD), δ_{ppm}: 1.69 (m, 2H, C−CH_2−C), 2.12 (m, 2H, CH_2−C═), 3.38−3.88 (m, all other H), 5.07 (m, 2H, CH_2═), 5.78 (m, 1H, C*H*═). ^{13}C NMR (CD_3OD), δ_{ppm}: 28.6, 30.2, 67.6, 69.7, 71.5, 71.8, 74.1, 98.6, 115.1, 137.9. MS/FAB, *m*/*z*: 411 (M + 1) (*14*, *15*).

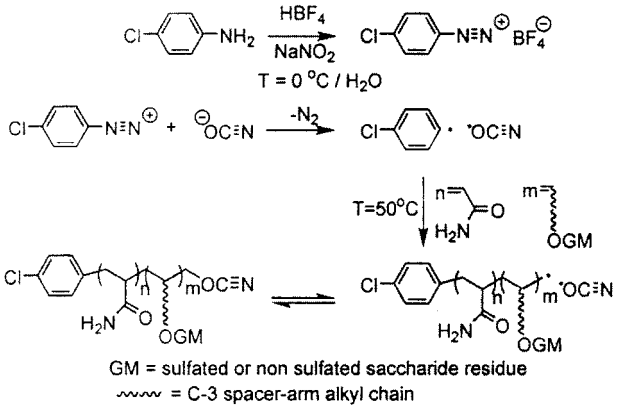
***n*-Pentenyl *O*-(2,3,4,6-Tetra-*O*-sulfo-*β*-D-galactopyranosyl)-(1→4)-2,3,6-tri-*O*-sulfo-*β*-D-glucopyranoside Heptasodium Salt, 4.** Under argon atmosphere, sulfur trioxide−trimethylamine (SO_3−NMe_3) complex (4 equiv for each hydroxyl group) was added to the nonsulfated glycomonomer (**3**) in DMF, and the mixture was stirred at 60 °C for 12 h. The reaction medium was then cooled to 0 °C, and a saturated $NaHCO_3$ aqueous solution was added. The crude mixture was stirred for 1 h and concentrated to a smaller volume that was passed through a diethylaminoethyl (DEAE)-sephacel anion-exchange resin column. It was first eluted with a 10 mmol/L sodium phosphate buffer (pH ∼ 7.0), thereby removing the unreacted nonsulfated compound. The sulfated homologue was then eluted with a 1 mol/L NaCl buffer (pH ∼ 7.0) and recovered as a mixture of its heptasodium salt with a NaCl excess. The latter eluate was concentrated, redissolved in a minimum amount of water, and passed through a Trisacryl (Gf05 M grade, Sigma-Aldrich) size-exclusion resin column for isolation of the sulfated compound free of NaCl. Yield: 45%; $[\alpha]^{20}_D = +64.7°$ (*c* 1.7, H_2O). ^{1}H NMR (D_2O), δ_{ppm}: 1.72 (m, 2H, C−CH_2−C), 2.21 (m, 2H, CH_2−C═), 3.42−3.92 (m, all other H), 5.09 (m, 2H, CH_2═), 5.81 (m, 1H, C*H*═). MS/FAB, *m*/*z*: 986 ($M^+ + 1Na^+$).

Statistical Copolymerization of Alkene-Derivatized Glycomonomers and Acrylamide Initiated by $ClC_6H_4N{\equiv}N^+BF_4^-$/NaOCN. In a three-neck flask, 6.03×10^{-5} mol (0.008 g) of *p*-chloroaniline was reacted with 9.04×10^{-5} mol of HBF_4 (actually 0.017 g of 48 wt % aqueous solution), at 0 °C, in 2 mL of water and under argon atmosphere. The diazonium salt $ClC_6H_4N{\equiv}N^+BF_4^-$ was then generated by adding 7.2×10^{-5} mol (0.005 g) of sodium nitrite ($NaNO_2$) to the reaction medium. After 30 min, a degassed mixture of 6.03×10^{-4} mol (0.225 g) of glycomonomer **1**(C-9), 2.41×10^{-3} mol (0.171 g) of acrylamide, and 6.03×10^{-5} mol (0.004 g) of sodium cyanate (NaOCN), dissolved in 1 mL of water/tetrahydrofuran (1/1), was introduced into the flask containing the diazonium salt. The polymerization medium was then

heated to 50 °C. The statistical copolymers formed after 1.5 and 16 h of reaction were isolated by precipitation in a 10-fold excess of cold methanol, dried, and weighed so as to determine the conversion.

Binding of FGF-2 to FGF Receptor-1 (FGFR-1). High-affinity binding of FGF-2 to CHO cells was performed as described in detail elsewhere (*10*, *16*). Briefly, confluent CHO-*pgs*A-745-*flg* cells, which are deficient in heparan sulfates and genetically engineered to express the FGF receptor-1, were incubated with 125 I-FGF-2 and increasing concentrations of test gycopolymer for 90 min at 40 °C. Low-affinity-bound FGF-2 was released from the cell surface by a 5 min incubation with a cold solution containing 1.6 M NaCl and 20 mM HEPES, pH 7.4. High-affinity-bound FGF-2 was determined by a 2 M NaCl and 20 mM acetate buffer, pH 4.0, extraction.

RESULTS AND DISCUSSION



1. Synthesis of Glycomonomers Bearing Nonsulfated and Sulfated *N*-Acetyl-D-glucosamine and Lactose. Three different glycosidation methods have been previously reported for the synthesis of monosaccharides containing spacer side chains. Specifically, $FeCl_3$ has been used as a catalyst for generating monosaccharides derivatized in positions C-1 (*17*). Similarly, trifluoromethanesulfonic acid (*18*), as well as 10-camphorsulfonic acid (CSA) (*19*, *20*), has been utilized for the synthesis of spacer-armed glycosides either from glucose or an oxazoline derivative. For our purpose, we resorted to the CSA/reflux method that provided a facile means of yielding nonsulfated and sulfated alkene-derivatized monosaccharides from *N*-acetyl-D-glucosamine (Figure 1) (*15*). The reflux of *N*-acetyl-D-glucosamine with a catalytic amount of CSA and a large excess of either *n*-pentenyl or *ω*-undecenyl alcohol provided a mixture of α- and *β*-anomers (**1**(C-3) or **1**(C-9)), with an average crude yield of 60−70%. The α- and *β*-anomeric configurations of the separated products were determined on the basis of unique $J_{1,2}$ coupling constants of 3.6 and 8.0 Hz, respectively. Compounds were separated by column chromatography with a ratio α/*β* of 3/1 for both C-3 and C-9 glycosides.

The preparation of compound **3** has been reported previously by two groups (*14*, *15*). Matsuoka et al. (*14*) synthesized **3** from bromolactose using HgCN during the glycosidation step with a 40% yield for the *n*-pentenyl lactose. Likewise, Allen and Danishefsky (*15*) reported that glycosidation proceeds smoothly using $AgCO_3$ with a 75% yield of the pentenyl glycoside and an overall yield from octaacetyl lactose of ∼65% in three to four steps. We elected to synthesize the *n*-pentenyl glycosides via CSA reflux methodology, which afforded the *n*-pentenyl lactoside **3** in a single step with moderate yield (∼45%) from inexpensive and commercially available D-lactose (Figure 1).

Chemoselective sulfation of all hydroxyl groups on α-anomers, namely compounds **1**(C-3), **1**(C-9), and **3**, was achieved by reaction with SO_3−NMe_3 at 60 °C in DMF. Preparative chromatography through successive columns containing diethylaminoethyl (DEAE)-sephacel anion-exchange resin and trisacryl size-exclusion resin was required for isolation of the pure sulfated product (Figure 1, compounds **2**(C-3), **2**(C-9), and **4**).

2. Synthesis of *ω*-Alkenyl Mono- and Disaccharide-Based Glycopolymers. Druliner (*11*) in the early 1990s and more recently Grande and Gnanou (*12*) have observed that a certain degree of control can be achieved when polymerizing a broad range of (meth)acrylic monomers, and particularly acrylamide, in the presence of

Scheme 1. Cyanoxyl-Mediated Free-Radical Copolymerization of AM with Alkene-Derivatized Unprotected Glycomonomers

cyanoxyl (•OC≡N) persistent radicals, as moderators of the polymerization reaction. Significantly, these persistent radicals function under milder conditions (25−70 °C) than those required for nitroxide-controlled free-radical polymerization or ATRP processes. Given the potential advantages of cyanoxyl-mediated free-radical polymerization, we investigated the copolymerization of acrylamide with a variety of unprotected alkene-derivatized saccharides (compounds **1**−**4**).

Cyanoxyl radicals were readily generated by an electron-transfer reaction between cyanate anions ($^-$OC≡N) from a NaOCN aqueous solution, and *p*-chlorobenzene-diazonium salts ($ClC_6H_4N{\equiv}N^+BF_4^-$) that were previously prepared in situ through a diazotization reaction of *p*-chloroaniline in water. In addition to cyanoxyl persistent radicals, aryl-type active radicals were simultaneously produced, and only the latter species were able to initiate chain growth (Scheme 1). A series of water-soluble glycopolymers were prepared by varying the nature of the *ω*-alkenyl glycomonomer (nonsulfated/sulfated, mono-/disaccharide-based), as well as the initial molar ratio of glycomonomer (GM) to AM in the statistical copolymerization of both comonomers performed at 50 °C (Table 1). These statistical copolymers were isolated by precipitation in a 10-fold excess of methanol and characterized by ^{1}H NMR spectroscopy, as well as by SEC coupled with both refractive index and laser light-scattering detectors (*13*). The absence of residual comonomers, including glycomonomer, was assessed by ^{1}H NMR. The ratio of the resonance signal intensity from the methyl protons of *N*-acetyl groups from sugar moieties (2.0 ppm) to that of methine protons from the hydrocarbon skeleton (2.1−2.4 ppm) enabled the determination of saccharide content, for those glycopolymers containing *N*-acetyl-D-glucosamine residues. As for lactose-based samples, elemental analysis was used to assess carbohydrate composition. Notably, saccharide contents as well as molar masses increased with monomer conversion while polydispersity indexes remained below 1.5. Regardless of the glycomonomer used (mono/disaccharide-based, nonsulfated/sulfated), an initial ratio GM/AM of 1/4, associated with a copolymerization time of 16 h, permitted the access to a copolymer that displayed a saccharide content in close agreement with that expected. Samples exhibiting sugar compositions as high as 69 wt % were thus obtained. Nonetheless, copolymers with higher carbohydrate contents were associated with an increase in the polydispersity index. This may be attributable to some loss of control over the copolymerization process in the presence of increasing concentrations of *ω*-alkenyl

glycomonomers, considering the innate low chemical reactivity of the vinyl group in these saccharide monomers. The limited reactivity of the vinyl group, particularly in association with disaccharide bearing monomers, may also be a contributory factor in reducing monomer conversion. Despite a 16-h reaction period, overall yields for polymers derived from glycomonomers **3** and **4** ranged from 15 to 30%.

In a comparative study, classical free-radical copolymerization of glycomonomers and AM were performed using APS/TMEDA as the initiating system. TMEDA accelerates the homolytic scission of APS yielding sulfate ($SO_4^{\bullet-}$), hemiTMEDA ($(CH_3)_2NCH_2CH_2(CH_3)$-$NCH_2^{\bullet}$), and hydroxyl ($^{\bullet}OH$) radical species. The reaction medium was homogeneous and the polymerization proceeded smoothly at room temperature (Table 2). Utilizing otherwise identical experimental conditions as those used for cyanoxyl-mediated processes ($[M]_0 = 1$ mol/L, $[I]_0 = 2 \times 10^{-2}$ mol/L), the resulting glycopolymers exhibited lower saccharide contents (maximum: 43 wt %) with higher molar masses and polydispersity indexes (1.6−2.0). Moreover, increasing the polymerization time from 1.5 to 16 h increased the polydispersity index, but otherwise had little influence on either saccharide content or molar mass. The observed increase in polydispersity, however, was offset by significantly higher polymer yields, ranging up to 80% for monomers **3** and **4**. In summary, these investigations illustrate the anticipated absence of control over the copolymerization process by employing the classical APS/TMEDA initiating system, while confirming the significant role of cyanoxyl radicals in moderating the polymerization process.

3. Binding of FGF-2 to FGF Receptor-1 (FGFR-1). The capacity of selected glycopolymers to promote the binding of FGF-2 to FGFR-1 was defined using CHO-*pgs*A-745-*flg* cells, which are deficient in heparan sulfates and genetically engineered to express a single FGF receptor subtype, FGFR-1. FGFR-1 is normally expressed on a wide variety of cell types and when activated can initiate cell proliferation and migration and other cell type-specific responses. Given the preliminary nature of these bioactivity studies, limited yields for glycomonomers, and low conversions associated with cyanoxyl-mediated polymerization for vinyl monomers bearing pendant disaccharides, both classical and cyanoxyl-mediated polymerization strategies were used to synthesize the glycopolymers available for receptor binding experiments (Table 3). Results of these investigations for polymers bearing mono- and disaccharides are summarized in Figures 2 and 3, respectively. As anticipated, heparin is a strong promotor of FGF-2 binding to FGFR-1. Monosaccharide bearing glycopolymers were all of similar saccharide content, nominal molecular weight, and polydispersity (Figure 2). Sulfation-enhanced receptor binding of FGF-2 with a biphasic response observed for polymers (**GP2**) composed of monomer **2**(C-3). The reduction in receptor binding at high glycopolymer concentrations is also characteristic of heparin and is likely related to a sequestration effect, which limits FGF-2 availability. Notably, the use of a longer (C-9) spacer arm (**GP3**) did not enhance receptor binding.

Table 3. Structure-bFGF Binding Activity Relationships Studies: Summary of Molecular Characteristics Associated with Glycopolymers

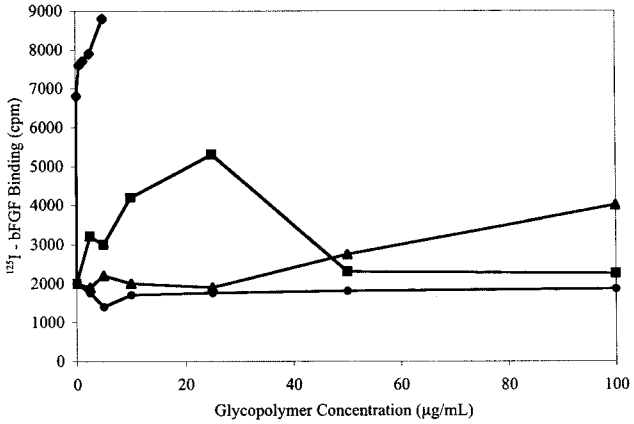

Figure 2. bFGF-binding assays for monosaccharide-based glycopolymers (◆ heparin, ● GP1, ■ GP2, ▲ GP3). The data are representative of binding assays performed in duplicate. Free sulfated monomer did not potentiate FGF-2 binding to heparan sulfate-deficient CHO cells.

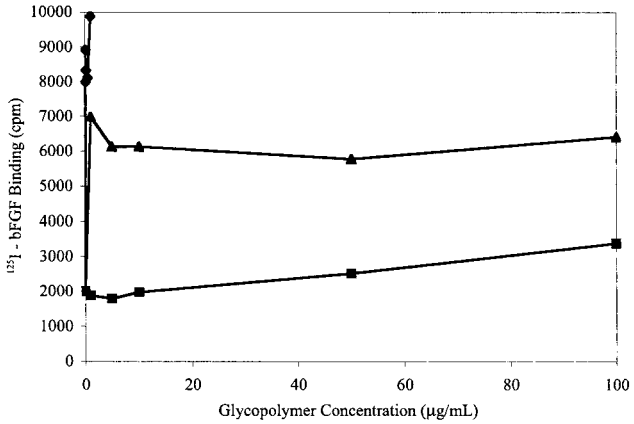

Figure 3. bFGF-binding assays for disaccharide-based glycopolymers (◆ heparin, ■ GP4, ▲ GP5). The data are representative of binding assays performed in duplicate. Free sulfated monomer did not potentiate FGF-2 binding to heparan sulfate-deficient CHO cells.

Disaccharide-bearing glycopolymers were all of similar saccharide content and polydispersity (Figure 3). Polymers bearing pendant lactose units (**GP4**) had little effect on receptor binding. A pronounced effect, however, was observed for polymers that contain sulfated lactose groups (**GP5**), even at very low polymer concentrations ($\sim$1 μg/mL). Of interest, an inhibitory effect on receptor binding was not observed as polymer concentration was increased.

CONCLUSIONS

We have synthesized a series of model mono- and disaccharide-carrying unprotected glycomonomers for the design of heparan sulfate glycomimetics. The present study broadens the family of vinyl monomers that are polymerizable with some degree of control by cyanoxyl-mediated free-radical polymerization. Both nonsulfated and sulfated alkene-derivatized monosaccharides and disaccharides were polymerized using this approach. While high carbohydrate contents and low polydispersity indexes ($1.1 < M_w/M_n < 1.6$) can be achieved further optimization of this strategy is required to enhance polymer yield, particularly for monomers bearing disaccharide units. Preliminary bioactivity studies reveal that glycopolymers containing pendant sulfated lactose groups significantly enhance FGF-2 binding to its receptor, FGFR-1, even at low polymer concentrations. We believe that tailored glycopolymers will contribute to the progress of glycotechnology, including the design of biomaterials for tissue regeneration and wound-healing applications.

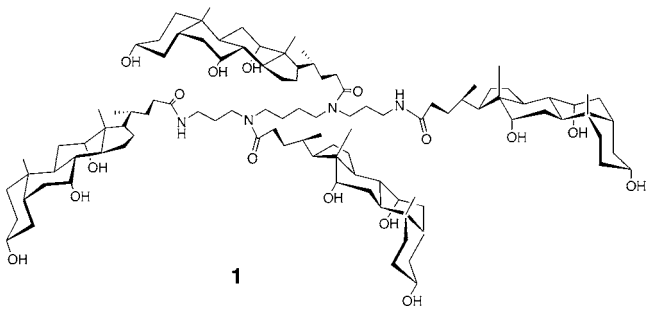
Ion Conductors Derived from Biogenic Amines, Bile Acids, and Amino Acids

Punam Bandyopadhyay, Prasun Bandyopadhyay, and Steven L. Regen*

Department of Chemistry, Lehigh University, Bethlehem, Pennsylvania 18015. Received May 24, 2002; Revised Manuscript Received August 20, 2002

A family of conjugates has been synthesized from spermine, putrescine, lysine, γ-aminobutyric acid, sarcosine, cholic acid, glycocholic acid, 3α,7α-dihydroxycholic acid, and 3α,12α-dihydroxycholic acid, based on a design principle previously reported (Bandyopadhyay, P., Janout, V., Zhang, L., Regen, S. L. (2001) *J. Am. Chem. Soc. 123,* 7691). Each of these conjugates was found to exhibit significant activity in promoting the transport of Na^+ across liposomal membranes derived from 1,2-dimyristoleoyl-*sn*-glycero-3-phosphocholine, and also from 1,2-dipalmitoleoyl-*sn*-glycero-3-phosphocholine. In all cases, plots of pseudo first-order rate constants, k_{obsd} vs (mol % of ion conductor)^2 were found to be linear, indicating that transport-active dimers are involved and that only a small fraction of the conjugates are in an aggregated form. An operational comparison that has been made within this series of conjugates indicates that Na^+ transport activity and membrane selectivity have a moderate dependency on the composition and the structure of the ion conductor.



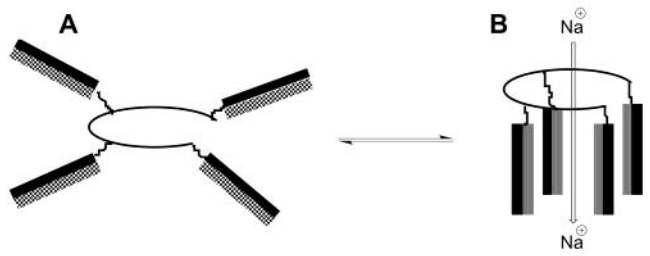
INTRODUCTION

We have been involved in the synthesis of new classes of ion conductors (i.e., molecules that transport ions across phospholipid bilayers) over the past several years (*1*). Our motivation for such work stems from belief that those ion conductors, which exhibit high activity and high membrane selectivity, have potential as antibiotics. In particular, ion conductors that are capable of selectively killing microorganisms in the presence of mammalian cells, by destroying their membrane integrity, would circumvent two of the major mechanisms of drug resistance; that is, enzymatic degradation within the cell and export pathways (*2*, *3*).

Recently, we introduced a new design principle for the construction of ion conductors in which two or more facial amphiphiles are covalently attached to a linear backbone (Scheme 1) (*1k*,*l*). When incorporated into a lipid bilayer, such conjugates are expected to favor conformation **B** where each hydrophobic face (darkened rectangle) is in intimate contact with the alkyl chains of neighboring phospholipids, and each hydrophilic face (lightly shaded rectangle) points toward a hydrophilic face of a nearest-neighbor.

Conformation **A**, on the other hand, is expected to be favored when the conjugate is adsorbed to the membrane surface. In principle, dimerization of **B** across a lipid bilayer should produce a contiguous pathway that permits a flow of ions. One prototype that was recently reported (i.e., **1**) exhibited ion conducting and monolayer properties that were consistent with this model. As noted previously, **1** is unique in the sense that it is derived from the direct conjugation of two underivatized biogenic precursors—spermine and cholic acid.

In the work that is reported herein, we sought to expand this class of ion conductors by preparing a series



1

of analogues; that is, *a variety of ion conductors from naturally occurring facial amphiphiles and biogenic amines or amino acids*. Our primary interest in this study was to determine the sensitivity of ion transport activity and membrane selectivity toward modest changes in the structure and composition of the ion conductor.

With this aim in mind, we focused on the synthesis of a series of conjugates derived from spermine, putrescine, lysine, γ-aminobutyric acid, sarcosine, cholic acid, glycocholic acid, 3α,7α-dihydroxycholic acid, and 3α,12α-dihydroxycholic acid, and a determination of their ability to promote Na^+ transport across liposomal bilayers made from 1,2-dimyristoleoyl-*sn*-glycero-3-phosphocholine [(C14:1)PC], and also from 1,2-dipalmitoleoyl-*sn*-glycero-3-phosphocholine [(C16:1)PC]. As discussed previously, the

ability of an ion conductor to respond to differences in membrane thickness raises the possibility of being able to exploit subtle differences between the membranes of mammals and of microorganisms from a therapeutic standpoint (*1j*). In particular, fungal and bacterial membranes are expected to have regions that are thinner and more susceptible toward ion transport than mammalian membranes, since the cholesterol that is present in the latter is known to condense and thicken bilayers.

Natural Building Blocks for Ion Conductors

Liposome-Forming Lipids

MATERIALS AND METHODS

General Methods. Unless stated otherwise, all reagents were obtained from commercial sources and used without further purification. Phospholipids that were used for preparing liposomes were obtained from Avanti Polar Lipids (Alabaster, AL). Specific procedures for preparing a paramagnetic shift reagent, for forming vesicles, and for measuring rates of Na^+ transport by NMR spectroscopy have previously been described in detail (*1l*). House-deionized water was purified using a Millipore Milli-Q-filtering system containing one carbon and two ion-exchange stages. Vesicle extrusions were carried out using a Lipex Biomembrane apparatus (Vancouver, BC). All ^1H NMR and $^{23}Na^+$ NMR spectra were recorded on 500 and 360 MHz instruments, respectively; chemical shifts are reported in ppm relative to residual solvent. The pH of the NaCl solution that was used in these transport experiments was typically ca. 6.

Conjugate 2. To a solution of glycocholic acid (0.200 g, 0.43 mmol) in 1 mL of DMF was added 0.10 mL of diisopropylethylamine (DIPEA) plus *O*-(3,4-dihydro-4-oxo-1,2,3-benzotriazin-3-yl)-*N*,*N*,*N*′*N*′-tetramethyluronium tetrafluoroborate (0.163 g, 0.47 mmol). After stirring this mixture for 2 h at room temperature, a solution of spermine (18.2 mg, 0.090 mmol) and DIPEA (0.3 mL) in 1 mL DMF was added, dropwise, followed by additional stirring for 16 h at 55 °C. Removal of solvent under reduced pressure at 50 °C afforded a residue, which was then dissolved in 1 mL of methanol. This solution was then added to 15 mL of a 10% aqueous $NaHCO_3$ solution, and the solid collected via filtration and purified by column chromatography (SiO_2, $CHCl_3$/MeOH/H_2O, 120/60/2, v/v/v) affording 80 mg (47%) of **2** having R_f 0.45 (SiO_2, $CHCl_3$/MeOH/H_2O, 120/60/2, v/v/v) and ^1H NMR (CD_3OD, 500 MHz) δ (ppm): 4.07 (m, 4 H), 3.95 (bs, 4 H) 3.79 (m, 8 H), 3.35 (m, 4 H), 3.30−3.10 (m, 12 H), 2.21−0.91 (m, 128 H), 0.71 (s, 12 H). HRMS for $C_{114}H_{190}N_8O_{20}(MNa^+)$: Calcd: 2014.3989. Found: 2014.4086.

Conjugate 3. A solution was prepared from cholic acid succinimide ester (2.0 g, 4 mmol), 10 mL of DMF, 2 mL of DIPEA, and 4-aminobutyric acid (0.404 g, 4 mmol) and stirred at 40 °C for 24 h. Removal of solvent under reduced pressure afforded a residue that was dissolved in 1.5 mL of methanol and then precipitated via the addition of 15 mL of a 10% aqueous $NaHCO_3$ solution. The resulting solid was filtered and purified via column chromatography (SiO_2, $CHCl_3$/MeOH/H_2O, 120/60/1, v/v/v) yielding 1.0 g (55%) of the corresponding 4-aminobutyric acid conjugate of cholic acid having R_f 0.50 (SiO_2, $CHCl_3$/MeOH/H_2O, 120/60/1, v/v/v) and ^1H NMR (CD_3OD 500 MHz) δ (ppm): 3.95 (s, 1 H), 3.78 (s, 1 H), 3.35 (m, 1 H) 3.21 (t, 2 H), 2.30−0.91 (m, 34 H), 0.70 (s, 3 H).

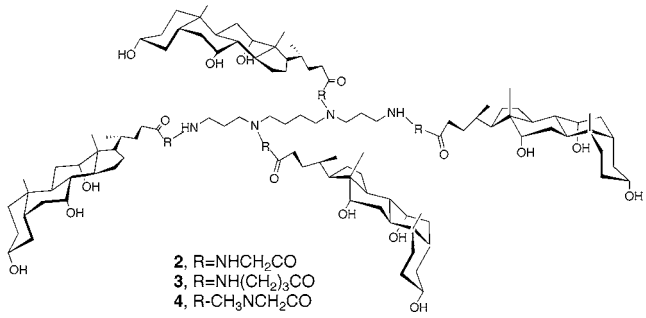
A solution was then made from 0.200 g (0.40 mmol) of the above conjugate, along with 1 mL of DMF, 0.2 mL of DIPEA, and *O*-(3,4-dihydro-4-oxo-1,2,3-benzotriazin-3-yl)-*N*,*N*,*N*′*N*′-tetramethyluronium tetrafluoroborate (0.152 g, 0.44 mmol), which was then stirred at room temperature for 2 h. To this solution was added, dropwise, a solution made from spermine (17.0 mg, 0.084 mmol) and 0.3 mL of DIPEA in 1 mL of DMF, and the resulting solution was stirred at 55 °C for 16 h. Removal of solvent under reduced pressure (50 °C) afforded a residue that was dissolved in 1 mL of methanol. Subsequent precipitation via the addition of 15 mL of a 10% aqueous $NaHCO_3$ solution, followed by filtration and purification via preparative thin-layer chromatography (SiO_2, $CHCl_3$/MeOH/H_2O, 120/73/2, v/v/v), afforded 60 mg (35%) of **3** having R_f 0.50 (SiO_2, $CHCl_3$/MeOH/H_2O, 120/73/2, v/v/v) and ^1H NMR (CD_3OD, 500 MHz) δ (ppm): 3.95 (br s, 4 H), 3.79 (m, 4 H), 3.35 (m, 4 H), 3.30−3.20 (m, 8 H), 3.18 (m, 12 H), 2.21−0.91(m, 144 H), 0.71 (s, 12 H). HRMS for $C_{122}H_{206}N_8O_{20}$ (Na^+) Calcd: 2126.5241. Found: 2126.5343.

Conjugate 4. A solution was prepared from cholic acid succinimide ester (1.015 g, 2 mmol), 7 mL of DMF, 1 mL of DIPEA, and sarcosine (0.178 g, 2 mmol) and allowed to stir at 50 °C for 48 h. The solvent was then removed under reduced pressure, and the residue purified by column chromatography (SiO_2, $CHCl_3$/MeOH/H_2O, 120/100/5, v/v/v) to give 0.450 g (45%) of the corresponding sarcosine conjugate of cholic acid having R_f 0.54 (SiO_2, $CHCl_3$/CH_3OH/H_2O, 120/100/5, v/v/v) and ^1H NMR (D_2O, 500 MHz): δ (ppm): 4.0−3.94 (m, 3 H); 3.79 (s, 1 H), 3.41 (m, 1 H), 2.90 (d, 3 H), 2.31−0.91 (m, 30 H), 0.64 (s, 3 H).

The above conjugate (0.100 g, 0.22 mmol) was dissolved in 0.2 mL of DIPEA plus 1 mL of DMF, followed by addition of *O*-(3,4-dihydro-4-oxo-1,2,3-benzotriazin-3-yl)-*N*,*N*,*N*′*N*′-tetramethyluronium tetrafluoroborate, (0.079 g, 0.23 mmol). This solution was then stirred at room temperature for 2 h, followed by the dropwise addition of a solution made from spermine (8.6 mg, 0.042 mmol)

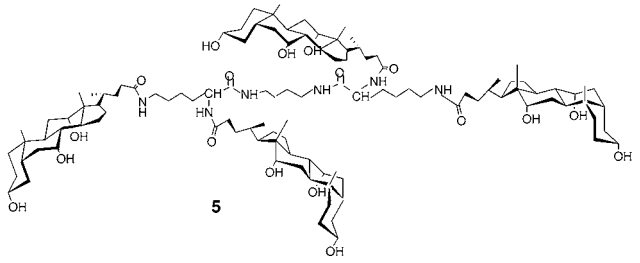
and 0.2 mL of DIPEA in 0.5 mL of DMF; stirring was continued for an additional 16 h. Removal of solvent under reduced pressure (50 °C) afforded a residue that was dissolved in a minimum volume of methanol and added, dropwise, to a stirred 10% aqueous $NaHCO_3$ solution (20 mL). The resulting solid was purified by column chromatography (SiO_2, $CHCl_3$/MeOH/H_2O, 120/80/3, v/v/v) to give 36 mg (45%) of **4** having R_f 0.65 (SiO_2, $CHCl_3$/MeOH/H_2O, 120/80/3, v/v/v) and ^{1}H NMR [$(CD_3)_2$SO, 500 MHz] δ ppm 4.15 (s, 4 H), 3.94 (s, 4 H); 3.83 (s, 4 H), 3.69 (s, 4 H), 3.32−3.13 (m, 16 H), 2.95 (br s, 12 H), 2.41−0.91 (m, 128 H), 0.70 (s, 12 H). HRMS: $C_{118}H_{198}N_8O_{20}$-(Na^+) Calcd: 2070.4615. Found: 2070.4578.

Conjugate 5. A suspension was prepared from cholic acid succinimide ester (0.566 g, 1.12 mmol), 1 mL of DIPEA, lysine (0.078 g, 0.5 mmol), and Na_2CO_3 (0.056 g, 0.5 mmol) in DMF and stirred for 16 h at 50 °C. Removal of solvent under reduced pressure (50 °C) afforded a residue that was dissolved in 1 mL of methanol. This methanolic solution was then added, dropwise, to a saturated aqueous Na_2CO_3 solution with stirring. The precipitate was removed by filtration and purified by column chromatography (SiO_2,$CHCl_3$/MeOH/H_2O, 65/25/4, v/v/v) to give 0.356 g (72%) of the corresponding lysine conjugate of cholic acid having R_f 0.30 (SiO_2,$CHCl_3$/MeOH/H_2O, 65/25/4, v/v/v) and ^{1}H NMR (CD_3OD, 360 MHz) δ ppm 4.25 (m, 1 H), 3.94 (m, 2 H), 3.79 (s, 2 H), 3.35 (m, 2 H); 3.16 (t, 2 H), 2.21−0.91 (m, 66 H), 0.70 (s, 6 H).



The above conjugate (0.100 g, 0.107 mmol) was dissolved in 0.2 mL of DIPEA plus 1 mL of DMF, followed by the addition of *N*,*N*,*N*′,*N*′-tetramethyl-*O*-(*N*-succinimidyl)uronium terafluoroborate (0.039 g, 0.129 mmmol). The resulting solution was then allowed to stir for 2 h at 50 °C. To this solution was added a solution that was made from putrescine (0.3 mL), 0.2 mL of DIPEA, and 0.5 mL of DMF. After stirring for 16 h at 50 °C, the solvent was then removed under reduced pressure (50 °C) and the residue dissolved in 1 mL of methanol. This solution was then added, dropwise, to an 10% aqueous Na_2CO_3 solution. The resulting solid was collected by filtration and purified by column chromatography (SiO_2, $CHCl_3$/MeOH/H_2O, 120/50/2, v/v/v) to give 30 mg (47%) of **5** having R_f 0.55 (SiO_2, $CHCl_3$/MeOH/H_2O, 120/50/2, v/v/v), and ^{1}H NMR [(CD_3OD), 360 MHz]: δ (ppm): 4.25 (m, 2 H), 3.94 (m, 4 H), 3.79 (s, 4 H), 3.35 (m, 4 H), 3.16 (t, 8 H), 2.21−0.91 (m, 136 H), 0.70 (s, 12 H). HRMS for $C_{122}H_{188}N_6O_{18}$(Na^+) Calcd: 1928.3872. Found: 1928.3809.

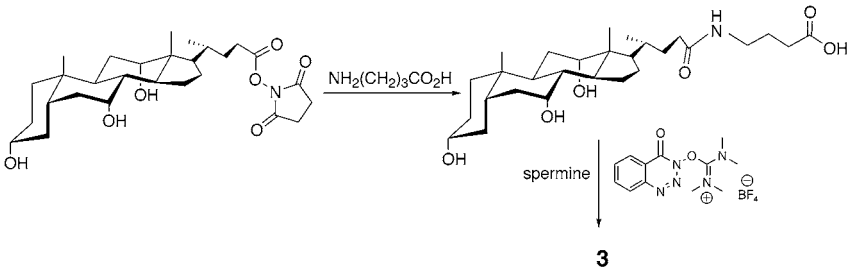
Conjugate 6. To a solution of 5β-cholanic acid-3α,7α-diol (0.106 g, 0.26 mmol) in 0.2 mL of DIPEA plus 1 mL of DMF was added *O*-(3,4-dihydro-4-oxo-1,2,3-benzotriazin-3-yl)-*N*,*N*,*N*′*N*′-tetramethyluronium tetrafluoroborate, (0.096 g, 0.28 mmol). After stirring for 2 h at room temperature, a solution of spermine (12.0 mg, 0.060 mmol) in 0.2 mL of DIPEA plus 0.5 mL of DMF was then added, dropwise, and the mixture was allowed to stir for an additional 16 h at room temperature. Removal of solvent under reduced pressure (50 °C) afforded a residue that was dissolved in 1 mL of methanol. Subsequent precipitation via addition to a saturated aqueous $NaHCO_3$ solution, followed by filtration and purification by preparative thin-layer chromatography (SiO_2, $CHCl_3$/MeOH/H_2O, 100/20/1, v/v/v), afforded 50 mg (50%) of **6** having R_f 0.45 (SiO_2, $CHCl_3$/MeOH/H_2O, 100/20/1, v/v/v) and ^{1}H NMR (CD_3OD 360 MHz) δ (ppm): 3.79 (bs, 4 H), 3.35 (m, 4 H), 3.22−3.36 (m, 8 H), 3.16 (m, 4 H), 2.21−0.91 (m, 136 H), 0.70 (s, 12 H). HRMS for $C_{106}H_{178}N_4O_{12}$-(Na^+) Calcd: 1722.3334. Found: 1722.3235.



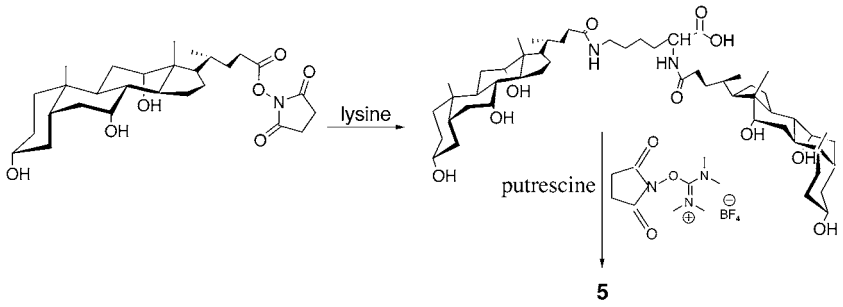
Conjugate 7. To a solution of 5β-cholanic acid-3α,12α-diol (0.106 g, 0.27 mmol) in 0.2 mL of DIPEA plus 1 mL DMF was added *O*-(3,4-dihydro-4-oxo-1,2,3-benzotriazin-3-yl)-*N*,*N*,*N*′*N*′-tetramethyluronium tetrafluoroborate, (0.096 g, 0.28 mmol). After stirring the mixture at room temperature for 2 h, a solution of spermine (12.0 mg, 0.060 mmol) and 0.2 mL of DIPEA plus 0.5 mL of DMF was added, dropwise, and the mixture was allowed to stir for an additional 16 h at room temperature. Removal of solvent under reduced pressure (50 °C) afforded a residue that was dissolved in 1 mL of methanol. Subsequent precipitation via addition to an aqueous solution that was saturated with $NaHCO_3$, and purification by preparative thin-layer chromatography (SiO_2, $CHCl_3$/MeOH/H_2O, 100/20/1, v/v/v), afforded 55 mg (55%) of **7** having R_f 0.50 (SiO_2, $CHCl_3$/MeOH/H_2O, 100/20/1, v/v/v) and ^{1}H NMR (CD_3OD, 360 MHz) δ (ppm): 3.90 (bs, 4 H), 3.35 (m, 4 H), 3.22−3.36 (m, 8 H), 3.16 (m, 4 H), 2.21−0.91 (m, 136 H), 0.70 (s, 12 H). HRMS for $C_{106}H_{178}N_4O_{12}$(Na^+) Calcd: 1722.3334. Found: 1722.3298.

RESULTS AND DISCUSSION

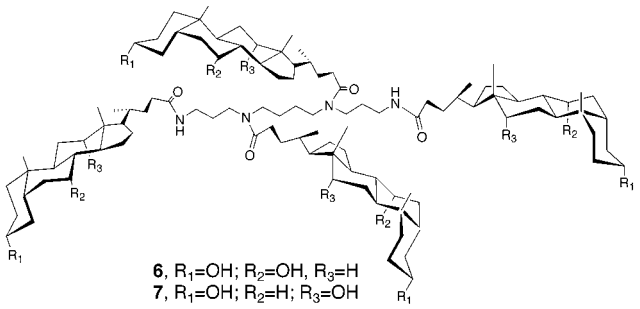
Ion Conductors from Biogenic Precursors. The specific molecules that were chosen as synthetic targets for this work were **2**, **3**, **4**, **5**, **6**, and **7**. Conjugates **2** and **3**, bearing sterols derived from glycocholic acid and a



conjugate of cholic acid plus γ-amino butyric acid, respectively, extend the distance between each facial amphiphile and the spermine backbone, relative to **1**; at the same time, they add four secondary amide groups, each of which may act as a hydrogen bond donor or acceptor—a feature that could promote aggregation of the ion conductor, leading to increased activity. Ion conductor **4**, which bears facial amphiphiles made from a conjugate of sarcosine and cholic acid, is an analogue of **2**. In this case, each of the four additional amide groups can only function as hydrogen bond acceptors. Conjugate **5**, de-



rived from four molecules of cholic acid, two lysine molecules, and one putrescine unit, may be viewed as an "expanded" analogue of **1**, which also has additional space between each of the sterol units. In addition, this conjugate contains a total of six secondary amide groups.



Scheme 2

Scheme 3

Finally, conjugates **6** and **7** are close analogues of **1**

having increased hydrophobicity; in this case, the hydroxyl group at the C12 and C7 carbons have been replaced by hydrogen atoms, respectively.

Conjugate **2** was synthesized by direct condensation of glycocholic acid with spermine (not shown). Conjugate **3** was prepared by first coupling γ-amino butryic acid to the cholic acid framework (Scheme 2); conjugate **4** was prepared similarly, using sarcosine in place of γ-amino butryic acid. Acylation of both amino groups of lysine with an activated form of cholic acid, followed by condensation of the resulting carboxylic acid with putrescine afforded **5** (Scheme 3). Finally, conjugates **6** and **7** were obtained by direct condensation of spermine with 3α,7α-dihydroxycholic acid and 3α,12α-dihydroxycholic acid, respectively (not shown).

Ion Conducting Properties. Liposomes that were used as model membranes in this work were in the form of 200 nm diameter unilamellar vesicles. Under the conditions used (i.e., 35 °C), liposomes derived from **C***14*, as well as from **C***16*, were maintained in the physiologically relevant fluid phase.

Using procedures similar to those that have been described in detail elsewhere, the rate at which Na^+ crosses these liposomal membranes was measured via $^{23}Na^+$ NMR spectroscopy (*1l, 4*). In all cases, varying percentages of ion conductor were introduced into the liposomes at the time of their preparation (i.e., "double-sided addition"). For these experiments, a membrane-impermeable paramagnetic shift reagent was added to the external aqueous phase so that liposomal-entrapped and external Na^+ could be distinguished. In all cases, pseudo-first-order rate constants (k_{obsd}) exhibited a second-order dependency on the mol % of the conjugate that was present. For one such experiment, where vesicles were made from **C***16*, and **2** was used as an ion conductor, both the rate of $^{23}Na^+$ influx and the rate of $^{7}Li^+$ efflux were monitored, simultaneously. Within experimental error, the rate constants for both transport processes were identical. This finding lends support for an antiport mechanism of transport. Figure 1 shows typical plots for k_{obsd} versus (mol % of **2**) (*2*) for the two different membranes investigated (**C***14* and **C***16*). As discussed previously, the linearity of such plots indicates that transport-active dimers are involved (*1g*). Here, it is assumed that only a small fraction of the conjugate is aggregated, where it can be shown that:

$$k_{obsd} = k_2[\text{monomer}]^2/K$$

where K is the equilibrium constant for dissociation of the dimer, k_2 is the rate constant for ion transport, and

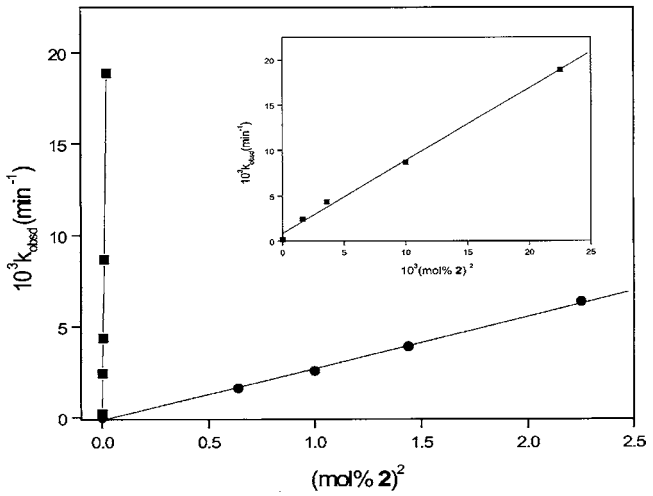


Figure 1. Plot of k_{obsd} versus (mol % **2**)^2 for vesicles made from (■) **C***14* and (●) **C***16* at 35 °C; inset shows data for **C***14* with an expanded *x*-axis.

Table 1. Ion Conducting Activities and Membrane Selectivities[a]

ion conductor	lipid	$10^4\ k_2/K$ (min^{-1} mol $\%^{-2}$)	S (**C***14*/**C***16*)
1	**C***14*	190000	1500
	C*16*	130	
2	**C***14*	8000	290
	C*16*	28	
3	**C***14*	54000	965
	C*16*	56	
4	**C***14*	29200	750
	C*16*	39	
5	**C***14*	35000	2258
	C*16*	15.5	
6	**C***14*	10560	297
	C*16*	35.6	
7	**C***14*	6028	262
	C16	23	

[a] All kinetic experiments were carried out at 35 °C; the error in k_{obsd} is estimated to be ±10%.

[monomer] is the analytical concentration of the ion conductor that is present in the dispersion.

Specific values of k_2/K that have been determined for **2**, **3**, **4**, **5**, **6**, and **7** are shown in Table 1. Since k_2 and K cannot be separated by such analysis, we are limited to operational comparisons among the conjugates. Also listed in Table 1 are membrane-selectivity factors, S, which represent the ratio of $(k_2/K)_{14}/(k_2/K)_{16}$, where *14* and *16* refer to liposomes derived from **C***14* and **C***16*, respectively.

In all cases, significant ion conductivity was observed. When the thicker **C***16* membranes were used as model systems, the differences in ion conducting activity were modest. Thus, the conjugate having the highest activity (**3**) and the one having the lowest activity (**5**), within the series **2**−**7**, differed by a factor of ca. 4. In addition, conjugate **1** was only ca. two times more active than **3**. In the thinner **C***14* membranes, however, the differences in activity were more pronounced. In this case, **3**, having the greatest activity, was ca. nine times more active than **7**. A greater difference in activity within the thinner membrane was also apparent when **1** was compared to analogues **6** and **7**. Here, removal of a single hydroxyl group from each of the sterols resulted in a reduction in Na^+ transport activity by factors of 18 and 32, respectively. An examination of the S factors in Table 1 further reveals that membrane selectivities range from 262 for **7** to 2258 for **5**. Thus, both the activity and membrane selectivity show a significant dependency on the structure and the composition of the ion conductor.

In a broader context, the present findings demonstrate the generality of our design principle. Thus, all members within this family of conjugates derived from spermine, putrescine, lysine, γ-aminobutyric acid, sarcosine, cholic acid, glycocholic acid, 3α,7α-dihydroxycholic acid, and 3α,12α-dihydroxycholic acid showed significant activity in promoting the transport of Na^+ across phospholipid membranes. Whether the observed variations in activity and membrane selectivity are due to differences in intrinsic activities (i.e., k_2) or to the extent of aggregation (K) remains to be established. In addition, the extent to which each of these conjugates is drawn into the membrane via conformation **B** (Scheme 1) is uncertain. Thus, one can rationalize the greater activity of **1**, relative to **6** and **7** in terms of a greater percentage of **1** being drawn into the bilayer through a larger number of intramolecular hydrogen bonds in conformation **B**. Alternatively, the larger number of hydroxyl groups of **1** could increase the extent of hydration of the pathway for diffusion, which, in turn, could facilitate the flow of ions; that is, its intrinsic activity could be higher. Depsite these uncertainties, the results reported herein demonstrate the feasibility of constructing an entire family of ion conductors that span a moderate range of ion transport properties, based on biogenic precursors. Efforts aimed at extending this approach with a view toward drug design are continuing in our laboratories.

Plasmid DNA-Entrapped Nanoparticles Engineered from Microemulsion Precursors: In Vitro and in Vivo Evaluation

Zhengrong Cui and Russell J. Mumper*

Division of Pharmaceutical Sciences, College of Pharmacy, University of Kentucky, Lexington, Kentucky 40536-0082. Received June 10, 2002; Revised Manuscript Received July 29, 2002

Nonviral gene therapy has been a rapidly growing field. However, delivery systems that can provide protection for pDNA and potential targeting are still desired. A novel pDNA−nanoparticle delivery system was developed by entrapping hydrophobized pDNA inside nanoparticles engineered from oil-in-water (O/W) microemulsion precursors. Plasmid DNA was hydrophobized by complexing with cationic surfactants DOTAP and DDAB. Warm O/W microemulsions were prepared at 50−55 °C with emulsifying wax, Brij 78, Tween 20, and Tween 80. Nanoparticles were engineered by simply cooling the O/W microemulsions containing the hydrophobized pDNA in the oil phase to room temperature while stirring. The nanoparticles were characterized by particle sizing, zeta-potential, and TEM. Nanoparticles were challenged with serum nucleases to assess pDNA stability. In addition, the nanoparticles were coincubated with simulated biological media to assess their stability. In vitro hepatocyte transfection studies were completed with uncoated nanoparticles or nanoparticles coated with pullulan, a hepatocyte targeting ligand. In vivo biodistribution of the nanoparticles containing I-125 labeled pDNA was monitored 30 min after tail-vein injection to Balb/C mice. Depending on the hydrophobizing lipid agent employed, uniform pDNA-entrapped nanoparticles (100−160 nm in diameter) were engineered within minutes from warm O/W microemulsion precursors. The nanoparticles were negatively charged (−6 to −15 mV) and spherical. An anionic exchange column was used to separate unentrapped pDNA from nanoparticles. Gel permeation chromatography of pDNA-entrapped and serum-digested nanoparticles showed that the incorporation efficiency was ∼30%. Free 'naked' pDNA was completely digested by serum nucleases while the entrapped pDNA remained intact. Moreover, in vitro transfection studies in Hep G2 cells showed that pullulan-coated nanoparticles resulted in enhanced luciferase expression, compared to both pDNA alone and uncoated nanoparticles. Preincubation of the cells with free pullulan inhibited the transfection. Finally, 30 min after tail vein injection to mice, only 16% of the 'naked' pDNA remained in the circulating blood compared to over 40% of the entrapped pDNA. Due to the apparent stability of these pDNA-entrapped nanoparticles in the blood, they may have potential for systemic gene therapy applications requiring cell and/or tissue-specific delivery.

INTRODUCTION

Gene therapy has attracted a great deal of attention in recent years. The current gene delivery systems can be divided into two categories: (1) viral-based systems, and (2) non-viral-based systems. Delivery of interesting genes with viral vectors has proven to the most efficient method. However, potential toxicity, including mutagenesis and carcinogenesis, from the viral vectors presents a major limitation. In contrast, delivery of genes with plasmid DNA (pDNA) may be much safer, and perhaps more pharmaceutically acceptable. However, the efficiency of current non-viral-based systems is very poor (Rolland and Felgner, 1998; Liu and Huang, 2002). Moreover, due to the presence of serum nucleases in the blood and the rapid clearance rate of pDNA, improved formulations and delivery systems for pDNA are needed for successful systemic gene therapy (Kawabata et al., 1995; Mahato et al., 1995a; Yoshida et al., 1997; Houk et al., 2001).

To date, many pDNA delivery systems, including lipoplexes (Clark and Hersh, 1999; Ishiwata et al., 2000), polyplexes (Nishikawa et al., 2000a and 2000b; Oh et al., 2001; Verbaan et al., 2001), and lipopolyplexes (Liu and Huang, 2002), have been developed. However, in general, these systems remain very sensitive to serum challenge. Moreover, these systems tend to aggregate due to extensive interaction with serum proteins and/or self-association in the blood (Chesnoy and Huang, 2000). Therefore, when administered by intravenous injection, these systems tend to accumulate into the lung. Significant work has been done to improve these systems and overcome the stated limitations. For example, for lipoplexes, complexes of cationic lipids or liposomes with pDNA, careful balance of the hydrophilicity/lipophilicity of the surface of the lipoplex particle, modification of the surface charge, and/or deposition of "shielding" agents such as poly(ethylene glycol) (PEG) on the surface of the lipoplexes, has proven to be able to extend the circulation of the complexes and therefore lead to increased distribution of pDNA to distal sites of interest (Ishiwata et al., 2000; Patel, 1992; Hong et al., 2002).

Despite some promising leads using the complexes described above, delivery systems that protect pDNA from serum nuclease digestion, provide stability for

Published on Web 10/12/2002

prolonged circulation in blood, and that can be easily modified for potential cell or tissue targeting are still needed. Recently, researchers have attempted to encapsulate or entrap pDNA inside stable lipid-based particles for potential systemic administration. Wheeler et al. described a method to prepare stabilized plasmid−lipid particles (SPLP) (around 70 nm in diameter) using a detergent dialysis procedure (Wheeler et al., 1999). The particles allowed for the encapsulation of pDNA within a lipid envelope, which in turn protected the plasmid from digestion by serum nucleases. The particles were further stabilized in aqueous media by PEG coating. The particles demonstrated extended circulation with approximately 10% of the intravenously injected dose accumulating in a distal tumor. Further, Bailey and Sullivan have described the encapsulation of pDNA in neutral liposomes (Bailey and Sullivan, 2000). Lipoproteins, or emulsion particles that consist of lipids and apolipoproteins, have also been described by Hara et al. (1997b). This group took advantage of the hydrophobic interior of these natural emulsions to solubilize DNA. Negatively charged DNA was first complexed with cationic lipids containing a quaternary amine headgroup. The resulting hydrophobized complex was extracted by chloroform and then incorporated into reconstituted chylomicron remnant particles (∼100 nm in diameter) with an efficiency of ∼65%. When injected into the portal vein of mice, the level of transgene expression in the liver was ∼100-fold greater than that of mice injected with 'naked' pDNA. Histochemical examination revealed that a large number of parenchymal cells and other types of cells in the liver expressed the transgene. Unfortunately, very poor expression was found in the liver after tail vein injection. In addition, other pDNA encapsulated cationic emulsions have been reported (Hara et al., 1997a). For example, Hara et al. formed a hydrophobic complex of pDNA with DC-Chol (3β[*N*-(*N*′,*N*′-dimethylaminoethane)carbamoyl]-cholesterol) and then encapsulated the complex into the oil core of emulsion prepared with castor oil, Tween 80, phosphatidylcholine, and DOPE (dioleoylphosphatidylethanolamine). More recently, Chesnoy et al. described stabilization of pDNA encapsulated cationic emulsions by coating with PEG (Chesnoy et al., 2001). Compared to the unmodified emulsions, stabilization with PEG (9−10%, w/w) significantly decreased the plasma clearance and liver uptake of the emulsion.

Our laboratories have likewise been interested in the development of improved nanoparticle-based pDNA delivery systems. Previously, we reported on a novel method to engineer stable cationic nanoparticles (∼100 nm) from oil-in-water (O/W) microemulsion precursors, comprised of emulsifying wax as the oil phase and CATB (cetyltrimethylammonium bromide) as the cationic surfactant (Cui and Mumper, 2002a and 2002b). Using this method, uniform nanoparticles were engineered within minutes in a single vessel without the use of organic solvents or the application of high torque mechanical mixing. Plasmid DNA was then coated on the surface of these preformed cationic nanoparticles and administered to mice resulting in significant enhancements in humoral, Th1-type, and proliferative immune responses over 'naked' pDNA after both topical and subcutaneous administration to mice.

In these present studies, we sought to further explore this novel nanoparticle engineering method by entrapping pDNA inside the nanoparticles. These pDNA-entrapped nanoparticles were characterized and evaluated both in vitro and in vivo.

EXPERIMENTAL PROCEDURES

Reagents. Plasmid containing a CMV promoter luciferase gene (pCMV-luc, 4.7 kp) was a gift from Valentis, Inc. (The Woodlands, TX). I-125 labeled plasmid pBR332 was purchased from the Lofstrand Labs, Ltd. (Gaithersburg, MD). Emulsifying wax, Tween 20, and Tween 80 were from Spectrum Chemical (New Brunswick, NJ). Brij 78 was a free sample from Uniqema (Wilmington, DE). Dimethyldioctadecylammonium bromide (DDAB), diethylaminoethyl (DEAE) Sepharose CL-6B anion exchanger, and mouse serum were purchased from Sigma-Aldrich Corporation (St. Louis, MO). 1.2-Dioleoyl-3-trimethylammoniopropane (DOTAP) and dioleoyl phosphotidylethanolamine (DOPE) were purchased from Avanti Polar Lipids, Inc. (Alabaster, AL). Sepharose CL-4B was purchased from Amersham Pharmacia Biotech, Inc. (Piscataway, NJ). Luciferase assay kits were purchased from Promega Corporation (Madison, WI). {*N*-[2-(Cholesterylcarboxyamino)ethyl]carbamorylmethyl}-pullulan (Chol-pullulan) was purchased from Dojindo Molecular Technologies, Inc. (Gaithersburg, MD). Lipofectin reagent was from Gibco BRL, Life Technologies (Gaithersburg, MD).

Bligh and Dyer Extraction. Bligh and Dyer extraction was performed as described by Reimer et al. with slight modification (Reimer et al., 1995). Briefly, DDAB or DOTAP and pDNA were solubilized in the monophase of chloroform/methanol/water (1:2.1:1 v/v/v). The pDNA concentration was fixed at 10 μg/mL while the concentrations of the lipids were varied so that the charge ratios of the cationic lipid to the pDNA were ranged from 0:1 to 2:1 (±). The mixtures were incubated at room temperature for 30 min in a total volume of 1 mL and then were partitioned into two phases by the addition of water and chloroform (250 μL each). The two phases were briefly mixed by vortexing. After a further incubation of 15 min, the lower organic phase and the upper aqueous phase were separated by centrifugation at 14000 rpm at room temperature for 5 min. The aqueous phase was removed and diluted with water, if necessary, for determination of the pDNA concentration using a F-2000 Fluorescence Spectrophotometer (Hitachi Instruments, Danbury, CT) after staining with PicoGreen (Molecular Probes, Eugene, OR).

DDAB/pDNA and DOTAP/pDNA complexes with charge ratio of 1:1 (±) were used to investigate the dissociation of these complexes by NaCl. Briefly, cationic lipid/pDNA complexes (1:1 ±) were prepared in Bligh and Dyer monophases. The required amount of NaCl (2 M in water) was then added into the monophase system. After 15 min of incubation at room temperature, Bligh and Dyer extractions and pDNA concentration determination were performed as described above.

Engineering of pDNA-Entrapped Nanoparticles. Nanoparticles were cured from warm microemulsion precursors engineered as previously described with modifications (Cui and Mumper, 2002a and 2002b). Cationic lipid/pDNA complexes (1:1 ±; pDNA concentration of 10 or 30 μg) were prepared in the monophase as described above. After Bligh and Dyer extraction, the lower organic phase was collected. Consequently, depending on the amount of pDNA formulated, either 2 or 6 mg of emulsifying wax was dissolved into this organic phase. The organic phase was then evaporated at room temperature to obtain a dried mixture of emulsifying wax and cationic lipid/pDNA complexes in glass scintillation vials. After melting of the mixture at 50−55 °C, a required volume of deionized and filtered (0.22 μm) water was

added to the vial. The suspension was vigorously stirred at 50−55 °C until a homogeneous milky slurry was formed. Then, required volumes of Brij 78 (100 mM in water), Tween 20 (1/4, w/w in water), and/or Tween 80 (1/4, w/w in water) were added while stirring. Stirring was maintained until a clear transparent microemulsion system was formed (within 3−5 min). The microemulsions, if formed, were then cooled to room temperature while stirring to cure nanoparticles. DOPE (5% w/w) was incorporated in the nanoparticles as previously described (Cui and Mumper, 2002a and 2002b).

For comparison and as a control, empty cationic nanoparticles with no pDNA were also prepared as previously described while maintaining the identical concentrations of all components. Plasmid DNA was then added to the preformed suspension for adsorption on the surface of the nanoparticles.

Physical Characterization of Nanoparticles. The nanoparticle size was measured by photon correlation spectroscopy (PCS) using a Coulter N4 Plus Submicron Particle Sizer (Coulter, Miami, FL) by scattering light at 90° at 25 °C for 120 s for each 1 mL sample. The zeta potentials of the nanoparticles were measured using a Zeta Sizer 2000 from Malvern Instruments (Southborough, MA).

Gel Permeation Chromatography. Nanoparticle purification and confirmation of pDNA entrapment were completed using gel permeation chromatography (GPC). For all GPC, 100 μL samples were applied to either Sepharose CL-4B or DEAE Sepharose CL-6B columns (10 × 55 mm). The samples were eluted with 5 mM HEPES in 150 mM NaCl pH 7.4 (HBS), and the fractions (0.5 mL) were assessed for pDNA concentration using either a gamma counter (for I-125 labeled pDNA) or PicoGreen fluorescence assay (for unlabeled pDNA). If the samples applied were nanoparticle suspension, the counts per second (CPS, an indication of nanoparticle concentration) of all eluted fractions were also measured with Coulter N4 Plus Submicron Particle Sizer.

Serum Stability Assays. The in vitro stability of the pDNA in the presence of mouse serum nucleases was investigated by mixing 50 μL of either pCMV-luc or nanoparticle suspensions (prepared with pCMV-luc and trace amount of I-125 labeled pBR332) with 150 μL of mouse serum (Sigma-Aldrich). The mixture was then allowed to remain at room temperature for 8 h for enzymatic digestion of the plasmid. One hundred microliters (100 μL) of the samples, before and after serum digestion, were applied to Sepharose CL-4B column as mentioned above to confirm the protection of pDNA from serum nucleases after entrapment in the nanoparticles. Intact pDNA eluded out in the void volume while digested pDNA was fractionated.

Stability of the Entrapped pDNA Extracted from the Nanoparticles. To investigate the stability of the pDNA after entrapment, pDNA was extracted from purified nanoparticles and was applied on a 1% Seakem Gold Agarose Ready-to-use Gel from BioWhittaker Molecular Applications (Rockland, ME) for electrophoresis. Specifically, nanoparticles containing DOTAP complexed pDNA (30 μg/mL) were prepared (see nanoparticle Composition **II**). The nanoparticles were purified with DEAE Sepharose CL-6B column and reconcentrated using ultrafiltration (100 kDa molecular weight cutoff, Brinkmann Instruments, Inc., Westbury, NY). The purified and concentrated nanoparticle suspensions were air-dried in a 37 °C incubator to form a dry nanoparticle powder. A combination of 200 μL of chloroform, 200 μL of NaCl solution (150 mM), and 420 μL of methanol were added to the nanoparticle dry powder. This mixed Bligh & Dyer system was then gently stirred for 30 min on hot plate maintained at 50−55 °C. Plasmid DNA was finally partitioned with water and chloroform (100 μL each) into the upper aqueous phase as mentioned above. The pDNA in the aqueous phase was then used for gel electrophoresis analysis. For comparison, pDNA was also extracted from a physical mixture of emulsifying wax with pDNA/DOTAP complexes. The extraction procedure was the same as that used for the pDNA-entrapped nanoparticles.

Chol-Pullulan Coated Nanoparticles. Chol-pullulan was deposited on the surface of the nanoparticles using a previously described method (Cui and Mumper, 2002a and 2002b). Briefly, 250 μg of chol-pullulan (suspension in water, 5 mg/mL) was added into the preformed warm microemulsions. After being stirred at 50−55 °C for 5 min, the microemulsions were cooled to room temperature while stirring to form nanoparticles. Overnight stirring at room temperature was continued for complete deposition of pullulan on the surface of the nanoparticles. Free surfactants and chol-pullulan were removed by GPC using a DEAE Sepharose CL-6B column.

Stability of the Nanoparticles in Simulated Biological Media. The stability of the nanoparticles, coated or uncoated with pullulan, in either normal saline (0.9% w/v NaCl) or 10% (v/v) fetal bovine serum (FBS) in normal saline was monitored as previously described by diluting the nanoparticle suspensions in these media and measuring the particle size over 30 min at 37 °C.

In Vitro Hep G2 Cell Transfection. In vitro cell transfection studies were completed as previously described (Cui and Mumper, 2002a and 2002b). Hep G2 cells were obtained from American Type Culture Collection (ATCC, Rockville, MD) and were maintained in Eagle's Minimum Essential Medium (EMEM) (Gibco, BRL) containing 10% fetal bovine serum (Gibco, BRL) and 1% penicillin−streptomycin (Gibco, BRL). Transfections were performed on cells that were approximately 80% confluent. Cells were plated in 48 well plates at a density of 5×10^5 cells/well and incubated overnight. The cells were coincubated with the formulations to provide a final plasmid (pCMV-luc) concentration of 2 μg/well. After 4 h of coincubation, the medium was replaced with fresh EMEM medium. Cells were harvested 48 h later by removing the medium, washing with 1X PBS buffer (three times), and then adding 200 μL 1 × lysis buffer (Promega), leaving for 5−10 min and freeze−thawing three times. A 20 μL sample was assayed for luciferase activity by injecting 100 μL reconstituted luciferase assay solution (Promega) and measuring the light produced for a period of 10 s using a ML2250 Dynatech Luminometer (Dynatech Laboratories, Chantilly, CA). The protein content of a 20 μL sample of the supernatant was determined using the Coomassie Plus Protein Assay Reagent (Pierce). In one treatment, the Hep G2 cells were preincubated with 100 μg of chol-pullulan for 5 min before the addition of the pullulan-coated pDNA-entrapped nanoparticles. As recommended by Dynatech, luciferase expression data were reported as the ratio of the full integral of the samples to that of the negative control, divided by the total amount of protein in the 20 μL of samples assayed.

Biodistribution of Nanoparticles after Tail-Vein Injection to Mice. Ten to twelve week old female Balb/C mice (average weight, 18 g) from Harlan Sprague−Dawley Laboratories were used for the animal studies. NIH guidelines for the care and use of laboratory animal were observed. The mice were anesthetized and then

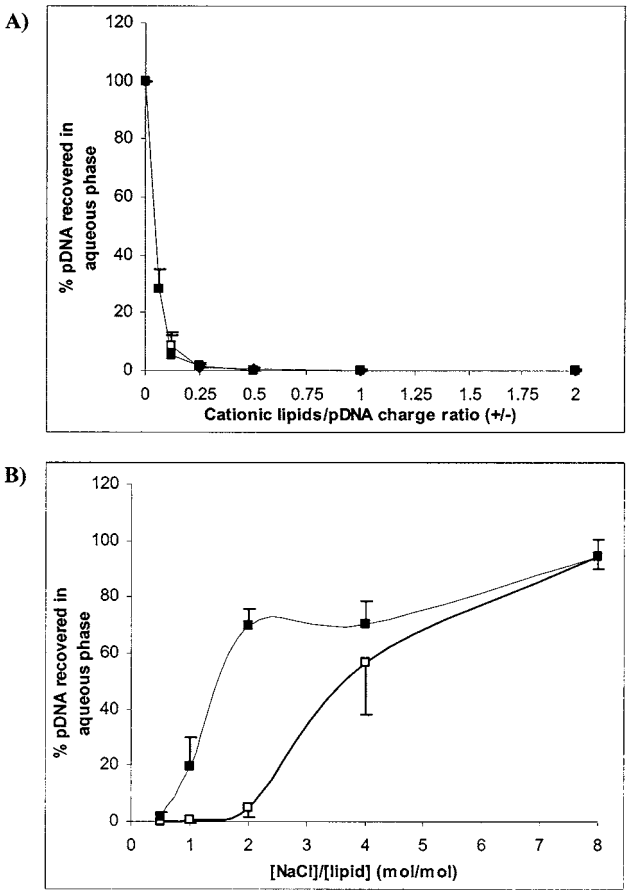

Figure 1. (A) The effect of increasing amounts of either DDAB (■) or DOTAP (□) on the recovery of pDNA in the upper aqueous phase following Bligh and Dyer extraction of the lipid/pDNA complexes (see Materials and Methods). (B) The effect of increasing amounts of NaCl on the recovery of pDNA from the aqueous phase following Bligh and Dyer extraction. The pDNA used was 10 μg. The charge ratio for the lipid vs pDNA was 1:1 (±). All data points are shown as the mean ± SD (n = 3).

injected via the tail vein with 200 μL (2 μg pDNA) of either pDNA alone in normal saline (n = 5), pDNA-entrapped nanoparticles (n = 5), and pullulan-coated pDNA-entrapped nanoparticles coated with pullulan (n = 7). The nanoparticles were purified using normal saline as the mobile phase before injection. In all formulations, a trace amount of I-125 labeled pDNA was included. Thirty minutes after tail-vein injection, blood (400 μL) was collected by cardiac puncture. The liver, lungs, heart, spleen, kidneys, and tail of the mice were also collected. Radioactivity in each sample was determined using a Cobra II Auto Gamma Counter from Packard BioScience Company (Meriden, CT). The total blood volume of a mouse was assumed to be 7.5% (v/w) of the total mouse weight (Mosqueira et al., 2001).

RESULTS AND DISCUSSION

Hydrophobizing Plasmid DNA. Cationic lipids have previously been used to complex pDNA by electrostatic interaction and thereby increase the lipophilicity of pDNA (Reimer et al., 1995). As expected, if pDNA alone was added into the Bligh and Dyer monophase system, almost all of the pDNA was recovered in the aqueous phase (Figure 1A). However, by complexing the pDNA with an increasing amount of either DDAB or DOTAP, a correspondingly decreasing amount of pDNA was recovered in the aqueous phase. In fact, starting from a charge ratio of 0.5:1 (±), no detectable pDNA was

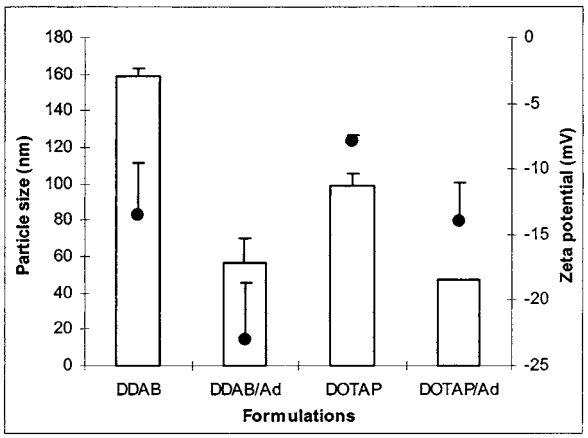

Figure 2. Particle size and zeta potential nanoparticles engineered from microemulsion precursors. DDAB = Composition **I** (pDNA-entrapped nanoparticles); DDAB/Ad = pDNA added to preformed nanoparticles having Composition **I**; DOTAP = Composition **II** (pDNA-entrapped nanoparticles); DOTAP/Ad = pDNA added to preformed nanoparticles having Composition **II**. (●) represents zeta potential measurements. All data points are shown as the mean ± SD (n = 3).

recovered from the aqueous phase as determined using the PicoGreen fluorescence DNA quantification assay. These results demonstrated that both DDAB and DOTAP can be used to hydrophobize pDNA.

To confirm that the complex formation was due to electrostatic interaction, and to determine the concentration of NaCl required to disrupt the formation of cationic lipids/pDNA complexes in Bligh and Dyer monophase system, an increasing amount of NaCl was added into the monophase system formed with either DDAB or DOTAP at a charge ratio of 1:1 (±) before extraction. As shown in Figure 1B, the addition of NaCl disrupted the cationic lipids/pDNA complexes and prevented the partition of pDNA into the lower organic phase. At a molar ratio of NaCl to cationic lipid of 8:1, binding of pDNA to both cationic lipids, was completely prevented, leading to almost no pDNA partitioning into the organic phase. This effective NaCl concentration was estimated to be only ~8 mM.

Preparation and Characterization of pDNA-Entrapped Nanoparticles. In formulation optimization studies, a matrix of various excipient combinations were tested to identify those systems that formed a clear and transparent microemulsion at 50−55 °C. After varying the concentrations of surfactants including Brij 78, Tween 20, and Tween 80, two different nanoparticle compositions were selected for further studies by monitoring the clarity of the microemulsions and measuring the size and uniformity of the cured nanoparticles. The two nanoparticle compositions were Composition **I**: 1:1 charge ratio (±) of either DDAB or DOTAP with pDNA (final pDNA concentration: 10 μg/mL), emulsifying wax (2 mg/mL), Brij 78 (5 mM), and Tween 20 (15 mM); and Composition **II**: 1:1 charge (±) ratio of either DDAB or DOTAP with pDNA (final pDNA concentration: 30 μg/mL), emulsifying wax (6 mg/mL), Brij 78 (14 mM), and Tween 20 (22 mM), and Tween 80 (2 mM).

Shown in Figure 2 are the particle sizes and zeta potentials of two representative nanoparticles. The DDAB containing nanoparticles (Composition **I**) had particle size and zeta potential of 159 ± 4 nm and −13.5 ± 4 mV, respectively. The DOTAP-containing nanoparticles (Composition **II**) had particle size and zeta potential of 99 ± 7 nm and −7.9 ± 0.5 mV, respectively. Figure 3 shows the distribution of the nanoparticles obtained from the

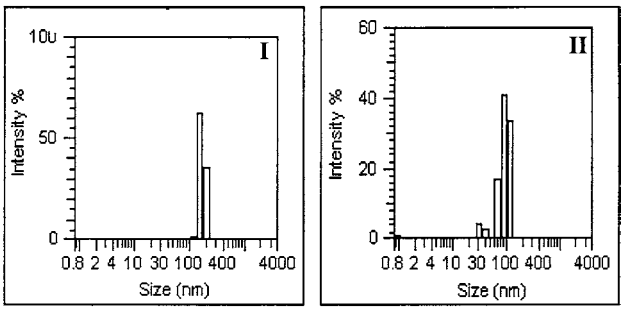

Figure 3. The particle size distribution of pDNA-entrapped nanoparticles (Composition **I** and **II**).

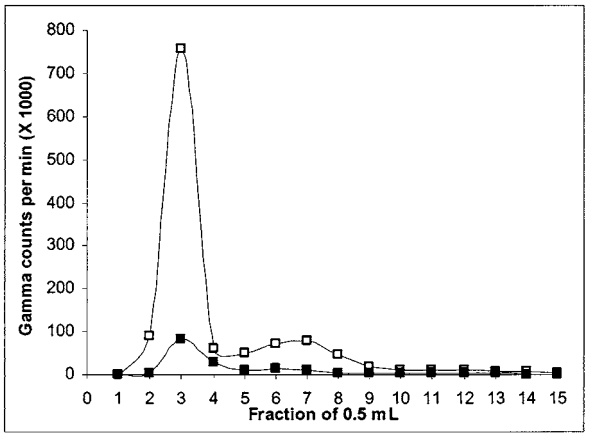

Figure 4. Gel permeation chromatograph (GPC) of pDNA with Sepharose CL-4B (□) or DEAE Sepharose CL-6B (■). A trace amount of I-125 labeled pDNA was included in the formulations. Columns were equilibrated and eluted with 5 mM HEPES in 150 mM NaCl pH 7.4 (HBS).

particle sizer. The very narrow distribution demonstrated that the nanoparticles were uniform. Moreover, the nanoparticles were spherical as demonstrated by TEM (data not shown).

Also shown in Figure 2 are nanoparticles (Composition **I** and **II**) as mentioned above except that the pDNA was added into preformed cationic nanoparticle suspensions for adsorption ("Ad"). Both particle size and zeta potential of these pDNA-coated nanoparticles were significantly different from that of the pDNA-entrapped nanoparticles. The particle size data showed that the entrapment of pDNA in nanoparticles resulted in larger nanoparticles, perhaps due to issues relating to packing of the lipid/pDNA complexes in the nanoparticles.

Confirmation of Plasmid DNA Entrapment in the Nanoparticles. The following studies were carried out to further confirm the entrapment of pDNA in the nanoparticles and to estimate the entrapment efficiency.

Using a Sepharose CL-4B column, pDNA eluted out mostly in fraction number 3 (void volume) demonstrated by the highest CPM in this fraction (Figure 4). However, as expected, the positively charged DEAE Sepharose CL-6B column efficiently bound most of the pDNA (>90%) (Figure 4). In contrast, after entrapment of the same pDNA into the nanoparticles, DEAE Sepharose CL-6B column was no long able to retard most of the pDNA from eluting out for both the Composition **I** nanoparticles (Figure 5A) and the Composition **II** nanoparticles (Figure 5B). Moreover, the nanoparticle eluent profiles, estimated by the counts per second (CPS), overlapped with the CPM strongly suggesting the association of pDNA with the nanoparticles.

The presence of pDNA inside the nanoparticles was further confirmed by an in vitro mouse serum digestion

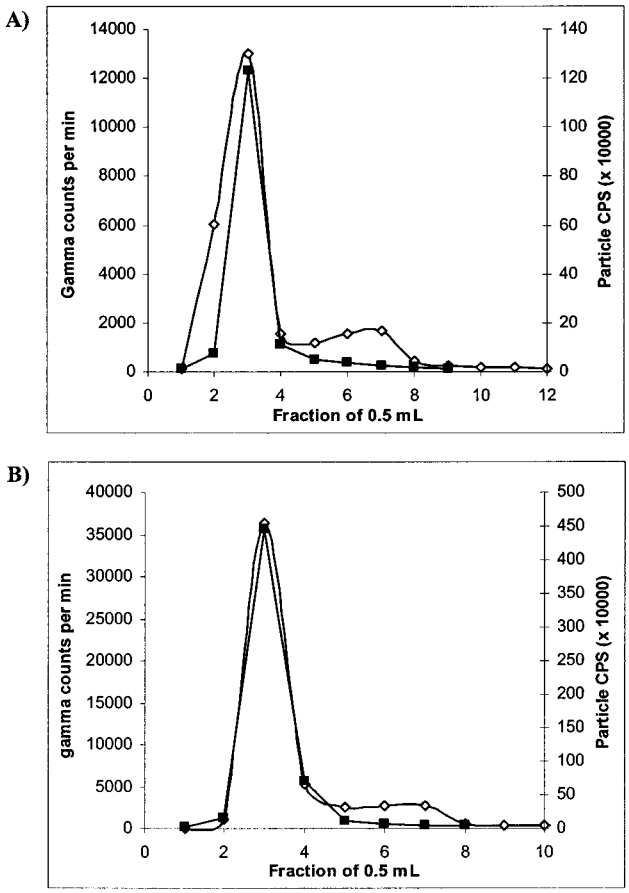

Figure 5. Gel permeation chromatograph of pDNA-entrapped nanoparticles. A trace amount of I-125 labeled pDNA was included in the formulations. One hundred microliters of nanoparticle suspensions was passed through the DEAE Sepharose CL-6B column. Eluent fractions (0.5 mL) were collected and measured in a gamma counter and particle sizer to determine radioactivity (counts per minute, CPM, ◊) and particle intensity (counts per sec, CPS, ■), respectively. (A) pDNA-entrapped nanoparticles (Composition **I**). (B) pDNA-entrapped nanoparticles (Composition **II**).

assay. As shown in Figure 6A, after 8 h of coincubation of the pDNA alone with mouse serum, all 'naked' pDNA was digested into small oligo- or mononucleotides as demonstrated by the shifted eluent profiles when applied to Sepharose CL-4B column. The same pDNA, when entrapped in the nanoparticles (Composition **I** and **II**), was not completely digested by the mouse serum nucleases (Figure 6B and 6C) demonstrating that the nanoparticles provided some protection against degradation. Serum digested plasmids were likely located in the bulk aqueous phase of the suspension or loosely associated on the surface of the nanoparticles. It was reported that cationic lipids, such as DDAB, may complex pDNA without condensing it. Therefore, it is likely that pDNA in these complexes were still susceptible to enzymatic degradation (Reimer et al., 1995). The entrapment efficiencies of pDNA in the nanoparticles were determined by area under curve (AUC) analysis using the Linear Trapezoidal Method. The entrapment efficiencies for the DDAB/DNA-entrapped nanoparticles (Composition **I**; Figure 6B) and the DOTAP/DNA-entrapped nanoparticles (Composition **II**; Figure 6C) were estimated to be 24.5 ± 3.4% and 29.4 ± 2.1%, respectively. As shown in Figure 7, entrapped pDNA remained stable after extraction from the nanoparticles. The entrapment efficiencies in nanoparticles were lower than expected based on the Bligh and Dyer extraction experiments wherein all

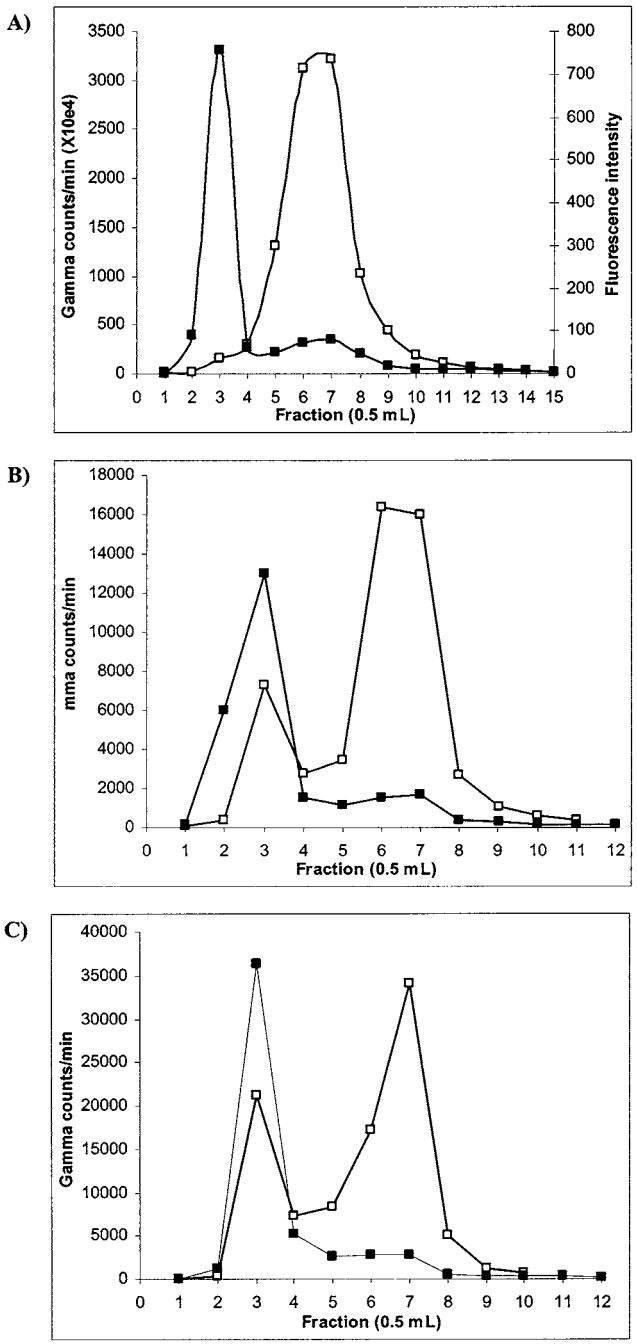

Figure 6. Gel permeation chromatograph of pDNA-entrapped nanoparticles with Sepharose CL-4B column for 'naked' pDNA alone (A) and pDNA-entrapped nanoparticles (B, C). A trace amount of I-125 labeled pDNA was included in the plasmids. One hundred microliters of nanoparticle suspensions, before (■) or after (□) mouse serum digestion, was passed through the column. Eluent fractions (0.5 mL) were collected and measured in a gamma counter to determine plasmid concentration (counts per min, CPM). (B) pDNA-entrapped nanoparticles (Composition **I**). (C) pDNA-entrapped nanoparticles (Composition **II**). In the case of 'naked' pDNA alone after digestion, the pDNA concentration was determined using PicoGreen and was reported as fluorescence intensity (A).

plasmid DNA was extracted into the organic (chloroform) phase when complexed with cationic lipid at a charge ratio of at least 0.5:1 (±). It is likely that the cationic lipid/pDNA complexes had lower affinity for the melted emulsifying wax oil phase in the microemulsion precursor as compared to the Bligh and Dyer organic (chloroform) phase. The reduced affinity of the complex in the melted

oil phase could therefore explain the lower than expected entrapment efficiencies of pDNA in the cured nanoparticles.

In Vitro Hep G2 Cell Transfection. Pullulan has been successfully used as a ligand for liver hepatocyte targeting (Cui and Mumper, 2002a; Tabata et al., 1999; Xi et al., 1996; Kaneo et al., 2001). In vitro cell transfections studies were completed to further assess the integrity and functionality of the entrapped pDNA and to investigate whether pullulan, coated on the nanoparticle surface, could enhance nanoparticle uptake and transgene expression. After coating with pullulan, the size of the nanoparticles (DDAB, composition **I**) was significantly increased to 254 ± 72 nm ($p = 0.01$, two-sample *t*-test). The zeta potential of the pullulan-coated nanoparticles, (−12.4 ± 5 mV) was comparable to that of uncoated nanoparticles (−13.5 ± 4 mV) uncoated nanoparticles. As shown in Figure 8, pDNA alone or pDNA entrapped into nanoparticles did not result in measurable transfection. Incorporation of DOPE as an endosomolytic lipid enhanced the transfection by about 4-fold. Moreover, after deposition of pullulan on the surface of these pDNA-entrapped nanoparticles (DOPE-free), significantly enhanced transfection was observed. Preincubation of the Hep G2 cells with free chol-pullulan significantly reduced the transfection enhancement (Figure 8), suggesting that the uptake of the pullulan-coated pDNA-entrapped nanoparticles may be via a receptor mediated endocytic process. These results were comparable to our previously reported in vitro transfection results using pDNA-coated cationic nanoparticles with pullulan (Cui and Mumper, 2002a and 2002b). In these previous studies, coating of pDNA on the surface of the cationic nanoparticles significantly enhanced in vitro cell transfection, compared to that of 'naked' pDNA. Further, the incorporation of DOPE in the pDNA-coated nanoparticles enhanced the transfection efficiency by over 5-fold. The coating of nanoparticles with pullulan increased the transfection ability of the pDNA-coated nanoparticles by over 40-fold to levels that were comparable to that of the Lipofectin. A similar trend was observed in these present studies; however, the overall magnitude of expression compared to Lipofectin using pDNA-entrapped nanoparticles was significantly lower. The lower relative levels of expression with pDNA-entrapped nanoparticles in these studies may have been

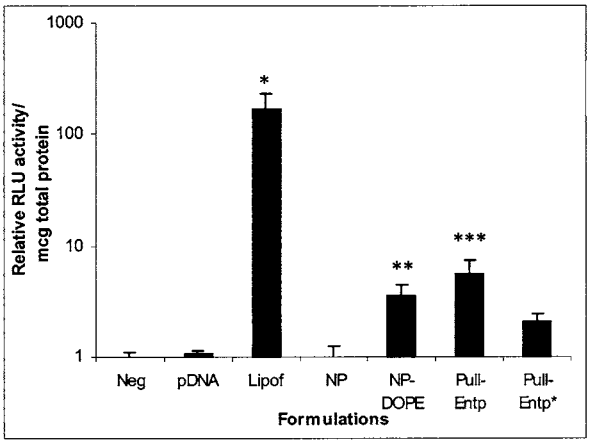

Figure 8. In vitro transfection of liver Hep G2 cells (500000 cells) ($n = 3$) in the presence of 10% FBS after 48 h with pDNA alone (pDNA), pDNA-Lipofectin (Lipof), uncoated pDNA-entrapped nanoparticles (NP), uncoated pDNA-entrapped nanoparticles with DOPE (NP-DOPE), or pullulan-coated pDNA-entrapped nanoparticles (Pull-Entp). For the group of Pull-Entp*, Hep G2 cells were preincubated with free chol-pull 5 min before the addition of the Pull-NPs. The pDNA dose was 2 μg for all samples. A one-way ANOVA followed by pairwise comparison with Fisher's protected least significant difference procedure (PLSD) was completed to analyze the data. *Indicates that the result of the Lipofectin was significantly different ($p < 0.05$) from that of the others. **Indicates that the result for NP-DOPE was significantly different ($p < 0.05$) from that of NP and pDNA alone. ***Indicates that the result for Pull-NP was significantly different ($p < 0.05$) from that of all other groups, except for NP-DOPE. NP = Composition **II**.

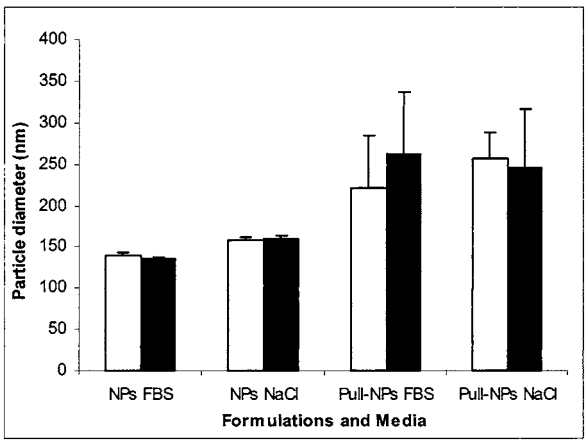

Figure 9. The particle size of the uncoated nanoparticles (NPs) and pullulan-coated nanoparticles (Pull-NPs) in various media at 37 °C for 30 min. For particle size measurement, the nanoparticle preparations were diluted with either 0.9% (w/v) of NaCl (normal saline) or 10% (v/v) of FBS in normal saline. Statistical analyses (two-sample *t*-test assuming equal variances) demonstrated no difference between the particle size at 0 and 30 min for all groups.

due to (1) the nanoparticles used in the present studies were net negatively charged while those in our previous studies were net positively charged even after pDNA coating, (2) the use of different nanoparticle compositions, and/or (3) issues relating to the kinetics of release of the entrapped pDNA from the nanoparticles. These factors are currently being assessed in ongoing experiments in our laboratories.

Biodistribution of the pDNA-Entrapped Nanoparticles in Mice. A short-term stability study of the nanoparticles in stimulated biological media was completed prior to the in vivo biodistribution studies to predict the nanoparticle stability. As shown in Figure 9, the size of pullulan-coated or uncoated nanoparticles did not change after 30 min of incubation at 37 °C in either normal saline (0.9% NaCl w/v) or 10% (v/v) of fetal bovine serum (FBS) in normal saline. Thirty minutes after tail vein injection, 47.6 ± 7.5%, 77.3 ± 10.4%, and 69.3 ± 3.8% of the total radioactivity administered was recovered from the mice injected with 'naked' pDNA alone, pDNA-entrapped nanoparticles, and pullulan-coated pDNA-entrapped nanoparticles, respectively. The majority of the recovered radioactivity was located in the blood and liver (Figure 10). Compared to only 16% for the 'naked' pDNA, 35−40% of the nanoparticle-entrapped pDNA were still circulating in the blood 30 min after tail-vein administration. The retention of pDNA in the blood at 30 min using both nanoparticle formulations was statistically significant over 'naked' pDNA alone. This suggests that the nanoparticles may have the potential for prolonged circulation and avoidance of the RES, problems commonly observed with other plasmid DNA delivery systems. Plasmid DNA, both free and entrapped, was also found in lung, heart, spleen, and kidney of the mice although in relatively low levels. The absence of a high level of radioactivity in the lung with both types of pDNA-entrapped nanoparticles strongly suggested that

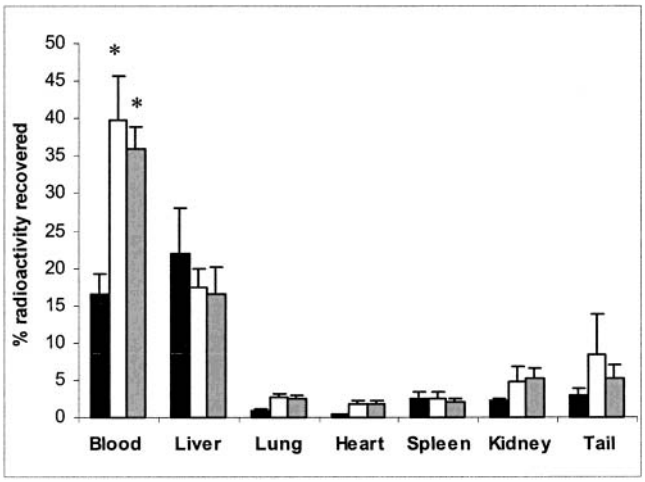

Figure 10. In vivo biodistribution of 'naked' pDNA alone (black bars, $n = 5$), pDNA-entrapped nanoparticles (white bars, $n = 5$), and pullulan-coated pDNA-entrapped nanoparticles (gray bars, $n = 7$) 30 min after tail vein injection to Balb/C mice. Statistical analyses were completed using a one-way ANOVA followed by pairwise comparison with Fisher's protected least significant difference procedure (PLSD). *Indicates that, in blood, the results for nanoparticles are significantly different from that for the free 'naked' pDNA alone.

these nanoparticles did not aggregate in blood resulting in rapid lung accumulation, an event that is common for cationic lipid complexes with pDNA (Mahato et al., 1995a and 1995b; Bailey and Sullivan, 2000; Takakura et al., 2001). The biodistribution results for both free 'naked' pDNA and pDNA-entrapped nanoparticles agreed both qualitatively and quantitatively to those of Bailey and Sullivan (2000). Bailey and Sullivan (2000) entrapped pDNA in neutral liposomes (~200 nm) with the aid of ethanol and calcium. Biodistribution studies with these pDNA-entrapped liposomes showed about 32−37% of the total dose remaining in the blood 1 h following tail vein injection to mice, with about 15−20% remaining in the liver. Interestingly, the total radioactivity recovered with the pDNA-entrapped liposomes (~60%) agreed well with that for pDNA-entrapped nanoparticles in our studies. Other organs/tissues that were not collected in either study that may account for unrecovered radioactivity include thyroid, brain, urine, extravascular tissue, and/

or intestines. Blood retention after tail-vein injection using these pDNA-entrapped nanoparticles compare very favorably to published reports of other systems. For example, Chesonyl et al. (2001) showed that 30 min after iv injection, 14−22% of the injected pDNA/emulsion complexes stabilized by 9−10% of PEG remained in mouse plasma. Further, Minchin et al. (2001) reported that 20 min after intraarterial injection, about 30% of the injected pDNA complexed with polyinosinic acid and polycationic liposomes was found in the circulation. Finally, Tam et al. (2000) showed that 4 h after iv injection, 55% of the injected plasmid−lipid particles (SPLP) were remained in the plasma.

It was also found in these present studies that the pullulan coating did not statistically enhance liver accumulation of pDNA entrapped in nanoparticles. The pullulan-coated nanoparticles were larger than the uncoated nanoparticles, thus it is possible that the larger pullulan-coated nanoparticles had reduced penetration through the sinusoidal endothelial barrier of the liver. Other possible reasons include (1) relatively low binding affinity of the pullulan ligand, (2) suboptimal concentration of the pullulan ligand on the nanoparticles. To this end, we are currently assessing the application of alternative hepatocyte-specific ligands and the optimization of the pullulan-coating on the nanoparticle surface.

Nonviral gene therapy involving the delivery of plasmid DNA has gained considerable attention over the past decade. However, to administer pDNA by intravenous injection, improved delivery systems are needed that can (1) protect DNA from serum nuclease digestion, (2) circulate in the blood long enough to reach distal organs and tissues, and (3) be readily modified for cell- and tissue-specific targeting. In addition to delivery strategies employing microparticles, liposomes, or cationic condensing agents such as lipids, polymer, and peptides/proteins, researchers have attempted to hydrophobize DNA and then incorporate the hydrophobized DNA into micron or nanometer sized particles. Examples include the stabilized plasmid-lipid particles (SPLP) prepared using a detergent dialysis procedure by Wheeler et al. (1999), reconstituted chylomicron remnant particles reported by Hara et al. (1997a), and more recently the poly(ethylene glycol)-stabilized DNA/emulsion systems based on the reconstituted chylomicron remnant particles described by Chesnoy et al. (2001).

The pDNA-entrapped nanoparticles reported in these present studies demonstrated prolonged circulation in blood (Figure 10). Although the mechanism(s) need further investigation, several possible explanations may be mentioned. The pDNA-entrapped nanoparticles were slightly net negatively charged. Therefore, possible association of negatively charged lipoproteins present in the blood with the nanoparticle surface may have been reduced and/or prevented (Nishikawa et al., 1998). Second, surfactants such as Brij 78, Tween 20, and Tween 80 may provide a more hydrophilic ('stealth'-like) surface on the nanoparticles, thereby precluding the aggregation of the nanoparticles by self-association or the rapid elimination by the RES (Lundberg et al., 1996). Similarly, the particle size of the nanoparticles was relatively small, perhaps reducing elimination of the nanoparticles by the mononuclear phagocytes in the liver (Kupfer cells) (Sakadea and Hirano, 1998).

It was demonstrated in this current study that pDNA-entrapped nanoparticles having diameters from 100 to 160 nm could be engineered from oil-in-water (O/W) microemulsion precursors formed at increased temperatures (i.e., 40−55 °C) and then simply cooled to form nanoparticles. The engineering process used in the present studies for pDNA-entrapped nanoparticle preparation has the following advantages: (i) the nanoparticle engineering process is rapid and spontaneous and completed in a single vessel, (ii) stable pDNA-entrapped nanoparticles (∼150 nm) can be engineered within minutes, and (iii) cell-specific ligands can be incorporated into the nanoparticles during the engineering process.

Nonionic emulsifying wax (comprised of cetyl alcohol and polysorbate 60 in a molar ratio of about 20:1) was selected as the oil phase since it is generally regarded as safe (GRAS) and has a melting point of ∼50−55 °C. The wax is typically used in cosmetics and topical pharmaceutical formulations and is generally regarded as a nontoxic and nonirritant material. For example, cetyl alcohol is currently used as an excipient in the marketed product Exosurf Neonatal. In addition, polysorbate 60 is used in many pharmaceutical products including parenteral products. In these present and previous studies using nanoparticles with similar compositions, no gross inflammatory, allergic, or toxic affects have been observed in mice after administration of these nanoparticles by the intravenous, subcutaneous, intramuscular, and topical routes (Cui and Mumper, 2002a and 2002b).

Engineering Tumor-Targeted Gadolinium Hexanedione Nanoparticles for Potential Application in Neutron Capture Therapy

Moses O. Oyewumi and Russell J. Mumper*

Division of Pharmaceutical Sciences, College of Pharmacy, University of Kentucky, Lexington, Kentucky 40536-0082. Received June 20, 2002; Revised Manuscript Received September 17, 2002

Microemulsions (oil-in-water) have been employed as templates to engineer nanoparticles containing high concentrations of gadolinium for potential application in neutron capture therapy of tumors. Gadolinium hexanedione (GdH), synthesized by complexation of Gd^{3+} with 2,4-hexanedione, was used as the nanoparticle matrix alone or in combination with either emulsifying wax or PEG-400 monostearate. Solid nanoparticles (<125 nm size) were obtained by simple cooling of the microemulsions prepared at 60 °C to room temperature in one vessel. The feasibility of tumor targeting via folate receptors was studied. A folate ligand was synthesized by chemically linking folic acid to distearoylphosphatidylethanolamine (DSPE) via a poly(ethylene glycol) (PEG; MW 3350) spacer. To obtain folate-coated nanoparticles, the folate ligand (0.75% w/w to 15% w/w) was added to either the microemulsion templates at 60 °C or nanoparticle suspensions at 25 °C. Efficiencies of folate ligand attachment/adsorption to nanoparticle formulations were monitored by gel permeation chromatography. Cell uptake studies were carried out in KB cells (human nasopharyngeal epidermal carcinoma cell line), known to overexpress folate receptors. The uptake of folate-coated nanoparticles was about 10-fold higher than uncoated nanoparticles after 30 min at 37 °C. The uptake of folate-coated nanoparticles at 4 °C was 20-fold lower than the uptake at 37 °C and comparable to the uptake of uncoated nanoparticles at 37 °C. Folate-mediated endocytosis was further verified by the inhibition of folate-coated nanoparticles uptake by free folic acid. It was observed that folate-coated nanoparticles uptake decreased to ~2% of its initial value with the coincubation of 0.001 mM of free folic acid. The results suggested that these tumor-targeted nanoparticles containing high concentrations of Gd may have potential for neutron capture therapy.

INTRODUCTION

Neutron capture therapy (NCT) is a potential cancer therapy that utilizes a stable, nonradioactive nuclide delivered to tumor cells, which upon irradiation by thermal or epithermal neutrons, produces localized cytotoxic radiations (Bath and Soloway, 1994; Bernard, 1995). Using several nuclides, the effectiveness of NCT in treating cases of malignant melanoma and glioblastoma have been reported (Matsumoto, 1992; Akine et al., 1993). Boron-10 was applied in most of the earlier clinical trial studies (Chen et al., 1997). A general requirement of a suitable NCT agent after accumulation in the target tumor is that upon exposure to external neutrons, it should emit radiation of sufficient energy and tissue penetration depth, so that the majority of cancer cells are killed with limited exposure to healthy tissues. Gadolinium has been proposed as an alternative to boron for neutron capture therapy of tumors (Martin et al., 1988; Tokumitsu et al., 2000). The tumor killing effect of Gd-neutron capture therapy (Gd-NCT) is attributed to the emission of γ rays and Auger electrons by the ^{157}Gd $(n,\gamma)^{158}$Gd reaction (Shih and Brugger, 1992; Shikata et al., 2002). The thermal neutron cross section of Gd-157 is 66-times greater than that of boron-10. Thus, compared to boron-10, Gd-157 has the ability to absorb neutrons much more efficiently, and as such, requires shorter neutron irradiation times. In addition, the emission of photons with long flight ranges in Gd-NCT will increase the probability of extensively hitting the target tumors thereby enhancing the overall therapeutic effect of NCT. Another factor that contributes to the attractiveness of Gd-NCT is the fact that many Gd-based compounds are already being used as contrast agents in magnetic resonance imaging (MRI). Therefore, the application of Gd in NCT may afford the opportunity of coordinating and achieving both diagnostic and therapeutic effects simultaneously.

In general, Gd-NCT may be described as a two-step radiotherapy in which a selective therapeutic effect on tumor cells is achieved by first targeting the tumor with nonradioactive Gd-157 and then exposing the target site to an external neutron source. Therefore, the success of Gd-NCT is dependent on localization and retention of high concentrations of Gd-157 within the target tumor site prior to neutron irradiation. In response to the challenge, Gd has been delivered previously through magnetic resonance imaging (MRI) contrast agents such as Gd-DTPA, Gd-DOTA, and Gd-EDTA (Shih and Brugger, 1992; Morel et al., 1998). However, the water solubility of these agents will likely make it difficult to achieve satisfactory tumor retention. New delivery systems are continually being sought that will achieve and retain high overall tumor concentrations of Gd.

Recently, the direct intratumoral injection of gadopentetic acid/chitosan complexes, gadolinium emulsions, and microspheres were reported (Jono et al., 1999; Tokumitsu et al., 1999; Miyamoto et al., 1999; Shikata et al., 2002). Most of the delivery systems applied in these earlier studies were untargeted and/or biologically unstable. Several groups using liposomes and other macromolecules have shown that particles less than 400 nm, and ideally less than 150 nm, are much more efficient in targeting tumors as compared to systems with larger particle sizes (Wu et al., 1993; Jain 1997; Desai et al., 1997; Hobbs et al., 1998; Bally et al., 1994). Thus, based on these previous studies, the goal of this work was to engineer stable nanoparticles (<100 nm) that could selectively deliver high concentrations of Gd to solid tumors.

It is known that, due to their small size, nanoparticles meeting specific criteria may be able to deliver molecules to specific tissues of interest and/or enhance the direct entry of entrapped drug molecules into cells (Kreuter, 1995). We recently demonstrated that oil-in-water microemulsions can serve as templates for engineering stable nanoparticles having diameters below 100 nm and entrap gadolinium acetylacetonate (GdAcAc; mp 143 °C). Apart from achieving high entrapment efficiencies of up to 1 mg of GdAcAc per 2 mg emulsifying wax or polyoxyl 2 stearyl ether (Brij 72) nanoparticles, it was also observed that the nanoparticle engineering process increased the apparent water solubility of GdAcAc by 2000-fold (Oyewumi and Mumper, 2001; Oyewumi and Mumper, 2002). The microemulsion templates were made at increased temperature (40−60 °C) and upon simple cooling in one vessel resulted in solid nanoparticles. Since the concentration of Gd is critical to the success of Gd-NCT, engineered nanoparticles containing higher concentrations of gadolinium in the form of gadolinium hexanedione were sought. The suitability of GdH over GdAcAc is due to the lower melting point of GdH (55 °C) and increased hydrophobicity that make it more amenable for incorporation into the oil phase of oil-in-water microemulsions. The therapeutic performance of GdH in NCT may also be enhanced since previous studies have shown that hydrophobic Gd-compounds were accumulated and retained in tumor cells longer than water soluble compounds (Jono et al., 1999; Shikata et al., 2002).

In these present studies, folate was used in targeting Gd to tumors, since it is known that many human cancer cells overexpress folate receptors (Weitman et al., 1992; Wang and Low, 1998). Folic acid binds to the folate receptors at cell surfaces with very high affinity and is internalized by receptor-mediated endocytosis (Kamen et al., 1986; Lee and Low, 1994). As a low molecular weight ligand, folic acid has the advantages of being stable and nonimmunogenic when compared to monoclonal antibodies. It has been shown that folate-conjugated macromolecules can be specifically taken up by cultured receptor-bearing tumor cells (Lee and Hang, 1996; Lee and Low, 1995; Atkinson et al., 2001). Folate-coated nanoparticles (<100 nm) containing high concentrations of GdH were engineered. Uptake studies in tumor-cultured cells were investigated. It is expected that achieving tumor-targeted delivery of nanoparticles containing high concentrations of Gd may enhance the overall success of Gd-NCT.

EXPERIMENTAL PROCEDURES

Materials. Emulsifying Wax and PEG-400 monostearate were obtained from Spectrum Chemicals (New Brunswick, NJ). Polyoxyl 20 stearyl ether (Brij 78) was purchased from Uniqema (Wilmington, DE). Gadolinium chloride and 2,4-hexanedione were purchased from Aldrich Chemicals (Milwaukee, WI). Sephadex G-75, Sepharose CL-4B, distearoylphosphatidylethanolamine (DSPE), folic acid, polyoxyethylene-bis-amine (PEG-bis-amine, Mw 3350), L-glutamine fetal bovine serum (heat inactivated), trypsin−EDTA, and penicillin−streptomycin solution were purchased from Sigma Chemicals (St. Louis, MO). Fluorescein−DOPE was purchased from Avanti Polar-Lipids (Alabaster, AL). KB cells (human nasopharyngeal epidermal carcinoma cell line) were obtained from ATCC (Manassas, VA).

Synthesis of Gadolinium Hexanedione. Gadolinium hexanedione (GdH) was synthesized using the modified method previously described by Mumper and Jay (1992). Briefly, 40 mL of an aqueous solution (pH 2.5) containing approximately 5 g of Gd chloride and approximately 6 mL of the complexing agent (2,4-hexanedione) was titrated with a standard solution of sodium hydroxide (1.038 N) to raise the pH to 7.0. All titrations were performed with continuous stirring at 25 °C, and the pH of the reaction mixture after each addition of NaOH was recorded. At pH 7.4, precipitated GdH was collected on a preweighed filter paper, washed with distilled/deionized water, and further purified as described by Mumper and Jay (1992), to remove excess complexing agent.

Preparation of Oil-in-Water Microemulsion Templates. GdH was used alone as the matrix material or in combination with either emulsifying wax or PEG-400 monostearate to prepare oil-in-water microemulsion templates at 60 °C. To prepare the microemulsions, matrix material (0.5−2.5 mg) and/or GdH (0−2.5 mg) were accurately weighed into a glass vial and melted using a hotplate. To the melted matrix materials and/or GdH at 60 °C, various concentrations (0−100 mM) of polyoxyl 20 stearyl ether (Brij 78) were added under magnetic stirring with subsequent addition of water (0.22 μm filtered) to make a final volume of 1 mL. The formation of oil-in-water microemulsions was verified by the clarity of the mixture and by photon correlation spectroscopy (PCS) using a Coulter N4 Plus Submicron Particle Sizer (Beckman Coulter Corporation, Miami, FL) at 60 °C by scattering light at 90° for 180 s. To prevent the warm microemulsions from cooling during the droplet size measurement, both the cuvette and the particle sizer sample holder were maintained at 60 °C.

Preparation and Characterization of GdH Nanoparticles. Using appropriate microemulsion templates, nanoparticles were prepared by various methods of curing the warm oil-in-water microemulsion templates including simple cooling to room temperature, dilution with cold water, and cooling of the entire template in a freezer. The particle sizes of the diluted solid nanoparticles (1:10 v/v with water) were determined using PCS at 20 °C by scattering light at 90° for 180 s. The retention of nanoparticles integrity was evaluated based on gel permeation chromatography (GPC) elution profiles. In brief, 80 μL of nanoparticle suspension was passed down the Sephadex G-75 column (1.5 cm × 8 cm), using water (0.22 μm filtered) as the mobile phase. The elution of nanoparticles in each fraction was detected by laser light scattering counts per second (CPS).

Stability of Nanoparticles in Biological Media. To assess the potential stability of nanoparticles in biological media, nanoparticles were diluted 1:10 v/v with 10% fetal bovine serum (FBS) in water or with 10 mM phosphate

buffered saline (pH 7.4). The particle size of nanoparticles in each media was monitored for 60 min at 37 °C.

Synthesis of Folate Ligand. A folate ligand was synthesized by chemically linking folic acid to distearoylethanolamine (DSPE) via a PEG spacer (MW 3350) using the modified method of Lee and Low (1995). Briefly, the procedure involved the synthesis of the two main components of the ligand: folate-PEG-NH_2 and *N*-succinyl-DSPE. Folate-PEG-NH_2 was synthesized by reacting overnight in the dark at room temperature, 450 mg of polyoxyethylene-bis-amine with equimolar amount of folic acid in 5 mL of dimethyl sulfoxide (DMSO) with dicyclohexylcarbodiimide (DCC), and 10 μL of pyridine. Folate-PEG-NH_2 was purified by (i) centrifugation (to remove the insoluble byproduct dicyclohexylurea), (ii) dialysis (to remove DMSO and unreacted folic acid), and (iii) by gel permeation chromatography using cellulose cation-exchange resin (to remove unreacted polyoxyethylene-bis amine). To synthesize *N*-succinyl-DSPE, 100 mg of DSPE was reacted overnight with a 1.2 mol equiv of succinic anhydride in chloroform. The product was precipitated with cold acetone. *N*-Succinyl-DSPE, whose carboxyl group had been previously activated with DCC, was reacted with folate-PEG-NH_2 overnight at room temperature in chloroform to obtain the final product (folate-PEG-DSPE). The solvent was removed, and the precipitate of folate-PEG-DSPE was washed three times with cold acetone and stored at −20 °C. To obtain fluorescence-labeled folate ligand, the procedure was modified appropriately by reacting 7-nitrobenzoxadiolzol-4-amine (NBD) and DSPE with succinic anhydride. The presence of NBD in the final folate ligand was detected by fluorescence spectroscopy (460 nm excitation and 534 nm emission). Characterization of folate−PEG−DSPE was carried out using the method of Lee and Low (1995) as well as by mass spectroscopy, GPC thin-layer chromatography, and infrared spectroscopy.

Addition of Folate Ligand to Engineered Gd Nanoparticles. Using a stock aqueous solution of folate ligand (0.5 mg/mL), two methods were used to add the ligand to nanoparticle formulations. First, various amounts were added to microemulsions templates at 60 °C, and the mixture was stirred for 15 min at 60 °C. The microemulsions were then cooled to room temperature under gentle stirring. The preparation was further stirred gently for 4 h at 25 °C to obtain folate-coated nanoparticles. In the second method, various amounts of folate ligand were added to nanoparticle suspension at 25 °C (after cooling the warm microemulsions). The mixture was then gently stirred for 4 h at 25 °C. The efficiency of folate ligand attachment/adsorption was assessed by gel permeation chromatography (GPC) elution profiles using both Sephadex G-75 and Sepharose CL-4B columns. In a separate study, the GPC elution profiles of control nanoparticles (without folate ligand) and free folate ligand were obtained using laser light scattering counts per second and fluorescence spectroscopy, respectively, to serve as references for folate-coated nanoparticles.

Cell Culture. Cell uptake studies were performed in KB cells, a human nasopharyngeal epidermal carcinoma cell line (ATCC, Manassas, VA). The cells were cultured in T-75 flasks at 37 °C in a humidified atmosphere containing 5% CO_2 using folate-free Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% heat-inactivated fetal bovine serum. The media contained final folate concentration similar to that of human plasma.

Nanoparticle Cell Uptake Studies. The growth medium was aspirated from each T-75 flask and KB cells monolayer was washed with sterile phosphate-buffered saline (154 mM PBS; pH 7.4). After aspirating the PBS, 1.5 mL of trypsin−EDTA was added to the flask to detach the cells. The suspended cells in growth medium were centrifuged at 1500 rpm (4 °C) for 5 min. After discarding the supernatant, the cells were dispersed in a known volume of growth medium, and the cells were counted using a hemocytometer. To study the cell uptake of nanoparticles, KB cells were seeded in 48-well plates at a density of 10^5 cells/well in complete growth medium and allowed to grow for 4 days, with the medium changed once on the second day. To determine the effect of nanoparticle concentration on uptake, various dilutions of folate-coated nanoparticles or control nanoparticles without folate ligand in complete growth medium were made in the concentration range of 20 to 600 μg/mL. The medium in each well was replaced with nanoparticles suspended in growth medium and incubated for 30 min. The experiment was carried out at 37 °C or 4 °C. In a separate experiment, nanoparticle suspensions (360 μg/mL) were incubated in the presence of various concentrations of free folic acid ranging from 0.001 mM to 100 mM. The effect of incubation time on nanoparticles uptake was also studied. At the end of the incubation period, nanoparticle suspensions were removed from the wells, and the cell monolayers were rinsed three times with cold PBS and lysed using 1% Triton X-100. Cell associated fluorescence was measured by a fluorometer (Hitachi, Model F-2000). The concentration of cell internalized Gd was measured by the fluorescence intensity of Gd at 270 nm (excitation) and 550 nm (emission) using a predetermined standard curve. In a separate study, Gd nanoparticle formulation (Formulation B) was prepared to contain fluorescein−DOPE, as an alternative fluorescence marker. Up to 0.25% w/w fluorescein−DOPE was entrapped in nanoparticles prior to folate ligand coating. The amount of nanoparticles taken up by KB cells was measured by the intensity of internalized fluorescence at 521 nm (emission) with excitation at 497 nm. In addition, 50 μL of the cell lysate from each well was used to determine the total cell protein content using the Coomassie Plus assay protocol (Pierce, Rockford, IL).

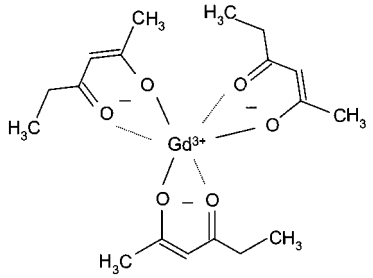

Figure 1. Structure of gadolinium hexanedione (GdH), synthesized by complexation of Gd^{3+} with 2,4-hexanedione.

RESULTS AND DISCUSSION

Synthesis of Gadolinium Hexanedione (GdH). GdH was synthesized by the complexation of Gd^{3+} with 2,4-hexanedione. GdH (94% yield) was subsequently characterized by mass spectroscopy, infrared spectroscopy, and differential scanning calorimetry. The basic steps involved in the synthesis of GdH are the loss of the acidic proton in 2,4-hexanedione at neutral pH and the subsequent complexation with Gd^{3+} in solution. The chemical structure of GdH is shown in Figure 1. Since the overall goal of the study was to engineer nanoparticles that can be employed in delivering high concentrations of Gd into tumors for Gd-NCT, GdH makes a very

Table 1. Components of Three Different Gadolinium Hexanedione (GdH) Nanoparticle Formulations. Each Formulation Was Made with Brij 78 (2 mM to 10 mM) and Water (0.22 μm filtered) To Make the Final Volume of 1 mL

suitable choice. Compared to other complexes of Gd (such as Gd-DTPA, Gd-DOTA, and Gd-EDTA), GdH has a relatively high weight percentage of Gd. Previous studies have also shown that lanthanides complexed with dicarbonyl chelating agents have favorable physical and thermal stability (Mumper and Jay, 1992). In particular, the high hydrophobicity and lower melting point of GdH were employed in this study to increase Gd concentration in the final nanoparticle formulations. We have reported earlier that oil-in-water microemulsions can be used as templates to engineer stable nanoparticles using matrix materials such as emulsifying wax and polyoxyl 2 stearyl ether (Brij 72). The nanoparticle matrix materials (mp 50−55 °C) served as the oil phase of the microemulsions that are produced at elevated temperatures (Oyewumi and Mumper, 2002). Therefore, since GdH possesses properties that are comparable to the matrix materials studied earlier, it was therefore thought that GdH could be used alone or in combination with other matrix materials to engineer stable nanoparticles having even higher concentrations of GdH in the final formulations.

GdH Nanoparticles Engineered from Microemulsion Templates. The feasibility of using GdH alone as a nanoparticle matrix material was initially investigated. It was observed that melted GdH was miscible with other melted matrix materials (emulsifying wax, Brij 72, PEG-400 monosterate) in weight ratios ranging from 1:1 to 1:6 (GdH/matrix materials). The final formulations were made using GdH alone or in a 1:5 (w/w) combination with other matrix materials. The components of the three GdH nanoparticle formulations are shown in Table 1 using GdH alone (Formulation A) or in combination with emulsifying wax (Formulation B) or PEG-400 monostearate (Formulation C). The oil-in-water microemulsions were prepared at 60 °C with polyoxyl 20 stearyl ether (Brij 78) as the surfactant. The microemulsion windows for the three nanoparticle formulations are shown in Figure 2 using Brij 78 concentrations ranging from 2 mM to 10 mM. The formation of the microemulsion was verified by both the visual clarity of the mixture and by the droplet sizes measured at 60 °C using PCS. As expected, microemulsions were not formed in systems without Brij 78 as the mixture remained turbid. As shown in Figure 2, microemulsions with large droplet sizes were obtained with a final Brij 78 concentration of 2.0 mM; however, the inclusion of either emulsifying wax or PEG-400 monostearate caused a reduction in microemulsion droplet sizes. The droplet sizes of microemulsions in Formulations A, B, and C were: 484 ± 35 nm, 171 ± 19 nm, and 144 ± 26 nm, respectively (Figure 2). Emulsifying wax is composed of cetyl alcohol and polysorbate 60 in a molar ratio of about 20:1. Thus, the presence of surfactants, polysorbate 60 and PEG-400 monostearate, most likely contributed to the formation of microemulsions even at the lower Brij 78 concentrations for these formulations.

Microemulsions that had small oil droplet sizes using lower Brij 78 concentrations were selected for subsequent

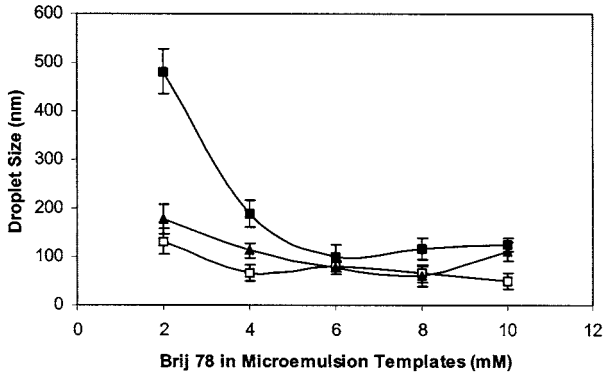

Figure 2. Microemulsion droplet sizes for three GdH Formulations: A (■), B (□), and C (▲). The microemulsions were prepared at 60 °C using Brij 78 at concentrations ranging from 2 mM to 10 mM. The final volume of 1 mL was obtained with water (0.22 μm filtered). The droplet sizes in each microemulsion were measured using laser light scattering at 60 °C. Each value represents the mean ± SD (n = 3).

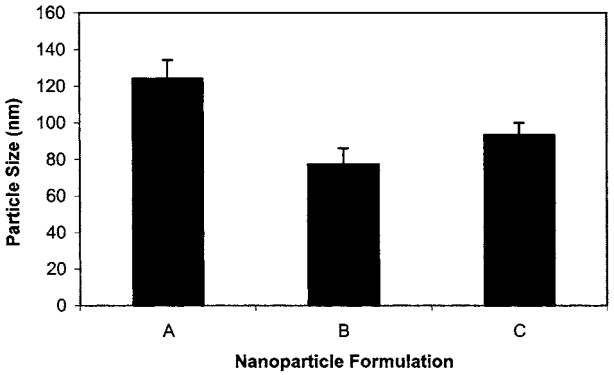

Figure 3. Particle size of GdH nanoparticle Formulations A, B, and C (3 mg/mL) made with 6.0 mM, 4.0 mM and 6.0 mM of Brij 78, respectively, and 0.2 μm filtered water. The nanoparticles were engineered by cooling warm microemulsions prepared at 60 °C to room temperature. The particle size of each sample (diluted 1:10 v/v in water) was determined by laser light scattering at 25 °C. Each value represents the mean ± SD (n = 3).

nanoparticle formulations. This was based on our earlier findings that demonstrated a direct correlation between the microemulsion droplet sizes and resulting cured nanoparticle size (Oyewumi and Mumper, 2001; Oyewumi and Mumper, 2002). In addition, previous studies showed that nanoparticles were unstable over time when higher concentrations of surfactant (about 10 mM) were used to prepare the microemulsion templates (Oyewumi and Mumper, 2002). Therefore, using the microemulsion window as a guide (Figure 2), the final formulation were made with 6 mM, 4 mM, and 6 mM Brij 78 in Formulations A, B, and C, respectively. Solid nanoparticles were cured from the selected microemulsions by simple cooling of the warm microemulsion prepared at 60 °C to room temperature (25 °C) in one vessel. The average particle size of cured nanoparticle Formulations A, B, and C measured at 20 °C are shown in Figure 3 demonstrating that solid nanoparticles were obtained directly from microemulsion templates. The nanoparticles sizes ranged from 77.2 to 124.1 nm. In addition, the polydispersity index of the three formulations ranged from 0.1 to 0.3, suggesting the uniformity of the particle size distribution. Compared to earlier studies, all of the nanoparticle formulations contained higher concentrations of GdH (2.5 mg/mL). The variations in particles sizes among Formulations A, B, C were directly attributed to the initial

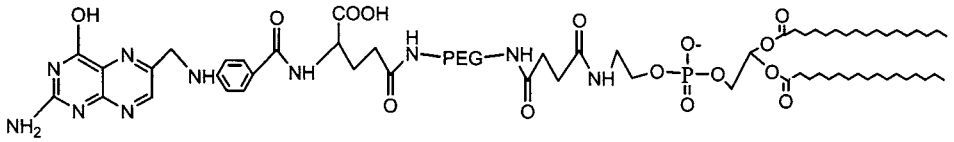

Figure 4. Chemical structure of folate−PEG−DSPE synthesized by linking folic acid to DSPE via a PEG spacer (MW 3350).

microemulsion droplet sizes. For example, Formulation A which had the largest droplet microemulsion droplet size using 6.0 mM Brij 78 (Figure 2) resulted in nanoparticles with the largest size (Figure 3). Additional studies were carried out to determine the effects of modifying the component ratios of nanoparticle matrix in the microemulsion pseudo-phase diagrams. It was observed that cured nanoparticle sizes increased with an increase in the GdH concentration in all formulations (data not shown). For instance, for Formulation C, increasing the GdH concentration from 0.5 mg/mL to 2.5 mg/mL, using a constant concentration of PEG-400 monostearate (0.5 mg/mL), resulted in a corresponding increase in nanoparticle size from 48.7 ± 7.8 nm to 93.4 ± 8.7 nm. Further, nanoparticles engineered with a concentration of GdH greater than 2.5 mg/mL had polydispersity indices ranging from 0.8 to 1.4, indicating that the formulations were not monodispersed. All formulations were purified and characterized by GPC using Sephadex G-75 and water as the mobile phase. Up to 10 fractions (1 mL each) were collected from the column. The GPC elution profiles were obtained using laser light scattering counts per second as well as fluorescence intensity of each fraction. It was observed that nanoparticles eluted primarily in fraction number 3 corresponding to the void volume of the column (data not shown).

Addition of Folate Ligand to Nanoparticles. The chemical structure of the synthesized folate ligand is shown in Figure 4. The basis of the synthesis of folate ligand was to link folic acid to DSPE via a PEG spacer. Previous studies have shown that folate retains its affinity to the receptor when derivatized via its γ-carboxyl group (Lee and Low, 1995; Wang et al., 1996; Atkinson et al., 2001). Since the folate ligand was added to nanoparticle formulations by physical mixing rather than by covalent attachment, adsorption of the ligand onto the nanoparticles was likely facilitated by the hydrophobic groups on DSPE. In addition, previous studies on folate-targeted delivery systems showed that the length and flexibility of PEG spacer influenced recognition by folate receptors and with little or no cell uptake occurring with systems that contained short PEG spacers (Lee and Low, 1994). The PEG used in the study (MW 3350) had earlier been proven to be a sufficient spacer (Lee and Low, 1994; Goren et al., 2000). Therefore, it is expected that the presence of DSPE and PEG spacer on the synthesized folate ligand will ensure both the attachment to nanoparticles as well as cell recognition. It was thought that addition of the folate ligand to microemulsion templates (before curing nanoparticles) may result in improved folate insertion, incorporation, and/or adsorption onto nanoparticles thereby enhancing the coating efficiency in the final nanoparticle formulations. Various concentrations of the folate ligand were added to either microemulsion templates at 60 °C (before cooling to room temperature) or nanoparticle suspensions at 25 °C. In the two cases, sufficient time was allowed to stir the mixture to ensure complete adsorption/insertion of folate ligand within the oil-in-water microemulsions or nanoparticles. Gel permeation chromatography (GPC) was used to determine the extent of folate ligand attachment on nanoparticles which was expressed as the coating

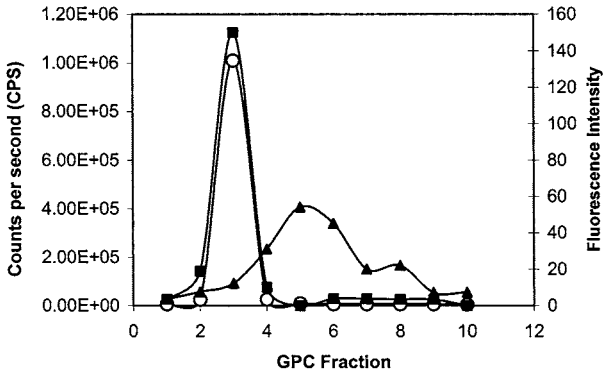

Figure 5. Gel permeation chromatography elution profiles demonstrating that the elution of free folate ligand (▲) was separated from folate-coated nanoparticles (○). Folate elution was detected by fluorescence intensity at 460 nm (excitation) and 534 nm (emission). The elution of folate-coated GdH nanoparticles (■) in the void volume was monitored by PCS as a control. Folate-coated nanoparticles (Formulation B) were obtained by adding the folate ligand (3% w/w) to the microemulsion template at 60 °C and then cooling the template to room temperature.

efficiency of the folate ligand. Particular attention was placed on the elution of free folate ligand and folate-coated nanoparticles. GPC elution profiles of folate were monitored by UV absorption at 363 nm as well as by fluorescence intensity at 460 nm (excitation) and 534 nm (emission) using fluorescent-labeled folate ligand that was synthesized using the procedure described earlier. The elution of nanoparticles after coating with 0.75% w/w folate ligand is shown in Figure 5. The results showed that folate-coated nanoparticles were engineered by the addition of folate ligand to microemulsion templates either at 60 °C (before curing nanoparticles) or to nanoparticle suspensions at 25 °C. To calculate the coating efficiency, both the elution of control nanoparticles (without folate ligand) and free folate ligand were obtained. Nanoparticle elution was monitored by laser light scattering counts per second which showed that the nanoparticles eluted in fraction 3 (void volume) while the elution of free folate ligand as detected by fluorescence intensity occurred later (Figure 5). Since it was possible to separate the elution of folate ligand as free ligand and folate-coated nanoparticles, the coating efficiency was calculated from folate elution profiles as follows:

$$\text{folate coating efficiency (\%)} = \frac{\text{area under nanoparticle elution profile}}{\text{area under the total elution profile}} \times 100\%$$

Using the equation above, the efficiency of coating nanoparticle Formulation A, B, and C with various amounts of folate ligand was calculated. Figure 6A demonstrates that folate ligand could be attached to all nanoparticle formulations. Up to 15% w/w folate ligand was added to all formulations, and the coating efficiency obtained was comparable in all the cases. However, the difference between folate addition to the microemulsion templates and onto cured nanoparticles was statistically significant for Formulation C ($P < 0.05$; two-sample t-test)

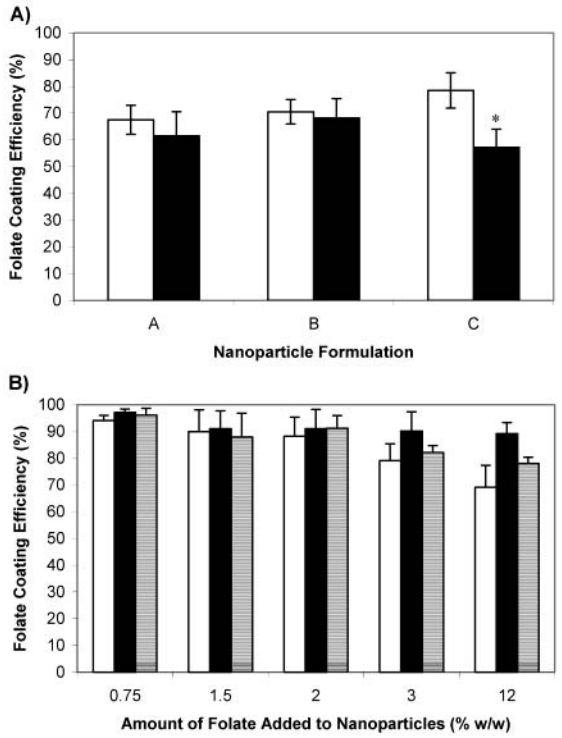

Figure 6. (A) Coating efficiencies of folate ligand (15% w/w) when added to nanoparticle Formulations A, B, and C either to the microemulsion template at 60 °C (□) or to nanoparticle suspensions at 25 °C (■). The coating efficiencies were obtained from GPC elution profiles of free folate ligand and folate-coated nanoparticles. Values represent mean ± SD ($n = 4$). (B) The effect of folate ligand concentration on the coating efficiency on nanoparticles. Folate ligand (0.75% w/w to 12% w/w) was added to microemulsion templates at 60 °C. Folate-coated nanoparticles Formulation A (□), Formulation B (■), and Formulation C (striped bars) were obtained after cooling to room temperature. Each data point represents mean ± SD ($n = 3$). *$P < 0.05$ as determined by a two-sample *t*-test assuming unequal variances.

where lower coating efficiency was obtained when the folate ligand was added to cured nanoparticles at 25 °C. Figure 6B shows the effects of the addition of various concentrations of folate ligand to the three nanoparticle formulations. For all formulations, high coating efficiencies (~96%) were obtained at low concentrations of folate ligand (0.75% w/w) added to microemulsion templates before curing nanoparticles. However, the coating efficiency decreased to below 90% when the final folate ligand concentration added to Formulations A, B, and C were above 2% w/w, 3% w/w, and 2% w/w, respectively. Since folate ligand attachment to cured nanoparticles was expected to be through the hydrophobic anchors (DSPE), the decrease in coating efficiency with increase in folate ligand concentration may be due to saturation of the nanoparticle surface with the folate ligand. For example, for Formulation A, increasing the folate ligand concentration from 0.75% w/w to 12% w/w resulted in a reduction in the coating efficiency from 96% to 55.6%. A slightly different trend was observed with Formulation B, wherein the addition of 25% w/w folate ligand to Formulation B resulted in a coating efficiency of 51.9% (data not shown), suggesting that higher amounts of folate ligand may be coated on these nanoparticles for reasons not yet known.

Cell Uptake of Folate-Coated Nanoparticles. Cell uptake studies were carried out in KB cells (human nasopharyngeal carcinoma cell lines), since it has been shown that they overexpress folate receptors (Lee et al., 1996). The cells were cultured in medium that contained no folic acid to facilitate the expression of folate receptors. Nanoparticle Formulation B coated with 3% w/w folate ligand was used in cell uptake studies based on their small size (below 100 nm) and high folate ligand coating efficiency. Since the addition of folate ligand (3% w/w) resulted in >92% coating efficiency, the final formulation was used without further purification by GPC. GdH cell uptake was monitored by fluorescence spectroscopy. The dependence of fluorescence intensity of Gd on concentrations had been previously published (Reisfeld and Biron, 1970). Preliminary studies showed that GdH fluorescence intensity was concentration dependent. The standard curve of concentration versus fluorescence was linear in the concentration range of 0−50 μg/mL, and the sensitivity of detection was as low as 0.1 μg/mL. Prior to the uptake studies, the stability of folate ligand coating on nanoparticles was investigated to account for any form of detachment or leakage of folate ligand from nanoparticles. The folate-coated nanoparticles were stable when incubated at 37 °C for 150 min in PBS (pH 7.4), 10% fetal bovine serum, and in the cell growth medium. The uptake of nanoparticles by KB cells was dependent on the concentration of the nanoparticles in the medium. The cell uptake of Gd nanoparticles increased with increasing nanoparticle dose exhibiting nearly a linear correlation (Figure 7). The reduction of cell uptake efficiency at higher concentrations of nanoparticles may suggest saturation. In contrast to the results obtained at 37 °C, uptake studies at 4 °C resulted in lower Gd uptake with an apparent plateau as from 90 μg/mL to 180 μg/mL nanoparticle concentrations (Figure 7). For instance, Gd uptake efficiency at nanoparticles concentration of 360 μg/mL was about 82% at 37 °C and only 4.5% at 4 °C. Since ligand binding and uptake is dependent on temperature (Holm et al., 1981; Holm et al., 1983), the uptake of Gd nanoparticles by KB cells was likely an energy dependent process. The enhanced cellular uptake at 37 °C was attributed to endocytosis that was active at 37 °C but suppressed at 4 °C. Suppression of uptake at 4 °C was perhaps due to geometrical changes in the receptor as reported by others (Hassan et al., 1992; Davda and Labhasetwar, 2002; Shikata et al., 2002). Thus, the results demonstrated that cultured KB cells could selectively take up folate-coated nanoparticles. The uptake of folate-coated nanoparticles was about 10-fold higher than uncoated nanoparticles after 30 min at 37 °C. The uptake of folate-coated nanoparticles at 4 °C was 20-fold lower than the uptake at 37 °C and comparable

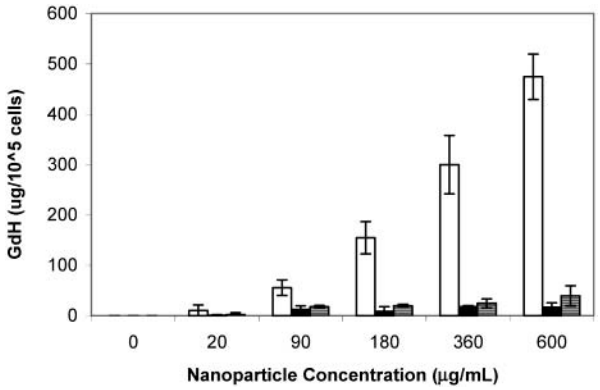

Figure 7. The effect of nanoparticle concentration on KB cells uptake for folate-coated nanoparticles after incubation for 30 min at 37 °C (□) and at 4 °C (■). In the control experiments, various concentrations of control nanoparticles (without folate) were also incubated with KB cells at 37 °C for 30 min (stripped bars). Each data point represents the mean ± SD ($n = 3$).

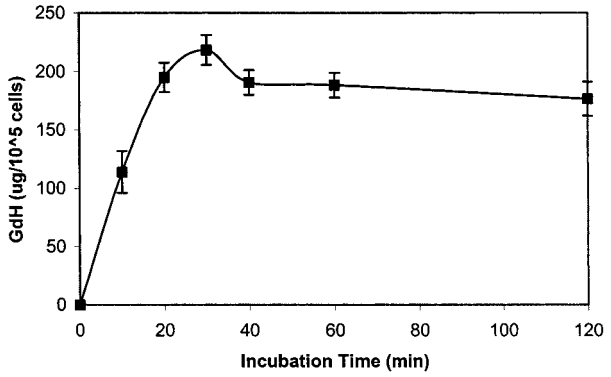

Figure 8. The effect of incubation time on the uptake of folate-coated nanoparticles (300 μg/mL) by KB cells. Nanoparticle Formulation B coated with 3% w/w folate ligand was used. Cell internalized fluorescence was measured at 497 nm (excitation) and 521 nm (emission) using fluorescein−DOPE as the marker. Entrapment of fluorescein−DOPE 0.25% w/w in nanoparticles as confirmed by gel permeation chromatography was ~100%. Values represent mean ± SD (n = 3).

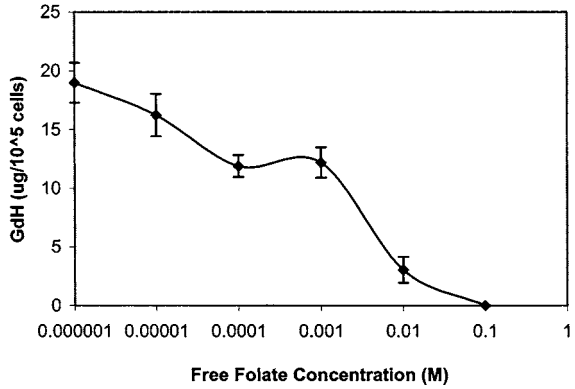

Figure 9. Inhibition of folate-coated nanoparticle uptake by free folic acid. KB cells were incubated at 37 °C for 30 min with folate-coated nanoparticles (360 μg/mL) in the presence of various concentrations of free folic acid. Each value represents the mean ± SD (n = 3).

to the uptake of uncoated nanoparticles at 37 °C. Similar levels of enhanced uptake of folate-targeted over non-targeted delivery systems have been published previously (Pan et al., 2002). Incubation time also played a role in the uptake of folate-coated nanoparticles as shown in Figure 8. Within 30 min of incubation, up to 290 μg GdH per 10^5 cells was internalized as indicated by the fluorescence intensity of fluorescein−DOPE entrapped in nanoparticles. The results showed a rapid cell uptake of GdH nanoparticles reaching an apparent maximum at 30 min (Figure 8). To verify the involvement of folate receptors on KB cell uptake of GdH nanoparticles, competition between folate-coated nanoparticles and free folic acid was carried out (Figure 9). Coincubation of free folic acid inhibited folate-coated nanoparticles uptake (Figure 9). At very high concentration of free folic acid of about 100 mM, little or no uptake of folate-coated nanoparticles was observed. In addition, reducing the concentration of free folic acid (as a competitive inhibitor) from 100 mM to 0.001 mM resulted in up to 18-fold increase in the uptake of folate-coated nanoparticles (Figure 9), demonstrating that free folic acid served as a competitive inhibitor. It was observed that the uptake of folate-coated nanoparticles decreased to only ~2% of its initial value with the coincubation of about 0.001 mM free folic acid (the lowest free folic acid concentration studied). The inhibition studies by coincubation with free folic acid indicated that the uptake of folate-coated nanoparticles occurred in much the same manner as free folic acid.

In general, these studies have indicated that folate-coated Gd nanoparticles may have potential of selectively delivering high concentrations of Gd to tumors thereby enhancing the success of NCT. Previous reports have suggested that targeted Gd-NCT strategies may be of therapeutic interest (Akine et al., 1990; Tokuuye et al., 2000). Folate-coated nanoparticles may therefore serve as effective carrier systems for Gd-NCT since (i) nanoparticle size of ~100 nm could facilitate internalization by tumor cells, (ii) the formulations contain high concentrations of Gd, (iii) nanoparticles may potentially enhance the therapeutic potential Gd-NCT via selective uptake by folate receptors, and (iv) previous studies have shown that presence of Gd in the intracellular space can enhance the therapeutic effectiveness of Gd-NCT (Akine et al., 1990). Current studies are evaluating the in vivo biodistribution of folate-coated nanoparticles in a KB cell tumor model in nude (nu/nu) mice.

Chemically modified cytochrome *c* with poly(ethylene glycol) (PEG) showed activity at temperatures higher than 100 °C and to be highly thermostable. The molecular size of PEG moieties and the coupling site affected the thermal stabilization. An optimal PEG/protein mass ratio of 2.8 was found, producing a fully thermostable biocatalyst at 80 °C. Site-directed mutagenesis on yeast cytochrome *c* showed an increased thermostabilization when lysine 79 residue, localized at the edge of the active site, was replaced by a nonreactive residue. Tertiary, secondary, and active-site structures were analyzed by fluorescence, CD, and UV/visible spectroscopies. Besides its disordered structure, the pegylated protein showed a lower unfolding rate at the active-site than the unmodified ones. A shell-like structure seems to protect the heme environment, in which PEG is coiled on the protein surface with a primary shield of rigid water molecules solvating the hydrophilic region of bound-PEG, and the PEG hydrophobic regions interacting with the hydrophobic clusters on protein surface.

INTRODUCTION

Enzymatic catalysis is increasingly used as an alternative to traditional chemical synthesis. The driving force behind this change is the necessity to innovate products and to establish new ecoefficient processes (*1*). However, in many cases the industrial application of enzymes is hampered by the instability of the biocatalyst under process conditions, which may involve extreme pH, high temperature, the presence of organic solvents, and other denaturing agents. The generation of robust biocatalysts can be accomplished by genetic and biochemical approaches, and progress will continue after the systematic identification of novel sources of enzymes with unusual properties, e.g., from extremophile microorganisms.

Any enhancement of the thermal stability of an enzyme would confer significant operational advantages such as higher reaction rates, increased substrate solubility in lower viscosity media, productive shifts in thermodynamic equilibrium, and reduced risks of microbial contamination. Genetic approaches have yielded significant results in obtaining more thermostable enzymes, with higher temperature optima through directed evolution (*2*−*4*). A combination of rational and random mutagenesis has been used to obtain a fungal peroxidase 174-times more thermostable than the wild-type protein (*5*). However, although directed evolution seems to be a powerful tool to enhance biocatalytic performance, its main drawback is that the knowledge of the properties gained during site-directed mutagenesis or evolution processes cannot be used as a general method to be applied to other proteins. On the other hand, chemical modification seems to be a more general method to improve intrinsic properties of proteins such as stability and activity without a deeper knowledge of the gene or protein structure. Several chemical methods have been employed to obtain more stable protein derivatives, including plastic conjugates (*6*, *7*), cross-linked enzyme crystals (CLECs) (*8*−*10*), attachment to polysaccharides (*11*−*12*), and chemical modification with amphiphilic polymers (*13*−*15*).

It is well-known that the modification with PEG or polysaccharides may confer certain thermostability to the enzymes at a temperature range from 50 to 70 °C (*15*, *16*). Stabilization of proteins was explained by the solvation of PEG-bound molecules, which restricted the molecular mobility, thus decreasing the unfolding rate of the protein.

Catalytically active and stable enzymes at temperatures higher than 80 °C are considered hyperthermophilic enzymes. Only two enzymatic preparations have been shown to be active and stable at temperatures higher than 100 °C in aqueous systems, both hydrolytic enzymes: a pegylated trypsin (*13*) and a dextran-glycosylated amylase (*12*). The thermal protective effect of PEG on trypsin was attributable to the presence of the polymer, which may change the microenvironment through the formation of a hydrogen-bond network around the protein (*13*). The higher the molecular mass of PEG, the higher the thermostability of trypsin. The effect of the size of the polymer on the thermostability of amylolytic enzymes has also been reported by Lenders et al. (*11*). The increased thermal stability of the dextran−protein conjugate was mainly due to the formation of multiple covalent links between the enzyme and the polymer leading to the formation of a more rigid conformation of the protein. It was also shown that the stability decreased when the number of linkages between the enzyme and the carbohydrate was lower. Only two peroxidases have been shown to be stable at temperatures higher than 80 °C in their native form: soybean (*17*) and palm oil (*18*) peroxidases, and this stability does not necessarily mean activity at high temperatures. However, no information is available on chemically modified peroxidases showing activity and stability at hyperthermophilic conditions (80 to ≥ 100 °C) in aqueous systems.

As a novel source of biocatalysts, we are exploring the peroxidase activity of nonenzymatic hemoproteins, such

as cytochrome *c* (*19*−*23*) and hemoglobin (*24*, *25*), with emphasis on the oxidation of polycyclic aromatic hydrocarbons (PAHs). The catalytic properties of these hemoproteins have been significantly improved by site-directed mutagenesis (*21*, *22*) and chemical modification (*22*, *23*). In addition, rational design methods have been used to obtain cytochrome *c* variants with higher stability against inactivation by hydrogen peroxide (*26*). In this work, we present the enhanced peroxidase catalytic performance of a chemically modified cytochrome *c* at temperatures above 80 °C, and we discuss the possible mechanism of thermoprotection.

EXPERIMENTAL PROCEDURES

Chemicals. Horse heart cytochrome *c*, *Saccharomyces cerevisiae* cytochrome *c*, methoxypoly(ethylene glycol) (MW 350, 750, and 2000 Da), cyanuric chloride-activated monomethoxypoly(ethylene glycol) (MW 5000 Da), hydrogen peroxide (30%), and cyanuric chloride (2,4,6 trichloro-1,3,5-triazine) were obtained from Sigma Chemical Company (St. Louis, MO). Pyrene, anthracene, benzo[*a*]pyrene, thianthrene, dibenzothiophene, and phenyl disulfide were obtained from Aldrich (Milwaukee, WI). Organic solvents (HPLC grade) were purchased from Fisher Scientific (Fairlawn, NJ). Ultrapure guanidine hydrochloride (GuHCl) was from Gibco BRL (Rockville, MD). All DNA restriction and modification reagents were from New England Biolabs (Beverly, MA). All other reagents were analytical grade.

Methoxypoly(ethylene glycol) (PEG) Activation. Activation of PEG species of different molecular sizes (350, 750, or 2000 Da) was carried out by a modification of the method reported by Abuchowski et al. (*27*). PEG aliquots (10 mmol) were dissolved in 40 mL of dry toluene containing 1 g of sodium carbonate. Cyanuric chloride (30 mmol) was added, and the resulting mixture was stirred overnight at room temperature. The solution was filtered, and the activated PEG fraction was recovered by adding the filtrate to 80 mL of cold petroleum ether followed by a 10 min centrifugation at 12100*g*. The resulting precipitate was separated and washed with cold petroleum ether until it was free of residual cyanuric chloride as detected by UV spectrometry. The chlorine content in activated PEGs was determined by titration with silver nitrate (0.02 N) after overnight hydrolysis in 50 mM sodium carbonate buffer, pH 10.0.

Chemical Modification of Cytochrome *c*. Poly(ethylene glycol)-modified horse heart cytochrome *c* (Cyt−PEG) was produced according to the method reported by Gaertner and Puigserver (*13*). Cytochrome *c* (9 mg) was dissolved in 5 mL of 40 mM borate buffer pH 10.0, and then a five molar excess in a free amino group basis of cyanuric chloride-activated monomethoxypoly(ethylene glycol) (MW 5000 Da) was added. The mixture was stirred for 1 h at room temperature and then diluted to 100 mL with 60 mM sodium phosphate buffer pH 6.1 and dialyzed extensively against the same buffer. The Cyt−PEG conjugate solution was concentrated using an Amicon ultrafiltration cell (Millipore, Bedford, MA) using a 10 kDa cutoff membrane. Yeast cytochrome *c* conjugates were obtained by the same procedure. The degree of protein modification was estimated by titration of the residual free amino groups with trinitrobenzenesulfonic acid (*28*).

Site-Directed Mutagenesis of *S. cerevisiae cyc1*. Single and double mutants of *cyc1* (Table 3) were obtained by megaprimer-extension (*29*) upon the pBTR1 plasmid (*30*) using the following primers: pf1 5′-cggtacccggggatccataactaac-3′, pr4 5′-aaaaagctagcctgtttactcagtgctttttcaagaaggtaattaagtc-3′, K79A 5′-cccaccaaaggccatcgcggtaccaggaatat-3′, K27A 5′-gtttggaccaaaccgcatgtgggccacc-3′.

All amplifications were performed using the high-fidelity DNA-polymerase Expand from Roche (Mannheim, Germany) following the manufacturer instructions. Megaprimers were obtained by amplification of plasmid pBTR1 with the primer sets pf1-K27A or K79A and purified from the gel. Extension of the megaprimers was performed upon plasmid pBTR1 using primer pr4. The extension products were purified from the gel, restricted with BamHI and NheI and ligated onto pBTR1 restricted with the same enzymes and harboring *cyc3* coding for the cytochrome *c*-heme lyase (*30*). The nucleotide sequence of all clones was confirmed twice using the Big dye Terminator kit (Applied Biosystems, Foster City, CA) in an ABI Prism 377 System (Applied Biosystems).

Overexpression and Purification of Mutant Cytochrome *c* Proteins. Transcription of cyc1 and cyc3 is driven from a low-constitutive *tet* promoter located upstream from the BamHI restriction site in plasmid pBTR1 and in all the derivatives here described. All plasmids were transformed into the *E. coli* strain JM101 and maintained in Luria-Bertani (LB) rich medium (*31*) supplemented with ampicillin (100 μg/mL). Accumulated expression of cytochrome *c* was achieved by growing each recombinant *E. coli* strain in a 2 L New Brunswick (Edison, NJ) fermenter in 1.5 L LB rich medium supplemented with ampicillin for 30 h. Typical cell yield was 2.5 g wet weight per fermenter. Cell pellets (5 g per strain) were resuspended in 50 mL of cold breaking buffer (20 mM sodium phosphate, pH 6.1, 25% sucrose, 10 mM EDTA, 0.2 mM DTT, 50 μg/mL lysozyme) and incubated in ice for 10 min. The cell suspension was then supplemented with 5 mg/mL Brij 35, 0.01 mM $MgCl_2$, 20 μg/mL RNAse, 100 μg/mL DNAse, 1 mM PMSF, and incubated at 37 °C for 10 min. Cells were disrupted by two 1 min pulses in a Sonicator (Sonics and Materials Inc., Danbury, CT). Cell debris was removed by centrifugation. Cell extracts were precipitated with one volume of saturated ammonium sulfate, and the supernatants were recovered and dialyzed overnight against 80 volumes of cold 20 mM sodium phosphate buffer, pH 6.1. Enriched extracts were subjected to cation-exchange chromatography using a Macro-Prep High S support (BioRad, Hercules, CA) packed column and the Econo System purification system from BioRad using a linear NaCl gradient. The chromatography was followed by absorbance at 280 and 410 nm. The cytochrome *c*-enriched peak was collected, concentrated by ultrafiltration in an Amicon system (Millipore, Bedford, MA) fitted with a 10 kDa cutoff membrane, and dialyzed overnight against 4 L of cold 20 mM sodium phosphate buffer, pH 6.1. All proteins were purified to homogeneity as assessed by SDS-PAGE and silver staining of the gel. Typical R_z values ranged from 4.8 to 5.4.

Protein Concentration. Cytochrome preparations were dissolved in 60 mM sodium phosphate buffer, pH 6.1. Unmodified cytochrome concentration was estimated in the reduced state using an extinction coefficient $\epsilon = 29.5\ mM^{-1}\ cm^{-1}$ at 550 nm (*32*). The absorption spectrum of Cyt−PEG was altered as a result of the chemical modification, the typical 550 nm band observed in the reduced state was lost, and the Soret band maximum was UV-shifted. Ahmad, et al. (*33*) reported a ϵ value of $1.061 \times 10^5\ M^{-1}\ cm^{-1}$ at 410 nm for the oxidized state of cytochrome *c*. We applied the same value to estimate the concentration of Cyt−PEG in the oxidized state using the

absorbance of the 402 nm Soret band. To confirm the concentration, Cyt−PEG samples were digested and iron was estimated by atomic absorption. The predicted Cyt−PEG concentration, obtained with each of the methods described above, gave a correlation of 0.994.

Activity Assays. Cytochrome *c* reaction mixtures contained 15% acetonitrile, 20 μM polycyclic aromatic hydrocarbons (PAHs) or organosulfur compounds as substrate and 0.5−3.5 μM of unmodified or chemically modified cytochrome in 1 mL of 60 mM sodium phosphate buffer, pH 6.1. Reactions were carried out in individual sealed vessels and started by the addition of 5 μL of 200 mM H_2O_2 (1 mM final concentration) and stopped by adding 1 mL of acetonitrile. The extent of the reaction was followed by substrate consumption on a HPLC (Perkin-Elmer, Norwalk, CT) equipped with a reverse phase C_{18} 5 μm column (15 × 3.9 mm). Specific activity was determined by measuring the moles of substrate oxidized per mole of cytochrome preparation in 1 min and expressed as min^{-1}. All reactions were performed in triplicate.

Activity vs Temperature Profile. Cytochrome *c* reactions were assayed from 20 °C to 120 °C in 4 mL glass vials sealed with Teflon septa. Reaction mixtures contained 15% acetonitrile, 20 μM pyrene, and 0.5−4.6 μM cytochrome preparation in 1 mL 60 mM sodium phosphate buffer, pH 6.1. Complete mixtures were kept at the desired temperature for 5 min before starting the reactions by the addition of H_2O_2 (1 μmol). Reaction extent was followed by the decrease in absorbance at 335 nm. Residual pyrene was estimated using the extinction coefficient $\epsilon = 32.6\ mM^{-1}\ cm^{-1}$ at 336 nm (*34*). Specific activity is expressed as min^{-1}.

Stability Assays. The horse-heart cytochrome *c* thermal stability was determined by estimating the specific activity after different incubation times at 80 °C in the absence or presence of substrate. Inactivation constants were determined by fitting the experimental data to the first-order equation ($A = A_0e^{-kt}$). Yeast cytochrome *c* thermal stability was assayed after 5 h at 70 °C using pyrene as substrate.

Circular Dichroism Measurements. CD measurements were performed on an AVIV 62Ds spectropolarimeter (Lakewood, NJ). Unmodified or modified cytochrome *c* samples (20 μM) were dissolved in 10 mM phosphate buffer, pH 6.1. Blank tests with buffer and controls containing 5 mM PEG (MW 5000 Da) in the same buffer were conducted, and the reference signals were subtracted from the sample signals. CD scans were performed from 180 to 260 nm and from 350 to 450 nm under the following conditions: bandwidth 1 nm, scan step 1 nm, and average time 1 s. For each sample, an average of three repetitions is given. For the assays at 7 or 24 h, incubations were carried out in a water bath previously equilibrated at 80 °C. Samples were contained in sealed vials to avoid evaporation. At the specified times, samples were removed from the water bath and placed in the quartz cell. Samples were equilibrated at the scan temperature for at least 10 min. Temperature in the cell compartment was controlled by a Peltier module. Protein concentration was determined before and after each assay.

Fluorescence Measurements. Fluorescence spectra were performed on a Perkin-Elmer LS-50B luminiscence spectrometer (Norwalk, CT). Samples containing 2 μM cytochrome *c* preparations were incubated at different GuHCl concentrations until reaching equilibrium. Afterward, each sample was excited at 295 nm, and three emission spectra from 300 to 500 nm were recorded and averaged. Data analyses were carried out using the center of mass obtained from each recorded spectrum.

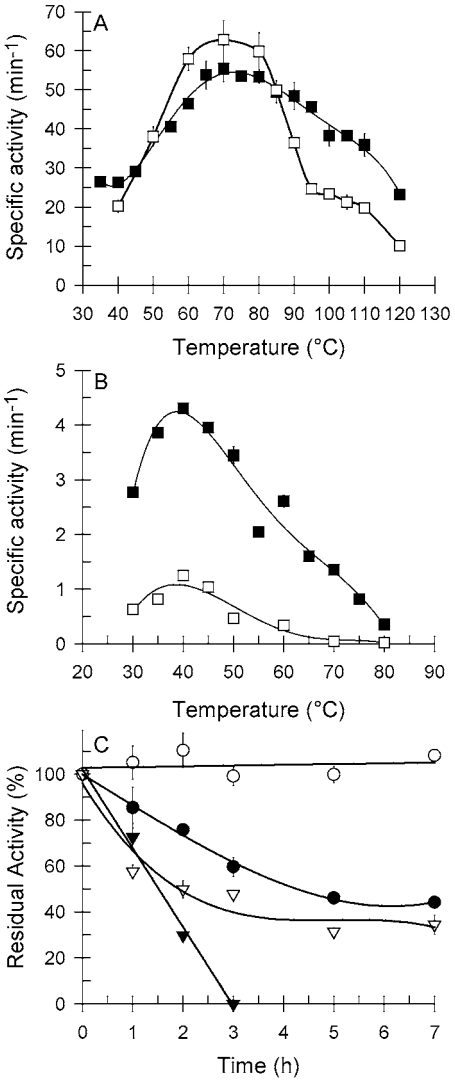

Figure 1. Biocatalytic oxidation of (A) pinacyanol chloride and (B) pyrene by unmodified (□) and chemically modified (■) cytochrome *c* at different temperatures. (C) Thermal stability of unmodified and chemically modified cytochrome *c* incubated at 80 °C with or without the presence of substrate (pinacyanol chloride). The reaction was started by the addition of hydrogen peroxide, and the residual activity was measured at 80 °C. (○) Cyt−PEG_{5000} incubated with substrate, (●) Cyt−PEG_{5000} incubated without substrate, (▽) Cyt incubated with substrate, (▼) Cyt incubated without substrate.

Data Analysis. Unfolding profiles were simultaneously fit by global analysis of the data obtained by fluorescence and CD. The thermodynamic and spectroscopic features were optimized in global fits by nonlinear least-squares analysis using an in-house version of Savuka 5.0 software package (*35*).

RESULTS AND DISCUSSION

Cytochrome *c* (Cyt) is a compact globular protein with an unusual intrinsic stability provided by a complex hydrogen-bond network (*36*, *37*). This stability leads Cyt to a remarkable catalytic performance as a peroxidase at temperatures as high as 120 °C (hyperthermophilic conditions), with maximal activity between 70 °C and 80 °C (Figure 1a). Horse heart cytochrome *c* was modified with PEG of 5000 Da MW (Cyt−PEG_{5000}). Chemical modification did not alter the specific activity nor the

temperature profile of cytochrome *c* when hydrophilic substrates are used, as in the case of pinacyanol chloride (Figure 1a). However, when the hydrophobic substrate pyrene is used, the Cyt−PEG_{5000} preparation showed higher specific activity than the unmodified Cyt (Figure 1b). Surprisingly, the maximal activity temperature was displaced from 70 °C with pinacyanol to 40 °C with pyrene for both preparations. Chemical modification with PEG produces an increase of the overall hydrophobicity of the protein (*38*, *39*) and an increased enzyme solubility in organic solvents with little loss of activity (*40*), facilitating homogeneous catalysis. Pinacyanol chloride is a relatively hydrophilic substrate; thus the activity toward this molecule was expected to be independent of the biocatalyst modification. On the other hand, the activity toward more hydrophobic molecules, such as polycyclic aromatic hydrocarbons and organosulfur compounds, would be especially increased by PEG modification of the enzyme, following a more favorable partition of the substrate from the solvent toward the active site (*22*, *41*).

Chemical modification dramatically increased the thermostability of the protein (Figure 1c). While Cyt lost all detectable activity after 3 h of incubation at 80 °C, Cyt−PEG_{5000} retained 45% of the initial activity after 7 h of incubation. In the presence of substrate (pinacyanol chloride), the intrinsic stability of both preparations was improved. In the case of Cyt−PEG_{5000}, the presence of substrate resulted in a stable catalyst, retaining 100% of the initial activity after 7 h of incubation at 80 °C. Poly(ethylene glycol) (PEG) is an amphiphilic polymer with the capability of binding water molecules (*42*) which might form an intricate hydrogen-bond lattice between the protein and the polymer. Chemical modification with PEG has been used to enhance the stability of several enzymes such as trypsin (*13*), horseradish peroxidase (*14*), chymotrypsin (*16*), and *C. rugosa* lipase (*15*, *16*). In this work, 80% of the surface lysine residues of the Cyt−PEG_{5000} were modified by PEG after the reaction, resulting in a biocatalyst with a predicted molecular weight of 94.7 kDa in which only 13% of the mass is protein. SDS−PAGE electrophoresis and gel filtration chromatography failed to confirm the average molecular weight of this preparation possibly due to the low motility of the polymer in gels (*43*) or to an increase in the hydrodynamic volume of the protein (*38*). The modified preparation was analyzed by electrospray mass spectrometry. The mass spectrum showed the presence of a variety of species; however, by deconvolution treatment the main species showed 94367 Da. Beside the complexity of the protein preparation and the limitations of the technique, the mass spectrum data showed that the chemical modification was extensive. The assumption of the complex hydrogen lattice as a stabilizing element suggests that it might contribute not only to enhance the tolerance of Cyt−PEG_{5000} to high temperatures, but also to stabilize the protein, which is in fact the case, as can be seen in Figure 1c.

Polycyclic aromatic compounds and organosulfur compounds were tested with cytochrome preparations at high temperature (Table 1). As expected, Cyt−PEG_{5000} showed higher activity against all substrates tested than the unmodified protein. This effect might be caused by the higher surface hydrophobicity of Cyt−PEG_{5000} active site, which in turn may be reflected in a more favorable partition of the hydrophobic substrate to the active site. The increased surface hydrophobicity has been reported to result in up to 9-fold increase in the overall catalytic efficiency of the biocatalyst (*22*).

The thermal stability of PEG-modified trypsin has been directly correlated to the molecular mass of the PEG moiety (*13*). To evaluate the effect of PEG sizes upon Cyt stability, we modified the protein with different methoxypoly(ethylene glycol)s previously activated with cyanuric chloride. Activation of low molecular weight PEG (350 Da) resulted in two batch preparations: PEG_{350} in which only one molecule of polymer was coupled to one molecule of 2,4,6 trichloro-1,3,5-triazine, and other, bisPEG_{350}, with two coupled molecules of polymer per molecule of activating reagent. The cyanuric chloride coupling with higher molecular weight polymers yielded mainly the mono derivatives. Incorporation of PEG_{350} and bisPEG_{350} into Cyt resulted in preparations with low degree of modification (20% to 30%), while modification with polymers of higher molecular masses produced biocatalysts with more than 70% modification (Table 2). A threshold value of the size of the polymer for the activity of the modified protein was found, independent of the temperature tested (Table 2). The specific activity increased as the polymer size and PEG/protein mass ratio increased up to values of 750 Da and 1.03, respectively. Then, the specific activity decreased as the polymer size and PEG/protein ratio increased. This effect might be the result of the steric hindrance of the active site by the polymer. In particular, PEG_{2000} and PEG_{5000} are molecules with a large exclusion volume that might prevent the interaction of substrates and the active site.

The thermal inactivation process for the Cyt−PEG preparations at 80 °C in all cases followed a first order kinetics. Surprisingly no loss in activity was found for Cyt−PEG_{2000} after 7 h at 80 °C in the absence of substrate, whereas the calculated half-lives for Cyt−PEG_{750} and Cyt−PEG_{5000} were 27 and 14 h, respectively (Table 2). The assumption of the protective effect of PEG upon the protein thermal stability through a shell-like structure suggested that the larger the PEG/Cyt ratio, the more stable would be the protein. This assumption was shown to be correct up to a threshold mass ratio of 2.8, while the preparation with larger value (PEG_{5000}) presented reduced stability. Thus, our results show that there is an optimal polymer/protein ratio for thermal stability of cytochrome *c*. The lower stability obtained at

both sides of the optimal ratio may be attributable at two different factors: (a) in the case of low ratios, a less structured hydrogen-bonded network caused by few polymer molecules on the protein surface, and (b) in the case of high ratios, an steric effect may occur with molecules having high exclusion volumes, which could distort the protein conformation.

The crystal structure of yeast cytochrome *c* (y-Cyt) (*36*) shows only two lysine residues close to the active site, Lys 27 and Lys 79. One of them, Lys79, is located at the edge of the active site and it is H-bonded with Ser 47 in yeast or Thr 47 in horse heart cytochrome *c*. Under reducing conditions, this H-bond results in the closure of the active site. The other lysine, Lys27, is part of a reversed γ-turn. This unusual structure is maintained by three main-chain H-bonds between Lys27, Gly29, and Cys17 and by one H-bond involving side-chain and main-chain atoms (Lys27 to Leu15). Substitution at this position with other residues makes the protein unable to form the last interaction, yielding a less stable protein (*36*). Despite the high homology between yeast and horse heart cytochromes, thermal and chemical denaturation studies had shown that yeast cytochrome *c* is less stable than those from mammalian sources (*44*). With the aim of clearing the polymer from the active site surface of cytochrome, Lys27 and Lys79 residues in y-Cyt were substituted by alanine, which has a nonreactive side-chain. Yeast cytochrome *c* has only 16 lysine residues, while horse heart cytochrome *c* has 19 lysine residues. Thus, it was expected a lower PEG/protein mass ratio for pegylated y-Cyt than that of horse heart cytochrome *c* preparations. We were unable to detect any activity in the yeast unmodified protein at temperatures above 70 °C (data not shown). Nevertheless, chemical modification with PEG_{5000} significantly increased the activity and stability of these preparations (Table 3). Our results indicate that (K27A)−PEG_{5000} retained only 54% of initial activity, while (K79A)−PEG_{5000} showed activity above 100% of the initial activity at 70 °C, both in the absence of substrate. On the other hand, the presence of the K27A substitution did not suppress the effect of K79A, as could be seen in the double mutant (K27A, K79A)−PEG_{5000} which showed the same residual activity as the single mutant. Our results suggest that in order to obtain higher stability, chemical modification of Lys27 is required and, at the same time, PEG must be excluded from Lys79. Four structural units have been described in horse heart cytochrome *c* (*37*). The fourth unit, reported as the less stable (*37*), is formed by the loop joining the 60−70 helix to the C-terminal helix and comprises the heme group axial coordinating side-chain Met80. It is reasonable to consider that the introduction of a very large molecule on the amino acid 79 would cause loop distortion and disruption of the Met80-heme ligation, which in turn would yield a less stable protein. On the other hand, the second unit contains the other proximal heme ligand, His18, being the second more stable unit within Cyt (*37*). Lys27 is located in this unit, leading its amino reactive group exposed to the solvent; thus it was expected that modification of Lys 27 would have no effect on the structural features of this unit.

To get a deeper understanding of the structural basis underlying PEG-induced thermal stabilization, we focused on the spectroscopic properties of horse heart Cyt−PEG_{5000} preparations. CD ellipticities at 222 nm have been widely used as an estimate of the α-helical content in proteins (*45*−*47*). Cytochrome *c* is a compact single domain protein of 104 amino acids with an α-helical content of about 30% (*33*). The changes in helical content of both Cyt and Cyt−PEG_{5000} after incubation at 80 °C are shown in Figure 2. A sharp decrease in ellipticity at 222 nm was observed for Cyt, when it was incubated at 80 °C for 24 h, indicating a complete loss of the protein secondary structure. Its noteworthy the increased noise in the Cyt−PEG_{5000} spectra. Control experiments in the presence of 5 mM of free PEG_{5000} did not show a significant signal in the wavelength range where the spectra were collected, discarding a contribution of the polymer to the signal. Thus, the increase in the noise is only attributable to the scattering produced by the chemical modification of cytochrome with PEG. Interestingly the signal minimum observed in Cyt−PEG_{5000} was displaced from 222 to 210 nm, suggesting that the chemical modification was enough to disturb the secondary structure. This fact is also confirmed by the lower mean residual ellipticity at 222 nm of the native Cyt−PEG as compared to Cyt (Figure 2). However, even if the initial structure of Cyt−PEG_{5000} was probably altered, with respect to the unmodified Cyt, its overall CD spectral features suffer a small decrement in CD signal at 222 nm during the first 10 min of incubation at 80 °C, after which remain unchanged even after extensive

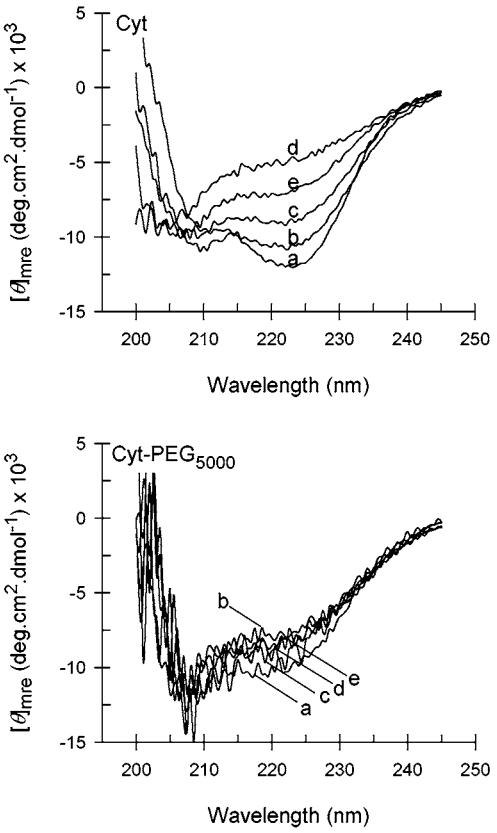

Figure 2. Mean residual ellipticity of cytochrome *c* preparations. Scans were obtained after samples were incubated under following conditions: (a) 30 °C, 10 min; (b) 80 °C, 10 min; (c) 80 °C, 7 h; (d) 80 °C, 24 h; (e) 80 °C, 24 h followed by cooling to 30 °C.

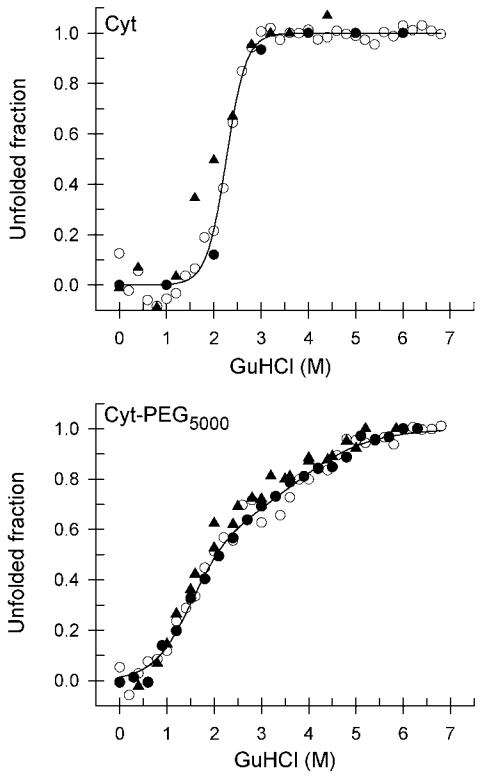

Figure 3. Equilibrium unfolding of Cyt and Cyt−PEG_{5000} after chemical denaturation by guanidine hydrochloride. Experimental data were fitted to a two-state model for Cyt and to a three-state model for Cyt−PEG_{5000}. Unfolding was followed by (○) fluorescence, (●) circular dichroism, and (▲) specific activity; (—) fit to a two-state model for Cyt and to a three-state model for Cyt−PEG_{5000}.

incubation at 80 °C (Figure 2). This result suggested a more conserved residual structure in Cyt−PEG_{5000}, which in turn could be the responsible for the thermotolerant activity found.

Urea denaturation studies of Cyt have shown that the unfolding proceeds through at least two intermediate states (*48*) while guanidine hydrochloride (GuHCl) denaturation has been considered as a two-state transition (*49*). Additionally, at least three intermediate states have been reported on unfolding of horse heart cytochrome *c*, which result from the cooperative unfolding of one or more of four known structural units (*37*). In this work we carried out the chemical denaturation of unmodified and modified cytochrome *c* with GuHCl and monitored the unfolding process through fluorescence and CD (Figure 3). For both preparations unfolding was found to be fully reversible. Denaturation data of Cyt fit into a two-state model, showing a highly cooperative transition between 1.6 and 2.8 M GuHCl. On the other hand, Cyt−PEG denaturation fit into a three-state model and the unfolding was less cooperative, showing a first transition between 0.6 and 2.2 M GuHCl and a second one between 3.4 and 4.8 M GuHCl. It is important to note that the loss of activity precede the loss of structure in the unmodified cytochrome and is less cooperative, while in the PEG-modified protein the activity is strongly associated to the loss of structure. The appearance of the intermediate state may explain the activity found at high temperature in the case of Cyt−PEG_{5000}.

The thermodynamic parameters for the unfolding of Cyt and Cyt−PEG_{5000} presented in Table 4 were calculated by fitting experimental data to the corresponding unfolding models (see Figure 3). The global unfolding free-energy for Cyt was estimated to be 6.4 kcal/mol which is close to the reported value of 7.27 kcal/mol (*50*, *51*). The calculated $\Delta(\Delta G)_{25°C}$ between the unmodified and the chemically modified preparations was 1.36 kcal/mol, indicating a reduced thermodynamic stability for Cyt−PEG_{5000}, which is contradictory to the higher stability conferred by the chemical modification on cytochrome activity. A striking difference between the denaturation profiles of Cyt and Cyt−PEG_{5000} is the absence of a well-

Table 4. Thermodynamic Unfolding Parameters of Cyt and Cyt−PEG_{5000} at 25 °C

parameter	Cyt[a]	parameter	Cyt−PEG[b]
ΔG_{nu} (kcal/mol)	6.4 (± 0.8)	ΔG_{ni} (kcal/mol)	2.19 (± 0.15)

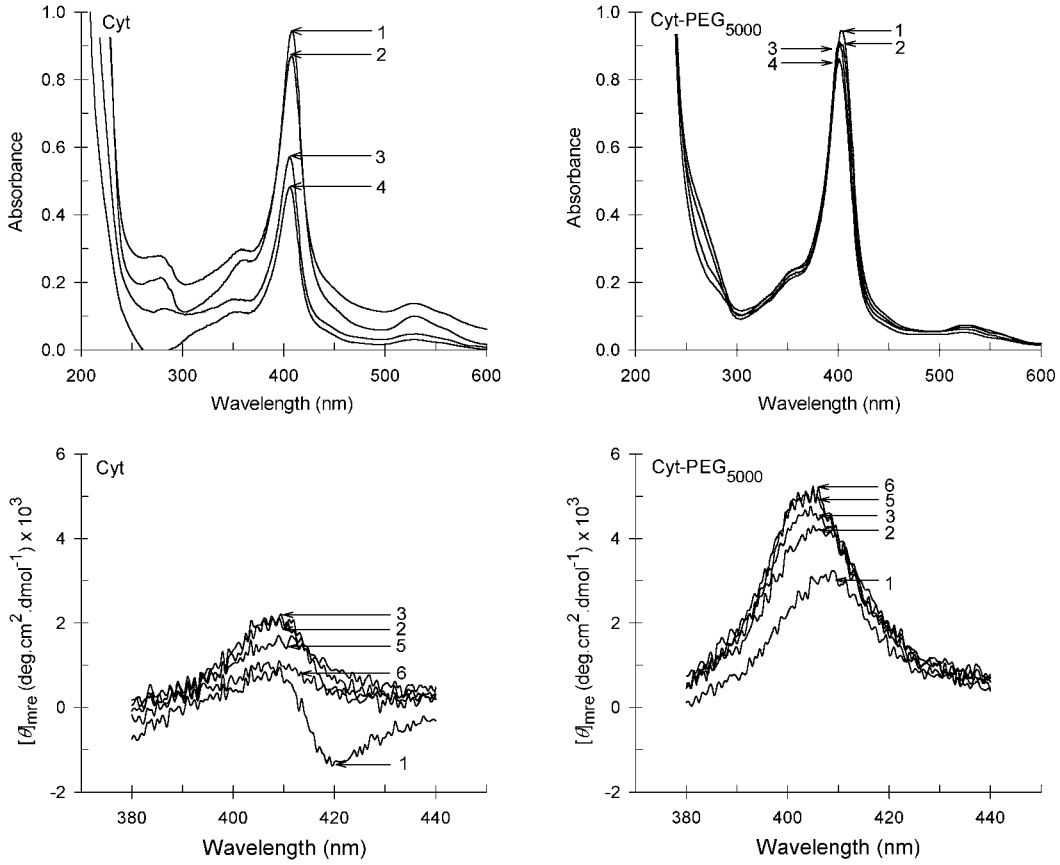

Figure 4. UV-visible (top panels) and CD (bottom panels) spectra of cytochrome *c* and Cyt−PEG_{5000} preparations. Scans were obtained after samples were incubated under following conditions: (1) 10 min at 30 °C; (2) 10 min at 80 °C; (3) 7 h at 80 °C; (4) 7 h at 80 °C and cooling to 30 °C; (5) 24 h at 80 °C; (6) 24 h at 80 °C and cooling to 30 °C.

defined native baseline in the latter. This feature can be interpreted as an altered initial structure, attributable to the chemical modification, and in agreement with the lower mean residual ellipticity observed at 222 nm.

To investigate the structural implications of the chemical modification upon Cyt activity, we performed the spectrometric study of the tertiary structure around the active site. The absorption signal at 695 nm has been associated to the heme-iron coordination state and can be used to follow coupled reactions, such as Met80-heme coordination, opening of the heme crevice, and global unfolding (*52*). As reported previously (*53*), none of our Cyt−PEG_{5000} preparations presented the 695 nm band, which may be the result of the loss of the Met80-heme sixth ligand. The spectrometric analysis of Cyt at the Soret region (350−450 nm) provides a mean to probe the active site conformation (*52*) in a nondisruptive manner. This analysis yielded additional evidence of the intrinsic active site distortion due to the chemical modification: (a) the analysis of the active site through CD showed that the negative signal at 420 nm is lost upon Cyt chemical modification (Figure 4, bottom panels); this band reflects the heme−polypeptide interactions and can be used to measure the integrity of heme crevice (*45*). On the other hand, this band is irreversibly lost during heating of the unmodified cytochrome, (b) the CD spectra of Cyt−PEG_{5000} showed an enhancement of the 410 nm signal during the first 10 min at 80 °C, after which the spectra remain unchanged, suggesting a more conserved secondary structure around the heme pocket, and (c) the Soret band of the Cyt−PEG_{5000} shifted from the 410 nm maximum to 402 nm, indicating a more hydrophobic heme microenvironment. As expected, our results showed that the Soret band of Cyt disappeared irreversibly after incubation at 80 °C, indicating the total disruption of the active site (Figure 4, top panels). On the other hand, the Soret band of Cyt−PEG_{5000} remained basically unaltered after the same treatment, reflecting the stable conformation of the active site (Figure 4). This more conserved structure around the heme could be responsible for the thermostable activity. The kinetics of unfolding of the active site was also evaluated by following the loss of the Soret band of cytochrome preparations. The results obtained indicated a half-life of 167 h for Cyt−PEG_{5000} at 80 °C, while for Cyt it was only 42 h under the same conditions. Thus, our results suggest that PEG acts as a cage in which the destabilized structure of Cyt−PEG_{5000} is trapped. In other words, the polymer works as a kinetic trap stabilizing an intermediate state upon unfolding of the modified protein. This catalytically active intermediate state may arise from a more conserved structure around the active site and seems to be responsible for the activity found after long periods of incubation at high temperature.

The conformation of PEG in aqueous solutions ranges from a random coil to a helix in which oxygen acts as an anchor for hydrogen bond formation. In fact, it has been demonstrated that each residue of ethylene in PEG is able to hydrogen-bond from two to three water molecules (*42*, *54*). It has also been found that PEG is flexible in nonpolar solvents and rigid in aqueous solutions. This entropy loss is explained by an increase in the water structure around the hydrophilic region of PEG and to a lesser extent in the hydrophobic region (*55*). Thus, the mechanism of stabilization of poly(ethylene glycol) seems to be due to the adduct amphiphilicity (*16*). A primary shield of rigid water molecules solvate the hydrophilic region of bound PEG, helping to maintain the structure

of the protein, whereas the hydrophobic regions in PEG interact with the hydrophobic clusters on protein surface. Those sets of interactions would produce a shell-like structure in which PEG is coiled on the protein surface avoiding direct contact with water molecules in the solvent and producing a more conserved structure around heme. The global effect of those interactions is a decreased unfolding rate of the active site as confirmed by UV−visible spectroscopy and CD.

CONCLUSIONS

Chemical modification with PEG has shown to be an interesting tool to enhance the kinetic stabilization of proteins and to obtain catalytic activity at very high temperatures. The polymer/protein ratio and the modification sites seem to be determinant factors on the protein stabilization. The absence of polymer near the active site is desirable in order to achieve higher stability. Contrary to what we expected, the overall effect of chemical modification was a thermodynamic destabilization of the protein conformation. However, the polymer also works as a cage in which the destabilized structure is trapped. This cage increases the activation barrier, and thus the resulting structure can stand longer times under destabilizing conditions. Our results suggest that the peroxidasic activity found for Cyt−PEG_{5000} at hyperthermophilic conditions might be the result of two factors, a more conserved structure of the heme pocket and a decreased unfolding rate of the active site. A thermostable biocatalyst obtained by chemical modification of cytochrome *c* and with enhanced activity on hydrophobic substrates may have potential industrial applications.

ACKNOWLEDGMENT

We thank Prof. Michael A. Pickard for the critical reading and discussion on protein thermostabilization, and Dr. Cesar Ferreira for the mass spectroscopy analysis. This work was supported by a grant from the Mexican Oil Institute (FIES 98-110-VI) and by the National Council for Science and Technology of México (grant 33611-U). We acknowledge Eugenio López Bustos and Paul Gaytán for their assistance in oligonucleotide synthesis.
