The present paper describes the chemical synthesis and in vitro characterization of a novel, high-affinity, fluorescent progesterone receptor (PR) antagonist. The three-step synthesis was carried out starting from mifepristone. After demethylation with calcium oxide, the methylamino group was alkylated with 6-bromohexanol, and the resulting compound was reacted with fluorescein 5-isothiocyanate, yielding the fluorescein−mifepristone conjugate. Interaction of the conjugate as well as of its precursors with PR was determined in cell culture (alkaline phosphatase assay and transactivation assay). Antiprogestagenic activity of the intermediates were comparable to that of the parent compound. Even after attachment of the bulky fluorescein moiety, considerable antiprogestagenic activity was maintained. Microscopic studies revealed that fluorescence of the conjugate was almost confined to the nuclei of steroid hormone receptor-positive cells, whereas the nuclei of steroid hormone receptor-negative cells remained unstained. To our knowledge, this is the first report on a fluorescent ligand for PR suitable for studies in living cells. It is proposed that the present fluorescent PR antagonist might serve as a lead compound for the development of contrast agents for PR imaging, e.g., by near-infrared optical imaging.

INTRODUCTION

The progesterone receptor (PR)[1] is a ligand-activated transcription factor that belongs to the nuclear receptor superfamily, which includes the steroid hormone receptors as well as thyroid, vitamin D, and retinoic acid receptors. It contains conserved functional domains, including the N-terminus, a centrally located DNA binding domain (DBD), and the C-terminal ligand binding domain (LBD). The human PR exists as two isoforms (A and B) in most PR-expressing cells, which arise from a single gene located in the region 11q22-q23 of chromosome 11. The isoform A (PRA) is a 164 amino acid N-terminally truncated variant of the isoform B (PRB). Although both isoforms have similar DNA and ligand binding properties, they have distinct functional properties. Current knowledge of the ligand−receptor interaction at the molecular level mainly relies on the crystal structure of the LBD of the PR complex formed after binding of progesterone (*1*) as well as on results of site-directed mutagenesis experiments (*2*) and classical molecular dynamics simulations (*3*). According to the physiological role of its natural ligand, i.e., establishment and maintenance of pregnancy, high PR levels are found in the female reproductive system. Current development of drugs interacting with the PR comprise (1) selective PR antagonists (*4, 5*) expected to be useful for the treatment of chronic conditions, e.g., endometriosis or leiomyomas, and (2) radioligands (*6*−*8*) to enable determination of PR levels in vivo for assessing the hormone responsiveness of breast cancer without tissue biopsy.

During the past decade, optical imaging using near-infrared (NIR) light has emerged as a new diagnostic modality, in particular for breast tissue (*9*). Since contrast and image resolution is limited by multiple scattering of the photons, reliable tissue characterization based on intrinsic absorption and scattering inhomogeneities is often difficult, in particular with respect to distinguish between benign and malignant lesions (*10, 11*). Similar to other clinical imaging modalities, it is likely that sensitivity and specificity of optical imaging will be improved by contrast agents. Considering photophysical properties, cyanine dyes are one of the most promising classes of compounds suitable as contrast agents for NIR optical imaging (*12, 13*). Recently, indocyanine green has been successfully applied to detect breast cancer probing tumor vascularization and vessel permeability (*14*). In addition to tumor targeting by such unspecific mechanisms, contrast agents which specifically target receptors overexpressed in tumor cells (*15*−*18*), or which are activated by tumor-associated enzymes (*19*−*23*), have recently been developed, thus enabling molecular imaging.

PR status of breast cancer was found to be an independent predictive factor for benefit from adjuvant

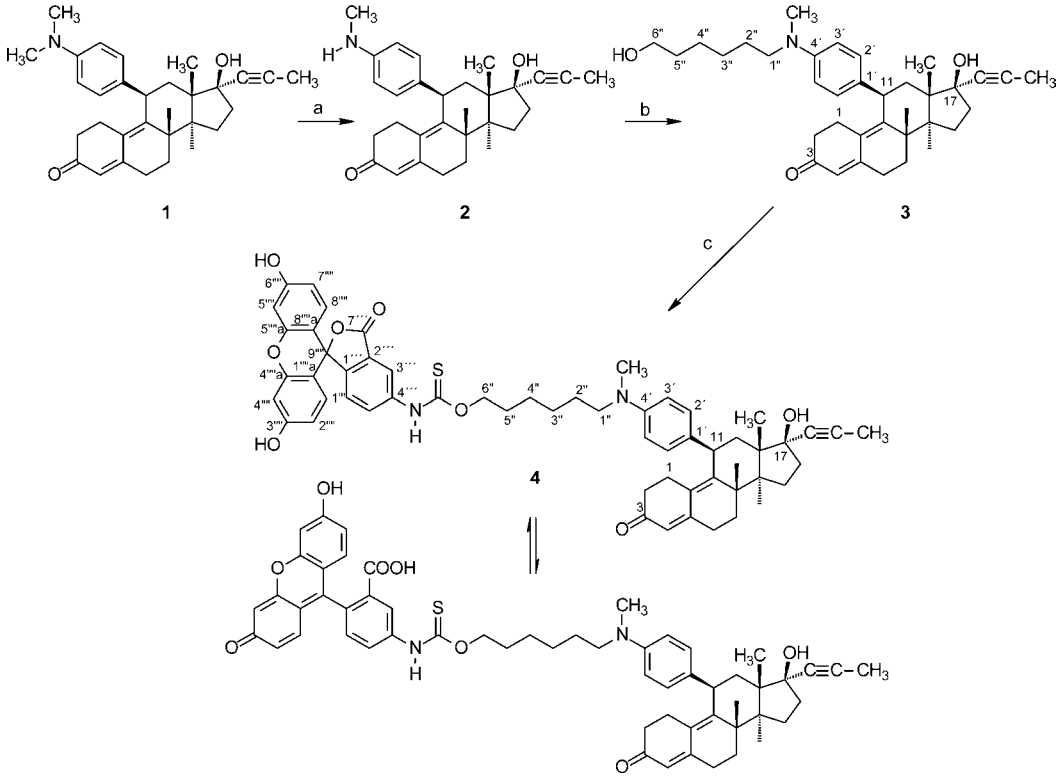
endocrine therapy. Patients with steroid hormone receptor-positive tumors, expressing estrogen receptor as well as PR, have the most favorable prognosis (*24*). Therefore, reliable and noninvasive determination of PR levels in breast cancer, preferentially with high sensitivity and without harmful radiation, i.e., by NIR optical imaging, seem to be highly desirable. However, no appropriate PR-binding contrast agent is known, so far. In the present paper, synthesis and in vitro studies of a novel, high-affinity, fluorescent PR antagonist is reported, which might serve as lead compound for the development of PR-binding contrast agents for NIR optical imaging.

EXPERIMENTAL PROCEDURES

Materials and Chemical Methods. (11β,17β)-17-Hydroxy-11-[4-(dimethylamino)phenyl]-17-(1-propynyl)-estra-4,9-dien-3-one (**1**) and fluorescein 5-isothiocyanate (FITC, isomer I) were obtained from Sigma-Aldrich. All other reagents for syntheses were purchased from either Sigma-Aldrich or Merck and were used without further purification. Reagent-grade solvents were obtained from Merck and were purified and dried using standard methods. Solvents of analytical and spectroscopic grade and deuterated NMR solvents were purchased from Merck and Uetikon, respectively.

UV/vis spectra were recorded on a Shimadzu UV-160A spectrometer. Absorption maxima λ_{max} are given in nm. Fluorescence spectra were measured using a Kontron Instruments spectrofluorometer. Excitation and emission maxima λ_{max} are given in nm. IR spectra were recorded on a Perkin-Elmer FTIR 2000 spectrometer. Absorption maxima ν_{max} are given in cm^{-1} and are referred to as s (strong), m (medium), w (weak), and br (broad). EI-mass spectra were measured with a Finnigan MAT 212 or Varian MAT 312 spectrometer at 70 eV ionizing voltage. Intensities are given in % of the base peak. NMR spectra were recorded at 300 K on a Varian Unity Inova 400 NMR spectrometer equipped with a tunable broad band probe. Inverse detected gradient selected 2D experiments (gCOSY, HSQC, HMBC) were performed using standard pulse sequence programs. HMBC experiments were optimized for a long range-coupling constant of 8 Hz. Spectra were referenced internally using tetramethylsilane. Chemical shifts δ are given in ppm. Coupling constants (*J* values) are expressed in Hz, and multiplicities are referred to as s (singlet), d (dublet), t (triplet), q (quartet), m (multiplet), and br (broad).



TLC analyses were performed on Merck F_{254} silica gel plates. Spots were visualized either by UV absorbance at 254 nm or fluorescence emission excited at 366 nm. Column chromatography was carried out on Merck silica gel 60, 70−230 mesh, using EtOAc:cyclohexane (CH) (3:2) as eluent. Preparative RP-HPLC was performed using a Labomatic HD-200 pump equipped with a Labocord-700 UV/vis detector.

(11β,17β)-17-Hydroxy-11-[4-(methylamino)phenyl]-17-(1-propynyl)estra-4,9-dien-3-one (2). (11β,17β)-17-Hydroxy-11-[4-(dimethylamino)phenyl]-17-(1-propynyl)-estra-4,9-dien-3-one (**1**) (500 mg, 1.164 mmol) was dissolved in a 1:1 mixture of MeOH and THF (7.0 mL), and freshly calcined CaO (555 mg, 9.897 mmol) was added. I_2 (739 mg, 2.912 mmol) dissolved in the same solvent (1.5 mL) was added dropwise at 0 °C. The reaction mixture was stirred at 0 °C for 1 h. After CaO removal, it was diluted with 10% $Na_2S_2O_3$ and extracted with CH_2Cl_2. The combined organic layers were washed with water and brine and dried over Na_2SO_4. The solvent was evaporated after filtration, and the crude product was purified by column chromatography. Fractions containing the steroidal compounds **1** and **2** were further purified by HPLC (ProntoSIL 120−5-C18H, 5 μm, 200 × 20 mm, MeCN:H_2O = 84:16, 23 mL/min, λ = 254 nm) to afford compound **2** as a white solid (135 mg, 28%) after lyophilization, t_R = 3.4 min. Educt **1** was recovered (130 mg, 26%), t_R = 4.3 min. TLC (EtOAc:CH = 3:2): R_f = 0.5; TLC (CH_2Cl_2:MeOH = 9:1): R_f = 0.71. UV/vis (MeOH): 209.0, 250.0, 303.5; UV/VIS (MeCN): 254.0, 295.5. Cell Culture and Media. T47-D cells (breast cancer, human, steroid hormone receptor-positive) were obtained from American Type Culture Collection (ATCC number HTB-133 (*25*)) and OV2774 cells (ovarian cancer, human, steroid hormone receptor-negative) were kindly provided by Prof. D. G. Kieback, Department for Obstetrics and Gynecology, Maastricht University Medical Center, The Netherlands. T47-D-Cl24 cells stably expressing luciferase under control of hormone responsive mouse mammary tumor virus (MMTV) promoter (*26*) were generated. Vectors ΔMa-Luc (generous gift of Prof. R. Schüle, Department of Obstetrics and Gynecology, University Hospital Freiburg, Germany) and pcDNA6/HisA (invitrogen) were cotransfected into T47-D cells using Rotifect (Roth) as recommended by the supplier. Stable transfectants were selected with blasticidin (2.5 μg/mL), and individual colonies were picked and cultured separately. Clones were screened for luciferase expression after incubation with progesterone (10^{-6} mol/L). Clone 24 was chosen considering level and dynamic range of luciferase expression after progesterone incubation (10^{-11} to 10^{-6} mol/L). T47-D and T47-D-Cl24 cells were maintained in RPMI 1640 medium (invitrogen) supplemented with 10% fetal calf serum (FCS, Biochrom) and antibiotics (penicillin (100.000 U/L), streptomycin (100.000 μg/L), invitrogen) and cultured in a humidified atmosphere containing 5% CO_2 at 37 °C. Twenty-four hours prior to the experiments cells were seeded at a density of 100 cells per mm^2 in 96-well plates (Nunc) or on microscope slides (Marienfeld) and were cultivated in RPMI 1640 medium

(without phenol red) supplemented with 5% dextran charcoal stripped FCS (DCS) and antibiotics at 5% CO_2 and 37 °C. Incubation media were made up by adding an appropriate volume of the stock solutions of compounds **1**−**4** and progesterone (prepared in dimethyl sulfoxide (DMSO) and stored at −20 °C) to RPMI 1640 medium (without phenol red, plus 5% DCS and all other supplements). In each case, the final DMSO concentration in the incubation medium was 0.1% (v/v). Incubations were performed after washing the cultures with phosphate-buffered saline (PBS).

Alkaline Phosphatase Assay. T47-D cells were coincubated with increasing concentrations of either compound **1** (reference antagonist) or test compounds **2**, **3**, or **4** (10^{-11} to 10^{-7} mol/L) and progesterone (10^{-9} mol/L). The alkaline phosphatase assay was performed as reported previously (*27*, *28*) with some minor modifications. Briefly, after 48 h incubation cells were washed with 0.9% saline and stored at −80 °C for at least 30 min.. After thawing cells were incubated with 50 μL *p*-nitrophenyl phosphate (5 mM, Fluka) dissolved in aqueous diethanolamine (1 M, supplemented with 0.5 mM magnesium chloride and 20 μM zinc sulfate, and adjusted to pH 9.8) for 2−5 h in the dark at room temperature. Absorbance of *p*-nitrophenolate was measured in a Lucy 1 multimode plate reader (anthos labtec instruments) at 405 nm (vs 690 nm as reference). For each compound, at least four independent experiments (with six data points each) were carried out. After background subtraction (absorbance of cells without hormonal treatment), absorbance was normalized to the absorbance resulting from the progesterone incubation. Median (central tendency) ± median absolute deviation (variability) were calculated. IC_{50} values were determined from dose−response curves and are given in nmol/L.

Transactivation Assay. T47-D-Cl24 cells were coincubated with increasing concentrations of compound **1** (reference antagonist) or test compounds **2**, **3**, or **4** (10^{-12} to 10^{-8} mol/l) and progesterone (10^{-9} mol/L). After 24 h incubation, luciferase activities were measured by the Reporter Gene Luciferase Assay, Constant Light Signal (Roche Diagnostics) as recommended by the supplier in the Lucy 1 reader. For each compound, four independent experiments (with six data points each) were carried out using white 96-well plates. Luciferase activity is given as normalized response value relative to the luciferase activity produced by progesterone. Median (central tendency) ± median absolute deviation (variability) were calculated. IC_{50} values were determined from dose−response curves and are given in nmol/L.

Fluorescence Microscopy. T47-D and OV2774 cells were incubated with either compound **4** or fluorescein (Riedel-de Haen) for 5−7 h at 37 °C. Incubation concentrations were varied between 10^{-8} mol/L and 10^{-6} mol/L. After incubation, cells were washed twice with PBS. Fluorescence images were obtained with an upright Axioplan I microscope (Zeiss) equipped with a highly sensitive CCD camera (ST138 (Princeton Instruments) equipped with a thermoelectrically cooled CCD-512EFT chip (EEV)) at 40× magnification (oil immersion NA 1.3). Fluorescence was excited in the blue spectral region (band-pass filter: 450−490 nm) and detected above 520 nm (dichroic mirror: 510 nm, long-pass filter: 520 nm). For both compounds, an identical exposure time of 1 s was applied to minimize photobleaching. Image acquisition was performed using WinView 32 (Princeton Instruments). Images were stored as TIFF files, and contrast and brightness were adjusted manually (Adobe Photoshop 6.0, Adobe Systems, Inc.).

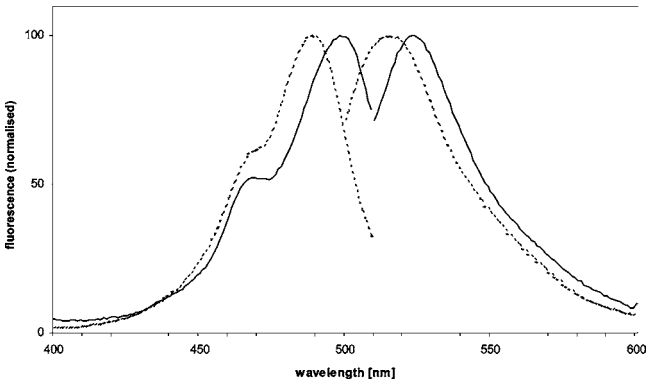

Figure 1. Fluorescence excitation and emission spectra of conjugate **4** (solid lines) and fluorescein (dotted lines) in PBS (supplemented with 10% FCS). Excitation spectra were recorded at the emission maxima (515 nm (fluorescein) and 524 nm (conjugate **4**)), and emission spectra were recorded at the excitation maxima of each compound (488 and 498 nm) at a concentration of 10^{-6} mol/L.

[a] Inhibition of progesterone-induced (10^{-9} mol/L) alkaline phosphatase activity in T47-D cells. [b] Inhibition of progesterone-induced (10^{-9} mol/L) transcriptional activity in T47-D-Cl24 cells. [c] IC_{50} values are were determined from dose−response curves and are given in nmol/L. [d] Relative potency is defined as the ratio of IC_{50} (**1**) to IC_{50} (x) with x = **2**, **3**, **4**.

RESULTS

Chemistry. Synthesis of the conjugate **4** was carried out starting from the antiprogestin **1**, mifepristone (RU486), which was converted to intermediate **2** by treating with calcium oxide and iodine in methanol/tetrahydrofuran (*29*). Alkylation of the methylamino group of **2** with 6-bromohexanol in anhydrous dimethylformamide in the presence of potassium carbonate resulted in intermediate **3**, which was reacted with FITC in dry dimethylformamide (*30*), yielding compound **4** as yellow crystals. The synthetic pathway of conjugate **4** is depicted in Scheme 1. The colorless, nonfluorescent lactone form of conjugate **4** was prevalent in the aprotic NMR solvent, whereas an aqueous environment as used in biological studies caused spontaneous conversion into its quinoid, fluorescent form. Fluorescence excitation and emission spectra of fluorescein and conjugate **4** are quite similar (Figure 1), although a bathochromic shift of about 10 nm was observed for excitation and emission maxima (488 nm vs 498 nm and 515 nm vs 524 nm).

Antiprogestagenic Activity. Antagonistic activity of conjugate **4** and intermediates **2** and **3** was determined in cell culture using the alkaline phosphatase assay in T47-D cells and a transactivation assay in T47-D-Cl24 cells stably transfected with the luciferase gene linked to the hormone responsive MMTV promoter. Inhibition of progesterone-induced increase of either alkaline phosphatase or luciferase activity was found for all compounds. IC_{50} values determined from dose−response curves and the relative potencies (defined as the ratio of the IC_{50} value of the reference antagonist **1** to the IC_{50} value of the individual test compound) are summarized in Table 1. Antiprogestagenic activity of the intermedi-

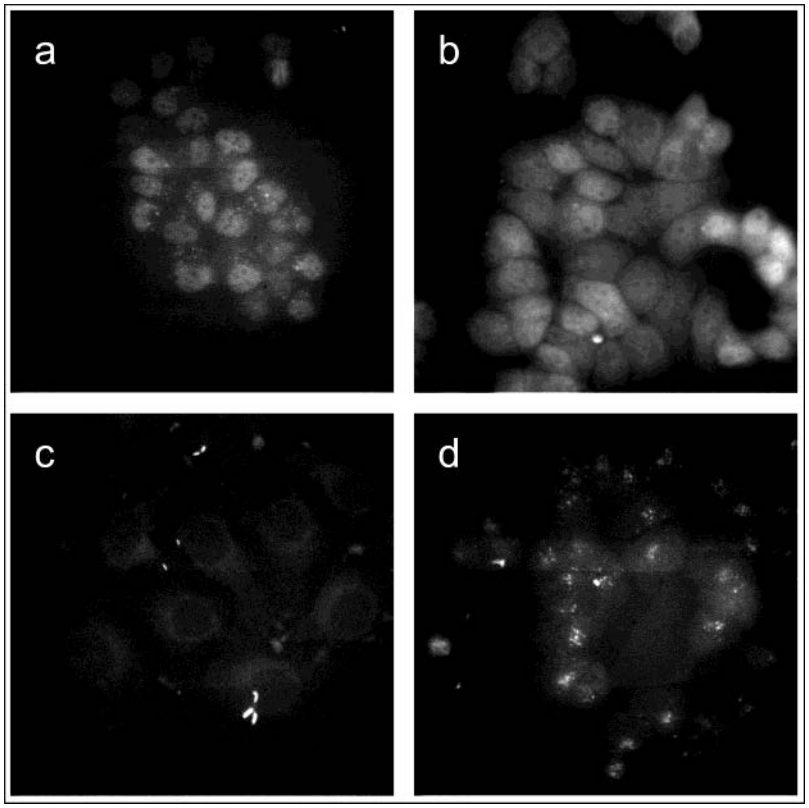

Figure 2. Fluorescence images (40× magnification) of conjuagte **4** in steroid hormone receptor-positive T47-D breast cancer cells at incubation concentrations of 10^{-8} mol/L (A) and 10^{-7} mol/L (B) as well as in steroid hormone receptor-negative OV2774 ovarian cancer cells (C, 10^{-7} mol/L), and fluorescence image of fluorescein in T47-D cells (D, 10^{-7} mol/L). Incubations were carried out 5−7 h prior to microscopy at 37 °C.

ates **2** and **3** were 3- to 4-fold lower than that of the reference antagonist **1**. Conjugate **4** exhibited considerable antiprogestagenic activity with IC_{50} values in the nanomolar range, although the relative potency of conjugate **4** was approximately 30-fold lower as compared with the parent compound **1**.

Fluorescence Microscopy. Subcellular distribution of conjugate **4** was examined by fluorescence microscopy. For steroid hormone receptor-positive T47-D cells, fluorescence of conjugate **4** was almost confined to the cell nuclei (without staining the nucleoli) at the lowest incubation concentration of 10^{-8} mol/L. Predominantly diffuse fluorescence arising from the cytoplasm was barely above background (intrinsic cell fluorescence) (Figure 2a). When incubation concentration was increased to 10^{-7} mol/L or 10^{-6} mol/L, fluorescence was distributed more homogeneously within the whole cell, and cell nuclei were stained prominently only in selected cases (Figure 2b). In contrast, fluorescence of conjugate **4** could not be detected in the cell nuclei of steroid hormone receptor-negative OV2774 cells independently of the incubation concentration. Cells exhibited a weak fluorescence with sometimes a distinct pattern within the cytoplasm at an incubation concentration of 10^{-7} mol/L (Figure 2c), whereas fluorescence intensity was close to intrinsic cell fluorescence at 10^{-8} mol/L. Control experiments performed with fluorescein in T47-D cells revealed diffuse fluorescence within the cytoplasm together with fluorescent granules in the perinuclear region, which is exemplified for an incubation concentration of 10^{-7} mol/L in Figure 2d.

DISCUSSION

Conjugate **4** was obtained in a three-step synthesis. After demethylation of mifepristone to intermediate **2** (step 1), the methylamino group was alkylated with 6-bromohexanol, resulting in intermediate **3** (step 2), which was reacted with FITC, yielding the desired conjugate **4** (step 3). Oxidative demethylation of 4-substituted *N*,*N*-dimethylanilines (*31*) has previously been applied to obtain intermediate **2** and a related antiprogestin (*29*). Alternatively, intermediate **2** could also be obtained by reacting **1** with iodobenzene diacetat (*32*). The other two steps were performed following standard procedures. Structures of all compounds were confirmed by NMR spectroscopy, and clean spectra were obtained in all cases. Although the protons at positions 3‴ and 5‴ as well as the carbon atoms 1‴ and 5‴ of conjugate **4** could not be resolved at the applied magnetic field strength, the NMR spectra clearly confirm the prevalence of the lactone form of conjugate **4** in the aprotic solvent. Several protolytic forms of fluorescein are known. The neutral species can be obtained as a solid as a colorless lactone, yellow zwitterion or red quinoid (*33*). Since covalent attachment of fluorescein does not perturb the protolytic transitions of the chromophore (*34*), the dianion form of conjugate **4** is the predominant fluorescent species in an aqueous environment at near neutral pH values (*33*, *34*).

To demonstrate ligand−receptor interaction of conjugate **4** and intermediates **2** und **3** in cell culture, antiprogestagenic activity of all compounds was determined using two independent assays, which was compared with that of the parent compound **1**, mifepristone, as reference antagonist. Compounds **1**−**3** exhibited antiprogestagenic activity in the same order of magnitude. Even after attachment of the bulky fluorescein moiety to intermediate **3**, considerable antiprogestagenic acitivity was maintained. Although the interactions of conjugate **4** and the intermediates **2** and **3** with other steroid hormone recep-

tors were not evaluated, it is likely that all three compounds display a similar receptor interaction profile as the parent compound **1**, e.g., considerable antiglucocorticoid activity (*35*). Since functional activity is roughly in agreement with receptor binding affinity (RBA) (*36*), considerable affinity of conjugate **4** to PR is supposed.

Specific binding of the conjugate **4** to PR is strongly supported by fluorescence microscopy. Nuclear localization was observed solely in steroid hormone receptor-positive T47-D cells, whereas nuclei of steroid hormone receptor-negative OV2774 cells remained unstained. Moreover, coincubation of conjugate **4** with a 10-fold excess of the antiprogestin **1** prevented nuclear staining (R. Sailer et al., unpublished data). Fluorescence microscopy of conjugate **4** is concordant to findings obtained recently with chimeras of PR and green fluorescent protein (GFP). Binding of either agonist (17,21-dimethyl-19-nor-pregn-4,9-diene-3,20-dione, promegestone, a synthetic progestin) or antagonist (compound **1**) to either GFP−PRA or GFP−PRB chimeras caused import of the receptors into the nucleus, but excluding the nucleoli (*37*). The different fluorescence intensity of conjugate **4** in the nuclei of different cells demonstrates the heterogeneity in PR expression, which varies during the cell cycle (*38*, *39*). Accumulation of conjugate **4** within the cytoplasm at higher incubation concentration is most likely to result from unspecific accumulation or binding to other proteins after saturation of the specific PR binding sites.

So far, efforts to develop fluorescent ligands with high affinity for PR resulted in the synthesis of a nitrobenzoxadiazole derivative of a 11β-substituted 19-nor-steroid ((11β,17β)-17-hydroxy-11-(4-[(7-nitro-4-benzofurazanyl)-amino-methyl]phenyl]-17-(1-propynyl)estra-4,9-dien-3-one (*40*)). This compound exhibits high affinities for PR as well as glucocorticoid receptor (*40*, *41*) and high fluorescence quantum yield in hydrophobic solvents (*41*). Although fluorescence was maintained after unspecific binding to proteins, the ligand became nonfluorescent after specific binding to PR (*41*). Since ligand−receptor interaction is not severely impaired after attachment of either the nitrobenzoxadiazole fluorophore or fluorescein to a 11β-substituted 19-nor-steroid, the distance between the fluorophore and the steroid moiety might be important to obtain a fluorescent PR complex. To our knowledge, this is the first report on a fluorescent ligand for PR suitable for studies in living cells. However, it should be mentioned that fluorescence polarization might be used to determine ligand−steroid hormone receptor interaction (Fluormone, Invitrogen; PCT International Application (*32*), Boehringer Ingelheim) in homogeneous systems. But it remains to be elucidated, whether the ligands used in these assays are also fluorescent in viable cells.

To summarize, conjugate **4** is a novel, high-affinity, fluorescent PR antagonist, which might serve as a lead compound for the development of PR-binding contrast agents for NIR optical imaging. It is anticipated that fluorescein can be replaced by an appropriate NIR dye (*12*, *13*) without further compromising ligand−PR interaction. However, further development of a contrast agent for PR imaging should consider (1) receptor binding profile and (2) tissue distribution. Ligand specificity is likely to be increased, when the conjugate is assembled with a highly selective antiprogestin (*4*, *5*, *42*, *43*), thus minimizing binding to other steroid hormone receptors. Minimizing the uptake of the conjugate into nontarget tissues is more challenging as outlined for several receptor-specific small-molecule radiopharmaceuticals (*44*).

ACKNOWLEDGMENT

Intein-mediated ligation provides a site-specific method for the attachment of molecular probes to proteins. The method is inherently flexible with regard to either the protein sequence or the attached probe, but practical difficulties have limited the widespread use of this valuable labeling system for the attachment of small- to medium-sized molecules. We report herein studies to improve the efficiency and practical application of these reactions, including the assembly of plasmids for the expression of target−intein fusion proteins and the analysis of their reaction with a fluorescent cysteine derivative under a range of conditions. Optimal ligation of the fluorophore to the target protein is critically dependent on the degree of oxidation of the fluorescent cysteine derivative. Efficient ligation has been achieved with freshly prepared fluorescent cysteine derivative under rigorously anaerobic conditions. Similar ligation yields have also been achieved using more practically convenient conditions including anaerobic reaction with addition of thiophenol, or aerobic reaction with the further addition of tricarboxyethylphosphine.

INTRODUCTION

Studies of a wide range of proteins and enzymes could potentially benefit from the site-specific attachment of molecular probes to the protein of interest. Recently, intein-mediated activation of the C-terminus of a protein domain has been shown to provide a general method for attaching a wide range of molecules, including proteins (*1*), peptides (*2*), fluorescent labels (*3*), carbohydrates (*4*), oligonucleotides (*5*), and affinity tags and metal chelators (*6*). Intein-mediated ligation has also been used for the assembly of selectively labeled proteins for NMR studies (*7, 8*) and to prepare cyclic peptides and proteins (*9, 10*).

Intein-mediated labeling reactions require two protein domains: the N-terminal domain which contains the protein sequence to be labeled (the target domain) and a C-terminal domain containing the intein (the intein domain). These domains are usually joined in a single fusion protein containing both the intein and target domains [a target−intein fusion protein Figure 1, **1**]. For those intein domains beginning with an N-terminal cysteine residue, the molecular basis of intein-mediated activation is a spontaneous reversible N → S transacylation step forming thioester (**2**) that occurs at this cysteine residue (Figure 1, **1** → **2**). The ligation of probes to target domains has been achieved using a range of cysteine derivatives (**4**) under appropriate conditions (*2*). Although the thioester (**2**) is more reactive toward nucleophiles than a backbone amide, direct reaction with peptides containing an N-terminal cysteine residue was unsuccessful, a result that has been rationalized in terms of steric hindrance from the bulky intein domain (*2*). The use of several thiols including thiophenol [195 mM (*2*)], ethanethiol [0.49 M (*11*)], or MESA[1] [30 mM (*6*)] has been reported to enhance intein-mediated ligation reactions, presumably by trans-thioesterification to the less hindered intermediate (**3**). Under these conditions, cysteine derivatives (**4**) are thought to form the kinetic product (**5**), then rearrange to the thermodynamically more stable amide (**6**) (*2, 12*).

Another potential problem with intein-mediated ligation chemistry is the possible oxidation of both the activating thiol reagent and the modified cysteine derivative to disulfides. The use of thiol reducing agents such as DTT is not possible, as these compounds effectively cleave and derivatize the target domain. This problem has been circumvented by the use of the water soluble phosphine TCEP (*3*), which efficiently reduces disulfides to thiols (*13*).

Since our initial attempts to utilize intein-mediated ligation for the fluorescent labeling of proteins gave disappointing and variable yields of labeled protein, we set out to identify the factors that are important in achieving efficient and consistent labeling. Herein we report the efficient expression and purification of target−intein fusion proteins and studies to determine the optimal conditions for ligation reactions.

EXPERIMENTAL PROCEDURES

Cloning and expression vectors pBAD TOPO and pBAD/HisA and TOP10 competent cells were obtained from Invitrogen (Groningen, NL). The plasmid pTYB1 from the IMPACT-CN system was obtained from New England Biolabs (Herts., UK). DNA was isolated from cultures or agarose gels using commercially available kits following the manufacturers' instructions. Fluorescein isothiocyanate (isomer I, 90%), Supelclean LC-18 reverse phase columns (60 mL), and HPLC solvents (Riedel-de Haën, chromasolv HPLC grade) were obtained from

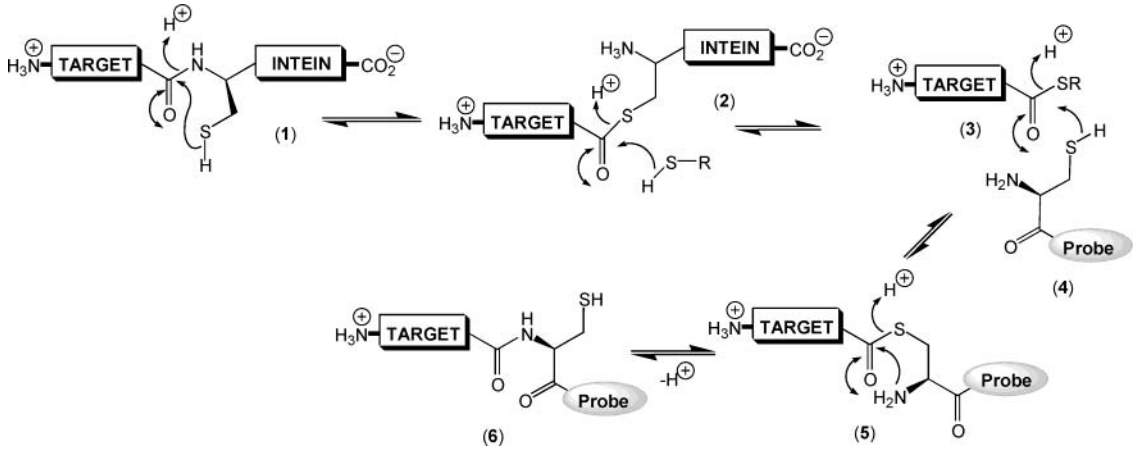

Figure 1. The mechanism of intein-mediated protein labeling. Acyl transfer of the target−intein fusion protein (**1**) from the α amino group to the thiol of the reactive cysteine yields thioester (**2**), which is attacked by a small molecule thiol to give the less hindered thioester (**3**). Attack of a cysteine based labeling reagent (**4**) yields thioester (**5**), which rearranges to give the thermodynamic amide product (**6**).

Sigma-Aldrich (Poole, UK). NMR spectra were recorded on Brucker AC300 or AC400 spectrometers. Electrospray ionization mass spectra were recorded on a Micromass Platform 2 single quadrupole MS, HP1050, in positive mode from methanol solutions. IR spectra were recorded on a BioRad FT-IR.

***N*-Boc-*S*-Trityl-*N*-2-aminoethyl-L-cysteinamide (8).** *N*-Boc-*S*-trityl-L-cysteine [1.0 g, 2.16 mmol, **7**] was dissolved in DMF (10 mL), and solid carbonyl diimidazole (420 mg, 2.6 mmol) was added. After 30 min, ethylenediamine (1.4 mL, 21.6 mmol) was added in a single portion and the reaction stirred at room temperature for a further 2 h. The DMF was then removed in vacuo and the residue dissolved in dichloromethane (50 mL). The solution was washed with water (5 × 50 mL) and saturated brine (50 mL) and dried with anhydrous magnesium sulfate. The solvent was reduced to ∼10 mL in vacuo, yielding **8** as a white crystalline solid which was collected by filtration and dried in vacuo (980 mg, 90%). Mp 76−80 °C; ^{1}H NMR (300 MHz, $CDCl_3$): δ 7.29 (6H, d, J = 8.1 Hz), 7.21 (9H, m), 6.65 (1H, t, J = 5.2 Hz), 4.89 (1H, d, J = 7.4 Hz), 3.85 (1H, dd, J = 12.5, 6.6 Hz), 3.25 (2H, ddd, J = 11.4, 4.7, 1.5 Hz), 2.78 (2H, t, J = 5.88 Hz), 2.71 (1H, m), 2.54 (1H, dd, J = 12.5, 5.15 Hz), 1.42 (9H, s). ESMS 506.3 (MH^+).

***N*-Boc-*S*-Trityl-*N*-[2-[[[(fluorescein-5-yl)amino]-thioxomethyl]amino]ethyl]-L-cysteinamide (10).** Compound **8** (500 mg, 0.99 mmol) was dissolved in methanol (20 mL) and a solution of fluorescein isothiocyanate [424 mg, 1.09 mmol, **9**] in methanol (30 mL) added dropwise. The reaction was stirred under nitrogen for 20 h. The solvent was removed in vacuo to yield an orange residue which was redissolved in 80% MeOH/20% water (20 mL). The solution was applied to a Supelclean LC-18 reverse phase column (60 mL) that had been preequilibrated in 80% MeOH/20% water and the compound eluted in the same solvent. The purest fractions were combined and the solvent removed in vacuo to afford the slightly unstable **10** as an orange solid (815 mg, 92% yield). Mp 184−190 °C; IR (neat) 3256, 2918, 2849, 1667, 1592, 1487, 1443, 1249, 1158, 840 cm^{-1}; ^{1}H NMR (400 MHz, CD_3OD), δ 8.0 (1H, s), 7.58 (1H, d, J = 8.0 Hz), 7.3−7.0 (15H, m), 6.97 (1H, d, J = 8.5 Hz), 6.66 (2H, d, J = 9 Hz), 6.6 (2H, d, J = 2 Hz), 6.44 (2H, dd, J = 8.8, 2.0 Hz), 3.88 (1H, m), 3.6−3.8 (2H, m), 3.37 (2H, t, J = 5.15 Hz), 2.48 (2H, d, J = 6.6 Hz), 1.31 (9H, s); ^{13}C NMR (100 MHz, CD_3OD) δ 182.8, 174.0, 173.3, 171.2, 157.0, 154.7, 146.0, 145.6, 141.5, 130.4, 129.5, 128.7, 128.6, 127.7, 127.6, 127.4, 126.4, 120.9, 114.8, 112.0, 103.3, 80.7, 67.7, 64.1, 55.0, 45.0, 39.9, 35.0, 28.4; ESMS 917.5 (MNa^+), 895.5 (MH^+).

HPLC Analysis of FTEC. The extent to which FTEC had oxidized to its disulfide was assessed by reverse phase HPLC using a Gilson System Workcenter and a Phenomenex Prodigy 5 μm ODS-2 (150 × 4.6 mm) column. HPLC Buffer A was 0.1% TFA in water; HPLC buffer B was 0.1% TFA in acetonitrile. The following conditions were used during the separation with linear gradients between time points: flow rate 0.8 mL/min; detector wavelength λ = 480 nm; detector wavelength 2, 280 nm; t = 0 min, 95% A, 5% B; t = 5.0 min, 95% A, 5% B; t = 40.0 min, 10% A, 90% B. The following retention times were recorded: FTEC, 19.7 min; FTEC disulfide, 21.3 min.

Construction of Plasmids for the Expression of Target−Intein Fusions. DNA manipulations were carried out using standard protocols (*14*). The desired genes were amplified by PCR from *E. coli, Sulfolobus sulfotaricus* genomic DNA, or from the plasmid pTYBI (New England Biolabs, Hertfordshire) as required, using *Pfu* Turbo polymerase and oligonucleotide primers as follows: *pfbioB* 5′-*ccatgg*ctcaccgcccacgc; *prbioB* 5′-*ggatcc*ttactcgagtaatgctgccgcgttgtaatattcg; *pfint* 5′-*ctcgag***ggc**tgctttgccaagggt; *print* 5′-*gaattc*tca**gtggtggtggtggtggtg**ttgaagctgccacaaggcaggaacgt; *pffpr* 5′-*ccatgg*ctgattgggtaacaggc; *prfpr* 5′-ttagcc*ctcgag*ccagtaatgctccgctgt;

pflipA 5′-*ccatgg*agaaaaaagttcaaattgc; *prlipA* 5′-ggatcct-ca*ctcgag*actatgattcttagcattttcaatcgcc. DNA encoding the VMAI intein−chitin binding protein fusion was amplified from pTYBI using primers *pfint* and *print* which add a *Xho*I site (italics) and a glycine codon (bold) to the 5′ end of the amplified gene and DNA encoding a His_6 tag (bold) and an *Eco*RI site (italics) to the 3′ end. The PCR amplification product was purified and inserted into pBAD TOPO according to the manufacturer's instructions, and the resultant plasmids were transformed into competent TOP10 cells. Ampicillin resistant colonies were screened by PCR for plasmids containing the correct insert and plasmid DNA isolated. The *Xho*I-*Eco*RI fragment containing the modified intein gene was inserted between the unique *Xho*I and *Eco*RI sites of pBAD/HisA to yield plasmid pRJW2960/82.

The *bioB* gene was amplified from *E. coli* genomic DNA using primers *pfbioB* and *prbioB* which added a 5′ *Nco*I site (italics), removed the native stop codon, and added a 3′ *Xho*I site (italics) to the wild-type DNA sequence. The PCR product was then inserted into pBAD TOPO, the resultant plasmid transformed into TOP10 cells, and plasmid DNA containing the desired insert isolated. The *Nco*I-*Xho*I fragment containing *bioB* was ligated to the large *Nco*I-*Xho*I fragment of pRJW2960/82 to give plasmid pRJW2960/89. Plasmids pRJW2960/88 and pRJW3104/40 were constructed in similar fashion from pRJW2960/82 by inserting the *E. coli fpr* and *Sulfolobus sulfataricus lipA* sequences amplified from genomic DNA. Primers *pffpr* and *prfpr* were used to construct pRJW2960/88 for expression of Fpr−intein fusion protein and primers *pflipA* and *prlipA* were used to construct pRJW3104/40 for expression of LipA−intein fusion protein. The overall design of the constructs is shown in Figure 3.

Expression and Purification of Target−Intein Fusion Proteins. All purification steps were carried out at 4 °C. Cell pastes and purified proteins were stored at −80 °C. Liquid and solid growth media contained ampicillin (100 mg/L) as required. Protein purity was judged by SDS−PAGE with Coomassie staining. *E. coli* BL21(DE3) (*15*) was transformed with plasmid pRJW2960/89, ampicillin resistant transformants were isolated on 2YT agar, and single colonies were grown for strain storage (*14*). 2YT medium (100 mL) was inoculated from stored strains and grown overnight in a shaking incubator at 37 °C, 220 rpm. This overnight culture was used as 1% innocula into fresh medium (4 × 1250 mL) and grown until the OD_{600} reached 0.6. The cultures were induced by addition of arabinose (20% w/v filter sterilized solution, 10 mL/L), and growth was continued at 27 °C for 4 h. Cells were harvested by centrifugation (10000*g*, 4 °C, 10 min), and the cell paste was stored at −80 °C until required.

The BioB−intein fusion protein was purified from cell paste (∼25 g) resuspended in 4 mL/g Lysis Buffer (50 mM Tris/HCl, 10% w/v glycerol, 0.2 mg/mL lysozyme, 50 U/mL benzonase, pH 8.1). The suspension was stirred (30 min) and then sonicated (10 × 30 s bursts) and the lysate cleared by centrifugation (22000*g*, 4 °C, 30 min). The supernatant was applied to a nickel charged Chelating Sepharose FF column previously equilibrated in Buffer A (50 mM Tris/HCl, 500 mM NaCl, pH 7). The column was washed with Buffer A (200 mL), and the proteins were eluted with Buffer B (Buffer A plus 500 mM imidazole). The purest fractions were pooled, concentrated to 25 mg/mL, and applied to a Superdex 200 column (33 mm ID × 80 cm) previously equilibrated in Buffer A. The column eluate was collected in fractions (9 mL), and the purest fractions stored to yield BioB−intein (150 mg from ∼25 g of cell paste).

The Fpr−intein fusion protein (180 mg from ∼ 95 g cell paste) was purified by a similar method from *E. coli* strain 821 (*16*) transformed with pRJW2960/88 except that (i) all buffers were adjusted to pH 8.1; (ii) Buffer A contained imidazole (50 mM); (iii) the gel filtration chromatography used Buffer C (50 mM Tris/HCl, 500 mM NaCl, pH 8.1). The LipA−intein fusion protein (140 mg from ∼50 g of cell paste) was purified from *E. coli* C43 (DE3) (*17*) transformed with pRJW3104/40 by the method used for the Fpr−intein fusion protein.

General Conditions for Cleavage and Fluorescent Labeling Reactions. Reagents were added to reactions as required to the following final concentrations: BioB−intein fusion protein (0.7 mg/mL), LipA−intein fusion protein (0.64 mg/mL), Fpr−intein fusion protein (1.3 mg/mL), thiols (thiophenol, 2-aminobenzenethiol, 2-methoxythiophenol, MESA, or 4-fluorobenzenethiol, 25 mM), TCEP (20 mM), FTEC (2.3 mM), Tris/HCl buffer (50 mM, pH 8.1). Reactions were stopped by rapid freezing to −80 °C. Protein samples (10 μL) were denatured in Gel Loading Buffer (5 μL) for 5 min at 80 °C (*14*) and analyzed by SDS−PAGE on 10% gels. Gels were visualized under UV illumination and after Coomassie staining using a Syngene GeneGenius imager. The images were analyzed using GeneTools software (Syngene, Cambridge, UK). Where required a sample of fluorescently labeled BioB was applied to the gel to provide a fluorescence intensity calibration. Where noted, reactions were maintained under anaerobic conditions using a glovebox (Belle Technology, Portesham, UK) maintained at 20 °C under nitrogen at <0.2 ppm O_2. Buffers for these experiments were introduced into the glovebox and allowed to deoxygenate overnight, then used to prepare the solutions of reagents. Aliquots of protein (100 μL) were allowed to deoxygenate for 1 h before use.

Comparison of Aerobic and Anaerobic Cleavage Reactions with Various Thiols. Cleavage reactions contained BioB−intein, Tris/HCl buffer, and one of five thiols: thiophenol, 2-aminobenzenethiol, 2-methoxythiophenol, MESA, or 4-fluorobenzenethiol. The reactions were incubated either aerobically at room temperature or anaerobically for 24 h and analyzed.

Assay of Thiol Dependent Fluorescent Labeling. Labeling reactions contained target−intein, FTEC, Tris/HCl buffer, and one of four thiols: thiophenol, 2-methoxythiophenol, MESA, or 4-fluorobenzenethiol. The reactions were incubated anaerobically for 24 h and analyzed.

Comparing the Progress of Labeling Reactions under Various Conditions. Anaerobic labeling reactions, with an initial total volume of 500 μL, contained BioB−intein fusion protein, FTEC, Tris/HCl buffer, and where indicated, TCEP and/or thiophenol. Aliquots (40 μL) were withdrawn and stored at −80 °C after 1, 2, 3, 4, 5, 6, 8, 10, 14, and 27 h. The aliquots were then thawed and immediately analyzed.

Effect of Thiophenol Concentration on Labeling Reactions. Labeling reactions (100 μL) contained BioB−intein, Tris/HCl buffer, and thiophenol at the following concentrations: 0, 0.5, 5, 10, 12.5, 25, 50 mM. The reactions were maintained under anaerobic conditions for 16 h and analyzed.

RESULTS AND DISCUSSION

Intein-mediated ligation appears to provide a general solution to the problem of site specifically attaching

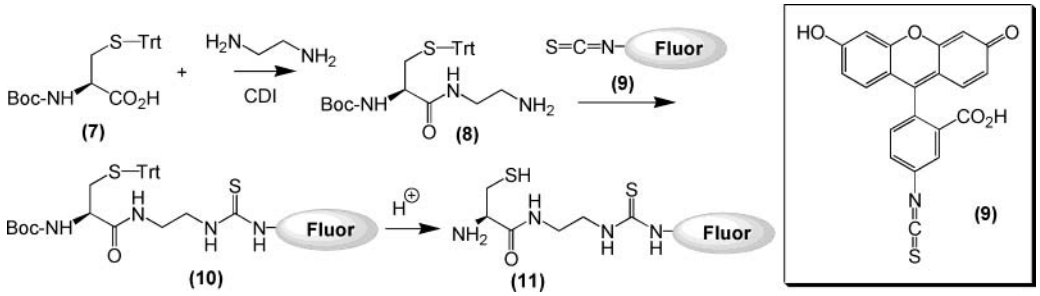

Figure 2. Synthesis of *N*-[2-[[[(fluorescein-5-yl)amino]thioxomethyl]amino]ethyl]-L-cysteinamide (FTEC, **11**).

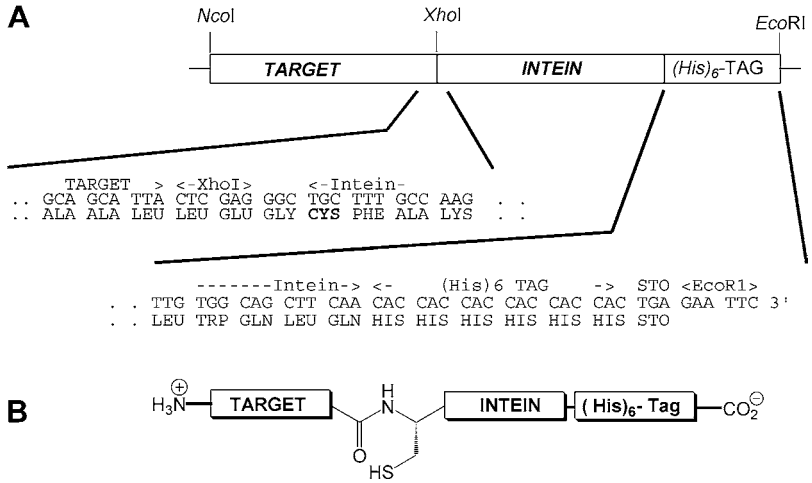

Figure 3. Design of plasmids (A) for the expression of target−intein fusion proteins (B). The target protein gene sequence is extended using PCR to remove the stop codon and incorporate a *Xho*I restriction site. A glycine codon was incorporated between the *Xho*I restriction site and the VMAI intein sequence from pTYB1. DNA encoding a $(His)_6$ affinity tag was introduced to the C-terminus of the intein domain. The domain labeled intein includes DNA encoding intein and chitin binding domains from pTYB1.

small- or medium-sized molecules to proteins under mild conditions (*18*). A variety of methods for intein-mediated ligation have been reported, with reaction under aerobic conditions in the presence of thiophenol (*2*) or MESA (*19*) being the most commonly used. However, a systematic analysis of the important factors for achieving efficient ligation using these fusion proteins has not been reported. We therefore set out to identify the optimal conditions for efficient and convenient fluorescent labeling using three model target−intein fusions. We have developed an efficient synthesis of a water soluble fluorescent labeling reagent and flexible plasmids for the expression of target−intein fusions and determined the optimal conditions for the labeling reaction.

Preparation of FTEC (11). The synthetic strategy (Figure 2) was to prepare a protected cysteine derivative (**8**) which is suitable for reaction with a diverse range of activated fluorescent reagents (*6*). Thus, reaction of **8** with fluorescein isothiocyanate (**9**) gave the fully protected derivative (**10**) in good yield (92%) after low-pressure reverse phase chromatography (**10** is not stable to silica flash chromatography).

As a precaution against the eventuality of FTEC disulfide formation, it is convenient to deprotect **10** in small aliquots (∼50 mg) for immediate use in labeling reactions. This simple three-step route to FTEC (**11**) has been completed in an overall yield of 74%.

Plasmids for the Expression of Target−Intein Fusion Proteins. Plasmid pRJW2960/82 was constructed to allow the straightforward assembly of vectors for the expression of target−intein fusion proteins under the control of an arabinose-inducible promotor (*20*). The plasmid contains an *Nco*I site for the insertion at the start codon of the gene for the target protein and a unique *Xho*I site for insertion in frame with the downstream gene encoding the intein domain. An inserted triplet encodes a glycine residue N-terminal of the splice site cysteine residue, a modification that has been demonstrated to allow efficient transacylation (*21*). DNA encoding a His_6 tag has been added at the 3′ end of the construct to allow purification of target−intein fusion proteins by metal affinity chromatography. The pTYBI-derived DNA also encodes a chitin binding protein domain as an alternative affinity purification tag. Finally a unique *Eco*RI site at the 3′ end of the construct allows the insertion of alternative intein domains as *Xho*I-*Eco*RI fragments if desired. Plasmids pRJW2960/89, pRJW2960/88, and pRJW3104/40 were constructed from pRJW2960/82 for the expression of *E. coli* BioB−, Fpr−, and *Sulfolobus sulfataricus* LipA−intein fusion proteins, respectively. The overall design of the constructs is shown in Figure 3.

Expression and Purification of Target−Intein Fusion Proteins. Fusion proteins were successfully expressed at high levels from each of the expression plasmids in a variety of *E. coli* strains. Protein isolated after nickel affinity chromatography always contained a mixture of the full-length fusion protein and intein domain (Figure 4), presumably as a result of in vivo cleavage by abundant intracellular thiols such as glutathione. While the selection of the optimal expression strain remains empirical, it may be significant that the proportion of full-length fusion protein could usually be increased by expression in *E. coli* 821 cells (data not shown), a mutant strain unable to produce glutathione (*16*). After preliminary small scale expression experiments, satisfactory yields of full-length proteins were obtained from BL21(DE3) for BioB−intein fusion, *E. coli*

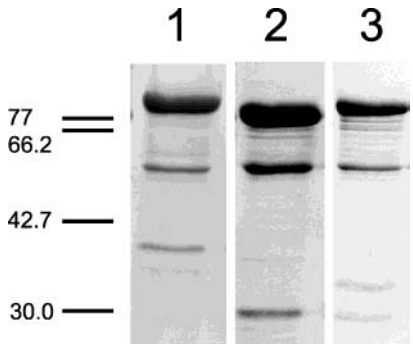

Figure 4. Coomassie-stained SDS−PAGE analysis of purified target−intein fusion proteins. Lanes: 1, BioB−; 2, Fpr−; 3, LipA−intein fusions. Molecular weights (kDa) are indicated on the left-hand side.

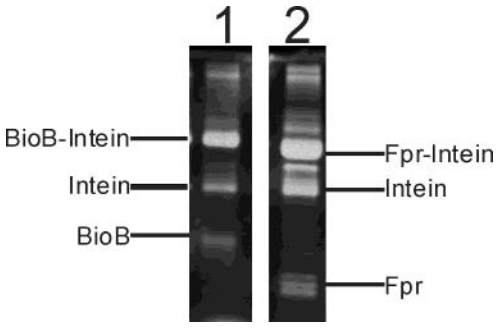

Figure 5. Fluorescent derivatization of target−intein fusion under nonreducing conditions. Thiophenol was not added to the labeling reaction and the sample was prepared for SDS−PAGE analysis with DTT-free Gel Sample Buffer. Lane 1, BioB−intein, lane 2 Fpr−intein. Bands as indicated were identified by comparison to Coomassie-stained gels.

821 for Fpr−intein fusion, and C43(DE3) for LipA−intein fusion (*17*).

Conditions for SDS−PAGE Analysis of Intein-Mediated Fluorescent Labeling Reactions. The conditions (5 min at 80 °C) used to prepare samples for SDS−PAGE were selected to allow efficient denaturation and reduction of disulfide bonds, without inducing extensive DTT dependent cleavage of the target−intein fusion protein. The use of Gel Loading Buffer without DTT resulted in nonspecific labeling (Figure 5), which presumably arises from disulfide bond formation between FTEC and cysteine residues in the proteins.

Comparison of Aerobic and Anaerobic Thiol Dependent Cleavage Reactions. Preliminary experiments with FTEC and BioB−intein fusion protein resulted in poor incorporation of the label, despite the use of large excesses of FTEC. In an attempt to resolve this problem, a range of thiols was investigated to assess their potential for aerobic cleavage of the target−intein fusion protein to yield the α-thioester (**3**). Aminobenzenethiol is effective at cleaving the fusion protein but is difficult to use as it forms an emulsion. 4-Fluorobenzenethiol showed the largest extent of cleavage under these conditions (Figure 6, compare lanes 1−6).

In reactions with thiophenol and 2-methoxybenzenethiol, a white precipitate was observed to form within 5 min, presumably as a result of oxidation of the thiol to the disulfide (*11*). In the case of 2-methoxythiophenol, this causes coprecipitation of some protein (Figure 6, lane 4). The poor performance of the thiols under aerobic conditions led us to explore the potential of rigorously anaerobic cleavage conditions (<0.2 ppm O_2). In each case, the extent of reaction was significantly enhanced and precipitation of the disulfide was avoided. Under

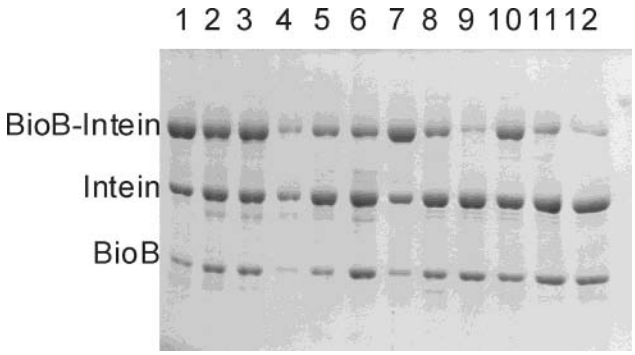

Figure 6. Cleavage of BioB−intein fusion protein by various thiols. Lanes 1−6, aerobic; lanes 7−12, anaerobic. Lanes 1 and 7, no thiol; lanes 2 and 8, thiophenol; lanes 3 and 9, 2-aminobenzenethiol; lanes 4 and 10, 2-methoxybenzenethiol; lanes 5 and 11, MESA; lanes 6 and 12, 4-fluorobenzenethiol.

these conditions, 2-amino- and 4-fluorobenzene thiols are most effective at cleaving the BioB−intein fusion protein (Figure 6, compare lanes 7−12) to yield the α-thioester intermediate (**3**).

Assay of Thiol-Activated Fluorescent Labeling. The anaerobic ligation of FTEC to target proteins was investigated, including the effect of thiol reagents and the target protein domain. Reactions conducted in the absence of thiols resulted in a variable extent of labeling (for example, estimated at less than 20% from the Coomassie-stained SDS PAGE gel, Figure 7, Fpr, lane 2) and could result in no labeling (Figure 7, BioB and LipA, lanes 2). The addition of thiols increased the cleavage of the target−intein fusion protein (Figure 7, lower panels) and the yield of fluorescently labeled protein (Figure 7, upper panels). The experiments showed that thiophenol and MESA were most efficient at promoting the introduction of the fluorescent label.

Comparing the Progress of Labeling Reactions under Various Conditions. The extent of fluorescent labeling could be quantified by integrating the fluorescent band intensity. Thus, by analyzing aliquots withdrawn from a labeling reaction at different time points, the progress of the reaction could be followed (Figure 8a). Moreover, by including a fluorescent standard on each gel to act as a calibrant (e.g. Figure 8a, lanes C), it was possible to directly compare data obtained from different gels. This allowed comparison of the kinetics of fluorescent labeling under different conditions. A plot of the fluorescence intensity of each band against time (Figure 8b) confirmed that the reaction proceeded most efficiently under anaerobic conditions in the presence of thiophenol. The data could be fitted to a single exponential to give an observed pseudo-first-order rate constant of 0.30 ± 0.04 hour^{-1}. A similar rate constant could be fitted to data obtained from a labeling reaction under aerobic conditions with added thiophenol and TCEP [$k = 0.23 \pm 0.04$)]. In multiple experiments, these rate constants consistently fell in the range 0.1−0.3 h^{-1}, a rate of reaction similar to that observed by Muir (*11*). In the case of an aerobic labeling experiment with thiophenol but no TCEP, while the reaction shows a similar initial rate to the previous examples, it did not proceed to completion, presumably as a result of thiophenol disulfide formation. Reactions under other conditions showed little fluorescent labeling (<10%). It is interesting to note that the most efficient cleavage reagents (2-amino- and 4-fluorobenzenethiols) are not the most efficient in promoting fluorescent labeling. This probably reflects the different rate-determining steps of cleavage and labeling reactions.

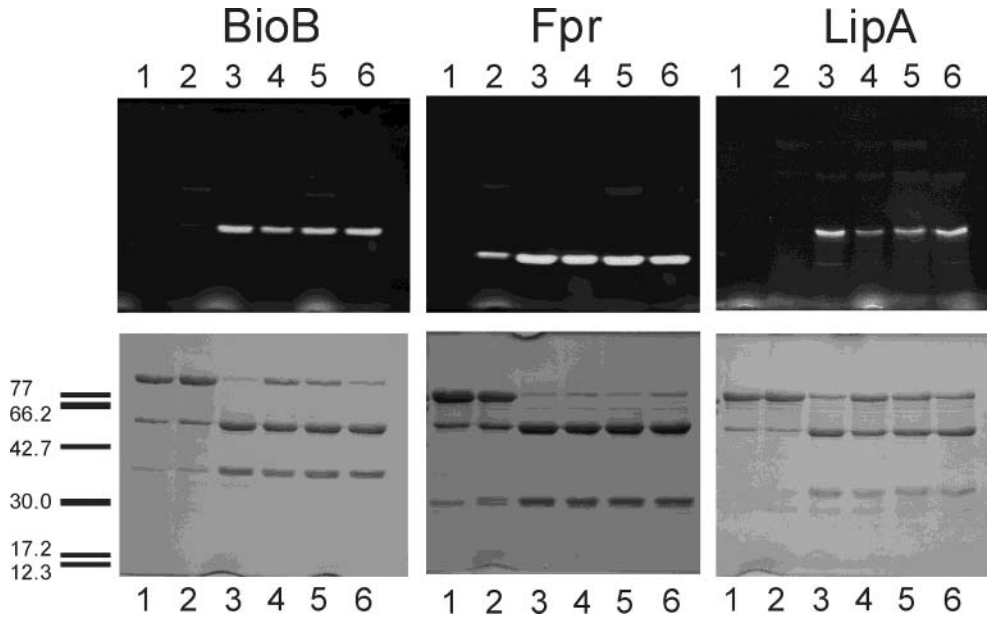

Figure 7. SDS−PAGE analysis of fluorescent labeling reaction with BioB−, Fpr−, and LipA−intein fusions in the presence of a variety of thiols (each 25 mM). Top panels are fluorescence images, lower panels are Coomassie stained. In each case: lane 1, no thiol, no FTEC; 2, FTEC only; 3, FTEC plus thiophenol; 4, FTEC plus 2-methoxybenzenethiol; 5, FTEC plus 4-fluorobenzenethiol; 6, FTEC plus MESA.

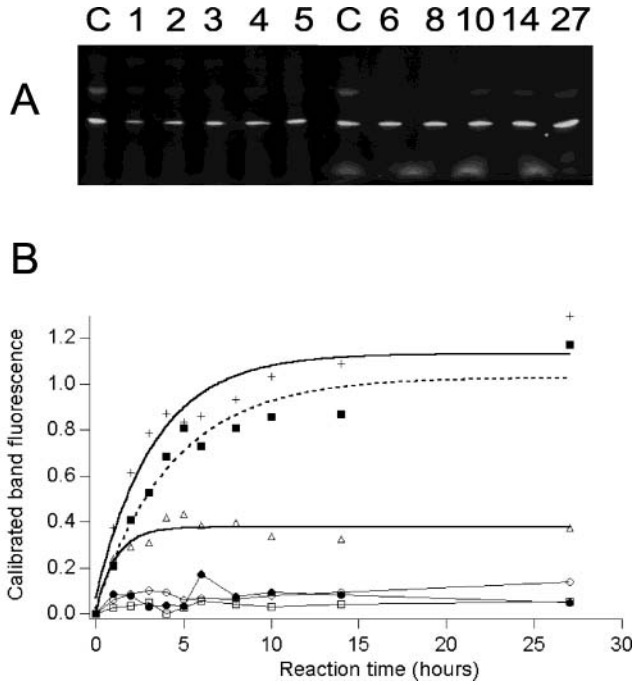

Figure 8. Time course of fluorescent labeling reaction with BioB−Intein fusion protein. (A). Gel showing timecourse of anaerobic labeling in the presence of thiophenol. Lanes marked C contain a previously prepared sample of fluorescent BioB used as a calibrant. Other lanes contain samples taken from the labeling reaction at the times (h) indicated. (B). Graph showing time course of fluorescent labeling under various conditions. The following conditions were compared: (□) aerobic; (●) aerobic plus phosphine; (△) aerobic with thiophenol; (■) aerobic with phosphine and thiophenol; (○) anaerobic; (+) anaerobic with thiophenol. Data for reactions with thiophenol and for aerobic reaction in the presence of thiophenol and TCEP were fitted to a first-order exponential. For the remaining slow reactions, data cannot be fitted and the points are connected to indicate the general trend.

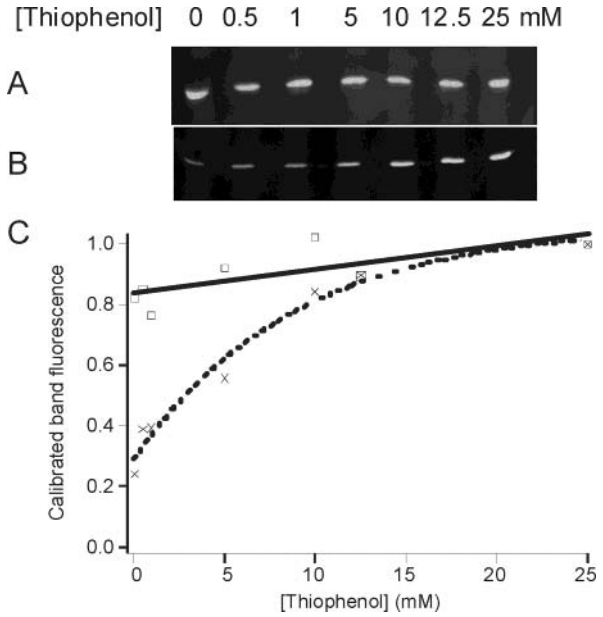

Figure 9. Examples of two fluorescent labeling reactions of BioB. (A and B) Two different samples of FTEC (2.3 mM) in the presence of increasing concentrations of thiophenol as shown. (C) Graph showing yield of fluorescent protein at various thiophenol concentrations: (□) A; (×) B. Data are fit to a straight line (A) and exponential curve (B).

Effect of Thiophenol Concentration on Labeling Reactions. While thiophenol has been reported to be essential in intein-mediated ligation reactions (*22*), it is a toxic and highly reactive compound. For example, thiophenol might react with the labile Fe−S cluster redox centers present in proteins such as LipA and BioB (*23, 24*). For these, and other delicate proteins, labeling reactions would ideally omit thiophenol or other small activating thiol. It is therefore of interest to determine the minimum concentration of thiophenol required for efficient fluorescent labeling.

In experiments where no thiophenol was added, the extent of target protein labeling was observed to be variable (e.g. Figure 9). The underlying reason for this variability has yet to be determined; however, it may simply be due to the oxidation of FTEC to the disulfide,

a process observed by HPLC analysis to occur in solution at pH 8.1, even under the low oxygen tension within the glovebox (<0.2 ppm O_2). The concentration of thiophenol required for consistent efficient labeling under anaerobic conditions was investigated (Figure 9). Over a wide range of experiments, it was found that a concentration of 10 mM thiophenol ensured efficient labeling within 16 h.

These observations suggest that thiophenol may have a 2-fold function in the labeling reactions, first to form a thioester intermediate (**5**) and second that it may be important in maintaining FTEC in a reduced and hence reactive state. In these relatively complex reactions, it is difficult to deconvolute the relative importance of these roles; indeed, the function of the thiophenol in efficient labeling may also depend on the anaerobicity of the reaction, the presence of other efficient reductants (such as TCEP), and the steric constraints of the target−intein junction.

CONCLUSIONS

Practical conditions for intein-mediated attachment of fluorescent labels to protein domains have been determined:

(a) Using FTEC and rigorously anaerobic reaction conditions to achieve labeling without the addition of either thiophenol or TCEP; however, these conditions should be used with caution, as the yield can be variable.

(b) For routine aerobic labeling reactions, the addition of thiophenol (10 mM) and TCEP to ensure a high yield of the fluorescently labeled derivative after 24 h of reaction.

(c) In our hands, reaction under anaerobic conditions with the addition of thiophenol (10 mM) consistently achieves the highest levels of label incorporation, and these conditions are suitable for labeling a wide range of proteins for biophysical studies.

Received September 19, 2003; Revised Manuscript Received January 27, 2004

Recombinant human-annexin-V was conjugated with 4-[F-18]fluorobenzoic acid (FBA) via its reaction with the *N*-hydroxysuccinimidyl ester (FBA-OSu) at pH 8.5. A series of reactions using varying amounts of annexin-V, unlabeled FBA-OSu, and time produced products with different conjugation levels. Products were characterized by mass spectrometry and a cell-binding assay to assess the effect of conjugation. In each case, the conjugated protein was a mixture of proteins with a range of conjugation. Annexin-V could be conjugated with an average of two FBA mole equivalents without decreasing its affinity for red blood cells (K_d 6−10 nM) with exposed phosphatidylserine. An average conjugation of 7.7 (range 3−13) diminished the binding 3-fold. Large-scale production and purification of [F-18]-FBA-OSu from [F-18]fluoride was accomplished within 90 min and in 77% radiochemical yield (decay-corrected to the end of cyclotron bombardment). The conjugation reaction of annexin with [F-18]FBA-OSu was studied with respect to activity level, protein mass, and concentration. Under the most favorable conditions, >25 mCi [F-18]fluoroannexin (FAN) was isolated in 64% yield (decay-corrected for a 22 min conjugation process) from labeling 1.1 mg of annexin-V. A pilot PET imaging study of [F-18]fluoroannexin in normal rats showed high uptake in the renal excretory system and demonstrated sufficient clearance from most other internal organs within 1 h. [F-18]Fluoroannexin should prove useful in imaging targeted apoptosis.

INTRODUCTION

Apoptosis is a normal physiological process of programmed cell death that plays a key role in maintaining constant cell density in tissues undergoing cell proliferation. It also provides a defense mechanism for eliminating abnormal cells with damaged DNA. As such, apoptosis plays an important role in cancer biology and cancer treatment. Cancer can result from a failure of apoptosis to balance cell proliferation, either by under-expressing genes that promote apoptosis or by overexpressing genes that inhibit it. In addition to genetic mutations that lead to unregulated cell proliferation, other mutations that affect the cell's ability to undergo apoptosis can also be part of the progress toward uncontrolled growth. For example, the *bcl-2* oncogene appears to contribute to the development of lymphoma by inhibiting apoptosis, without affecting cell proliferation (*1*). Furthermore, chemotherapy and radiation therapy generally kill cells by activating apoptosis. In this context, a sensitive method for imaging apoptosis in vivo should prove useful for monitoring cancer treatment.

In contrast to normal cells, high levels of phosphatidylserine are exposed on the outer membrane leaflet of apoptotic cells. This provides a selective and accessible target for molecular imaging. Annexin-V (36 kDa) is an endogenous protein ligand with a high affinity (K_d ~10 nM) for phosphatidylserine (PS) (*2*). Consequently, it has been adapted for use as a radiopharmaceutical after labeling it with technetium-99m (*3*−*5*). Studies with [Tc-99m]annexin-V have demonstrated that apoptosis imaging is feasible in animal models of induced apoptosis and with human subjects (*6*−*8*). This success prompted us to develop a fluorine-18-labeled annexin-V analogue for quantitative 3-D imaging with PET. We were also attracted by the potential application of combining [F-18]-fluoroannexin-V and [C-11]thymidine in the same imaging session to investigate the balance between cell death and growth rates in tumors.

In this report we show that annexin-V can be effectively labeled using the *N*-hydroxysuccinimidyl ester of [F-18]fluorobenzoic acid (Figure 1) and that the biological activity of the acylated product, [F-18]fluoroannexin (FAN), is equivalent to that of annexin-V. Exploratory PET imaging of [F-18]FAN in normal rats showed rapid blood clearance and low background activity in organs other than the kidneys and bladder, which are involved in clearance of the protein.

EXPERIMENTAL PROCEDURES

Materials and Methods. (a) Chemicals. Reagent chemicals were obtained from Aldrich Chemical Co. (Milwaukee, WI) and were used as received. The labeling precursor for [F-18]FBA-OSu:ethyl 4-trimethylammonium benzoate trifluoromethanesulfonate salt was prepared according to Haka et al. (*9*) and stored in the cold. Unlabeled 4-fluorobenzoic acid *N*-hydroxysuccinimide ester (FBA-OSu) was prepared using standard peptide methods with 4-fluorobenzoic acid, *N*-hydroxysuccinamide, and dicyclohexylcarbodiimide in ether. The isolated solid was recrystallized twice from ether (mp 110−112 °C). Anhydrous dimethyl sulfoxide (DMSO), contained in break-seal ampules, was used for labeling experiments. Enriched (95%-atom) [O-18]water was obtained from Isonics Corp. (Golden, CO). AG 1-X8 ion-exchange resin, for separating [F-18]fluoride from [O-18]water, was obtained from Rio-Rad (Hercules, CA). cartridges were obtained from the Waters Corporation (Milford, MA).

(b) Annexin-V Protein. Laboratory grade recombinant (*E. coli*) human annexin-V (*rh*-annexin-V) was purified as described by Wood et al. (*10*). Stock protein solutions (1.0, 7.6, or 8.7 mg/mL) were prepared with 10 mM NaH_2PO_4 pH 7.4 buffer containing 140 mM sodium chloride and stored frozen (−15 °C) until used. Clinical grade *rh*-annexin-V was provided (1.0 mg/mL, 10 mM NaH_2PO_4 pH 7.4 buffer, 140 mM NaCl) as a gift from the Theseus Imaging Corporation (Worcester, MA) and stored at −80 °C until used.

(c) Buffers. HNKGB buffer (10 mM HEPES pH 7.4, 136 mM NaCl, 2.7 mM KCl, 5 mM glucose, 1 mg/mL fatty acid free bovine serum albumin) was prepared as needed. Sodium chloride (0.9%, USP) was obtained from Baxter (Deerfield, IL) and used for the size exclusion HPLC purification of [F-18]fluoroannexin. For animal work, pH 7.4 PBS was used. Borate buffers (0.025 M and 0.50 M, pH 8.5) were prepared from sodium tetraborate decahydrate (Borax, 99.999%) and hydrochloric acid. The more concentrated buffer solution (9.52 g Borax + 2.53 mL concentrated HCl/50 mL) must be prepared with heating to dissolve the salt. The solution (rt) was used before recrystallization initiated (∼30 min).

(d) Chromatography Systems and Detectors. Purifications were performed using a Thermo-Separation Products (Riviera Beach, FL) Constametric 4100 HPLC pump, Rheodyne (Cotati, CA) 7125 and 7725i injectors and flow-through radiation detector systems from Beckman (Fullerton, CA; model 170) or Carroll & Ramsey Associates (Berkeley, CA; model 105-S). For studies with unlabeled annexin a variable wavelength V^4-UV absorbance detector from ISCO (Lincoln, NE) was used. HPLC columns were obtained from Phenomenex (Torrance, CA): column-A (LUNA-5 μm C18(2)) 250 × 10 mm i.d.; column-B (BioSep SEC−S 2000) 300 × 7.8 mm i.d.; column-C (LUNA-5 μm C18(2)) 250 × 4.6 mm i.d.. Radioactivity >100 μCi was measured using an ion chamber Capintec CRC-12 Radioisotope Calibrator (Pittsburgh, PA) and <0.1 μCi measurements were made with a Packard Auto-Gamma 500 series instrument (Downers Grove, IL).

(e) Reactions of Unlabeled FBA-OSu and Annexin-V with Varied Stoichiometry and Time. A series of FBA-OSu/annexin-V conjugation reactions with mole ratios of 4:1, 8:1, 16:1, and 32:1, and reaction times of 15, 30, and 60 min, was performed. In each case, 150 μg of annexin-V (150 μL, 1 mg/mL, 10 mM PBS, 140 mM NaCl) was reacted with FBA-OSu in pH 8.5 borate buffer (150 μL, 0.025 M) and acetonitrile (32 μL). The buffer was added to the acetonitrile/FBA-OSu reagent solution followed by the protein solution. After incubation for the required time at room temperature, the reaction was terminated using size-exclusion HPLC (Column-B eluted with PBS at 2 mL/min). The conjugation product was collected in an elution volume characteristic for the elution of annexin-V. UV-detection at 267 nm was used, and the chromatographic profiles of the purifications mimicked those seen during the radiosynthesis of [F-18]-fluoroannexin. In each case, the chromatography revealed the presence of some unreacted FBA-OSu that eluted late from the column. Selected purified products were analyzed by mass spectrometry, as described in section-k, to determine the extent of conjugation on individual annexin-V protein molecules and their population within the product mixture. Individual product solutions were stored frozen for up to 3 days before mass analysis was performed. Results from these reactions are presented in Table 1.

(f) Radiolabeling and Purification of *O*-(*N*-Hydroxysuccinimidyl)[F-18]fluorobenzoate (FBA-OSu). Our radiosynthesis modifies the original report by Wester et al. (*11*). Our adaptations substituted the previously described solid-phase extraction media with standard SepPak (C-18) cartridges. We have also included a HPLC purification and isolation of the active ester prior to its

reaction with *rh*-annexin-V. A timeline for the process is presented in Figure 1.

Enriched [O-18]water (95%) was bombarded with 11 MeV protons in a pressurized silver target (1.25 mL) using a CTI (Knoxville, TN) RDS-111 cyclotron. Post-irradiation, [F-18]fluoride was separated from target water by passing the solution through a short plug of anion-exchange resin (12−15 mg, OH^- form, 200−400 mesh) using the method reported by Schlyer (*12*). Resin-bound fluoride was eluted with 0.1 M potassium carbonate (250 μL) and collected in a borosilicate test tube (100 × 16 mm i.d., Kimax 51) containing Kryptofix [2.2.2] (19 mg, 50 μmol). The tube was placed in a dry-block at 100 °C, and water was removed by azeotropic distillation with MeCN (4 × 1 mL) under a rapid stream of argon. Typically, 350−400 mCi of dried [F-18]KF/carbonate/Kry-[2.2.2] complex was produced within 30 min after the end-of-bombardment (EOB). The residue was treated with ethyl 4-trimethylammonium benzoate trifluoromethanesulfonate salt (15.5 mg, 43 μmol) in DMSO (300 μL) at 100 °C for 7 min, and then 1 N KOH (100 μL) was added to saponify the ester group. After 7 min, the mixture was acidified with 0.1 N HCl (10 mL) and the solution was pulled through a C-18 SepPak. A water rinse (4 mL) of the reaction vessel was also extracted. The retained 4-[F-18]fluorobenzoic acid was eluted from the SepPak with MeOH into a test tube (100 × 16 mm) containing tetramethylammonium hydroxide (25 wt % in MeOH, 10 μL). The resultant solution was concentrated at 100 °C under a rapid stream of argon, and the residue (ca. 100 μL) was azeotropically dried with MeCN (2 × 1 mL).

Solid *O*-(*N*-succinimidyl)-*N*,*N*,*N*′*N*′-tetramethyluronium tetrafluoroborate (30 mg, 73 μmol) was added to the residual film of tetramethylammonium 4-[F-18]fluorobenzoate, and then dry MeCN (400 μL) was used to wash down the tube wall. The reaction mixture was heated at 100 °C for 3 min and then quenched with 5% acetic acid (8 mL). The acidic solution was pulled into an intervening septum-sealed vial (10 mL) and then forced (60 psi air) through a 0.2 μm self-venting filter (Braun: Bethlehem, PA; PFE−2000) attached to the HPLC injector port. The injector was fitted with a precolumn that substituted for a regular sample injection loop. The precolumn was made from an empty 50 × 4.6 mm (i.d.) guard column filled with C-18 SepPak media and was conditioned with EtOH (4 mL) and then water (6 mL) before use. Concentration of the sample on the precolumn was followed by a water (3 mL) rinse. The retained active ester was eluted with 45% MeCN−water at 6 mL/min and purified using Column-A. The product fraction was collected in ∼6 mL after 8 min. A representative chromatogram is shown in Figure 2. The collected product solution was diluted with water (20 mL) and then pulled through a tandem pair of C-18 SepPaks at ∼5 mL/min. The SepPaks were washed with brine (4 mL) and then eluted with ether (4 mL). The coeluted brine (∼0.5 mL) was removed before adding anhydrous magnesium sulfate (0.1 g) to the collected ether solution. The dried solution and a rinse (2 mL) were filtered using a 10-mm platform 0.2 μm ceramic micron filter (Anotop: Alltech, Deerfield, IL). The precautions taken with drying and filtering are recommended to standardize the quality of [F-18]FBA-OSu and provide consistent annexin-V labeling yields. Drying is designed to minimize ester hydrolysis during temporary storage or while concentrating solutions to residual films for reaction. Filtration is designed to eliminate small amounts of high surface area particles that always shed from eluted SepPaks and which may interfere with protein labeling or recovery.

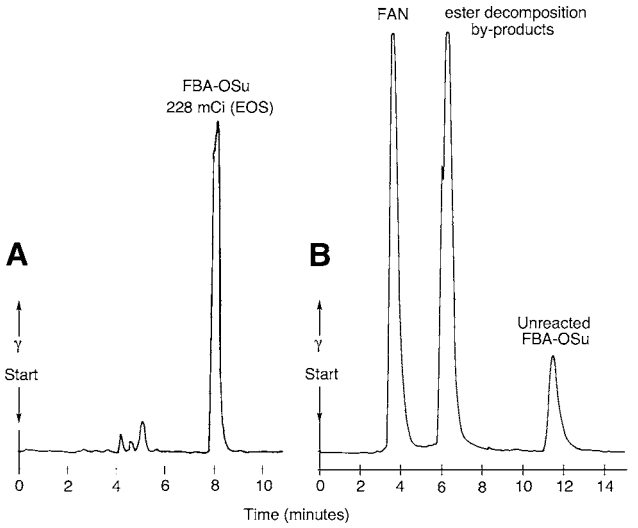

Figure 2. Typical HPLC-radiochromatograms for [F-18]FBA-OSu and [F-18]fluoroannexin purifications. Trace A: C18 column eluted with 45% MeCN-water. Trace B: Size exclusion column eluted with 0.9% saline.

(g) Radiosynthesis of 4-[F-18]Fluorobenzoyl *rh*-Annexin-V. The purified active ester in dry ether was concentrated at room temperature in a 100 × 16 mm test tube under a rapid stream of argon. To the residual colorless film was added stock annexin-V and then pH 8.5 borate buffer solution (see Table 2 for protein mass and reaction volumes), and the labeling mixture was incubated at room temperature, with periodic agitation. Labeled [F-18]fluoroannexin was isolated using a silica-based semipreparative size-exclusion chromatography (SEC) column (Column-B) eluted at 2 mL/min with 0.9% saline for studies involving K_d determinations, or with PBS for animal experiments. Characteristically, [F-18]-fluoroannexin is the first component eluted from the column and is collected in a ∼3 mL fraction starting at 3.8 min. A representative chromatogram is shown in Figure 2. A timeline for the process, along with typical activity levels and yields, also appears in Figure 1. The fraction of activity lost to the reaction tube wall can be high (>30%) if the active ester is not concentrated to a small area prior to its reaction. To minimize the problem we evaporated the stock aliquot (∼4 mL) to dryness and then used a small volume of ether (400 μL) to wash down the tube wall, followed by gentle evaporation to a final residual film.

(h) Cell Binding Assay for Labeled Annexin. A previously developed cell-binding assay (*5*) was used to determine the affinity of labeled annexin samples to a standard preparation of human red blood cells with externalized (PS+) phosphatidylserine. The assay was conducted in the absence and presence of calcium, which is essential for annexin binding. Briefly, labeled annexin at a final concentration of 10 nM (the approximate K_d of annexin-V) was incubated for 15 min at rt in HNKGB buffer (total volume 1 mL) containing either 2.5 mM Ca^{2+} or 5 mM EDTA, and 100 μL of PS+ cells (∼4 × 10^8 erythrocytes). The specific binding (1-[cpm (Ca^{2+})/cpm total]) was measured after pelleting cells by centrifugation at 10 000*g* (Eppendorf model 5415D; Hamburg, Germany) for 3 min. Typically, the specific binding ranged from 80 to 90%, and this value was used to correct for nonbinding annexin in the determinations of K_d (section-j).

(i) Determining Unlabeled Fluoroannexin-V Inhibition Concentration (IC_{50}) Relative to FITC-

Table 2. Radiochemical Yields and Product Analysis for [F-18]Fluoroannexin-V Production

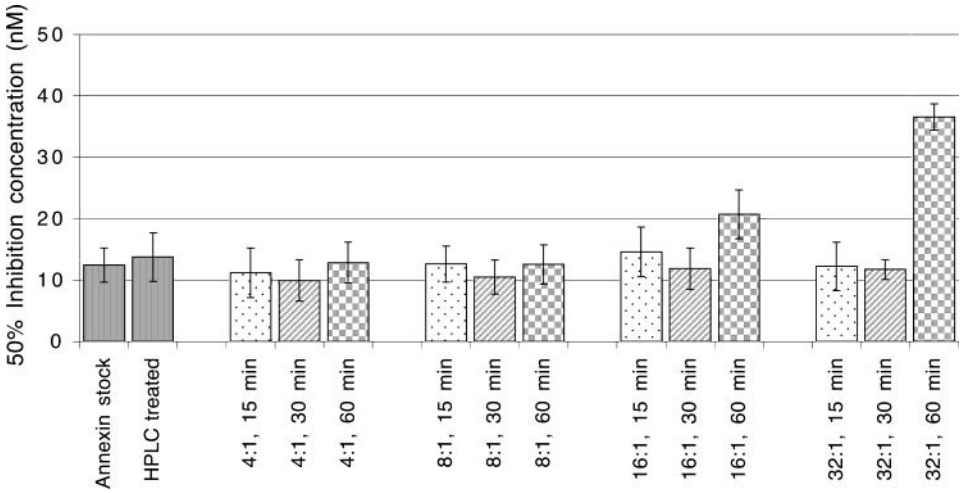

Figure 3. Fluoroannexin IC_{50} values vs reaction conditions for fluoroannexin syntheses. Product protein IC_{50} values were determined using a competitive binding assay with FITC-annexin as described in section-i; error bars (2 × SD).

Annexin-V Binding to PS+ (phosphatidylserine) Red Blood Cells. The concentration of purified fluoroannexin protein samples was first assayed by the Bradford method (*13*) using reagents from BioRad (Hercules, CA) with BSA fraction-V (Pierce, Rockford, IL) as a standard. Fluoroannexin samples were added at concentrations from 2 to 100 nM to a reaction tube containing 5 nM fluorescein-labeled annexin-V (FITC-annexin) (*5*) and 8×10^6 PS+ erythrocytes in HNKGB buffer, in a final volume of 1 mL. After incubating for 15 min at room temperature, cells were pelleted by centrifugation at 10 000*g* for 3 min. The supernatant was removed to a separate tube, and the FITC-annexin-V bound to the pellet was released by adding 950 μL of 5 mM EDTA/HNKGB. The sample was recentrifuged, and 800 μL of supernatant was assayed for FITC-annexin-V content by fluorometric analysis using an Abbott TDX analyzer (Abbott Park, IL). The results from these inhibition experiments are shown in Figure 3.

(j) Determining the Apparent K_d for [F-18]Fluoroannexin Bound to PS+ Red Blood Cells. Quantitative titrations were used to determine the dissociation constant, as described previously (*5*). Briefly, labeled fluoroannexin (2−300 nM) was added to 10^7 PS+ erythrocytes in HNKGB buffer (250 μL total volume) with either 2.5 mM Ca^{2+} or 5 mM EDTA. After incubation at room temperature for 15−30 min, bound and free fluoroannexin were separated by centrifugation through 40 μL of DC550 silicone oil (Dow Chemical, Midland, MI) in 0.3 mL small-tipped microtubes (Sarstedt; Nuembrecht, Germany) at 10 000*g* for 3 min. After cutting off the tube tip to isolate the pellet, the bound fluoroannexin in the cell pellet was counted. Counts were converted to molecules bound/cell using the known specific activity of the protein. The concentration of free annexin was determined by measuring activity remaining in the supernatant and correcting for nonbindable fluoroannexin, as determined using the method described in section-h. A typical data set is shown in Figure 4. K_d and B_{max} values were calculated using a nonlinear least-squares analysis (Microsoft Excel) to fit data to a model of noncooperative binding to homogeneous sites.

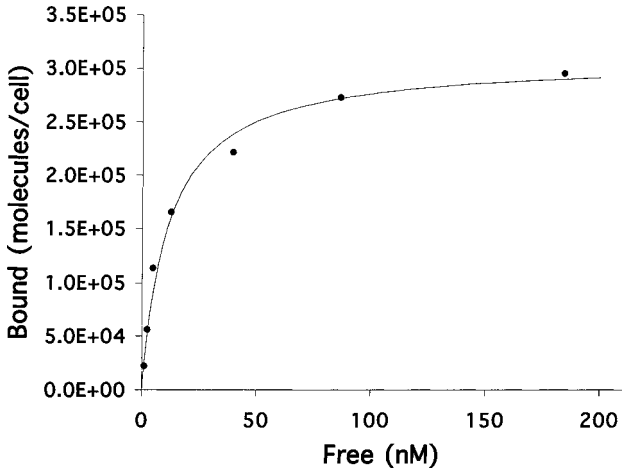

Figure 4. PS^+-red blood cell binding data for [F-18]fluoroannexin.

(k) Mass Spectrometry. A Micromass (Manchester, UK) Quattro II Tandem Quadrupole Mass Spectrometer, that has unit resolution over a 4000 *m*/*z* range, was used with electrospray ionization (ESI^+) for analysis of fluoroannexin samples containing mixed levels of protein conjugation with 4-fluorobenzoic acid. Samples were desalted by HPLC prior to their infusion into the electrospray source. The chromatographic method used a

Poros RP1 packed column (150 × 2.1 mm, wide pore cross-linked polystyrene media supplied by Applied Biosystems Inc, Foster City, CA) and a Shimadzu (Columbia, MD) LC-10AD pump. The RP1 column was eluted at 300 μL/min using mixtures of mobile phase: A = water−0.05% trifluoroacetic acid (TFA) and B = MeCN−0.05%TFA. The mobile phase profile was 90:10 (A/B) between 0 and 5 min, followed by a linear gradient to 5:95 (A/B) between 5 and 20 min, and a final isocratic elution to 30 min. Micromass MassLynxNT 3.2 software was used to control the HPLC, the spectrometer, and data acquisition. The column eluate flow was diverted from the electrospray source for 2 min with a VICI Valco Instruments (Houston, TX) six-port injection valve. After 15 min of programmed elution, the fluoroannexin proteins eluted unseparated over a 4-min period. The spectrometer scan-time was 3.5 s between 500 and 2000 Da, with an interscan period of 0.1 s. MaxEnt, a statistical software package within the MassLynx operating system, was used to deconvolute complex multiple-charge-state mass spectral envelopes. A uniform Gaussian width-at-half-height of 2 Da was applied for mass peak recognition. An example data set and analysis is provided as Supporting Information.

(m) PET Imaging. Normal male Sprague−Dawley rats (260−280 g) were purchased from Animal Technologies Ltd. (Kent, WA). Animals were housed according to institutional guidelines, and all procedures were approved by the University of Washington Institutional Animal Care and Use Committee (IACUC). Prior to imaging, rats were anesthetized with ketamine (68 mg/kg) and xylazine (4.4 mg/kg) by iv injection. Anesthesia was maintained by booster injections of ∼7 mg/kg ketamine every 20 min. PET images were obtained using a GE (Waukesha, WI) Advance PET system. Image data was collected for 3 h, in 10 min time bins, starting 30 s after tail vein injection of [F-18]fluoroannexin (1−1.5 mCi). The specific activity was 13 μCi/μg at the time of injection. Data were collected in 2D-mode and reconstructed using the attenuated weighted OSEM algorithm (2 iterations, 28 subsets) with a 4 mm Gaussian postfilter. The reconstructed field of view was 20 cm.

RESULTS AND DISCUSSION

[F-18]Fluoroannexin (FAN) was prepared by adapting a general protein labeling protocol developed by Wester et al. (*11*). The method uses the *N*-hydroxysuccinimidyl ester of 4-fluorobenzoic acid (FBA-OSu). Our choice was based on initial success with labeling FBA-OSu and the previous claim that, in vivo, protein−(fluoro)benzamide conjugation was more stable than protein−(fluoro)alkylamide conjugation (*11*). We have further investigated the production of [F-18]FBA-OSu and evaluated its potential for labeling annexin-V. The basic scheme is illustrated in Figure 1. The issue of fluorobenzoic acid (FBA) conjugate load was addressed with experiments using unlabeled FBA-OSu and annexin-V.

Study of Annexin-V Conjugation. Annexin-V has 22 lysine residues and a free amino terminus that provide potential sites for fluorobenzoic acid (FBA) conjugation. Prior to this work, no information was available on how many FBA conjugations could be tolerated before the characteristic PS-binding of the parent protein (K_d 10 nM) was compromised. This issue was addressed by a series of experiments that varied the stoichiometry (1:1 to 32:1 FBA-OSu/annexin) of 15 min−pH 8.5−room temperature reactions. Fluoroannexin reaction products were purified by size exclusion HPLC and analyzed by mass spectrometry to determine the distribution of annexin molecules with different numbers of FBA groups. Table 1 lists annexin-xFBA distributions within each sample and the associated IC_{50} values (50% inhibitory concentration) that measure the ability of protein samples to competitively displace FITC-annexin (K_d 10 nM) bound to PS+ cell membranes. The data showed that even a 32:1 molar ratio yields quite a low (2.1) average FBA substitution level and that the reaction protocol could yield adequate specific activity without loss of phosphatidylserine binding. The average level of FBA conjugation with annexin-V was linearly related (r^2 = 0.99) to the offering ratio up to the highest ratio tested, 32:1. Extended reaction times (30 and 60 min) with a 32:1 mole ratio were also examined to test the limits of conjugation. These experiments are summarized in Figure 3, which indicated that only an extended reaction time and a high FBA-OSu:annexin molar ratio (60 min, 32:1) yields a protein conjugate with significantly compromised binding to PS+ membranes. The two control samples were stock annexin solution and a stock sample that was purified by SEC. The product from the most heavily treated reaction was analyzed by mass spectrometry to determine how many FBA/annexin were present. The range of conjugation was 3−13, and the average was 7.7 (Supporting Information). Collectively, these data showed that it should be possible to prepare [F-18]fluoroannexin with high protein specific activity and maintain competitive binding.

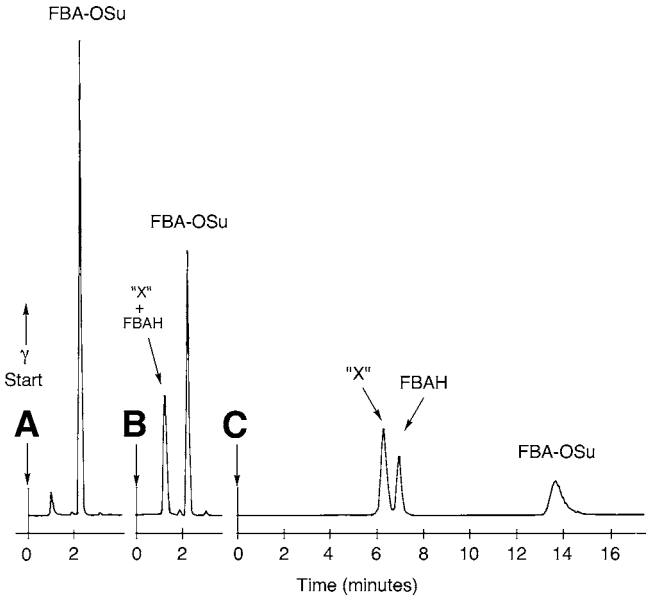

Figure 5. Radiochromatographic study of [F-18]FBA-OSu stability. Injection-A and -B: C18 column eluted with 60% MeCN−water; Injection-C: size exclusion column eluted with 0.9% saline.

Radiolabeling FBA-OSu and Annexin-V. The production of [F-18]FBA-OSu was accomplished in 77% radiochemical yield (EOB). We chose to include a HPLC purification of FBA-OSu to circumvent potential problems with protein labeling and to eliminate unlabeled or labeled impurities that might interfere with the [F-18]-FAN bioassay. Using the pure ester offered better quality control for evaluating the protein-conjugation reaction. The extra time taken to purify and isolate the ester in dry ether may be optional, but we have demonstrated that large quantities of the ester can be made. A typical timeline for the process is shown in Figure 1. Time points B and C mark, respectively, the collection of the ester from the HPLC column (91 min) and its subsequent

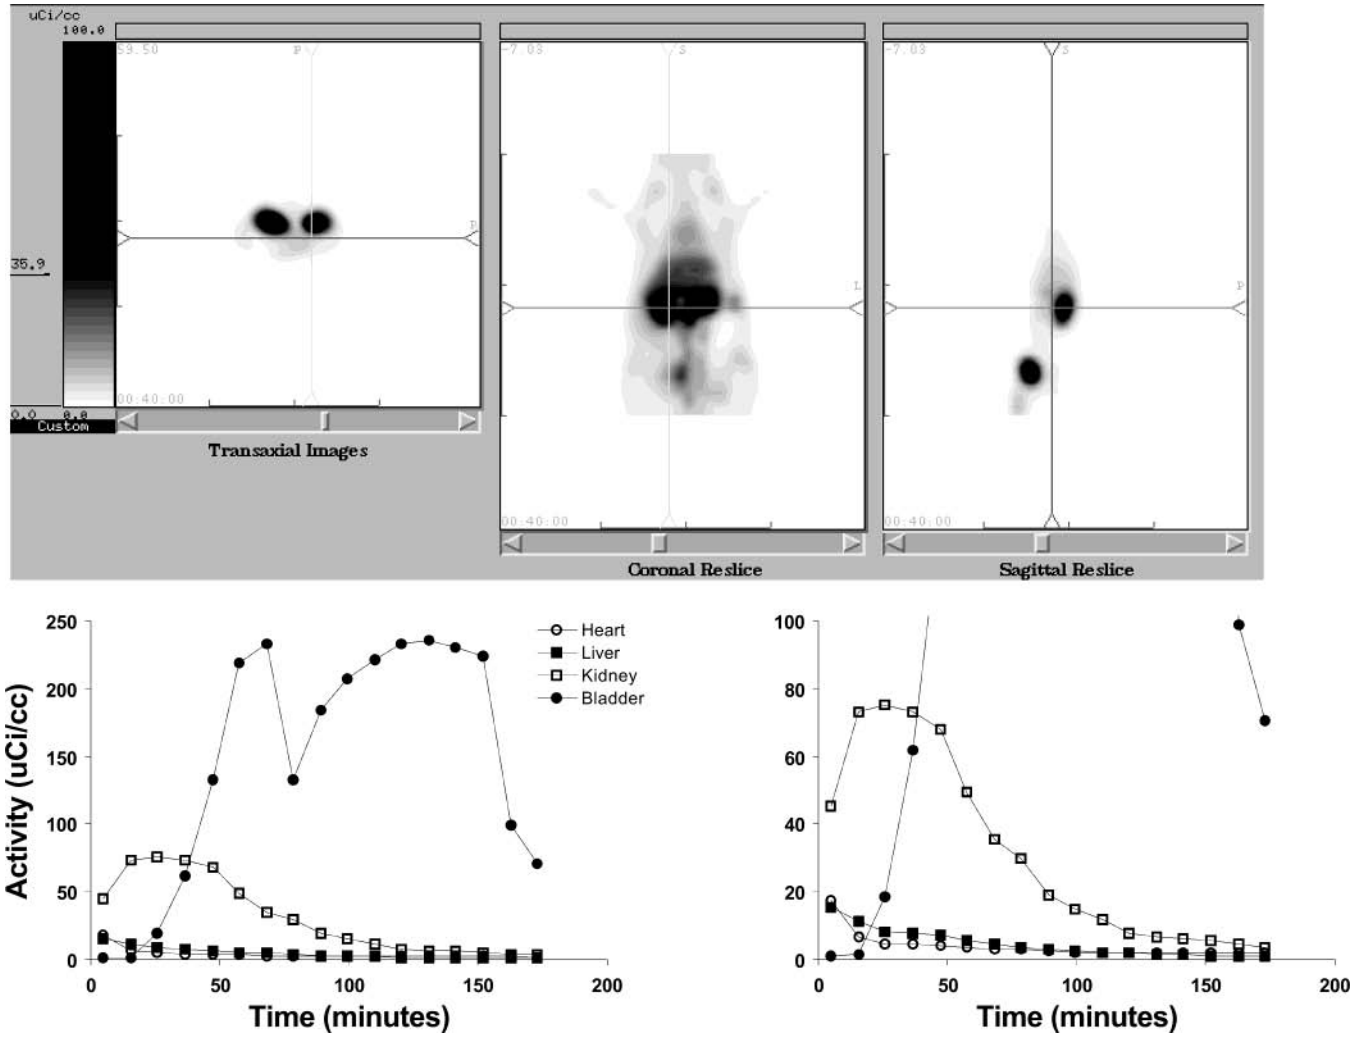

Figure 6. PET image of a male rat injected with [F-18]fluoroannexin and tissue TAC's. PET image set (top); tissue TAC: full scale (left); expanded scale (right).

reformulation in dry ether (108 min, 35% radiochemical yield, not decay corrected). Isolation of the ester in dry ether minimized its decomposition and provided a convenient solvent for rapidly evaporating aliquots. Figure 2 illustrates a set of HPLC radiochromatographic profiles for FBA-OSu and FAN purifications. Initial attempts with FBA-OSu production gave a 25% (not decay corrected) radiochemical yield (55%, decay corrected to the end of cyclotron bombardment (EOB)) on a >350 mCi scale. With practice, however, the yields steadily increased to 44% (not decay corrected) for collecting FBA-OSu off the HPLC column, requiring 90 min overall.

Figure 5 is a series of radiochromatograms that demonstrate the stability of FBA-OSu. Chromatogram-A shows a sampling of FBA-OSu in dry ether after the solution was allowed to stand for 2 h (initial activity 80 mCi/6 mL). Clearly the ester has good stability in ether. Another stability test of FBA-OSu at pH 8.5 mimicked the labeling conditions with annexin-V. An aliquot of ester stock solution was evaporated and treated with a 16% solution of acetonitrile in 0.025 M borate buffer (150 μL). Chromatogram-B represents a sample after 15 min at room temperature. Assuming FBA-OSu decomposes by hydrolysis or attack by other ambient species at the active ester site, a crude estimate of FBA-OSu decomposition gives a first order kinetic half-time of 32 min. This value acceptable compared to the 15 min labeling protocol. The identity of the FBA-OSu decomposition byproducts in chromatogram-B was partially clarified using the size exclusion HPLC method involved with FAN purification. Chromatogram-C identified 4-fluorobenzoic acid (verified by coinjection) and an unidentified component "x". Considering the composition of the test mixture, "x" is likely derived from acetonitrile decomposition byproducts that become labeled. This implicated fluorobenzamide or *N*-fluorobenzoylacetamide, but the issue was not pursued further.

Table 2 lists selected fluoroannexin labeling results using [F-18]FBA-OSu. [F-18]FAN activity values are referenced to the end-of-synthesis (EOS) to reflect the quantities typically encountered with the 22 min reaction and purification process. In some cases (1, 2, and 7) radiochemical yields were influenced by low protein recovery.

The poor yields (6%) seen for reactions 1 and 2 showed that a 1 mg/mL protein concentration diluted (1:1) with pH 8.5 buffer was impractical. By comparison, the higher protein stock concentration (7.4 mg/mL) used in reactions 3 and 4 improved the yields through gains in protein recovery and labeling efficiency. Protein recovery showed a practical limit of ~85% when the protein content was above 1.1 mg (reactions 3−6). In these cases, unrecovered activity was accounted for by the reaction vessel residue and transfer loss to the HPLC column. Further improvement in yield (2.3-fold) was realized (e.g. reaction 5 vs 4) when the buffer volume was reduced 10-fold (15 μL vs

150 μL). A supersaturated borate buffer (0.5 M) was used. Less concentrated buffers may be as effective but were not tested. The 64% yield for reactions 5 and 6 appears to be the limit, considering transfer losses in the process and the competing FBA-OSu decomposition. Overall, the final protein concentration in the reaction was the most important factor that determined the percent conjugation of FBA with annexin-V.

Reactions 6−8 used a common batch of FBA-OSu and comparable amounts of activity and protein. This series also evaluated clinical grade (1.0 mg/mL) *rh*-annexin-V. Reaction 6 used the same research grade *rh*-annexin-V as reactions 1−5. In comparison to the yield for reaction 1, the yield for reaction 7 is higher than expected. This could be ascribed to differences in FBA-OSu batches A and E at the start of the labeling reaction. The specific activities in FBA-OSu batches A−D were not measured. However, fluoride activity levels for all batches were comparable (average 478 mCi, range 335−535 mCi). FBA-OSu specific activity for batch E (2 Ci/μmol) was determined indirectly by performing mass spectrometry on the FAN product from reaction 7. The value was calculated by dividing the protein specific activity (88 μCi/μg decay corrected to SOS) by the average number of FBA conjugations per FAN protein molecule (1.6). The FAN−*x*FBA distribution frequency was 0-FBA(13%), 1-FBA-(37%), 2-FBA(32%), 3-FBA(12%), 4-FBA(3%), and 5-FBA-(3%), and the FBA-OSu/annexin ratio for reaction 7 was 5.3:1. Figure 4 shows rbc-binding profile for FAN from reaction 7. The apparent K_d and B_{max} values (±2SD) for the protein were 10.8 ± 5.0 nM and 3.04 + 0.35 × 10^5/cell, respectively, as calculated from a nonlinear least-squares fit. The apparent K_d values compare favorably with the reported K_d for annexin V, which is between 6 and 10 nM at this Ca^{2+} concentration (2.5 mM) (*5*). From a collection of similarly prepared samples (n = 8) the average K_d; B_{max} values were 9.6 nM (± 20%) and 3.1 × 10^5/cell (± 13%), respectively.

PET Imaging. Our goal is to use [F-18]fluoroannexin to image apoptosis in humans. As a preliminary step, normal rats were injected with [F-18]fluoroannexin and imaged to study which organs had the highest uptake and how rapidly the activity was cleared from tissues. Figure 6 shows the first PET images obtained with FAN in a normal rat. This series of 10-min frames centered on 45 min postinjection demonstrates the high uptake in the renal excretory system. The heart and liver are discernible above the kidneys, and the ureters are even visible. This figure also illustrates tissue time−activity curves (TAC) for heart, liver, kidney, and bladder. The graph on the right-hand side uses an expanded scale for activity values in order to better display the lower valued curves. It is clear from these curves and the image set that there is sufficiently rapid clearance of [F-18]fluoro-annexin so that only modest activity remains in most internal organs after 1 h. The clearance characteristics of [F-18]fluoroannexin should prove useful for early imaging of apoptosis. We are currently investigating the use of [F-18]fluoroannexin in imaging apoptosis in animal models.

ACKNOWLEDGMENT

Financial support was provided by the National Institutes of Health (CA42045). We thank William Howald and Ross Lawrence for their assistance with protein mass measurements. We also thank Theseus Imaging Corporation for the gift of clinical grade *rh*-annexin-V

Design and Synthesis of Visible Isotope-Coded Affinity Tags for the Absolute Quantification of Specific Proteins in Complex Mixtures

Patricia Bottari,[†] Ruedi Aebersold,[§] Frantisek Turecek,*[,†] and Michael H. Gelb*[,†,||]

Departments of Chemistry and Biochemistry, University of Washington, Seattle, Washington 98195, and Institute for Systems Biology, Seattle, Washington 98103-8904. Received September 22, 2003; Revised Manuscript Received December 18, 2003

Identification of proteins in complex mixtures by mass spectrometry is most useful when quantitative data is also obtained. We recently introduced isotope-coded affinity tags (ICAT reagents) for the relative quantification of proteins present in two or more biological samples. In this report, we describe a new generation of ICAT reagents that contain the following additional features: (1) a visible tag that allows the electrophoretic position of tagged peptides during separation to be easily monitored; (2) a photocleavable linker that allows most of the tag to be removed prior to mass spectrometric analysis; (3) an isotope tag that contains carbon-13 and nitrogen-15 atoms instead of deuterium to ensure precise comigration of light and heavy tagged peptides by reverse-phase HPLC. These reagents contain an iodoacetyl group that selectively reacts with peptide cysteine residues. Peptide modification chemistry is also reported that allows tagging of peptides that are devoid of cysteine. The synthesis of these visible isotope-coded affinity tags (VICAT reagents), and their reaction with peptides are described in this report. VICAT reagents containing a carbon-14 visible probe or an NBD fluorophore are described. These reagents are most useful for the determination of the absolute quantity of specific target proteins in complex protein mixtures such as serum or cell lysates.

INTRODUCTION

Mass spectrometry has emerged as one of the most useful techniques for the detection of proteins and protein-derived peptides. Since mass spectrometry often depends on internal standards for quantification, there have been recent efforts to develop novel chemical reagents that, when combined with mass spectrometry, provide protein abundance information on a quantitative level (*1*−*3*). Most of these methods involve the use of an internal standard, that is a compound identical to the analyte whose level is desired but is distinguished by different molecular mass due to heavy isotopic substitution. Along these lines, we have developed a reagent called the isotope-coded affinity tag (ICAT) and first applied this reagent to detect changes in the relative levels of specific proteins in yeast in response to changes in growth conditions (*4*). This is an example of a survey-type method in which abundance information is obtained on as many proteins as possible in a complex protein mixture (*5*, *6*). ICAT reagents are used to selectively tag the SH groups of peptide cysteine residues, with the introduction of a light and heavy isotope tag and a biotin residue for selective enrichment of tag peptides. Another cysteine peptide enrichment and isotope tagging scheme has been developed by Johnson and co-workers (*7*).

There is also a clear need for the development of reagents that allow a specific set of known proteins to be detected in complex mixtures and their absolute abundance determined. Detection of specific proteins in a complex mixture is usually carried out by one or more immunological methods including immunoblotting (western blotting) and ELISA. Although these methods are routinely used and provide valuable information, they have a number of limitations as discussed previously (*8*). For example, it often requires ∼1 year of work at a substantial cost to develop a highly specific antibody required for an ELISA-based detection of low levels of a specific protein in a complex biological fluid such as serum. Thus, it is not practical for a single laboratory to develop an immunological assay of a set of say 10−20 proteins, for example to evaluate the levels of proteins discovered by other techniques such as nucleic acid microarrays.

When the sequence of the peptide derived from the protein of interest is known, the mass spectrometer can be used to selectively monitor the particular parent ion mass of the target peptide of interest. Additional selective monitoring is provided by tandem mass spectrometry, in which a specific fragment ion or ions derived from the peptide parent ion is detected (specific or multiple reaction monitoring). Typically this type of experiment is done by separation of the peptide mixture on a reverse-phase, microbore HPLC column, which is interfaced directly with an electrospray ionization mass spectrometer. However, HPLC separation combined with specific reaction monitoring is probably not generally sufficient to detect specific peptides in complex peptide mixtures such as a trypsin digest of a eukaryotic cell lysate. This is because such tryptic digests may contain hundreds of thousands of distinct peptides, and the peptide of interest may be present in relatively small amounts compared to highly abundant peptides. For example, sequential separation is employed in the AQUA method (*9*), which makes use of protein electrophoresis (Laemmli gel) prior to

combined HPLC/multiple reaction monitoring via tandem mass spectrometry for the absolute quantification of specific proteins in cell lysates.

In the present study, we describe the design and synthesis of modified ICAT reagents that contain a visible probe that allows tagged peptides to be detected by methods independent of mass spectrometry. These visible isotope-coded affinity tag reagents (VICAT reagents) are designed to be used in a analytical scheme in which peptides tagged with VICAT reagents are first resolved by isoelectric focusing (IEF) on a commercial gel strip containing an immobilized pH gradient. The presence of the visible probe allows the precise position of the desired tagged peptide to be immediately determined following one-dimensional separation by IEF. The desired region of the IEF gel strip is then excised, and eluted peptides are analyzed by combined reverse-phase, microbore HPLC/electrospray ionization tandem mass spectrometry. The visible probe also allows the absolute amount of the target peptide to be quantified at all steps in the process from postpeptide tagging to quantification in the mass spectrometer. This is an important feature since losses of analyte are inevitable in any multistep process.

In the present paper, we report the first phase of our development of VICAT reagents, the full experimental details for their synthesis and a demonstration of their reactivity with peptides and subsequent transformation prior to chromatographic separation and quantification by mass spectrometry. We also describe a peptide modification sequence, which allows tagging with ICAT and VICAT reagents of peptides that lack cysteine residues. In a subsequent, more biologically oriented study (*8*), we demonstrate the use of VICAT reagents for the absolute quantification of specific target proteins in eukaryotic cell lysates.

EXPERIMENTAL PROCEDURES

General Procedures. The structures of the VICAT reagents are shown in Figure 1, and their syntheses is outlined in Figures 2 and 4. Tetrahydrofuran (THF) was distilled from sodium/benzophenone under Ar, and methylene chloride (CH_2Cl_2) and triethylamine (TEA) were distilled from CaH_2 under Ar. Anhydrous dimethylformamide (DMF), pyridine, [^{13}C,^{15}N]-potassium cyanide, and 1,2-[$^{13}C_2$]-dibromoethane were purchased from Aldrich. Unless otherwise noted, all other compounds are reagent grade and were used as received. Unless otherwise noted, all nonaqueous reactions were carried out under Ar with oven-dried glassware. Electrospray ionization mass spectrometry (ESI-MS) was carried out on a Bruker Daltonics Esquire ion trap mass spectrometer, and MALDI data was obtained on a Applied Biosystems 4700 Proteomics Analyzer. Silica gel flash chromatography was performed using 230−400 mesh silica gel 60 (Merck, Darmstadt, Germany). Thin-layer chromatography was performed on aluminum-backed silica 60 plates with F254 indicator (Merck). Unless otherwise noted, reverse-phase HPLC separations were performed using a Vydac (Hisperia, CA) semipreparative column (up to 5 mg total loading, 10 μm packing, 10 mm × 250 mm, catalog no 218TP1010) at 4 mL/min, or a preparative column (up to 300 mg total loading, 10 μm packing, 20 mm × 250 mm, catalog no 218TP1022), or an a large preparative column (up to 1 g total loading, 10−15 μm packing, 5 × 25 cm, catalog no 218TP101550).

Synthesis of Sulfhydryl-Specific VICAT Reagents ($VICAT_{SH}$). *Biotin Tetrafluorophenyl Ester (**1**).* (+)-Biotin (4.5 g, 18.4 mmol) was dissolved in warm anhydrous DMF (90 mL). After the solution was cooled to room temperature, TEA (4.7 mL, 33.8 mmol) was added, followed by dropwise addition of tetrafluorophenyl trifluoroacetate (7.3 g, 27.4 mmol, (*10*)). After being stirred for 30 min at room temperature, the solvent was removed under reduced pressure. The residue was triturated with dry diethyl ether, and the product was filtered. The solid was dried under vacuum to afford 6.2 g (86%) of a white solid. ^1H NMR (300 MHz, d_6-DMSO) δ 7.9 (m, 1H); 6.4 (d, 2H); 4.35 (t, 1H); 4.15 (t, 1H); 3.2 (m, 1H); 2.75−2.9 (m, 3H), 2.6 (d, 1H); 1.4−1.8 (m, 6H).

*Biotin 2′-Aminoethylamide (**2**).* To a round-bottom flask containing ethylenediamine (8.5 g, 141.7 mmol) at 0 °C was transferred via cannula a solution of **1** (5 g, 12.8 mmol) in dry DMF (100 mL), also at 0 °C. After the mixture was stirred for 2 h at 0 °C, ethyl ether (100 mL) was added, and the solid was filtered and washed with ether. The white solid was left under vacuum overnight, and 3.15 g (86%) of the product was obtained. ^1H NMR (300 MHz, d_6-DMSO) δ 7.75 (bs, 1H); 6.4 (d, 2H); 4.35 (t, 1H); 4.15 (t,1H); 3.1 (m, 1H); 3.0 (q, 2H); 2.85 (dd, 1H); 2.5 (m, 3H); 2.0 (t, 2H), 1.2−1.7 (m, 6H). ESI-MS $(M + H^+)^+$: 287.0, $(2M + H^+)^+$: 573.0.

*Biotin 2′-(2″-Methylcarbonyl-1″-nitro-4″-phenylamino)-ethylamide (**3**).* To a round-bottom flask containing a solution of compound **2** (2.4 g, 8.4 mmol) in dry DMF (72 mL) and diisopropylethylamine (DIPEA) (2.9 mL, 16.7 mmol) at 0 °C was slowly added a solution of 5-bromomethyl-2-nitroacetophenone (*11*, *12*) (2.4 g, 9.3 mmol) in dry DMF (24 mL). After stirring for 3 h at 0 °C, the pH was adjusted to ∼5 with concentrated HCl (moist pH paper), and the solvent was removed in vacuo. The product was purified on a silica column packed with 5:1 CH_2Cl_2:MeOH. The column was developed with the same solvent, and the product was obtained in 64% yield (2.5 g). ^1H NMR (300 MHz, d_4-MeOH) δ 8.0 (d, 1H, J = 8.3 Hz); 7.75 (m, 2H); 4.45 (dd, 1H); 4.25 (dd,1H); 4.1 (s, 2H); 3.4 (t, 2H); 3.2 (m, 1H); 2.95 (m, 3H); 2.85 (d, 1H); 2.55 (s, 3H); 2.1 (t, 2H), 1.25−1.8 (m, 6H). ESI-MS $(M + H^+)^+$: 464.2, $(M + Na^+)^+$: 486.1.

*Compound **4**.* To a round-bottom flask containing a solution of compound **3** (2.5 g, 5.4 mmol) in MeOH (100 mL) and TEA (750 μL, 5.4 mmol) was added di-*tert*-butyl dicarbonate (1.3 g, 6.0 mmol). The mixture was stirred at 50 °C for 2 h and then cooled to room temperature. Sodium borohydride (650 mg,16.2 mmol) was added, and the reaction was stirred for an additional 1 h. Solvent was removed under reduced pressure and the residue resolubilized in CH_2Cl_2 (80 mL). The resulting solution was washed with water (40 mL) and brine (40 mL) and dried over anhydrous Na_2SO_4. Solvent was removed under reduced pressure to afford the product in 78% overall yield (2.4 g). ^1H NMR (300 MHz, $CDCl_3$) δ 7.8 (d, 1H, J = 8.4 Hz); 7.75 (bs, 1H); 7.2 (m, 1H); 6.9 (d, 1H); 5.9 (d, 1H); 5.35 (m, 1H); 4.4 (m, 3H); 4.25 (m,1H); 4.1 (d, 1H); 3.0−3.4 (m, 5H); 2.8 (dd, 1H); 2.65 (d, 1H); 2.1 (m, 2H); 1.8 (bs, 1H), 1.20−1.75 (m, 18H). ESI-MS $(M + Na^+)^+$: 588.5.

*N-(2-Aminoethyl)carbamate of **4** (**5**).* To a round-bottom flask containing a solution of compound **4** (224 mg, 0.4 mmol) in dry CH_2Cl_2 (4 mL) was added a solution of carbonyl diimidazole (CDI) (97.2 mg, 0.6 mmol) in dry CH_2Cl_2 (10 mL). After the mixture was stirred 2 h at room temperature in the presence of 4 Å molecular sieves, ethylenediamine (53.4 μL, 0.8 mmol) was added. After 1 h, the solvent was removed in a Speed-Vac (Savant Instruments). The residue was purified by HPLC: preparative C_{18} column, λ = 240 nm, 6 mL/min, solvent A = H_2O with 0.08% trifluoroacetic acid (TFA), solvent B =

CH_3CN with 0.08% TFA, gradient: 0′−20′: 0−20% B; 20′−70′: 20−70% B. The TFA salt of the product (244 mg, 79.7%) eluted between 38.7 and 44.3% B. ^{1}H NMR (300 MHz, d_4-MeOH) δ 7.9 (d, 1H); 7.5 (m, 1H); 7.35 (dd, 1H); 6.2 (m, 1H); 4.6 (bd, 2H); 4.45 (dd, 1H); 4.3 (m,1H); 3.25−3.5 (m, 6H); 3.2 (m, 1H); 3.0 (m, 2H); 2.8 (dt, 1H); 2.65 (dd, 1H); 2.2 (m, 2H); 1.25−1.8 (m, 18H). ESI-MS $(M + H^+)^+$: 652.4, $(M + Na^+)^+$: 674.3.

*Compound **6***. To a vial containing compound **5** (244 mg, 0.32 mmol) in dry THF (8 mL) in the presence of 4 Å molecular sieves was added DIPEA (112 μL, 0.64 mmol), followed by a solution of iodoacetic anhydride (170 mg, 0.48 mmol) in dry THF (2 mL). After the mixture was stirred 1.5 h at room temperature, the pH was adjusted to ∼5 with TFA (moist pH paper). The solvent was removed under reduced pressure and the residue purified by HPLC. Preparative C_{18} column, $\lambda = 240$ nm, 6 mL/min, gradient: 0′−20′: 0−20% B; 20′−80′: 20−70% B. The product (160 mg, 61%) eluted between 50.5 and 52% B. ^{1}H NMR (300 MHz, d_4-MeOH) δ 7.95 (d, 1H); 7.55 (m, 1H); 7.35 (dd, 1H); 6.2 (m, 1H); 4.55 (bs, 2H); 4.45 (dd, 1H); 4.25 (dd,1H); 3.65 (bs, 2H); 3.1−3.45 (m, 9H); 2.9 (dd, 1H); 2.65 (dd, 1H); 2.2 (m, 2H); 1.25−1.8 (m, 18H). ESI-MS $(M + Na^+)^+$: 842.2.

*Deprotection of **6** (**7**)*. To a vial containing a solution of compound **6** (160 mg, 0.2 mmol) in $CHCl_3$ (0.5 mL) was added TFA (200 μL). The reaction mixture was stirred for 1.5 h at room temperature. Solvent was removed in a Speed-Vac. MeOH was added, and the resulting solution was concentrated in a Speed-Vac. This procedure was repeated three times to remove excess TFA. The TFA salt of the product was obtained in 98.5% yield (160 mg). ^{1}H NMR (300 MHz, d_4-MeOH) δ 8.0 (d, 1H); 7.8 (bs, 1H); 7.6 (dd, 1H); 6.1 (m, 1H); 4.5 (m, 1H); 4.4 (bd, 2H); 4.3 (dd, 1H); 4.25 (dd,1H); 3.7 (bs, 2H); 3.55 (m, 2H); 3.0−3.45 (m, 7H); 2.9 (dd, 1H); 2.65 (dd, 1H); 2.2 (t, 2H); 1.25−1.8 (m, 9H). ESI-MS $(M + H^+)^+$: 720.

^{14}C-VICAT$_{SH}$(−28). To an Eppendorf tube containing a solution of compound **7** (7.34 mg; 8.8 μmol) in MeOH (272 μL) was added 1% [^{14}C]formaldehyde in water (v/v, 51 μL, 17.6 μmol, 1 mCi, specific activity 56 Ci/mol, Perkin-Elmer) followed by 1.2 M methanolic $NaCNBH_3$ (15 μL, 17.6 μmol) and 1.2 M methanolic DIPEA (22 μL, 26.4 μmol). The capped Eppendorf tube was placed in a shaker at 168 rpm for 6 h. The pH was adjusted to ∼5 (moist pH paper) with a 1.2 M aqueous solution of TFA (20 μL). The mixture was diluted with 30% CH_3CN in water and injected on to the HPLC column. Preparative C_{18} column, $\lambda = 240$ nm, 6 mL/min, gradient: 0′−20′: 0−20% B; 20′−80′: 20−70% B. The product (4.6 mg, 0.19 mCi) eluted between 34.4 and 36.7% B.

*N-(4-Aminobutyl)carbamate of **4** (**8**)*. To a round-bottom flask containing a solution of compound **4** (2.0 g, 3.54 mmol) in dry CH_2Cl_2 (20 mL) was added a solution of carbonyl diimidazole (860 mg, 5.31 mmol) in dry CH_2Cl_2 (20 mL). After the mixture was stirred 2 h at room temperature in the presence of 4 Å molecular sieves, 1,4-diaminobutane (putrecine) (623 mg, 7.08 mmol) was added. After an additional 2 h, the solvent was removed in a Speed-Vac. The residue was solubilized in water and the pH adjusted to ∼5 with TFA. The solution was injected onto the HPLC column. Large preparative C_{18} column, $\lambda = 240$ nm, 50 mL/min, gradient: 0′−10′: 20% B; 10′−60′: 70% B. The product as the TFA salt (2.15 g, 77%) eluted between 37 and 41.7% B. ^{1}H NMR (300 MHz, d_4-MeOH) δ 7.9 (d, 1H); 7.5 (m, 1H); 7.35 (dd, 1H); 6.2 (m, 1H); 4.6 (bd, 2H); 4.45 (dd, 1H); 4.3 (m,1H); 3.25−3.5 (m, 4H); 3.2 (m, 1H); 3.1 (m, 2H); 2.95 (m, 3H); 2.8 (dd, 1H); 2.2 (m, 2H); 1.25−1.8 (m, 22H). ESI-MS $(M + H^+)^+$: 680.5.

*N-(4-Iodoacetamidobutyl)carbamate of **4** (**9**)*. To a vial containing compound **8** (1.0 g, 1.26 mmol) in dry THF (15 mL) in the presence of 4 Å molecular sieves was added DIPEA (440 μL, 2.52 mmol), followed by a solution of iodoacetic anhydride (670 mg, 1.89 mmol) in dry THF (5 mL). After the mixture was stirred 1.5 h at room temperature, the pH was adjusted to ∼5 with TFA (moist pH paper). The solvents were removed under reduced pressure, and the residue was purified by HPLC. Large preparative C_{18} column, $\lambda = 240$ nm, 50 mL/min, gradient: 0′−10′: 20% B; 10′−80′: 70% B. The product (657 mg, 61%) eluted at 46.6% B. ^{1}H NMR (300 MHz, d_4-MeOH) δ 8.0 (d, 1H, $J = 8.3$ Hz); 7.6 (m, 1H); 7.4 (d, 1H, $J = 8.3$ Hz); 6.15 (m, 1H); 4.55 (d, 2H); 4.5 (dd, 1H); 4.3 (dd,1H); 3.65 (bs, 2H); 3.1−3.45 (m, 9H); 2.95 (dd, 1H); 2.75 (dd, 1H); 2.2 (t, 2H); 1.25−1.8 (m, 22H). ESI-MS $(M + H^+)^+$: 848.0; $(M + Na^+)^+$: 870.5.

*Deprotection of **9** (**10**)*. To a vial containing a solution of compound **9** (603 mg, 0.71 mmol) in $CHCl_3$ (3 mL) was added TFA (1.2 mL). The reaction mixture was stirred for 2 h at room temperature. Solvent was removed using in a Speed-Vac. MeOH was added, and the resulting solution was concentrated in the Speed-Vac. This procedure was repeated three times to remove excess TFA. The TFA salt of the product was obtained in 100% yield (611 mg). ^{1}H NMR (300 MHz, d_4-MeOH) δ 8.0 (d, 1H); 7.8 (bs, 1H); 7.6 (dd, 1H); 6.1 (m, 1H); 4.5 (m, 1H); 4.4 (bd, 2H); 4.3 (dd, 1H); 4.25 (dd,1H); 3.65 (bs, 2H); 3.55 (m, 2H); 3.1−3.35 (m, 7H); 2.95 (dd, 1H); 2.65 (dd, 1H); 2.25 (t, 2H); 1.4−1.8 (m, 13H). ESI-MS $(M + H^+)^+$: 748.4

^{14}C-VICAT$_{SH}$. To an Eppendorf tube containing a solution of compound **10** (7.54 mg; 8.8 μmol) in MeOH (272 μL), was added 1% [^{14}C]formaldehyde in water (v/v, 59 μL, 17.6 μmol, 1 mCi, 49.5 Ci/mole) followed by 1.2 M methanolic $NaCNBH_3$ (15 μL, 17.6 μmol) and 1.2 M methanolic DIPEA (22 μL, 26.4 μmol). The capped Eppendorf tube was placed in a shaker at 168 rpm for 6 h. The pH was adjusted to ∼5 (moist pH paper) with a 1.2 M aqueous solution of TFA (20 μL). The reaction was diluted with 30% CH_3CN:water and injected on to the HPLC column. Preparative C_{18} column, $\lambda = 240$ nm, 6 mL/min, gradient: 0′−10′: 0−20% B; 10′−70′: 20−70% B. The product (3.5 mg, 0.162mCi) eluted between 36.8 and 39.3% B.

VICAT$_{SH}$. The nonradioactive reaction was carried out as for ^{14}C-VICAT$_{SH}$ using compound **10** (1.09 g, 1.27 mmol), 37% formaldehyde in water (207 μL, 2.54 mmol), $NaCNBH_3$ (168 mg, 2.54 mmol), MeOH (50 mL) and DIPEA (662 μL, 3.81 mmol). The compound was purifed on the large preparative C18 column, $\lambda = 240$ nm, 50 mL/min, gradient: 0′−10′: 0−20% B; 10′−60′: 20−70% B. The product (900 mg, 81.8%) eluted at 32% B. ^{1}H NMR (300 MHz, d_4-MeOH) δ 8.0 (d, 1H); 7.8 (s, 1H); 7.6 (dd, 1H); 6.1 (m, 1H); 4.5 (dd, 1H); 4.25 (dd,1H); 3.65 (bs, 2H); 3.6 (m, 2H); 3.1−3.45 (m, 9H); 2.95 (m, 4H); 2.65 (dd, 1H); 2.25 (t, 2H); 1.25−1.8 (m, 13H). ESI-MS $(M + H^+)^+$: 762.3.

*[$^{15}N_2$,$^{13}C_4$]butanedinitrile (**11**)*. Potassium [^{13}C, ^{15}N]-cyanide (176.3 mg, 2.63 mmol) and [1,2-$^{13}C_2$]-dibromoethane (0.5 g, 2.63 mmol) were refluxed for 5 h in 70% ethanol (2 mL). The reaction mixture was cooled to room temperature and passed through a silica plug with benzene. The solvent was removed under reduced pressure to afford the product in 80% yield (90 mg). ^{1}H NMR (300 MHz, $CDCl_3$) δ 3.0 (m, 2H); 2.55 (m, 2H).

*[$^{14}N_2$,$^{13}C_4$]-1,4-Butanediamine dihydrochloride (**12**)*. Compound **11** (137.1 mg, 1.59 mmol) and a 1 M solution of

borane in dry THF (16 mL, 15.9 mmol) were refluxed for 24 h. After the reaction was cooled to room temperature, anhydrous ethanol (18 mL) was added. The reaction was stirred for 24 h, and HCl gas was bubbled through the solution for 10 min, or until saturation. The di-chloride salt was filtered, washed with anhydrous ethanol, and dried under vacuum to afford 146.5 mg (55.2%) of a white solid. ^{1}H NMR (300 MHz, D_2O) δ 3.5 (m, 2H); 2.75 (m, 2H); 2.15 (m, 2H); 1.75 (m, 2H).

*N-([$^{14}N_2$,$^{13}C_4$]aminobutyl)carbamate of **4** (**13**).* A solution of compound **12** (30 mg, 0.18 mmol), and TEA (368 μL, 2.62 mmol) in DMSO (1 mL) was heated at 80 °C for 2 h. In another round-bottom flask containing a solution of compound **4** (25.4 mg, 0.045 mmol) in dry CH_2Cl_2 (1 mL) was added a solution of carbonyl diimidazole (10.9 mg, 0.067 mmol) in dry CH_2Cl_2 (0.5 mL). The reaction was stirred at room temperature for 2 h, and transferred to the DMSO solution that was being heated. The resulting reaction was kept at the same temperature for 1.5 h. The pH was adjusted to ~5 with TFA (moist pH paper), and the CH_2Cl_2 was evaporated under reduced pressure. The residue was diluted with water and injected on to the HPLC column. Preparative C_{18} column, λ = 240 nm, 6 mL/min, gradient: 0′−10′: 0−20% B; 10′−70′: 20−70% B. The product as the TFA salt (26.8 mg74.7%) eluted between 43.8% B. ^{1}H NMR (300 MHz, d_4-MeOH) δ 7.9 (d, 1H); 7.5 (m, 1H); 7.35 (dd, 1H); 6.2 (m, 1H); 4.6 (bd, 2H); 4.45 (dd, 1H); 4.3 (m,1H); 3.1−3.45 (m, 7H); 2.9 (m, 3H); 2.75 (dd, 1H); 2.2 (m, 2H); 1.25−1.8 (m, 22H). ESI-MS $(M + H^+)^+$: 686.3.

*Compound **14**.* The same procedure as described for compound **9** was used. The following amounts were used: Compound **13** (37.5 mg, 0.047 mmol); iodoacetic anhydride (25 mg, 0.07 mmol), DIPEA (16.3 μL, 0.094 mmol), and dry THF (0.6 mL). The product was purified by HPLC. Preparative C_{18} column, λ = 240 nm, 6 mL/min, gradient: 0′−10′: 0−20% B; 10′−70′: 20−70% B. The product (compound **16**) (24.5 mg, 61.3%) eluted between 50.8 and 53% B. ESI-MS $(M + H^+)^+$: 854.5; $(M + Na^+)^+$: 876.5.

*Compound **15**.* The same procedure as described for compound **10** was used. The following amounts were used: Compound **14** (24.5 mg, 0.029 mmol); TFA (160 μL), and $CHCl_3$ (240 μL). The TFA salt of the product was obtained in 94.8% yield (23.6 mg). ^{1}H NMR (300 MHz, d_4-MeOH) δ 8.0 (d, 1H); 7.8 (bs, 1H); 7.6 (dd, 1H); 6.1 (m, 1H); 4.5 (m, 1H); 4.4 (bd, 2H); 4.3 (dd, 1H); 3.65 (bs, 2H); 3.55 (m, 2H); 3.15−3.35 (m, 7H); 2.95 (dd, 2H); 2.70 (m, 1H); 2.65 (dd, 1H); 2.25 (t, 2H); 1.4−1.8 (m, 13H). ESI-MS $(M + H^+)^+$: 754.4.

VICAT$_{SH}$(+6). The same procedure as described for VICAT$_{SH}$ was used. The following amounts were used: Compound **15** (23.6 mg, 0.027 mmol); 1% aqueous solution of formaldehyde (83 μL; 0.054 mmol); 1.2 M methanolic $NaCNBH_3$ (23 μL; 0.054 mmol); 1.2 M methanolic DIPEA (34 μL; 0.081 mmol); and MeOH (800 μL). The reaction was diluted with 30% CH_3CN in water, and injected on to the HPLC column. Preparative C_{18} column, λ = 240 nm, 6 mL/min, gradient: 0′−10′: 0−20% B; 10′−70′: 20−70% B. The product (14.8 mg, 70.8%) eluted between 36.2 and 39% B. ^{1}H NMR (300 MHz, d_4-MeOH) δ 8.0 (d, 1H); 7.8 (s, 1H); 7.6 (dd, 1H); 6.15 (m, 1H); 4.45 (dd, 1H); 4.30 (dd,1H); 3.65 (bs, 2H); 3.6 (m, 2H); 3.1−3.5 (m, 7H); 2.9−3.0 (m, 6H); 2.6 (dd, 1H); 2.2 (t, 2H); 1.2−1.8 (m, 13H). ESI-MS $(M + H^+)^+$: 768.4; $(M + Na^+)^+$: 790.3.

^{14}C-VICAT$_{SH}$(+6). This compound was made using a variation of the procedure used to make ^{14}C-VICAT$_{SH}$. To a vial with a Teflon septum-lined screw cap containing a solution of compound **15** (17.3 mg; 20 μmol) in MeOH (765 μL) was added 1 M aqueous sodium acetate, pH 6.7 (139 μL). To a tube containing 60 μL of 0.33 M formaldehyde in water (19.8 μmol, prepared by diluting reagent grade 37% (w/v) formaldehyde with water), was added 49 μL of an aqueous solution of [^{14}C]formaldehyde in water (25 mCi/mL, 1.23 mCi, 21.9 μmol, 56 mCi/mmol, Perkin-Elmer). This mixture was transferred to the reaction vial. To the vial was added 1.2 M methanolic $NaCNBH_3$ (105 μL, 40 μmol). After the mixture was stirred for 30 min at room temperature, most of the solvent was removed with a stream of N_2. The residue was diluted with 100 μL of water containing 0.08% TFA, and the solution was injected onto the HPLC column. Preparative C18 column, λ = 240 nm, 6 mL/min, gradient: 0′−10′: 0−20% B; 10′−70′: 20−70% B. The TFA salt of the product (12.4 mg, 70.4% yield) eluted between 36.5 and 40% B. The compound was characterized by its HPLC retention, which matched that of the nonradiolabeled VICAT$_{SH}$(+6).

The specific radioactivity of ^{14}C-VICAT$_{SH}$(+6) was determined by accurately weighing several milligrams of the HPLC-purified material (after three rounds of evaporation to dryness in a Speed-Vac followed by dissolution in 0.4 mL of MeOH and drying in vacuo to constant weight), dissolving the compound in 1 mL of CH_3CN, and submitting a 5 μL aliquot to scintillation counting. The counter was calibrated using a vial of ^{14}C standard. Final specific activity is 22.0 mCi/mmol.

*Compound **16**.* To a vial containing a solution of compound **10** (5 mg; 5.81 mmol) in MeOH (179 μL) was added 1 M sodium acetate pH 6.7 (76 μL), followed by a 1.2 M methanolic solution of *tert*-butyl *N*-(2-oxyethyl)-carbamate (19.3 μL, 23.2 mmol, Aldrich) and a 1.2 M methanolic solution of $NaCNBH_4$ (19.3 μL, 23.2 mmol). The reaction was stirred at room temperature for 1 h. The solvent was partially removed, a mixture of 20% acetonitrile in water was added, and the reaction mixture was injected onto the HPLC column. Preparative C18 column, λ = 240 nm, 6 mL/min, gradient: 0′−20′: 0−20% B; 20′−80′: 20−100% B. The TFA salt of product **16** (5.8 mg, 92.6% yield) eluted between 53.8 and 58% B. ^{1}H NMR (300 MHz, d_1-$CHCl_3$/d_4-MeOH) δ 7.9 (d, 1H); 7.85 (m, 1H); 7.55 (m, 1H); 6.1 (m, 1H); 4.45 (m, 3H); 4.2 (m, 1H); 3.6 (s, 2H); 2.9−3.4 (m, 13H); 2.8 (dd, 1H); 2.6 (d, 1H); 2.2 (t, 2H); 1.25−1.65 (m, 22H). ESI-MS $(M + H^+)^+$: 891.0; $(M + Na^+)^+$: 913.5.

*Compound **17**.* To a vial containing a solution of **16** (5 mg, 5.07 mmol) in $CHCl_3$ (30 μL) was added TFA (12 μL). The reaction mixture was stirred for 1.5 h at room temperature. Solvent was removed using a Speed-Vac. MeOH was added, and the resulting solution was concentrated in the Speed-Vac. This procedure was repeated three more times to remove excess TFA. The TFA salt of the product (compound **17**) was obtained in 95.6% yield (4.3 mg) as an oil. ^{1}H NMR (300 MHz, acetone-d_6) δ 7.9 (d, 1H); 7.7 (s,1H); 7.5 (d, 1H); 6.1 (m, 1H); 4.6 (m, 1H); 4.4 (m, 1H); 3.9 (m, 2H); 3.7 (s, 2H); 3.4−2.9 (m, 12H); 2.7 (m, 3H); 2.2 (t, 2H); 1.4−1.8 (13H, m). ESI-MS $(M + H^+)^+$: 791.5; (M + Na+)+: 813.5.

NBD-VICAT$_{SH}$. To a vial containing **17** (4.2 mg, 4.64 mmol) was added a solution of NBD-F (2.86 mg, 15.6 mmol, 70% pure, Dojindo Molecular Technologies) in DMF (220 μL), followed by DIPEA (3.15 μL, 18.1 mmol). After being stirred for 2 h at room temperature, the solvent was partially removed in a Speed-Vac. The residue was solubilized in 20% acetonitrile in water and injected onto the HPLC. Preparative C18 column, λ = 500 nm, 6 mL/min, gradient: 0′−20′: 0−20% B; 20′−

80′: 20−100% B. The orange solid product (3.5 mg, 81.4%) eluted between 61.3 and 69.7% B. ^{1}H NMR (300 MHz, CD_3CN) δ 8.43 (d, 1H); 7.65 (d, 1H); 7.6 (bs, 1H); 7.4 (d, 1H); 6.0 (m, 2H); 4.4 (m, 1H); 4.25 (m, 1H); 3.75 (d, 2H); 3.6 (s, 2H); 2.9−3.2 (m, 12H); 2.65 (m, 3H); 2.22 (t, 2H); 1.35−1.8 (m, 13H). ESI-MS $(M + H^+)^+$: 954.5, $(M + Na^+)^+$: 976.4.

NBD-VICAT$_{SH}$(−28). This compound was prepared from **7** as described for the preparation of NBD-VICAT$_{SH}$ starting from **10**. HPLC Preparative C18 column, $\lambda = 500$ nm, 6 mL/min, gradient: 0′−20′: 0−20% B; 20′−80′: 20−100% B. The product as an organge solid (4.6 mg, 43.8%) eluted at 51% B. ^{1}H NMR (500 MHz, CD_3CN) δ 8.43 (d, 1H); 7.7 (bs, 1H); 7.6 (bs, 1H); 7.4 (bs, 1H); 6.16 (bs, 1H); 6.05 (bs, 1H); 4.4 (m, 1H); 4.25 (m, 1H); 3.8 (m, 2H); 3.65 (s, 2H); 2.9−3.2 (m, 12H); 2.7 (m, 3H); 2.22 (t, 2H); 1.35−1.9 (m, 9H). ESI-MS $(M + H^+)^+$: 926.6, $(M + Na^+)^+$: 948.7.

Peptide Modification Reactions. *Conversion of Peptide Amines into Thioacetamido Groups*. The reaction sequence is shown in Figure 5. To a 1.5 mL Eppendorf tube was added 280 μL of DMF:0.1 M Hepes, pH 8.0 (1:1) (pH adjusted before DMF added), followed by 20 μL of 1 mM angiotensin I peptide in water (DRVYIHPFHL, Sigma) and then 100 μL of *N*-succinimidyl S-acetylthioacetate (SATA, Pierce, 40 mM in dry DMF, freshly prepared). After incubation for 2 h at room temperature, 40 μL of deacetylation solution (0.5 M NH_2OH, 25 mM EDTA, 50 mM sodium phosphate, pH 7.5, store at 4 °C) was added, and the mixture was incubated for 2 h at room temperature. Then 150 μL of tris(2-carboxylethyl)-phosphine (TCEP, Aldrich, 0.2 M in water, store at −20 °C) was added followed by a 1 h incubation at 37 °C. The pH was dropped to 3−4 by adding 50 μL of 2% TFA, and the mixture was loaded onto a C18 reverse-phase, solid-phase extraction cartridge (500 mg resin, Varian) previously washed with 80% CH_3CN/0.1% TFA and then equilibrated with 0.1% TFA. The cartridge was washed with 0.1% TFA (2 × 1 mL) and then with 5% CH_3CN/0.1% TFA (4 × 1 mL), and peptide was eluted into a new tube with 1 mL of 80% CH_3CN/0.1% TFA. The solution was concentrated to dryness (Speed-Vac) in an Eppendorf tube.

Conjugation of Thioacetylated Peptide with VICAT$_{SH}$. All steps involving VICAT$_{SH}$ reagents were carried out in normal room light (fluorescent overhead lights) and away from windows exposed to bright sunlight. The residue from the previous step was resuspended in 50 μL of 20% CH_3CN. Buffer (4.8 μL of 0.5 M sodium phosphate, 0.5 M sodium borate, pH 8.4) was added, followed by 5.2 μL of VICAT$_{SH}$ stock (22.9 mM in CH_3CN, stored at −20 °C). The tube was wrapped with foil to exclude light and left for 12 h at room temperature. The reaction was examined by HPLC by adding 100 μL of 2% TFA and injecting the solution onto the column (Vydac 218TP52) previously equilibrated with 0.08% TFA (solvent A). The column was developed as follows: 0−15 min, 0% B (CH_3CN/0.08% TFA); 15−20 min, 0−10% B; 20−60 min, 10% B, 60−110 min, 10−80% B. The flow rate was 0.2 mL/min, and the absorbance at 217 nm was monitored. Peak fractions were examined by ESI-MS and MALDI.

Photocleavage of VICAT$_{SH}$-Tagged Peptides. The desired peptide conjugate HPLC fraction (see above) was concentrated to dryness (Speed-Vac) in an Eppendorf tube and the residue dissolved in 100 μL of 20% CH_3CN/0.1% TFA. Neat 2-mercaptoethanol (1 μL) was added, and the tube was shaken in an Eppendorf vibrating rack mixer at room temperature with irradiation for 20 min at room temperature from a UV lamp (Black-Ray long wave ultraviolet lamp model 100AP, VWR) with the bulb face held 10 cm from the tube. The intensity of the lamp was routinely checked with a UV light meter (Mannix UV340, Professional Equipment, Inc.). The reaction mixture was examined by HPLC (same column as above) using a solvent program of 0−60 min, 0−70% B. Fractions were examined by ESI-MS and MALDI.

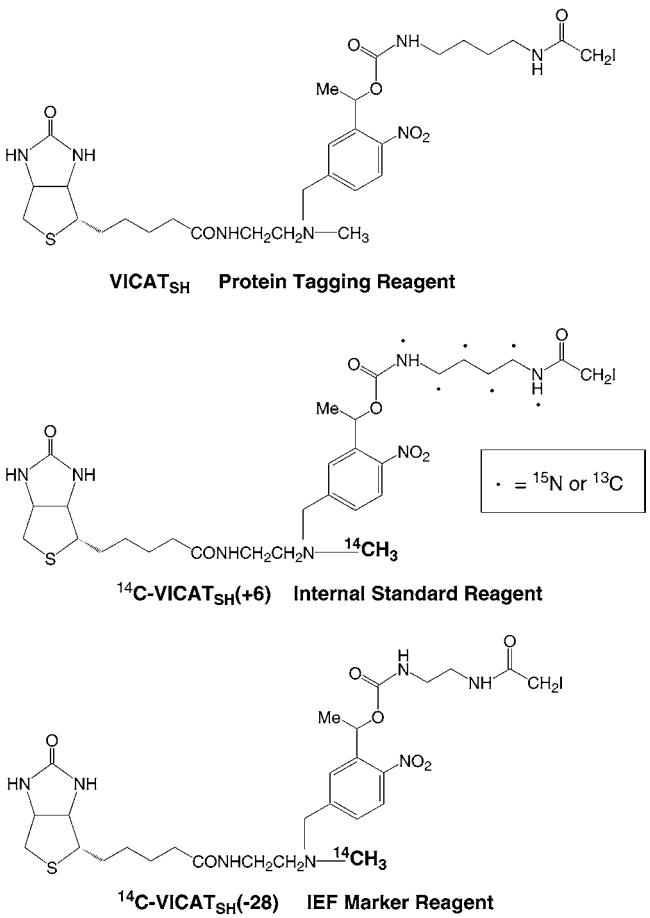

Figure 1. VICAT$_{SH}$ reagents.

The photocleavage of bead-bound peptide conjugate was also carried out. A 50 μL aliquot of beads (streptavidin-Agarose, 1:1 suspension in buffer as supplied by the manufacturer, Sigma) was pelleted in an Eppendorf tube (1 min full speed spin in a microfuge), and the pellet was washed twice with 1 mL portions of phosphate-buffered saline and resuspended in 1 mL of the same buffer. The peptide−VICAT$_{SH}$ conjugation reaction mixture (see above) was added to the bead suspension. The tube was placed on a rocking platform for 1 h at room temperature. The beads were pelleted and washed twice with 1 mL portions of water and resuspended in 100 μL of 20% CH_3CN/0.1% TFA. 2-Mercaptoethanol (1 μL) was added, and the tube was irradiated with UV light as described above. A 2 μl aliquot was analyzed by MALDI.

RESULTS AND DISCUSSION

VICAT Reagents. The present paper describes the design and synthesis of VICAT reagents and their reaction with peptides. In a subsequent study we will illustrate the usefulness of these reagents to determine the absolute quantity of specific target proteins in complex protein mixtures (*8*). The set of three VICAT reagents is shown in Figure 1. These reagents contain an iodoacetyl group and thus react specifically with the

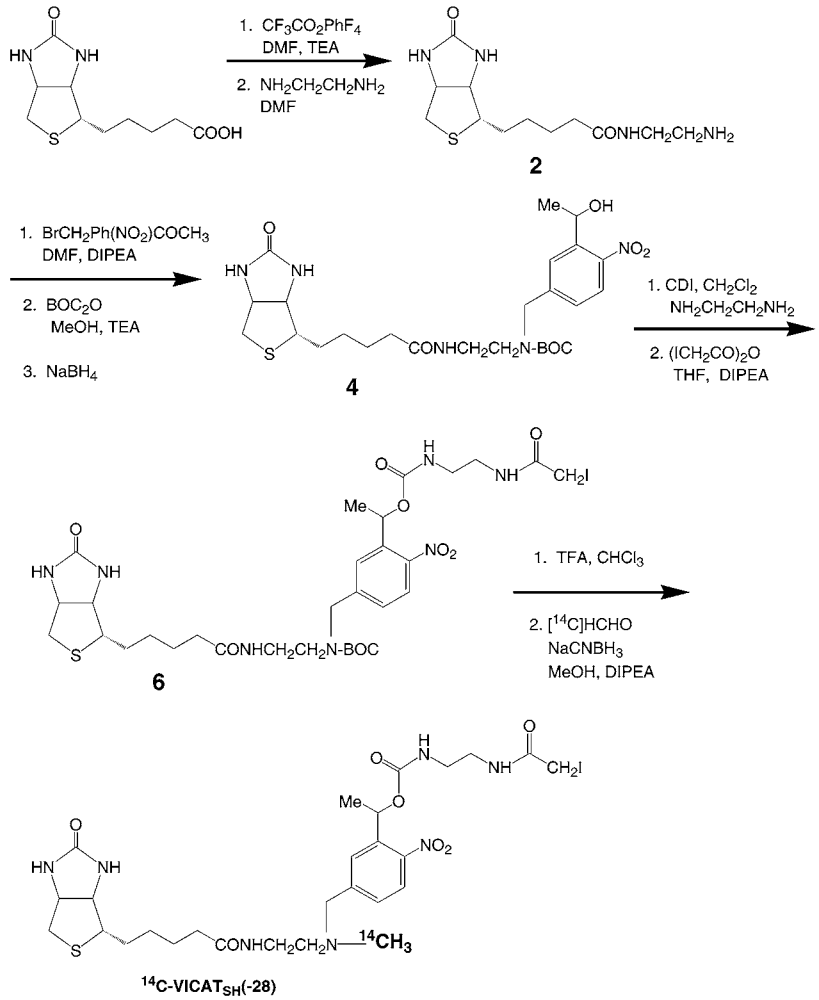

Figure 2. Synthesis of ^{14}C-VICAT$_{SH}$(−28).

SH group of cysteine-containing peptides. Thus we refer to these as VICAT$_{SH}$ reagents. We also show below that peptides without cysteine can be modified to contain an SH group which can be reacted with VICAT reagents. The VICAT reagents are used for (1) derivatization of SH-containing peptide fragments derived from all of the proteins in the sample including the target protein of interest, (2) preparation of an internal standard suitable for absolute quantification of the target protein of interest, and (3) preparation of a marker suitable for locating the tagged peptide derived from the target protein of interest following separation on an IEF gel strip. The VICAT-derivatized peptides are distinguished by the different masses of the tag introduced into the peptide as shown below.

The first reagent, VICAT$_{SH}$, is the "protein tagging" reagent as it is used to tag the SH groups present in peptides generated by proteolytic digestion of all of the proteins present in the biological sample to be analyzed. This reagent contains a 1,4-diaminobutane linker attached to the iodoacetyl group (Figure 1).

The second reagent, VICAT$_{SH}$(+6) is chemically identical to VICAT$_{SH}$ except for the presence of four ^{13}C and two ^{15}N labels in the diaminobutane linker (Figure 1). VICAT$_{SH}$(+6) is used as the "internal standard" reagent to tag the authentic synthetic peptide (prepared by solid-phase peptide synthesis) whose sequence is identical to the tryptic peptide derived from the target protein of interest. The mass difference of 6 Da between the sample-derived and internal standard peptides is sufficient for the distinction of both singly and doubly charged ions produced by electrospray ionization. A precise amount of the VICAT$_{SH}$(+6)−peptide conjugate is added to the sample and serves as an internal standard that is differentiated in the mass spectrometer from the protein sample-derived, tagged peptide. Integration of the ion chromatogram peaks, observed by mass spectrometry, from the sample-derived and internal standard conjugates in the mass spectrometry analysis provides the absolute abundance of the former and thus the absolute abundance of the specific protein in the complex protein mixture. We also prepared ^{14}C-VICAT$_{SH}$(+6), which can also be used to prepare the internal standard. This reagent is radiolabeled and of known specific activity and thus offers the ability to readily determine the absolute quantity of purified internal standard by scintillation counting.

The third reagent, ^{14}C-VICAT$_{SH}$(−28), contains the radioactive label and functions as the "IEF marker" for peptide visualization on the IEF strip. This reagent is used to derivatize the same synthetic peptide used to prepare the internal standard. ^{14}C-VICAT$_{SH}$(−28) contains a shorter (two-carbon) diamine linker that is attached to the iodoacetyl group (Figure 1). The purpose of using a shorter linker is 2-fold. First, the tagged peptide formed after photocleavage (see below) is more polar than the tagged peptides derived from the other VICAT$_{SH}$ reagents and is expected to have a slightly shorter reverse-phase HPLC retention time than the internal standard and sample protein-derived tagged

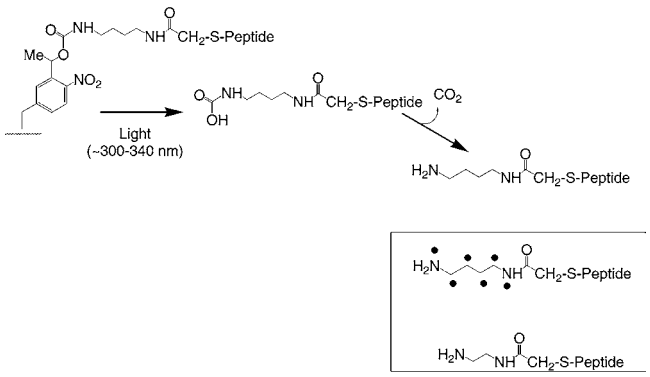

Figure 3. Photocleavage of VICAT$_{SH}$-tagged peptide. Shown is the photocleavage of the peptide tagged with VICAT$_{SH}$, which generates the carbamic acid, which spontaneously decarboxylates to give the peptide derived from the sample protein of interest bearing a tag with the diaminobutane linker. Shown in the box are the tagged peptides resulting from photocleavage of the internal standard and IEF marker, respectively. The black dots on the internal standard tag designate ^{15}N and ^{13}C labels.

peptides, both of which have a four-carbon linker in their tags. Second, the tag left on the IEF marker peptide is 28 Da lighter than the tag left on the sample protein-derived peptide and 34 Da higher than the tag left on the internal standard and so is readily distinguished by mass spectrometry. Both factors are important for achieving a high dynamic range in the detection of peptides from low-level sample proteins in the presence of a substantially larger (10−1000-fold) amount of the visible marker applied to the IEF strip.

Following IEF, peptides are eluted from the appropriate region of the IEF gel strip using the IEF marker as a guide (*8*). The biotinyl moiety of these VICAT$_{SH}$ reagents is used for affinity capture of tagged peptides using streptavidin−agarose. Peptides are then released from the solid phase by photocleavage as shown in Figure 3. This has the advantage that the impurities in the sample after IEF, including soluble ampholytes, are not carried forward to the next step. Note that a small isotope tag remains on the peptides after photocleavage (Figure 3). This allows differentiation between the sample-derived and internal standard peptides in the mass spectrometer. The use of ^{15}N and ^{13}C present in VICAT$_{SH}$(+6) is advantageous over substitution with deuterium since the latter sometimes causes a slight change in the reverse-phase HPLC retention time of the isotope tagged peptide relative to that of the peptide tagged with the light isotope. The lack of precise coelution of heavy and light tagged peptides complicates the accurate integration of ion peaks observed in the mass spectrometer. Note that the peptide derived from the IEF marker bears a tag that is two methylene groups shorter than the tags left on the sample-derived and internal standard peptides (Figure 3). The IEF marker is typically used in much larger quantities than the internal standard because mass spectrometry is more sensitive than ^{14}C radiometric analysis. Since the IEF marker-derived peptide is 28 Da lighter than the sample-derived peptide, it is easily excluded during selective ion monitoring with the mass spectrometer. The use of a relatively large amount of IEF marker actually offers the important advantage of serving as a carrier to minimize nonspecific losses of trace amounts of sample-derived and internal standard peptides present throughout the analytical process. Such nonspecific losses can be severe when analyzing femtomole amounts of material.

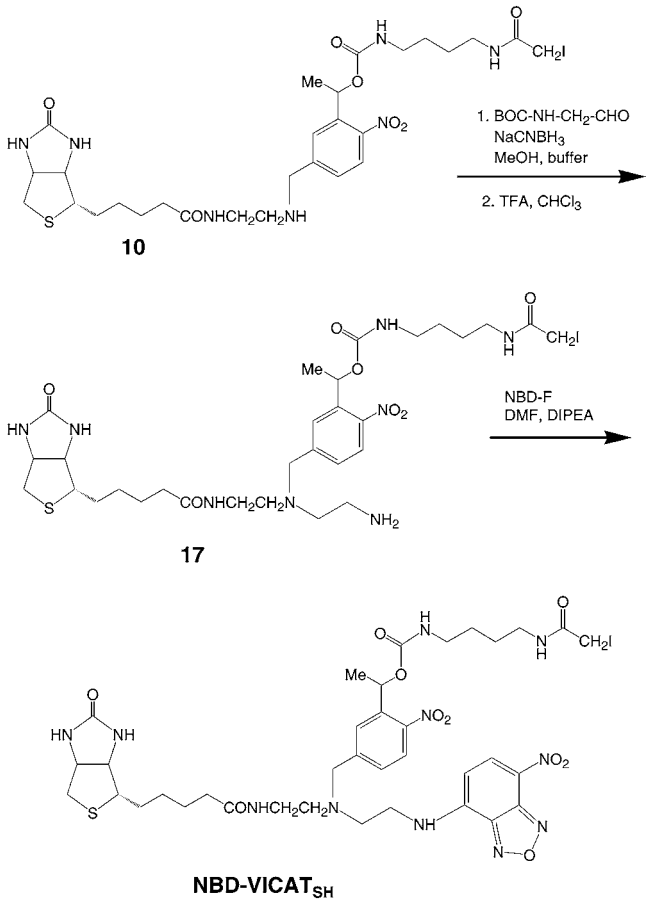

Figure 4. Synthesis of NBD-VICAT$_{SH}$.

Synthesis of VICAT$_{SH}$ Reagents. A highly efficient synthesis of VICAT$_{SH}$ reagents was developed as shown in Figure 2. This scheme allows the radiolabel of ^{14}C-VICAT$_{SH}$(−28) to be introduced in the last synthetic step using readily available ^{14}C-H_2CO. All of the steps proceed in acceptable yields. The heavy atom substituted 1,4-diaminobutane used to prepare VICAT$_{SH}$(+6) was readily prepared by a simple two-step scheme starting from the relatively inexpensive heavy isotopic materials [^{13}C,^{15}N]-potassium cyanide and 1,2-[$^{13}C_2$]-dibromoethane.

Using this scheme, we have been able to prepare gram quantities of VICAT$_{SH}$ reagent, sufficient for tens of thousands of VICAT$_{SH}$-based analyses. The other two reagents, ^{14}C-VICAT$_{SH}$(+6) and ^{14}C-VICAT$_{SH}$(−28), are required in relatively small amounts since each VICAT$_{SH}$-based analysis requires femtomole amounts of internal standard and nanomole amounts of IEF marker.

We have also designed a variant of VICAT$_{SH}$ reagents in which the visible probe is an NBD fluorophore rather than a radiolabel. As shown in Figure 4, intermediate **10** can be reductively aminated with commercially available BOC-NHCH$_2$CHO. Removal of the BOC group provides primary amine **17**, which can be reacted with a variety of different amine-reactive fluorophores including NBD-F as shown in Figure 4. Thus, both radioactive and fluorescent VICAT$_{SH}$ reagents can be prepared from a common synthetic intermediate. The availability of VICAT$_{SH}$ reagents bearing a fluorophore as the visible probe is advantageous in laboratories that are not approved for use of radioisotopes. The use of these fluorimetric reagents for the absolute quantification of specific proteins in complex protein mixtures is being currently developed in our laboratories. In cases were ^{14}C-VICAT$_{SH}$ is used, it may be noted that the carbon-14

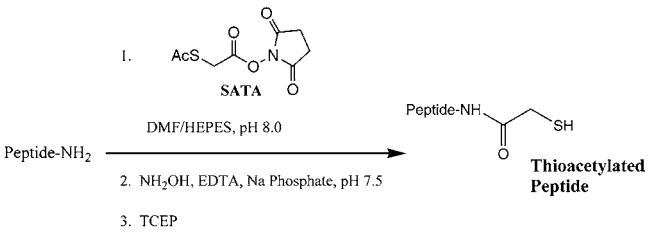

Figure 5. Thioacetylation of amino groups in peptides and reaction with $VICAT_{SH}$ reagents.

remains bound to the solid-phase streptavidin−agarose following photocleavage; thus, radioisotopes do not come in contact with the mass spectrometer.

Introduction of the SH Group into Peptides That Lack Cysteine. The use of ICAT and $VICAT_{SH}$ reagents to selectively tag cysteine-containing peptides has the advantage that complex mixtures of peptides, such as those derived from a cell lysate, are greatly simplified. However, in some cases it is desirable to tag peptides that lack cysteine, i.e., to quantify a protein that lacks cysteine or to quantify a protein segment that contains a post-translational modification and that also lacks cysteine. Thus, we desired a simple and quantitative method to introduce SH groups into peptides lacking cysteine. We chose the modification of amino groups since every tryptic peptide will contain an N-terminal amino group (except for the N-terminal peptide of N-terminally modified proteins), and those that have a lysine at the C-terminus will also have an ϵ-amino group. It is possible to design peptide-tagging reagents that contain a functional group such as an acylating agent that reacts with peptide amino groups. However, agents such as active esters that efficiently acylate amino groups also undergo hydrolysis in water, and thus an excess of tagging reagent is required, which is not desirable when using isotopically substituted tagging reagents. Thus, we desired a simple method for the conversion of peptide amino groups into sulfhydryl groups using inexpensive reagents and prior to tagging with $VICAT_{SH}$ reagents. This has the advantage that a large excess of acylating agent can be used to drive the amino group modification to completion and that the same ICAT and $VICAT_{SH}$ reagents can be used for peptides that contain or lack cysteine.

The previously described reagent *N*-succinimidyl-S-acetylthioacetate (SATA) is known to react with the amino group to give the amide which can be treated with hydroxylamine, resulting in the replacement of the amino group with a 2-sulfhydryl-acetamido group (Figure 5) (*13*). We examined this reaction sequence with a variety of peptides containing one or two amino groups (Table 1). A concentration of SATA of 10 mM was found to give quantitative acylation of peptide amino groups after 2 h at room temperature. Acylation studies at pH 6−9 revealed incomplete reaction at pH 6 (presumably due to protonation of the peptide amino groups) and at pH 9 (presumably due to hydrolysis of SATA). Addition of NH_2OH in slight excess over the amount of SATA led to incomplete deacylation; thus, a large excess (>100 mM) was optimal. It was found that after deacylation, a significant amount of the disulfide peptide-$NHCOCH_2$-$SSCH_2COOH$ was detected by MALDI and HPLC. Thus, the reaction mixture was treated with tricarboxylethylphosphine (TCEP), which led to quantitative reduction to the free thiol.

Using the optimized conditions, we obtained quantitative thioacetylation of amino groups in the peptides shown in Table 1. Thioacetylated peptides were examined by reverse phase HPLC, and single symmetrical product peaks were observed in all cases (not shown). Furthermore, MALDI mass spectrometry analysis of the HPLC product fraction showed only the desired product, with no trace of starting material or side products (not shown). The peptides in Table 1 have one to three amino groups, which were fully thioacetylated in all cases. Amino acids with nucleophile-containing side chains other than the amino group, Arg, Asp, Cys, Glu, His, Ser, and Tyr were not thioacetylated (any acylation of these nucleophiles during reaction with SATA would be reversed during treatment with NH_2OH).

Reaction of Peptides with $VICAT_{SH}$ Reagents. Thioacetylated angiotensin I peptide [(thioacetyl)DRVYIHPFHL] was desalted by solid-phase extraction on a C18 reverse-phase cartridge and then subjected to tagging with $VICAT_{SH}$. Conjugation of peptide SH group with $VICAT_{SH}$ reagent (~6 equiv based on peptide SH groups) was carried out in 20% CH_3CN/aqueous buffer to ensure good solubility of most peptides and tagging reagent and at pH 8.4, which is standard for reaction of peptide SH groups with iodoacetamido reagents. Reverse-phase HPLC analysis of the reaction mixture (not shown) showed the desired tagged peptide (confirmed by ESI-MS and MALDI), remaining $VICAT_{SH}$ reagent (confirmed by ESI-MS and MALDI), a trace amount of $VICAT_{SH}$-TCEP adduct (ESI-MS and MALDI gave $m/z = 884$), and a trace amount of $VICAT_{SH}$ cyclization product (ESI-MS and MALDI analyses show a m/z of 634, which is presumed to result from an intramolecular reaction of the tertiary amine of $VICAT_{SH}$ with the iodoacetyl group). No other HPLC peaks were observed, and spiking the reaction mixture with nontagged thioacetylated angiotensin I peptide confirmed that peptide tagging went to completion.

Thioacetylated angiotensin I tagged with $VICAT_{SH}$ was subjected to solution phase photocleavage or to affinity capture with streptavidin−agarose followed by on-resin photocleavage. HPLC analysis (not shown) of both reaction mixtures revealed only two peaks, one due to the desired photocleavage product, NH_2-$(CH_2)_4$−$NHCOCH_2SCH_2CONH$-peptide, and the other due to the photofragmented $VICAT_{SH}$ reagent containing the 2-nitrosoacetophenone moiety (products confirmed by ESI-MS and MALDI). Only these two products were seen when both photocleavage reaction mixtures were examined by MALDI prior to HPLC (not shown). This indicates that the $VICAT_{SH}$-tagged peptide undergoes quantitative photocleavage to the desired peptide containing the isotope tag (see above).

Application of VICAT$_{SH}$ Reagents and Future Prospects. There are numerous examples where the use of VICAT$_{SH}$ reagents will be useful. A major advantage of VICAT$_{SH}$ reagents is that they permit the absolute quantification of specific proteins in complex mixtures (*8*). In contrast, immunological methods require the lengthy and costly production of highly specific antibodies. Furthermore, immunoblot analyses (western blots) provide only qualitative data. Microarray nucleic analysis of changes in gene expression often need to be validated at the protein level. Furthermore, the search for markers in readily available biological fluids such as serum that have diagnostic value for human diseases will require a method for the absolute quantification of specific proteins. Microarray analyses often suggest tens if not hundreds of proteins that might be upregulated in human tumors for example. The validation of these candidate proteins using immunological methods is probably not practical, especially for a single laboratory effort.

The tagging of cysteine SH groups by VICAT$_{SH}$ reagents offers an important simplification of the peptide mixture in that many peptides will be removed following the purification of tagged peptides with streptavidin−agarose. Nevertheless, in some cases it will be beneficial to tag peptides that lack cysteines with VICAT reagents. A simple and efficient method to introduce SH groups into peptides lacking cysteine has been developed, and such peptides may be tagged with the same VICAT$_{SH}$ reagents used to modify cysteine-containing peptides. In a subsequent study (*8*), we will illustrate the usefulness of these reagents to determine the absolute quantity of specific target proteins in complex protein mixtures.

During the completion of the present study, the AQUA method was introduced for obtaining the absolute quantity of proteins in complex mixtures (*9*). The availability of two methods is beneficial, especially since it seems unlikely that a single method will provide useful data in every attempted experiment. It may be noted that with both the AQUA and VICAT$_{SH}$ methods, the amount of added internal standard should be within an order of magnitude of the amount of sample-derived peptide, given the issues of dynamic range in the mass spectrometry analysis. A detailed comparison of the AQUA and VICAT$_{SH}$ methods will be presented (*8*). VICAT$_{SH}$ reagents are available from the authors upon request.

C-11- and I-123-labeled long chain fatty acid derivatives have been reported as useful radiopharmaceuticals for the estimation of myocardial fatty acid metabolism. We have reported that Tc-99m-labeled *N*-[[[(2-mercaptoethyl)amino]carbonyl]methyl]-*N*-(2-mercaptoethyl)-6-aminohexanoic acid ([^{99m}Tc]-MAMA-HA), a medium chain fatty acid derivative, is metabolized by β-oxidation in the liver and that the MAMA ligand is useful for attaching to the omega-position of fatty acid derivatives as a chelating group for Tc-99m. On the basis of these findings, we focused on developing a Tc-99m-labeled long chain fatty acid derivative that reflected fatty acid metabolism in the myocardium. In this study, we synthesized a dodecanoic acid derivative, MAMA-DA, and a hexadecanoic acid derivative, MAMA-HDA, and performed radiolabeling and biodistribution studies. [^{99m}Tc]MAMA-DA and [^{99m}Tc]MAMA-HDA were prepared using a ligand-exchange reaction. Biodistribution studies were carried out in normal mice and rats. Then, a high initial uptake of Tc-99m was observed, followed by a rapid clearance from the heart. The maximum heart/blood ratio was 3.6 at 2 min postinjection of [^{99m}Tc]MAMA-HDA. These kinetics were similar to those with postinjection of *p*-[^{125}I]iodophenylpentadecanoic acid. Metabolite analysis showed [^{99m}Tc]MAMA-HDA was metabolized by β-oxidation in the body. In conclusion, [^{99m}Tc]MAMA-HDA is a promising compound as a long chain fatty acid analogue for estimating β-oxidation of fatty acid in the heart.

INTRODUCTION

Radiopharmaceuticals of long chain fatty acid analogues have important roles in the diagnosis of heart disease. C-11- and I-123-labeled long chain fatty acid derivatives have been reported as useful radiopharmaceuticals for the estimation of myocardial fatty acid metabolism (*1*−*4*), especially in the differential diagnosis of unstable angina or severe heart ischemia (*5*). However, an on-site cyclotron is needed to produce positron nuclides such as C-11, and radioiodinated compounds must be obtained from radiopharmaceutical companies. Since heart disease generally requires an urgent examination, it would be useful if an on-site radiopharmceutical could be used for clinical diagnosis. A Tc-99m-labeled radiopharmaceutical is most desirable because this nuclide can be supplied from a generator system whenever needed. Although many Tc-99m-labeled long chain fatty acid derivatives have been reported (*6*−*10*), no compound has been put to practical use.

We have reported that [^{99m}Tc]MAMA-HA, a medium chain fatty acid derivative, is metabolized by β-oxidation in the liver and the MAMA ligand is useful for attaching to the omega-position of fatty acid derivatives as a chelating group with Tc-99m (*11*). Based on these findings, we focused on developing a Tc-99m-labeled long chain fatty acid derivative that reflected fatty acid metabolism in the myocardium.

An appropriate chelating group is needed in the chemical structure to label it with Tc-99m, as mentioned above. The effect of the chelating group on the biodistribution of long chain fatty acid analogues has not been clarified. In this study, some Tc-99m-labeled fatty acid analogues, varying in carbon chain length, were synthesized and the heart uptake of these compounds was compared in vivo.

MATERIALS AND METHODS

Materials. Proton nuclear resonance (^{1}H NMR) spectra were recorded on a Bruker AC-200 spectrometer, and the chemical shifts reported in parts per million (ppm) downfield from an internal tetramethylsilane standard. Fast atom bombardment mass spectra (FABMS) were obtained with a JMS−HX/HX 110 A (JEOL Ltd. Tokyo). [^{99m}Tc]Pertechnetate ($^{99m}TcO_4^-$) was eluted in saline solution on a daily basis from Daiichi Radioisotopes Labs generator (Chiba, Japan). Reversed-phase high performance liquid chromatography (RP-HPLC) was performed

using a Cosmosil 5C_{18}-AR 300 column (150 × 4.6 mm; Nacalai Tesque Co., Ltd., Kyoto) eluted with a gradient solvent system (from 10% methanol/5 mM phosphate buffer pH 7.0 to 100% methanol in 60 min) at 1.0 mL/min. TLC analysis was performed with silica plates (Merck Art 5553) using 100% acetone or chloroform/methanol/water = 50/10/1 as developing solvent systems. All chemicals were of reagent grade and were used as received.

Synthesis of Fatty Acid Derivatives. Each fatty acid derivative was synthesized according to the method shown in Figure 1. In brief, the amino group of trityl-MAMA was alkylated with a ω-bromo-fatty acid analogue and hydrolyzed.

*N-[[[[2-[(Triphenylmethyl)thio]ethyl]amino]carbonyl]-methyl]-N-[2-[(triphenylmethyl)thio]ethyl]-6-aminohexanoic Acid (Trt-MAMA-HA)(**1**, n = 5).* Trt-MAMA-HA was synthesized according to a previous report (*11*).

*N-[[[[2-[(Triphenylmethyl)thio]ethyl]amino]carbonyl]-methyl]-N-[2-[(triphenylmethyl)thio]ethyl]-12-aminododecanoic Acid Ethyl Ester (**4**, n = 11, R = Et).* 12-Bromodecanoic acid (**2**) was esterified in ethanol bubbled with HCl gas. *N*-[[[2-[(Triphenylmethyl)thio]ethyl]amino]-acetyl]-*S*-(triphenylmethyl)-2-aminoethanethiol (Trt-MAMA, 250 mg, 0.37 mmol) and diisopropylethylamine (100 μL) were dissolved in 6 mL of DMF. To this mixture was added ethyl 12-bromodecanoate (**3**, $n = 11$, R = Et) (110 mg, 0.38 mmol) in DMF under stirring. After being heated at 140 °C for 12 h, the mixture was subjected to silica gel column chromatography with ethyl acetate/hexane = 4/7 as an eluting solvent. Yield: 150 mg (yellow oil, 43.8%). ^{1}H NMR ($CDCl_3$): δ 7.45−7.15 (overlapped m, 30H), 4.08 (q, 2H), 2.97 (td, 2H), 2.82 (s, 2H), 2.40−2.23 (overlapped m, 10H), 1.58−1.22 (overlapped, 21H). FABMS calcd for $C_{58}H_{68}N_2O_3S_2$ (M + H^+): *m/z* 905. Found: 905.

*N-[[[[2-[(Triphenylmethyl)thio]ethyl]amino]carbonyl]-methyl]-N-[2-[(triphenylmethyl)thio]ethyl]-12-aminododecanoic Acid (Trt-MAMA-DA) (**5**, n = 11).* Compound **4** was hydrolyzed by sodium hydroxide in methanol. Yield: 99.9%. ^{1}H NMR (CD_3OD): δ 7.42−7.16 (overlapped m, 30H), 3.02(t, H), 2.82−2.69 (overlapped m, 8H), 2.33 (t, 2H), 2.23 (t, 2H), 1.60−1.25 (overlapped m, 18H). FABMS calcd for $C_{56}H_{64}N_2O_3S_2$ (M+ H^+): *m/z* 876. Found: 876. Elemental analysis agreed with the calculated value for $C_{56}H_{64}N_2O_3S_2$: C; 76.66%, H; 7.37%, N; 3.19%. Found: C; 76.51%, H; 7.41%, N; 2.92%.

*N-[[[[2-[(Triphenylmethyl)thio]ethyl]amino]carbonyl]-methyl]-N-[2-[(triphenylmethyl)thio]ethyl]-16-aminohexadecanoic Acid Ethyl Ester (**9**, n = 15, R = Et).* 16-Hydroxyhexadecanoic acid (**6**) (1.0 g, 3.67 mmol) was added to 50 mL of dry ethanol followed by concentrated sulfonic acid (0.5 mL). The reaction mixture was stirred for 5 h at room temperature. After evaporation of the solvent, 1.1 g of ethyl 16-hydroxyhexadecanoate as white crystals (**7**) (yield > 99%) was obtained. A mixture of 1.0 g of ethyl 16-hydroxyhexadecanoate (**7**) (3.49 mmol), *N*-bromosuccinimide (0.62 g, 3.49 mmol), and triphenylphophine (0.92 g, 3.49 mmol) was dissolved in 30 mL of dry chloroform. After being heated for 1 h at 50 °C, the solvent was evaporated in vacuo. The residue was purified by column chromatography with ethyl acetate/hexane = 1/3, and ethyl 16-bromohexadecanoate (**8**) was obtained as a pale yellow oil in a yield of 400 mg (32.8%). The bromo compound (400 mg, 1.10 mmol) was dissolved in 5 mL of DMF, and the DMF solution was added to a mixture of Trt-MAMA (900 mg, 1.32 mmol) and diisopropylethylamine (400 μL) dissolved in 6 mL of DMF. After being heated at 140 °C for 12 h, the mixture was subjected to silica gel column chromatography with ethyl acetate/hexane = 4/7 as an eluting solvent. Yield: 170 mg (yellow oil, 16.1%). ^{1}H NMR ($CDCl_3$): δ 7.45−7.15 (overlapped m, 30H), 4.08 (q, 2H), 2.97 (td, 2H), 2.82 (s, 2H), 2.40−2.23 (overlapped m, 10H), 1.58−1.22 (overlapped, 29H). FABMS calcd for $C_{62}H_{76}N_2O_3S_2$ (M+ H^+): *m/z* 961. Found: 961.

*N-[[[[2-[(Triphenylmethyl)thio]ethyl]amino]carbonyl]-methyl]-N-[2-[(triphenylmethyl)thio]ethyl]-16-aminohexadecanoic Acid (Trt-MAMA-HDA) (**10**, n = 15).* Compound **9** was hydrolyzed by sodium hydroxide in methanol. Yield: 99.9%. ^{1}H NMR ($CDCl_3$): δ 7.40−7.15 (overlapped m, 30H), 3.30(t, 2H), 2.90 (t, 2H), 2.84 (s, 2H), 2.47−2.22 (overlapped m, 12H), 1.59−1.23 (overlapped m, 26H). FABMS calcd for $C_{62}H_{76}N_2O_3S_2$ (M + H^+): *m/z* 933. Found: 933. The result of the elemental analysis agreed with the calculated value for $C_{62}H_{76}N_2O_3S_2$: C; 77.20%, H; 7.79%, N; 3.00%. Found: C; 77.00%, H; 7.76%, N; 2.83%.

Tc-99m-Labeling of Fatty Acid Derivatives. Each compound was labeled with Tc-99m by a ligand exchange reaction according to a previously reported method with a slight modification (*11*). In brief, a bistritylated fatty acid analogue (1 mg) was treated with TFA under cation-trapping conditions (5% triethylsilane) (*12*). After removal of the solvent under a stream of N_2, the residue was solved in 0.5 mL of a 40% methanol/phosphate buffer (0.1 M, pH 8.0). [^{99m}Tc]GH (0.5 mL) was added to a solution of a bisthiol compound, and the reaction mixture was heated for 1 h at 90 °C. The labeled compound was extracted with a mixture of ethyl acetate/hexane = 1/4, and the organic layer was evaporated in vacuo.

The radiochemical yield and purity of Tc-99m-labeled fatty acid analogues were determined by RP-HPLC, and the TLC was developed with acetone.

Radiolabeling of *p*-Iodophenylpentadecanoic Acid (IPPA). *p*-Iodophenylpentadecanoic acid (IPPA) (0.5 mg) was solved in a mixture of acetonitrile 950 μL and water 50 μL. Copper sulfate (4 mM, 20 μL), ammonium chloride (0.15 M, 10 μL), and [^{125}I]NaI were added to the IPPA solution, and the reaction mixture was heated in a closed system for 3 h at 120 °C. [^{125}I]IPPA was purified by RP-HPLC eluted with a gradient mobile phase starting from 100% water to 100% methanol for 20 min at a flow rate of 1 mL/min. The retention volumes of IPPA and NaI were 26 mL and 2.5 mL, respectively. The radiochemical yield was 84.7%.

Stability of [^{99m}Tc]MAMA-Fatty Acids. To evaluate the stability of [^{99m}Tc]MAMA-fatty acids, [^{99m}Tc]MAMA-HA, [^{99m}Tc]MAMA-DA, and [^{99m}Tc]MAMA-HDA were each incubated in a 40% ethanol/0.1 M phosphate buffer (pH 7.4) at 37 °C. After incubation for 3, 6, and 12 h, the radiochemical purity was analyzed by TLC developed with chloroform/methanol/water = 50/10/1. Moreover, the stability of these fatty acid compounds in rat plasma was

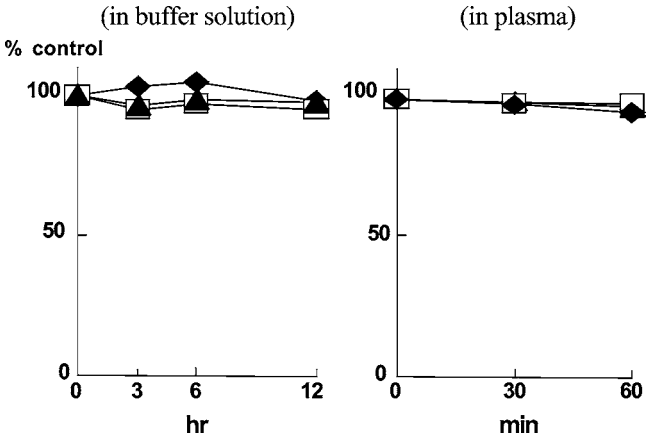

Figure 2. Stability of Tc-99m-MAMA-fatty acid analogues. Closed diamonds, [^{99m}Tc]MAMA-HA; open squares, [^{99m}Tc]-MAMA-D; closed triangles, [^{99m}Tc]MAMA-HDA.

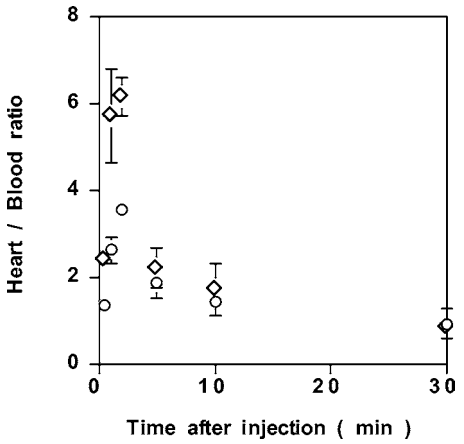

Figure 3. Comparison of heart/blood ratio of Tc-99m-MAMA-HDA and I-125-IPPA in normal rats. Open diamonds, [^{125}I]IPPA; open circles, [^{99m}Tc]MAMA-HDA.

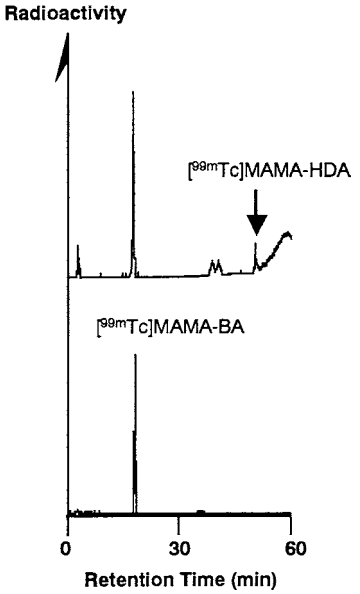

Figure 4. Metabolite analysis in urine postinjection of Tc-99m-MAMA-HDA in normal rats. Upper chart: radiochromatogram in urine at 30 min postinjection of [^{99m}Tc]MAMA-HDA; lower chart: radiochromatogram of authentic labeled compound of [^{99m}Tc]MAMA-BA.

evaluated. Then, 10 μL of labeled compound was added to 1 mL of rat plasma and the mixture was incubated at 37 °C. After incubation for 30 and 60 min, 100 μL of the mixture was sampled and 200 μL of ethanol was added. The mixture was filtered with a 0.45 μm Millipore filter, and the radiochemical purity was analyzed by RP-HPLC.

Biodistribution Studies. Male ddY mice (25−30 g) and male Wistar rats (150−200 g) were housed for 1 week under a 12-h light/12-h dark cycle with free access to food and water for subsequent biodistribution studies and metabolic analyses. Animals were fasted before experiments for 12 h.

For biodistribution studies, [^{99m}Tc]MAMA-HA was solved in saline. [^{99m}Tc]MAMA-DA and [^{99m}Tc]MAMA-HDA were solved in a 40% ethanol solution after being radiolabeled and 100 μL of the solution was added to 1 mL of saline, containing 1% human serum albumin. After passing through a 0.22 μm Millipore filter, the solution (37 kBq in 0.1 mL) was administered to normal mice via the tail vein. At appropriate time points after the administration, mice were sacrificed by decapitation. Samples of blood and organs of interest were excised and weighed, and radioactivity was quantified using a NaI-(Tl) gamma scintillation counter (Packard Auto-Gamma 500, Packard Inst. Co., Albertville, MI). The results are expressed as the percent injected dose/gram of blood or organs after decay correction.

A mixture of [^{99m}Tc]MAMA-HDA and [^{125}I]IPPA was injected into normal rats via the tail vein. At appropriate time points after the administration, rats were sacrificed by decapitation and calculations made as mentioned above.

Metabolic Analysis. At 30 min postinjection of [^{99m}Tc]-MAMA-HDA in normal rats, urine samples were obtained from the bladder. After filtration of the urine samples through a 0.22 μm Millipore filter, the filtrate was analyzed by RP-HPLC eluted with a gradient mobile phase starting from 10% methanol in a 0.05 M phosphate buffer (pH 7.0) to 100% methanol for 60 min at a flow rate of 1 mL/min.

RESULTS

Synthesis of Fatty Acid Derivatives. Each fatty acid derivative was synthesized according to the method shown in Figure 1. In brief, the amino group of trt-MAMA was alkylated with a ω-bromo-fatty acid analogue. After hydrolysis of the ester group, trt-MAMA-DA and trt-MAMA-HDA were obtained as a yellow oil with overall yields of 43.8% and 5.3%, respectively (calculated from the starting compound of fatty acid derivative).

Tc-99m-Labeling of Fatty Acid Derivatives. Each compound was labeled in a ligand exchange reaction with [^{99m}Tc]pertechnetate reduced by Sn(II) glucoheptonate in diluted ethanol solution and purified by HPLC. The retention times of [^{99m}Tc]MAMA-DA and [^{99m}Tc]MAMA-HDA were 43 and 49 min, respectively. The retention time of [^{99m}Tc]MAMA-HA was 23 min (*11*). The radiochemical yields of [^{99m}Tc]MAMA-DA and [^{99m}Tc]MAMA-HDA were 70% and 75%, respectively. The radiochemical purity of both labeled compounds was >99%.

Stability of [^{99m}Tc]MAMA-Fatty Acids in Vitro. Figure 2 shows the stability of three [^{99m}Tc]MAMA-fatty acids, [^{99m}Tc]MAMA-HA, [^{99m}Tc]MAMA-DA, and [^{99m}Tc]-MAMA-HDA, in a phosphate-buffered solution and rat plasma in vitro. High stability was observed for all radiochemical compounds in these solutions.

Biodistribution Studies. Table 1 shows the biodistribution of Tc-99m-labeled fatty acids in normal mice. A rapid clearance of radioactivity from the blood was observed for all compounds. [^{99m}Tc]MAMA-HDA showed

the highest uptake in the mouse heart among the three Tc-99m-labeled fatty acids. Only [^{99m}Tc]MAMA-HDA had a heart-to-blood ratio greater than one through to 2 min postinjection of the compound.

[^{99m}Tc]MAMA-HDA and [^{125}I]IPPA were simultaneously injected into normal rats. The heart-to-blood ratio was 3.6 at 2 min postinjection of [^{99m}Tc]MAMA-HDA in normal rats, while it was 6.2 at 2 min postinjection of [^{125}I]IPPA. The kinetics of the clearance of radioactivity from the heart were very similar between [^{99m}Tc]MAMA-HDA and [^{125}I]IPPA (Figure 3).

Metabolic Analysis. Rat urine samples were collected at 30 min postinjection of [^{99m}Tc]MAMA-HDA and the metabolites in them were analyzed by RP-HPLC. The lower chart of Figure 4 shows a typical chromatogram of [^{99m}Tc]MAMA-BA (*11*). The retention time of [^{99m}Tc]-MAMA-BA was 17 min. The major peak in the urine samples was observed at retention time of 17 min on RP-HPLC (Figure 4, upper).

DISCUSSION

External imaging of energy production levels of living cells with Tc-99m-labeled compounds is a challenging task for the development of Tc-99m-radiopharmaceuticals. Indeed, efforts have been made to develop Tc-99m-labeled long chain fatty acid analogues for myocardial imaging studies. However, their application has been hampered by poor accumulation in the heart, and it appeared that these Tc-99m-labeled fatty acid analogues were not recognized as substrates for β-oxidation (*8*, *9*).

In this study, two long chain fatty acid derivatives, including the MAMA group as a chelating group with Tc-99m, were synthesized according to the method shown in Figure 1. Their chemical structures were assigned based on instrumental analyses. Tc-99m labeling reactions were carried out according to a previously reported method (*11*) with a slight modification. MAMA-HA, which is a medium chain fatty acid derivative reported previously, was radiolabeled with Tc-99m in solution because of its hydrophilicity. However, the long chain fatty acid derivatives MAMA-HDA and MAMA-DA were radiolabeled in a 40% ethanol solution because their solubility in solution was poor compared with that of the medium chain fatty acid analogues. Tc-99m-labeled compounds were obtained at a good yield by this method, despite the ethanol-containing condition. This exchange labeling method is useful for Tc-99m labeling of MAMA chelating groups. Moreover, the high stability of each labeled compound is shown in Figure 2.

The myocardium uses long chain fatty acids as its energy source under normal conditions, although it is affected by the blood sugar or nonesterified fatty acid concentration in the serum (*13*). Biodistribution studies in mice showed that the longer the carbon chain, the higher the heart uptake. Only [^{99m}Tc]MAMA-HDA showed a heart-to-blood ratio of radioactivity uptake greater than one in the early phase postinjection of the compound (Table 1).

Then, a mixture of [^{99m}Tc]MAMA-HDA and [^{125}I]IPPA was injected into normal rats, and the heart uptake of both was compared. Although the uptake of the radioactivity of Tc-99m was almost half the value of that of I-125, the heart-to-blood ratio (%dose/g) of both Tc-99m and I-125 showed similar curves (Figure 3). The heart-to-blood ratio of Tc-99m was about 3.6 at 2 min postinjection. Metabolites in urine were evaluated (Figure 4). In this figure, [^{99m}Tc]MAMA-BA was observed at 30 min postinjection of [^{99m}Tc]MAMA-HDA. This [^{99m}Tc]MAMA-BA was observed after six rounds of β-oxidation. The result indicated that [^{99m}Tc]MAMA-HDA was recognized as a fatty acid in the body. The metabolite [^{99m}Tc]MAMA-BA has been observed postinjection of the medium chain fatty acid derivative, [^{99m}Tc]MAMA-HA (*11*). Since long chain fatty acids are metabolized by β-oxidation in the liver as well as in the heart, β-oxidation of the compound in the heart should be evaluated. Although the metabolism of [^{99m}Tc]MAMA-HDA is now being evaluated, this compound has been recognized as a long chain fatty acid in vivo.

In conclusion, [^{99m}Tc]MAMA-HDA is a promising compound as a long chain fatty acid analogue for estimation of the β-oxidation of fatty acids in the heart. Further investigation with metabolites is now under way.

Synthesis of Ultrasmall Superparamagnetic Iron Oxides Using Reduced Polysaccharides

Kenneth G. Paul,[§] Timothy B. Frigo,* Jesse Y. Groman,[†] and Ernest V. Groman[§]

Advanced Magnetics, Inc., 61 Mooney Street, Cambridge, Massachusetts 02138-1038. Received October 22, 2003; Revised Manuscript Received January 6, 2004

Investigation into the effect of the reducing sugar of dextran on formation and stability of dextran-coated ultrasmall superparamagnetic iron oxides (USPIO) has demonstrated that reduction of the terminal reducing sugar can have a significant effect on particle size, coating stability, and magnetic properties. Four aspects of polysaccharide-coated USPIO particle synthesis were investigated: (i) the effect reduction of the terminal polysaccharide sugar has upon polysaccharide usage, particle size, stability, and magnetic susceptibility; (ii) the effect an exogenous reducing sugar can have upon particle synthesis; (iii) the effect the molecular weight of the reduced polysaccharide has on particle synthesis; and (iv) the effectiveness of reduced and native dextrans in stabilizing a preformed magnetic sol. For low molecular weight dextrans (MW ≤10 kDa), reduction resulted in a 10 fold or greater decrease in the carbohydrate-to-iron ratio necessary during particle formation to produce the desired particle size (<20 nm). Particles prepared at the equivalent dextran-to-iron ratio using the equivalent native dextrans yielded larger particles except for a 70 kDa dextran where reduced and native dextran yielded identical particles with respect to size and magnetic properties. The stability of particle size and coating was studied using 10 kDa native and reduced dextran. Particles prepared with reduced dextran yielded a more stable coating as evidenced by stability on autoclaving. For native dextrans (MW < 70 kDa), small (≤30 nm) particles could be obtained at much higher dextran-to-iron ratios, but only the 10 kDa dextran gave a particle with comparable magnetic properties (susceptibility > 20 000 × 10^{-6} cgs). Similar results were obtained with a 12 kDa pullulan. The effect of polysaccharide molecular weight on particle size was studied, wherein higher molecular weight reduced dextrans produced larger particles. The effectiveness of the reduced and native dextrans in stabilizing a preformed magnetic sol was compared. Reduced dextrans were found to be superior for stabilizing the magnetic sol. The observed effects of reduction of the terminal sugar in dextran compared with the native dextran were modeled using the Langmuir adsorption isotherm. A good fit of experimental data with this model was found.

INTRODUCTION

Ultrasmall superparamagnetic iron oxides (USPIO) have been investigated in many biological applications, both in vitro and in vivo. As a result of their small size (diameter < 30 nm), these particles are not immediately removed from the circulation by the reticuloendothelial system. This results in a longer blood half-life and a wider biodistribution for the particle and allows potential targeting with appropriate bioconjugates to specific tissues both normal and tumorous. For example, MION (*1*), prepared by chromatography of ferumoxides (*2*), and similar materials (*3*) that may be prepared without chromatographic separation have been proposed for use as contrast agents in magnetic resonance angiography (*4*) and lymph node imaging (*5*). Several of these particles are now in late-phase clinical trials (*6*). In addition, attachment of small, bioactive peptides (*7*) or antibodies (*8*) to the particle coating has been reported to allow site-specific directability. Other applications being actively pursued include cell sorting, magnetically directed drug transport, localized therapeutic hyperthermia, immunoassays, and related applications (*9*−*12*).

In the majority of these potential uses, attachment of a drug or bioconjugate to USPIO for targeting is a prerequisite or greatly improves efficacy. Bioconjugation must attach to the organic coating surrounding the magnetic core. The preponderance of USPIO described in the literature has been prepared with a polysaccharide coating, most often dextran. For the purpose of bioconjugation, the dextran may be activated for attachment, for example by periodate oxidation (*13*). Alternatively, the dextran may be activated or the bioconjugate prepared prior to particle formation. Since the coating process is highly inefficient (most of the coating is lost after particle formation through purification by ultrafiltration) and the conditions of particle formation (high pH and heat) will inactivate most biologically derived conjugates, this second approach is unattractive. Any change in particle synthesis that addresses these problems would be desirable for making the second approach viable.

Considering the wide use of dextran-coated particles, it is surprising that even the most elementary aspects of particle synthesis, the effect of polymer molecular weight

and the effect of polymer modification on particle size, stability, and coating efficiency, have not been reported in the literature. In this initial report, we describe the effect of reduction of the terminal reducing sugar in the coating polysaccharide on the particle size and magnetic properties of USPIO. This effect was investigated for a series of dextrans of varying molecular weight as well as a nondextran polysaccharide. Finally, we modeled these effects using a Langmuir isotherm and obtained a reasonable fit of experimental data with this model.

EXPERIMENTAL SECTION

Analytical Methods. Particle sizes were determined by dynamic light scattering in a Microtrac UPA instrument (Honeywell IAC Microtrac, Fort Washington, PA) and are reported as the mean volume diameter (MVD). Magnetic susceptibility was determined with a Mathey Johnson magnetic susceptibility balance. Iron concentrations were determined utilizing a bipyridyl assay (*14*). Size exclusion chromatography was used to determine retention times of reduced and native polysaccharides using a Waters Ultrahydrogel 250 column with RI detection. The elution buffer and flow rate were 20 mM phosphate containing 0.25% sodium chloride and 0.1% sodium azide (pH 7.3) and 0.4 mL/min. Residual aldehyde concentrations was determined using a modified tetrazolium blue assay (*15*). Dextran was determined by a phenol/sulfuric acid assay. (*16*)

Materials. Dextrans T1, T10, and T70 were obtained from Pharmacia (Upsala, Sweden) and dextran T5 was obtained from Carbomer (Westborough, MA). Pullulan was obtained from Waters (Milford, MA). All other chemicals were obtained from common commercial sources and used without purification.

Modified Dextrans. Reduced polysaccharides were prepared by treatment with excess sodium borohydride and generally purified using five cycles of ultrafiltration. In the case of pullulan, the reduction mixture was used without further purification. In all cases the products showed less than 5% residual aldehyde content. In cases where ultrafiltration was omitted, it was demonstrated that, except for the dextran T1, the residual borate salts did not affect particle formation. When ultrafiltration was used to purify the modified dextrans, a small decrease in retention times for the reduced dextrans relative to the starting native dextrans was sometimes observed.

Reduced Dextran T1. Dextran T1 (10 g) was dissolved in 100 mL of deionized water at 25 °C, 1 g of sodium borohydride was added, and the mixture was stirred 12 h. The pH was brought to 5.0 using 6 M HCl, and 200 mL of ethanol (absolute) was added. The ethanol/water layer was decanted, and the residue was dissolved in 100 mL of deionized water. Adding 200 mL of absolute ethanol made a second precipitation, and the ethanol/water was again decanted. The product was dissolved in water and lyophilized to produce a white solid in 60% yield. HPLC retention times (min): reduced dextran = 24.4; native dextran = 24.4.

Reduced Dextran T5. Dextran T5 (4 g) was dissolved in 25 mL of deionized water at 25 °C, 83 mg of sodium borohydride was added, and the mixture was stirred 12 h. The pH was brought to 5.0 using 6 M HCl. The mixture was ultrafiltered against a 1 kDa membrane. The product was lyophilized to produce a white solid in 70% yield. HPLC retention times (min): reduced dextran = 22.9; native dextran = 21.9.

Reduced Dextran T10. Dextran T10 (10 g) was dissolved in 100 mL of deionized water at 25 °C, 1 g of sodium borohydride was added, and the mixture was stirred 12 h. The pH was brought to 5.0 using 6 M HCl. The mixture was ultrafiltered against a 3 kDa membrane. The product was lyophilized to produce a white solid in 63% yield. HPLC retention times (min): reduced dextran = 21.6; native dextran = 21.1.

Reduced Dextran T70. Dextran T70 (10 g) was dissolved in 100 mL of deionized water at 25 °C, 0.2 g of sodium borohydride was added, and the mixture was stirred 12 h. The pH was brought to 5.0 using 6 M HCl. The mixture was ultrafiltered against a 10 kDa membrane. The product was lyophilized to produce a white solid in 68% yield. HPLC retention times (min): reduced dextran = 18.4; native dextran = 18.4.

Reduced Pullulan. Pullulan (90 mg) was dissolved in 0.8 mL of deionized water at 25 °C, 1 mg of sodium borohydride was added, and the mixture was stirred 12 h. This material was used directly in the preparation of pullulan-coated iron oxide particles.

Preparation of Polysaccharide-Coated Particles. Identical procedures were utilized for the preparation of polysaccharide-coated iron oxide particles with each pair of native and reduced polysaccharide having the same molecular weight. In particular, polysaccharide-to-iron ratios and iron concentrations were chosen for the reduced polysaccharide-coated particles to yield a 0.2 μm filterable particle with a diameter of less than 30 nm and a magnetic susceptibility of greater than 20 000 $\times$ 10^{-6} cgs. The same conditions were then used in the particle synthesis for the native polysaccharide of the same molecular weight. The general procedure involves addition of excess ammonium hydroxide to a solution of iron salts (Fe^{3+}/Fe^{2+}) and dextran, followed by heating and six cycles of ultrafiltration against deionized water using a 100 kDa membrane. After ultrafiltration, the reduced dextran particles were 0.2 μm filtered and stored at 4 °C. In the preparations with the native dextran, only the native dextran T10- and T70-coated particles could be 0.2 μm filtered. The size and magnetic susceptibility were then measured except for those samples containing particulate materials.

Preparation of Native and Reduced Dextran T1-Coated Particles. Native or reduced dextran T1 (1.7 g) was dissolved in 20 mL of deionized water. A mixture of 3 g of ferric chloride hexahydrate and 1.5 g of ferrous chloride tetrahydrate dissolved in 32 g of deionized water was added. The mixture was purged with nitrogen for 30 min and cooled to 5 °C, and 12.7 g of ammonium hydroxide (28%) added with stirring over 2 min. The mixture was heated to 60 °C over 40 min, at 80 °C for 2 h, and purified as indicated above.

Preparation of Native and Reduced Dextran T5-Coated Particles. Native or reduced dextran T5 (0.45 g) was dissolved in 13 mL of deionized water. A mixture of 0.5 g of ferric chloride hexahydrate and 0.25 g of ferrous chloride tetrahydrate dissolved in 4.5 g of deionized water was added. The mixture was purged with nitrogen for 30 min and cooled to 5 °C, and 1.42 g ammonium hydroxide (28%) added with stirring over 2 min. The mixture was heated at 80 °C for 2 h and purified as indicated above.

Preparation of Native and Reduced Dextran T10-Coated Particles. Native or reduced dextran T10 (2.7 g) was dissolved in 70 mL of deionized water. A mixture of 2.0 g of ferric chloride hexahydrate and 1.0 g of ferrous chloride tetrahydrate dissolved in 27 g of deionized water was added. The mixture was purged with nitrogen for 30 min and cooled to 5 °C, and 8.5 g of ammonium hydroxide (28%) added with stirring over 2 min. The

Table 1. Conditions Used in the Formation of Reduced and Native Dextran-Coated Magnetic Sol

dextran	sol[a] mg Fe	polysaccharide/Fe g/g	[Fe] mg/mL
T1	24	1.6	12
T5	24	2.9	12
T10	13	4.6	6.5
T70	3	8.7	1.5

[a] An amount of magnetic sol was added to a solution of dextran or reduced dextran as shown.

mixture was heated at 80 °C for 2 h and purified as indicated above.

Preparation of Native and Reduced Dextran T70-Coated Particles. Native or reduced dextran T70 (0.2 g) was dissolved in 10 mL of deionized water. A mixture of 0.06 g of ferric chloride hexahydrate and 0.03 g of ferrous chloride tetrahydrate dissolved in 15 g of deionized water was added. The mixture was purged with nitrogen for 30 min and cooled to 5 °C, and 1.0 g of ammonium hydroxide (28%) added with stirring over 2 min. The mixture was heated at 80 °C for 1 h and purified as indicated above.

Preparation of Native and Reduced Pullulan-Coated Particles. Native or reduced pullulan (0.045 g) was dissolved in 0.4 mL of deionized water. A mixture of 0.106 g of ferric chloride hexahydrate and 0.05 g of ferrous chloride tetrahydrate dissolved in 1.3 g of deionized water was added. The mixture was purged with nitrogen for 30 min and cooled to 5 °C, and 0.044 g of ammonium hydroxide (28%) added with stirring over 2 min. The mixture was heated at 80 °C for 0.67 h and purified as indicated above.

Effect of Molecular Weight of Reduced Dextrans on Particle Size Using Constant Polysaccharide/Fe Ratios and Constant [Fe]. Reduced dextran (T1, T5, T10, or T70) (0.26 g) was dissolved in 6.8 g of deionized water, and a mixture of 0.193 g of ferric chloride hexahydrate and 0.096 g of ferrous chloride tetrahydrate dissolved in 2.4 g of deionized water was added. The mixture was purged with nitrogen for 30 min and cooled to 5 °C, and 0.82 g of ammonium hydroxide (28%) added with stirring over 2 min. The mixture was heated at 80 °C for 1 h. The mixture was diluted to 25 mL with deionized water, 0.2 μm filtered when possible, and analyzed for size and magnetic susceptibility without further purification.

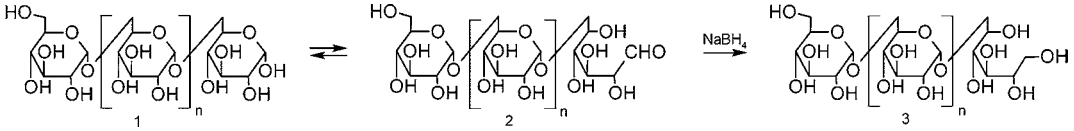
Preparation of Magnetic Sol. At 25 °C, 60 g of ammonia hydroxide (28%) was added to 30.0 g of ferric chloride hexahydrate and 15.1 g of ferrous chloride tetrahydrate dissolved in 321 g of deionized water. After 5 min of mixing, concentrated HCl was added to reach pH 1.6. The sol was ultrafiltered against a 100 kDa membrane to achieve pH 3.25. Deionized water was the diluent. The magnetic sol was 0.2μ filtered, concentrated to 50 mg Fe/g, and stored at 5 °C. Yield of iron: 55%. MVD = 16 nm.

Reaction of Reduced Dextrans with Magnetic Sol. An amount of magnetic sol was added to a solution of dextran or reduced dextran as shown in Table 1. The dextran/iron ratios and iron concentrations were identical to those that yielded magnetic particles with the reduced dextrans during in situ formation. The mixture was incubated for 15 min, and the pH was adjusted to 7.4 ± 0.4. The size was determined without purification.

RESULTS

Effect of Reduction of the Terminal Sugar on Particle Size, Magnetic Susceptibility, and Stability. The treatment of a polysaccharide such as dextran with sodium borohydride results in the conversion of the terminal reducing sugar to a linear polyol. This very minor change of the polysaccharide structure is shown in Scheme 1.

Further illustrating the small magnitude of the change produced by reduction, we note that in a dextran of molecular weight 10 kDa only one of its 63 glucose residues is altered by reduction. This residue represents 1.6% of the total mass of the polymer. Additionally, there are 191 hydroxyl groups in the hemiacetal and aldehyde forms of the native polysaccharide and 192 hydroxyls in the reduced polysaccharide. The one additional hydroxyl is introduced by the formation of the linear polyol. The gross structure of the reduced and native dextran is identical as indicated by hydrodynamic measurements. The mol percent that the terminal sugar represents in each of the polysaccharides studied is listed in Table 2.



The profound effect that reduction of the terminal sugar in polysaccharides can have in the synthesis of USPIO is illustrated in Table 2 which presents the mean volume diameters (MVD) determined for particles formed with native and reduced polysaccharide pairs. The polysaccharide/Fe ratio and dilution of these reagents were optimized to yield particles with diameters of ≤30 nm with the reduced polysaccharide; the same ratio was used with native polysaccharides. For the lower molecular weight polysaccharides, the native dextran gave a consistently larger particle. As the size of the polysaccharide increased the effect became less pronounced and disappeared when the molecular weight reached 70 kDa. In all cases, particles synthesized with reduced polysaccharides yielded higher susceptibility values than the corresponding particles synthesized with native polysaccharide.

Ultrasmall iron oxide particles were prepared with the low molecular weight native dextrans but this required about a 10 to 34-fold increase in the polysaccharide-to-iron ratio relative to that used for USPIO prepared with reduced dextrans of corresponding molecular weight (Table 3). For particles prepared with native dextran T1 and T5 the magnetic properties of the particles were markedly inferior to corresponding particles prepared with their reduced counterpart. Particles prepared with native and reduced dextrans T70 used identical polysaccharide/Fe ratios and each yielded nearly identical particles with respect to size and magnetic susceptibility.

Besides providing a more efficient use of the polysaccharide in USPIO synthesis than the corresponding native dextran, the reduced dextran-coated USPIO is more stable. When USPIO prepared with reduced dextran T10 was autoclaved for 30 min at 121 °C, its size did not change (Table 4); however, when USPIO prepared with native dextran T10 is similarly treated its size increases dramatically. Another indicator of stability is provided by the bound dextran/Fe ratio. A higher ratio suggests more stability and tighter binding. Both before and after autoclaving particles prepared with reduced dextran had higher ratios than the corresponding particles prepared with native dextran.

Effect of Addition of Glucose to Reduced Dextrans on Particle Size and Magnetic Susceptibility. To determine whether the effect of reduced polysaccharide on particle size resulted from removal of the reducing sugar from the reaction mixture, reduced dextran T10 colloidal USPIO were prepared as described in Experimental except that increasing amounts of glucose were added to the dextran/iron-solution before addition of ammonium hydroxide. The effect on particle size and

Scheme 1. Illustration of the Chemical Change in a Polysaccharide Such as Dextran upon Treatment with Sodium Borohydride[a]

[a] The hemiacetal form of the polysaccharide (structure **1**) is in equilibrium with the aldehyde form of the polysaccharide (structure **2**). Structure **2** represents less than 0.01% of the equilibrium mixture (*17*). Treatment of structure **2** with sodium borohydride results in its irreversible conversion to the linear polyol form of the polysaccharide (structure **3**). The dynamic equilibrium between structures **1** and **2** allows complete conversion, when treated with sodium borohydride, to the linear polyol (structure **3**).

native dextran	0.026[d]	>700	31252

[a] The amount of glucose added in each experiment is expressed as a percent of the weight of reduced dextran. [b] Colloids were not purified by ultrafiltration resulting in slightly larger particle size measurements. [c] Magnetic susceptibility ($\times 10^{-6}$ cgs/g Fe). [d] [Reducing glucose]/[Fe] of native dextran T10 for the conditions as shown in Table 2.

magnetic susceptibility was determined (Table 5). Even the addition of 50 wt % glucose to the reduced dextran T10 had only minimal effect on particle size, resulting in an increase of only 10 nm compared with particles prepared in the absence of glucose. This last addition of glucose represents a greater than 40-fold increase in reducing sugar concentration over that present in the native dextran T10 preparation in Table 1. For comparison, particles prepared with native dextran T10 had a particle size of greater than 700 nm. Evidently, simple elimination of reducing sugar from the reaction solution is not a controlling factor in particle size. The decrease in particle size, improvement in polysaccharide usage, and increased colloid stability must all, therefore, result from introduction of the linear polyol. When present in sufficient concentration; added glucose lowers the magnetic susceptibility of the particles by 1 order of magnitude.

Effect of the Molecular Weight of Reduced Dextrans on Size of USPIO. Because the iron and polysaccharide concentrations varied for the different molecular weight dextrans in obtaining the data shown in Table 2, no conclusion regarding the effect of polymer molecular weight alone on particle formation could be derived from these results. Therefore, the data shown in Table 6 were obtained at a constant concentration by weight of both dextran and iron. The constant concentration by weight for each reduced dextran represents a constant molar concentration of glucose monomeric units but a decreasing concentration of terminal polyol with increase in polymer molecular weight. The results demonstrate an increase in USPIO particle size with an increase in dextran molecular weight. Because these particles were not purified by ultrafiltration somewhat larger sizes are observed than for comparable data in Table 2.

Coating of Magnetic Sol. The preparations of USPIO described thus far have involved formation of the mag-

netic particle by precipitation of the iron salts in the presence of polysaccharide. In this complex system the coating polysaccharide can participate both in the synthesis of the particle and in its ultimate stabilization by acting as a steric repulsion-coating agent. To separate these two functions and allow study of the stabilizing function of the coating polysaccharide alone, USPIO were prepared without a coating agent by precipitation of the iron salts with base (*18*). These magnetic sols are unstable and aggregate at pH greater than 3. Measurement of particle size, after addition of native or reduced dextrans to the magnetic sol and neutralization of the mixture, was used to assess the effectiveness of these polysaccharides to bind to the iron oxide surface (Table 7). Colloidal material could not be obtained with either native or reduced dextran T1, dextran T5, or with native dextran T10. Reduced dextran T10 yielded a colloidal product. For colloidal USPIO prepared with dextran T70, the reduced dextran was slightly more effective at coating the iron oxide surface than native dextran T70.

From consideration of the results presented in Tables 2 and 7, we see that reduced dextrans coat USPIO particles more effectively while present during iron oxide crystal formation compared with coating preexisting iron oxide particles. Whether iron oxide particles are coated with polysaccharide during particle growth or post particle synthesis, the reduced dextran is a more effective coating and steric stabilizing agent than the corresponding native dextran.

DISCUSSION

General Observations. While we are not the first to suggest using reduced polysaccharides for coating USPIO particles (*19*), no reports detail the profound effect this seemingly small change within the polysaccharide polymer (Scheme 1) can have upon resulting particle properties. Four aspects of polysaccharide-coated USPIO particle synthesis were investigated: (i) the effect reduction of the terminal polysaccharide sugar has upon polysaccharide usage, particle size, stability, and magnetic susceptibility; (ii) the effect an exogenous reducing sugar can have upon particle synthesis; (iii) the effect the molecular weight of the reduced polysaccharide has on particle synthesis; and (iv) the effectiveness of reduced and native dextrans in stabilizing a preformed magnetic sol. In this study, we investigated four characterizing aspects of particle formation: particle size, coating efficiency, coating stability, and magnetic properties.

We discovered that a significant decrease in dextran-to-iron ratio could be employed with low molecular weight reduced dextrans to obtain the same particle size with equal or improved magnetic properties relative to the native polymer. Moreover, using reduced polysaccharides increases coating stability as evidenced by the stability of particles to autoclaving. The effect of exogenous reducing sugar on particle size is minimal as shown by addition of high concentrations of glucose to the reaction mixture used in the synthesis of reduced dextran T10-coated USPIO. An inverse relationship between polysaccharide molecular weight and particle size was observed. Finally, reduced dextrans proved to be more effective in coating preformed iron oxide crystals than their corresponding native dextrans.

Our results suggest that the coating polysaccharides are involved in the earliest stages of USPIO formation affecting particle composition and magnetic properties. With low molecular weight reduced dextrans small magnetite crystals are obtained with high magnetic susceptibility. In contrast with low molecular weight native dextrans small particle size can be achieved only at the expense of magnetic properties. This suggests that in these cases the presence or absence of reducing sugar affect crystal growth. In the presence of reducing sugar the transformation of the initially formed ferric and ferrous hydroxides into superparamagnetic magnetite crystals is inhibited. (The identity of these oxides has not been determined.) Further support for the early involvement of the polysaccharide in particle synthesis is the relative inability of the native and reduced dextrans to coat and stabilize preformed magnetite crystals. This decreased effectiveness of polymer to coat oxide demonstrates that polymer is involved early in particle formation and is not limited to determining particle size alone, i.e., to coating completed particles.

Modeling of our data using equations derived from the Langmuir isotherm (see Appendix and Figure 1) indicate that binding of dextran to the iron oxide surface requires two binding events. Data from Table 2 suggests that polyol binding is rate limiting, and modeling suggests that a second internal glucose residue must contact the iron oxide surface to achieve tight and relatively irreversible binding. These conclusions are consistent with previously published observations that multiple sites of attachment are necessary for the noncovalent adsorption of polymer to surfaces (*20*). Modeling further predicts that particle size will increase with increasing molecular weight of the coating polymer. A good fit of the experimental data was found after making corrections for diffusional effects of the polymer.

We are surprised to discover that a seemingly simple change in the terminal sugar of a coating polysaccharide used during USPIO particle formation can have a large effect on polysaccharide usage and particle stability. This result suggests that other modifications of both the terminal and backbone sugars in polysaccharides such as introduction of charged species (e.g., amino and carboxyl groups) will have a profound effect on USPIO particle formation. We have also observed that oxidation of dextran with sodium periodate followed by reduction

by sodium borohydride to introduce open chain alcohols into the polymer chain also increases coating efficiency (*21*). The results observed with reduced polysaccharides as coating agents of USPIO particles may be expected to apply to other metal oxides and minerals and may very well be found to generalize to other surfaces (*22*).

APPENDIX

Langmuir Isotherm Modeling. Our results, particularly the decrease in size of particles obtained in the presence of reduced dextrans of low molecular weight, suggest that polysaccharide exerts a kinetic control over particle synthesis where the terminal, open chain reduced sugar (linear polyol) is more effective than either the reducing or chain sugars in complexing with the iron oxide surface. Two conclusions follow from this suggestion. First, if adsorbed polymer blocks crystal growth and aggregation, then use of polymers that adsorb to the iron oxide surface faster and with greater tenacity should result in smaller particles. Second, as the molecular weight of the dextran increases, the decreasing concentration of linear polyol relative to the chain sugars will minimize the effect the linear polyol has on particle synthesis.

The observations for the reduced and native dextrans described in Tables 3 and 6 can be modeled to fit the Langmuir isotherm for competitive adsorption onto a surface by treating the backbone sugars and terminal open chain polyol as competitive inhibitors to crystal growth. The Langmuir isotherm for competitive gas adsorption onto a surface is expressed in eq 1 (*23*),

$$\nu_x = \frac{k_x p_x}{1 + K_x p_x + \sum K_i p_i} \tag{1}$$

where ν_x is the velocity of adsorption of gas x, k_x is the rate constant for adsorption of x, K_x is the equilibrium constant for adsorption of x, K_i is the equilibrium constant for competitive inhibitor i, p_x is the partial pressure of x, and p_i is the partial pressure for inhibitor i.

Assuming crystal growth is inhibited by the adsorption of backbone glucose monomeric units (G) and either the terminal reducing sugar (R) for the native dextran or the terminal linear polyol (P) of the reduced dextran and ν_x = rate of adsorption of an iron species X (crystal growth); then the expressions for the crystal growth in the presence of native dextran (ν_{ND}) or reduced dextran (ν_{RD}) are given by eqs 2 and 3 by expansion of eq 1 to two terms with appropriate substitutions of X and the growth controlling factors G, R, and P and substituting concentrations for partial pressures,

$$\nu_{ND} = \frac{k_X[X]}{1 + K_X[X] + K_G[G] + K_R[R]} \tag{2}$$

$$\nu_{RD} = \frac{k_x[X]}{1 + K_X[X] + K_G[G] + K_P[P]} \tag{3}$$

where k_x is the rate constant for iron adsorption, K_X is the equilibrium constant for iron adsorption, K_G is the equilibrium constant for glucose adsorption, K_R is the equilibrium constant for terminal reducing sugar adsorption, and K_P is the equilibrium constant for polyol adsorption. In eqs 2 and 3 the glucose monomeric units, terminal reducing sugar and polyol are treated as independent binding species and their concentrations are related by eqs 4−7

$$[M] = \frac{\text{dextran mass/volume}}{MW_G} \tag{4}$$

$$[P] = [R] = \frac{\text{dextran mass/volume}}{MW_D} \tag{5}$$

$$[P] = [R] = [M]\frac{MW_G}{MW_D} \tag{6}$$

$$[G] = [M]\left(1 - \frac{MW_G}{MW_D}\right) \approx [M] \tag{7}$$

where M is the total number of monomeric units as shown in Table 2 including terminal reducing sugar or polyol, MW_G is the molecular weight of a glucose monomeric unit (162), and MW_D is the molecular weight of the dextran. For simplicity the small MW_G/MW_D term in the expression for [G] will be neglected; when included it has no significant effect on the fit to experimental data.

Dividing eq 2 by eq 3 and expressing the inhibitor concentrations in terms of [M] yields eq 8 which defines the relative rates of crystal growth for native and reduced dextrans of identical molecular weights,

$$\frac{\nu_{ND}}{\nu_{RD}} = \frac{1 + K_X[X] + K_G[M] + K_p[M]\frac{MW_G}{MW_D}}{1 + K_X[X] + K_G[M] + K_R[M]\frac{MW_G}{MW_D}} = \frac{\alpha + K_p[M]\frac{MW_G}{MW_D}}{\alpha + K_R[M]\frac{MW_G}{MW_D}} \tag{8}$$

where $\alpha = 1 + K_X[X] + K_G[M]$.

Qualitative analysis of eq 8 shows that as the molecular weight of dextran increases, the ratio of crystal growth rates for the reduced versus native dextran pair decreases and tend to approach a value of 1. As a consequence of increasing polymer molecular weight, the linear polyol concentration becomes so small that its contribution becomes negligible as was observed with the particles prepared with native or reduced dextran T70.

A more quantitative approach may be taken by making the following two assumptions. First, the ratio of the rate of crystal growth ν_x is proportional to the final particle diameter. Second, because the ratio of rates (diameters) for the particles is mathematically very dependent on the MVDs obtained for the small reduced dextran particles where the analytical method has a larger percentage error, we assume a constant small size for the reduced dextran particles. As a result, the particle diameters for the native dextrans (MVD_{ND}) are proportional to the ratio of the rates of crystal growth for native and reduced dextran for a particular polymer molecular weight (eq 9).

$$MVD_{ND} \approx \frac{\nu_{ND}}{\nu_{RD}} \tag{9}$$

Applying these assumptions, a theoretical fit to the experimental data can be calculated by setting α to a constant value. Since any value of α will give the same solution, we set α equal to 1, insert the values for [M] as shown in Table 2, and calculate K_p by an iterative process minimizing the difference between the data and theoretical points. As can be seen in Figure 1, the fit with experimental data is poor. However, as shown in Figure

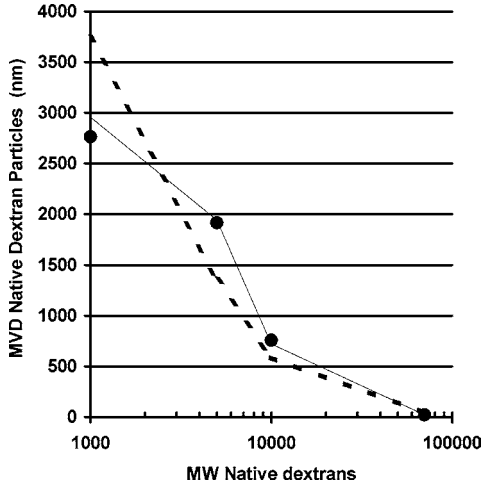

Figure 1. Plot of particle size versus dextran molecular weight; observed data, ● and model data calculated from eq 8 assuming a dependence on [M], - - - -; and $[M]^2$, ——.

1, an excellent fit is obtained if the same iterative process is employed using the values of $[M]^2$ in place of [M]. This can best be explained if it is assumed that simple adsorption of polyol or the reducing sugar is insufficient to form a thermodynamically stable attachment and further adsorption of a second sugar is necessary. Then ν_{RD} is more properly defined as in eq 10 than eq 2 (ν_{ND} is treated the same way). Substituting [P] (or [R] for native dextran) from eq 6 gives eq 11, and eq 8 becomes eq 12, in agreement with experimental data. Since the experimental data gives no information on the number of sugars necessary for stable attachment without involvement of polyol a $[M]^n$ term has been introduced in eq 10. From the values of K_P and K_G determined by fitting the plot a value of K_P/K_G of 1.3×10^9 was determined. The actual values of K_P and K_G are dependent on the true value of α; however, their ratio is independent of α. This large value may be the result of two factors: first, the inherent increased binding strength of the polyol, and second, that in the case of the reducing sugar, two or more additional sugars in the chain must bind to obtain a thermodynamically stable attachment; i.e., the reaction order shown in eq 13 is greater than 2 and K_G as shown includes additional concentration terms [M]

$$\nu_{RD} = \frac{k_X[X]}{1 + K_X[X] + K_G[G]^n + K_P[P][G]} \quad (10)$$

$$[P][G] = [M]^2\frac{MW_G}{MW_D}\left(1 - \frac{MW_G}{MW_D}\right) \approx [M]^2\frac{MW_G}{MW_D} \quad (11)$$

$$\frac{\nu_{ND}}{\nu_{RD}} = \frac{1 + K_X[X] + K_G[M]^n + K_P[M]^2\frac{MW_G}{MW_D}}{1 + K_X[X] + K_G[M]^n + K_R[M]^2\frac{MW_G}{MW_D}} = \frac{\alpha + K_P[M]\frac{MW_G}{MW_D}}{\alpha + K_R[M]\frac{MW_G}{MW_D}} \quad (12)$$

where $\alpha = 1 + K_X[X] + K_G[M]^n$.

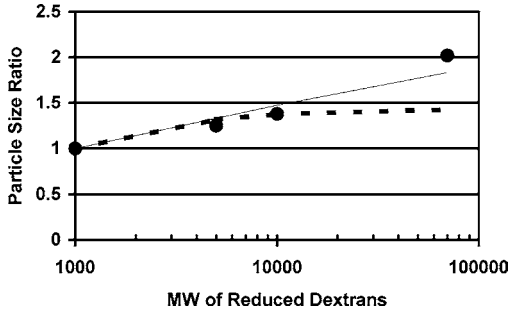

Figure 2. Plot of relative particle size versus reduced dextran molecular weight; observed data, ●, and model data calculated from eq 12, - - - -, or eq 13,——. Particle size ratio is particle size relative to the reduced T1-coated particle from Table 6.

Our model can also be used to predict the observed effect of polymer molecular weight for a series of reduced dextrans on particle size as shown in Table 6. In this case, we are comparing the formation of two particles prepared with reduced dextrans of different molecular weight at identical concentrations of glucose monomer, [M]. Equation 13 is obtained by dividing eq(s) 8 (expanded for multiple attachments as in eq 13) for reduced dextrans of different molecular weights ($\nu_{RD1} = MW_{D1}$, $\nu_{RD2} = MW_{D2}$). In this case, the concentration related terms for each molecular weight dextran are equal resulting in an expression dependent only on MW

$$\frac{\nu_{RD2}}{\nu_{RD1}} = \frac{1 + K_X[X] + K_G[M]^n + K_P[M]^2\frac{MW_G}{MW_{D1}}}{1 + K_X[X] + K_G[M]^n + K_P[M]^2\frac{MW_G}{MW_{D2}}} = \frac{\alpha + K_P[M]\frac{MW_G}{MW_{D1}}}{\alpha + K_P[M]\frac{MW_G}{MW_{D2}}} \quad (13)$$

where

$$\alpha = \frac{1 + K_X[X] + K_G[M]^n}{K_P[M]^2}$$

As with eq 7 a value for α can be determined to give a best fit to experimental data. The comparison of the theoretical plot versus the experimental results is shown in Figure 2. Qualitatively, the results agree with the experimental data showing an increase in particle size associated with an increase in polymer molecular weight. The theoretical plot predicts that as the particle size increases a maximum will be reached as the polyol concentration becomes negligible. The unexpectedly large size obtained for the particle prepared with dextran T70 compared to the predicted value is probably the result of a diffusion term in K_G and K_P making these values molecular weight dependent. Since the rate of diffusion is proportional to $MW^{-1/3}$, an approximation for this effect can be introduced as shown in eq 14. The improved correlation with the experimental data is also shown in Figure 2.

$$\frac{\nu_{RD2}}{\nu_{RD1}} = \frac{1 + K_X[X] + K_G\frac{[M]^n}{MW_{D1}^{1/3}} + K_P[M]^2\frac{MW_G}{MW_{D1}^{4/3}}}{1 + K_X[X] + K_G\frac{[M]^n}{MW_{D2}^{1/3}} + K_P[M]^2\frac{MW_G}{MW_{D2}^{4/3}}} = \frac{\alpha + \frac{\beta}{MW_{D1}^{1/3}} + \frac{1}{MW_{D1}^{4/3}}}{\alpha + \frac{\beta}{MW_{D2}^{1/3}} + \frac{1}{MW_{D2}^{4/3}}} \quad (14)$$

where

$$\alpha = \frac{1 + K_X[X]}{K_P[M]^2 \times MW_G}, \beta = \frac{K_G[M]^{n-2}}{K_P \times MW_G}$$

O^6-Benzylguanine derivatives with suitable radionuclides attached to the benzyl ring are potentially useful in the noninvasive imaging of the DNA repair protein, alkylguanine-DNA alkyltransferase (AGT). Previously, O^6-3-[^{131}I]iodobenzylguanine ([^{131}I]IBG) was prepared using a two-step approach; we now report its synthesis in a single step by the radioiododestannylation of O^6-3-(trimethylstannyl)-benzylguanine in 85−95% radiochemical yield. The in vitro specific uptake of [^{131}I]IBG in DAOY human medulloblastoma cells, in TE-671 human rhabdomyosarcoma cells and a CHO cell line transfected to express AGT was linear (r^2 = 0.9−1.0) as a function of cell density. After intravenous injection of [^{131}I]IBG in athymic mice bearing TE-671 xenografts, tumor uptake was 1.38 ± 0.34% ID/g at 0.5 h and declined at 2 and 4 h. Preadministration of O^6-(3-iodobenzyl)guanine (IBG) at 0.5 h increased uptake not only in tumor but also in several normal tissues. Notable exceptions were thyroid (p < 0.05), lung (p <0.05) and stomach. After intratumoral injection of [^{131}I]IBG in the same xenograft model, the uptake in tumors that were depleted of AGT by BG treatment (165.8 ± 27.5% ID/g) was about 60% of that in control mice (272.4 ± 48.2% ID/g; p < 0.05).

INTRODUCTION

The cytotoxicity of alkylating chemotherapeutic agents stems primarily from their ability to alkylate DNA guanine residues at their O^6-position, which in turn triggers a cascade of events ultimately resulting in DNA strand breaks (*1*). Although a number of other factors are involved, drug resistance in alkylator chemotherapy is often mediated by the role played by the DNA repair protein, alkylguanine-DNA alkyltransferase (AGT) (*2*, *3*). This protein transfers alkyl groups such as methyl, ethyl, benzyl, or pyridyloxybutyl from the O^6-position of the guanine residues in DNA to the Cys-145 residue in its active site in a suicidal manner. The alkylated protein is ubiquitinated and undergoes degradation, and its recovery is entirely from de novo synthesis (*4*). The ability of tumor cells to be resistant to the toxic effects of alkylating agents is thus dependent on cellular AGT levels; the higher the AGT content, the less effective will be the cytotoxicity by alkylator therapy. It is highly imperative, therefore, to determine the cellular AGT content in tumor cells in order to compensate for the AGT-mediated repair process, or select alternative therapies that will not be compromised by elevated AGT levels.

Methods currently exist for quantifying AGT (*5*−*7*); however, these techniques are performed in vitro or ex vivo and therefore necessitate that tumor samples be obtained by invasive procedures. A method to assay AGT by a noninvasive means in individual patients would greatly enhance proper therapy planning. Because O^6-benzylguanine (BG) is a substrate of AGT (*8*), it might be possible to radiolabel AGT in vivo by administering a suitable BG analogue substituted with radionuclides such as ^{18}F or $^{124/123}$I on its benzyl moiety.

With regard to currently available potential radiolabeled AGT probes, the preparation of ^{125}I-labeled guanosine derivatives has been reported but their usefulness as an AGT labeling agents was not evaluated (*9*). A ^{14}C-labeled guanosine derivative (*10*) and a BG derivative labeled with ^{3}H (*11*) also have been described; however, it is not practical to perform external imaging of these radionuclides. More recently, the synthesis of several BG derivatives labeled with ^{11}C and ^{18}F have been reported but the in vivo behavior of these tracers has largely been unexplored (*12*−*17*).

The efforts of our group in developing a radioligand for monitoring AGT have involved the synthesis and preliminary evaluation of O^6-4-[^{18}F]fluorobenzylguanine ([^{18}F]FBG) and O^6-3-[^{131}I]iodobenzylguanine ([^{131}I]IBG) (*18*). The ability of unlabeled IBG and FBG to deplete AGT in CHO cells transfected with AGT was similar to that of BG and the labeled compounds bound specifically to pure AGT. The labeled IBG was prepared, by first radioiodinating O^6-3-(trimethylstannyl)benzyl-N^9-(trimethylsilyl)ethoxymethylguanine (SEM-TMSBG) and subsequently removing the SEM group of the intermediate product. In this paper, we describe the synthesis of O^6-3-(trimethylstannyl)benzylguanine and its conversion to [^{131}I]IBG in a single step. Moreover, we have evaluated further the potential of this compound for imaging by performing additional in vitro assays and by determining its biodistribution in a murine xenograft model.

EXPERIMENTAL SECTION

General. All chemicals were purchased from Aldrich Chemical Co. except as noted. O^6-(3-Iodobenzyl)guanine was prepared as reported before (*18*). Sodium [^{131}I]iodide in 0.1 N NaOH was supplied by Perkin-Elmer Life Sciences (North Billerica, MA).

High-pressure liquid chromatography (HPLC) was performed using one of two systems: (1) a Beckman System Gold HPLC equipped with a Model 126 programmable solvent module, a Model 168 diode array detector, a Model 170 radioisotope detector, and a Model 406 analog interface module; or (2) a Beckman System Gold HPLC equipped with a Model 126 programmable solvent module, a Model 166 NM variable wavelength detector, a Model 170 radioisotope detector, and a Beckman System Gold remote interface module SS420X; the data was acquired using a 32 karat software. Normal-phase HPLC was performed using a 4.6 × 250 mm Partisil (10 μm) column (Alltech, Deerfield, IL). Analytical TLC was performed on aluminum-backed sheets (Silica gel 60 F_{254}), and normal-phase column chromatography was performed using Silica gel 60, both obtained from EM Science (Gibbstown, NJ). Column chromatography fractions were collected using a ISCO Foxy 200 fraction collector (Lincoln, NE) with an ISCO UA-6 UV−Vis detector placed between the column outlet and the fraction collector to identify fractions. The homogeneity of fraction composition was verified by TLC. Preparative thick layer chromatography was performed using 20 × 20 cm, 1000 μm plates (Whatman, Clifton, NJ). Before applying the sample, the plates were run in ethyl acetate to clean the plates of any adsorbed impurities. Radio-TLC was initially analyzed using a System 200 Imaging Scanner (BioScan, Washington, D.C.) and then cut into strips and counted using an automatic gamma counter (LKB 1282, Wallac, Finland). NMR spectra (^{1}H-300 MHz) were obtained on a Varian Mercury 300 spectrometer. Chemical shifts are reported in δ units; solvent peaks were referenced appropriately. Mass spectra were obtained on a JEOL SX-102 high-resolution mass spectrometer.

***O*^{6}-3-(Trimethylstannyl)benzylguanine (TMS-BG).** Dichlorobis(triphenylphosphine)palladium (50 mg, 0.07 mmol) was added to a mixture of IBG (84 mg, 0.23 mmol), hexamethylditin (820 mg, 2.5 mmol), and 5 mL of anhydrous dioxane in a dry, argon-purged flask. The flask was heated in an oil bath at 100 °C for 1−2 h. Dioxane was evaporated, and the residue was applied to a bed of silica gel containing fluorescent indicator in a frit funnel with a quartz body. The most nonpolar components were eluted out using hexane, and the required product and other polar impurities were eluted from the bed with 5% (v/v) methanol in ethyl acetate. A UV lamp was used to visualize the bands. The latter fractions were concentrated and the required product was isolated from this crude mixture as an oil (80 mg; 86%) by silica gel chromatography using 0−5% methanol in ethyl acetate. ^{1}H NMR (CD_3OD) 0.27 (s, 9H [^{119}Sn−H, d]), 5.53 (s, 2H), 7.33 (t, 1H), 7.44 (m, 2H), 7.61 (s, 1H), 7.83 (s, 1H). MS (FAB$^+$) *m/z*: cluster peaks around 406 (MH^+), 390. HRMS (FAB$^+$) calcd for $C_{15}H_{20}N_5O^{116}Sn$ (MH^+) 406.0690. Found 406.0693 ± 0.0012.

***O*^{6}-3-[^{131}I]Iodobenzylguanine.** A solution of TMS-BG in methanol (0.2 mg in 50 μL) was taken in a half-dram vial and the methanol evaporated with argon. To this was added ^{131}I (1−2 mCi in 1−3 μL 0.1 N NaOH) followed by 10 μL of 3:1 (v/v) mixture of acetic acid and 30% (w/v) hydrogen peroxide. The mixture was sonicated for 1 min and injected into a normal phase HPLC column eluted isocratically with 2% MeOH in EtOAc at 1 mL per min. The product (t_R = 13 min) was isolated in 85−95% radiochemical yield. Quality control HPLC has shown a single radioactive peak with no UV peaks, suggesting more than 99% chemical and radiochemical purity. In the preparative runs, a small coeluting peak has been observed. From comparison with HPLC of IBG standards, a specific activity of 200 Ci/mmol has been achieved to date. For biological assays, the solvents were evaporated from the HPLC fractions and resolubilizing the residual activity in PBS or tissue culture medium. While this process takes only 5−10 min with about 5% loss of radioactivity, the tracer is not very soluble in aqueous buffers. However, sufficient quantities can be solubilized in PBS for using it in biological assays.

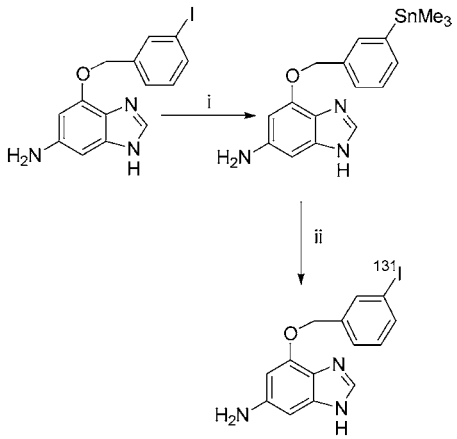
In Vitro Uptake of [^{131}I]IBG as a Function of Cell Concentration. (*A) TE−671 and DAOY Cells*. The uptake of [^{131}I]IBG in TE-671 human rhabdomyosarcoma and DAOY human medulloblastoma cell lines (*19*) was measured at three different cell concentrations. About 100 nCi of nca [^{131}I]IBG was incubated in quadruplicate for 30 min at 37 °C with these two cell lines in a 96-well plate having filters at densities of (1.25, 2.5, and 5) × 10^5 cells per well in 0.3 mL of zinc option media. To determine nonspecific binding, the cells were preincubated with 25 μM BG for 10 min. At the end of incubation, the plate was placed on a vacuum manifold to remove media. Each well was washed twice with 0.25 mL of ice-cold buffer and dried overnight. The filters were removed using a punch apparatus and counted for ^{131}I activity.

(B) B4 CHO Cells Transfected To Express AGT. CHO-K1 cells were grown in α-MEM supplemented with 10% fetal bovine serum. Cells were transfected with pCMV-Neo-Bam or pCMV-AGT (*20*; obtained from Professor A. E. Pegg, Hershey Medical Center, Pennsylvania State University) using the FuGene 6 transfection reagent (Roche Applied Science). After 2 days of culture, transfectants were selected by the addition of 0.5 mg/mL Geneticin (Invitrogen). Clones were isolated by picking resistant foci.

B4 CHO cells were plated at densities of (6.25, 12.5, 25, and 50) × 10^4 per 3 mL medium/well in six-well plates. After 24 h at 37 °C, the medium was removed and supplemented with 1 mL of fresh medium (α-MEM with L-glutamine and without ribonucleosides, deoxynucleosides, and FBS), with or without 25 μM BG, and the cells were incubated for 4 h at 37 °C. Subsequently, 25 nCi of [^{131}I]IBG was added to all wells in 5−10 μL of the medium and the cells were allowed to take up the tracer for 2 h at 37 °C. After removing unbound radioactivity, the cells were solubilized by incubation with 0.5 N NaOH overnight at 37 °C and harvested with cotton swabs. The cell-associated radioactivity was counted using a gamma counter.

Biodistribution of [^{131}I]IBG in Mice Bearing TE−671 Rhabdomyosarcoma Xenografts. Animal studies were performed under the guidelines established by the Duke University Institutional Animal Care and Use Committee. Athymic mice were obtained from a closed breeding colony maintained at the Duke University Cancer Center Isolation Facility. Age- and sex-matched BALB/c *nu/nu* mice weighing 25−30 g were utilized in these studies. TE-671 human rhabdomyosarcoma xenografts were established as reported (*21*). Briefly, (1−4) × 10^8 TE-671 cells in 1−4 mL of zinc option minimal essential medium were inoculated subcutaneously in the right flank of mice. Tumors were allowed to grow and

then removed from animals after killing them by cervical dislocation. Tumor homogenate was prepared by first passing tumor fragments through a bilayered 20-mesh screen in a tissue press and then passing them consecutively through smaller gauge needles. Thirty microliters of the tumor homogenate was inoculated with a 19-gauge needle into the right flank of recipient mice. Subcutaneous tumors were measured periodically until they reached a volume of 250−500 mm^3.



(A) Intravenous Administration. Three groups of five mice were administered nca [^{131}I]IBG (2 μCi/100 μL PBS/mouse) via the tail vein. Mice were killed by an overdose of halothane at 0.5, 2, and 4 h after injection of the tracer. Tissues of interest were isolated, blot-dried, weighed, and counted for radioactivity, along with injection standards, using an automated gamma counter. The uptake in each tissue was expressed as percent of injected dose per gram of tissue (%ID/g). To determine the effect of unlabeled IBG on tissue distribution, another group was pretreated with the unlabeled compound (0.22 mg/100 μL/mouse; 8 mg/kg; iv) 30 min before injecting the tracer and then killed 30 min thereafter. Preliminary studies with ^{18}F-labeled BG showed maximum tumor uptake at 30 min postinjection (unpublished results). It was expected that AGT will be depleted to a maximum extent 30 min after iv administration of unlabeled IBG. The dose of IBG for this experiment was prepared by dissolving it in a 3:1 (v/v) mixture of Cremophor-EL (Sigma) and DMSO (22.2 mg/mL) and diluting it 10 times with PBS. The statistical significance of differences of uptake in various tissues between the two 0.5 h groups was calculated using an unpaired Student's *t* test. A *p* value of less than 0.05 was considered to be statistically significant.

(B) Intratumoral Administration. Using the same xenografts model, a group of five mice were administered BG (1.5 mg BG in 300 μL of 40% PEG 400/PBS; 60−75 mg/kg) ip 1 h prior to injection of [^{131}I]IBG in order to deplete tumor AGT content. A second group of five mice received just the vehicle. One hour later, all mice were injected with about 1 μCi of no-carrier-added [^{131}I]IBG in 5 μL of PBS by the intratumoral route. The 1 h duration was chosen based on the fact that in mice bearing D456 intracranial glioma tumor or A549 lung tumor, tumor AGT levels were reduced to 50% and 20%, respectively 1 h after intraperitoneal injection of BG in PEG/saline vehicle (*22*). Mice were killed 30 min later, and the uptake of radioactivity in tumor and normal tissues was determined.

RESULTS AND DISCUSSION

With the goal of developing a tracer that could be used for the noninvasive mapping of AGT levels, several laboratories including our own have undertaken the synthesis of radiolabeled derivatives of BG based on the fact that BG is the prototypical AGT depleting agent. Earlier, we described a method for the synthesis of [^{131}I]-IBG involving two radiochemical steps (*18*). Our attempts to synthesize a tin derivative of 4-bromobenzylguanine, from which radioiodinated 4-IBG could have been generated in a single step, were not successful. It was reasoned that this might be due to the poor solubility of the bromobenzylguanine in dioxane, the solvent used for the stannylation reaction. We assumed that the same problem would be encountered with the 3-iodo derivative; therefore, we introduced a protecting group at the N^9-position to increase the solubility of 3-IBG and to make the synthetic manipulations more facile. This necessitated the use of an additional step in removing this protecting group after radioiodination. It is highly desirable that the synthesis of radiolabeled compounds be performed via a single, fast and high yielding step. To achieve this goal for [^{131}I]IBG preparation, we now have succeeded in synthesizing O^6-3-(trimethylstannyl)benzylguanine from IBG via a modified Stille coupling (*23*). It was possible to convert this tin derivative to [^{131}I]IBG in about 90% radiochemical yield in a reaction time of only 1 min (Scheme 1).

Scheme 1 [a]

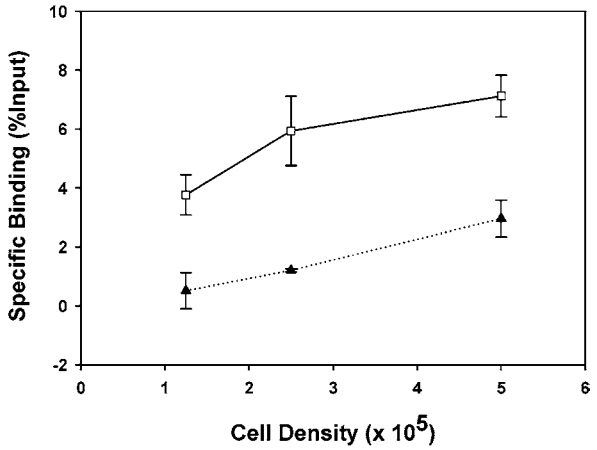

Figure 1. Cell density-dependent binding of [^{131}I]IBG to DAOY (□) and to TE-671 (▲) cells: Cells at various densities were incubated with [^{131}I]IBG in the absence or presence of 25 μM BG. Results expressed are specific binding values (difference between total and that in the presence of BG).

Our ultimate objective is to quantify AGT in tumor cells, and therefore it is imperative to demonstrate that labeled BG analogues bind to tumor cells proportionate to their AGT content. To investigate this, the specific binding of [^{131}I]IBG to two cell lines that are known to contain AGT was determined as a function of cell density. As shown in Figure 1, the specific binding of [^{131}I]IBG increased as a function of cell density in both cases, and although only three cell densities were studied in this preliminary experiment, no saturation of binding was observed. A good correlation was seen between the tracer uptake and cell density with each cell line; the r^2 values were 0.88 and 1.00 for DAOY and TE-671 cells, respectively. The percent specific binding for DAOY was higher than that for TE-671. Although we did not estimate the AGT content of these cells, typical literature values for DAOY and TE-671 cells are about 350 (*24*) and 100 fmol/mg protein (*25*), respectively. The relative uptake of [^{131}I]-

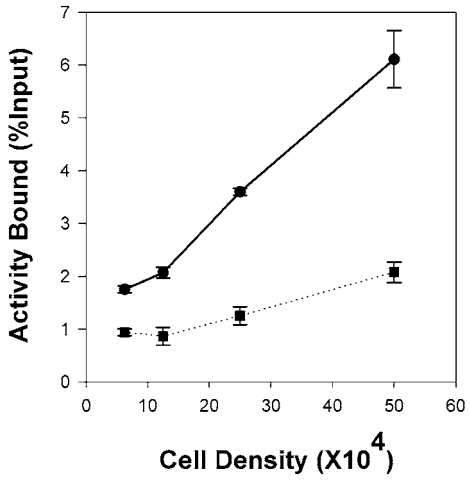

Figure 2. Total (●) and nonspecific binding (■) of [^{131}I]IBG to B4 CHO cells transfected with AGT. Cells were pretreated with 25 μM BG 4 h before adding the tracer to determine the nonspecific binding.

IBG uptake in these two cell lines was reasonably consistent with these values. It should be pointed out that a considerable amount of nonspecific binding (up to 67% of total binding values) was seen with both cell lines at all cell densities.

We also studied the cell-density-dependent uptake of [^{131}I]IBG using a CHO cell line transfected to express AGT. As shown in Figure 2, the cell line B4 demonstrated a linear increase ($r^2 = 1.0$) in cell-bound radioactivity with increasing cell density, and the total-to-nonspecific binding ratios were higher than that seen for DAOY and TE-671 cells.

The nonspecific binding seen in the above assays was rather high. A possible reason for this in the case of DAOY and TE-671 cells may be that the cells were preincubated with 25 μM BG only for 10 min before the addition of the tracer. We chose this time based on the fact that the AGT levels of HT 29 human colon carcinoma cells were reduced to 10% of the original level when incubated for 10 min with 2.5 μM BG (*26*). However, in the case of CHO cells, we did pretreat the cells for 4 h. This was done because a number of studies in the literature have used a 4 h incubation time when determining the potency of newer BG analogues. Even with the 4 h pretreatment, 34−54% of nonspecific binding was observed. Besides the above methodological considerations, the high nonspecific binding also may be due to factors including lipophilicity and metabolic degradation (loss of radionuclide-carrying benzyl group) of [^{131}I]IBG, or binding of [^{131}I]IBG to other proteins. AGT is located in the nuclei of the cells (*27*, *28*) and it is necessary that the labeled BG analogues reach the nuclei intact before it can react with the AGT. Thus, cellular transport may be another factor. Cellular transport of oligodeoxynucleotides has been shown to be a major obstacle for their inhibition of telomerase activity (*29*). Also, 8-[^{3}H]-O^6-benzylguanine was more rapidly distributed to the tumor in vivo when administered in a poly(ethylene glycol) vehicle than in Cremophor-EL (*30*). It has been suggested that the ability of BG analogues to react with AGT in cells may be influenced by their ability to pass through cell membranes and on their metabolism (*31*). If this process plays the primary role in determining cell uptake and retention of IBG analogues, then it may be difficult to use these molecules for measuring AGT in tumor cells. On the other hand, it may be possible to achieve higher specific binding by modifying the structure of labeled BG analogues in such a way that they will be less lipophilic and less susceptible to metabolism. The N^9-position of BG is a potentially valuable site for such modifications (*31*, *32*).

Table 1. Tissue Distribution of ^{131}I in Nude Mice Hosting TE-671 Human Rhabdomyosarcoma Xenografts after Administration of nca [^{131}I]IBG

	%ID/g (mean ± SD; $n = 5$)			
tissue	0.5 h (−IBG)	0.5 h (+IBG)	2 h	4 h
liver	5.80 ± 2.48	9.54 ± 1.67[b]	2.17 ± 0.73	2.37 ± 0.87
spleen	1.86 ± 0.42	2.46 ± 0.90	1.02 ± 0.31	0.85 ± 0.21
lungs	4.44 ± 0.88	2.76 ± 1.37[b]	2.17 ± 1.09	2.34 ± 0.35
heart	1.42 ± 0.23	4.04 ± 1.40[b]	0.56 ± 0.17	0.66 ± 0.25
kidneys	2.24 ± 0.34	5.90 ± 1.53[b]	0.87 ± 0.20	0.82 ± 0.25
stomach	18.29 ± 5.36	12.78 ± 4.36	6.65 ± 2.76	16.23 ± 4.23
sm. int.	18.67 ± 3.05	20.48 ± 1.39	3.19 ± 0.90	2.56 ± 1.11
lg. int.	1.51 ± 0.23	3.16 ± 0.60[b]	26.03 ± 2.18	18.96 ± 2.59
thyroid[a]	0.60 ± 0.12	0.18 ± 0.03[b]	1.66 ± 0.45	2.16 ± 0.77
muscle	0.65 ± 0.14	1.35 ± 0.43	0.26 ± 0.08	0.29 ± 0.08
blood	2.72 ± 0.40	2.81 ± 0.59	1.13 ± 0.45	1.20 ± 0.35
tumor	**1.38 ± 0.34**	**1.94 ± 0.39**[b]	**0.47 ± 0.14**	**0.73 ± 0.57**

[a] %ID/organ. [b] Difference between the values at 0.5 h for pretreated and nonpretreated groups are statistically significant ($p < 0.05$).

Yet another reason for the observed higher nonspecific binding in the case of CHO cells might be the incomplete inhibition of AGT as a result of faster cell growth especially because an incubation time of 4 h was used. A doubling time of 19 h has been reported for a CHO line transfected with pSV2dhfr plasmid (*33*). We obtained a doubling time of 14 h for the B4-CHO cells used in our study following a protocol similar to that utilized by the above authors. Thus, it is unlikely that the cells must have multiplied to a considerable degree during this incubation period. On the other hand, the cells may not divide normally when AGT is inhibited. At a concentration of 100 μM, BG is known to arrest 70% of CHO cells in G_1 phase of the cell cycle (*34*). In our laboratories, various cells were routinely maintained at 10 μM BG, and no such effect was seen (unpublished results). A study using P19 embryonic carcinoma cells has shown that their growth and differentiation is not affected by BG at concentrations of 5 and 10 μM whereas slight effects were seen (decrease of <5% of control) at concentrations of 25 μM; significant effects were seen only at 100 μM of BG (*35*).

Then again, the higher nonspecific binding may be simply due to the fact that the concentration of BG (25 μM) that was used to deplete AGT was insufficient, especially at the higher cell densities. While IC_{50} values to deplete AGT from CHO cells were 50 nM and 15 nM for FBG and IBG, respectively, the concentration of IBG and FBG necessary to reduce the binding of their respective labeled derivatives to pure AGT to 50% of control values was in the micromolar range (*18*). Although the IC_{50} values for depleting AGT by BG decreases in the order of pure AGT, cell-free extracts, and intact cells (*31*), it is necessary to establish the concentration of BG needed to reduce the binding of labeled BG derivatives to AGT present in intact cells to a nonspecific level for each individual cell line. This work is currently in progress.

The biodistribution of [^{131}I]IBG was first measured after iv administration in athymic mice bearing subcutaneous TE-671 rhabdomyosarcoma xenografts, and the results are summarized in the Table 1. The distribution pattern in tumor and normal tissues was somewhat similar to that reported for 8-[^{3}H]-O^6-benzylguanine (8-[^{3}H]BG) in athymic mice bearing D456 MG human

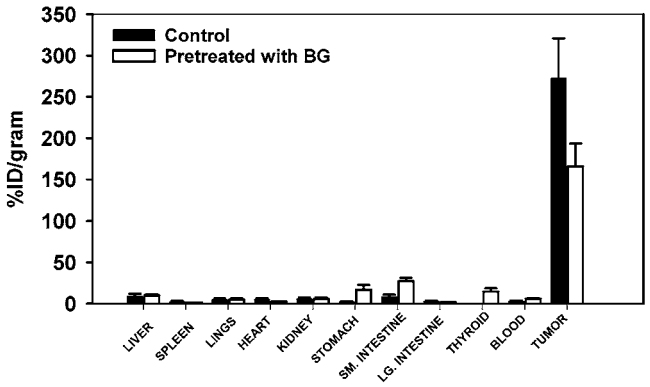

Figure 3. Radioiodine uptake in tumor and selected tissues 0.5 h after intratumoral injection of [^{131}I]IBG in athymic mice hosting TE-671 rhabdomyosarcoma xenografts ($n = 5$).

glioblastoma multiforme xenografts and that for [^{14}C]-O^6-benzyl-*N*-acetylguanosine ([^{14}C]BNAG; label at the benzylic carbon) in nude mice bearing M4Beu human melanoma xenografts (*30*, *36*). A majority of the activity was cleared rapidly via urine. Tumor uptake was 1.38 ± 0.34% ID/g at 0.5 h and decreased at 2 and 4 h. Preadministration of unlabeled IBG 30 min prior to the labeled molecule increased the uptake of radioiodine at 0.5 h postinjection not only in tumor but also in a number of other normal tissues. Notable exceptions were thyroid ($p < 0.05$), lung ($p < 0.05$), and stomach. We speculate that the increase in the uptake in some tissues when unlabeled IBG was preadministered may be due to two processes. First, a higher concentration of IBG may enhance transfer of label to AGT, as the transfer of alkyl groups to AGT follows a second-order kinetics (*37*, *38*). Substantially higher concentrations of unlabeled IBG may be needed to have saturation effects. Second, the presence of unlabeled IBG decreased the rate of dehalogenation of the labeled IBG as reflected in the lower uptake of radioactivity in thyroid and stomach. High uptake of activity in normal tissues, especially liver and intestine, is not surprising due to the fact that a number of human, rat, and mouse tissues including liver and intestines contain a significant amount of AGT (*39*). Other labeled BG derivatives whose biodistribution has been studied also have exhibited relatively high uptake in normal tissues such as the liver and intestines. For example, in mice bearing D456 MG tumors, the hepatic and intestinal uptake of 8-[^{3}H]-BG at 1 h postinjection was about 8% ID/g compared to about 2% ID/g in tumor (*30*). Relatively high uptake in the gastrointestinal tract for [^{14}C]BNAG also has been reported (*36*). Caution should be exercised, however, in comparing our data with these because the label was in the guanine skeleton in 8-[^{3}H]BG and, unlike BG, BNAG is not a free base.

Although the tumor uptake of [^{131}I]IBG was lower than that observed in several normal tissues (particularly those that contain significant levels of AGT), this may not interfere with the intended application of this tracer if a correlation can be obtained between the tumor AGT content and the magnitude of tumor uptake. Our goal is not to develop an imaging agent for tumor identification but rather to quantify AGT levels present in tumors whose anatomic location is known by other means. For comparison, it should be noted that the tumor uptake reported in rats and mice for agents used in the functional imaging of P-glycoprotein (P-gp), a transmembrane pump responsible for multidrug resistance, is generally less than 1% ID/g. For example, the uptake of [^{99m}Tc]-sestamibi in P-gp-lacking MDA 435 and the drug-resistant MDA/T03 human breast carcinoma xeografts in mice was 0.80 ± 0.21% ID/g and 0.30 ± 0.07% ID/g, respectively, at 15 min postinjection of the tracer (*40*). Similarly, the tumor uptake in the Mat B rat breast carcinoma xenograft and in its drug resistant Adr^R xenograft implanted in the same rat was 0.40 ± 0.08% ID/g and 0.28 ± 0.01% ID/g, respectively (*41*). Thus, the modest tumor uptake of [^{131}I]IBG after intravenous injection, while not ideal, may not prohibit its use for its intended purpose.

Another biodistribution study was performed after administration of [^{131}I]IBG via intratumoral injection. Intratumoral administration was performed in order to minimize potential problems related to tumor blood flow, transmembrane transport, and tumor morphology in the delivery and retention of labeled BG analogues. Although a tracer that requires delivery to the tumor, via i.t. administration, is not useful for clinical applications, the purpose of the i.t. experiment was to investigate the effect of BG under conditions where tracer delivery issues were excluded. Figure 3 shows the %ID/g values for tumor and a number of normal tissues in both control and BG-treated mice 0.5 h after injecting the tracer. The tumor uptake of [^{131}I]IBG in BG-treated mice (165.8 ± 27.5% ID/g; 60% of control) was significantly lower than that of the control mice (272.4 ± 48.2% ID/g; $p < 0.05$). SDS PAGE was performed on tumor removed from these animals. A band corresponding to AGT was seen in the mice not receiving the blocking dose of BG, while this band was absent in sample obtained from BG-treated

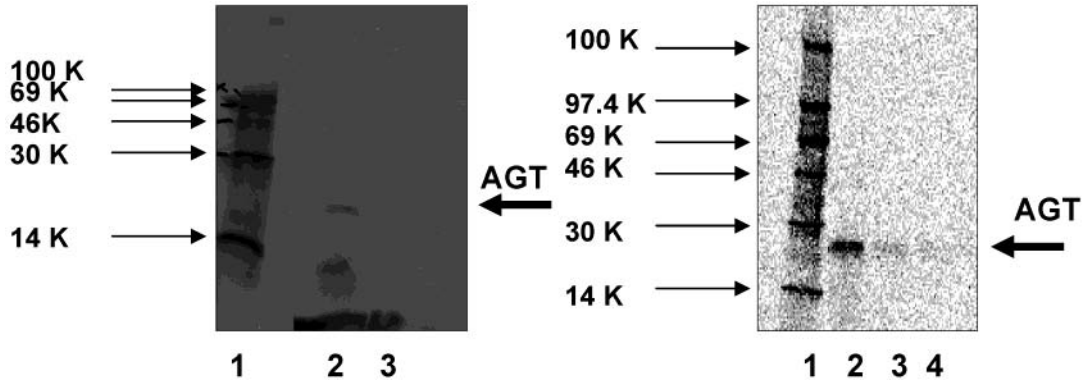

Figure 4. Left panel: Gel electrophoresis of tumor samples obtained from mice 0.5 h after receiving [^{131}I]IBG via intratumoral injection. Lane 1: C-14 protein standards; Lane 2: Sample obtained from control mice; Lane 3: Sample from mice pretreated with BG. Right panel: Lane 1: C-14 protein standards; Lane 2−4: pure AGT labeled with [^{125}I]IBG and serially diluted. Note that electrophoresis conditions (gel gradient) are different from those used to obtain data in the left panel; also, phosphor imaging (versus regular film for the data in left panel) was used to visualize the bands.

mice (Figure 4). Although this was a very preliminary experiment, the results suggest that it may be possible to differentiate between tumors with high and low AGT content in vivo. Unlike the iv injection experiment, BG treatment increased the uptake in thyroid and stomach in addition to lowering tumor uptake. The higher uptake in stomach and thyroid could be due to greater leakage of the tracer into the remainder of the body. In the iv injection experiment, like the tracer, the unlabled IBG also was injected intravenously and at a much lower dose than the dose of BG used in i.t. experiment. That IBG dose was chosen roughly based on its IC_{50} value determined from the binding of [^{131}I]IBG to pure AGT (*18*). As discussed before, it appears that substantially higher doses are needed to deplete AGT completely. In the intratumoral injection experiment, BG was administered i.p. at 60−75 mg/kg dose. This was based on the fact that BG at this dose depletes AGT in HT29 xenografts to less than 2% of untreated controls (*42*).

In summary, a method has been developed by which [^{131}I]IBG could be prepared in a single step rapidly (<1 min) and in excellent radiochemical yields. Although the uptake in tumor cells in vitro and in xenografts in vivo after intratumoral administration suggests that [^{131}I]IBG may be potentially useful in quantitating AGT, a tracer with more optimal properties is desired. Efforts are under way to develop other analogues of BG that may be less lipophilic, more metabolically stable, and that can be translocated to the nucleus.

ACKNOWLEDGMENT

Silicon Nanoparticles as a Luminescent Label to DNA

L. Wang,* V. Reipa, and J. Blasic

Biotechnology Division, National Institute of Standards and Technology, Gaithersburg, Maryland 20899-8312.
Received October 28, 2003; Revised Manuscript Received December 26, 2003

We successfully conjugated 1−2 nm diameter silicon nanoparticles to a 5′-amino-modified oligonucleotide (60mer) that contains a C6 linker between amide and phosphate groups. The conjugation was implemented via two photoinduced reactions followed by a DNA labeling step through formation of a carboxamide bond. Photoluminescence of the conjugates is dominated by two blue bands (400 and 450 nm maximal) under 340 nm excitation. The quantum yield of oligonucleotide-conjugated nanoparticles was determined to be 0.08 as measured against quinine sulfate in 0.1 M $HClO_4$ as a reference standard. We report a conjugation process that allows labeling of Si nanoparticles to an oligonucleotide in aqueous solutions. Ways to further optimize the procedure in order to achieve narrower and brighter photoluminescence are discussed.

INTRODUCTION

The rapid development of pharmacogenomic research and drug discovery, diagnostics of infectious and genetic disease, and methodologies for forensic and genetic identification has stimulated the search for novel fluorophores. Recently, binary semiconductor quantum dots have been demonstrated to possess certain advantages over organic fluorophores (*1*). However, their inherent toxicity and chemical instability require polymer encapsulation before the bioconjugation step (*2*). Si nanoparticles (*3*) have been shown to have similar room-temperature photoluminescence quantum yields, but higher chemical stability, thus making them attractive for bioconjugation.

The surface chemistry of silicon is still a very active field despite the ubiquitous presence of silicon in microelectronics since the 1960s (*4*). The growing interest is partly attributed to novel applications of silicon chips, which require fine controls over the interfacial characteristics. Recently, silicon nanoparticles with discrete sizes and distinct emission in the blue, green, and red were produced by using anodic etching in hydrofluoric acid (*3*). Similar to binary semiconductor nanocrystals (*5*), Si nanoparticles display a relatively narrow emission and high quantum efficiency.

Several studies have been published, aiming at functionalizing bulk Si surfaces for biomolecule attachment (*6*−*9*). Wagner and co-workers (*6*) produced bioreactive self-assembled monolayers on hydrogen-passivated Si(111) as atomically flat substrates for biological scanning probe microscopy. Wojtyk et al. (*9*) also reported the formation of activated ester monolayers on porous silicon surfaces that could be readily attached to biomolecules. The present study is intended for conjugating individual Si nanoparticles suspended in an organic medium to an oligonucleotide in water through chemical derivatization of the nanoparticle outer layer. We have characterized the nanoparticle-labeled nucleotide in terms of the overall size, absorbance, and luminescence quantum yield.

MATERIALS AND METHODS

Si nanoparticles were produced using lateral electrochemical anodization (*10*). (100) Si wafer (p-type, B doped, resistance $R = 2$ to 10 Ω, Virginia Semiconductor, VA)[1] was cut into 5 cm × 5 cm pieces and etched in (vol) 20% HF, 60% H_2O_2, 20% ethanol bath at room temperature. A constant current of 50 mA was maintained by a galvanostat while the etching solution was slowly pumped into the cell. Electrical contact to the substrate was provided by InGa eutectic, and Pt mesh served as a cathode. A 100 W halogen lamp illuminated both wafer sides in the procedure. Total etching time per wafer was 30 min. Following etching, wafers were flushed with ethanol and dried in the Ar stream. They were immediately placed in Ar purged 1-octene (or 1-hexene) and sonicated for 1 h in an ultrasound bath (model SC507H, Sonicor Inc., Copiaque, NY). After centrifugation to remove aggregates, the nanoparticles in supernatant were illuminated by 236 nm light (Spectroline, ENF-240C) in a 10 mL quartz cell for 2 h while maintaining a vigorous Ar purge. The residual solvent was evaporated under the Ar flow, resulting in dry 1-octene (or 1-hexene) monolayer-coated Si particles.

Activation was carried out by adding 0.2 mL of a 15 mM solution of 4′-[3-(trifluoromethyl-3*H*-diazirin-3-yl)]-benzoic acid, *N*-hydroxysuccinimide ester (TDBA-OSu) [Photoprobes, Industrie Nord, Switzerland] in anhydrous carbon tetrachloride to dried silicon particles and immediately illuminating with a 365 nm lamp (Spectroline, ENF-240C) for 15 min under vigorous magnetic stirring to ensure uniform illumination. After the reaction, carbon tetrachloride was evaporated using an Ar stream. The dried, activated silicon nanoparticles were dissolved in 15 μL of anhydrous DMSO and slowly added to 0.5 mL of the 5′-amino-modified oligonucleotide solution (2 μg/mL) in water. The 5′ amino-modified oligonucleotide (60mer) was obtained from Qiagen (Valencia, CA, se-

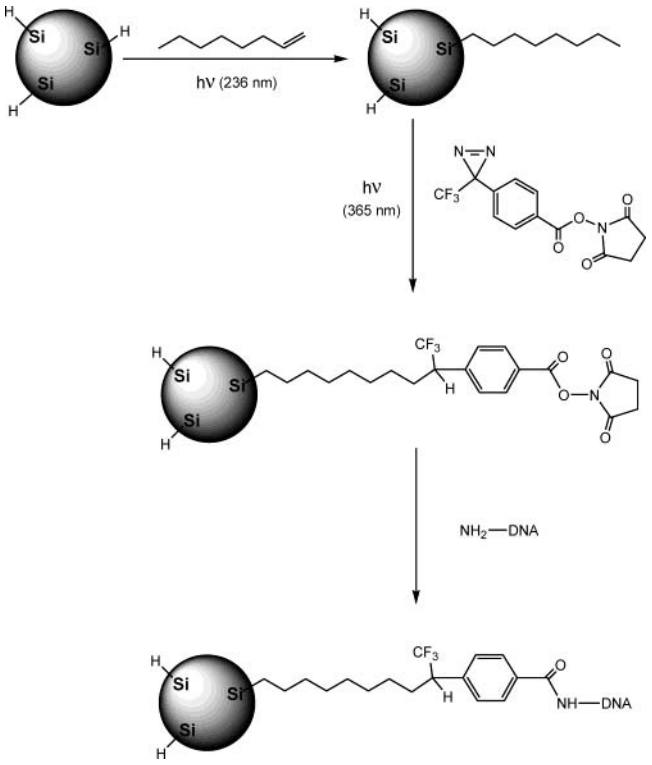

Figure 1. A reaction diagram displaying the three steps used to produce oligonucleotide-conjugated Si nanoparticles by using single-surface Si−H bond and 1-octene as an example. In this case, carbene addition at the terminal methyl group is the main outcome of the reaction between the 1-octene-coated nanoparticle and the cross-linker, TDBA-OSu.

quence: 5′-TTAAAAGAGAACTCCAGCTTGGACTTCT-TTCCGTAGTCGACAGAGAGCCTCTCCATCAGC-3′) and contained a C6 linker between amide and phosphate groups at the 5′ end. This sequence is part of the rat tubulin gene. The reaction was carried out in the dark for 1 h with magnetic stirring. The total volume was then decreased to ∼20 μL by vacuum centrifugation before purification by electrophoresis in 18% polyacrylamide gel with TBE (90 mM Tris, 90 mM boric acid, 2 mM EDTA) as the running buffer and the voltage set at 115 V for 40 min. A 10 bp DNA ladder from Invitrogen Corporation (Carlsbad, CA) was used to examine the equivalence in the size of Si nanoparticle-labeled oligonucleotide relative to double-stranded DNA. The labeled nucleotide was recovered from polyacrylamide gel using Ultrafree-MC centrifugal filter devices (Durapore 0.22 μm, Millipore Corporation Bedford, MA). The hybridization between the gel-purified nanoparticle-labeled nucleotide and the complementary strand was performed in 100 mM Tris-HCl, 1 mM EDTA, pH 7.5, using the following protocol: 95 °C for 30 s, then decreasing the temperature to 60 °C at the rate of 0.2 °C/s, incubation for 30 s at 60 °C and then lowering the temperature to 4 °C. The complementary strand was also obtained from Qiagen with the sequence, 5′-GCTGATGGAGAGGCTCTCTGTCGACTA-CGGAAAGAAGTCCAAGCTGGAGTTCTCTTTTAA-3′.

RESULTS AND DISCUSSION

The multiple chemical steps for obtaining oligonucleotide-conjugated Si nanoparticles are illustrated in Figure 1. Under 236 nm illumination in 1-octene (or 1-hexene), hydrogen-passivated silicon particles attained from electrochemical etching are coated with a layer of 1-octene (or 1-hexene). The reaction is driven by formation of free radicals that interact with 1-octene to generate Si−C bonds (*11*−*13*). In the following step, TDBA-OSu, a photoactivatable aryldiazirine cross-linker, is inserted into the C−H bonds of the CH_2 groups within the hydrocarbon chain through a highly reactive carbene intermediate under 365 nm illumination in dry carbon tetrachloride (*14*, *15*). The report by Nassal (*14*) has demonstrated that under the radiation of high pressure mercury lamp the singlet carbene can react even with cyclohexane that is considered as an inert solvent. The author carefully characterized the photolysis products with cyclohexane in the presence and absence of oxygen. While purging argon prior to photolysis, the relative yield of carbene addition product is as high as 73% in addition to byproducts from the reaction of triplet carbene with residual oxygen. On the other hand, Cicero and co-

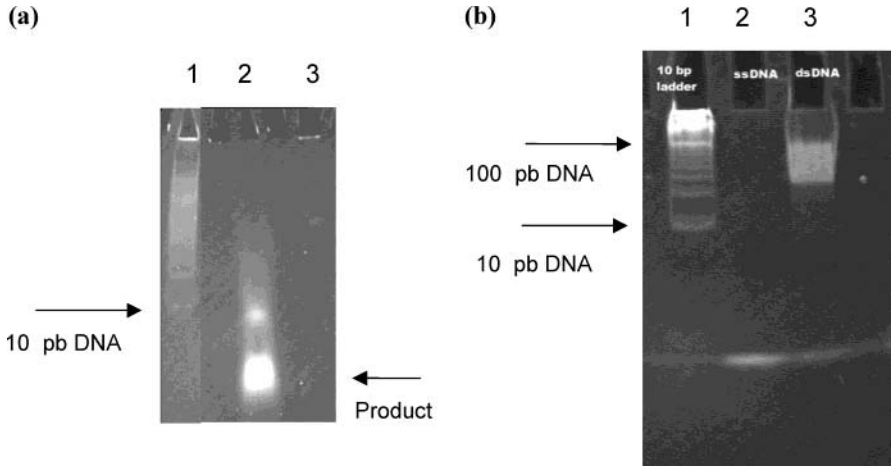

Figure 2. (a) Polyacrylamide gel electrophoresis of the products of the labeling reaction (Figure 1) in the presence (lane 2) and absence (lane 3) of TDBA-OSu as well as the 10 bp DNA ladder (lane 1). The gel portion with the DNA ladder was stained with ethidium bromide (5 μg/mL in TBE). The brightly luminescent band (the first band) in lane 2 is from nanoparticle-labeled oligonucleotide (the main product), which was cut and extracted for the spectral characterization and hybridization with the complementary strand. No luminescent product was detected for the labeling reaction in the absence of TDBA-OSu. (b) Polyacrylamide gel electrophoresis of gel-purified silicon nanoparticle-labeled oligonucleotide (lane 2) and its hybridization product with the complementary strand (lane 3) as well as the 10 bp DNA ladder (lane 1). The gel was stained with ethidium bromide in order to examine the positions of Si nanoparticle-labeled oligonucleotide and the hybridization product relative to double-stranded DNA. The band of the labeled nucleotide is below that of 10 bp DNA, and the band of the hybridization product is located near the 60mer, double-stranded DNA.

workers (*13*) demonstrated that in the absence of oxygen, 1-octene could form a compact monolayer on the surface of hydrogen-terminated silicon(111) just alike 1-octadecene. In our case, since C6 hydrocarbon chains surrounding the nanoparticles might not form an ordered monolayer like C8 hydrocarbon chains the carbene addition could take place at multiple CH_2 sites within the C6 carbon chain. However, we anticipate the insertion yields at sites closer to the surface of the particle are much lower than those at sites away from the surface of the particle because of the spatial hindrance of the sites near particle surface. As suggested by Nassal (*14*), the reactions by triplet carbene will not involve the silicon particles. The CH insertion at the terminal methyl group will likely be the main product, particularly in the case of C8 hydrocarbon chain-coated particles shown in Figure 1 as an example of the outcomes by the reactive singlet carbene. Additional control experiments were carried out to compare the results in the presence and absence of the photoactivatable aryldiazirine cross-linker, TDBA-OSu. Figure 2a shows the products of the labeling reactions with TDBA-OSu (lane 2) and without the reagent (lane 3) as well as a 10 bp DNA ladder (lane 1). The bright, intrinsic luminescent band in lane 2 (the first band) is from silicon nanoparticle-labeled oligonucleotide. In the absence of the cross-linker, the labeling reaction was not successful (lane 3). Only the gel piece with DNA ladder was stained with ethidium bromide (EtBr). The control experiment clearly shows the importance of the photoactivatable cross-linker. The photoinduced reaction generates amino-reactive *N*-succinimidyl groups on the outer layer of the particles, which are used to immobilize the amino-modified oligonucleotide in the final step. Note that it is critically important to dissolve TDBA-OSu-activated particles in dry DMSO prior to the immobilization of the nucleotide. Without such step we were unable to produce nucleotide-conjugated nanoparticles.

Figure 2b shows polyacrylamide gel electrophoresis of purified silicon nanoparticle-labeled 60mer oligonucleotides (lane 2) and their hybridization products with the complementary strand (lane 3) as well as the 10 bp DNA ladder (lane 1). The band of the labeled nucleotides and the hybridization products can be visualized under a UV lamp. The gel was stained with ethidium bromide (EtBr), and a transilluminator equipped with a UV lamp centered at 302 nm and a band-pass filter for EtBr detection was used to image the gel. This allows visualizing the DNA ladder and more importantly, confirming the existence of the hybridization products. The single-stranded 60mer oligonucleotide as a control runs out the gel in the time setting for the electrophoresis (40 min). Considering the diameter of B-form double-stranded DNA is about 2 nm, it is reasonable to estimate the diameter of Si nanoparticle conjugated to the 60mer oligonucleotide to be smaller than 2 nm. The diameter and mass of Si-nanoparticle resulted in the running location of labeled nucleotide in the polyacrylamide gel. The band of the hybridization products is somewhat spread out. This observation clearly shows that Si nanoparticles are conjugated to the 60mer oligonucleotide. The band at the same running position (lane 3) as that of Si nanoparticles (lane 2) is mostly due to the unhybridized particles. An additional experimental control in the absence of the 5′-amino-modified oligonucleotide in the final immobilization step (Figure 1) did not produce a detectable band at this position.

The absorption spectrum of the purified nucleotide is shown in Figure 3a. Absorbance above 300 nm is due to Si nanoparticles, while below 290 nm it can be attributed

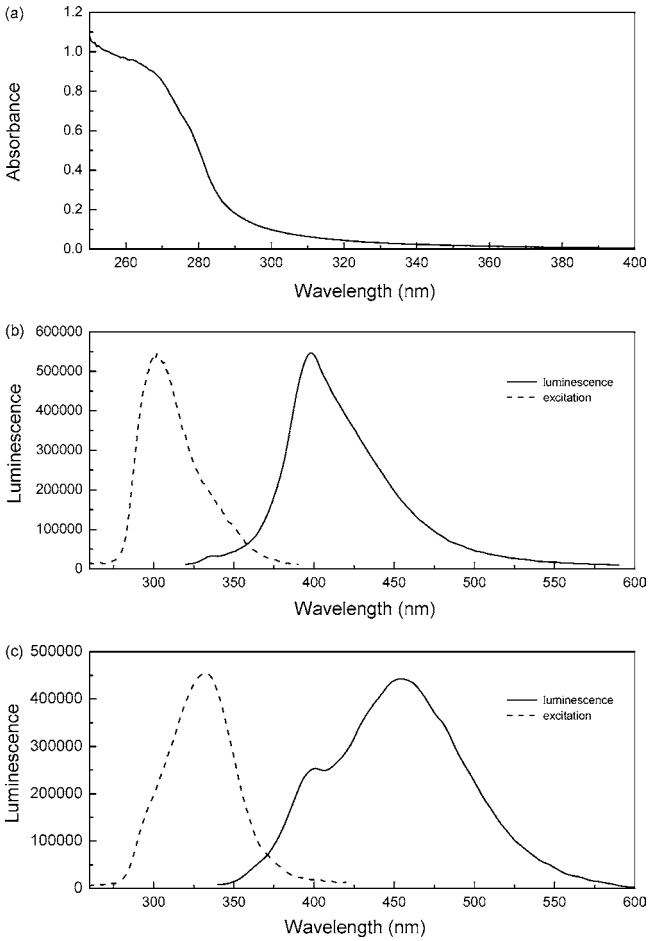

Figure 3. Spectroscopic characterization of purified oligonucleotide-conjugated Si nanoparticles: (a) absorbance; (b) excitation spectrum with luminescence monitored at 400 nm (dash line) and emission spectrum under 300 nm excitation (solid line), 1-hexene used in the first step; (c) excitation spectrum with luminescence monitored at 450 nm (dash line) and emission spectrum under 330 nm excitation (solid line), 1-octene used in the first step (see text).

to both DNA and nanoparticles. Figure 3b shows the excitation and photoluminescence spectra of the labeled nucleotides coated with a layer of 1-hexene. The excitation profile was recorded with photoluminescence fixed at 400 nm, and the emission spectrum was obtained with the excitation wavelength set at 300 nm. The excitation spectrum is peaked at 300 nm and luminescence spectrum contains a peak at 400 nm with a shoulder above 440 nm. When 1-octene is used instead of 1-hexene, both excitation and luminescence peaks shift to 332 and 450 nm, respectively (Figure 3c). Interestingly, the 400 nm emission peak is clearly resolved from the dominant peak at 450 nm. It may be that Si nanoparticles with two discrete sizes are present. According to Belomoin and coworkers (*16*), the emission at 400 and 450 nm is characteristic to ∼1 nm and ∼1.2 nm Si particles based on high-resolution transmission electron microscopy measurements. It is worthy to mention that the diluted nucleotide-conjugated Si nanoparticles are stable in aqueous solutions at least a week without deterioration in the luminescence.

We determined the photoluminescence quantum yield of nucleotide-conjugated Si nanoparticles, using quinine sulfate in 0.1 M $HClO_4$ as a reference standard (*17*). The quantum yields are 0.08 ± 0.002 (standard deviation) and 0.05 ± 0.003 for 1-octene- and 1-hexene-coated nanoparticles, respectively. Since a homogeneous nanoparticle

preparation would be expected to have about 20 nm to 30 nm photoluminescence bandwidth (*5*), our conjugates suggest moderate size inhomogeneity; therefore, size exclusion chromatography separation would be justified in addition to ultracentrifugation prior to 1-alkene monolayer binding. Moreover, the use of a longer carbon chain would be expected to provide a better-ordered self-assembled monolayer (SAM), thus lowering nonradiative recombination channel concentration and increasing photoluminescence quantum yield.

CONCLUSIONS

A key requirement for the effective use of Si nanoparticles in biological applications is aqueous solubility. In the present study, we successfully conjugated 1−2 nm diameter silicon nanoparticles to a 5′-amino-modified oligonucleotide through a three-step procedure. Under UV excitation, photoluminescence of the conjugates is dominated by two blue bands (400 and 450 nm maximal). The quantum yield of oligonucleotide-conjugated nanoparticles that were coated with a layer of 1-octene was determined to be 0.08 as measured against quinine sulfate in 0.1 M $HClO_4$ as a reference standard. We have demonstrated the feasibility of the present coupling chemistry to obtain Si nanoparticle-labeled nucleotides. Ways to reduce size inhomogeneity and surface defects of Si nanoparticles in order to achieve narrower and brighter photoluminescence will be addressed in further studies.

AMD3100 Conjugates as Components of Targeted Nonviral Gene Delivery Systems: Synthesis and in Vitro Transfection Efficiency of CXCR4-Expressing Cells

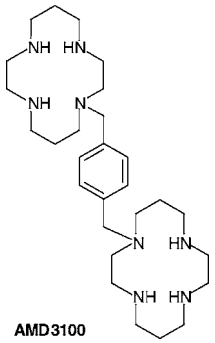
Bertrand Le Bon,[†] Nathalie Van Craynest,[†] Jean-Michel Daoudi,[†] Christophe Di Giorgio,[†] Abraham J. Domb,[‡] and Pierre Vierling*[,†]

Laboratoire de Chimie Bioorganique, UMR 6001 CNRS, Faculté des Sciences, Université de Nice-Sophia Antipolis, 06108 Nice Cédex 2, France, and Department of Medicinal Chemistry and Natural Products, School of Pharmacy, Faculty of Medicine, The Hebrew University, Jerusalem 91120, Israel. Received December 5, 2003

We describe the synthesis of a series of AMD3100−lipid and AMD3100−polycationic conjugates which were used as components of targeted lipoplexes (in conjunction with (poly)cationic lipids) and polyplexes, respectively, for mediating specific gene transfer into cells expressing CXCR4 which displays a high affinity for AMD3100. Transfection studies were investigated with suspension CXCR4(+) human lymphoma Jurkat cells and with adherent CXCR4(−) human glioblastoma T98G and human lung carcinoma A549 cells lines in order to demonstrate a receptor-mediated endocytosis pathway and to minimize nonspecific transfection pathways. Altogether, our results show that polyplexes formulated with AMD-labeled polymers constitute, under certain conditions, specific gene transfer systems into suspension CXCR4(+) Jurkat cells. This is more particularly the case when the nonspecific transfection pathways are minimized (i.e. for $N/P \leq 2.5$ AMD-labeled polyplexes) and in the presence of phorbol myristate acetate which triggers CXCR4 receptor endocytosis of the AMD-labeled polyplexes to a larger extent than that of their respective nonlabeled ones. Although encouraging, the transfection specificities and efficiencies obtained with these compounds should however be improved. This study also illustrates the difficulties to demonstrate and to obtain a specific and efficient gene transfer system with cationized ligand-labeled DNA particles which also provide receptor-independent nonspecific gene transfer to cells, and more particularly to adherent cells.

INTRODUCTION

The specific and efficient delivery of therapeutic genes into targeted cells such as cancer or virus-infected cells is one of the important goals in gene therapy. To increase DNA uptake by cells, viral and nonviral vehicles have been developed. To trigger receptor-mediated gene delivery and to increase cell and tissue DNA uptake specificity, various cell targeting ligands (for a recent review see ref 1)), including RGD peptides (*2*), folate (*3*, *4*), transferrin (*5*), saccharides (*6*, *7*), or antibodies (*7*), were conjugated to the DNA vectors. As part of our contribution into this field, we elaborated novel AMD3100-lipid and polycationic conjugates as targeting components of nonviral DNA vectors (lipoplexes or polyplexes) for specific gene transfer into CXCR4(+) cells. AMD3100 (Figure 1) is one of the rare nonpeptidic and small synthetic molecules that binds with a high affinity and selectivity to CXCR4 thus blocking HIV entry into T-lymphocytes (*8*−*12*). The CXCR4 chemokine receptor is indeed the coreceptor used by HIV-1 X4 strains for infecting T-lymphocytes which are one of the predominant cell HIV reservoirs (*13*−*15*). CXCR4 plays an important role not only in HIV progression but also in chemotactic T-cell responses and in T-lymphocyte recruitment at sites of inflammation (*16*). CXCR4 has been recently described as one of the overexpressed receptors on glioblastoma tumors (*17*−*23*). CXCR4 appears also to play a central role in breast carcinoma metastasis (*24*).



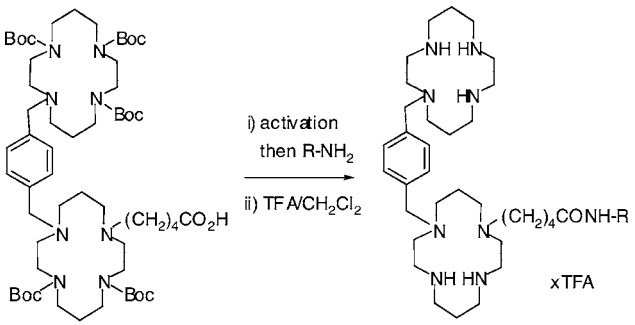


Figure 1. Chemical structure of AMD3100 (*8*).

In an effort to address a specific gene delivery toward CXCR4-expressing tumors and T-lymphocytes, we report herein on (i) the synthesis of the AMD3100-lipid and AMD3100-polycationic conjugates (derivatives DC18-[NH]-[AMD], PEI-[AMD]*p*, or ^{i}Bu[NH_2]-80-[AMD]4 in Figure 2, respectively), and (ii) our in vitro attempts to transfect Jurkat cells, a CXCR4(+) human cell line grown in suspension, via a receptor-mediated endocytosis pathway with AMD3100-labeled DNA complexes. However, cationized DNA particles can also provide receptor-independent gene transfer to cells, owing to electrostatic interactions with anionic proteins which might be expressed on their cell surface (*25*, *26*). Therefore, we also report on the ability of AMD3100-labeled lipoplexes and polyplexes to mediate, in vitro, a nonspecific gene transfer into adherent CXCR4(−) A549 and T98G cells. Indeed,

adherent cells are easier to transfect nonspecifically than cells grown in suspension. This is likely due to overexpression of anionic proteoglycans on the surface of adherent cells (*25*, *26*) and to sedimentation of the DNA complexes onto the adherent cell monolayer recovering the well bottom. This study was aimed at optimizing the conditions under which a specific gene transfer into suspension CXCR4(+) Jurkat cells could more likely be evidenced by minimizing the nonspecific transfection pathways. The AMD3100-labeled lipoplexes and polyplexes were formulated with the DC18-[NH]-[AMD] conjugate and well-documented (poly)cationic lipids (i.e. DOTAP (*27*), DOGS (*28*), or DC18-[NH_2]20 (*29*)), and with the AMD3100-labeled polycationic polymers shown in Figure 2, respectively. With the aim at demonstrating a specific receptor-mediated transfection process, all these assays were performed in the absence or presence of an excess of "free" AMD3100 as CXCR4 antagonist. These additional control experiments were also intended to highlight the effects of AMD3100 (i) on the nonspecific transfection of control CXCR4(−) cells with AMD3100-labeled DNA complexes, and (ii) on the specific transfection of CXCR4(+) cells with control nonlabeled DNA complexes. Indeed, AMD3100 is an octaamine that might coat onto the DNA complexes and/or adsorp onto the cells and, consequently, it can then take part in both these transfection processes. In the case of the CXCR4(+) Jurkat cells, transfection experiments were also performed in the absence or presence of phorbol myristate acetate (PMA) which was shown to enhance the transfection of these suspension cells (*30*) and to trigger CXCR4 receptor endocytosis (*31*), even in the presence of AMD3100 (*32*).

MATERIALS AND METHODS

General Experimental and Analytical Conditions. All the reactions were performed in anhydrous solvents under dry and oxygen-free nitrogen. The purifications by column chromatography were carried out using silica gel 60 (Merck, 70−230 mesh) and chloroform ($CHCl_3$), dichloromethane (CH_2Cl_2), methanol (MeOH), or mixtures thereof as indicated. Purifications by exclusion gel chromatography were performed on Sephadex LH-20 or LH-60 (Fluka, Amersham) in methanol. Advancement of the reactions was followed by thin-layer chromatography (TLC) on silica plates (SDS 60F254, 60/15 μm). The following development systems were used: UV light (254 nm); Draggendorff reagents (Sigma), ninhydrin (Sigma), H_2SO_4, and $KMnO_4$.

DOGS (dioctadecylamidoglycylspermin tetrafluoroacetate) (*28*), DC18-[NH_2], DC18-[NH_2]20 (*29*), ^{i}Bu-[NH_2]-95 (*33*), AMD3100, and Boc-AMD-$(CH_2)_4$COOH (see structure in Figure 2) (*34*) were prepared according to the literature. DOTAP (1,2-dioleoyloxy-3-(trimethylammonio)propane iodide), DOPE (dioleylphosphatidylethanolamine), DCC (dicyclohexylcarbodiimide), NHS (*N*-hydroxysuccinimide, Sigma), HOBt (hydroxybenzotriazole), EDC (*N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide), NEt_3 (triethylamine), and TFA (trifluoroacetic acid) were purchased from Sigma. BOP (benzotriazol-1-yloxytris-(dimethylamino)phosphonium hexafluorophosphate) came from Calbiochem. These chemicals were used without further purifications.

^{1}H, ^{13}C, and ^{19}F NMR spectra were recorded on a Bruker AC-200 at 200, 50.3, and 188.3 MHz, respectively. Chemical shifts (δ) were measured relative to $CHCl_3$ (δ 7.27 ppm) or CH_3OD (δ 3.35 ppm) for ^{1}H, to $CDCl_3$ (δ 76.9 ppm) for ^{13}C and expressed indirectly in relation to TMS, and to CCl_3F as internal reference for ^{19}F. The following abbreviations are used to describe the signal multiplicities: s (singlet), d (doublet), t (triplet), q (quadruplet), and m (multiplet). The signals are listed as follows: δ in ppm (multiplicity, integration, coupling, and attribution). Melting points were measured on a Electrothermal Digital Series 9100 and were not corrected. Mass spectra (MS) were recorded on a Finnigan MAT TSQ 7000 equipped with an atmospheric pressure ionization (API) source. Electrospray ionization mass spectrometry (ESI-MS) was used. This method used in positive mode can give either a $(M + H)^+$ or a $(M + Na)^+$ signal.

Chemistry. *General Boc-Deprotection Procedure.* The *N*-Boc-protected derivatives in 4 mL of anhydrous TFA:CH_2Cl_2 (1:1 v:v) were stirred for 1−5 h at 0 °C and then for a further 4 h period at room temperature until disappearance of the starting material (TLC and/or ^{1}H NMR monitoring). The reaction mixture was then evaporated under reduced pressure, followed by several coevaporations with a CH_2Cl_2:cyclohexane mixture (1:1 v:v), and the crude residue was purified by alumina column chromatography, size exclusion gel column chromatography, or directly lyophilized giving the desired derivatives as TFA salts.

Synthesis of DC18-[NH]-AMD. To a solution of 28 mg (0.03 mmol) of DC18-[NH_2], 36 mg (0.03 mmol) of Boc-AMD-$(CH_2)_4$COOH, and 10 μL (0.07 mmol) of NEt_3 in 2 mL of CH_2Cl_2 at 0 °C was added 16 mg (0.03 mmol) of BOP. The solution was stirred during 4 h at room temperature. After completion of the reaction followed by TLC, the organic phase was washed successively with $NaHCO_3$ (5%), $KHSO_4$ (5%), and water and dried over Na_2SO_4. The solution was then filtered and concentrated under vacuum. The residue was further purified by silica gel column (CH_2Cl_2:MeOH, from 100:0 to 9:1: v/v as eluent) and LH-20 gel permeation chromatography (CH_2Cl_2) to give 44 mg (0.02 mmol 74%) of DC18-[NH]-AMD-(Boc) as a white solid [TLC (CH_2Cl_2:MeOH, 9:1 v:v, ninhydrin): R_f = 0.6; ^{1}H NMR ($CDCl_3$): 0.85 (t, 6H, $^3J_{HH}$ = 6.5 Hz, CH_3); 1.10−1.30 (m, 60H, $(CH_2)_{15}$); 1.30−2.00 (m, 61H, CH_3(Boc), CH_2CH$_2$N and CH_2CH$_2$CO); 2.00−2.70 (m, 20H, CH_2CO and CH_2N); 2.70−2.90 (m, 4H, CH_2S); 3.10−3.60 (m, 28H, CH_2NBoc and CH_2Ph); 6.70−

7.10 (m, 2H, NHCO); 7.15 (s, 4H, Ph); ^{13}C NMR $CDCl_3$): 14.2 (s, CH_3); 22.7 (s, CH_2CH_3); 27.1 and 28.1 (s, CH_2S); 28.4 and 28.5 (s, CH_3(Boc)); 26.9, 27.1,27.8, 29.1, 29.4, 29.5 and 29.7 (s, $(CH_2)_{14}$); 31.9 (s, $CH_2CH_2CH_3$); 33.3 and 36.5 (s, CH_2CO); 39.8 and 40.0 (s, CH_2NH); 46.3 and 48.0 (s, CH_2NCO); 45.0−49.0 and 51.0−56.0 (m, CH_2N et CH_2-NBoc); 59.4 (sl, CH_2Ph); 79.5 and 79.7 (s, C(Boc)); 128.9 (sl, CH_2Ph); 137.2 (sl, C(Ph)); 155.6 (s, CO(Boc)); 170.6 (s, CON); 172.3 and 174.1 (s, CONH); resonances for $CH_2CH_2CH_2CO$ and $CH_2CH_2CH_2N$ could not be detected]. The Boc-deprotection procedure, when applied to 44 mg (0.02 mmol) DC18-[NH]-AMD(Boc), afforded, after purification by alumina column chromatography (eluent CH_2-Cl_2:MeOH from 100:0 to 50:50 v:v) and lyophilization, 21 mg (0.01 mmol, 39%) of DC18-[NH]-AMD as its octa-TFA salt (white solid). ^{1}H NMR ($CDCl_3$): 0.85 (t, 6 H, $^3J_{HH}$ = 6.5 Hz, CH_3); 1.10−1.40 (m, 60H, $(CH_2)_{15}$); 1.40−2.10 (m, 16H, $CH_2CH_2CH_2N$ and $CH_2CH_2CH_2CO$); 2.10−3.10 (m, 44H, CH_2CO, CH_2N and CH_2S); 3.10−3.80 (m, 12H, CH_2-NHCO, CH_2NCO and CH_2Ph); 4.20−4.90 (m, 8H, NH); 7.31 (s, 4H, Ph); 7.65−8.10 (m, 2H, NHCO). ^{13}C NMR ($CDCl_3$): 14.2 (s, CH_3); 22.7 (s, CH_2CH_3); 23.9, 24.7, 24.9, 25.8, 26.6 and 27.3 (s, CH_2CH_2N and $CH_2CH_2CH_2CO$); 27.1 and 28.1 (s, CH_2S); 26.9, 27.4, 27.8, 29.1, 29.4, 29.5 and 29.7 (s, $(CH_2)_{14}$); 31.9 (s, $CH_2CH_2CH_3$); 33.5 (s, CH_2-CO); 36.5 (sl, CH_2CO); 39.4 and 39.8 (s, CH_2NHCO); 46.2 and 48.0 (s, CH_2NCO); 45.5, 46.5, 46.6, 47.6, 48.4, 49.1, 49.5, 49.7, 50.4, 51.5, 51.9 and 52.5 (s, CH_2N); 57.5 and 58.2 (s, CH_2Ph); 129.6 (sl, CH(Ph)); 130.0 (s, CH(Ph)); 136.4, 136.5, 136.7 and 138.3 (s, C(Ph)); 170.7 (s, CON); 171.9 and 172.1 (s, CONH); 174.1 and 174.5 (s, CONH). The CF_3CO_2 resonances could not be located. The doubling of some signals is due to the restricted rotation of the amide bond. ^{19}F NMR (CD_3OD): −76.7 ($CF_3CO_2^-$). ESI-MS: $m/2z$ = 655.5 and m/z =1309.2 in agreement with the mass calculated for $[C_{77}H_{149}N_{11}O_3S + 2H^+]/2$ and $[C_{77}H_{149}N_{11}O_3S + H^+]$, respectively.

Synthesis of ^{i}Bu-[NH_2]80-[AMD]4. A 10 mg (9.0 μmol) amount of Boc-AMD-$(CH_2)_4$COOH, 4.0 mg (9.0 μmol) of BOP, 12.6 μL (90 μmol) of NEt_3, and 10 mg (0.47 μmol) of ^{i}Bu-[NH_2]95 were dissolved in 4 mL of CH_3CN at 0 °C. The solution was stirred overnight at room temperature. The solution was concentrated under vacuum. The resulting residue was washed with Et_2O and purified by gel permeation chromatography using a LH-20 column (MeOH) to give 6.0 mg (0.24 μmol) of compound ^{i}Bu-[NH_2]-*n*-[AMD(Boc)]*p* with n = 80 and p = 4, as a white amorphous solid [^{1}H NMR (CD_3OD):0.74−0.90 (m, 12H, CH_3, ^{i}Bu); 1.00−2.80 [m, 539 (= 3*n* + 73*p* + 7)H, CH_2-CH, CH_2S, CH_2CO, $C(CH_3)_3$, $N(CH_2)_4CO$, NCH_2CH_2-CH_2N, NCH_2CH_2N,]; 2.90−3.70 [m, 420 (= 4*n* + 24*p* + 4)H, CH_2NH]; 7.26 (sl, 16 (= 4*p*)H, Ph) in agreement with n = 80 and p = 4]. The Boc-deprotection procedure, when applied to 6.0 mg (0.24 μmol) of ^{i}Bu-[NH_2]80-[AMD-(Boc)]4, led after purification by LH-20 gel permeation chromatography (MeOH) and lyophilization to 5.9 mg (0.24 μmol) of ^{i}Bu-[NH_2]80-[AMD]4 as a white solid. ^{1}H NMR (CD_3OD): 0.70−0.90 (m, 12H, CH_3 ^{i}Bu); 1.10−2.80 [m, 359 (= 3*n* + 28*p* + 7)H, CH_2CH, CH_2S, CH_2CO, $NCH_2CH_2CH_2N$, $N(CH_2)_4CO$, NCH_2CH_2N]; 2.85−3.70 [m, 420 (= 4*n* + 24*p* + 4)H, CH_2NH_2, CH_2Ph]; 7.34 (m, 16 (= 4*p*)H, CH−Ph) in agreement with n = 80 and p = 4. ^{19}F NMR (CD_3OD): −76.7 ($CF_3CO_2^-$).

Synthesis of PEI-[AMD]p (p = 17, 28) Conjugates. A 21 mg (1.9 μmol) amount of Boc-AMD-$(CH_2)_4$COOH, 7.3 mg (38 μmol) of EDC, and 7.7 mg (57 μmol) of HOBt were dissolved at 0 °C in 4 mL of CH_3CN. The solution was stirred overnight at room temperature and then cooled to 0 °C before 16.4 mg (0.65 μmol) of PEI (25 kDa) (respectively 7.8 mg, 0.31 μmol) in 4 mL of H_2O (respectively 2 mL) was added. After disappearance of the activated acid (TLC monitoring), the solution was concentrated under vacuum. The residue was then purified by several LH-20 and LH-60 gel permeation chromatographies (MeOH) to give 18.2 mg of PEI-[AMD(Boc)]17 (respectively 9.3 mg of PEI-[AMD(Boc)]28) as a resin [^{1}H NMR (CD_3OD): 1.00−2.00 [m, 57pH, $C(CH_3)_3$, CH_2CH_2-CH_2N, $NCH_2(CH_2)_2CH_2CON$]; 2.00−3.70 [m, (40*p* + 2320)H, CH_2-PEI, CH_2CO, CH_2N, CH_2Ph]; 7.24−7.29 (m, 4pH, CH−Ph), in agreement with p = 17 (respectively p = 28)]. The general BOC-deprotection procedure, when applied to 18.2 mg of PEI-[AMD(Boc)]17 (respectively 9.3 mg of PEI-[AMD(Boc)]28), gave 33 mg of PEI-[AMD]17 (respectively 13 mg of PEI-[AMD]28) as a white powder. ^{1}H NMR (D_2O): 0.70−2.70 [m, 12pH, $NCH_2CH_2CH_2$, $NCH_2(CH_2)_2CH_2CON$]; 2.75−4.20 (m, (40*p* + 2320)H, CH_2-PEI, CH_2N, CH_2CO, CH_2Ph]; 7.30−7.40 (m, 4pH, CH−Ph) in agreement with p = 17 (respectively p = 28). ^{19}F NMR (CD_3OD): −76.7 ($CF_3CO_2^-$).

Preparation of the DNA Complexes. The lipoplexes and polyplexes were formulated with the luciferase-encoding plasmid pTG11033 (pCMV-intronHMG-luciferase-SV40pA; 9572 bp) and pTG11236 (pCMV−SV40pA, 5739 bp), respectively. These plasmids were produced by Transgène SA (Strasbourg, France). The endotoxin content of the plasmid preparation was checked using a Limulus Amebocyte Lysat kit (Biogenic, Maurin, France). This value was below 1 endotoxin unit/mg of plasmid, hence below the 5 e.u./mg of DNA recommended for in vivo protocols.

The lipoplexes were formulated from (poly)cationic lipids, CL (CL = DOGS, DOTAP or DC18-[NH_2]20), with and/or without DOPE or DC18-[NH]-AMD. These lipids were dissolved in an appropriate solvent ($CHCl_3$ and/or MeOH or EtOH) at a concentration of 10 mg/mL. Adequate volumes of each of the desired lipid solution were mixed in order to obtain DOGS:DOPE:DC18-[NH]-AMD and DOTAP:DOPE:DC18-[NH]-AMD 1:1:*x* (*x* = 0 and 0.1) mol, and DC18-[NH_2]20:DC18-[NH]-AMD 1:*x* (*x* = 0, 0.1 and 0.2) mol solutions. Each solution was concentrated under vacuum and dispersed in a glucose solution (5%) in order to obtain a final concentration of 1 mg/mL with respect to CL. The preparations were stirred during 14 h and finally homogenized in an ultrasound bath (Branson B-30) for 5 min in order to obtain liposomal dispersions. The volumes of liposomal dispersion used to form lipoplexes were calculated according to the desired DNA concentration of 0.1 mg/mL, the *N*/*P* ratio, the molar weight, and the number of potential positive charges in the selected CL (*N* represents the number of cationic amine equivalents brought by CL only; *P* represents the number of phosphate equivalents in DNA). The DNA complexes were formulated by adding a desired volume of liposomal preparation at a CL concentration of 1 mg/mL (in 5% glucose) to the desired volume of DNA solution to reach the desired DNA concentration of 0.1 mg/mL, as described in the literature (*35*, *36*). This preparation was vortexed for 10 s and was used within 24 h for the particle size measurements and the in vitro transfection experiments.

A similar procedure was used for the ^{i}Bu-[NH_2]95, ^{i}Bu-[NH_2]80-[AMD]4, PEI, or PEI-[AMD]*p* (*p* = 17 or 28) polyplexes (final DNA concentration of 0.1 mg/mL), except that they were formulated from solutions of the respective polymer in 5% glucose at a concentration of 10 mg/mL, as described in the literature (*36*, *37*). In the *N*/*P* ratio of the AMD-labeled polyplexes, *N* represents the number of amine equivalents of the labeled polymer which was calculated by dividing the amount of polymer

used by the molecular weight of the monomer unit (as the number of AMD equivalents in the labeled polymers is low with respect to the number of monomer units, this number can be neglected).

Measurement of the Sizes of the DNA Complexes. The average sizes were measured by photon correlation spectroscopy using a Coulter N4Plus particle size analyzer. The analyses were performed at 25 °C, after equilibrating the sample at 25 °C for 20 min. The sample was diluted with 5% glucose in the measurement tube and homogenized. These analyses were carried out on naked plasmids and on complexes having a 10 μg/mL concentration of DNA. Formulations and analyses were reproduced twice.

Agarose Gel Electrophoresis. Each sample (0.5 μg of plasmid) was analyzed by electrophoresis for about 30 min under 75 V/cm, through a 0.8% agarose gel in TAE 1 x (Tris−acetate−EDTA) buffer. The DNA was visualized in 400 mL of TAE buffer containing 40 μL of ethidium bromide (10 mg/mL, Sigma, Saint Quentin Fallavier, France). The plasmid integrity in each sample (0.25 μg) was confirmed by electrophoresis after decomplexing the lipoplexes or polyplexes (10 μL of a plasmid 0.05 mg/mL) with sodium dodecyl sulfate, SDS (10 μL, 80 g/L).

In Vitro Transfection. Twenty-four hours before transfection, adherent A549 (epithelial cells derived from human pulmonary carcinoma) or T98G cells (neural cells derived from human glioblastoma, gift from Laboratoire de Neurobiologie Fondamentale et Clinique, Université de Nice-Sophia Antipolis, France) were grown in Dulbecco's-Modified Eagle culture Medium (DMEM) (Invitrogen, Life Technologies, Cergy Pontoise, France) with 10% fetal calf serum, FCS (Sigma) in 96-well plates (2×10^4 cells per well), in a wet (37 °C) and 5% CO_2/95% air atmosphere. The medium also contained 1% glutamine (200 mM, Sigma), 0.4% gentamicine (10 μg/mL, Sigma) for A549 cells, and 1% glutamine (200 mM, Sigma), 100 μg/mL penicillin and 100 μg/mL streptomycin (Sigma) for T98G cells. Volumes of 10 μL and 5 μL of the above-described lipoplex dispersion were diluted to 100 μL in DMEM supplemented with 10% FCS in order to obtain 1 and 0.5 μg of DNA per well, respectively. The resulting solutions were then added to the cells after the culture medium had been removed. After 4 and 24 h, 50 μL and 100 μL of DMEM supplemented with 30 and 10% FCS were added, respectively. Forty-eight hours after transfection, the culture medium was discarded, and the cells were washed with 100 μL of PBS and then lysed with 50 μL of lysis buffer (Promega, Charbonnières, France). The lysates were frozen at −32 °C awaiting analysis of luciferase activity.

A similar procedure was applied for the transfection of Jurkat cells (T lymphocytes from human leukemia, gift from Dr N. Taylor, UMR−CNRS 5535, IGMM, Montpellier, France). Twenty-four hours before transfection, Jurkat cells were grown in suspension in RPMI-1640 Glutamax II (Invitrogen, Life Technologies, Cergy Pontoise, France) containing 100 μg/mL penicillin and 100 μg/mL streptomycin with 10% FCS in 96-well plates (1×10^5 cells per well). The 96-well plates were centrifuged (5 min, 500 rcf), and the medium was removed and replaced by 100 μL of RPMI-1640 supplemented with 10% FCS containing the desired amount of complexed DNA. After 4 and 24 h, 50 μL and 100 μL of RPMI-1640 supplemented with 30 and 10% FCS, respectively, were added. Forty-eight hours after transfection, the plates were centrifuged (5 min, 500 rcf), the culture medium was removed, and the cells were then lysed with 50 μL of lysis buffer (Promega, Charbonnières, France). The lysates were frozen at −32 °C awaiting analysis of luciferase activity.

For the transfection experiments of the A549 or T98G cells (respectively Jurkat cells) performed in the presence of AMD3100, 30 min before addition of the DNA complexes, the medium was removed (respectively after centrifugation of the 96-well plates for 5 min at 500 rcf) and replaced by 50 μL of AMD3100 solution (0.6 mg/mL; respectively 2 mg/mL) in DMEM (respectively RPMI-1640) containing 10% FCS. A 50 μL volume of a solution containing the DNA complexes at a DNA concentration of 20 or 10 μg/mL was then added to the medium to reach a final volume of 100 μL and a DNA concentration of 1 or 0.5 μg per well. These solutions were obtained by diluting 20 or 10 μL of the above-described stock DNA complexes at DNA concentration of 0.1 mg/mL with DMEM (respectively RPMI-1640) containing 10% FCS to 100 μL.

For the transfection experiments of the Jurkat cells performed in the presence of PMA (Phorbol-Myristate-Acetate, Sigma) which were also run at 37 °C, 3 h after addition of the above-described DNA complexes to the cells, 1 μL of PMA solution (10 μg/mL in DMSO) was added to the medium in order to reach a final concentration of 100 ng/mL per well.

Determination of Luciferase Expression. The measurement was done for 10 s on 10 μL of the lysis mixture in a Berthold LB96P luminometer in dynamic mode, using the "Luciferase" determination system (Promega) in 96-well plates. The total protein concentration per well was determined using conventional techniques (BCA test, Pierce, Montluçon, France). For cells grown in the absence of DNA complexes, a well contains 30−50 μg of proteins for the T98G and A549 cells, and 90−110 μg of proteins for the Jurkat cells. Each DNA formulation was prepared twice, and each preparation was tested at least in triplicate.

Statistical Analyses. Statistical tests were performed with STATGRAPHICS Plus5.0 software. Analysis of variance (Anova) was run on the logarithmic transformation of luciferase expression levels (Log10(fg luciferase/mg protein)) or on cell viability percentages to fit normal distributions of the data. Up to five factors, i.e., component(s) of the lipoplex or polyplex formulation, DNA amount per well (0.5 and 1 μg per well), *N*/*P* ratio, presence or not of AMD3100, and presence or not of PMA, were analyzed as sources of the variation of logarithmic transformation of the transfection levels, using a multiple comparison procedure. Tukey's honestly significant difference (HSD) method was used to discriminate among the means of the logarithmic transformation of luciferase expression levels.

RESULTS AND DISCUSSION

Synthesis. Conjugation of AMD3100 to the aminolipid DC18-[NH_2] (*29*), telomer ^{i}Bu-[NH_2]95 (*33*), or branched 25 kDa PEI was performed from the *N*-pentanoic *N*-Boc-protected AMD3100 derivative, Boc-AMD-$(CH_2)_4$COOH (*34*), using a conventional two-step procedure (Figure 2). This procedure consisted of (i) the coupling of Boc-AMD-$(CH_2)_4$COOH with the amino derivative via BOP/NEt_3, EDC/NHS, or HOBt activation, followed by (ii) the Boc-deprotection of the AMD moiety with an excess of TFA: CH_2Cl_2 (1:1).

For the reactions involving the ^{i}Bu-[NH_2]95 and PEI polyamines which contain a mean of 95 and 145 primary amino functions, respectively, the conjugation was per-

formed with 1 equiv of Boc-AMD-$(CH_2)_4$COOH for 10 amino equivalents of ^{i}Bu-[NH_2]95 or PEI and for 30 amino equivalents of PEI. The resulting Boc-AMD conjugates were purified by exclusion gel chromatography (LH-20 or LH-60). The average numbers of grafted Boc-AMD residues and of unsubstituted NH_2 groups in (i) ^{i}Bu-[NH_2]80-[AMD(Boc)]4 and (ii) PEI-[AMD]*p* ($p = 17$ and 28) were determined by ^{1}H NMR by comparing the integration of the aromatic and Boc protons with the integration (i) of the methyl (isobutyl) and all the other remaining protons, and (ii) of the methylene protons of PEI, respectively. The quantitative Boc-deprotection was confirmed by ^{1}H NMR (absence of the resonances corresponding to the Boc protons).

Formation and Characterization of Targeted DNA Complexes. The nontargeted (control) and targeted lipoplexes were formulated from the cationic DOGS: DOPE (1:1 mol), DOTAP:DOPE (1:1 mol), or DC18-[NH_2]20 formulations without and with 10 or 20 mol % of the DC18-[NH]-AMD conjugate, respectively. The control and targeted polyplexes were prepared from ^{i}Bu-[NH_2]95 or PEI and from the telomer ^{i}Bu-[NH_2]80-[AMD]4 or PEI-[AMD]*p* ($p = 17$, 28) conjugates, respectively. In addition, DNA complexes were also formulated with AMD3100 alone. All these targeted and control DNA complexes were further prepared using various *N*/*P* ratios (10, 5, 2.5, 1.25, and 0.8) where *N* is the number of amine equivalents of the DNA-condensing (poly)cationic lipid or polymer, and *P* the number of DNA phosphate equivalents. Thus, for a given *N*/*P* ratio and a given CL, the various CL:DOPE:DC18-[NH]-AMD (1:*x*:*y* mol with $x = 0$ or 1 and $y = 0$, 0.1, or 0.2) lipoplexes listed in Table 1 contain the same molar amount of CL. However, their exact N_{total}/P ratios are equal to 1.4 × *N*/*P* or 1.8 × *N*/*P* when 10 or 20 mol % of DC18-[NH]-AMD was included in the formulation, respectively. Indeed, one AMD unit is equivalent, at physiological pH, to four protonated amines, considering the fact that the pK_a values of the cyclam moiety are of 11.5, 10.3, 1.6, 0.9 (*38*). These studies were performed with luciferase-encoding plasmids, also used for the in vitro transfection screening assays (see below). The procedure applied for the formulation of the DNA complexes relied on the dilution from CL:DOPE:DC18-[NH]-AMD (1:*x*:*y* mol with $x = 0$ or 1 and $y = 0$, 0.1, or 0.2) liposomal dispersions, or from ^{i}Bu-[NH_2]80-[AMD]4, PEI-[AMD]*p* ($p = 17$, 28), ^{i}Bu-[NH_2]95, or PEI solutions in 5% glucose. Their mean average sizes and those of the naked plasmids were measured by light scattering spectroscopy and are collected in Table 1. All the formulations were also analyzed by gel electrophoresis (data not shown) which indicated the presence of fully complexed (not accessible to ethidium bromide) plasmids for $N/P \geq 2.5$ whereas accessible DNA was observed for *N*/*P* 1.25 and 0.8. It is noticeable that all the targeted and control lipid formulations and polymers as well as the octaamine AMD3100 alone were able to condense DNA into often small-sized particles (Table 1). Furthermore, gel electrophoresis assays performed in the presence of excess SDS showed that, with respect to dissociation, the DNA/AMD3100 complexes displayed a stability that is comparable and higher to that of the polyplexes and lipoplexes, respectively: indeed for $N/P \geq 2.5$, the plasmid remained still partially complexed to AMD3100 or to any of the targeted and control polymers, while fully decomplexed plasmid was detected for any of the lipoplexes investigated here (data not shown).

It is worth noting that formulation of labeled lipoplexes with 10 or 20% mol of DC18-[NH]-AMD conjugate had no effect on their mean particle sizes (Table 1). Indeed, for a given cationic lipid and *N*/*P* ratio, polydispersed preparations of particles in the 90−250 nm range or precipitates for a *N*/*P* ratio of 1.25 were measured, whether DC18-[NH]-AMD was added or not. Similar results were obtained with the nontargeted and targeted polyplexes which display a mean size in the 115−300 and 90−250 nm range, respectively (Table 1).

It should be further emphasized that several *N*/*P* 2.5, 1.25 and even 0.8 formulations do not precipitate while most often precipitates were formed with (poly)cationic lipids for *N*/*P* 2.5 or 1.25 (*35*, *39*, *40*). These results are indeed worth being noted if in vivo uses of such formulations are contemplated.

[a] *N* = amine equivalents of the cationic lipid or polymer: *P* = plasmid phosphate equivalents. For the formulations containing 10 or 20 mol % of DC18-[NH]-AMD, the exact N_{total}/P ratio is equal to 1.4 × *N*/*P* or 1.8 × *N*/*P*, respectively. [b] nd = not determined. [c] nr = not reproducible. [d] p = precipitate. [e] l = large. [f] With plasmid pTG11033 and in italics with plasmid pTG11236.

In Vitro Transfection. Our main objective was to demonstrate that targeted lipoplexes or polyplexes formulated with AMD3100 conjugates (used as targeting component in the lipoplexes or as condensing and targeting components in the polyplexes), were able to specifically deliver genes to cells expressing CXCR4 chemokine receptors. However, cationic DNA complexes also provide receptor-independent gene transfer to cells (and more particularly to adherent cells) which involves electrostatic interactions between the cationized-DNA particles and the anionic cell proteoglycans expressed on the cell surface (*25*, *26*). It was therefore necessary to determine the conditions under which a nonspecific gene transfer process into CXCR4(−) or CXCR4(+) cells can occur with the AMD-labeled lipoplexes and polyplexes. To evaluate the "nonspecific" transfection potential of the targeted formulations into CXCR4(−) cells and to further minimize the nonspecific transfection pathway into CXCR4-(+) cells, we selected adherent cells (i.e. human lung carcinoma A549 and human glioblastoma T98G cells) and suspension cells (i.e. lymphoma Jurkat cells), respectively. Indeed, adherent cells, which overexpress anionic proteoglycans on their cell surface, are much easier to transfect non specifically than suspension cells.

Aiming at these goals, the potential of the various above-described CL:DOPE:DC18-[NH]-AMD (1:*x*:*y* mol with $x = 0$ or 1 and $y = 0.1$ or 0.2) lipoplexes and ^{i}Bu-[NH_2]80-[AMD]4, PEI-[AMD]*p* polyplexes for mediating a nonspecific and a specific transfection was screened in vitro on control adherent CXCR4(−) A549 and T98G cells, and on suspension CXCR4(+)Jurkat cells, respectively. The (non)expression of CXCR4 on these three cell lines was attested by FACS analysis. Though literature has reported CXCR4-expression on various human primary and cultured glioblastoma cells (*17*−*23*) as well as on A549 cells (*41*), we found that CXCR4 was neither expressed on the glioblastoma T98G cells nor on the A549 cells we used for our in vitro transfection assays. Control experiments were also realized with nontargeted CL:DOPE (1:*x* mol with $x = 0$ or 1) lipoplexes, ^{i}Bu-[NH_2]95 and PEI polyplexes, AMD3100/DNA complexes, and naked DNA. The transfection efficiency of these DNA complexes (expressed in femtograms (fg) of luciferase/mg of protein) was evaluated (i) in the absence or presence of AMD3100 (1 mg/well) for the reasons stated in the Introduction, (ii) for a *N*/*P* ratio of 0.8, 1.25, 2.5, 5, and/or 10, (iii) for a DNA dose of 0.5 and 1 μg/well, and (iv) in the presence of 10% serum. The cell viability of the DNA complexes was also checked by determining the total protein amount per well of the transfected cells relative to that measured for untreated cells. It should also be emphasized that two different plasmids were used for transfecting the adherent and suspension cells, respectively. Importantly, we selected pTG11236 for transfecting the latter ones. Indeed, it was found in our laboratory that higher luciferase expression levels (up to 2 orders of magnitude) were obtained upon transfection of adherent A549 cells with pTG11236-based lipoplexes rather than with pTG11033-based ones (*29*, *33*). This was more particularly of concern with the suspension cells that are more difficult to transfect than the adherent ones. The higher efficiency of pTG11236 is to some extent related to its shorter size (5739 bps vs 9572 bps for pTG11033), owing to the shorter size of its 16S/19S SV40 intron as compared to that of the HMG intron of pTG11033. Thus, for a given DNA amount, a larger number of DNA copies can be delivered with pTG11236 than with pTG11033.

Transfection of CXCR4(−) A549 and T98G Cells. The results concerning the transfection and cell viability of the control CXCR4(−) A549 and T98G cells with the lipoplexes and their statistical analyses are illustrated in Figures 3 and 4, respectively. As comparable levels of luciferase were obtained in most cases with a DNA dose of 0.5 and 1 μg/well (analysis not shown), only the data for a DNA dose of 1 μg/well are presented in Figure 3. However, the data obtained for both DNA doses were taken for the statistical analyses.

Both cell lines gave very similar results. Indeed, the highest levels of luciferase were obtained with the DOTAP:DOPE lipoplexes and the *N*/*P* 10 PEI polyplexes (Figure 4A and 4B). More importantly, the statistical analysis of the transfection data indicated that labeled lipoplexes, whether formulated with DOGS:DOPE, DOTAP:DOPE, or DC18-[NH_2]20, and 10 or 20 mol % of DC18-[NH]-AMD, do allow DNA transfection with an efficiency comparable with that of their respective nonlabeled formulation (see abscissas b, d, and g(h) as compared to abscissas a, c, and f, respectively in Figure 4A and 4B, and curves g, h as compared to curve f, in Figure 4C and 4D). Furthermore, transfection of the labeled lipoplexes increased with increasing their *N*/*P* ratio, as illustrated in Figure 4C and 4D. It should be noted that lipoplexes formulated with DC18-[NH]-AMD alone, but for a *N*/*P* ratio of 10 only, were able to transfect significantly T98G cells (curve e in Figure 4C). All these observations together led us to foresee a nonspecific endocytosis mechanism proceeding by electrostatic interactions between the cationic (un)labeled lipoplexes and the proteoglycans expressed at the cell membrane of these adherent cells. It is also noticeable that no significant in(de)crease of cell viability could be detected when DC18-[NH]-AMD conjugate was used as lipoplex component (see abscissas b, d, and g(h) as compared to abscissas a, c, and f, respectively, in Figure 4G and 4H).

It should further be emphasized that the various DNA complexes obtained from AMD3100 alone, whatever their *N*/*P* ratio, were unable to transfect the A549 or T98G cells. For these formulations, the levels of luciferase expression were indeed close to those measured for naked DNA (Figure 3). The absence of transfection activity of AMD3100, despite its strong interactions with DNA, are likely related to its pK_a values (11.5, 10.3, 1.6, and 0.9 (*38*)) which are out of the pH range found in the endosomes. As a consequence, AMD3100 is unable to prevent endosome acidification and, consequently, to facilitate the escape of the DNA complexes from the endosomes before their lysosomal destruction.

To highlight the effects of AMD3100 on nonspecific-mediated transfection with the labeled and nonlabeled lipoplexes (Figure 4E and 4F), control experiments were performed in the presence of 30 μg of AMD3100 per well. This dose corresponds to a 30-fold (respectively 2000-fold) molar excess over DC18-[NH]-AMD conjugate for the formulations that contain the highest (respectively lowest) number of AMD equivalents tested, i.e., *N*/*P* 10 lipoplexes containing 20 mol % of DC18-[NH]-AMD and for a DNA dose of 1 μg per well (respectively *N*/*P* 0.8 formulations containing 10% mol of DC18-[NH]-AMD and for a DNA dose of 0.5 μg per well). The statistical analysis of our results showed that AMD3100 likely does not interfere with the nonspecific transfection process of these cells with any type of lipoplexes, except for the transfection of the A549 cells with DOTAP:DOPE:DC18-[NH]-AMD lipoplexes (abscissa d in Figure 4F). In this latter case, the presence of AMD3100 enhanced luciferase expression, and more particularly that with the *N*/*P* 0.8

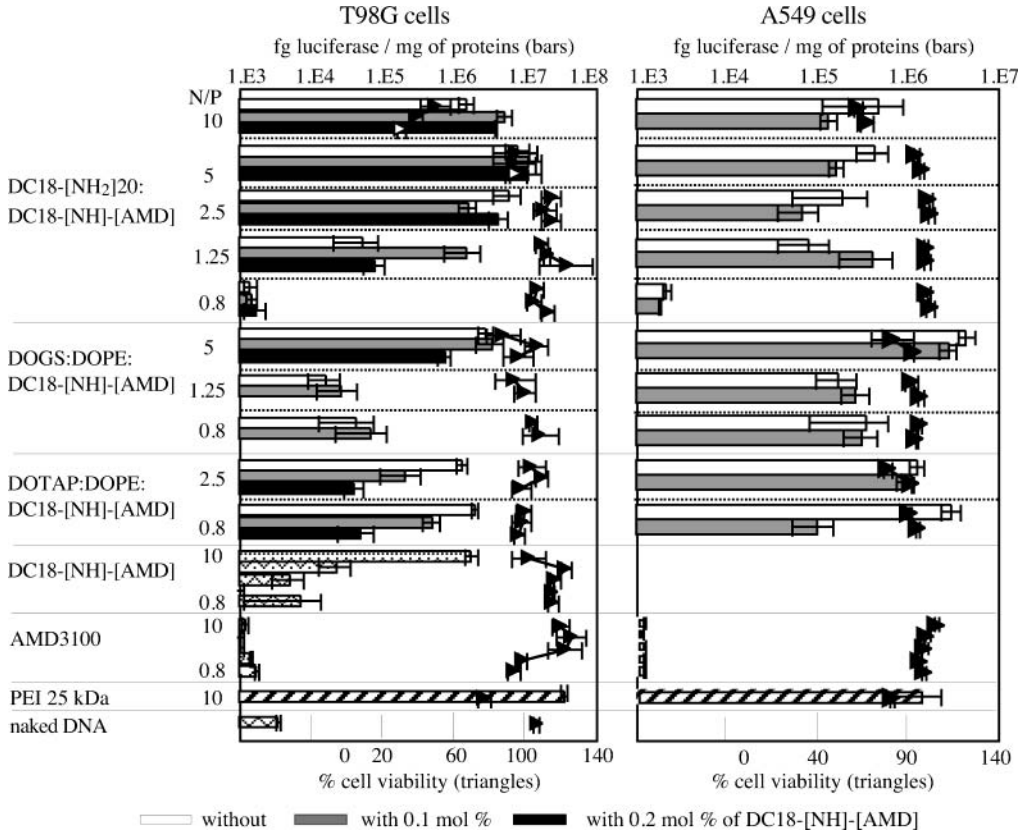

Figure 3. Luciferase expression (bars) and cell viability (triangles) of the pTG11033 complexes made with various lipid formulations [DOGS:DOPE:DC18-[NH]-AMD, DOTAP:DOPE:DC18-[NH]-AMD 1:1:*x* (*x* = 0 and 0.1) mol, and DC18-[NH_2]20:DC18-[NH]-AMD 1:*x* (*x* = 0, 0.1, and 0.2) mol], PEI or AMD3100 in T98G and A549 cells, and for a DNA dose of 1 μg per well. Transfection was performed in the presence of 10% fetal calf serum. Data represent the means ± SEM from two independent experiments, each performed in triplicate (for more details, see Materials and Methods). For more details concerning the *N*/*P* ratio, see footnote of Table 1.

ones (analysis not shown). These results are likely attributable to the electrostatic coating of these "negatively charged" lipoplexes by polycationic AMD3100 and/or to the strong DNA complexing properties of AMD3100 which is accessible in these lipoplexes, as mentioned in the preceding section. The DNA complexing properties of AMD3100 have, in turn, more incidence on lipoplexes that are formulated with monocationic lipids (i.e. DOTAP) than with polycationic lipids (i.e. DOGS).

Transfection of CXCR4(+) Jurkat Cells. The transfection and cell viability results obtained with the CXCR4(+) Jurkat cells and their statistical analyses are illustrated in Figures 5 and 6, respectively. To minimize nonspecific-mediated transfection pathways, mostly formulations of *N*/*P* ratio ≤ 2.5 were investigated. With the aim at demonstrating a specific receptor-mediated transfection process, these experiments were run without and with an excess of "free" AMD3100 as CXCR4 antagonist (100 μg per well, which corresponds to 500 to 1000 equivalents for one AMD-ligand equivalent in the labeled DNA complexes). Therefore, transfection experiments were performed only with polyplexes. Indeed, agarose gel electrophoresis with and without SDS highlighted the much lower stability of the AMD-labeled lipoplexes as compared with that of the AMD3100/DNA, PEI/DNA, or ^{i}Bu-[NH_2]95/DNA complexes (data not shown). The strong interactions between polycationic AMD3100 and DNA were thus expected to modify the integrity of the lipoplexes more drastically than that of the polyplexes. Moreover, AMD3100 was found in some cases to increase the nonspecific transfection pathway (see preceding section). It was thus feared that an unambiguous analysis of the assays run with the labeled lipoplexes and in the presence of AMD3100 could not be performed. The transfection experiments were also run without and with PMA (100 ng per well). Although PMA is a protein kinase C (PKC) activator and a tumor promoter, we selected PMA for this in vitro model study because PMA is known to induce phorbol ester-receptor endocytosis of DNA complexes and to increase transgene expression in Jurkat cells (*30*). As comparable luciferase levels were obtained for a DNA dose of 0.5 and 1 μg per well, only the data corresponding to a DNA dose of 1 μg per well are shown in Figure 5. However, the statistical analyses were performed with the data obtained for both DNA doses.

The control nonlabeled *N*/*P* ≤ 2.5 PEI and ^{i}Bu-[NH_2]-95 polyplexes displayed a transfection efficiency that is comparable to naked DNA (Figure 5), indicating that an enhancement of transfection of the CXCR4(+) Jurkat cells through a CXCR4-receptor-mediated endocytosis process could likely be detected for *N*/*P* ≤ 2.5 polyplexes. These results also confirmed the difficulty of transfecting cells in suspension through a nonspecific pathway (*30*, *43*). Indeed, the Jurkat cells could be transfected only with the *N*/*P* 10 PEI formulation, although moderate levels of luciferase expression (10^4 fg per mg of protein) were obtained (Figures 5 and 7).

When the transfection of the Jurkat cells with the nonlabeled *N*/*P* ≤ 2.5 PEI or ^{i}Bu-[NH_2]95 polyplexes was performed in the presence of AMD3100, neither a decrease nor an increase of luciferase expression was detected (Figure 6). This was also the case for the *N*/*P* 10 polyplexes (Figure 7). These data indicate that polycationic AMD3100 is not able to trigger transfection of the CXCR4(+) Jurkat cells with the nonlabeled PEI or ^{i}Bu-[NH_2]95 polyplexes neither (i) nonspecifically by

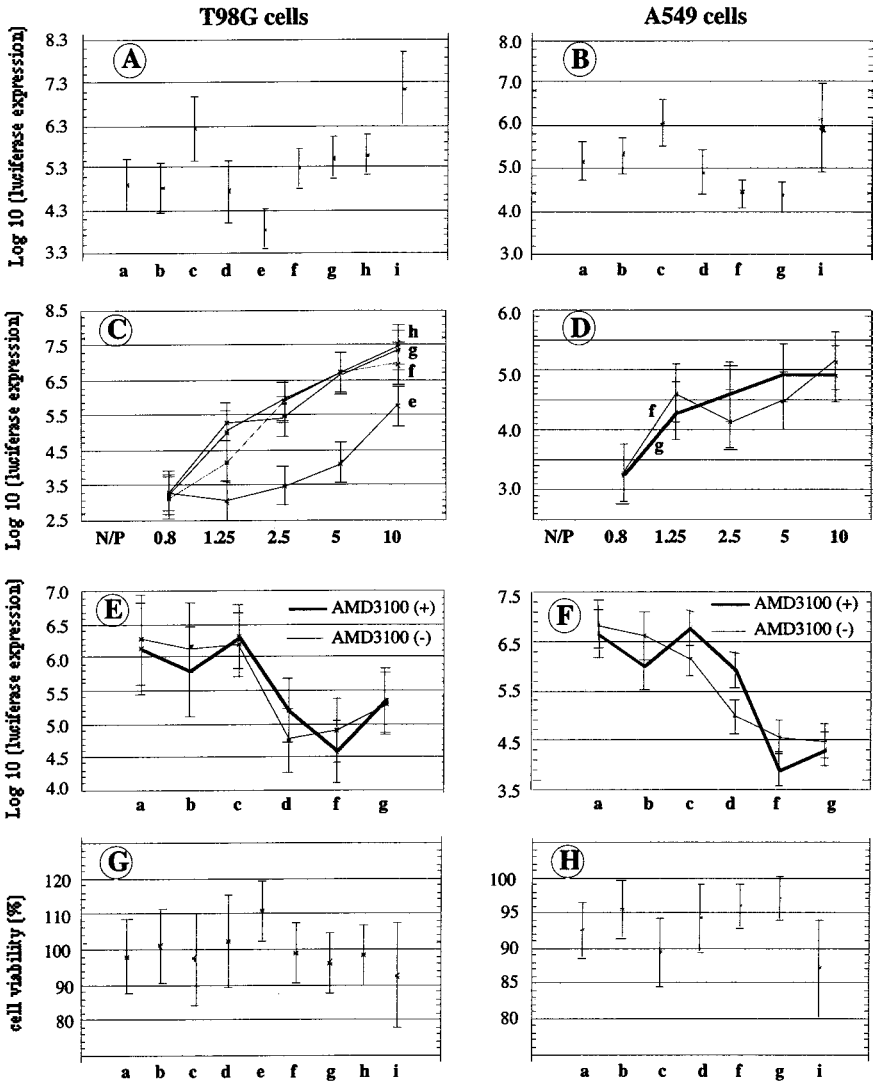

Figure 4. Means and 95.0% Tukey HSD intervals of the logarithmic transformation of luciferase expression levels (log_{10} (fg luciferase/mg protein)) (Panels A to F) and of cell viability percentages (Panels G and H) for the pTG11033 formulations of Figure 3 in T98G cells (left panels) and A549 cells (right panels). Panels A, B, G, and H: irrespective of the DNA dose (1 and 0.5 μg/well) and of the *N*/*P* ratio (0.8, 1.25, and 5 for a and b; 0.8 and 2.5 for c and d; 0.8, 1.25, 2.5, 5, and 10 for e, f, and g; 10 for PEI). Panels C and D: irrespective of the DNA dose (1 and 0.5 μg/well) and as a function of the *N*/*P* ratio for the indicated formulations. Panels E and F: irrespective of the DNA dose (1 and 0.5 μg/well) and of the *N*/*P* ratio (5 for a and b; 0.8 and 2.5 for c and d; 1.25 and 2.5 for f and g), and as a function of the presence of AMD3100 (30 μg per well) or not. Statistical tests were performed with STATGRAPHICS Plus5.0 software. This comparison was performed using the multiple sample comparison procedure, and the method used to discriminate among the means of the logarithmic transformation of luciferase expression levels or of the cell viability percentages was the Tukey's honestly significant difference (HSD) procedure. a: DOGS:DOPE (1:1); b: DOGS:DOPE:DC18-[NH]-[AMD] (1:1:0.1); c: DOTAP:DOPE (1:1); d: DOTAP:DOPE:DC18-[NH]-[AMD] (1:1:0.1); e: DC18-[NH]-[AMD]; f: DC18-[NH_2]20; g: DC18-[NH_2]20:DC18-[NH]-[AMD] (1:0.1); h: DC18-[NH_2]20:DC18-[NH]-[AMD] (1:0.2); i: PEI. For more details concerning the *N*/*P* ratio, see footnote of Table 1.

increasing the cationic charge of the polyplexes and consequently their nonspecific binding through electrostatic interactions to anionic proteins expressed on the cell membrane surface, nor (ii) specifically by increasing their binding to CXCR4 leading to a receptor-mediated endocytosis pathway.

Where transfection of the Jurkat cells with the $N/P \leq 2.5$ AMD-labeled polyplexes is concerned, no improvement of luciferase expression was obtained with any of the labeled polyplexes investigated as compared with that of their respective controls (abscissas c, and e(f) versus abscissas b and d, respectively, in Figure 6). That no substantial increase of transfection through specific AMD-CXCR4 interactions was detected with any of these targeted formulations could likely be attributed to the AMD inhibition of CXCR4-mediated endocytosis pathway. Indeed, recent research has demonstrated that the binding of AMD3100 to CXCR-4 receptor in human astroglioma U87 cells inhibited the endocytosis process of this receptor (*32*). To evaluate this hypothesis, we performed a series of transfection experiments in the presence of PMA which is known to trigger lipoplex and polyplex endocytosis of the Jurkat cells grown in suspension (*30*) and also to mediate CXCR4 receptor endocytosis (*31*), even in the presence of AMD3100 (*32*).

Concerning the PMA-triggered transfection assays with the nonlabeled $N/P \leq 2.5$ PEI or ^{i}Bu-[NH_2]95 polyplexes, one observed a statistically significant 2- and 4-fold increase of luciferase expression, respectively (Figure 6A, curve PMA(+)/AMD(−)). Very interestingly, a significantly larger increase (6- to 12-fold) was obtained with the AMD-targeted polyplexes and even with AMD3100/DNA complexes (9-fold). The larger transfection improvements obtained with the AMD-labeled poly-

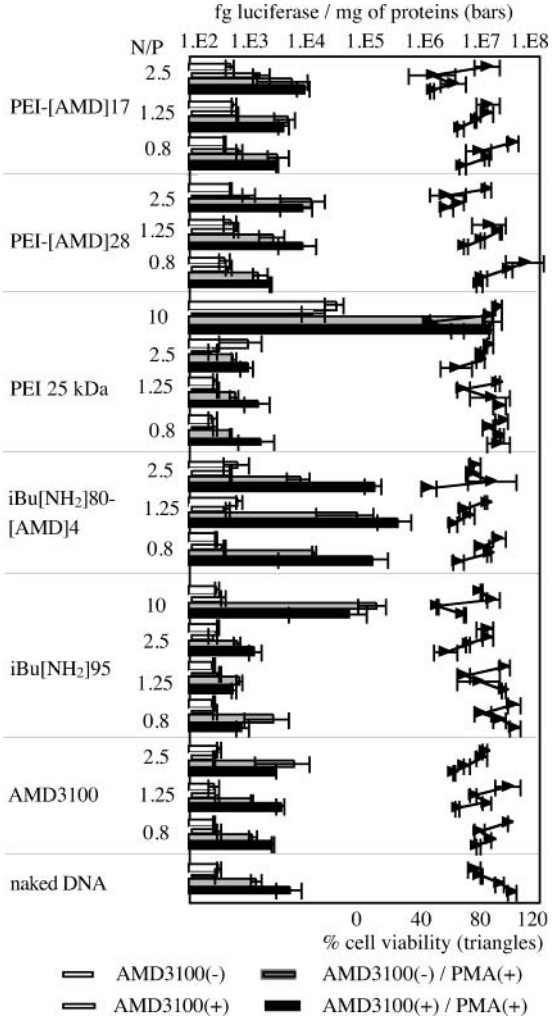

Figure 5. Luciferase expression (bars) and cell viability (triangles) in suspension CXCR4(+) Jurkat cells of the pTG11236 complexes made with various AMD-labeled polycationic polymers [PEI-[AMD]*p* (p = 17, 28), ^{i}Bu[NH_2]80-[AMD]4], PEI, ^{i}Bu[NH_2]95, or AMD3100 and for a DNA dose of 1 μg per well. Transfection was performed in the presence of 10% fetal calf serum, without and with AMD3100 or PMA. Data represent the means ± SEM from two independent experiments, each performed in triplicate (for more details, see Materials and Methods).

plexes as compared with their respective nonlabeled polyplexes in the presence PMA are likely attributable to a specific adsorption of the labeled AMD-polyplexes onto the CXCR4(+) cells, as a result of AMD-CXCR4 interactions and, consequently, to a higher receptor-mediated cellular uptake of the DNA complexes triggered by PMA. Surprisingly, when these transfection experiments were further run in the presence of AMD3100 (curve PMA(+)/AMD(+) in Figure 6A), a statistically significant additional 5-fold increase of luciferase expression was measured for the ^{i}Bu-[NH_2]80-[AMD]4 polyplexes. This represents an overall 60-fold increase with respect to the luciferase level obtained without AMD3100 and PMA. That transfection with these AMD-labeled polyplexes in the presence of PMA was increased by AMD3100 indicates that AMD3100 could serve as a template between the polyplexes and CXCR4. However, the lack of transfection inhibitory effects of AMD3100 indicates likely that nonspecific PMA-induced endocytotic pathways of the polyplexes involving other cellular receptors than CXCR4 take place. This is strongly supported, as illustrated in Figure 7A, by the nearly

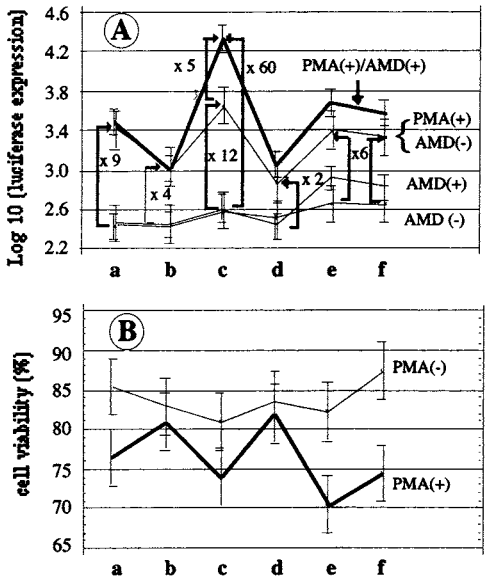

Figure 6. Means and 95.0% Tukey HSD intervals of the logarithmic transformation of luciferase expression levels ($\log_{10}$ (fg luciferase/mg protein)) (Panel A) and of cell viability percentages (Panel B) for the pTG11236 formulations of Figure 4 in Jurkat cells. Panels A and B: irrespective of the DNA dose (1 and 0.5 μg/well) and of the *N*/*P* ratio (0.8, 1.25, and 2.5 for a to f). Panel A, curve AMD(−): without AMD3100; curve AMD(+): with AMD3100 (100 μg per well); curve PMA(+)/AMD(−): with PMA (100 ng per well) and without AMD3100; curve PMA(+)/AMD(+): with PMA (100 ng per well) and AMD3100 (100 μg per well). For more details concerning the statistical analyses, see caption of Figure 3.

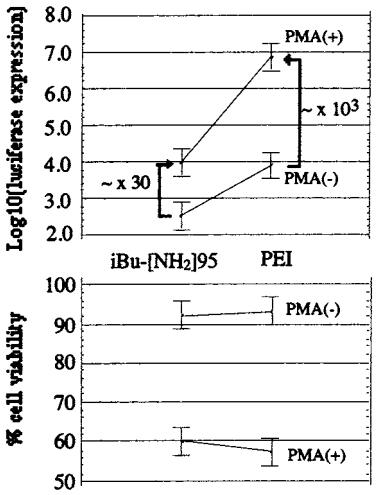

Figure 7. Means and 95.0% Tukey HSD intervals of the logarithmic transformation of luciferase expression levels ($\log_{10}$ (fg luciferase/mg protein)) (Panel A) and of cell viability percentages (Panel B) for the *N*/*P* 10 ^{i}Bu[NH_2]95 or PEI polyplexes made with plasmid pTG11236 in Jurkat cells with respect to the presence or absence of PMA (curves PMA(+) and PMA(−), respectively). Panels A and B: irrespective of the DNA dose (1 and 0.5 μg/well) and of the presence or absence of AMD3100. For more details concerning the statistical analyses, see caption of Figure 3.

1000- and 30-fold increase of luciferase expression obtained with the highly cationic *N*/*P* 10 PEI or ^{i}Bu-[NH_2]-95 polyplexes, respectively, when the assays were run in the presence of PMA.

It is, however, worth noting that the transfection enhancements in the presence of PMA were accompanied

by a significant cell viability decrease (Figure 6B and 7B). Furthermore, the higher the transfection enhancement, the lower the cell viability. These observations are in agreement with a higher cellular uptake of the DNA complexes.

Altogether, our results show that polyplexes formulated with AMD-labeled polymers constitute, under certain conditions, specific gene transfer systems into suspension CXCR4(+) Jurkat cells. This is more particularly the case when the nonspecific transfection pathways are minimized (i.e. for $N/P \leq 2.5$ AMD-labeled polyplexes) and in the presence of phorbol myristate acetate (PMA) which triggers CXCR4 receptor endocytosis of the AMD-labeled polyplexes to a larger extent than of their respective nonlabeled ones. These targeted AMD-polymers appear thus as promising synthetic vectors for specific in vivo gene delivery to CXCR4-expressing tumors, providing however that CXCR4-mediated endocytosis can be induced by nontumor promoters (e.g. prostratin (*43*, *44*)) by contrast to PMA which is a tumor promoter. The effect of the chemokine SDF-1, the natural ligand of CXCR4 (*13*, *15*), on the CXCR4-mediated transfection should also be investigated. These assays are further of interest as SDF-1 does not inhibit CXCR4 endocytosis by contrats to AMD3100 (*32*). Although encouraging, the transfection efficiencies and specificities obtained with these compounds should, however, be improved. This study also illustrates the difficulties to demonstrate and obtain a specific and efficient gene transfer system with cationized ligand-labeled DNA particles which also provide receptor-independent nonspecific gene transfer to cells and more particularly to adherent cells.

ACKNOWLEDGMENT

B. Le Bon is grateful to the Région Provence-Alpes-Côte d'Azur and Transgène SA (Strasbourg, France) for a grant. We wish to thank Transgène, Drs. S. Braun, O. Meyer, and B. Cavallini (from Transgène) for their interest in this project and for supplying plasmids. Many thanks to Dr. N. Taylor (UMR-CNRS 5535, IGMM, Montpellier, France) for performing the FACS analyses on the A549, T98G, and Jurkat cells. We are also grateful to the AFIRST, French-Israeli Cooperation on Gene Therapy, for financial support.

TECHNICAL NOTES

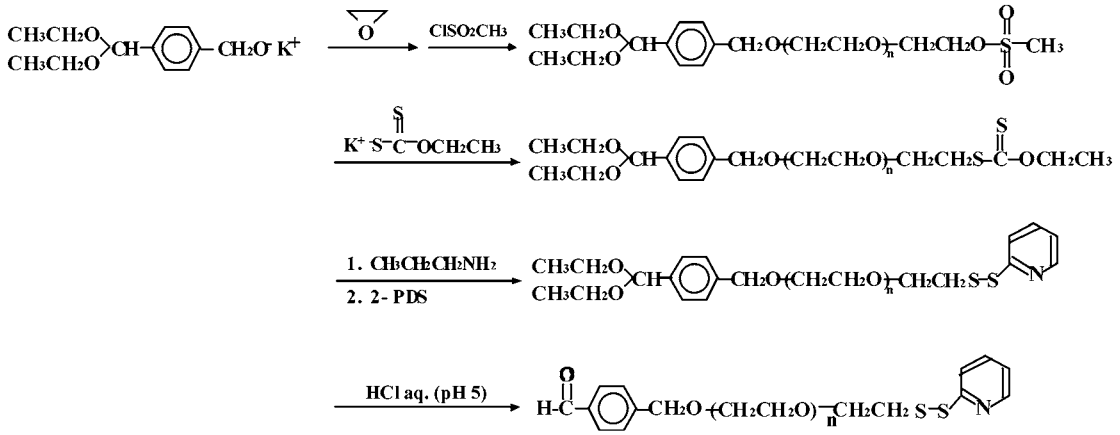
Synthesis of Heterotelechelic Poly(ethylene glycol) Derivatives Having α-Benzaldehyde and ω-Pyridyl Disulfide Groups by Ring Opening Polymerization of Ethylene Oxide Using 4-(Diethoxymethyl)benzyl Alkoxide as a Novel Initiator

Yoshitsugu Akiyama,[†] Yukio Nagasaki,[‡] and Kazunori Kataoka*,[†]

Department of Materials Science, Graduate School of Engineering, The University of Tokyo, 7−3−1 Hongo, Bunkyo-ku, Tokyo 113-8656, Japan, and Department of Material Science & Technology, Tokyo University of Science, 2641 Yamazaki, Noda-shi, Chiba 278-8510, Japan. Received September 30, 2003; Revised Manuscript Received January 15, 2004

New heterotelechelic PEG-containing benzaldehyde and 2-pyridyldithio endgroup (CHO-Bz-PEG-SSpyl) was synthesized with high efficiency and high selectivity. An α-benzylacetal-ω-methansulfonyl PEG was prepared as the first step to CHO-Bz-PEG-SSpyl through the ring-opening polymerization of ethylene oxide (EO) initiated by potassium 4-(diethoxymethyl)benzyl alkoxide (PDA), followed by the successive conversion of the end-alkoxide group to a methanesulfonyl group and then to dithiocarbonate derivative. Further, deprotection of the dithiocarbonate derivative and subsequent conversion to the 2-pyridyldithio group at the ω-end was successfully performed through a one-step reaction to form α-benzylacetal-ω-2-pyridyldithio PEG (aceBz-PEG-SSpyl). The aceBz-PEG-SSpyl was then treated with an aqueous HCl solution (pH 5.0) to generate the benzaldehyde group at the α-end. Molecular functionalities of the benzaldehyde and the 2-pyridyldithio end group of the heterotelechelic PEG (CHO-Bz-PEG-SSpyl) thus prepared were characterized by ^{1}H and ^{13}C NMR, showing that the reaction proceeded almost quantitatively. The benzaldehyde end group is available to conjugate various ligands having a primary amino group by forming the pH-sensitive imine linkage (−N═CHC$_6$H$_4$−).

Heterotelechelic poly(ethylene glycol) (PEG) derivatives possessing different functional groups at the α- and ω-chain ends have received increasing interest as PEGylation reagents (*1*−*4*) in such areas as drug delivery systems (DDS) (*5*−*7*) and diagnostics (*8*−*11*). For example, protein conjugates with heterotelechelic PEG are expected not only to have a propensity of decreased immunogenicity due to steric repulsion effects, but also to possess the availability of further conjugation of the ligand moiety to the distal end of PEG. Although several types of heterotelechelic PEGs have already been prepared based on the derivatization of α,ω-dihydroxy-PEG (*12*−*15*), there are still many obstacles such as complicated reaction steps with low yield and limited selectivities. These obstacles in the heterotelechelic PEG synthesis may be resolved by taking the alternative approach of the direct ring opening polymerization of ethylene oxide (EO) using a metal alkoxide initiator with a protected functional group (*16*−*20*).



As a novel heterotelechelic PEG with high potential utility in bioconjugation field, we focused on the one with α-benzaldehyde and ω-2-pyridyldithio groups. The benzaldehyde group is able to react with the primary amino group under physiological condition (pH 7.4), generating a stable imine linkage (−N═CHC$_6$H$_4$−) which needs no further reductive amination. The imine linkage is also known to be hydrolyzed at acidic condition (*21*, *22*). Furthermore, self-condensation of PEG due to an aldol reaction, which is a major side reaction in the utilization of aldehyde-functionalized PEG derivatives, does not occur in the benzaldehyde-functionalized PEG due to a lack of α-proton. The 2-pyridyldithio group at the ω-end can be utilized for the selective PEGylation at the cysteine residue of natural as well as recombinant protein molecules (*23*, *24*). Note that the α-benzaldehyde-ω-2-pyridyldithio PEG is also useful for the functional PEGylation of gold and silver substrates used in bioassay systems, including surface plasmon resonance and colloidal colorimetry (*25*). In this study, a novel synthetic route was established for α-benzaldehyde-2-pyridyldithio-PEG (CHO−Bz-PEG-SSpyl) through the ring opening polymerization of EO initiated with potassium 4-(diethoxymethyl)benzylalkoxide (PDA) as summarized in Scheme 1.

4-(Diethoxymethyl)benzyl alcohol was prepared by the reduction of 4-(diethoxymethyl)benzaldehyde with sodium borohydride ($NaBH_4$) in dry methanol according to the literature with a slight modification (*26*). Conversion to the 4-(diethoxymethyl)benzyl alcohol was confirmed by ^{1}H and ^{13}C NMR (JEOL EX 300 spectrometer) analysis (S-1,2; Supporting Information). Potassium 4-(diethoxy-

Scheme 1

methyl)benzylalkoxide (PDA) as an initiator for EO polymerization was then prepared by metalation of 4-(diethoxymethyl)benzyl alcohol with potassium naphthalene. The synthesis of the heterotelechelic PEG possessing benzylacetal and methansulfonyl endgroups (aceBz-PEG-OSO_2CH_3) was done as the first step to CHO-Bz-PEG-SSpyl as follows: THF solutions of 4-(diethoxymethyl)benzyl alcohol (0.19 g, 0.90 mmol) and potassium naphthalene (0.90 mmol) were mixed into dry THF (30 mL) under an argon atmosphere to form PDA. After the mixture was stirred for 10 min, 4.5 g (102 mmol) of liquid EO, cooled below 0 °C, was added to the solution via a cooled syringe. After the mixture was allowed to react for 2 days at room temperature, potassium naphthalene (0.4 mmol) and triethylamine (0.82 g, 8.1 mmol) were added to the stirring polymer solution. Then, the solution was slowly added dropwise into methanesulfonyl chloride (0.72 g, 6.3 mmol) in dry THF (10 mL), to introduce methanesulfonyl groups at one of the PEG ends without any side reactions, and then added to the chloroform followed by washing with saturated $NaCl_{aq}$ for purification. The organic layer was dried with anhydrous $MgSO_4$. After evaporation of excess solvent, samples were reprecipitated into diethyl ether to obtain the polymer as a white precipitate. The recovered polymer was dried in vacuo and then freeze-dried from benzene. The yield of the obtained polymer after purification was 82% (3.69 g).

From the GPC diagram (TOSOH HLC-8220: a TSKgel column ($G4000H_{HR}$ and $G3000H_{HR}$)), the number-average molecular weight (M_n) and the molecular weight distribution (MWD) were determined to be 5410 and 1.03, respectively (S-3, Supporting Information). The polymer has a very narrow MWD, and its M_n is close to the calculated value derived from the monomer/initiator ratio, indicating that the polymerization of EO from PDA as an initiator proceeds without any remarkable side reactions. The end-group analysis was then done by ^{1}H NMR spectroscopy according to the assignments of PEG and 4-(diethoxymethyl)benzyl alcohol (S-4, Supporting Information). The molecular weight determined from the intensity ratio of the oxymethylene peak of the PEG signals (OCH_2CH_2) with the methyl proton peaks of benzylacetal ($(CH_3CH_2O)_2CH$) was 5820, which is in a good agreement with the M_n determined by GPC analysis (M_n 5410).

To convert a methanesulfonyl group to a *O*-ethyldithiocarbonate group, the aceBz-PEG-OSO_2CH_3 was reacted with potassium *O*-ethyldithiocarbonate in the mixture of THF and DMF under an argon atmosphere for 4 h. The ω-end conversion from methanesulfonate to the ethyldithiocarbonate moiety was confirmed to be quantitative based on the ^{1}H NMR data (S-5, Supporting Information). The ω-end conversion to the 2-pyridyldithio group was then performed by the deprotection of the dithiocarbonate moiety in THF as follows: AceBz-PEG-S(C=S)OCH_2CH_3 (100 mg, 0.0186 mmol) and 2-pyridyl 2-disulfide (410 mg, 1.86 mmol) were dissolved in dry THF (15 mL), and *n*-propylamine (1.75 mL) was slowly added. The mixture was stirred for 3 h at room temperature and then dialyzed against MeOH followed by the complete evaporation of the solvent under vacuum. The polymer was purified by ether reprecipitation from $CHCl_3$ solution. Finally, the obtained polymer was freeze-dried from benzene (yield: 89 mg (89%)). Figure 1 shows the ^{1}H NMR spectrum of the obtained aceBz-PEG-SSpyl. The signals of the methyl (1.4 ppm) and methylene (4.6 ppm) protons of the *O*-ethyldithiocarbonate moiety had completely disappeared, while new peaks appeared at 7.1, 7.7, 7.8, and 8.5 ppm assignable to the pyridyl moiety. The ω-end conversion of *O*-ethyldithiocarbonate to the 2-pyridyldithio group was confirmed to be 99% based on the peak ratio of pyridyl to benzylacetal in the ^{1}H NMR spectrum. The aceBz-PEG-SSpyl was then treated with an aqueous HCl solution (pH 5.0) to generate the benzaldehyde group at the α-end through the deprotection of the benzylacetal moiety under the following conditions:

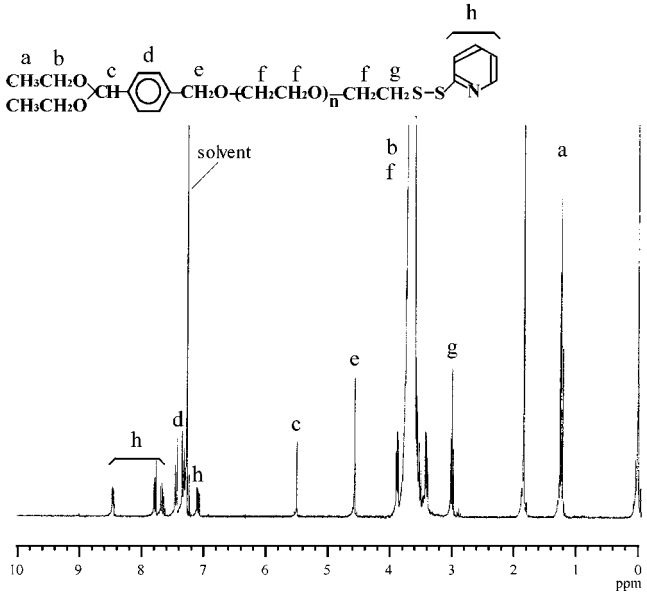

Figure 1. ^{1}H NMR spectrum of aceBz-PEG-SSpyl in $CDCl_3$ at room temperature.

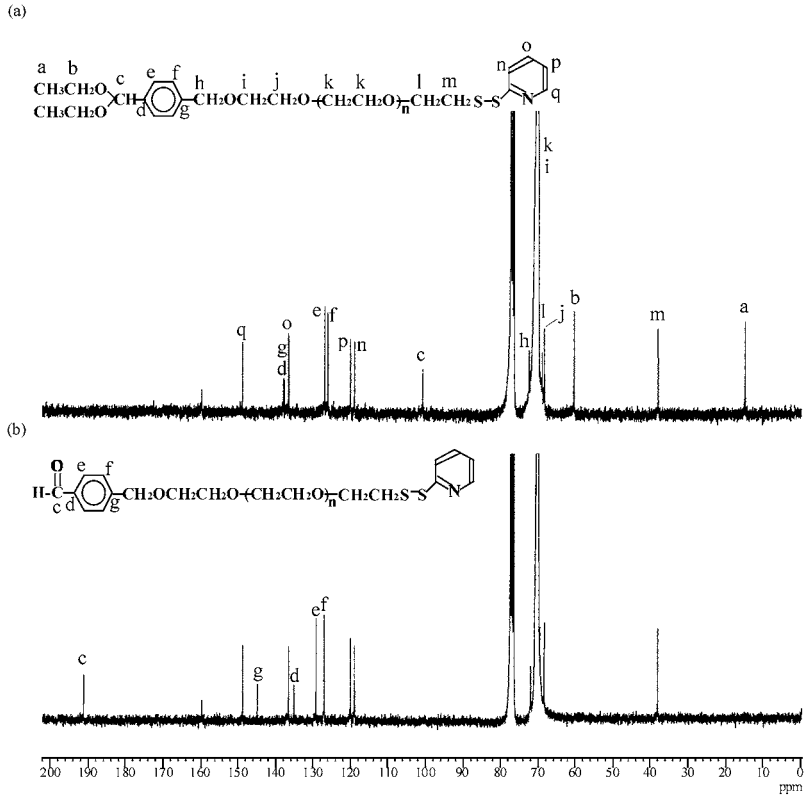

Figure 2. ^{13}C NMR spectra in $CDCl_3$ at room temperature of (a) aceBz-PEG-SSpyl and (b) CHO−Bz-PEG-SSpyl.

aceBz-PEG-SSpyl (70 mg, 0.013 mmol) was dissolved in an aqueous HCl solution (pH 5.0; 10 mL) and allowed to react for 6 h at room temperature. Dialysis against distilled water was then carried out followed by freeze-drying. Figure 2 shows ^{13}C NMR spectra of the polymer sample before and after the deprotection of the benzylacetal group. Carbon signals of the benzylacetal group, such as CH_3CH_2O and CH_3CH_2O appearing at 15.0 and 60.8 ppm, respectively, completely disappeared after the treatment with the aqueous HCl solution (pH 5.0) (Figure 2b). On the other hand, the deprotected sample has a new peak in the ^{13}C NMR spectrum appearing at 191.8 ppm, assignable to the aldehyde of the benzaldehyde group. These results clearly indicate the successful conversion of the α-benzylacetal group to the benzaldehyde group, which was further confirmed by ^1H NMR analysis as shown in Figure 3. Signals of the methyl and methylene groups of the benzylacetal group completely disappeared, while a new peak appeared at 10.06 ppm (s, 1H), which was attributable to the benzaldehyde proton at the end of the polymer chain. The α-end conversion from the benzylacetal to benzaldehyde moiety was again confirmed to be almost quantitative (90%) based on the peak intensity ratio of the aldehyde proton of the benzaldehyde group (10.06 ppm) and the methylene protons next to the 2-pyridyl disulfide group (3.0 ppm) in the ^1H NMR, indicating an almost quantitative conversion of the α-end to the benzaldehyde group. It should be noted that the intensity of the signals derived from the pyridyl end groups did not change throughout the deprotection process under the acidic conditions, indicating that the obtained PEG contains benzaldehyde (α-end) and 2-pyridyldithio (*ω*-end) groups. Worth mentioning is the fact that the benzaldehyde group has no active proton on the α-carbon to undergo aldol condensation. Indeed, the peak for dimerization products was not detected (data not shown). Consequently, the obtained heterotelechelic

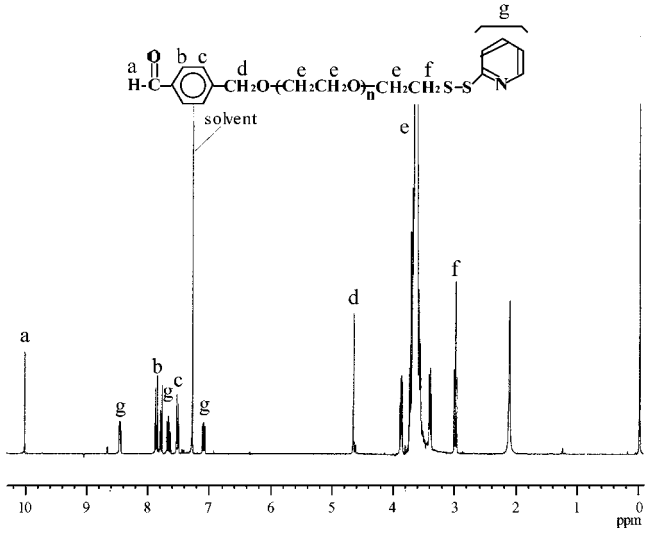

Figure 3. ^1H NMR spectrum of CHO-Bz-PEG-SSpyl in $CDCl_3$ at room temperature.

CHO-Bz-PEG-SSpyl and its precursor, aceBz-PEG-SSpyl, have a wide potential utility as selective heterolinkers in various bioconjugation reactions as well as surface modifiers of gold and silver substrates to construct reactive PEG-brush layers useful for biosensing, such as surface plasmon resonance (SPR) sensor technology. Research in this direction is now underway in our laboratory, and the results will be reported elsewhere.

ACKNOWLEDGMENT

A simple route to the introduction of a number of chemoselective functional groups into peptoids (oligo(N-substituted glycines)) by an extension of the standard solid-phase submonomer method is reported. The following groups were introduced: aminooxyacetamide, *N*-(carbamoylmethyl)acetohydrazide, mercaptoacetamide, 2-pyridinesulfenylmercaptoacetamide, and aldehyde-terminated peptoids. The method uses commercially available reagents, is fully compatible with standard peptoid submonomer synthesis conditions, is easily automated, and generates the desired functionalized peptoid in high yield and purity. Peptoids with suitable pairs of chemoselective ligation groups were joined in high yield.

INTRODUCTION

Biomolecules conjugated to particles, surfaces, or reporter groups are widely used to measure molecular interactions in rapid screening procedures (*1*−*5*) and in diagnostics and therapeutics (*6*). These bioconjugates are expensive to prepare and are often of limited stability. With the advent of combinatorial libraries, scientists now want to attach synthetic compounds to surfaces, biomolecules, and reporter groups to perform similar analyses.

Advances in combinatorial chemistry have made huge numbers of synthetic molecules available; and small organic molecules, shorter peptide oligomers (*7*), and nucleic acids (*8*, *9*), as well as nonnatural oligomers (peptoids (*10*) and other peptomimetics), have found numerous practical applications. The ability to attach synthetic ligands to surfaces has led to discoveries in chemical genomics (*11*), proteomics (*12*, *13*), and drug discovery (*7*).

Screening procedures that require the synthetic molecules to be attached to a solid phase, such as a bead, or a planar surface, can be prepared by chemical synthesis of the synthetic compound library directly onto the surface, or by synthesis, cleavage, and reattachment of the compound. Some methods involve synthesis of peptides and DNA oligomers directly on glass (*9*), cellulose membranes (*14*), and hydrophilic beads (*15*). The main disadvantage of these approaches, however, is that it is not possible to analyze or purify the immobilized compounds prior to screening.

We were interested in approaches where individual compounds of a library are assembled by chemical synthesis on a solid support in a form suitable for subsequent specific conjugation to a surface or a reporter group. This route facilitates compound analysis and purification, as well as conjugation of the compound library to the type of surface that is best suited for the actual screening procedures. Alternatively, synthetic soluble ligands with appropriate functional groups can be conjugated to another molecule to add useful properties (such as a drug, toxin, fluorophore, photoprobe, inhibitor, enzyme, hapten, reporter group, and (poly(ethylene glycol)) spacer). Synthetic proteins have been assembled from short functionalized peptides using conjugation techniques that rely on unique chemical moieties (native protein ligation (*16*), protein analogues (*17*), cyclic peptides (*18*), template-assembled synthetic proteins (*19*)).

Many chemoselective groups are conveniently introduced into peptides and other ligands by direct chemical solid-phase synthesis, but the necessary reagents are seldom commercially available and have in the past required the elaborate synthesis of protected amino acid compounds (*20*, *21*). It is therefore highly desirable to simplify the introduction of chemoselective groups into molecules, especially in the parallel synthesis of large numbers of potential ligands.

Peptoids (N-substituted glycines) are an important class of biomimetic oligomers that in recent years have made a significant impact in the areas of combinatorial drug discovery (*22*), gene therapy (*23*), drug delivery (*24*), and biopolymer folding (*25*, *26*). Sequence-specific peptoid oligomers are easily assembled from primary amines by a solid-phase submonomer method (*27*, *28*).

Here we describe a simple direct chemical route to the introduction of a number of chemoselective groups into peptoids by an extension of the standard solid-phase submonomer method: aminooxyacetamide, *N*-(carbamoylmethyl)acetohydrazide, mercaptoacetamide, *S*-acetylmercaptoacetamide, 2-pyridinesulfenylmercaptoacetamide, and aldehyde-terminated peptoids. The method uses commercially available reagents, is fully compatible with standard peptoid submonomer synthesis conditions, is easily automated, and generates the desired functionalized peptoid in high yield and purity. We also demonstrate the conjugation of these functionalized peptoids with themselves to generate peptoid dimers, a necessary step toward the synthesis of artificial proteins (*26*). These methods should also be applicable to the synthesis of

reactant 1	reactant 2	type of bond formed
aldehyde/ketone	hydrazide	hydrazone
aldehyde/ketone	aminooxy	oxime
thiol	maleimide	thioether
thiol	iodoacetyl	thioether
thiol	activated disulfide	disulfide

many other molecules (heterocycles, peptides, β-peptides, and others (*29*)) assembled on a solid support. These features should greatly expand the utility of synthetic combinatorial libraries, since a diverse set of compounds can be simultaneously functionalized and conjugated to another molecule or surface of interest.

RESULTS AND DISCUSSION

Formation of chemically defined conjugates requires the introduction of uniquely reactive chemical moieties into each ligation partner, preferably at a specific location that does not interfere with the desired activities. These conjugation methods rely on chemoselective pairs of functionalities that are orthogonal to other groups in the molecules to be conjugated. Additionally, the conjugation reaction conditions should be conducted under mild conditions and be compatible with physiological conditions to preserve biological activity. A number of electrophile−nucleophile pairs, that fulfill these requirements, are listed in Table 1.

Peptoids can be efficiently prepared by submonomer solid-phase synthesis (Figure 1). Each monomer addition cycle consists of two steps: (1) acylation of an N-terminal amino group with bromoacetic acid in the presence of a condensing agent, and (2) nucleophilic displacement of the bromide with excess primary amine (*27*). These two steps are repeated with the appropriate amines to build the desired N-substituted glycine sequence.

Chemoselective ligation groups are introduced at the N-terminus with one additional submonomer cycle. The N-terminus, typically a secondary amine, is bromoacetylated and the desired ligation group is then introduced by displacement of the bromide by an excess of a nucleophilic reagent. In a final step, any protecting group on the newly introduced functionality is removed with an appropriate reagent, or further treatment converts it into the desired ligation group prior to cleavage of the product peptoid from the solid support. In some cases the protecting group comes off during trifluoroacetic acid (TFA[1]) cleavage. If desired, a spacer can be added prior to introduction of the ligation group to increase the distance between the conjugated molecules.

To demonstrate the utility of this method, a simple model peptoid (Figure 2) was synthesized and functionalized with several useful ligation groups. The product peptoids were characterized by reverse-phase HPLC and electrospray mass spectrometry (Table 2).

Aminooxyacetamide (aldehyde-specific). Oxime bond formation has been utilized extensively for the introduction of aminooxyacetamide-containing ligands into biomolecules. An aminooxy linker was added to a DNA oligomer during solid-phase synthesis, and conjugation with an aldehyde-containing reporter group was efficient and rapid (*30*). Site-specific modification of peptides and proteins with aminooxy groups was used to prepare well-defined biosensors and probes assembled via oxime linkages (*31*). A new strategy for the assembly of triple-function branched peptides through stepwise chemoselective ligations via oxime bonds has been reported (*32*). Oxime linkages have also been used in the assembly of peptide-based conjugates, such as peptide vaccine candidates (*33*) and in protein conjugates of defined structure (*34*). In those reports an N-Boc-protected aminooxyacetic acid was coupled to the N-terminus of peptides during solid-phase synthesis in the presence of a condensing agent (*34*−*37*). The N-protected aminooxyacetic acid reagent is, however, a rather expensive intermediate.

We introduced the same conjugation moiety by a much simpler submonomer route. The aminooxyacetamide functionality was generated in high yield using *N*-hydroxysuccinimide in the displacement of a solid supported N-terminal bromoacetamide−peptoid (Scheme 1A). Removal of the *N*-succinimide protection with hydrazine hydrate gave the free aminooxyacetamide−peptoid, **1**. *N*-Aminooxyacetamide−peptoid reacted rapidly with benzaldehyde in dilute aqueous solution at pH 4.5 to give the oxime in nearly quantitative yield (data not shown). An aminooxyacetamide−peptoid was ligated to an aldehyde−peptoid (see Peptoid-to-Peptoid Ligation).

Carboxyhydrazide (aldehyde-specific). Carboxyhydrazides form hydrazones with aldehydes and ketones that in general are fairly stable (*38*). They have been used

Scheme 1. Ligation Groups from Bromoacetylated Peptoids[a]

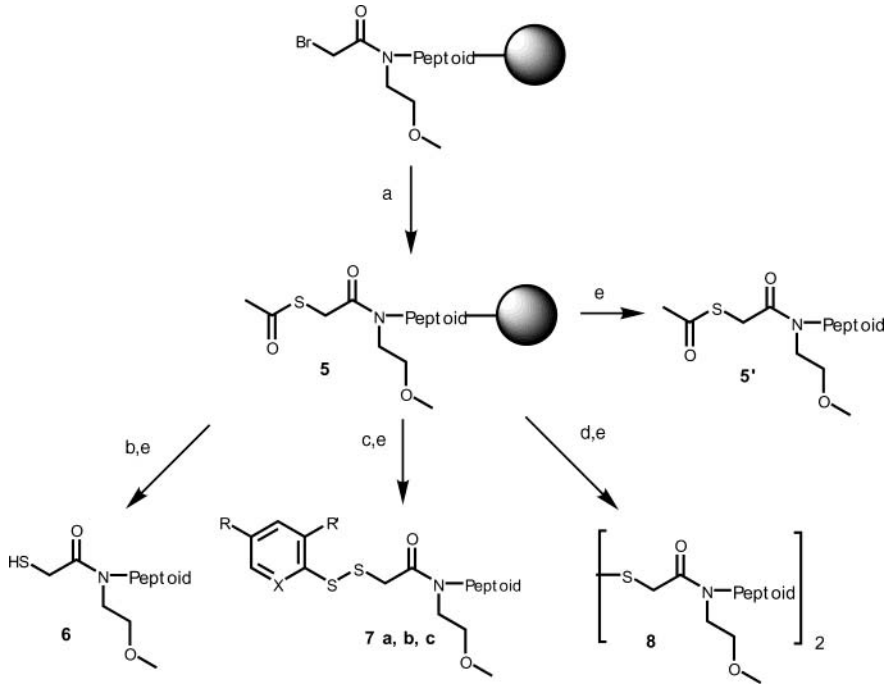
[a] Reagents: (a) (i) *N*-hydroxysuccinimide/DBU, (ii) hydrazine; (b) (i) Boc-$NHNH_2$, (ii) Ac_2O/pyridine; (c) KI; (d) (i) $(CH_3O)_2CHCH_2CH_2NH_2$, (ii) Ac_2O/pyridine; (e) 95% aq TFA.

extensively for conjugation of ligands with biomolecules that contain saccharides (glycoproteins such as antibodies, glycoconjugates, and enzymes (like horseradish peroxidase)) because aldehyde groups are readily introduced into such molecules by enzymatic or chemical (periodate) oxidation (*39*).

Many reporter groups, such as hydrazide derivatives of biotin and fluorescein dyes, are commercially available. Peptides containing a C-terminal hydrazide have been prepared by using an ester linkage to the solid support and cleaving the completed peptide chain by hydrazinolysis (*40*). Reagents have also been developed for converting lysine residues in peptides and proteins into hydrazide functionalities in aqueous solution (*41*), and in a scheme for the chemoselective acylation of 2-hydrazinylacetamide peptides a tris-Boc derivative of 2-hydrazinylacetic acid had to be prepared in order to avoid polymerization of 2-(2-*tert*-butoxycarbonylhydrazinyl)-acetic acid during coupling (*21*).

Using the new modified submonomer procedure, a hydrazide group is readily introduced at N-terminal and internal positions of a peptoid oligomer. Displacement of the bromoacetamide with N-Boc-protected hydrazine (Boc-$NHNH_2$), followed by acetylation with acetic anhydride (Ac_2O) in pyridine produced the N-terminal *N*-(carbamoylmethyl)acetohydrazide−peptoid, **2**. Displacement with N-Boc protected hydrazine (Boc-$NHNH_2$) and continuation of peptoid synthesis produced a peptoid with an internal hydrazide function. Cleavage of the product peptoid with TFA simultaneously removed the Boc group. The resulting hydrazide−peptoid undergoes rapid hydrazone formation with benzaldehyde in dilute aqueous solution at pH 4.5 (data not shown). The N-terminal 2-hydrazinylacetamide peptoid is the product if the acetylation step is omitted. A hydrazide group, incorporated at internal position of a peptoid, reacted with an intramolecular aldehyde to generate a cyclic peptoid (E. Beausoleil, personal communication). A *N*-(carbamoylmethyl)acetohydrazide peptoid was ligated to an aldehyde−peptoid (see Peptoid-to-Peptoid Ligation).

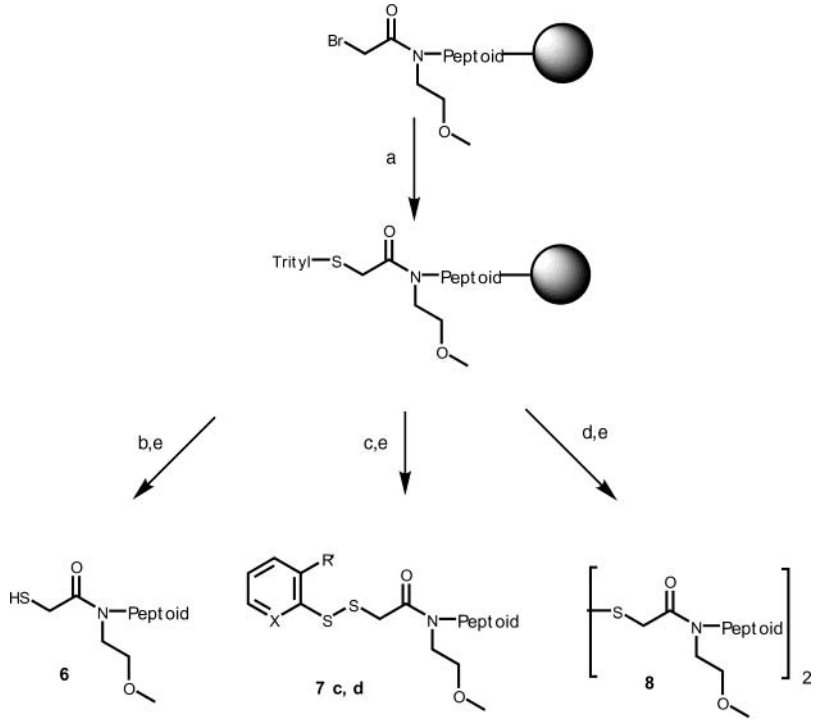
Iodoacetyl (thiol-specific). The iodoacetyl and maleimido groups are thiol-specific ligation groups that generate a stable thioether linkage. Numerous iodoacetyl reagents are commercially available (such as fluorescent derivatives from Molecular Probes). We have also routinely coupled iodoacetic acid and 3-maleimidopropionic acid (*42*) to the N-terminus of peptides and peptoids during solid-phase synthesis, and they have been used successfully for ligations.



To simplify the synthesis of a thiol-specific group, we first investigated the N-terminal bromoacetamide−peptoid but found that the bromoacetamide group is not completely stable to the acid cleavage and deprotection conditions (using 95% aqueous TFA), resulting in the formation of 5−10% 2-hydroxyacetamide−peptoid byproduct. Instead, we used a displacement reaction on-resin (as an alternative to direct coupling of iodoacetic acid to the peptoid) to generate the more stable iodoacetamide−peptoid, **3**, by a Finkelstein reaction with potassium iodide in DMF (*43*), a reaction that proceeded in quantitative yield. The iodoacetamide−peptoid reacts readily with a thiol compound in aqueous solution at pH 8 to form a thioether (data not shown).

Aldehyde Groups. Peptides with aldehyde moieties have often been synthesized by incorporation of an N-terminal serine. After synthesis, the serine is oxidized to a terminal aldehyde with aqueous sodium periodate. Others have synthesized peptides as the C-terminal ester on a PAM support and released the C-terminal masked aldehyde by aminolysis with aminoacetaldehyde dimethyl acetal followed by TFA treatment to give the unprotected peptide aldehyde. This could then be coupled to aminooxyacetamide peptide derivatives by chemoselective ligation in aqueous solution (*44*). Recently, DNA probes that incorporate a modified nucleoside containing a ketone functionality allowed postsynthetic introduction of several aminooxyacetyl ligands under physiological conditions (*45*). The synthesis of oxime-linked mucin mimics was accomplished via the incorporation of multiple ketone residues into a peptide followed by reaction with aminooxy sugars corresponding to the tumor-related TN and sialyl TN (STN) antigens (*46*).

Peptoids containing aldehyde groups are readily synthesized. An aldehyde is incorporated at any position of the peptoid using commercially available amino aldehydes where the aldehyde function is protected (1-amino-2,2-dimethoxyethane and 1-amino-3,3-diethoxypropane were used in this study) as a submonomer. The CHO−peptoid, **9**, was synthesized in high yield. It reacted with aminooxyacetic acid in aqueous solution at pH 4 to give the oxime in high yield (data not shown). An aldehyde−peptoid was ligated to aminooxyacetamide− and hydrazide−peptoids (see Peptoid-to-Peptoid Ligation).



Thiol/Activated Disulfide/Homodisulfide Peptoids. Properly protected cysteine (Cys) residues incorporated during peptide synthesis have been used extensively to modify peptides for conjugation with proteins, labels, surfaces, etc., and typically results in a cleavable disulfide or thioether linkage (*47*) in the conjugate. To introduce a thiol functionality by a simple submonomer protocol we used potassium thioacetate (1 M in DMF/water (95:5 v/v)) and triphenylmethylmercaptan (0.25 M in DMF containing 1 equiv of DBU) to displace the bromide in the bromoacetamide−peptoid to generate key

Scheme 2. Thiol Peptoids via 2-(*S*-Acetylthio)acetamide Intermediate[a]

[a] Reagents: (a) Ac-S$^-$K$^+$; (b) NH_2OH/pyridine; (c) (i) NH_2OH/pyridine, (ii) 2,2′-dithiodipyridine (for **7a**), 5,5′-dithiobis(2-nitrobenzoic acid) (for **7b**), or 2,2′-dithiobis(5-nitropyridine) (for **7c**); (d) (i) NH_2OH/pyridine, (ii) iodine; (e) 95% aq TFA.

Scheme 3. Thiol Peptoids via 2-(*S*-Tritylthio)acetamide−Peptoid Intermediate[a]

[a] Reagents: (a) triphenylmethylmercaptan/DBU; (b) TFA/Et_3SiH; (c) 3-nitro-2-pyridinesulfenyl chloride (for **7c**) or 2-nitrophenylsulfenyl chloride (for **7d**); (d) iodine; (e) 95% aq TFA.

intermediate S-protected mercaptoacetamide−peptoids, 2-(S-acetylthio)acetamide−peptoid, **5** (Scheme 2), and 2-(S-tritylthio)acetamide−peptoid, **10** (Scheme 3). Both can be directly converted into the free thiol or into a number of useful thiol derivatives as described below.

Free Thiol. The free mercaptoacetamide peptoid, **6**, can be obtained in high yield from the *S*-acetyl derivative, **5**, by treatment with hydroxylamine (1 M hydroxylamine hydrochloride in pyridine) (*48*) followed by cleavage with TFA. The 2-mercaptoacetamide peptoid can also be obtained from the *S*-trityl derivative by a modified TFA cleavage mixture that contains a scavenger (TFA/H_2O/triethylsilane (Et_3SiH) (92.5:5:2.5 v/v)) (*49*). A mercaptoacetamide−peptoid forms the mixed disulfide with 5,5′-dithio-bis(2-nitrobenzoic acid) (Ellman's reagent; DTNB) in sodium phosphate buffer at pH 8 (data not shown).

We have successfully reacted the solid-supported mercaptoacetamide−peptoid, derived from the *S*-acetylmercaptoacetamide derivative, **5**, by treatment with hydroxylamine, with maleimide compounds, and reaction with

fluorescein-5-malemide (25 mM in pyridine for 1 h) resulted in the formation of the acid-stable thioether-linked chromophore adduct in 90% yield (data not shown).

A thiol is readily incorporated into peptoids at internal positions using the standard 2-(*S*-tritylthio)ethanamine monomer unit (*50*). The intermediate 2-(*S*-tritylthio)-ethyl−peptoid can be manipulated on the support as described for the terminal 2-(*S*-tritylthio)acetamide−peptoid. A mercaptoacetamide−peptoid was ligated to disulfide-activated peptoids (see Peptoid-to-Peptoid Ligation).

Activated Disulfides. The resin-bound *N*-mercaptoacetamide peptoid, **6**, is readily converted into activated disulfides. Treatment with 2,2′-dipyridyl disulfide (1 M in DMF/acetic acid (95:5 v/v)) resulted in the formation of 2-pyridinesulfenylmercaptoacetamide−peptoid, **7a**, in high yield. Other activated disulfides are also readily prepared by disulfide exchange: 4-nitro-3-carboxybenzenesulfenylmercaptoacetamide, **7b**, by treatment with 5,5′-dithiobis(2-nitrobenzoic acid) (1 M in pyridine), and 3-nitro-2-pyridinesulfenylmercaptoacetamide, **7c**, with 2,2′-dithiobis(5-nitropyridine) (1 M in DMF/acetic acid (95:5 v/v)). The activated disulfides are stable to TFA deprotection and underwent complete exchange with excess thiol compounds under mildly acidic conditions at pH 6 (for **7a** and **7c**) (*47*) and mildly basic conditions at pH 8 (for **7b**) (data not shown).

Treatment of resin-bound 2-(*S*-tritylthio)acetamide−peptoid, **10**, with 2-nitrophenylsulfenyl chloride (0.25 M in dichloroethane/acetic acid (95:5 v/v)) converts it directly into 2-nitrophenylsulfenylmercaptoacetamide−peptoid, **7d**. (*47*, *51*) This activated disulfide is completely stable to TFA deprotection, and it underwent complete exchange with excess thiol compounds under mildly basic conditions at pH 8 (*47*) (data not shown). 3-Nitro-2-pyridinesulfenyl chloride can also be used, and the resulting 3-nitro-2-pyridinesulfenylmercaptoacetamide−peptoid, **7b**, is stable to acid deprotection. It underwent complete exchange with excess thiol compounds under mildly acidic conditions at pH 6 (*47*) (data not shown). Treatment on the support or in solution with tris(2-carboxyethyl)phosphine (TCEP) (*52*) or dithiothreitol (DTT) (*53*) completely reduced the activated disulfides to the mercaptoacetamide−peptoid. Disulfide activated peptoids were ligated to a mercaptoacetamide−peptoid (see Peptoid-to-Peptoid Ligation).

Peptoid Disulfides. Exposure of resin-bound mercaptoacetamide peptoid, **6**, or 2-(*S*-tritylthio)acetamide−peptoid, **10**, to dilute iodine in DCE resulted in complete conversion to the homo-peptoid disulfide which was cleaved from the support and deprotected with TFA to give free homo-peptoid disulfide, $(SAc\text{-}N\text{−}peptoid\text{-}NH_2)_2$, **8**, in high yield. We have successfully used this route to dimerize the model pentamer peptoid at the N-terminus, and a hexamer peptoid that contains a 2-(*S*-tritylthio)-ethyl side group near the C-terminus. Mercaptoacetamide−peptoids were also readily oxidized with iodine in aqueous solution to the corresponding homo-peptoid disulfides, $(SAc\text{-}N\text{−}peptoid\text{-}NH_2)_2$ and $(Ac\text{-}N\text{−}peptoid\text{-}N\text{-}(ethyl\text{-}S\text{-})CH_2CONH_2)_2$, respectively, in high yield (data not shown).

The acid-stable 2-(*S*-acetylthio)acetamide−peptoid, **9**, was also cleaved from the support with TFA. The *S*-acetyl protection group could conveniently be removed in situ with hydroxylamine (0.05 M) in aqueous solution (phosphate buffer at pH 7.5), and the liberated mercaptoacetamide reacted completely with 3-maleimidopropionic acid or Ellman's reagent in a reaction sequence similar to bioconjugations using *N*-succinimidyl *S*-acetylthioacetate (SATA) (*48*).

Peptoid-to-Peptoid Ligations. To demonstrate the utility of some of the ligation groups, we chose to synthesize peptoid dimers. We joined peptoids using several of the most common ligation pairs (Table 1, entries a−c). Reactions were performed with the two types of peptoids in 1:1 stoichometry in dilute solution (0.1 and 0.5 mM of each component) for 30 min. Higher yields could be expected if higher concentrations and longer reaction times were used. Hydrazone formation by reaction of an aldehyde and a hydrazide peptoid proceeded in 45% yield (a result that is comparable to yields recorded in the literature (*38*)). Oxime formation between aldehyde and aminooxyacetamide peptoids resulted in dimer formation in 83% yield (Rose et al. (*36*) observed near-quantitative yields after 20 h). Disulfide formation between mercaptoacetamide peptoid and 2-nitrophenylsulfenylmercaptoacetamide and 2-pyridylsulfenylmercaptoacetamide peptoids proceeded in 88% and 92% yield, respectively. HPLC chromatograms of peptoid-to peptoid ligations are available in the Supporting Information.

CONCLUSION

We have shown that several chemoselective functionalities can readily be introduced into peptoids (and presumably into peptides and many other solid-phase organic chemistries) using a simple extension of the standard solid-phase peptoid submonomer method. The method was implemented primarily for N-terminal modification. Several of the functionalities can also be incorporated into peptoids at internal positions using standard monomers: thiol, aldehyde, and hydrazide functions are added using 2-(*S*-tritylthio)ethanamine (*50*), 1-amino-3,3-diethoxypropane, and $Boc\text{−}NHNH_2$, respectively. Alternatively, this method can be adapted so the desired functional group can be placed at other positions by using orthogonal protection of a lysine residue (for peptides) or an alkyl diamine monomer (for peptoids and peptides (*54*)). Some of the steps in this method may not be fully compatible with all functionalities in peptides, or non-standard protection schemes may be required.

The method uses commercially available reagents, is fully compatible with standard peptoid submonomer synthesis conditions, is easily automated, and generates the desired peptoid in high yield and purity. The method should simplify the introduction of chemoselective functionalities into molecules assembled by a solid-phase synthesis strategy (combinatorial libraries of ligands) for further screening for compounds with useful properties.

EXPERIMENTAL PROCEDURES

All chemicals were purchased from Aldrich, except for fluorescein-5-malemide (Molecular Probes, Eugene, OR), hydroxylamine hydrochloride, and tris(2-carboxyethyl)-phosphine (TCEP) (Pierce). The 2-(S-tritylthio)ethanamine monomer unit was prepared as described (*50*).

General Procedures. *Peptoid Synthesis.* Peptoid oligomer syntheses were performed on a robotic synthesizer (*55*). The syntheses were conducted with Rink amide polystyrene resin (50 μmol; 65 mg; substitution level 0.75 mmol/g). Acylation reactions were performed by the addition of bromoacetic acid (0.83 mL of 1.2 M in DMF; 1 mmol), followed by *N*,*N*′-diisopropylcarbodiimide (200 μL, 1.25 mmol). Reaction mixtures were agitated at 35 °C for 20 min. Displacement reactions were performed by addition of primary amine as 1 M solutions in DMF (1.0 mL; 1.0 mmol), followed by agitation for 20 min at

35 °C. These two steps are repeated with the appropriate amines to build the desired N-substituted glycine sequence.

Chemoselective Ligation Group Synthesis. The chemoselective ligation group was next introduced at the N-terminus with one additional submonomer cycle. The N-terminus, typically a secondary amine, was bromoacetylated, as described above, and the desired ligation group was introduced by displacement of the bromide by an excess of a nucleophilic reagent. In each reaction 1.25 mL of reagent was used, and the reaction mixture was agitated at 35 °C for 20 min. A common wash cycle consisting of 5 × 2 mL of DMF was used after each reagent addition with agitation at 35 °C for 1 min. All nucleophilic displacement reagents and auxiliary solutions were prepared immediately before use.

Aminooxyacetamide, 1. Bromoacetylated peptoid was treated with (a) *N*-hydroxysuccinimide/DBU (1.25 mL; 1 M/1 M in DMF) for 20 min, followed by (b) hydrazine hydrate (1.25 mL; 1 M in DMF) for 20 min.

***N*-(Carbamoylmethyl)acetohydrazide, 2.** Bromoacetylated peptoid was treated with Boc-$NHNH_2$ (1.25 mL; 1 M in DMF) for 20 min, followed by acetic anhydride (1.25 mL; 1 M in pyridine) for 20 min.

Iodoacetamide, 3. Bromoacetylated peptoid was treated with KI (1.25 mL; 1 M in DMF) for 20 min.

Aldehyde, 4. Bromoacetylated peptoid was treated with (a) 1-amino-3,3-diethoxypropane or 1-amino-2,2-dimethoxyethane (1.25 mL; 1 M in DMF) for 20 min, followed by (b) acetic anhydride (1.25 mL; 1 M in pyridine) for 20 min.

2-(*S*-Acetylthio)acetamide, 5. Bromoacetylated peptoid was treated with potassium thioacetate (1.25 mL; 1 M in DMF/water (95:5 v/v)) for 20 min.

2-Mercaptoacetamide, 6. *S*-Acetylmercaptoacetamide, **5**, was treated with hydroxylamine-HCl (1.25 mL; 1 M in pyridine) for 20 min.

2-Pyridinesulfenylmercaptoacetamide, 7a. *S*-Acetylmercaptoacetamide, **5**, was treated with a) hydroxylamine·HCl (1.25 mL; 1 M in pyridine) for 20 min, followed by b) 2,2′-dithiodipyridine (1.25 mL; 0.25M in DMF/acetic acid (95:5 v/v)) for 20 min.

4-Nitro-3-carboxyphenylsulfenylmercaptoacetamide, 7b. Acetylmercaptoacetamide, **5**, was treated with (a) hydroxylamine·HCl (1.25 mL; 1 M in pyridine) for 20 min, followed by (b) 5,5′-dithiobis(2-nitrobenzoic acid) (1.25 mL; 0.25 M in pyridine) for 20 min.

3-Nitro-2-pyridinesulfenylmercaptoacetamide, 7c. Acetylmercaptoacetamide, **5**, was treated with (a) hydroxylamine-HCl (1.25 mL; 1 M in pyridine) for 20 min, followed by (b) 2,2′-dithiobis(5-nitropyridine) (1.25 mL; 0.25M in DMF/acetic acid (95:5 v/v)) for 20 min.

Homo-disulfide-acetamide (SAc-N−peptoid-NH_2)$_2$, 8. Acetylmercaptoacetamide, **5**, was treated with (a) hydroxylamine-HCl (1.25 mL; 1 M in pyridine) for 20 min, followed by (b) iodine (1.25 mL; 0.05 M in DCE) for 20 min.

2-(*S*-Tritylthio)acetamide, 10. Bromoacetylated peptoid was treated with triphenylmethanethiol/DBU (1.25 mL; 0.25 M/0.25 M in DMF) for 40 min. The triphenylmethanethiol/DBU reagent is prepared by first dissolving triphenylmethanethiol in DMF followed by addition of the equimolar amount of DBU.

2-Mercaptoacetamide, 6. 2-(*S*-Tritylthio)acetamide, **10**, was treated with TFA/H_2O/triethylsilane (92.5:5:2.5 v/v; 2.5 mL) for 60 min.

3-Nitro-2-pyridinesulfenylmercaptoacetamide, 7c. 2-(*S*-Tritylthio)acetamide, **10**, was treated with 3-nitro-2-pyridinesulfenyl chloride (1.25 mL; 0.25 M in DCE/acetic acid (95:5 v/v)) for 20 min.

2-Nitrophenylsulfenylmercaptoacetamide, 7d. 2-(*S*-Tritylthio)acetamide, **10**, was treated with 2-nitrophenylsulfenyl chloride (1.25 mL; 0.25 M in DCE/acetic acid (95:5 v/v)) for 20 min.

Homo-disulfide-acetamide (SAc-N−peptoid-NH_2)$_2$, 8. 2-(*S*-Tritylthio)acetamide, **10**, was treated with iodine (1.25 mL; 0.05 M in DCE) for 20 min.

After conclusion of the synthesis, side-chain protecting groups were removed, and the oligomer was released from the resin support by treatment of the oligomer-resin with 95% trifluoroacetic acid in water (2.5 mL) for 60 min at room temperature, followed by filtration, dilution, and lyophilization. The crude products were analyzed by reversed-phase HPLC using the following conditions: Duragel G C18 (5 mμ; 50 × 2 mm) column; 5−95% gradient at 1 mL/min over 10 min at 60 °C; solvent A: water + 0.1% (v/v) TFA, solvent B: acetonitrile + 0.095% (v/v) TFA.

Ligation of Peptoids. The crude functionalized peptoids were purified by reversed-phase HPLC prior to ligation using the following conditions: Duragel G C4 HS (5 mμ; 50 × 20 mm) column; 20−65% gradient at either 20 or 40 mL/minute over 30 min at 60 °C; solvent A: water + 0.1% (v/v) TFA, solvent B: acetonitrile + 0.1% (v/v) TFA, using a Rainin dynamics SD-200 solvent delivery system.

Aldehyde/Aminooxyacetamide and Aldehyde/Hydrazide Ligations. Aminooxyacetamide−peptoid, **1**, or *N*-(carbamoylmethyl)acetohydrazide−peptoid, **2** (2 μL of a 5 mM stock solution in water containing 20% acetonitrile) and aldehyde−peptoid **4** (88 μL of a 100 μM stock solution in water containing 30% acetonitrile and 0.1% TFA) were added to 10 μL of a 1 M sodium acetate (pH 4.7) buffer. The reaction mixture was incubated at 20 °C for 30 min prior to HPLC analysis.

Mercaptan and Activated Disulfide Ligations. Mercaptoacetamide−peptoid, **6** (5 μL of a 5 mM stock solution in water containing 20% acetonitrile) and activated disulfide−peptoid, **7a** or **7d** (5 μL of a 5 mM stock solution in water containing 45% acetonitrile), were added to 40 μL 20mM tris-HCl buffer (pH 8.0) containing 0.4 mM EDTA/acetonitrile (1:1 v/v). The reaction mixtures were incubated at 20 °C for 30 min prior to hplc analysis.

Ligation mixtures were analyzed by reversed-phase HPLC using the following conditions: Duragel G C4 (5 micron; 50 × 2 mm) column; 5−95% gradient at 0.8 mL/minute over 10 min at 60 °C; solvent A: water + 0.1% (v/v) TFA, solvent B: acetonitrile + 0.095% (v/v) TFA. HPLC chromatograms of peptoid-to peptoid ligations are available in the Supporting Information.

ACKNOWLEDGMENT

The authors wish to thank Dr. Deborah H. Charych and Dr. Eric Beausoleil for suggestions and advice during this investigation.

Supporting Information Available: HPLC chromatograms of functionalized peptoids and of peptoid dimer ligations. This material is available free of charge via the Internet at http://pubs.acs.org.

Native Chemical Ligation of Hydrophobic Peptides in Lipid Bilayer Systems

Christie L. Hunter[†] and Gerd G. Kochendoerfer*

Gryphon Therapeutics, 600 Gateway Boulevard,
South San Francisco, California 94080. Received February 19, 2004; Revised Manuscript Received March 9, 2004

The covalent modification of water-insoluble membrane polypeptides incorporated into lipid bilayers by native chemical ligation is described. The key feature of this strategy is the use of cubic lipidic phase (CLP) matrixes as reaction media. The CLP-matrix consists of a lipid bilayer into which hydrophobic polypeptides and folded membrane proteins can be inserted and two unbounded aqueous channels that give the aqueous phase access to both sides of an infinite lipid bilayer and thus ensure that modification of solvent-exposed sites is independent of the topology of membrane incorporation. The enzymatic removal of an N-terminal proteolytic cleavage sequence from the membrane polypeptide exposes an N-terminal cysteine residue. Subsequently, a C-terminal thioester peptide is joined to the N-terminus of the polypeptide by a native chemical ligation reaction. By use of this approach, incorporation of a variety of molecular tools, such as spectroscopic probes, unnatural amino acids, and molecular markers into membrane proteins that cannot be easily solubilized in detergent or denaturant solutions, may be achieved.

Chemical synthesis and modification of membrane proteins (*1*−*3*) employing chemoselective ligation strategies (*4*−*7*) such as native chemical ligation (NCL)[1] (*5*) is a powerful strategy to introduce noncoded amino acids and reporter groups into members of this important class of proteins. Semisynthetic approaches such as expressed protein ligation apply NCL (*5*) to the linkage of polypeptides in which one or both reaction partners have been produced by recombinant means (*8*−*11*). A truncated version of the ion channel protein Kcsa of *Streptomyces lividans* has been synthesized and subsequently folded by the addition of a synthetic peptide to the C-terminus of a recombinantly produced thioester peptide (*12*). Typically, such reactions are performed in mixed aqueous−organic solvents, or in the presence of detergents (*1*−*3,12*). By contrast, it would be desirable to modify synthetic or recombinant hydrophobic polypeptides in their native lipid environment and thus take advantage of the lipid as the reaction medium or "solvent". This would be applicable to peptide and bioconjugate chemistry, both for the enzymatic modification of polypeptides

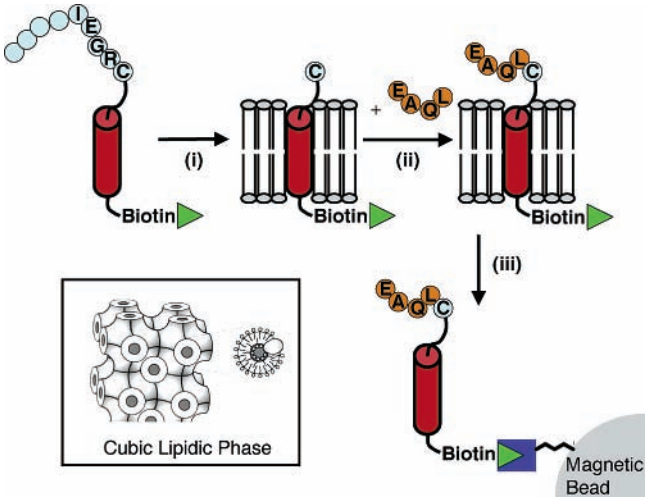

Figure 1. Schematic of the experimental design demonstrating native chemical ligation in cubic lipidic phases. After incorporation of a peptide corresponding to the first membrane-spanning helix of bacteriorhodopsin (bR) into the lipid bilayer, a peptide containing the protease recognition site was removed by Factor Xa cleavage (i). A peptide tetramer corresponding to the N-terminus of bR was then ligated to the transmembrane peptide to obtain the full bacteriorhodopsin N-terminus (ii). The extent of cleavage and the progress of the ligation inside the CLP was followed by MALDI-TOF mass spectrometry of the respective peptides after extraction with β-D-octylglucopyranoside and affinity capture on streptavidin beads through an *N*-imino-biotin label (iii). The inset shows a schematic of a cubic lipidic phase (reprinted from plate 9, ref 14, with kind permission from Elsevier).

and for native chemical ligation reactions. Here, we describe a strategy for the introduction of wild-type or labeled peptides to the N-terminus of a synthetic membrane polypeptide in a lipid bilayer environment. As outlined in Figure 1, the enzymatic removal of a proteolytic cleavage sequence from the N-terminus (*10, 11*) of a membrane polypeptide incorporated into a lipid bilayer generates a free N-terminal cysteine residue. Subsequently, a C-terminal thioester peptide is added to the N-terminus of the protein by a NCL reaction, yielding the desired construct. If desired, ligated polypeptides can be isolated from the lipidic phase after completion of the reaction.

A key feature of the approach is the cleavage and ligation reaction of a membrane polypeptide reconstituted into a cubic lipidic phase (CLP). The CLP-matrix consists of a lipid bilayer into which hydrophobic polypeptides and folded membrane proteins can be inserted and two aqueous channels that are both topologically unbounded, giving the aqueous phase access to both sides of an infinite lipid bilayer (*13, 14*). This feature ensures that all modifications are independent of the topology of membrane incorporation. By contrast, if a more traditional lipid system such as a standard liposome preparation were used for the reaction, the population of peptides that are incorporated with the N-terminus protruding to the inside of the vesicle would not be able to react with extraneously added reactants and vice versa. Since CLPs do not exhibit "inside" or "outside" regions, both the N-terminus and C-terminus of a polypeptide will be amenable for reaction with water-soluble reactants.

Since lipid and water diffusion rates inside the CLP-matrix are comparable or slightly slower than those in lamellar lipid phases and bulk water, respectively, sufficient reaction and modification rates can be achieved as also demonstrated in this study (*14*−*16*). Incorporation into a CLP also may overcome the difficulty in refolding membrane proteins after ligation reactions under denaturing conditions (*1*−*3, 12, 17*), since the reaction can be performed on a membrane polypeptide in the folded state under mild conditions. Finally, a possible shielding effect of detergent molecules that has been observed previously to prevent the ligation reactions of hydrophobic peptides (our own unpublished observation) can be avoided.

To demonstrate this approach, we performed an NCL reaction between a synthetic, membrane-incorporated polypeptide (named bRhel)[2] derived from the first transmembrane helix of bacteriorhodopsin (bR) of *Halobacterium salinarium*, and a four-amino acid residue oligopeptide corresponding to the N-terminus of bR (Figure 1). Dissolution of this peptide into typical denaturant buffers was not successful, and ligation thus could not be performed using traditional chemoselective reaction conditions (*4*−*7*). By contrast, incorporation into the CLP overcame this solubility problem. To facilitate ligation, Thr^5 of bR was replaced with Cys^5 to serve as ligation site. This Cys residue was capped with the N-terminal Factor Xa protease recognition site, IEGR (*10, 11*), to avoid the presence of a free N-terminal cysteine residue during the bilayer reconstitution process and to extend applicability of this approach to recombinant membrane proteins. Alternatively, intein-based expression approaches could be employed to generate proteins with N-terminal cysteines (*18*).

To form the CLP, the bRhel peptide in powder form was mixed with 1-monooleoyl-*rac*-glycerol (C18:1,[*cis*]-9) (MO) and 200 mM Tris-HCl buffer (pH 8), forming a cloudy suspension. The suspension was spun in a tabletop centrifuge for 3 h (see Supporting Information for more details). The formation of CLPs was indicated by the formation of optically clear, gellike phases, suggesting that the water-insoluble peptide was incorporated into the lipid phase. The phases remained optically clear at room temperature for at least two months, suggesting high thermodynamic stability. CD and polarized FTIR spectroscopy and proteolysis protection experiments on a bRhel analogue lead to the prediction that this peptide inserts into lipid bilayers in an α-helical structure (*19*). bRhel proved to be insoluble in aqueous buffers, even in the presence of strong denaturants such as 6 M guanidinium chloride, leading to turbid solutions of aggregated peptide. By contrast, no visible aggregation of hydrophobic peptide was observed after incorporation of bRhel peptide into a CLP at a lipid:peptide ratio of 100:1 and prolonged centrifugation of the CLPs. Taken together, these observations suggest that bRhel is associated with the cubic lipidic phase bilayer, possibly in a helical conformation.

Rapid monitoring of the progress of the ligation reaction within the CLP was essential for method development; therefore, an assay was developed that employs affinity capture and subsequent MALDI-TOF mass spectrometry to qualitatively follow the extent of ligation (Figure 2). An *N*-imino-biotin label was introduced at position Lys^{41} to facilitate purification and to allow for subsequent affinity capture. MALDI-TOF analysis was performed directly from the affinity beads in order to monitor the ligation reaction immediately without any chromatographic purification step and to avoid errors due to differential ease of release from the affinity beads of

[2] The sequence of bRhel is GKGYI EGR ^{5}CG ^{7}RPEWI ^{12}WLALG ^{17}TALMG ^{22}LGTLY ^{27}FLVKG ^{32}MGVSD ^{37}PDAKK. The residues are numbered according to their position in the sequence of wild-type bacteriorhodopsin.

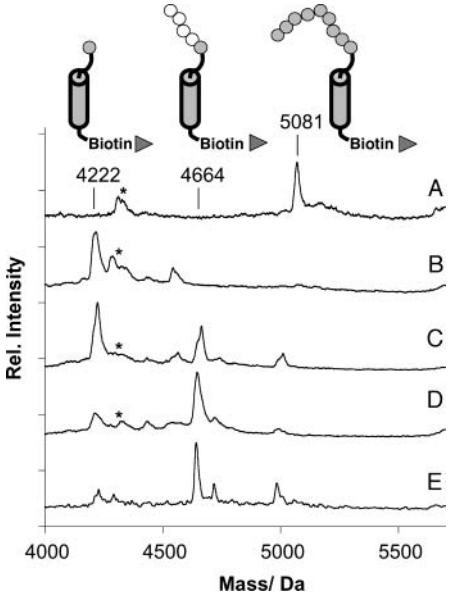

Figure 2. MALDI-TOF analysis of the progress of native chemical ligation in cubic lipidic phases. (A) MALDI-TOF spectra of bRhel prior to protease cleavage. (B) MALDI-TOF spectra of this peptide after protease cleavage. (C−E) MALDI-TOF spectra of this peptide after ligation with peptide EAQL after 25 min (C), 75 min (D), and overnight (E). The peaks of varying intensity marked with an asterisk are due to impurities associated with the purification and analysis process. Spectra were obtained directly from the affinity beads plated on MALDI slides.

the various constructs. The uneven surface of the matrix spot due to the presence of the beads on the plate is the cause of the low resolution and mass accuracy observed in the mass spectra shown.

Spectrum A presents a MALDI-TOF spectrum of bRhel after incorporation into a CLP, followed by dissolution of the CLP in a buffer containing 20 mM Bis-Tris Propane buffer (1,3-bis[tris(hydroxymethyl)methylamino]propane) (pH = 9.5), 27% β-D-octylglucopyranoside, and 20% β-mercaptoethanol, and affinity capture onto streptavidin-coated beads. The reducing agent was added to keep all peptide components and ligation products in the reduced, disulfide-free state during analysis and workup. The spectrum displays one major peak at m/z = 5081, corresponding to the mass of uncleaved bRhel. Smaller peaks (labeled with an asterisk) represent impurities from the lipid matrix, extraction process, and/or the affinity beads and were also present in the mass spectra in the absence of protein (data not shown). Whereas these impurities vary in intensity between individual time-points due to variations in the number of beads spotted on the plate, they do not interfere with the peaks of most interest and therefore the monitoring of the progress of the reaction. Spectrum B presents a mass spectrum of the same peptide after cleavage with Factor Xa inside the CLP overnight. The disappearance of the major peak at m/z = 5081 concomitant with the appearance of a major peak at m/z = 4222 is consistent with efficient removal of the Cys-capping sequence GKGYIEGR by the Factor Xa protease.

Spectra C, D, and E show the appearance of ligation product after addition of a 2-fold excess of N-terminal peptide EAQL thioester with 0.5% thiophenol to the CLP after 25 and 75 min and overnight incubation, respectively. The gradual disappearance of the peak at m/z = 4222 Da with a concomitant increase of a peak at m/z = 4664 Da demonstrates the progress of the formation of a native amide bond between the bR transmembrane peptide and the bR N-terminus.

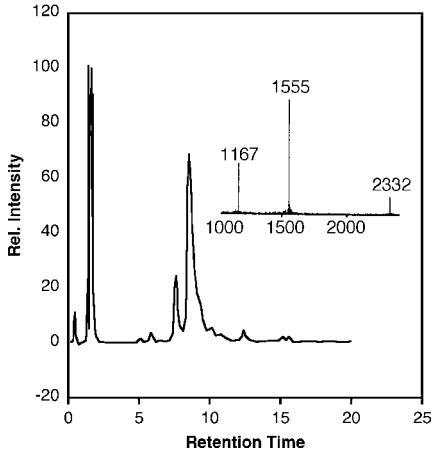

Figure 3. RP-HPLC chromatogram (detected at 280 nm) after dissolution of the CLP in 60% 2-propanol, 30% acetonitrile, and 10% water containing 0.1% trifluoroacetic acid. The major peak at 9 min correlates with the desired reaction product (observed MW = 4663 ± 1 Da (theoretical MW = 4663, average isotope composition).

After the reaction was complete, the reaction mixture was further analyzed and purified by RP-HPLC and subsequent electrospray mass spectrometry. For this analysis, the CLP was dissolved in 60% 2-propanol, 30% acetonitrile, and 10% water containing 0.1% trifluoroacetic acid. The analytical RP-HPLC chromatogram of an aliquot of the resultant solution is presented in Figure 3. The chromatogram exhibits a dominant peak at ∼ 9 min retention time. ESI-MS analysis of this peak indicates this component has the same mass as the desired reaction product (4663 ± 1 Da, see Figure 3 inset) and that it can be isolated with high purity. Reactions were typically performed at a 600 μg scale starting material (see Supporting Information), and the overall yield of pure product purified by RP-HPLC was typically ∼33% (200 μg). Preparation of CLPs is scalable and is expected to be amenable to multi-milligram scale modification of hydrophobic polypeptides.

The synthetic strategy described in this communication has several applications in the synthesis and modification of hydrophobic polypeptides. The limited solubility of hydrophobic membrane polypeptides in aqueous solvents has been a challenge to their modification (*1*−*3*, *12*). Application of lipid bilayer systems, in particular CLPs, may make chemoselective ligation techniques more applicable to this important class of peptides. Our approach may allow researchers to modularly assemble such membrane proteins from separately synthesized (or recombinantly expressed) subunits. In particular, multiple-membrane spanning proteins can be assembled from individual membrane-spanning domains without possible worries of incorporation of the peptides in incompatible relative orientation due to the unique topological features of the CLP system.

Incorporation of a variety of molecular tools, such as spectroscopic probes, unnatural amino acids, and molecular markers into membrane proteins at yields that significantly exceed those accessible with currently available techniques, may thus be achieved.

NOTE ADDED AFTER PRINT PUBLICATION

In the manuscript title, the word “Hydrophobic” was misspelled in the version of this paper published 4/24/2004 (ASAP) and in the May/June 2004 issue

(Vol. 15, No. 3, pp 437−440). The correct electronic version was published on the Web 6/4/2004, and a Correction appears in the July/August 2004 issue (Vol. 15, No. 4).

ACKNOWLEDGMENT

We thank Stephen B.H. Kent (University of Chicago) for advice and encouragement.

Core-Cross-Linked Polymeric Micelles as Paclitaxel Carriers

Xintao Shuai,[†] Thomas Merdan,[†] Andreas K. Schaper,[‡] Fu Xi,[§] and Thomas Kissel*[,†]

Department of Pharmaceutics and Biopharmacy, and Department of Geosciences & Materials Science Center, Philipps-University of Marburg, Ketzerbach 63, D-35032 Marburg, Germany, and Institute of Chemistry, The Chinese Academy of Sciences, Beijing 100080, China. Received July 8, 2003; Revised Manuscript Received November 11, 2003

Cross-linkable di- and triblock copolymers of poly(ϵ-caprolactone) (PCL) and monomethoxyl poly(ethylene glycol) (MPEG) were synthesized. These amphiphilic copolymers self-assembled into nanoscale micelles capable of encapsulating hydrophobic paclitaxel in their hydrophobic cores in aqueous solutions. To further enhance their thermodynamic stability, the micelles were cross-linked by radical polymerization of the double bonds introduced into the PCL blocks. Reaction conditions were found to significantly affect both the cross-linking efficiency and the micelle size. The encapsulation of paclitaxel into the micelles was confirmed by the proton nuclear magnetic resonance (^{1}H NMR) spectroscopy. Encouragingly, paclitaxel-loading efficiency of micelles was enhanced significantly upon micelle core-cross-linking. Both the micelle size and the drug loading efficiency increased markedly with increasing the PCL block lengths, no matter if the micelles were core-cross-linked or not. However, paclitaxel-loading did not obviously affect the micelle size or size distribution. The cross-linked micelles exhibited a significantly enhanced thermodynamic stability against dilution with aqueous solvents. The efficient cellular uptake of paclitaxel loaded in the nanomicelles was demonstrated by confocal laser scanning microscopy (CLSM) imaging. This new biodegradable nanoscale carrier system merits further investigations for parenteral drug delivery.

INTRODUCTION

Paclitaxel (Taxol), an anticancer agent isolated from the bark of the pacific yew tree (*Taxus brevifolia*) (*1*), is active against a wide range of solid tumors such as advanced ovarian and breast cancer (*2*). Major problems encountered in paclitaxel chemotherapy are the low aqueous solubility of paclitaxel and the severe side effects (*3*−*5*). Currently, a Cremophor EL−ethanol vehicle (50:50 mixture) is clinically used for paclitaxel chemotherapy. However, serious side effects (*6*−*8*), such as hypersensitivity and neurotoxicity, were induced by Cremophor EL. To overcome these problems, liposomes (*9*−*10*) and polymeric micelles (*11*−*12*) are two promising alternatives for the Cremophor EL−ethanol vehicle. The distinct characteristics of polymeric micelles formed from amphiphilic block copolymers (*13, 14*) include nanoscale size, thermodynamic stability in aqueous solution compared to small molecular micelles, and a unique core−shell-type architecture, which can mimic naturally occurring transport systems such as lipoproteins and viruses (*15*). The hydrophobic core of the micelles offers a carrier compartment that accommodates predominately hydrophobic drugs, and the shell consists of a brushlike protective corona that stabilizes the nanoparticles in aqueous solution (*15*−*17*). Using encapsulation within the micelles, one obtains systems in which solubility limits for hydrophobic drugs can be exceeded. In addition to their nanoscale dimension, which is favorable for intravenous administration and cellular uptake, polymeric micelles for drug delivery offer other advantages, e.g. their high and controllable drug loading and release capacities, their biocompatibility, and the diversity of drugs they can accommodate (*16*−*18*). Therefore, polymeric micelles are particularly promising carriers of many hydrophobic anticancer agents including paclitaxel.

Another advantage of polymeric micelles is a passive targeting effect due to an increased permeability of tumor endothelia in connection with a lack of normal lymphatic drainage and hypervasculature of the tissue (*19*). This effect is known as enhanced permeability and retention effect (EPR) and leads to capture of macromolecular structures within the tumor interstitium. The EPR effect has been demonstrated for a variety of macromolecules (*20*) and liposomes (*21*). Through this passive targeting mechanism, highly selective delivery of anticancer agent to specific tumor sites using polymeric micelles as carriers can be achieved (*22*).

Several reports have demonstrated controllable encapsulation efficacy, high antitumor activity, and desirable biodistribution of paclitaxel-loaded micelles based on biodegradable block copolymers such as poly(ethylene glycol)-b-poly(D,L-lactide) (*23*), poly(ϵ-caprolactone)-b-poly(ethylene glycol) (*24*), and poly(ϵ-caprolactone)-b-poly(2-ethyl-2-oxazoline) (*25*). These micelles are formed through interactions of intermolecular hydrophobic blocks

of linear amphiphilic block copolymers. Although thermodynamically more stable in aqueous media than micelles formed with small molecular surfactants, they are still subject to in vivo disintegration upon dilution that occurs in biological fluids. Kataoka et al. have proven micelle core cross-linking to be an effective way to avoid the micellar disintegration upon dilution. They demonstrated that core-cross-linked micelles of poly(ethylene glycol)-b-poly(D,L-lactide) possess high stability against dilution, temperature change, and even dissolution of surfactants (*26*).

In the present work, we aimed at developing novel core-cross-linked micelles for efficient paclitaxel encapsulation and delivery. To this end, we synthesized di- and triblock copolymers of MPEG and PCL, with cross-linkable double bonds located in the PCL block. Core-cross-linked micelles (<200 nm in diameter) were prepared, using the cross-linked polymers synthesized under optimized reaction conditions. Paclitaxel loading and in vitro release was investigated. The efficient cellular internalization of paclitaxel-loaded micelles was demonstrated using confocal laser scanning microscopy.

EXPERIMENTAL SECTION

Materials. ϵ-Caprolactone (Sigma-Aldrich, Taufkirchen, Germany) was purified by vacuum distillation over calcium hydride (CaH_2). Toluene (Sigma-Aldrich, Taufkirchen, Germany) for azeotropic distillation was dried by refluxing over sodium (Sigma-Aldrich, Taufkirchen, Germany) and distilled under dry argon. Monomethoxyl poly(ethylene glycol)s (Sigma-Aldrich, Taufkirchen, Germany) were first purified by precipitation from tetrahydrofuran (THF, Sigma-Aldrich, Taufkirchen, Germany) into hexane (Sigma-Aldrich, Taufkirchen, Germany), and then the vacuum-dried precipitates were further dried by azeotropic distillation with dry toluene. Stannous(II) octoate (SnOct), maleic anhydride, thionyl chloride, α,α'-azoisobutyronitrile, and potassium persulfate ($K_2S_2O_8$) were all from Sigma-Aldrich, Taufkirchen, Germany, and used as received. Paclitaxel (Genexol) is a kind gift from Sam Yang Genex, Korea. The fluorescent-labeled paclitaxel, Oregon Green 488, was purchased from Molecular Probes (USA). Bovine serum albumin (BSA) was purchased from Sigma. Phosphate-buffered saline (PBS) was prepared in our laboratory. All organic solvents are of analytic grade.

NIH/3T3 (Swiss mouse embryo) cell line was purchased from the German Collection of Microorganisms and Cell Cultures (DSMZ, Braunschweig, Germany). Cells were cultured according to the protocols suggested by the supplier.

Synthesis of Monohydroxy-Terminated and Maleic-Capped Diblock Copolymers of PCL and MPEG. Detailed synthetic methods for these two types of block copolymers have been described in our recent publication (*27*). Briefly, the monohydroxy-terminated diblock copolymers were synthesized by ring-opening polymerization of ϵ-caprolactone at 115 °C using MPEG as a macroinitiator and SnOct as a catalyst, with yields >95%. The maleic-capped diblock copolymers were then synthesized by esterification of the monohydroxy-terminated diblock copolymers and maleic anhydride, with yields >92%.

Synthesis of Cross-Linkable Triblock Copolymers. To activate the diblock copolymer, maleic-capped diblock copolymer (1 g) and thionyl chloride (3 times the molar amount of polymer) were dissolved in dry toluene (10 mL) and then refluxed under argon for 2 h at 50 °C. Toluene and the excessive thionyl chloride were then removed by distillation under reduced pressure. The hydroxyl-terminated and the carbonyl-chloride-activated diblock copolymers (1:1 in molar ratio) were mixed in the reaction vial. Under high vacuum, the mixture was magnetically stirred for 2∼8 h at 80 °C.

The crude product was dissolved in toluene and then precipitated in hexane. The triblock copolymer, monomethoxylpoly(ethylene glycol)-b-poly(ϵ-caprolactone)-b-monomethoxylpoly(ethylene glycol) (MPEG-PCL-MPEG), was then recovered by filtration, and dried under vacuum, with yields >95%.

Controlled Cross-Linking of Di- and Triblock Copolymers. To obtain core-cross-linked micelles smaller than 200 nm in diameter, the control of polymer cross-linking conditions was crucial. Reaction was conducted under various reaction conditions, i.e., reaction temperature and time, solvent, and catalyst, etc. In an optimized cross-linking reaction, cross-linkable di- or triblock copolymer (300 mg) was dissolved in acetone (20 mL) in a reaction vial equipped with refluxing condenser, magnetic stirring bar, and argon inlet protection pipe. Distilled water (40 mL) was then added. After the solution was bubbled for 30 min with argon, $K_2S_2O_8$ (1 wt % polymer) was added to the mixture and subsequently the reaction temperature was raised to 50 °C. The solution under argon protection was stirred at 50 °C for 24 h. After the reaction, solvents (acetone and water) were removed by rotary evaporation. The product was redissolved in acetone, filtered to remove insoluble inorganic initiator residues, dialyzed against acetone to eliminate the non-crosslinked polymer, and precipitated into hexane. The cross-linked polymer recovered by filtration was finally dried under vacuum, with yields >87%.

Preparation of Paclitaxel-Loaded Micelles. Polymeric micelles containing paclitaxel were prepared as follows: polymer (20 mg) and paclitaxel (2 mg) were added to acetone (4 mL) in a glass beaker. The solution was heated to 40 °C to codissolve the polymer and paclitaxel and then was cooled to room temperature. Afterward, the solution was dropwise added to pure water (20 mL) under vigorous agitation. The beaker was then opened to air overnight, allowing slow evaporation of acetone and formation of micelles. The residual acetone was completely removed by vacuum distillation with a rotary evaporator, and then the micelle solution was filtered with a microfilter (pore size: 0.4 μm) to eliminate the uncomplexed paclitaxel and aggregated particles. The micelles thus obtained were directly characterized with ^{1}H NMR, dynamic light scattering (DLS), and ultraviolet (UV) measurements. To obtain the powder samples, the micelle solutions were frozen and lyophilized.

The paclitaxel-loading content (PLC) and efficiency (PLE) was calculated from the following equations:

$$\mathrm{PLC} = \frac{\text{amount of paclitaxel in micelle}}{\text{amount of paclitaxel-loaded micelle}} \times 100$$

$$\mathrm{PLE} = \frac{\text{paclitaxel amount in micelle}}{\text{paclitaxel amount used for micelle preparation}} \times 100$$

Characterization of Polymers. Fourier transform infrared (FTIR) spectral studies were carried out with a Nicolet 510P FTIR spectrometer in the range between 4000 and 400 cm^{-1}, with a resolution of 2 cm^{-1}. All powder samples were compressed into KBr pellets for the FTIR measurements. ^{1}H NMR spectra were recorded on a JEOL GX 400 D spectrometer in deuterated chloroform ($CDCl_3$) or water (D_2O) at room temperature.

Gel permeation chromatography (GPC) was employed to determine the molecular weight and the molecular weight distribution. GPC analysis was carried out using a SDV Linear M 5μ 8 × 300 mm column (Polymer Standard Service, Mainz, Germany) with dichloromethane (DCM) as an eluent (1 mL/min) and polystyrene standards for column calibration. 20 μL samples were injected with a Merck Hitachi autosampler AS-2000A. The eluent was analyzed with a differential refractive index (RI) detector RI-71 from Merck and 18 angle laser light scattering detector from Wyatt Technologies (DAWN EOS, GaAs laser 690 nm, 30 mW, K5 cell).

Determination of Paclitaxel-Loading Content (PLC). PLC was determined by UV measurements. The freeze-dried micelle particles were dissolved in a mixture of methanol and *N*,*N*-dimethylacetamide (1:2, v/v). The absorbance at 265 nm was detected with a Shimadzu UV-160 UV−visible recording spectrophotometer. Paclitaxel solutions of various concentrations were prepared, and the absorbance at 265 nm was measured to generate a calibration curve for calculating the PLC of various micelles.

Photon Correlation Spectroscopy. The size and size distribution of the polymeric micelles were determined by photon correlation spectroscopy. Measurements were performed on a Zetasizer 3000 HS from Malvern Instruments, Herrenberg, Germany (10 mW HeNe laser, 633 nm). Scattered light was detected at 90° angle through a 400 micron pinhole at a temperature of 25 °C. For each sample, data obtained in three measurements were averaged to get the final size and size distribution.

Electron Microscopy. Paclitaxel-loaded micelle based on a cross-linked diblock copolymer, MPEG5k-b-PCL18k, was chosen for the transmission electron microscopy study (TEM). The paclitaxel-loading content in these micelles is 5.1%. A drop of the micelle solution was deposited on the carbon hole-coated grid and then allowed to dry overnight at room temperature. The grid was exposed to the vapor of a 2% solution of osmium tetroxide for 2 h. TEM observations were made with a JEOL 3010 transmission electron microscope supplemented with a 2k × 2k CCD camera at 300 kV.

Confocal Laser Scanning Microscopy. For confocal microscopy experiments, a Zeiss Axiovert 100M microscope coupled to a Zeiss LSM 510 scan module was used. NIH/3T3 cells were seeded at a density of 50 000 cells per well in eight-well chamber slides (LabTek, Nunc, Wiesbaden, Germany). After 24 h, medium was removed and micelles containing Oregon Green 488 labeled paclitaxel (Sigma-Aldrich, Taufkirchen, Germany) were added in fresh media. After 4 h, the medium was removed again and cells were washed four times with phosphate-buffered saline (PBS). Fixation of cells was done by incubation with 400 μL paraformaldehyde solution 3% in PBS for 20 min. Cells were regarded in FluorSave Reagent (Calbiochem, San Diego, CA). Excitation of Oregon Green was performed using an argon laser with a wavelength of 488 nm and a long-pass filter of 505 nm. Paclitaxel-loaded micelle based on a cross-linked triblock copolymer (MPEG5k-(PCL3.8k)$_2$-MPEG5k) was used in the CLSM study. The paclitaxel-loading content in this micelle is 2.7%.

RESULTS AND DISCUSSION

Polymer Synthesis. Synthesis of block copolymer of PCL and PEG, using hydroxyl-terminated PEG as an initiator and stannous(II) octoate as a catalyst, has been reported earlier (*27*). The ring-opening polymerization was conducted in bulk at an elevated temperature (115 °C). In this way, we synthesized the monohydroxyl-terminated diblock copolymers of MPEG and PCL (MPEG-b-PCL-OH), which were then reacted with maleic anhydride to introduce a reactive maleic moiety to the PCL block end. Activation of a carboxyl-terminated diblock copolymer with thionyl chloride resulted in the maleic chloride-capped diblock copolymer, which was esterified with MPEG-b-PCL-OH to yield a triblock copolymer (MPEG-PCL-MPEG) bearing a reactive maleic ester moiety in the middle of the PCL block, as shown in Scheme 1. Properties of cross-linkable di- and triblock copolymers thus synthesized are summarized in Table 1.

Scheme 1. Synthetic Approach to Cross-Linkable Di-and Triblock Copolymers

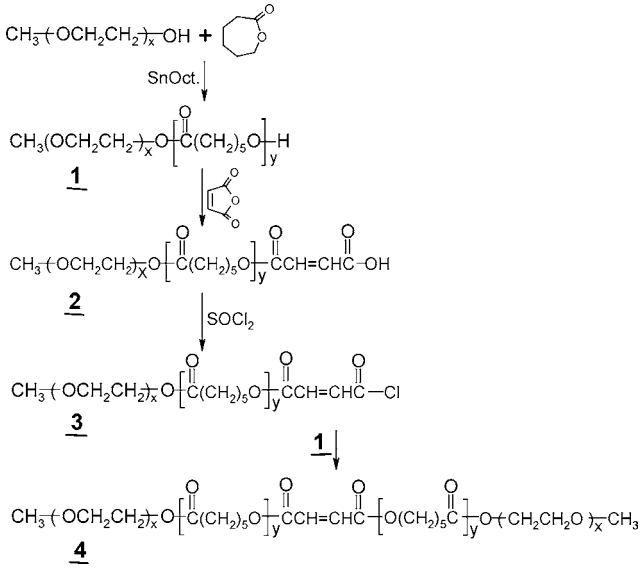

Table 1. Molecular Weights of Di- and Triblock Copolymers

entry	M_{n-MPEG}	diblock copolymer: $M_{n-copolymer}$[a]	triblock copolymer: $M_{n-copolymer}$[b]

5	5000	8800	19500
6	5000	23500	41760

[a] ^{1}H NMR results. [b] GPC results.

FTIR, ^{1}H NMR, and GPC measurements were employed to demonstrate the successful synthesis of the block copolymers. Figure 1 shows the FTIR spectra of a hydroxyl-terminated diblock copolymer and the cross-linkable di- and triblock copolymers. PCL and PEG blocks were characterized by prominent absorptions at 1726 cm^{-1} (s, $\nu_{C=O}$) and 1105 cm^{-1} (s, ν_{C-O}), respectively. Obviously, both PCL and PEG blocks are present in all block copolymers. A strong absorption of the incorporated maleic segment at 1635 cm^{-1} (s, $\nu_{C=C}$), which is absent in the spectrum of the hydroxyl-terminated prepolymer, was observed for both cross-linkable di- and triblock copolymers. In addition, the maleic-capped cross-linkable diblock copolymer showed very strong and broad absorption around 3450 cm^{-1}, which results from the stretching vibration of carboxylic end group (s, ν_{O-H}). In comparison, other two copolymers showed only very weak absorption in this region, likely due to residual humidity in the samples.

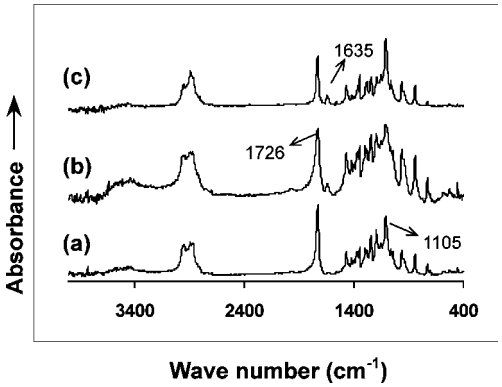

Figure 1. FTIR spectra of HO-terminated diblock copolymer MPEG2k-b-PCL1.2k (a), carboxyl-terminated MPEG2k-b-PCL1.2k (b), and triblock copolymer MPEG2k-(PCL1.2k)$_2$-MPEG2k (c).

In the ^{1}H NMR spectra of all block copolymers, the characteristic resonances of both PCL (1.376 ppm, 1.65 ppm, 2.306 ppm, and 4.057 ppm) and MPEG (3.385 ppm and 3.643 ppm) were observed, suggesting the coexistence of two blocks (*27*). For the diblock copolymers, the lengths of PCL blocks were estimated from the integrals of characteristic peaks of PEG (e.g. CH_3O at ~3.38 ppm) and PCL (e.g. C(=O)CH_2 at ~2.3 ppm), using the known molecular weights of MPEGs (*27*). The expansion of ^{1}H NMR spectra, as shown in Figure 2, provides evidence for the expected structures of block copolymers. Cross-linkable di- and triblock copolymers exhibited distinct resonance signals of maleic moieties at ~6.4 ppm (two *doublets*, C(=O)C*H*=C*H*C(=O)OH) and at ~6.83 ppm (*singlet*, C(=O)C*H*=C*H*C(=O)) respectively, which are not present in the spectrum of MPEG-b-PCL-OH containing no maleic moiety. ^{1}H NMR absorptions around ~4.2 ppm, i.e., triplet peaks a and b, strongly demonstrated the exact local linkage structures between PCL and PEG blocks, and between PCL blocks and maleic moieties, as expected from Scheme 1. Molecular weights characterized by GPC measurements also demonstrated the successful synthesis of block copolymers. For all block copolymers, unimodal distributions were observed in the GPC elugrams (not shown). It is noteworthy that, for the diblock copolymers, molecular weights detected by GPC are in reasonable agreement with those calculated from ^{1}H NMR data. Unfortunately, it is impossible to calculate the molecular weights of the triblock copolymers based on the ^{1}H NMR data, unless the samples are completely free of the diblock copolymers. Therefore, the molecular weights of the triblock copolymers were all estimated from the GPC measurements.

Micelle Preparation and Core Cross-Linking. Micelles were prepared by a solvent-evaporation method (*28*, *19*). Acetone was selected as the organic solvent because it dissolves both copolymer and paclitaxel, evaporates easily at room temperature, and is miscible with water. Most of the micelles possess sizes < 100 nm in mean diameter independent of paclitaxel loading (Table 2).

We investigated various approaches to achieve the core-cross-linked micelles and to control the micelle size < 200 nm. In all cases, radical polymerization was conducted under argon as described in the Experimental Section. Direct core cross-linking of micelles of poly(ethylene glycol)-b-poly(D,L-lactide) was achieved successfully in aqueous micellar solution by Kataoka et al., using either inorganic (*30*) or organic (*26*) initiators for radical polymerization. In light of their discovery, we attempted to directly cross-link the core of micelles in the aqueous micelle solutions. Micelles were first prepared with the cross-linkable di- and triblock copolymers. Then the radical polymerization was initiated at elevated temperatures (e.g. 50 °C) using α,α′-azoisobutyronitrile or $K_2S_2O_8$. α,α′-Azoisobutyronitrile was dissolved in DCM (2 mg/mL) and then added to the micelle solution (*26*). After stirring for 2 h at room temperature to distribute the initiator to the micelle cores, DCM was removed by rotary evaporation before the core radical polymerization at elevated temperatures. When $K_2S_2O_8$ was used as an initiator, it was added directly to the micelle solution. The radical polymerization progress was followed by ^{1}H NMR spectroscopy, monitoring the decrease of maleic protons (C*H*=C*H*). In contrast to poly(ethylene glycol)-b-poly(D,L-lactide) micelles, we found that the direct polymerization of MPEG-b-PCL micelles in solution at 40 °C, 50 °C, and 60 °C did not proceed effectively, independent of the initiator used. We believe that differences in both double bond densities and intrinsic reactivities of the double bonds have contributed to these results. Steric hindrances as well as different electron

[a] Core-cross-linked micelles were prepared by solvent-evaporation method with copolymers cross-linked in solution of acetone and water (1:2 v/v) for 24 h at 50 °C. [b] Triblock copolymers.

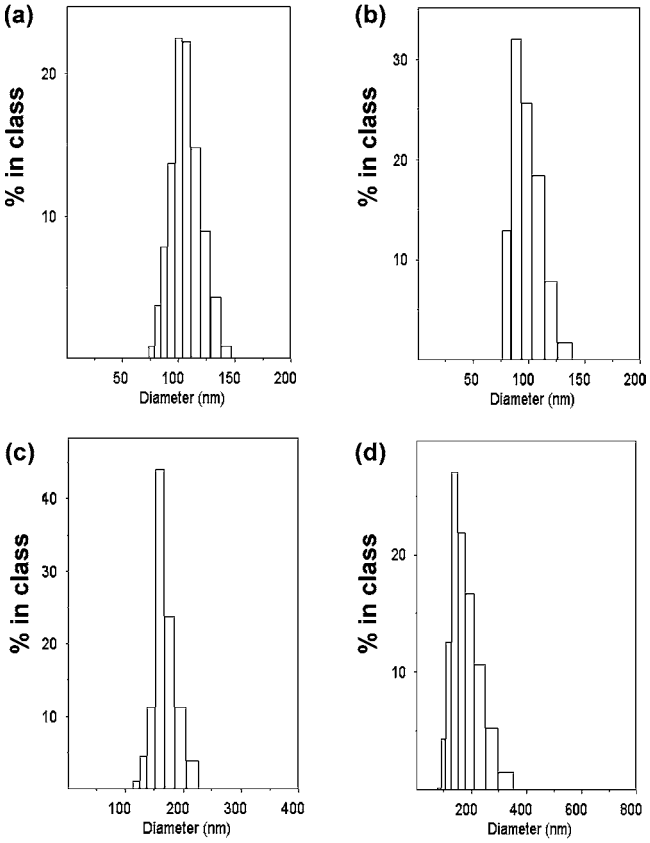

Figure 3. Size distributions of paclitaxel-free non-cross-linked micelle (a), paclitaxel-loaded non-cross-linked micelle (b), paclitaxel-free cross-linked micelle (c), and paclitaxel-loaded cross-linked micelle (d), based on the cross-linkable diblock copolymer MPEG5k-b-PCL18k.

densities of the maleic moieties in cross-linkable MPEG-b-PCL, compared to methacrylate, are likely reasons for inefficient cross-linking of our micellar structures.

Furthermore, it is known that once a crystalline polymer phase is formed, it can no longer accommodate foreign substances such as initiator molecules. Therefore, the direct core polymerization of MPEG-b-PCL micelles was not possible at temperatures < 60 °C, due to the tendency of PCL to form a crystalline phase. As expected, slow polymerizations were indeed detected at temperatures > 80 °C. However, DLS measurements demonstrate that polymerization > 3 days, at 80 °C or above generally resulted in significant size increase (up to 800 nm) and broad size distribution (up to ~20) of micelles.

As an alternative we studied the radical polymerization of cross-linkable polymers in toluene solution at a reaction temperature of 60 °C or in a mixture (50 °C) of acetone and water (1:2 in v/v). Using α,α′-azoisobutyronitrile as an initiator, micelles in toluene solutions underwent fast cross-linking reaction. High degrees of cross-linking were achieved within 8 h. However, micelles prepared with these cross-linked copolymers also showed significant size increase and broad size distributions (data not shown).

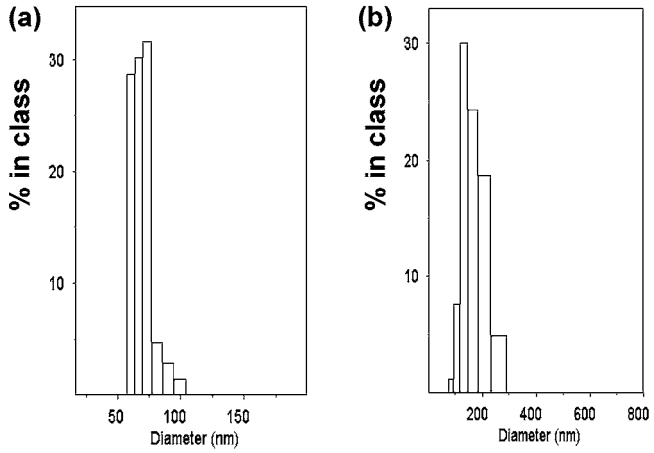

Figure 4. Size distributions of non-cross-linked MPEG2k-$(PCL2.7k)_2$-MPEG2k micelle in water (a), and a 1:2 mixture (v/v) of acetone and water (b).

Polymerization in solvent mixtures of acetone and water (1:2 in v/v), using $K_2S_2O_8$ as an initiator, proceeded smoothly. When reaction time reached 72 h, precipitates were generally observed. This phenomenon can be explained by high molecular weight polymers, which are insoluble in the solvent. However, polymerization for 24 h at 50 °C in the mixed solution was found to be suitable for a sufficient and controlled cross-linking of cross-linkable di- and triblock polymers.

As shown in Table 2, the micelle size increased upon cross-linking, both for drug-free and drug-loaded cross-linked micelles, but they were smaller than 200 nm in diameter. DLS measurements further demonstrated that cross-linked micelles have similar narrow size distributions compared to their non-cross-linked counterparts (Figure 3). From these results, we speculate that a "pseudomicellar" structure is achieved, in which the micelle cores were no longer compact and highly crystalline because the PCL solubility was increased upon adding acetone. DLS measurements demonstrated that the particle size increased in acetone/water mixtures. Consequently, the initiator molecules may diffuse into the PCL phase, and the chance for reactive double bonds to react was increased due to the enhanced chain mobility resulting from the swelling of PCL cores. For instance, as exemplified in Figure 4, the size of the non-cross-linked MPEG2k-$(PCL2.7k)_2$-MPEG2k micelle in an ac-

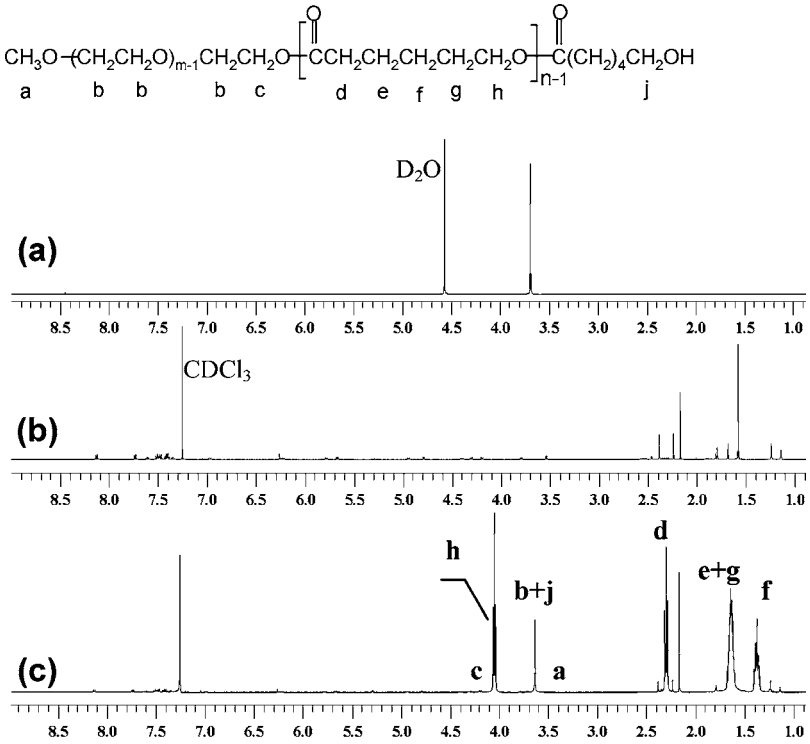

Figure 5. ^{1}H NMR spectra of the paclitaxel-loaded micelle in D_2O (a), paclitaxel in $CDCl_3$ (b), and the paclitaxel-loaded micelle in $CDCl_3$ (c). The micelle was formed with the hydroxyl-terminated MPEG5k-b-PCL18k.

etone/water mixed solution (1:2 in v/v) increased to ~140 nm from ~50 nm, the size of micelle in water. Hence, by controlling the reaction time and solvent composition, a predominantly intra-pseudomicellar radical polymerization leads to controlled micellar sizes.

As shown in Table 2, micelle size also depends on the copolymer composition. In general, copolymers with longer PCL blocks formed larger micelle particles. Despite the micelle size increase, the cross-linked micelles are small enough for the intravenous administration. Interestingly, paclitaxel-loading did not affect the sizes of micelles. In addition, as reported also by Lee et al. (*24*), paclitaxel-loading did not change the narrow size distributions of micelles (Figure 3).

Encapsulation of paclitaxel inside the micelle cores was demonstrated by ^{1}H NMR measurements of the freeze-dried micelle particles. Figure 5 shows the ^{1}H NMR spectra of a paclitaxel-loaded MPEG-b-PCL-OH micelle in D_2O (a), and $CDCl_3$ (c), in comparison with the spectrum of paclitaxel in $CDCl_3$ (b). PCL, MPEG, and paclitaxel resonance peaks were observed in $CDCl_3$ indicating that the micelle contains paclitaxel. In contrast, only MPEG resonance was detected, and both the PCL and the paclitaxel resonance peaks were not detected in D_2O. These results strongly demonstrated the core−shell structure of micelles. The micelle shells consisting of PEG blocks were well dissolved in D_2O and therefore showed clear ^{1}H NMR resonance signals. By contrast, paclitaxel was included inside the micelle cores consisting of the PCL solid phase. Consequently, resonances of PCL blocks and paclitaxel were not observed in D_2O because of their insufficient mobility in solid phase.

From the results summarized in Table 3, two major factors were found to affect paclitaxel content and loading efficiency. Micelles studied in this work encapsulated paclitaxel at a level of 0.2−5.1%, depending on the PCL length and cross-linking. Long PCL blocks apparently favor paclitaxel-loading into the micelles. For instance,

Table 3. Influence of Core-Cross-Linking on Paclitaxel Loading[a]

	before crosslinking		after cross-linking

$(PCL18k\text{-}b\text{-}MPEG5k)_2$[b]	2.7	45	4.3	72

[a,b] See the footnotes to Table 2.

in comparison with the MPEG2k-b-PCL1.2k micelle, the MPEG5k-b-PCL18k micelle showed 10× higher loading and loading efficiency (PLC: 2.3% vs 0.2%, PLE: 38% vs 3.3%). Paclitaxel loading into micelles was enhanced significantly through the micelle core-cross-linking, especially for micelles bearing long PCL blocks.

We have noted that long PCL block and core-cross-linking led to increase in micelle size. The micelle size is critical for a drug delivery via intravenous injection and for efficient targeting and cell uptake. Particles < 100 nm seem to cross endothelial and epithelial barriers more efficiently. Therefore, micelle size, cross-linking and paclitaxel loading capacity need to be carefully adjusted. In this sense, cross-linked micelles based on the di- and triblock copolymers of PCL3.8k and MPEG5k showed an excellent combination in micelle size and paclitaxel-loading efficiency.

The spherical morphology and nanoscale dimension of micelle particles were demonstrated using the TEM micrographs of paclitaxel-loaded micelles prepared with the cross-linked MPEG5k-b-PCL18k, as shown in Figure 6. Micelle spheres are less than 200 nm in mean diameter. In excellent agreement with the DLS measurement results, the TEM images also indicate that the

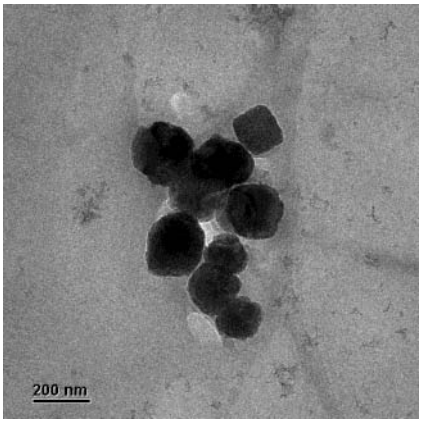

Figure 6. TEM image of a cross-linked micelle loaded with paclitaxel. The micelle was prepared with the cross-linked diblock copolymer MPEG5k-b-PCL18k. The paclitaxel-loading content in this micelle is 5.1%.

micelle particles possess quite narrow distribution of sizes.

The stability of the micelles under various conditions was investigated. For all cross-linked micelles, particle sizes increased when the micelle particles were redissolved in acetone (data not shown). Acetone is a good solvent for both PCL and PEG, indicating the swelling of micelle cores rather than the dissociation of particles. Similar results were observed by Kataoka et al. when they dissolved the core-cross-linked poly(ethylene glycol)-b-poly(D,L-lactide) micelles in dimethyl formamide (DMF) (*24*).

Further, the core-cross-linked micelles were stable against dilution in water. No micelle collapse was detected by DLS and GPC measurements when the micelle solutions were diluted by a factor of 1000×. Micelle stability against storage at 4 °C depended on the polymer composition but showed no correlation with the micelle cross-linking and drug loading. No size change was detected within two weeks for all micellar systems. However, large aggregates or even precipitates were observed when the micelles containing PCL3.8k or PCL18k were stored for three months, independent of cross-linking and paclitaxel loading.

Micelle stability in the presence of serum albumin (BSA, 2.5 wt %) and/or relatively high ionic strength (10 mM PBS) was again dependent on the PCL block length. With longer PCL blocks, large aggregates were formed faster. For examples, when BSA solution (2.5 wt %) or 10 mM PBS solution was mixed (1:1 in v/v) with the 0.5% cross-linked MPEG5k-b-$(PCL18k)_2$-b-MPEG5k micellar solution, precipitates formed immediately. However, under the same conditions, MPEG2k-b-$(PCL1.2k)_2$-b-MPEG2k micelle solutions did not show any aggregates upon storage for two weeks at 4 °C. This unsatisfactory stability of the micelle solutions in the presence of serum protein (BSA, 2.5 wt %) and/or relatively high ionic strength is obviously a drawback for the in vivo application, especially for the micelles containing long PCL blocks and needs further optimization.

The inhibition of tumor cell proliferation by the paclitaxel-loaded micelles has been reported (*25*). However, only limited information is available on the interaction between micelles and cells. Very recently, Maysinger et al. demonstrated the cellular internalization of a fluorescent-labeled MPEG-b-PCL micelle into 3T3 mouse fibroblasts (*18*, *31*). This type of micelle can encapsulate DAF (a membrane selective dye) and transport it into cytoplasm. In the present work using confocal laser scanning microscopy technique, we investigated the uptake of a micelle loaded with the fluorescent-labeled paclitaxel into 3T3 fibroblasts. As shown in Figure 7, paclitaxel loaded in the cross-linked micelle was transported efficiently into the cytoplasm.

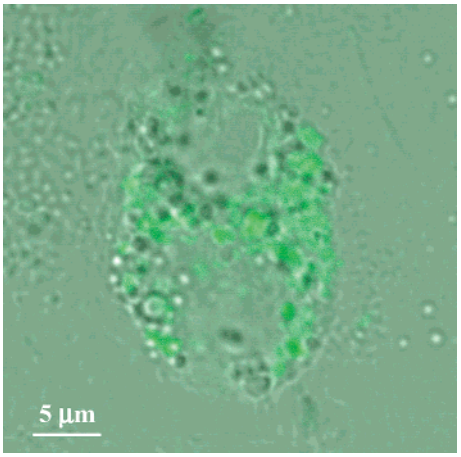

Figure 7. CLSM-imaged 3T3 cellular internalization of fluorescent-labeled paclitaxel encapsulated inside the cross-linked MPEG5k-$(PCL3.8k)_2$-MPEG5k nano particles. The paclitaxel-loading content in this micelle is 2.7%. The incubation time was 4 h.

The investigation of the controlled release behavior of different paclitaxel-loaded micelles is now under way in our lab. Our preliminary results indicate that the cross-linking of micelle cores does not markedly change the paclitaxel-releasing profile of the non-cross-linked micelles, i.e., both micelles showed rather fast paclitaxel release in the initial stage, and then a sustained slow release was detected.

NMR Studies of Fully Modified Locked Nucleic Acid (LNA) Hybrids: Solution Structure of an LNA:RNA Hybrid and Characterization of an LNA:DNA Hybrid

Katrine E. Nielsen, Jill Rasmussen, Ravindra Kumar, Jesper Wengel, Jens Peter Jacobsen, and Michael Petersen*

Nucleic Acid Center, Department of Chemistry, University of Southern Denmark, 5230 Odense M, Denmark.
Received August 22, 2003; Revised Manuscript Received December 17, 2003

LNA is a bicyclic nucleic acid analogue that contains one or more 2′-*O*,4′-*C* methylene linkage(s), which effectively locks the furanose ring in a C3′-endo conformation. We report here the NMR solution structure of a nonamer LNA:RNA hybrid and a structural characterization of a nonamer LNA:DNA hybrid, where the LNA strands are composed entirely of LNA nucleotides. This is the first structural characterization of fully modified LNA oligonucleotides. The high-resolution structure reveals that the LNA:RNA hybrid adopts an almost canonical A-type duplex morphology. The helix axis is almost straight and the duplex geometry is regular. This shows that fully modified LNA oligomers can hybridize with complementary RNA and form duplexes within the Watson−Crick framework. The LNA:DNA hybrid structurally resembles an RNA:DNA hybrid as shown by determination of deoxyribose sugar puckers and analysis of NOESY NMR spectra.

INTRODUCTION

High-affinity binding to complementary nucleic acids has a number of applications, for example in oligonucleotide-based therapeutics and in the general area of biotechnology. From the vast number of chemically modified nucleotide analogues synthesized, it appears that a sugar engineered into an N-type (RNA-like) pucker usually conveys an increase in helical thermostability when hybridized with complementary RNA (*1*). Prominent examples of such N-type nucleic acid analogues are 2′-*O*-alkylated RNA (*2*), 2′F-RNA (*3*), phosphoramidates (*4*), HNA (*5*), and LNA (*6*−*9*).

In LNA (see Figure 1), the furanose conformation is chemically locked in an N-type (C3′-endo) conformation by the introduction of a 2′-*O*,4′-*C* methylene linkage. LNAs[1] have shown hitherto unprecedented thermal affinities when hybridized with either DNA ($\Delta T_m = 1-8$ °C per modification) (*6*−*11*), RNA ($\Delta T_m = 2-10$ °C per modification) (*6*−*9*, *11*−*13*) or LNA ($\Delta T_m > 5$ °C per modification) (*14*). The high thermal stability of LNA modified nucleic acids is achieved with sequence specificity comparable to or slightly better than native nucleic acids (*6*). Thus, short, fully modified LNA oligonucleotides combine high-affinity binding toward DNA and RNA with minimal oligonucleotide length.

LNA is emerging as a useful tool in therapeutics and diagnostics with an increasing number of reports appearing. In the context of antisense therapeutics, LNA/DNA gapmers are recognized and cleaved by RNase H (*13*). Thus, the high-affinity binding properties of LNA can be employed to access mRNA targets with highly ordered tertiary structures. In a broader therapeutical view, LNAs have been employed as aptamers for transcription factor κB (NF-κB) (*15*) and have been successfully incorporated into DNAzymes (*16*). For use in diagnostics, LNA probes are employed for the detection of single nucleotide polymorphisms (*17*, *18*). Reference 9 is a recent review on applications of LNA oligonucleotides.

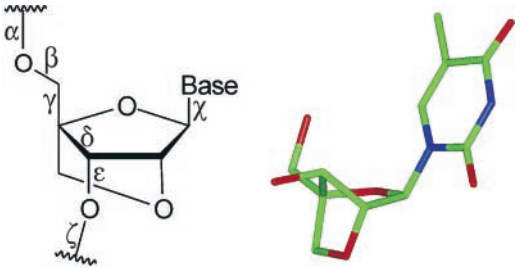

Figure 1. Structure of LNA with torsion angles labeled (left) and stick plot showing the C3′-endo furanose conformation (right).

In this study, we have characterized an LNA:DNA hybrid and determined the solution structure of an LNA:RNA hybrid. In both of these hybrids the LNA strand is composed entirely of LNA monomers. This is the first structural study of fully modified LNA oligonucleotides. The base composition and numbering of the two hybrids is shown in Scheme 1.

As for the LNA:RNA hybrid, we have previously studied the corresponding, isosequential unmodified DNA:RNA hybrid and the two partly modified hybrids with LNA modifications at position 5 and positions 2, 5, and 7, respectively (these hybrids are labeled LNA1:RNA and LNA3:RNA henceforth) (*12*, *19*). These studies showed that with an increasing number of LNA nucleotides incorporated into the hybrids, an increasing A-like character of the duplex structure ensued. This is due to the LNA nucleotides being locked in a C3′-endo confor-

mation and because LNA nucleotides, in addition, steer the sugar conformations of neighboring nucleotides, predominantly in the 3′-direction, into N-type (C3′-endo) sugar conformations. Indeed, in the LNA3:RNA hybrid, all nonterminal deoxyriboses were found with N-type sugar puckers, even though deoxyriboses possess an inherent preference for S-type sugar puckers, and hence this hybrid adopts an A-like duplex geometry. We now extend the studies of this nonamer LNA:RNA series with the high-resolution structure of the fully modified hybrid. The structure was determined employing NOE-derived distance restraints in a simulated annealing scheme.

With respect to the LNA:DNA hybrid, we have hitherto studied a number of LNA:DNA hybrids with varying numbers of LNA monomers incorporated in one of the strands. As for LNA:RNA hybrids, a conformational tuning of neighboring deoxyriboses is observed, albeit in a less pronounced manner, as it requires two flanking LNA monomers to shift the deoxyribose pucker into a pure N-type conformation. For LNA:DNA hybrids, we also observe a slight increase in N-type conformation of the deoxyriboses on the base-paired strand. We extend here our studies of LNA:DNA hybrids, with the characterization of a fully modified hybrid by analysis of 2D NMR spectra. In addition, we have determined the sugar puckers of the deoxyribose strand by analysis of COSY-type spectra.

MATERIALS AND METHODS

Sample Preparation. The modified oligonucleotide was synthesized as described elsewhere (*6*, *20*). The DNA oligonucleotide was purchased from DNA Technology, Århus, Denmark, and the RNA oligonucleotide was synthesized at University of Copenhagen. All oligonucleotides were purified by site-exclusion on a Sephadex G15 column. The samples were obtained by dissolving equimolar amounts of the two single strands in 0.5 mL of 10 mM sodium phosphate buffer (pH 7.0), 100 mM NaCl, and 0.05 mM NaEDTA. For experiments carried out in D_2O, the duplex solutions were lyophilized three times from D_2O and redissolved in 99.96% D_2O (Cambridge Isotope Laboratories). Mixtures of 90% H_2O and 10% D_2O (0.5 mL) were used for experiments examining exchangeable protons. The final concentration of the hybrids were 0.8 mM (LNA:RNA) and 2.0 mM (LNA:DNA).

NMR Experiments. NMR experiments were performed on either a Varian INOVA 500 spectrometer or a Varian INOVA 800 spectrometer at 25 °C. For the LNA:RNA hybrid the following spectra were obtained: NOESY spectra (mixing times: 80 and 250 ms) were acquired at 800 MHz in D_2O using 1110 t_1-experiments with 24 scans, 2048 complex points in t_2, a pulse repetition time of 2.5 s, and spectral widths of 8000 Hz. The States phase cycling scheme was used, and the residual signal from HOD was removed by low-power presaturation. An inversion recovery experiment to extract the T_1 relaxation rates was also obtained at 800 MHz. The remaining spectra were all obtained at 500 MHz. A NOESY spectrum in H_2O (mixing time: 200 ms) using the WATERGATE NOESY pulse sequence with 2048 complex points in t_2, 900 t_1-experiments with 112 scans, and a spectral width of 10000 Hz. TOCSY spectra (mixing times: 60 and 90 ms) using 1024 complex points in t_2 and 600 t_1-experiments with 42 scans. A DQF−COSY spectrum using 4096 complex points in t_2, 1024 t_1-experiments with 64 scans, and a gradient $^1H-^{13}C$ HSQC spectrum using 2048 complex points in t_2, 750 t_1-experiments with 80 scans, and spectral widths of 5000 and 10000 Hz for the ^1H and ^{13}C dimensions, respectively.

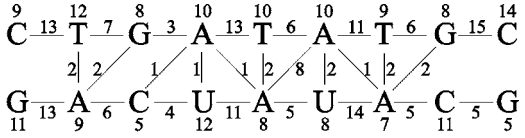

Figure 2. The distribution of the NOE restraints. The numbers of intranucleotide, sequential and cross-strand restraints are indicated. In addition to the restraints shown, six further restraints were also obtained (C1-G3, T7-C9, A6-U15, T7-A14 (two), C9-A12).

For the LNA:DNA hybrid, the following spectra were obtained at 500 MHz: A NOESY spectrum (mixing time: 200 ms) in D_2O using 640 t_1-experiments with 96 scans, 2048 complex points in t_2, a pulse repetition time of 2.4 s, and spectral widths of 5000 Hz. The States phase cycling scheme was used, and the residual signal from HOD was removed by low-power presaturation. A NOESY spectrum in H_2O (mixing time: 200 ms) using the WATERGATE NOESY pulse sequence with 2048 complex points in t_2, 512 t_1-experiments with 128 scans, and a spectral width of 10000 Hz. A TOCSY spectrum (mixing time: 90 ms) using 1024 complex points in t_2 and 512 t_1-experiments with 64 scans. In addition, selective DQF−COSY and E-COSY spectra were acquired using a pulse sequence where the first pulse was replaced with an E-BURP type selective pulse (*21*) in order to enhance the digital resolution in F1. These spectra were acquired with spectral widths of 5000 Hz in F2 and 1200 Hz in F1, respectively. For the DQF−COSY spectrum, a total of 1472 t_1-experiments were recorded, each with 64 scans, with 4096 complex points in t_2. For the E-COSY spectrum, a total of 700 t_1-experiments were recorded, each with 96 scans, with 2048 complex points in t_2.

The acquired data were processed at optimal conditions using FELIX (version 98.0, MSI, San Diego, CA). Particularly, the NOESY spectra recorded in the build-up of the LNA:RNA hybrid were linear predicted from 555 points to 750 points in t_1 and baseline-corrected in F2 using the FLATT algorithm (*22*).

Distance Restraints. A total of 333 distance restraints were obtained from 2D NOE cross-peak intensities using the method of Wijmenga et al. (*23*); in this variation of the isolated spin pair approximation, spin diffusion is accounted for in an average manner. NOESY cross-peak intensities from the 80 and 250 ms spectra were corrected for saturation effects using T_1 relaxation times obtained from an inversion recovery experiment and were subsequently transformed to distance restraints by calibrating against all known distances. Upper and lower distance bounds were set to the calculated distances ±15%. The distribution of NOE restraints for the LNA:RNA hybrid is shown in Figure 2. In total we had 166 intranucleotide, 139 internucleotide and 28 cross-strand restraints. The average width of the distance restraints was 1.50 Å, and the average restraint length 4.66 Å.

Normal Watson−Crick base pairing was inferred from the NOESY spectrum acquired in H_2O, and consequently 22 hydrogen bond distance restraints were included in the calculations. Target values for these restraints were taken from crystallographic data (*24*).

All distance restraints were incorporated into the AMBER potential energy by a flat-well pseudopotential with the form:

$$E_{NOE} = \begin{cases} -K_{NOE}r + (r_1 - 0.25\ \text{Å})K_{NOE}, & \text{if } r \le r_1 - 0.5\ \text{Å} \\ K_{NOE}(r - r_1)^2, & \text{if } r_1 - 0.5\ \text{Å} < r < r_1 \\ 0, & \text{if } r_1 \le r \le r_2 \\ K_{NOE}(r - r_2)^2, & \text{if } r_2 < r < r_2 + 0.5\ \text{Å} \\ K_{NOE}r + (r_2 + 0.25\ \text{Å})K_{NOE}, & \text{if } r \ge r_2 + 0.5\ \text{Å} \end{cases}$$

where the force constants, K_{NOE}, are in units of kcal/(mol Å) or kcal/(mol Å^2), and r_1 and r_2 are the lower and upper distance bounds, respectively.

Structure Calculations. All calculations were performed with the AMBER6 suite of programs (*25*) on SGI/O2 workstations. A simulated annealing (SA) protocol was utilized to obtain the structure of the hybrid. The starting structure (A-form duplex) was obtained with the *nucgen* module of AMBER6. The appropriate nucleotides were modified to LNA nucleotides, and atomic charges for the modified nucleotides were calculated using the RESP procedure (*26*). A table with atomic charges for the four LNA nucleotides is included in Supporting Information.

Initially the starting structure was restrained energy minimized before being subjected to 28 ps of molecular dynamics in time-steps of 1 fs: 4 ps at 600 K followed by cooling to 250 K over 24 ps. Finally, a further restrained energy minimization was carried out. In the SA scheme, the force constant, K_{NOE}, was ramped from 50 kcal/(mol Å^2) to 250 kcal/(mol Å^2) over the initial 2 ps, kept constant at 250 kcal/(mol Å^2) from 2 to 8 ps, decreased to 50 kcal/(mol Å^2) from 8 to 12 ps, and afterward kept constant at 50 kcal/(mol Å^2). A distance dependent dielectric constant, $\epsilon = 4r$, was used and the nonbonded cutoff was 30 Å.

Deoxyribose Ring Conformations. The H1′ to H2′ and H2″ region of the selective DQF−COSY and E-COSY spectra, respectively, was used as input to CHEOPS (*27*) to obtain the values of the *J* coupling constants for the H1′, H2′, H2″, and H3′ deoxyribose ring protons. The deoxyribose ring conformations were analyzed assuming a fast two-state equilibrium between N- and S-type conformations with a modified version of the program PSEUROT (*28*). The standard version of PSEUROT obtains the best fit of the parameters P_N, P_S, $\Phi_{max,N}$, $\Phi_{max,S}$, and %N to the experimental coupling constants. $P_{N,S}$ and $\Phi_{N,S}$ are the pseudorotation angle and puckering amplitude, respectively, of the N- and S-type conformation and %N is the mole fraction of N-type conformation. In our randomized version of PSEUROT, we include the effect of uncertainties in the determined set of coupling constants by generating 1000 sets of coupling constants according to a normal distribution in which the dispersion is set according to the uncertainty of each determined coupling constant. Uncertainties of the coupling constants were carefully assessed by how well the back-calculated spectra correlated with the experimental spectra and by the difference in the coupling constants obtained by analysis of the two types of COSY spectra. Subsequently, PSEUROT calculations were performed for all the generated sets of coupling constants and the mean values and standard deviations of the parameters returned by PSEUROT were calculated.

Table 1. Melting Temperatures of LNA:RNA and LNA:DNA Hybrids. Unmodified Duplexes of Identical Base Sequence Are Included for Comparison[a]

duplex	T_m, °C	ΔT_m per modification, °C	duplex	T_m, °C	ΔT_m per modification, °C
LNA:RNA	74	5.2	LNA:DNA	62	3.8
LNA3:RNA	52	8.3	LNA3:DNA	44	5.3
LNA1:RNA	37	10.0	DNA:DNA[b]	28	–
DNA:RNA	27	–	RNA:DNA[b]	27	–
RNA:RNA[b]	38	–			

[a] T_m is the duplex melting temperature and ΔT_m the increase in melting temperature per LNA monomer compared with that of the corresponding unmodified duplex. [b] In these duplexes, one of the terminal base pairs is switched, i.e. C−G to G−C, relative to the duplexes in this work. These data are from S. K. Singh and J. Wengel (1998) *Chem. Commun.*, 1247−1248.

Thermal Stability Studies. The thermal stability of the hybrids was determined spectrophotometrically with a spectrophotometer equipped with a thermoregulated Peltier element. The hybridization mixtures were prepared by dissolving equimolar amounts (ca. 2.5 μM) of the oligonucleotides in 10 mM sodium phosphate buffer (pH 7.0), 100 mM NaCl, and 0.05 mM EDTA. The absorbance at 260 nm was monitored while the temperature was raised linearly from 10 to 80 °C (1 °C/min). The melting temperatures (T_m values) were obtained as the maxima of the first derivative of the melting curves.

Circular Dichroism Spectra. A CD spectrum of the LNA:RNA hybrid from 350 to 200 nm was measured on a JASCO 710/720 spectropolarimeter. The sample was prepared by dissolving equimolar (65 μM) amounts of the oligonucleotides in 10 mM sodium phosphate buffer (pH 7.0) and 0.05 mM EDTA. The spectrum of the buffer solution was subtracted from the spectrum. The molar CD of the duplex was calculated from eq 1 (*29*, *30*), where θ is the measured ellipticity in degrees, L is the path length in centimeters, and C is the concentration of the duplex. An absorbance spectrum was measured on a Lambda 17 spectrophotometer. The concentration of the duplex was determined from the absorbance at 260 nm using an extinction coefficient $\epsilon = 161.800\ M^{-1}\ cm^{-1}$.

$$\Delta\epsilon = \frac{\theta}{32.98CL} \quad (1)$$

Protein Data Bank Accession Codes. Coordinates and restraints employed in calculations have been deposited in the Protein Data Bank (accession code: 1h0q).

RESULTS

Thermal Stabilities. The thermal stabilities of the two hybrids studied were determined and compared with those of hybrids with isosequential base composition (Table 1). Sharp monophasic transitions were obtained with hyperchromicities of 1.2−1.3. No indications of biphasic transitions were detected. For the fully modified LNA:RNA and LNA:DNA hybrids, we observe increases in the melting temperatures of 5.2 °C and 3.8 °C per modification relative to the unmodified DNA:RNA and dsDNA reference duplexes, respectively. These results emphasize the substantial increases in thermal stability displayed by LNA modified oligonucleotides when hybridized with complementary RNA or DNA.

Spectral Analysis. The 1D ^{1}H NMR spectra of the two hybrids both show exclusively lines from the expected LNA:RNA and LNA:DNA hybrids at 25 °C. No signs of

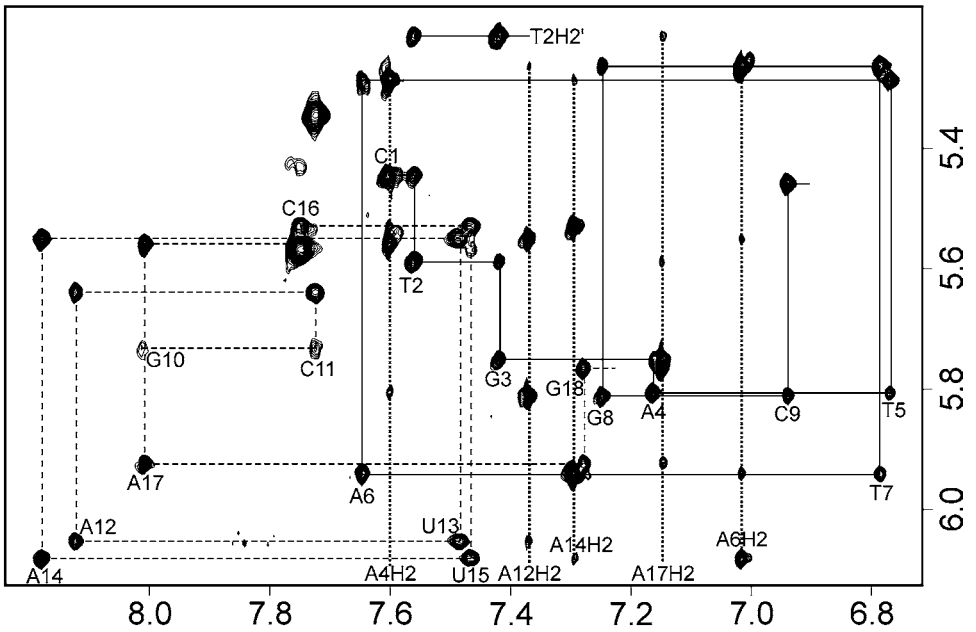

Figure 3. The aromatic to H1′ region of the NOESY spectrum with a mixing time of 250 ms of the LNA:RNA hybrid. The sequential H1′(n-1)−H6/8(n)−H1′(n) connectivity pathways are indicated; unbroken line for the LNA strand and broken line for the RNA strand. Adenine H2 resonances are shown with dotted lines.

alternative hybridization were observed. The NOESY spectra of both hybrids display the characteristic connectivities of right-handed nucleic acid duplexes with an overall A-type geometry, as gauged from cross-peaks involving adenine H2 protons, and with all the nucleobases in the anti conformation. The assignment of the nonexchangeable protons was performed using standard methods (*31*−*34*). The NOESY spectra with short mixing times allowed unambiguous assignments of the H2′ and H2″ resonances. The H6′ and H6″ resonances in the 2′-*O*,4′-*C*-methylene bridge of the LNA nucleotides were assigned by their strong intranucleotide cross-peaks to H1′ of the modified nucleotides. The aromatic to H1′ region of the 200 ms NOESY spectrum of the LNA:RNA hybrid is shown in Figure 3. The NOESY spectra acquired in H_2O exhibited normal Watson−Crick connectivities and were employed in the assignment of the exchangeable protons. Selections of chemical shift values for the hybrids are included in Supporting Information.

Furanose Ring Conformations in the LNA:DNA Hybrid. All nucleotides in the LNA strand are found in N-type conformations as shown by the absence of COSY cross-peaks between the H1′ and H2′ protons due to cancelation of anti-phase lines ($J_{H1'H2'} < \sim 2$ Hz). The favorable spectral dispersion of the H1′, H2′, and H2″ resonances of the deoxyriboses allowed simulation of all cross-peaks and consequently determination of sugar puckers for the entire DNA strand. In Figure 4, a comparison between the experimental DQF−COSY spectrum and the spectrum obtained by spectral simulations with CHEOPS is shown. Very good agreement between the simulated and the experimental spectrum is observed. The simulated E-COSY spectrum of the hybrid agreed equally well with the experimental one. The coupling constants returned by CHEOPS were used as input for our randomized version of PSEUROT. The uncertainties of the coupling constants were gauged by monitoring the dependence of the simulation procedure on alterations in the input parameters and the difference in the coupling constants obtained from each of the two types of spectra. The coupling constants obtained, molar fractions of S-type sugar conformations, and pseudorotation angles calculated for the LNA:DNA hybrid are given in Table 2.

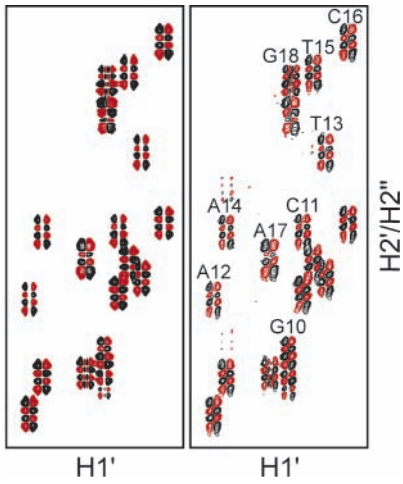

Figure 4. Comparison of the H1′ to H2′/H2″ regions of the calculated (left) and the experimental (right) DQF−COSY spectra for the LNA:DNA hybrid.

We tried to fit the experimental coupling constants to a one-state model; however, the RMSD between calculated and experimental coupling constants was on average 1.9 Hz, which is more than the uncertainty on the experimental coupling constants. When fitting with a two-state model, the average RMSD was 0.5 Hz. In the two-state model, we allowed three parameters (the two pseudorotation angles and the molar fraction of N-type conformation) to be fitted, while in the one-state fit only two parameters (the pseudorotation angle and the puckering amplitude) were free. Obviously, the larger number of degrees of freedom in the two-state fit dictates a lower RMSD than in the one-state fit; however, we think that the decrease observed in RMSD is significant although we did not perform any statistical analysis.

All deoxyribose sugars in the LNA:DNA hybrid possess sugar puckers in equilibria between N- and S-type conformations. The population of S-type conformation ranges from 57% (A12) to 80% (A17) with the populations

Table 2. Coupling Constants for the Deoxyribose Sugar Protons in the LNA:DNA Hybrid and the Sugar Conformations Derived[a]

	$J_{1'2'}$/Hz	$J_{1'2''}$/Hz	$J_{2'3'}$/Hz	$J_{2''3'}$/Hz	%S[b]	P_S, deg[c]	P_N, deg[d]
G10	6.1	4.7	4.7	3.8	62 (7)	165 (12)	−28 (16)
C11	5.7	6.4	4.3	4.0	62 (9)	185 (15)	−11 (17)
A12	5.2	6.2	4.5	4.3	57 (8)	183 (16)	−16 (17)
T13	6.1	6.4	5.5	4.0	60 (9)	172 (25)	−9 (33)
A14	5.7	6.4	4.7	4.0	62 (9)	183 (18)	−14 (21)
T15	6.5	6.5	4.9	3.8	65 (9)	178 (18)	−5 (32)
C16	7.0	6.3	4.7	3.8	68 (8)	175 (16)	−5 (26)
A17	8.7	5.4	4.6	3.0	80 (7)	164 (12)	
G18	8.4	6.4	5.7	2.4	76 (13)	160 (28)	

[a] The coupling constants were derived from the H1′−H2′ and H1′−H2″ cross-peaks in the selective DQF−COSY and E-COSY spectra using CHEOPS. The $J_{2'2''}$ coupling constants returned were between −14.2 and −15.0 Hz, values typical for deoxyribose. The sugar conformations were calculated using a randomized version of the PSEUROT program. In PSEUROT calculations, the puckering amplitudes were fixed at 36°. The standard deviations are given in brackets. [b] Percent S-type sugar conformation calculated using PSEUROT. [c] Pseudorotation angle calculated for the S-type sugar conformation. [d] Pseudorotation angle calculated for the N-type sugar conformation. If the mole fraction of the N-type conformer was calculated to be below 25%, the *P* value was not considered to be determined with sufficient accuracy.

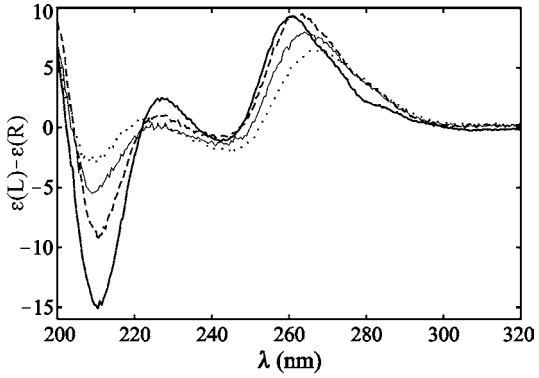

Figure 5. The CD spectra of various DNA:RNA and LNA:RNA hybrids of identical base sequence; DNA:RNA (dotted line), LNA1:RNA (thin line), LNA3:RNA (dashed line), and the fully modified hybrid (thick line).

being fairly uniform (at 60−65%) except for the two 3′-terminal nucleotides, A17 and G18, which possess slightly higher populations of S-type puckers than the remaining nucleotides in the DNA strand. This is also shown by the slightly larger $J_{H1'H2'}$ coupling constants for these nucleotides (see Table 2).

CD Spectra. The CD spectrum of the fully modified LNA:RNA hybrid is shown in Figure 5 along with the spectra of the unmodified reference hybrid and the LNA1:RNA and LNA3:RNA hybrids. All of the hybrids adopt an overall A-type duplex geometry as evidenced by the negative bands at ∼210 nm and the positive bands at ∼260 nm. These bands become progressively more intense upon introduction of either one or three LNA modifications in accordance with our previous structural studies showing an increase in the A-like character of these duplexes (*12*, *19*). For the fully modified LNA:RNA hybrid, the band at ∼260 nm has approximately the same intensity as for the hybrid with three modifications. This band is progressively blue-shifted with an increasing number of LNA monomers. The band at ∼210 nm is even more intense for the fully modified hybrid than for any of the other hybrids. Altogether, the CD spectrum of the fully modified LNA:RNA hybrid points to a regular A-like duplex structure.

Table 3. Structural Parameters for the LNA:RNA Structure[a]

structure	E_{AMBER} (kcal/mol)	E_{NOE} (kcal/mol)	Δd_{av} (Å)	RMSD (Å)
A-type	208.8	412.6	0.058	1.06
NMR	98.4	8.2	0.023	0.64[b]

[a] Force field (E_{AMBER}) and restraint (E_{NOE}) energies, average restraint violations (Δd_{av}), and atomic RMSD for the A-type starting structure and the NMR structure. All-atomic RMSDs were calculated for all atoms of the seven internal base pairs. [b] Average pair-wise atomic RMSD for the 20 structures calculated.

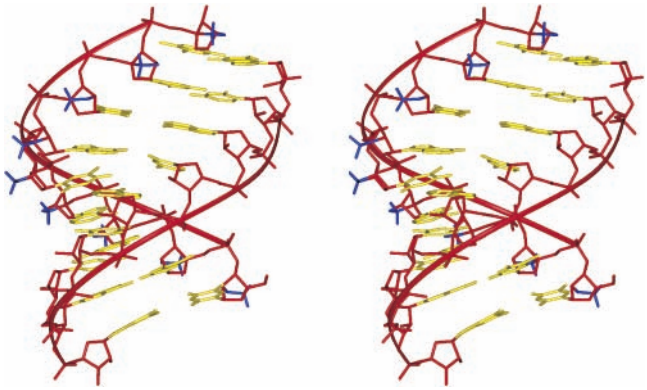

Figure 6. Stereoview of the LNA:RNA structure viewed into the minor groove. For clarity, only hydrogens on the 2′-*O*,4′-*C* LNA methylene bridge are shown. The coloring scheme: nucleobases, yellow; sugar−phosphate backbone, red; 2′-*O*,4′-*C* methylene bridges, blue.

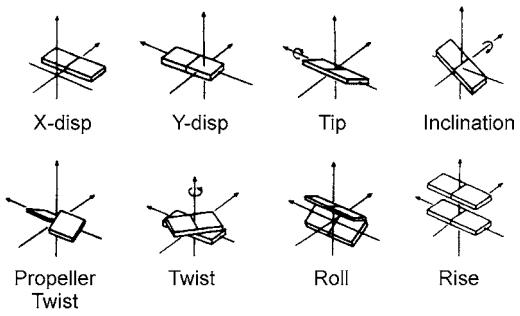

Structure of the Fully Modified LNA:RNA Hybrid. The high-resolution structure was generated starting from a canonical A-type duplex geometry (see Materials and Methods). The use of an A-type structure as starting structure is justified as the N-type conformation of both the LNA and RNA nucleotides is demonstrated by the absence of H1′−H2′ cross-peaks in COSY spectra. A total of 20 final structures were calculated using the protocol described by randomly varying the initial atomic velocities. These structures all converged to one family of structures with an average pair-wise all-atomic RMSD of 0.85 Å (0.64 Å for nonterminal base pairs). Only one distance violation in excess of 0.2 Å was observed, and in addition the hybrid features a low distance restraint energy (see Table 3) and low distance violations as compared to the starting structure.

General Description of the Structure. As suggested by the CD spectrum and by inspection of the NOESY spectra, the fully modified LNA:RNA hybrid has the overall appearance of an A-type duplex; for example, the minor groove is very wide and shallow, and the base pairs are displaced relative to the long axis of the helix. The RMSD between the calculated NMR structure and the energy-minimized A-type starting structure is 1.1 Å. The 2′-*O*,4′-*C* methylene bridges of the LNA nucleotides are located at the brim of the minor groove where they pose no steric hindrance for duplex formation (see Figure 6). All glycosidic angles are in anti conformations and Watson−Crick base pairing is maintained for all base pairs. The hybrid is regular as shown by the nearly straight helix axis as calculated by CURVES 5.2 (*35*, *36*). Thus, the structure shows that a nucleic acid strand composed entirely of LNA monomers can be hybridized with an RNA strand and still retain a normal Watson−

Table 4. A Selection of Helix Parameters for the LNA:RNA Hybrid. Values for Standard A- and B-Type Duplexes Are Included for Comparison

Scheme 2. Graphical Representations of Helix Parameters Discussed in the Text

Crick duplex framework. A stereoview of the structure is presented in Figure 6.

Interstrand purine−purine stacking is observed between G3/A17, A6/A14, and G8/A12. This stacking arrangement stabilizes the inherently weaker pyrimidine−purine base pair steps in which little/no intrastrand stacking is taking place. An identical stacking pattern was observed for the previously studied LNA:RNA hybrids and for the unmodified hybrid as well, and is, as such, not a property specific for LNA modified hybrids but rather a sequence-specific property (*19*). The minor groove width of the hybrid is uniform along the helix ranging from 9.7 to 10.3 Å, with the average being 10.0 Å.

Helix Parameters. The global helix axis and helical parameters were calculated with CURVES 5.2. The global helix axis is rather straight with a slight bend at the T5pA6 base pair step. In general the helix parameters are uniform along the duplex, with slight variations toward the 3′-end of the LNA strand for some parameters and some minor variations in the T5pA6 base pair step as a consequence of the slight bend in the helix axis. A selection of the helical parameters is given in Table 4, and graphic representations of the helical parameters discussed are shown in Scheme 2. X-displacement, Y-displacement, inclination, and tip are the helix parameters with which the global helix axis is determined. X-displacement, with an average value of −5.8 Å, and inclination, with an average of 10.4°, are both close to the values expected for an A-type duplex. The Y-displacement and tip parameters both show that the duplex is regular in its geometry. Other parameters indicative of the A-type geometry are the average propeller twist of −13.1° and the average rise of 2.55 Å. Rise shows some variations in the A4pT5, T5pA6, and A6pT7 steps, which is caused by the curvature of the helix axis at this point. This decreases rise for the T5pA6 step which, in turn, is balanced by increases in the two juxtaposed base pair steps. The kink in the helix axis is shown by a roll of 10° in the T5pA6 step, and a negative value of opening for A6 shows that the axis is bending toward the major groove. The average base pair twist is 29.6°, and this corresponds to a slight unwinding of the helix (for a canonical A-type duplex geometry, the base pair twist is 33°). In the corresponding unmodified DNA:RNA hybrid and the LNA3:RNA hybrid, we found average twists of 32.8° and 33.4°, respectively (*19*). As such, a slight unwinding of the helix might be a consequence of the fully modified LNA strand.

Table 5. Average Backbone Torsion Angles and Sugar Puckers (in degrees) in the Two Strands of the LNA:RNA Hybrid[a]

	α	β	γ	δ	ϵ	ζ	χ	*P*	Φ_{max}
LNA	−72	179	59	66	−165	−61	−164	13	60
RNA	−78	181	61	79	−161	−68	−162	15	39

[a] A complete table with torsion angles for individual nucleotides is included in Supporting Information.

Sugar Conformations. All nucleotides in the hybrid adopt N-type sugar puckers, the average pseudorotation angles being 13° and 15° for LNA and RNA strands, respectively. The corresponding puckering amplitudes are 60° and 39°, respectively. The sugar puckers are experimentally corroborated by vanishing H1′−H2′ cross-peaks ($J_{H1'H2'} < \sim 2$ Hz) in DQF−COSY spectra. The very large puckering amplitude for the LNA sugars is a consequence of the locked bicyclic ring system. The large puckering amplitude shifts the δ backbone angle to 66° (see below).

Backbone Geometry. The regularity of the duplex is accentuated by analysis of the backbone torsion angles as these all lie in the standard genus for an A-type duplex geometry, that is (α to ζ) gauche−, trans, gauche+, gauche+, trans, gauche−, with only very slight variations along each of the strands (see Table 5). In the LNA strand, the average δ angle is 66° (as compared to 79° in the RNA strand) owing to the large puckering amplitude of the LNA furanoses (see above). This alteration of 13° is absorbed by slight changes in the ϵ and ζ angles and appears not to translate into any global perturbation of the duplex geometry.

For the ribose nucleotides C11, A12, and U13, we observe that in some of the 20 structures calculated for the hybrid, the α and γ torsion angles adopt α,γ:trans,-trans conformations. This is a consequence of the dynamic nature of the nucleic acid sugar−phosphate backbone and because both the α,γ:gauche−,gauche+ and α,γ:trans,trans backbone conformations are allowed by the NOE restraints employed in the structure calculations.

The glycosidic angles, χ, are found in anti conformations for all nucleotides as expected from the NOESY spectra. Again there are only minute variations along the duplex, and between the strands, with the average value being −163°.

DISCUSSION

The LNA:DNA Hybrid. The LNA:DNA hybrid exhibits NMR spectral features typical of an A-like right-handed nucleic acid duplex with normal Watson−Crick base pairs and all nucleobases in anti conformations.

The chemical shifts of the hybrid are somewhat altered in the LNA strand relative to the corresponding hybrid with three LNA nucleotides incorporated (*37*). This is a consequence of changes in the geometry owing to the added LNA nucleotides. As for the DNA strand, the chemical shift values are fairly unchanged, which shows that the overall geometry of the strand is unaltered even though the sugar equilibria of the deoxyriboses are changed (see below).

Our analysis of the deoxyribose conformations in the LNA:DNA hybrid show that they all exist in equilibria between N- and S-type puckers, with the population of S-type ranging from 57 to 80% (Table 2). In the corresponding unmodified dsDNA duplex, all deoxyriboses possessed in excess of 80% S-type conformation and in a partly modified isosequential LNA:DNA hybrid (LNA monomers at positions 2, 5 and 7), the deoxyriboses of the DNA strand possessed between 71 and 93% S-type conformation (*38*). Obviously, the inclusion of LNA monomers in one of the strands gradually tunes the base paired strand into larger populations of N-type sugar puckers. If analyzed with a two-state model, deoxyriboses in RNA:DNA hybrids usually possess approximately 60−70% S-type sugar conformation (*19*, *39*−*42*). As such, the pucker pattern of the deoxyriboses in the LNA:DNA hybrid resembles that of an RNA:DNA hybrid.

Although we have not determined the structure of the fully modified LNA:DNA hybrid, it appears reasonable from the evidence presented above to assume that such a hybrid structurally resembles an RNA:DNA hybrid. That is, repuckering deoxyribose sugars, a geometry intermediate of A- and B-type (albeit closer to A-type than B-type), with, for example, a minor groove width intermediate of that of A- and B-type geometries (∼8−9 Å).

There is some debate as to whether the deoxyriboses in RNA:DNA hybrids are best described by an O4′-endo sugar pucker, (*43*, *44*) a two-state model (*39*, *41*, *45*), or a model including more than two states (*46*). We have in this and previous work (*19*) experienced that *J* coupling constants can generally be fitted better with a two-state N/S model than with a single-state O4′-endo model. However, a two-state N/S model does not exclude that intermediate conformations are transiently occupied. If one assumes an S-type population of 67%, the energy difference between the two low-energy conformations would be ∼0.4 kcal/mol (based on a Boltzmann distribution), which is in good agreement with gas-phase ab initio calculations on a deoxyribose model system (*47*). In these calculations, the O4′-endo energy barrier to pseudorotation is ∼1.5 kcal/mol. Doing a statistical weighting with these energies, Brameld and Goddard calculates that the population of the "eastern" quadrant of the pseudorotation circle is 18%. This is actually in very good agreement with the 20% O4′-endo conformation proposed by Damha and co-workers based on NOE distances in a study of an RNA:DNA hybrid (*46*). Summarizing, we propose that it is apt to apply a two-state model to describe the sugar pucker of deoxyriboses in RNA:DNA hybrids; however, one should interpret the two sugar puckers determined as the two low-energy conformations and keep in mind that a continuum of conformations will be populated according to a Boltzmann distribution.

The LNA:RNA Hybrid. The chemical shifts of this hybrid show only the expected changes owing to the LNA nucleotides relative to the unmodified, LNA1:RNA and LNA3:RNA hybrids. In particular the chemical shifts of the RNA strand are almost unaltered between the four hybrids, and this shows that the conformation of the RNA strand is rather unperturbed by the increasing number of LNA nucleotides incorporated in the cognate strand.

The structure of the fully modified LNA:RNA hybrid has the general appearance of an A-type duplex as indicated by the large displacement of base pairs relative to the helix axis, by a number of helical parameters, and by sugar conformations in the N-range of the pseudorotation cycle. In addition, we find a minor groove width of 10.0 Å which is typical for an A-type duplex. This is in perfect agreement with the CD spectrum of the hybrid, which displayed all the characteristics of an A-type duplex geometry. Analysis of helical parameters and backbone torsion angles show that the duplex is regular; particularly the distributions of the backbone torsion angles are very uniform along the duplex with only very small variations between the LNA and RNA strands. The slight alteration of the δ angle, as imposed by the very large puckering amplitude of the LNA nucleotides, is absorbed by the neighboring torsion angles.

Altogether, we have shown that a fully modified LNA strand can be hybridized with its complementary RNA strand in the usual Watson−Crick manner; moreover, the resulting hybrid adopts an almost canonical A-type duplex geometry. Thus, LNA acts as an RNA mimic, and LNA fits seamlessly into an A-type Watson−Crick duplex framework.

Fully modified LNA:RNA hybrids do not elicit RNase H cleavage of the RNA strand (*48*). The predominant hypothesis is that RNase H recognizes a minor groove width intermediate of A- and B-type duplexes (∼8−9 Å), and the A-like structure, with a broad minor groove, of the fully modified LNA:RNA hybrid explains the RNase H inamenability of these hybrids.

We have determined the structure of the corresponding partly modified LNA:RNA hybrid with three LNA modifications (at positions 2, 5, and 7; LNA3:RNA) (*19*). This hybrid also adopts an almost canonical A-type duplex geometry. As such, the structural alteration introduced by the increased number of LNA monomers is small, yet the increase in helical thermostability is substantial (ΔT_m = 22 °C; although the inclusion of the two 5-methylcytosines may account for approximately 2 °C).

The NMR structure does not give any clues as to the origin of this thermostability. It is very likely that the 2′-oxygen of the LNA nucleotides partake in the solvation of the minor groove. Water bridges between the O2′ of the LNA bridge and O4′ of the 3′-flanking sugar are possible, thus enhancing the minor groove hydration. Such a hydration pattern would be less pronounced in the hybrid with just three LNA nucleotides. In addition, the T1 relaxation times measured for the fully modified LNA:RNA hybrid are very long (data not shown). For example, H1′ and aromatic protons have T1 relaxation times of ∼7 s and the adenine H2 proton a T1 relaxation time of ∼8 s. T1 relaxation times are influenced by a number of experimental parameters and thus can be difficult to compare between different samples. However, the values observed for the fully modified hybrid are distinctly longer than those for the LNA3:RNA and unmodified hybrids. This, qualitatively, points to a very rigid molecule with little internal motion. This would be favorable for establishing a well ordered shell of hydration.

CONCLUSION

We have studied two fully modified LNA hybrids, an LNA:RNA, and an LNA:DNA hybrid. In both contexts, the LNA nucleotides appear as RNA mimics. As such, LNA:RNA or dsLNA duplexes might be employed as aptamers for proteins recognizing dsRNA duplexes, and LNA:DNA hybrids as RNA:DNA aptamers, for example to probe the importance of the 2′-OH of RNA in enzymatic reactions. In addition, with their high affinity toward RNA, LNAs might be utilized to target highly structured regions of tertiary RNA structure.

ACKNOWLEDGMENT

We thank The Instrument Centre for NMR Spectroscopy of Biological Macromolecules at The Carlsberg Laboratory, Copenhagen, granted by The Danish Natural Science Research Council for providing spectrometer time at the 800 MHz spectrometer. The Danish National Research Foundation is thanked for financial support and Britta M. Dahl (Department of Chemistry, University of Copenhagen) is thanked for oligonucleotide synthesis. The Nucleic Acid Center is funded by the Danish National Research Foundation for studies on the chemical biology of nucleic acids.

Supporting Information Available: Tables giving RESP atomic charges for the four different LNA nucleotides, chemical shifts for the two hybrids, and minor groove widths, and a comprehensive table giving backbone torsion angles. We previously demonstrated that the introduction of a tag consisting of several contiguous lysines at the N- or C-terminus of a recombinant protein greatly improved the covalent grafting of the protein onto negatively charged maleic anhydride-*alt*-methyl vinyl ether (MAMVE) copolymer, under many different experimental conditions (Ladavière, C., et al. (1998) *Bioconjugate Chem. 9*, 655; Allard, L., et al. (2002) *Biotechnol. Bioeng. 80*, 341). The grafting efficiency was dependent on the charge and amine density of the tag, characteristics which were determined by the tag composition. The six lysine tag (Lys6) was found to be the most efficient (Allard, L., et al. (2001) *Bioconjugate Chem. 12*, 972). In the present work, the biological activity of Lys6-proteins covalently bound to polymer was investigated. N- or C-terminal Lys6-tagged HIV-1 p24 recombinant proteins (RK24H and RH24K) were grafted onto MAMVE, and the antigenicity each of the bioconjugates was evaluated using six monoclonal antibodies that recognized different epitopes distributed along the protein. We demonstrate that the position of the tag and the hydrolysis rate of the anhydride moieties of the polymer are the two main parameters involved in the conservation of the biological activity of the immobilized protein. We thus present a process which allows an efficient oriented immobilization of proteins onto copolymers with optimal biological activity that is suitable for the controlled production of active bioconjugates.

INTRODUCTION

Covalent immobilization of proteins onto polymers has found numerous applications in several fields, such as in chemotherapy to reduce proteolytic degradation (*1*) in gene therapy for targeted gene delivery (*2*) and in diagnostics to increase the stability of ELISA capture phase (*3*). However, immobilization may occur via a random attachment of the proteins to the support through several amino acid residues, leading to a partial loss of biological properties (*1*). Since protein covalent immobilization is a chemical alteration of the biomolecule, it is of great interest to make this reaction occur at a specific site of the protein that is not involved in the biorecognition process (*4*).

The approach we developed consisted in introducing an oligoamino acid sequence (tag) at a defined position on the protein. The rationale for this was that an increase in the density of reactive groups at a particular position of the protein would direct the grafting and should enhance the efficiency of the immobilization reaction. The advantage in using amide bond formation to tether biomolecules to carriers is that the chemistry is simple, reproducible, and can sustain a diversity of experimental conditions which are prerequisites for the development of a generic grafting method. We have previously shown that addition of a hexalysine tag (Lys6) at the N- or C-terminal region of a p24 recombinant protein led to a dramatic increase in the yield of the tagged protein (more than 90% versus 30% for the nontagged p24 protein) coupled to maleic anhydride-*alt*-methyl vinyl ether copolymer (MAMVE) (*5*, *6*). The presence of the Lys6 peptide allowed the immobilization of up to 50 protein molecules per polymer chain. In addition, we have shown that the efficiency of the regioselective immobilization of the tagged protein onto the copolymer depended directly on the composition of the tag. The reactivity of the tag was determined by both the density of positive charges and by the number of reactive amino groups. The most efficient tag was found to be the Lys6 tag which contained both cationic groups and primary amine groups (*7*).

Although such a tag allows quantitative efficient grafting, the localization of the tag should be carefully chosen to maintain the biological activity of the protein. We thus designed two recombinant proteins characterized by the N- or C-terminal position of the Lys6 tag, respectively termed RH24K and RK24H. The protein model used was the capsid p24 protein from HIV-1, which is well expressed in *Escherichia coli*, soluble, efficiently purified by immobilized metal affinity chromatography (IMAC) (*8*), and structurally characterized (*9*). The structure of the p24 allowed us to accurately locate domains involved in molecular recognition processes (such as epitopes and protease cleavage sites) and to evaluate the accessibility of internal lysines.

The RH24K and RK24H recombinant proteins were grafted onto MAMVE, and the antigenicity of the bioconjugates was evaluated using monoclonal antibodies (mAbs). These mAbs were selected because they recognized different epitopes distributed along the protein, in the N-terminal domain, in the flexible interdomain peptide and in the C-terminal domain. The accessibility of the different epitopes on the bound proteins was

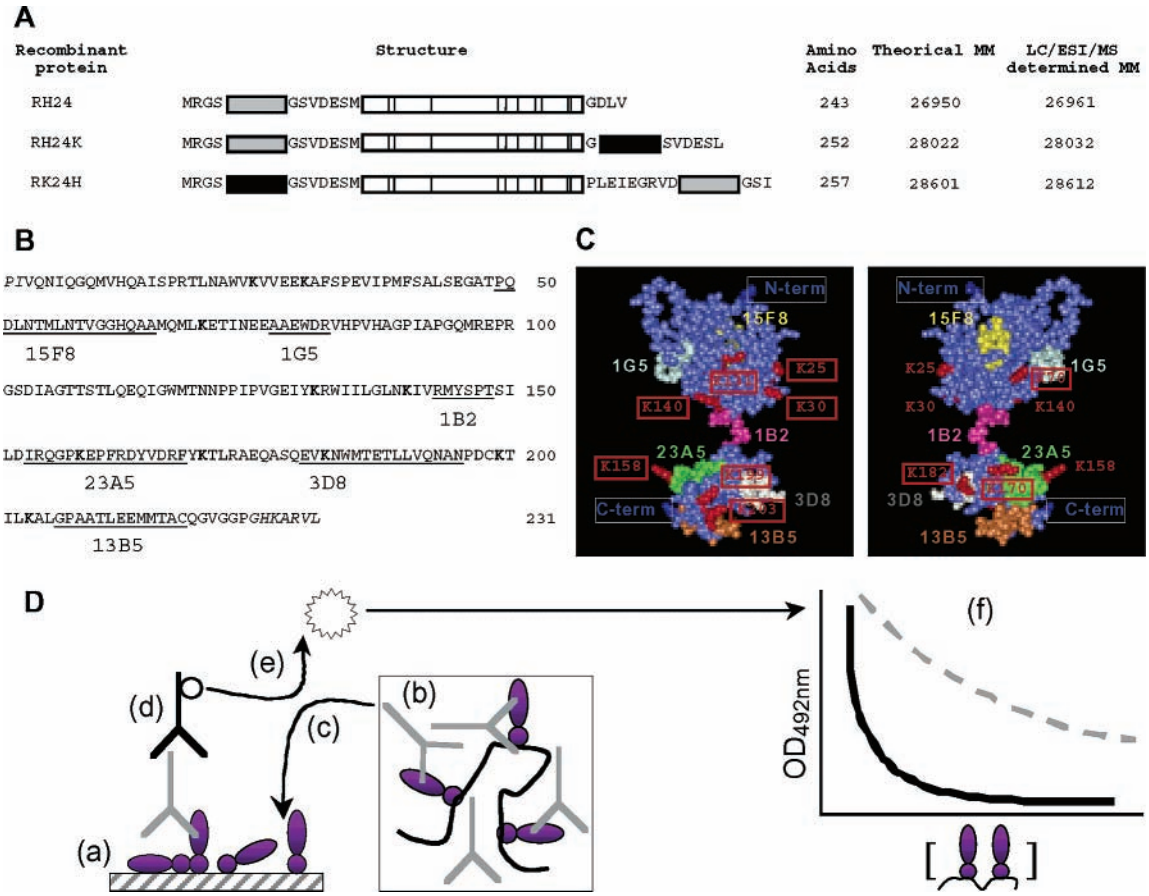

Figure 1. Chemical and antigenic features of the recombinant proteins derived from the HIV-1 p24 capsid protein. (A) Features of the three recombinant proteins, including the Lys6 (■) and His6 (■) tags, the main conserved domain (□), and specific AA residues. For each recombinant protein are indicated the length in AA and the theoretical and experimental molecular masses (MM) obtained using Mac Vector Version 6.5.3 and mass spectrometry (LC/ESI/MS), respectively. (B) Amino acid (AA) sequence of the native p24 protein from isolate HXB2. AA 3 (valine) to 224 (proline) represent the sequence conserved in all recombinant proteins. Lysine residues (K) are indicated in bold letters and epitopes recognized by 15F8, 1G5, 1B2, 23A5, 3D8, and 13B5 monoclonal antibodies (mAb) underlined. (C) In the context of a front and back RH24 3D structure, location of the N- and C-terminal ends of the protein and of the six epitopes and the 10 conserved lysines (red-squared). (D) Principle of the competitive ELISA test: (a) the RH24 protein was adsorbed on the microtiter plate, (b) various amounts of protein−polymer bioconjugate were incubated with the relevant mAb and then (c) loaded onto the RH24 capture phase; after a washing step which eliminated the bioconjugate−mAb complex, (d) the RH24 bound mAb was detected by adding an anti-mouse IgG peroxidase conjugate and (e) incubated with a colorimetric substrate; (f) curves representing the OD as a function of the bioconjugate concentrations were plotted, a rapid decrease indicating an efficient competition (black), a slow (dotted gray) or no decrease indicating an inefficient competition, which reflected an optimal or poor accessibility of the epitope, respectively.

evaluated using a competition ELISA test. The assay showed the recognition pattern of the bioconjugate epitopes was altered according to the N- or C-position of the tag. This was due to the involvement in the grafting reaction (in addition to the tag-driven grafting) of an internal lysine with spatial location close to the tag. We demonstrated that the reaction of internal lysine with the copolymer was avoided by modulating the reactivity of the latter, via controlled hydrolysis of some anhydride moieties. The location of the lysines involved in the covalent grafting of the protein onto the copolymer was determined by proteolytic digestion of the bioconjugates followed by MALDI-TOF mass spectrometry analysis. Thus, in addition to the previously demonstrated importance of the tag composition in the grafting reaction efficiency (*7*), all these results showed that the two main parameters involved in the conservation of the biological activity of the immobilized protein were the tag position and the number of reactive groups of the copolymer.

EXPERIMENTAL PROCEDURES

Isolation and Characterization of Tagged Recombinant Proteins. The p24 gene was cloned in pMR (*10*) and pMK81 and pMK83 expression vectors (*6*). Three HIV-1 p24 recombinant proteins were then obtained from *E. coli* using a procedure derived from Cheynet et al. (*8*). Each of the proteins present a His6 tag (H) at their N- or C-terminal end, allowing a one-step purification using IMAC, and two of the proteins display an additional N- or C-terminal Lys6 tag which allows efficient coupling of the protein to the copolymer (*6*, *7*). The proteins were termed RH24, RH24K, and RK24H for recombinant protein with respectively no Lys6 tag, a C-terminal tag, and a N-terminal Lys6 tag (Figure 1A). Briefly, *E. coli* strain XL1 was transformed with the expression plasmids. The extracts of soluble proteins were purified by IMAC on FPLC (Äkta explorer; Amersham Pharmacia Biotech) using a Zn−NTA-activated gel. Collected fractions were analyzed by SDS−PAGE, and the most concentrated fraction was dialyzed against phosphate buffer 50 mM, pH 7.8.

Mass spectrometry (LC-ESI-MS) analysis was performed on a single quadrupole API 100 mass spectrometer, 140B pumps, and a 785A detector (Perkin-Elmer). Reversed-phase liquid chromatography was performed on a C4 column (Vydac ref 214PT5115, 5 μm particle size).

Solvent A was 0.1% (v/v) formic acid in water, and solvent B was 0.1% (v/v) formic acid in water/acetonitrile mixture (5:95 v/v). A gradient of 40 to 60% B was used. Theoretical molar masses were determined with the Mac Vector software (version 6.5.3) and compared with the experimental values obtained by mass spectrometry.

p24 Epitope Mapping. To identify epitopes distributed along the p24 protein, we created a library of bacterial clones expressing peptide sequences of p24 (NovaTope System, Novagen). Briefly, the p24 gene was randomly cleaved in 50−150 bp fragments using DNase, and all fragments have been cloned in a plasmid designed for the inducible expression of small peptides as part of larger fusion proteins, i.e., p24 epitopes fused to phage T7 protein 10. Sixteen antibodies obtained by immunizing mice with whole HIV-1 virus extract (15F8, 1G5, 14D4, 1B2, 23A5, 3D10, 11D11, 9A4, 13H4, 11C10, 9B5) or RH24 recombinant protein (9A9, 7A1, 3D8, 4H3, 13B5) were used to screen the p24 epitope library by standard colony lift method. For each antibody, positive clones were analyzed by DNA sequencing and the epitope determined by aligning the overlapping sequences.

Isolation and Characterization of Bioconjugates. The MAMVE alternated copolymer (molar mass = 67 000 g/mol) was supplied by Polysciences Inc (Warrington, PA). The copolymer was dissolved to a final concentration of 1 g/L in either anhydrous dimethyl sulfoxide (DMSO from Aldrich) at 37 °C (named nonhydrolyzed polymer) or DMSO containing 10% (v/v) H_2O and incubated for 48 h at 37 °C (named hydrolyzed polymer). A standard reaction consisted of 36 μg of protein (12.4 μM final concentration) and 5 μg of polymer (0.71 μM final concentration) in 100 μL of 50 mM phosphate buffer, pH 7.8. The reaction mixture was stirred for 3 h at 37 °C, and then the bioconjugates were stored at 4 °C.

Bioconjugates were analyzed by size exclusion chromatography (SEC) using a Shodex Protein KW-803 (Waters), a Kontron HPLC 422 pump, a Kontron HPLC autosampler 465, and a Kontron UV diode array detector. Analyses were run in 0.1 M phosphate buffer, pH 6.8, containing 0.5% (w/v) sodium dodecyl sulfate (SDS) with a flow rate of 0.5 mL/min. Detection was achieved by measuring the absorbance at 280 nm (at the concentration used, the polymer had no absorption at 280 nm). The ratio of the peak area corresponding to the polymer-bound proteins versus the sum of the two peaks corresponding to the unbound and bound proteins (i.e. the total amount of protein involved in the reaction) gave the coupling yield.

Epitope Accessibility. The capacity of each antibody to recognize its cognate epitope was evaluated by ELISA competition. ELISA 96-well plates (Nunc Immuno Plate MaxiSorp surface) were coated overnight at room temperature with a 0.25 μg/mL solution of RH24 proteins in PBS buffer. After being coated, plates were saturated for 2 h at 37 °C with phosphate buffer saline (PBS) containing 1% dry milk. mAb and various amounts of protein−polymer bioconjugate (ranging from 0.01 to 15 μg/mL) in PBS−0.2% dry milk were incubated for 2 h at 37 °C and then added to the RH24-coated microtiter-plates. After 2 h incubation at 37 °C, plates were washed three times with PBS-0.05% Tween 20. The mAb bound to the adsorbed antigen was detected by adding 100 μL of goat anti-mouse IgG (H+L) peroxidase conjugate (Jackson ImmunoResearch) (2×10^3 fold diluted in PBS dry milk) and incubating for 1 h at 37 °C. Plates were then washed and incubated for 10 min with *O*-phenylenediamine (OPD 30 mg) (Sanofi Pasteur) diluted in 10 mL substrate buffer 0.03% H_2O_2 (Sanofi Pasteur) for 10 min in the dark at room temperature. OD values were measured at 492 nm.

Amine Titration. Protein modification rate was evaluated using fluorescamine (Acros ref 19167-5000, FW 278,26) (11), a compound which reacts with primary amines leading to the formation of fluorescent products. A standard reaction consisted of 30 μL of fluorescamine solution (0.4 g/L in anhydrous DMSO) and 90 μL of recombinant protein solution (0.34 g/L in phosphate buffer 50 mM. pH 7.8). The reaction was allowed to proceed for 20 min in the dark, at room temperature, and the fluorescence emission intensity was measured at 477 nm for an excitation wavelength of 416 nm (Perkin-Elmer LS50 fluorimeter). The modification rate of the immobilized protein was determined as follows: 100 − [fluorescence of the bound protein (assay) × 100/ fluorescence of the unbound protein].

Enzymatic Digestion of the RH24K−MAMVE67 Bioconjugates and Mass Spectrometry Analysis of the Fragments. RH24K immobilized onto nonhydrolyzed and hydrolyzed MAMVE67 copolymer was digested using Endoproteinase LysC (Roche ref 1 420 429) and protease V8 from *Staphyloccocus aureus* (Glu-C) (Roche ref 1 420 399) with an enzyme/protein ratio of 25/1 (w/w). Prior to digestion, the bioconjugates were reduced in a solution of 3 M guanidine and 20 mM DTT for 1 h at 37 °C and alkylated in 45 mM iodoacetamide for 1 h at 37 °C. Bioconjugates were then dialyzed overnight at 4 °C against 50 mM ammonium bicarbonate (Sigma lot 10K0261). Free RH24 and RH24K proteins were digested under the same conditions. Digested bioconjugates were stored at 4 °C before molecular-mass analysis on a MALDI-TOF Biflex III (Bruker, Wissembourg, France) mass spectrometer.

RESULTS AND DISCUSSION

Characterization of the p24 Recombinant Proteins. The three recombinant proteins, containing a His6 tag for IMAC purification, differed by the absence (RH24) or the presence at their N-terminal (RK24H) or C-terminal (RH24K) end of a Lys6 reactive tag for coupling onto copolymer (Figure 1A). All three recombinant proteins exhibited a high expression level representing up to 30% of the total amount of protein production by *E. coli*. Following purification by IMAC on a Zn−NTA-activated gel, the purity of the proteins was greater than 95% as determined on a Coomassie Blue stained SDS polyacrylamide gel, as described for other batches used in previous studies (*5*−*8*). Experimental determination of the molar masses was in accordance with the expected theoretical value for all recombinant proteins (Figure 1A). The amino acid sequence shared by all proteins is reported in Figure 1B. Ten lysine groups are almost evenly spaced along the nontagged RH24 protein macromolecule (residues 25, 30, 70, 131, and 140 in the N-terminal domain, residues 158, 170, 182, 199, 203 in the C-terminal domain. Residue numbering corresponds to the wild-type HIV-1 p24 HXB2 strain), and these lysine groups are conserved within all three recombinant proteins. NMR (*12*) and crystal structure data (*9*, *13*−*14*) demonstrated that, in the 3D structure, the 10 lysine groups were accessible for grafting (Figure 1C) although they displayed different reactivities (*15*).

Characterization of the p24 Recombinant-P(MAMVE) Bioconjugates. The RH24K and RK24H proteins were bound to MAMVE, and the coupling yields were determined by HPLC analysis. The coupling yields were close to 100%, irrespective of the N- or C-terminal

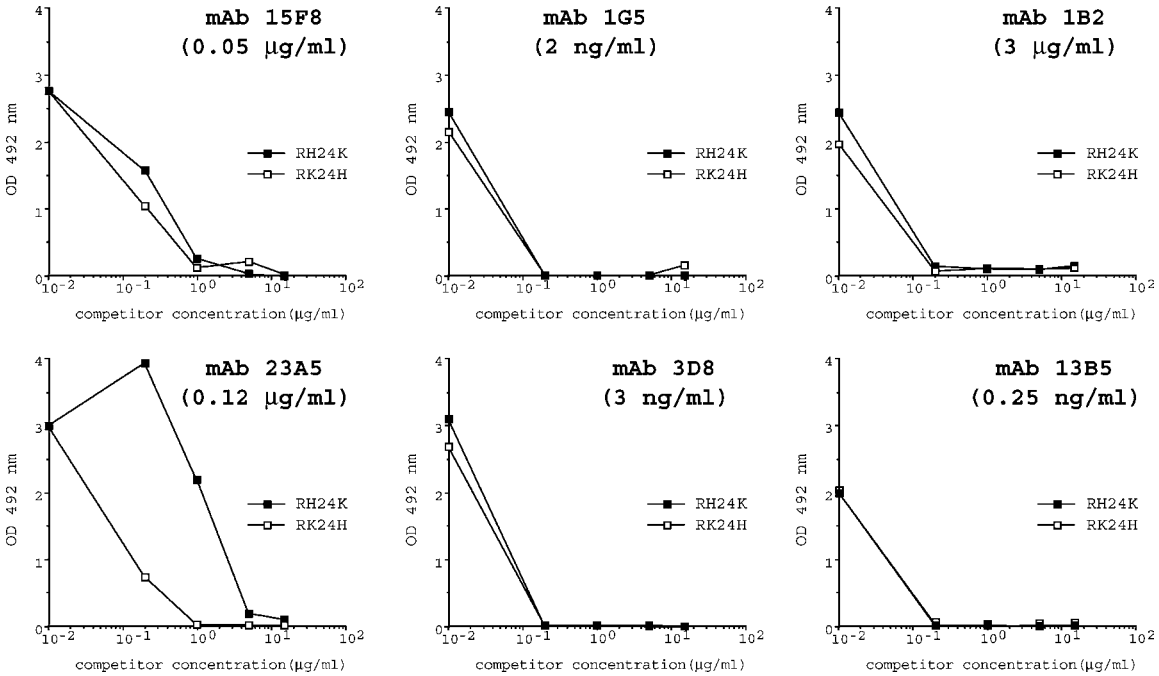

Figure 2. Influence of the Lys6 tag position on epitope accessibility on the bioconjugate. Competitive ELISA curves representing OD as a function of the bioconjugate concentration were obtained for the six mAbs used at an optimal concentration (see text) as indicated (in brackets). The two bioconjugates consisted of N- or C-terminal Lys6-tagged recombinant proteins, RK24H (□) and RH24K (■), respectively, grafted onto MAMVE copolymer. 15F8 and 1G5 mAbs targeted the N-terminal domain of p24, 1B2 the interdomain, and 23A5, 3D8, and 13B5 mAbs the C-terminal domain.

position of the Lys6 tag, as previously described (*6*), highlighting the robustness of the process. RK24H and RH24K proteins were bound to partially hydrolyzed MAMVE (48 h in DMSO, 10% H_2O; see below), and the coupling yields were 100% and 94.4% and 90%, respectively. The 0% to 10% coupling yield reductions observed with these Lys6-tagged proteins grafted onto partially hydrolyzed versus nonhydrolyzed polymers were much lower than the 82% decrease previously observed with the RH24 nontagged counterpart in similar conditions (*7*), illustrating the high grafting efficiency of the Lys6 tag which compete efficiently with the water-induced hydrolysis during the coupling reaction (*5*, *7*). Thus, the high coupling yields allowed use of the bioconjugates without subsequent purification. Although the tag position did not affect the yields, it could potentially be detrimental to the biological reactivity of the bioconjugate. We decided to use antigen (p24 epitopes)−antibody (monoclonal antibodies paratopes) recognition as a tool to analyze the biological reactivity of the immobilized proteins.

P24 Epitope Mapping. All p24-derived proteins contained a principal conserved domain which was used to construct an epitope library in order to make an epitope map of the p24 protein. The epitope library was used to screen 16 anti-p24 monoclonal antibodies (mAb). These 16 antibodies covered seven epitope regions including six nonoverlapping epitopes. Six monoclonal antibodies were retained, 15F8, 1G5, 1B2, 23A5, 3D8, 13B5 (Figure 1B). Four out of the six identified epitopes, recognized by 15F8, 1G5, 1B2, and 23A5 mAb, were in agreement with previous identifications using peptide technologies (*16*, *17*). One out of the six identified epitopes, recognized by 13B5 mAb, was in agreement with previous structural characterization determined during cocrystallization of RH24 and 13B5 Fab (*9*, *18*). More precisely, 15F8 (residues 49−65) and 1G5 (77−82) mAb recognize epitopes located in the N-terminal domain, 1B2 (143−148) in the flexible interdomain peptide, and the three remaining 23A5 (153−168), 3D8 (179−195), and 13B5 (206−218) mAb in the C-terminal domain (Figure 1B,C). As those epitopes were evenly dispersed along the p24 protein, they were flanked or contained potentially reactive lysine groups (Figure 1B,C).

Antigenicity of the Bioconjugates. Due to the homogeneous distribution and the close vicinity of epitopes and internal lysines (not belonging to the Lys6 tag), one can assume that, in the context of a protein coupled to a copolymer, any alteration of epitope−paratope interaction may reflect the involvement in the grafting reaction of residues other than those contained within the tag, leading to end-on (tag dependent) or side-on (tag unrelated) orientations as previously suggested (*5*). The bioreactivity of recombinant proteins immobilized onto copolymer was investigated in an ELISA competition test (Figure 1D), as the random adsorption of the bioconjugate onto a solid phase might have randomly hidden and/or damaged some of the recognition sites. We first determined the optimal concentration for each monoclonal antibody, using a classical ELISA test with RH24 as a coated antigen. Using a serial dilution of mAbs, we obtained OD as a function of mAb concentration curves and thus calculated the mAb concentration at the center of the linear part of the curve. This mAb concentration should be the most informative in competition assay as small variations in recognition efficiency should induce large signal variations. Determined optimal concentrations were 0.05 μg/mL, 2 ng/mL, 3 μg/mL, 0.12 μg/mL, 3 ng/mL and 0.25 ng/mL, for 15F8, 1G5, 1B2, 23A5, 3D8, 13B5 mAbs, respectively.

The bioreactivity of RH24K and RK24H proteins immobilized onto MAMVE was investigated in an ELISA competition test with the six monoclonal antibodies. No influence of the position of the tag was observed for five out of the six mAbs. This was indicated by the exponential decrease of the OD signal as a function of the bioconjugate concentration (Figure 2). Conversely, the competition curves for 23A5 mAb showed that RH24K−

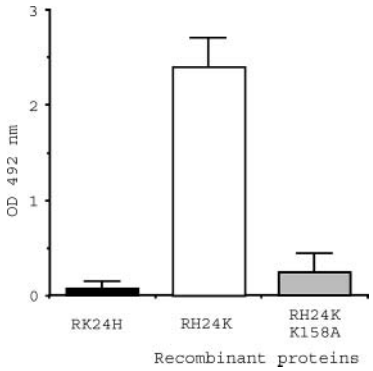

Figure 3. Influence of an internal lysine on epitope accessibility on the bioconjugate. Three bioconjugates were analyzed by competitive ELISA with the 23A5 mAb. Antibody and bioconjugate concentrations were 0.12 μg/mL and 1 μg/mL, respectively. The bioconjugates consisted of N-terminal, RK24H (black bar), or C-terminal, RH24K (empty bar), Lys6-tagged recombinant proteins, or a Lys 158 mutated form RH24K−K158A (grey bar), grafted onto MAMVE copolymer. Experiments were performed in triplicate. The indicated OD is the mean value ± two standard deviations.

MAMVE bioconjugate competes much less efficiently than the RK24H−MAMVE counterpart. This may suggest that in the context of a C-terminal Lys tag grafted protein, the 23A5 corresponding epitope is poorly recognized or not accessible. This epitope is located in the C-terminal domain of the p24 protein, as were the 3D8 and 13B5 epitopes which remained unaltered during the grafting reaction. The 23A5 epitope contained a very accessible primary amine on lysine 158, as determined by analysis of the 3D structure (SwissPdbViewer v3.6) and previously experimentally described (*15*). Another lysine (K170) was present within the 3D8 epitope but exhibited a lower accessibility than lysine 158, as determined from the 3D structure and previously observed experimentally (*15*). Overall, this suggested that the position of the tag might favor the reactivity (coupling) of the K158 intrinsic lysine, which was detrimental to the epitope accessibility.

To demonstrate the involvement of this lysine in the covalent reaction, we designed a new p24 recombinant protein, derived from the C-terminal Lys6 tag protein RH24K, where the K158 lysine was replaced with alanine, a neutral amino acid that is unable to react covalently with the anhydride moieties of the polymer. The binding of this protein, termed RH24K−K158A, onto the 23A5 mAb was not affected by the single amino acid mutation within the epitope, in a direct ELISA test (data not shown). RH24K−K158A was coupled onto MAMVE (coupling yield 100%, 90% after partial hydrolysis), and the reactivity of the 23A5 mAb toward RK24H−MAMVE, RH24K−MAMVE, and RH24K−K158A−MAMVE bioconjugates was evaluated in the ELISA competition assay. The competition effect obtained with the RH24K−K158A−MAMVE bioconjugate was approximately 10 times higher than the one produced by the original RH24K−MAMVE and was indeed similar to the inhibition produced by the N-terminal Lys6-tagged protein−polymer bioconjugate, RK24H−MAMVE (Figure 3). This result clearly demonstrated that, in the context of a C-terminal Lys6 p24, lysine 158 was involved in the coupling reaction with the polymer.

A simple way to avoid internal lysine reactivity would be to decrease the density of reactive groups on the polymer. Such a modulation of reactivity could be achieved by partial hydrolysis of the anhydride moieties of the MAMVE copolymer in DMSO containing 10% water for 48 h at 37 °C (*7*). The RH24K protein was therefore grafted onto nonhydrolyzed and partially hydrolyzed (MAMVE.hy) polymers, and the antigenic determinants reactivity of the two bioconjugates was investigated in the ELISA competition test with the six monoclonal antibodies. First, the competition curves for 23A5 mAb showed that the RH24K−MAMVE.hy bioconjugate competed much more efficiently than the RH24K−MAMVE counterpart (Figure 4A). This indicated that, in the context of a less reactive polymer, the 23A5 corresponding epitope was efficiently recognized and accessible onto the bioconjugate, in a similar way to that obtained for the RH24K−K158A−MAMVE and RK24H−MAMVE bioconjugates. These three different situations are likely to avoid the involvement of lysine 158 in the coupling reaction. It was also found that 1G5, 1B2, 3D8, and 13B5 mAbs behaved similarly, independently of the hydrolysis or nonhydrolysis status of the copolymer, as illustrated by 3D8 mAb in Figure 4A. Finally, the 15F8 mAb presented an opposing situation to the 23A5 mAb, the less competitive bioconjugate being the RH24K−MAMVE.hy, from 1 μg/mL bioconjugate concentrations (Figure 4A). In addition, independently of the C-terminal or N-terminal position of the Lys6 tag on the protein, the 15F8 corresponding epitope was less efficiently recognized following immobilization of the protein onto the partially hydrolyzed copolymer than on the nonhydrolyzed form, again from 1 μg/mL bioconjugate concentrations (data not shown). To understand why the epitope accessibility of the 15F8 mAb was lowered after grafting onto partially hydrolyzed copolymer, we compared the reactivity of 23A5, 3D8, and 15F8 mAbs in an ELISA competition assay using the unbound RH24 protein as a competitor. Classical competition curves were obtained for 23A5 and 3D8 mAbs, although they illustrated different efficiencies, probably due to different affinities, 4.1×10^8 M^{-1} and 3.6×10^9 M^{-1}, respectively (Figure 4B). Conversely, an inverted bell shape curve was obtained with 15F8 antibody which had an affinity similar to the 23A5 antibody (2.9×10^8 M^{-1}). Antigen concentrations from 1 μg/mL induced, intriguingly, a signal increase (Figure 4B). Overall, this strongly suggested that the 15F8 mAb recognized an epitope which was more efficiently displayed on the RH24K−MAMVE bioconjugate, probably as a result from several points of attachment of the protein on to the nonhydrolyzed polymer. This is in agreement with previous observations showing that a modification of the lysine residues of a recombinant p24 protein by a maleic anhydride monomer increased the affinity of a murine mAb (*15*) that recognized an epitope sharing eight residues with 15F8 mAb related epitope. Conversely, this epitope would be partially hidden either on bioconjugate defined by a tag-restricted attachment (hydrolyzed polymers) or at high concentration of noncoupled protein. These features correspond to a cryptic epitope. Indeed, (i) the 15F8 mAb was obtained by immunization with viral lysate, (ii) it recognized an epitope located within a pocket formed by the dimerization of two p24 N-terminal domains (*19*), (iii) the N-terminal composition of all p24 recombinant proteins is altered in comparison with the native p24 form, which may affect both N-terminal domain structure and self-association properties (*12*, *19*, *20*), and finally (iv) the p24 surface plasticity allows N−N and N−C intermolecular interfaces (*9*, *13*, *14*, *19*).

Identification of the Lysines Involved in the Coupling Reaction. The main results from the antigenic analysis were (i) that depending on the position of the polylysine tag, intrinsic lysines could react with

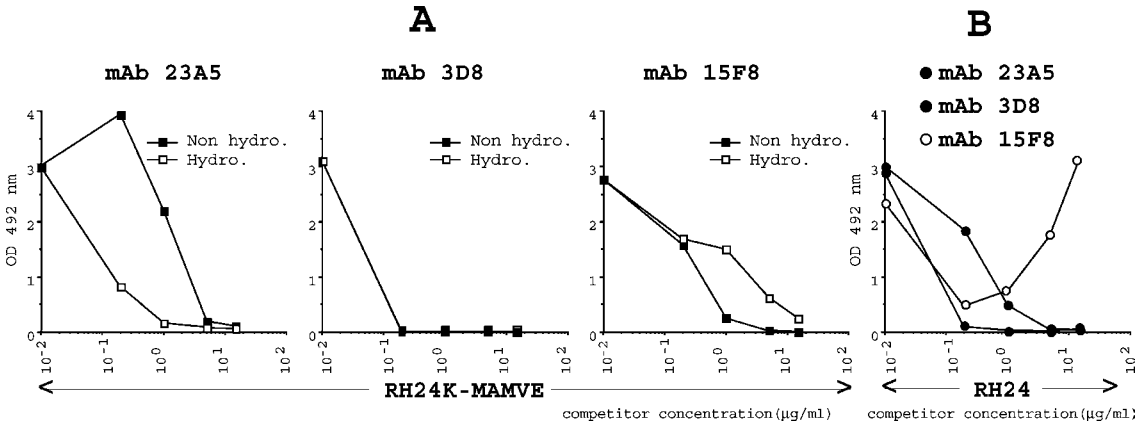

Figure 4. Influence of the hydrolysis of the polymer on epitope accessibility on the bioconjugate. (A) Competitive ELISA curves representing OD as a function of the bioconjugate concentration were obtained for the mAbs used at an optimal concentration. The two bioconjugates consisted of C-terminal Lys6-tagged recombinant protein RH24K, grafted onto nonhydrolyzed (■) or hydrolyzed (□) MAMVE copolymer. Hydrolysis of the polymer improved inhibition efficiency for the 23A5 mAb, had no effect for the 3D8 mAb (and 1G5, 1B2, and 13B5 mAbs, see text), and reduced inhibition efficiency for the 15F8 mAb. (B) Competitive ELISA curves representing OD as a function of the RH24 concentration were obtained for all mAbs. Classical inhibition curves were observed for 23A5 (●), 3D8 (●) (and 1G5, 1B2, and 13B5 mAbs), and an inverted bell shape curve was obtained for 15F8 (○) mAb.

Table 1. Quantitation of Free Amino Groups of the Unbound and Polymer-Bound Recombinant Proteins[a]

	RH24K		RH24-K158A		RK24H	
tested product[b]	$OD_{477\,nm}$	modification[c]	OD_{477nm}	modification[c]	OD_{477nm}	modification[c]
unbound proteins	747		806		863	
proteins grafted onto MAMVE	369	50.6	475	41.1	609	29.5
proteins grafted onto hydrolyzed MAMVE	593	20.6	713	11.5	750	13

[a] The presence of free amino groups was measured by detecting fluorescent products generated by the chemical reaction of fluorescamine with primary amines of the tested product (OD_{477nm}). [b] Tested product consisted of unbound proteins (RH24K, RH24K-K158A, RK24H) or proteins grafted onto nonhydrolyzed or partially hydrolyzed MAMVE copolymers. [c] The percentage of modification of the bound protein is defined as 100 − (fluorescence of bound protein × 100/fluorescence of unbound protein).

anhydride groups of MAMVE and (ii) that this involvement of internal lysines could be impeached by a decrease in the density of reactive groups of MAMVE via a controlled hydrolysis. To strengthen these conclusions, two additional methods were used to perform both quantitative and qualitative analyses.

A rough estimate of the number of lysines participating in the reaction was indirectly evaluated using fluorescamine, a compound which reacts specifically with primary amines to produce fluorescent products. Amine titers of three free p24-derived recombinant proteins and of their corresponding polymer bioconjugates were compared, and the percentages of protein modification were calculated (Table 1). The mean modification ratio of nonhydrolyzed polymer-based bioconjugates (40.4 ± 10.6) was 2.3 to 3.6 times higher than that obtained with the partially hydrolyzed ones (15.0 ± 4.9). Thus, irrespective of the recombinant protein tested, these results confirmed that the reduction of the amount of reactive groups onto the polymer reduced alterations of the grafted protein, as a consequence of a lowered involvement of intrinsic lysines in the grafting process. Nevertheless, the higher modification ratio in RH24K−MAMVE conjugates as compared to RK24H−MAMVE ones suggested that the C-terminal position of the tag might favor the involvement of intrinsic lysines, as confirmed by the RH24K−K158A mutant (Table 1).

To identify lysine residues which were involved in the coupling reaction and the direct incidence of the polymer partial hydrolysis on avoiding internal lysine reaction, we performed a comparative enzymatic digestion of the unbound C-terminally tagged RH24K protein and of the nonhydrolyzed and hydrolyzed polymer-based bioconjugates. Two different proteolytic enzymes were used, and the generated fragments were analyzed by MALDI-TOF mass spectrometry.

The three substrates were digested by *Staphylococcus aureus* protease V8, which cleaved on the C-terminal side of glutamic and aspartic acids residues in order to produce fragments containing lysines, and endoproteinase Lys-C which cleaved on the C-terminal side of lysines in order to directly check the involvement of an intrinsic lysine in the coupling reaction. Mass spectrometry analysis of peptides from protease V8 digestion of RH24K, RH24K−MAMVE, and RH24K−MAMVE-hydrolyzed allowed identification of three out of eight fragments with specific features (Table 2). First, the isolation of a 2363.2 kDa fragment, obtained exclusively after digestion of the free RH24K protein and identified as the tag-containing C-terminal portion of the protein, confirmed the direct involvement of the hexalysine tag in the grafting reaction. Second, the 1758.8 kDa fragment, absent exclusively from the RH24K−MAMVE bioconjugate and identified as the N-terminal part of the protein, suggested that the N-terminal amino group was involved in the coupling reaction onto a nonhydrolyzed polymer, but that such an involvement was avoided by partial hydrolysis of the polymer. Third, the detection of a 3291.7 kDa fragment, obtained after digestion of RH24K and RH24K−MAMVE-hydrolyzed but not RH24K−MAMVE and corresponding to the S1-E29 region, showed that the primary amino group of internal lysine 25 was involved in the grafting reaction onto the nonhydrolyzed polymer. This parasitic coupling could be avoided by partial hydrolysis of the polymer, as described above.

Mass spectrometry analysis of peptides from endoproteinase Lys-C digestion of all three substrates was indeed more informative concerning the involvement of

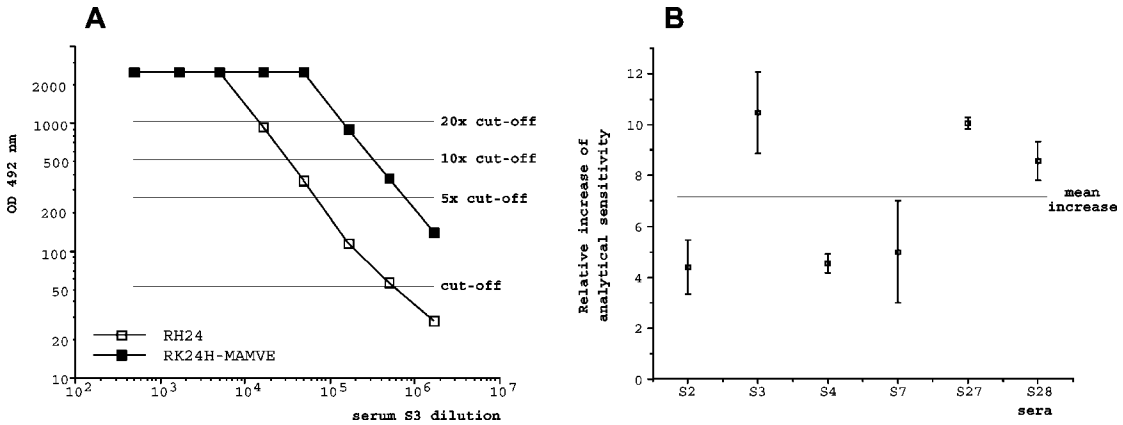

Figure 5. Relative analytical sensitivity of protein−polymer bioconjugate. (A) RH24 (□) or RK24H−MAMVE (■) antigens were coated onto microtiter plates (1 μg/mL), and anti-p24 antibodies were detected in direct ELISA, using serial dilutions of serum from one HIV-1 seropositive patient ranging from 1/500 to 1/1 665 000. OD as a function of the serum dilution is plotted. The cutoff value (mean + three standard deviations) was determined with pooled OD obtained from three control sera, from HIV-1 seronegative individuals, tested in the same conditions as in the HIV-1 assay. OD values corresponding to 5×, 10×, and 20× the cutoff value are indicated. (B) The relative increase in sensitivity was calculated for six HIV-1 positive sera tested as indicated above. For each serum, the indicated data corresponded to the mean ± two standard deviations of the increase calculated at 5×, 10×, and 20× the cutoff value. The overall mean increase is indicated by a horizontal lane.

several internal lysine residues in the coupling reaction onto nonhydrolyzed polymer (Table 2). Six clearly identified peptide fragments were generated after digestion of the RH24K protein. Five peptides were not detected after digestion of the bioconjugate based on a nonhydrolyzed polymer. This suggested an involvement of lysines 70 (N-terminal domain), 140 (flexible inter domain peptide), 158, 170, and 199 (C-terminal domain) in the formation of amide bonds with the copolymer. These results were in agreement with the antibody binding analysis showing the involvement of lysine158 (23A5 mAb analyses) and suggested the multipoint attachment process (15F8 mAb analyses) in grafting conditions with nonhydrolyzed polymer. Conversely, peptide T171-K182 was also observed after digestion of the bioconjugate based on a nonhydrolyzed polymer. It contained lysine K182 which according to the 3D structure (SwissPdbViewer v3.6) was poorly accessible and hence did not contribute to the grafting reaction. Finally, the six peptides obtained with the unbound protein were all identified after digestion of the RH24K−MAMVE-hydrolyzed bioconjugate, confirming the partial hydrolysis as a powerfull process to avoid the side-on grafting by intrinsic lysines.

CONCLUSION

We had previously demonstrated that the introduction of a six-lysine tag into a recombinant protein drastically improved the immobilization of the protein onto a copolymer, with the nature of the buffer and the nature, size, and reactivity of the polymer being minor parameters with respect to the control of the covalent immobilization (*5*, *7*). The present work demonstrated that the two main parameters involved in the conservation of the biological activity of the immobilized protein were the tag position and the number of reactive groups on the copolymer. This demonstration was achieved using bioconjugates derived from coupling of RK24H or RH24K, two recombinant proteins containing a N- or C-terminal six-lysine tag characterized by positive charges and primary amines, onto MAMVE, a copolymer bearing negative charges and anhydride moieties.

The alteration of the recognition by a specific monoclonal antibody of a bioconjugate consisting of a C-terminal Lys6-tagged p24 protein grafted onto MAMVE reflected a loss of accessibility of the corresponding epitope. The local protein conformational alteration was due to the involvement, in the grafting reaction, of an internal lysine with a spatial location close to the tag.

Such an alteration could be avoided by reducing the reactivity of the polymer, a parameter controlled by the partial hydrolysis of the anhydride moieties. These observations were confirmed by another molecular recognition process, i.e., the site specific digestion of the bioconjugates by protease V8 and endoproteinase Lys-C followed by mass spectrometry analysis. This technique highlighted the close relationships between the tag position, the position and accessibility of internal lysines, and the density of reactive anhydride groups of the copolymer.

So we have developed a process to engineer bioconjugates by using judiciously tagged recombinant proteins and polymers with a modulated reactivity. The interest of this methodology was illustrated by the using of RK24H grafted onto hydrolyzed MAMVE as a capture antigen in an ELISA test format. Serial dilutions (up to 2×10^6) of sera from six HIV-1 seropositive patients were used as sources of antibodies to compare the immunoreactivity of RK24H−MAMVE with the RH24 antigen classically used in immunoassay (*21*). A significant signal increase was observed with the bioconjugate as compared to the standard assay using RH24 (Figure 5). More precisely, the mean increase of analytical sensitivity was 7.2 ± 2.7, the minimal and maximal increase being 3.9 and 11.4, respectively. The evaluation of this bioconjugate with a panel of sera from 107 HIV-1 seropositive individuals at various stages of HIV infection, including two seroconversion panels, confirmed that such a protein−copolymer bioconjugate allowed the detection of antibody titers lower than the adsorbed protein (*6*).

Thus, based on this antigen(s)/antibody(s) model illustrating the local modifications due to the immobilization process and how to control/avoid them, we propose a versatile technology of oriented covalent immobilization of biologically active recombinant protein onto MAMVE polymer. The isolation of biologically active bioconjugates would be based on three main parameters consisting of introducing a tag of a defined composition (six lysines), in a predefined position (N- or C-terminal) with respect to the predicted or determined protein active site(s) and/or the intrinsic lysine content and/or accessibility, and using hydrolysis to control the density of reactive groups onto the polymer if the protein functional requirements imposed the tag position. To validate this concept with other proteins such as antigens, enzymes, or cell-binding ligands, a set of expression vectors was developed (*6*). More generally, it will be of interest to evaluate if the physicochemical parameters identified as critical in this protein−polymer system (refs 5−7, this study) would lead to a generic process of immobilization onto other negatively charged supports compatible with amide bond formation.

ACKNOWLEDGMENT

The authors are grateful to François Penin and Christophe Geourjon for helpful discussions, and Jennifer Burgess et Saint John Skilton for critical reading of the manuscript. We would like to thank Marcelle Sauzon for mass spectrometry analysis. L.A. is thankful to Fondation Mérieux for financial support.

Cross-Linked Microparticles as Carriers for the Delivery of Plasmid DNA for Vaccine Development

Sarah L. Goh, Niren Murthy, Mingcheng Xu, and Jean M. J. Fréchet*

Center for New Directions in Organic Synthesis, University of California, Department of Chemistry, Berkeley, California 94720-1460, and E. O. Lawrence Berkeley National Laboratory, Division of Materials Science, Berkeley, California 94720. Received September 8, 2003; Revised Manuscript Received February 26, 2004

Plasmid DNA was directly encapsulated into biocompatible polymer microparticles via radical polymerization in an inverse emulsion system. Acrylamide-based microspheres 0.2−1 μm in diameter were prepared using an acid-cleavable difunctional monomer. Retention of the DNA payload at physiological pH with complete release under acidic conditions at lysosomal pH was demonstrated. By trapping the plasmid DNA within the cross-linked microparticle, enzymatic degradation was prevented when exposed to serum nucleases. For vaccine development, these delivery vehicles were also investigated for their ability to generate immune responses when delivered to phagocytic cells of the immune system. Encapsulated plasmid DNA demonstrated immunostimulatory activity in macrophages, leading to cytokine secretion of IL-6 with a response ~40-fold higher than that achieved with DNA alone.

INTRODUCTION

Recent advances in polymeric drug delivery have focused on the encapsulation of biomolecules, such as protein, peptide, and DNA antigens, in microgel and hydrogel systems (*1*−*3*). DNA is a promising therapeutic for use in gene therapy applications (*4*) but may also be applicable as a coadjuvant for protein-based vaccines to stimulate the immune system (*5*, *6*). It is well-known that bacterial DNA is recognized by vertebrate immune systems as foreign and elicits a response, such as the release of cytokines or antimicrobial agents (*7*−*10*). Characteristics of bacterial DNA responsible for this activity are the higher frequency of CpG dinucleotides within the sequence as compared to vertebrate DNA, as well as the presence of unmethylated cytosine bases (*11*, *12*). Both plasmid DNA and short oligonucleotides have been shown to elicit an immune response in vertebrate systems (*12*−*15*); the incorporation of unmethylated bases is accomplished for oligonucleotides using the standard cytosine monomer during solid-phase chemistry, and for plasmid DNA through bacterial transformation. The sequence of these antigens can be selected to either provoke or prevent an immune response as desired (*14*−*17*). Delivery of immunostimulatory DNA results in the release of inflammatory triggers such as IL-6, IL-12, TNF-α, and IFN-γ. These cytokines are crucial in the maturation and activation of T cells and dendritic cells (*18*).

Encapsulation of plasmid DNA provides protection from nuclease degradation in the serum and can aid in directing its delivery to target cells, phagocytes. Current delivery vehicles for DNA-based therapeutics include cationic liposomes, lipoplexes, and polymer complexes (*19*−*31*). Many of these systems require the use of cationic polymers to entrap plasmid DNA via an electrostatic interaction with the negatively charged backbone, in addition to a neutral component to mitigate the toxicity effects. However, by using a cross-linked microparticle, we are able to encapsulate plasmids physically, rather than electrostatically, and without the use of polycations, which also allows this delivery system to be compatible with biomolecules of other charged states such as proteins. Previously, much attention has been focused on biodegradable systems, such as poly(lactic-*co*-glycolic acid), which release DNA via hydrolysis of the polymer chains (*32*−*37*). The ester backbone of these microparticles readily degrades under basic conditions and much more slowly under physiological pH. As the particles circulate throughout the body, a slow release of the encapsulated payload is observed. In contrast, we chose to design a polymer-based system that would exhibit minimal degradation in the serum at pH 7.4 until the particles encounter an acidic environment. Once internalized in lysosomal compartments of the desired cell type, the particles would rapidly degrade and deliver the encapsulated antigen.

Taking advantage of the pH differential between serum (pH 7.4) and the lysosome (pH 5.0), we have recently developed a new strategy for the delivery of protein-based vaccines using an acid-degradable microbead (*38*, *39*). Given their size of roughly 500 nm in diameter, the cross-linked microparticles should not be readily taken up by most cells. Instead, phagocytic cells such as macrophages and dendritic cells, which play a key role in the activation and maturation of the immune system, selectively ingest the microparticles, delivering the particle and its encapsulated payload to a lysosomal compartment within the cell. Cross-linked with a pH sensitive linker, the polymer microbead degrades in the acidic environment, resulting in an increase in osmotic pressure within the compartment and leading to lysosomal disruption, thus providing cytoplasmic delivery of the encapsulated biomolecule intact. Protein delivery using this microbead system has been successful at demonstrating class I antigen presentation with macrophages through the activation of cytotoxic T cells, a necessary step in vaccine development.

Therefore, it would be beneficial to combine the T cell activation ability of immunostimulatory DNA with these protein microparticles to further enhance the effectiveness of protein vaccines. Here, we extend the versatility of our acid-sensitive polymer microparticle by investigating the encapsulation and release of plasmid DNA in macrophages and examining the immunostimulatory effects as a next step in microparticle vaccine strategies.

MATERIALS AND METHODS

Reagents and Materials. β-Galactosidase reporter plasmid (*p*SV-β-gal vector, Promega, Madison, WI) was amplified by bacterial transformation with DH5α (Invitrogen, Carlsbad, CA) competent cells in Luria broth (Sigma, St. Louis, MO) and purified using a Qiagen Mega kit (Qiagen, Valencia, CA). Double-stranded DNA quantification assays were performed using PicoGreen (Molecular Probes, Eugene, OR). Absorbance and fluorescence readings were taken on a SPECTRAmax 190 and a SPECTRAmax Gemini XS, respectively, microplate reader (Molecular Devices, Sunnyvale, CA). Macrophage cell lines RAW 309.1CR and RAW 264.7 and 293T kidney cells (ATCC, Manassas, VA) were prepared by the University of California Tissue Culture/Media Facility by plating at the density indicated and then incubating overnight at 37 °C and 5% CO_2 before use.

Polyacrylamide Microparticle Synthesis. Microparticles were prepared by inverse microemulsion polymerization using a modification of a previously published procedure (*38*). β-Galactosidase reporter plasmid was dissolved in 400 μL of 300 mM sodium phosphate buffer pH 7.4 along with acrylamide (100 mg, 1.4 mmol), an acid labile cross-linker *N*,*N*′-bisacryloylbis(2-aminoethoxy)-[4-(1,4,7,10-tetraoxaundecyl)phenyl]methane (*38*) (**2**) (25 mg, 0.052 mmol, 3.6 mol %), and potassium persulfate (6 mg, 0.022 mmol) as the initiator. The organic phase consisted of 4 mL of hexane containing 120 mg of a 3:1 weight ratio of Span 80 (sorbitan monooleate) and Tween 80 (poly(ethylene glycol)−sorbitan monooleate). The emulsion was prepared by sonicating the two phases for 30 s using a Branson Sonifier 450 with an output setting of 2 and a duty cycle of 40%. Polymerization initiated by the addition of 25 μL of *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA) to the stirred mixture was continued for 10 min at room temperature before recovering the microparticles by centrifugation. The particles were washed twice with hexane to remove residual surfactant and then with acetone and finally dried under vacuum overnight. The particles were analyzed by scanning electron microscopy using a WDX ISI-ds130C instrument (Microspec Corporation, Inc.) at 15 kV.

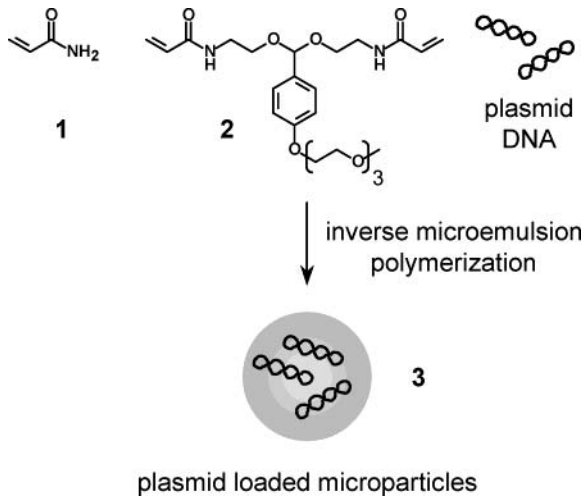
Nondegradable beads encapsulating plasmid DNA were prepared in similar fashion, using the same wt % of cross-linker. For this set of microparticles, the aqueous phase consisted of acrylamide (100 mg, 1.4 mmol), *N*,*N*′-methylenebisacrylamide (25 mg, 0.162 mmol), and 0.50 mg of the β-galactosidase reporter plasmid in 400 μL of 300 mM sodium phosphate buffer pH 7.4 along with initiating species.

Determination of Plasmid DNA Loading. The plasmid DNA-loaded particles were washed by dispersing the particles in 300 mM sodium phosphate buffer at pH 7.4 at a concentration of 5 mg/mL using a series of sonication and vortex steps. The particles were collected as a pellet by centrifuging for 10 min. The wash supernatant was removed by pipet, and an equivalent volume of acidic buffer (pH 5.0, 300 mM acetic acid) was added to maintain the concentration. The sample was then heated overnight at 37 °C, and the hydrolyzed solution was analyzed for the concentration of double-stranded DNA using PicoGreen. All loadings were determined in triplicate.

pH Dependent Release. Plasmid-loaded microparticles were washed with 300 mM sodium phosphate pH 7.4, as described above, at a concentration of 5 mg/mL. The wash supernatant was removed, and either sodium phosphate buffer, pH 7.4, or acetic acid buffer, pH 5.0, was added, and the particle solutions were incubated at 37 °C. After the desired time point, the beads were collected by centrifugation and the supernatant removed. Any remaining particles were hydrolyzed at 37 °C overnight in acidic buffer, and both the supernatants and the hydrolyzed solutions were analyzed for the concentration of double-stranded DNA. All samples were performed in triplicate. The percent release was defined as the ratio of the concentration of DNA in the hydrolyzed solution compared to that found in both the hydrolyzed and supernatant solutions.

Microparticle Toxicity. RAW 309.1CR macrophages were plated at a cell density of 5×10^4/well in a 96-well format. Microparticles with DNA loadings of 0 (empty beads), 0.88, 2.14, and 4.29 μg plasmid DNA/mg bead were suspended in Dubelcco's Modified Eagle Medium (DMEM) at a concentration of 10 mg/mL. An aliquot of the bead solution was added to the cells, along with DMEM containing 10% fetal bovine serum (FBS) to give a final volume of 100 μL with an overall concentration of 5% FBS and 0.5 to 5 mg of beads/mL. After being incubated overnight at 37 °C and 5% CO_2, the supernatant was aspirated, and the cells were washed three times with DMEM to removed any remaining beads from the wells. To each well, 100 μL of DMEM + 10% FBS was added, and the cells were incubated for an additional 24 h. Toxicity was measured using the MTT assay (*40*); briefly, the supernatant was aspirated, and 100 μL of DMEM + 10% FBS along with 20 μL of a 5 mg/mL solution of MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-2*H*-tetrazolium bromide) in medium were added to each well. The cells were incubated for 4 h at 37 °C and 5% CO_2, after which time the supernatant was removed, and the MTT crystals were dissolved in 200 μL of dimethyl sulfoxide (DMSO). The purple solutions (10 μL) were further diluted with 190 μL of DMSO and 25 μL of a glycine buffer (0.1 M glycine, 0.1 M NaCl, pH 10.5). The concentration of MTT was determined by measuring the UV absorbance at 570 nm.

Nuclease Stability of Encapsulated Plasmid. Microparticles with a loading of 2.14 μg DNA/mg bead were suspended in DMEM + 10% FBS to give a final concentration of 5 mg of beads/mL. The solutions were incubated at 37 °C for the desired time (0, 0.5, 1, and 2 h), and then the microparticles were collected by centrifugation. The supernatant was decanted, and the pelleted beads were washed with 300 mM sodium phosphate buffer pH 7.4 to remove the color from residual medium, as well as any fragmented DNA. Finally, the microparticles were incubated overnight at 37 °C in 300 mM acetic acid buffer pH 5.0 to fully release any remaining plasmid DNA. The stability for a given time point was calculated as the concentration of double-stranded DNA in the hydrolyzed beads compared to the concentration determined at 0 h. DNA released from the exposed beads was analyzed by agarose gel electrophoresis.



Fluorescence Microscopy. Microscopy studies were performed with both degradable and nondegradable, dextran-encapsulated microparticles. For degradable

beads, fluorescein-labeled dextran (5 mg, FITC-dextran, MW 70 kDa, Molecular Probes) was encapsulated using the inverse emulsion polymerization procedure described above using the acid sensitive cross-linker, *N*,*N*′-bisacryloylbis(2-aminoethoxy)-[4-(1,4,7,10-tetraoxaundecyl)phenyl]-methane (*38*). FITC-dextran microparticles were also prepared using 25 mg of *N*,*N*′-methylenebisacrylamide, a nondegradable cross-linker. Scanning electron micrographs of both samples showed spherical beads of similar size to the DNA-loaded microparticles. RAW 264.7 cells were prepared in a 24 well plate with cover slips at a density of 3×10^5 cells/well. The beads were suspended in DMEM + 10% FBS (5 mg/mL), and the solution delivered to the cells with additional medium to give a final volume of 1 mL and a final concentration of 0.25 mg beads/mL. After incubation overnight, the supernatant was aspirated, and the cells were washed five times with DMEM. DMEM + 10% FBS (1 mL) was then added to the cells, and they were allowed to grow for another 24 h. The cells were washed five times with phosphate-buffered saline (PBS, Gibco) and fixed to the cover slips by the addition of 1 mL per well of a paraformaldehyde solution. The cells were incubated for 10 min at room temperature and then washed twice with PBS. To prepare the paraformaldehyde solution, 1.5 g of paraformaldehyde was dissolved in 20 mL of H_2O and 20 μL of 10 M NaOH that was previously equilibrated to 56 °C. The solution was cooled to room temperature, and 25 mL of H_2O and 5 mL of 3 M sodium phosphate were added. The resulting solution was brought up to pH 10.5 using 10 M NaOH, sterilized by passing it through a 0.22 μm filter, and stored at 4 °C until needed. Micrographs were taken with a Nikon Eclipse TE300 inverted microscope, equipped with a Nikon Plan Fluor 40×/0.60 objective and the appropriate excitation/emission filters (494 nm/519 nm).

Transfection Studies. Plasmid-encapsulated beads (60 mg) were hydrolyzed by incubating them overnight in 3 mL of 300 mM acetic acid pH 5.0. The resulting plasmid was recovered by first passing the hydrolyzed solution through a Nap-25 column (Amersham, Piscataway, NJ) that had been equilibrated with water. Fractions displaying a UV absorbance at 260 nm were reduced in volume and then isolated again using a Qiagen Tip-20. 293T kidney cells were plated at a density of 6×10^4 cells/well in a 24-well plate. To each well, 500 μL of DMEM + 10% FBS was delivered along with 100 μL of a solution containing either original or isolated plasmid DNA (0.25 or 0.5 μg total) in OPTI-MEM (Gibco), in which the DNA had been complexed with 5 μg of Lipofectamine 2000 (Invitrogen) for 15 min. Control wells contained either medium alone or DNA without transfection agent. The cells were incubated overnight at 37 °C and 5% CO_2. The cells were aspirated, and 400 μL of Z buffer (*41*) was delivered to each well and incubated for an additional 6 h. The supernatant was transferred to a 96-well plate, and β-galactosidase activity was determined by monitoring the UV absorbance of the hydrolyzed phenolate at 570 nm. The Z buffer was made according to literature (*41*): 100 μM 2-mercaptoethanol, 9 mM $MgCl_2$, 0.125% NP-40 (Sigma), and 0.15 mM sodium chlorophenol red β-galactopyrandoside (CPRG, CalBioChem, San Diego, CA) in PBS.

IL-6 ELISA. A 96-well plate of RAW 264.7 macrophages at a density of 2×10^4 cells/well was incubated overnight with 100 μL of a 5 mg/mL solution of microparticles in DMEM + 10% FBS. Microparticles with DNA loadings of 0 (empty beads), 0.88, 2.14, 4.29 μg plasmid DNA/mg bead made with degradable and nondegradable cross-linkers were analyzed. Control wells consisted of untreated cells and cells with plasmid DNA alone. The media was diluted 5-fold and analyzed using an IL-6 ELISA kit (Pierce, Rockford, IL). Absorbance values were measured at $\lambda = 450$ nm and corrected using $\lambda = 550$ nm as a background reference. IL-6 concentrations were calculated using a standard curve.

Scheme 1. Synthesis of Plasmid-Loaded Microparticles

RESULTS AND DISCUSSION

Synthesis of Polyacrylamide Microparticles. Microparticles prepared using inverse microemulsion polymerization (*42*, *43*) were successfully loaded with plasmid DNA. The β-galactosidase reporter plasmid (pSV-β-gal, Promega, 6820 bp) was dissolved in aqueous buffer along with acrylamide **1** and 3.6 mol % of a bisacrylamide acetal cross-linker **2** (Scheme 1). This cross-linker was previously shown to be readily incorporated with acrylamide under free radical polymerization conditions to produce protein-loaded microparticles (*38*). The aqueous phase was dispersed in hexane containing 3% (w/v) surfactants (Span 80/Tween 80) using sonication. These neutral surfactants do not coordinate the phosphate backbone of DNA, as would ionic surfactants, thus resulting in disruption of the inverse emulsion. The radical polymerization was initiated using potassium persulfate and TMEDA, effectively trapping the plasmid inside the cross-linked beads, **3**. Following the synthesis, plasmid-loaded particles **3** were washed with excess solvent and dried under vacuum, with yields ranging from 50 to 85%. While these polymerization conditions were mild enough for protein encapsulation as shown previously, further analyses were performed to validate the stability and integrity of the encapsulated plasmid DNA.

The isolated microbeads were analyzed in the dry state using scanning electron microscopy (Figure 1). Ranging from 0.2 to 1 μm in diameter, plasmid-loaded microparticles displayed similar surface characteristics to beads that contained no DNA. This size is appropriate for targeting delivery to macrophages, which readily ingest particles of 0.5−1 μm (*44*).

Microparticle Loadings and DNA Integrity. The concentration of plasmid DNA in the microparticles was determined by first washing the microparticles in 300 mM sodium phosphate at pH 7.4. A small amount of plasmid DNA is detected in this washing step, corresponding to the removal of DNA that is physisorbed to the surface of the microparticle. The sample was then heated overnight at 37 °C in an acidic buffer to fully

8.0	4.29 ± 0.17	54

hydrolyze the acetal cross-links, releasing linear polyacrylamide chains, a tri(ethylene glycol)-functionalized benzaldehyde, and plasmid. The concentration of double-stranded DNA in the acidic buffer was determined using PicoGreen (Table 1).

An initial loading of 2.0 μg/mg of plasmid DNA on a 125 mg scale was used in the synthesis of the acid-degradable microparticles. After the beads were washed and isolated, a loading of 0.88 μg of DNA/mg of polymer was determined, giving an encapsulation efficiency of 44%. Increasing the concentration of plasmid in the polymerization mixture to 4.0 and 8.0 μg/mg produced higher DNA loadings within the resulting microparticles. While the encapsulation efficiency remained fairly constant, the amount of DNA found encapsulated in the particles roughly doubled for each 2-fold increase in the initial concentration, with the largest loading being slightly higher than those reported with PLGA particles of comparable size (*36*, *37*).

Having successfully encapsulated plasmid DNA in microparticles, we next sought to verify that the structure of the released DNA remained intact. Should the DNA be degraded into smaller fragments during the course of the polymerization procedure, the fragments could diffuse out of the microparticle prior to phagocytosis and hydrolysis. Also of interest is preserving the tertiary structure of the plasmid. Possible detrimental conditions prevailing during the microparticle polymerization and subsequent acidic degradation include sonication to form the emulsion, reactions involving free radicals, and the use of a treatment at pH 5.0, 37 °C, for 18 h. In other microparticle formulations, plasmid DNA has been shown to be sheared during sonication in addition to being susceptible to cleavage and degradation during homogenization or drying steps (*37*, *45*, *46*). Therefore, DNA recovered from our polyacrylamide microparticles after acidic cleavage of the acetal cross-linkers was analyzed by agarose gel electrophoresis to investigate its integrity (Figure 2). The original plasmid DNA, prepared by bacterial transformation, is shown in lane 2; the upper band corresponds to the open circular form of isolated plasmid DNA and the lower to the supercoiled structure, as it is more compact and therefore migrates faster through the agarose gel. After the polymerization and hydrolysis steps, the plasmid DNA is composed mostly

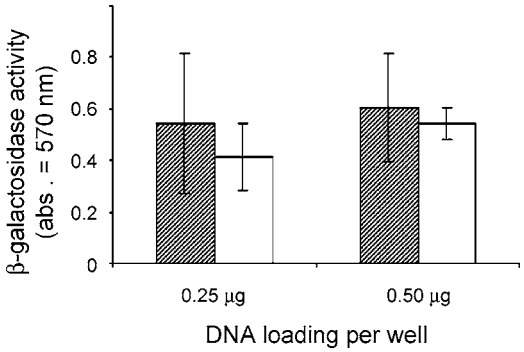

Figure 3. Transfection of 293T Cells. β-Galactosidase activity was measured as the absorbance of hydrolyzed CPRG for control (shaded) and recovered DNA (open), complexed with Lipofectamine 2000.

of the open circular form, with some linear and supercoiled structures as also seen in lane 3. A double restriction digest of each of these samples yielded identical linear fragments, another indication that the double-stranded DNA remained unchanged during the polymerization procedure and that only the tertiary structure is affected by the processing conditions. While the tertiary structure of plasmid DNA has not been studied with respect to its immunostimulatory efficiency, it has been shown that open circular and supercoiled DNA have roughly equivalent transfection capabilities (*47*, *48*).

To verify the activity of the plasmid DNA, the transfection ability of the recovered plasmid was evaluated using 293T kidney cells. Control DNA, as well as plasmid recovered from hydrolyzed microparticles, was complexed with Lipofectamine 2000, a commercially available transfection agent. From the agarose gel analysis described above, the isolated plasmid is mostly in the open circular form, whereas the original sample of DNA is mostly supercoiled (Figure 2). Both of these structures are capable of undergoing transcription in cells, but not, however, the linear species that are present in the recovered plasmid (*47*, *48*). Figure 3 depicts the transfection results of the DNA complexes with 293T kidney cells. Untreated cells or wells with DNA alone showed no β-galactosidase activity. For DNA−Lipofectamine assemblies, there is a minor decrease in the transfection ability of the isolated plasmid compared to the original DNA vector, most likely due to the presence of a small amount of linear plasmid in the isolated DNA sample. Encapsulated DNA is capable of transfection, as only the tertiary structure of the plasmid is altered by the polymerization and hydrolysis procedures. The inverse

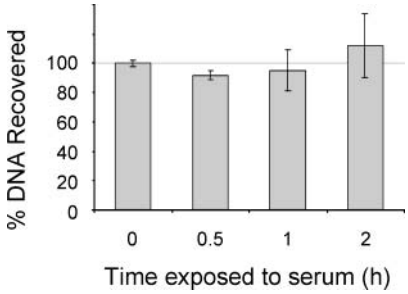

Figure 4. Nuclease stability of plasmid-encapsulated microparticles.

microemulsion polymerization technique described herein is compatible with both DNA and proteins (*38*), making possible future studies in vaccine delivery involving the encapsulation of biomolecules that vary by function (specific T cell activation, immunostimulation, or antisense) and classification (protein, DNA, or RNA).

Nuclease Stability of Encapsulated Plasmid. Stability of the microparticles at pH 7.4 is also important as the polymer scaffold functions to protect the encapsulated plasmid. Within 5 min of exposure to serum nucleases, plasmid DNA begins to break down rapidly and is completely degraded within 1 h (*49*); at pH 7.4, however, the DNA does not diffuse out of the microparticle as demonstrated in the release experiments. The pores of the microparticle are small enough to keep the plasmid DNA encapsulated until the delivery vehicle reaches the acidic environment of the phagolysosome. The serum stability of the plasmid microparticles was investigated to determine whether nucleases could enter the microparticle and degrade the DNA. To demonstrate that the microparticles actually protect the encapsulated DNA, the beads were exposed to serum nucleases by combining them with Dubelcco's modified Eagle medium containing 10% fetal bovine serum at 37 °C (Figure 4). The amount of DNA remaining in the beads was analyzed. Any degradation of the plasmid by the nucleases present in this medium would result in small, linear fragments. Since short DNA sequences cannot be retained, they would readily diffuse out of the particles. However, no appreciable decrease in the concentration of double-stranded DNA was observed with the plasmid-encapsulated particles and thus, no degradation of the DNA was observed over a period of 2 h. Additionally, when analyzed by agarose gel electrophoresis, no change was detected for the DNA recovered from microparticles that had been exposed to serum nucleases.

The toxicity of the beads was tested in RAW 309 macrophages. The cells were >65% viable for all samples tested, even at concentrations as high as 5 mg of beads/mL. There were minimal toxicity differences between polymer microparticles and plasmid-loaded particles. While polyacrylamide itself is nontoxic, the effects of the aldehyde byproducts of the degradation have yet to be examined (*50*).

pH Dependent Release of Plasmid Encapsulated Microparticles. The pH dependence of DNA release from the microparticles was evaluated by incubating the microbeads at 37 °C in pH 7.4 sodium phosphate buffer or pH 5.0 acetic acid buffer. After the desired time point, the beads were collected by centrifugation and the supernatant analyzed for DNA (Figure 5). At physiological pH, there was an initial burst release of 10%, indicating that some of the DNA is not fully encapsulated within the beads. Additional incubation at neutral pH showed no further release of DNA since the pores of the

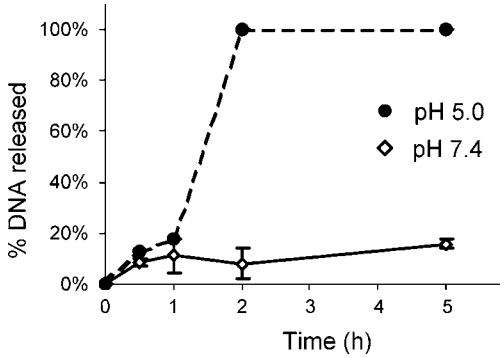

Figure 5. pH dependent release of plasmid DNA from microparticles at 37 °C.

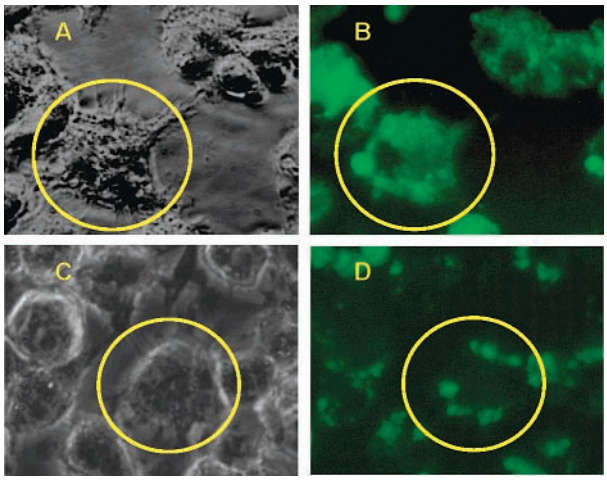

Figure 6. Fluorescence microscopy of macrophages. Phase contrast and fluorescence images of dextran-loaded microparticles with a degradable (A, B, respectively) and a nondegradable (C, D) cross-linker.

cross-linked microparticles are too small to allow for diffusion of the plasmid out of the beads. Presumably then, the microparticles would not release the DNA payload until the microparticle hydrolyzed in an acidic environment.

Under acidic conditions, however, full release of the DNA is achieved within 2 h at pH 5. The hydrolysis kinetics of acetal cross-linkers similar to **2** have been measured previously with a half-life of 24 h at pH 7.4 and only 5 min at pH 5.0 (*39*). The release of plasmid from the microbeads is slower, as would be expected given their incorporation in a cross-linked network.

Fluorescence Microscopy Studies. A key issue with DNA delivery is its distribution within the cellular environment. To examine where the payload is delivered in a macrophage, polyacrylamide microparticles were prepared encapsulating fluorescently (FITC) labeled dextran, MW 70 kDa. Dextran was labeled instead of DNA because fluorescent tags for DNA may dissociate and intercalate into cellular DNA, giving misleading results as to the location of the encapsulated biomolecule. Particles with degradable and nondegradable cross-linkers were prepared and added to RAW 264.7 macrophages. After incubation overnight, the cells were examined by phase contrast mode and with fluorescein excitation (Figure 6). Cells alone showed no autofluorescence. In contrast, cells treated with beads containing the acid sensitive cross-linker showed a diffuse fluorescence in the cytoplasm, (B), indicating that the acid labile linkage degraded in the lysosome and released the fluorescently labeled payload into the cytoplasm with no

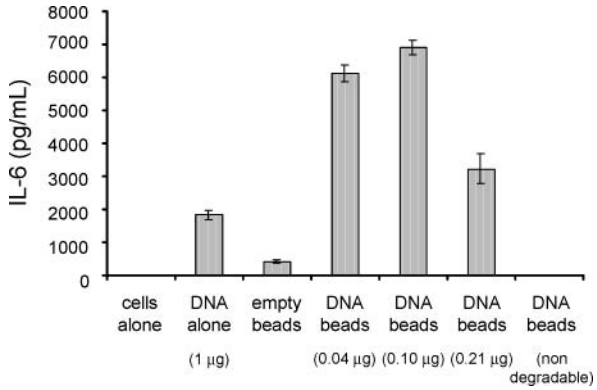

Figure 7. Interleukin-6 ELISA. Below each bar in the graph is the total mount of plasmid DNA added per well.

migration of the FITC-dextran to the nucleus. Nondegradable beads made with *N*,*N*′-methylenebisacrylamide as the cross-linker showed a much more punctate fluorescence (D), indicating that the FITC-dextran remained localized in the lysosome of the cell. The nondegradable beads are readily phagocytosed by the macrophages, but are sequestered in the lysosome as the particles possess no synthetic switch to initiate lysosomal escape.

IL-6 ELISA. Differences between bacterial and vertebrate DNA are recognized by vertebrate immune systems such that bacterial DNA will invoke a general immune response that can be characterized by the secretion of interleukins, radicals, and prostraglandins. The cytosine residues of bacterial DNA are not methylated as they are in vertebrates. In addition, there is a 6-fold increase in the percentage of CG motifs in bacterial DNA, typically ∼1.2% in vertebrate and 6−7% in bacterial plasmids (*15*). The β-galactosidase plasmid sequence used in these studies contains 6.7% of the CpG dinucleotide and therefore should be capable of inducing an immune response in macrophages.

This response is mediated by a Toll-like receptor, TLR9, which is thought to be located within the lysosome or on the cell surface (*51*−*53*). Receptor binding of TLR9 on the cell surface can only be accomplished by DNA that is located on the outside of the particle, as there is negligible release observed at neutral pH in the extracellular environment. However, if the TLR9 is recruited to the lysosome, then an immunostimulatory response should be observed when plasmid encapsulated microparticles are delivered to cells, as it has been discussed above that the DNA will be released when it encounters the acidic environment of the phagolysosome. Upon interaction of the encapsulated plasmid with TLR9, macrophages secrete IL-6 to mediate the growth and differentiation of T cells, a vital component of vaccine treatment.

To examine the immunostimulatory properties of the plasmid-loaded microparticles, RAW 264.7 macrophages were incubated overnight with 1 μg of naked plasmid or 50 μg of plasmid microbeads of various loadings. Nondegradable beads with an initial loading of 2.0 μg/mg of plasmid DNA were also tested. It was not possible to determine the true loading of these microparticles, as they are not capable of acidic degradation so the DNA cannot be recovered. Assuming a similar encapsulation efficiency as with the degradable system, the final loading of these beads should correspond to the medium-loaded beads in which 0.10 μg of plasmid were delivered per well. The supernatant was analyzed for interleukin-6 (IL-6) production using an ELISA kit (Figure 7). Beads encapsulating plasmid DNA successfully induced the secretion of IL-6, with a general trend of higher loaded plasmid beads producing larger amounts of IL-6. The maximum response is observed when just 0.1 μg of encapsulated DNA is delivered per well using beads with a loading of 2.14 μg/mg and resulted in an IL-6 response of 6890 pg/mL, which is 3.75 times that when 1 μg of DNA alone was added. Treatment with more highly loaded particles, 0.2 μg of DNA per well, did not produce an increased cytokine response, indicating that a response to DNA loading had reached a maximum. Untreated cells secreted a minimal amount of IL-6. Furthermore, negligible IL-6 concentrations were measured when unloaded beads were delivered to the cells, indicating that the polymeric microparticles themselves do not induce IL-6 production. With nondegradable particles, there was minimal immunostimulation as indicated by the ELISA results. Because the plasmid DNA is trapped inside the beads, it is not available to be recognized by Toll-like receptors either on the cell surface or within the lysosomal compartment. Only when the microparticles are capable of releasing the encapsulated DNA inside the lysosome is an enhanced response observed.

CONCLUSION

The flexibility of the inverse microemulsion polymerization allows for the encapsulation of both plasmid and protein to produce microparticles for vaccine development. The polymer scaffold serves to protect the DNA from nuclease degradation and prevents unwanted release at physiological pH. The particles are readily phagocytosed by macrophages and induce an immune response, resulting in IL-6 secretion. Knowing that the plasmid DNA released from the microparticles is capable of undergoing transfection and that, according to fluorescent microscopy studies using dextran-encapsulated microparticles, a bioactive payload is directed to the cytoplasm of macrophages, further improvements in the polymeric carrier are required to affect nuclear delivery, which would allow gene therapy applications to be accessible with this degradable microparticle system. In addition, further experiments are underway to develop multicomponent microparticles containing both protein for antigen-specific T cell activation and immunostimulatory DNA for general T cell stimulation for enhanced vaccine capabilities.

ACKNOWLEDGMENT

Financial support of this research by the United States Department of Energy, Basic Energy Sciences, Biomolecular Program at Lawrence Berkeley National Laboratory is acknowledged with thanks (Grant No. DE-AC03-76SF00098), and partial support of the biological studies by the National Institutes of Health (Grant RO1EB00-2047) is acknowledged with thanks. The Center for New Directions in Organic Synthesis is supported by Bristol-Myers Squibb as a Sponsoring Member and Novartis as a Supporting Member. We thank Tom Barber for his assistance with the fluorescent microscopy studies, and Ann Fischer at the University of California Tissue Culture/Media Facility and Kelly Flook for assistance with cell studies.

Arginine-rich peptide-mediated protein delivery into living cells is a novel technology for controlling cell functions with therapeutic potential. In this report, a novel approach for the intracellular delivery of histidine-tagged proteins was introduced where a Ni(II) chelate of octaarginine peptide bearing nitrilotriacetic acid [R8-NTA-Ni(II)] was used as a membrane-permeable carrier molecule. Significant internalization of histidine-tagged enhanced green fluorescent protein (EGFP) into HeLa cells was observed by confocal microscopic observation in the presence of R8-NTA-Ni(II). Nuclear condensation characteristic in apoptotic cell death was also induced in the cells treated with a histidine-tagged apoptosis-inducing peptide [pro-apoptotic domain peptide (PAD)], indicating that the cargo molecules really went through the membrane to reach the cytosol. The apoptosis-inducing activity of the peptide thus delivered was compared with that of the PAD peptide covalently connected with the octaarginine peptide.

INTRODUCTION

Peptide-mediated protein delivery into living cells has become recognized as a powerful tool for controlling cellular function and as a novel methodology in pharmaceutical research (*1*−*3*). The cellular introduction of the cargo molecules is easily conducted by simply conjugating cargo proteins with a peptide having a carrier function and adding these chimera molecules to the culture media. The internalization can be accomplished in a few minutes to substantially all cells. Proteins of molecular weight as high as ∼120 kDa were introduced by this methodology (*4*). One of the typical peptides to have this function is that derived from HIV-1 Tat protein [HIV-1 Tat (48-60): GRKKRRQRRRPPQ] (*5*). The peptide is highly basic and rich in arginines and lysines. We and others have shown that arginine or its guanidino moiety play a crucial role in exerting the carrier function (*6*−*10*). Using this methodology, various cellular functions such as the cell cycle and signal transduction have been successfully regulated (*2*). This methodology is thus regarded as an effective tool for understanding and controlling cellular functions.

On the other hand, the histidine-tag method is known to be one of the most efficacious means for the purification of in vivo produced proteins (*11*). The trick in this method is to prepare proteins of interest so as to have an extra tag peptide segment comprising a continuous array of histidines of about six residues. By elution of the cell extracts containing the histidine-tagged proteins of interest through a column with immobilized Ni(II), the proteins are retained in the columns by chelating with Ni(II), whereas other molecules that lack histidine tags are not. Washout of nonspecifically adsorbed materials from the column followed by the elution with an imidazole-containing buffer will yield the desired purified proteins. This method is especially useful for the purification of a small amount of products from other cellular components, and various plasmids and kits are now available for the efficient production and purification of these histidine-tagged proteins (*12*). This method would be applicable not only for the purification of proteins but also for the detachable cross-link formation between proteins.

In this report, we have developed a novel Ni(II) chelate carrier peptide and exemplified that histidine-tagged proteins were successfully delivered into the cells together with the Ni(II) chelate of octaarginine bearing nitrilotriacetic acid (NTA).

EXPERIMENTAL PROCEDURES

Preparation of Octaarginine-Bearing Nitrilotriacetic Acid (R8-NTA). Preparation of the above compound was conducted as shown in Figure 1. The peptide chain was constructed by Fmoc-solid-phase peptide synthesis (Fmoc = 9-fluorenylmethyloxycarbonyl) (*13*) on a 2-chlorotrityl chloride resin (*14*) using the standard protocol of a Shimadzu PSSM-8 peptide synthesizer. A combination of benzotriazole-1-yloxytrispyrrolidinophosphonium hexafluorophosphate (PyBOP) (*15*), 1-hydroxybenzotriazole (HOBt), and 4-methylmorpholine (NMM) was employed for a coupling system. The N-terminal was acetylated using acetic anhydride in the presence of NMM. Treatment of the peptide resin with acetic acid (AcOH)−trifluoroethanol (TFE)−dichloromethane (DCM) (1:1:8) at 20 °C for 1 h gave a protected peptide segment Ac-[Arg(Pbf)]$_8$-Gly-OH [Ac = acetyl; Pbf = N^G-2,2,4,6,7-pentamethyldihydrobenzofuran-5-sulfonyl (*16*)]. After Ac-[Arg(Pbf)]$_8$-Gly-OH was treated with diisopropylcarbodiimide (DICDI) and *N*-hydroxysuccinimide (HOSu) (2 equiv each) in DMF at 25 °C for 2 h to form the corresponding succinimidyl ester, 5 equiv of *N*-(5-amino-

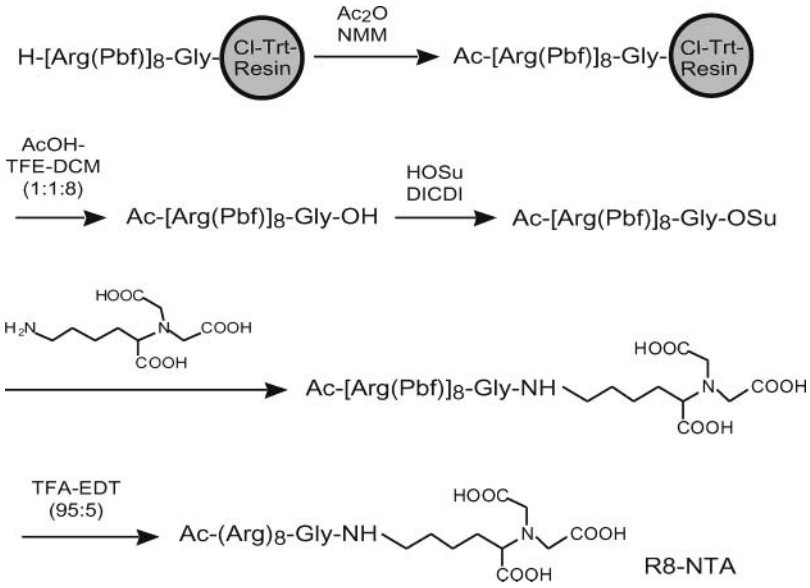

Figure 1. Design and synthesis of octaarginine bearing nitrilotriacetic acid (R8-NTA).

1-carboxypentyl)iminodiacetic acid (Dojin, Japan) in H_2O−DMF (1:3) was added to the mixture and allowed to react overnight. After evaporation of the solvent, the mixture was directly treated with trifluoroacetic acid (TFA)−ethanedithiol (EDT) (95:5) at 25 °C for 2 h. HPLC purification of the sample gave the desired compound. Yield from the starting resin, 31%. MALDI-TOFMS: 1611.7 [calcd for $(M + H)^+$: 1611.8]. Retention time in HPLC, 16.2 min [Column, Cosmosil 5C18-AR−II (10 × 250 mm); eluate, A = H_2O containing 0.1% CF_3COOH, B = CH_3CN containing 0.1% CF_3COOH; gradient, 5−65% B in A over 40 min; flow, 2 mL/min; detection, 220 nm].

Rhodamine-Labeled Octaarginine Bearing Nitrilotriacetic Acid (Rho-R8-NTA). The title compound was similarly prepared as described above, except that the N-terminus of the protected octaarginine was labeled with tetramethylrhodamine using 5(6)-carboxytetramethylrhodamine *N*-hydroxysuccinimide ester (Sigma). The peptide corresponding to the main peak on HPLC was fractionated. Yield from the starting resin, 31%. MALDI-TOFMS: 2040.8 [calcd for $(M + H)^+$: 2040.3]. Retention time in HPLC, 17.5 min [column, Symmetry 300 C18 (4.6 × 150 mm); eluate, A = H_2O containing 0.1% CF_3COOH, B = CH_3CN containing 0.1% CF_3COOH; gradient, 10−50% B in A over 40 min; flow, 1 mL/min; detection, 215 nm].

Preparation of Histidine-Tagged Enhanced Green Fluorescent Protein [H6-EGFP] and R8-Bearing EGFP (R8-EGFP). The EGFP protein bearing a $(His)_6$ segment and a thrombin cleaving site on its N-terminus was prepared as follows. The gene of the EGFP derivative was created by PCR. The 720 bp fragment (679−1398) of pEGFP-N1 (Clontech) containing the EGFP domain was amplified by primers possessing the sequences for *Bam*H I followed by $(His)_6$ and thrombin sites and for the *Eco*R I site. The amplified fragment was cleaved by *Bam*H I and *Eco*R I and cloned into pEV29b, which is a derivative of pET29b (Novagen) and has cloning sites identical to that of pEV3b (*17*). The sequence of the plasmid for H6-EGFP thus obtained was confirmed by a GeneRapid DNA sequencer (Amersham Biosciences). The H6-EGFP protein was overexpressed in the *E. coli* strain BL21(DE3)pLysS in soluble form and purified by a His·Bind Quick Column (Novagen) to give a single band in SDS−PAGE. R8-EGFP was similarly prepared using a PCR primer where the synthetic $(Arg)_8$ gene was also included between the thrombin site and the EGFP domain in the PCR primers.

H-(His)$_6$-(Gly)$_2$-D(KLAKLAK)$_2$-NH$_2$ [histidine-tagged pro-apoptotic domain peptide, H6−PAD]. The peptide chain was constructed by Fmoc-solid-phase peptide synthesis on a Rink amide resin (*18*) by a Shimadzu PSSM-8 synthesizer using a PyBOP/HOBt/NMM coupling system. Fmoc-His(Trt), Fmoc-Gly, Fmoc-D-Lys(Boc), Fmoc-D-Leu, and Fmoc-D-Ala were employed as amino acid derivatives (Trt = trityl, Boc = *tert*-butyloxycarbonyl). Treatment of the peptide resin with TFA-EDT (95:5) and HPLC purification of the deprotected sample gave a pure peptide. Yield from the starting resin, 73%. MALDI-TOFMS: 2460.3 [calcd for $(M + H)^+$: 2461.0]. Retention time in HPLC, 20.9 min [column, Cosmosil 5C18-AR−II (10 × 250 mm); eluate, A = H_2O containing 0.1% CF_3COOH, B = CH_3CN containing 0.1% CF_3COOH; gradient, 5−95% B in A over 45 min; flow, 2 mL/min; detection, 215 nm].

H-(Arg)$_8$-(Gly)$_2$-D(KLAKLAK)$_2$-NH$_2$ [R8−PAD]. The title peptide was prepared similarly to H6-PAD. Yield from the starting resin, 35%. MALDI-TOFMS: 2886.5 [calcd for $(M + H)^+$: 2886.6]. Retention time in HPLC, 20.8 min [column, Cosmosil 5C18-AR−II (10 × 250 mm); eluate, A = H_2O containing 0.1% CF_3COOH, B = CH_3CN containing 0.1% CF_3COOH; gradient, 5−95% B in A over 45 min; flow, 2 mL/min; detection, 215 nm].

H-D(KLAKLAK)$_2$-NH$_2$ (PAD). The title peptide was prepared similarly to H6-PAD. Yield from the starting resin, 39%. MALDI-TOFMS: 1524.0 [calcd for $(M + H)^+$: 1524.0]. Retention time in HPLC, 16.9 min [column, Cosmosil 5C4-AR-300 (4.6 × 150 mm); eluate, A = H_2O containing 0.1% CF_3COOH, B = CH_3CN containing 0.1% CF_3COOH; gradient, 5−95% B in A over 40 min; flow, 1 mL/min; detection, 215 nm].

Cell Culture. Human cervical cancer-derived HeLa cells (obtained from Riken BRC Cell Bank) were maintained in alpha-minimum essential medium (α-MEM) (Invitrogen) with 10% heat-inactivated calf serum (Invitrogen). Cells were grown on 60-mm dishes and incubated at 37 °C under 5% CO_2 to approximately 70% confluence. A subculture was performed every 3−4 days.

Protein Internalization and Microscopic Observation. For each assay, 5×10^4/mL cells were plated on a 35-mm glass-bottom dish (Iwaki) (2 mL/dish) and cultured for 48 h to attain complete adhesion. A typical

experiment employing 50 μM of R8-NTA-Ni(II) and 10 μM of H6-EGFP was conducted as follows. Prior to incubating with cells, R8-NTA in phosphate-buffered saline (PBS) (500 μM, 20 μL), $NiCl_2$ in H_2O (500 μM, 20 μL), and α-MEM containing 10% heat-inactivated calf serum (140 μL) were mixed together and allowed to stand for 15 min. H6-EGFP in PBS (100 μM, 20 μL) was then added to the above mixture and allowed to stand for another 1 h. The cells were incubated with the above mixture (total volume, 200 μL) at 37 °C for 3 h. The cells were washed three times with PBS. Distribution of the EGFP was analyzed using a confocal scanning laser microscope LSM 510 (Zeiss) equipped with an ×40 lens without fixing the cells. When the cells were treated with Rho-R8-NTA-Ni(II)/H6-EGFP complex, the complex was similarly prepared as stated above and applied to a Microcon YM-10 centrifugal filter (normal molecular weight limit 10 000) (Millipore) to remove excess Rho-R8-NTA-Ni(II) before addition to the cells. When the cells were treated with a complex of R8-NTA-Ni(II) with H6-EGFP at 4 °C, the cells and the medium containing R8-NTA-Ni(II)/H6-EGFP were stored at 4 °C for 1 h prior to mixing with each other. After treatment for 1 h, the cells were washed with ice-cold PBS and subjected to the microscopic observation.

In the case of observing nuclear condensation, the cells were incubated with the PAD peptides in α-MEM with 10% heat-inactivated calf serum at 37 °C for 24 h under 5% CO_2, and the medium was changed to a fresh one. Hoechst 33258 was then added to the medium (final concentration, 50 μM), and the cells were incubated for another 30 min at 37 °C under 5% CO_2. Cells were washed twice with PBS, soaked in a fresh α-MEM, and analyzed on an Olympus IX-70 fluorescence microscope using an × 20 lens.

Flow Cytometry. To analyze the internalization of EGFP proteins by FACS, 1.5×10^5 HeLa cells in fresh culture medium (1.5 mL) were plated on a 12-well microplate (Iwaki) and cultured for 48 h in α-MEM containing 10% heat-inactivated calf serum. After complete adhesion the cells were incubated at 37 °C for 1 h with fresh medium (400 μL) containing R8-NTA-Ni(II)/H6-EGFP prior to washing with PBS. The cells were then treated with 0.01% trypsin (Invitrogen) (400 μL) at 37 °C for 10 min prior to adding 600 μL of PBS. The cells were centrifuged at 2000 rpm for 5 min, and after removing the supernatant, they were washed with 1 mL of PBS and centrifuged at 2000 rpm for 5 min. After this washing cycle was repeated, the cells were suspended in PBS (1 mL) and subjected to fluorescence analysis on a FACScalibur (BD Biosciences) flow cytometer using 488-nm laser excitation and an 515−545 nm emission filter.

DNA Fragmentation Assay. HeLa cells were treated with a mixture of R8-NTA-Ni(II) (50 μM) and H6-PAD (10 μM) as described above for 24 h. DNA ladder formation was then examined by isolating oligonucleosomal DNA from cellar extracts and analyzing DNA by ethidium bromide staining after electrophoresis through 2% agarose gels, using Quick Apoptotic DNA Ladder Detection Kit (BioVision).

Evaluation of Apoptotic Cells by FITC-Annexin-V. Cells were stained with FITC-Annexin-V according to the manufacturer's specification using Vybrant Apoptosis Assay kit #3 (Molecular Probes). For analysis, 1.5×10^5 cells were plated on a 12-well plate as described above and incubated for 48 h. Cells were then incubated with fresh medium containing R8-NTA-Ni(II)/H6-PAD complex for 2 h, harvested by trypsinization and then washed with PBS. Cells were suspended in Annexin-V binding buffer (10 mM HEPES, 140 mM NaCl, and 2.5 mM $CaCl_2$, pH 7.4) (200 μL), and then incubated with FITC-Annexin-V (FITC = fluorescein isothiocyanate) (10 μL) and the propidium iodide (PI) working solution (100 μg/mL, 2 μL) at room temperature for 15 min. After the incubation period, the cells were diluted with Annexin-V binding buffer (800 μL). Apoptotic cells, which were positive for FITC-Annexin-V and negative for PI staining, were analyzed by FACS.

MTT Assay. The MTT [= 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-2*H*-tetrazolium bromide] assay was conducted basically in the same manner as already reported (*6*). Cells (1.5×10^3/well) were cultured on 96-microtiter plates in α-MEM with 10% heat-inactivated calf serum in the presence of peptides. Prior to incubation with the cells, R8-NTA in α-MEM (500 μM, 5 μL), $NiCl_2$ in α-MEM (500 μM, 5 μL), and fresh α-MEM containing 10% heat-inactivated calf serum (35 μL) were mixed together and allowed to stand for 15 min. H6-PAD in α-MEM (100 μM, 5 μL) was then added to the above mixture, and allowed to stand for another 1 h. The cells were incubated with the above mixture (total volume, 50 μL) at 37 °C under 5% CO_2 for 24 h. MTT (Sigma) in PBS (0.05 mg/10 μL) was added to the above medium, and the cells were further incubated for 4 h. The precipitated MTT formazan was dissolved overnight in 0.04 N HCl in 2-propanol (100 μL). The absorbance at 570 nm was then measured. Cell viability was expressed as the ratio of the A_{570} of cells treated with peptide to the control samples.

RESULTS

Design and Synthesis of Octaarginine Bearing Nitrilotriacetic Acid (NTA). Intracellular protein delivery using the Tat and other arginine-rich membrane-permeable peptides has become recognized as a novel and promising technology for the modulation of cell functions (*1*−*3*). However, it has been regarded that covalent cross-linking between the cargo proteins and the carrier peptides is necessary for the cellular introduction. Because various histidine-tagged proteins have been prepared up to now, it would be beneficial if we could develop a means of bringing these proteins into cells for the study and modulation of cellular functions without reconstruction of plasmids or systems for expression and purification. Protein purification using the histidine-tags employs immobilized Ni(II) on a chelating adsorbent bearing a nitrilotriacetic acid (NTA) derivative, which occupies four positions in the metal coordination sphere of Ni(II). The remaining two ligand positions in the octahedral coordination sphere are available for selective protein interactions. We developed a novel carrier peptide bearing NTA (Figure 1). As a membrane-permeable carrier peptide, octaarginine was selected as a representative, which was connected to the *N*-(5-amino-1-carboxypentyl)iminodiacetic acid via a glycine residue as a spacer. In the presence of Ni(II), the carrier peptide R8-NTA, and the histidine-tagged protein should form a noncovalent complex which is expected to penetrate into cells.

The synthetic scheme of the carrier peptide is shown in Figure 1, which is based on the condensation of the carrier peptide segment Ac-$[Arg(Pbf)]_8$-Gly-OH with *N*-(5-amino-1-carboxypentyl)iminodiacetic acid. Ac-$[Arg(Pbf)]_8$-Gly-OH was prepared by Fmoc-solid-phase peptide synthesis on a 2-chlorotrityl chloride resin followed by N-terminal acetylation using acetic anhydride and detachment from the resin by a treatment with AcOH-TFE-DCM (1:1:8). After the C-terminus of Ac-$[Arg(Pbf)]_8$-Gly-OH was activated as a succinimidyl ester, excess *N*-(5-

amino-1-carboxypentyl)iminodiacetic acid was added. Treatment of the sample with TFA-EDT (95:5) followed by HPLC purification yielded R8-NTA. The structure of the compound was ascertained by MALDI-TOFMS.

Intracellular Delivery of Histidine-Tagged EGFP (H6-EGFP) by R8-NTA-Ni(II). To assess the ability of the Ni(II) chelate of R8-NTA [R8-NTA-Ni(II)] for intracellular delivery of histidine-tagged proteins, we prepared an N-terminus histidine-tagged enhanced green fluorescent protein (H6-EGFP), which was expressed in *E. coli* and purified using a Ni(II) chelate affinity column to be sufficiently pure. The apparent dissociation constant (K_D) between NTA and H6-EGFP was reported to be 4.2×10^{-7} M (*19*).

Internalization of the histidine-tagged EGFP was monitored by laser confocal microscopic observation after a 3-h incubation of the protein with HeLa cells at 37 °C. Prior to incubation with the cells, R8-NTA was mixed with $NiCl_2$ and allowed to stand for 15 min, and H6-EGFP was added to the above solution and allowed to stand for another 1 h (Figure 2A). The mixture was then added to the cells and incubated for 3 h. Significant internalization of H6-EGFP was observed when the cells were treated with H6-EGFP (10 μM) in the presence of R8-NTA-Ni(II) (50 μM), showing a very similar manner of cellular localization with that of R8-EGFP (a fusion protein of an octaarginine segment and EGFP) (Figure 2B, (i) and (ii)) Particulate signals from EGFP were observed which accumulated around the perinuclear area, suggesting that significant parts of these proteins were trapped in the cellular vesicles or formed aggregates in the cell. When the cells were treated with R8-NTA-Ni(II)/H6-EGFP at 4 °C, no significant internalization of H6-EGFP was observed (data not shown). This fact suggested that an endocytic pathway predominantly contributed to the cellular uptake of H6-EGFP, as reported for the HIV-1 Tat peptide (*20*). Equimolar amounts of H6-EGFP and R8-NTA-Ni(II) (10 μM each) gave somewhat less efficient internalization of the protein (data not shown). On the other hand, little internalization of H6-EGFP was observed in the absence of R8-NTA-Ni(II) (Figure 2B, (iii)). No significant improvement in the cellular uptake of H6-EGFP was observed with the addition of R8 peptide [$(Arg)_8$-amide] (50 μM) that lacked the NTA moiety (data not shown). FACS analysis of the cells treated with H6-EGFP (10 μM) in the presence of R8-NTA-Ni(II) (50 μM) for 3 h showed that the amount of the internalized protein was almost half of that of the cells treated with R8-EGFP (10 μM) (Figure 2C). When the cells were treated with the double amount of H6-EGFP (20 μM) in the presence of R8-NTA-Ni(II) (100 μM), the amount of the internalized protein became almost comparable to that for R8-EGFP (10 μM). The above studies indicated that histidine-tagged proteins were successfully brought into the cells with the aid of R8-NTA-Ni(II), although the efficiency in the delivery of cargo proteins was not comparable to that using a covalently attached arginine peptide segment.

Interestingly, R8-NTA retained carrier ability even when R8-NTA was not treated with $NiCl_2$ (Figure 2B, (iv)); though considerably less compared with the case when R8-NTA was complexed with $NiCl_2$, some amount of H6-EGFP was still brought into the cells. Presumably, some divalent cations present in the cells or culture medium formed a complex with R8-NTA to help the internalization of H6-EGFP.

Less efficiency in the delivery using the R8-NTA-Ni(II)/H6-EGFP system in comparison with that using R8-EGFP suggested that H6-EGFP partially dissociated from R8-NTA-Ni(II) in the cells, presumably due to the presence of other cations and nucleophiles in the cells and the culture medium to compete for the coordination site of Ni(II). Acidification of the endosomic particles may also reduce the binding of H6-EGFP to R8-NTA-Ni(II). To obtain information on this matter, we prepared rhodamine-labeled R8-NTA (Rho-R8-NTA) and examined the cellular localization in comparison with that of H6-EGFP. Figure 2D shows a picture of the cells when treated with a mixture of Rho-R8-NTA-Ni(II) and H6-EGFP. The fluorescent signals from these molecules showed particulate distribution in the cells. Superimposition of these pictures yielded yellow signals. This fact suggested that a considerable part of H6-EGFP retained the complex structure with Rho-R8-NTA-Ni(II). On the other hand, signals of the respective colors were simultaneously observed, suggesting that some part of these components dissociated from each other and formed vesicles or aggregates abundant with one of these components. To confirm that proteins delivered into the cells can actually modulate biological functions and to estimate the efficiency of the delivery system of histidine-tagged proteins using R8-NTA-Ni(II), we conducted other experiments to introduce an apoptosis-inducing peptide into the cells.

Delivery of Apoptosis-Inducing Peptide. Ellerby et al. reported that an amphiphilic basic antibacterial peptide showed apoptosis-inducing activity when delivered in mammalian cells [pro-apoptotic domain peptide (PAD): $_D$(KLAKLAK)$_2$-amide] (*21*). The mechanism of apoptosis caused by this peptide is attributed to interaction with the mitochondrial membranes to disturb the mitochondrial structure. They selectively targeted this peptide to cancer cells by attaching a cyclic RGD segment to it. We have prepared a PAD peptide bearing a H6 segment (H6-PAD, Figure 3A) and assessed the internalization efficiency through its apoptosis-inducing activity in comparison with PAD covalently linked with membrane-permeable octaarginine (R8-PAD).

Condensation of the nucleus is one of the typical phenomena of apoptotic cells. We first confirmed that the intracellular delivery of the PAD peptide caused apoptosis. When the cells were treated with R8-NTA-Ni(II)/H6-PAD for 24 h, significant condensation of the nucleus was observed (Figure 3B). Similarly, condensation of the nucleus was induced by R8-PAD. On the other hand, little change was observed in the size of the nucleus after treatment of the cells with the PAD peptide (10 μM) (data not shown). Even when the peptide concentration was raised to 50 μM, only a slight extent of apoptosis was observed. The above result indicated that intracellular delivery of the PAD peptide using arginine peptides effectively promoted the induction of apoptosis for the target cells.

Induction of apoptosis by the PAD peptide was further confirmed by DNA fragmentation assay (Figure 3C). Typical ladder formation of nuclear DNA isolated from the cells treated with H6-PAD (20 μM) in the presence of 5 equiv of R8-NTA-Ni(II) was observed in the gel-electrophoresis (Figure 3C, lane 4).

Apoptosis inducing activity of the PAD peptides was assessed by a FACS analysis using FITC-conjugated Annexin-V (FITC-Annexin-V) (*22*). Annexin-V is a human anticoagulant that has high affinity for binding to phosphatidylserine (PS). In normal healthy cells, PS in the plasma membrane is oriented toward the cytoplasm. As an early event of apoptosis, the translocation of PS to the extracellular environment is observed, which can be evaluated with Annexin-V staining followed by FACS

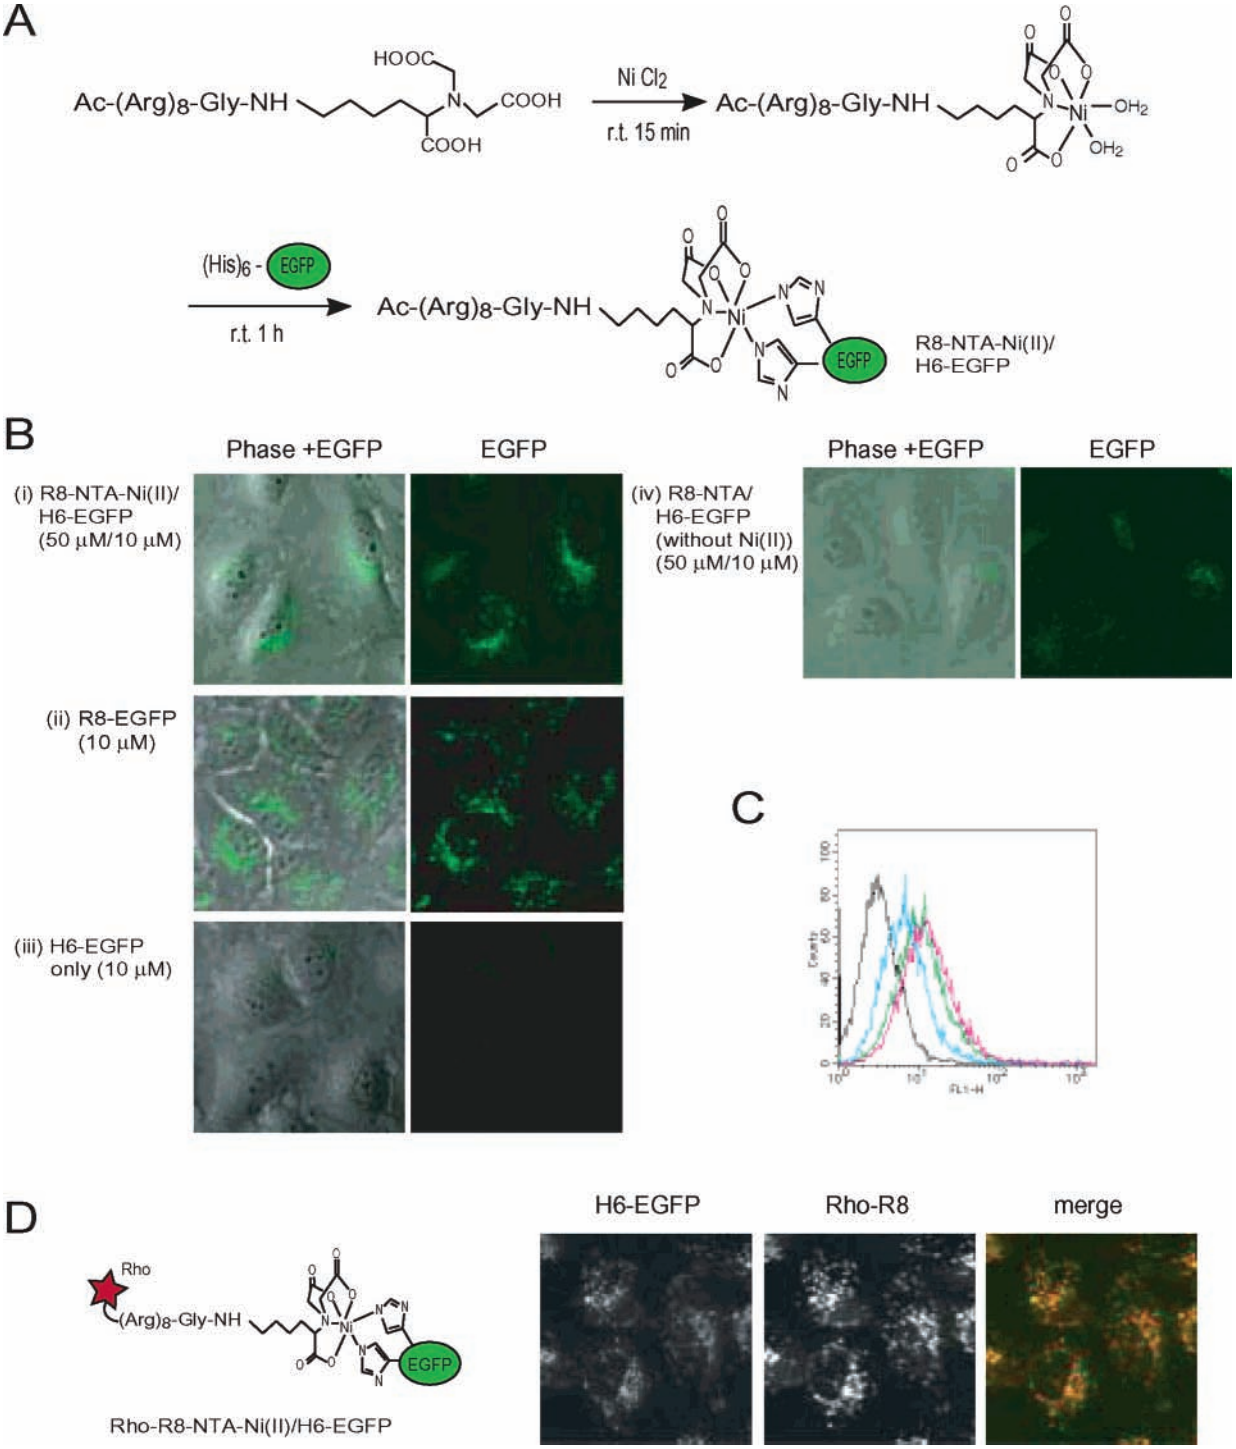

Figure 2. (A) Complex formation of H6-EGFP with the Ni(II) chelate of R8-NTA [R8-NTA-Ni(II)] and (B) confocal microscopic observation of the HeLa cells treated with R8-NTA-Ni(II)/H6-EGFP for 3 h. The R8-NTA-Ni(II)/H6-EGFP complex was formed as described in the Experimental Section. (C) FACS analysis of the internalized EGFP proteins. HeLa cells were treated with H6-EGFP (10 μM (blue) or 20 μM (red)) in the presence of 5 equiv of R8-NTA-Ni(II). Green line represents the cells treated with R8-EGFP (10 μM) and black line control cells (untreated). (D) Confocal microscopic observation of the cells treated with rhodamine-labeled R8-NTA-Ni(II) [Rho-R8-NTA-Ni(II)] and H6-EGFP. Rho-R8-NTA-Ni(II) and H6-EGFP were mixed together at a molar ratio of 5:1 to facilitate the complex formation and then applied to a Microcon YM-10 centrifugal filter (normal molecular weight limit 10 000) (Millipore) to remove excess Rho-R8-NTA-Ni(II) before addition to the cells (final concentration of H6-EGFP, 10 μM).

analysis. In combination with the cell impermeable nucleic acid stain propidium iodide (PI), apoptotic cells (Annexin-V positive/PI negative) can be differentiated from necrotic (Annexin-V positive/PI positive) and normal (Annexin-V negative/PI negative) cells. HeLa cells were treated with R8-NTA-Ni(II)/H6-PAD or R8-PAD for 2 h. FACS analysis showed that the treatment with H6-PAD (10 μM) in the presence of 5 equiv of R8-NTA-Ni(II) induced apoptosis in cells to the same extent to those treated with a typical apoptosis-inducing agent, staurosporine (400 nM). H6-PAD (20 μM) in the presence of R8-NTA-Ni(II) (100 μM) gave comparable effect with R8-PAD (10 μM) to induce apoptosis in >40% of cells, four times higher than those treated with staurosporine (400 nM).

The apoptosis-inducing activity of the peptides was also assessed in terms of the cell viability determined by the

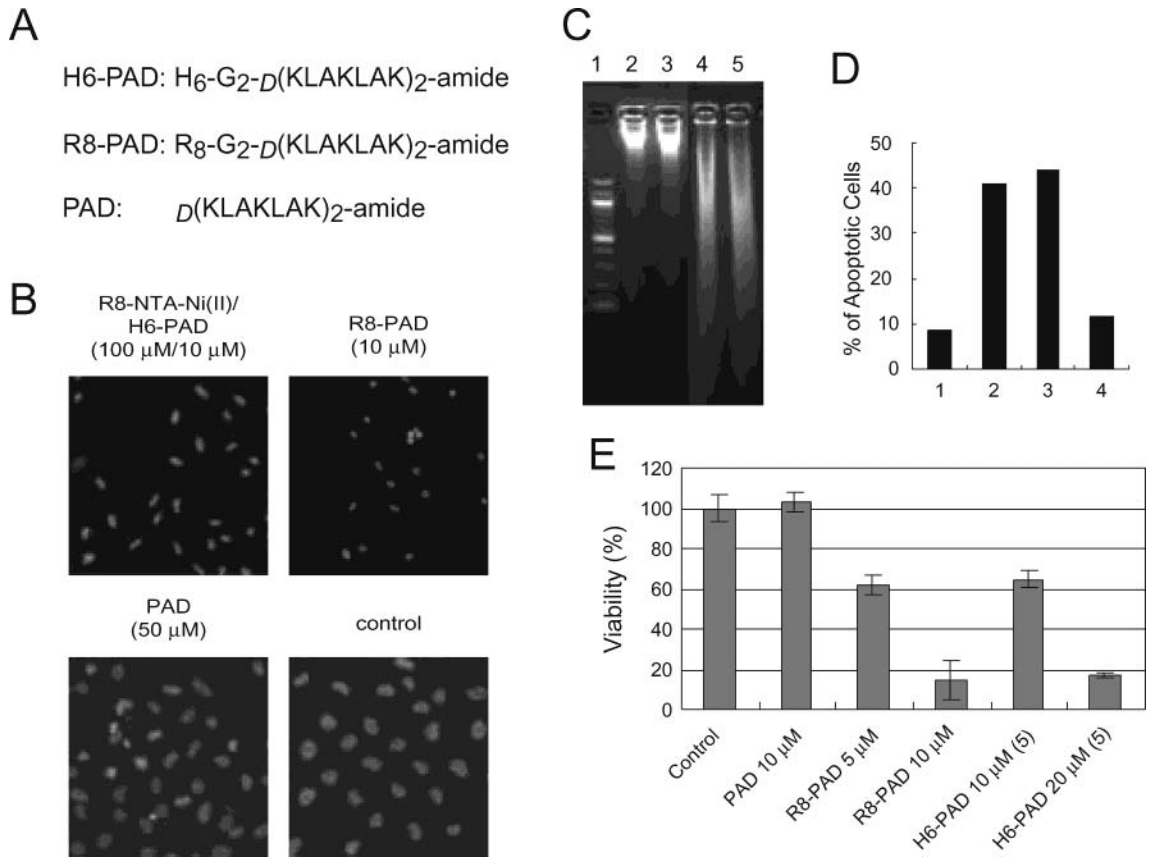

Figure 3. (A) Primary structure of histidine-tagged pro-apoptotic domain peptide (H6-PAD) and its related peptides. Amino acids are expressed by a one-letter abbreviations (H, histidine; G, glycine; R, arginine; K, lysine; L, leucine; A, alanine). (B) Nuclear condensation in apoptotic cells treated with PAD peptides for 24 h. (C) Fragmentation of the chromosomal DNA by the PAD peptides. Lane 1 contains a size marker, lane 2 contains DNA isolated from control cells (untreated), and lane 3−5 contain DNA from cells treated with PAD peptide (10 μM), H6-PAD (20 μM) in the presence of R8-NTA-Ni(II) (100 μM), and staurosporine (400 nM) for 24 h, respectively. (D) Apoptosis analysis by Annexin-V staining. Cells untreated and treated with H6-PAD (10 μM (1) and 20 μM (2)) in the presence of 5 equiv of R8-NTA-Ni(II), R8-PAD (10 μM) (3), and staurosporine (400 nM) (4) were stained with FITC-Annexin-V in the presence of PI and analyzed by flow cytometry. The percentages of cells positive for Annexin-V and negative for PI were shown. (E) Apoptotic cell death induced by the PAD peptides. The viability of the cells was determined by the MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-2*H*-tetrazolium bromide] assay. HeLa cells were incubated in the medium containing a peptide at the indicated concentration for 24 h. Treatment of the cells with the PAD peptide at the concentration of 10 μM did not cause significant cytotoxicity to the cells. H6-PAD 10 μM (5) and H6-PAD 20 μM (5) represent the results of the cells treated with H6-PAD (10 and 20 μM) in the presence of 5 equiv of R8-NTA-Ni(II), respectively. Error bars represent the mean ± standard deviation of three to four samples.

MTT assay (Figure 3E). The peptide-induced apoptotic cell death caused a decrease in the population of live cells among the total cells. The HeLa cells were treated with H6-PAD (10 and 20 μM) in the presence of 5 equiv of R8-NTA-Ni(II) for 24 h. In such cases, viability of the cells ranged around 65% and 17%, respectively, compared with untreated cells. These values were comparable to those for R8-PAD (5 μM) (62%) and R8-PAD (10 μM) (15%). On the other hand, PAD (10 μM) showed no significant cytotoxicity under the given condition. Viability of the R8 peptide (octaarginine amide) (10 μM) was judged to be 88% (data not shown). Thus, although the internalization efficiency of the PAD peptide was a slightly less effective in the case of using the R8-NTA-Ni(II)/H6-PAD system as compared with R8-PAD, it was judged that the H6-PAD peptide was actually delivered into the cytosol to interact with the mitochondrial membranes. These facts were suggestive of the effectiveness of the R8-NTA-Ni(II) system for the intracellular delivery of histidine-tagged proteins.

DISCUSSION

In this paper, we have shown that histidine-tagged peptides and proteins were efficiently brought into the cells using a membrane-permeable octaarginine peptide bearing nitrilotriacetic acid (R8-NTA). The histidine-tagged method is one of the most popular methods for the efficient purification of proteins, and numerous proteins bearing the tag have been prepared. Using this approach, these histidine-tagged proteins are expected to be delivered into cells without modifying the plasmids and expression systems. The results obtained here also raised the possibility of bringing other chelating molecules and noncovalently assembled supramolecular complexes into cells. Other tagged systems can be applicable to the arginine-peptide mediated protein delivery into cells. Although application of the Tat peptide chelated with ^{99m}Tc was reported for in vivo imaging and radiotherapy (*23*), this is, to the best of our knowledge, the first report on the delivery achieved while retaining a chelating complex structure as a 'coupler' between carrier peptides and cargo proteins.

As shown in Figure 2D, a certain population of the carrier peptide (R8-NTA) and cargo H6-EGFP were observed without significant colocalization. This is presumably because of the nonspecific competition of intracellular nucleophilic compounds with the coordination center of Ni(II) to H6-EGFP. Protonation of histidine in

H6-EGFP by acidification of endocytic particles may also explain this fact. Although the apparent internalization efficiency of the proteins is hampered by partial dissociation of the complexes, the cargo molecules can be unequivocally delivered into cytosol to control cellular function as shown in the delivery of the PAD peptide. This characteristic may be useful when the covalent attachment of carrier peptides is undesirable for the exertion of their function or cellular localization of the cargo proteins.

Particulate cellular distribution of the cargo EGFP suggested the involvement of endocytosis in the internalization. It is also suggested that the cargo proteins diffuse into cytosol to give considerably less intense signals than when retained in endosomes. Thinking about this methodology having been successfully applied in modulating various cellular functions, the modulation may be achieved even when only a small portion of the cargo proteins trapped in endosome are released into cytosol. Thus, assessment of the internalization efficiency of proteins not only by microscopic observation or FACS analysis (corresponding to the total cellular uptake of proteins) but also by activities induced by the cargo proteins (reflecting the amount of the cytosol-released proteins) becomes crucial.

It would be implausible that the chelating molecules with dissociation constants of micromolar range can internalize into cells bearing their complex structure by direct penetration through the membranes with an unfolding process. This fact will be a criterion for discussing the mechanism of membrane permeation of the arginine-rich carrier systems.

Cellular Trajectories of Peptide-Modified Gold Particle Complexes: Comparison of Nuclear Localization Signals and Peptide Transduction Domains

Alexander G. Tkachenko, Huan Xie, Yanli Liu, Donna Coleman, Joseph Ryan, Wilhelm R. Glomm, Mathew K. Shipton, Stefan Franzen,* and Daniel L. Feldheim*

Department of Chemistry, North Carolina State University, Raleigh, North Carolina 27695. Received October 14, 2003; Revised Manuscript Received February 28, 2004

Gold nanoparticles modified with nuclear localization peptides were synthesized and evaluated for their subcellular distribution in HeLa human cervical epithelium cells, 3T3/NIH murine fibroblastoma cells, and HepG2 human hepatocarcinoma cells. Video-enhanced color differential interference contrast microscopy and transmission electron microscopy indicated that transport of nanoparticles into the cytoplasm and nucleus depends on peptide sequence and cell line. Recently, the ability of certain peptides, called protein transduction domains (PTDs), to transclocate cell and nuclear membranes in a receptor- and temperature-independent manner has been questioned (see for example, Lundberg, M.; Wikstrom, S.; Johansson, M. (2003) *Mol. Ther. 8,* 143−150). We have evaluated the cellular trajectory of gold nanoparticles carrying the PTD from HIV Tat protein. Our observations were that (1) the conjugates did not enter the nucleus of 3T3/NIH or HepG2 cells, and (2) cellular uptake of Tat PTD peptide−gold nanoparticle conjugates was temperature dependent, suggesting an endosomal pathway of uptake. Gold nanoparticles modified with the adenovirus nuclear localization signal and the integrin binding domain also entered cells via an energy-dependent mechanism, but in contrast to the Tat PTD, these signals triggered nuclear uptake of nanoparticles in HeLa and HepG2 cell lines.

INTRODUCTION

The diagnosis and treatment of disease at the cellular level would be greatly enhanced by the ability to deliver analyte probes and therapeutic agents into specific cells and cellular compartments. The nucleus is the desired target for cancer therapies that involve DNA−drug interactions, genes, short interfering RNA, and antisense strategies that target RNA splicing. These therapeutic agents are often prevented from reaching the cell nucleus because of size, charge, or, in the case of small molecules, because P-glycoproteins pump them out of the cell. Vectors that cross cell and nuclear membrane barriers efficiently and are unaffected by cellular pumping mechanisms could aid in the implementation of many novel disease treatments.

Targeted nuclear delivery is a challenging task, however, as any cell-specific nuclear probe must satisfy the following requirements: it must (i) be small enough to enter cells and cross the nuclear membrane (<100 nm for uptake by receptor-mediated endocytosis (RME) and <30 nm for import through nuclear pores), (ii) penetrate cellular membranes or bind to cell-specific plasma membrane receptors, (iii) bypass or escape endosomal/lysosomal pathways, (iv) penetrate nuclear membranes or access importins to pass through the nuclear pore complex, and (v) have low toxicity. Although viruses have evolved to deliver genes to cell nuclei, the design of synthetic systems (nonviral vectors) capable of performing all of these functions remains a challenge. Nonviral vectors such as dendrimers and liposomes currently appear to be safer and more cost-effective than viral vectors, but they are relatively less efficient at nuclear delivery (*1*). By combining membrane-translocation peptides from viruses with noninfectious materials, a potential route to safe *and* efficient nuclear targeting vectors may be afforded.

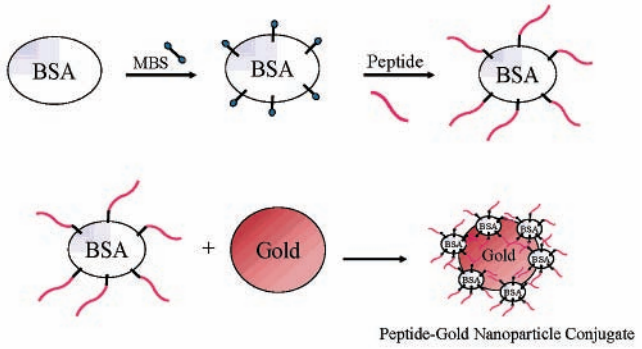

Figure 1. Illustration of the synthesis of peptide-modified gold nanoparticle conjugates for cellular targeting. A surface lysine residue of BSA is labeled using MBS (3-maleimidobenzoic acid *N*-hydroxysuccinimide ester) (*22*). The desired peptide containing a terminal cysteine is cross-conjugated by reaction with a succinimide group on the MBS reagent.

The present study demonstrates nuclear targeting by synthetic cellular targeting peptides complexed to a nanometer-sized gold particle scaffold (Figure 1). Gold makes an excellent intracellular targeting vector for three reasons. First, gold can be synthesized routinely in sizes varying continuously from 0.8 to 200 nm with <10% size dispersity. Second, gold can be modified with a large collection of small molecules, peptides, proteins, DNA, and polymers. Moreover, all of these functional elements can be combined on a single particle simultaneously, often via simple one-pot procedures. Finally, gold par-

ticles have enormous visible light extinction characteristics, ($\epsilon > 10^8$ M^{-1} cm^{-1} at ∼520 nm) (*2*), a behavior we have exploited in a modified form of video enhanced differential interference contrast light microscopy for tracking nanoparticle trajectories inside cells.

Gold particles modified with the nuclear localization signal (NLS) from SV-40 virus have been used extensively for investigating nuclear transport in the pioneering work of Feldherr and co-workers (*3*−*8*). The KKKRK sequence from the SV-40 virus has been shown to bind to importin-α, a nuclear transport protein that binds importin-*β* and enters the nucleus through the nuclear pore complex. However, in those studies the nanoparticle−peptide complex was injected directly into the cytoplasm near the nucleus, thus bypassing cellular membrane entry and endosomal/lysosomal pathways. The studies described here build on this established procedure to examine the ability of a number of viral targeting peptides to target the nucleus from outside intact cells.

The peptide sequence RKKRRQRRR from the Tat protein has been widely studied because of its role in initiation of transcription of the HIV genome. This sequence has also been found to promote uptake into cells across the plasma membrane (*9*, *10*). For example, peptides containing this sequence have been used to shuttle nanoparticles (45 nm) into progenitor cells, allowing their detection by magnetic resonance imaging (*11*). Herein we describe experiments designed to assess the ability of peptide−gold nanoparticle complexes to cross the barriers of intact cells and reach the nucleus. It is shown that particle uptake and nuclear translocation depend strongly on the surface-bound peptide sequence and on the cell type for three cell lines studied, HeLa, 3T3/NIH, and HepG2. Although a single targeting peptide can traverse multiple cellular barriers (endosomal uptake, endosomal escape, and nuclear transport), as shown in HeLa cells, this is not a general feature. On the basis of this study, we conclude that combinations of peptides may be an effective strategy for targeting the nucleus of intact cells. Indeed, in previous work, we have shown that nanoparticles carrying both NLS and RME peptides are capable nuclear targeting vectors in HepG2 cells (*12*).

MATERIALS AND METHODS

Materials. Gold nanoparticles (20 nm diameter) were purchased from Ted Pella. Bovine serum albumin (BSA) was purchased from Roche (MW: 67000). 3-Maleimidobenzonic acid *N*-hydroxysuccinimide ester (MBS) and dithiothreitol (DTT) were obtained from Pierce Chem, Co., Rockford, IL. Sephadex G10, G25, and G50 (for size exclusive liquid chromatograph) were purchased from Sigma. Centricon YM-30 and Microcon YM-100 were purchased from Millipore. 7.5% Tris-HCl prepacked gels (SDS−PAGE) (for electrophoresis) and protein assay kit (for protein concentration estimation) were purchased from Bio-Rad. Peptides were custom-made at UNC Microprotein Sequencing & Peptide Synthesis Facility (Chapel Hill, NC).

Peptides. A list of the four peptides that have been complexed to gold particles and incubated with the three cell lines is shown in Table 1. In this study, we focus on the peptide nuclear localization signal (NLS) derived from the Large T antigen of the SV40 virus (M1 in Table 1), a peptide derived from the HIV Tat protein (M2), and adenovirus fiber protein (M3), as well as a modified integrin binding domain peptide (M4). M1 is considered a classic NLS peptide and has been used as a targeting agent in cytochemical studies (*6*, *7*). The CGGRKKRRQRRRAP sequence in peptide M2 is an HIV NLS that is believed to employ an alternative nuclear transport pathway that involves only importin-*β* (*13*−*18*). The CGGFSTSLRARKA sequence in peptide M3 is derived from the adenoviral fiber protein and is also a known NLS (*19*). While the NLS sequences of peptides M1, M2, and M3 are derived from viruses, peptide M4 is largely synthetic in nature, containing only the integrin binding domain and a segment of basic lysine residues. The integrins are a family of transmembrane glycoproteins exploited by a number of viruses (adenovirus, echovirus, and foot-and-mouth-disease virus), as well as bacterial intracellular pathogens, for cell entry (*20*). We expect that vectors carrying the integrin binding domain will have high affinity for integrins that will facilitate cell binding and internalization. The short stretch of positively charged lysine residues was added to mimic the cationic nature of many nuclear localizations signals. Peptides M3 and M4 have not been used previously for intracellular nanoparticle delivery. Each peptide was prepared with a terminal cysteine to permit conjugation to the lysine residues on the surface of BSA (see below) and tested with PSORT software package, which predicts relative probability of subcellular localization of proteins based on their amino acid sequences using AAindex Analysis (*21*). Predictions for nuclear localization are shown in Table 1. The design criteria thus included both the targeting sequence and a structural component required for nanoparticle attachment and signal flexibility for proper signal−receptor interaction. Addition of six lysine residues to peptide M4 increased the calculated prediction for nuclear delivery from ∼21% to ∼74%.

Preparation of Gold Nanoparticle Vectors. Peptide−gold particle complexes were assembled by conjugating peptides to bovine serum albumin (BSA) and then attaching BSA−peptide conjugates to gold nanoparticles (Figure 1). To prepare BSA−peptide conjugates, BSA was mixed with 3-maleimidobenzoic acid *N*-hydroxysuccinimide ester (MBS) in a 1:50 ratio (*22*). The number of MBS ligands bound to BSA was determined experimentally by a fluorescent assay using fluorescamine (*22*).

The succinimide ester group of MBS subsequently was reacted with a cysteine-terminated peptide using a BSA: peptide ratio of 1:20. After purification by gel filtration on Sephadex G50, the efficiency of peptide conjugation was estimated by mobility shift assay on SDS−PAGE (7.5%).

Cell Culture and Particle Delivery. HeLa, HepG2, and 3T3/NIH cell lines were obtained from the American Type Culture Collection (Rockville, MD) and maintained in Minimum Essential Medium Eagle (EMEM) or Dulbecco's Modified Eagles Medium (DMEM) growth media (BioWhittaker, Walkersville, MD) without addition of antibiotics at 37 °C in controlled CO_2 atmosphere. For investigating the cellular localization of peptides, cells were plated on glass coverslips and grown to 75% confluency in 12-well plates and then incubated with nanoparticle conjugates (150 pM) for various times. It has been shown that the presence of serum in the culture medium inhibits cellular binding/uptake of cationic lipids and reduces their efficiency as nucleic acid carriers (*23*); therefore, most cellular delivery agents available today require serum-free media during delivery. The presence of BSA contributed greatly to the stability of nanoparticle conjugates in serum-containing media. All studies shown herein were conducted using media which contain 10% FBS. At indicated time points the coverslips were rinsed extensively with phosphate-buffered saline (PBS), and the cells were fixed with 4% paraformaldehyde in PBS for 15 min at room temperature and then rehydrated in PBS. Following fixation, the cover slip with cells were mounted onto glass slides with FluorSave (Calbiochem, San Diego, CA) mounting media and allowed to dry overnight prior to microscopy analysis.

The stability of protein−gold nanoparticle conjugates vs flocculation or protein exchange in EMEM growth media with 10% FBS was determined as follows. An aqueous suspension of gold nanoparticles (450 μL of 1.16 nM) was adjusted to pH 9 by adding 50 μL of 10 mM sodium carbonate buffer. Fluorescein isothiocyanate (FITC)-terminated M3 peptide was conjugated to BSA, and the BSA conjugate was slowly added to the gold sol. The final concentration of gold nanoparticles and M3−BSA conjugate was 0.98 nM and 1.78 μM, respectively. The mixture was incubated at room temperature for 15 min, and native BSA (20 μL of 2 mg/mL) was added to prevent flocculation. Six identical solutions were prepared using this protocol. In three of the solutions, any unbound FITC-labeled M3−BSA conjugates were removed by centrifugation. The fluorescence of the supernatant was measured to determine the concentration of unbound M3−BSA conjugate. The number of bound M3−BSA conjugates per gold nanoparticle was calculated by subtracting the number of unbound conjugates from the total number of conjugates added initially. The remaining three solutions were diluted 1:5 in EMEM growth medium without phenol-red (Cambrex Bio Science, Walkersville, MD). Visible absorption spectra of the solutions were acquired after 4 h, and no change of the gold nanoparticle plasmon absorption band was observed. The solutions were centrifuged, and the M3−BSA gold nanoparticle conjugates were then resuspended in 450 μL of sodium phosphate buffer (10 mM, pH 7). Dithiothreotol (DTT) (94 μL of 480 mM) was added and incubated for 24 h to exchange the bound M3−BSA conjugates on the gold nanoparticles. The solutions were centrifuged and the supernatants analyzed by fluorescence spectroscopy to determine the amount of bound M3−BSA conjugate on gold nanoparticles after exposure to growth medium. Since DTT may not remove all surface-bound proteins, this experiment yields an upper limit to the number of M3−BSA conjugates that are displaced in the growth medium.

Characterization of Particle Trajectories. The unique optical properties of colloidal gold enable their identification by relatively simple light microscopy techniques. Particles as small as 10 nm can be observed with video-enhanced microscopy techniques (albeit as an inflated diffraction image) (*24*, *25*). However, high contrast microscopy techniques available currently rely on time-consuming postacquisition processing. In addition, high-density cellular granules can easily be mistaken for gold nanoparticles (*26*).

To improve the visibility of gold nanoparticles in cells, we combined the high resolution afforded by color video-enhanced microscopy with the high contrast and pseudo three-dimensional imaging capabilities of differential interference contrast microscopy (DIC). This hybrid technique (video-enhanced color differential interference contrast microscopy, VECDIC) easily distinguishes gold nanoparticles from cellular granules and organelles under polarized light conditions of DIC. Since DIC allows optical sectioning of the sample, the approximate location of nanoparticles inside cells was determined by varying the focal plane of the image. VECDIC allows cells and nanoparticles as small as 20 nm to be observed simultaneously without image overlays, albeit image resolution remains at the limits of optical microscopy $\sim$ 200 nm (*27*). Thus, high throughput data analysis at the rate of several hundred slides per day is possible. VECDIC data were confirmed by TEM analysis. The colorimetric lactose dehydrogenase assay (LDH) was used to evaluate the cytotoxicity of peptide−BSA−gold nanoparticle conjugates (Cytotox 96, Promega).

Microscopy. Video-enhanced color DIC microscopy was performed on an upright Leica DMLB microscope equipped with a 0.9 numerical aperture (NA) condenser, differential interference contrast (DIC) optics, and 100× plan (NA 1.3) oil objective. The video system comprises a Nikon DMX-1200 color CCD digital camera, with software-based manual control of color balance and contrast enhancement on live and captured images.

TEM analysis was performed on a Philips CM-12 TEM (accelerating voltage was 100 kV) at the University of North Carolina Dental School Research Electron Microscopy Center. Cells were prepared for TEM by staining in 1% OsO_4, dehydrating in ethanol gradient, immersing in LR white embedding resin, and curing under UV light. Microtomed sections were then placed on Formvar grids and poststained with uranyl acetate and lead acetate. A Malvern Zetasizer 1000HS was used to determine the hydrodynamic diameter of gold nanoparticle−BSA complexes.

RESULTS

Preparation of Gold Nanoparticle Vectors. Peptide−gold particle complexes were assembled by conjugating peptides to bovine serum albumin (BSA) and then attaching BSA−peptide conjugates to gold nanoparticles (Figure 1). Since the purity of BSA varies, it is important to determine the binding efficiency of the MBS and peptides to each batch of BSA. An initial ratio MBS:BSA of 50:1 resulted in 28 ± 3 MBS linkers per BSA molecule as measured by a fluorescamine assay (*22*). The reaction of cysteine-terminated peptides with MBS−BSA conjugates was measured by gel shift assays and was found to be peptide dependent (Table 2).

BSA−peptide conjugates were complexed to 20 nm diameter gold particles in 25 mM pH 11 carbonate buffer to prevent colloidal gold aggregation caused by positively charged peptides. Dynamic light scattering and transmission electron microscopy revealed that BSA−peptide conjugates add $\sim$4 nm to the hydrodynamic diameter of a 22 nm gold particle. Prior to complexation, gold particles and BSA had average hydrodynamic diameters

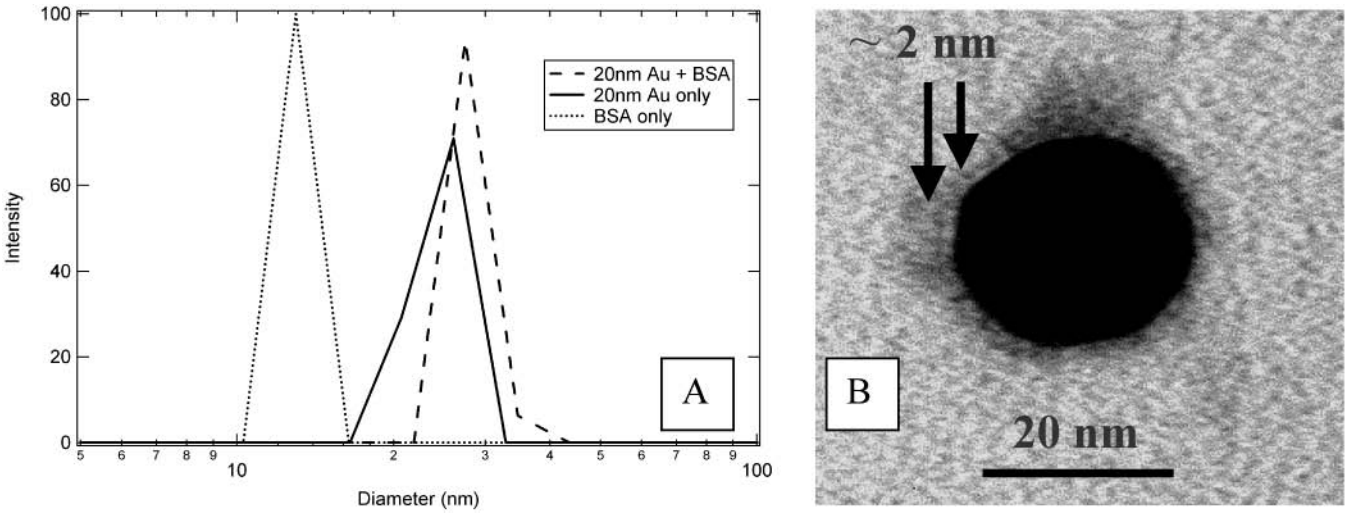

Figure 2. DLS (A) and TEM (B) data showing complex formation between 20 nm colloidal gold and BSA.

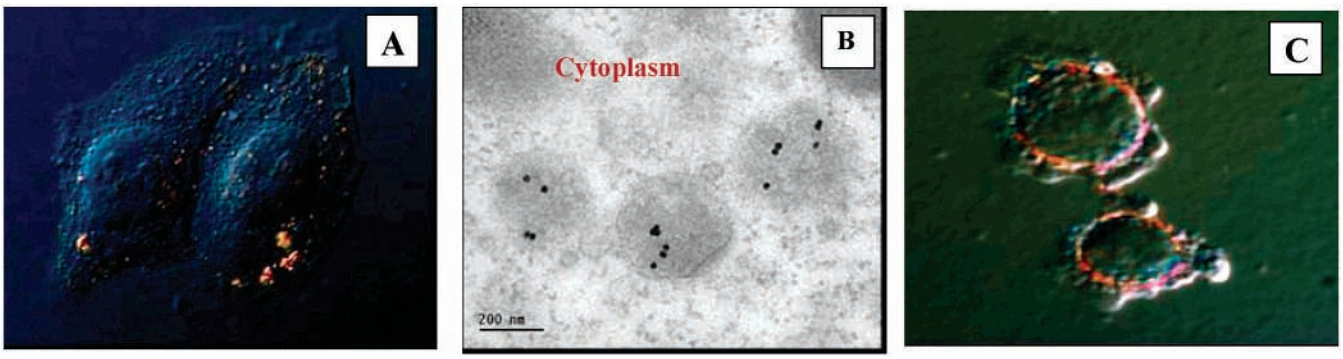

Figure 3. M1 nanoparticles incubated with HeLa cells. After 1 h nanoparticles were observed by video-enhanced color differential interference contrast microscopy (A) and transmission electron microscopy (B) clustered in compartments inside the cytoplasm. After 2 h, nanoparticles were found accumulated around the nuclear membrane (C).

Table 2. Number of Peptides Bound to BSA As Determined by 7.5% SDS−PAGE

no.	peptide sequence	peptide/BSA
M1	CGGGPKKKRKVGG	7 ± 2
M2	CGGRKKRRQRRRAP	3 ± 1
M3	CGGFSTSLRARKA	8 ± 2
M4	CKKKKKKGGRGDMFG	5 ± 2

of 22 and 12 nm, respectively (Figure 2). The average hydrodynamic diameter of the BSA−gold-nanoparticle complex increased to 26 nm. BSA is an oblong molecule that can be approximated by a cylinder 3 nm in radius and 10 in length. Since the data show that BSA adds much less than 10 nm to the diameter of gold nanoparticles, it seems likely that BSA binds to the nanoparticle along its length. The fact that BSA does not add greatly to the size of the gold particle is important in its use in constructing intracellular targeting vectors because only particles with diameters below ca. 30 nm are capable of entering cell nuclei.

A surface coverage of 160 ± 8 BSA per 20 nm gold nanoparticle was determined previously by time-resolved fluorescence spectroscopy (*22*). This amount is difficult to rationalize if BSA adsorbs along its long axis; thus, we cannot rule out that some multilayer adsorption occurs on gold nanoparticles. Quantitative exchange studies performed in the presence of EMEM/10% FBS revealed that no more than 30% of M3−BSA conjugates were displaced from the gold nanoparticle surface in 4 h. This may represent exchange of more loosely bound multilayers. Irrespective of the location of the exchangeable protein (surface or multilayer), within the time scale of a typical delivery experiment (<3 h), the data suggest that >300 peptides are bound to each nanoparticle.

Cellular trajectories of peptide−gold particle complexes were characterized in the following three cell lines: HeLa, 3T3/NIH, and HepG2. These cell lines were chosen to illustrate cell-specific differences in nuclear targeting for each peptide investigated.

Nanoparticle Delivery to HeLa Cells. The fate of nanoparticles inside HeLa cells depended upon the targeting peptide complexed to the gold surface. In general, nanoparticle uptake followed one of three pathways: (i) cell entry followed by exocytosis; (ii) cell entry and transport up to the nuclear membrane; (iii) cell entry and nuclear translocation.

Nanoparticles modified with each of the peptides listed in Table 1 were observed inside HeLa cells by video-enhanced color differential image contrast microscopy. Cellular localization was corroborated by co-analysis of samples by transmission electron microscopy (TEM) (Figure 3).

After 1 h of incubation with HeLa cells, all four peptide−nanoparticle conjugates were found clustered together in cellular compartments that appear to be endosomes as observed by TEM (see M1 conjugates in Figures 3A and B). The behaviors of the peptide−nanoparticle complexes differed once they escaped the endosomal pathway.

After 1 h, nanoparticles carrying peptide M1 were able to escape the endosomal pathway and reach the nuclear membrane. At longer times (2−3 h), M1 nanoparticles were found clustered around the cytoplasmic side of the

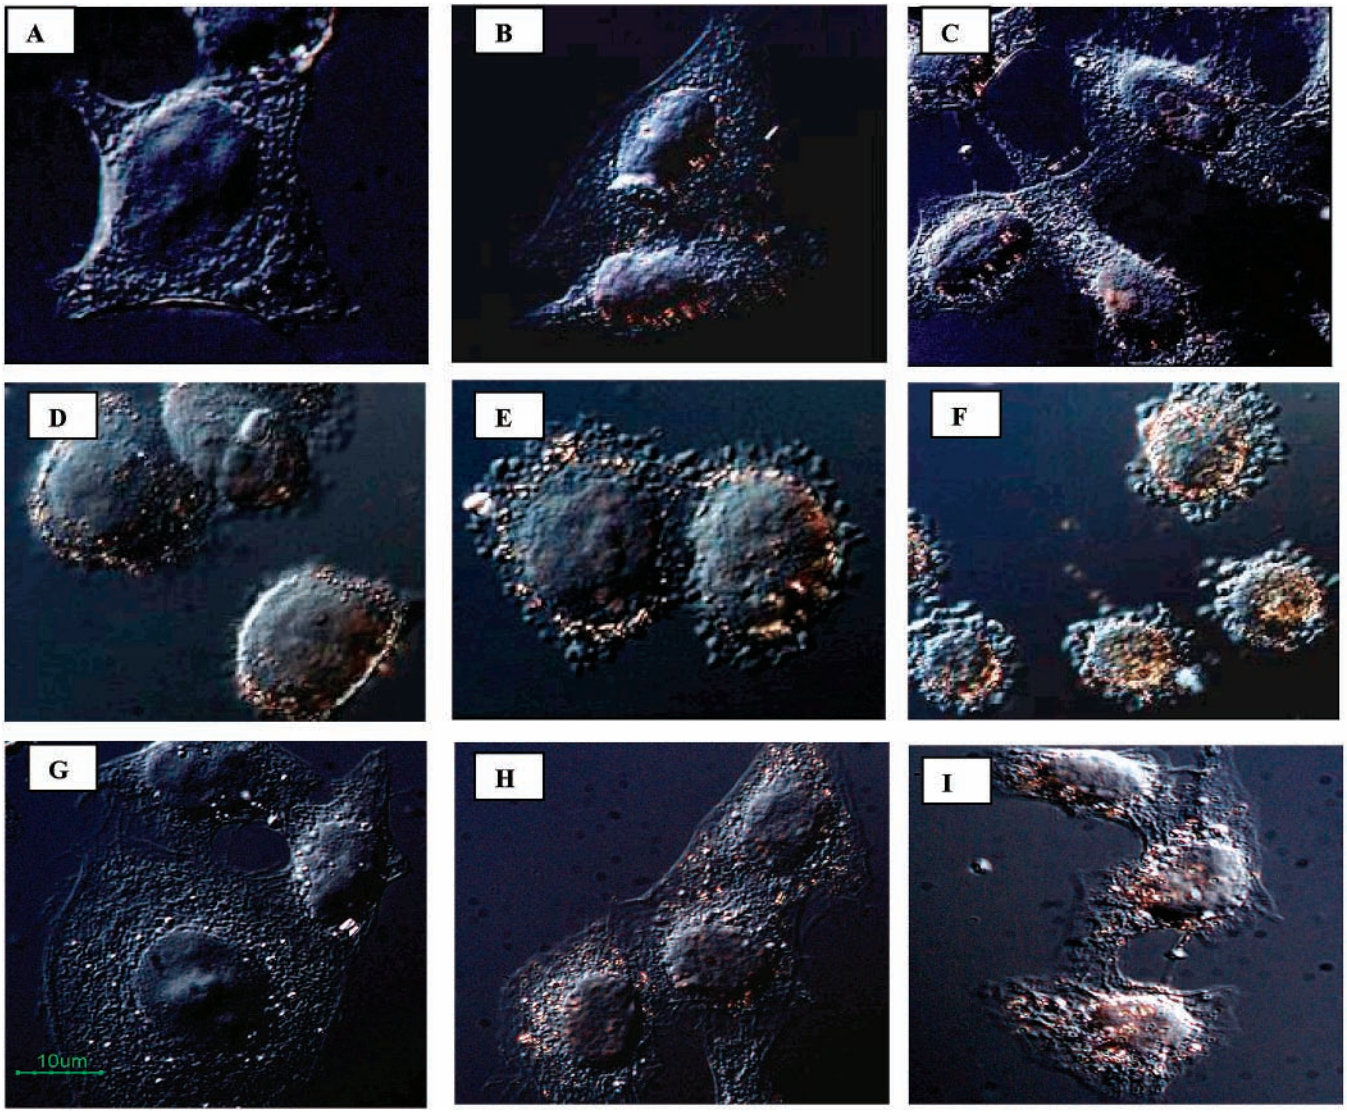

Figure 4. Incubation of HeLa cells with 20 nm diameter gold nanoparticles observed by VECDIC. Figure 4 (A−C) 0.5, 1.5, and 3 h incubation with nanoparticles carrying peptide M2; (D−F) 0.5, 1.5, and 3 h incubation with nanoparticles carrying peptide M3; (G−I) 0.5, 1.5, and 3 h incubation with nanoparticles carrying peptide M4.

nuclear membrane with relatively few located inside the nucleus (Figure 3C). Apparently, M1 nanoparticle complexes were able to enter HeLa cells and escape the endosomal pathway, but were unable to interact properly with the nuclear pore complex.

Nanoparticles carrying peptide M2 were found in the cytoplasm of HeLa cells after 1 h, and in 3 h only minimal nuclear localization was observed (Figure 4A−C). The peptide sequence from HIV Tat protein has been observed previously to bypass endosomal pathways. This occurred on a time scale of minutes, via mechanisms that are not yet well understood (*16*). In contrast to those reports, we observed slow uptake and primarily cytoplasmic uptake of M2 nanoparticles.

Nanoparticles carrying peptide M3 accumulated around the nuclear membrane after 2 h of incubation with HeLa cells; after 3 h M3 nanoparticles were also found inside the nucleus of over 70% of the observed cells (Figures 4D−F). Nuclear targeting was also observed during the delivery of nanoparticles carrying peptide M4 (Figure 4G−I). In contrast to the other peptides studied, M4 peptides do not have any previously known NLS function, carrying only the integrin binding domain plus six lysine residues.

Nanoparticle Delivery to 3T3/NIH Cells. 3T3/NIH cells appear to be more selective than HeLa cells. While M1, M3, and M4 nanoparticles were able to enter the cytoplasm after 30 min of incubation with 3T3/NIH, none of them were able to translocate the nuclear membrane within 6 h (Figure 5). M2 nanoparticles were not found inside the cytoplasm of 3T3/NIH cells by VECDIC microscopy.

Nanoparticle Delivery to HepG2 Cells. Entry into the cytoplasm of HepG2 cells was strongly dependent on the peptide sequence attached to nanoparticles. M1 and M2 nanoparticles were able to enter the cytoplasm of HepG2 cells but were not found near the nuclear membrane or inside the nucleus, which suggests that these nanoparticles were unable to escape from endosomes. While M3 nanoparticles were observed in the nucleus of HeLa cells and the cytoplasm of 3T3/NIH cells, no cellular uptake was observed when they were introduced to HepG2 cells (Figure 6D−F). The most surprising results were observed with M4 nanoparticles (Figure 6G−I). M4 nanoparticles not only entered the cytoplasm of HepG2 cells, but also accumulated inside the nucleus after 2 h of incubation time (Figure 6H,I).

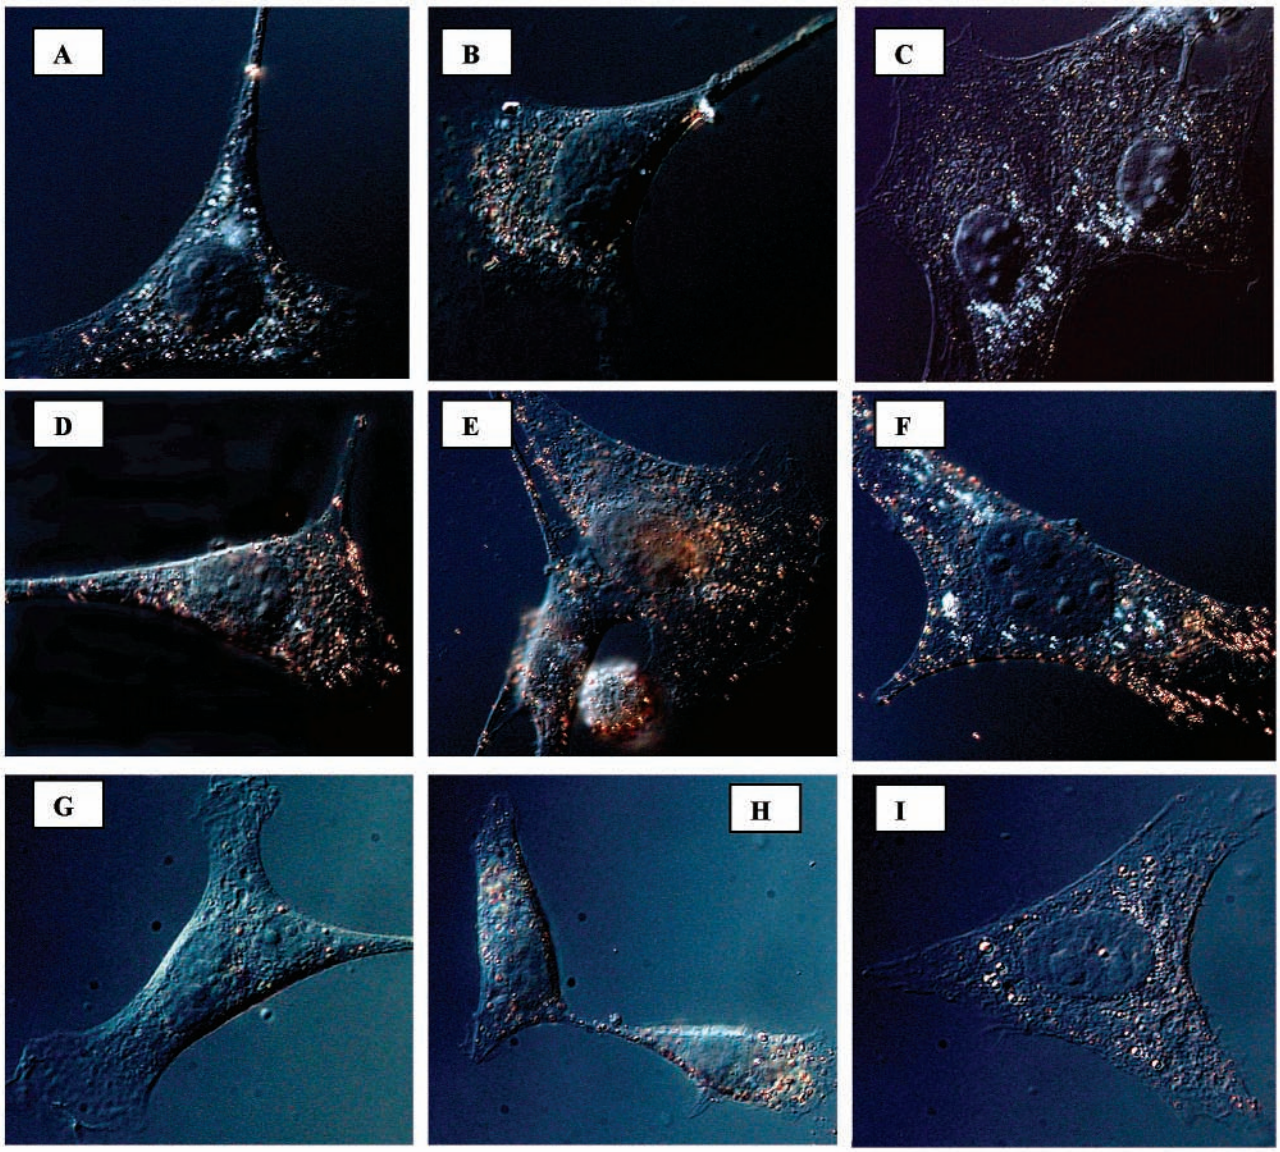

Figure 5. Incubation of NIH/3T3 cells with 20 nm diameter gold nanoparticles observed by VECDIC. (A−C) 0.5, 1.5, and 3 h incubation with nanoparticles carrying peptide M1; (D−F) 0.5, 1.5, and 3 h incubation with nanoparticles carrying peptide M3; (G−I) 0.5, 1.5, and 3 h incubation with nanoparticles carrying peptide M4.

Temperature Studies. BSA−peptide conjugates are polycationic proteins with pI values above 7.0 as determined by isoelectric focusing gel electrophoresis (not shown), and the cell membrane is a negatively charged complex aggregate of proteins, lipids, and carbohydrates. While xenobiotics are normally taken up by passive diffusion, considering the size of peptide−BSA−gold conjugates, passive diffusion is an unlikely translocation mechanism here. Pinocytosis and receptor-mediated endocytosis (RME) are the prime mechanisms for the uptake of large molecular structures (*28*). Cellular uptake of nanoparticles coated with peptide−BSA conjugates could occur by RME, or for the Tat RKKRRQRRR sequence, via the less understood peptide transduction domain mechanism (PTD). Endocytosis occurs within minutes to several hours and is energy dependent. Cell uptake by PTDs is reported to occur within minutes and is energy independent. The peptide−nanoparticle constructs reported here did not enter cells in the first 30 min of delivery, suggesting either that the PTD mechanism is slowed by the nanoparticle or that it is not the mechanism of cell entry. To test the energy dependence of uptake, experiments were performed at 4 °C. At 4 °C sufficient energy is not available to support RME pathways (*29*). Internalization of all peptide−nanoparticle complexes was inhibited at low temperature suggesting an energy-dependent transport process. These results support the involvement of endocytosis as the major route for the internalization of all peptide-nanoparticle complexes studied here, including the M2 peptide.

DISCUSSION

Cellular trajectories of the NLS peptides studied here are summarized in Table 3. Notably, the data reveal a strong dependence of cellular targeting on the cell line and peptide studied. M1 nanoparticles were able to enter all cell lines studied, but there was little or no nuclear transport of these particles although M1 is a well-known NLS. Prior results have shown that when M1 nanoparticles are injected into the cytoplasm, thus bypassing the endosomal pathway, they will translocate the nuclear membrane (*3*−*9*). If M1 can trigger RME, and is capable of nuclear translocation once in the cytoplasm, why then can it not reach the nucleus from outside an intact cell? Two possible answers are that the M1 construct is trapped in endosomes or is somehow altered inside the

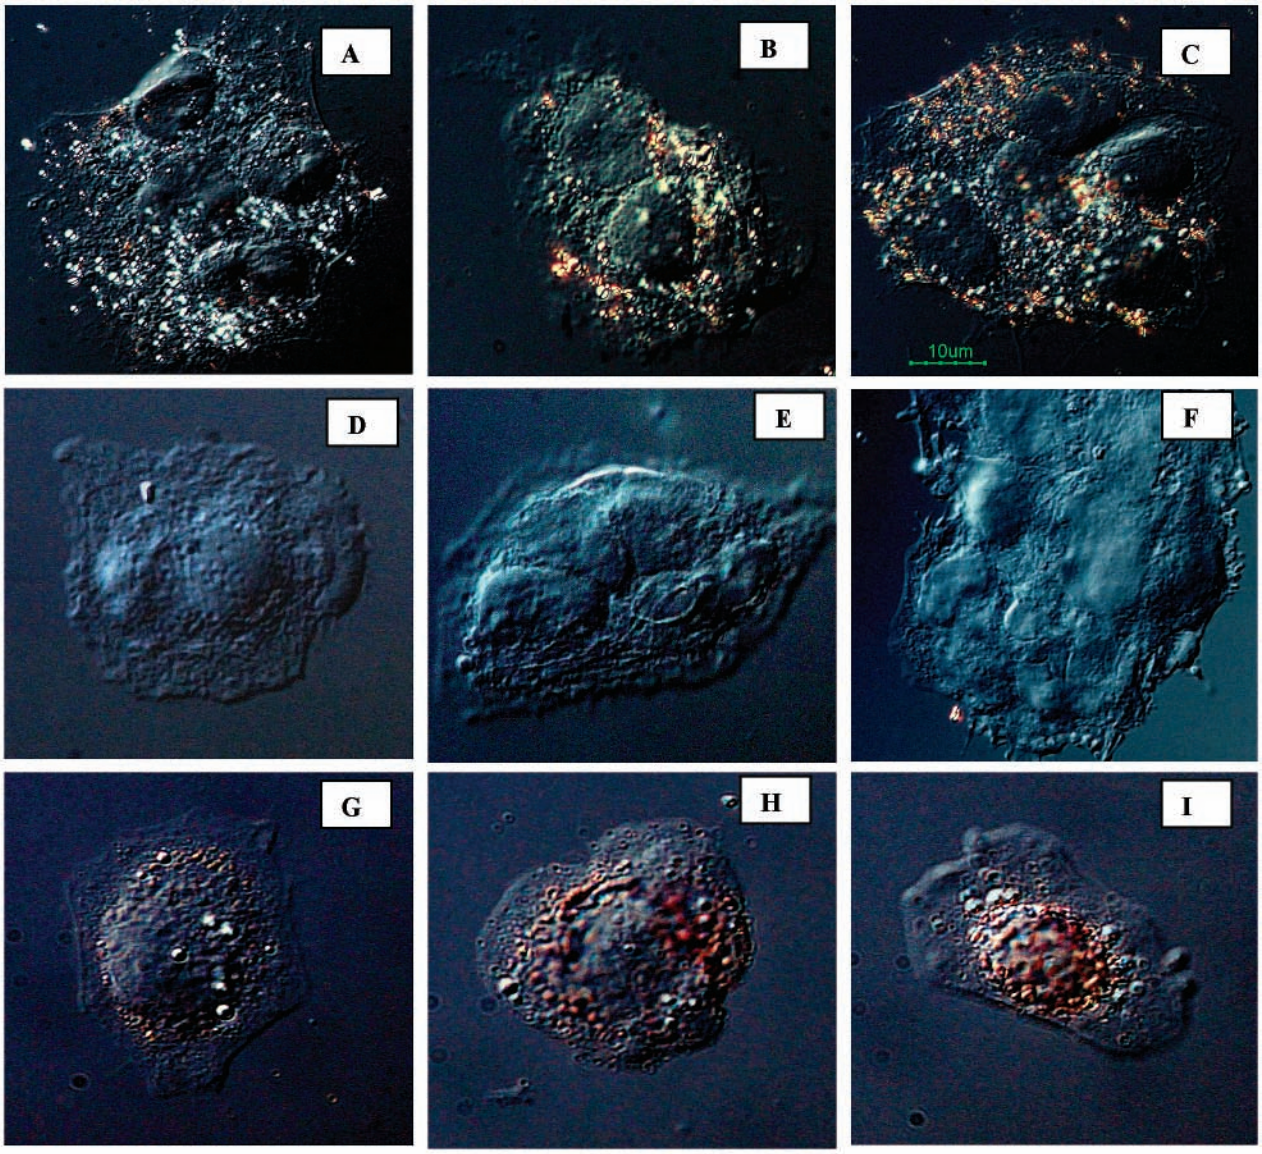

Figure 6. Incubation of HepG2 cells with 20 nm diameter gold nanoparticles observed by VECDIC. (A−C) 0.5, 1.5, and 3 h incubation with nanoparticles carrying peptide M1; (D−F) 0.5, 1.5, and 3 h incubation with nanoparticles carrying peptide M3; (G−I) 0.5, 1.5, and 3 h incubation with nanoparticles carrying peptide M4. Peptide M4 was observed in the nucleus in over 70% of cells imaged.

Table 3. Location of Peptide-Coated Nanoparticles after 3-h Incubation Times with Various Cell Lines

no.	peptide sequence	HeLa	3T3/NIH	HepG2
M1	CGGGPKKKRKVGG	cytoplasm	cytoplasm	cytoplasm
M2	CGGRKKRRQRRRAP	cytoplasm	no uptake	cytoplasm
M3	CGGFSTSLRARKA	nucleus	cytoplasm	no uptake
M4	CKKKKKKGGRGDMFG	nucleus	cytoplasm	nucleus

endosome in a way that renders it incapable of interacting with importin-α. TEM and VECDIC show that M1 nanoparticles are evenly distributed throughout the cytoplasm, rather than clustered together. It is therefore likely that the physicochemical properties of M1 are altered during endosomal transport. Whether this involves a structural or chemical change is currently unknown.

In contrast, M3 nanoparticles were seemingly unaffected by endosomal transport of HeLa cell lines. This peptide was able to enter HeLa cells, escape endosomes, and pass through the nuclear pore complex. In 3T3/NIH cells, however, M3 nanoparticles were found clustered together in endosomes, apparently unable to escape and reach the nuclear membrane. Finally, there was no observed uptake of M3 nanoparticles in HepG2 cells. These differences were also reflected in the LDH cytotoxicity assay. M3−BSA−gold nanoparticle conjugates caused 20% cell death in HeLa cells after 3 h, a result that was traced solely to the M3−BSA construct. After 3 h incubation with the same construct, 3T3/NIH cells were 95% viable. Such large differences in cell viability are likely attributable to the strong nuclear delivery of the M3 conjugate in HeLa cells. We speculate that the highly cationic M3 peptide can interact strongly with DNA inside the HeLa nucleus.

The synthetic peptide M4, composed of the integrin binding domain (RGD) and a stretch of six lysine residues, was unable to reach the nucleus 3T3/NIH cells but was the only peptide capable of targeting the nucleus of HepG2 cells. Integrin binding domains are known to induce cellular uptake by both RME and phagocytosis. However, they typically do not interact with the nuclear pore complex. Thus, it is likely that M4 nanoparticles enter the cell via the integrin binding domain and escape endosomes due to the presence of positively charged lysines, which are known to induce leakage of negatively charged vesicles and cells (*30*). The fragment of M4

consisting of six lysine residues could also be involved in nuclear transport, as it resembles the classic NLS sequences rich in lysines (e.g., large T NLS).

Perhaps the most surprising result of this study is the failure of M2 to target the nucleus of any cell line studied. M2 contains the arginine-rich sequence of the Tfr24 peptide from the HIV Tat protein. This sequence is known to bind the TAR RNA hairpin and is also one of a class of peptides known commonly as peptide transduction domains (PTDs). The observation of a PTD led to further refinement of the sequence to determine the region that was most active for transport through cell membranes. The minimal sequence for PTD activity has been determined to be the nine amino acids (RKKRRQRRR) (*18*). Most peptides that contain this sequence of nine amino acids appears to function as a PTD. PTDs have been reported to target nuclei of all cell lines using an energy-independent mechanism (*10*−*12*). Several recent studies have attributed the efficient nuclear targeting of PTDs to an artifact of cell fixation (*31*−*33*). According to these studies the positively charged peptides that contain the arginine-rich sequence bind tightly to the cell membrane. Once the cells are fixed, the membrane is disrupted and the peptides can diffuse into the cell. Once inside the cell there is a strong electrostatic attraction to DNA in the nucleus. Although similar protocols were used here for cell fixation, nuclear targeting was not observed for the M2 conjugated to gold nanoparticles. On the basis of these observations, we speculate that nanoparticle size may minimize the reported artifacts of cell fixation. This is logical since diffusion in the medium is greatly reduced for a particle of molar mass 50 MDa compared to a single small peptide.

CONCLUSIONS

Targeted nuclear delivery of diagnostic probes and therapeutics could improve disease detection and treatment. Accessing the nucleus from outside an intact cell is difficult, however, because of three membrane barriers: (1) outer cell membrane, (2) endosomal membrane, and (3) nuclear membrane. This paper highlighted the challenges associated with crossing these barriers. For example, the SV40 NLS is capable of entering HeLa cells via receptor-mediated endocytosis (this work). It is also able to cross the nuclear membrane if it is directly injected into the cytoplasm (*3*−*9*). Despite this, the SV40 NLS is not translocated from outside an intact HeLa cell to the nucleus because it cannot break free of endosomal compartments or is somehow altered as it travels through the endosomal pathway. These observations suggest that the most efficient nuclear targeting may result from a combination of targeting peptides attached to a single vector. This can be accomplished in many ways, e.g., using liposomes, dendrimers, or cyclodextrans. Our goals are to study further the ability of multipeptide gold nanoparticle conjugates to target cell nuclei.

ACKNOWLEDGMENT

The authors wish to thank The David and Lucile Packard Foundation, NSF-DMR (9900073), and NIH NCI 98194-01 for support of this work. We also thank Dr. Wallace Ambrose at the University of North Carolina—Chapel Hill for help acquiring the TEM images.

Peptidyl Linkers for Protein Heterodimerization Catalyzed by Microbial Transglutaminase

Tsutomu Tanaka,[†] Noriho Kamiya,[§] and Teruyuki Nagamune*[,†]

Department of Chemistry and Biotechnology, School of Engineering, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-8656, Japan, and Department of Applied Chemistry, Graduate School of Engineering, Kyushu University, 6-10-1 Hakozaki, Fukuoka 812-8581, Japan Received November 11, 2003; Revised Manuscript Received February 21, 2004

Specific peptidyl linkers that result in the heterodimerization of functional proteins, which is catalyzed by microbial transglutaminase from *Streptomyces mobaraensis* (MTG), were generated based on a ribonuclease S-peptide using site-directed mutagenesis. The peptidyl linkers designated as Lys-tag and Gln-tag were designed to possess sole reactive Lys or Gln residue that was amenable for selective Lys-Gln cross-linkage of different proteins. Green fluorescent protein variants, ECFP and EYFP, were employed as model proteins, and those Lys- and Gln-tags were fused to the N-termini of ECFP and EYFP, respectively. As a result, we succeeded in solely obtaining the ECFP-EYFP heterodimer without forming multiply cross-linked byproducts. It was found that the reactivity of peptidyl linkers varied according to the type of amino acid to be replaced. Peptidyl linkers with a basic amino acid (Arg) exhibited the highest reactivity in the cross-linking reaction, suggesting the cationic residue substrate preference of MTG. Kinetic analysis utilizing fluorescent resonance energy transfer (FRET), that is only observed upon the heterodimeric ECFP-EYFP conjugation, revealed that the amino acid replacement contributed to the acceleration of cross-linking reactions by increasing catalytic turnover (k_{cat}), rather than substrate binding affinity (K_m). Finally, using a ribonuclease S-protein, the manipulation of enzymatic protein cross-linking based on specific S-peptide:S-protein interactions was explored. Since newly designed Lys- and Gln-tags retained binding affinities to the S-protein, the heterodimerization was perfectly restrained by wrapping them with the S-protein. The results suggest the possibility of limited protein conjugation by tuning steric hindrance against the MTG. Tailoring enzymatic posttranslational modifications with either engineering peptidyl substrates or by taking specific peptide−protein interactions into consideration may facilitate the development of a new sequential protein conjugation method for the preparation of multifunctional protein.

INTRODUCTION

Site-specifically modified proteins have become a powerful research tool in many fields of biology. The introduction of probes into the desired position of target proteins is of importance when studying protein function and protein−protein interactions. In fact, the conjugation of biologically active molecules has brought about drastic developments in biotechnology. Simple combinations of distinct protein functions can generate practical advantages. For instance, bifunctional protein conjugates such as the antibody−enzyme complex in enzyme immunoassays depict the potential of such protein conjugates. Therefore, a variety of strategies for protein conjugation have been investigated. Chemical conjugation has been utilized to prepare functional protein conjugates (*1*). In this approach, functional groups on the protein surface, such as the ϵ-amino group of Lys residue and the sulfhydryl group of Cys residue, were routinely exploited. One disadvantage of this chemical approach is the heterogeneity of products caused by random modification, resulting in partial or crucial inactivation of target proteins. This is because functional groups of a protein molecule often play an important role in recognition, interaction, and enzymatic activities. To obviate such obstacles, a fully bioactive Lys-deficient protein was prepared for the site-specific conjugation at the N-terminal amino group (*2*); however, major reconstruction of a target protein seems challenging and somewhat time-consuming. Thiol-specific reagents can be utilized in site-specific coupling between a variety of functional compounds and recombinant proteins to which the Cys residue is genetically introduced at a suitable position (*3*−*6*). The combination of a Cys-specific biotinylation of proteins and a specific biotin−streptavidin interaction should be a choice in assembling proteins into designed networks (*7*). The potential of native chemical ligation and expressed protein ligation, which also utilizes thiol chemistry, has been acknowledged in protein engineering research (*8*, *9*). However, these approaches require Cys residues at desired positions, which is often not the case with natural proteins, and even in the case of recombinant proteins, the introduction of Cys residues is sometimes difficult to conduct, especially by bacterial secretion−expression system.

For comparison, genetic manipulation has enabled the preparation of chimeric fusion proteins. In addition to the direct linkage of two DNA fragments encoding the target proteins to be fused, specific protein−protein interactions have recently been employed in obtaining multifunctional fusion proteins (*10*−*12*). However, in general, the larger the size of the chimeric protein is, the

lower the yield of the active proteins. This is mainly due to misfolding and the formation of inclusion bodies, which could be accelerated by the incorporation of additional protein fragments (*10*, *12*). In addition, genetic engineering has one technical limitation: it is only applicable to the preparation of a fusion protein that is in tandem from the N-terminus to the C-terminus, such as the scFv (single chain antibody variable fragment region). An alternative strategy for covalent, site-specific protein conjugation is thus requisite for a designed arrangement of functional proteins.

Transglutaminase, which can catalyze acyl transfer reactions between Gln and Lys residues (*13*), provides a unique opportunity to assemble protein molecules as opposed to conventional techniques. The capability to posttranslationally modify target proteins allows the engineering of wide range of proteins that are expressed from appropriate hosts (*14*−*17*). The enzymatic approach to the preparation of protein conjugates can be highly selective and mild compared with conventional methods. In addition, potential advantages of the enzymatic approach are as follows: (1) The utilization of short peptidyl linkers is compatible to the current protein expression systems in which a number of peptidyl tags are employed (for protein purification and detection). (2) It is possible to create protein conjugates in which N-termini or C-termini were covalently connected because peptidyl linkers can be genetically tethered to N- and/or C-termini of target proteins.

In our previous work, it was discovered that ribonuclease S-peptide works as a specific peptidyl linker for tunable site-specific protein cross-linking (*18*). However, since this S-peptide possesses both Gln and Lys residues in its sequence, multiply cross-linked byproducts were obtained in addition to the target cross-linked dimers. More sophisticated peptidyl linkers may facilitate the limited conjugation of the two separate proteins in a stoichiometric 1:1 molar ratio, which will lead us to utilize this enzymatic method in reliable, predictable organization of different protein functions. In this study, we thus focused on MTG-mediated protein heterodimerization through designed peptidyl linkers. New peptidyl linkers were prepared, of which sole Lys or Gln residue was amenable for the selective Lys-Gln cross-linkage of different proteins. To rationally control protein cross-linking, the MTG-mediated cross-linking was investigated from both a kinetic and a structural point of view, and several conclusions were thus derived. It is suggested that the strategy proposed here will increase the versatility of enzymatic protein engineering with transglutaminase.

MATERIALS AND METHODS

Materials. Semipurified MTG was provided by Ajinomoto Co. Inc. (Japan). S-protein was purchased from Sigma-Aldrich. All other reagents used in this study were of the highest purity commercially available.

Sample Preparation. Purification of MTG was conducted using a Blue Sepharose CL-6B affinity column (Amersham Pharmacia Biotech Co.) as reported previously (*19*). The catalytic activity of purified MTG was measured using a colorimetric procedure described elsewhere (*20*). S-Peptide-based peptidyl linkers with sole glutamine or lysine residue (abbreviated as Gln- or Lys-tags)[1] were prepared as follows: A polymerase chain reaction (PCR) with Pyrobest DNA polymerase (Takara, Japan) was performed using pET32b(+) (Novagen) as a template, and the amplified gene product encoding the S-peptide was subcloned into pBluescriptSKII(+) with *Eco*RV/*Bam*HI double digestion. Site-directed mutagenesis was performed using a QuikChange site-directed mutagenesis kit (Stratagene). The primer sequences were 5′-GGT ATG AAA GAA ACC GCT GCT GCT AGA TTC GAA CGC (K11R), 5′-GGT ATG AAA GAA ACC GCT GCT GCT GAA TTC GAA CGC (K11E), 5′-GGT ATG AAA GAA ACC GCT GCT GCT AGC TTC GAA CGC (K11S), 5′-GGT ATG AAA GAA ACC GCT GCT GCT GGA TTC GAA CGC (K11G), 5′-TTC GAA CGC GCG CAC ATG GAC AGC (Q15A), and 5′- TTC GAA CGC AAC CAC ATG GAC AGC (Q15N), and complementary strands (sites of mutation are underlined). DNA fragments encoding enhanced cyan fluorescent proteins (ECFP) and enhanced yellow fluorescent proteins (EYFP) were prepared from pECFP and pEYFP plasmids (Clontech), respectively, and subcloned into Gln- or Lys-tag/pBluescript SKII with *Nco*I/*Not*I double digestion. The fragments encoding Gln- or Lys-tag-EC(Y)FP were cloned into pET32b(+) with *Msc*I/*Not*I double digestion.

All proteins were successfully expressed and purified as described before (*18*). The resultant proteins were designated as K11X/Q15A-ECFP (X = R, E, S, G: Lys-tag-ECFPs) and K5A/K11A-EYFP (Gln-tag-EYFP), respectively. In the case of Lys-tag-ECFPs, K11X/Q15N-ECFPs were also prepared. The N-terminal additional peptide sequence of Lys-tag ECFPs was thus GSG-M**K**ETAAA-X_1-EFR-X_2-HMDSGS (X_1 = R, E, G, S; X_2 = A, N) and that of Gln-tag-EYFP was GSGMAETAA-AAFER**Q**HMDSGS (the reactive residues in the cross-linking reaction are shown in bold letters, and the sequences corresponding to the original S-peptide are underlined). The homogeneity of the purified proteins was verified by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE). The concentration of MTG was determined using a BCA assay kit (Pierce). The protein concentrations of Lys-tag-ECFPs and Gln-tag-EYFP were measured with a V550 UV/vis spectrophotometer (JASCO, Japan) and calculated assuming molar extinction coefficients of 83 mM^{-1} cm^{-1} (for EYFP at 515 nm) and 32 mM^{-1} cm^{-1} (for ECFP at 434 nm) (*20*).

Protein Cross-Linking Reactions. A Lys-tag-ECFP and a Gln-tag-EYFP (1.2 μM each) were dissolved in 10 mM sodium phosphate buffer (pH 7.5). The cross-linking reaction was initiated by the addition of MTG (0.25 U/mL). After incubation for 2 h at 4 °C, the reaction was terminated immediately by mixing with SDS−PAGE sample buffer (50 mM Tris, 2% SDS, 6% 2-mercaptoethanol) and boiling, and then the products were analyzed with SDS−PAGE.

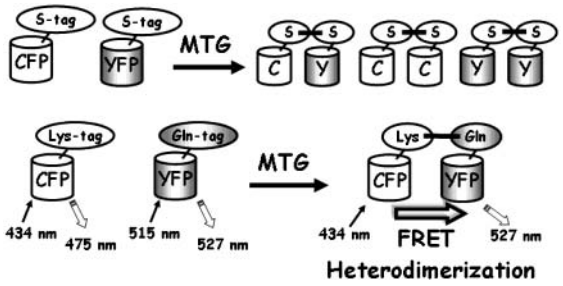
Evaluation of the Reactivity of Lys-tag-ECFPs with Gln-tag-EYFP by Kinetic Analysis Using FRET. An aqueous solution of Lys-tag-ECFP and Gln-tag-EYFP were prepared in 10 mM sodium phosphate buffer (pH 7.5). After initiation of the cross-linking reaction by the addition of MTG, changes in the fluorescence spectra

[1] Abbreviations: ECFP, enhanced cyan fluorescent protein; EYFP, enhanced yellow fluorescent protein; MTG, microbial transglutaminase; FRET, fluorescence resonance energy transfer; Lys-tag, a peptidyl linker containing the sole reactive Lys residue for MTG; Lys-tag-ECFP, ECFP whose N-terminus is fused to a Lys-tag; Gln-tag, a peptidyl linker containing the sole reactive Gln residue for MTG; Gln-tag-EYFP, EYFP whose N-terminus is fused to a Gln-tag.

(excited at 434 nm) were recorded every 4 to 20 min depending on the reaction rate of each Lys-tag-ECFP using an F-2000 fluorescence spectrophotometer (Hitachi, Japan). The ratio of fluorescence emission intensity at 527 nm (EYFP) to that at 475 nm (ECFP) was normalized by the ratio at time zero (the value without MTG) and used as the FRET signal. The FRET signal increase was successfully followed as a function of time. Steady-state kinetic analysis of the cross-linking reaction was conducted. To determine the kinetic parameters of Lys-tag-ECFPs, the concentration of Gln-tag-EYFP was kept constant at 11 μM while Lys-tag-ECFP concentrations were varied from 0.01 to 3.75 μM. Initial reaction rates were evaluated by increases in FRET signal (I_{527}/I_{475}) as a function of time and fitted to the Michaelis−Menten equation using the nonlinear least-squares method with KaleidaGraph software (Synergy Software). V_{max} values were normalized by the V_{max} of K11R/Q15A-ECFP.

Inhibition of Cross-Linking Reactions. S-Protein (5 μM) and Lys-tag-ECFP (1.2 μM) as the starting material were mixed in 10 mM of sodiunm phosphate buffer (pH 7.5). After incubation for 1 h on ice, Gln-tag-EYFP (1.2 μM) was added to the mixture, and MTG treatment was conducted as described above. The same inhibition experiment by S-protein was performed using Gln-tag-EYFP as the starting material.

Measurements of Dissociation Constants. Dissociation constants between Lys-tag-ECFP, Gln-tag-EYFP, or S-tag-EYFP, and the S-protein were determined using a surface plasmon resonance (SPR) sensor, BIAcore 2000 instrument (BIAcore Inc.). The S-protein (50 μg/mL in 10 mM sodium acetate buffer, pH 4.5) was covalently attached to a CM5 carboxylated dextran sensor chip according to the manufacturer's protocol. Interaction analyses were carried out at 25 °C by injecting different amounts of the protein (10 nM ∼ 1 μM), Lys-tag-ECFP, Gln-tag-EYFP, or S-tag-EYFP (10 nM ∼ 1 μM) into 10 mM HEPES, 150 mM NaCl, 3 mM EDTA, and 0.005% Surfactant P20 (HBS-EP buffer, BIAcore Inc.) at a flow rate of 75 μL/min, signal responses (in RUs) were measured. Association and dissociation rate constants were determined using BIA evaluation software (BIAcore Inc.), in which binding curves for each set of concentrations were fit simultaneously to a 1:1 (Langmuir) binding model. The standard deviation for each parameter was calculated from the results of four independent experiments.



Molecular Modeling. Energy minimization of the S-protein and S-peptide or S-protein and other peptidyl tag complexes was carried out on the basis of X-ray structure of RNase S (pdb code: 1RNU) with Discovery Studio Modeling (Accelrys) following the manufacturer's procedure.

RESULTS AND DISCUSSION

Design of Peptidyl Linkers for Heterodimerization. Efficient preparation of bifunctional proteins from different proteins is the first step in preparing multifunctional proteins. The aim of this study was thus to prepare a peptidyl linker for the controlled heterodimerization of target proteins. Ribonuclease S-peptide was found to be a good candidate (*18*). However, this is not a sufficient peptidyl linker, since homodimerization, heterodimerization, and oligomerization were observed due to both reactive Gln and Lys residues located in its sequence. For instance, when S-peptide-fused ECFP and S-peptide-fused EYFP are cross-linked by MTG, the homodimeric forms, ECFP-ECFP and EYFP-EYFP, and the heterodimeric form, ECFP-EYFP, are simultaneously produced (Scheme 1). To evaluate a preferred substrate's reactivity of the cross-linking reaction for heterodimerization, and since little information is available on peptidyl tags that work as acyl acceptors in MTG-catalyzed protein cross-linking (*21*, *22*), this study focused on obtaining a Lys-tag (i.e. a peptidyl tag containing a reactive Lys residue for selective heterodimerization). Lys-tags were prepared by replacing one of the S-peptide's identified acyl acceptors, Lys11 (*18*), with Arg (cationic), Glu (anionic), Ser (nonionic), and Gly (Figure 1). The acyl donor in the Lys-tags, Gln15 (*18*), was substituted with Ala or Asn (the latter is thought to have similar chemical properties as Gln). In the case of the Gln-tag, both the acyl acceptors, Lys5 and Lys11, were substituted with Ala (Figure 1).

It was confirmed that independently, both ECFP and EYFP are not susceptible to MTG-catalyzed cross-linking, suggesting that intrinsic cross-linkable sites are not presented in those model proteins. Lys-tag-ECFP alone and Gln-tag-EYFP alone are also not susceptible to MTG-catalyzed cross-linking, suggesting the homodimeric form is not produced (data not shown). As shown in Figure 2A, Lys-tag-ECFPs and Gln-tag-EYFPs are distinctly cross-linked, yielding corresponding heterodimers based on the molecular mass of the target proteins (ca. 58 kDa). Because intrinsic cross-linkable sites are unavailable in both ECFP and EYFP, it is possible that the heterodimer was formed through Lys5-Gln15 cross-linkage. The residual fraction of the monomeric form can be produced with competitive hydrolysis of Gln to Glu (deamidation) using MTG. The upward shift of the protein band could

Scheme 1. Schematic Illustration of MTG-Mediated Protein Heterodimerization between Lys-tag-ECFP and Gln-tag-EYFP

[a] The upper half shows the cross-linking of S-peptide-fused ECFP/EYFP, yielding homo- and hetero-dimeric forms (S-peptide is denoted as S-tag). The lower half shows the selective heterodimerization of a designed peptidy tag-fused ECFP/EYFP. FRET occurs only when ECFP/EYFP heterodimer is formed.

Figure 1. Extra N-terminal peptide sequences of linkers tethered to ECFP (in the case of Lys-tag) and EYFP (in the case of Gln-tag). All peptidyl linkers were prepared by site-directed mutagenesis of the S-peptide (original sequence is shown as an S-tag).

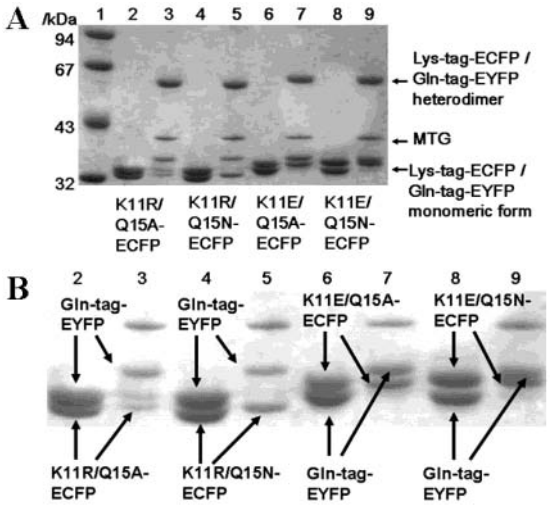


Figure 2. (A) SDS−PAGE analysis of the reaction products following MTG-catalyzed cross-linking of Lys-tag-ECFPs and Gln-tag-EYFP (lane 1, low molecular weight markers; lane 2, K11R/Q15A-tag-ECFP; lane 3 K11R/Q15A-tag-ECFP with MTG; lane 4, K11R/Q15N-tag-ECFP; lane 5, K11R/Q15N-tag-ECFP with MTG; lane 6, K11E/Q15A-tag-ECFP; lane 7 K11E/Q15A-tag-ECFP and Gln-tag-EYFP with MTG; lane 8, K11E/Q15N-tag-ECFP; lane 9, K11E/Q15N-tag-ECFP with MTG. All samples (lanes 2 to 9) contain the same amounts of Gln-tag-EYFP). (B) Magnification of the lower portion of Figure 2 (A).

be ascribed to an increase in negative charge of the Gln-tag-EYFP. This was confirmed by observations that the K11E/Q15A(N)-tag-ECFP fraction shifted slightly upward compared with the K11R/Q15A(N)-tag-ECFP fraction (compare lanes 2 and 6, or lanes 4 and 8 in Figure 2B). SDS−PAGE analysis of cross-linking reactions with all Lys-tags (results with K11S(G)/Q15A(N)-tag-ECFPs are not shown) revealed that when employing K11R/Q15A(N)-tag-ECFP, the amount of residual monomeric fraction was at its lowest among the peptidyl tags prepared, indicating that K11R substitution might enhance the reactivity in cross-linking.

Quantitative Evaluation of the Reactivity of Lys-tags in the Heterodimerization with FRET-Based Kinetic Analysis. The direct monitoring of cross-linking reactions were previously conducted with FRET analysis between the S-peptide tagged EBFP and EGFP (*18*). This analytical technique is suitable for investigating heterodimerization because FRET is only observed when a ECFP/EYFP heterodimer, not a homodimeric form (Scheme 1), is produced. In this study, the fluorescent proteins were changed from EBFP/EGFP to ECFP/EYFP to obtain more stable FRET signals. This did not affect the fluorometric monitoring of the cross-linking reaction and encouraged the application of this system in kinetic analysis of the reactivity of the peptidyl linkers in cross-linking. It is well-known that the distance between two chromophores (in this case, ECFP and EYFP) has a dominant effect on FRET efficiency. Hence, the cross-linking Lys-tag-ECFP and Gln-tag-EYFP sites were fixed at Lys5 and Gln15, respectively. This allows the assumption that the distance between the chromophores in the heterodimers with different peptidyl linkers is constant, and that an increase in FRET signal is related to the amount of heterodimer produced. To investigate the effect of Q15 substitutions, a series of Q15A and Q15N mutants were prepared.

As shown in Figure 3, K11R replacement appears to have a dominant effect on cross-linking efficiency among the peptidyl tags whereas K11E replacement has a negative effect (black bars). These results correlated well

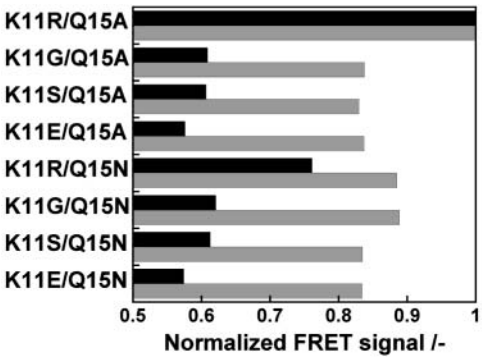

Figure 3. Comparison of FRET signals in the cross-linking reactions of Lys-tag-ECFPs and Gln-tag-EYFP. The cross-linking reaction was conducted with an equimolar mixture of a Lys-tag-ECFP and Gln-tag-EYFP (black bar) at a molar ratio of Lys-tag-ECFP to Gln-tag-EYFP of 10/1 (gray bar). All FRET signals were normalized using the value obtained with K11R/Q15A-tag-ECFP.

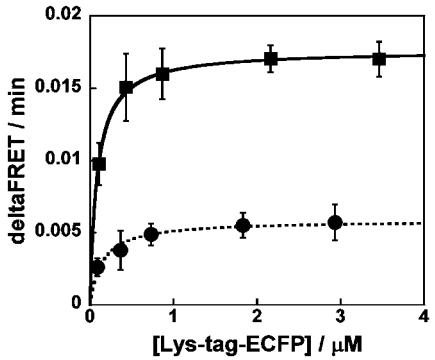

Figure 4. Kinetic analysis of the cross-linking reactions of K11R/Q15A- or K11E/Q15A-tag-ECFP and Gln-tag-EYFP (s−v plot). The reactions were conducted with excess amounts of Gln-tag-EYFP (11 μM) compared with Lys-tag-ECFPs. All FRET signals were normalized using the value obtained without MTG [closed circles with the results of curve fitting (dotted line), K11E/Q15A-tag-ECFP; closed squares and bold line, K11R/Q15A-tag-ECFP].

to those observed in Figure 2; however, it is worth noting that differences of the reactivity in cross-linking among tags is more clearly visualized with FRET-based analysis. It has been suggested that many negatively charged amino acids are located around the acyl acceptor (Lys) binding site of MTG, and therefore cationic substrates might be favorable (*23*). The results of this study seem to fit this assumption: the substitution of amino acid Lys 11 adjacent to the reactive Lys 5 to positively charged Arg (K11R) might enhance cross-linking ability more so than the negatively charged Glu (K11E). One simple strategy to increase heterodimer yield is to increase concentrations of a nucleophilic substrate (Lys-tag-ECFP). When 10-fold higher amounts of Lys-tag-ECFP were applied, the difference in FRET signal between the Lys-tag-ECFPs decreased (gray bars in Figure 3), suggesting that the cross-linking reaction surpasses competitive hydrolysis (deamidation).

Further quantitative analysis was conducted by investigating cross-linking reactions. In kinetic analysis, the initial rate of FRET signal increase was assumed to be the initial rate of heterodimerization. Figure 4 shows a typical s−v plot (with K11R/Q15A- or K11E/Q15A-ECFP and Gln-tag-EYFP) with the data fitting well to the Michaelis−Menten equation. Kinetic parameters obtained with the Lys-tag-ECFPs are listed in Table 1. K11R replacement was the most efficient in conducting successful cross-linking with respect to the specific

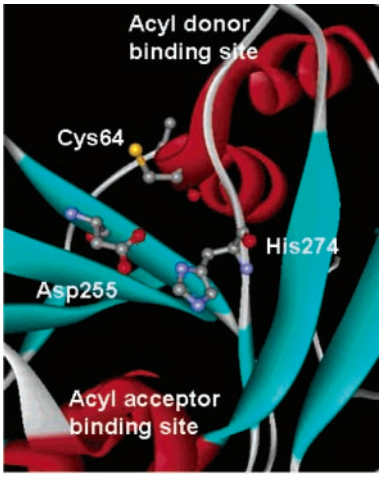

Figure 5. X-ray structure of the area around the active site of MTG (pdb code: 1IU4). The catalytic triad (Cys64, Asp255, and His274) is represented with the ball-and-stick model. The illustrations were drawn using the Weblab viewer Lite program (Molecular Simulation Inc.) Proposed acyl donor and acceptor binding sites (*23*) are also presented.

Table 1. Kinetic Parameters Obtained in Cross-Linking with Various Lys-tag-ECFPs and Gln-tag-EYFPs

amino acid substitution	normalized V_{max} (−)	K_m (μM)	normalized V_{max}/K_m (−)
K11R/Q15A	1.00 ± 0.03	0.14 ± 0.02	1.00
K11G/Q15A	0.42 ± 0.03	0.44 ± 0.01	0.13
K11S/Q15A	0.56 ± 0.06	0.62 ± 0.20	0.13
K11E/Q15A	0.33 ± 0.01	0.19 ± 0.30	0.24
K11R/Q15N	0.70 ± 0.03	0.29 ± 0.06	0.34
K11G/Q15N	0.33 ± 0.02	0.41 ± 0.04	0.11
K11S/Q15N	0.49 ± 0.04	0.36 ± 0.10	0.19
K11E/Q15N	0.36 ± 0.01	0.26 ± 0.03	0.19

constant (V_{max}/K_m) in both K11X/Q15A or K11X/Q15N series (Figures 3 and 4).

The K_m values of K11R- and K11E-substituted tags are comparable, suggesting that these oppositely charged peptidyl tags bind to the active site of MTG with a similar affinity. These results seem contradictory to the assumption that cationic K11R-tags might have a higher affinity to the negatively charged acyl acceptor-binding site of MTG than anionic K11E-tags. However, all experimental data supports distinct reactivity of K11R-tags in the cross-linking reaction among these tags: K11R substitution significantly promotes cross-linking reactions. The difference of the reactivity in cross-linking between K11R and K11E substitutions is largely due to the discrepancy of the V_{max} values, implying that retaining positive charge at position 11 contributes to an accelerated nucleophilic attack of the ϵ-amino group of reactive Lys (K5) in the formation of a ϵ-(γ-glutamyl)lysine bridge rather than substrate binding. Based on the proposed structure−function relationship and the X-ray structure of MTG (Figure 5, pdb code: 1IU4), it can be assumed that the acyl acceptors (the Lys-tags) most likely bind to the active site cleft, which covers the catalytic triad, Cys64-Asp255-His274 (*23*). The distance between Cys64 and His274 is estimated as approximately 0.7 nm, which roughly corresponds to the distance between position 5 and 11 of the Lys-tags when fully extended. Hence, an amino acid at position 11 of Lys-tags might affect the charge state of the catalytic triad especially around Asp255 and His274. It has been proposed that in an MTG-catalyzed reaction, the negatively charged Asp255 nucleophilically attacks a proton of the acyl acceptor (*23*). A possible explanation for the variation in catalytic activity is that the positive charge at position 11 (K11R) might stabilize aninonic Asp255 in the catalytic cycle and accelerate the nucleophilic reaction, while the negative charge (K11E) might lower the reaction rates (Table 1).

With respect to position 15, the replacement of Q15A to Q15N in both K11R and K11E resulted in an approximately 2-fold increase in K_m values, suggesting a decrease in affinity of the acyl acceptors. On the other hand, the substitution of Q15A to Q15N resulted in decreased V_{max} values in all Lys-tags except K11E. There is currently no clear way to interpret these phenomena.

Scheme 2. Schematic Illustration of the Suppression of Heterodimerization with the Coexistence of S-Protein

Table 2. Dissociation Constants between the S-Protein and Peptidyl Linker-Tagged Target Proteins Determined by SPR Analysis Using BIAcore 2000

target proteins	S-tag-EYFP	K11R/Q15A-tag-ECFP	Gln-tag-EYFP
K_d ($\times 10^{-7}$ M)	5.25 ± 0.60	2.85 ± 1.23	15.8 ± 0.60

Suppression of the Cross-Linking Reaction Using S-Protein as a Protecting Group. Controlling protein cross-linking reactions is important in the application of transglutaminase in protein engineering, especially when the target protein possesses multiple cross-linkable sites. If one of the cross-linkable sites of a target protein is temporally blocked and the blocking reagent is removed before the subsequent cross-linking reaction, it becomes possible to conduct sequential protein conjugation. Since ribonuclease S-protein has a high affinity with S-peptide, by wrapping around it (*24*), S-protein could be employed as the blocking reagent in protein conjugation using the S-peptide-based peptidyl linkers designed here. In this section, controllable heterodimerization is evaluated by observing specific peptide−protein interactions using Lys(K11R/Q15A)-tag, Gln-tag, and S-protein (Scheme 2).

To rationally carry out protection and deprotection during the cross-linking reaction, the affinity of peptidyl tags fused to the fluorescent proteins to the S-protein should be examined and compared with that of a S-tag-fused EYFP (possessing the intact S-peptide sequence as shown in Figure 1). Dissociation constants were determined with SPR analysis and are listed in Table 2. The K_d value obtained for S-tag-EYFP was lower than the reported value of free S-peptide (15mer), $K_d = 10^{-9}$ M (*25*−*27*), but the S-protein proved to be accessible to the S-peptide tethered to the N-terminus of the model protein. K11R/Q15A-tag-ECFP appeared to have slightly higher affinity, while Gln-tag-EYFP showed a lower affinity with the S-protein than the S-tag-EYFP. To evaluate the difference in affinity, energy minimization was conducted using DS modeling on the basis of X-ray structure of RNase S, the S-peptide:S-protein complex. With a K5A/K11A substitution for the Gln-tag, no significant difference of RNase S in solvent accessibility was observed. On the other hand, with a K11R/Q15A substitution for a Lys-tag, solvent accessibility of Phe12 (Phe8 in the original S-peptide) decreased (from 8% to 0%) and the distance from Phe12 to Val88 of the S-protein significantly shortened. Hence, the hydrophobic interaction between Phe12 (S-peptide) and Val88

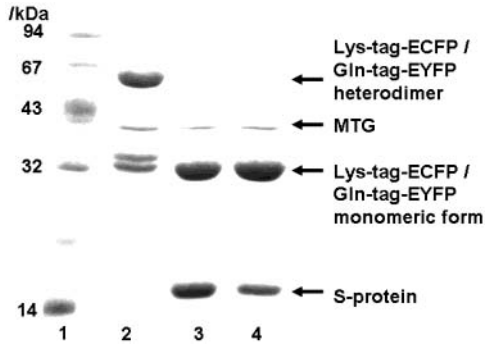

Figure 6. SDS−PAGE analyses of inhibitions of the cross-linking reactions with S-protein. Lane 1, low molecular weight markers; lane 2, K11R/Q15A-tag-ECFP and Gln-tag-EYFP treated with MTG; lane 3, after incubation of K11R/Q15A-tag-ECFP with the S-protein, Gln-tag-EYFP was added and the mixture was treated with MTG; lane 4, the protocol was the same as that outlined above for lane 3 except that Gln-tag-EYFP was used as the starting material in place of K11R/Q15A-tag-ECFP.

(S-protein) might be responsible for generating the higher affinity of the K11R/Q15A-tag with the S-protein.

The results in Table 2 indicate that the S-protein can be employed as a blocking reagent, and this was experimentally confirmed according to Scheme 2. As shown in Figure 6, when Gln-tag-EYFP or Lys-tag-ECFP was capped with an S-protein, the cross-linking reaction with MTG was restrained in both cases (lanes 3 and 4), indicating that the S-protein can be used as a protective reagent for the peptidyl tags designed in this study. It seems that differences in K_d values do not affect the capability of protection under experimental conditions (approximately 99% of engineered peptide tags were protected). Given that an engineered peptide tag is bound to the S-protein in the same manner as an S-peptide, Q15 of a Gln-tag (corresponding to Q11 in an intact S-peptide) is buried within the interior protein structure and has less solvent accessibility, suggesting that the S-protein: Gln-tag-EYFP complex is not susceptible to the cross-linking reaction. On the other hand, K5 of the Lys-tag-ECFP (corresponding to Lys1 in the intact S-peptide) seems to be exposed to the solvent, regardless to the binding of the S-protein. Furthermore, Glu6 and Thr7 of the Lys-tags should have little interaction with the S-protein (*25*, *28*), and so MTG might be accessible to the polypeptide from the Gly1 to Thr7 of K11R/Q15A-tag. However, the S-protein:K11R/Q15A-tag-ECFP complex was not recognized by the MTG, implying that the steric hindrance between MTG and the S-protein has a dominant effect on the inhibition of the cross-linking reaction. This is supported by the following experimental results: first, Ribonuclease S, which exposes the Lys1 of the S-peptide to the solvent (*28*), was not cross-linked with casein, which is MTG's preferred Gln and Lys substrate. Second, the S-protein:K11R/Q15A-tag-ECFP complex was not cross-linked with casein (data not shown). If the S-protein cannot work as a protecting group and the cross-linking reaction occurs, a heterodimer should be observed. No appearance of a heterodimer indicates that the S-protein is working as an effective protecting group (lanes 3 and 4 in Figure 6).

In closing, in the present study we validated the potential of MTG-mediated protein cross-linking in controlled protein conjugation (i.e. heterodimerization) with designed specific peptidyl linkers. The strategy proposed here addresses highly selective protein cross-linking when intrinsic cross-linkable sites targeted by MTG are unavailable in the proteins of interest. Although this limitation would narrow the application of MTG in protein conjugation, in our experience, most globular proteins would not be subjected to MTG-catalyzed protein cross-linking. The enzymatic protein cross-linking directed to recombinantly incorporated peptidyl tags into target proteins can be tuned by substrate preference of MTG and by taking specific peptide−protein interaction (e.g., S-tag:S-protein, peptidyl tag:anti peptidyl tag antibody) into consideration. Our concept was clearly illustrated by site-specific heterodimerization of the model proteins. The fact that a number of peptidyl tags are utilized in current biotechnological applications indicates the potential applicability of this enzymatic method in functional protein engineering. Our research interest has now directed to establish sequential protein conjugation coupled with reversible protection of peptidyl linkers, which will offer one way to prepare multifunctional protein conjugates.

ACKNOWLEDGMENT

We are grateful to Ajinomoto Co. Inc., for providing samples of MTG. The present work was supported mainly by a Grant-in-Aid for Exploratory Research (13875156) and partly by a Grant-in-Aid for the 21st Century COE Program, entitled "Human-Friendly Materials Based on Chemistry" from the Ministry of Education, Culture, Science, Sports and Technology, Japan.

3′-Methylphosphonate-Modified Oligo-2′-*O*-methylribonucleotides and Their Tat Peptide Conjugates: Uptake and Stability in Mouse Fibroblasts in Culture

Chrissy E. Prater and Paul S. Miller*

Department of Biochemistry and Molecular Biology, Bloomberg School of Public Health, Johns Hopkins University, 615 North Wolfe Street, Baltimore, Maryland 21205. Received January 8, 2004; Revised Manuscript Received February 18, 2004

Antisense oligo-2′-*O*-methylribonucleotides and their methylphosphonate derivatives show high binding affinities for their complementary targets under essentially physiological conditions. Additionally, the methylphosphonate linkage is resistant to nuclease hydrolysis. Here we show that a single methylphosphonate internucleotide linkage at the 3′-end of an oligo-2′-*O*-methylribonucleotide is sufficient to prevent degradation by the 3′-exonuclease activity found in mammalian serum. Complexes formed between a cationic lipid, Oligofectamine, and 5′-[^{32}P]-labeled methylphosphonate modified oligo-2′-*O*-methylribonucleotides are taken up by mouse L_{929} fibroblasts in culture. The extent of uptake appears to be dependent upon the sequence of the oligonucleotide. Examination of lysates of oligonucleotide treated cells by polyacrylamide gel electrophoresis showed that no degradation of the oligonucleotide occurred, even after incubation for 24 h. A fluorescein-derivatized oligomer was shown to localize mainly in the cell nucleus as monitored by fluorescence microscopy. Covalent conjugates of fluorescein-derivatized 3′-methylphosphonate modified oligo-2′-*O*-methylribonucleotides with Tat peptide, a cell permeating peptide, were also prepared. The Tat peptide was coupled to the 5′-end of the oligonucleotide using either disulfide coupling chemistry or conjugation of a keto derivative of the Tat peptide via a 4-(2-aminooxyethoxy-2-(ethylureido)quinoline group at the 5′-end of the oligonucleotide. Although formation of the Tat peptide conjugates was confirmed by mass spectrometry, the propensity of these oligonucleotides to form aggregates and their apparent high affinity for plastic and glass made the conjugates unsuitable for studies of uptake by cells in culture.

INTRODUCTION

Antisense research has evolved to include many modifications that render chemically synthesized oligonucleotides resistant to hydrolysis by nucleases, while enhancing the binding affinity of these oligonucleotides for their targets. We have recently described the syntheses and binding properties of antisense oligo-2′-*O*-methylribonucleotides that contain nuclease resistant methylphosphonate internucleotide linkages (*1*−*6*). These studies demonstrated that methylphosphonate-modified oligonucleotides have high affinities for their complementary RNA targets under essentially physiological conditions. To further characterize these oligonucleotide analogues, we have studied their uptake by, and stability in, mammalian cells in culture. Here we describe the cationic lipid-mediated uptake of methylphosphonate containing oligo-2′-*O*-methylribonucleotides by mouse L_{929} fibroblasts and show they are delivered intact to the cell's nucleus. We also describe efforts to prepare covalent conjugates of fluorescein-derivatized oligomers with Tat peptide, a peptide derived from the "protein transduction domain" of HIV-1 Tat protein, which has been reported to facilitate cellular uptake of macromolecules including oligonucleotides.

EXPERIMENTAL PROCEDURES

Materials. Protected 2′-*O*-methylribonucleoside-3′-*O*-(β-cyanoethyl-*N*,*N*-diisopropyl) phosphoramidites, 5′-fluorescein phosphoramidite (6-FAM), 5′ nucleoside-derivatized controlled pore glass supports, 4,5-dicyanoimidazole, 1*H*-tetrazole, Cap Mix A, Cap Mix B, and oxidizing solution were purchased from Glen Research Inc., Sterling, VA. The exocylclic amino groups of the 2′-*O*-methylribonucleoside phosphoramidites mr-C and mr-G were protected with acetyl and isobutryl protecting groups, respectively. Protected 2′-*O*-methylribonucleoside-3′-*O*-(*N*,*N*-diisopropyl) methylphosphonamidites were purchased from ChemGenes Corp., Ashland, MA. The exocyclic amino groups of the mr-C and mr-G methylphosphonamidites were protected with isobutryl groups. The phosphoramidite and phosphonamidite solutions were prepared using synthesis grade acetonitrile (Fisher) that was dried and stored over calcium hydride. Tat peptide, residues 48−60, with the addition of a C-terminal cysteine (GRKKRRQRRRPPQC), was synthesized by the Johns Hopkins University School of Medicine Protein/Peptide Sequencing Core Facility. MALDI analysis was performed in the AB Mass Spectrometry/Proteomics Facility at Johns Hopkins School of Medicine (www.hopkinsmedicine.org/msf/) with support from a National Center for Research Resources shared instrumentation grant 1S10−RR14702. Mouse L_{929} fibroblasts were obtained from American Type Culture Collection (ATCC), Manassas, VA.

General Methods. Strong anion exchange (SAX) HPLC was carried out using Dionex DNAPac PA-100 analytical (4 × 250 mm) or semiprep (9 × 250 mm) columns purchased from Dionex Corp., Sunnyvale, CA. The columns were eluted with a 20 min (analytical) or

30 min (semiprep) linear gradient of 0.0 M to 0.5 M sodium chloride in a buffer containing 100 mM Tris−hydrochloric acid, pH 7.8, and 10% acetonitrile at a flow rate of 1.0 mL/min (analytical) or 1.5 mL/min (semiprep). The columns were monitored at 260 nm for analytical runs, and 290 nm for preparative runs. C-18 reversed-phase HPLC was carried out using a Microsorb C-18 column (0.46 × 15 cm) purchased from Varian Analytical, Sunnyvale, CA. Unless otherwise noted, the column was eluted with a 20 mL linear gradient of 2−30% acetonitrile in 50 mM sodium phosphate, pH 7.8, at a flow rate of 1.0 mL/min. Denaturing polyacrylamide gel electrophoresis (PAGE) was carried out on 20 × 20 × 0.75 cm gels containing 20% acrylamide and 7 M urea. The running buffer (TBE) contained 90 mM Tris, 90 mM boric acid, and 0.2 mM ethylenediaminetetraacetate buffered at pH 8. The gel loading buffer contained 90% formamide, 0.05% xylene cyanol, and 0.05% bromophenol blue.

Syntheses of Anti-TAR and Anti-RRE Oligonucleotides. The sequences of the oligonucleotides are shown in Table 1. The 5′-phosphate derivative of oligonucleotide **1** (2) was a gift from Dr. Tomoko Hamma; it was dephosphorylated by incubating 0.03 A_{260} unit of the oligonucleotide with 1 unit of arctic shrimp alkaline phosphatase in 10 μL of buffer containing 10 mM Tris, pH 8.0, and 10 mM magnesium chloride for 60 min at 37 °C. The solution was then heated at 65 °C for 15 min to deactivate the enzyme. The other oligonucleotides were synthesized on an ABI Model 392 DNA/RNA synthesizer. The protected nucleoside methylphosphonamidites and nucleoside β-cyanoethylphosphoramidites were dissolved in anhydrous acetonitrile at a concentration of 0.15 M. The nucleoside methylphosphonamidite solutions were stored over 3 Å molecular sieves 1 h prior to use. The coupling time for nucleoside methylphosphonamidites was 120 s using a 0.25 M solution of 4,5-dicyanoimidazole (DCI) as the activating agent. A "low-water" oxidizing agent consisting of 1.27 g of iodine, 37.5 mL of tetrahydrofuran, 12.5 mL of 2,6-lutidine, and 100 μL of water was used. The capping solutions consisted of Cap A (10% acetic anhydride, 10% pyridine in tetrahydrofuran (v/v)) and Cap B (1.25 g 4-(dimethylamino)pyridine in 50 mL of anhydrous pyridine). The coupling time for nucleoside β-cyanoethylphosphoramidites was 360 s using the synthesis reagents listed above for the methylphosphonamidites, or 120 s using a solution of 1*H*-tetrazole as the activating agent and standard synthesis reagents purchased from Glen Research Inc. Fluorescein phosphoramidite coupling times were 10 min using standard synthesis reagents. Derivatization of oligonucleotide **4** with the 4-(2-aminooxyethoxy)-2-(ethylureido)quinoline (AOQ) group was performed by Dr. Tomoko Hamma using methods reported previously (*5*).

Deoxyribo and 2′-*O*-methylribo diester oligonucleotides were deprotected in 0.4 mL of concentrated ammonium hydroxide for 5 h at 65 °C in a 4.5 mL autosampler vial. After cooling, the supernatant was removed, and the support was washed twice with 0.2 mL aliquots of 50% aqueous acetonitrile. The combined supernatant and washings were evaporated to dryness. The methylphosphonate containing oligo-2′-*O*-methylribonucleotides were removed from the support by incubation in 0.4 mL of concentrated ammonium hydroxide for 2 h at room temperature in a 4.5 mL autosampler vial. The support was washed as above, and the combined supernatant and washings were evaporated to dryness under vacuum at room temperature. The residue was then deprotected with a solution containing 10 μL of water, 22.5 μL of acetonitrile, 22.5 μL of 95% ethanol, and 50 μL of ethylenediamine for 6 h at room temperature. The solution was cooled on ice and neutralized by addition of 600 μL of ice-cold 2 N hydrochloric acid. After neutralization, the solution was diluted into 10 mL of 2% acetonitrile in 50 mM sodium phosphate buffer at pH 5.8 (C-18 buffer A). This solution was loaded onto a C-18 SEP PAK cartridge (Waters Inc.) that had been preequilibrated with 10 mL of acetonitrile, 10 mL of 50% aqueous acetonitrile, and 10 mL of C-18 buffer A. The SEP PAK was washed with 10 mL of water, and the oligomer was eluted with 3 mL of 50% aqueous acetonitrile.

The AOQ-derivatized oligonucleotide was deprotected in a solution containing 5 μL of water, 11.25 μL of 95% ethanol, 11.25 of μL acetonitrile, and 25 μL of ethylenediamine for 1.5 h at room temperature and was immediately purified by C-18 HPLC as previously described (*5*).

The remaining oligonucleotides were purified by SAX HPLC. 10−40 A_{260} units of the crude oligomer was evaporated to dryness then dissolved in 500 μL of SAX buffer A (0.1 M Tris, 10% aqueous acetonitrile). These samples were then injected onto the SAX column, and the column was eluted with a linear gradient of 0−0.5 M sodium chloride for oligomers **1-2mp** and **2**, 0−0.75 M sodium chloride for oligomer **3**, 0−0.6 M sodium chloride for oligomer **2-1mp**, 0−0.65 M sodium chloride for oligomer **3-1mp**, and 0−1.0 M sodium chloride for fluoresceinated oligomer **3-1mp-F**. Oligonucleotide **3-2mp** was purified by PAGE on a 20% gel run under denaturing conditions. The oligomer was located by UV shadowing and was isolated by incubating the gel slice in 1 mL of a solution containing 0.1 M ammonium acetate and 20% aqueous acetonitrile overnight at 37 °C. The supernatant was evaporated to dryness and the residue was desalted on a C-18 SEP PAK cartridge as described above.

Oligonucleotides (with the exception of oligomer **1**) were analyzed by MALDI-TOF mass spectrometry: dT_{10} (*m*/*z*: calcd 2967.5, found 2968.5); **1-2mp** (*m*/*z*: calcd 4931.9, found 4931.4); **2** (*m*/*z*: calcd 5279.0, found 5279.1); **2-1mp** (*m*/*z*: calcd 5277.0, found 5277.1); **3** (*m*/*z*: calcd 4935.9, found 4936.4); **3-1mp** (*m*/*z*: calcd 4933.9, found 4934.8); **3-1mp-F** (*m*/*z*: calcd 5471.0, found 5474.1); **3-2mp** (*m*/*z*: calcd 4931.9, found 4931.8); **3-2-mp-F** (*m*/*z*: calcd 5748.1, found 5750.8); **4** (*m*/*z*: calcd 1598.0, found 1598.5); **AOQ-4-F** (*m*/*z*: calcd 2531.5, found 2534.6).

Oligonucleotide Stability in Serum. Oligonucleotides were phosphorylated by incubation of 2 × 10^{-7} mmol oligomer with 5 units of T_4 polynucleotide kinase in 10 μL of buffer that contained 60 μM γ-^{32}P-ATP, (specific activity, 100 Ci/mmol), 50 mM Tris, pH 7.6, 10 mM magnesium chloride, and 10 mM mercaptoethanol for 60 min at 37 °C. A 14 μL aliquot of the reaction mixture was diluted with 140 μL of 0.1 M imidazole buffer, pH 6.0, and 16 μL of 1 M 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide (Sigma). The solution was incubated at room temperature for 4 h after which 6.4 μL of ethylenediamine and 13 μL of 12 N hydrochloric acid were added. The pH of the solution was adjusted to 7.4 by further addition of hydrochloric acid, and the solution was incubated overnight at room temperature. The reaction mixture was diluted into 10 mL of C-18 buffer A, and the solution was loaded onto a preequilibrated C-18 SEP PAK cartridge and desalted as described above. The 5′-aminoethylphosphoramidate-derivatized oligomers were purified by electrophoresis on a 20% denaturing polyacrylamide gel. The oligomers were extracted from the gel by incubation of the gel slice with 1 mL of 0.1 M ammonium acetate, 20% aqueous acetoni-

trile overnight at 37 °C. The oligomers were then desalted on C-18 SEP PAK cartridges.

The 5′-aminoethylphosphoramidate derivatized oligomers (1.1×10^5 cpm) were each dissolved in 10 μL of RPMI medium supplemented with 10% fetal calf serum and incubated at 37 °C. One microliter aliquots were removed at various times, diluted into 4 μL of gel loading buffer, and analyzed on a 20% denaturing polyacrylamide gel. Products were visualized by phosphorimaging the wet gel. Percent intact oligonucleotide for each timepoint was quantitated using Image Quant 5.2 (Molecular Dynamics).

Oligofectamine Uptake of Fluorescent Oligonucleotides in L_{929} Fibroblasts. Mouse L_{929} fibroblast cells were plated at a density of 55 000 cells per 1.9 cm diameter slide chamber 24 h prior to the experiment. For each experiment, 1 μL of Oligofectamine (Invitrogen) was preincubated with 9 μL of serum-free Eagle's minimum essential media (EMEM) for 10 min at room temperature. For oligonucleotide **3-1mp-F**, 0.1 nmol was resuspended in 90 μL of serum-free EMEM, then mixed with 10 μL of preincubated Oligofectamine/EMEM and incubated at room temperature for 20 min. The cells were washed twice with 500 μL of serum-free EMEM and incubated with a solution that contained 400 μL of serum-free EMEM and 100 μL of the preincubated oligonucleotide/Oligofectamine mixture for 4 h in a 37 °C humidified CO_2 incubator. Prior to viewing, the live cells were washed twice with 1 mL of Hanks Balanced Salt Solution (HBSS), and coverslips were mounted with HBSS. The live cells were viewed on an inverted Ziess fluorescence microscope. Phase contrast and green fluorescence images of the cells treated with fluorescent oligonucleotide with or without Oligofectamine were taken at both 40× and 100× magnification.

Oligonucleotide Stability in Mouse L_{929} Fibroblasts. Oligonucleotides were phosphorylated by incubating 2.5×10^{-6} mmol oligonucleotide with 15 units T_4 polynucleotide kinase in 15 μL of buffer that contained 250 μM γ-^{32}P-ATP, (specific activity, 10 Ci/mmol), 50 mM Tris, pH 7.6, 10 mM magnesium chloride, and 10 mM mercaptoethanol overnight at 37 °C. The labeled oligomers were purified by electrophoresis on a 20% denaturing polyacrylamide gel and desalted as described above. The L_{929} cells were plated at a density of 70 000 cells/well in 12-well tissue culture plates 24 h prior to the experiment. For each timepoint, 4 μL of Oligofectamine was incubated with 6 μL of serum-free EMEM for 10 min at room temperature. For each timepoint, 0.25 nmol of oligonucleotide was resuspended in 90 μL of serum-free EMEM and mixed with 10 μL of preincubated Oligofectamine/EMEM and incubated for 20 min at room temperature. The cells were washed twice with 500 μL of serum-free EMEM and incubated with a solution containing 400 μL of serum-free EMEM and 100 μL of the preincubated oligonucleotide/Oligofectamine mixture for 4 h in a 37 °C humidified CO_2 incubator. After 4 h of incubation, all cells were washed twice with 500 μL of serum-free EMEM. At 4 h and beyond, the cells for the 8 and 24 h timepoints were incubated in 1 mL of EMEM containing 10% fetal calf serum. The cells were again washed twice with 500 μL of serum-free EMEM, then harvested by brief incubation with 500 μL of 50% aqueous acetonitrile, collected by scraping with a pipet tip, and stored at −20 °C until all timepoints were taken. The harvested cells in 50% acetonitrile were then incubated at −80 °C for 1 h to improve lysis. The majority of the cell debris was pelleted by centrifugation in a tabletop microcentrifuge at maximum speed for 3 s. The supernatants were removed and quantitated by scintillation counting. Equivalent counts (about 550 cpm/lane) of each oligonucleotide timepoint were run on a 20% denaturing polyacrylamide gel. Gel-purified, ^{32}P-labeled oligonucleotide stocks (4500 cpm/lane) were run as T_0 controls. Products were visualized by phosphorimaging the dried gels overnight.

Oligonucleotide Conjugation to Tat Peptide via 2, 2′-Dithiodipyridine. Cystamine dihydrochloride was exchanged on Amberlite quaternary amine resin (Fisher). Amberlite resin (5 g) was prepared in 20 mL of 0.5 N sodium hydroxide, poured into a 1.25 cm diameter glass column, and then equilibrated with 30 mL of 0.5 N sodium hydroxide, 50 mL of 0.1 N sodium hydroxide, and 200 mL of water. Cystamine dihydrochloride (3 mmol, 675 mg) was dissolved in deionized water and passed over the equilibrated Amberlite resin. Free cystamine was collected, evaporated, and stored at 4 °C.

Controlled-pore glass (CPG) support-bound dT_{10} (Scheme 1, **1.1**) was reacted with 81.7 mg (0.5 mmol) of carbonyldiimidazole in 1 mL of anhydrous acetonitrile for 2 h at room temperature in an ABI synthesis column. The support was washed with 10 mL of anhydrous acetonitrile and reacted with 3.4 mg of free cystamine in 200 μL of anhydrous acetonitrile at room-temperature overnight in a small Reactivial. The support was transferred back to the synthesis column and washed with 10 mL of anhydrous acetonitrile and dried on a vacuum line. The disulfide bond of the cystamine derivative was reduced by passing 1 mL of 100 mM dithiothreitol (DTT) in 50% aqueous acetonitrile through the column for 2 h at room temperature. The support was washed with 10 mL of 50% aqueous acetonitrile, followed by 10 mL of acetonitrile and dried. The support was transferred to a small Reactivial and incubated at 37 °C for 3 days in 100 μL of 0.05 M sodium phosphate buffer containing 50% acetonitrile and saturated with 6 mg of 2,2′-dithiodipyridine (Fluka). The support was then washed with 10 mL of 50% aqueous acetonitrile followed by 10 mL of acetonitrile and dried. The pyridyl disulfide-derivatized dT_{10} (Scheme 1, **1.5**) was cleaved from the support by treatment with 0.4 mL of concentrated ammonium hydroxide for 2 h at room temperature. Full-length **1.6** was purified by C-18 HPLC. Each step of the derivatization was monitored by deprotecting a small amount of the support in 100 μL of concentrated ammonium hydroxide for 1 h. The oligonucleotide derivatizations were confirmed by C-18 HPLC and by MALDI-TOF mass spectrometry: **1.3** (*m*/*z*: calcd 3147.5, found 3146.8); **1.4** (*m*/*z*: calcd 3072.4, found 3072.2); **1.6** (*m*/*z*: calcd 3181.4, found 3182.6). Purified **1.6** (0.2 A_{260} units) was reacted with a 2-fold molar excess of Tat peptide in 5 μL of 50% aqueous acetonitrile overnight at room temperature. Conjugation of the oligonucleotide with Tat resulted in a substantial change in the mobility of the oligonucleotide when the reaction mixture was analyzed on a 20% denaturing polyacrylamide gel as detected by UV shadowing. The presence of the Tat−oligonucleotide conjugate in the reaction mixture was further confirmed by MALDI-TOF mass spectrometry: **1.7** (*m*/*z*:calcd 4891.5, found 4890.1).

The above protocol was used for the conjugation of oligonucleotide **3-2mp-F** with the Tat peptide except the reaction time in DTT was decreased to 30 min. Also, the majority of the pyridyl disulfide oligonucleotide **3-2mp-F** was released from the CPG support during the pyridyl disulfide reaction and was recovered from solution. The pyridyl disulfide derivatized oligonucleotide, **3-2mp-F**, was deprotected with ethylenediamine as described above for 2′-*O*-methyl methylphosphonate-containing oligonu-

[a] The notations "**mr-**" and "**d-**" denote 2′-*O*-methyl and deoxy sugars, respectively. Methylphosphonate linkages are denoted by "**p**" within the sequence, and the "**#mp**" suffix on the oligo name. **T*p** is 5-fluorescein derivative of deoxythymidine, whose structure is shown in Scheme 1, and **Fp** is a derivative of 6-carboxyfluorescein, whose structure is shown in Scheme 2.

cleotides, purified by C-18 HPLC, and reacted with the Tat peptide as above. The presence of Tat-conjugated **3-2mp-F** was confirmed by MALDI-TOF mass spectrometry: (*m*/*z*: calcd 7670.2, found 7674.6).

Oligonucleotide Conjugation to Tat Peptide via 4-(2-Aminooxyethoxy)-2-(ethylureido)quinoline. Tat peptide (0.5 mg) was reacted with 0.2 M bromoacetone in 50 μL of acetonitrile overnight at room temperature. The keto-Tat peptide product (Scheme 2, **2.4**) was purified by C-18 HPLC using a 20 mL linear gradient of 2−35% acetonitrile in 0.1% TFA at a flow-rate of 1.0 mL/min and analyzed by MALDI-TOF mass spectrometry: (*m*/*z*: calcd 1879.0, found 1878.3). The peptide was stored dry at −20 °C.

Approximately 9.4 μg of keto-Tat peptide was reacted with 0.1 A_{260} unit of oligonucleotide **AOQ-4-F** (Scheme 2, **2.1**) in the presence of 0.09 A_{260} unit of a dT_{21} in a total volume of 10 μL of 50% aqueous acetonitrile for 1 h at room temperature. Analysis of the reaction mixture by MALDI-TOF mass spectrometry confirmed the formation of the conjugate, **Tat−4-F** (*m*/*z*: calcd 4390.6, found 4392.0).

RESULTS AND DISCUSSION

Oligonucleotides containing 2′-*O*-methylribonucleotides have been shown to have high binding affinity for RNA targets (*2*, *3*, *7*−*11*). Further modification with alternating methylphosphonate linkages has been shown to impart nuclease resistance to oligo 2′-*O*-methylribonucleotides while maintaining high binding affinity for complementary RNA (*1*, *2*). Recent reports suggest that oligo-2′-*O*-methylribonucleotides have some level of nuclease resistance (*12*−*14*) compared to oligodeoxyribonucleotides. Consequently incorporation of one or few methylphosphonate linkages into an oligo- 2′-*O*-methylribonucleotide already possessing partial nuclease resistance may be sufficient to impart nuclease resistance in vitro and in the cell. To test this possibility, we prepared oligo-2′-*O*-methylribonucleotides that contain one (Figure 1) or two methylphosphonate linkages at the 3′-end of the molecule and studied their uptake by and stability within cells in culture.

Oligo-2′-*O*-methylribonucleotides and Their Methylphosphonate Derivatives. The sequences of the three antisense oligo-2′-*O*-methylribonucleotides used in this study are shown in Table 1. Oligomer **1**, a 15-mer that is complementary to nucleotides 21−35 (GenBank accession number NC_001802) of the TAR element of HIV-1 RNA, binds with high affinity to this site (*1*, *2*). Oligomers **2**, a 16-mer, and **3**, a 15-mer, are complementary to nucleotides 7370−7385 and 7362−7385, respectively, of the Rev Response Element (RRE) of HIV-1 RNA (GenBank accession number NC_001802). Like the anti-TAR oligomer, oligomers 2 and 3 bind with high affinity to their target RNA in vitro under essentially physiological conditions, that is at 37 °C in pH 7.0 buffer containing 0.1 M sodium chloride (unpublished data).

The sequences of the methylphosphonate derivatives of these oligonucleotides are also shown in Table 1. Oligomers **1-2mp** and **3-2mp** contain two methylphosphonate linkages separated by a phosphodiester linkage at their 3′-end. Oligomers **2-1mp** and **3-1mp** contain a single 3′-terminal methylphosphonate linkage.

Oligomers **1**, **2** and **3** were synthesized using commercially available, protected 2′-*O*-methylribonucleoside-3′-*O*-β-cyanoethyl-(*N*,*N*-diisopropyl)phosphoramidites. These oligomers were deprotected by treatment with concentrated ammonium hydroxide at 55 °C and were purified by strong anion exchange (SAX) HPLC. The methylphosphonate-derivatized oligomers were prepared using commercially available 2′-*O*-methylribonucleoside-3′-*O*-methylphosphonamidites. To avoid cleavage of the methylphosphonate linkages during deprotection, the oligomers were treated briefly with concentrated ammonium hydroxide at room temperature followed by treatment with ethylenediamine at room temperature (*2*). These oligonucleotides were purified either by SAX HPLC or by preparative polyacrylamide gel electrophoresis.

Stability of Oligo-2′-*O*-methylribonucleotides in Serum. The stabilities of the 5′-[^{32}P]-labeled oligonucleotides in RPMI culture medium containing 10% fetal calf serum (FCS) was determined. To prevent possible loss of label due to serum phosphatase activity, the 5′-terminal phosphate group was converted to its 2-aminoethyl phosphoramidate derivative by reaction with ethylenediamine in the presence of 1-ethyl-3-[3(dimethylamino)propyl]carbodiimide (*2*). The labeled oligonucleotides were incubated in RPMI medium containing 10% FCS for up to 24 h at 37 °C. The reaction mixtures were then analyzed by polyacrylamide gel electrophoresis, and the gels were visualized by phosphorimaging.

Figure 2, panel A, compares the stability of all-phosphodiester oligonucleotide **1** with that of oligomer **1-2mp**, which contains two alternating methylphosphonate linkages at it's 3′ end. As shown in panel E, which shows the percentage of intact oligomer versus time, essentially all of **1-2mp** remains intact after a 2 h incubation, whereas only 18% of intact oligomer **1** is

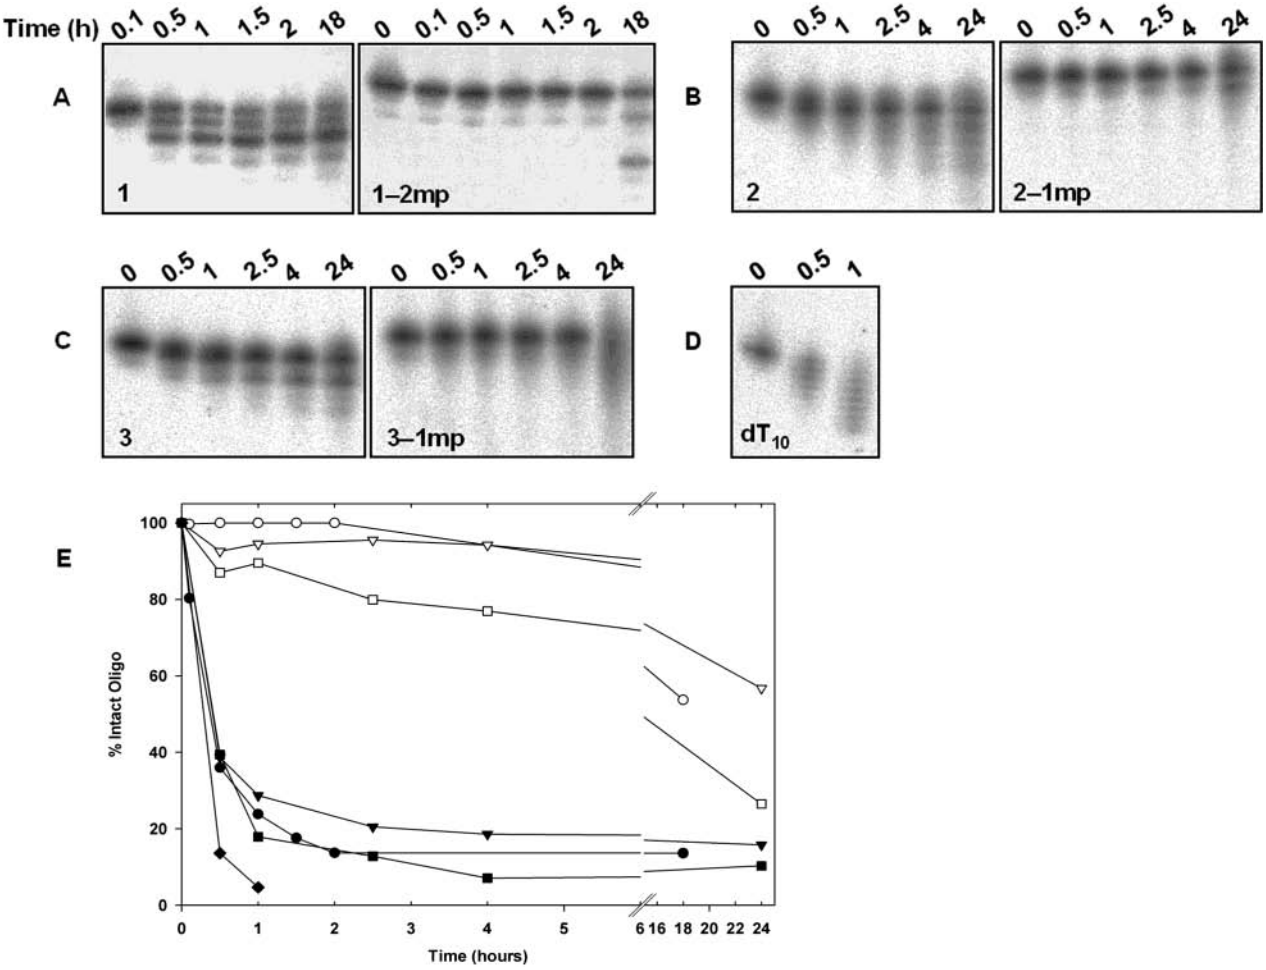

Figure 2. Stabilities of oligonucleotides in 10% fetal calf serum. ^{32}P-labeled oligonucleotides were incubated in medium containing 10% serum for the indicated lengths of time, and the reaction mixtures were analyzed by polyacrylamide gel electrophoresis. The gels (A) **1** vs **1-2mp**; (B) **2** vs **2-1mp**; (C) **3** vs **3-1mp**; (D) dT_{10} were visualized by phosphorimaging. (E) Quantitation of percent intact oligonucleotide at each timepoint: oligonucleotide **1** (●), **1-2mp** (○), **2** (▼), **2-1mp** (▽), **3** (■), **3-1mp** (□), **d−T$_{10}$** (◆).

observed. Even after an 18 h incubation, approximately 55% of **1-2mp** remains intact.

Oligomers **2-1mp** and **3-1mp**, each of which contains a single 3′-methylphosphonate linkage, display stabilities similar to that of **1-2mp** (Figure 2B and C). Thus after a 2 or 4 h incubation, between 80% to 95% of these oligomers remain intact. Even after a 24 h incubation, between 30% and 60% of each oligomer is observed intact. As was the case for oligomer **1**, the all-phosphodiester oligomers **2** and **3** were degraded approximately 80% after 2 h of incubation. However, consistent with previous findings, the rates of degradation of these all-phosphodiester oligo-2′-*O*-methylribonucleotides were significantly less than that of dT_{10}, an all-phosphodiester oligodeoxyribonucleotide that was 80% degraded after 0.5 h of incubation (Figure 2D and E).

These data are consistent with our previous results for the serum stability of a methylphosphonate-derivatized hairpin oligo-2′-*O*-methylribonucleotide (*4*) and with oligodeoxyribonucleotides having a 3′-terminal methylphosphonate linkage (*15*). The combined results show that methylphosphonate linkages located in the 3′-terminal portion of the oligomer can impart considerable protection against degradation by 3′-exonuclease activity found in mammalian sera. Furthermore, addition of a single methylphosphonate linkage at the 3′ end of oligonucleotides **2** and **3** is sufficient to significantly enhance the serum exonuclease resistance of the 2′-*O*-methyl sequences (Figure 2E) and addition of a second (alternating) methylphosphonate linkage to oligo **3-1mp** did not further enhance the nuclease resistance of the oligomer (data not shown). In separate studies, we have found that the single methylphosphonate linkage in either oligomer **2-1mp** or **3-1mp** does not perturb binding of the oligomer with its RRE RNA target (unpublished data)

Stability of Oligo-2′-*O*-methylribonucleotides in Mouse L$_{929}$ Fibroblasts. We next examined the stability of the oligo-2′-*O*-methylribonucleotides and their methylphosphonate derivatives in mouse L_{929} fibroblasts. Cationic lipids are commonly used to transfect oligonucleotides into cells in culture (*16*, *17*). Complexes of Oligofectamine, a cationic lipid, and ^{32}P-labeled oligonucleotides **2**, **2-1mp**, **3**, **3-1mp**, or dT_{15} were prepared in serum-free medium. Mouse L_{929} cells were incubated with the complexes for 4 h at 37 °C after which the cells were washed with serum-free EMEM and incubated an additional 0, 4, or 20 h with fresh oligonucleotide-free medium. No morphological changes in the cells indicative of toxicity were observed even after 24 h of incubation. The cells were then washed and lysed, cell debris were removed by centrifugation, and the amounts of radioactivity from the oligonucleotides were measured by scintillation counting. The results are shown in Table 2.

Introduction of a single methylphosphonate linkage reduces the net charge of the oligonucleotide by one, which might be expected to affect the uptake of oligonucleotides in the presence of cationic lipids. This appears to be the case for oligonucleotides **2** versus **2-1mp**, as

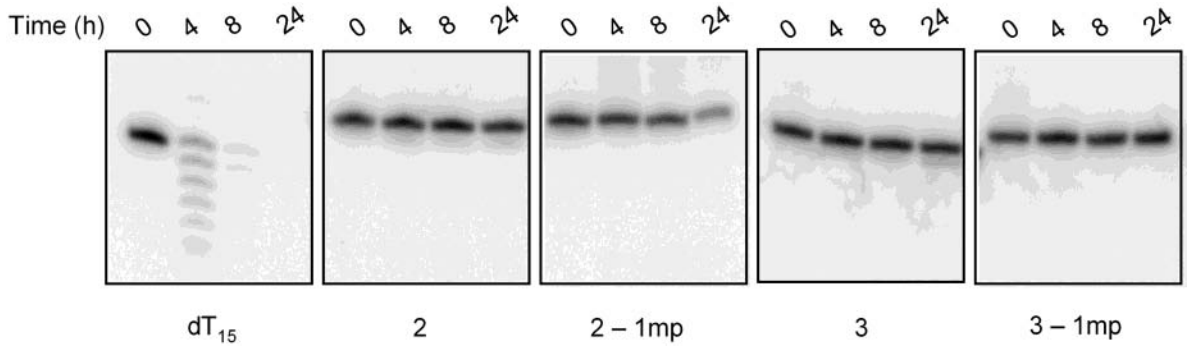

Figure 3. Stabilities of oligonucleotides in mouse L_{929} cells in culture. Mouse L_{929} fibroblasts were incubated with Oligofectamine complexes of the ^{32}P-labeled oligonucleotides for the indicated lengths of time. Lysates from the washed cells were analyzed by polyacrylamide gel electrophoresis, and the gels were visualized by phosphorimaging.

Table 2. Oligonucleotide Recovery from L_{929} Cell Lysates[a]

	oligonucleotide				
	2	**2-1mp**	**3**	**3-1mp**	dT_{15}
pmols recovered	4.61	1.14	11.8	11.8	0.335

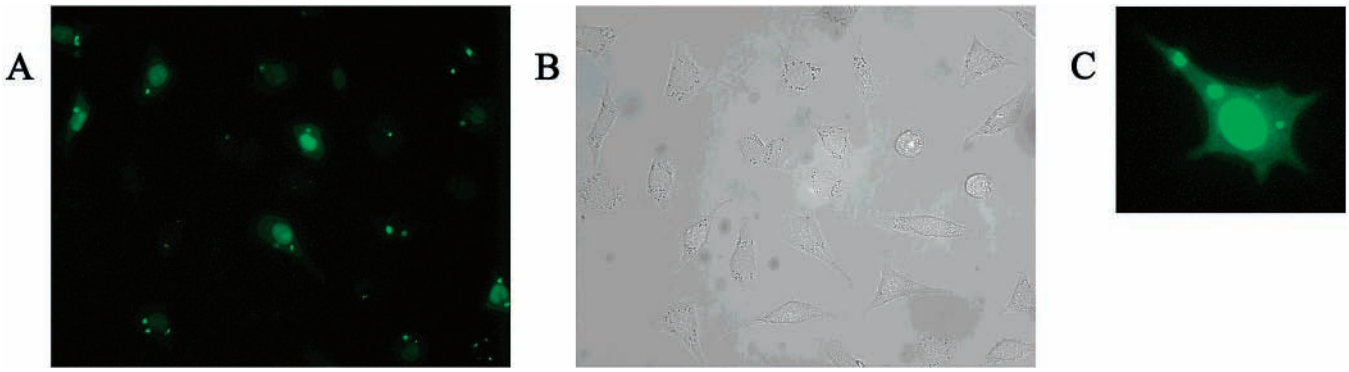
[a] pmol of oligonucleotide recovered after Oligofectamine delivery into L_{929} cells. Quantitation based on scintillation counts of cell lysates after 4 h of incubation.

introduction of a single methylphosphonate linkage results in a significant decrease in the uptake of the oligonucleotide/Oligofectamine complex as determined by oligonucleotide recovery after 4 h (Table 2). However, essentially no difference in uptake is seen for oligonucleotides **3** versus **3-1mp**, which also differ by a single negative charge. These observations would suggest that in addition to overall charge, oligonucleotide sequence and chain length also contribute to cationic lipid-mediated uptake. Consistent with this idea is the observation that oligonucleotides **2-1mp** and **3**, which both have a net negative charge of −14 but differ in their size and sequence, show significantly different uptake when complexed with Oligofectamine.

To determine the extent of degradation of each oligonucleotide, radioactivity from the cell lysates was analyzed by denaturing polyacrylamide gel electrophoresis. The phosphorimages of these gels are shown in Figure 3. Similar to the behavior of dT_{10} in the in vitro serum stability assay (Figure 2), the oligodeoxyribonucleotide dT_{15} was degraded rapidly to give a "ladder" of oligonucleotides each differing by one nucleotide unit. The decreasing intensities of the shorter oligonucleotides in this ladder suggest that degradation occurs in a stepwise manner starting at the 3′-end of the dT_{15}. Such behavior would be consistent with the activity of a 3′-exonuclease. Only 40% of recovered dT_{15} oligonucleotide remains intact after 4 h incubation in L_{929} cells. Unlike the oligodeoxyribonucleotide, both the oligo-2′-*O*-methylribonucleotides **2** and **3**, as well as their methylphosphonate derivatives **2-1mp** and **3-1mp**, were remarkably resistant to cellular nuclease degradation. Due to low oligonucleotide recovery of sequence **2-1mp** after 24 h cell incubation, the corresponding lane in Figure 3 is underloaded with respect to adjacent lanes. As expected, the methylphosphonate-containing oligonucleotides **2-1mp** and **3-1mp** were recovered intact, with no evidence of degradation throughout the 24-h experiment Surprisingly however, similar results were seen with the all-phosphodiester oligomers **2** and **3**. Despite the appearance of a minor n-1 band in the later timepoints of panels **2** and **3** in Figure 3, 99% of the recovered oligo-2′-*O*-methylribonucleotide is full-length even after 24 h of incubation with L_{929} cells. This behavior, which is in contrast to that seen in the in vitro serum stability assay (Figure 2), suggests that the oligonucleotides may be protected from degradation by the cationic lipids and/or their exposure to exonuclease activity is limited within this particular intracellular environment.

Cationic lipids generally deliver oligodeoxyribonucleotides and oligodeoxyribonucleotide phosphorothioates to the nucleus. The localization of the fluorescein derivative of methylphosphonate oligo-2′-*O*-methylribonucleotide **3-1mp** was determined using fluorescence microscopy. The fluorescein derivative of **3-1mp** was synthesized using a commercially available fluorescein phosphoramidite and after deprotection was purified by SAX HPLC. The resulting fluorescein-derivatized oligomer, **3-1mp-F**, was complexed with Oligofectamine and incubated with mouse L_{929} fibroblasts for 4 h at 37 °C. To avoid potential artifacts due to fixing (*18*), the live cells were then washed and viewed by fluorescence microscopy as previously described (*19*). Panels A and B of Figure 4 show a representative field of cells at 40× magnification, with approximately 70% (19/26) of the live cells exhibiting fluorescence, and 40% (11/26) of the cells exhibiting nuclear fluorescence. As shown in Figure 4C, the most intense fluorescence was observed in the nucleus, with the exception of several punctate regions that may represent endosomal entrapment of the oligonucleotide/Oligofectamine complex. Additionally, weak fluorescence was observed in the cytoplasm. These results are similar to those seen for cationic lipid complexes of fluorescently derivatized all phosphodiester oligo-2′-*O*-methylribonucleotide **4-F** (data not shown). Primary localization of the oligo-2′-*O*-methylribonucleotide/Oligofectamine complexes in the nuclear compartment may explain their impressive stability in L_{929} cells versus the in vitro serum assay.

Tat Peptide−Oligonucleotide Conjugates. The experiments described above show that Oligofectamine can be used to deliver oligo-2′-*O*-methylribonucleotides and their methylphosphonate derivatives to the nuclei of mouse fibroblasts. Recent research with "protein transduction domains" (PTDs) has led to the discovery of several peptides that are reported to translocate conjugated molecules, including oligonucleotides, through the plasma membrane. This group of so-called cell-penetrating peptides contains highly basic regions from some well-known proteins including Antennapedia, VP22 herpes virus protein, and HIV−Tat (*20*). Although the mechanism by which cell-penetrating peptides deliver their cargo to the nucleus is not well understood and is the subject of some debate (*18*, *21*−*25*), a number of studies have reported enhanced antisense activity of



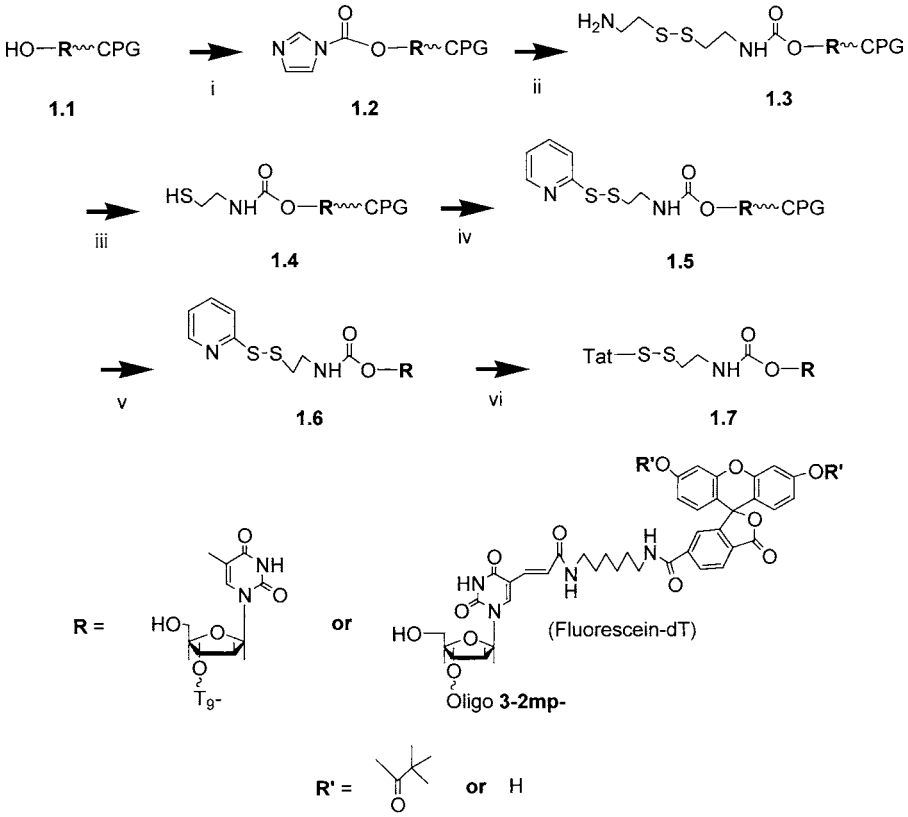


Figure 4. Fluorescence photomicrograph of mouse L_{929} fibroblasts treated with a complex of Oligofectamine and oligonucleotide **3-1mp-F**. Panels A and B show a representative field of cells at 40× magnification in fluorescence and phase-contrast modes, respectively. Panel C, single cell, 100× magnification.

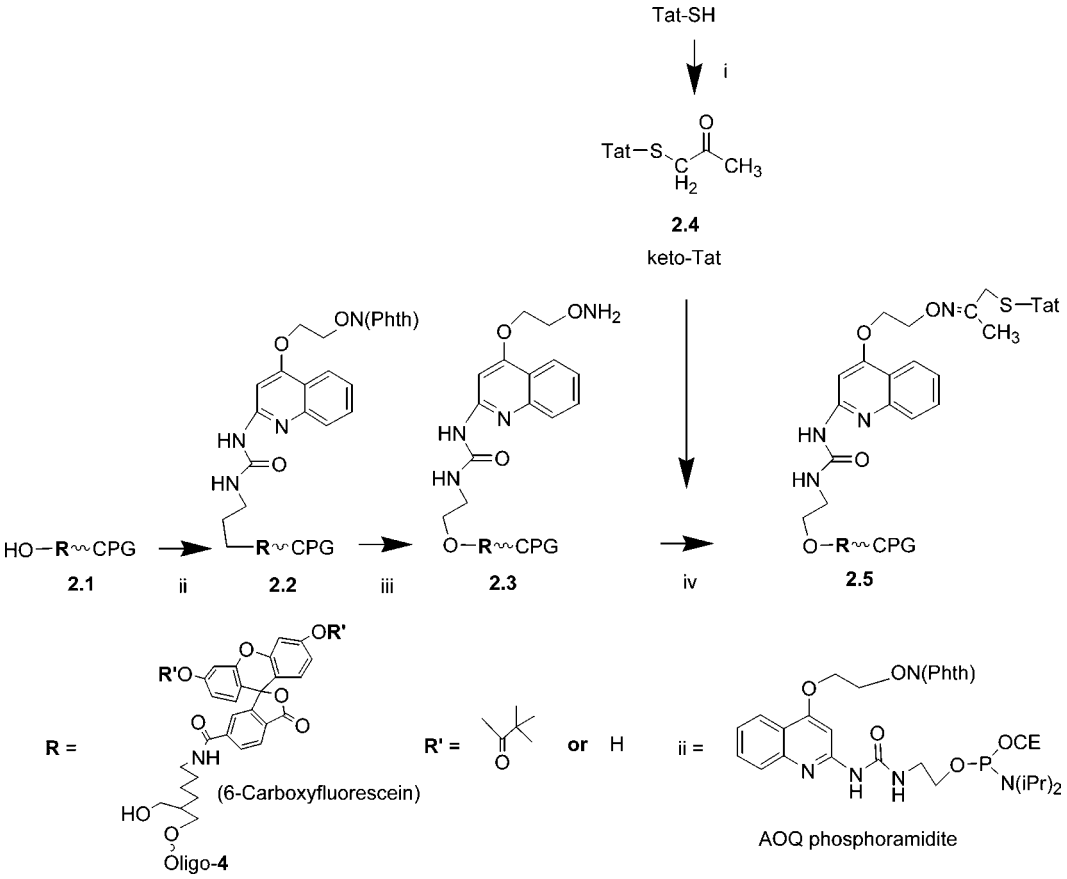
Scheme 1. Tat-Oligonucleotide Conjugate Formation via Dithiodipyridine[a]



[a] Reagents: (i) carbonyldiimidazole; (ii) cystamine; (iii) dithiothreitol; (iv) dithiodipyridine; (v) deprotection and purification (see methods); (vi) Tat-SH.

oligonucleotides (*26*−*29*) and peptide nucleic acids (*30*−*32*) when covalently conjugated to cell-penetrating peptides. To explore the potential of this alternative delivery strategy, we attempted to prepare Tat derivatives of fluorescently labeled oligo-2′-*O*-methylribonucleotides and study their uptake by mouse L_{929} fibroblasts in culture.

Two approaches were used to synthesize Tat-conjugated oligonucleotides. The first, which is outlined in Scheme 1, employed disulfide-coupling chemistry to attach Tat to the oligonucleotide. We first attempted to carry out the derivatization and coupling chemistry on CPG-bound dT_{10}. The potential advantage of this approach is the oligonucleotide would remain bound to the CPG throughout the entire conjugation process, allowing excess reagents to be washed away and thus requiring minimal purification steps. Support-bound dT_{10} (Scheme 1, **1.1**) was reacted with carbonyldiimidazole to give the 5-imidazole carbamate intermediate, **1.2**, which was then converted to the 5′-cystaminyl derivative, **1.3**. The disulfide bond of **1.3** was reduced with dithiothreitol, and the resulting free sulfhydryl group was reacted with 2,2′-dithiodipyridine to give 5′-pyridyl disulfide derivatized oligonucleotide **1.5**. The progress of each derivatization step was monitored by deprotecting a small portion of the support and analyzing the reaction mixture by C-18 reversed phase HPLC. The compositions of the intermediates were also confirmed by MALDI-TOF mass spectrometry.

We encountered problems when we attempted to couple the C-terminal cysteine sulfhydryl group of Tat peptide (GRKKRRQRRRPPQC), to the oligonucleotide by exchange with the pyridylsulfide group. It appeared that the resulting conjugate strongly adhered to the CPG after ammonium hydroxide cleavage because no oligonucleotide could be recovered from the support. To circumvent this problem, we removed the 5′-pyridyl disulfide-deriva-

Scheme 2. Tat−Oligonucleotide Conjugate Formation via 4-(2-Aminooxyethoxy-2-(ethylureido)quinoline[a]

[a] Reagents: (i) bromoacetone; (ii) AOQ phosphoramidite; (iii) deprotection and purification (see methods); (iv) keto-Tat (**2.4**).

tized dT_{10}, **1.5**, from the support and purified it by C-18 reversed phase HPLC. The purified oligonucleotide, **1.6**, was then reacted with an excess of Tat peptide. Examination of the reaction mixture by polyacrylamide gel electrophoresis showed the presence of a new compound whose reduced electrophoretic mobility was consistent with formation the conjugate. Analysis of the reaction mixture by MALDI-TOF mass spectrometry confirmed the presence of the Tat−dT_{10} conjugate, **1.7**, and suggested that all of the dT_{10} had been converted to conjugate.

The same reaction protocol was applied to the fluorescein conjugate of oligomer **3-2mp**, **3-2mp-F**. This oligonucleotide was prepared using a commercially available fluorescein-dT phosphoramidite. The support-bound oligomer, **1.1**, was converted to its 5′-pyridyl disulfide derivative, **1.6**, as described above for the preparation of the dT_{10} derivative. Reaction of purified oligonucleotide with the Tat peptide resulted in almost immediate formation of a sticky orange precipitate. Similar behavior has been reported for the reaction of Tat peptide with the pyridyl disulfide derivatives of rhodamine- and fluorescein-conjugated oligonucleotides (*33*, *34*). Analysis of the reaction mixture by MALDI-TOF mass spectrometry confirmed the presence of the **Tat-3-2mp-F** conjugate. Precipitation did not occur when Tat peptide was added to fluorescein derivatized oligomer that lacked a 5′-pyridyl disulfide group, suggesting that precipitation was a property of the covalent Tat-oligonucleotide conjugate. This aggregation phenomenon proved to be an insurmountable problem in our hands and essentially prevented the purification of the conjugate in any useful amounts by C-4, C-8, or C18 reversed phase HPLC, strong anion exchange HPLC, gel filtration, diethylaminoethyl (DEAE), or carboxymethyl (CM) Sephadex. When the fluorescinated Tat−oligonucleotide conjugate was applied to DEAE or CM Sephadex loaded in a glass column, most of the conjugate appeared as a visible orange band, which could not be eluted from the column. In addition to this aggregation problem, we found that the **Tat−3-2mp-F** conjugate adhered to plastic and glass tubes, behavior that has also been observed with Tat conjugates of peptides (*35*).

In a second approach, we used oxime formation to conjugate Tat to a fluorescein derivative of penta-2′-*O*-methylribonucleotide **4**. Oligomer **4** was synthesized on controlled pore glass and derivatized with 6-carboxyfluorescein phosphoramidite to give support-bound oligomer **2.1** as shown in Scheme 2. The hydroxyl group of **2.1** was reacted with 4-(2-aminooxyethoxy-2-(ethylureido)quinoline phosphoramidite (*5*) to give 4-(2-aminooxyethoxy-2-(ethylureido)quinoline (AOQ) derivative **2.2**. The AOQ-derivatized oligomer was deprotected and purified by C-18 reversed phase HPLC to give oligomer **2.3**. Conjugation of **2.3** with keto-Tat derivative **2.4**, formed by reaction of Tat peptide with bromoacetone (*5*), gave Tat conjugate **2.5**, which precipitated from the reaction mixture. We found that this precipitation could be prevented by running the reaction in the presence of an excess of dT_{21}. Under these conditions, the reaction solution remained clear. The extent of the reaction could be determined by following the disappearance of AOQ-oligomer **2.3** on C-18 reversed phase HPLC. Based on this criterion, the reaction appeared to go to completion. However, we were unable to observe Tat conjugate **2.5** on the HPLC column, although we could detect the presence of the conjugate in the reaction mixture by MALDI-TOF mass spectrometry.

It is unclear why the Tat conjugates of the fluorescein-derivatized oligomers are insoluble. As described above, simply mixing Tat peptide with the oligonucleotide does not result in precipitation. Rather it appears that Tat must be linked covalently with the oligonucleotide for precipitation to occur. Possibly formation of a covalent conjugate between the negatively charged oligomer and the positively charged Tat peptide promotes intramolecular electrostatic interactions between the oligomer and Tat peptide that lead to a decreased solubility of the conjugate (*36*). Consistent with this idea is the observation that addition of dT_{21} prevented precipitation of the Tat-4-F during the conjugation reaction. Under these conditions, the negatively charged dT_{21} could interact with the positively charged Tat peptide to help prevent precipitation of the conjugate. However, even in the presence dT_{21} we found that **Tat−4-F** was strongly absorbed to glass surfaces (data not shown), and this absorption served as an impediment to further studying the uptake of these oligonucleotides in cell culture.

CONCLUSIONS

Our studies show that 3′-methylphosphonate-modified oligo-2′-*O*-methylribonucleotides are stable to the 3′-exonuclease activity found in mammalian serum. These oligonucleotides may be transfected into cells in culture by complex formation with cationic lipids, which deliver the oligonucleotides to the cell nucleus. Oligonucleotides delivered in this manner can be recovered intact from the cells suggesting that they are stable in the intracellular environment. These properties, along with their ability to bind with high affinity to complementary RNA targets, suggest that 3′-methylphosphonate-modified oligo-2′-*O*-methylribonucleotides may be suitable for use as antisense agents in cell culture. Our experience with the Tat-conjugated oligonucleotides suggests that they are prone to aggregation, which makes purification difficult, and that they have high affinity for glass and plastic surfaces. These properties and the recent reports questioning the mode of uptake of Tat-conjugated molecules (*18*, *21*−*25*) suggests that caution should be used when designing Tat−oligonucleotides for uptake studies.

ACKNOWLEDGMENT

The authors thank Dr. Michael Matunis for the use of his fluorescence microscope, and members of the Matunis laboratory for their valuable assistance. We thank Dr. Tomoko Hamma for providing us with oligonucleotide **1**, and for her assistance in the preparation of the AOQ phosphoramidite. This research was supported by a grant from the National Institutes of Health, GM057140.

Cationic Oxyethylene Lipids. Synthesis, Aggregation, and Transfection Properties

Santanu Bhattacharya* and Padinjarae Vangasseri Dileep

Department of Organic Chemistry, Indian Institute of Science, Bangalore, India - 560 012. Received February 13, 2003; Revised Manuscript Received December 30, 2003

Four cationic lipids (**1**−**4**) with oligo-oxyethylene units at the linkage region between the pseudoglyceryl backbone and the hydrocarbon chains have been synthesized. Two of these lipids (**1** and **2**) have an equal number of $(CH_2CH_2O)_n$ units attached to both C-1 and C-2 positions of the pseudoglyceryl backbone, making their linkage regions similar, while the other two (**3** and **4**) are unsymmetrical in terms of the number of oxyethylene units in the linkage. Synthesis of lipids **1** and **2** involved the coupling of benzyl glycerol with the corresponding tosylates as a key step. Each of these lipids formed membranous aggregates when dispersed in water and exhibited clear thermotropic phase transitions typical of vesicular assemblies. The lipids **1**−**4** exhibited enhanced biological activities as gene transfer agents compared to their non-oxyethylene diether analogue, DHTMA. Transfection experiments using aqueous suspensions of these lipids and also their mixtures with cholesterol or dioleoyl phosphatidyl ethanolamine (DOPE) were performed on HeLa cells. The best transfection activity was demonstrated by unsymmetrical lipid **3**, which had two oxyethylene units only at the C-1 position of the pseudoglycerylbackbone.

INTRODUCTION

The recent concept of "the genetic material itself as the drug" identifies the need for efficient DNA delivery vectors (*1*, *2*). This has led to the development of many synthetic gene transfer vectors; among them are the formulations based on cationic lipids (*3*−*8*). Due to the ease of preparation and low levels of toxicity and immunogenic responses, cationic lipid-mediated transfection offers wide scope, especially in in vivo experiments (*9*) and clinical trials (*10*). However, the transfection efficiency of cationic lipid formulations has not yet been optimized to its maximum level (*11*) Due to this, the design and synthesis of novel cationic lipid molecules capable of efficient gene delivery is attracting much attention (*12*−*14*).

We have been investigating the role of various molecular level modifications in different synthetic lipids on their membrane properties and further influence on gene delivery events. We have observed that the linkage functionality between the hydrocarbon chain and the polar headgroup of a lipid molecule has significant influence on its aggregation behavior in water (*15*). Since this linkage is in a dynamic interfacial region in an aqueous suspension, even small changes at the linkage modulate the aggregation properties significantly. Such small modulations at the linkage regions of a cationic lipid is also known to have pronounced effects on its transfection efficiencies (*4*, *16*, *17*).

Along this direction, recently we have designed four cationic lipids **1**−**4** (Figure 1) having hydrophilic oxyethylene ($(CH_2CH_2O)_n$) groups at the linkage region (*18*). We envisaged the design of two types of oxyethylene-bearing cationic lipids. In one case we introduced an equal number of $(CH_2CH_2O)_n$ units to both C-1 and C-2 positions of the pseudoglyceryl backbone. In the other case, only one $(CH_2CH_2O)_2$ unit was introduced either at the C-1 or C-2 positions of the backbone, to result in an unsymmetrical system. Though synthetically more demanding, an ether linkage functionality was chosen between the pseudoglycerol backbone and the hydrophobic chains mainly due to the enhanced biological activities of cationic lipids having ether linkages compared to their ester analogues in gene delivery events (*16*, *17*), and also due to the enhanced chemical stability of ether bonds.

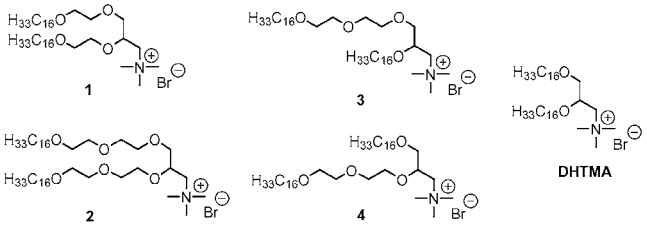

Figure 1. Molecular structures of the cationic lipids mentioned in the present study.

Though unnatural, such synthetic lipid molecules form an important class. The incorporation of $(CH_2CH_2O)_n$ groups at the linkage regions is expected to widen the membrane-bound water layer in such aggregates. Such variations at the interfacial region should in turn influence the association of such assemblies with various biomolecules. Ethyleneoxy units were chosen to be the appropriate hydrophilic linkage functionality in these lipid molecules by considering its literature precedence (*19*, *20*). Incorporation of oxyethylene units in lipid molecules have been attempted before, also for achieving some specific biological functions (*21*, *22*). We observed a pronounced enhancement in the gene delivery capabilities of cationic lipids upon incorporation of oxyethylene units at the linkage region (*23*). In this paper, we describe the detailed, optimized synthetic procedures of these biologically important compounds. We also present their aggregation properties and biological activities. To put

our results in appropriate perspective, we compare the physicochemical and biological properties of the new lipids **1**−**4** with that of DHTMA. The molecular structure of DHTMA closely resembles that of *N*-(1-[2,3-dioleyloxy]-propyl)-*N*,*N*,*N*-trimethylammonium chloride (DOTMA), an ingredient which has been used in several commercially available formulations for gene transfection.

MATERIALS AND METHODS

General. All the reagents and chemicals used in this study were of the highest purity available. Cationic lipids were synthesized and characterized fully by their IR, ^{1}H NMR, mass spectra, and elemental analysis. 1,2-Dioleoyl-*sn*-glycero-3-phosphatidylethanolamine (DOPE) was purchased from Avanti Polar Lipids. ^{1}H NMR was recorded on JEOL JNM λ-300 (300 MHz for ^{1}H) or Bruker DRX-500 (500 MHz for ^{1}H) spectrometers. Chemical shifts (δ) are reported in ppm downfield from the internal standard; TMS, in the case of proton NMR. IR spectra were recorded on a Perkin-Elmer-781 spectrometer or on a Jasco FT-IR 410 spectrometer. Mass spectra were recorded on a Kratos PCKompact SEQ V1.2.2 MALDI-TOF spectrometer. Eluents for column chromatography, MeOH, EtOAc, $CHCl_3$ and petroleum ether (60−80 fraction), were distilled before use. Solvents used for reactions were dried before use. DMF, CH_2Cl_2, CH_3CN, and Et_3N were dried over P_2O_5. Et_3N and pyridine were stored over KOH. THF, benzene, and toluene were dried over sodium benzophenone ketyl prior to use. DMSO was dried over CaH_2, vacuum distilled, and was stored over molecular sieves. The purity of all the final lipids was checked by thin-layer chromatography (TLC) on silica gel G-60 plates (Merck) prior to vesicle preparation. TLC employed chloroform/methanol mixture as the eluent as indicated in the synthesis, and spots were visualized by staining the plates with iodine vapor. All the lipids used in this study exhibited single spots on TLC plates.

***O*-Hexadecyl Monoethylene Glycol Tosylate (6a) and *O*-Hexadecyl Diethylene Glycol Tosylate (6a).** Either of the alcohols (ethylene glycol monohexadecyl ether or diethylene glycol monohexadecyl ether) was dissolved in CH_2Cl_2 and cooled in an ice−water bath. To this was added dry pyridine (5 equiv), and the mixture was stirred for 10 min. *p*-TsCl (2.5 equiv) was added, and the mixture was stirred at 0 °C for 15 min and then for 25−50 h at rt. At the end of the reaction, the reaction mixture was dissolved in $CHCl_3$ and washed with aq 1.2 N HCl followed by 25% $NaHCO_3$, water, and brine solution. The organic layer was dried over anhyd Na_2SO_4. The desired product was isolated by silica gel column chromatography using an EtOAc−hexane solvent mixture. The isolated yields were 82% for **6a** ($R_f \sim 0.5$ in EtOAc−hexane (8:92) solvent mixture) and 68% for **6b** ($R_f \sim 0.5$ at EtOAc−hexane (10:90) solvent mixture). ^{1}H NMR ($CDCl_3$, 300 MHz): δ: (**6a**) 0.88 (t, terminal CH_3, 3H), 1.25 (br. m, CH_2 × 13, 26H), 1.54 (p, $C_{14}H_{29}CH_2$-CH_2O, 2H), 2.45 (s, CH_3Ar, 3H), 3.39 (t, $C_{15}H_{31}CH_2O$, 2H), 3.46−3.5 (m, $C_{15}H_{31}CH_2OCH_2$, 2H), 3.54−3.57 (m,$C_{15}H_{31}$-$CH_2OCH_2CH_2O$, 2H), 3.69 (t, CH_2CH_2OTs, 2H), 4.14 (t, CH_2CH_2OTs, 2H), 7.33 (d, meta H, 2H), 7.79 (d, ortho H, 2H); MS (MALDI-TOF): Calcd for $C_{25}H_{44}O_4S$: 440.7 Found: 463.9 (M + Na^+); Anal. Calcd for $C_{25}H_{44}O_4S\cdot 0.5H_2O$: C 66.77, H 10.09 Found: C 66.73, H 9.54. (**6b**) 0.88 (t, terminal CH_3, 3H), 1.26 (br. m, CH_2 × 13, 26H), 1.48 (p, $C_{14}H_{29}CH_2CH_2O$, 2H), 2.45 (s, CH_3Ar, 3H), 3.36 (t, $C_{15}H_{31}CH_2O$, 2H), 3.59 (t, CH_2CH_2OTs, 2H), 4.13 (t, CH_2CH_2OTs, 7.32 (d, meta H, 2H), 7.79 (d, ortho H, 2H); IR (cm^{-1}): 1590 (w), 1100−1150 (br. s, O−C−O str.); MS (MALDI-TOF): Calcd for $C_{27}H_{48}O_5S$: 484.7. Found: 507.9 (M + Na^+), 523.9 (M + K^+); Anal. Calcd for $C_{27}H_{48}O_5S\cdot 0.7H_2O$: C 65.21, H 10.01. Found: C 65.18, H 9.44.

***O*-Benzyl Glycerol (8).** 1,2-*O*-Isopropylidene glycerol (10 g, 75.6 mmol) was mixed with 8.8 g (156.6 mmol, 2 equiv) of powdered KOH in 45 mL of dry benzene. The solution turned yellow and then rose red within 5 min. To that was added 18 mL (19.8 g, 156.6 mmol, 2 equiv) of benzyl chloride. The mixture was refluxed at 100 °C for 23 h. The water formed during the reaction was removed by means of a phase-separating head (Deans−Stark apparatus). Then the cooled mixture was diluted with benzene (100 mL) and washed successively with water (50 mL), 0.1 N aq HCl (50 mL), 2.5% aq $NaHCO_3$ (50 mL), and again with water. The benzene phase was dried over anhyd Na_2SO_4, and the solvent was removed under reduced pressure. The crude product, 1,2-*O*-isopropylidene glycerol benzyl ether was homogenized in 100 mL of MeOH−H_2O (2:1) and to that was added 5.75 g (30.3 mmol) of *p*-TsOH. The mixture was stirred at room temperature for 1 h. The reaction mixture was neutralized with $NaHCO_3$ powder. The mixture was filtered and washed with $CHCl_3$, and then the organic layer was evaporated under reduced pressure. Traces of the remaining acid were removed by a subsequent base workup. The concentrated organic layer was diluted with $CHCl_3$ and washed with saturated aq $NaHCO_3$ (100 mL), water (50 mL), and saturated brine (50 mL). The organic layer was dried over anhyd Na_2SO_4. A 53% yield (7.3 g) of the pure compound was obtained by column chromatography on silica gel (*24*). Compound was eluted in 5% MeOH−$CHCl_3$ ($R_f \sim 0.8$ at MeOH−$CHCl_3$ (2:98)). ^{1}H NMR ($CDCl_3$, 300 MHz): δ: 2.65 (br. s, OH, 2H), 3.45−3.7 (m, 2 × CH_2O, 4H), 3.75−4 (q, OCH_2CHOCH_2O), 4.05 (s, OCH_2Ar, 2H), 7.35 (s, Ar, 5H); IR (cm^{-1}): 3100−3650 (br., OH).

1,2-Bis(2′-hexadecyloxyethoxy)-3-benzyloxypropane (9a). *O*-Benzyl glycerol (300 mg, 1.65 mmol) in 5 mL of dry DMSO was added to a precooled DMSO suspension (5 mL) of NaH (55% in oil) (237 mg, 3.3 equiv; prewashed with dry hexane) in a two-necked flask equipped with a septum and a guard tube. The mixture was stirred for 2 h at room temperature. To that were added 1.6 g of O-hexadecyl monoethylene glycol tosylate (**11a**) (3.6 mmol, 2.2 equiv) and 150 mg of $Bu_4N^+I^-$ (0.4 mmol, 0.25 equiv) in 2 mL of DMSO through a syringe. The reaction mixture was further stirred at room temperature for 24−30 h (till the alkyl tosylate was consumed, as indicated by TLC). Once the reaction was over, the reaction mixture was diluted with EtOAc and washed with 1 N aq HCl followed by 2.5% aq $NaHCO_3$, water, and brine. The aqueous layer was extracted again with EtOAc. The organic phase was dried over anhyd Na_2SO_4. Pure compound was isolated as a pale yellowish liquid by column chromatography over silica gel using 5% EtOAc−hexane as the solvent system. The isolated yield was 880 mg (74%) ($R_f \sim 0.4$ at EtOAc−hexane (5:95)). ^{1}H NMR ($CDCl_3$, 300 MHz): δ: 0.88 (t, 2 × terminal CH_3, 6H), 1.25 (br. m, 26 × CH_2, 52H), 1.55 (p, 2 × $C_{14}H_{29}CH_2$-CH_2O, 4H), 3.41 (t, 2 × $C_{15}H_{31}CH_2O$, 4H), 3.49−3.75 (m, [2 × OCH_2CH_2O] + [2 × OCH_2CHO] + OCH_2CHOCH_2O, 13H), 4.53 (s, OCH_2Ar, 2H), 7.23−7.37 (m, Ar, 5H); IR (cm^{-1}): 1100 (br. strong, C−O−C str.); MS (MALDI-TOF): Calcd for $C_{46}H_{86}O_5$: 719.2. Found: 742.5 (M + Na^+).

1,2-Bis(2′-[2″-hexadecyloxyethoxy]ethoxy)-3-benzyloxypropane (9b). 9b was synthesized following the same procedure for that of **9a**. Pure compound was isolated in 67% yield as a colorless liquid (which forms a wax on standing) by column chromatography over silica

gel using EtOAc−hexane (15:85) as the solvent system ($R_f \sim 0.4$ at EtOAc−hexane (15:85)). ^{1}H NMR ($CDCl_3$, 300 MHz): δ: 0.88 (t, 2 × terminal CH_3, 6H), 1.20 (br. m, 26 × CH_2, 52H), 1.5 (p, 2 × $C_{14}H_{29}CH_2CH_2O$, 4H), 3.6 (t, 2 × $C_{15}H_{31}CH_2O$, 4H), 3.44−3.71 (m, [4 × OCH_2CH_2O] + [2 × OCH_2CHO] + OCH_2CHOCH_2O, 21H), 4.47 (s, OCH_2Ar, 2H), 7.17−7.28 (m, Ar, 5H); IR (cm^{-1}): 1110 (br. strong, C−O−C str.); MS (MALDI-TOF): Calcd for $C_{50}H_{94}O_7$: 806.7. Found: 829.7 ($M + Na^+$).

2,3-Bis(2′-hexadecyloxyethoxy)-1-propanol (10a). **9a** (500 mg) was dissolved in 10 mL of EtOAc-MeOH mixture in a hydrogenation setup, and to that was added 240 mg of 10% Pd−charcoal. Hydrogenation was performed for 12 h at atmospheric pressure. Then Pd−charcoal was filtered off from the reaction mixture with a sintered funnel and was washed with $CHCl_3$ and EtOAc. Solvent was evaporated under reduced pressure, and the pure compound was isolated as a slight yellow gummy solid by column chromatography over silica gel with EtOAc−hexane (1:4) as the eluting solvent ($R_f \sim 0.7$ at EtOAc−hexane (1:4) solvent mixture). The isolated yield was 380 mg (87%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ: 0.88 (t, 2 × terminal CH_3, 6H), 1.25 (br. m, 26 × CH_2, 52H), 1.55 (p, 2 × $C_{14}H_{29}CH_2CH_2O$, 4H), 3.4−3.71 (m, [2 × $C_{15}H_{31}CH_2O$] + [2 × OCH_2CH_2O] + [2 × OCH_2CHO], 16H), 3.82−3.88 (m, OCH_2CHOCH_2O, 1H); MS (MALDI-TOF): Calcd for $C_{39}H_{80}O_5$: 628. Found: 651 ($M + Na^+$), 667 ($M + K^+$); Anal. Calcd for $C_{39}H_{80}O_5$: C 74.46, H 12.82. Found: C 74.46, H 12.61.

2,3-Bis(2′-[2″-hexadecyloxyethoxy]ethoxy)-1-propanol (10b). **9b** (400 mg) was dissolved in 8 mL of EtOAc-MeOH mixture in a hydrogenation setup, and to that was added 135 mg of 10% Pd−charcoal. Hydrogenation was performed for 12 h at atmospheric pressure. Then Pd−charcoal was filtered off from the reaction mixture with a sintered funnel and was washed with $CHCl_3$ and EtOAc. Solvent was evaporated under reduced pressure and the pure compound was isolated as a yellow wax by column chromatography over silica with EtOAc−hexane (1:1) as the eluting solvent ($R_f \sim 0.7$ at EtOAc−hexane solvent (1:1) mixture). The isolated yield was 350 mg (80%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ: 0.88 (t, 2 × terminal CH_3, 6H), 1.25 (br. m, 26 × CH_2, 52H), 1.56 (p, 2 × $C_{14}H_{29}CH_2CH_2O$, 4H), 3.42 (t, 2 × $C_{15}H_{31}CH_2O$, 4H), 3.47−3.73 (m, [4 × OCH_2CH_2O] + [2 × OCH_2CHO], 20H), 3.8−3.87 (m, OCH_2CHOCH_2O, 1H); IR (cm^{-1}): 1110 (br. strong, C−O−C str.), 3400−3480 (br., OH); Anal. Calcd for $C_{43}H_{88}O_7 \cdot 0.6H_2O$: C 70.95, H 12.35. Found: C 71.04, H 12.25.

2,3-Bis(2′-hexadecyloxyethoxy)-1-propyl Tosylate (11a). 2,3-Bis(2′-[2″-hexadecyloxyethoxy]ethoxy)-1-propanol (**10a**) (130 mg, 0.2 mmol) was dissolved in 1 mL of dry CH_2Cl_2 and was cooled in an ice−water bath. To that were added 2 mL of dry pyridine and 78.8 mg of freshly recrystallized *p*-TsCl (2 equiv). The reaction mixture was stirred at 0 °C for 30 min and then for 24 h (till the starting alcohol disappeared as indicated from TLC) at room temperature. The reaction mixture was then diluted with $CHCl_3$ and was washed with water followed by 2 N aq HCl and again with water. The organic phase was washed with brine and dried over anhyd Na_2SO_4. Solvent was evaporated under reduced pressure, and pure compound was isolated (140 mg, 85%) as a white wax by column chromatography over silica gel using EtOAc−hexane solvent mixture ($R_f \sim 0.5$ at EtOAc−hexane (15:85) solvent mixture). ^{1}H NMR ($CDCl_3$, 300 MHz): δ: 0.88 (t, 2 × terminal CH_3, 6H), 1.26 (br. m, 26 × CH_2, 52H), 1.54 (p, 2 × $C_{14}H_{29}CH_2CH_2O$, 4H), 2.45 (s, CH_3Ar, 3H), 3.38−3.67 (m, [2 × $C_{15}H_{31}CH_2O$] + [2 × OCH_2CH_2O] + [2 × OCH_2CHO], 14H), 3.72 (q, OCH_2CHOCH_2O, 1H), 4.06 (dd [J = 9 Hz, 6 Hz], HCHOTs, 1H), 4.17 (dd, [J = 9 Hz, 3 Hz], HCHOTs, 1H), 7.34 (d, meta H, 2H), 7.79 (d, ortho H, 2H); IR (cm^{-1}): 1110 (br. strong, C−O−C str.)

2,3-Bis(2′-[2″-hexadecyloxyethoxy]ethoxy)-1-Propyl Tosylate (11b). 2,3-Bis(2′-[2″-hexadecyloxyethoxy]-ethoxy)-1-propanol (**10b**) (150 mg, 0.2 mmol) was dissolved in 5 mL of dry CH_2Cl_2 and was cooled in an ice−water bath. To that were added 0.09 mL (1 mmol, 5 equiv) of dry pyridine and 79.7 mg of recrystallized *p*-TsCl (2 equiv). The reaction mixture was stirred for 27 h (till the starting alcohol disappeared as indicated from TLC) at room temperature. The reaction mixture was then diluted with $CHCl_3$ and washed with water followed by 2 N aq HCl and again with water. The organic phase was washed with brine and dried over anhyd Na_2SO_4. Solvent was evaporated under reduced pressure, and pure compound was isolated as a yellow liquid by column chromatography over silica gel. Yield was practically quantitative ($R_f \sim 0.5$ at EtOAc−hexane (30:70) solvent mixture). ^{1}H NMR ($CDCl_3$, 300 MHz): δ: 0.88 (t, 2 × terminal CH_3, 6H), 1.25 (br. m, 26 × CH_2, 52H), 1.57 (p, 2 × $C_{14}H_{29}CH_2CH_2O$, 4H), 2.45 (s, CH_3Ar, 3H), 3.43 (t, 2 × $C_{15}H_{31}CH_2O$, 4H), 3.48−3.76 (m, [4 × OCH_2CH_2O] + [2 × OCH_2CHO] + [OCH_2CHOCH_2O], 19H), 4.06 (dd [J = 9 Hz, 6 Hz], HCHOTs, 1H), 4.17 (dd, [J = 9 Hz, 3 Hz], HCHOTs, 1H), 7.34 (d, meta H, 2H), 7.80 (d, ortho H, 2H).

1-Bromo-2,3-bis(2′-hexadecyloxyethoxy)propane (12a). 2,3-Bis(2′-hexadecyloxy ethoxy)-1-propyl tosylate (**11a**) (140 mg, 0.17 mmol) and LiBr (46.56 mg, 0.53 mmol, 3 equiv) were dissolved in 2 mL of dry DMF and refluxed at 70 °C for 24 h. Then the reaction mixture was diluted with 125 mL of EtOAc and was washed with 100 mL of water followed by brine. The organic phase was dried over anhyd Na_2SO_4. Pure compound was isolated in 81% yield (100 mg) by column chromatography over silica gel ($R_f \sim 0.8$ at EtOAc−hexane (15:85)). ^{1}H NMR ($CDCl_3$, 300 MHz): δ: 0.88 (t, 2 × terminal CH_3, 6H), 1.25 (br. m, 26 × CH_2, 52H), 1.56 (p, 2 × $C_{14}H_{29}CH_2CH_2O$, 4H), 3.4−3.74 (m, [7 × CH_2O] + CH_2Br + OCH_2CHOCH_2O, 17H); IR (cm^{-1}): 1100−1130 (broad, C−O−C str.)

1-Bromo-2,3-bis(2′-[2″-hexadecyloxyethoxy]ethoxy)propane (12b). 2,3-Bis(2′-[2″-hexadecyloxy ethoxy]-ethoxy)-1-propyl tosylate (**11b**) (200 mg, 0.23 mmol) and LiBr (59.80 mg, 0.7 mmol, 3 equiv) were dissolved in 3 mL of dry DMF and refluxed at 70 °C for 8 h. Then the reaction mixture was dissolved in 100 mL of EtOAc and washed twice with water (2 × 20 mL) followed by brine. The organic phase was dried over anhyd Na_2SO_4. EtOAc was evaporated under reduced pressure, and pure compound was isolated in 84% yield (150 mg) by column chromatography over silica gel ($R_f \sim 0.7$ at EtOAc−hexane (3:7)). ^{1}H NMR ($CDCl_3$, 300 MHz): δ: 0.88 (t, 2 × terminal CH_3, 6H), 1.25 (br. m, 26 × CH_2, 52H), 1.56 (p, 2 × $C_{14}H_{29}CH_2CH_2O$, 4H), 3.42 (t, 2 × $C_{15}H_{31}CH_2O$, 4H), 3.46−3.75 (m, [9 × CH_2O] + CH_2Br + OCH_2CHOCH_2O, 21H); IR (cm^{-1}): 1140, 1200−1240 (broad, C−O−C str.)

***N*-(2,3-Bis[2′-hexadecyloxyethoxy]propyl)*N*,*N*,*N*-trimethylammonium Bromide (1).** Trimethylamine was introduced into dry CH_3CN (1 mL) in a pressure tube in an ice−acetone bath. This resulted in a 3-fold expansion of the initial volume of acetonitrile. 1-Bromo-2,3-bis(2′-hexadecyloxyethoxy)propane (**12a**) (100 mg, 0.15 mmol) was dissolved in CH_3CN−toluene mixture by slight warming and was transferred to the pressure tube.

The reaction mixture was heated at 80 °C for 24 h. The reaction mixture was cooled, and the excess trimethylamine was evaporated by warming in a water bath. Solvent was then removed under reduced pressure. Pure compound was isolated as a white solid by column chromatography over silica using MeOH−$CHCl_3$ as the solvent mixture. Yield of the reaction was 74% (80 mg). ^{1}H NMR (500 MHz, $CDCl_3$): δ: 0.88 (t, 2 × terminal CH_3, 6H), 1.26 (br. m, 26 × CH_2, 52H), 1.52−1.57 (m, 2 × $C_{14}H_{29}CH_2CH_2O$, 4H), 3.41 (s, 3 × N^+CH_3, 9H), 3.43−3.71 (m, 7 × CH_2O, 14H), 3.90−3.92 (m, OCH_2−CHO−CH_2N^+, 1H), 4.11−4.18 (m, CH_2N^+, 2H); IR (cm^{-1}): 1060−1150 (broad, C−O−C str.); MS (MALDI-TOF): Calcd for $C_{42}H_{88}O_4N$: 671.2. Found: 672.2 (M + H^+); Anal. Calcd for $C_{42}H_{88}O_4NBr{\cdot}1.5H_2O$: C 64.83, H 11.79, N 1.8. Found: C 64.93, H 12.03, N 1.65.

***N*-(2,3-Bis[2′-{2″-hexadecyloxyethoxy}ethoxy]-propyl)-*N*,*N*,*N*-trimethylammonium Bromide (2).** Trimethylamine was introduced into dry CH_3CN (1 mL) in a pressure tube in an ice-acetone bath which nearly resulted in a 3-fold expansion of the volume of CH_3CN from its initial value. 1-Bromo-2,3-bis(2′-[2″-hexadecyloxyethoxy]ethoxy)propane (**12b**) (150 mg, 0.19 mmol) was dissolved in CH_3CN−toluene mixture by light heating and was transferred to the pressure tube. The reaction mixture was heated at 80 °C for 24 h. The reaction mixture was cooled, and the excess Me_3N was evaporated by warming. Solvent was then removed under reduced pressure. Pure compound was isolated as a white wax (110 mg, 68%) by column chromatography over silica gel (100−200 mesh) using MeOH−$CHCl_3$ (1:9) as the solvent mixture. After the chromatography separation, the compound was dissolved in chloroform and was passed through a sintered funnel to remove any silica gel impurity in the eluant ($R_f \sim 0.5$ at MeOH−$CHCl_3$ (1:9) solvent mixture). ^{1}H NMR (500 MHz, $CDCl_3$): δ: 0.88 (t, 2 × terminal CH_3, 6H), 1.26 (br. m, 26 × CH_2, 52H); 1.55 (p, 2 × $C_{14}H_{29}CH_2CH_2O$, 4H), 3.38 (s, 3 × N^+CH_3, 9H), 3.39−3.67 (m, 11 × C H_2O, 22H), 3.89−3.91 (m, OCH_2−CHO−CH_2N^+, 1H), 4.04 (d, HCH−N^+, 1H), 4.16 (m, HC H-N^+, 1H); IR (cm^{-1}): 1100 (broad, C−O−C str.); MS (MALDI-TOF): Calcd for $C_{46}H_{96}O_6N$: 759.3. Found: 760.1 (M + H^+); Anal. Calcd for $C_{46}H_{96}O_6NBr{\cdot}1.9H_2O$: C 63.26, H 11.52, N 1.6. Found: C 63.25, H 11.77, N 1.43.

2-(2′-Chloroethoxy)ethyl-2″-tetrahydropyranyl Ether (13). To 2 g of 2-(2′-chloroethoxy)ethanol (16.1 mmol) were added 2.03 g of dihydropyran (24.1 mmol, 1.5 equiv) and 1 drop of concentrated HCl. It was stirred at rt for 2.5 h. The reaction mixture was initially neutralized by the addition of solid $NaHCO_3$. The reaction mixture was then diluted with EtOAc and washed with saturated aq $NaHCO_3$ solution followed by brine. The organic phase was dried over anhyd Na_2SO_4. Pure compound was isolated as a colorless liquid (quantitative conversion) chromatographically by passing through a short column of silica gel and eluting with EtOAc−hexane solvent (2:98) mixture (*25*). ^{1}H NMR (90 MHz, $CDCl_3$): δ: 1.4−2 (m, 3 × CH_2, 6H), 3.3−4 (m, [4 × C H_2O] + CH_2Cl, 10H), 4.65 (t, O−CH_2C HCH_2−O, 1H); IR (cm^{-1}): 1120 (broad, C−O−C str.)

3-Benzyloxy-2-hydroxy-1-(2′-[2″-hydroxyethoxy]-ethoxy)propane (14). To a solution containing *O*-benzyl glycerol (**8**) (0.5 g, 2.75 mmol) were added 2-(2′-chloroethoxy)ethyl 2″-tetrahydropyranyl ether (**13**) (1.72 g, 8.24 mmol, 3 equiv) and 82.1 mg of $Bu_4N^+HSO_4^-$ (0.242 mmol, 0.09 equiv) dropwise in 2 mL of 50% aq NaOH (2 g, 55 mmol, 20 equiv). The mixture was stirred and heated at 65 °C for 5 h. Then the reaction mixture was diluted with CH_2Cl_2 and washed with water followed by brine. The organic phase was dried over anhyd Na_2SO_4. However, mono- and diether derivatives could not be isolated upon column chromatography. The mixture was isolated by silica gel column chromatography using EtOAc−hexane (1:1) as the solvent system (R_f of the mixture being 0.5 at this solvent mixture). This mixture was then subjected to the acid-catalyzed deprotection of THP by stirring the compound with 10 drops of concentrated HCl in 10 mL of 1:1 MeOH−CH_2Cl_2 solvent mixture for 2 h at room temperature. The reaction mixture was then carefully neutralized with solid $NaHCO_3$ and was extracted in EtOAc and finally with $CHCl_3$. The organic solvent from the organic extracts was evaporated under reduced pressure and the required mono derivative was isolated in the pure form, as a yellow liquid, by column chromatography over silica using MeOH-EtOAc solvent system (R_f of the required mono derivative ∼ 0.6 at EtOAc). The isolated yield was 250 mg (34% overall). ^{1}H NMR (300 MHz, $CDCl_3$): δ: 3.41−3.83 (m, 6 × CH_2, 12H), 3.94 (q, $OCH_2CHOHCH_2O$, 1H), 4.48 (s, OCH_2Ar, 2H), 7.19−7.31 (m, Ar, 5H); LRMS: Calcd for $C_{14}H_{22}O_5$: 270. Found: 271 (MH^+)

1-(2′-[2″-Hexadecyloxyethoxy]ethoxy)-2-hexadecyloxy-3-benzyloxypropane (15). To a mixture containing 3-benzyloxy-2-hydroxy-1-(2′-[2″-hydroxyethoxy]-ethoxy)propane (**14**) (320 mg, 1.2 mmol), $Bu_4N^+HSO_4^-$ (26.7 mg, 0.79 mmol, 0.09 equiv), and hexadecyl chloride (699 mg, 2.68 mmol, 2.2 equiv) was added dropwise 1.4 mL of 50% NaOH. The mixture was then stirred vigorously at 65 °C for 5 days. After the reaction, CH_2Cl_2 was added to it and the organic layer was washed with water followed by brine. The organic phase was dried over anhyd Na_2SO_4, and the solvent was evaporated under reduced pressure. Pure compound was isolated as a slight yellow liquid at 53% yield (450 mg) by silica gel column chromatography using EtOAc−hexane (15:85) as the solvent system ($R_f \sim 0.8$ at this solvent system). ^{1}H NMR (300 MHz, $CDCl_3$): δ: 0.86 (t, 2 × terminal CH_3, 6H), 1.23 (br. m, 26 × CH_2, 52H), 1.54 (p, 2 × $C_{14}H_{29}CH_2CH_2O$, 4H), 3.42 (t, 2 × $C_{15}H_{31}CH_2O$, 4H), 3.48−3.67 (m, 6 × CH_2O, 12H), 3.76 (q, OCH_2CHOCH_2O, 1H), 4.53 (s, OCH_2Ar, 2H), 7.26−7.32 (m, Ar, 5H); IR (cm^{-1}): 1100 (broad, C−O−C str.)

2-Hexadecyloxy-3-(2′-[2″-hexadecyloxyethoxy]-ethoxy)-1-propanol (16). 1-(2′-[2″-Hexadecyloxyethoxy]-ethoxy)-2-hexadecyloxy-3-benzyloxypropane (**15**) (450 mg, 0.6 mmol) was dissolved in EtOAc−MeOH solvent mixture. To that was added activated 10% Pd-charcoal (100 mg). Hydrogen gas was introduced into the flask, and hydrogenation was carried out under atmospheric pressure, at room temperature for 12 h. Pd−charcoal was filtered off from the reaction mixture, and the pure compound was isolated as a low melting white solid (340 mg, 85% yield) by column chromatography over silica gel ($R_f \sim 0.4$ at EtOAc−hexane (1:4) solvent mixture). ^{1}H NMR (300 MHz, $CDCl_3$): δ: 0.86 (t, 2 × terminal CH_3, 6H), 1.23 (br. m, 26 × CH_2, 52H), 1.55 (m, 2 × $C_{14}H_{29}CH_2$-CH_2O, 4H), 3.42 (t, 2 × $C_{15}H_{31}CH_2O$, 4H), 3.47−3.7 (m, 6 × CH_2O, 12H), 3.83 (m, OCH_2CHOCH_2O, 1H); IR (cm^{-1}): 1100−1130 (broad, C−O−C str.), 3400 (br., OH); LRMS Calcd for $C_{39}H_{80}O_5$: 628. Found: 629 (MH^+); Anal. Calcd for $C_{39}H_{80}O_5{\cdot}0.4H_2O$: C 73.62, H 12.8. Found: C 73.67, H 12.84.

2-Hexadecyloxy-3-(2′-[2″-hexadecyloxyethoxy]-ethoxy)-1-propyl Tosylate (17). 2-Hexadecyloxy-3-(2′-[2″-hexadecyloxyethoxy]ethoxy)-1-propanol (**16**) (140 mg, 0.2 mmol) was dissolved in 1 mL of dry CH_2Cl_2 and cooled in an ice−water bath. To that were added 2 mL of dry pyridine and 106 mg of freshly recrystallized *p*-TsCl (0.5

mmol, 2.5 equiv). The reaction mixture was stirred at 0 °C for 15 min and then at room temperature for 24 h (till the starting alcohol disappeared as indicated from TLC). The reaction mixture was then diluted with CH_2Cl_2 and was washed with water followed by 2 N aq HCl and again with water. The organic phase was washed with brine and dried over anhyd Na_2SO_4. Solvent was evaporated under reduced pressure, and pure compound was isolated as a colorless liquid (140 mg, 80% yield) by column chromatography over silica ($R_f \sim 0.3$ at EtOAc−hexane (15:85) solvent mixture). The isolated product was found to be very hygroscopic. ^{1}H NMR ($CDCl_3$, 300 MHz): δ: 0.88 (t, 2 × terminal CH_3, 6H), 1.25 (br. m, 26 × CH_2, 52H), 1.46 (m, $C_{14}H_{29}CH_2CH_2O$, 2H), 1.55 (m, $C_{14}H_{29}CH_2CH_2O$, 2H), 2.46 (s, C H_3Ar, 3H), 3.32−3.7 (m, [7 × CH_2O] + [OCH_2CHOCH_2O], 15H), 3.96−4.01 (m, HC*H*OTs, 1H), 4.13 (dd [9 Hz, 3 Hz], HC*H*OTs, 1H), 7.32 (d, meta H, 2H), 7.78 (d, ortho H, 2H); IR (cm^{-1}): 1080−1120 (br., C−O−C str.)

1-Bromo-2-hexadecyloxy-3-(2′-[2″-hexadecyloxyethoxy]ethoxy)propane. 2-Hexadecyloxy-3-(2′-[2″-hexadecyloxyethoxy] ethoxy)-1-propyl tosylate (140 mg, 0.2 mmol) and LiBr (46.6 mg, 0.5 mmol, 3 equiv) were dissolved in 2 mL of dry DMF, and the mixture was refluxed at 70 °C for 8 h. Then the reaction mixture was diluted with 100 mL of EtOAc and was washed twice with 30 mL portions of water. The water layer was extracted with EtOAc. The organic phase was then washed with brine and was dried over anhyd Na_2SO_4. EtOAc was evaporated under reduced pressure, and the pure compound was isolated in 73% yield (90 mg) by column chromatography over silica gel ($R_f \sim 0.8$ at EtOAc−hexane (1:9)). The bromo compound was used for the next step immediately without further characterization.

***N*-(2-Hexadecyloxy-3-[2′-{2″-hexadecyloxyethoxy}-ethoxy] propyl)-*N*,*N*,*N*-trimethylammonium Bromide (3).** Dry NMe_3 gas was passed into dry CH_3CN (1 mL) in a pressure tube which was precooled cooled using an ice−acetone bath. 1-Bromo-2-hexadecyloxy-3-(2′-[2″-hexadecyloxyethoxy]ethoxy)propane (90 mg, 0.13 mmol) was dissolved in a mixture of CH_3CN (2 mL)−toluene (0.5 mL) by slight warming and was transferred to the pressure tube. (It may be mentioned herein that the bromide was not soluble in CH_3CN while it was very soluble in toluene. Thus, good yields were obtained when a minimum amount of toluene was used for the reaction.) The reaction mixture was then heated at 80 °C for 24 h. The resulting material was then cooled, and the excess trimethylamine was evaporated. This was then dissolved in $CHCl_3$, and the solvent was removed under reduced pressure. Pure compound was isolated as a colorless waxy solid (100 mg, quantitative conversion) by column chromatography over silica gel (100−200 mesh) using 10% MeOH−$CHCl_3$ as the eluting solvent. ^{1}H NMR (500 MHz, $CDCl_3$): δ: 0.90 (t, 2 × terminal CH_3, 6H), 1.27 (br. m, 26 × CH_2, 52H), 1.55 (br. m, 2 × $C_{14}H_{29}CH_2CH_2O$, 4H), 3.41−3.72 (m + s, singlet at 3.49, [7 × CH_2O] + [3 × CH_3N^+], 14H + 9H), 3.97−4.14 (m, [$OCH_2CHOCH_2N^+$] + [CH_2N^+], 1H + 2H); IR (cm^{-1}): 1100 (broad, C−O−C str.); MS (MALDI-TOF): Calcd for $C_{42}H_{88}O_4N$: 671.2. Found: 672.0 (M + H$^+$); Anal. Calcd for $C_{42}H_{88}O_4NBr\cdot 0.3H_2O$: C 66.69, H 11.81, N 1.85. Found: C 66.73, H 12.1, N 1.56.

3-Benzyloxy-2-hydroxy-1-hexadecyloxypropane (18). *O*-Benzyl glycerol (**8**) (299 mg, 1.6 mmol) was dissolved in dry THF and was cooled in an ice−water bath. NaH (55% in oil) (144 mg, 3.2 mmol), washed with dry hexane (to remove oil), was added to it and stirred at 0 °C for 15 min. To this was added 0.5 g (1.3 mmol) of hexadecyl tosylate, and the reaction mixture was refluxed for 24 h. CH_2Cl_2 was added to the reaction mixture, and the resulting mass was acidified with 1.2 N aq HCl. The organic phase was then washed with water, followed by brine. The organic layer was isolated and dried over anhyd Na_2SO_4. Solvent was evaporated under reduced pressure and the pure compound was separated (200 mg, 40%) as a colorless liquid by column chromatography over silica gel ($R_f \sim 0.5$ at EtOAc−hexane(1:4)). The spectroscopic properties match those of the reported compound. ^{1}H NMR ($CDCl_3$, 300 MHz): δ: 0.88 (t, terminal CH_3, 3H), 1.25 (br. m, 13 × CH_2, 26H), 1.55 (p, $C_{14}H_{29}C$ H_2-CH_2O, 2H), 3.4−3.71 (m, 3 × CH_2O, 6H), 3.93 (q, OCH_2CHOCH_2O, 1H), 4.54 (s, OC H_2Ar, 2H), 7.25−7.34 (m, Ar, 5H); IR (cm^{-1}): 1120 (br., C−O−C str.), 3400 (br., OH).

1-Hexadecyloxy-2-(2′-[2″-hexadecyloxyethoxy]-ethoxy)-3-benzyloxypropane (19). The alcohol **18** was taken (200 mg) in dry THF and was cooled in an ice−water bath. NaH (55% in oil) (1.5 equiv) was washed with dry hexane to remove oil and was added to the solution of alcohol in THF. The mixture was stirred at room temperature for 15 min. A white precipitate was formed in the reaction mixture. To that was added 1.5 equiv of *O*-hexadecyl diethylene glycol tosylate, and the mixture was refluxed at 89 °C. After the reaction, THF was removed by evaporation under reduced pressure. Crude mixture was then dissolved in CH_2Cl_2 and washed with 1 N aq HCl, followed by water and brine. The organic phase was dried over anhyd Na_2SO_4. The required compound was isolated in 74% isolated yielding pure form as a slight yellow colored liquid by silica gel column chromatography using 20 EtOAc−hexane ($R_f \sim 0.4$) as the elution mixture. ^{1}H NMR ($CDCl_3$, 300 MHz): δ: 0.88 (t, 2 × terminal CH_3, 6H), 1.25 (br. m, 26 × CH_2, 52H), 1.55 (p, 2 × $C_{14}H_{29}CH_2CH_2O$, 4H), 3.38−3.76 (m, [8 × CH_2O] + [OCH_2CHOCH_2O], 17H), 4.53 (s, OCH_2Ar, 2H), 7.25−7.31 (m, Ar, 5H); IR (cm^{-1}): 1110 (br., C−O−C str.).

3-Hexadecyloxy-2-(2′-[2″-hexadecyloxyethoxy]-ethoxy)-1-propanol (20). 1-Hexadecyloxy-2-(2′-[2″-hexadecyloxyethoxy]ethoxy)-3-benzyloxypropane (**19**) (260 mg, 0.36 mmol) was dissolved in 5 mL of a mixture of dry EtOAc−MeOH (1:1). To that was added activated 10% Pd−charcoal (340 mg). Hydrogen gas was introduced to the flask. Hydrogenation was allowed to continue at atmospheric pressure, at room temperature for 15 h. Pd−charcoal was filtered off from the reaction mixture, and the pure compound was isolated as a low melting white solid (180 mg, 79% yield) by column chromatography over silica gel ($R_f \sim 0.5$ at EtOAc−hexane (1:1)). ^{1}H NMR ($CDCl_3$, 300 MHz): δ: 0.88 (t, 2 × terminal CH_3, 6H), 1.25 (br. m, 26 × CH_2, 52H), 1.54−1.56 (m, 2 × $C_{14}H_{29}CH_2$-CH_2O, 4H), 3.36−3.72 (m, 8 × CH_2O, 16H), 3.83−3.87 (m, OCH_2CHOCH_2O, 1H); IR (cm^{-1}): 1100 (br., C−O−C str.), 3400 (br., OH).

3-Hexadecyloxy-2-(2′-[2″-hexadecyloxyethoxy]-ethoxy)-1-propyl Tosylate (21). 3-Hexadecyloxy-2-(2′-[2″-hexadecyloxyethoxy]ethoxy)-1-propanol (180 mg, 0.29 mmol) was dissolved in 5 mL of dry CH_2Cl_2 and was cooled in an ice−water bath. To that were added 0.2 mL of dry pyridine and 138 mg of freshly recrystallized *p*-TsCl (0.725 mmol, 2.5 equiv). The reaction mixture was stirred at 0 °C for 15 min and then at room temperature for 24 h (till the starting alcohol disappeared as indicated from TLC). The reaction mixture was then diluted with CH_2Cl_2 and was washed with 2 N aq HCl followed by water and brine. The organic layer was separated and dried over anhyd Na_2SO_4. Solvent was evaporated under reduced pressure, and the pure compound was isolated

as a colorless liquid in 85% yield by column chromatography (silica) ($R_f \sim 0.4$ at EtOAc−hexane (1:9) solvent mixture). ^{1}H NMR ($CDCl_3$, 300 MHz): δ: 0.88 (t, 2 × terminal CH_3, 6H), 1.25 (br. m, 26 × CH_2, 52H), 1.47−1.55 (m, 2 × $C_{14}H_{29}CH_2CH_2O$, 4H), 2.45 (s, CH_3Ar, 3H), 3.32−3.71 (m, [7 × CH_2O] + [OCH_2CHOCH_2O], 15H), 3.98−4.15 (m, C H_2OTs, 2H), 7.32 (d, meta H, 2H), 7.79 (d, ortho H, 2H); IR (cm^{-1}): 1080−1110 (br., C−O−C str.)

1-Bromo-2-(2′-[2″-hexadecyloxyethoxy]ethoxy)-3-hexadecyloxypropane. 3-Hexadecyloxy-2-(2′-[2″-hexadecyloxyethoxy]ethoxy)-1-propyl tosylate (190 mg, 0.24 mmol) and LiBr (63.2 mg, 0.7 mmol, 3 equiv) were dissolved in 3 mL of dry DMF and refluxed at 70 °C for 8 h. The reaction mixture was then diluted with 150 mL of EtOAc and washed twice with 30 mL portions of water. The water layer was extracted with EtOAc. The organic layers were collected together, washed with brine, and dried over anhyd Na_2SO_4. EtOAc was evaporated under reduced pressure, and pure compound was isolated in 59% yield (90 mg) by column chromatography over silica gel ($R_f \sim 0.5$ at EtOAc−hexane(5:95)). ^{1}H NMR ($CDCl_3$, 300 MHz): δ: 0.88 (t, 2 × terminal CH_3, 6H), 1.25 (br. m, 26 × CH_2, 52H), 1.54−1.56 (m, 2 × $C_{14}H_{29}CH_2CH_2O$, 4H), 3.42 (t, 2 × $C_{15}H_{31}CH_2O$, 4H), 3.46−3.75 (m, [5 × CH_2O] + [OCH_2CHOCH_2Br] + [CH_2Br], 13H); IR (cm^{-1}): 1100−1120 (br., C−O−C str.)

***N*-(3-Hexadecyloxy-2-[2′-{2″-hexadecyloxyethoxy}-ethoxy]propyl)-*N*,*N*,*N*-trimethylammonium Bromide (4).** Dry trimethylamine gas was passed into dry CH_3CN (1 mL) in a pressure tube. 1-Bromo-2-hexadecyloxy-3-(2′-[2″-hexadecyloxyethoxy]ethoxy)propane (90 mg) was dissolved in CH_3CN−toluene (1:1) mixture by warming and was transferred to the pressure tube. The reaction mixture was heated at 80 °C for 24 h. The reaction mixture was then cooled, and the excess trimethylamine was evaporated by warming the mixture on a water bath. The crude mixture was then diluted with $CHCl_3$, and the solvent was removed under reduced pressure. Pure compound was isolated as a colorless waxy solid (70 mg, 72%) by column chromatography over silica gel (100−200 mesh) using MeOH−$CHCl_3$ (1:9) as eluent. ^{1}H NMR (500 MHz, $CDCl_3$): 0.88 (t, 2 × terminal CH_3, 6H), 1.25 (br. m, 26 × CH_2, 52H), 1.54 (p, 2 × $C_{14}H_{29}CH_2$-CH_2O, 4H), 3.35 (s, 3 × CH_3N^+, 9H), 3.39−3.66 (m, 7 × CH_2O, 14H), 3.89−3.91, 4.13 (m, [CH_2N^+] + [OCH_2CHO-CH_2N^+], 2H + 1H); IR (cm^{-1}): 1070−1150 (broad, C−O−C str.); MS (MALDI-TOF): Calcd for $C_{42}H_{88}O_4N$: 671.2. Found: 671.6; Anal. Calcd for $C_{42}H_{88}O_4NBr\cdot 0.2H_2O$: C 66.84, H 11.81, N 1.86. Found: C 66.8, H 11.93, N 1.51.

Vesicle Preparation. Thin lipid films from individual lipids **1**−**4** were made in Wheaton glass vials by dissolving individual lipids in chloroform and evaporating the organic solvent under a steady stream of dry nitrogen. Last traces of organic solvent were removed by keeping these films under vacuum overnight. Water was added to each individual film and kept for hydration at 4 °C for 6−10 h. Then these samples were repeatedly freeze−thawed (ice-cold water to 50 °C) with intermittent vortexing to afford multilamellar vesicular aggregates (MLVs). Small unilamellar vesicles (SUV) were prepared by sonicating these MLVs in a bath sonicator above the phase transition temperature of the individual lipids for 10−15 min.

Transmission Electron Microscopy. Lipid suspensions were examined under transmission electron microscopy by negative staining with 1% uranyl acetate. Vesicular suspensions were made in 1% uranyl acetate solution at a concentration of 1 mM. Sonicated suspensions were spreaded onto carbon-Formvar coated copper grids (400 mesh), and the vesicles were allowed to settle onto the grid. Excess solution was wicked off using a filter paper, and the grid was air-dried for 30 min before examining under TEM. TEM was performed on a JEOL-200 CX electron microscope typically with an accelerating voltage of 100 keV. Micrographs were recorded at a magnification of 80 000.

Differential Scanning Calorimetry. Multilamellar vesicles were prepared in degassed water as mentioned above (concentration = 1 mM), and their thermotropic behavior was investigated by differential scanning calorimetry using a CSC-4100 model multicell Differential Scanning Calorimeter (Calorimetric Sciences Corporation, Utah). Baseline thermogram was obtained by using degassed water in all the ampules including the reference cell to normalize cell to cell differences. Water (0.5 mL) was used for the baseline thermogram. The measurements were carried out in the temperature range of 25 °C to 65 °C at a scan rate of 20 °C/h. Prior to the experimental thermogram, samples were subjected to repeated heating and cooling scans in DSC. The thermograms for the vesicular suspensions were obtained by subtracting the respective baseline thermogram from the sample thermogram using the software 'CpCalc' supplied by the manufacturer. Peak position in the plot of excess heat capacity vs temperature was taken as the gel to liquid crystalline phase transition temperature for each vesicular suspension. The molar heat capacities, calorimetric enthalpies (ΔH_c) and entropies (ΔS) were also computed using the same software. The size of the cooperativity unit (CU) for the phase transition of each lipid was determined using the formula

$$\mathrm{CU} = \frac{\Delta H_{\mathrm{VH}}}{\Delta H_{\mathrm{c}}}$$

where ΔH_{VH} is the vant Hoff enthalpy and ΔH_{c} is the calorimetric enthalpy. vant Hoff enthalpy was calculated from the equation

$$\Delta H_{\mathrm{VH}} = \frac{6.9 T_{\mathrm{m}}^2}{\Delta T_{1/2}}$$

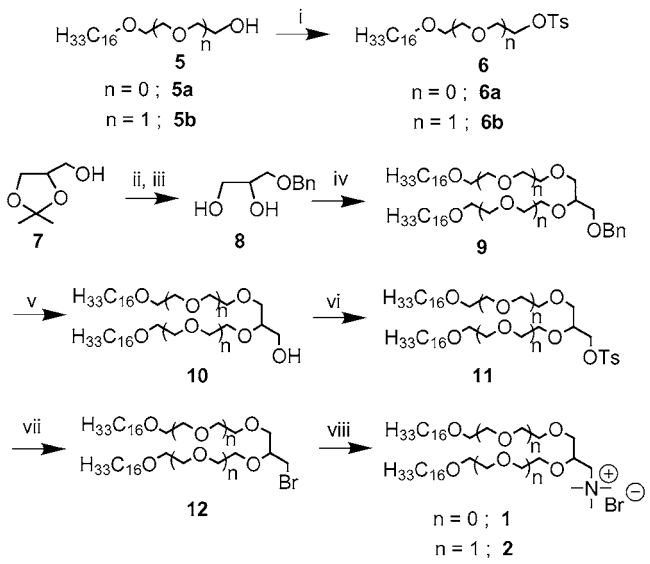
where T_{m} is the phase transition temperature (in Kelvin) and $\Delta T_{1/2}$ is the full width at half-maximum of the thermogram (*26*−*28*).

Cell Culture, Plasmid DNA. HeLa cells were cultured in DMEM (Gibco BRL) supplemented with 10 fetal bovine serum (FBS) in T-25 culture flasks (Nunc, Denmark) and were incubated at 37 °C in a humidified atmosphere containing 5% CO_2. Cells were regularly passaged by trypsinization using 0.1 trypsin (EDTA 0.02%, dextrose 0.05%, and trypsin 0.1%) in PBS (pH 7.2).

Plasmid *p*EGFP−N1 (Clontech), which encodes for an enhanced green fluorescence protein (GFP) under a CMV promoter, was amplified in *Escherichia coli* (DH5α) and purified using Qiagen Maxi Prep Plasmid Purification protocol (Qiagen, Germany). Purity of the plasmid was checked by electrophoresis on 0.8% agarose gel and was found to be more than 80% supercoiled. Concentration of the DNA was estimated spectroscopically by measuring the absorption at 260 nm.

Cytotoxicity. Toxicity of each cationic lipid formulation toward HeLa cells in the presence of 10% FBS was determined using 3-(4,5-dimethyl thiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) reduction assay following literature procedures (*29*, *30*). MTT gets converted

to an insoluble blue dye, formazan, in actively respiring cells. The assay estimates the concentration of the formazan formed, which, in turn, gives a measure of the population of cells that are metabolically active.



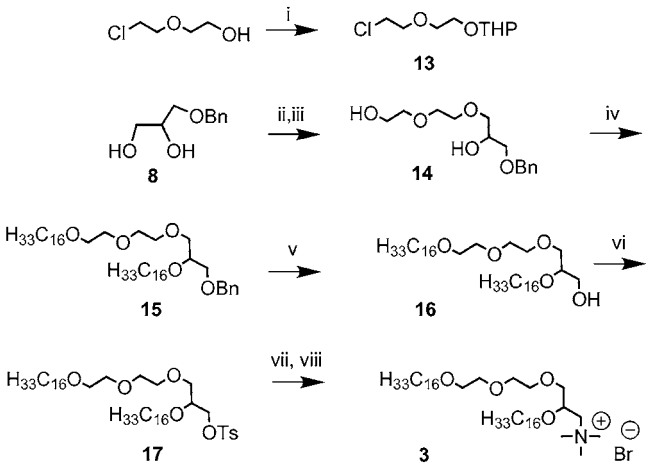
A range of liposomal concentrations between 200 nM to 500 μM were investigated for toxicity studies. Cytotoxicity of the lipid formulations optimal for transfection experiments were found out under conditions exactly similar to transfection experiments. The lipid formulations (lipid + DOPE) were complexed with DNA (0.1 μg) at various charge ratios in a range that was found to be optimal for transfections (lipid to DNA charge ratio 1−4). DNA−lipid complexes were added to the cells in the absence of serum. After 5 h of incubation, enough serum containing medium was added so as to have a final serum concentration of 10%. After 44 h, 20 μL media was replaced with 20 μL of MTT solution and was incubated further for 5 h. Following 5 h of incubation, blue formazan microcrystals were seen at the wells when checked under the microscope. One hundred microliters of 10% SDS in 0.01 N HCl was then added to each well and incubated at 37 °C for 10 h for the lysis of the cells and the solubilzation of the formazan formed. The absorbance was measured using a microtiter plate reader. The % viability was then calculated as $(OD_{570} - OD_{690})_{sample}/(OD_{570} - OD_{690})_{control} \times 100$, where the untreated cells (where no lipid suspension was added) were used as control. The assay was carried out in triplicates.

Transfection. All transfection experiments were carried out in antibiotic-free media. In a typical experiment, 96-well plates were seeded with 9000 cells/well in antibiotic-free DMEM 24 h before transfection such that they were ~70% confluent at the time of transfection. Lipid formulation and DNA were serially diluted separately in DMEM containing no serum to have the required working stocks. DNA was used at a concentration of 0.1 μg/well. The lipid and DNA were complexed in a volume of 20 μL by incubating them together at room temperature for about 30 min. The lipid concentrations were varied so as to obtain the required lipid/DNA charge ratios of 0.6, 0.8, 1.0, 1.2, 1.4, 1.6, 1.8, and 2.0. Charge ratios here represent the ratio of charge on cationic lipid (in moles) to nucleotide base molarity and were calculated by considering the average nucleotide mass of 330. After 30 min of complexation, 50 μL of medium was added to the complexes (final DNA concentration = 4.33 μM). Old medium was removed from the wells, and lipid−DNA complexes in 70 μL media were added to the cells. The plates were then incubated for 5 h at 37 °C in a humidified atmosphere containing 5% CO_2. At the end of the incubation period, 130 μL of DMEM containing 15.4% FBS was added per well such that final serum concentration in the medium is 10%. Plates were further incubated for a period of 43 h before checking for the reporter gene expression. GFP expression was estimated by fluorescent microscopy and was quantified by flow cytometry analysis. All the experiments were performed in duplicate, and the results presented are the average of at least four such independent experiments.

RESULTS AND DISCUSSION

Synthesis. The synthesis of the symmetric cationic lipids (**1** and **2**), which contain an equal number of oxyethylene units in both the chains at the C-1 and C-2 positions of the pseudoglyceryl backbone, is outlined in Scheme 1. The main step employed the coupling of the tosylates **6a** and **6b** with benzyl glycerol. The ether bond formation between benzyl glycerol and hexadecyl tosylate

Scheme 1[a]

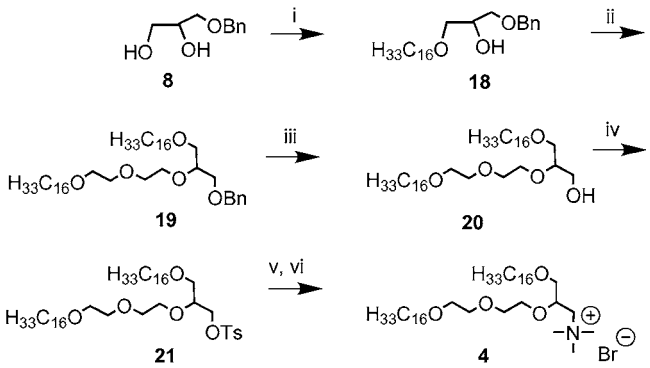


[a] Reagents and conditions: (i) *p*TsCl, Py, CH_2Cl_2, rt, 25−50 h (82% for **a** and 68% for **6b**); (ii) KOH, $PhCH_2Cl$, benzene, reflux, 23 h; (iii) *p*-TsOH, MeOH,CH_2Cl_2, rt, 5 h (overall 53% for the steps ii and iii); (iv) **6**, NaH, DMSO, $Bu_4N^+I^-$, rt, 24−30 h (74 for $n = 0$ and 67% for $n = 1$); (v) H_2, Pd/C, MeOH, EtOAc, 10 h (88% and 80%); (vi) *p*-TsCl, Py, CH_2Cl_2, rt, 27h (87% and 98%); (vii) LiBr, DMF, 70 °C, 8 h (81% and 84%); (viii) NMe_3, MeCN−toluene, 80 °C, pressure tube, 24 h (74% (68%).

works reasonably well under classical etherification conditions involving KOH/benzene (*24*) or NaH/benzene under reflux. But, we observed that, in case of tosylates containing hydrophilic oxyethylene groups **6a** and **6b**, although such conditions (NaH/benzene, reflux, 24 h) yielded the required products **9a** and **9b**, the yields were only moderate (48% and 45%, respectively) (*18*). The reaction of benzyl glycerol with the corresponding chlorides under phase-transfer conditions (50% aq NaOH, $Bu_4N^+HSO_4^-$) (*31*) also yielded the required compounds, but again the yields were substantially lower. Moreover, in this case, isolation of the pure compounds from the reaction mixture was also cumbersome. The coupling under NaH/DMF (*21*) and KOH/DMSO reflux conditions were also not satisfactory. Interestingly, good yields were obtained when benzyl glycerol was treated with the corresponding tosylates **6a** and **6b** under NaH/DMSO in the presence of a phase-transfer catalyst, $Bu_4N^+I^-$. The reaction could be carried out at room temperature, and the yields were much better (74% for **9a** and 67% for **9b**). More importantly, isolation of the pure products by column chromatography was comparatively easier under this condition. We found this method to be the most suitable one for etherification involving such hydrophilic tosylates.

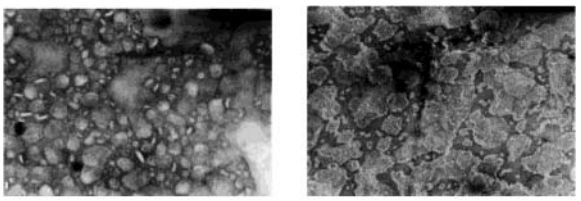
In general, the synthesis of lipids **1** and **2** was achieved as follows (Scheme 1). Ethylene glycol monohexadecyl ether **5a** and diethylene glycol monohexadecyl ether **5b** on reaction with tosyl chloride in the presence of pyridine in CH_2Cl_2 afforded the corresponding tosylates **6a** and **6b**. Benzyl glycerol **8** was synthesized by slight modification of a literature procedure from (±)-1,2-*O*-isopropylidene glycerol (*24*). Benzyl glycerol **8** on reaction with either tosylate, **6a**, or **6b** in the presence of NaH/DMSO/$Bu_4N^+I^-$ at room temperature afforded **9a** or **9b**, respectively, in good yields. Debenzylation of **9** to the glycerol derivatives **10** were achieved conveniently by hydrogenolysis. The direct bromination of **10** to the primary bromide **12** under Appel conditions (CBr_4/PPh_3 in CH_2Cl_2) was a very low-yielding reaction. So the alcohols were

Scheme 2[a]



[a] Reagents and conditions: (i) DHP, concentrated HCl, rt, 1 h (98%); (ii) **13**, aq NaOH (50%), $Bu_4N^+HSO_4^-$, 65 °C, 5 h; (iii) MeOH−CH_2Cl_2, concentrated HCl, rt, 2 h (overall 34% for the steps ii and iii); (iv) $C_{16}H_{33}Cl$, aq NaOH (50%), $Bu_4N^+HSO_4^-$, 65 °C, 5 days (53%); (v) H_2, Pd/C, MeOH, EtOAc, 12 h (85%); (vi) *p*-TsCl, Py, CH_2Cl_2, rt, 24 h (80%); (vii) LiBr, DMF, 70 °C, 6 h (73%); (viii) NMe_3, MeCN−toluene, 80 °C, pressure tube, 24 h (95%).

first converted to the corresponding tosylates **11a** or **11b** which on further reaction with LiBr in DMF under refluxing conditions yielded the corresponding bromides in good yields. The substitution of the tosylate residue in **11** with NaBr in acetone was, in contrast, very sluggish. The bromides **12a** and **12b** were finally converted in good yields to the corresponding cationic lipids **1** and **2**, respectively, by reaction with trimethylamine in acetonitrile−toluene mixture in a screw-top pressure tube.



Scheme 2 depicts the synthesis of the mixed-chain lipid, **3**, in which one hydrophilic $(CH_2CH_2O)_2$ linkage has been introduced only at the C-1 position of the pseudoglyceryl backbone. The alcohol **14** was synthesized by modification of a literature procedure (*31*). Briefly, chloroethoxyethanol was protected as a tetrahydropyranyl (THP) ether, **13** (*25*, *32*). Benzyl glycerol **8** was alkylated at the primary position using **13** at the primary OH residue via a phase-transfer-catalyzed reaction, followed by the subsequent removal of the THP protecting group to yield the diol **14**. The yield of this reaction was found to be strongly dependent upon the reaction time since the corresponding dialkylated derivative (*31*) was also formed if the reaction was allowed to continue beyond 4−5 h. The separation of the individual diol derivatives resulting from mono- and dialkylation of **8** was possible although difficult. The positional identity of the diol derivative **14**, obtained by the monoalkylation, was established by converting the isolated diol **14** to a diester with palmitic acid. The downfield chemical shift of the methine proton (OCH_2CHOCH_2O) upon esterification was clearly observable. The diol **14** upon reaction with hexadecyl chloride under a similar phase-transfer etherification condition gave **15** in moderate yields. From **15**, the cationic lipid **3** was then prepared via removal of the benzyl protecting group under hydrogenolytic conditions, conversion of the alcohol to bromide via tosylate, and quaternization with trimethylamine in a manner similar to the one described in Scheme 1.

The synthesis of cationic lipid **4**, in which the $(CH_2CH_2O)_2$ unit remains at C-2 of the pseudoglyceryl backbone, has been achieved as summarized in the Scheme 3. Benzyl glycerol **8** was refluxed with 1 equiv of hexadecyl tosylate in the presence of NaH in THF to yield the monoalkylated derivative **18**. It was then treated with **6b** in the presence of NaH in dry THF to afford **19**. This upon hydrogenolysis yielded the corresponding alcohol, which was finally converted to the desired lipid **4** following the same route as described in the previous cases. All the final compounds and those intermediates that are stable upon isolation were appropriately characterized by TLC, FT-IR, ^{1}H NMR, mass spectrometry, and elemental analysis (cf. Experiment Section).

Scheme 3[a]

[a] Reagents and conditions: (i) $C_{16}H_{33}OTs$, NaH, THF, reflux, 24 h (40%); (ii) **6b**, NaH, THF, reflux, 48 h (74%); (iii) H_2, Pd/C, MeOH, EtOAc, 12 h (79%); (iv) *p*-TsCl, Py, CH_2Cl_2, rt, 24 h (85%); (v) LiBr, DMF, 70 °C, 20 h (59%); (vi) NMe_3, MeCN−toluene, 80 °C, pressure tube, 24 h (72%).

(a) lipid **1**. (b) lipid **3**.

Figure 2. Negatively stained transmission electron micrographs of aqueous suspensions of lipids **1** and **3** (scale: 90 nm for 1 cm).

Aggregation Properties. All the lipid molecules mentioned here formed stable suspensions in water. No precipitation was observed even after one month when these suspensions were stored at 4 °C. Upon hydration, the lipids having oxyethylene units at the linkage regions (**1**−**4**) were found to get dispersed in water with greater ease when compared to the lipid having just an ether linkage (DHTMA). Moreover, the suspensions formed from the lipids **1**−**4** were optically clear in contrast to DHTMA which yielded translucent suspension.

Transmission Electron Microscopy. TEM examination of air-dried aqueous suspensions revealed the existence of membranous structures for all the four lipids **1**−**4**. The suspensions formed from the lipids **1** and **2** having symmetrical chains appeared as distinct spherical aggregates in the micrographs. In contrast, the lipid **3** that has a di(oxyethylene) linkage only at the C-1 chain formed aggregates of irregular morphologies (See Figure 2). Lipid **4** formed vesicular aggregates which were considerably larger in comparison with the aggregates observed with the other lipids (not shown). The diameters of the aggregates formed from the symmetrical lipids **1** and **2** were in the range of 40−100 nm. Lipid **3** formed vesicles of diameters 90−150 nm whereas relatively larger aggregates (∼220 nm) were observed in the aqueous suspensions of lipid **4** (Table 1).

Table 1. Characteristics of the Aggregates Formed by the Lipids 1−4

[a] The maximum deviation was ±0.1 °C. [b] Enthalpy and entropy for the heating scan. The ΔH and ΔS values are average of three successive runs and the values are within ±5%, [c] Size of cooperativity unit. [d] Average diameter as indicated from TEM. [e] Concentration that caused 50% cell death. [f] At [cationic lipid] = 250 μM. [g] Could not be measured reliably due to baseline drifts.

Differential Scanning Calorimetry. With all the lipid suspensions examined, clear thermotropic solid gel to fluid liquid crystalline-like phase transitions typical of membranous aggregates were observed. The phase transitions of all the individual liposomal suspensions were found to be reversible with subsequent heating and cooling scans showing essentially the same histograms. The experimentally obtained phase transition temperature (T_m) values obtained are presented in Table 1. The phase-transition temperatures of lipids **1**, **2,** and **4** were comparable to that of DHTMA (45−46 °C). In contrast, the phase transition temperature of **3** was relatively lower (41 °C). These cationic lipids **1**−**4** and DHTMA have identical headgroup and hydrocarbon chain lengths. However, they differ at the linkage region in terms of the number of oxyethylene units. Clearly the DSC results suggest that insertion of oxyethylenes at the linkage region do not affect the phase-transition temperature of the resulting membranes. In a given series of lipids, the lengthening of the chain length is expected to enhance the phase-transition temperature (*15*). However, since the T_m values do not increase relative to that of DHTMA, it is clear that incorporated oxyethylene units do not significantly contribute to chain melting transition. It may be further noted that even the unsymmetrical lipid, **4** exhibited comparable T_m as that of DHTMA. Only the lipid **3** showed a lower T_m value. Therefore the effect on the thermal properties of these membranes are manifested only when the oxyethylenes are incorporated in the C-1 position alone.

In general, there was a decrease in the enthalpy of phase transition upon incorporation of oxyethylene units at the linkage region of cationic lipids. Incorporation of oxyethylene units at the interfaces most likely enhances the hydration of the lipid assemblies. The effect of such interfacial hydration will be more predominant in the melted, disordered phase of the lipid assemblies. This may be responsible for lower phase-transition enthalpies observed with lipids **1**−**4**.

The nature of the thermal transitions of these oxyethylene-bearing cationic lipids were found to be more cooperative compared to their diether analogue DHTMA (see Table 1). Again enhanced hydration could be responsible for more cohesive interactions among such lipids leading to the manifestation of higher cooperativity.

Biological Activity: Cytotoxicity and Gene Delivery. Having investigated the aggregation properties of these lipids **1**−**4** by electron microscopy and calorimetry, we were interested in examining their biological usefulness. Toward this end, we first systematically examined the cytotoxicity manifested by these lipids and then investigated their gene transfer activity in HeLa cells.

The cytotoxic effects of the cationic lipids **1**−**4** and their diether counterpart DHTMA toward HeLa cells are shown in Figure 3 and are summarized in Table 1 along with their ID_{50} values. Incorporation of the oxyethylene units at the linkage region of a lipid molecule is found to increase its cytotoxicity. Among the lipids investigated, the lipid **2**, containing two oxyethylene units in both of the chains, is found to be the most cytotoxic formulation. The morphology of dying cells in the case of these oxyethylene lipids were considerably different from that of DHTMA. The lipid DHTMA, which has just an ether functionality at the linkage region, was least cytotoxic. Its ID_{50} value was above the range of concentrations studied (>500 μM). Notably, all the ID_{50} values were much higher than the range of concentration at which a typical transfection experiment was performed (i.e., ∼5 μM).

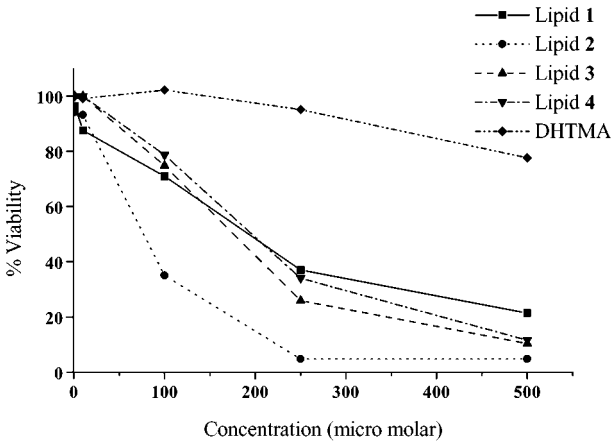

Figure 3. Cytotoxicity exhibited by the cationic lipids **1**−**4** toward HeLa cells. Toxicity exhibited by the diether lipid DHTMA is also shown. Shown are the data from one representative experiment. Standard deviations were within 5%.

The transfection efficiencies (% of fluorescent cells due to the expressed green fluorescence protein (GFP)) of various cationic lipid formulations are shown in Figure 4. The untransfected control cells and the cells exposed only to the plasmid DNA did not show any fluorescent cells 48 h posttransfection. The cationic lipid, DHTMA which possess single ether links between the pseudoglyceryl skeleton and the hydrocarbon chains, showed only basal level transfection activity. A clear enhancement in transfection efficiencies were observed with the cationic lipids bearing oxyethylene linkage functionalities. The unsymmetrical lipids **3** and **4** were more efficient than the symmetrical ones **1** and **2**. Lipid **3**, bearing two oxyethylene units only at the C-1 position of the pseudoglyceryl backbone, was found to be the best cytofectin among the lipids studied.

Effect of Helper Lipids. Incorporation of helper lipids such as cholesterol (*33, 34*) and dioleyoyl phosphatidyl ethanolamine (DOPE) (*3, 4*) is known to enhance the transfection efficiencies of many of the cationic lipid-based formulations. So, we decided to investigate how these helper lipids modify the activities of presently described oxyethylene bearing cationic lipids.

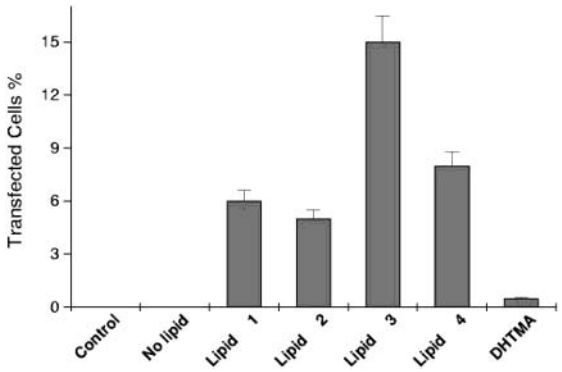

Figure 4. Potentiation of transfection abilities of cationic lipids toward HeLa cells upon incorporation of oxyethylene units at the linkage region. (control: untransfected cells; no lipid: cells exposed to DNA alone). Shown are the optimal transfection efficiencies of each liposomal formulation. Lipid to DNA charge ratio was 1−1.4. Cell viability was >80% for all the lipid formulations.

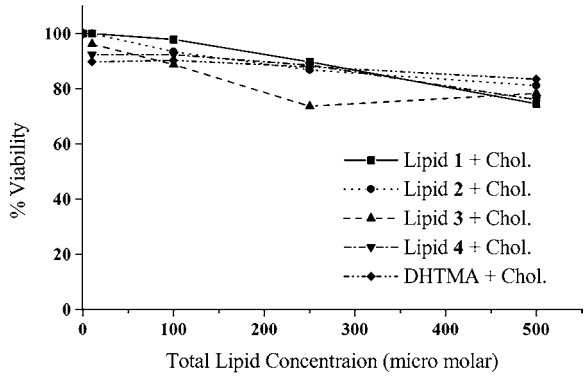

Figure 5. Cytotoxicity exhibited by the cationic liposomes containing 50 mol of cholesterol toward HeLa cells. Shown are the data from one representative experiment. Standard deviations were within 5%.

Cholesterol-Containing Cationic Liposomes. The cytotoxicities of all the oxyethylene-bearing cationic lipids were significantly reduced when cholesterol was incorporated in their liposomal formulations (Figure 5). When cholesterol was present at a 1:1 molar ratio, the ID_{50} values of all the lipid formulations were much above the range of concentrations studied. This reduction in toxicity was as high as 94% in case of lipid **2** at a cationic lipid concentration of 250 μM (Table 1). For lipids **1**, **3**, and **4**, the cell viability was increased by 50%, 66%, and 55%, respectively, upon incorporation of cholesterol under similar conditions. It is not clear whether the reduction in cytotoxicity upon inclusion of cholesterol in these liposomes is just due to the cholesterol inhibiting the cellular liposomal uptake in some fashion.

The liposomal formulations containing cholesterol at molar ratios 20 or 50 was investigated for their transfection efficiencies. The formulations in the mol-to-mol ratios of cholesterol/cationic lipid (1:4) and (1:1) were prepared by freeze−thaw followed by sonication. The transfection efficiencies of both multilamellar and unilamellar aggregates against HeLa cell line for plasmid *p* EGFP−N1 were investigated. No significant improvement in the transfection efficiencies was observed upon incorporation of cholesterol at either of these molar ratios. The observed trasnsfection efficiencies of cholesterol containing formulations were comparable to that of neat lipid formulations.

Effect of Inclusion of Dioleyoyl Phosphatidyl Ethanolamine. Though cholesterol did not influence gene transfection of cationic lipids **1**−**4**, DOPE, when used as a helper lipid, increased their transfection efficiencies significantly. There was ∼3−4 times enhancement in transfection efficiency when the liposomal formulations contained 50 mol of DOPE (see Figure 7). The lipid formulation involving the unsymmetrical lipid **3** (lipid 3/DOPE at molar ratio 1:1) was the most efficient formulation under this condition also. The addition of DOPE to DHTMA also improves the transfection efficiency, but the efficiency of formulation, 1:1 DHTMA/DOPE, is orders of magnitude lower than the highly active formulations, e.g. **3**/DOPE. It is known that lipoFECTACE (a recipe composed of 1:1 DOPE and cationic lipid) is better than the cationic lipid alone (*35*). The modulation of transfection efficiencies were only moderate when DOPE was present at 25 and 75 mol % in the lipid formulations. The transfection efficiencies showed a bell-shaped dependency on cationic lipid concentration, reaching an optimal value near lipid/DNA charge ratio 1.2 (see Figure 8). The active formulations (formulations containing 50 mol % of DOPE) exhibited very little cytotoxicity during transfection experiments. The % viability of HeLa cells under exact transfection conditions is presented in Figure 9. The toxicities of all the lipid formulations were <20% at concentrations that was optimal for maximum transfection efficiency.

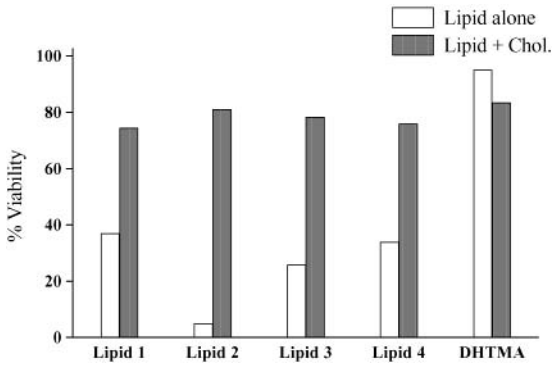

Figure 6. Reduction of cytotoxicity of cationic lipids **1**−**4** on incorporation of 50 mol % of cholesterol. Cationic lipid concentraion was 250 μM in all the formulations.

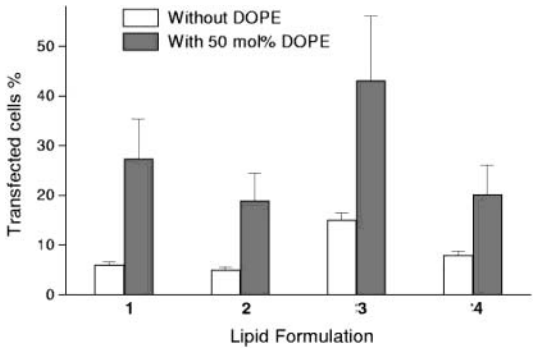

Figure 7. Enhancement in transfection efficiencies of cationic lipids **1**−**4** upon incorporation of 50 mol % of DOPE. Shown are the optimal transfection efficiencies of each lipid formulations.

CONCLUSION

Synthesis of four cationic lipids **1**−**4** with varying number of oxyethylene units at the linkage region has been achieved. These lipids formed optically clear suspensions in water with greater ease when compared to their diether analogue, DHTMA. Electron microscopy revealed the presence of closed membranous aggregates. The aqueous suspensions of all the lipids exhibited clear,

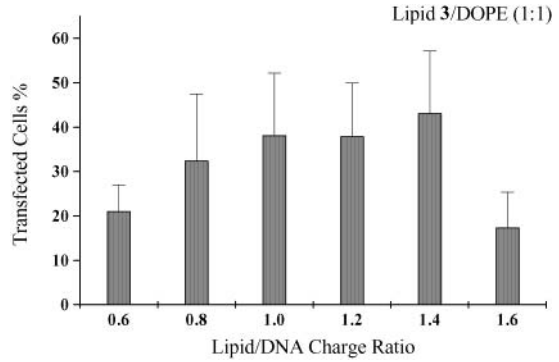

Figure 8. Optimization of lipid/DNA charge ratio for lipid **3**/DOPE (1:1) formulation. [DNA] = 0.1 μg.

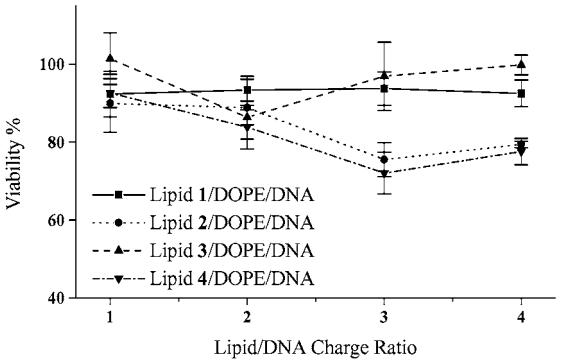

Figure 9. Viability of HeLa cells under transfection conditions. Toxicity is <20% for all the lipid formulations under optimal transfection conditions (i.e., at lipid/DNA charge ratios < 1.5).

thermotropic solidlike gel to liquid-crystalline phase transitions that are typical of lamellar aggregates. The cytotoxicities of these lipid formulations were relatively higher when compared with their diether analogue, DHTMA. The incorporation of oxyethylene units at linkages brought about a significant enhancement in the in vitro gene delivery efficiencies of the cationic lipids in mammalian cell lines. Inclusion of cholesterol in these liposomes did not modify the transfection capabilities, but it reduced their cytotoxicity. However, when DOPE was included in the cationic liposomes of **1**−**4**, a significant enhancement in transfection efficiency was observed. Optimal transfection efficiencies were observed with slightly positively charged (charge ratio ∼1.2) lipoplexes. Cytotoxicity exhibited by the lipid formulations optimized for maximal transfections were negligibly small. Thus, it has been demonstrated that the incorporation of hydrophilic oxyethylene units at the linkage region of a glyceryl-based cationic lipid in a regiospecific manner could be a useful strategy to improve its potential as promising gene delivery agents.

Although the DNA delivery to eukaryotic cells involves several steps and the mechanism of many of these steps is not very clear at the molecular level, it would be important to note some correlation between the membrane level properties and the transfection efficiencies of the present set of cationic lipids. The membrane characteristics of these oxyethylene cationic lipids were found to be very much different from that of conventional lipid, DHTMA. Oxyethylene units at the linkage region bring about significant disorder in the hydrocarbon chain packing of the lipid aggregates. It has been previously shown that the membrane perturbations due to the vector lipids are an important factor in cationic lipid-mediated DNA delivery (*36*). An oxyethylene unit in the linkage region might also affect the hydration of lipoplexes, and the hydration of lipoplexes is known to influence gene transfer events (*37*).

The unsymmetrical lipids **3** and **4** exhibited higher transfection efficiencies compared to the symmetrical ones **1** and **2**. The mismatch in the linkage region disturbs the lipid packing of such aggregates, making them more susceptible to complex with negatively charged DNA. Lipid **3** possesses the lowest gel-to-liquid crystalline phase-transition temperature among the lipids studied and it is quite close to the physiological temperature, at which transfection studies were performed. The zeta potential value of the aggregates of lipid **3** was notably higher compared to all the other lipid formulations (*38*). These factors might be responsible for the enhanced transfection efficiency of lipid formulations based on **3**. Whatever may be the actual mechanism for transfection mediated by this class of lipid formulations, the interesting and meaningful results obtained with these novel lipids should be of interest to researchers working in the field of nonviral vectors.

Efficient Conjugation and Characterization of Distamycin-Based Peptides with Selected Oligonucleotide Stretches

Sumana Ghosh,[†] Eric Defrancq,[‡] Jean H. Lhomme,[†] Pascal Dumy,[‡] and Santanu Bhattacharya*[,†]

Department of Organic Chemistry, Indian Institute of Science, Bangalore 560 012, India and LEDSS, UMR CNRS 5616, Université Joseph Fourier, BP 53, 38041 Grenoble Cedex 9, France. Received September 21, 2003; Revised Manuscript Received December 10, 2003

Selected sequences of oligodeoxyribonucleotides (ODNs) have been conjugated efficiently with distamycin-based peptides containing reactive cysteine and oxyamine functionalities at the C-terminus. The conjugation was performed easily within 30−60 min, using individual modified oligonucleotide stretches having sequences of 5′-d(GCTTTTTTCG)-3′, 5′-d(GCTATATACG)-3′, and 5′-AGCGCGCGCA-3′. Two types of linkages were used for making the covalent connection: (i) a five-membered thiazolidine ring and (ii) an oxime. These distamycin-like polyamide−ODN conjugates were then converted to the corresponding DNA duplexes using complementary oligonucleotide sequences. To elucidate the binding specificity of the distamycin−oligonucleotide conjugates, UV−melting temperature measurements were performed. These studies indicated that the distamycin−ODN conjugate favored binding with the duplex with sequence 5′-d(GCTTTTTTCG)-3′ rather than 5′-d(GCTATATACG)-3′. On the other hand, no stabilization of the duplex with sequence 5′-d(AGCGCGCGCA)-3′ was observed. UV results also suggest that the thiazolidine and oxime linkages do not significantly influence the process of distamycin binding to the minor groove surface of the DNA duplex. The results obtained from duplex UV−melting studies were further corroborated by a temperature-dependent study of the circular dichroism spectra of the conjugates and a fluorescence displacement titration assay using Hoechst 33258 fluorophore as a competitive binder for the minor groove. All these studies reinforce the fact that the specific stabilization of A/T rich DNA−DNA duplexes by distamycin was preserved upon conjugation with oligonucleotide stretches.

INTRODUCTION

The complete sequencing of the human genome has a tremendous impact on biological and biomedical research (*1*). The intricate and precise regulation of the expression of various genes encoded in the DNA nucleotide sequence was achieved by influencing transcription (using groove binder, intercalator, or antigene strategy), translation (antisense strategy), or inhibiting the function of proteins (aptamer strategy) (*2*−*6*). Among all of these, the crucial factor involves reading and recognition of specific nucleotide bases on DNA. This specificity is important for the synthesis of any drug or inhibitor that can mimic the function of DNA binding proteins or enzymes.

Among the naturally occurring drugs with low molecular mass, distamycin and netropsin are well-known. They bind selectively to A/T rich sequences of the B-DNA minor groove (*7*−*11*). Hydrogen donor groups located on the concave side of these molecules establish contacts with the hydrogen bond acceptor atoms such as N-3 nitrogen of adenine and C-2 carbonyl oxygen of thymine bases in the minor groove of DNA (*12*). Such oligopeptides, by virtue of their crescent shape, adopt nearly isohelical orientation with the B-form of the duplex. Functional groups that protrude into the minor groove, such as the 2-amino group of dG-dC base pairs, (*13*, *14*) interfere with optimal binding and give rise to the noted sequence preferences. Tight binding within the minor groove by these ligands typically results in increased duplex stability (*15*).

By combining the minor groove-based selectivity with the Hoogsteen binding of an ODN in the major groove, a variety of groove-binding agents have been tethered to DNA sequences to further improve the anti-sense and anti-gene activities and to achieve greater stabilization of the duplex and triplex structures (*16*−*25*). It has been found that the affinity of some of these conjugates for the target site is enhanced by over 100-fold than that of the unlinked subunits (*26*). In an early communication (*24*), the stabilization of certain DNA/DNA duplexes by *N*-methylpyrrolecarboxamide peptide-tethered ODN has been reported. These derivatives were required to possess a spacer at the C-terminal tagged with a 2-[[4-(phenylazo)benzyl]thio]ethyl dye to facilitate the monitoring of the covalent coupling between the peptide and ODN. It was not ascertained how the presence of such an interfering spacer affected the DNA recognition event. Moreover, the synthesis of these molecules was never described. Unfortunately, however, the methods of such tethering are often not available and sometimes not reproducible. Therefore, there is a necessity to develop efficient procedures for conjugation.

In recent years, new strategies for the conjugation of oligonucleotide with a reporter group have focused on the utility of the oxime linkage. This linkage has been used efficiently for the chemical ligation of peptides (*27*, *28*), conjugation of peptides with carbohydrates (*29*−*31*), and oligonucleotides (*32*−*34*).

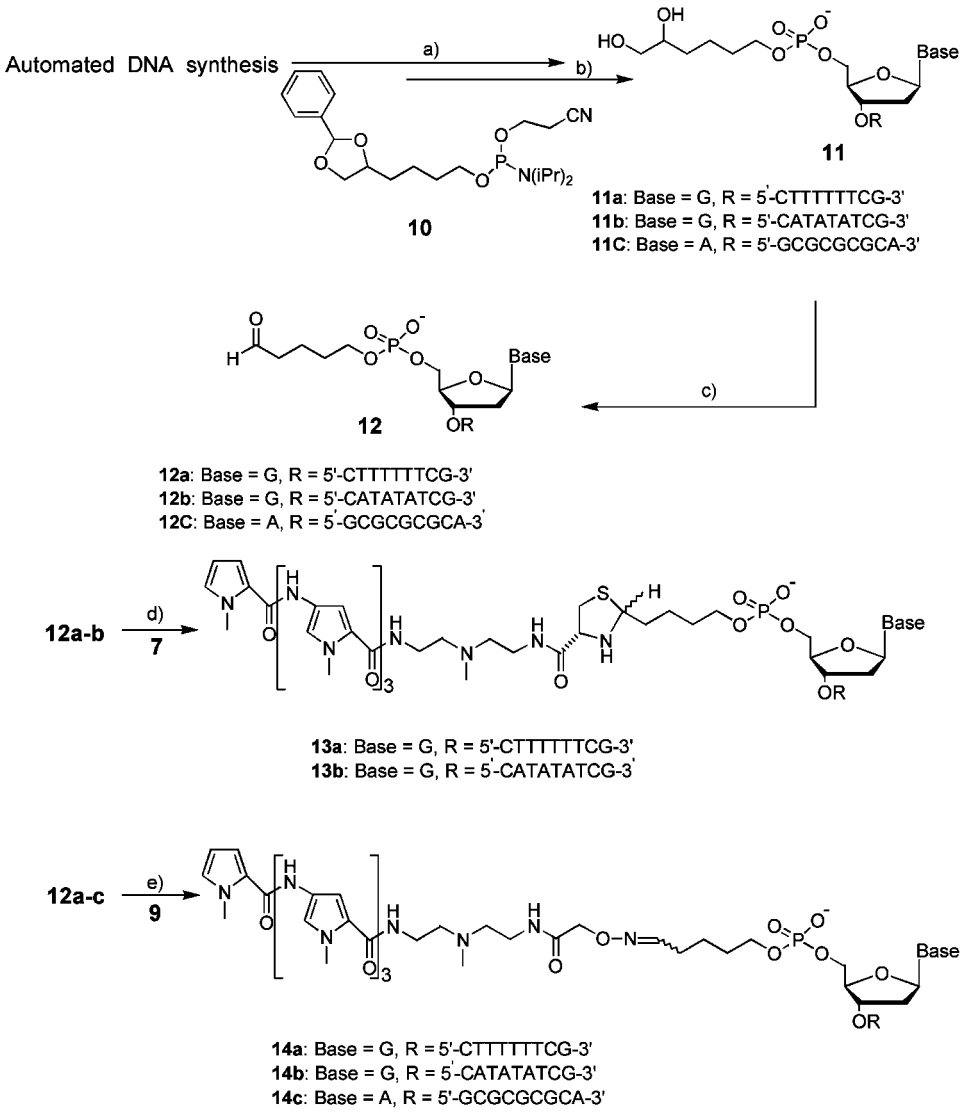
Scheme 1. Synthesis of Distamycin Analogues 7 and 9[a]

[a] Reagents: (a) $(Boc)_2O$, K_2CO_3, H_2O/dioxane (1:1, v:v), rt, 48 h, 60%; (b) HOSu, DCC, DMF, 0 °C for 1 h, then rt for 6 h, 80%; (c) **3**, $CHCl_3$, rt., 2 h, 50%; (d) CH_2Cl_2, TFA, EDT (1:1:0.2, v:v:v), rt, 2 h, 80%; (e) **4**, $CHCl_3$, rt., 2 h, 50%; (f) CH_2Cl_2:TFA (1:1, v:v), rt, 2 h, 80%.



The major advantage of this ligation technique is that it requires neither a coupling reagent nor chemical manipulations except mixing of the two components, namely the oxyamine and the aldehyde moieties. Adopting this highly chemoselective ligation procedure, we have now accomplished a convenient and efficient synthesis of five novel distamycin−ODN conjugates. In these conjugates, the C-terminus of a distamycin derivative (lacking the *N*-methylformamide unit) has been covalently attached to the 5′-end of selected ODN stretches. We describe herein the method of conjugation in detail. We also discuss the results of investigation on the specificity of distamycin binding and the duplex stabilizing properties resulting from the hybridization of these ODN−distamycin conjugates to sequences of appropriate ODN stretches by UV−melting temperature measurements, temperature-dependent circular dichroism studies, and a fluorescence displacement assay using Hoechst 33258 as a minor groove competitor.

RESULTS AND DISCUSSION

Synthesis of Distamycin−Oligopeptide Derivatives 7 and 9 (Scheme 1). The *N*-methylpyrrole-based tetrapeptide **5** containing a free amine at the C-terminus represents the key intermediate for the introduction of the 1,2-aminothiol and the oxyamine moieties. The tetrapeptide **5** was synthesized in solution phase as described previously (*35*, *36*). Covalent attachment of the 1,2-aminothiol moiety to **5** was achieved upon coupling with the *N*-hydroxysuccinimide-activated ester of the cysteine derivative **3**, in which the amino terminus and the thiol residue were protected with a *t*-Boc group. Deprotection of the *t*-Boc group was carried out by treating **6** with TFA/CH_2Cl_2 solution (1:1, v/v) at room temperature for 1 h. To prevent the oxidation of thiol to the corresponding disulfide, 2% dithiotheritol (DTT) was also included in the solution. Introduction of the oxyamino group to the oligopeptide was performed via the coupling of the activated ester of *N*-*t*-Boc-*O*-(carboxymethyl)-hydroxylamine **4** with the tetrapeptide **5**. Subsequent acidic treatment with TFA/CH_2Cl_2 solution (1:1, v/v) for 1 h at room temperature of the protected intermediate **8** led to distamycin analogue **9**. The distamycin analogues **7** and **9** containing cysteine and oxyamine functionalities, respectively, were then used for conjugation with ODN stretches without further purification.

Oligonucleotides Synthesis. *Aldehyde-Containing Oligonucleotides.* The preparation of the oligonucleotides containing an aldehyde linker at the 5′-extremity was

Scheme 2. Synthesis of Different Oligonucleotides 13a,b and 14a−c[a]

[a] Reagents: (a) Incorporation of phosphoramidite **10** at the last stage of the oligonucleotide synthesis and then NH_4OH, 50 °C for 16 h; (b) aq 80% AcOH; (c) polymer-supported $NaIO_4$, rt., 1 h; (d) **7**, CH_3COONa buffer (0.2 M, pH 5.4), CH_3CN, 1 h, rt.; (e) **9**, CH_3COONa buffer (0.2 M, pH 5.4), CH_3CN, 30 min, rt.

accomplished upon minor modification of a previously reported procedure (*32*). Briefly, the strategy included the preparation of the oligonucleotides **11a**−**c** containing the 1,2-diol moiety using the corresponding phosphoramidite **10** (Scheme 2). Peroxidation of the diol upon reaction with 10-fold excess of polymer-supported $NaIO_4$ for 1 h gave the corresponding aldehydes **12a**−**c**. Subsequent conjugations were carried out without further purification of the aldehyde in the case of the preparation of the oxime conjugate. However, for the synthesis of the thiazolidine conjugate, it was necessary to purify the aldehyde from excess of periodate by reverse phase chromatography to avoid thiol oxidation (*33*).

Conjugation via Thiazolidine and Oxime Linkage. The ligation involved the reaction between aldehyde-containing ODN at the 5′-terminus with a 1,2-aminothiol for thiazolidine formation and with an oxyamino moiety for oxime bond formation as depicted in Figure 1. For both type of linkers, the conjugates were obtained in good yields under mild conditions within 1 h and without the need for a protection/deprotection step.

Thiazolidine conjugation was carried out by reacting the peptide **7** with either of the oligonucleotides **12a** or

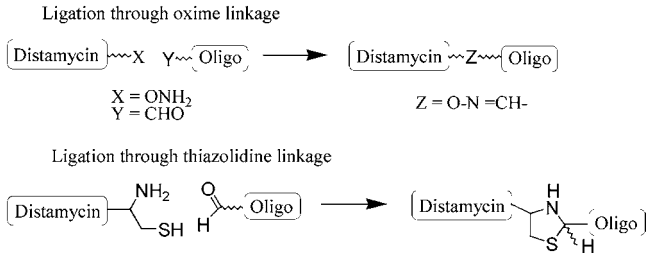


Figure 1. Strategy of efficient and facile synthesis of distamycin−ODN conjugates by using oxime and thiazolidine linkages.

12b at room temperature in sodium acetate buffer (0.2 M, pH = 5.4). The progress of the reaction was followed by C18 reverse-phase HPLC. The reaction was completed in 1 h when 4 equiv of distamycin derivative **7** were used. Figure 2A shows the evidence of clear separation of the conjugate from the crude mixture containing **12a** and **7**. After purification by RP-HPLC, the conjugates **13a**,**b** were obtained in ∼20−30% isolated yields. Formations of **13a**,**b** were confirmed by ESI-MS analysis (Table 1).

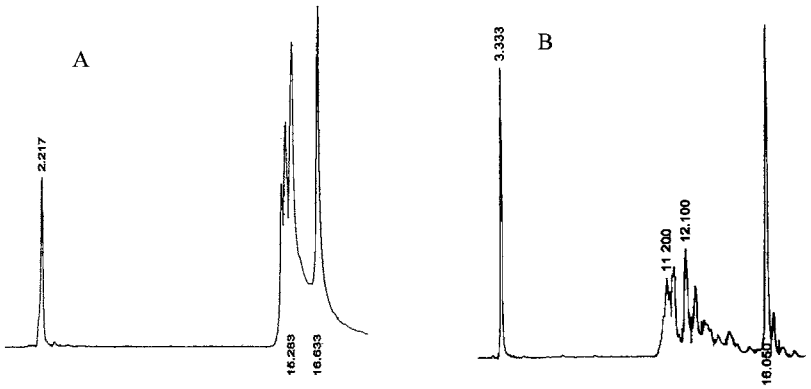

Figure 2. HPLC profiles (detection at 260 nm) of the crude reaction mixture, after 30 min of reaction of the peptide **7** (thiazolidine conjugation) (A) and **9** (oxime conjugation) (B) with the corresponding aldehyde-containing ODN **12a**. (A) Retention times 2.2, 15.3, and 16.6 min correspond to **7**, modified ODN **12a**, and the thiazolidine-conjugated distamycin−ODN **13a** respectively. (B) Retention times 3.3, 16.1 min correspond to **9** and the *N*-oxime-conjugated distamycin−ODN **14a,** respectively. Modified ODN **12a** has already been consumed within 30 min of the reaction with the peptide **9**.

[a] Optical melts were generated in 0.01 M sodium phosphate buffer/0.001 M EDTA containing the relevant concentrations of NaCl, pH 7.4, with [duplex] = [**7**] = 9.31×10^{-6} M. ΔT_m correspond to the difference in T_m between the modified and unmodified duplex. [b] NaCl concentrations (40, 100, 500 mM). [c] Duplex melting was measured only at 0.04 M NaCl concentration.

Oxime conjugation reaction was similarly performed by reacting the oligonucleotides **12a−c** with the peptide **9** at room temperature in sodium acetate buffer (0.2 M, pH = 5.4). This reaction was found to be quite rapid and was completed within ∼30 min when 4 equiv of peptide **9** was used. Figure 2B shows the HPLC profile of the crude reaction mixture with oligonucleotide **12a**. The yields after purification by RP-HPLC ranged from 38 to 48% and each of the conjugates **14a−c** were characterized by ESI-MS. In all cases, the experimentally determined molecular weights were in excellent agreement with the calculated values (Table 1).

Although in principle, both thiazolidine- and oxime-based oligopeptide-linked ODN should have two diastereomeric forms, but they could not be identified as two separate peaks during RP-HPLC purification process. The conjugated products (**13a**,**b**, **14a−c**) exhibited UV−vis spectra having characteristics of both DNA (λ_{max} = 260 nm) and the distamycin (λ_{max} = 316 nm) band.

Duplex-Stabilizing Properties. *Melting Temperature Analysis of Hybridization with a Target Oligonucleotide Stretch (Table 2).* The hybridization properties of the conjugates **13a**,**b** and **14a−c** were investigated by UV−melting (thermal denaturation) temperature measurements (T_m). The study was carried out with the following objectives. First, to evaluate the influence of covalent coupling of distamycin-like polyamide with the oligonucleotides and second, to examine the effects of the two kinds of linkages used to tether distamycin with ODN stretches and also their impact on the stability of the corresponding duplex oligonucleotides.

The thiazolidine conjugates **13a**,**b** and the oxime conjugates **14a−c** were individually hybridized with the corresponding complementary oligonucleotide sequences, **15a−c** 3′-d(CGAAAAAAGC)-5′, 3′-d(CGATATATGC)-5′, and 3′-d(TCGCGCGCGT)-5′, respectively. The melting temperatures of the resulting duplexes were determined by following changes in absorbance at 260 nm as a function of temperature from 20 to 80 °C. There was no hysteresis observed during heating and cooling processes of the duplex melting, suggesting a reversible binding process of tethered distamycin to the minor groove surface of duplex. The ODNs, **11a−c**, containing the diol linker at the 5′-ends were also compared. Furthermore, the effect of free distamycin analogue was verified with the corresponding unconjugated duplex. It was found that distamycin-conjugated oligonucleotides with A/T rich sequences (**13a**,**b** and **14a**,**b**) were significantly stabilized in their duplex forms. In contrast, the distamycin-linked ODNs possessing alternating G/C base pairs (**14c**) did not enhance the duplex melting temperature. This suggests that the hybridization of the DNA−distamycin conjugates with the target sequences generates a DNA minor groove surface and facilitates the binding event by the tethered distamycin unit. Besides, continuous

stretches of A/T (**13a** and **14a**) were stabilized to a greater extent than their counterparts with alternating AT base pairs (**13b** and **14b**).

Earlier studies based on NMR and chemical nuclease-mediated footprinting experiments suggest that distamycin induces a 'collapse' of a normal minor groove into a narrower groove (*37*, *38*). This should enhance the hydrogen bonding and van der Waals interactions. Such deep penetration of the drug to the walls of the minor groove in turn should favor enthalpic contribution for the binding. The ATAT sequence in the decamer d(5′-GCTATATACG-3′)$_2$ has a low intrinsic propeller twist angle, which may not facilitate the formation of a narrower minor groove for favorable binding of the distamycin (*37*). Thus the readjustment of the backbone in case of alternating A/T stretches would be difficult. This may account for the low affinity of ODN-conjugated distamycin to the alternating A/T sequence in comparison to that of a contiguous A or T sequence.

The enhancement of melting temperature (ΔT_m) was almost comparable for both thiazolidine- and *N*-oxime-linked distamycin conjugates. This suggests that the nature of linker (five-membered thiazolidine ring vs linear oxime bond) does not significantly influence and contribute to the duplex stabilization. The stabilization upon duplex formation between a complementary oligonucleotide sequence with the oligonucleotide-conjugated distamycin was also compared with respect to free distamycin binding to the corresponding DNA duplex. In each case, the stabilization was found to be more pronounced for the covalently conjugated distamycin than that of the free duplex.

Effect of Salt on Hybridization to the Target Oligonucleotides. Most of the ligands including distamycin or netropsin that bind to DNA are cationic. Therefore, experiments at varying salt concentrations provide useful information pertaining to the relative importance of nonspecific (electrostatic) and specific (hydrogen bonding, van der Waals interactions) factors on the DNA recognition process. Salt-induced ligand−DNA complex dissociation experiments are often useful for comparing the relative affinities and mode of ligand binding toward DNA (*39*). Generally for compounds with similar binding modes, the higher the binding affinity, the lower should be the dissociation of the ligand−DNA complex with increasing salt concentration. Additionally, DNA is known to undergo structural transition in the presence of high salt concentration (*40*, *41*). Strong precomplexation of a ligand with DNA should also resist such structural transition.

Duplex melting was examined at various NaCl concentrations (40, 100, 500 mM) to analyze the electrostatic effect of distamycin binding on T_m enhancement. It was observed that on increase in salt concentration, the T_m value for a given duplex was increased (Table 2). This is in agreement with known salt effects on polyelectrolyte solutions, explained on the basis of the counterion condensation theory (*42*−*45*). According to this concept, an increase in bulk salt concentration should lead to the stabilization of the duplex state of DNA as having a higher charge density as compared with the single-stranded form. This would result in an increase in T_m for the helix-to-coil transition. However, at high salt concentration such as in 500 mM, although the T_m increased to the highest extent, the ΔT_m value was found to be less compared to the ΔT_m in low salt conditions (40, 100 mM) in case of both free and covalently conjugated distamycin except for **14a**/**15a** duplex. This fact is correlated with the energetic contribution (large negative enthalpy and positive entropy value) in the distamycin−DNA binding process described earlier (*46*, *47*). The favorable entropic gain arises because of the release of ordered water molecules from the hydration shell of the DNA backbone during any ligand binding. At high salt concentration, the release of water molecules is expected to be less. This in turn would reduce the entropy gain as well as the binding energy. This may result in low ΔT_m value at higher salt concentration. Thus, for the peptide−ODN conjugates, there may be two opposite influences on the T_m of duplex formation as the concentration of salt increases, namely increased stability of the double-stranded DNA region and decreased association of the peptide portion with the oligonucleotide target.

CD Spectral Analysis of the Distamycin−ODN Conjugates. Considerable information on the binding of distamycin to nucleic acid duplex has been obtained from circular dichroism measurements (*48*, *49*). Since free distamycin does not exhibit optical activity and is therefore CD-silent. However, its binding to double-stranded nucleic acid induces a CD signal that can be used to monitor the binding process. In the present case, the conjugates **13a**,**b** and **14a**−**c** alone exhibited two positive peaks at 280 nm (DNA-CD) and 334 nm (distamycin-CD) that were characteristics of the single-stranded ODN and conjugated distamycin moiety, respectively. Efficient intraduplex binding of the covalently attached distamycin to the minor groove of the duplexes (**13a**/**15a**, **13b**/**15b**) intensifies the magnitude of molar ellipticity at 334 nm compared to their corresponding unmodified duplexes (**11a**/**15a**, **11b**/**15b**) bound with free distamycin. Between these two duplexes (**13a**/**15a**, **13b**/**15b**), the former one (with continuous A/T stretch) showed a more intense CD band than the latter (with alternating A/T stretch). These results are consistent with the data obtained from the UV−melting temperature study, suggesting that covalently conjugated distamycin stabilizes the duplex ODN more than the ODN bound noncovalently with distamycin, and it has greater sequence selectivity toward the continuous stretch of A/T rich tract than the one with alternating A/T stretch.

The nature and specificity of distamycin binding to the minor groove surface of different A/T stretch DNA duplex was further examined by duplex melting at 334 nm (distamycin-CD) as a function of temperature from 20 to 80 °C (Figure 3). The sequence specificity and mode of distamycin binding to the different ODN stretches were analyzed from the peak height and the magnitude of the peak minima of such derivative plot of d(CD)/dT vs T at 334 nm. The CD intensity (peak height) at 334 nm was higher in both ODN−distamycin conjugates (e.g. **14a**/**15a**) than the one with unmodified duplex (e.g. **11a**/**15a)** containing free distamycin. This might be due to a favorable binding of the covalently attached distamycin to an ODN stretch, owing to its higher effective concentration at the DNA minor groove. Moreover, the peak height was higher in case of continuous A/T stretch than alternating A/T sequence. Magnitude of peak minima was almost same for continuous A/T stretch duplexes (**14a**/**15a** and **11a**/**15a** + **9**). In this case, it is possible that more efficient binding of distamycin to a continuous A/T tract (as in **11a**/**15a**) probably does not allow any further conformational change of distamycin in ODN irrespective of whether it is covalently conjugated with the distamycin or not. This is in contrast to what was observed with the ODN bearing alternating A/T tract, where peak magnitude was differed by ca. 4 °C between (**14b**/**15b** and **11b**/**15b** + **9**). It may be that covalent attachment of distamycin induced a conformational change of ODN that

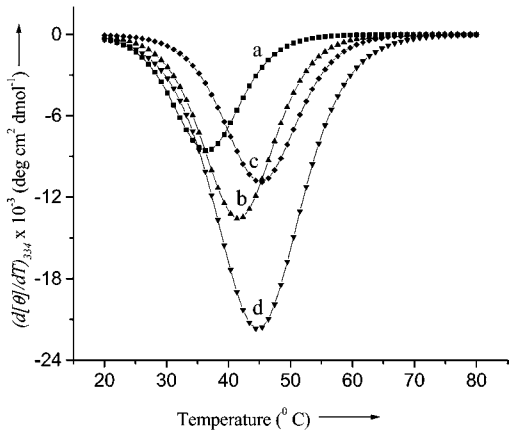

Figure 3. First derivative plot of molar ellipticity vs temperature during duplex melting at 334 nm. CD melting curves of the duplexes, 5′-dis-ox-GCATATATCG-3′ **14b**/3′-CGTATATAGC-5′ **15b** (a, ■), 5′-XGCATATATCG-3′ **11b**/3′-CGTATATAGC-5′ **15b** + **9** (b, ▲) 5′-XGCTTTTTTCG-3′ **11a**/3′-CGAAAAAAGC-5′ **15a** + **9** (c, ◆), 5′-dis-ox-GCTTTTTTCG-3′ **14a**/3′-CGAAAAAAGC-5′ **15a** (d, ▼) with change in temperature at the rate of 1 °C/min from 20 to 80 °C at 334 nm. In each case CD spectra were recorded in 0.01 M Na_2HPO_4 buffer, 0.04 M NaCl, 0.001 M EDTA, pH 7.4, with [duplex] = [**9**] = 1.3×10^{-5} M. (X = diol-modified oligonucleotide, dis = distamycin, and 'ox' corresponds to oxime-conjugated ODN−distamycin hybrid).

enhanced hydrogen-bonding interaction at its minor groove surface compared to the unmodified ODN where distamycin was not covalently attached.

It had been observed that the equilibrium between free distamycin and DNA in the binding process was affected by addition of salt to the preformed noncovalent distamycin−DNA complex. This complex dissociation process as a function of salt concentration can be followed by examining the changes in magnitude and the nature of the CD band at 334 nm. A gradual decrease in the CD band at 334 nm with a minute change at 280 nm was observed for **5**, noncovalently bound to duplex with increasing salt concentration up to ca. 1 M (*50*). But no significant change in the corresponding bands at 280 and 334 nm was observed for **14a**/**15a** and **14b**/**15b** duplexes. In both cases, addition of salt (NaCl, up to ca. 1 M) to the preformed distamycin−DNA complex and also the formation of such complexes under different salt concentrations did not lead to any significant change in the 334 nm CD band. Therefore, high salt concentration could not dissociate the tightly bound, covalently attached distamycin arm from the DNA surface, preserving the structural integrity of both the DNA and the distamycin moiety.

Competition with Hoechst 33258 Binding. In this study Hoechst 33258 fluorophore was used as a minor groove competitor, which has the same sequence selectivity but a higher DNA binding constant (ca. 10^8 mol^{-1}) (*51*) than that of distamycin (ca. 10^5 to 10^6 mol^{-1}). To determine the accessibility of strong groove binding ligands such as Hoechst 33258 to the minor groove of the distamycin−ODN conjugates, we performed fluorescence titration using the above probe. For this purpose, we compared the binding of Hoechst 33258 with unmodified ODN in the presence and absence of distamycin and also with the corresponding distamycin−ODN conjugates having two different A/T stretches.

The fluorescence intensity of Hoechst 33258 is very low in its free state in solution. However, the emission due to Hoechst 33258 increases dramatically upon binding to duplex DNA (*52*). Fluorescence titrations were performed at a fixed concentration of ODNs while varying the Hoechst 33258 concentration till saturation, as indicated from emission spectroscopy. In all the cases, the enhanced fluorescence intensity was measured after each addition (Figure 4) and the binding efficiency was compared from Hoechst 33258 concentration required to saturate its fluorescence intensity. A significantly higher concentration of Hoechst 33258 was required to saturate its fluorescence intensity in either free or covalently bound distamycin, in comparison to the duplex itself. Duplexes **11a**/**15a** and **11b**/**15b** containing noncovalently bound distamycin-like polyamide at its minor groove surface required 1 and 0.7 μM greater Hoechst 33258, respectively, to saturate its binding with respect to the duplex ODN without distamycin. In the case of duplex ODN bearing covalently tethered distamycin derivatives such as **14a**/**15a** and **14b**/**15b**, respectively, a greater Hoechst 33258 concentration was required (0.3−0.4 μM) with respect to the unconjugated duplex ODN. In both cases it was found that more Hoechst 33258 was required to saturate its fluorescence intensity in duplexes containing a continuous A/T stretch (**14a**/**15a**, **11a**/**15a** + **9**) rather than an alternating A/T stretch (**14b**/**15b**, **11b**/**15b** + **9**).

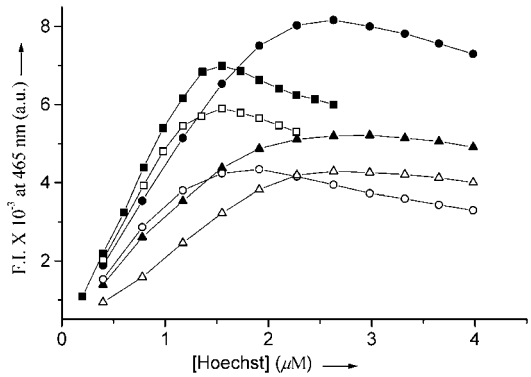

Figure 4. Fluorescence titration of corresponding duplexes with minor groove competitor Hoechst 33258, 5′-XGCTTTTTTCG-3′ **11a**/3′-CGAAAAAAGC-5′ **15a** (■), 5′-XGCTTTTTTCG-3′ **11a**/3′-CGAAAAAAGC-5′ **15a** + **9** (●), 5′-dis-ox-GCTTTTTTCG-3′ **14a**/3′-CGAAAAAAGC-5′ **15a** (▲), and 5′- XGCATATATCG-3′ **11b**/3′-CGTATATAGC-5′ **15b** (□), 5′- XGCATATATCG-3′ **11b**/3′-CGTATATAGC-5′ **15b** + **9** (○), 5′-dis-ox- GCATATATCG-3′ **14b**/ 3′-CGTATATAGC-5′ **15b** (△) in 0.01 M Na_2HPO_4 buffer, 0.04 M NaCl, 0.001 M EDTA, pH 7.4 with [duplex] = [**9**] = 3×10^{-6} M. Spectra were recorded at λ_{ex} = 350 nm, λ_{em} = 465 nm, slit width Ex/Em = 10 nm/10 nm. (X= 5′-diol modified oligonucleotide, dis = distamycin and 'ox' corresponds to oxime-conjugated ODN−distamycin hybrid).

It is known that fluorescence intensity of the Hoechst-like fluorophore is quenched after it saturates its binding to the DNA minor groove surface (*52*). This was due to the nonspecific binding of excess Hoechst 33258 molecules to the phosphate backbone of DNA. In our displacement assay, there was less quenching observed for duplexes containing free distamycin, and no such quenching was observed for the covalently bound distamycin analogue (Figure 4). When distamycin is noncovalently complexed with the duplex ODN, addition of Hoechst 33258 releases distamycin molecules from its minor groove. Such released distamycin molecules then compete for the nonspecific binding with the phosphate backbone, impeding further approach of Hoechst molecule to these sites. Interestingly, when distamycin is covalently conjugated, nonspecific binding to the phosphate sites by Hoechst was completely inhibited. Importantly, this study reinforces the fact that the duplex formation is facilitated by a covalently attached distamycin analogue

and also supports its sequence preference for a continuous A/T stretch rather than an alternating A/T sequence.

CONCLUSIONS

In summary we have reported two chemical methods for the conjugation of oligonucleotides to a minor groove-binding (MGB) polyamide. Although conjugates of MGB polyamides have been prepared in the past, the utility of the present approach is that it would be possible to prepare a selection of appropriately derivatized polyamides and oligonucleotides and ligate together in a modular fashion. Thus, if the goal is to prepare a library of compounds, then this would be a time-saving approach. The chemistry employed here for the conjugation of an ODN to a distamycin-like polyamide is an extension of existing techniques based on the reaction of an aldehyde to form an oxime linkage or a thiazolidine ring. After HPLC purification and characterization of these conjugates, we investigated the influence of tethered distamycin on duplex formation and assessed the stability with the complementary strand through interactions mediated by an A/T stretch. Hybridization by the conjugate to a target sequence converts a single-stranded species to a double-stranded complex and generates a secondary structure with both major and minor grooves. The hybridization event triggers a binding event by the 5′-end ODN-tethered distamycin within the generated minor groove structure. This was proved by the enhanced thermal denaturation temperature (ΔT_m) at 260 nm, increased CD intensity at 334 nm, and a requirement of more Hoechst 33258 molecules during the fluorescence displacement assay. Taken together, it is evident that the distamycin conjugates are more selective in binding to ODNs containing a continuous stretch of A/T base pairs rather than the one having alternating A/T tract. CD studies at different salt concentrations reinforce the specific interaction of distamycin conjugates to the corresponding duplexes. No significant binding preference was observed for the five-membered thiazolidine linker over the linear *N*-oxime-conjugated distamycin to the duplex. This could be due to long linker length between the ODN and the peptide, allowing the linker part to loop during the distamycin−DNA binding process. The combination of such hybridization-triggered binding events should provide the basis for the development of DNA-based diagnostic properties of antigens or therapeutic ODNs by enhancing its target-binding properties, cellular uptake, or exonuclease stability or can be used as an in situ hybridization probe. Since distamycin is known to form a stacked, antiparallel dimer upon binding to AT tracts of DNA (*53*, *54*), it is possible to employ distamycin−ODN conjugates for pseudo-cyclized duplex DNA and triple helix formation. Work is currently underway in this direction.

EXPERIMENTAL SECTION

Materials and Methods. All chemical reagents were of the highest purity available and were used without purification. Solid-supported $NaIO_4$ (polystyrylmethyl)-trimethylammonium metaperiodate, loading 2.5 mmol/g, was purchased from Novabiochem and 2-cyanoethyl diisopropylchlorophosphoramidite from Aldrich. The phosphoramidite **10** was prepared by analogy with the previously described protocol (*29*). The activated ester **4** of *N*-Boc-*O*-(carboxymethyl)hydroxylamine was prepared as described earlier (*55*). Thin-layer chromatography (TLC) was performed using silica gel-G, and preparative column chromatography was performed on silica gel (60−120 mesh size). DMF, CH_2Cl_2, and $CHCl_3$ were dried over P_2O_5, Et_3N was dried over KOH, and THF was dried using sodium and benzophenone ketyl. HPLC purification as well as HPLC analysis of oligonucleotides and conjugates was performed on a water system equipped with two M510 pumps, a M490E detector, and an M680-system controller. The oligonucleotides and the conjugates were purified on a μ-bondapak C-18 column (Macherey-Nagel Nucleosil: 10 × 250 mm, 7 μm) using the following system of solvent: solvent A, 20 mM ammonium acetate/CH_3CN, 95:5 (v:v); solvent B (CH_3CN); flow rate, 4 mL/min; a linear gradient from 0 to 30% B in 20 min was applied. ^{1}H NMR and ^{13}C NMR spectra were recorded on JEOL JNM λ-300 or using a Bruker AMX 400 (400 MHz for ^{1}H and 100.6 MHz for ^{13}C) NMR spectrometer. Chemical shifts (δ) are reported in ppm downfield from the internal standard (TMS). Electrospray ionization (ESI) mass spectra were measured on an Esquire spectrometer (Bruker). Analysis was performed in the negative mode for both the oligonucleotides and conjugates and in the positive mode for the peptides. The oligonucleotides and the conjugates were dissolved in 50% aqueous acetonitrile, and 1% of NEt_3 was added. The peptides were dissolved in 50% aqueous acetonitrile containing 1% of TFA.

2-*tert*-Butoxycarbonylamino-3-*tert*-butoxycarbonylsulfanylpropionic Acid 2. To a cooled aqueous/dioxane solution (1:1, v/v, 1.2 mL) of L-cysteine, **1** (0.4 g, 3.3 mmol), were added potassium carbonate (2.4 g, 18.3 mmol) and di(*tert*-butyl) dicarbonate (2.8 g, 13.2 mmol), and the mixture was stirred for 48 h at room temperature. The resulting mixture was then washed with ether to remove excess of di(*tert*-butyl) dicarbonate and acidified with 0.2 N aq HCl. The aqueous layer was then extracted with EtOAc. The organic layer was washed with brine solution, dried over anhydrous Na_2SO_4, and evaporated in a vacuum. Purification by column chromatography over silica gel (MeOH/$CHCl_3$ 1:49) afforded a white solid compound. Yield: 0.28 g, 60%; ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.43 (s, 9H, C(CH_3)$_3$), 1.47 (s, 9H; C(CH_3)$_3$), 3.16−3.23 (dd, ^1J (H, H) = 14.4 Hz, ^2J (H, H) = 7.8 Hz, ^2J(H, H) = 6.6 Hz, 1H; CH_2S(Boc)), 3.3−3.4 (dd, ^1J(H, H) = 14.1 Hz, ^2J(H, H), = 4.5 Hz, ^2J(H, H) = 3.3 Hz, 1H; CH_2S(Boc)), 4.5 (m, 1H; C*H*-CH_2), 5.4 (m, 1H; N*H*); ^{13}C NMR (100.6 MHz,$CDCl_3$): δ 28.1, 28.3, 32.6, 54.4, 80.5, 85.7, 155.6, 168.7, 174.5 ppm; Elemental analysis: calcd (%) for $C_{13}H_{23}O_6NS$ (321.4): C 48.58, H 7.21, N 4.36; found: C 49.0, H 7.3, N 4.3.

2-*tert*-Butoxycarbonylamino-3-*tert*-butoxycarbonylsulfanylpropyl 2,5-Dioxopyrrolidin-1-yl Ester, 3. 2-*tert*-Butoxycarbonylamino-3-*tert*-butoxycarbonylsulfanylpropionic acid **2** (0.1 g, 0.3 mmol) was dissolved in DMF (1 mL) and cooled in an ice bath. *N*-Hydroxysuccinimide (HOSu, 0.04 g, 0.4 mmol) was added to the above solution, followed by dicyclohexylcarbodiimide (0.08 g, 0.4 mmol). The resulting solution was stirred for 1 h at 0 °C and then at room temperature for another 6 h. The precipitated dicyclohexylurea was filtered off, and the filtrate was diluted with EtOAc. The EtOAc layer was washed successively with $NaHCO_3$ and brine, dried over anhydrous Na_2SO_4, and evaporated to obtain the succinimide ester **3** as practically pure solid. Yield: 0.16 g, 80%. This was directly used for the next step without further purification; ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.41 (s, 9H; C(CH_3)$_3$), 1.46 (s, 9H; C(CH_3)$_3$), 2.8 (s, 4H; CO(CH_2CH_2)-CO), 3.17−3.25 (dd, ^1J(H, H) = 14.1 Hz, ^2J(H, H) = 8.1 Hz, 1H; CH_2S(Boc), 3.4−3.45 (dd, ^1J = 14.1 Hz, ^2J = 4.6 Hz, 1H; CH_2S(Boc)), 4.82 (m, 1H; C*H*(CO)NH), 5.4 (m, 1H; N*H*).

***N*2-2-[[2-(2-*tert*-Butoxycarbonylamino-3-*tert*-butoxycarbonylsulfanylpropylamino)ethyl](methyl)amino]ethyl-1-methyl-4-[(1-methyl-4-[(1-methyl-4[(1-methyl-1*H*-pyrrol-2-yl)carbonyl]amino-1*H*-pyrrol-2-yl)carbonyl]amino-1*H*-pyrrol-2-yl)carbonyl]amino-1*H*-2-pyrrolecarboxamide, 6.** To a solution of N2-2-[(2-aminoethyl)(methyl)amino[(1-methyl-4-[(1-methyl-4-[(1-methyl-4[(1-methyl-1*H*-pyrrol-2-yl)carbonyl]amino-1*H*-pyrrol-2-yl)carbonyl]amino-1*H*-pyrrol-2-yl)carbonyl]-amino-1*H*-2-pyrrolecarboxamide **5** (0.2 g, 0.3 mmol) in $CHCl_3$ (5 mL) was added activated *N*-hydroxysuccinimide ester **3** (0.15 g, 0.4 mmol), and the resulting solution was stirred at room temperature for 2 h. At the end of this period, the reaction mixture was filtered off and the filtrate evaporated under vacuum. The resulting mixture was purified by column chromatography over silica gel using MeOH/$CHCl_3$ (3/47) as eluent. This furnished **6** as a yellow powder. An equal volume of TFA (0.2 mL, 2.6 mmol) was added into it under cold conditions, and the reaction was continued for 2 h at room temperature under an argon atmosphere. After completion of the reaction, the excess TFA and solvent were removed in vacuo. To the residue were added $CHCl_3$ and H_2O (500 μL:500 μL) and the biphasic solution was mixed thoroughly. The excess ethane dithiothreitol (EDT) was removed in organic phase, and the aqueous phase was lyophilized to obtain **7**. It was directly used without further purification due to its instability and high reactivity. Yield: 6.1 mg, 80%; MS (ESI): *m*/*z* (%) = 694.22 (50) [M + H]$^+$, 347.76 (100) [(M + H)/2]$^+$

***N*2-2-[[2-(2-Aminooxyacetylamino)ethyl](methyl)amino]ethyl-1-methyl-4-[(1-methyl-4-[(1-methyl-4[(1-methyl-1*H*-pyrrol-2yl)carbonyl]amino-1*H*-pyrrol-2-yl)carbonyl]amino-1*H*-pyrrol-2yl)carbonyl]amino-1*H*-2-pyrrolecarboxamide, 9.** To a solution of **8** (10 mg, 0.013 mmol) in dichloromethane (0.2 mL) was added an equal volume of TFA (0.2 mL, 2.6 mmol), and the reaction mixture was stirred at room temperature for 2 h. The solvent and excess TFA was removed under vacuum, and the residue was directly used for the conjugation reaction without further purification due to its high reactivity. Yield: 6.9 mg, 80%; MS (ESI): *m*/*z* (%) = 664.22 (100) [M + H]$^+$.

Oligonucleotide Synthesis. Automated DNA synthesis was performed on a Perkin-Elmer model Expedite DNA synthesizer using standard cyanoethyl nucleoside phosphoramidite chemistry on a 1 μM scale. After cleavage from the solid support and deprotection by treatment with concentrated ammonia (28%) for 16 h at 55 °C, the oligonucleotides were purified by RP-HPLC.

Diol-Containing Oligonucleotides 11a−c. The 5′-protected oligonucleotides were treated with 80% aq AcOH for 1 h. The residue obtained after lyophilization was dissolved in water, and the aqueous layer was extensively washed with Et_2O to remove the benzylidene byproduct. Subsequent lyophilization afforded the oligonucleotides **11a**−**c**, which were characterized by ESI-MS (Table 1).

Aldehyde-Containing Oligonucleotides 12a−c. To a solution of the oligonucleotide **11a** (1 mg, 0.3 μmol) in water (1 mL) was added solid-supported $NaIO_4$ (0.67 mg, 3 μmol), and the mixture was shaken gently for ∼1 h. The solution was then decanted, and the polymer was washed twice with H_2O. Washings were added to the solution, and the resulting solution was evaporated under vacuum to remove volatiles. The product was then directly used for oxime conjugation without further purification. For thiazolidine-containing oligonucleotides, it was purified by RP-HPLC to remove excess periodate. The decamers **12b**,**c** were prepared in the same manner.

Conjugation through Thiazolidine and Oxime Linkages. *Preparation of Oligonucleotides **13a**,**b** and **14a**−**c**.* The cysteine-tethered peptide **7** (0.4 mg, 0.64 μmol) was dissolved in 0.2 M NaOAc buffer (pH = 5.4, 30 μL) and was added into 0.2 M NaOAc buffer solution (130 μL) containing the aldehyde-containing oligonucleotide **12a** (500 μg, 0.16 μmol). The mixture was stirred at room temperature, and the progress of the reaction was followed by RP-HPLC. Disappearance of the starting material **12a** was achieved in 1 h (Figure 2A). In Figure 2A, **12a** showed three peaks in HPLC profile, which correspond to the imine formation of some part of the aldehyde-containing ODN with ammonium acetate buffer used as a solvent during the HPLC elution period. Purification by HPLC afforded the conjugate **13a** in 30%

yield. The conjugate **13b** was obtained in the same manner from the oligonucleotide **12b**.

The oligonucleotides **14a**−**c** were prepared in the same manner by adding 0.2 M NaOAc buffer (pH = 5.4, 30 μL) containing oxyamine-containing peptide **9** into 0.2 M NaOAc buffer solution (130 μL) containing the reactive oligonucleotide **12a**−**c**. Disappearance of the starting material **12a**−**c** was achieved within ∼30 min, and purification by HPLC afforded the conjugate **14a**−**c** in 40% yield (Figure 2B). Subsequent lyophilization afforded the distamycin−ODN conjugates **13a**,**b** and **14a**−**c**, which were characterized by ESI-MS (Table 1).

Hybridization Experiments. Duplex formation and the melting T_m experiments were carried out by mixing equimolar amounts of the two decamer oligonucleotide strands in 10 mM Na_2HPO_4 buffer, 1 mM EDTA, and varying concentrations of NaCl (40, 100, 500 mM) at pH 7.4. All measurements were performed at 9.31 μM concentration of each strand, and the mixtures were heated at 90 °C for 6 min and then cooled slowly to room temperature to allow the formation of duplex. The melting curves (absorbance at 260 nm vs temperature) were generated using a Lambda 5 UV−vis spectrophotometer equipped with a Perkin-Elmer C570−070 temperature controller using a scan rate of 0.5 °C/min (from 20 to 70 °C) and 1 °C/min (from 70 to 80 °C). The data were recorded at each 0.1 °C interval. In all cases the buffer-corrected absorbance vs temperature curves were converted to relative absorbance, $\theta = (A_t - A_{20})/(A_{80} - A_{20})$ vs temperature (A_t correspond to the absorbance at any temperature t) to obtain the value of T_m.

Circular Dichroism Measurements. CD spectra were recorded on a JASCO (J-715) model spectropolarimeter equipped with a Perkin-Elmer temperature controller. CD melting experiments were performed using a scan rate of 1 °C/min from 20 to 80 °C, and the data were recorded at each 0.2 °C interval. All CD spectra were averaged over two acquisitions, and the scan rate was maintained at 100 nm/min with optical cells of path length 1 cm in the CD melting study and 0.2 cm for recording other CD spectra. The CD values, expressed as molar ellipticity (θ), has been calculated from the equation, $(\theta) = (100 \times \phi/l \times c)$ deg cm^2 dmol^{-1} where ϕ is the observed ellipticity in degrees, l is the path length of the cell in centimeters, and c is the concentration of DNA in base molarity. All the experiments including CD melting study were carried out in 0.01 M Na_2HPO_4 buffer and 0.04 M NaCl, pH 7.4, with 1.31×10^{-5} M duplex concentration.

Fluorescence Measurements. Fluorescence spectra were recorded on a Hitachi model F-4500 spectrofluorimeter at 25 °C with excitation and emission bandwidths fixed at 10 nm (λ_{ex} = 350 nm, λ_{em} = 464.8 nm). In each case duplex concentration was taken as 3×10^{-6} M and each time an aliquot (10 μL) of Hoechst 33258 (4.2×10^{-5} M) was added into the duplex solution in 0.01 M Na_2HPO_4 buffer, 0.04 M NaCl, pH 7.4. In the case of the duplex containing free distamycin, 3×10^{-6} M distamycin was added to the duplex and the solution was incubated for 10 min prior to the addition of Hoechst 33258. The same concentration was also maintained for the duplex ODN covalently conjugated with distamycin. The enhanced fluorescence intensity was measured at each point after 5 min of equilibration of added Hoechst 33258 into individual duplex solutions.

ACKNOWLEDGMENT

Received September 3, 2003; Revised Manuscript Received February 3, 2004

Three peptides, YGAA[KKAAKAA]$_2$ (AKK), KLFKRHLKWKII (SC4), and YG[AKAKAAKA]$_2$ (KAK), were conjugated with lauric acid and tested for the effect on their structure, antibacterial activity, and eukaryotic cell toxicity. The conjugated AKK and SC4 peptides showed increased antimicrobial activity relative to unconjugated peptides, but the conjugated KAK peptide did not. The circular dichroism spectrum of AKK showed a significantly larger increase in its α-helical content in the conjugated form than peptide KAK in a solution containing phosphatidylethanolamine/phosphotidylglycerol vesicles, which mimics bacterial membranes. The KAK and AKK peptides and their corresponding fatty acid conjugates showed little change in their structure in the presence of phosphatidylcholine vesicles, which mimic the cell membrane of eukaryotic cells. The hemolytic activity of the KAK and AKK peptides and conjugates was low. However, the SC4 fatty acid conjugate showed a large increase in hemolytic activity and a corresponding increase in helical content in the presence of phosphatidylcholine vesicles. These results support the model of antimicrobial peptide hemolytic and antimicrobial activity being linked to changes in secondary structure as the peptides interact with lipid membranes. Fatty acid conjugation may improve the usefulness of peptides as antimicrobial agents by enhancing their ability to form secondary structures upon interacting with the bacterial membranes.

INTRODUCTION

Multicellular organisms produce a wide variety of antimicrobial peptides, suggesting that they play a crucial role in innate immunity (*1*). Antimicrobial peptides are secreted constantly at low levels to prevent infection, but local production can be increased in response to an infection (*1*). The peptides are cationic, which allows them to preferentially target the negatively charged cell membranes of prokaryotes such as bacteria. Eukaryotic cells have a different lipid composition in the outer leaflet of their cell membranes, resulting in a zwitterionic surface that is less attractive to the peptides. This difference between eukaryotic and prokaryotic membranes can be utilized effectively to target many pathogens, since major changes to their membrane composition would be necessary to develop resistance (*1*). As a result, efforts are being made to develop antimicrobial peptides into drugs that will retain their effectiveness against pathogens, especially against those strains of bacteria that have already become multiple drug-resistant.

Antimicrobial peptides share two common features: an overall positive charge and the ability to assume a three-dimensional structure with distinct hydrophobic and hydrophilic faces, called an amphipathic structure (*2*). Despite these common features there is very little sequence conservation between antimicrobial peptides. One of the most common classes of antimicrobial peptides are linear peptides that adopt an α-helical amphipathic structure (*2*). The mode of action of this class of peptides, which includes magainins (*3*, *4*), cecropins (*5*, *6*), and mellitins (*4*, *7*) have been extensively studied. The currently accepted model for the mechanism of action of helical antimicrobial peptides involves peptides that are typically unfolded in solution but fold in the presence of membranes to form an amphipathic structure (*8*, *9*). The formation of an amphipathic structure seems to be required for membrane binding and lytic activity (*2*, *10*). When the concentration of peptide bound to the membrane reaches a critical concentration, the peptides either insert into the membrane to form pores, or destabilize the membrane by disrupting the membrane curvature (*11*).

Although they are effective antimicrobial agents in vitro, antimicrobial peptides require high doses to be effective when administered systemically, so much so that toxicity to the host becomes an issue (*12*). Clinical use of antimicrobial peptides requires improving efficacy without also increasing their toxicity to eukaryotic cells.

Some natural antimicrobial peptides, such as the polymyxin (*13*) and lipopetaibols (*14*) are coupled to fatty acid tails. Removal of the fatty acid tail decreases the

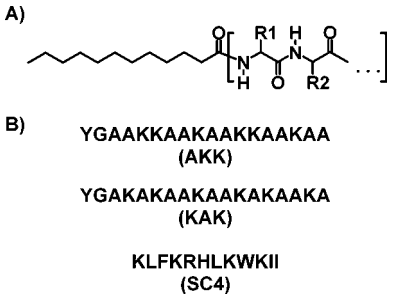

Figure 1. (A) Chemical structure of a fatty acid-conjugated peptide. The portion within the square brackets represents the two N-terminal amino acids of the peptide. (B) Sequence of the AKK, KAK, and SC4 peptides starting with the N-terminus. SC4 has an amidated C-terminus.

antimicrobial activity of polymyxin (*15*), demonstrating that it was intimately linked to the peptide activity. This has inspired attempts to increase antimicrobial activity by conjugating naturally occurring antimicrobial peptides with fatty acid tails (*16*−*18*). The effect of fatty acid tails on antifungal activity (*19*) and antiprotozoal activity (*20*) has also been studied. Work in our group (*21*−*23*), and in a group of our collaborators (*24*), has shown that addition of hydrocarbon tails to short peptides, to form peptide amphiphiles, can promote the formation of secondary structure. Since formation of secondary structure appears to be requisite for activity in antimicrobial peptides, we conjecture that fatty acid conjugation will increase activity by facilitating the formation of secondary structure.

We have conjugated three peptides to lauric acid to study the effect of fatty acid tail addition on peptide secondary structure as well as the correlation between structure and antimicrobial activity (Figure 1). Peptide AKK is based on the sequence of a previously studied synthetic leucine-lysine antimicrobial peptide (*25*). This peptide segregates its hydrophobic and hydrophilic amino acids into distinct regions on the helical wheel diagram (Figure 2). Peptide KAK is a reordering of the peptide AKK with the same amino acid composition and is based on a sequence shown to form nonamphipathic helices (*26*). Peptide SC4 is a naturally derived, α-helical antimicrobial peptide that has antimicrobial activity in the micromolar range (*27*). The helical wheel diagram of SC4 suggests a distinct hydrophilic face and a strongly hydrophobic face. All three peptides were coupled with lauric acid to form peptide amphiphiles, C12-AKK, C12-KAK, and C12-SC4. The structure of these peptides and peptide amphiphiles was studied in aqueous buffer, in the presence of vesicles composed of phosphatidylcholine (zwitterionic) or in the presence of vesicles composed of phosphatidylethanolamine mixed with phosphatidylglycerol (anionic). The peptide and peptide amphiphiles were further tested for their ability to kill bacteria, destabilize the inner membrane of Gram-negative bacteria, and lyse human red blood cells. We also observed the aggregation state of peptide amphiphiles in solution.

MATERIALS AND METHODS

Materials. Peptides AKK and KAK were synthesized by Synpep Corporation. Peptide SC4 was prepared by the Microchemical Facility at the University of Minnesota. *N*-Hydrobenzotriazole (HOBt) and 2-(1*H*-benzotriazole-1yl)1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) were purchased from Nova Biochemem. 1,2-Dilauroyl-*sn*-glycero-3-phosphocholine (DLPC), 1,2-dilauroyl-*sn*-glycero-3-phospoethanolamine (DLPE), and 1,2-dilauroyl-*sn*-glycero-3-phospoglycerol (DLPG) were purchased from Avanti Polar Lipids. All other chemical reagents were purchased through Sigma-Aldrich. Bacteria strains used to determine antimicrobial activity are *Escherichia coli* DH5α and ML-35 and *Staphylococcus epidermidis* (ATCC#12228). *E. coli* ML-35 was also used to determine cell membrane permeability.

Peptide Amphiphile Synthesis. Resin-bound peptide was received from either the Microchemical Facility at University of Minnesota or Synpep Corporation. Resin-bound peptide was deprotected with 20 vol % piperidine in dimethyl formaldehyde (DMF) for 2 h. Following deprotection, the resin-bound peptide was washed three times with DMF and then coupled to lauric acid using a 4-fold molar excess of HTBU, HOBt, *N*,*N*′-diisopropylethylamine, and lauric acid. The peptide amphiphile was then cleaved, purified, and characterized according to the method below.

Peptide Cleavage and Purification. AKK, KAK, C12-AKK, and C12-KAK were cleaved using a mixture of 95/5 vol % trifloroacetic acid (TFA)/water solution and precipitated in cold methyl *tert*-butyl ether. SC4 and C12-SC4 were cleaved a mixture of 82.5 vol % TFA, 5 vol % thioanisole, 5 vol % phenol, 5 vol % water, and 2.5 vol % ethanedithiol and then precipitated in cold methyl-*tert*-butyl-ether. Peptides were purified by reverse phase HPLC on a Vydac C4 column using 99.9/0.1 vol % water/TFA and 99.9/0.1 vol % acetonitrile/TFA as the mobile phases. The samples were lyophilized and then analyzed for molecular mass using a Thermo Bioanalysis MALDI-TOF system.

Minimum Bactericidal Concentration (MBC) Determination. Overnight cultures of test bacteria, either Gram-negative *E. coli* (strains DH5α or ML-35) or Gram-positive *S. epidermidis* (ATCC#12228), were grown at 37 °C in tryptic soy broth (TSB) for at least 18 h. The following day, subcultures were prepared by diluting the overnight cultures 1:100 in TSB. The subcultures were grown to log phase (OD_{600} of 0.5) and then diluted to a concentration of 1×10^5 to 1×10^6 colony forming units (CFU)/mL. A stock solution of test peptide was prepared at a concentration of 1 mg/mL in Millipore water to avoid aggregation. The stock peptide concentration was verified by amino acid analysis performed at the molecular structure facility at University of California—Davis. Test

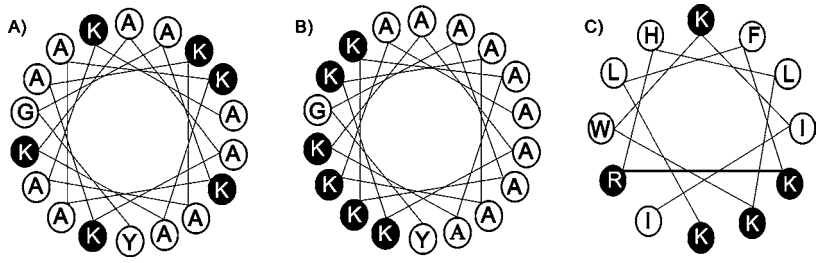

Figure 2. Helical wheel diagram of peptides (A) KAK (B) AKK and (C) SC4. The black filled circles are charged amino acids.

peptide solutions were added to polypropylene tubes and diluted with TSB to the desired concentration. The sample tubes were then inoculated with a bacterial stock solution to a final bacteria concentration of 1×10^4 to 1×10^5 CFU/mL. After incubation for 18 h at 37 °C, 50 μL aliquots were plated out and grown overnight. The MBC was taken as the lowest concentration where no colonies grew.

Hemolysis. Fresh human red blood cells were centrifuged and washed three times with phosphate-buffered saline (PBS). The red blood cells were diluted to a concentration of 0.4 vol % in PBS and placed in Eppendorf tubes. Peptide or peptide amphiphile was added at various concentrations, and the samples were incubated for 1 h at 37 °C. The samples were then centrifuged to sediment the intact red blood cells. Hemolytic activity was determined by measuring the UV absorbance at 414 nm. One hundred percent hemolysis was determined by addition of 1 vol % Triton-X100. The percentage of hemolysis was calculated as follows:

$$\% \text{ hemolysis} = 100(A_{414} \text{ with peptide} - A_{414} \text{ in plain PBS})/(A_{414} \text{ in Triton-X100} - A_{414} \text{ in plain PBS})$$

Vesicle Preparation. A chloroform solution of lipids, either 70/30 wt % DLPE/DLPG or DLPC, was dried under nitrogen until a thin film was formed. The film was then further dried under vacuum for at least 12 h. The lipids were dispersed in 10 mM sodium phosphate buffer, pH 7.4, to a concentration of 2.4 mM. The solution was then extruded through a 100 nm Millipore polycarbonate filter five times. Vesicle size was confirmed to be approximately 100 nm using dynamic light scattering. Henceforth, vesicles prepared with phosphatidylcholine are referred to as PC, and vesicles prepared with phosphatidylethanolamine and phosphatidylglycerol mixture are referred to as PE/PG.

Circular Dichroism. Circular dichroism spectra were recorded on an Olis-RSM CD with a 5 mm quartz cell. Data reported are an average of three scans. Spectra were recorded at 37 °C in 10 mM sodium phosphate buffer, pH 7.4, with a peptide concentration of 0.02 mM. Spectra were also recorded in the presence of either PE/PG or PC vesicles at a vesicle concentration of 0.3 mM. To estimate secondary structure contribution, a least-squares fit was performed using a linear combination of standard α-helix and random coil spectra (*28*).

Membrane Permeability. *E. coli* inner membrane permeability was determined by the ability of the peptide or peptide amphiphile to unmask β-galactosidase activity using ONPG (*o*-nitrophenyl-β-D-galactopyraniside) as a substrate (*29*). *E. coli* ML-35 produces the enzyme β-galactosidase, which hydrolyzes the colorless substrate ONPG to yellow *o*-nitrophenol. ONPG cannot cross an intact bacterial membrane, so the rate of hydrolysis of ONPG can be related to the rate of permeabilization of the bacterial inner membrane. Logarithmic phase *E. coli* ML-35 was centrifuged, and the resulting pellet was washed three times in 10 mM sodium phosphate buffer, pH 7.4, containing 100 mM NaCl and resuspended to a concentration of 1×10^8 CFU/mL in the same buffer. Solutions of peptide and ONPG were prepared in the same buffer, and bacteria solution was added to a final concentration of 0.02 mM peptide, 1.5 mM ONPG, and 1×10^7 CFU/mL *E. coli*. The production of *o*-nitrophenol was measured over time by UV absorbance at 420 nm.

Aggregation Assay. The aggregation state of the peptide amphiphiles was determined according to the pyrene solubilization method presented by Kim and coworkers (*30*). Pyrene is a polycyclic aromatic hydrocarbon with low solubility in aqueous solutions. Pyrene can be solubilized within the hydrophobic core of micelles providing a method to test for the presence of micelles. A test peptide dissolved in 10 mM sodium phosphate buffer, pH 7.4, containing 100 mM NaCl was added to an excess of pyrene at various concentrations. The suspension was sonicated for at least 8 h and then centrifuged. The supernatant was added to a 50 mM solution of sodium dodecyl sulfate, and the absorbance at 336 nm was recorded.

Table 1. Bactericidal Activities of AKK, KAK, SC4, C12-AKK, C12-KAK, and C12-SC4. All MBC Values Are ± 2 μM

	MBC (μM)		
	E. coli DH5α	*E. coli* ML-35	*S. epidermidis* ATCC 12228
AKK	>65	>65	>65
KAK	>65	>65	>65
SC4	17	34	48
C12-AKK	11	11	30
C12-KAK	>65	>65	>65
C12−SC4	1	4	2

RESULTS

Bactericidal activities of peptides AKK, KAK, SC4 and the peptide amphiphiles C12-AKK, C12-KAK, and C12-SC4 were measured against two strains of the Gram-negative bacteria *E. coli* (ML-35 and DH5α) and one strain of the Gram-positive bacteria S. epidermidis (ATCC#12228) (Table 1). Among the unmodified peptides only SC4 had an MBC below 65 μM, which was the highest concentration studied. The MBC of C12-SC4 was between 9- and 20-fold lower than that of SC4, indicating that fatty acid conjugation increased antimicrobial activity. C12-AKK was moderately antimicrobial. Neither KAK nor C12-KAK showed bactericidal activity in this assay.

The ability of the peptides and peptide amphiphiles to permeabilize the cytoplasmic membranes of *E. coli* ML-35 was assessed. As expected, both C12-SC4 and C12-AKK rapidly destabilized the target membrane (Figure 3A). SC4, which had moderate antimicrobial activity as measured by MBC tests, showed low membrane permeabilization activity. This result implies that SC4 may kill bacteria by another mechanism in addition to destabilization of bacterial membranes. AKK and C12-KAK showed moderate rates of ONPG hydrolysis, whereas KAK showed the lowest rate.

The toxicities of the peptides and peptide amphiphiles to eukaryotic cells were tested by their ability to lyse human red blood cells (Figure 3B). C12-KAK had no detectable hemolytic activity within the concentrations studied. AKK, KAK, and C12-AKK showed no hemolytic activity up to concentrations of 500 μM, and only exhibited mild (<15%) hemolysis at 500 μM. SC4 showed mild (<15%) hemolytic activity at 3 μM that increased slightly over the range of concentrations tested. The hemolytic activity of C12-SC4 was low at 0.3 μM but rapidly increased to over 90% hemolysis at concentrations of 18 μM. However, when tested against endothelial cells neither SC4 nor C12-SC4 demonstrate lytic activity up to 1 mM concentrations (data not shown).

Circular dichroism was used to assess the structure of the peptide and peptide amphiphiles in various environments (Figure 4). The resulting spectra were fit to evaluate the helical content in each environment (Table

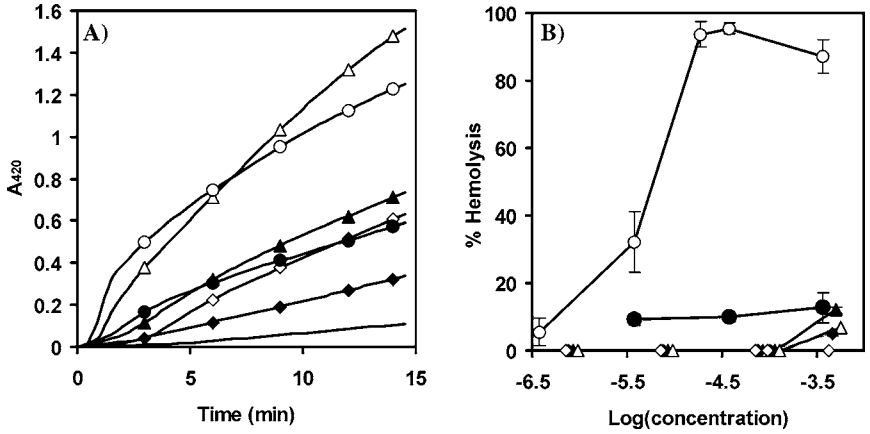

Figure 3. (A) Rate of ONPG hydrolysis of peptides SC4 (●), AKK (▲), and KAK (◆) as well as peptide amphiphiles C12-SC4 (○), C12-AKK (△), and C12-KAK (◇). The unmarked line is the baseline (no peptide added). (B) Hemolytic activity as a function of concentration for the same peptide and peptide amphiphiles (the same symbols are used).

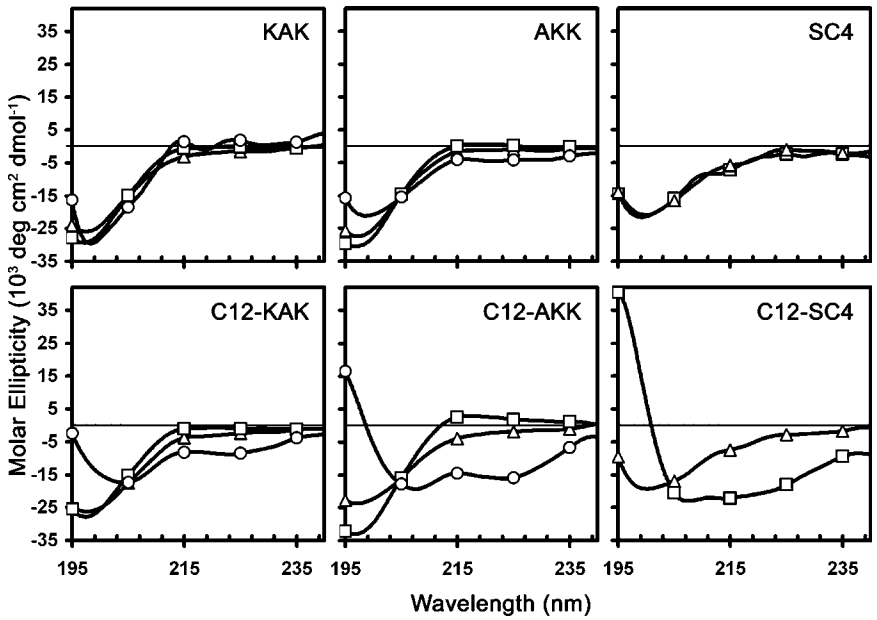

Figure 4. CD traces of peptides KAK, AKK, SC4, and peptide amphiphiles C12-KAK, C12-AKK, and C12-SC4. Experiments are conducted in sodium phosphate buffer (△) with the addition of DLPC vesicles (□) or DLPE/DLPG vesicles (○) (symbols are not data points but are solely to differentiate curves).

Table 2. Degree of Helix Formation in Sodium Phosphate Buffer Alone, with the Addition of PC Vesicles or PE/PG Vesicles

	buffer: % α-helix	PC: % α-helix	PE/PG: % α-helix
AKK	12	5	26
KAK	15	8	17
SC4	26	27	–
C12-AKK	17	0	73
C12-KAK	18	11	44
C12-SC4	32	100	–

2). AKK and C12-AKK had little α-helical character in benign sodium phosphate buffer solution or PC environments. In the presence of PE/PG vesicles, α-helical structure developed. The increase in structure with the addition of PE/PG vesicles was four times greater for C12-AKK than AKK. KAK and C12-KAK showed a similar relationship; neither had α-helical structure in sodium phosphate buffer or PC, but both showed an increase in structure in PE/PG. Again, the change in structure between the environments was greater in the peptide amphiphile than the unmodified peptide, but by less than 3-fold. KAK formed a precipitate with PE/PG vesicles, although we were still able to obtain a spectrum. Both SC4 and C12-SC4 formed precipitate in the presence of PE/PG, which prevented the collection of useable data. C12-SC4 did, however, show a significant increase in structure in PC, when compared to SC4 in PC or either sample in $NaPO_4$.

Aggregation of C12-AKK, C12-AKA, and C12-SC4 was probed by their ability to solublize the hydrophobic molecule pyrene. All the peptide amphiphiles were tested at concentrations from 1 μM to 250 μM in 10 μM sodium phosphate, 100 μM sodium chloride solutions. None of the molecules showed the ability to solubilize pyrene, implying the molecules are not aggregated below 250 μM (data not shown).

DISCUSSION

Membrane binding and membrane insertion, processes involved in the initial steps of cell lysis, are influenced by both hydrophobic and electrostatic interactions of antimicrobial peptides. Conjugation of lauric acid to antimicrobial peptides shifts the balance of electrostatic and hydrophobic forces. Increasing the hydrophobicity of the peptide can stabilize the membrane-bound secondary

structures requisite for antimicrobial activity. One potential drawback to fatty acid conjugation is that it may promote peptide folding in solution, which was previously shown to inhibit membrane binding (*31*). A second potential drawback is peptide self-assembly in solution which was previously shown to increase the potency of peptides toward zwitterionic membranes (*32*).

Fatty acid conjugation affects the structure and activity of peptides in an environment-specific manner. The high positive charge density on peptides and peptide amphiphiles tends to destabilize helical secondary structures. All the studied peptides are unstructured in solution; addition of a fatty acid tail is insufficient to overcome charge repulsion in that environment. Previous studies on peptide amphiphiles have shown stabilization of helical secondary structures in solution at concentrations above the critical micelle concentration, implying that conjugation of peptides to hydrocarbon tails facilitates cooperative folding in solution (*23*, *24*). Although all three peptide amphiphiles clearly show greater ability to fold, adhere, and destabilize bacterial membranes than their parent peptides, our pyrene solution tests indicate that the peptide amphiphiles have not formed micelles at these concentrations. These results are consistent with the low α-helical content of the samples in solution; one would expect to see more α-helical structure if the peptide amphiphiles were micellized. It is possible that some sort of peptide amphiphile self-organization takes place on the target membranes, where the local concentration of peptide amphiphile will be greater than in free solution. It is also believed that the insertion of peptides into a membrane is a cooperative process (*9*). The peptide−peptide interaction of peptide amphiphiles may be higher in the membrane-bound state, which would help the cooperative insertion into the membrane.

Activity, hemolytic or bactericidal, appears to be correlated with the degree of structure induced in the peptide by the presence of the appropriate lipids. Results of circular dichroism, MBC assays, and ONPG hydrolysis assays indicate that the interaction between the peptide and PE/PG membranes is enhanced through the addition of hydrocarbon tails. Thus, the hydrophobic attraction between lipid membranes and the antimicrobial peptides serves to promote folding of the peptide and binding to membranes independent of membrane charge. In fact, increasing the hydrophobicity of the antimicrobial peptides decreases their selectivity for bacterial membranes (*33*). Our findings are consistent with these trends. Peptide amphiphiles are more hydrophobic than their parent peptides and thus have increased interaction with membranes. This may account for the observed improved bactericidal activity for all the peptide amphiphiles compared to their simple peptide counterparts.

KAK is neither very hydrophobic, nor does it have a strong amphipathic character; thus, it is expected to be the least bactericidal of all three peptides. The addition of a lipid tail increases the hydrophobicity sufficiently that C12-KAK forms a partial helix in the presence of a bacterial membrane. Although the antimicrobial activity of C12-KAK was not detectable by MBC test, fatty acid conjugation improved the ability of KAK to permeablize *E. coli* membrane. While it is generally believed that amphipathic structure is required for wide-spectrum antimicrobial activity, studies show that some nonamphipathic peptides have mild bactericidal activity against Gram-negative bacteria (*34*). It is possible that such peptides fold into structures other than α-helices in order to maximize their amphipathicity and allow them to be mildly antimicrobial (*35*). This may also be the case with C12-KAK; we speculate that it may form a helical structure with either greater or fewer amino acids per turn than an α-helix.

AKK also lacks strongly hydrophobic amino acids, which accounts for its low antimicrobial activity. However, the hydrophobic residues create a wide hydrophobic face when the peptide is folded into an α-helix, giving AKK a greater potential for activity than KAK. We conjecture that the lipid tail of C12-AKK increases both its ability to fold and its attraction to membranes. The strong antimicrobial activity of the C12-AKK peptide amphiphile supports this conclusion. It is interesting that even the addition of the hydrophobic fatty acid tail does not cause this peptide to have significant hemolytic activity.

SC4 is the most hydrophobic of the peptides tested here and is the only peptide with measurable hemolytic activity. It has been observed that highly hydrophobic peptides tend to be more hemolytic (*36*). C12-SC4 shows a much higher degree of hemolytic activity than the SC4 peptide, which can be attributed to its even higher hydrophobicity.

In conclusion, our results indicate that peptide amphiphiles have increased formation of secondary structures in the presence of vesicles that mimic bacterial membranes. The increase in bactericidal activity accompanying coupling of the fatty acid tail clearly establishes a structure−activity relationship. Thus, the addition of fatty acid tails to form peptide amphiphiles may be a viable strategy to improve the antimicrobial activity of certain peptides. It is interesting that the improvement of bactericidal activity for C12-AKK is not accompanied by a concomitant increase in hemolytic activity as with C12-SC4. It is important to further explore the underlying reasons for the differences in the selectivity of these two antimicrobial peptides. It may elucidate other features that are important to the design of effective antimicrobial peptides with minimal toxicity to eukaryotes.

ACKNOWLEDGMENT

We would like to thank the group of Robert Hancock at the University of British Columbia for kindly providing us with *E. coli* ML-35. This work made use of MRL Central Facilities supported by the MRSEC Program of the National Science Foundation under award No. DMR00-80034. This work was supported by the National Institute of Health (award #HL62427).

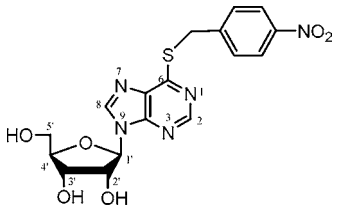
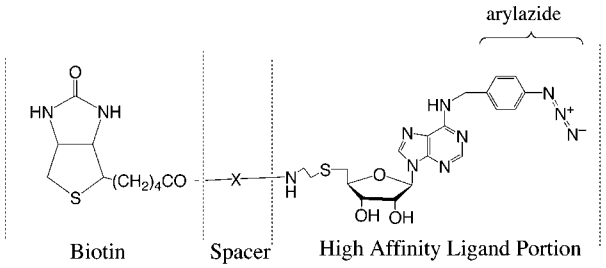
Design, Synthesis, and Evaluation of 5′-*S*-Aminoethyl-N^6-azidobenzyl-5′-thioadenosine Biotin Conjugate: A Bifunctional Photoaffinity Probe for the *es* Nucleoside Transporter



James K. Addo and John K. Buolamwini*

Department of Pharmaceutical Sciences, College of Pharmacy, University of Tennessee, Memphis, Tennessee 38163. Received September 11, 2003; Revised Manuscript Received March 12, 2004

A bifunctional biotinylated photoaffinity label for the nitrobenzylmercaptopurine riboside (NBMPR)-sensitive (*es*) nucleoside transporter (ENT1) has been synthesized and evaluated. This new probe, 5′-*S*-aminoethyladenosine-N^6-azidobenzyl-5′-thioadenosine biotin conjugate (SAEATA-14-biotin), exhibited high-affinity binding to the *es* transporter in K562 cells as determined by flow cytometry, with a K_i of 2.69 nM in competition against 5-(SAENTA)-x8-fluorescein. It also exhibited covalent linking to the *es* transporter in BeWo cell membranes upon UV irradiation. This new bifunctional probe is a potential tool for determining the amino acid residues involved in ligand binding at the NBMPR-binding site of the ENT1 nucleoside transporter, as well as for the purification of the transporter.



INTRODUCTION

Nucleoside transporters are integral membrane glycoproteins required for the cellular uptake of physiological nucleosides such as adenosine and their synthetic analogues. Two families of nucleoside transporters have been identified: (i) equilibrative (facilitated diffusion) transporters, ENTs, and (ii) concentrative (sodium ion-coupled) transporters, CNTs (*1*−*5*). The equilibrative transporters are found in most mammalian cells and tissues studied, whereas the concentrative transporters are limited to specialized epithelial tissues and some cultured cell lines. The ENT1 transporter also known as the *es* transporter is by far the predominant nucleoside transporter of most mammalian cells examined and can be distinguished from the other equilibrative transporter, ENT2, also known as *ei* transporter, by its high sensitivity to inhibition by S^6-(4-nitrobenzyl)mercaptopurine riboside (NBMPR, **1**). Inhibition of the *es* transporter by NBMPR arises from high-affinity binding (K_d 0.1−1.0 nM) (*6*). The *ei* transporter is at least 1000-fold resistant to inhibition by NBMPR (*4*, *7*).

1, NBMPR

Interest in nucleoside transporters has been on the increase because of their involvement in the efficacy of anticancer and antiviral nucleoside drugs, as well as their regulation of tissue adenosine levels and thereby modulation of its signal transduction functions in cardioprotection and neuroprotection. Thus, nucleoside transport inhibitors (NTIs) have potential therapeutic uses in several therapeutic areas including ischemic heart disease and stroke, cancer and viral chemotherapy, and the preservation of donor organs for transplantation (*8*). The known inhibitors are mostly unsuitable for clinical applications, and therefore novel inhibitors are needed. Several nucleoside transporters have been cloned (*9*), but structural biology studies of these transporters have been hampered by the lack of the appropriate chemical probes. Devising appropriate molecular probes for elucidation of the amino acid residues involved in inhibitor-binding will go a long way to promote these studies. In the absence of a 3D structure of the *es* transporter or its complex with an inhibitor, photoaffinity labeling offers a useful approach to identifying the amino acid residues involved in ligand binding. In this regard, NBMPR and its analogues, which bind with high affinity and high specificity to the ENT1 transporter, are excellent templates for designing affinity labels of this transporter. In this paper, we describe the design, synthesis, and evaluation of such an ENT1 transporter probe, a biotinylated azido analogue of NBMPR, termed SAEATA-x14-biotin (compound **2**).

EXPERIMENTAL SECTION

Synthesis. Thin-layer chromatography (TLC) was conducted on silica gel F_{254} plates (Analtech). Compounds were visualized by UV light or 5% H_2SO_4 in EtOH spraying reagent. ^1H and ^{13}C spectra were recorded on Bruker ARX (500 MHz) instrument, using $CDCl_3$, CD_3OD, $(CD_3)_2SO$, or CD_3COCD_3 as solvents and tetramethylsilane (TMS) as internal standard. Flash column chromatography was performed on Fisher silica gel (170−400 mesh). Melting points were determined using a Fisher-Johns melting point apparatus and are reported uncorrected. Mass spectra were obtained on a Bruker-HP Esquire-LC mass spectrometer, and IR spectra with a Perkin-Elmer System 2000 FT-IR spectrometer. All solvents and reagents were bought from Sigma-Aldrich Chemical Co. and used without further purification, unless where specified. HPLC was performed on a GILSON Instrument with UV detection. Biotinylated SAENTA (SAENTA-x14-biotin, **3**) was prepared by reacting Biotin-xx SE (Molecular Probes, Eugene, OR) with SAENTA phthalhydrazide salt (*10*) in dimethylformamide (Buolamwini and Paterson, unpublished results). [^{3}H]NBMPR (23 Ci/mmol, 1 Ci = 37 GBq) was purchased from Moravek Biochemicals (Brea, CA). 5-(SAENTA)-x8-fluorescein was prepared as previously reported (*11*).

5′-*S*-(2-(6-(6-Biotinamidohexanoyl)aminohexanoyl)-aminoethyl)-*N*^{6}-(4-aminobenzyl)-5′-thioadenosine (4). A mixture of SAENTA-x14-biotin (**3**, 100 mg, 0.109 mmol), activated carbon (20.0 mg, G-60, 100 mesh), ferric chloride hexahydrate (10.00 mg, 0.036 mmol), and methanol (5 mL) was refluxed for 10 min with stirring. To this boiling mixture was added hydrazine hydrate (40 mg, 1.25 mmol, 99.1%) dropwise, and the mixture was stirred under reflux for an additional 12 h, cooled, and filtered, and the residue was washed with methanol (3 × 5 mL). The filtrate was evaporated to give a solid residue. The residue was recrystallized from EtOAc to give compound **4** as colorless crystals: 88 mg, 91% yield, mp 184−185 °C. ^1H NMR (500 MHz, $CDCl_3$) δ 1.166−2.022 (m), 2.484−2.571 (m), 2.782−3.316 (m), 3.98−4.01 (m), 4.08−4.14 (m), 4.26−4.31 (m), 4.511 (bs), 4.712 (bs), 5.33 (d, J = 6.0, 1H), 5.49 (d, J = 5.56 5.56, 1H), 5.88 (d, J = 5.56 Hz, 1H), 6.350 (s), 6.41 (s), 6.49 (d, J = 8.29 Hz, 1H), 7.01 (d, J = 8.29 Hz, 1H), 7.70−7.74 (m), 7.88−7.89 (m), 8.14−8.19 (m), 8.34 (bs), 9.39 (bs); IR (neat) ν_{max} (3255, 2933, 2340, 1623, 1541, 1245, 1036, 920 cm^{-1}. MS (ESI) m/z 915 $(M + H)^+$.

5′-*S*-(2-(6-(6-Biotinamidohexanoyl)aminohexanoyl)-aminoethyl)-*N*^{6}-(4-azidobenzyl)-5′-thioadenosine (2, SAEATA-x14-biotin). A solution of sodium nitrite (5.64 mg, 0.082 mmol) in cold water (0.20 mL) at 0 °C was made and added with stirring to a cold (0 °C to −5 °C) solution of compound **4** (65 mg, 0.074 mmol) in glacial acetic acid (0.5 mL). The mixture was then stirred at 0 °C for another 20 min. To the resulting solution of diazonium salt, at 0 °C, was added a solution of NaN_3 (5.33 mg, 0.082 mmol) in cold water (0.20 mL). The mixture was then allowed to stir at 0 °C for an additional 1.5 h in the dark. The reaction mixture was then evaporated to give a solid residue. H_2O (1 mL) was then added, and the reaction mixture was extracted with EtOAc (3 × 5 mL). The combined organic extracts were dried (anhydrous Na_2SO_4) and filtered. The solvent was evaporated in vacuo to give a crude solid residue. This residue was washed three times with H_2O (3 × 5 mL) and the solid obtained dried in vacuo and recrystallized in MeOH/EtOAc (1:1) to give the target compound **2** (57 mg, 85.20% yield): mp 115−116 °C. ^1H NMR (500 MHz, $CDCl_3$) δ 1.22− 2.11 (m), 1.18−2.02 (m), 2.54−3.17 (m), 3.92−4.11 (m), 4.15 (bs), 4.22−4.28 (m), 4.66−4.70 (m), 4.79−4.80 (m), 5.88 (d, J = 5.857, 1H), 7.036 (d, J = 8.785, 1H), 7.36 (d, J = 8.785 Hz, 1H) 8.19 (bs), 8.37 (s); IR (neat) ν_{max} 3303, 2925, 2854, 2363, *2110*, 1763, 1631, 1541, 1507, 1466, 1294, 1211, 1120, 1053 cm^{-1}. MS (ESI) m/z 910 $(M + H)^+$. The purity was checked by reversed phase HPLC using a C_{18} column and two different solvent systems: (1) methanol/acetonitrile (1:1 v/v) and (2) solvent methanol/water (4:1 v/v) (Fisher HPLC grade).

Cell Culture. K562 chronic myelogenous leukemia and BeWo choriocarcinoma cells were purchased from American Type Culture Collection (Rockville, MD). Stock cultures were grown in antibiotic-free growth media consisting of RPMI 1640 supplemented with 10% fetal bovine serum for K562 cells, or RPMI 1640 supplemented with 5% fetal bovine serum plus 5% Nuserum type IV for BeWo cells. Cultures were incubated at 37 °C in a humidified atmosphere containing 5% CO_2 in air.

Flow Cytometry. K562 suspension cells maintained in exponential growth (0.5×10^5 to 5×10^5 cells/mL) were used in flow cytometric evaluation of probe binding to the ENT1 (es) nucleoside transporter as previously described (*11*). Briefly, cells were washed once and suspended at 4×10^5 cells/mL in phosphate-buffered saline at pH 7.4 and incubated with 5-(SAENTA)-x8-fluorescein (25 nM) in the presence or absence of varying concentrations of test compounds at room temperature for 45 min. Flow cytometric measurements for cell-associated fluorescence were performed at the end of the incubation period with a FACSCalibur (Becton Dickinson, San Jose, CA) equipped with a 15 mW argon laser (Molecular Resources Flow Cytometry Facility, University of Tennessee Health Sciences Center). In each assay, 5000 cells were analyzed. The units of fluorescence were arbitrary mean channel numbers. Percentage (%) of control (*es* transporter-specific fluorescence in the presence of SAENTA-fluorescein without test compounds) was calculated for each sample by eq 1.

$$\% \text{ control} = \frac{(SF_s)}{(SF_f)} \times 100 \qquad (1)$$

where SF_s is the *es* transporter-specific fluorescence of test samples, and SF_f is the *es* transporter-specific fluorescence of the SAENTA-fluorescein ligand. The inhibition constant (K_i) values were calculated from the IC_{50} value obtained by nonlinear regression fitting of the concentration-effect curves using eq 2.

$$K_i = IC_{50}/(1 + [L]/K_L) \qquad (2)$$

where [L] and K_L are the concentration and the K_d value of the SAENTA-fluorescein ligand, respectively. The IC_{50} value was obtained by regression fitting to the data in Figure 1 using the Prism program (GraphPad, San Diego, CA).

BeWo Cell Membrane Preparation. BeWo cell membranes were prepared according to the protocol described in Boumah et al. (*12*). Cells were harvested by trypsinization and disrupted by sonication in the presence of a protease inhibitor (2 mM AEBSF, a water soluble analogue of the protease inhibitor PMSF). The lysates were fractionated in a 20% Percoll gradient and washed twice by centrifugation at 40000*g*, for 15 min at 4 °C in 50 mM Tris/HCl buffer (pH 7.4). Protein concentration was determined by the Lowry method (*13*).

Photolabeling. Membranes with 10−50 μg of protein were incubated with 100 nM of compound **2** in the

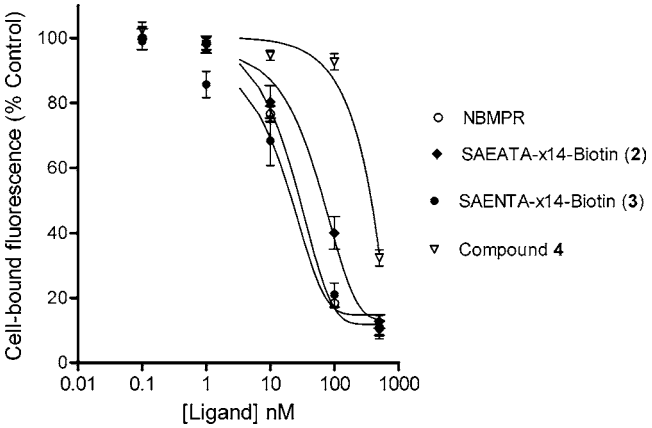

Figure 1. Flow cytometric analysis of the binding of nbmpr and biotinylated analogues to the *es* transporter of k562 leukemia cells. Cells were incubated with graded concentrations of test compounds in the presence of 25 nM 5-(SAENTA)-x8-flourescein at 22 °C for 45 min. Each data point represents the mean ± SEM for three different experiments.

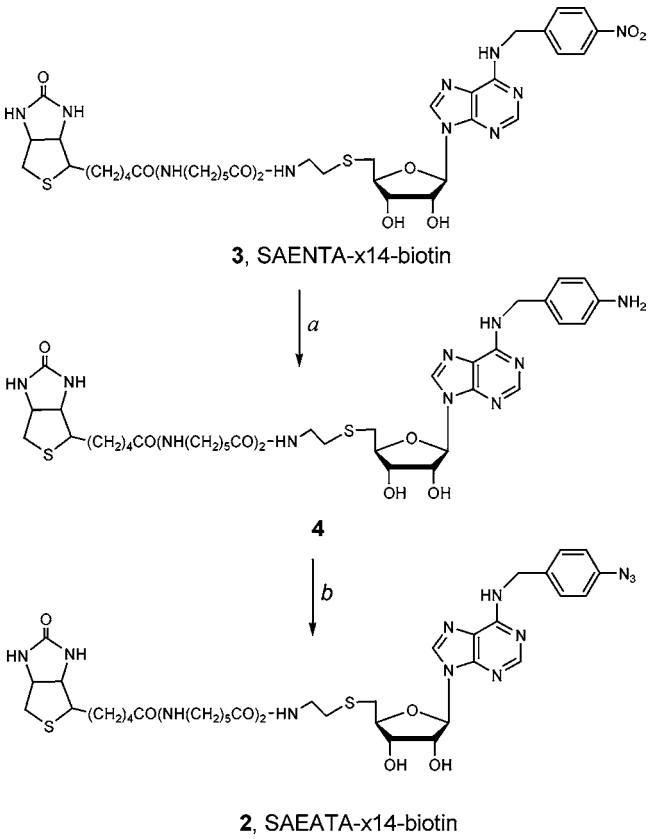
presence or absence of 10 μM NBMPR in Tris/HCl buffer in the presence of AEBSF for 30 min at 22 °C, cooled to 4 °C, and then irradiated with shortwavelength UV light for 3−5 min at a distance of 3 cm. The reaction was stopped by addition of an equal volume of Tris buffer containing 12% trichloroacetic acid (TCA). The membranes were pelleted and washed twice with Tris/HCl containing TCA. For indirect determination of photo-cross-linking by compound **2**, the membranes were washed and used in [^{3}H]NBMPR binding as described below.



[^{3}H]NBMPR Binding to Membranes. Membrane samples containing 10 μg of protein each were incubated with [^{3}H]NBMPR (1.0 nM; 15 Ci/mmol) in binding medium (50 mM Tris/HCl, pH 7.4, 20 mM dithiothreitol) in the presence or absence of 10 μM nonradioactive NBMPR for 30 min at 22 °C. Bound and free [^{3}H]NBMPR were then separated from each other by rapid filtration with Whatman GF/B filters. The radioactivity that was retained on the filters, i.e., bound [^{3}H]NBMPR was measured by liquid scintillation counting.

Streptavidin Detection of Photo-Cross-Linked Compound 2. To detect photo-cross-linking of protein by SAEATA-x14-biotin (**2**), BeWo cell membranes (50 μg) photolabed with the probe were subjected to SDS−PAGE electrophoresis, after which the protein was electroblotted onto polyvinylidine fluoride membranes (Immobilon-P; Millipore, Bedford, MA). Membranes were blocked in BLOTTO (5% nonfat dried milk) in TBS-T: (20mM Tris-HCl, pH 7.6, 137mM NaCl, and 0.1% Tween-20) at 4 °C overnight. This was followed by incubation with horseradish peroxidase-conjugated streptavidin diluted in BLOTTO (0.5μg/mL) for 1 h. After three washes in TBS-T, the blot was treated with Enhanced ChemiLuminescence (ECL, Amersham) detection reagents as described by the manufacturer. Biotinylated proteins were visualized by exposure to X-ray film and development.

RESULTS AND DISCUSSION

Our bifunctional probe design took into consideration the following: (1) Experimental evidence shows that nucleoside analog *es* transporter inhibitors such as NBMPR do not require a free 5′-OH group on the ribose ring, and that with an appropriate spacer, the 5′-position of inhibitors is very tolerant of bulky substituents (*10*, *11*, *14*). For example, bulky fluorescein derivatives can be tethered to the 5′-position and still retain high affinity

Scheme 1. Synthetic Route to Compound 2[a]

[a] Reagents and conditions: (a) $NH_2NH_2.\cdot H_2O/FeCl_3\cdot 6H_2O$/activated carbon/MeOH/reflux; (b) (i) $NaNO_2$/aq AcOH, 0 °C, (ii) NaN_3, 0 °C.

binding with K_d values as low as 2 nM (*11*). Therefore, we decided to tether a biotin moiety via an appropriate spacer chain to the 5′-position of the nucleoside portion of the probe for avidin or streptavidin affinity purification and detection purposes. (2) The NO_2 group in NBMPR was replaced by an azido photoreactive group to use for photo-cross-linking to the transporter. The azidobenzyl moiety, like the nitrobenzyl moiety of NBMPR, affords high-affinity binding at the *es* transporter (*15*). Furthermore, *p*-azidobenzyladenosine (ABA) has been used successfully to photolabel the *es* transporter of human erythrocytes (*16*). Although NBMPR itself is a photolabeling agent, the radical species for covalent linking to the protein is produced by cleavage of the sulfur−benzyl bond (*17*), which means that before covalent linking, the high-affinity conferring nitrobenzyl group is lost. This is disadvantageous for specific labeling, because the loss of the nitrobenzyl moiety could cause a dissociation of the bound inhibitor (*18*) from the binding site prior to cross-linking with the protein, which increases the likelihood of labeling residues not involved in binding. Replacing the sulfur by NH prevents the loss of the benzyl portion upon irradiation and increases the likelihood of binding-site specific photo-cross-linking.

The synthesis of the probe followed Scheme 1 and began with the derivatizable high-affinity *es* transporter ligand 5′-*S*-(2-aminoethyl)-N^6-(4-nitrobenzyl)-5′-thioadenosine (SAENTA). In SAENTA, a 2-aminoethylthio ($H_2NCH_2CH_2S$-) has replaced the 5′-OH group to provide a handle for tethering a reporter or other group (*10*). Compound **3**, SAENTA-x14-biotin, was obtained by a procedure involving the reaction of the phthalhydrazide salt of SAENTA with (6-((6-((biotinoyl)amino)hexanoyl)-amino)hexanoic acid succinimydyl ester (biotin-xx, SE)

Table 1. K_i Values for Inhibition of SAENTA-fluor Binding to the *es* Transporter (ENT1) in K562 Cells

compound	K_i (nM)[a]
SAEATA-x14-biotin (**2**)	2.69 ± 0.36
SAENTA-biotin (**3**)	1.03 ± 0.40

in the presence of Et_3N to give this biotinylated derivative (Buolamwini and Paterson, unpublished, results). Scheme 1 was then followed for the rest of the synthesis. Reduction of the nitro group of compound **3** was effected by treatment with $FeCl_3/H_2N-NH_2 \cdot xH_2O$ in the presence of activated carbon in methanol to obtain the amino compound, **4**. Diazotization of compound **4** using aqueous $NaNO_2$ in acetic acid and subsequent displacement of the diazonium group with the azido group by treatment with NaN_3 yielded the target bifunctional photaffinity label, compound **2**.

Biological Evaluation. *Binding at the es Transporter.* The ability of this new bifunctional *es* transporter label to bind to the transporter was determined by a flow cytometric ligand-binding assay using a SAENTA-fluorescein conjugate, 5-(SAENTA)-x8-fluorecein (*11*) as the fluorescent *es* transporter competitive ligand. The results of the flow cytometric evaluation are presented in Figure 1, which shows potent concentration-dependent displacement of the competitive ligand by all the compounds but the amino compound (**4**), which is consistent with the known structure−activity relationship (*15*). The K_i values used to compare how tightly the ligands bound to the ENT1 transporter are presented in Table 1. These results indicate that the novel bifunctional photoaffinity label, compound **2**, has a high affinity for the ENT1 transporter (K_i 2.69 nM), which makes it suitable for photolabeling and probing the transporter.

Photolabeling. For the purpose of determining if compound **2** will cross-link at the NBMPR-binding site of the ENT1 transporter, cell membranes prepared from BeWo cells, known to express large numbers of ENT1 (*12*), were incubated with compound **2** in the absence or presence of the potent ENT1 inhibitor NBMPR, and the samples were irradiated with shortwave UV light. The membranes were then washed to get rid of noncovalently bound ligands and then used for [^{3}H]NBMPR specific binding analysis. The [^{3}H]NBMPR binding results for the irradiated and washed membranes are shown in Figure 2. They indicate that in the absence of the ENT1 competitive ligand NBMPR, compound **2** covalently bound to (cross-linked) the membranes and could not be completely washed off. In the samples that contained the NBMPR, cross-linking and covalent blocking of the NBMPR-binding site on ENT1 by compound **2** was inhibited. This demonstrates that the new photoaffinity probe can photo-cross-link ENT1 at the NBMPR binding site and will be a useful tool in identify amino acid residues at the NBMPR-binding site of the ENT1 (*es*) nucleoside transporter.

*Streptavidin Detection of Cross-Linked Compound **2**.* To demonstrate that the pendant biotin group of compound **2** can be detected and used as a handle in streptavidin affinity purification as well as probe detection, BeWo cell membranes were photolabeled with compound **2**, subjected to SDS−PAGE, blotted unto PVDF membranes, and probed with streptavidin horseradish peroxidase conjugate. The results shown in Figure 3 show that not only can compound **2** be used to photolabel amino acids at the NBMPR-binding site on the ENT1 transporter (Figure 2), but it can also be detected by binding it to streptavidin. Figure 3 confirms that the probe cross-links protein and suggests that compound **2** can be used as a bifunctional probe to cross-link the ENT1 transporter and be used for affinity isolation of ENT1 polypeptides. Efforts are underway to use this novel probe for photolabeling and identification of the amino acid residues of the ENT1 transporter involved in ligand binding, by mass spectrometric means similar to a recent characterization of the dexniguldipine binding site of P-glycoprotein (*19*).

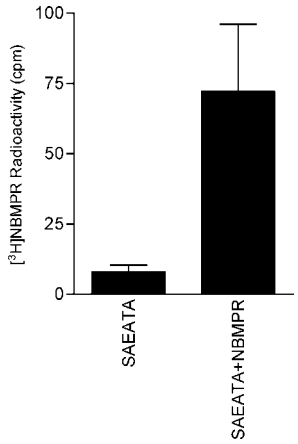

Figure 2. [^{3}H]NBMPR binding to BeWo membranes that were washed after incubation with test compounds followed by irradiation with UV light. Membranes were from samples incubated with 100 nM SAEATA-x14-biotin, samples incubated with 100 nM SAEATA-x14-biotin in the presence of 10 μM NBMPR. The data represent the mean and minimum and maximum values from two separate experiments.

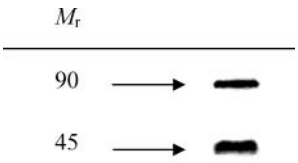

Figure 3. Streptavidin detection of compound **2** photocross-linked to BeWo cell membranes. BeWo cell membrane preparation (50 μg protein) irradiated with UV light was loaded onto 12% SDS-polyacrylamide gel and electrophoresis carried out. Protein was electroblotted unto polyvinylidine fluoride membranes (Immobilon-P; Millipore, Bedford, MA), blocked with 5% nonfat dried milk in TBS-T: (20 mM Tris-HCl, pH 7.6, 137 mM NaCl, and 0.1% Tween-20) at 4 °C overnight, followed by incubation with a horseradish peroxidase-conjugated streptavidin (0.5 μg/mL) in BLOTTO for 1 h. The membrane was washed in TBS-T, and treated with Enhanced ChemiLuminescence (ECL, Amersham) detection reagents as described by the manufacturer. Biotinylated proteins were visualized by exposure to X-ray film and development.

Received October 6, 2003; Revised Manuscript Received January 26, 2004

Synthetic analogues of triacylated and diacylated lipopeptides derived from the N-terminal domain of respectively bacterial and mycoplasmal lipoproteins are highly potent immunoadjuvants when administered either in combination with protein antigens or covalently linked to small peptide epitopes. Because of their amphipathic properties, lipopeptides, such as *S*-[2,3-bis(palmitoyloxy)-(2*RS*)-propyl]-*N*-palmitoyl-(*R*)-cysteinyl-alanyl-glycine (Pam_3CAG), can be conveniently incorporated into liposomes and serve as anchors for antigens that are linked to them. To design vaccination constructs based on synthetic peptides and liposomes as vectors. we have accordingly synthesized a series of lipopeptides that differ by the number (Pam_3C vs Pam_2C) and nature of the acyl chains (palmitoyl vs oleoyl) and by the presence at their C-terminus of thiol-reactive functions, such as maleimide or bromoacetyl. When incorporated into liposomes, these latter functionalized lipopeptides allow, in aqueous media, a well controlled chemoselective conjugation of HS-peptides to the surface of the vesicles. Using a BALB/c mice splenocyte proliferation assay ([^{3}H]thymidine incorporation), we have measured the lymphocyte activation potency of the different lipopeptides. We found that, compared to their free (emulsified) forms, the liposomal lipopeptides were endowed with enhanced mitogenic activities; i.e., up to 2 orders of magnitude for Pam_3CAG which was more potent than Pam_2CAG. The impact of functionalization on the cellular activity of Pam_3CAG was dependent on the thiol-reactive group introduced: whereas the bromoacetyl derivative retained its full activity, the presence of a maleimide group virtually abolished the lymphocyte activation of the lipopeptide. Finally, the substitution of saturated palmitoyl chains by unsaturated oleoyl chains was inhibitory. Thus, thiol-reactive Ol_3CAG derivatives were the least active mitogens in our assay. Taken together, our findings are of importance for the further optimization of antigen-specific liposomal-based synthetic vaccines; the bromoacetyl derivative of Pam_3CAG should be a promising lipopeptide derivative serving as an anchor for peptide epitopes while retaining its lymphocyte activation activity.

INTRODUCTION

Synthetic peptide or epitope-based vaccines present a particularly attractive potential for infectious diseases or cancer (*1*−*5*). However, a major limitation in the use of short peptides resides in their poor immunogenicity which can be circumvented, to a certain extent, by their coupling to a variety of carriers such as proteins or synthetic/multimeric polymers (*6, 7*). During this past decade our understanding of the cellular and molecular aspects of the immune response has increased dramatically, and this includes also a much better knowledge of the role and mode of action of immunoadjuvants (*8*−*10*). We have now a much clearer view of what are the indispensable elements of a "designer" vaccination construct and the function(s) they are supposed to carry out at cellular levels. In the field of peptide-based vaccines, lipopeptides such as *S*-[2,3-bis(palmitoyloxy)-(2*RS*)-propyl]-*N*-palmitoyl-(*R*)-cysteinyl-alanyl-glycine (Pam_3CAG) or Pam_3CSS have a prominent position (*11*−*13*). These amphipathic synthetic analogues of the N-terminus of *Escherichia coli* lipoprotein are highly potent and nontoxic adjuvants; they are able to induce cell-mediated (*14*) as well as humoral immune responses, depending on the nature of the epitope, against low molecular weight peptides that are covalently coupled to them (*15, 16*). Among their many properties, they have been shown to be polyclonal activators of B-lymphocytes (*17*) and to trigger the synthesis of, for example, cytokines in macrophages (*18*). At molecular and cellular levels, the mode of action of these lipopeptides is far from being unraveled. A major advance came nevertheless with the realization that such structures, which constitute pathogen-associated molecular patterns (PAMPs), participate to the innate immune response by interacting with Toll-like receptor 2 (TLR2) (*19*) and to the adaptive response by triggering the maturation of dendritic cells (DC) and eliciting T-cell activation and cytokine production (*20, 21*). In addition, lipopeptides have also been shown to readily diffuse from the plasma membrane of cells, via poorly understood mechanisms, to most subcellular compartments (*22, 23*); this property presumably allows the lipopeptides to deliver their peptide cargo to the MHC class I/II molecules. At this point it should be noted that

Scheme 1. Synthesis of Pam_3CAG-Br

subcellular delivery and peptide processing were studied more thoroughly with the simpler types of lipopeptides (see below) in, for example, dendritic cells (*24, 25*). Because of these highly attractive features, lipopeptide conjugates, which are well suited for the design of novel synthetic vaccines, have been tested in a variety of applications (*11*−*13*). However, because of their physicochemical properties and relative insolubility, these molecules can prove difficult to develop even though more soluble analogues have been made (*26, 27*). The same holds true, despite their proven efficacy in producing, for example, strong cytotoxic $CD8^+$ T-cell responses against many pathogens, for less complex lipopeptides obtained by lipidation, such as palmitoylation, of terminal lysine residues of peptide epitopes (*28*−*30*).

To design epitope-driven vaccines our group has developed a somewhat different strategy based on liposomes that are used as multivalent carriers (*31*−*35*). Synthetic lipopeptide derivatives such as Pam_3CAG-Mal, which

contain a thiol-reactive maleimide function (*36*), were first incorporated into the bilayers of small unilamellar vesicles, masking the hydrophobic nature of the adjuvant. In the following steps, peptide epitopes that carry a free thiol function, either at their N- or C-terminus, are conjugated to the surface of these preformed and functionalized liposomes (*35*). An a posteriori coupling of peptide epitopes to lipopeptides, that play also the role of anchors, is thus achieved under mild conditions in aqueous media, via a well controlled, quasistoichiometric, and high yield chemoselective ligation (*37*). Because of its versatility, this strategy can be extended to the preparation of multiepitope constructs to which several different types of HS-peptides can be conjugated (*35, 37*). This approach has been used successfully for the design of highly immunogenic biepitope liposomal constructs that combine for example structurally independent B- and T-cell peptide epitopes (*35*) and also recently to antitumor vaccines (A. Roth et al., to be published).

Up to now, however, we ignore whether the C-terminal modification of lipopeptides by thiol-reactive functions is detrimental to the adjuvanticity of these molecules. Therefore, we could not answer the question whether the highly intense and long lasting immune responses, induced for example by our liposomal biepitope constructs, could be attributed to the adjuvanticity of the lipopeptides (e.g. cell activation) and/or (only) to their capacity to deliver intracellularly the linked epitopes to the MHC-I/II molecules. Therefore, to better grasp the functions of the lipopeptides and their thiol-reactive derivatives in our constructs, we have now undertaken the synthesis of several analogues and studied their comparative cellular properties. These new lipopeptides include the thiol-reactive bromoacetyl derivative of Pam_3CAG (i.e., Pam_3-CAG-Br; Scheme 1) which is chemically more stable than the Pam_3CAG-Mal (*36*) we have used previously. To increase the epitope density at the surface of the liposomal constructs we have also prepared analogues in which the palmitoyl chains have been replaced by unsaturated oleoyl chains, i.e., Ol_3CAG-Mal and Ol_3CAG-Br. These compounds are expected to be more miscible with the phospholipids used to fabricate the liposomes and less prone to engage into lateral phase separation. Finally, during the recent years it was found that MALP-2 (Pam_2-CGNNDESNISFKEK), a lipopeptide derived from a mycoplasma lipoprotein is a highly potent adjuvant when coadministered with antigens, e.g. via the mucosal route (*38*), or when conjugated to B/T peptide epitopes (*39*). This molecule which, compared to the "classical" lipopeptides, lacks the *N*-acyl chain was shown to interact with TLR2 and TLR6 (*40*−*42*), to serve as potent cytokine inducer for monocytes/macrophages and to induce the maturation of dendritic cells (*43*). For that reason we have also included in our present study the synthesis of Pam_2CAG and Pam_2CAG-Mal, i.e., analogues of the immunologically active *R*-stereoisomer (*44*) of MALP-2. We have demonstrated previously that Pam_3CAG and Pam_3CSS when incorporated into liposomes kept their ability to induce, in vitro, the proliferation of BALB/c mice splenocytes (*34*) which has been often correlated with the adjuvanticity of these compounds (*15, 17*). A similar approach was performed here which yielded a very valuable insight into the biological activity of these lipopeptide derivatives and also guidelines for the design of more efficient liposomal vaccination constructs.

EXPERIMENTAL PROCEDURES

General. Reagent-grade solvents were used without further purification. The phospholipids egg yolk L-α-

phosphatidylcholine (PC) and L-α-phosphatidyl-DL-glycerol (PG) transesterified from egg yolk PC were purchased from Sigma-Aldrich (Saint-Quentin-Fallavier, France), and their purity (over 99%) was assessed by TLC. Silica gel 60 F 254 plates for thin-layer chromatography (TLC) were purchased from Merck (Darmstadt, Germany). Column chromatographic separations were carried out as flash chromatography using silica gel (Merck) with a particle size of 0.040−0.063 mm. 2-Mercaptoethanol was obtained from Sigma-Aldrich (L'Isle d'Abeau Chesnes, France), fluorescamine (Fluram) from Fluka (L'Isle d'Abeau Chesnes, France), and Boc-Ala-Gly-OSu from Bachem (Voisins-le-Bretonneux, France). The peptide HA 307-319-C (PKYVKQNTLKLAT-C) was obtained from Neosystem (Strasbourg, France). The cysteine residue added to the C-terminus allows a facile coupling of the peptide on the lipopeptide maleimide or bromoacetyl functions. The purity of the peptide, as assessed by HPLC, was at least 80%. Pam_3CAG, prepared as previously described (*34*, *45*), was converted into the maleimide derivative Pam_3CAG-Mal by reaction with 1-(2-aminoethyl)pyrrole-2,5-dione according to Boeckler et al. (*36*). The lipopeptide Fmoc-Pam_2C was synthesized as described in the literature (*46*). Free lipopeptides used for cellular assays were suspended in PBS (pH 7.4) and emulsified by sonication for 1 h. *N*-(*tert*-butyloxycarbonyl)aminoethoxyethoxyethylamine was prepared by a simple monoprotection with a Boc moiety (*47*). ^{1}H and ^{13}C NMR were recorded on Bruker DPX-200 (200 MHz) and DPX 300 (300 MHz) spectrometers. Chemical shifts are expressed as parts per million using $CHCl_3$ ($\delta = 7.27$ ppm for ^{1}H and 77.7 ppm for ^{13}C) or CH_3OH ($\delta = 3.35$ ppm for ^{1}H and 49.0 ppm for ^{13}C) as the internal standard ($\delta = 0.0$ ppm). Mass spectra (ES-MS) were recorded on a ESI/TOF Mariner mass spectrometer by electrospray. [^{3}H]Thymidine was obtained from Amersham Biosciences (Buckinghamshire, England) with a specific activity of 25.0 Ci/mmol.

***N*-(*tert*-Butyloxycarbonyl)aminoethoxyethoxyethyl-2-bromoacetamide (1).** To a solution of *N*-(*tert*-butyloxycarbonyl)aminoethoxyethoxyethylamine (1 g, 3.25 mmol) in CH_2Cl_2 (40 mL) were added bromoacetic acid succinimidyl ester (1.15 g, 4.87 mmol) and DIEA (850 μL, 4.87 mmol). After being stirred for 22 h at room temperature, the organic phase was washed with 3 × 40 mL of a citric acid solution (5%, w/v) followed by 3 × 40 mL of water. After passage over $MgSO_4$, the solvent was evaporated to dryness. The reaction product **1** (887 mg; yield 74%) was obtained after purification by chromatography on silica gel eluted with AcOEt:hexane 2:1 to 3:1. R_f 0.63 (CH_2Cl_2:MeOH 9:1). ^{1}H NMR (300 MHz, $CDCl_3$): δ 3.84 (s, 2H, CH_2Br), 3.57−3.26 (m, 12H, (CH_2)$_2$O(CH_2)$_2$O(CH_2)$_2$), 1.40 (s, 9H, C(CH_3)$_3$). ^{13}C NMR (75 MHz, $CDCl_3$:MeOD 1:1): δ 165.59 (*C*(O)CH_2Br), 155.81 (*C*(O)OC(CH$_3$)$_3$), 79.07 (*C*(CH$_3$)$_3$), 69.16, 69.99, 70.17 (4 × *C*H$_2$O(*C*H$_2$)$_2$O*C*H$_2$), 40.16 (O(CO)NH*C*H$_2$), 39.71 (CH_2(CO)NH*C*H$_2$), 28.86 (*C*H$_2$Br), 28.23 (3 × C(*C*H$_3$)$_3$). ES-MS *m*/*z*: 392.1047 ([M + Na]$^+$), calcd: 369.1147 for $C_{13}H_{25}BrN_2O_5$.

Aminoethoxyethoxyethyl-2-bromoacetamide (2). Compound **1** (100 mg, 0.27 mmol) was dissolved in 9 mL of TFA/CH_2Cl_2 (1/4, v/v). The deprotection reaction was conducted at room temperature and under stirring. After 1 h, the solvents were evaporated under vacuum and compound **2** was obtained, with trifluoroacetate as counterion, as an oil (103 mg; yield 100%). R_f 0.12 (CH_2Cl_2 :MeOH 9:1). ^{1}H NMR (300 MHz, $CDCl_3$:MeOD 1:1): δ 3.81 (s, 2H, CH_2Br), 3.70−3,39 (m, 10H, (CH_2)$_2$O(CH_2)$_2$-OCH_2), 3.11−3.07 (m, 2H, CH_2(CO)NHCH_2).

***N*-{[2,3-Bis(palmitoyloxy)-(2*RS*)-propyl]-*N*-palmitoyl-(*R*)-cysteinyl-(*S*)-alanyl-glycyl}aminoethoxyethoxyethyl-2-bromoacetamide (3).** DCC (9.5 mg, 46.2 μmol), DIEA (10 μL, 57.8 μmol), and NHS (1.0 mg, 7.7 μmol) were added to a solution of Pam_3CAG (40 mg, 38.5 μmol) in CH_2Cl_2 (1.2 mL). The amine **2** (22 mg, 57.8 μmol) was then added to the mixture, and the reaction was left at room temperature. After 8 h, the formed precipitate was removed by filtration and the organic phase was then washed with 3 × 6 mL of 5% (w/v) citric acid in water followed by 3 × 6 mL of water. After being dried over $MgSO_4$, the solvent was evaporated to dryness. Compound **3** was finally recrystallized from $CHCl_3$:MeOH 1:4 at −20 °C, and it afforded a white powder after lyophilization from *tert*-butyl alcohol (33 mg; yield 66%). R_f 0.42 (CH_2Cl_2:MeOH 13:1). ^{1}H NMR (200 MHz, $CDCl_3$:MeOD 1:1): δ 5.21 (m, 1H, SCH$_2$C*H*(O)), 4.69 (m, 1H, SCH$_2$C*H*(NH)), 4.68−4.56 (m, 1H, NHC*H*(CH$_3$)), 4.43−4.13 (m, 2H, SCH$_2$CH(O)C*H*$_2$(O)), 4.06 (m, 2H, NHC*H*$_2$C(O)), 3.86 (s, 2H, C*H*$_2$Br), 3.65−3.43 (m, 12H, (C*H*$_2$)$_2$O(C*H*$_2$)$_2$O(C*H*$_2$)$_2$), 3.04−2.87 (m, 2H, SC*H*$_2$CH(N)), 2.81 (m, 2H, SC*H*$_2$CH(O)), 2.42−2.26 (m, 6H, CH$_3$-(CH$_2$)$_{13}$C*H*$_2$C(O)), 1.63 (m, 6H, CH$_3$(CH$_2$)$_{12}$C*H*$_2$-CH$_2$C(O)), 1.44−1.41 (d, $J = 7.3$ Hz, 3H, NHCH(C*H*$_3$)C(O)), 1.40−1.25 (m, 72H, CH$_3$(C*H*$_2$)$_{12}$(CH$_2$)$_2$C(O)), 0.90 (t, $J = 6.6$ Hz, 9H, C*H*$_3$(CH$_2$)$_{14}$C(O)). ^{13}C NMR (50 MHz, $CDCl_3$): δ 174.82 (CH$_3$(CH$_2$)$_{14}$*C*(O)N), 173.60, 173.89 (2 × CH$_3$-(CH$_2$)$_{14}$*C*(O)O), 173.50 (NHCH(CH$_3$)*C*(O)), 172.04 (SCH$_2$-CH(NH)*C*(O)), 169.34 (NHCH$_2$*C*(O)), 166.32 (NH*C*(O)-CH$_2$Br), 69.42, 70.26 (SCH$_2$*C*H(O), 4 × *C*H$_2$O(*C*H$_2$)$_2$O*C*H$_2$), 63.76 (SCH$_2$CH(O)*C*H$_2$(O)), 51.94 (SCH$_2$*C*H(NH)), 50.02 (NH*C*H(CH$_3$)), 42.93 (NH*C*H$_2$C(O)), 39.59, 39,94 (2 × NH*C*H$_2$CH$_2$O), 36.28 (S*C*H$_2$CH(NH)), 34.33 (2 × CH$_3$-(CH$_2$)$_{13}$*C*H$_2$C(O)O), 34.07 (CH$_3$(CH$_2$)$_{13}$*C*H$_2$C(O)N), 29.30, 29.33, 29.67, 31.90 (30 × CH$_3$CH$_2$(*C*H$_2$)$_{10}$(CH$_2$)$_3$C(O), *C*H$_2$-Br), 24.85, 25.53 (6 × CH$_3$(CH$_2$)$_{11}$(*C*H$_2$)$_2$CH$_2$C(O)), 22.66 (3 × CH$_3$*C*H$_2$(CH$_2$)$_{13}$C(O)), 17.14 (NHCH(*C*H$_3$)C(O)), 14.07 (3 × *C*H$_3$(CH$_2$)$_{14}$C(O)). ES-MS *m*/*z*: 1312.8418 ([M + Na]$^+$), calcd: 1289.8518 for $C_{67}H_{126}BrN_5O_{11}S$.

***N*-[*N*-(*tert*-Butyloxycarbonyl)-(*S*)-alanylglycyl]aminoethoxyethoxyethyl-2-bromoacetamide (4).** *N*-α-Boc-L-alanylglycine *N*-hydroxysuccinimide ester (282 mg, 0.822 μmol) was dissolved in CH_2Cl_2 (3 mL). The amine **2** (282 mg, 738 μmol) and DIEA (100 μL, 578 μmol) were then added, and the reaction was left at room temperature. After 12 h, the organic phase was washed with 10 mL of saturated NaCl followed by 3 × 10 mL of water. It was then dried over $MgSO_4$, and the solvent was evaporated to dryness. The reaction product was purified by column chromatography on silica gel by elution with CH_2Cl_2:MeOH 95:5 to obtain compound **4** as an oily form (250 mg; yield 68%). R_f 0.71 (CH_2Cl_2:MeOH 6:1). ^{1}H NMR (200 MHz, $CDCl_3$): δ 4.18−4.11 (m, 1H, NHC*H*-(CH$_3$)), 4.05 (m, 2H, NHC*H*$_2$C(O)), 3.87 (s, 2H, C*H*$_2$Br), 3.75−3.30 (m, 12H, (C*H*$_2$)$_2$O(C*H*$_2$)$_2$O(C*H*$_2$)$_2$), 1.41 (s, 9H, C(C*H*$_3$)$_3$), 1.37−1.34 (d, $J = 7.1$ Hz, 3H, NHCH(C*H*$_3$)-C(O)). ^{13}C NMR (50 MHz, $CDCl_3$): δ 173.72 (NHCH(CH$_3$)-*C*(O)), 169.34 (NHCH$_2$*C*(O)), 166.47 (NH*C*(O)CH$_2$Br), 155.64 (*C*(O)OC(CH$_3$)$_3$), 79.96 (*C*(CH$_3$)$_3$), 69.16, 70.00 (4 × *C*H$_2$O(*C*H$_2$)$_2$O*C*H$_2$), 50.37 (NH*C*H(CH$_3$)), 42.77 (NH*C*H$_2$-C(O)), 39.08, 39.72 (2 × NH*C*H$_2$CH$_2$O), 28.69 (*C*H$_2$Br), 28.10 (3 × C(*C*H$_3$)$_3$), 17.91 (NHCH(*C*H$_3$)C(O)). Liposome Preparation. Liposomes were prepared by mixing, in a round-bottom flask, phospholipids (PC, PG) and cholesterol (75/20/50 molar ratio), in chloroform with the appropriate thiol-reactive functionalized or nonfunctionalized lipopeptides at 5 mol %. After solvent evaporation under high vacuum, the dried lipid film was hydrated by vortex mixing after addition of 1 mL buffer (for 10 μmol lipids) containing 5% (w/v) sorbitol as follows: 10 mM HEPES buffer (pH 6.5) for the maleimide derivatives, 10 mM CHES buffer (pH 9.0) for the bromoacetyl derivatives, and HEPES buffer (pH 7.4) for the nonfunctionalized lipopeptides. The resulting suspensions were sonicated at 25 °C for 1 h (5 s cycles interrupted for 1.25 s) under a continuous flow of nitrogen, using a 3 mm diameter probe sonicator (Vibra Cell, Sonics and Material Inc, Danbury, CT) at 300 W. The SUV preparations were finally centrifuged for 10 min at 10 000*g* to remove the titanium dust originating from the probe. All the liposomal formulations were freshly prepared and sterilized before use with the cells.

Peptide Conjugation to Liposomes Containing Thiol-Reactive Lipopeptide Derivatives. HA307-319-C, pretreated with TCEP (0.7 equiv vs peptide) to reduce the disulfide bond of any oxidized form of the peptide, was added to freshly prepared liposomes containing thiol-reactive functionalized lipopeptides (2 molar excess of peptide vs surface accessible thiol-reactive functions). The coupling of the peptide was performed at room temperature, under argon, in 10 mM HEPES (pH 6.5) or CHES (pH 9.0) buffers containing 5% (w/v) sorbitol (see above). After 2 h, a 10-fold excess of 2-mercaptoethanol was added to the preparation to derivatize all the unreacted maleimide or bromoacetyl groups. This step was performed for 1 h under argon after which the liposomal preparation was dialyzed extensively against 10 mM HEPES buffer (pH 7.4) containing 5% (w/v) sorbitol, to eliminate unconjugated peptides and excess reagents.

Analytical Techniques. Phosphorus content of the liposomes preparations was analyzed by a previously described method (*49*). The quantification of peptide associated to the vesicles was achieved by acid hydrolysis of the liposomal formulations (*35*). The amino acids that were generated were then quantitated using a fluorimetric assay with fluorescamine (*50*) as follows: 50 μL of the hydrolysis solution (containing 10 to 50 nmol of amines) were added to 1.5 mL of 50 mM sodium borate buffer (pH 9.0), followed by the addition of 500 μL of a fluorescamine solution in dioxane (300 μg/mL). After rapid mixing, the fluorescence was read immediately at λ_{em} = 475 nm (λ_{exc} = 390 nm). The contribution of the liposomes alone was evaluated using the same conditions and subtracted from the total fluorescence. Hydrolysis of known quantities of free peptides was used as standard. Liposomes were immediately used for the in vitro assays.

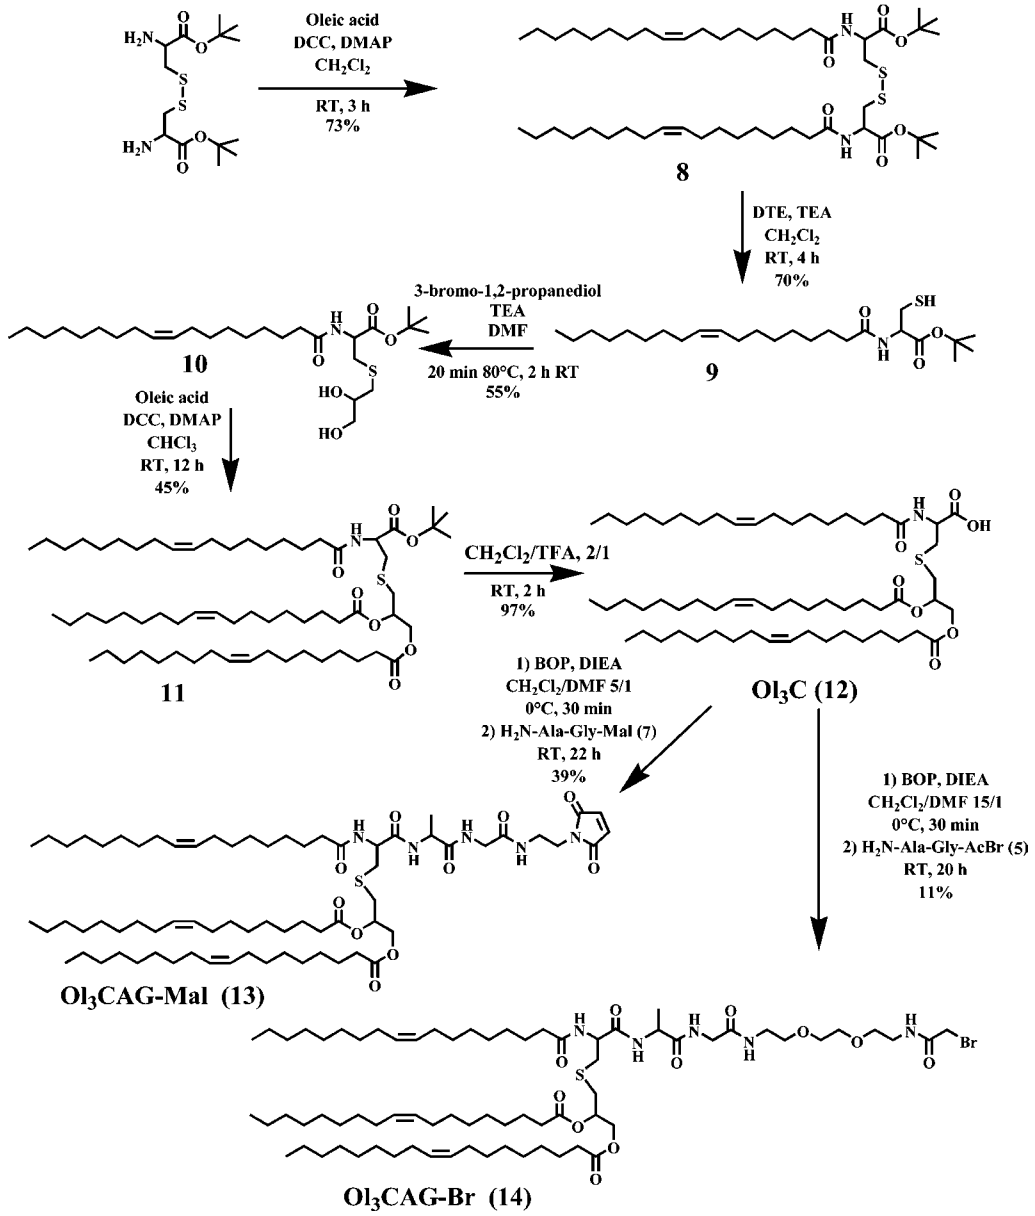
Light-Scattering Measurements. The size of the liposomes was determined by dynamic light scattering using a Zeta-master 3000 (Malvern Instruments, Paris, France) with the following specifications: sampling time, 30 s; medium viscosity, 1.014 cP; refractive index, 1.34; scattering angle, 90°; temperature, 25 °C. Data were collected using the multimodal number distribution software included in the instrument. All the formed vesicles were uniformly distributed in size and exhibited average diameters of 50 to 80 nm (±30 nm). No significant vesicles size changes (less than 5%) was measurable after the conjugation of the peptides.

Spleen Cell Proliferation Assay. Approximately 8−12 weeks old BALB/c female mice were sacrificed by cervical dislocation. Their spleens were excised and placed in sterile Petri dishes containing RPMI-1640 medium. Splenocyte suspensions were prepared by passing the minced spleens through a 40 μm cell strainer and were hemolyzed with Gey's buffer (HBSS, 650 mM NH_4Cl, 27 mM glucose). Cells were washed twice and resuspended in culture medium (RPMI-1640 medium

Scheme 2. Synthesis of the Functionalized Spacer-Arms 5 and 7

supplemented with 10% (v/v) fetal bovine serum (FBS), penicillin G and streptomycin, 1% nonessential amino acids, and 50 μM 2-mercaptoethanol). One hundred microliters of the splenocyte suspension at 1.5×10^6 cells/mL was plated in round-bottomed 96-well plates containing 100 μL of different lipopeptide formulations. The splenocytes were incubated for 48 h. [^{3}H]Thymidine (0.7 μCi/well) was then added, and after 18 h, the cells were collected on glass-fiber filters (Wallac, Filtermat A) with an automatic cell harvester (Micro96 Harvester, Skatron). The incorporated radioactivity, expressed as cpm, was determined by liquid scintillation counting (1205 Betaplate, Wallac).

RESULTS



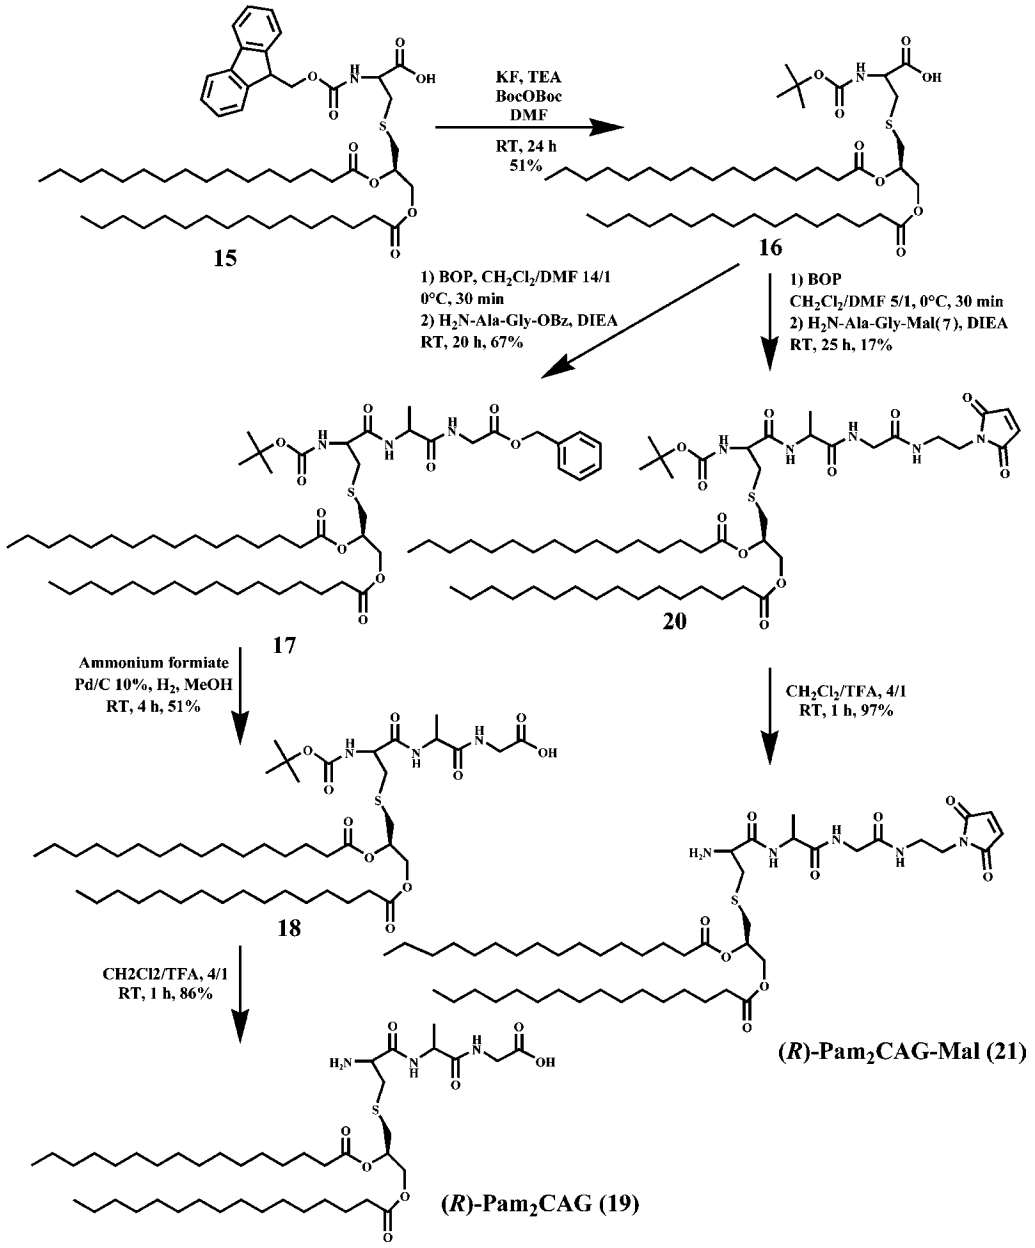
Synthesis. The synthesis of lipopeptides functionalized with the maleimide and bromoacetyl thiol-reactive groups was performed according to the procedures outlined in Schemes 1−4. The preparation of Pam_3CAG-Br (**3**) (Scheme 1) involves the reaction of monoprotected 1,8-diamino-3,6-dioxaoctane with bromoacetic acid succinimidyl ester to afford **1**. After cleavage of the Boc group, the resulting functionalized spacer arm **2** was conjugated to the racemic form of the lipopeptide Pam_3CAG, previously prepared according to refs 45 and 34, to yield **3**.

The synthesis of the two oleoyl chain-containing functionalized lipopeptides **13** and **14** (Scheme 3) first required the production of *S*-[2,3-bis(oleoyloxy)-(2*RS*)-propyl]-*N*-oleoyl-(*R*)-cysteine (Ol_3C; **12**). This was achieved in five steps, essentially following the procedure described by Wiesmuller et al. for the synthesis of Pam_3C (*45)* in which oleic acid was used instead of palmitic acid. The last step consisted of the coupling, in liquid phase, of **12** to the functionalized alanyl-glycine peptides **5** and **7**. The preparation of these two molecules is shown in Scheme 2. Compound **2** or 1-(2-aminoethyl)pyrrole-2,5-dione (*36*) were reacted with the commercially available Boc-AlaGly-OSu in the presence of DIEA to give respectively **4** and **6**. In the latter case, DMF was necessary to dissolve the TFA salt of the maleimide derivative. The final products **5** and **7** were obtained after deprotection of the Boc groups with 20% (v/v) TFA in CH_2Cl_2.

The preparations of Pam_2CAG (**19**) and its maleimide derivative (**21**) are represented in Scheme 4. These syntheses begin with the Fmoc-protected compound **15** prepared as described previously by Metzger et al. (*48)*. However, in contrast to the racemic Pam_3C and Ol_3C series of lipopeptides described above, in the present case we have synthesized the (2*R*)-stereoisomer by using (*S*)-(−)-glycidol as chiral precursor. This was justified because the *R*-isomer has been reported to be a much more potent adjuvant than the opposite isomer (*44*). The Fmoc-protecting group was first converted into a Boc derivative in a single step, by deprotection of the Fmoc with a base, potassium fluoride in the presence of triethylamine, and replacement in situ with a Boc group by reaction with Boc_2O in DMF. This change of protecting group was required by the sensitivity of the malemide moiety (step **20** → **21**) to the basic conditions generally used in Fmoc group removal. The resulting compound **16** was used for the parallel syntheses of **19** and **21**. The preparation of the lipopeptide **19** was performed in three steps. The first one consisted in the conjugation of the Ala-Gly moiety (protected with a benzyl group) by reaction with H_2N-Ala-Gly-OBz after activation of the carboxylic acid of **16** with BOP. Two different conditions were necessary to remove the Boc and benzyl protecting groups. This latter one was classically removed by catalytic hydrogenation with 10% Pd/C in methanol; however, addition of ammonium formate was needed to accelerate the process. The Boc group of the resulting compound **18** was finally cleaved by TFA in CH_2Cl_2 yielding the lipopeptide (*R*-stereoisomer) Pam_2CAG (**19**). The same lipopeptide, but functionalized with a maleimide group (**21**), was synthesized from **16** activated with BOP at 0 °C. The amine **7** (Scheme 2) and DIEA were added to achieve the coupling of the Ala-Gly-Mal moiety and yield compound **20**. A final deprotection gave in quantitative yield the functionalized lipopeptide Pam_2CAG-Mal (2*R*-stereoisomer) (**21**).

Liposome Preparation. Liposomes (small unilamellar vesicles, 50−80 nm diameter) were prepared from egg phosphatidylcholine, phosphatidylglycerol, and cholesterol (molar ratio 75/20/50) to which the different synthesized lipopeptides were added at a 5 mol % ratio. The thiol-reactive group-derivatized lipopeptides incorporated into liposomes were treated with a large excess of the permeant 2-mercaptoethanol before in vitro experiments to inactivate all the reactive functions. The conjugation of a C-terminus thiol functionalized Th peptide (HA 307−319) to the surface of preformed liposomes, containing the lipopeptide derivatives (lipopeptides were quantitatively incorporated into liposomes (*36*)), was also performed under well-defined conditions as described in the Experimental Procedures section. This coupling, which was nearly quantitative, was done to verify whether the covalent linkage of a peptide to our synthetic lipopeptides

Scheme 3. Synthesis of the Functionalized Lipopeptides Ol_3CAG-Mal (13) and Ol_3CAG-Br (14)



results in a modification of their cellular activities (e.g. mitogenicity).

In Vitro Mouse Splenocyte Proliferation Effect of Free and Liposomal Lipopeptides. In agreement with previous reports (*34*), free (emulsified) synthetic lipopeptide Pam_3CAG induced a dose-dependent BALB/c mouse spleen cell proliferation that was measured by [^{3}H]-thymidine incorporation (Figure 1). After 2 days of culture, cell proliferation was detected with 0.5 nmol of the lipopeptide/mL (Figure 1A). In contrast, the free diacyl lipopeptide Pam_2CAG (**19**) was about 2 times less active, and its mitogenic activity became only measurable at concentrations above 1 nmol/mL (Figure 1B). The incorporation of tripalmitoyl or dipalmitoyl lipopeptides into liposomes (SUV) was not detrimental to their cellular effect; on the contrary, it increased their mitogenic activity, and this effect was more pronounced for Pam_3CAG. Thus, the mitogenicity of Pam_3CAG and Pam_2CAG (**19**) were already measurable at concentrations of about 0.001 (see Figure 1A) and 0.1 nmol/mL (Figure 1B) of liposomal incorporated lipopeptide respectively, i.e., corresponding to about 2 and 1 orders of magnitude increase in potency, respectively.

We next examined the mitogenic activity of the liposomal thiol-reactive lipopeptides that were synthesized in order to conjugate peptide epitopes to the surface of the vesicles. We found that Pam_3CAG-Mal (*36*) lost most of its activity (Figure 1A). In sharp contrast, Pam_3CAG which has been functionalized with a bromoacetyl group (i.e., lipopeptide **3**) remained fully active (Figure 1A). In the dipalmitoyl lipopeptide series, functionalization of Pam_2CAG (**19**) by a maleimide group (lipopeptide **21**) also did not result in a change of its mitogenic activity (Figure 1B). Furthermore, conjugation of a peptide epitope to such a structure did not alter its property (Figures 1A). Finally, lipopeptides containing three oleoyl moieties and functionalized either by a maleimide (**13**) or a bromoacetyl (**14**) group induced, respectively, only a very weak or no proliferative response in splenocytes (Figure 1B). These results underline the major influence of the lipid moiety on the mitogenic properties of these lipopeptide derivatives. Mitogenic activity of the lipopeptides used in this study are also summarized in Table 1. In this table the minimal concentrations necessary to observe a doubling, over control, of [^{3}H]thymidine incorporation in murine splenocytes are compared.

Scheme 4. Synthesis of the Lipopeptides (*R*)-Pam$_2$CAG (19) and (*R*)-Pam$_2$CAG-Mal (21)

DISCUSSION

The aim of this work was the synthesis of analogues of the Pam$_3$C series of immunoadjuvants (*11*−*13*) functionalized with thiol-reactive groups which can be readily incorporated into liposomes and conjugated, under chemically well controlled conditions (*37*), to HS-peptide epitopes to realize self-adjuvanting and molecularly defined vaccination constructs (*35*). To test a representative biological activity of these new lipopeptides we have selected, among the many in vivo and in vitro activities of the "classical" lipopeptides, a prominent characteristic of these molecules such as the in vitro mitogenicity of mouse splenocytes which was shown to result more specifically from a polyclonal activation of B-lymphocytes (*17*, *51*) and to be correlated with their adjuvanticity. Although the molecular mechanisms of splenocytes/B-cell activation remain unknown they most probably involve the mediation of TLRs as was found for LPS (*52*) and some lipopeptides (*53*).

Before studying the thiol-reactive lipopeptide derivatives we have first checked whether incorporation of their nonfunctionalized precursors into liposomes had any incidence on their cellular activity. Compared to its free form, incorporation of the lipopeptide Pam$_3$CAG into phospholipid vesicles resulted in a large (2 orders of magnitude) increase in its mitogenic potency (Table 1). This improvement in activity could be due to a better solubilization of the adjuvant compared to its emulsified form. It also indicates that Pam$_3$CAG is not "buried" within the bilayer of the liposomes but remains fully accessible for example to receptor binding, either at the cell surface (e.g. TLR2), or after internalization. A similar observation, but of lesser amplitude (1 order of magnitude), was found when comparing free and liposomal (2*R*)-Pam$_2$CAG (**19**). Because free diacylated lipopeptides are more soluble per se, their insertion into vesicles might afford a lesser advantage in their stimulating activity. This hypothesis is in agreement with previous reports about the benefits of improved solubility of lipopeptides on increased in vitro stimulation of macrophages (*54*). Similarly, the in vivo immunogenicity of different lipopeptide constructs has been correlated with increased

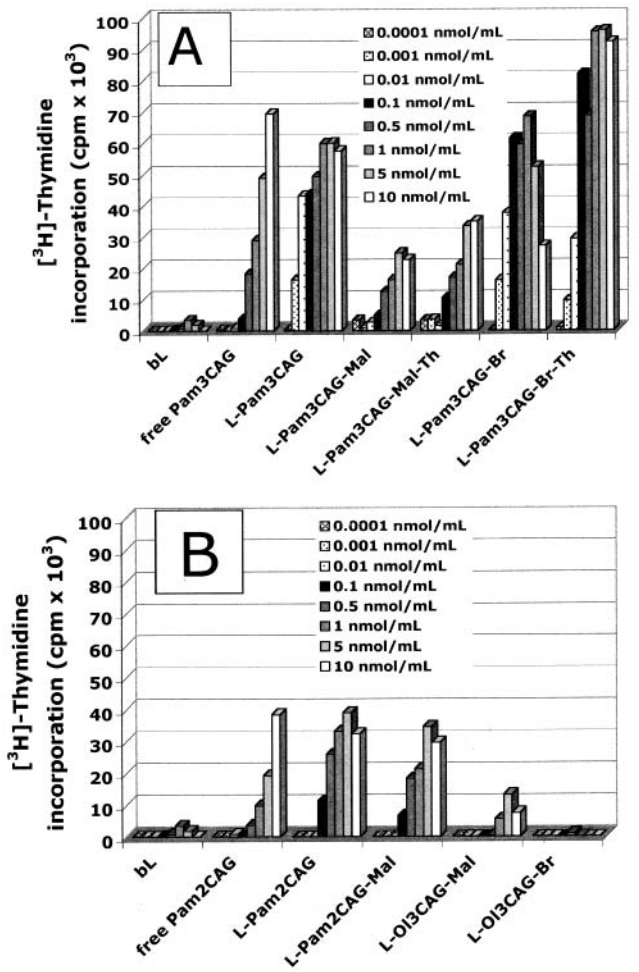


Figure 1. Dose−response relationship for the incorporation of [^{3}H]thymidine in BALB/c mice splenocytes treated with (1A) Pam_3CAG and (1B) Ol_3CAG or (2*R*)-Pam_2CAG, either nonmodified or functionalized by a maleimide or a bromoacetyl group, incorporated in liposomes. Nonmodified lipopeptides were also tested in a free (emulsified) form. Suspensions of 1.5×10^5 splenocytes per well in 200 μL of RPMI 1640 were given lipopeptides (0.0001−10 nmol/mL). After 48 h, 0.7 μCi of [^{3}H]-thymidine was added per well, and the cells were incubated for an additional period of 24 h. The values given as cpm/well and represent means ($n = 3$) for a representative experiment (SD < 6%). Similar results were obtained in four independent experiments. bL, blank liposomes; L, liposomal lipopeptide; maleimide or bromoacetyl functions have been reacted with 2-mercaptoethanol or with the T-helper (Th) peptide PKYVKQNTLKLAT-C (see Experimental Procedures).

solubility (*39*). Finally, these data are also in agreement with those published recently by Dieters and Mühlradt, who showed that MALP-2 in liposomes remains an active macrophage stimulator, both in vitro and in vivo (*55*). At this point, it should also be underlined that free (2*R*)-Pam_2CAG, which we have synthesized because of the particularly powerful activation of immunocompetent cells by MALP-2 (see Introduction), is a less potent activator of murine splenocytes proliferation than Pam_3-CAG (Figure 1 and Table 1) and the previously described Pam_2CFEPPPATTT, i.e., the only other MALP-2 analogue studied on such a cellular model (*56*). This observation indicates that in the MALP-2 series the peptide moiety might be of importance in the solubility and cellular activity of these lipopeptides.

When Pam_3CAG was transformed into Pam_3CAG-Br (**3**) and incorporated into liposomes no change in mitogenic activity could be observed; in comparison liposomal

Table 1. Comparative Mitogenic Activity of the Lipopeptides Used in This Study

	mitogenic activity

L-Ol_3CAG-Br	no effect	no effect	1

[a] Minimal lipopeptide concentration necessary to observe a 100% increase of [^{3}H]thymidine incorporation in murine splenocytes compared to control (i.e., incorporation observed with blank liposomes; see Figure 1). [b] Mitogenic efficacy of the lipopeptides and their formulations compared to free Pam_3CAG taken as the test compound. The values were deduced from the first column. [c] Maximal [^{3}H]thymidine incorporation over background (blank liposomes) observed in the concentration range of the lipopeptides, and their formulations, given in Figure 1. [d] L, liposomal lipopeptide; Th, maleimide or bromoacetyl functions have been reacted with the T-helper peptide PKYVKQNTLKLAT-C instead of 2-mercaptoethanol (see Experimental Procedures).

Pam_3CAG-Mal was about 4 orders of magnitude less active. With regard to our vaccination strategy this is a unexpected and important result. It indicates that the C-terminus derivatization of Pam_3CAG with a maleimide or a bromoacetyl group, followed by reaction with a thiol such as 2-mercaptoethanol (or a HS-peptide), can result in dramatic differences in mitogenic potency and probably also in adjuvanticity of the functionalized lipopeptides. This underlines the sensitivity of these molecules to structural changes, e.g. thioether linkages connected to acyclic or cyclic spacers, but at the moment we have no explanation for such a wide difference in cellular activity. It should be stressed, however, that despite the large decrease of mitogenicity of the maleimide derivative, we have previously shown that liposomal constructs in which the T-helper epitopes were conjugated to Pam_3CAG-Mal afforded highly intense and long lasting T-dependent humoral immune responses (*35*). This observation indicates that in these experiments the immunization outcome was largely independent of the lipopeptide-induced B-lymphocyte mitogenicity. Taken together, the results of the present study seem to show that in our previous constructs, the lipopeptide Pam_3CAG-Mal, in the absence of its "normal" adjuvanticity (e.g. via interaction with TLR2), played another prominent role. We propose that it consists of the conveying of the Th epitope cargo within the antigen presenting cells (APCs) and its delivery to the right intracellular compartments containing the MHC-II molecule (see Introduction). Thus, in our future constructs, it would be interesting to use Pam_3CAG-Br to harness the full cellular potential of the "classical" lipopeptide adjuvants in addition to their cellular delivery properties.

A different picture has emerged with lipopeptide analogues in which the number or the nature of the acyl chains have been altered. In contrast to the Pam_3C series, derivatization of (*R*)-Pam_2CAG with a maleimide group did not result in much changes of the mitogenic potency. Thus, liposomal **21** was still active, i.e., about 1 order of magnitude more than Pam_3CAG-Mal. Such a result could originate from the differences in receptor types of the di- and triacyl lipopeptides. Whereas Pam_3CAG is a ligand

of TLR2, the MALP-2 lipopeptides interact preferentially with TLR6 which could be more lenient toward the structural modifications introduced by a maleimide moiety. Finally, the unsaturated acyl chains containing analogues Ol_3CAG-Mal (**13**) and Ol_3CAG-Br (**14**), which were synthesized to be incorporated at higher concentrations in the bilayers of liposomes and thus increase the epitope density at the surface of these vesicles, were the least mitogenic compounds of the series studied here. In analogy to Pam_3CAG-Mal, these analogues should not be expected to be very potent activators of immunocompetent cells in an immune response based, for example, on lymphocytes activation. A similar observation was made recently in a study by v.d. Esche et al. (*27*)., which showed by screening of a fatty acid lipopeptide library, that the Ol_3CSK_4 was much less active in, for example, the induction of NO release by macrophages, than Pam_3CSK_4, which is one of the most powerful lipopeptide adjuvants known. This result, which underlines the paramount importance of the nature of the lipopeptides fatty acid chains on the adjuvanticity of these compounds, does not, however, a priori, exclude the use of these analogues when the subcellular delivery of peptide epitopes is the sole aim.

In conclusion, our studies indicate that within the Pam_3C series of lipopeptides, C-terminus derivatization of the tripeptide moiety with a bromoacetyl group, to conjugate a HS-peptide epitope, bears no significant incidence on mouse splenocyte proliferation which is a hallmark of these adjuvants. It follows that liposomal Pam_3CAG-Br, which is a potent mitogen, represents a very attractive adjuvant for the design of synthetic epitope-driven vaccines. Pam_2C and Ol_3C, the other series studied here, are less mitogenic and consequently will benefit less, as immunoadjuvants, from some of the cellular activities of the "classical" lipopeptides; however, their liposomal forms could still be of great interest for the subcellular delivery of epitopes in APCs.

Microwave-Supported Preparation of ^{68}Ga Bioconjugates with High Specific Radioactivity

I. Velikyan,[†,‡] G. J. Beyer,[§] and B. Långström*[,†,‡]

Department of Organic Chemistry, Institute of Chemistry, BMC, Uppsala University, Box 599, SE-751 24 Uppsala, Sweden, Uppsala Imanet AB, PO Box 967, SE-751 09 Uppsala, Sweden, and Cyclotron Unit, Geneva University Hospital, 1211 Geneva, Switzerland. Received November 7, 2003; Revised Manuscript Received March 15, 2004

The generator-produced positron-emitting ^{68}Ga ($T_{1/2}$ = 68 min) is of potential interest for clinical PET. ^{68}Ga as a metallic cation is suitable for complexation reactions with chelators, naked or conjugated, with peptides or other macromolecules. Large ^{68}Ga generator eluate volumes, metal traces from the generator column material, or reaction reagents, however, disturb a fast, reliable, and quantitative labeling procedure. In this paper we describe a simple technique, based on anion exchange, aiming first, to increase the ^{68}Ga concentration, second to purify it from competing impurities, and third to obtain a fast and quantitative ^{68}Ga-labeled peptide conjugate that can be applied in humans without further purification. Within 5 min one can obtain from the original 6 mL generator eluate a 200 μL ^{68}Ga preparation (volume reduction by a factor 30) that is suitable for direct and quantitative labeling of peptide conjugates. DOTATOC (DOTA-D-Phe^1-Tyr^3-octreotide, DOTA = 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) was used as a test tracer for comparing the labeling properties of the different ^{68}Ga preparations. In combination with microwave heating, peptide conjugates of 0.5−1 nmol quantities could be labeled within 10 min with the full ^{68}Ga activity of a generator. Further purification of the ^{68}Ga-labeled peptide conjugate was no longer required since the nuclide incorporation was quantitative. The specific radioactivity (with respect to the peptide) was improved by a factor ∼100 compared to the previously applied techniques using the original generator eluate. The commercial ^{68}Ge/^{68}Ga generator from Obninsk in combination with this system for purification and concentration with an integrated microwave-supported labeling technology resulted in a kitlike technology for ^{68}Ga-tracer production. The first automated prototype using this technology is being tested.

INTRODUCTION

The positron-emitting ^{68}Ga ($T_{1/2}$ = 68 min) radionuclide is of great practical interest for clinical PET. Especially the new approaches in radionuclide therapy based on radiolabeled peptides call for an individual dosimetric PET imaging protocol. The ^{68}Ga is a generator-produced nuclide and does not require cyclotron on site. The long half-life of the parent nuclide ^{68}Ge (270.8 d) provides in principle a long life-span generator. The ^{68}Ga decays by 89% through positron emission of 1.92 MeV max energy, without additional gamma contribution. The short half-life of ^{68}Ga ($T_{1/2}$ = 68 min) permits application of suitable ^{68}Ga activities while maintaining an acceptable radiation dose to the patient. The only stable chemical form in solution is the ^{68}Ga^{3+} cation, which forms stable complexes with many ligands containing oxygen and nitrogen as donor atoms. Thus, ^{68}Ga is suitable for complexation with chelators, naked or conjugated with peptides, or other macromolecules.

Many ^{68}Ga radiopharmaceuticals have been used so far for imaging of brain, renal, bone, blood pool, lung, vascular pool, and tumor (*1*). Some of the restrictions for wider use of ^{68}Ga are the chemical form in which it is obtained from the generator and contamination of the generator eluate with traces of the generator column material. Column materials proposed so far for ^{68}Ge/^{68}Ga generators are inorganic oxides such as aluminum dioxide, titanium dioxide, or tin dioxide or selective organic resins comprising phenolic hydroxyl groups or pyrogallol (*2*−*5*). Elution of the ^{68}Ga is performed using EDTA solution (*5*), relatively high concentrated HCl (*3*), or 0.1 M HCl (Cyclotron Co., Ltd, Obninsk, Russia). There are advantages with the latter generator: the ^{68}Ge is loaded onto a titanium dioxide column that is a nontoxic material, and, more importantly, ^{68}Ga is eluted in the cationic form with 0.1 M HCl, allowing universal application for radiopharmaceutical preparations. A general disadvantage related to all generators is the large primary ^{68}Ga eluate volume leading consequently to a low ^{68}Ga concentration. Contamination with the long-lived parent nuclide ^{68}Ge (breakthrough) is generally a critical value, and cationic metal ions (mainly from the column material) disturb the labeling procedure because of competition in the complexation reaction. A method based on anion exchange to purify the eluate and to reduce the volume and HCl concentration of a generator eluate has been proposed previously (*3*). Nevertheless, the final volume obtained was still large (∼4 mL). Evaporation to dryness causes activity loss due to the time factor as well as uncontrolled release losses since

the $GaCl_3$ is relatively volatile. The anion-exchange approach, however, seems to be a promising way to solve both concentration and purification problems of ^{68}Ge/^{68}Ga generator eluate more generally.

The adsorption behavior of the elements from HCl solutions on the anion-exchanger DOWEX AG1-X8 is well-known (*6*). In HCl solution, gallium forms strong anionic complexes with Cl^-, and the corresponding $[GaCl_6]^{3-}$ and $[GaCl_4]^-$ complexes are strongly adsorbed on the mentioned anion-exchange resin from HCl concentrations > 3 M. In contrast, germanium is practically not adsorbed from <5 M HCl solution; only from HCl > 6 M is it found that Ge follows Ga.

The factor that is most crucial for radiolabeling procedures with short-lived radionuclides is the time needed for a certain process. Microwave heating providing the acceleration is an attractive tool. This technique has been used for labeling different organic molecules with [^{131}I], [^{11}C], [^{15}O], [^{18}F], and [^{13}N] (*7*). Microwave heating not only shortens the chemical reaction time, but also reduces side reactions, increases the yield, and improves reproducibility (*7*). Microwave heating is especially useful for microscale organic chemistry such as radiolabeling where the size of the sample is comparable to the penetration depth of the microwave field (*7*, *8*). Microwave heating has already shown its potential in speeding up ^{68}Ga complexation with DOTA[1] bifunctional chelator coupled to oligonucleotides (*9*).

In the present paper we wish to describe a simple technological procedure based on anion-exchange reaction that allows purification of ^{68}Ga obtained from a commercial generator and reduction of the volume of the preparation in one step, thus meeting the requirement for direct highly efficient labeling of modern bioconjugates under microwave heating conditions. Special attention has been paid to reasonable high speed, reliability and simplicity, quantitative product yield, and purity. DOTA-D-Phe^1-Tyr^3-octreotide (DOTATOC,[1] where DOTA is the chelator 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) was used as a test molecule to study and optimize the labeling procedure.

MATERIALS AND METHODS

^{68}Ga and ^{68}Ge/^{68}Ga Generator Characterization. ^{68}Ga ($T_{1/2}$ = 68 min, β^+ = 89% and EC = 11%) was available from a ^{68}Ge/^{68}Ga generator system (Cyclotron Co., Ltd, Obninsk, Russia) where ^{68}Ge ($T_{1/2}$ = 270.8 d) was attached to a column of an inorganic matrix based on titanium dioxide. The nominal ^{68}Ge activity loaded onto the generator column was 1850 MBq (50 mCi). The specified shelf live of the generator was 2−3 years. The ^{68}Ga was eluted with 6 mL of 0.1 M hydrochloric acid. The elution profile was determined by fractionating and measuring the ^{68}Ga activity in each successive fraction of the eluate. The ^{68}Ga elution yield was expressed as the ratio between the obtained ^{68}Ga and the ^{68}Ge activity (in equilibrium with the ^{68}Ga daughter nuclide) on the generator column at the time of elution. Aliquots of the generator eluates were counted using an ionization chamber and a NaI(Tl) scintillation detector immediately and after 24−48 h in order to determine the ^{68}Ge breakthrough in the eluate. The ^{68}Ge contamination was expressed as % ^{68}Ge in the ^{68}Ga eluate in each sample. The ^{68}Ga generator eluates were analyzed for the content of trace metals by inductively coupled plasma atomic emission spectrometry (ICP-AES) using a Spectroflame P instrument (Spectro, Germany). The instrument was calibrated toward standards from Spectrascan (Reference material AB, Ulricehamn, Sweden). The detection limit of the applied inductively coupled plasma atomic emission spectroscopy (ICP-AES) analysis was approximately 0.0001%.

Table 1. Characterization of the Anion-Exchange Resins and Cartridges Used in the ^{68}Ga Purification and Preconcentration Study[a]

no.	sorbent	counter-ion	retention, %	recovery, %
1	AG 1-X8 (100−200 mesh)	HO^-	81 ± 4	69 ± 3
2	AG 1-X8 (200−400 mesh)	HO^-	98 ± 2	85 ± 5
3	AG 1-X4 (100−200 mesh)	HO^-	65 ± 5	80 ± 3
4	AG 1-X2 (200−400 mesh)	HO^-	45 ± 4	68 ± 2
5	SAX SPEC, Isolute, 50 mg	Cl^-	<4	–
6	SAX SPEC, NTK kemi, 15 mg	Cl^-	<4	–
7	SAX SPEC, Isolute, 50 mg	OH^-	9	–
8	SAX SPEC, NTK kemi, 15 mg	OH^-	7	–
9	SAX SPEC, Chromafix, 45 mg	HCO_3^-	99 ± 1	93 ± 2

[a] With retention of over 98% and a recovery yield of better than 90%, the commercial anion cartridge SAX SPEC Chromavix showed the most promising results.

Purification and Concentration of the ^{68}Ga Eluate Using Anion-Exchange Resins. Several strong basic anion-exchange resins were investigated for optimization [Dowex AG 1-X8 (100−200 mesh), AG 1-X8 (200−400 mesh), AG 1-X4 (100−200 mesh), and AG 1-X2 (200−400 mesh), see Table 1]. Three commercially available strong anion-exchange cartridges were tested as well: Isolute (50 mg, 1 mL, Cl^- form); NTK kemi, (15 mg, 3 mL, Cl^- form,), and Chromafix 30-PS−HCO_3, Macharey-Nagel. The resins were suspended in 1 M HCl for 1 h, washed several times with deionized water, suspended in 1 M NH_3 for 10 min, washed with water, and resuspended in 1 M HCl. After this procedure, the resins were centrifuged and kept under 5 M HCl for the further use. Small plastic tubes of different sizes were used as small columns. They were plugged with glass wool or polyethylene filter elements and packed with the wet resin. Just before use, the packed columns were conditioned and activated washing successively with 5 M HCl, 1 M HCl, H_2O, and again 5 M HCl. The commercial cartridges were preconditioned in the same way.

The ^{68}Ge/^{68}Ga-generator was eluted according to the manufacturer protocol with 6 mL 0.1 M solution. Five microliters of 30% HCl was added to the 6 mL of the generator eluate giving a final HCl concentration of 4.0 M. The resulting 11 mL solution in total was passed through a pretreated anion-exchange column at a flow rate of 4 mL/min (linear flow speed 25 cm/min) at room temperature. The columns were washed with 2 mL of 4 M HCl and then dried by sucking filtered air through the column, to eliminate excess 4 M HCl. The ^{68}Ga was then eluted with small fractions of deionized water (50−200 μL) at a flow rate of 0.5 mL/min. The elution profile of the small purification columns and the elution yield of ^{68}Ga were determined by measuring the ^{68}Ga activity in the 50 μL fractions of the eluate and normalizing to the end of the elution. The elution yield is expressed as % of eluted ^{68}Ga from the total ^{68}Ga activity present at

[1] Abbreviations: DOTA, 1,4,7,10-Tetraazacyclododecane-1,4,7,10-tetraacetic acid; DOTATOC, 4,7,10-Tricarboxymethyl-1,4,7,10-tetraazacyclododecan-1-yl-acetyl-D-Phe-Cys-Tyr-D-Trp-Lys-Thr-Cys-L-threoninol (DOTA-D-Phe^1-Tyr^3-octreotide); DOTA-RGD, Cys2−6; c[CH_2CO-Lys(DOTA)-Cys-Arg-Gly-Asp-Cys-Phe-Cys]-CCX_6-NH_2); ESI, electrospray ionization; NOTA, 1,4,7-triazacyclononane-1,4,7-triacetic acid; NODAGATATE, 1,4,7-tricarboxymethyl-1,4,7-triazacyclononan-1-ylacetyl-D-Phe-Cys-Tyr-D-Trp-Lys-Thr-Cys-L-Thr (NODAGA− Tyr^3−octreotate).

the generator column at the beginning of elution. The ^{68}Ge contamination was determined by recounting the fractions 48 h after collection.

Distribution Coefficients. The distribution coefficients D of ^{68}Ga between the stationary and mobile phase were determined by the column method as weight distribution coefficients, D.

$$D = \frac{A_{res}}{A_{liq}} \times \frac{m_{liq}}{m_{res}}$$

with A_{res} = ^{68}Ga activity of the dry resin (Bq), A_{liq} = ^{68}Ga activity of the solution passed through the column (Bq), m_{res} = amount of dry resin (g), m_{liq} = amount of the solution (g).

The HCl concentration of the ^{68}Ga solution was altered in the range between 0.1 and 4.3 M by addition of corresponding amounts of 30% HCl for this systematic study. Aliquot samples of the ^{68}Ga solutions (starting and eluate) were measured with a well-type scintillation counter under standardized geometry conditions. D rises from 10^5 to 2×10^6 for [HCl] = 3.5−4.3 M. ^{68}Ga retention on the cartridge of ∼99% is assured under these conditions.

Microwave Heating. Microwave heating was performed with a SmithCreator oven (Personal Chemistry AB, Uppsala, Sweden) with monomodal radiation.

Labeling of DOTATOC with the Original ^{68}Ga Generator Eluate. The pH of the original ^{68}Ge/^{68}Ga-generator eluate (6 mL, containing full ^{68}Ga activity or the 1 mL peak fraction that contained 60−65% of the available ^{68}Ga activity) was adjusted to pH ∼ 4.6 by adding sodium acetate (Aldrich, in solid form) to give finally a 0.4 M solution with regard to acetate or to pH ∼ 4.2 by adding HEPES (4-(2-hydroxyethyl)piperazine-1-ethanesulfonic acid, Sigma) to give finally a 1.0 M solution with regard to HEPES. Then 0.1−20 nmol in 1−20 μL of 1 mM and 1−5 μL of 0.1 mM DOTATOC solution (in water) were added. The reaction mixture was transferred into a Pyrex glass vial for microwave heating and exposed for 1 min to 90 ± 5 °C. Alternatively, the mixture was heated to 95 °C in a conventional heating block for up to 20 min.

Quality Control. Analytical liquid chromatography (LC) was performed using a HPLC system from Beckman (Fullerton, CA) consisting of a 126 pump, a 166 UV detector, and a radiation detector coupled in series. Data acquisition and handling was performed using the Beckman System Gold Nouveau Chromatography Software Package. The column used was a Vydac RP 300 Å HPLC column (Vydac, USA) with the dimensions 150 mm × 4.6 mm, 5 μm particle size. We applied gradient elution with the following parameters: A = 10 mM TFA; B = 70% acetonitrile (MeCN), 30% H_2O, 10mM TFA with UV-detection at 220 nm; flow was 1.2 mL/min; 0−2 min isocratic 20% B, 20−90% B linear gradient 8 min, 90−20% B linear gradient 2 min. Retention time (t_R) for the radio-HPLC signals was 6.56 ± 0.02, 5.66 ± 0.03, and 6.66 ± 0.02 min for DOTATOC, DOTA-RGD,[1] and NODAGATATE,[1] respectively.

In addition, electrospray ionization mass spectrometry (ESI-MS)[1] was performed using a Fisons Platform (Micromass, Manchester, UK) with positive mode scanning and detecting $[M + 2H]^{2+}$ and $[M + 3H]^{3+}$ species. DOTATOC was detected at m/z = 711.26, ^{69,71}Ga-DOTATOC at m/z = 746.0, DOTA-RGD at m/z = 823.44 for $[M + 2H]^{2+}$ and 549.1 for $[M + 3H]^{3+}$, ^{69,71}Ga-DOTA-RGD at m/z = 857 for $[M + 2H]^{2+}$ and 571 for $[M + 3H]^{3+}$, NODAGATATE at m/z = 704 for $[M + 2H]^{2+}$ and 470 for $[M + 3H]^{3+}$, ^{69,71}Ga-NODAGATATE at m/z = 738 for $[M + 2H]^{2+}$. The ^{69,71}Ga conjugates synthesized under identical to labeling conditions were used for the identification of the radio-HPLC chromatogram signals.

Labeling of the DOTA Conjugates with the Preconcentrated and Purified ^{68}Ga Eluate: 1. Using Sodium Acetate Buffer. Five microliters of 10 M NaOH solution were added to the 200 μL of the ^{68}Ga preconcentrated eluate containing 92 ± 4% of the initially available activity. Then the mixture was added to 16 mg of solid sodium acetate, buffering the solution to pH ∼ 4.2. Then 0.1−10 nmol of an aqueous solution of DOTATOC were added (1−10 μL of a 1 mM solution for the range of 1−10 nmol or 1−5 μL of 0.1 mM solution for the range of 0.1−0.5 nmol of the peptide conjugate, respectively). The reaction mixture was transferred to a Pyrex glass vial with an insert to accommodate the small volume (200 ± 20 μL) for microwave heating. The heating time in a conventional heating block at 95 °C was up to 20 min and in the microwave furnace 1 min at 90 ± 5 °C. The obtained product was analyzed applying the identical protocol as described above.

2. Using HEPES Buffer. The procedure was identical to the sodium acetate protocol; however, instead of 16 mg of solid sodium acetate, we used 72 mg of powdered HEPES to obtain similar pH conditions. The labeling was performed for DOTATOC and DOTA-RGD (RGD is Cys2−6; c[CH_2CO-Lys(DOTA)-Cys-Arg-Gly-Asp-Cys-Phe-Cys]-CCX_6-NH_2) conjugates.

Labeling of NOTA[1] Conjugate with Preconcentrated and Purified ^{68}Ga Eluate. NODAGATATE (NODAGA-Tyr^3-octreotate), where the bifunctional chelator is 1,4,7-triazacyclononane-1,4,7-triacetic acid, was labeled with the preconcentrated and purified ^{68}Ga eluate according to the following standardized protocol: 3 μL of 10 M NaOH solution was added to the 200 μL of the ^{68}Ga preconcentrated eluate containing 92 ± 4% of the initially available ^{68}Ga activity. Then the mixture was transferred to a vial containing 72 mg HEPES powder buffering the solution to 3 < pH < 3.5. Then 0.2−5 nmol of the NODAGATATE were added in 1−5 μL of 1 mM aqueous solution or 2−5 μL of 0.1 mM aqueous solution of the conjugate. The resulting 200 ± 20 μL reaction mixture was then transferred to a Pyrex glass vial with an insert to accommodate the small volume for microwave heating. The heating time in the microwave furnace was 1 min at 95 ± 5 °C. The obtained product was analyzed applying the protocol described above.

RESULTS AND DISCUSSION

Elution Characteristics. The generator elution yield over time revealed reproducible performance of the generators (Figure 1). In the first month the elution yield was 78 ± 2% of the theoretical amount and then it decreased slowly and continuously down to 41% after 29 month use. The ^{68}Ge elution profile and the ^{68}Ge breakthrough are presented in Figure 2. By fractionating the ^{68}Ga eluate, one can obtain approximately 65% of the available activity with only 1 mL (the third fraction, Figure 2). The ^{68}Ge breakthrough with respect to the eluted ^{68}Ga activity was found to be 0.001−0.007%, and the ^{68}Ga/^{68}Ge ratio did not change during the investigation period. It should be mentioned that ^{68}Ge breakthrough losses of 0.001% per elution are insignificant compared with ^{68}Ge decay loss, assuming two elutions per day.

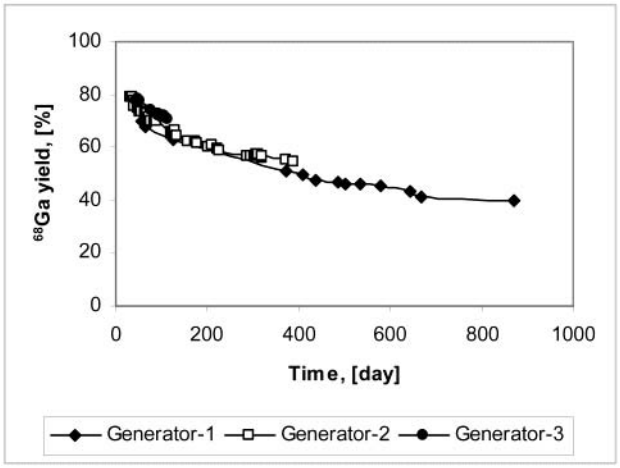

Figure 1. ^{68}Ga elution efficiency for generator-1 during 29 months, generator-2 during 14 months, and generator-3 during 3 months.

Metal Content. The metal ion content of the ^{68}Ge/^{68}Ga generator eluate depending upon elution frequency is shown in Figure 3. The concentration of the metal ions, except for Pb, was constant for a given elution frequency. The generator requires daily elution in order to keep the concentration of the contaminant metal ions as low as possible. A preventive elution 4 h prior to the synthesis is recommended since the interfering metal ion concentration can be kept at its minimum value. The generator matrix material (TiO_2) may cause relatively high nontoxic Ti concentration (close to 1000 ppm) in the eluate if the generator is not eluted regularly. The metals act as pseudocarriers requiring, consequently, higher macromolecule conjugate concentrations. The consequence is lower ^{68}Ga incorporation (low labeling yield) or a drop in the specific radioactivity of the final ^{68}Ga-labeled peptide conjugate. The proposed concentration and purification step will reduce the metal content as shown below and increase the specific radioactivity of the final product.

Labeling Reaction. The complexation reaction of ^{68}Ga with a macrocyclic chelator conjugated to the peptide already starts at room temperature, but the analytical radiochemical yield (RCY) did not exceed 24% and 30% for sodium acetate and HEPES buffers, respectively (Figure 4A). Conventional heating improved the situation but the yield and reaction time were still unsatisfactory. In the case of the HEPES buffer, the ^{68}Ga incorporation time was shorter. Microwave heating of the reaction mixture considerably shortened the reaction time and improved reproducibility. Nevertheless, a final purification step was still required for obtaining a high quality labeled peptide conjugate (Figure 4A). It was expected that a smaller volume of the reaction mixture would improve both, RCY and reaction time. In the first phase, the reduction of the reaction mixture volume was achieved by fractionation of the generator eluate (Figure 2). The third fraction of the eluate (1 mL) contained over 60% of the total available ^{68}Ga activity. Using this ^{68}Ga peak fraction the RCY for the reaction at room temperature, conventional heating as well as for microwave heating was improved (Figure 4B). Under conventional heating conditions, quantitative ^{68}Ga incorporation was achieved within 5 min for 5 nmol of DOTATOC using the HEPES buffer system. For the sodium acetate buffer system, a 3-fold amount of peptide (15 nmols) and 20 min heating were required. With microwave heating the labeling reaction was complete within 1 min, the incorporation of the activity was quantitative and the reproducibility of the reaction was improved. No further purification of the labeled peptide conjugate was required. From this study we learned that the amount of peptide needed for

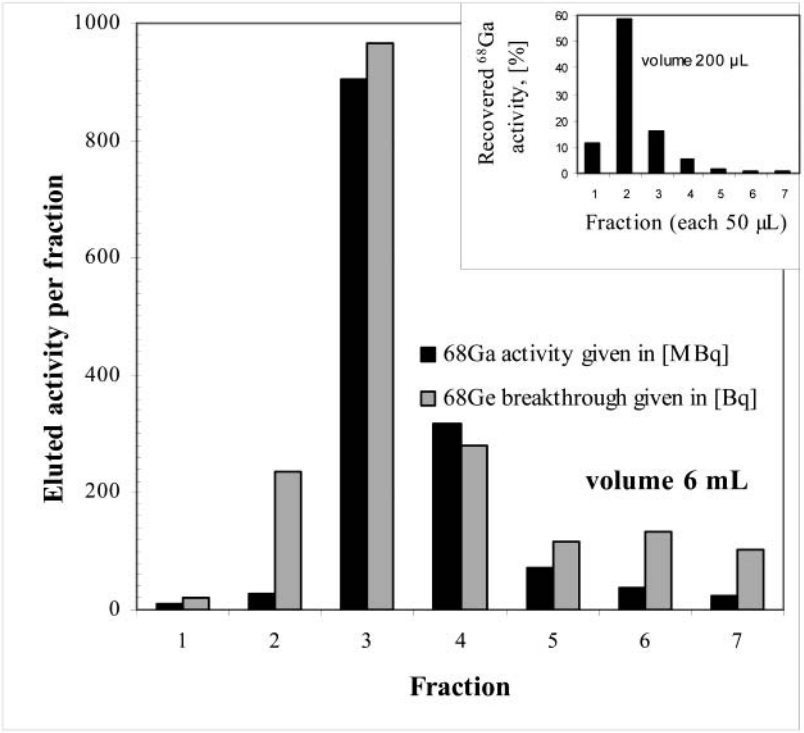

Figure 2. Elution profile of the ^{68}Ge/^{68}Ga generator where one fraction was 1 mL (fraction 1 = 0.3 mL, fraction 7 = 0.7 mL), giving a total eluted volume of 6 mL. The profiles for the ^{68}Ga elution and the ^{68}Ge breakthrough are identical; the ^{68}Ge breakthrough is $\sim 10^{-3}$%. Fraction 3 (1 mL) contains over 60% of the available ^{68}Ga activity. The insert shows the elution profile of ^{68}Ga eluted from the small SAX SPE Chromafix cartridge with small volumes of deionized water. More than 90% of the initial ^{68}Ga activity was obtained in 200 μL of solution.

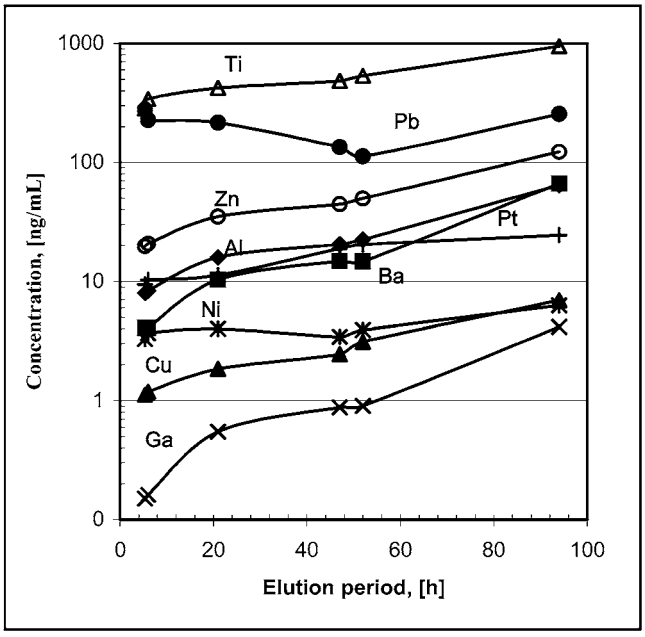

Figure 3. Metal ion content in 6 mL of the generator eluate as a function of the elution time period.

quantitative ^{68}Ga incorporation was 15 nmol at least when using sodium acetate buffer and 5 nmol in the case of HEPES (Figure 5). It is worth noting that the difference in the buffer influence is more pronounced at lower peptide quantities, indicating the sensitivity of the reaction to potential metal impurities present in the buffers as well as complexing ability of sodium acetate itself competing with DOTA when used at high concentration.

Although the ^{68}Ga incorporation was quantitative using only 5 nmol of DOTATOC, there were still drawbacks in this approach. First, about 40% of the ^{68}Ga activity is wasted and the second, even smaller peptide amounts may be required due to cost and biological properties. Thus a fast technique for the ^{68}Ge/^{68}Ga generator eluate purification and concentration was introduced.

Concentration and Purification of ^{68}Ga. Our preconcentration protocol utilized $[^{68}GaCl_4]^-$ complex formation in 4 M HCl medium. This anionic complex can be efficiently adsorbed on anion-exchange resins from HCl solutions and is efficiently eluted with a very small volume of water.

The results of the optimization studies concerning the capabilities of different anion-exchange resins are presented in Table 1. The adsorption of ^{68}Ga from HCl solution on anion-exchange cartridges increased rapidly from 0.8% at 0.1 M HCl to almost 100% at 3.8 M HCl under our conditions (4 mL/min, 4 mm column diameter) in agreement with literature data on distribution coefficients ($D > 10^5$) (*6*). The best ^{68}Ga recovery was obtained using a column diameter of 4 mm. The linear flow rate of the deionized water was 25 cm/min. Among the class of AG1-resins, Bio-Rad AG 1-X8 with fine mesh (200−400 mesh) showed the best retention and recovery characterstics and a sharp elution profile. The best agent for eluting the ^{68}Ga from the small anionic cartridges was deionized water: the HCl content at the resin was more than sufficient to avoid hydrolysis. To use sodium acetate solution directly as eluting agent is not recommended since the recovery yield of ^{68}Ga is very poor (>30% losses) as most likely the anionic Ga-acetate complex is adsorbed to the resin. Fifty percent EtOH as eluting agent could be an alternative and shows nearly the same recovery properties as pure water alone. Since the parent nuclide ^{68}Ge is not retained on the anion resin, the concentration step can also be seen as a purification of ^{68}Ga from ^{68}Ge breakthrough. In the same way the original generator eluate was purified from Ti by 90% as shown by the ICP-AES analysis data.

As seen in Table 1, among the tested commercial anionic cartridges only the SAX SPEC Chromafix cartridge showed very satisfactory results. This cartridge contains 45 mg of a strong basic anion-exchange resin based on polystyrene−divinylbenzene with HCO_3^- as the counterion and quaternary amine functional groups. Using this cartridge, we obtained 99.1% retention at a flow rate of 2 mL/min and still 98% at a flow rate of 5 mL/min. Although the lower flow rate assured higher and stable retention values, the decay losses due to time were important. Thus, it is generally more beneficial to apply a higher flow rate and accept 1−3% worse retention. Elution with deionized water resulted finally in 90 ± 2% of ^{68}Ga recovery in a total volume of 200 μL only. Another 150 μl water volume would provide only 3% increase of the ^{68}Ga recovery (Figure 2, insert). AG 1-X8 (200−400 mesh) resin and Chromafix SAX SPEC cartridges showed comparable results with respect to retention, recovery, and elution profile (Table 1). However, the Chromafix SAX SPEC cartridge as a standardized commercial product is much more suited for further standardization and automation. In total the preconcentration procedure

[a] Due to quantitative radionuclide incorporation, no further purification of the labeled product is needed.

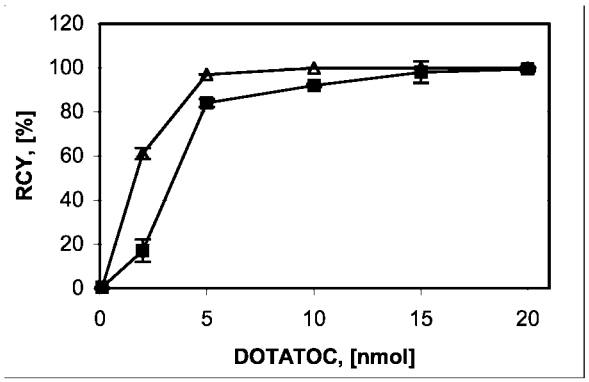

Figure 5. Influence of the buffering system (■ sodium acetate, Δ HEPES) on the radiochemical yield of ^{68}Ga complexation reaction for different DOTATOC quantities under 1 min microwave heating at 90 ± 5 °C. The reaction was conducted using the 1 mL peak fraction of the original generator eluate (see Figure 2).

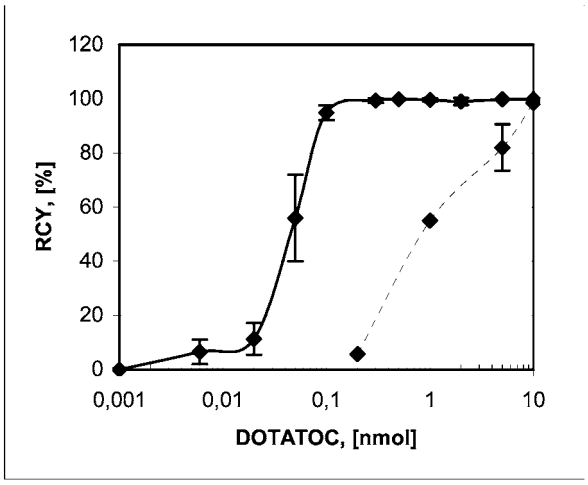

Figure 6. Influence of the DOTATOC amount on the radiochemical yield of the ^{68}Ga complexation reaction using the full available ^{68}Ga activity in 200 μL volume after the preconcentration and purification step in HEPES buffer system. solid line: 1 min microwave heating at 90± 5 °C, dashed line: 5 min conventional heating at 95 °C.

required 4 to 6 min, including filtration of the original ^{68}Ga eluate in 4 M HCl through the cartridge, the drying procedure, and the elution of the ^{68}Ga in 200 μL of pure water.

Combined Protocol: Preconcentration of ^{68}Ga and Microwave-Supported Labeling. The influence of the preconcentration step of the ^{68}Ga eluate in combination with microwave heating is demonstrated in Figure 6 and Table 2. Figure 6 illustrates that one can incorporate the full ^{68}Ga radioactivity eluted from the generator into less than 1 nmol of a peptide conjugate. In this combination the original full ^{68}Ga eluate is purified and concentrated as described, and the labeling is performed during 1 min microwave heating. Table 2 contains more details concerning the age of the generator, variation of the amount of peptide conjugate, and variation of the ligand itself. Labeling tests with equimolar quantities (^{68}Ga: bioconjugate = 1:1) using 6 pmol of DOTATOC resulted in a maximum activity incorporation of 11% and the specific radioactivity of the labeled bioconjugate only a factor 10 less than the theoretical value. Independent of the age of the generator and over a period of 2.5 years, we obtained stable and reproducible ^{68}Ga incorporation of >99% into 0.3−1 nmols of the peptide conjugate. It should be stressed that even with the lower ^{68}Ga amount and concentration with time (2.5 years) it is still possible to obtain quantitative incorporation with 1 nmol of the bioconjugate.

Quality Control. The HPLC conditions were selected so that the QC of the radiopharmaceutical prior injection could be completed within 10 min. The retention time (t_R) was 6.56 ± 0.02, 5.66 ±0.03, and 6.66 ±0.02 min for DOTATOC, DOTA-RGD, and NODAGATATE, respectively (Figure 7).

CONCLUSIONS

The introduction of the purification and concentration step in combination with the microwave heating may have very positive impact on the further utilization of ^{68}Ga in nuclear medicine, generally. The proposed technique allows elimination of an additional purification step in the preparation of ^{68}Ga labeled peptide conjugates and improves the specific radioactivity of the product by a factor 100. The over-all process can be performed in 10−12 min starting from the end of the original generator elution. The HPLC quality control (another 10 min) can be performed prior to injection in humans. Because of the excellent ^{68}Ga activity economy, one can expect to use

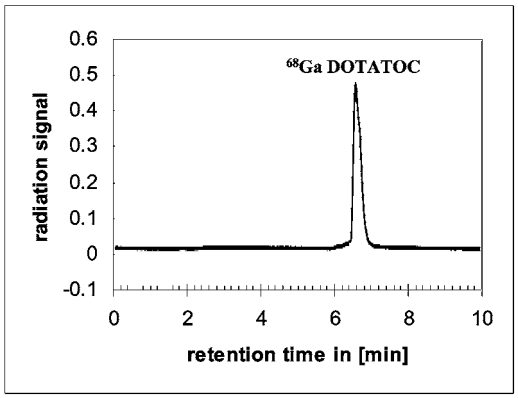

Figure 7. HPLC radiochromatogram of a ^{68}Ga-DOTATOC preparation (0.5 nmol of DOTATOC, 1 min microwave heating at 90 ± 5 °C, total reaction volume 220 μL). The ^{68}Ga incorporation is over 99.9% and the specific activity of the labeled peptide conjugate was 2 GBq/nmol.

the commercial 1850 MBq generator over a period of more than 2 years for patient studies. The proposed technique is suited for automation, and the development of a corresponding kitlike technology is in progress.

ACKNOWLEDGMENT

The authors sincerely thank Prof. Helmut Maecke (Institute of Nuclear Medicine, Division of Radiological Chemistry, University Hospital Base, Basel, Switzerland) for providing us with DOTATOC and NODAGATATE and Dr. Hege Karlsen (Department of Synthetic Chemistry, Amersham Health, Olso, Norway) for the provision of DOTA-RGD. Jean Pettersson, Department of Analytical Chemistry, Uppsala University, is gratefully acknowledged for performing the ICP analysis. The Swedish Council is acknowledged for its support by grant K3464. European Union COST Action B12 is acknowledged for its support.

A broad spectrum of radiolabeled peptides with high affinity for receptors expressed on tumor cells is currently under preclinical and clinical investigation for scintigraphic imaging and radionuclide therapy. The present paper evaluates two ^{99m}Tc-labeled forms of the C-terminal octapeptide of cholecystokinin (CCK8): sulfated (s)CCK8, with high affinity for CCK1 and CCK2 receptors, and nonsulfated (ns)CCK8, with high affinity for CCK2 receptors but low affinity for CCK1 receptors. Peptides were conjugated with the bifunctional chelator *N*-hydroxysuccinimidyl hydrazino niconitate (s-HYNIC). ^{99m}Tc-labeling, performed in the presence of nicotinic acid and tricine, was highly efficient (∼95%) and yielded products with a high specific activity (∼700 Ci/mmol) and good stability (∼5% release of radiolabel during 16 h incubation in phosphate buffered saline at 37 °C). Chinese hamster ovary cells stably expressing the CCK1 receptor (CHO-CCK1 cells) internalized ∼3% of added ^{99m}Tc-sCCK8 per confluent well during 2 h at 37 °C. Internalization was effectively blocked by excess unlabeled sCCK8. CHO-CCK1 cells did not internalize ^{99m}Tc-nsCCK8. Displacement of ^{99m}Tc-sCCK8 and -nsCCK8 by unlabeled CCK-8 (performed at 0 °C to prevent internalization) revealed 50% inhibitory concentrations (IC_{50}) of 8 nM and >1 μM, respectively. CHO-CCK2 cells internalized ∼25% and ∼5% of added ^{99m}Tc-sCCK8 and -nsCCK8, respectively. In both cases internalization was blocked by excess unlabeled peptide. IC_{50} values for the displacement of ^{99m}Tc-sCCK8 and -nsCCK8 were 3 nM and 10 nM, respectively. CHO-CCK1 cell-derived tumors present in one flank of athymic mice accumulated 2.0% of injected ^{99m}Tc-sCCK8 per gram tissue at 1 h postinjection. This value decreased to 0.6% following coinjection with excess unlabeled peptide. Uptake of ^{99m}Tc-nsCCK8 was low (0.2%) and not did change by excess unlabeled peptide (0.3%). Accumulation of ^{99m}Tc-sCCK8 and -nsCCK8 by CHO-CCK2 cell-derived tumors (present in the other flank) amounted to 4.2% and 0.6%, respectively. In both cases uptake was significantly reduced by excess unlabeled peptide to 1.0% and 0.4% for sCCK8 and nsCCK8, respectively. Accumulation of ^{99m}Tc-sCCK8 was also high in pancreas (11.7%), stomach (2.0%), and kidney (2.1%), whereas uptake of ^{99m}Tc-nsCCK8 was high in stomach (0.7%) and kidney (1.4%). Both radiolabeled peptides showed a rapid blood clearance. In conclusion, these data show that CCK8 analogues can be efficiently labeled with ^{99m}Tc using s-HYNIC as chelator and nicotinic acid/tricine as coligand system without compromising receptor binding. Furthermore, the present study demonstrates that CCK1 tumors hardly accumulate ^{99m}Tc-nsCCK8, CCK2 tumors accumulate 2 times more ^{99m}Tc-sCCK8 than CCK1 tumors, and CCK2 tumors accumulate 15 times more ^{99m}Tc-sCCK8 than ^{99m}Tc-nsCCK8. Although accumulation in some nontarget organs was also higher with ^{99m}Tc-sCCK8, this may not reflect the human situation due to a different receptor expression pattern in humans as compared to mice. Therefore, further studies are warranted to investigate the possible use of ^{99m}Tc-sCCK8 for scintigraphic imaging of CCK receptor-positive tumors in humans.

INTRODUCTION

Radiolabeled peptides with high affinity for receptors on tumor cells can be used for scintigraphic imaging and for radionuclide therapy. A broad spectrum of peptides, ranging from somatostatin analogues, RGD[1] peptides, neurotensin analogues to gastrin analogues is currently under (pre)clinical evaluation (*1*). The gastrin analogues gained interest since the discovery of the presence of cholecystokinin (CCK)/gastrin receptors on a variety of tumors (*2*). Several studies described the radiolabeling of gastrin analogues with indium-111 (^{111}In) or iodine-131 (^{131}I) for imaging and/or therapy (*3*−*6*). However,

Chart 1. Structural Formulas of HYNIC-Conjugated Nonsulfated CCK8 (upper panel) and Sulfated CCK8 (lower panel)

both radionuclides have less favorable imaging characteristics due to their high γ energies (171 and 245 keV for ^{111}In and 364 keV for ^{131}I). Technetium-99m with a γ energy of 141 keV has the ideal characteristics for imaging, combined with a relatively short half-life of 6 h. In the present paper, we report on the ^{99m}Tc labeling of two CCK8 analogues which are known to bind to CCK receptors with high affinity.

CCK receptors can be distinguished pharmacologically by their affinity for gastrin, a 33 amino acid peptide hormone involved in gastric motility (*7*). The CCK1 receptor (formerly known as CCK-A) has a low affinity for gastrin, whereas the CCK2 receptor (formerly known as CCK-B) has a high affinity for gastrin. Both receptors belong to a superfamily of G-protein-coupled receptors. The peptides of the gastrin and CCK family are characterized by an amidated C-terminal receptor binding sequence Trp-Met-Asp-Phe-NH_2. Both groups of peptides differ by the location of their tyrosyl residue in relation to the receptor binding sequence. Peptides of the gastrin family have one amino acid (usually Gly), and peptides of the CCK-family have two amino acids (Met-Gly or Thr-Gly), between this Tyr moiety and the receptor binding sequence. This Tyr residue plays a role in the receptor specificity. When this Tyr residue is sulfated, the peptides display high affinity for both the CCK1 and the CCK2 receptor. In contrast, the nonsulfated peptides show a 1000-fold lower affinity for the CCK1 receptor than for the CCK2 receptor (*8*). The CCK2 receptor is abundantly expressed in most small cell lung cancers, medullary thyroid carcinomas and in some stromal ovarian cancers and astrocytomas (*2*).

For preclinical evaluation, the rat pancreatic AR42J tumor and the human medullar thyroid carcinoma cell line TT, both expressing the gastrin/CCK2 receptor are generally used (*3*,*4*). To investigate CCK1 and CCK2 receptor binding affinity of the peptides separately we used chinese hamster ovary (CHO) cells stably transfected with cDNA encoding for either the CCK1 or CCK2 receptor. These cells are well defined with regard to their receptor expression and allow a more detailed study of the receptor specificity of the radiolabeled CCK8 peptides (*8*).

Several methods are described to radiolabel peptides with ^{99m}Tc, mostly based on the use of a bifunctional chelator. *N*-Hydroxysuccinimidyl hydrazino nicotinate (s-HYNIC) is a well-known bifunctional chelator which has proven to yield ^{99m}Tc-labeled conjugates with excellent stability, high specific activity, and high radiochemical purity (*9*). HYNIC has been used for ^{99m}Tc-labeling of proteins, peptides, and lipids (*9*−*11*). HYNIC can be conjugated to primary amino groups by using *N*-hydroxysuccinimidyl-HYNIC. The succinimidyl group facilitates conjugation of HYNIC with primary amino groups, either N-terminal or Lys residues.

The ^{99m}Tc is bound to the hydrazino moiety by forming a Tc═N bond. This binding requires coligands for proper coordination of the Tc(V) species (*12*). The nature of the coligand determines the labeling efficiency, stability, and specific activity of the ^{99m}Tc-labeled compound. Moreover, it has been reported that these coligands can affect the in vivo behavior of the ^{99m}Tc-labeled peptide or protein (*13*−*16*).

In the present study we investigated the HYNIC conjugation of both sulfated and nonsulfated CCK8 (Chart 1) (sCCK8 and nsCCK8, respectively). Furthermore, the effect of different coligand systems—tricine, ethylenediaminediacetic acid (EDDA), and tricine/nicotinic acid—on the labeling efficiency, radiochemical stability, and purity was investigated. Receptor binding and internalization studies were performed with both ^{99m}Tc-nsCCK8 and ^{99m}Tc-sCCK8 on the CCK receptor-transfected CHO cells. In addition, the in vivo receptor targeting was studied in athymic mice with CCK1 or CCK2 receptor expressing tumors on each flank.

EXPERIMENTAL PROCEDURES

Chemicals. Sulfated and nonsulfated cholecystokinin fragment 26−33 (sCCK8 and nsCCK8, respectively) were obtained from Sigma-Aldrich Chemical Co. (St. Louis,

MO). Amino acid sequences were as follows. Sulfated CCK8: Asp-Tyr(SO_3H)-Met-Gly-Trp-Met-Asp-Phe-NH_2. Nonsulfated CCK8: Asp-Tyr-Met-Gly-Trp-Met-Asp-Phe-NH_2. Tricine (*N*-[tris(hydroxymethyl)methyl]glycine) was purchased from Fluka (Buchs, Switzerland). Ethylenediaminediacetic acid (EDDA) and nicotinic acid were from Sigma-Aldrich. The propylaldehyde hydrazone of succinimidyl hydrazinonicotinate (s-HYNIC) was synthesized essentially as described by Abrams et al. (*17*) and Schwartz et al. (*18*). $Na^{99m}TcO_4$ was eluted from a commercial $^{99}Mo/^{99m}TcO_4^-$ generator (Tyco Mallinckrodt, Inc., Petten, The Netherlands). $^{111}InCl_3$ was also obtained from Tyco Mallinckrodt.

Cell Lines. Chinese hamster ovary (CHO) cells stably transfected with cDNA encoding for either the CCK1 or CCK2 receptor were used. Generation and characterization of the cell lines is described elsewhere (*8*). Cells were cultured in Dulbecco's modified Eagle's medium (DMEM, Gibco Life Technologies, Gaithersburg, MD), supplemented with 2 mmol/L glutamine, 10% (v/v) fetal calf serum, penicillin (100 U/mL), streptomycin (100 μg/mL), and gentamicin (50 μg/mL). The cells were cultured in humidified atmosphere with 5% CO_2 at 37 °C.

RP-HPLC. An Agilent 1100 series LC system (Agilent Technologies, Palo Alto, CA) equipped with an in-line Radiomatic A-500 series radiodetector (Canberra-Packard, Meriden, CT) was used for analytical and preparative reversed phase HPLC. A Zorbax R_x C18 column (5 μm, 4.6 × 250 mm) was used at a flow rate of 1 mL/min and the following solvent system. Gradient: 0−10 min 100% TFA in water (0.1% v/v), 10−20 min 0% to 100% acetonitrile. Retention times for the nonsulafted peptide were as follows: nsCCK8: 17.5 min, HYNIC-nsCCK8: 17.7 min and ^{99m}Tc-HYNIC-nsCCK8 (nicotinic acid/tricine as coligands): 18.1 min. Retention times of the sulfated peptide were: sCCK8: 17.4 min, HYNIC-sCCK8: 17.6 min, and ^{99m}Tc-HYNIC-sCCK8 (nicotinic acid/tricine as coligands): 17.9 min. Unbound pertechnetate eluted with the void volume (3.4 min).

SPE Purification. Solid-phase extraction (SPE) was used for purification of the radiolabeled peptides in the stability studies. A C_{18} SepPak-cartridge (Waters, Inc., Milford, MA) was activated with ethanol and rinsed with 5 mL of water. The radiolabeled peptide was loaded onto the cartridge. The cartridge was washed with 5 mL of water, the radiolabeled peptide was eluted with 1 mL of acetonitrile and subsequently the solvent was evaporated under vacuum. The eluted fraction was reconstituted in phosphate buffered saline (PBS), pH 7.4.

HYNIC Conjugation of CCK8. The CCK8 peptides were conjugated with s-HYNIC essentially as described previously (*10*). Briefly, 10 μL of $NaHCO_3$ (1.0 M, pH 8.2) was added to 200 μL of peptide (0.1 μmol). Subsequently, a 10-fold molar excess of s-HYNIC in 10 μL of dry DMSO was added dropwise to the mixture. The conjugation mixture was incubated for 30 min at room temperature. To remove unreacted s-HYNIC, the mixture was passed through an activated C_{18} SepPak cartridge as described above. The dried fraction was reconstituted in water, and the HYNIC-conjugated peptide was separated from underivatized peptide by preparative RP-HPLC. The fraction containing the HYNIC-CCK8 was collected and the solvent was evaporated under a stream of nitrogen.

HYNIC-nsCCK8: MALDI-TOF-MS: analysis ($C_{58}H_{71}N_{13}O_{14}S_2$) calculated 1238.4 $(M + H)^+$, found 1238.7 $(M + H)^+$. HYNIC-sCCK8: MALDI-TOF-MS: analysis ($C_{58}H_{71}N_{13}O_{17}S_3$) calculated 1318.5 $(M + H)^+$, found 1318.6 $(M + H)^+$.

^{99m}Tc-Labeling of HYNIC-CCK8. *(i) Tricine as Coligand.* Tricine (150 μL, 100 mg/mL in PBS) was added to 5 μL of HYNIC-CCK8 (1 mg/mL). Fifteen microliters of a freshly prepared solution of $SnSO_4$ (1 mg/mL in nitrogen purged 0.1 N HCl) and 100−370 MBq of $Na^{99m}TcO_4$ were added. The solution was incubated at room temperature for 30 min.

(ii) EDDA as Coligand. EDDA (500 μL, 10 mg/mL in PBS) was added to 5 μL of HYNIC-CCK8 (1 mg/mL). Five microliters of a freshly prepared solution of $SnSO_4$ (1 mg/mL in nitrogen purged 0.1 N HCl) and 100−370 MBq of $Na^{99m}TcO_4$ were added. The mixture was incubated at 75 °C for 30 min.

(iii) Nicotinic Acid/Tricine as Coligands. Tricine (400 μL, 100 mg/mL in PBS) and nicotinic acid (100 μL, 20 mg/mL in 25 mM benzoate buffer, pH 5.0) were added to 5 μL of HYNIC-CCK8 (1 mg/mL). Twenty five microliters of a freshly prepared solution of $SnSO_4$ (1 mg/mL in nitrogen purged 0.1 N HCl) and 100−370 MBq of $Na^{99m}TcO_4$ were added. The mixture was incubated at 75 °C for 30 min.

(iv) Stability Tests. The in vitro stability of both the sulfated and the nonsulfated ^{99m}Tc-labeled CCK8 peptides was investigated. Peptides were radiolabeled and purified by SPE as described above. After evaporation of the solvent, the dried ^{99m}Tc-labeled peptide was reconstituted in 200 μL of PBS. The mixture was incubated at 37 °C for 16 h. Samples of the incubation mixture were taken at 5 min and 16 h and radiochemical purity (RCP) was assessed by RP-HPLC analysis according to the method described above.

^{111}In-Labeling of sCCK8. As a control, sCCK8 was conjugated with dicyclic anhydride of diethylenetriamine pentaacetic acid (DTPA) to allow labeling with ^{111}In (*6*). Conjugation was performed at a 1:10 molar ratio, and the DTPA-conjugated peptide was purified by SPE and RP-HPLC as described above. DTPA-sCCK8 was radiolabeled with ^{111}In by incubation with $^{111}InCl_3$ in 0.15 M ammonium acetate buffer, pH 5.0, for 30 min at room temperature.

In Vitro Characterization of ^{99m}Tc-Labeled HYNIC-CCK8. *IC_{50} Determination.* The 50% inhibitory concentration (IC_{50}) for binding the CCK1 and CCK2 receptor of both peptides was determined on CCK-receptor expressing CHO cells. CHO-CCK1 and CHO-CCK2 cells were grown to confluency in 24-well plates. Cells were washed twice with binding buffer (HEPES-buffered DMEM with 1% (w/v) bovine serum albumine). After 10 min incubation at 37 °C with binding buffer, unlabeled peptide was added in a range from 0.1 to 1000 nM in combination with a trace amount of radiolabeled peptide. To prevent internalization, cells were incubated for 2 h at 0 °C. Medium was removed, and cells were washed twice with ice-cold binding buffer. Cells were scraped, and cell-associated radioactivity was counted in 3" well-type γ counter (Perkin-Elmer, Boston, MA).

Internalization Assay. Internalization of the radiolabeled peptide was assessed as follows. Cells were cultured and pretreated as described above. Radiolabeled peptides were added at a concentration of 0.1 nM (~10 000 cpm/well). Cells were incubated at 37 °C for 2 h, medium was removed, and cells were washed with ice-cold binding buffer. To remove receptor bound radiolabeled peptide, cells were incubated with acid buffer (0.1 M acetic acid, 154 mM NaCl, pH 2.0) for 10 min at 4 °C. After washing the cells twice with ice-cold binding buffer, the internalized fraction was determined by counting the cells in a γ counter.

Table 1. Labeling Efficiency (%) and Specific Activity (Ci/mmol) of Sulfated and Nonsulfated HYNIC-CCK8 Peptides, Labeled with ^{99m}Tc in the Presence of Different Coligands (n = 3/coligand)[a]

	tricine		EDDA		NA/tricine	
	labeling efficiency (%)	S.A. (Ci/mmol)	labeling efficiency (%)	S.A. (Ci/mmol)	labeling efficiency (%)	S.A. (Ci/mmol)
^{99m}Tc-HYNIC-nsCCK8	93 ± 2	400	9 ± 1	88	93 ± 3	678
^{99m}Tc-HYNIC-sCCK8	98 ± 1	445	19 ± 1	200	96 ± 3	764

[a] Labeling conditions are described in the Methods section. Tricine: *N*-[tris(hydroxymethyl)methyl]glycine; EDDA: ethylenediaminediacetic Acid; NA: nicotinic acid. S.A.: specific activity.

Release of radiolabel from the cells was studied in a separate experiment; ^{99m}Tc-sCCK8 or ^{111}In-sCCK8 (each 0.1 nM) were added to CHO-CCK-2 cells and incubated at 37 °C for 2 h. Cells were washed with acid-buffer as described above and subsequently incubated for 2 h at 37 °C with fresh medium (without peptide). Subsequently, the medium was removed and eluted over an activated C_{18} SepPak-cartridge to determine whether the radioactivity released by the cells was pertechnetate or another metabolite.

Receptor Targeting of ^{99m}Tc-Labeled HYNIC-CCK8 in Vivo. Tumor-targeting of the radiolabeled peptides was studied in female athymic BALB/c mice bearing subcutaneous tumors of CCK-receptor transfected CHO-cells. Mice were inoculated with 4×10^6 CHO-CCK1 cells in the right flank and with 4×10^6 CHO-CCK2 cells in the left flank. When tumors had reached a weight of approximately 0.2 g, mice were randomly divided into four groups of six mice each. Mice were injected intravenously with 100 μCi (17 ng) ^{99m}Tc-labeled sulfated CCK8 or nonsulfated CCK8 (tricine/nicotinic acid as coligands) with or without a 1000 molar excess of unlabeled sulfated or nonsulfated CCK8, respectively. Mice were killed by CO_2 asphyxiation 1 h after injection. Organs of interest, including the tumors, were dissected, weighed, and counted in a gamma-counter. The animal experiments were approved by the local animal welfare committee and performed according to national regulations.

RESULTS

HYNIC Conjugation and ^{99m}Tc Labeling. The efficiency of the conjugation reaction was 28 ± 3% (n = 3) for the sulfated and 34 ± 2% (n = 3) for the nonsulfated CCK8 peptide, as based on the HPLC chromatograms of the conjugation mixtures. Performing the reaction with a 50:1 or 2:1 molar excess of s-HYNIC instead of 10:1 or when using dimethylformamide (DMF) rather than PBS as the solvent, the conjugation efficiency did not improve (data not shown). The conjugated peptides were obtained carrier-free, i.e., without nonderivatized CCK8. After 6 months of storage in PBS at −20 °C, the peptides could still be labeled with high labeling efficiency, comparable to the freshly conjugated peptides (data not shown).

Technetium-99m labeling of both peptides was studied using three coligand systems: (i) tricine, (ii) EDDA and (iii) a combination of nicotinic acid and tricine. The labeling efficiency was determined by RP-HPLC. Results of the labeling efficiency are summarized in Table 1. Labeling efficiency after labeling with tricine or the combination of tricine and nicotinic acid was always higher than 90%, whereas labeling efficiency with EDDA as coligand was lower than 20%. Varying the amount of tin (from 5 to 50 μg), used for the reduction during the ^{99m}Tc-labeling, did not improve the labeling efficiency (data not shown).

Since serum proteins are known to stabilize ^{99m}Tc-HYNIC labeled peptides and proteins (*19*), the stability of the ^{99m}Tc-labeled HYNIC-peptides was studied in PBS. Moreover, the excess of coligand was removed from the labeling mixture by SPE, to prevent possible stabilization by excess unbound coligand. As summarized in Table 2, the ^{99m}Tc-peptides labeled in the presence of tricine are highly unstable. Immediately after the SPE purification, the RCP dropped to 81 ± 3% and 88 ± 2%, for ^{99m}Tc-HYNIC-nsCCK8 and ^{99m}Tc-HYNIC-sCCK8, respectively (n = 3) and were as low as 27 ± 4% and 42 ± 3% (n = 3) after overnight incubation at 37 °C. Although the labeling efficiency was low when EDDA was used as coligand, after SPE purification the peptides released less than 5% radiolabel during 16 h in PBS. Although less stable than the EDDA-labeled peptides, the combination of nicotinic acid and tricine also showed good stability, with only 4−6% of radiolabel released from the peptides during 16 h at 37 °C in PBS. Liu et al. (*20*) recently suggested that acetonitrile could also act as coligand and could lead to the formation of mixed coligand systems. Therefore, in additional experiments we used methanol instead of acetonitrile to elute peptides during SPE and found similar results, indicating no exchange of coligands with acetonitrile (data not shown).

Table 2. Stability of ^{99m}Tc-Labeled HYNIC-nsCCK8 and HYNIC-sCCK8 after SPE, during Overnight Incubation in PBS at 37 °C[a]

		tricine (%)	EDDA (%)	NA/tricine (%)
^{99m}Tc-HYNIC-nsCCK8	5 min	81 ± 3	97 ± 1	91 ± 2
	16 h	27 ± 4	92 ± 3	87 ± 4
^{99m}Tc-HYNIC-sCCK8	5 min	88 ± 2	99 ± 1	83 ± 3
	16 h	42 ± 3	92 ± 2	77 ± 2

[a] Aliquots of the incubation mixture were taken at times indicated, and RCP was assessed by RP-HPLC. Values are expressed as percentage RCP ± SD (n = 3).

In Vitro Characterization of ^{99m}Tc-Labeled HYNIC-CCK8. The 50% inhibitory concentration (IC_{50}) of the peptides was determined on the CCK-receptor expressing CHO cells. On the basis of the results obtained in the stability test, peptides were labeled with ^{99m}Tc using nicotinic acid and tricine as coligands. The IC_{50} value of nsCCK8 was 10 nM for the CCK2 receptor, and >1 μM for the CCK1 receptor. IC_{50} values for sCCK8 were 8 nM and 3 nM, for the CCK1 and CCK2 receptor, respectively.

Both ^{99m}Tc-labeled CCK8-analogues showed rapid binding to the respective receptors and a time-dependent internalization (Figure 1) in both CCK receptor-positive cell lines. Since the nsCCK8 has virtually no affinity for the CCK1 receptor no binding and internalization was observed. After 2 h incubation at 37 °C, 2.7% of the added ^{99m}Tc-sCCK8 was internalized by the CHO-CCK1 cells and 27% in the CHO-CCK2 cells. After 2 h, 4.6% of nsCCK8 was internalized in CHO-CCK2 cells, while no binding and internalization was observed in the CHO-CCK1 cells. Addition of excess unlabeled peptide blocked the binding and internalization of the radiolabeled peptides, indicating their receptor-specific binding and internalization (data not shown).

Table 3. Biodistribution of ^{99m}Tc-Labeled SCCK8 and NsCCK8 in Athymic Mice Bearing CHO-CCK1 and CHO-CCK2 Receptor Expressing Tumors in Each Flank[a]

	^{99m}Tc-sCCK8	^{99m}Tc-sCCK8 excess unlabeled	^{99m}Tc-nsCCK8	^{99m}Tc-nsCCK8 excess unlabeled
blood	0.31 ± 0.13	0.38 ± 0.08	0.21 ± 0.05	0.23 ± 0.08
muscle	0.08 ± 0.04	0.09 ± 0.02	0.05 ± 0.01	0.09 ± 0.03

spleen	0.09 ± 0.03	0.12 ± 0.03	0.10 ± 0.02	0.18 ± 0.04
kidney	2.14 ± 0.23	2.87 ± 0.57	1.36 ± 0.25	1.68 ± 0.14
stomach	2.01 ± 0.46	0.86 ± 0.13	0.68 ± 0.13	0.58 ± 0.14
liver	0.29 ± 0.06	0.39 ± 0.10	0.39 ± 0.07	0.68 ± 0.12
intestine	0.38 ± 0.08	0.46 ± 0.25	0.24 ± 0.04	0.31 ± 0.09
tumor 1-to-blood	7.1 ± 2.6	1.5 ± 0.2	0.9 ± 0.2	1.5 ± 0.8
tumor 2-to-blood	14.7 ± 4.3	2.8 ± 0.6	4.0 ± 2.6	1.9 ± 0.7
tumor 2/tumor 1	2.2 ± 0.8	1.8 ± 0.4	4.3 ± 2.9	1.4 ± 0.5

[a] Mice were injected with 17 ng of Tc-99m-labeled peptide (100 μCi) and were killed at 1 h postinjection. Values are expressed as percentage of the injected dose per gram tissue (% ID/g) ± SD (n = 5 mice/group).

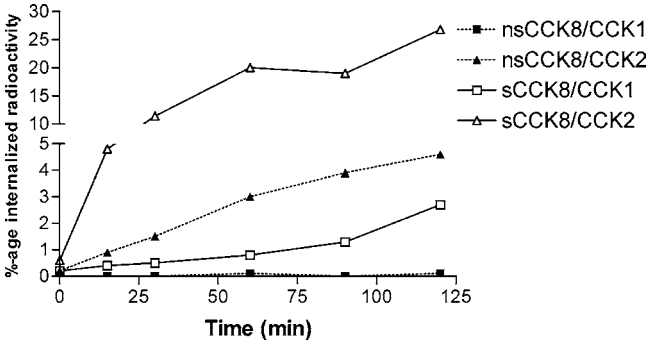

Figure 1. Internalization curve of ^{99m}Tc-nsCCK8 (dotted lines) and ^{99m}Tc-sCCK8 incubated with CHO-CCK1 (square symbols) or CHO-CCK2 (triangle symbols) cells at 37 °C. Values are expresssed as percentage of the added radioactivity present in the cells after acid wash.

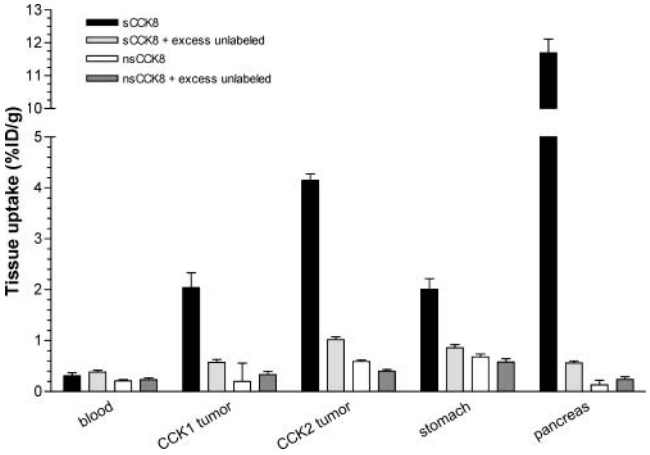

Figure 2. Biodistribution of ^{99m}Tc-nsCCK8 and ^{99m}Tc-sCCK8 in athymic mice bearing CCK1 and CCK2 receptor expressing tumors in each flank. Values are expressed as percentage of the injected dose per gram tissue (n = 5 mice/group). Blocking was performed by coinjection of a 20 000 molar excess of unlabeled minigastrin. Mice were dissected at 1 h postinjection.

In a separate in vitro experiment it was shown that the internalized radioactivity (i.e., after adding ^{99m}Tc-sCCK8) was rapidly excreted by the CHO-CCK-2 cells. After 2 h incubation in fresh medium without peptide, 36% of the internalized radiolabel was excreted into the medium, indicating that the ^{99m}Tc was not residualized in the cell. As a control, the internalization and residualization of sCCK8 labeled with the residualizing radionuclide^{111}In was investigated. In this case, no release of radioactivity from the cell was measured over a 2-h period, indicating residualization of the ^{111}In label. An additional experiment using SPE showed that 14 ± 4% (n = 3) of the excreted ^{99m}Tc activity was pertechnetate.

Receptor Targeting of ^{99m}Tc-Labeled HYNIC-CCK8 in Vivo. Both ^{99m}Tc-labeled CCK8 analogues showed a rapid blood clearance. At 1 h pi, the blood level of ^{99m}Tc-nsCCK8 was 0.21 ± 0.05% ID/g and that of ^{99m}Tc-sCCK8 was 0.31 ± 0.13% ID/g. Uptake of ^{99m}Tc-sCCK8 in CCK1 receptor-positive pancreas was 90-fold higher than that of ^{99m}Tc-nsCCK8. The biodistribution data are summarized in Table 3 and Figure 2.

Marked differences between the sulfated and nonsulfated peptides were observed in the tumor uptake in CCK2 receptor-positive tumors. Uptake of ^{99m}Tc-sCCK8 was 4.15 ± 0.28% ID/g at 1 h pi, whereas the tumor uptake of ^{99m}Tc-nsCCK8 was 7-fold lower (0.59 ± 0.06% ID/g). Blocking with an excess of unlabeled peptide resulted in a significantly lower uptake in the tumor. Uptake of ^{99m}Tc-sCCK8 dropped to only 1.02 ± 0.12% ID/g and uptake of ^{99m}Tc-nsCCK8 was reduced to 0.40 ± 0.07% ID/g, indicating CCK receptor-mediated binding of the radiolabeled peptides in the tumor. Blood levels of the radiolabeled peptides were unaffected by the excess of unlabeled peptide. Therefore, the tumor-to-blood ratios decreased from 14.7 ± 4.3 to 2.8 ± 0.6 and from 4.0 ± 2.6 to 1.9 ± 0.7 for ^{99m}Tc-sCCK8 and ^{99m}Tc-nsCCK8, respectively.

Uptake of the ^{99m}Tc-sCCK8 in the CHO-CCK1 tumor was 2.04 ± 0.65% ID/g, whereas uptake of the ^{99m}Tc-nsCCK8 was only 0.20 ± 0.08% ID/g. Tumor-to-blood ratios were 7.1 ± 2.9 and 0.9 ± 0.2 for ^{99m}Tc-sCCK8 and ^{99m}Tc-nsCCK8, respectively. ^{99m}Tc-sCCK8 uptake in the CCK1 receptor positive tumor could be specifically blocked by an excess of unlabeled sCCK8 (0.57 ± 0.13% ID/g). An excess of unlabeled nsCCK8 did not affect the tumor uptake of ^{99m}Tc-nsCCK8, indicating that this nonsulafted peptide did not localize specifically in the CCK1 receptor positive tumor. The tumor uptake remained in the same low range at 0.33 ± 0.15% ID/g.

DISCUSSION

The present study describes the characterization of the CCK8 peptide both in its sulfated and nonsulfated form and labeled with ^{99m}Tc via the bifunctional chelator hydrazino nicotinamide. Both peptides were conjugated with an efficiency of approximately 30%. This efficiency is in the same range as has been reported previously for the HYNIC conjugation of other peptides (*10*). The HYNIC-conjugated peptides showed a good shelf life

stability over a 6-month period. Although it is well-recognized that HYNIC has good stability in lyophilized products, its stability in aqueous solutions is reduced (*21*). Therefore, in the present study we used the propylaldehyde hydrazone protected HYNIC, which previously has shown improved stability in aqueous solutions (*15*). The propylaldehyde protecting group can be easily removed under mild conditions (*12*).

To obtain ^{99m}Tc-labeled peptides with maximal stability and specific activity, three different coligand systems were tested. Although tricine is the most commonly used coligand, mainly due to the high labeling efficiency obtained at room temperature, we showed that the combination of tricine and nicotinic acid yielded ^{99m}Tc-labeled peptides with the highest specific activity and improved stability in PBS. The labeling efficiency with the tricine coligand system was high, while the stability of these ^{99m}Tc-labeled peptides was poor. After 16 h incubation in PBS at 37 °C, only 27% of the ^{99m}Tc activity was still peptide associated. This is in line with other studies in which it was found that the ^{99m}Tc-tricine-HYNIC complex is stable in serum, but unstable when diluted in PBS (*22*). Most likely, the ^{99m}Tc-tricine-HYNIC complex is stabilized by the serum proteins. Ono et al. hypothesized that one of the two tricine molecules in the complex is replaced by plasma proteins which might greatly affect the circulatory half-life, especially of smaller molecules such as peptides (*19*). The EDDA coligand system showed excellent in vitro stability. However, the specific activity which could be obtained with EDDA was only 12%−25% of that obtained with the other coligand systems. Since the sulfated form of CCK8 is extremely biologically active, its possible clinical application will markedly improve when the peptide can be labeled with high specific activity preventing pharmacological side effects. Therefore, EDDA is less favorable as coligand for the CCK8 peptides.

Receptor binding and internalization studies were performed on CHO cells stably transfected with cDNA encoding for either the CCK1 or CCK2 receptor. This enabled us to investigate the receptor specifity and binding to each receptor in more detail than when using tumor cells. We found a high affinity of ^{99m}Tc-sCCK8 for both the CCK1 and CCK2 receptor and high affinity of ^{99m}Tc-nsCCK8 for the CCK2 receptor. These results are in line with those of Smeets et al., using the same cell lines but underivatized peptides (*8*). Moreover, these low IC_{50} values are in the same range as those reported for indium-111-labeled DTPA-nsCCK8 (*5*).

Both CCK receptors belong to the superfamily of G-protein-coupled receptors (GPCR) and are known to be internalized when gastrin or CCK8 binds to the receptor. Once internalized, the receptor can be recycled and re-expressed on the cell surface or be metabolized. Recycling of the receptor takes approximately 1 h (*23*). It has also been demonstrated that after internalization the peptides can end up in lysosomes and are rapidly degraded by proteolytic enzymes (*23*). In our studies we found a steady release of the ^{99m}Tc label after internalization. This released radioactivity could not be bound by the cells again, confirming processing of the radiolabeled peptide. Studies with ^{111}In-labeled nsCCK8 described internalization and subsequent retention of the radiolabel (*4*). Duncan et al. showed that ^{111}In-DTPA-labeled peptides are degraded in the lysosomes to yield ^{111}In-DTPA-amino acids, which are retained by the lysosomes (*24*). Shankar and colleagues stated that trapping in lysozomes requires the complex to be protonated at lysozomal pH ∼ 5 (*25*). Ono et al. confirmed that ^{99m}Tc-HYNIC-labeled peptides are degraded in a similar way as ^{111}In-DTPA-labeled peptides (*26*). Here we show that the ^{99m}Tc-coligand-HYNIC-amino acid complex is apparently not positively charged at lysozomal pH and is excreted by the lysosomes, because radioactivity was released by the tumor cells. Although the residualizing property of ^{111}In is beneficial for therapy purposes, residualization may not be required for receptor-mediated peptide scintigraphy, due to the shorter time frame (1−3 h postinjection) necessary for imaging with ^{99m}Tc.

The in vivo characteristics of both ^{99m}Tc-labeled peptides were investigated in athymic mice bearing subcutaneous tumors expressing either the CCK1 or CCK2 receptor. This allowed us to investigate the specificity of receptor binding in vivo. Because ^{99m}Tc-nsCCK8 had no affinity for the CCK1 receptor it did not localize specifically in the CHO-CCK1 tumor. The same holds for the pancreas, in which the CCK1 receptor is abundantly expressed in mice (*27*). The biodistribution of ^{99m}Tc-sCCK8 was markedly different from that of the ^{99m}Tc-labeled nonsulfated peptide. In general, uptake of ^{99m}Tc-sCCK8 was higher in all CCK-receptor (either CCK1 or CCK2) expressing tissues, including both tumors. Uptake in the CCK2 tumor could be blocked by an excess of unlabeled (non)sulfated CCK8, indicating receptor-mediated uptake of the ^{99m}Tc-labeled peptide in this tumor. The ^{99m}Tc-nsCCK8 uptake in the CCK1 tumor could not be blocked, indicating that the low uptake of the ^{99m}Tc-nsCCK8 was not receptor-mediated.

We showed that both CCK1 and CCK2 tumor uptake of ^{99m}Tc-sCCK8 was approximately 15-fold higher than that of ^{99m}Tc-nsCCK8. Several studies reported on the use of radiolabeled nonsulfated CCK8 for the scintigraphic imaging and/or therapy of CCK2/gastrin receptor positive tumors. The rationale for the use of nsCCK8 is its CCK2 receptor specificity, resulting in low background accumulation in CCK1 receptor-positive tissues (*3*, *4*). However, the results of the present study suggest that ^{99m}Tc-labeled sulfated CCK8 might be much more favorable for imaging and/or therapy, based on its significantly higher uptake in both the CCK1 and the CCK2 receptor positive tumors. This higher uptake may be due to the higher affinity for the CCK2 receptor (*2*). We showed in mice that uptake of the ^{99m}Tc-labeled sulfated peptide in nontarget tissue such as pancreas and stomach is also higher as compared to the accumulation of the ^{99m}Tc-labeled nonsulfated peptide, but this may be different in humans. Weinberg et al. (*28*) analyzed the CCK-receptor expression in a wide range of human tissues and in several human tumors. They showed that the CCK1 receptor is expressed mainly in gall bladder, small intestine, colon, and spleen. The CCK2 receptor is expressed in a much broader range of tissues, including pancreas, small intestine, liver, colon, stomach, spleen, and lung. Interestingly, the CCK1 receptor is expressed in pancreatic adenocarcinomas but not in normal pancreas (*28*). In contrast, in mice and rats the CCK1 receptor is abundantly expressed in the pancreas (*27*, *29*). Therefore, it is tempting to speculate that the biodistribution of both peptides in humans will be different from that observed in mice and that ^{99m}Tc-labeled sulfated CCK8 might be a good candidate for clinical testing.

CONCLUSION

CCK8 peptides can be rapidly and efficiently labeled with ^{99m}Tc using HYNIC as chelator and tricine/nicotinic acid as coligand system, without compromising the receptor binding affinity of the peptides. Both ^{99m}Tc-

labeled sulfated and nonsulfated CCK8 bind with high affinity to the CCK2 receptor, whereas ^{99m}Tc-sCCK8 also showed high affinity toward the CCK1 receptor. Studies in athymic mice revealed that uptake of ^{99m}Tc-sCCK8 in CCK1 or CCK2 receptor-positive tumors was fifteen-fold higher than that of ^{99m}Tc-nsCCK8. Although accumulation in some nontarget organs was also higher with ^{99m}Tc-sCCK8, this may not reflect the human situation, due to a different receptor expression pattern in human tisssues as compared to that in mice. Therefore, further studies are warranted to investigate the possible use of ^{99m}Tc-sCCK8 for the scintigraphic imaging of CCK receptor-positive tumors in humans.

ACKNOWLEDGMENT

We thank Mr. Gerrie Grutters and Mrs. Bianca Lemmers-de Weem (Central Animal Laboratory, University of Nijmegen, Nijmegen, The Netherlands) for skilled assistance in the animal experiments. We thank Mr. Matthias Broekema (Department of Medicinal Chemistry, Utrecht University, Utrecht, The Netherlands) for performing the MALDI-TOF-MS analysis.

Methoxyoxalamido Chemistry in the Synthesis of Novel Amino Linker and Spacer Phosphoramidites: A Robust Means for Stability, Structural Versatility, and Optimal Tether Length

A. Michael Morocho, Valeri N. Karamyshev, and Nikolai N. Polushin*

Fidelity Systems, Inc., 7961 Cessna Avenue, Gaithersburg, Maryland 20879. Received December 2, 2003; Revised Manuscript Received March 4, 2004

We have developed a general route to the synthesis of novel amino linker and spacer phosphoramidites utilizing methoxyoxalamido (MOX) chemistry. The synthesis makes use of readily available and inexpensive primary aliphatic amino alcohols and diamines to produce a rich and diverse variety of phosphoramidites. Among these are monomers with exceptionally long (up to 56 atoms in length) amphipathic tethering arms. The chemistry bestows exceptional control over the physical characteristics within the tethers through the selection of appropriate building blocks. Furthermore, MOX chemistry enables fairly rapid assembly of these discrete-length tethers in a modular fashion. All novel phosphoramidites were successfully used in automated syntheses of 5′-modified oligonucleotides.

INTRODUCTION

Amino linker phosphoramidites are used to introduce an amino group onto the 5′-end of a synthetic oligonucleotide. Such 5′-amino-modified oligonucleotides are routinely utilized in DNA microarray production and as intermediates to functionally labeled oligonucleotides (*1*, *2*). Spacer phosphoramidites are commonly used to substitute for bases in a sequence, to incorporate hairpin loops and to position labels at a desired distance from the oligonucleotide (*3*, *4*).

Some amino linkers and spacers are commercially available (*5*), but they generally possess at least three limitations. First, these phosphoramidites are mainly derived from aliphatic primary alcohols and thus are not very stable even at low temperatures due to susceptibility to undergo Arbuzov rearrangement (*6*). This instability presents preparation and storage complications and also necessitates fairly rapid phosphoramidite consumption on automated DNA synthesizers, making the commercially available amino linkers and spacers less than ideal for reliable large-scale oligonucleotide production. Second, the available amino linker and spacer phosphoramidites are quite limited in variety. They are primarily flexible in nature, since they contain methylene or oxyethylene units within the tether chain and are rather short not exceeding 19 atoms in length. Third, the production chemistry for these phosphoramidites is not amenable to constructing a vast number of distinctly different monomers, each possessing varying degrees of flexibility, hydrophobicity, and length.

To overcome the aforementioned limitations, we report here on a general synthetic route toward amino linker and spacer phosphoramidites. The method is based on robust methoxyoxalamido (MOX)[1] chemistry (*6*) and offers great control over tether composition, rigidity, and length. All synthesized β-cyanoethyl phosphoramidites are derived from secondary alcohols and can be used on the synthesizer for at least two weeks without any loss in coupling efficiency.

EXPERIMENTAL PROCEDURES

MOX precursors **1** and **2** were prepared as previously described (*6*). Dimethyl oxalate, triethylamine, tetrazole, 4,7,10-trioxa-1,13-tridecanediamine (TTDD), 2,4,8,10-tetraoxaspiro[5.5]undecane-3,9-dipropanamine (TUDA), hexamethylenediamine (HMDA), 1,10-diaminodecane (DAD), 1,12-dodecanediamine (DDD), cystamine (CA), ethylenediamine (EDA), ethanolamine (EA), 2-(2-aminoethoxy)ethanol (AEE), 6-amino-1-hexanol (AH), monomethoxytrityl chloride (MMT-Cl), dimethoxytrityl chloride (DMT-Cl), and all solvents were purchased from Aldrich (Milwaukee, WI) and used without further purification. 2-Cyanoethyl-*N*,*N*,*N*′*N*′-tetraisopropylphosphorodiamidite was purchased from ChemGenes (Ashland, MA). Protected nucleoside cyanoethyl phosphoramidites were purchased from Transgenomic (Aston, PA). Tetrazole (0.45 M in acetonitrile), 5-ethylthio-1*H*-tetrazole (ETT, 0.25 M in acetonitrile), and all ancillary DNA synthesis reagents were purchased from Glen Research (Sterling, VA). Synthesis columns were purchased from Biosset (Novosibirsk, Russia). NMR and MS data for all novel compounds are presented in Supporting Information.

Thin-layer chromatography (TLC) was performed on Kieselgel 60 F_{254} plates (EM Science, Gibbstown, NJ). TLC plates were visualized under shortwave UV light, I_2-silica chamber, or by heating. Flash chromatography was performed with 200−400 mesh, 60 silica gel (EM Science). Electrophoretic gels were 1 mm thick 15−20% acrylamide−7 M urea and were run at 400−600 V using

TBE buffer. Crude oligonucleotides were loaded as 7 M aqueous urea solutions (1 A_{260}/10 μL) at 1−2 A_{260} units/well (12 mm long). The gels were visualized by UV shadowing over a fluorescent TLC plate or by staining with Stains-all dye (Aldrich). Purified oligonucleotides were prepared by cutting out the corresponding bands, extraction with 0.25 M triethylaminobicarbonate (TEAB) for 3−5 h at room temperature, and desalting the oligonucleotide solutions on Sephadex G-25 NAP-10 columns (Pharmacia, Uppsala, Sweden).

Oligodeoxyribonucleotides were synthesized on Biosset ASM 800 DNA/RNA synthesizers (Novosibirsk, Russia). To allow ethanolamine deprotection N^4-acetyl protected deoxycytidine phosphoramidite was used (*6* and references therein). For the 5′-end derivatization the following conditions were used: 0.1 M solutions of spacer and amino linker phosphoramidites in CH_3CN or in 1:1 mixture of CH_3CN and CH_2Cl_2, a 3−5 min coupling time, and 0.25 M ETT in CH_3CN as a catalyst. Oligonucleotides were deprotected by treatment the CPG supports with ethanolamine (30 μL per 0.1−1 μmol scale) at 70 °C for 15−20 min. The reaction mixtures were diluted with water (up to 1 mL) and desalted on Sephadex G-25 NAP-10 columns (Pharmacia, Uppsala, Sweden).

Matrix-assisted laser desorption ionization mass spectra of oligonucleotides were recorded on a Voyager-DE mass spectrometer (PerSeptive Biosystems, Framingham, MA). Oligonucleotide samples were first ethanol precipitated from 5 M aqueous ammonium acetate. 3-Hydroxypicolinic acid was used as a matrix.

Procedure A. *Derivatization of a MOX Precursor/Intermediate with an Aliphatic Primary Amino Alcohol.* To a stirring solution of an aliphatic primary amino alcohol (12 mmol) in methanol (50 mL) a 10 mmol solution of MOX precursor (**1** or **2**) or MOX intermediate (**12b**, **14b**, or **16b**) in methanol/dichloromethane (1:1, v/v, 25 mL) was added. The reaction mixture was stirred for 2 h, during which time a partial precipitation of the product was typically observed. The precipitation was completed by addition of diethyl ether (300 mL). The reaction mixture was cooled to +4 °C and incubated at this temperature for 2 h. The precipitate was filtered, washed with diethyl ether (2 × 30 mL), and dried. The synthesized diol was used without further purification.

Following Procedure A, **3a** was prepared from **1** and AEE (77%), **4a** from **1** and AH (60%), **5a** from **14b** and AEE (89%), **6a** from **12b** and AEE (90%). **7a** was prepared from **16b** and AEE (91%) following Procedure A, except dichloromethane was used as solvent. All prepared diols were white solids.

Procedure B. *Derivatization of a MOX Precursor/Intermediate with an Aliphatic Primary Diamine.* The reaction was carried out analogously to Procedure A except that, instead of an amino alcohol, an aliphatic primary diamine (40 mmol, 4 times excess over MOX component) was used and the solution of MOX precursor was added portionwise over a 30-min period. The synthesized amino alcohol was used without further purification.

Following Procedure B, **8a** was prepared from **1** and EDA (95%), **9a** from **1** and HMDA (93%), **12a** from **1** and TTDD (85%), **13a** from **1** and TUDA (77%), **14a** from **2** and TTDD (82%), **15a** from **14b** and TTDD (83%), **16a** from **12b** and TTDD (85%), **17a** from **16b** and TTDD (87%). **10a** was prepared from **1** and DAD (79%), and **11a** from **1** and DDD (77%)**,** following Procedure B, except that diamines were dissolved in 100 mL of MeOH, and the products were filtered without ether addition. All prepared amino alcohols were white solids.

Procedure C. *Protection of a Primary Hydroxyl Group with DMT-Cl.* To a stirring solution or a slurry of a diol (10 mmol, prepared as described in Procedure A) in anhydrous DMF/pyridine (1:1, v/v, 100 mL) was added DMT-Cl (11 mmol). The reaction mixture was stirred overnight at room temperature. If after this time the reaction was not completed (as monitored by TLC), another portion of DMT-Cl (2 mmol) was added and the reaction mixture was stirred for an additional 5 h. The reaction was diluted with chloroform (400 mL) and extracted with a saline solution (400 mL). The organic layer was dried over anhydrous Na_2SO_4 and concentrated to ∼50 mL. To this were added diethyl ether (300 mL) and then pentane (200 mL) with stirring. The slurry was cooled to +4 °C and incubated at this temperature for 2 h. The precipitate was filtered, washed with diethyl ether/pentane (1:1, v/v, 2 × 30 mL), and dried. The synthesized DMT-protected diols were phosphitylated without further purification.

Following Procedure C, **3b** was prepared from **3a** (78%), **4b** from **4a** (85%), **5b** from **5a** (81%), **6b** from **6a** (75%), and **7b** from **7a** (86%). Compounds **3b**, **4b**, and **6b** were yellowish solids. Compounds **5b** and **7b** were white solids.

Procedure D. *Protection of a Primary Amino Group with MMT-Cl.* Protection of the primary amino group of amino alcohols (prepared as described in Procedure B) with MMT-Cl was executed analogously to Procedure C except that, due to generally poorer solubility of the amino alcohols, the reaction time was extended to 2−3 days and the chloroform solution was filtered through a thin layer of silica gel before the extraction. The synthesized MMT-protected amino alcohols were phosphitylated without further purification.

Following Procedure D **8c** was prepared from **8a** (56%), **9c** from **9a** (51%), **12c** from **12a** (65%), **13c** from **13a** (67%), **14c** from **14a** (83%), **15c** from **15a** (72%), **16c** from **16a** (61%) and **17c** from **17a** (66%). Compounds **8c**, **9c** and **12c**−**14c** were yellowish solids. Compounds **15c**−**17c** were white solids.

MMT-Protected Amino Alcohol 10c. 10a (1.68 g, 4.91 mmol) was dissolved in hot dioxane (100 mL, 70−80 °C). To this were added DBU (2.94 mL, 19.6 mmol) and MMT-Cl (0.91 g, 2.95 mmol) with stirring. The reaction mixture was stirred at 70−80 °C for 30 min. A second portion of MMT-Cl (0.91 g, 2.95 mmol) was added, and the reaction mixture was stirred for an additional 1 h. The reaction was quenched with water (400 mL) and stirred for 2 h at room temperature. The precipitate was filtered, washed with water, (2 × 100 mL) and recrystallized from ethanol to give **10c** as a white solid (1.66 g, 55%).

MMT-Protected Amino Alcohol 11c. 11c was prepared from **11a** exactly as **10c** to give a white solid (58%).

Procedure E. *Derivatization of a Primary Amino Group with Dimethyl Oxalate.* To a stirring solution of dimethyl oxalate (40 mmol) and triethylamine (20 mmol) in methanol (50 mL) was added the amino alcohol (10 mmol, prepared as described in Procedure B) portionwise over a 2-h period. The reaction mixture was stirred for an additional 1 h and concentrated to dryness. The excessive dimethyl oxalate was sublimed out at ∼3 Torr and 70 °C. The residue was dissolved chloroform, and the MOX derivative was separated by flash chromatography on silica gel (gradient of methanol in chloroform).

Following Procedure E, **12b** was prepared from **12a** (87%), and **16b** from **16a** (71%). **14b** was prepared from **14a** (90%) following procedure E, except that pyridine

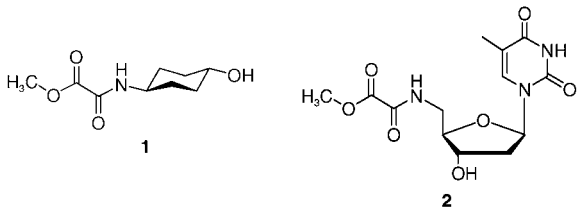

Figure 1. MOX precursors.

was used as solvent. Compounds **12b, 14b**, and **16b** were white solids.

Procedure F. *Phosphitylation of a Secondary Hydroxyl Group.* To the mixture of a dry secondary alcohol (5 mmol, prepared as described in Procedure C or D) and tetrazole (4.75 mmol) were consecutively added anhydrous dichloromethane (50 mL) and 2-cyanoethyl-*N*,*N*,-*N*′,*N*′-tetraisopropylphosphoramidite (6.5 mmol). The reaction mixture was stirred for at least 1 h or until complete disappearance of the initial solids. During the course of the reaction crystals of diisopropylamine tetrazolide were typically formed. The reaction was diluted with dichloromethane (200 mL) and extracted with a 10% aqueous $NaHCO_3$ solution (200 mL). The organic layer was dried over anhydrous Na_2SO_4 and concentrated to ~20 mL. The residue was precipitated into diethyl ether/pentane mixture (1:1, v/v, 500 mL) and allowed to settle down, at which point the supernatant was decanted. The residue was purified by flash chromatography (gradient of ethyl acetate in pentane or gradient of pyridine in ethyl acetate, where ethyl acetate contained 4% of triethylamine).

Following Procedure F, **3c** was prepared from **3b** (85%), **4c** from **4b** (84%), **5c** from **5b** (68%), **6c** from **6b** (65%), **7c** from **7b** (69%), **8d** from **8c** (85%), **9d** from **9c** (62%), **10d** from **10c** (65%), **11d** from **11c** (80%), **12d** from **12c** (91%), **13d** from **13c** (87%), **14d** from **14c** (72%), **15d** from **15c** (80%), **16d** from **16c** (83%), and **17d** from **17c** (70%). All prepared spacer phosphoramidites (compounds **3c**−**7c**) were white amorphous solids. Amino linker phosphoramidite **8d, 9d**, and **13d**−**17d** were white amorphous solids. Amino linker phosphoramidite **10d**−**12d** were clear oils.

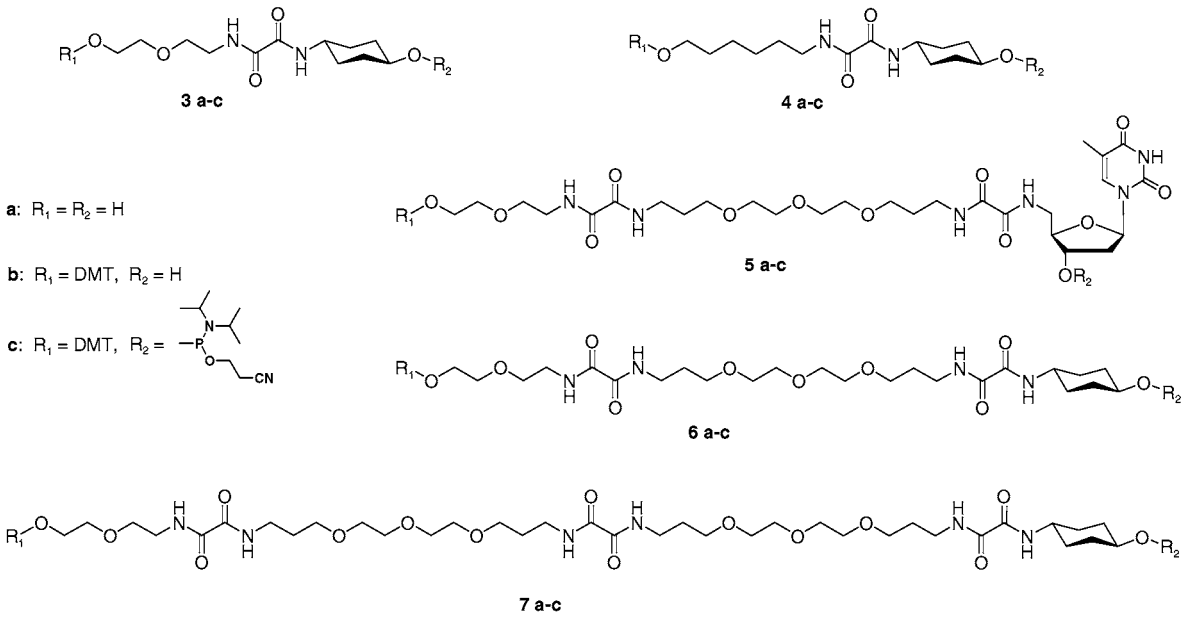
RESULTS AND DISCUSSION

For the synthesis of novel amino linker and spacer phosphoramidites, we have engaged methoxyoxalamido chemistry that proved to be very reliable in our previous work (*6*, *7*). As starting materials, we have used *trans*-4-methoxyoxalamido-1-cyclohexanol **1** and 5′-methoxyoxalamido-5′-deoxythymidine **2** (Figure 1) based on the reasoning that both compounds could easily be synthesized from commercially available *trans*-4-amino-1-cyclohexanol and 5′-amino-5′-deoxythymidine, respectively, and both have secondary hydroxyls that endow stability to the corresponding phosphoramidites. The use of carbon skeletons with a secondary hydroxyl group also greatly facilitates the protection at the primary hydroxyl during spacer phosphoramidite preparations.

Phosphoramidite Synthetic Routes. The general synthetic routes toward novel amino linker and spacer phosphoramidites are outlined in Scheme 1. Phosphoramidite preparations proceeded by either a single synthon addition (Scheme 1A) or by means of a serial addition of tether synthons (Scheme 1B). The first route is, naturally, easier to execute. In the case of spacer phosphoramidite syntheses the MOX precursor was first reacted with a slight excess of an aliphatic amino alcohol, the amino and hydroxyl groups both being primary. The introduced primary hydroxyl was then selectively protected with DMT group, and the resultant intermediate was phosphitylated on the secondary hydroxyl to give a final product. When an amino linker had to be synthesized the MOX precursor was treated with a 4-fold excess of an aliphatic primary diamine. The excess amount of diamine was necessary to suppress dimer formation. However, due to substantial differences in solubility between the diamine and the formed amino alcohol, the former could easily be separated and recycled, if needed. The amino group of the intermediate amino alcohol was protected with MMT group, and the secondary hydroxyl of the protected amino alcohol was phosphitylated to furnish the amino linker phosphoramidite. In both spacer and amino linker preparations the reactions proceeded in a straightforward manner, and the synthesis proved to be robust. The stepwise yields were high, and crystallization or precipitation effectively cleaned up the majority of the reactions leading up to the phosphoramidite. Thus, column chromatography was only used at the final phosphitylation step. DMT/MMT-protected alcohol intermediates were generally synthesized in 50−80% isolated yields based on their MOX precursors and then converted into phosphoramidites in 60−90% isolated yields. Simple spacer phosphoramidites **3c** and **4c** and preceding intermediates **3a**,**b** and **4a**,**b** are shown in Figure 2. Simple amino linker phosphoramidites **8d**−**14d** and their intermediates **8a**,**c**−**14a**,**c** are displayed in Figure 3.

The route to compound spacer and amino linker phosphoramidites is depicted in Scheme 1B. The MOX precursors **1** and **2** were treated with appropriate diamine, and the amino group of the formed amino alcohols was reacted with a 4-fold excess of dimethyl oxalate, thus generating new two-component MOX intermediates. The excessive amount of dimethyl oxalate was necessary to suppress dimer formation, but, if needed, the excess reagent could easily be recovered from the reaction mixture by sublimation. Further treatment of these MOX intermediates with amino alcohols or diamines, followed by protection and phosphitylation, led to three-component compound spacer phosphoramidites **5c** and **6c** (Figure 2) and amino linker phosphoramidites **15d** and **16d** (Figure 3). Again, all the reactions proceeded in high or good yields, and column purification was applied only to the MOX intermediates and the final phosphoramidites. Obviously, diamine/dimethyl oxalate treatments could be applied repeatedly to the initial MOX precursor leading to multicomponent MOX precursors and, accordingly, to multicomponent phosphoramidites. To prove this concept four-component spacer phosphoramidites **7c** (Figure 2) and amino linker phosphoramidite **17d** (Figure 3) were successfully synthesized from the three-component MOX precursor **16b**.

Phosphoramidite Stability. Many of the currently available amino linker and spacer phosphoramidites are derived from primary alcohols and are generally less stable than monomers derived from secondary alcohols. The phosphoramidites in this paper have been synthesized from cyclic carbon scaffolds with a secondary hydroxyl and are as stable in solution as standard phosphoramidites. ^{31}P NMR time course experiments showed that phosphoramidite **8d**, based on a cyclohexanol skeleton, has substantially greater stability compared to commercially available C6 amino linker that has the phosphoramidite moiety attached through a primary hydroxyl (Figure 4). As one can see from Figure 4, after 20 days, phosphoramidite **8d** was still more than 90% intact while more than 40% of C6 amino linker were



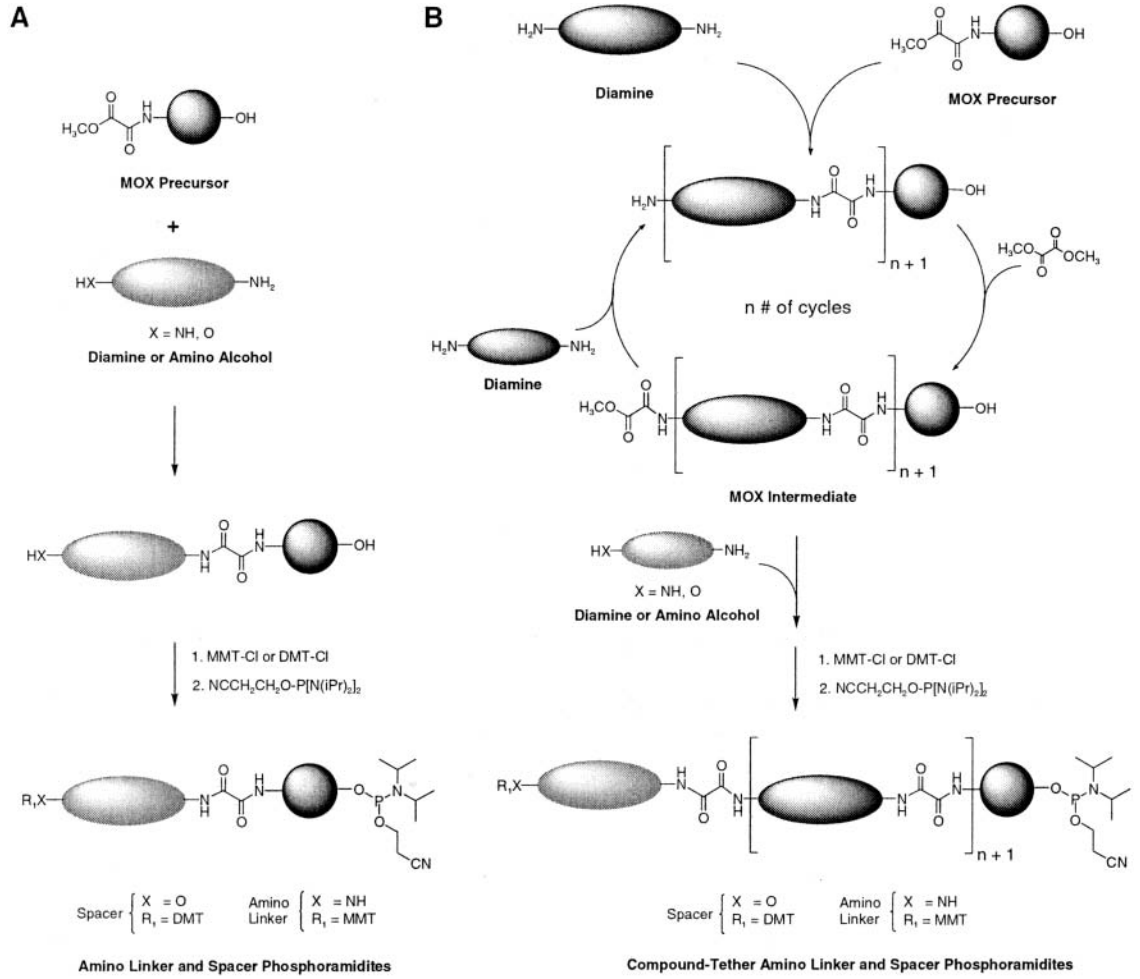


Figure 2. Spacer intermediates and phosphoramidites.

Scheme 1. Synthetic Pathways to Spacer and Amino Linker Phosphoramidites Possessing Simple (A) and Compound (B) Tethers

decomposed. We have repeated these experiments with phosphoramidite **16d**, which has a longer tether, and obtained the stability curve practically identical to the one of **8d**.

The coupling yields of the present phosphoramidites did not deteriorate within at least 2−3 weeks after phosphoramidite installation on the synthesizer. In an extreme case, PAGE analysis of amino-modified oligonucleotides using phosphoramidite **12d** showed acceptable coupling even after a 30-day sitting on the synthesizer (gel data can be viewed at http://www.fidelitysystems.com/Stability.html).

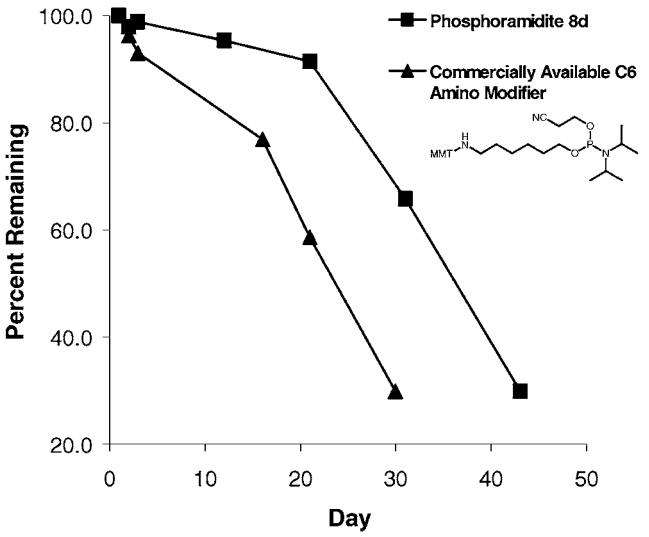

Figure 4. Comparative solution stability of an aminocyclohexanol-based phosphoramidite **8d** and one derived from a primary alcohol. Values were determined from duplicates by integration of ^{31}P NMR peaks. Conditions: 0.3 M solutions in CD_3CN under a blanket of argon at room temperature.

Structural Versatility. The practical advantage of our synthetic approach lies in its amenability to structural versatility by utilizing an arsenal of distinctly different, commercially available diamines and amino alcohols. It is possible to tailor the synthesis to suit practically any requirement in chemical or physical properties of the tethers. The present selection of tethers encompasses a short range of hydrophobicity, rigidity, and length, but the synthetic strategy can easily produce a wide variety of chain features, such as tethers possessing variable flexibility within the chain or tethers with cleavable bonds. MOX chemistry delivers great control over the physical properties of the tether because different diamines can be incorporated directly at specific regions within the chain.

Since formation of a compound tether proceeds in a modular fashion through the use of oxalamido bonds, it is easy to selectively modify the physical nature of the tether at each step. For example, if more rigidity is needed at the ends of the tether, a diamine with a constrained configuration can be used at the last step of tether construction. While the number of cycle iterations determines the overall extension of the tethering arm, it is also possible to decrease chain flexibility by repeatedly using a short diamine, which would produce a tether with fewer degrees of freedom in rotation due to shorter spacing between rigid oxalamido groups. The range in hydrophobicity can span from a highly lipophilic amino linker **11d** to the hydrophilic trioxa-tethered amino linkers **12d** and **14d**. Therefore, not only are we able to choose where to incorporate the tether building blocks, but most importantly, we are able to utilize different combinations of available diamines to make complex chains.

Optimal Tether Length. The ideal length of tethering arms on oligonucleotides is entirely application dependent (*8*−*11*). Of all the tethering arms reported in the literature, polydispersed PEG-based tethers are the longest (*8*). We have determined that amidites having

polydispersed, extremely long tethering arms based on PEG (>1500 MW) cannot be effectively used in some applications, such as Sanger fragment capture in sequencing reactions, due to track peaks smearing (unpublished results). Therefore, our approach toward long amino linkers and spacers was to synthesize the tethers embedded with discrete polyoxyethylene units. By exploiting the serial addition strategy, we have been able to synthesize a 56-atom amino linker **17d**, and a 48-atom spacer **7c**. Theoretically, there is no limit to the length that can be achieved using this strategy, and the serial addition can be increased to 5−6 repetitions to make discrete compound tethers, challenging the chain lengths achieved through the use of short (~2000 MW) polydispersed PEG tethers (*8*).

The tether length is ultimately determined by the choice of diamines or amino alcohols used in the synthesis. The simplest and shortest tether was obtained through the use of EDA for the synthesis of amino linker **8d** (Figure 3). The longest amino linker **17d** was obtained by incorporating TTDD three times to make the compound tether. On the basis of recently reported computational and crystallographic studies of oxalamide-based compounds (*12*, *13*), we presume that the most favorable configuration for the oxalamido moieties in our tethers is the trans arrangement for the carbonyl groups. This should maximize the extension of the tethering arm, and, therefore, should be beneficial for applications utilizing immobilized oligonucleotides, extending them away from an otherwise crowded solid surface (*9*, *14*).

Several reports have shown that the tether length of immobilized oligonucleotides at a solid surface is an important parameter having a significant effect on hybridization (*9*−*11*). For example, it has been shown that steric hindrance, rather than the efficiency of hybridization between the template and the immobilized oligonucleotide, is the major reason for loss in solid-phase primer extension. In one report (*11*) unfavorable interactions were minimized by increasing the tether length to 5−10 hexaethyleneglycol (HEG) units. However, by coupling HEG units sequentially to the oligonucleotide 5′-terminus two adverse events occur. The overall synthetic yield of the primer is decreased, and a net negative charge, due to phosphodiester bonds, is incorporated within the tether. This negative charge density on the tether has been shown in a previous study to decrease the yield of hybridization due possibly to electrostatic repulsion to the target (*9*). The longest amino linker **17d** with a 56-atom tether is more than 3 times the length of a HEG unit and is somewhat more rigid to ensure greater arm extension of the tether. Therefore, when used together with cyclohexanol-based long spacers (up to 48 atoms long), fewer sequential additions to the 5′-end of the oligonucleotide are necessary to attain an extended tether and, in the process, less negative charge density is incorporated.

Synthesis of Modified Oligonucleotides. Coupling and Deprotection. Most of the prepared phosphoramidites are solids, making them easy to handle, and most are freely soluble in acetonitrile. For the monomers with limited acetonitrile solubility, especially the ones possessing long aliphatic tethers, such as **10d** and **11d**, dichloromethane (50%, v/v) was used as cosolvent. The average coupling efficiency of the phosphoramidites at 0.1 M concentrations, a 3−5 min coupling time, and ETT as a catalyst was greater than 95%.

The spacers and linkers presented here have been used to synthesize a number of 5′-modified oligonucleotides. The modified oligonucleotides were observed as distinct bands on polyacrylamide gel with mobility less than that of an unmodified counterpart. As an example, Figure 5 shows a series of crude T_{10} oligonucleotides modified with amino linkers (Figure 5A) and spacers (Figure 5B). MS data for these oligomers are presented in Table 1. In the case of modification with amino linkers **9d**−**11d** (Figure 5A, lanes 3−5) some side product with mobility slightly greater than that of unmodified T_{10} (Figure 5A, lane 1) was produced. The amount of the side product depended on the solvent used for coupling and did not exceed 15% in CH_3CN/CH_2Cl_2. Leaving the MMT group on did not significantly change the extent of side product formation, ruling out susceptibility of the modified oligo to the free amine. The nature of this side product and the reason it is formed in the case of phosphoramidites **9d**−**11d**, amino linkers with aliphatic chains ranging from six to twelve carbons in length, is yet to be found. All other modifiers essentially produced a single product (Figure 5).

To determine the effect of deprotecting conditions on simple and compound tethers, we subjected several DMT/MMT-protected intermediate diols and amino alcohols to neat ethanolamine, ammonia/methylamine (30% aqueous ammonium hydroxide/2 M methanolic methylamine, 1:1, v/v), and aqueous NaOH (0.2 M NaOH in a water/

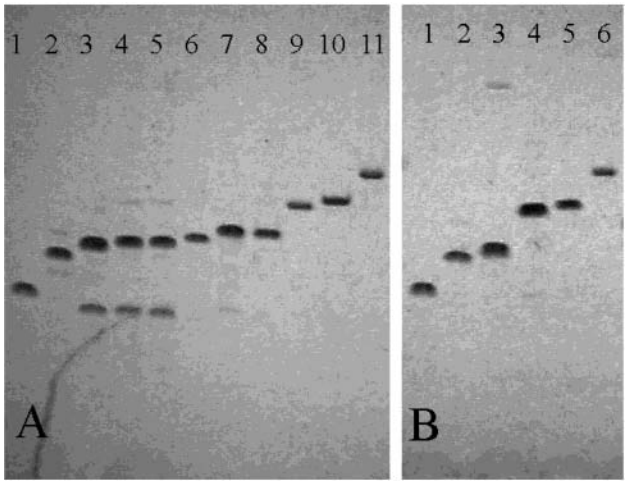

Figure 5. Amino linker (A) and spacer (B) modified crude T_{10} oligonucleotides. Lane 1 in each gel corresponds to unmodified T_{10} oligonucleotide. The other lanes are T_{10} modified by the following phosphoramidites: **8d** (A2), **9d** (A3), **10d** (A4), **11d** (A5), **12d** (A6), **13d** (A7), **14d** (A8), **16d** (A9), **15d** (A10), **17d** (A11), **3c** (B2), **4c** (B3), **6c** (B4), **5c** (B5), **7c** (B6).

methanol mixture, 1:1, v/v). Exposure to NaOH, even for 1 h at ambient temperature, was too harsh, and some degradation of all tethers was detected under this condition. The tethers, however, did hold up to ammonia, methylamine, and ethanolamine and were stable at the temperature and duration required for complete deprotection of the modified oligonucleotides.

CONCLUSIONS

We have presented a facile, efficient, and versatile synthetic strategy for the preparation of novel phosphoramidites possessing a variety of tethers, including exceptionally long tethering arms. By utilizing the oxalamido bond as a "coupler", we can serially add appropriate diamines multiple times to make long tethers or to incorporate functionality from commercially available reagents. The only limitation of our tethering strategy lies in the requirement of using aliphatic primary diamines or amino alcohols to react with the methoxyoxalamido moieties of the starting MOX precursors and intermediates. In our experience this approach, yielding linkers and spacers with discrete lengths, has proven beneficial in minimizing steric interference for enzymatic events staged at the surface by immobilizing the oligonucleotides sufficiently away from the solid phase (unpublished results).

The synthetic method described here presents the following advantages: (i) the synthesis is robust and straightforward; (ii) the phosphoramidites are derived from secondary alcohols, making them more stable than those derived from primary alcohols; (iii) a wide range of tethers having varying degrees of hydrophobicity, flexibility, and length can be rapidly prepared; (iv) since the monomers can be coupled to the oligonucleotide 5′-terminus in high efficiency, there is no need to drastically alter standard automated DNA synthesis cycles.

We believe that the synthetic approach outlined here and the phosphoramidites derived from this methodology should find a comfortable niche in the production of microarrays and DNA chips, where unfavorable steric and electrostatic factors experienced at the surface of bound oligonucleotides may dictate the use of uncharged, selectively designed tethers. Ongoing research using this synthetic strategy includes the development of monomers with even longer tethering arms, >100 atoms in length, and the synthesis of long tethers possessing other functionalities, such as biotin. Additional phosphoramidites, that have successfully been synthesized using MOX chemistry and are beyond the scope of this paper, possess tethers with cleavable diols and disulfide linkages. It is hoped that our synthetic methodology will lead to an abundance of easily prepared monomers to supplement and offer significant advantages over currently available amino linker and spacer phosphoramidites.

Analytical data for the synthesized compounds

NMR chemical shifts are reported in p.p.m. (δ units) downfield from TMS for ^{1}H-NMR and from H_3PO_4 for ^{31}P-NMR spectra. Spectra were recorded on a Varian Mercury-300 spectrometer at 300 and 121 MHz, respectively. Intermediates 10a, 10c, 11a, 11c and phosphoramidites 10d and 11d with poor solubility in DMSO-d_6 required longer acquisition times. Electrospray Ionization mass spectra (ESI MS) were recorded on a Mariner spectrometry system (PerSeptive Biosystems, Framingham, MA). Samples were dissolved in MeOH/H_2O (1:1).

Leiden Institute of Chemistry and ProSensa B.V., Gorlaeus Laboratories, University of Leiden, P.O. Box 9502, 2300 RA Leiden, The Netherlands. Received December 4, 2003; Revised Manuscript Received February 24, 2004

We report the synthesis of novel artificial ribonucleases with potentially improved cellular uptake. The design of trifunctional conjugates **1a** and **1b** is based on the specific RNA-recognizing properties of PNA, the RNA-cleaving abilities of diethylenetriamine (DETA), and the peptide $(KFF)_3K$ for potential uptake into *E. coli*. The conjugates were assembled in a convergent synthetic route involving native chemical ligation of a PNA, containing an N-terminal cysteine, with the C-terminal thioester of the cell-penetrating $(KFF)_3K$ peptide to give **12a** and **12b**. These hybrids contained a free cysteine side-chain, which was further functionalized with an RNA-hydrolyzing diethylenetriamine (DETA) moiety. The trifunctional conjugates (**1a**, **1b**) were evaluated for RNA-cleaving properties in vitro and showed efficient degradation of the target RNA at two major cleavage sites. It was also established that the cleavage efficiency strongly depended on the type of spacer connecting the PNA and the peptide.

INTRODUCTION

Peptide nucleic acids (PNAs)[1] are nonionic DNA mimics composed of repeating *N*-(2-aminoethyl)glycine units, whose secondary amino atoms are anchored through methylenecarbonyl linkers to the natural nucleobases. PNAs are resistant to nuclease and protease digestion and bind exceptionally tight and with high affinity to complementary DNA and RNA (*1*−*3*). The latter features have led to the successful in vitro application of PNA as antisense agents (*4*−*8*).

A few years ago we reported the design and synthesis of an artificial ribonuclease (see Figure 1) composed of a PNA strand attached to a diethylenetriamine (DETA) moiety via a urethane bond (*9*). In vitro studies revealed that this hybrid almost completely degraded a complementary ^{32}P-labeled RNA strand within 24 h at 40 °C and pH 7.

This encouraging result was an incentive to study the potential ribonucleolytic activity of this type of artificial ribonuclease in a biological system. However, the in vivo evaluation of PNA is severely hampered by its poor membrane permeability (*10*). This obstacle can in principle be circumvented by attachment of lipophilic groups such as adamantyl (*11*, *12*) or phosphonium cation (*13*) to the PNA or by conjugation of PNA to membrane-permeable peptides (*14*−*17*). For instance, Good et al. investigated (*18*, *19*) the invasive properties of a peptide with the sequence $(KFF)_3K$—a cationic peptide that had previously been shown to permeate bacterial membranes (*20*, *21*)—attached through a spacer to the N-terminus of an antisense PNA. Markedly higher cellular uptake of the conjugate was found as judged by the dramatically increased antisense activity of the PNA−peptide conjugate compared to "naked" PNA. A recent study by Geller et al. (*22*) also demonstrated that antisense phosphorodiamidate morpholino oligomers (PMOs) showed highly improved bactericidal effects when bound covalently to the peptide $(KFF)_3KC$.

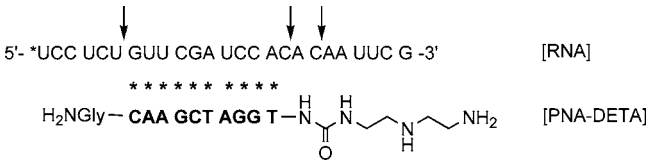

Figure 1. PNA−DETA conjugate (PNA marked in bold) synthesized by Verheijen et al. (*9*). The target RNA was cleaved at the sites indicated, the major cleavage taking place after C-17 and C-19.

It occurred to us that trifunctional constructs **1a** or **1b**, as depicted in Figure 2, containing an antisense PNA, a DETA moiety, and the $(KFF)_3K$ peptide may display enhanced cellular uptake and site-specific nuclease activity in *E. coli*.

We here report the synthesis and the in vitro nucleolytic properties of conjugates **1a** and **1b**, having different types of spacers connecting the $(KFF)_3K$ peptide to the N-terminus of the PNA.

EXPERIMENTAL PROCEDURES

General Remarks. All reagents were of analytical or peptide synthesis grades and used as obtained from the suppliers. All solvents were of HPLC grade or peptide synthesis grade. Analytical LC-MS was conducted on a JASCO system using an Alltima C_{18} analytical column (5 μm particle size, flow: 1.0 mL/min). The absorbance was measured at 214 and 254 nm. The solvent system was A: 100% Water, B: 100% ACN, C: 0.5% TFA. Gradients of B in A containing 10% C were applied over 15 min. Mass spectra were recorded on a Perkin-Elmer Sciex API 165 equipped with an electrospray interface (ES). MALDI-TOF-MS spectra were recorded on a Voyager-DE PRO mass spectrometer (PerSeptive Biosystems) using a 4-hydroxy-α-cyanocinnamic acid matrix (10 mg/mL 0.2% TFA in ACN/Water, 1/1). Purifications were conducted using a BioCAD "Vision" automated HPLC system (PerSeptive Biosystems), supplied with a semi-preparative Alltima C_{18} column (5 μm particle size, running at 4.7 mL/min). Solvent system: A: 100% Water, B: 100% ACN, C: 1% TFA. Gradients of acetonitrile (B) in A containing 10% C were applied over 3 column volumes (CV). A TitroLine alpha machine or Merck Universalindikator pH 1−10 paper was used to measure the pH of buffers. The peptide and PNA fragments were prepared using an ABI 433A (Applied Biosystems) automatic peptide synthesizer. ^{1}H NMR and ^{13}C NMR spectra were recorded with a Bruker AC-200 spectrometer (200/50.1 MHz). Chemical shifts are given in ppm (δ) relative to tetramethylsilane (^{1}H NMR) as an internal standard or to the peak of the used solvent (^{13}C NMR).

Synthesis. (KFF)$_3$K−Spacer−Thioester 7a. To a suspension of 4-sulfamylbutyryl safety-catch resin **2** (1 g, loading capacity = 1.1 mmol/g, 1.1 mmol) in DMF were added DiPEA (1.92 mL, 11 mmol) and *N*-Fmoc-Gly-OH (1.64 g, 5.5 mmol). The reaction mixture was shaken for 20 min and then cooled to −40 °C, and PyBOP (2.86 g, 5.5 mmol) was added. The mixture was shaken for 1 h at −40 °C and then 5 h at −20 °C. The resin was removed by filtration and washed with DMF (3×), MeOH (3×), and DCM (3×) and then dried under a flow of air. The loading of the resin (0.4 mmol/g) was determined by standard Fmoc quantification. The peptide synthesis was carried out automatically on an ABI 433a peptide synthesizer on a 50 μmol scale using an excess (5 equiv) of the amino acid building blocks *N*-Fmoc-Phe-OH, *N*-Fmoc-Lys(Boc)-OH, and *N*-Boc-Lys(Boc)-OH, the activating agents BOP/HOBT, DiPEA as a base, and Ac_2O/DiPEA for capping. After complete synthesis, the resin was treated with trimethylsilyldiazomethane (1 M in THF/hexane, 1:1, 3 mL) and shaken for 2 h. The solvents were removed, and the resin was washed with THF (3×), DMF (3×), and THF (3×) and resubjected to trimethylsilyldiazomethane (0.66 M in THF/hexane, 2:1, 3 mL) for 45 min. The solvents were removed, and the resin was washed with THF (3×) and DMF (3×), and treated with a solution of ethyl 3-mercaptoproprionate (2 mmol, 1 M in DMF, 2 mL) containing sodium thiophenolate (2.5 mg, 0.02 mmol). The mixture was shaken for 2 days, and the resin was removed by filtration. The resin was additionally washed with DMF (3×), and the combined filtrates were evaporated under reduced pressure. The residue was treated with 95% TFA/H_2O (5 mL) and shaken for 1.5 h, and the product **7a** was precipitated from Et_2O and collected by centrifugation. LC-MS: 10−55% B, t_R = 13.4 min; ES MS: found/calcd: 1687.1/1687.1 $(M + H)^+$, 843.9/844.1 $(M + 2H)^{2+}$.

(KFF)$_3$K−Spacer−Thioester 7b. 4-Sulfamylbutyryl safety-catch resin **2** was loaded with the *N*-Fmoc-protected diethyleneglycol linker **3**, using the same method as described above, to give immobilized **4b**. After determination of the loading by standard Fmoc quantification (0.31 mmol/g), the peptide **7b** was synthesized according to similar procedures as described for thioester **7a**. LC-MS: 10−55% B, t_R = 14.2 min; ES MS: found/calcd: 1676.4/1676.1 $(M + H)^+$, 838.2/838.6 $(M + 2H)^{2+}$.

Synthesis of Cys(S*t*Bu)-PNA 11. PNA **11** was synthesized automatically on an ABI 433a peptide synthesizer on a 10 μmol scale using an excess (5 equiv) of the Fmoc/Bhoc-protected PNA monomers or Fmoc/S*t*Bu-protected cysteine (0.11 M monomer concentration) for the couplings on tentagel resin containing the Fmoc-protected Rink amide linker (loading 0.2 mmol/g). Monomers were preactivated (1 min) with HATU (4.9 equiv) and a mixture of DiPEA/lutidine as base (0.2 M DiPEA, 0.3 M lutidine in NMP). The coupling time was 30 min. Ac_2O/lutidine/NMP (5:6:89) was used for capping. After complete synthesis, the resin was treated with TFA/TIS/H_2O (90:5:5, 5 mL) for 2 h at ambient temperature, and the product **11** was precipitated from Et_2O and used without further purification. LC-MS: 5−35% B, t_R = 12.9min; ES MS: found/calcd: 1439.4/1439.5 $(M + 2H)^{2+}$, 959.8/960.0 $(M + 3H)^{3+}$, 720.2/720.3 $(M + 4H)^{4+}$.

Synthesis of PNA−Peptide Conjugates 12a, 12b. Crude PNA **11** (approximately 2 μmol) and crude peptide **7a** or **7b** (approximately 4 μmol) were dissolved in a degassed buffer solution (400 μL) containing 6 M guanidine·HCl, 0.1 M tris(2-carboxyethyl)phosphine·HCl (TCEP), and 0.1 M Na_2HPO_4. The pH was adjusted to 7.5 using 2 M NaOH. Thiophenol was added (4%, 16 μL), and the solution was shaken overnight. Complete consumption of PNA **11** was verified by LC-MS analysis. 1,4-Dithiothreitol was added, and the desired conjugate was purified by RP HPLC. PNA−peptide conjugate **12a**: LC-MS: 5−55% B, t_R = 12.4 min; ES MS: found/calcd: 2171.2/2171.3 $(M + 2H)^{2+}$, 1448.0/1447.9 $(M + 3H)^{3+}$, 1086.6/1086.2 $(M + 4H)^{4+}$, 869.4/869.1 $(M + 5H)^{5+}$, 724.6/724.4 $(M + 6H)^{6+}$. MALDI TOF MS: found/calcd: 4341/4342 $(M + H)^+$. PNA−peptide conjugate **12b**: LC-MS: 5−55% B, t_R = 12.3 min ES MS: found/calcd: 2166.2/2165.8 $(M + 2H)^{2+}$, 1444.2/1444.2 $(M + 3H)^{3+}$, 1083.6/1083.4 $(M + 4H)^{4+}$. MALDI TOF MS: found/calcd: 4329/4333 $(M + H)^+$.

({2-[*tert*-Butoxycarbonyl-(2-*tert*-butoxycarbonylaminoethyl)amino]ethylcarbamoyl}methyl)carbamic Acid 9*H*-Fluoren-9-ylmethyl Ester 14. To a solution of (2-aminoethyl)−(2-*tert*-butoxycarbonylaminoethyl)carbamic acid *tert*-butyl ester **13** (2.73 g, 9.0 mmol) in DMF (35 mL) were added *N*-Fmoc-glycine (3.48 g, 11.7 mmol), BOP (5.17 g, 11.7 mmol), HOBT (1.58 g, 11.7 mmol), and DiPEA (4.65 mL, 27 mmol). After 45 min, TLC analysis (4/1 EtOAc/PE, v/v) indicated complete consumption of the starting material. The mixture was concentrated in vacuo, and the residue was taken up in EtOAc. After being washed with 10% $KHSO_4$, 10% $NaHCO_3$, and finally with brine, the organic layer was

dried with $MgSO_4$, filtered, and evaporated under reduced pressure. The residue was applied to a silica gel column and eluted with a gradient of EtOAc in PE (50 → 100%), to yield 4.1 g (7.0 mmol, 78%) of the desired product as a white foam. ^{1}H NMR ($CDCl_3$): δ 7.43−7.25 (8H, CH arom. Fmoc), 4.40 (2H, d, CH_2 Fmoc), 4.24 (1H CH Fmoc), 3.87 (2H, bd, CH_2), 3.39 (4H, bs, 2 × CH_2), 3.28 (4H, bs, 2 × CH_2), 1.46 (9H, s, tBu Boc), 1.42 (9H, s, tBu Boc). ^{13}C{^{1}H} NMR ($CDCl_3$): δ 169.5 (C═O Fmoc), 154.2, 153.1 (C═O Boc), 127.7, 127.0, 125.0, 119.9 (CH arom Fmoc), 79.2, 80.8 (C_q, tBu), 67.1 (CH_2 Fmoc), 48.1, 44.4, 39.2 (CH_2), 47.0 (CH Fmoc), 28.3 (tBu Boc). ES MS: 583.4 $(M + H)^+$.

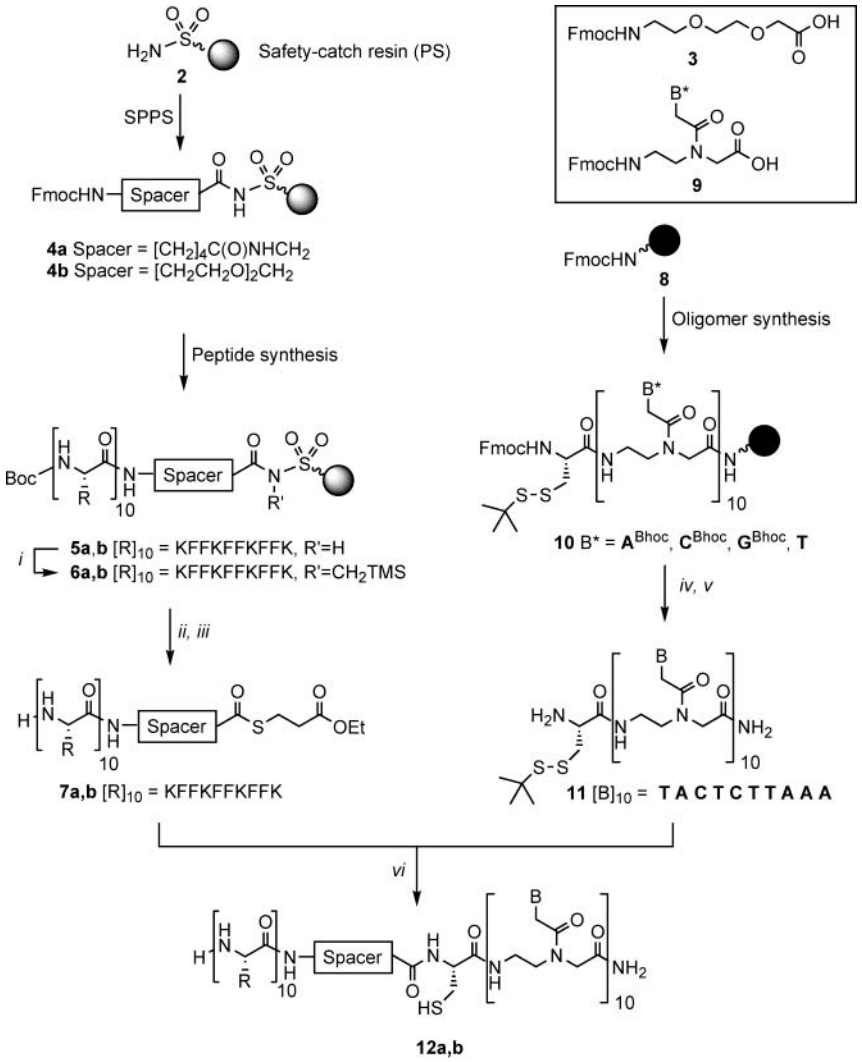
(2-*tert*-Butoxycarbonylaminoethyl)-{2-[2-(2-chloroacetylamino)acetylamino]ethyl}carbamic Acid *tert*-Butyl Ester 15. Compound **14** (0.5 mmol, 0.292 g) was dissolved in 20% piperidine in DMF (4 mL). After 15 min the reaction mixture was concentrated and coevaporated with toluene (3×). The residue was dissolved in dioxane (7.5 mL) to which a solution of chloroacetic acid anhydride (0.170 g, 1 mmol) in dioxane (3 mL) was added dropwise. The reaction mixture was stirred for another 1 h and then concentrated to dryness in vacuo. The residue was taken up in EtOAc and washed with 0.1 M NaOH (2×). The organic layer was dried with $MgSO_4$, filtered, and evaporated under reduced pressure. The product was purified by silica gel column chromatography (80 → 100% EtOAc in PE) to yield 0.163 g (0.37 mmol, 75%) of compound **15**. ^{1}H NMR ($CDCl_3$): δ 4.09 (2H, s, $ClCH_2$), 3.99 (2H, bs, CH_2 Gly), 3.39 (4H, bs, 2 × CH_2), 3.29 (4H, bs, 2 × CH_2), 1.46 (9H, s, tBu), 1.44 (9H, s, tBu). ^{13}C{^{1}H} NMR ($CDCl_3$): δ 168.4 (C═O amide), 166.5 (C═O amide), 158.0, 156.1 (C═O Boc), 80.4, 79.5 (C_q, tBu), 48.0, 47.3, 42.9, 42.3, 39.3, 39.2 (6 × CH_2), 28.3 (2 × tBu). ES MS: 437.2 $(M + H)^+$.

***N*-{[2-(2-Aminoethylamino)ethylcarbamoyl]methyl}-2-chloroacetamide 16.** To a solution of compound **15** (0.140 g, 0.32 mmol) was added TFA (4 mL), and the reaction mixture was stirred for 15 min. TLC analysis indicated complete disappearance of the starting compound into a baseline product. The mixture was concentrated and coevaporated with toluene under reduced pressure to yield a light yellow oil. The residue was dissolved in water and divided over 10 eppendorfer vessels (∼30 μmol/vessel) and lyophilized. ^{1}H NMR (CD_3OD): δ 4.15 (2H, s, $ClCH_2$), 3.93 (2H, s, CH_2 Gly), 3.57−3.51 (2H, m, CH_2), 3.39−3.35 (4H, m, 2 × CH_2), 3.26−3.21 (2H, m, CH_2). ^{13}C{^{1}H} NMR (CD_3OD): δ 174.8, 173.3 (C═O, amide), 50.5, 47.0, 45.4, 44.7, 38.5, 38.1 (6 × CH_2). ES MS: 236.9 $(M + H)^+$.

Synthesis of PNA−Peptide−DETA Conjugates 1a, 1b. The PNA−peptide conjugates **12a** or **12b** (approximately 0.2 μmol) were dissolved in an aqueous buffered solution (300 μL) containing 0.05 M tris(2-carboxyethyl)-phosphine (TCEP) and 0.1 M Na_2HPO_4. Compound **16** (30 μmol) was dissolved in the same buffer solution (150 μL) and added. After adjustment of the pH to 8 (2 M NaOH), the solution was shaken overnight. The progress of the reaction was monitored by LC-MS analysis. RP HPLC gave homogeneous **1a** or **1b**. PNA−peptide−DETA conjugate **1a**: LC-MS: 5−55% B, t_R = 11.9min; ES MS: found/calcd: 2272.2/2271.5 $(M + 2H)^{2+}$, 1514.4/1514.6 $(M + 3H)^{3+}$, 1136.6/1136.2 $(M + 4H)^{4+}$, 909.2/909.2 $(M + 5H)^{5+}$, 758.0/757.8 $(M + 6H)^{6+}$. MALDI TOF MS: found/calcd: 4544/4542 $(M + H)^+$, 2272/2271 $(M + 2H)^{2+}$. PNA−peptide−DETA conjugate **1b**: LC-MS: 5−50% B, t_R = 12.9 min; ES MS: found/calcd: 2266.2/2265.9 $(M + 2H)^{2+}$, 1511.0/1510.9 $(M + 3H)^{3+}$, 1133.4/1133.5 $(M + 4H)^{4+}$, 906.8/907.0 $(M + 5H)^{5+}$, 756.4/756.0 $(M + 6H)^{6+}$. MALDI TOF MS: found/calcd: 4528/4531 $(M + H)^+$.

Synthesis of PNA 17. The N-terminal Fmoc group in resin **10** (18 mg, 3.5 μmol) was cleaved with 20% piperidine/NMP followed by thorough washing of the resin with NMP and DCM. The resin was treated with Ac_2O/lutidine/NMP (5:6:89, 4 mL) for 2 min and then washed with NMP (3×) and DCM (3×). Treatment with TFA/TIS/H_2O (90:5:5, 4 mL) for 2 h at ambient temperature led to the desired product **17**, which was precipitated from Et_2O and purified by RP-HPLC. LC-MS: 5−35% B, t_R = 14.9min; ES MS: found/calcd: 1460.8/1460.5 $(M + 2H)^{2+}$, 973.8/974.0 $(M + 3H)^{3+}$. MALDI TOF MS: found/calcd: 2921/2920 $(M + H)^+$.

Synthesis of PNA−DETA 18. PNA **17** (approximately 0.5 μmol) was dissolved in a buffered solution (200 μL) containing 0.1 M tris(2-carboxyethyl)phosphine (TCEP) and 0.1 M Na_2HPO_4. The mixture was shaken for 1 h followed by addition of the DETA derivative **16** (30 μmol) dissolved in the same buffer solution (200 μL). After adjustment of the pH to 8 (2 M NaOH), the solution was shaken overnight and the product was purified by RP HPLC. LC-MS: 5−35% B, t_R = 10.6min; ES MS: found/calcd: 1517.2/1516.5 $(M + 2H)^{2+}$, 1011.4/1011.3 $(M + 3H)^{3+}$. MALDI TOF MS: found/calcd: 3032/3032 $(M + H)^+$.



In Vitro RNA Degradation Studies. All buffers were made from highly purified Milli Q water and were sterilized before use. The radioactively labeled RNA 25-mer and the conjugate to be tested (**1a**, **1b**, **12b**, or **18**) were mixed in a Tris·HCl buffer (10 mM, pH 7) containing NaCl (100 mM) and EDTA (0.1 mM) to give the following concentrations: [RNA] = 60 nM, [conjugate] = 2 μM, as determined by A_{260} units. The samples (70 μL) were incubated at 40 °C for 16 h. After incubation, the RNA was immediately precipitated by addition of 3 M NaOAc (pH 5, 7 μL), EtOH (225 μL), and 10 μg μL^{-1} tRNA (1 μL). The precipitated RNA was recovered by centrifugation, dried, and then redissolved in 5 μL of H_2O and 5 μL of loading buffer. The solutions were heated at 80 °C for 1 min, centrifuged, and analyzed on a 20% denaturing polyacrylamide electrophoresis gel. The gel was exposed to a phosphor screen (Molecular Dynamics), and the intensity of the RNA fragments was quantified by scanning the exposed screen on the Personal Molecular Imager FX System (Bio-Rad) followed by computer analysis with Quantity One software (Bio-Rad).

RESULTS AND DISCUSSION

The synthesis of the target compound **1a** (Scheme 2) entails two distinct stages. First, PNA−peptide conjugate **12a** (Scheme 1) is prepared by native chemical ligation (*23*, *24*) of the separately prepared peptide thioester **7a** and the *S-tert*-butylthio-protected cysteine-functionalized PNA derivative **11**. The advantage of using chemical ligation is that the resulting PNA−peptide conjugate **12a** contains an exposed sulfhydryl group which can be directly used for the installation (see Scheme 2) of the DETA moiety **16** in the second step, to afford the target compound **1a**.

Peptide thioester **7a**, as depicted in Scheme 1, was prepared according to protocols developed by Pessi et al. (*25*). Thus, commercially available 4-sulfamylbutyryl safety-catch resin **2** was loaded with *N*-Fmoc-Gly-OH (5 equiv) using the coupling reagent PyBOP at temperatures ranging from −40 °C to −20 °C. Fmoc deprotection with piperidine was followed by BOP/HOBT-mediated condensation of the resulting free amine with *N*-Fmoc-5-aminopentanoic acid to give resin **4a**. Peptide elongation was executed using standard solid-phase Fmoc chemistry employing the amino acid building blocks *N*-Fmoc-Phe-OH and *N*-Fmoc-Lys(Boc)-OH. Final elon-

Scheme 1[a]

[a] Reagents and conditions: (i) TMS−CHN_2, THF/DMF, (ii) $HSCH_2CH_2CO_2Et$, NaSPh, (iii) 95% TFA/H_2O, (iv) 20% piperidine, (v) TFA/TIS/H_2O (90:5:5), (vi) 0.1 M TCEP, 6 M guanidine·HCl, 0.1 M Na_2HPO_4, pH 7.5, 4% (v/v) thiophenol.

gation with *N*-Boc-Lys(Boc)-OH led to the immobilized peptide **5a**. Cleavage of the peptide from the resin was achieved by subsequent alkylation of the sulfonamide in **5a** using trimethylsilyldiazomethane (*25*) and substitution of resulting **6a** with excess ethyl 3-mercaptopropionate in the presence of a catalytic amount of sodium thiophenolate. Cleavage of all Boc protective groups from the released peptide thioester with 95% TFA/H_2O afforded compound **7a**, which was sufficiently pure, as gauged by LC-MS analysis, for the crucial native chemical ligation step.

The decameric PNA derivative **11**, having a sequence complementary to the start codon region of the mRNA of the essential *E. coli acpP* gene and the N-terminal *S*-*tert*-butylthio protected cysteine residue, was assembled (see Scheme 1) on a solid support according to standard PNA synthesis protocols following Fmoc strategy (*26*). Thus, removal of the Fmoc group on the commercially available Rink Amide-Tentagel resin **8** with piperidine was followed by sequential elongation with Fmoc/benzhydryloxycarbonyl (Bhoc)-protected PNA building blocks **9** using the activating agent HATU (*27*) and a mixture of the bases DiPEA and lutidine (*28*). The elongation process was terminated by coupling with *N*-Fmoc-*S*-*tert*-butylthio-protected cysteine to give immobilized PNA oligomer **10**. The resin was subjected to TFA, resulting in deblocking of the Bhoc protective groups and concomitant release from the resin to afford the required major product Cys(S*t*Bu)-PNA **11** as judged by LC-MS analysis. It is worth mentioning that the cysteine *S*-*tert*-butylthio protecting group is resistant to TFA treatment, thus preventing scavenging of released benzhydryl cation by the thiol group (*26*).

At this stage, conjugate **12a** was assembled by native chemical ligation of the crude peptide thioester **7a** with the crude PNA derivative **11**. Accordingly, Cys(S*t*Bu)-PNA **11** and an excess of peptide thioester **7a** were dissolved in a denaturing phosphate buffer (0.1 M Na_2HPO_4, pH 7.5, 6 M guanidine·HCl) containing the water-soluble reducing agent tris3(2-carboxyethyl)phosphine (TCEP, 0.1 M) for the in situ unmasking of the cysteine *tert*-butylthio protective group. Additionally, an excess of thiophenol (4% (v/v)) was used as a ligation enhancer (Scheme 1).

LC-MS analysis, after 16 h incubation at ambient temperature (Figure 3), revealed complete conversion of the PNA derivative **11** and the corresponding *tert*-butylthio deprotected analogue, into the conjugate **12a**. Furthermore, we observed impurities originating from the synthesis of the PNA fragment **11** (peaks a, Figure 3) and byproducts having a mass corresponding to a possible intramolecular lactamization of the excess peptide **7a** (peaks b and c, Figure 3). RP-HPLC purification of the cude ligation product afforded homogeneous **12a**,

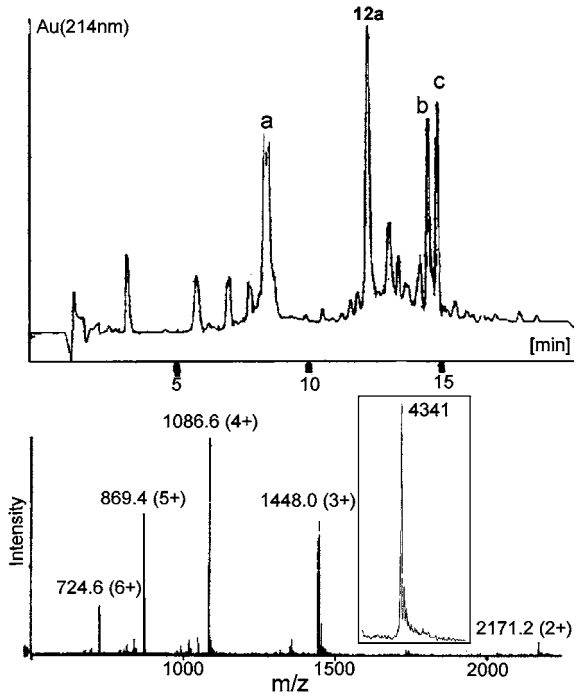


Figure 3. Top: HPLC chromatogram of the native chemical ligation mixture between thioester **7a** and Cys(S-*t*Bu)-PNA **11** after overnight incubation. The product **12a** is seen as a distinct peak together with byproducts from the PNA synthesis (peak a) and presumably lactamized peptide thioester **7a** (peaks b, c). Bottom: ES MS and MALDI-TOF MS (insert) of the purified product **12a**.

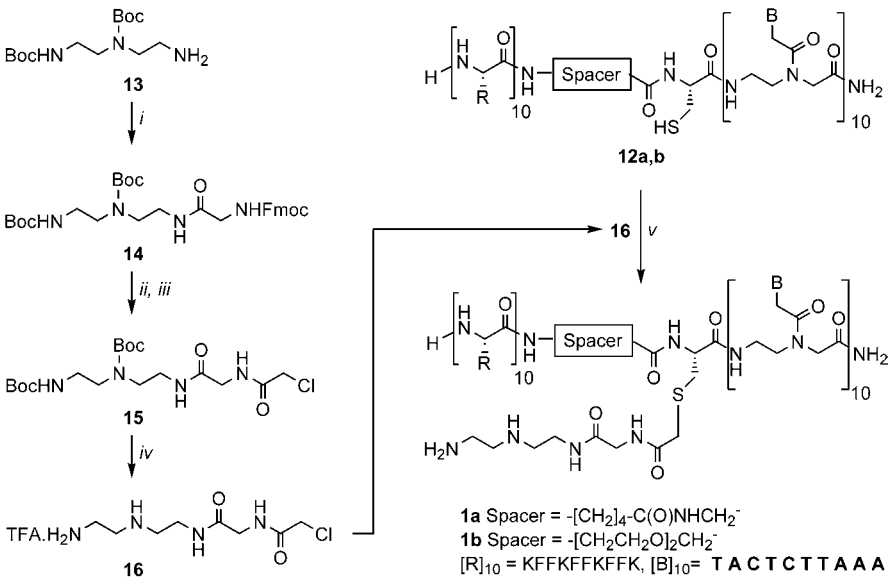
Table 1. MALDI TOF MS Values for the Conjugates

compound	spacer	MALDI (found) $(M + H)^+$	MALDI (calcd) $(M + H)^+$
18	–	3032	3032
12a	$(CH_2)_4C(O)NHCH_2$	4341	4342
12b	$(CH_2CH_2O)_2CH_2$	4329	4331
1a	$(CH_2)_4C(O)NHCH_2$	4544	4542
1b	$(CH_2CH_2O)_2CH_2$	4528	4531

the identity of which was ascertained by LC-MS analysis and MALDI-TOF mass spectrometry (Figure 3, Table 1).



Having the PNA−peptide conjugate **12a** in hand, we focused attention on the construction of the DETA moiety **16** required for the intended condensation with the conjugate **12a** (Scheme 2). The synthesis of chloride **16** commenced with a BOP/HOBT-mediated coupling of the known di-Boc-protected diethylenetriamine **13** (9) with *N*-Fmoc-glycine to afford the Fmoc/Boc-protected compound **14** in 78% yield. Subsequent removal of the Fmoc group in **14** with piperidine and treatment of the resulting free amine with chloroacetic anhydride led to conversion of **14** into the chloride **15** in 75% yield. Removal of the Boc protective groups with TFA gave the target compound **16** as the TFA salt in a near quantitative yield.

Condensation of PNA−peptide conjugate **12a** with an excess of DETA derivative **16** (see Scheme 2) was executed under buffered conditions (0.1 M Na_2HPO_4) at pH 8. The buffer contained an additional amount of TCEP to prevent dimerization of **12a** by disulfide formation. LC-MS analysis (Figure 4), after 16 h incubation at room temperature, showed complete consumption of all starting material **12a** and formation of the product **1a**. HPLC purification afforded homogeneous **1a** as judged by LC-MS and MALDI-TOF analysis (Figure 4, Table 1).

With the objective to study the influence of the type of spacer connecting the PNA and the peptide units, compound **1b** containing an ethylene glycol linker was prepared. To this end, the safety-catch resin **2** (see Scheme 1) was loaded with the Fmoc-protected ethylene glycol spacer **3** to give immobilized **4b** which was processed further, as described for **7a**, to give peptide thioester **7b**. Compounds **12b** and **1b** were assembled starting from **7b** according to similar procedures as described earlier for the synthesis of **12a** and **1a** (Schemes 1 and 2, Table 1).

Additionally, compound **18**, lacking the $(KFF)_3K$ peptide, was synthesized to serve as a positive control (Scheme 3). Thus, the Fmoc group on immobilized PNA **10** was removed with piperidine followed by acetylation of the resulting free amine with Ac_2O. The resin was then treated with TFA/TIS/H_2O (90:5:5), leading to simultaneous cleavage of the Bhoc protection groups and release of the desired PNA derivative **17**, which was purified by RP-HPLC. Finally, **17** and chloride **16** were condensed

Scheme 2[a]

[a] Reagents and conditions: (i) Fmoc-Gly-OH, BOP, HOBT, DiPEA; 78%, (ii) 20% piperidine/DMF, (iii) $(ClCH_2CO)_2O$, 75% (two steps), (iv) 50% TFA/DCM, (v) **16**, buffer (0.05 M TCEP, 0.1 M Na_2HPO_4, pH 8).

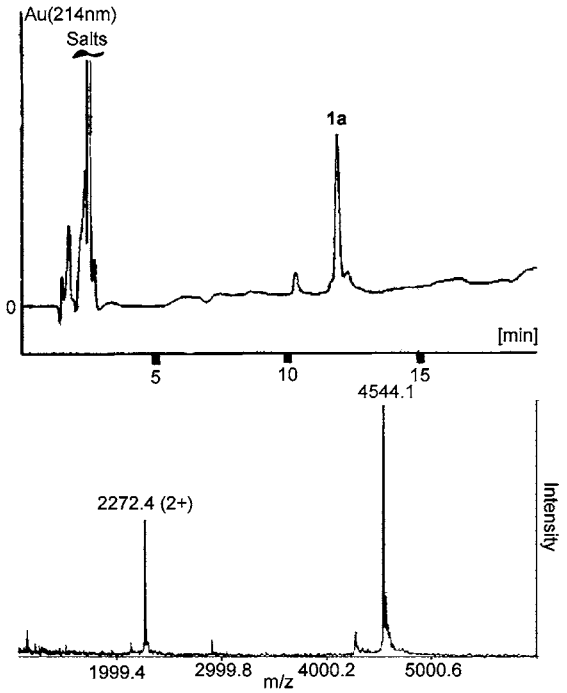


Figure 4. Top: HPLC chromatogram of the reaction mixture after overnight reaction of compounds **12a** and **16**. The product **1a** is seen as a distinct peak. Bottom: MALDI-TOF MS of the pure product **1a**.

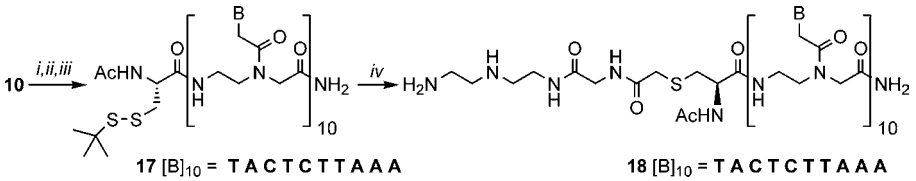
as described earlier for the conversion of **12a** into **1a** to afford the desired product **18**, which could be readily purified by HPLC.

Having the requisite compounds in hand, we turned our attention to the in vitro degrading abilities of both PNA−peptide−DETA conjugates **1a**,**b**, the PNA−DETA **18** and the PNA−peptide conjugate **12b** as a negative control. To this end, the compounds were incubated with the 25-mer ^{32}P-labeled RNA having a sequence resembling part of the *E. coli acpP* mRNA. After 16 h at 40 °C and pH 7, the RNA fragments were precipitated, applied to a 20% denaturing polyacrylamide electrophoresis gel, and quantified.



A representative gel is depicted in Figure 5 (left) whereas the quantification is shown as the average result of three separate experiments (Figure 5, right). Gratifyingly, incubation of the RNA with the conjugates **1a** and **1b** as well as the PNA−DETA **18**, lacking the $(KFF)_3K$ peptide sequence, led to the formation of two major RNA degradation products stemming from cleavage at the CA and the UA sites marked in Figure 5. The cleavage sites were determined by comparison of the mobility of the bands with those of a T1 digest of the RNA (Figure 5) and a basic hydrolysis ladder (not shown). The intensity of the fragment spots revealed that incubation of the RNA with PNA−DETA **18** resulted in significant cleavage (20%) of the RNA compared to the negative controls (i.e. PNA−peptide conjugate **12b** and RNA without any conjugate added), which only showed background cleavage of approximately 3.5%. An unexpected difference between the hydrolysis efficiency of conjugates **1a** and **1b** was observed. Conjugate **1a** showed an even improved cleavage efficiency (30%) compared to the positive control **18** (20%), whereas conjugate **1b** cleaved only 10% of the target RNA. This difference in hydrolysis ability renders conjugate **1a** three times more potent than conjugate **1b**.

CONCLUSIONS

We have reported a straightforward route to the synthesis of unprecedented, highly functionalized PNA derivatives **1a** and **1b** based on native chemical ligation between the membrane permeable peptide thioesters **7a** or **7b** and the cysteine-containing antisense PNA derivative **11**. The exposed cysteine side-chain residue in the resulting PNA−peptide conjugates was exploited for the installation through a thioether bond of a DETA-based RNA cleaving agent.

In addition, we have demonstrated that the two trifunctional conjugates **1a** and **1b**, differing only in the type of spacer connecting the PNA and the peptide, both hydrolyzed the complementary 25-mer RNA at two major cleavage sites under physiological conditions. The re-

Scheme 3[a]

[a] Reagents and conditions: (i) 20% Piperidine/NMP, (ii) Ac_2O/Lutidine/NMP (5:6:89), (iii) TFA/TIS/H_2O (90:5:5), (iv) **16**, 0.1 M Na_2HPO_4, 0.1 M TCEP, pH 8.

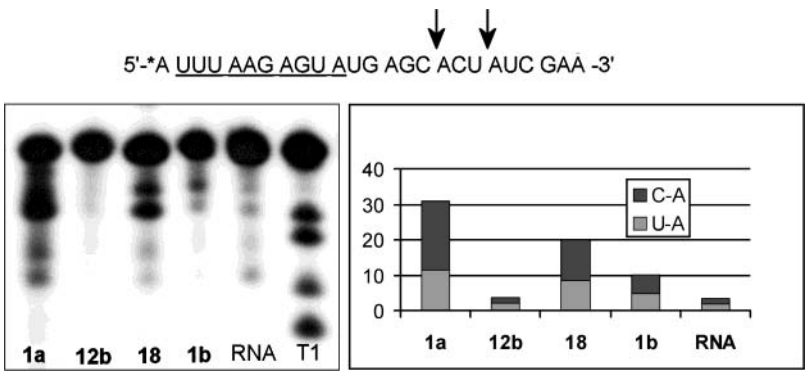


Figure 5. Top: Major cleavage sites of the target 25-mer RNA. The PNA binding region is marked underlined. Left: Autoradiograph for the cleavage of the 5′-labeled RNA 25-mer, after 16 h at pH 7 and 40 °C of compounds **1a**, **12b**, **18**, **1b**, RNA (no additives), T1 (T1 digestion); $[RNA]_0 = 60$ nM, [Conjugates] = 2 μM. Right: Average cleavage efficiency (in % degradation of mRNA) over three experiments.

markable difference in the cleaving efficiency of the two conjugates (**1a** is three times more potent than **1b**) indicate that the choice of spacer may have a great influence on the properties of the conjugate (*29*). On the other hand, the presence of the peptide does not seem to have a decisive effect on the cleavage capabilities. Although the RNA hydrolysis activity of conjugates **1a**,**b** is somewhat lower than the earlier by us reported PNA−DETA conjugate (*9*), it is still considerably improved compared to the DNA−DETA conjugate of Komiyama and co-workers (*30*). Other amine-based RNA-cleaving moieties, e.g. cyclen which efficiently hydrolyzed the HIV-1 TAR−RNA (*31*), can be easily implemented in our synthetic strategy and may further enhance the cleavage activity. Currently, the bacterial uptake of the conjugates **1a**,**b** and their effects on cell proliferation is in progress, and these results will be reported in due course.

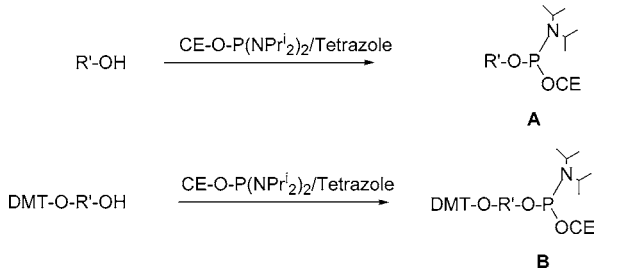
A Modular Approach to the Synthesis of New Reagents Useful in the Chemical Synthesis of Modified DNA Probes: Derivatives of 3-(*tert*-Butyldimethylsiloxy)glutaric Anhydride as Versatile Building Blocks in the Synthesis of New Phosphoramidites and Modified Solid Supports

Zbigniew Skrzypczynski* and Sarah Wayland

Third Wave Technologies, 502 South Rosa Road, Madison, Wisconsin 53719. Received December 9, 2003; Revised Manuscript Received March 17, 2004

We present a flexible and cost-efficient synthetic strategy for the preparation of a new family of phosphoramidite and solid-support reagents that can introduce a broad range of modifications into DNA probes. The key intermediate material **3** is synthesized using the inexpensive and commercially available 3-(*tert*-butyldimethylsiloxy)glutaric anhydride **1** and can be used as common starting material for the preparation of new labeling reagents.

INTRODUCTION



Chemically modified DNA probes and their conjugates play increasingly sophisticated roles in the disparate areas of biotechnology (*1*−*15*) medicine (*16*−*34*), and nanotechnology (*35*−*44*). Recent chemical literature reports the synthesis of a variety of reagents and modified solid supports that allow modifications to be introduced into the structure of chemically synthesized oligonucleotides (*45*−*67*). Among the many existing synthetic methods, the phosphoramidite approach is used most frequently in the synthesis of a wide variety of modified DNA probes (*68*−*73*). The efficiency and synthetic flexibility of the phosphoramidite method in preparing modified DNA probes continually stimulates interest in the development of new cost- and labor-efficient methods to prepare phosphoramidite reagents that expand the scope of available DNA probe modifications.

Generally, phosphoramidite reagents used in the synthesis of modified DNA probes can be divided into two groups: A and B (Scheme 1). Group A phosphoramidites introduce the modification into the 5′ loci of the synthesized oligonucleotide, and group B phosphoramidites introduce the modification into the 3′ or 5′ or internal loci of the synthesized DNA molecule.

Group A phosphoramidites can be prepared with the appropriate starting compound R′ that has a hydroxyl group available for further transformations. All other functional groups of compound R′ should be blocked with protecting groups that are compatible with the phosphoramidite method of oligonucleotide synthesis (*74*). The synthesis of group B phosphoramidites, however, requires preparation of an intermediate material that contains two hydroxyl groups, one of which must be selectively protected with a DMT protecting group, and one that is kept available for the phosphitylation reaction. In consequence, the preparation of group B reagents requires more labor and time-consuming synthetic effort.

Scheme 1. Preparation of Phosphoramidite Reagents for Terminal and Internal Oligonucleotide Labeling

Here we report a flexible and effective strategy for the synthesis of a new family of phosphoramidite reagents and specifically modified solid supports.

MATERIALS AND METHODS

Abbreviations used: DCC, 1,3-Dicyclohexylcarbodiimide; DMAP, 4-(dimethylamino)pyridine; DMF, *N*,*N*-dimethylformamide; EDAC, 1-ethyl-(3-dimethylaminopropyl)carbodiimide hydrochloride; HBTU, *O*-benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium; HOBT, 1-hydroxybenzotriazole hydrate; TBAF, tetrabutylammonium fluoride; TBDMS, *tert*-butyldimethylsilyl; TEA, triethylamine; THF, tetrahydrofuran.

Instruments and Reagents. HPLC analyses were performed with a Hitachi D-7000 Interface, L-7100 gradient pump, and L-7400 UV detector using a Varian Omnisphere 5 C18 column (250 × 4.6 mm) and 100 mM TEAA, pH 7/acetonitrile gradients. MS analysis of all DNA-containing species was performed using a PerSeptive Biosystems Voyager-DE Biospectrometry Workstation V800520. MS analysis of small molecules was performed using an Applied Biosystems/MDS Sciex API 365 LC/MS/MS triple quadrapole with an electrospray ionization source. Automated oligonucleotide synthesis was performed using a PerSeptive Biosystems Expedite Nucleic Acid Synthesis System. Silica gel was obtained from Sigma-Aldrich (Milwaukee, WI). Analytical TLC was carried out on EM Science F_{254} glass-backed fluo-

rescence indicator plates. Lcaa-CPG, used in the synthesis of **10c** and **10d**, was obtained from Glen Research (Sterling, VA). DNA synthesis reagents and columns were purchased from Applied Biosystems (Foster City, CA). All other reagents were purchased from Sigma-Aldrich and used without further purification. Solvents were dried over activated 3 Å molecular sieves.

Synthesis of Ethanolamine Trifluoroacetamide. In a round-bottom flask, methyl trifluoroacetate (10.5 g, 81.9 mmol) was added to neat ethanolamine (4.0 g, 66 mmol) at room temperature with continuous stirring. Reaction completion was determined by the absence of ninhydrin activity. After 2 h, the reaction was concentrated by rotary evaporation and purified by distillation (11 mmHg, bp 127 °C), yielding a colorless oil, 9.5 g, 93%.

Synthesis of *O*-Dimethoxytrityl Ethanolamine Trifluoroacetamide. Ethanolamine trifluoroacetamide (4.5 g, 29 mmol) was dissolved in 100 mL pyridine in a round-bottom flask. With stirring, 4,4′-dimethoxytrityl chloride (9.7 g, 29 mmol) was added to the solution as a solid. After being stirred 2 h, the slurry was filtered, and the filtrate was concentrated by rotary evaporation. The residue was purified by silica column chromatography (25% ethyl acetate/75% hexane). The product was obtained as a yellow oil (12 g, 91%). $R_f = 0.56$ (25% ethyl acetate/75% hexane).

Synthesis of *O*-Dimethoxytrityl Ethanolamine. *O*-Dimethoxytrityl ethanolamine trifluoroacetamide (12 g, 26 mmol) was dissolved in 400 mL methanol. Subsequently, 400 mL of concentrated ammonium hydroxide was added to the flask with continuous stirring. The reaction mixture was stirred for 16 h at room temperature. The mixture was concentrated by rotary evaporation, and the crude product was purified by silica column chromatography (2% methanol/5% TEA/methylene chloride), yielding a yellow oil, 9.2 g, 97%. $R_f = 0.41$ (5% methanol/5% TEA/methylene chloride). ^{1}H NMR, CD_3CN, 400 MHz, δ 7.45 (m, 2H), 7.31 (m, 6H), 7.22 (t, 1H), 6.86 (m, 4H), 3.76 (s, 6H), 3.02 (t, 2H), 2.78 (t, 2H), 2.07 (s, 2H) ppm. ESI-MS: calculated for $C_{23}H_{24}NO_3$ $(M + K)^+$ 402, found 402.

Synthesis of 2, R′ = CH_2CH_2. A 250 mL round-bottom flask was charged with *O*-dimethoxytrityl ethanolamine (4.0 g, 11 mmol), *N*,*N*-diisopropylethylamine (2.1 g, 16 mmol), and 50 mL of acetonitrile. 3-(*tert*-Butyldimethylsilyloxy)glutaric anhydride **1** (3.0 g, 12 mmol) was added as a solid with stirring. After 2h, the reaction was concentrated and the crude material was purified by silica column chromatography (2% methanol/5% TEA/methylene chloride), yielding a white solid, 6.4 g, 96%. $R_f = 0.35$ (2% methanol/5% TEA/methylene chloride). ^{1}H NMR, CD_3CN, 400 MHz, δ 7.43 (m, 2H), 7.30 (m, 6H), 7.22 (m, 1H), 6.85 (m, 5H), 4.96 (s, 1H), 4.42 (m, 1H), 3.76 (s, 6H), 3.35 (m, 2H), 3.04 (m, 2H), 2.40 (m, 4H), 0.82 (s, 9H), 0.05 (s, 3H), 0.01 (s, 3H) ppm. ESI-MS: calculated for $C_{34}H_{45}NO_7Si$ $(M + K)^+$ 646, found 646.

Synthesis of 3, R′ = CH_2CH_2. Combined material **2** (4.8 g, 7.9 mmol) and 100 mL 1,4-dioxane. *N*-hydroxysuccinimide (1.16 g, 10.1 mmol) and DCC (2.66 g, 12.9 mmol) were added as solids and the reaction was stirred for 1h. The slurry was filtered and the filtrate was evaporated to a residue that was purified by silica column chromatography (ethyl acetate). Compound **3,** R′ = CH_2CH_2, was obtained as an off-white solid (5.2, 93%). $R_f = 0.62$ (ethyl acetate). ^{1}H NMR, CD_3CN, 400 MHz, δ 7.43 (m, 2H), 7.31 (m, 6H), 7.23 (m, 1H), 6.86 (m, 4H), 6.61 (t, 1H), 4.52 (m, 1H), 3.76 (s, 6H), 3.35 (m, 2H), 3.05 (m, 2H), 2.85 (m, 2H), 2.75 (s, 4H), 2.43 (d, 2H), 0.83 (s, 9H), 0.06 (s, 3H), 0.02 (s, 3H) ppm. ESI-MS: calculated for $C_{38}H_{48}N_2O_9Si$ $(M + K)^+$ 743, found 743.

One-Pot Synthesis of 3, R′ = CH_2CH_2. Added *O*-dimethoxytrityl ethanolamine (2.7 g, 7.4 mmol) to a solution of 3-(*tert*-butyldimethylsilyloxy)glutaric anhydride **1** (2.0 g, 8.2 mmol) in THF (100 mL) with stirring. The *O*-dimethoxytrityl ethanolamine starting material was consumed after 1 h (TLC 5% methanol/5% TEA/methylene chloride), and *N*-hydroxysuccinimide (0.94 g, 8.2 mmol) and DCC (2.3 g, 11 mmol) were added to the reaction mixture. After 4 h, the reaction slurry was filtered, and the filtrate was concentrated. The crude residue was purified by silica column chromatography (50% ethyl acetate/50% hexane), and the product was isolated as an off-white solid (3.8 g, 73%). $R_f = 0.62$ (ethyl acetate). ESI-MS: calculated for $C_{38}H_{48}N_2O_9Si$ $(M + K)^+$ 743, found 743.

Synthesis of 4a. Combined compound **3**, R′ = CH_2-CH_2 (0.55 g, 0.78 mmol), with 1.5 mL of THF and dried overnight over activated sieves. 2-(Aminoethyl)-18-crown-6 (0.25 g, 0.85 mmol) was dissolved in 20 mL of THF and combined with the THF solution of **3**. The reaction mixture was stirred for 1 h, concentrated by rotary evaporation, and purified by silica column chromatography (5% methanol/5% TEA/methylene chloride), yielding a pale yellow solid 0.68 g, 99%. $R_f = 0.32$ (5% methanol/5% TEA/methylene chloride). ESI-MS: calculated for $C_{47}H_{70}N_2O_{12}Si$ $(M + K)^+$ 922, found 922.

Synthesis of 11. *N*-Hydroxysuccinimide (0.27 g, 2.3 mmol) and DCC (0.48 g, 2.3 mmol) were added to a solution of 1-pyrenebutyric acid (0.58 g, 2.0 mmol) in 1,4-dioxane (20 mL). The solution was stirred for 20 h at room temperature. Ethyl acetate (30 mL) was added, and the slurry was filtered. The filtrate was concentrated, and the resulting brown oil was used in the next step without further purification, 0.77 g. $R_f = 0.38$ (50% ethyl acetate/50% hexane). A solution of the prepared NHS ester of 1-pyrenebutyric acid (0.77 g, 2.0 mmol) in 1,4-dioxane (20 mL) was added to a solution of 4,7,10-trioxa-1,13-tridecanediamine (2.6 g, 12 mmol) in 1,4-dioxane (20 mL). The resulting solution was stirred for 1 h, concentrated by rotary evaporation, and purified by silica column chromatography (10% methanol/5% TEA/methylene chloride). Compound **11** was obtained as an oil (0.89 g, 90%). $R_f = 0.33$ (10% methanol/5% TEA/methylene chloride). ESI-MS: calculated for $C_{30}H_{38}N_2O_4$ $(M + H)^+$ 491, found 491.

Synthesis of 4b. A solution of **11** (0.89 g, 1.8 mmol) in acetonitrile (5 mL), THF (5 mL), and diisopropylethylamine (0.26 g, 2.0 mmol) was combined with a solution of **3**, R′ = CH_2CH_2 (1.2 g, 1.7 mmol), in THF (30 mL). The reaction mixture was concentrated after 1 h by rotary evaporation. The crude residue was purified by silica chromatography (5% methanol/5% TEA/methylene chloride), resulting in a pale yellow solid with a yield of 1.2 g, 68%. $R_f = 0.52$ (5% methanol/5% TEA/methylene chloride). ESI-MS: calculated for $C_{64}H_{81}N_3O_{10}Si$ $(M + Na)^+$ 1103, found 1103.

Synthesis of 4c. A solution of **3**, R′ = CH_2CH_2 (3.1 g, 4.4 mmol), in 1,4-dioxane (5 mL) and acetonitrile (30 mL) was added to a solution of 4,7,10-trioxa-1,13-tridecanediamine (3.8 g, 17 mmol) in acetonitrile (20 mL). The resulting slurry was stirred for 30 min, concentrated by rotary evaporation, and purified by silica column chromatography (10% methanol/5%TEA/methylene chloride) with a yield of 1.4 g, 40%. The product was confirmed by a positive ninhydrin test. $R_f = 0.34$ (10% methanol/5% TEA/methylene chloride). ESI-MS: calculated for $C_{44}H_{67}N_3O_9Si$ $(M + H)^+$ 811, found 811.

Synthesis of 12c. Biotin (0.86 g, 3.5 mmol), DMF (5 mL) diisopropylethylamine (1.4 g, 11 mmol), and HOBT (0.96 g, 7.2 mmol) were added to a round-bottom flask with stirring. A solution of **4c** (1.4 g, 1.8 mmol) in methylene chloride (5 mL) was added to the flask, and HBTU (1.2 g, 3.7 mmol) was added to the resulting mixture. After 2 h, the reaction mixture was concentrated and purified by silica column chromatography (10% methanol/5% TEA/methylene chloride). The product was obtained as an oil (1.5 g, 80%). $R_f = 0.44$ (10% methanol/5% TEA/methylene chloride). ESI-MS: calculated for $C_{54}H_{81}N_5O_{11}SSi$ $(M + Na)^+$ 1059, found 1059.

Synthesis of 4d. Compound **3**, $R' = CH_2CH_2$ (0.62 g, 0.88 mmol), was dissolved in 1,4-dioxane (10 mL) and added to a solution of polytetrahydrofuran-bis(3-aminopropyl) terminated, average M_n ca.. 1100 (3.9 g, 3.5 mmol) in 1,4-dioxane (20 mL). After stirring for 2 h, the solvent was evaporated and the residue was purified by silica column chromatography (7.5% methanol/5% TEA/methylene chloride), yielding an oil, 0.85 g, 57%. $R_f = 0.44$ (7.5% methanol/5% TEA/methylene chloride). MALDI-TOF MS: The mass dispersion of the starting bis-amine was centered at 580. The mass dispersion of the products (separated by 72 amu) was centered at 1190.

Synthesis of 12d. To a solution of **4d** (0.85 g, 0.71 mmol) in acetonitrile (10 mL) and THF (5 mL) were added diisopropylethylamine (0.26 g, 2.0 mmol) and *S*-ethyl trifluorothioacetate (0.32 g, 0.20 mmol) with stirring. The absence of ninhydrin activity after 3.5 h confirmed the complete protection of the amine group. The reaction mixture was concentrated and purified by silica column chromatography (7.5% methanol/5% TEA/methylene chloride). Desired product was isolated as an oil, 0.78 g, 85%. $R_f = 0.46$ (7.5% methanol/5% TEA/methylene chloride). ESI-MS: The mass dispersion of the products (separated by 72 amu) was centered at 1290.

Synthesis of 5a. Dissolved **4a** (0.68 g, 0.77 mmol) in 10 mL of TBAF (1.0 M in THF) and incubated for 20 min at room temperature. The solvent was evaporated, and the residue was purified by silica column chromatography (5% methanol/5% TEA/methylene chloride), yielding a pale yellow oil, 0.38 g, 64%. $R_f = 0.29$ (5% methanol/5% TEA/methylene chloride). ESI-MS: calculated for $C_{41}H_{56}N_2O_{12}$ $(M + K)^+$ 808, found 808.

Synthesis of 5b. Compound **4b** (1.2 g, 1.1 mmol) was dissolved in THF (5 mL), and TBAF (5 mL of 1.0 M in THF) was added to the resulting solution. The reaction mixture was incubated for 30 min and concentrated, and the residue was purified by silica column chromatography (2% methanol/5% TEA/methylene chloride). Material **5b** was obtained as an off-white solid (0.66 g, 60%). $R_f = 0.58$ (5% methanol/5% TEA/methylene chloride). ESI-MS: calculated for $C_{58}H_{67}N_3O_{10}$ $(M + H)^+$ 967, found 967.

Synthesis of 5c. Compound **12c** (1.5 g, 1.4 mmol) was dissolved in THF (5 mL), and TBAF (5 mL of 1.0 M in THF) was added to the resulting mixture. The reaction mixture was incubated for 1 h and concentrated, and the residue was purified by silica column chromatography (10% methanol/5% TEA/methylene chloride), yielding an oil, 1.3 g, 94%. $R_f = 0.32$ (10% methanol/5% TEA/methylene chloride). ESI-MS: calculated for $C_{48}H_{67}N_5O_{11}S$ $(M + K)^+$ 961, found 961.

Synthesis of 5d. Dissolved **12d** (0.50 g, 0.43 mmol) in 10 mL of TBAF (1.0 M in THF) and incubated for 15 min at room temperature. The solvent was evaporated, and the residue was purified by silica column chromatography (5% methanol/5% TEA/methylene chloride). Material **5d** was obtained as a pale brown solid (0.44 g, 98%). $R_f = 0.49$ (5% TEA/1,4-dioxane). MALDI-TOF MS: The mass dispersion of the products (separated by 72 amu) was centered at 1170.

Synthesis of 18. *N*-Hydroxysuccinimide (0.50 g, 4.3 mmol) and DCC (1.5 g, 7.3 mmol) were added to a vigorously stirred suspension of *p*-(*p*-dimethylaminophenylazo)benzoic acid, sodium salt (1.0 g, 3.4 mmol) in anhydrous 1,4-dioxane (30 mL). The resulting reaction mixture was stirred overnight at room temperature and subsequently diluted with 100 mL of dry ethyl acetate. The slurry was filtered, and the filtrate was concentrated yielding the dabcyl-NHS ester (1.1 g, 87%) as a dark red powder. TLC analysis confirmed the purity of the material. $R_f = 0.54$ (ethyl acetate). The isolated NHS active ester was dissolved in THF (50 mL) and immediately added to a vigorously stirred solution of 4,7,10-trioxa-1,13-tridecanediamine (10 g, 0.045mol) in THF (250 mL). The resulting reaction mixture was stirred at room temperature for 2 h and concentrated by rotary evaporation. Compound **18** was isolated by silica column chromatography (20% methanol/5% TEA/methylene chloride) as an orange solid (0.33 g, 26%). $R_f = 0.30$ (20% methanol/5% TEA/methylene chloride). ESI-MS: calculated for $C_{25}H_{37}N_5O_4$ $(M + H)^+$ 472, found 472.

One-Pot Synthesis of 21. 3-(*tert*-Butyldimethylsilyloxy)glutaric anhydride (0.20 g, 8.2 mmol) was added to a rapidly stirred solution of compound **18** (0.33 g, 7.1 mmol) and *N*,*N*-diisopropylethylamine (0.10 g, 7.8 mmol) in 10 mL of 1,4-dioxane. After 15 min, TLC analysis indicated the disappearance of the starting material and the formation of a new product, $R_f = 0.48$ (10% methanol/5% TEA/methylene chloride). In the subsequent step, *N*-hydroxysuccinimide (0.12 g, 1.0 mmol) and DCC (0.42 g, 2.0 mmol) were added to the reaction mixture. The DCC was added in two aliquots, 0.22 g initially and 0.20 g after 1 h. The resulting reaction mixture was stirred at room temperature for an additional 15 h. TLC analysis of the reaction mixture indicated the formation of a new, less polar material, $R_f = 0.58$ (1,4-dioxane). In the final step, 2-(2-aminoethoxyethyl)ethanol (0.73 g, 7.0 mmol) was dissolved in 4 mL of dry THF and added to the rapidly stirred reaction mixture described above. Stirring was continued for 1 h at room temperature. TLC analysis indicated the formation of a new product, $R_f = 0.38$ (1,4-dioxane). The reaction product was isolated by silica column chromatography (1,4-dioxane), yielding compound **21** as an orange solid (0.48 g, 85%). ESI-MS: calculated for $C_{40}H_{66}N_6O_9Si$ $(M + H)^+$ 804, found 804.

Synthesis of 22. Compound **21** (0.44 g, 0.55 mmol) was dissolved in 100 mL of pyridine in a round-bottom flask. With stirring, 4,4′-dimethoxytrityl chloride (0.30 g, 0.90 mmol) was added to the solution as a solid. After stirring 2 h, the solution was concentrated by rotary evaporation. The residue was purified by silica column chromatography (ethyl acetate followed by 2% methanol/5%TEA/methylene chloride). The product was obtained as an orange solid (0.40 g, 66%). $R_f = 0.20$ (5% methanol/5% TEA/methylene chloride). ESI-MS: calculated for $C_{61}H_{84}N_6O_{11}Si$ $(M + K)^+$ 1144, found 1144.

Synthesis of 5e. Compound **22** (0.40 g, 0.36 mmol) was dissolved in THF (5 mL), and tetrabutylammonium fluoride (7 mL of 1.0 M in THF) was added to the resulting solution. The reaction mixture was incubated for 30 min and concentrated, and the residue was purified by silica column chromatography (2% methanol/5% TEA/methylene chloride followed by 5% methanol/5% TEA/methylene chloride and finally 10% methanol/5% TEA/methylene chloride to elute the product), yielding an orange solid, 0.33 g, 92%. $R_f = 0.67$ (5% TEA/1,4-dioxane).

ESI-MS: calculated for $C_{55}H_{70}N_6O_{11}$ $(M + K)^+$ 1030, found 1030.

Synthesis of 8a. 5a (0.38 g, 0.50 mmol) was dissolved in methylene chloride (8 mL), and to the resulting solution were added 2-cyanoethyl-*N*,*N*,*N*′,*N*′-tetraisopropyl phosphorodiamidite (0.18 g, 0.59 mmol) and tetrazole (0.83 mL of 0.45 M in acetonitrile) with vigorous swirling. The reaction mixture was vortexed at room temperature, and after 1 h, additional 2-cyanoethyl-*N*,*N*,*N*′,*N*′-tetraisopropyl phosphorodiamidite (0.18 g, 0.59 mmol) was added. After 1.5 h, methylene chloride (30 mL) was added to the reaction to increase the volume, and the crude solution was washed with 5% sodium bicarbonate/0.5% TEA (50 mL). The organic layer was dried over magnesium sulfate for 10 min, filtered, concentrated, and coevaporated twice with acetonitrile (10 mL). The residue was dissolved in acetonitrile (6 mL) and dried over several granules of calcium hydride. The product solution was aliquoted (3 aliquots of 2 mL, 155 μmol) into amber Expedite bottles, concentrated by aspiration vacuum, and then dried overnight under vacuum in a desiccator over phosphorus pentoxide (0.45 g, 94%). $R_f = 0.63$ (5% TEA/1,4-dioxane).

Synthesis of 8b. Compound **5b** (0.66 g, 0.68 mmol) was dissolved in methylene chloride (5 mL). 2-Cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite (0.25 g, 0.82 mmol) was added, followed by the addition of tetrazole (1.2 mL of 0.45 M in acetonitrile) with vigorous swirling. The reaction was vortexed at room temperature for 3 h. Methylene chloride (50 mL) was added to the reaction to increase the volume, and the crude solution was washed with 5% sodium bicarbonate/0.5% TEA (75 mL). The organic layer was dried over magnesium sulfate, filtered, concentrated, and coevaporated twice with acetonitrile (10 mL). The residue was dissolved in acetonitrile (6 mL) and dried over several granules of calcium hydride. The product solution was aliquoted (3 aliquots of 2 mL, 200 μmol) into amber Expedite bottles, concentrated by aspiration vacuum, and then dried overnight under vacuum in a desiccator over phosphorus pentoxide (0.76 g, 96%). $R_f = 0.52$ (5% TEA/1,4-dioxane).

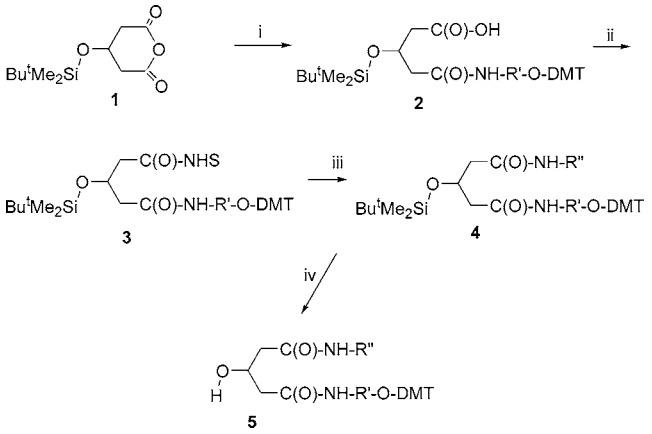
Synthesis of 8e. 5e (0.33 g, 0.33 mmol) was dissoved in methylene chloride (10 mL), and to the resulting solution were added 2-cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite (0.15 g, 0.50 mmol) and tetrazole (0.58 mL of 0.45 M in acetonitrile) with vigorous swirling. The reaction mixture was vortexed at room temperature, and after 1 h, additional 2-cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite (0.15 g, 0.50 mmol) was added. After 2 h, methylene chloride (50 mL) was added to the reaction to increase the volume, and the crude solution was washed with 5% sodium bicarbonate/0.5% TEA (75 mL). The organic layer was dried over magnesium sulfate for 10 min, filtered, concentrated, and coevaporated twice with acetonitrile (10 mL). The residue was dissolved in acetonitrile (3 mL) and dried over several granules of calcium hydride. The product solution was transferred to an amber Expedite bottles and concentrated by aspiration vacuum then dried for 1 h under vacuum in a desiccator over phosphorus pentoxide (0.37 g, 92%). $R_f = 0.83$ (5% TEA/1,4-dioxane).

Synthesis of 9c. Combined **5c** (0.24 g, 0.26 mmol), TEA (0.03 g, 0.3 mmol), and DMAP (16 mg, 0.13 mmol) in acetonitrile (20 mL). Succinic anhydride (0.04 g, 0.4 mmol) was added, and the resulting mixture was stirred for 17 h under a drying tube. The solvent was evaporated, and the crude residue was purified by silica column chromatography (10% methanol/5% TEA/methylene chloride). Compound **9c** was obtained as a white solid (0.28 g, 95%). $R_f = 0.1$ (10% methanol/5% TEA/methylene chloride). ESI-MS: calculated for $C_{52}H_{71}N_5O_{14}S$ $(M + H)^+$ 1123, found 1123.

Synthesis of 9d. Combined **5d** (0.44 g, 0.42 mmol), TEA (0.05 g, 0.5 mmol), and DMAP (26 mg, 0.21 mmol) in acetonitrile (30 mL). Succinic anhydride (0.06 g, 0.6 mmol) was added, and the resulting mixture was stirred for 3.5 h under a drying tube. The solvent was evaporated and the crude residue was purified by silica column chromatography (2% methanol/5% TEA/methylene chloride). Compound **9d** was obtained as an off-white solid (0.5 g, 96%). $R_f = 0.32$ (5% methanol/5% TEA/methylene chloride). MALDI-TOF MS: The mass dispersion of the product was centered at 1270.

Synthesis of 10c and 10d. One gram of lcaa-CPG (Glen Research, #20−0001, 1000A, 69 μmol/g) was added to a 50 mL round-bottom flask. Compound **9c** (0.14 g, 0.13 mmol) or compound **9d** (0.2 g, 0.16 mmol), respectively, was dissolved in 10 mL of pyridine and added to the CPG. DMAP (4 mg, 0.03 mmol), TEA (0.02 g, 0.02 mmol), and EDAC (0.12 g, 0.64 mmol) were added, and the reaction mixtures were vortexed at room temperature for 16 h. For the preparation of **10c**, additional aliquots of EDAC (total of 0.1 g, 0.5 mmol) and **9c** (total of 0.14 g, 0.13 mmol) were added to the reaction slurry to achieve a final loading of at least 10 μmol/g CPG. For the preparation of **10d**, additional aliquots of EDAC (total of 0.40 g, 2.1 mmol) and **9d** (total of 0.33 g, 0.26 mmol) were required. The support was filtered, washed with pyridine, methanol, and methylene chloride, and dried with argon flow. The material was capped with an equal mixture of 6% DMAP in acetonitrile and 2/3/5 (acetic anhydride/2,4,6-collidine/acetonitrile) (100 mL total volume) for 2 h and dried overnight under vacuum. The loading was calculated by combining a known mass of CPG and 3% dichloroacetic acid/methylene chloride and measuring A_{504} of the solution to determine the released trityl. The loading of the final products was calculated to be 18 μmol/g CPG and 10 μmol/g CPG for **10c** and **10d**, respectively.

Synthesis of 13a, 13b, 14c, 14d, 15, 16, 17, and 23. Oligonucleotide synthesis was carried out using standard phosphoramidite chemistry. Solutions of phosphoramidites **8a**, **8b**, and **8e** were prepared at 100 mM in acetonitrile and dried over calcium hydride granules prior to use. The coupling efficiency of the phosphoramidite **8e** was strongly dependent on the drying time over calcium hydride. In the case of **8e**, we applied extended coupling times (3 × 10 min).



Modified CPGs **10c** and **10d** were used in Expedite columns at 1.0 μmol. Following synthesis, the support was incubated for 17 h at 55 °C in concentrated ammonium hydroxide. Volatile components were evaporated under vacuum, and the crude material was purified by C18 RP-HPLC. The purified product was confirmed by MS analysis.

RESULTS AND DISCUSSION

Our synthetic strategy is outlined in Scheme 2. This method uses commercially available and relatively inexpensive 3-(*tert*-butyldimethylsiloxy)glutaric anhydride **1** as the starting material that reacts easily with the primary amine H_2N-R′-OH containing a DMT-protected hydroxyl group, leading to the formation of **2**. Compound **2** can be converted into its NHS active ester **3** representing a key intermediate material used in the subsequent transformations

The group R′ in the structure of active ester **3** can be selected from a wide variety of hydroxy amines, depend-

Scheme 2. Synthesis of Compounds 2−5[a]

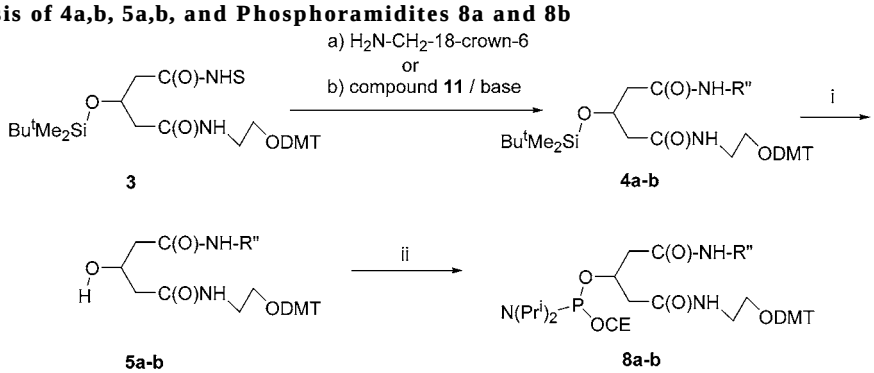
ing on the specific purpose of the intended modification (i.e. linker length, physicochemical or spectral properties). In the subsequent step, compound **3** can be easily converted into compound **4** by reacting with the amine H_2N-R″. Removal of the TBDMS group from material **4** leads to the formation of the compound **5** possessing a deprotected secondary hydroxyl group. In the next step of the described procedure, synthesized compound **5** is transformed into phosphoramidite **8** or modified solid support **10** as illustrated in Scheme 3. Both Schemes 2 and 3 represent general overviews which outline both the structures of the materials available from the 3-(*tert*-butyldimethylsiloxy)glutaric anhydride **1** and the reaction sequences leading to the preparation of new phosphoramidites **8** and solid supports **10**. Detailed structures of the prepared materials are presented in subsequent sections of this paper.

For our experiments, we selected R′ = CH_2CH_2 due to the relative ease of preparing *O*-DMT-protected ethanolamine. The reaction between the anhydride **1** and the *O*-DMT-protected ethanolamine was efficient and straightforward and led to the formation of an intermediate material **2**, R′= CH_2CH_2, which was isolated easily by silica gel column chromatography. However, the preparation of compound **2**, R′= CH_2CH_2, was associated with the formation of a trace amount of material that had a higher polarity than the desired reaction product. The mass spectral analysis and TLC mobility (R_f) of the isolated impurity were identical to those of the material formed when compound **2**, R′= CH_2CH_2, was treated with TBAF solution (*75*). No detailed study addressing the conditions promoting the formation of a trace amount of the desilylated material was conducted. To overcome this minor inconvenience and to simplify the synthetic protocol, we demonstrated that the active ester **3**, R′= CH_2-CH_2, could be synthesized in a one-pot procedure without isolating the corresponding intermediate material **2**.



The relatively low polarity of material **3**, R′= CH_2CH_2, enabled fast and efficient purification by silica gel flash chromatography using ethyl acetate or ethyl acetate/hexane as a mobile phase. We have found that compound **3**, R′= CH_2CH_2, was stable when stored in its crystalline form at 4 °C for six months. In addition, its preparation was easily scaled up. Synthesized NHS ester **3**, R′= CH_2-CH_2, represents the key intermediate material. Schemes 4 and 5 illustrate the synthesis of four different com-

pounds **5a**−**d** from the same starting material **3**, (R′ = CH_2CH_2).

Compounds **4a** and **4b** (Scheme 4) were synthesized correspondingly by the direct reaction of NHS ester **3**, R′= CH_2CH_2, with commercially available 2-(aminomethyl)-18-crown-6 (*76*, *77*) or with the amino derivative of the pyrene butyric acid **11** (*78*−*82*)**.** Removal of the TBDMS from synthesized compounds **4a** and **4b** with the THF solution of TBAF under standard reaction conditions (*75*) yielded compounds **5a** and **5b** with deprotected secondary hydroxyl groups. In the subsequent step, synthesized compounds **5a** and **5b** were converted into phosphoramidites **8a** and **8b**, as illustrated in Scheme 4. When used in the synthesis of 5′-modified probes **13a** and **13b**, these phosphoramidites demonstrated full

13a

13b

compatibility with the standard phosphoramidite protocol for automated oligonucleotide synthesis.

The synthesis of compounds **5c** and **5d** (Scheme 5) required additional steps. In the first step, the active NHS ester **3**, R′= CH_2CH_2, was reacted with an excess of the appropriate bis-amine (4,7,10-trioxa-1,13-tridecanediamine or polytetrahydrofuran-bis(3-aminopropyl) terminated. The resulting intermediate compounds **4c** and **4d**, containing free primary amino groups, were isolated by silica gel chromatography.

In the next step the primary amino groups present in the isolated intermediate compounds **4c** and **4d** were reacted with either biotin NHS active ester producing compound **12c** or *S*-ethyl trifluorothioacetate (*75*) producing compound **12d**. As with the synthesis of compounds **5a** and **5b**, treatment of the amino-protected intermediate materials **12c** and **12d** with TBAF caused the removal of the TBDMS protecting group and resulted in compounds **5c** and **5d**. In all cases, standard reaction conditions for the described chemical transformations were applied. Detailed experimental procedures for the preparation of compounds **4a**−**d**, **12c**,**d**, and **5a**−**d** are in the Experimental Section.

In all described synthetic steps, the presence of the TBDMS and/or DMT protecting group significantly facilitated the chromatographic purification of their respective reaction products, particularly those with high molecular weight polymeric linkers, UV-inactive organic moieties, or moieties introducing increased polarity into the synthesized material. The advantage of using the active ester **3**, R′ = CH_2CH_2, as starting material was particularly pronounced in the synthesis of the amino derivatives **5c** and **5d**. The synthesis of those compounds required prior synthesis of derivatives **4c** and **4d**, in which the primary amino group is linked to the rest of the molecule through long polar linkers that usually contribute to difficulties in the purification process. In our experiments, however, it was found that both compounds were easily separated from the excess of the bis-amine used in the reaction through purification by silica gel chromatography.

Compounds **5c** and **5d** were used to prepare the respective solid supports, **10c** and **10d** (Scheme 5), which were used in the synthesis of 3′-modified DNA probes **14c** and **14d**.

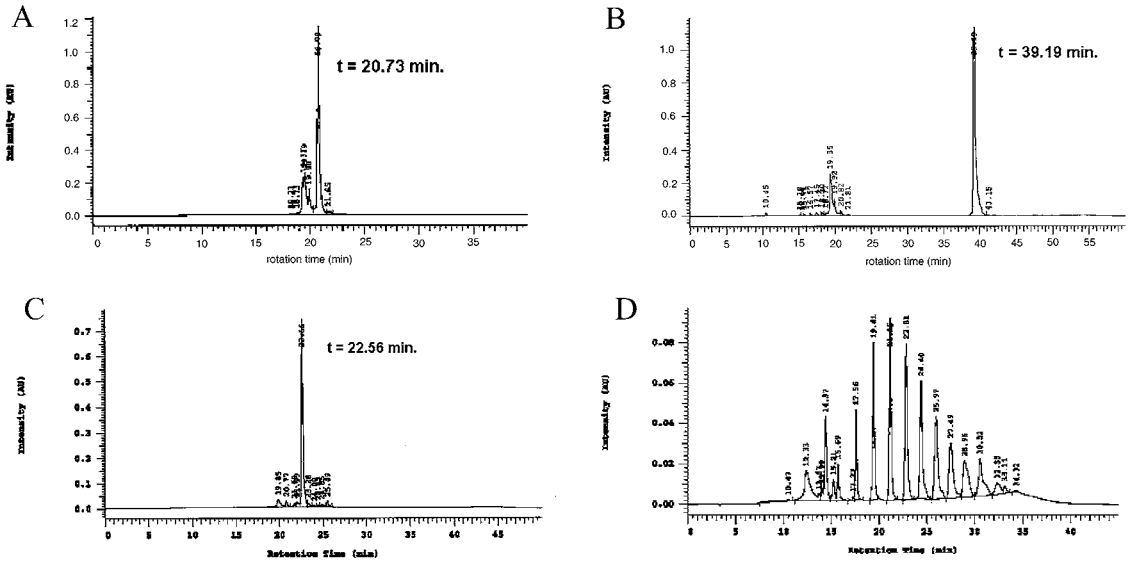

Figure 1. C18 RP HPLC analysis of the labeled probes (A) probe **13a**, 1%/min acetonitrile gradient; (B) probe **13b**, 1%/min acetonitrile gradient; (C) probe **14c**, 1%/min acetonitrile gradient; (D) probe **14d**, 2%/min acetonitrile gradient.

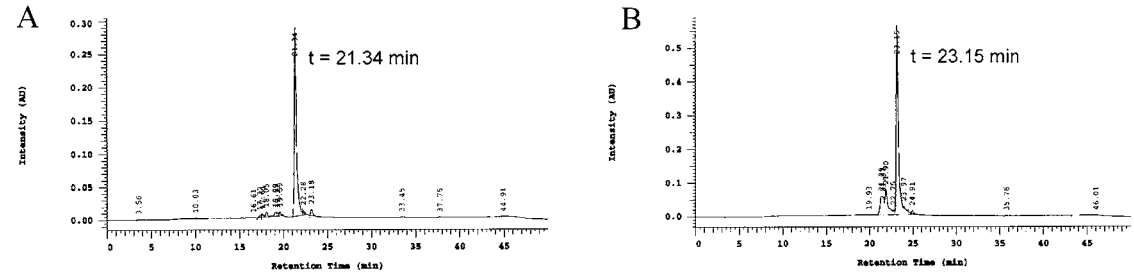

Figure 2. C18 RP HPLC analysis for the labeled probes (A) probe **15**, 1%/min acetonitrile gradient; (B) probe **16**, 1%/min acetonitrile gradient.

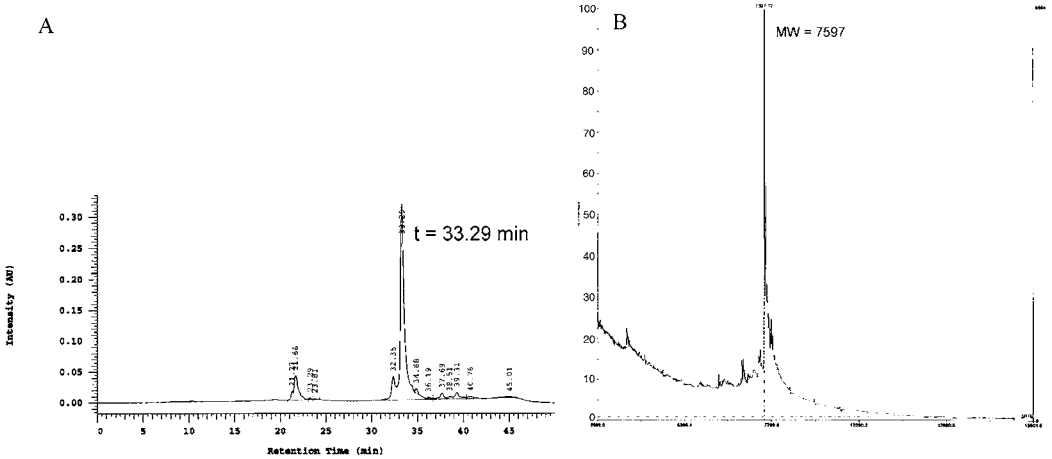

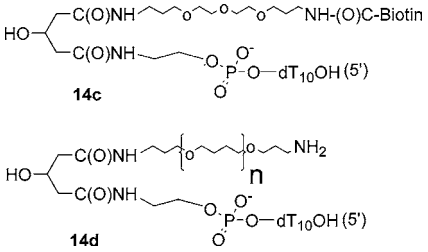

Figure 3. (A) C18 RP HPLC analysis of labeled probe **17**, 1%/min acetonitrile gradient; (B) MALDI TOF analysis of labeled probe **17**, calculated MW 7600.

Successful preparation of the 3′-amino-modified probe **14d** (R″ = poly-THF-NHC(O)CF_3, average M_n ca. 1100), in which the amino group is separated from the DNA moiety by a long polymeric linker, deserves special attention. Despite strong interest in methods that introduce polymeric linkers into DNA probes or conjugates, few procedures exist for the preparation of such materials (*83*−*92*), probably due to difficulties associated with the synthesis and purification of selectively protected derivatives of polymeric hydroxylamines or monoprotected polymeric bis-amines. The efficiency of the synthesis of modified oligonucleotide probes using phosphoramidites **8a**,**b** and modified supports **10c**,**d** is illustrated in Figure 1, where the reverse phase HPLC profiles of crude materials **13a**,**b** and **14c**,**d** are demonstrated. Synthe-

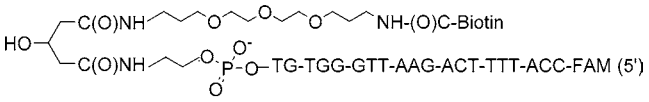
Scheme 6. Alternate Route of the Synthesis of Compound 5e



sized 5′-modified probes **13a**,**b** and 3′-modified probes **14c**,**d** were isolated by RP HPLC, and their structure was confirmed by MALDI TOF analysis.

In further attempt to test the compatibility of the synthesized reagents with the automated solid-phase synthesis of chemically modified DNA probes, we performed the synthesis of the 5′-FAM-modified, mixed base DNA probe **15** utilizing only commercial reagents and the 3′-biotin- and 5′-FAM-modified mixed base DNA probe **16** utilizing solid support **10c.**

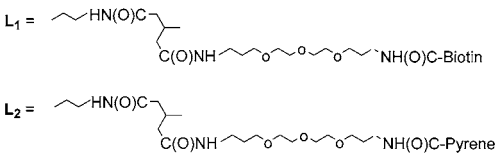
15



16

Comparison of the analytical RP HPLC profiles of the synthesized crude material **15** and the crude material **16** supports the conclusion that the synthetic performance of the biotin-modified solid support **10c** is similar to that of the commercially available dT-CPG solid support, Figure 2.

The applicability of the phosphoramidites **8** to the synthesis of internally modified DNA probes was additionally demonstrated by the successful synthesis of the 3′-modified and internally modified DNA probe **17**, which was performed using the solid support **10c** and the phosphoramidite **8b**.

17

The analytical RP HPLC profile of the crude material **17** along with the MALDI TOF analysis of the HPLC-purified reaction product are presented in Figure 3.

In the course of our experiments, we have also found that the synthetic strategy utilizing 3-(*tert*-butyldimethylsiloxy)glutaric anhydride **1** as a starting material can be successfully applied to the alternate approach of the synthesis of the compound **5** presented in Scheme 6. For example, the reaction of the anhydride **1** with the desired amino derivative **18** leads to the formation of compound **19**. The conversion of **19** into the NHS ester **20** and its subsequent reaction with an excess of unprotected 2-(2-aminoethoxyethyl)ethanol, leads to the formation compound **21** in a convenient one-pot reaction without isolation of the intermediate materials **19** and **20**.

After separation by column chromatography from other components present in the reaction mixture, compound **21** was easily converted into the DMT-protected derivative **22** and finally, after the removal of the TBDMS protecting group, into compound **5e**. In some cases this alternate synthetic approach may offer significant synthetic advantages, particularly when the preparation of a specific *O*-DMT-protected hydroxyloamine is synthetically difficult. Similarly, as it was observed in the synthesis of phosphoramidites **8a**,**b**, compound **5e** was easily converted into the phosphoramidite **8e** under standard reaction conditions. The reactivity of the phosphoramidite **8e** was documented by the synthesis of the 5′-modified DNA probe **23**. The structure of the phosphoramidite **8e** and compound **23** are illustrated in Figure 4. Figure 4 includes the analytical RP HPLC profile of the crude material **23** and the MALDI TOF analysis of purified **23**.

In conclusion, the presented modular approach for the synthesis of new phosphoramidites or new modified solid supports offers significant preparative advantages. The described procedure uses common starting material **3** and efficiently synthesizes new reagents that can introduce diverse modifications into DNA probes, including those which are difficult to prepare due to their physical or spectral properties (e.g. high molecular weight or lack of UV absorbency). We believe the presented approach will contribute to the cost-efficient preparation of a broader range of modified oligonuclotide probes and DNA conjugates, which can be applied in different areas of technology and biotechnology.

ACKNOWLEDGMENT

We wish to thank Andrea Mast for her assistance in preparing this manuscript and Annie Weber for her assistance in mass spectral analysis of the synthesized materials.

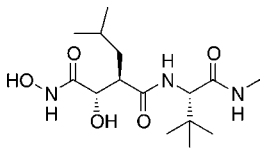
Synthesis of Marimastat and a Marimastat Conjugate for Affinity Chromatography and Surface Plasmon Resonance Studies

Kai Jenssen, Katherina Sewald, and Norbert Sewald*

Department of Chemistry, University of Bielefeld, Universitätsstrasse 25, D-33615 Bielefeld, Germany. Received December 10, 2003; Revised Manuscript Received March 22, 2004

Immobilized small-molecule inhibitors are suited for enrichment of biomolecules by affinity chromatography, as it is shown for metalloproteinases and an immobilizable derivative of the hydroxamate-type inhibitor marimastat. A new asymmetric synthesis of marimastat is presented that allows for site-specific attachment to a solid surface, e.g., a chromatography matrix or a surface plasmon resonance sensor chip. The latter technique is shown to be a valuable tool for the optimization of binding and elution conditons of biomolecules in affinity chromatography.



INTRODUCTION

Affinity chromatography is one of the most favored techniques for the isolation of biological macromolecules. It relies on covalent attachment of a specific ligand, which interacts with the desired macromolecule, to an insoluble solid and inert support. Then a solution containing the compound to be enriched is passed through the column, and all compounds which, under the given experimental conditions, have no affinity to the ligand will not be retarded. Compounds that display affinity will be bound by the immobilized ligand (*1*). A difficulty lies in the development of an affinity chromatography process for a certain macromolecule or a family of related macromolecules, because of the diversity of parameters that have to be taken into account. Even the optimization of appropriate elution conditions often relies on a trial and error approach. Nowadays surface plasmon resonance (SPR) provides a tool for real-time monitoring of biomolecular interactions (*2*). It also allows for optimization of the binding and elution conditions in affinity chromatography, especially because of the small sample amounts required. In a typical SPR analysis, three phases can be distinguished. Association occurs when the soluble analyte is passed through the flow cell where the binding partner is immobilized. The complex dissociates when the analyte is not present in the solution anymore. Finally, the sensor chip can be regenerated using appropriate buffer systems. The curve shape and the response difference allow for the evaluation of thermodynamic and kinetic binding parameters.

Here we describe our approach toward the development of specific, mechanism-based affinity chromatography materials that relies on a small synthetic inhibitor. With such an immobilizable inhibitor construct in hands, not only affinity purifications of proteins can be performed, but also applications in functional proteomics are feasible. This includes, in general, enrichment of overall subsets of cellular proteins, which can subsequently be resolved by one- or two-dimensional SDS−PAGE prior to indentification by mass spectrometry. This proteomics approach enables the identification of novel members of a protein family (*3*). It provides an efficient tool to identify cellular targets of the inhibitor used. Moreover, even interaction partners of the target protein can be enriched. The general process outlined has been optimized for the enrichment of metalloproteinases, especially matrix metalloproteinases.

Matrix metalloproteinases (MMPs) are a family of zinc-containing metalloendopeptidases which includes collagenases, gelatinases, and stromelysins. They are capable of degrading extracellular matrix (ECM) components, e.g., collagen, gelatin, fibronectin, and elastin (*4*, *5*). MMPs are necessary for tissue restructuring and remodeling. Therefore, they play an important role, for example, in growth and wound healing processes. However, overexpression of MMP leads to pathophysiological effects which are responsible for a variety of diseases such as arthritis, cancer, multiple sclerosis, and Alzheimer's disease (*6*).

Hydroxamic acids are known to be potent inhibitors of MMPs. Marimastat **1** was developed as a drug by British Biotech (*7*). It is an inhibitor with a good potency and shows activity toward a wide range of MMPs. The main advantage of **1** is the oral bioavailability, and clinical studies were performed. Indeed, inhibition of primary and secondary tumor growth and metastasis could be verified, but the development was finally discontinued because of severe side effects mainly caused by the lack of selectivity (*8*).

1

However, the lack of selectivity of **1** among the MMPs renders it an ideal candidate for diagnostic purposes. It can be derivatized in a way that allows for either immobilization on a chromatography matrix (affinity purification) or on a surface plasmon resonance sensor chip for binding studies. This requires the molecule to be attached covalently to a solid support with a functional group that does not interfere with binding to MMPs. Comparison of X-ray crystallographic data of MMPs, which were cocrystallized with hydroxamic acid based

inhibitors, indicates significant structure homology between these complexes. The essentials are that the hydroxamic acid moiety binds to the zinc ion whereas the *N*-methyl carboxamide terminus of **1** is exposed to the protein surface and freely accessible. This should make a derivatization and linker attachment of **1** feasible.

EXPERIMENTAL PROCEDURES

General. Unless otherwise mentioned, materials were obtained from commercial suppliers and were used without further purification. DMF was distilled at 55 mbar over ninhydrin, and dichloromethane was distilled first over calcium chloride and then dried over calcium hydride. Diethyl ether was dried over sodium benzophenone ketyl. Melting points were recorded on a Büchi melting B-540 apparatus and are uncorrected. For thin-layer chromatography (TLC), silica gel plates Merck 60 F_{254} were used. Flash chromatography was performed using silica gel Merck 60 (size 0.040−0.063 mm).

Preparative RP-HPLC was carried out using a Thermo Separation Products system consisting of a UV1000 detector and a P4000 pump equipped with a Vydac C18 (protein and peptide, 22 × 250 mm) column. Eluents: A = water/acetonitrile/trifluoroacetic acid (95/5/0.1), B = water/acetonitrile/trifluoroacetic acid (5/95/0.1). Method: flow rate 10 mL/min, gradient (A:B) 0−5 min: 100:0, 5−30 min: 100:0−70:30, 30−40 min: 70:30−0:100, 40−50 min: 0:100−100:0. Analytical RP-HPLC was carried out using a Thermo Separation Products system consisting of a UV6000 detector and a P4000 pump equipped with a Vydac C18 (protein and peptide, 4.6 × 250 mm) column. Method: flow rate 1 mL/min, same gradient as for preparative RP-HPLC.

^{1}H NMR, ^{13}C NMR, and ^{19}F NMR spectra were recorded at room temperature on a Bruker DRX500 instrument. ^{1}H NMR and ^{13}C NMR chemical shifts are given in ppm relative to TMS as the internal standard. Infrared spectra (IR) were recorded on a Jasco FT/IR-410 spectrometer; peaks are reported in wavenumbers (cm^{-1}). Optical rotation indices were measured on a Jasco DIP-360. MALDI-ToF mass spectra were obtained on a PerSeptive Biosystems Voyager-DE and were calibrated with a PEG standard as external reference. The synthetic steps during the synthesis on solid support were monitored by MALDI-ToF MS after cleavage of small amounts from the resin. Electrospray ionization (ESI) mass spectrometry experiments were performed on a Bruker Esquire 3000. ESI- and MALDI-FT-ICR mass spectrometry experiments were performed on a Bruker Apex III spectrometer with internal calibration. Electron impact ionization (EI) and chemical ionization (CI) mass spectrometry were performed on a Micromass VG Autospec X. For the surface plasmon resonance measurements a BIAcore 3000 instrument was used. The sensor chips and coupling kits were purchased from BIAcore. The following buffer compositions were used: buffer A: 0.05 M Tris/HCl pH 7.5, 0.2 M NaCl, 5 mM $CaCl_2$, 0.02% Brij35, 0.02% NaN_3; HBS-EP buffer: 0.01 M HEPES pH 7.4, 0.15 M NaCl, 3 mM EDTA, 0.005 Surfactant P20; both buffers were sterile filtered and degassed.

Diethyl (2*S*,3*R*)-3-Isobutylmalate 4. Isobutylmagnesium bromide was prepared by dropwise addition of isobutyl bromide (6.85 g, 50.0 mmol) in diethyl ether (30 mL) to a suspension of magnesium turnings (1.21 g, 50.0 mmol) in ether (20 mL). After the addition was complete, the reaction mixture was heated for 1 h under reflux and was then allowed to settle overnight. The supernatant was withdrawn using a syringe, and the solution was kept under nitrogen atmosphere. CuCN (4.78 g, 53.3 mmol) was suspended under nitrogen atmosphere in dry diethyl ether (30 mL) and cooled to −30 °C. The Grignard solution was added quickly with mechanical stirring. After 20 min, the suspension turned yellow and then a solution of diethyl (2*S*,3*S*)-epoxysuccinate **3** (*11*) (5.00 g, 26.6 mmol) in ether (20 mL) was added dropwise. After being stirred for 1 h at −25 °C, the reaction was quenched by the addition of satd ammonium chloride solution and was then filtered through a pad of silica gel. The phases were separated, and the aqueous phase was extracted three times with ether. The combined organic layers were washed with brine and dried over Na_2SO_4. After the solvent was removed by rotary evaporation, the crude product was purified by flash chromatography (petroleum ether/ethyl acetate 7:1) (*12*). Yield: 3.02 g (12.3 mmol, 46%), colorless oil. TLC: $R_f = 0.68$ (petroleum ether/ethyl acetate (2:1)); ^{1}H NMR (500 MHz, $CDCl_3$, TMS): δ 0.92 (d, 3H, $^3J = 6.4$ Hz), 0.95 (d, 3H, $^3J = 6.4$ Hz), 1.25 (t, 3H, $^3J = 7.1$ Hz), 1.31 (t, 3H, $^3J = 7.2$ Hz), 1.50 (m, 1H), 1.59−1.84 (m, 2H), 2.93 (m, 1H), 3.66 (br. s, 1H), 4.14 (m, 1H), 4.22−4.32 (m, 4H); ^{13}C NMR (125.7 MHz, $CDCl_3$, TMS): δ 14.1 (CH_3), 14.2 (CH_3), 22.5 (CH_3), 22.6 (CH_3), 25.8 (CH), 36.9 (CH_2), 46.6 (CH), 60.8 (CH_2), 61.8 (CH_2), 71.3 (CH), 173.1 (C), 173.5 (C); MS (EI, 70 eV): *m*/*z* (%) = 247 (1, $M^{+\bullet}$ + H), 231 (0.5), 201 (5), 173 (100), 143 (10), 127 (70), 117 (26), 101 (14); $[\alpha]^{21}_D = +8.8 \pm 0.1$ (*c* = 2; ethyl acetate); IR (NaCl, cm^{-1}): $\tilde{\nu}$ = 3504, 2960, 2360, 1741, 1468, 1371, 1246, 1198, 1097, 1029, 900, 858; elemental analysis calcd for $C_{12}H_{22}O_5$ [230.30] (%) C 58.52, H 9.00, N 0.00, found C 57.85, H 8.89, N 0.00.

(2*S*,3*R*)-2-Hydroxy-3-isobutylsuccinic Acid 5. A solution of diester **4** (7.62 g, 31.0 mmol) and NaOH (5.00 g, 124 mmol) in water/1,4-dioxane (120 mL/80 mL) was stirred for 16 h at rt. Then the reaction mixture was extracted twice with diethyl ether (50 mL). The organic layer was discarded, and the aqueous phase was acidified to pH 1.5 and extracted five times with ether (200 mL). The combined organic phases were then washed with a small amount of brine and dried over Na_2SO_4, and the solvent was removed in vacuo. If necessary, the product could be purified by flash chromatography (petroleum ether/ethyl acetate/acetic acid 7:3:1). Yield: 5.24 g (27.9 mmol, 90%), slightly yellow, very viscous oil. TLC: R_f = 0.11 (petroleum ether/ethyl acetate/acetic acid (7:3:1)); ^{1}H NMR (500 MHz, $CDCl_3$, TMS): $\delta = 0.95$ (d, 3H, $^3J = 6.9$ Hz), 0.96 (d, 3H, $^3J = 6.3$ Hz), 1.60 (m, 1H), 1.68−1.79 (m, 2H), 3.10 (ddd, $^3J = 3.4$ Hz, $^3J = 7.4$ Hz, $^3J = 7.4$ Hz, 1H), 4.31 (d, 1H, $^3J = 3.1$ Hz), 8.30−9.20 (br. s, 2H); ^{13}C NMR (125.7 MHz, $CDCl_3$, TMS): δ = 22.1 (CH_3), 22.5 (CH_3), 25.6 (CH), 36.7 (CH_2), 46.2 (CH), 70.5 (CH), 177.9 (C), 178.9 (C); MS (EI, 70 eV): *m*/*z* (%) = 189 (0.1; $M^{\bullet+}$ − H), 145 (45, $M^{\bullet+}$ − ^{i}Pr), 134 (10), 126 (100, $M^{\bullet+}$ − ^{i}Pr − H_2O), 115 (20, ^{i}Bu$CH_2COO^{+\bullet}$); $[\alpha]^{21}_D = +18.7 \pm 0.2$ (*c* = 0.5; ethyl acetate); IR (NaCl, cm^{-1}): $\tilde{\nu}$ = 3500−3000, 2959, 1717, 1388, 1208, 1145, 1097, 901, 812; elemental analysis calcd for $C_8H_{14}O_5$ [190.19] (%) C 50.52, H 7.42, N 0.00, found C 50.35, H 7.39, N 0.00.

(2*R*)-4-Methyl-2-((4*S*)-5-oxo-2,2-bis(trifluoromethyl)-1,3-dioxolan-4-yl)pentanoic Acid 6. A stream of gaseous hexafluoroacetone was directed onto the surface of a well stirred solution of **5** (4.26 g, 22.4 mmol) in DMSO (15 mL). The reaction vessel was equipped with a methanol/dry ice condenser. After 3 h, completion of the reaction was indicated by a reflux of hexafluoroacetone. The solution was poured into a mixture of ice water/dichloromethane (DCM) (200 mL/200 mL), and the aqueous phase was extracted three times with DCM (100 mL). The combined organic layers were washed three times

with cold water (100 mL), the organic phase was dried over Na_2SO_4, and the solvent was removed in vacuo (*13*, *14*). Yield: 6.38 g (18.9 mmol, 84%), gray solid; mp 61 °C; ^{1}H NMR (500 MHz, $CDCl_3$, TMS): δ = 0.97 (d, 6H, ^3J = 6.3 Hz), 1.65 (m, 1H), 1.73 (m, 1H), 1.83 (m, 1H), 3.04 (ddd, 1H, ^3J = 5.8 Hz, ^3J = 8.9 Hz, ^3J = 8.9 Hz), 4.72 (d, 1H, ^3J = 5.7 Hz), 8.60 (br. s, 1H); ^{13}C NMR (125.7 MHz, $CDCl_3$, TMS): δ = 22.3 (CH_3), 22.5 (CH_3), 25.6 (CH), 35.7 (CH_2), 44.9 (CH), 75.0 (CH), 97.6 (sept, ^2J = 35.7 Hz) 118.6 (q, ^1J = 287.2 Hz, CF_3), 119.7 (q, ^1J = 288.0 Hz, CF_3), 166.4 (C), 175.1 (C); ^{19}F NMR (470.6 MHz, $CDCl_3$, $CFCl_3$ external): δ = −80.3 (q, ^3J = 7.5 Hz), −81.1 (q, ^3J = 7.5 Hz). ***N*-(*N*′)-Benzyloxy-(2*R*,3*S*)-2-hydroxy-3-isobutyl-4-succinamoyl)-(*S*)-*tert*-leucine-*N*″-methylamide 15a.** A solution of *O*-benzylhydroxylamine hydrochloride (192 mg, 1.20 mmol) and triethylamine (180 μL, 1.20 mmol) in DCM (5 mL) was added at rt to a solution of **13a** (55 mg, 0.12 mmol) in DCM (2 mL). The reaction was stirred at rt for 3 h. The solvent was removed, and the residue was diluted with 20 mL of ethyl acetate/water (10:1). The phases were separated, and the organic layer was washed three times with 5% $KHSO_4$ solution, satd $NaHCO_3$ solution, and finally with brine and dried over Na_2SO_4. The solvent was removed in vacuo, and the residue was purified by flash chromatography (DCM/ethanol 30:1).

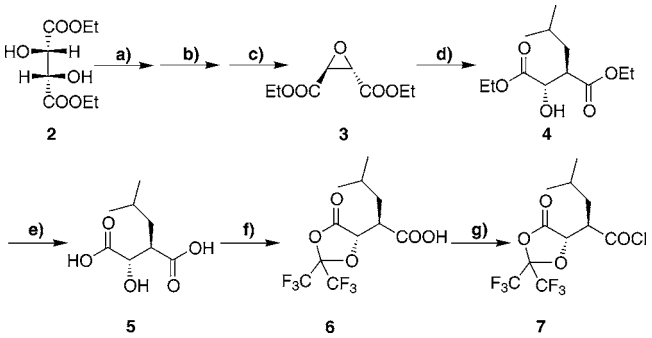
Yield: 43 mg (0.10 mmol, 85%), colorless oil; ^{1}H NMR (500 MHz, methanol-d_4): δ = 0.88 (d, 3H, ^3J = 6.5 Hz), 0.91 (d, 3H, ^3J = 6.5 Hz), 0.98 (s, 9H), 1.24 (m, 1H), 1.49−1.62 (m, 2H), 2.69 (s, 3H), 2.83 (ddd, 1H, ^3J = 5.0 Hz, ^3J = 9.5 Hz, ^3J = 9.5 Hz), 4.00 (d, 1H, ^3J = 5.8 Hz), 4.22 (s, 1H), 4.80−4.85 (m, 2H), 7.32−7.37 (m, 3H), 7.41−7.44 (m, 2H); ^{13}C NMR (125.7 MHz, methanol-d_4): δ = 22.4 (CH_3), 23.5 (CH_3), 26.0 (CH_3), 26.8 (CH), 27.2 (CH_3), 35.4 (C), 39.7 (CH_2), 61.9 (CH), 72.9 (CH), 79.0 (CH_2), 129.5 (CH), 129.7 (CH), 130.3 (CH), 136.7 (C), 171.7 (C), 173.1 (C), 175.3 (C); MS (MALDI-ToF, α-cyano-4-hydroxycinnamic acid): *m/z* (%) = 422.4 (100, $[M + H]^+$, calcd 422.2), 444.4 (76, $[M + Na]^+$, calcd 444.2), 460.4 (42, $[M + K]^+$, calcd 460.2), $C_{22}H_{35}O_5N_3$ [421.65]; IR (NaCl, cm^{-1}): $\tilde{\nu}$ = 3312, 3033, 2957, 2871, 2086, 1643, 1535, 1369, 1256, 1237, 1213, 1146, 1083, 1016, 749, 698.

***N*-((2*R*,3*S*)-3,*N*′-Dihydroxy-2-isobutyl-4-succinamoyl)-(*S*)-*tert*-leucine-*N*″-methylamide 1.** A suspension of **15a** (42 mg, 0.10 mmol) and 10% Pd/C (2.0 mg) in methanol (50 mL) was reacted under hydrogen atmosphere for 4h at rt. The catalyst was removed by filtration through a pad of silica gel. After removal of the solvent in vacuo, the crude product was further purified by RP-HPLC. Yield: 30.5 mg (0.092 mmol, 92%), colorless solid; preparative RP-HPLC: t_R = 35.5 min; analytical HPLC t_R = 30.9 min; ^{1}H NMR (500 MHz, methanol-d_4): δ = 0.88 (d, 3H, ^3J = 6.5 Hz), 0.92 (d, 3H, ^3J = 6.5 Hz), 0.98 (s, 9H), 1.26 (m, 1H), 1.54 (m, 1H), 1.64 (m, 1H), 2.71 (s, 3H), 2.84 (ddd, 1H, ^3J = 5.2 Hz, ^3J = 9.2 Hz, ^3J = 9.2 Hz), 4.02 (d, 1H, ^3J = 4.7 Hz), 4.20 (m, 1H), 7.86 (d, 1H, ^3J = 9.2 Hz); MS (MALDI-ToF, α-cyano-4-hydroxycinnamic acid): *m/z* (%) = 332.5 (40, $[M + H]^+$, calcd 332.2), 354.5 (100, $[M + Na]^+$, calcd 354.2), 370.5 (38, $[M + K]^+$, calcd 370.2), $C_{15}H_{29}O_5N_3$ [331.39].

Synthesis of 15b on Solid Support. 2-Chlorotrityl chloride resin (50 mg, Advanced ChemTech, max. capacity 1.4 mmol g^{-1}) was preswollen in DCM (100 μL). After 10 min, most of the solvent was removed and 1,8-diamino-3,6-dioxaoctane **12** (1.00 mL, 6.00 mmol) was added quickly. The reaction was stopped by the addition of methanol (2 mL) after 2 h. The resin was washed with DCM/DIPEA (19:1, 4 mL), three times with DMF (4 mL), and three times with DCM (4 mL) (*19*). Fmoc-L-*tert*-leucine (89 mg, 0.25 mmol) was dissolved together with TBTU (85 mg, 0.25 mmol) in DMF (350 μL) and added to the washed resin (two times with DMF), followed by DIPEA (90 μL). After 1 h, the resin was washed three times with DMF and three times with DCM. Estimation of the resin loading by Fmoc cleavage and UV spectroscopy gives 0.6−0.8 mmol/g. Removal of the Fmoc protecting group was accomplished by treatment with 25% piperidine/DMF (5 mL) (twice for 20 min) and by washing the resin three times with DMF and three times with DCM.

A solution of **7** (100 mg, 0.28 mmol) in THF (5 mL) was cooled to −65 °C, and then triethylamine (40 μL) and the dry, loaded resin were added portionwise. After 1 h, the resin was washed three times with triethylamine/DCM (1:2) (4 mL) and three times with DCM (4 mL). *O*-Benzylhydroxylamine hydrochloride (192 mg, 1.20 mmol) and triethylamine (180 μL, 1.20 mmol) in DCM (5 mL) were added to the resin. After 4 h, the resin was filtered and washed four times with DCM. The product **15b** was then cleaved from the resin by the addition of 1% TFA in DCM (5 mL). After 10 min, the resin was filtered and fresh cleavage solution was added. This step was repeated four more times. The volatiles were removed from the filtrate in vacuo, and the product was isolated by RP-HPLC. Overall yield: 15 mg (0.02 mmol, 28%), colorless solid; preparative RP-HPLC: t_R = 30.5 min; analytical RP-HPLC: t_R (%) = 29.3 min (94); 30.0 (5); ^{1}H NMR (500 MHz, $CDCl_3$, TMS): δ = 0.94 (d, 3H, ^3J = 6.1 Hz), 0.96 (d, 3H, ^3J = 6.5 Hz), 1.00 (s, 9H), 1.42 (m, 1H), 1.52−1.68 (m, 2H), 2.94 (m, 1H), 3.05−3.24 (m, 2H), 3.40−3.85 (m, 10H), 4.19 (m, 1H), 4.32 (m, 1H), 4.55 (br. s, 1H), 4.86−4.88 (m, 2H), 7.19 (d, 1H, ^3J = 6.8 Hz), 7.34−7.35 (m, 3H), 7.37−7.39 (m, 2H), 7.80 (s, 1H), 7.88 (br. s, 3H), 10.45 (br. s, 1H); ^{13}C NMR (125.7 MHz, $CDCl_3$, TMS): δ = 22.1 (CH_3) 22.9 (CH_3), 25.7 (CH), 26.7 (CH_3), 33.8 (C), 38.2 (CH_2), 39.3 (CH_2), 39.9 (CH_2), 47.9 (CH), 61.5 (CH), 66.5 (CH_2), 69.3 (CH_2), 69.9 (CH_2), 70.1 (CH_2), 71.8 (CH), 78.4 (CH_2), 128.6 (CH), 128.9 (CH), 129.3 (CH), 134.8 (C), 170.1 (C), 171.4 (C), 174.6 (C); MS (MALDI-ToF, α-cyano-4-hydroxycinnamic acid): *m/z* (%) = 539.5 (100, $[M + H]^+$, calcd 539.3), 561.5 (32, $[M + Na]^+$, calcd 561.3), 577.6 (9, $[M + K]^+$, calcd 577.3), $C_{29}H_{47}O_9F_3N_4$ [652.71].

A suspension of **15b** (15 mg, 0.02 mmol) and 10% Pd/C (1.0 mg) in methanol (20 mL) was reacted in a hydrogen atmosphere for 4h at rt. The catalyst was removed by filtration through a pad of silica gel. After removal of the solvent in vacuo, the crude product is further purified by RP-HPLC. Yield: 9 mg (0.016 mmol, 80%), colorless solid; preparative RP-HPLC: t_R = 25.6 min; analytical HPLC: t_R = 20.3 min; ^{1}H NMR (500 MHz, DMSO-d_6): δ = 0.77 (d, 3H, ^3J = 6.6 Hz), 0.79 (d, 3H, ^3J = 6.6 Hz), 0.89 (s, 9H), 1.22 (m, 1H), 1.35 (m, 1H), 1.45 (m, 1H), 2.69 (m, 1H), 2.91−2.98 (m, 2H), 3.13−3.20 (m, 2H), 3.22−3.28 (m, 2H), 3.52−3.58 (m, 6H), 3.69 (d, 1H, ^3J = 8.2 Hz), 4.20 (d, 1H, ^3J = 9.4 Hz), 5.35 (br. s, 1H), 7.48 (d, 1H, ^3J = 9.7 Hz), 7.47 (br. s, 3H), 7.99 (t, 1H, ^3J = 5.6 Hz), 8.87 (s, 1H), 10.55 (s, 1H); MS (MALDI-ToF, α-cyano-4-hydroxycinnamic acid): *m/z* (%) = 449.5 (95, $[M + H]^+$, calcd 449.3), 471.5 (100, $[M + Na]^+$, calcd 471.3), 487.4 (30, $[M + K]^+$, calcd 487.2). MS (ESI-FT-ICR): *m/z* found 449.29707, monoisotopic mass calculated for the cation $C_{20}H_{41}O_7N_4^+$ 449.29698.



Activation of MMP-2. A freshly prepared stock solution (3 μL) of 4-aminophenyl mercuric acetate (APMA) (25 mM) in 0.1 mM NaOH was mixed with MMP-2 (30 μL, purchased from Calbiochem (Lot B41215), 40 μg mL^{-1}) and then incubated for 2 h at 37 °C.

SPR Measurements. The marimastat derivative **16** was immobilized on a CM5 sensor chip under the following conditions: flow 5 μL min^{-1}; contact time 7 min; running buffer HBS-EP buffer. The sensor chip was then activated with the EDC/NHS coupling kit on the reference and measurement flow cell. A solution of **16** in HBS-EP buffer (1.8 mM) was injected on the measurement flow cell, and the sensor chip was deactivated by the injection of ethanolamine on both flow cells. The immobilization level that could be achieved lies in the range of 40−60 RU.

Binding Studies. The system was primed with MMP-buffer A, and the flow was set to 20 μL min^{-1}; the flow path was set to both flow cells with reference subtraction. Different concentrations of MMP-2 in MMP-buffer A were injected (Figure 1). Regeneration of the surface was possible by the injection of HBS-EP buffer (two times for 10 min).

Competition in Solution Experiment. Constant concentration of MMP-2 was incubated for 30 min with varying concentrations of **16**. The samples were subsequently injected to both flow cells with reference subtrac-

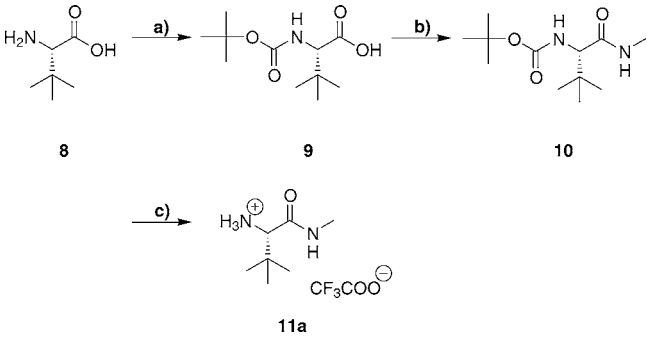
tion. After each injection, the surface was regenerated with HBS-EP buffer (two times for 10 min).

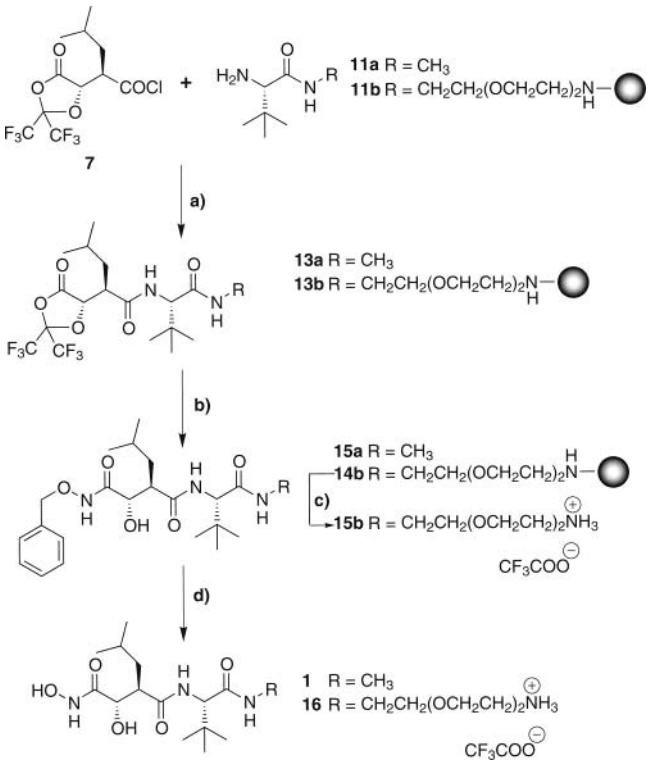
RESULTS



We succeeded to synthesize marimastat **1** and a new marimastat derivative **16** by a novel synthetic route. It differs from published syntheses of 2,3-disubstituted succinate derivatives, which are usually prepared by a stereoselective Ireland−Claisen rearrangement (*9*). The synthesis of marimastat analogues on solid support, where the α-hydroxy group was replaced by an α-amino group, has recently been reported (*10*).

Starting from (−)-D-diethyltartrate **2**, the C_2-symmetric epoxide **3** is obtained according to Mori et al. (Scheme 1) (*11*). According to the ^{1}H NMR integrals, an amount of 5−7% of the unwanted meso-diastereomer is obtained, which can be removed by flash chromatography. Alternatively, the undesired byproduct may be completely removed on a later stage by RP-HPLC. Compound **3** undergoes ring-opening with the Grignard-based organocuprate *i*BuCu(CN)MgBr generated in situ (*12*). Saponification of the diester **4** gives α-hydroxy acid **5**. It is known that α-hydroxy acids regioselectively form dioxolanone rings upon reaction with hexafluoroacetone (*13*). Hexafluoroacetone is especially suited as a protecting reagent for α-amino or α-hydroxy dicarboxylic acids. The lactone moiety of **6** displays high reactivity toward nucleophiles. Advantageously, ring opening and derivatization occur simultaneously in one synthetic step and usually with good yields (*14*). Moreover, conversion of the free carboxy group of **6** into the acid chloride confers the highest electrophilicity to this group and allows for the alternative regioselective derivatization. Treatment of compound **6** with thionyl chloride provides the corresponding acid chloride **7**, which serves as a common precursor for **1** and **16**.

For the synthesis of **1**, L-*tert*-leucine-*N*-methylamide **11a** is obtained as the trifluoroacetate in a three-step synthesis similar to known procedures (Scheme 2). L-*tert*-Leucine **8** is Boc-protected and then reacted with *N*-methylamine using TBTU as coupling reagent to give compound **10** (*15*, *16*). Cleavage of the Boc-protecting group by standard procedures yields compound **11a**.



A dilute solution of **11a** and dry triethylamine in dry THF is added slowly to a solution of **7** at −65 °C (Scheme 3). Concentration, temperature, and base are very important for the success of the reaction, e.g., the amine hydrochloride formed during the reaction should be insoluble in the solvent and precipitate. Higher temperature leads to the concomitant opening of the dioxolanone ring and only to a small amount of product **13a**.

Scheme 2[a]

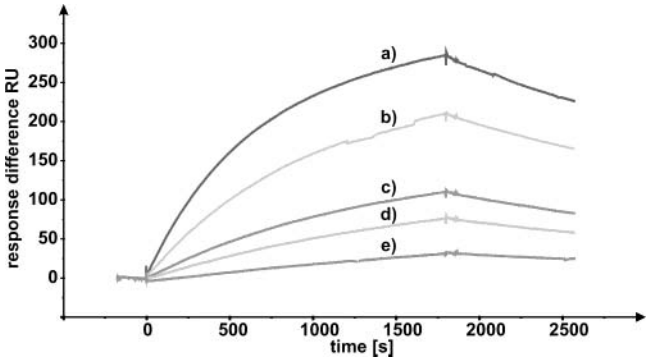
[a] Reagents and conditions: Boc_2O, NaOH, *tert*-butyl alcohol/H_2O, rt, 12 h, 93%; (b) *N*-methylamine, TBTU, DIPEA, acetonitrile, rt, 14 h, 71%; (c) TFA/DCM (1:1), rt, 1 h, 99%.

Scheme 3[a]

[a] Reagents and conditions: THF, NEt_3, −65 °C, 1.5 h; (b) $BnONH_2$. HCl, NEt_3, DCM, rt, 2 h; (c) 1% TFA/DCM, rt, 1 h; (d) H_2, Pd/C (5%), MeOH, rt, 4 h.

Ring-opening of the dioxolanone ring in **13a** quickly occurs upon addition of *O*-benzylhydroxylamine, an O-protected reagent suited for the synthesis of hydroxamic acids. The intermediate **15a**, obtained from **13a** has the advantage that it can be purified by column chromatography. The benzyl protecting group of **15** is easily removed by hydrogenation on Pd/C in a protic solvent like methanol or ethanol. Small amounts of catalyst prevent reductive N−O bond cleavage. Further purification of the free marimastat **1** by RP-HPLC is usually not necessary.

To permit a modular assembly of the new immobilizable marimastat derivative **16**, a linker had to be attached. The L-leucinamide derivate **11b** with a tether for immobilization attached to the amide nitrogen is obtained by solid-phase synthesis. The highly acid-labile 2-chlorotrityl chloride resin was chosen to be loaded with a large excess of the diamino triethylene glycol derivative



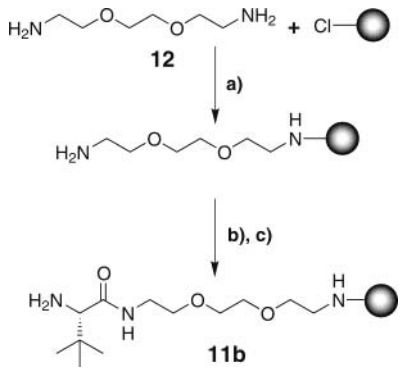


Figure 1. Binding studies with immobilized marimastat derivative on a CM5 sensorchip. Increasing concentrations of activated MMP-2 result in increasing response: (a) 55 nM, (b) 28 nM, (c) 19 nM, (d) 14 nM, (e) 3 nM.

Scheme 4[a]

[a] Reagents and conditions: DCM, rt, 2 h; (b) Fmoc-L-*tert*-leucine, DIPEA, TBTU, DMF, rt, 1 h; (c) 25% piperidine/DMF, rt, 1 h.

12 (Scheme 4), which should serve as a linker and also provide good water solubility (*17*−*19*). After the residual reactive positions are capped with methanol, Fmoc-*tert*-leucine is smoothly coupled to the free amino group using the standard TBTU coupling protocol followed by Fmoc cleavage (Scheme 4). Subsequently, coupling of the hexafluoroacetone protected acid chloride **7** to the free amino group of **11b** results in formation of resin-bound dioxolanone **13b** (Scheme 3). The dioxolanone ring is then opened with $BnONH_2$, and treatment with 1% TFA in CH_2Cl_2 cleaves the product **15b** from the resin. It is isolated in 28% overall yield after purification by RP-HPLC. After hydrogenation, product **16** is obtained in good purity, so that additional RP-HPLC is usually not necessary.

In contrast to the known synthetic routes for marimastat **1**, which start with the alkylation of (2*S*)-2-hydroxysuccinic dimethyl ester with methallyl bromide at C3 and lead to overalls yields of 5−6% (*5*), our synthesis gives overall yields which usually lie in range of 11%, although we need three more steps. Surface plasmon resonance experiments are suited to prove whether the new marimastat derivative **16** is still capable of binding MMP. The marimastat derivative **16** is successfully immobilized across the free amino group on a CM5 sensor chip using the standard EDC/NHS coupling protocol. Binding studies with activated MMP-2 show that MMP-2 binds in a concentration-dependent manner to the immobilized marimastat derivate **16**. The response levels correlate linearly with the concentration of the injected protein solution as to be expected for specific, mechanism-based binding (Figure 1). The K_D value for this complex is calculated to be 12 nM, which is in the same range of

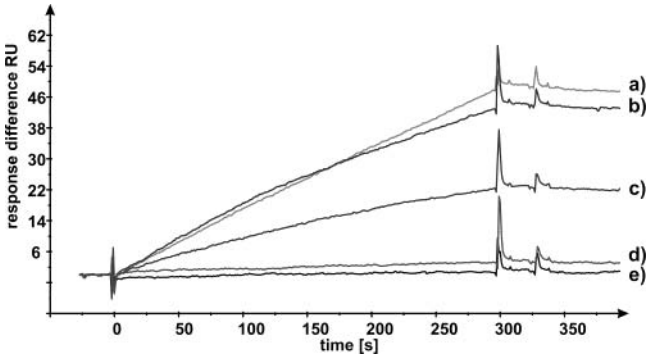

Figure 2. Competition in solution with soluble marimastat derivative **16**: 14 nM MMP-2 was incubated for 30 min with different concentrations of marimastat derivative **16** prior to the SPR experiments: (a) 0 nM, (b) 9 nM, (c) 18 nM, (d) 45 nM, (e) 180 nM.

the reported IC_{50} value for marimastat (BB-2516) against MMP-2 (6 nM) (*6*). Hence, the modified marimastat derivative **16** binds to MMP-2 with comparable affinity as the parent compound **1**. Binding specificity is clearly proven by competition in solution experiments with nonimmobilized **16** (Figure 2).

The elution conditions of bound protein are important for the application of affinity chromatography. Different approaches were tested to elute the protein from the chip surface. A shift to higher or lower pH and also a higher sodium chloride concentration do not lead to a considerable reduction of the response level. The use of a 0.5 solution of SDS causes rapid elution of MMP-2 but results in denaturation of the protein. A smooth procedure to get the bound protein released is accomplished by treatment with HBS-EP buffer (pH 7.4). Two injections over 10 min are necessary to completely release all bound MMP-2 from the surface. These conditions are supposed to be directly applicable to affinity chromatography.

DISCUSSION

Starting from D-diethyl tartrate **2**, an enantiomerically pure, selectively protected and activated marimastat precursor is obtained that permits a new route for the synthesis of both marimastat **1** and an immobilizable marimastat derivative **16**. The latter can be used for surface plasmon resonance studies with metalloproteinases. MMP-2 as the representative proteinase binds to the surface-immobilized broad-spectrum inhibitor in a concentration-dependent manner. Binding can be potentially used for affinity purification of metalloproteinases under optimized elution conditions, determined in surface plasmon resonance studies.

Biotin Reagents in Antibody Pretargeting. 6. Synthesis and in Vivo Evaluation of Astatinated and Radioiodinated Aryl- and *nido*-Carboranyl-biotin Derivatives

D. Scott Wilbur,*,† Donald K. Hamlin,† Ming-Kuan Chyan,† Brian B. Kegley,† Janna Quinn,‡ and Robert L. Vessella‡

Departments of Radiation Oncology and Urology, University of Washington, Seattle, Washington 98195. Received December 18, 2003; Revised Manuscript Received February 21, 2004

An investigation has been conducted to prepare and evaluate several radiohalogenated biotin derivatives as part of our studies to develop reagents for carrying ^{211}At in cancer pretargeting protocols. The primary goal of the investigation was to determine the in vivo stability and distribution properties of astatinated biotin derivatives. In addition to astatination, the biotin derivatives were radioiodinated for in vitro and in vivo comparison. Biodistributions were conducted in athymic mice, with sacrifice times of 1, 4, and 24 h to correspond to 9%, 32%, and 90% of ^{211}At decay ($t_{1/2}$ = 7.21 h). In the investigation, two biotin derivatives, **1a** and **2a**, were synthesized which had structures that contain a biotin moiety, a biotinidase-blocking moiety, an ether linker moiety, and an aryl stannane moiety for radiohalogenation. Biotin derivatives **1a** and **2a** were radiolabeled with $^{125/131}$I to give [$^{125/131}$I]**1b** or [^{125}I]**2b** and with ^{211}At to give [^{211}At]**1c** or [^{211}At]**2c**. In vivo studies demonstrated that co-injected [^{125}I]**2b** and [^{131}I]**1b** had very similar tissue distributions in athymic mice. Co-injection of [^{211}At]**2c** and [^{125}I]**2b** provided data that indicated that rapid deastatination occurred in vivo. A second set of biotin derivatives, **3a**, **4a**, and **5a**, were synthesized which had structures that contain a biotin moiety, a biotinidase-blocking moiety, and an anionic *nido*-carborane moiety for radiohalogenation. The biotin derivatives **4a** and **5a** contained an aryl moiety not present in **3a**, and **5a** had a trialkylamine functionality not present in **3a** or **4a**. Biotin derivative **3a** was radioiodinated, but was not further investigated. Biotin derivatives **4a** and **5a** were radiolabeled with ^{211}At and ^{125}I to produce [^{125}I]**4b**/[^{211}At]**4c** and [^{125}I]**5b**/[^{211}At]**5c**. Comparison of [^{125}I]**4b** and (separately) [^{125}I]**5b** with [^{131}I]**1b** showed that the *nido*-carborane containing biotin derivatives were retained in blood and tissue more than the aryl iodide derivative. In vivo evaluations of [^{211}At]**4c**/[^{125}I]**4b** and (separately) [^{211}At]**5c**/[^{125}I]**5b** indicated that some deastatination occurred in these compounds, but it was much less than observed for the aryl derivative [^{211}At]**2c**. While the *nido*-carborane containing biotin derivatives provide a significant improvement in astatine stability over biotin derivatives previously studied, additional derivatives need to be prepared and studied to further improve the in vivo stability and blood/tissue clearance of these compounds.

INTRODUCTION

We are investigating the use of the α-particle-emitting radionuclide astatine-211 (^{211}At) in "targeted radionuclide therapy" [1] (TRT[2]) of metastatic cancer. α-Particle-emitting radionuclides have properties that make them favorable for use in the therapy of small groups of cancer cells (micrometastatic disease) and single cancer cells (*1*−*5*). Those favorable properties include very short path lengths (50−85 μm) of the α-particle, allowing irradiation of only a few cell diameters, and very high cellular toxicity due to a large energy deposition (e.g. 100 keV/μm) over that short path length (*6*). Among the few α-emitting radionuclides that have favorable decay properties for in vivo use (*7*), ^{211}At is particularly attractive, as it is readily prepared in quantities sufficient for clinical application (*8*). Importantly, it has a half-life that is short enough ($t_{1/2}$ = 7.2 h) for use in an outpatient approach but long enough to allow adequate targeting of cancer cells in vivo. This latter point is only true if the cancer-targeting carrier molecule used in combination with ^{211}At has appropriate pharmacokinetics.

A number of cancer-targeting intact monoclonal antibodies (mAb) and their F(ab′)$_2$ fragments have been labeled with ^{211}At (*9*). However, except in special applications, these carrier molecules do not have appropriate cancer targeting and blood clearance properties for use with ^{211}At due to its short half-life (*10*). Smaller mAb

fragments, such as Fab′ or single chain Fv fragments, have more appropriate pharmacokinetics, but they have a propensity to localize to kidney making their use unfavorable. To improve the pharmacokinetics of the astatine carrier molecule, we are investigating an alternative approach, termed "pretargeting" (*11*−*14*), which employs radiolabeled biotin derivatives to deliver ^{211}At to cancer cells in vivo. In the pretargeting approach, a monoclonal antibody−streptavidin conjugate (mAb−SAv) is injected and allowed to bind antigens on cancer cells. After a period of time for adequate tumor targeting (e.g. 24 h), a clearing agent is used to remove excess mAb−SAv conjugate from blood. After an appropriate time (e.g. 1−3 h), the ^{211}At-labeled biotin derivative is administered such that it can bind with the prebound (pretargeted) mAb−SAv on cancer cells. Importantly, this approach has been shown to provide very good tumor targeting, with cures for human tumor implants (xenografts) in athymic mice using other therapeutic radionuclides (*15*, *16*), and has progressed to clinical trials (*17*).

While a number of radiometal-chelated biotin derivatives have been used successfully in pretargeting protocols, there have been no reports of successful applications of radiohalogen-labeled biotin derivatives. Thus, our initial studies were focused on improving the in vivo characteristics of radiohalogenated biotin derivatives. Importantly, those studies provided information on structural requirements for blocking the serum enzyme biotinidase (*18*, *19*) while retaining the desired high binding affinity of the biotin derivatives (*20*). In some of the studies, the required structural features were combined with stannylbenzoates to prepare radioiodinated biotin derivatives for evaluation. We knew from previous studies with aryl stannanes that they could be used for astatination (*21*, *22*), leading us to believe that an astatinated biotin derivative for in vivo use could be readily obtained. However, as the studies described herein point out, astatinated aryl-biotin derivatives can be quite unstable to in vivo deastatination. Therefore, additional biotin derivatives were prepared which incorporated an alternate ^{211}At-binding moiety, a *nido*-carborane.[3]

Previous studies by Hawthorne et al. demonstrated that a *nido*-carborane conjugate could be used to radioiodinate antibodies (*23*). We also investigated *nido*-carboranes as hydrophilic pendant groups for coupling radionuclides of iodine to biomolecules (*24*, *25*). Those investigations demonstrated that *nido*-carborane-containing molecules radioiodinated rapidly (<10 s) and provided high radiochemical yields (85−99%). Importantly, the resultant radioiodinated *nido*-carboranes were stable to in vivo dehalogenation. Subsequently, we demonstrated for the first time that *nido*-carboranes could be rapidly and efficiently labeled with ^{211}At (*26*). More recently we undertook a detailed in vivo evaluation of astatinated benzamides and *nido*-carboranes, and found that some *nido*-carborane derivatives appeared to provide increased in vivo stability (*27*). On the basis of the information gained from the prior studies, we undertook the study described herein to determine if biotin derivatives containing a *nido*-carboranyl moiety were more stable to deastatination than a biotin derivative astatinated on an aryl moiety. The investigation included (a) astatination of two biotin-aryl derivatives (**1a**, **2a**), (b) in vivo evaluation of the radiohalogenated aryl-biotin derivative (**2a**), (c) syntheses and radiohalogenations of

[3] The term "*nido*-" (nestlike) signifies an icosahedral carborane cage molecule that has a boron atom removed from its apex. Borane cage molecules that have a complete (closed) icosahedron structure are referred to as "*closo*-carboranes". The borane cage molecules evaluated in this study can be referred to as dicarbaboranes, as they contain two carbon atoms. For simplicity, they are termed "carboranes" herein.

three of *nido*-carboranyl-biotin derivatives (**3a**, **4a**, **5a**), and (d) in vivo evaluations of two *nido*-carboranyl-biotin derivatives (**4a**, **5a**). In some of the studies, biotin derivatives were dual labeled (^{211}At and ^{125}I) such that a comparison of the ^{211}At and ^{125}I concentrations in tissues, particularly lung, spleen, and thyroid, of the mice could be made.

EXPERIMENTAL PROCEDURES

General. Chemicals purchased from commercial sources were analytical grade or better and were used without further purification, except where noted. 4-Pentynoic acid, **13**, was obtained from Lancaster (Windham, NC) or Farchan Laboratories (Gainesville, FL). L-Aspartic acid α-*tert*-butyl ester, **7**, and L-lysine-ϵ-*N*-*tert*-butoxycarbonyl-(Boc), **16**, were obtained from Calbiochem-Novabiochem Corp. (San Diego, CA). Chloramine-T (ChT), D-biotin, and phosphate-buffered saline (PBS) were obtained from Sigma (Sigma-Aldrich Corp., St. Louis, MO). Dimethylaminopropylamine, *N*-chlorosuccinimide, tetrafluorophenol, 1,3-phenylenediamine, **19**, 3,5-diaminobenzoic acid, **23**, and most other chemicals were obtained from Aldrich (Sigma-Aldrich Corp., Milwaukee, WI). Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μm) prior to use. Tetrafluorophenyl trifluoroacetate (TFP-OTFA) was prepared as previously described (*28*). Biotin deficient/egg white enriched (avidin rich) mouse chow (#5836 test diet from basal diet #5755) was obtained from Purina Test Diets (Richmond, IN).

Radioactivity. All radioactive materials were handled according to approved protocols at the University of Washington. ^{211}At production was accomplished by α-particle irradiation (28 MeV) of natural bismuth, via ^{209}Bi(α, 2n)^{211}At reaction, on the University of Washington Scandatronix MC-50 cyclotron. The ^{211}At activity was distilled from the bismuth target at 650−700 °C into a cooled trap as previously described (*29*). The dry distillation of ^{211}At was conducted in a charcoal-filtered glovebox (Innovative Technologies, radioisotope glovebox). The ^{211}At was trapped in a cooled (−78 °C) vial and was rinsed from the vial with 0.05 N NaOH for use in the labeling experiments.

All radiohalogenation reactions ($^{125/131}$I or ^{211}At) were conducted in vials capped with Teflon-coated septa, within a radioactivity-approved fume hood. The reaction vials were vented through a 10 mL charcoal-filled syringe. Additions of reagents and radionuclides to, or removal of materials from, radiohalogenation vessels were conducted by passing a syringe needle through the septa. All radiohalogenation reactions were conducted in a charcoal-filtered Plexiglas enclosure within a radiochemical fume hood.

Na[^{125}I]I and Na[^{131}I]I were purchased from Perkin-Elmer Life and Analytical Sciences (formerly NEN/Dupont, Billerica, MA) as high concentration/high specific activity radioiodide in 0.1 N NaOH. Measurement of ^{125}I, ^{131}I, and ^{211}At was accomplished in one of two different dose calibrators. Measurements were conducted on either a Capintec CRC-15R or a Capintec CRC-6A Radioisotope Calibrator using calibration #44. Tissue samples containing these radionuclides were counted in a Wallac Wizard gamma counter with the following window settings: channels 35 to 102 (20−90 keV) and channels 165 to 185 (300−450 keV) when ^{125}I and ^{131}I were counted together. Tissue samples containing ^{211}At and ^{125}I were counted in all channels to get total radioactivity. The tissue samples were recounted in all channels after 3−5 days (0.1% of ^{211}At or less remaining) to obtain ^{125}I counts. These data were transferred to an Excel (Microsoft Corp., Redmond, WA) spreadsheet where the ^{211}At radioactivity was calculated by subtracting the ^{125}I counts from the total counts for each tissue sample. ^{211}At counts were corrected for decay during the counting process.

Spectroscopic Data. ^{1}H NMR spectra were obtained on a Bruker AC-200 (200 MHz), Bruker AF-301 (300 MHz), or Bruker AM-500 (500 MHz) instrument. The chemical shifts are expressed as ppm using tetramethylsilane as an internal standard ($\delta = 0.0$ ppm). ^{11}B NMR were obtained at 160 MHz (500 MHz for ^{1}H) and 96 MHz (300 MHz for ^{1}H). The spectra are referenced ($\delta = 0.0$ ppm) to $BF_3{\cdot}O(Et)_2$ as an external standard (insert) in the NMR tube. ^{11}B NMR included ^{1}H-coupled and -decoupled spectra for all samples examined. Only ^{1}H decoupled resonances are reported. All ^{11}B resonances were split when in the coupled spectra except in iodinated samples where one proton was not coupled. IR data were obtained on a Perkin-Elmer 1420 infrared spectrophotometer. Mass spectral data were obtained on a VG 70SEQ mass spectrometer with 11250J data system. Fast atom bombardment (FAB^+) mass spectral data were obtained at 8 kV using a matrix of 90% thioglycerol, 9% DMSO, and 1% TFA (DMIX) or propylene glycol 600 containing thioglycolate. Electrospray mass spectral data was obtained on a Micromass Quattro II Tandem Quadrupole Mass Spectrometer.

Analytical Chromatography. All reactions were monitored by HPLC. Nonradioactive samples were assessed on a system that contained a Hewlett-Packard quaternary 1050 gradient pump, a variable wavelength UV detector (254 nm), and a Varex ELSD MKIII or ELSD 2000 evaporative light-scattering detector. Analyses of the HPLC data were conducted on Hewlett-Packard HPLC ChemStation software. Reversed-phase HPLC chromatography was carried out on an Alltech Altima C-18 column (5 μm, 250 × 4.5 mm) using a gradient solvent system at a flow rate of 1 mL/min. Solvent A in the gradient was methanol. Solvent B was aqueous 0.1% HOAc. Starting from 40% A, the initial solvent mixture was held for 2 min, and then the gradient was increased linearly to 100% A over the next 10 min and 100% A was held for 8 min. Retention times (t_R) of biotin derivatives are provided with the experimental for each compound.

Radioiodinated and astatinated compounds were evaluated by reversed-phase HPLC analyses. All radioiodinated compounds were characterized by correlation with nonradioactive iodinated standards on the HPLC. Astatinated compounds generally had slightly longer retention times on reversed-phase HPLC than did the iodinated standards. The HPLC system consisted of two Beckman model 110B pumps, a Beckman 420 controller, a Beckman model 153 UV detector (254 nm), and a Beckman model 170 radioisotope detector. Analysis of the HPLC data were conducted on a PC running Hewlett-Packard HPLC ChemStation software. Reversed-phase HPLC chromatography was carried out on an Alltech Altima C-18 column (5 μm, 250 × 4.5 mm) using a gradient solvent system at a flow rate of 1 mL/min. Retention times (t_R) of biotin derivatives are provided with the experimental for each compound.

Syntheses of the following compounds were conducted as previously described in the literature: *N′*-(13-(*p*-tri-*n*-butylstannylbenzamido)-4,7,10-trioxatridecanyl)-*N*-methylglycylbiotinamide, **1a** (*18*), *N′*-(13-(*p*-iodobenzamido)-4,7,10-trioxatridecanyl)-*N*-methylglycylbiotinamide, **1b** (*18*); biotin tetrafluorophenyl ester, **6** (*30*), N-biotinyl-α-*tert*-butyl-L-aspartate TFP ester, **8** (*20*); *N*-(*tert*-butoxycarbonyl)-4,7,10-trioxa-1,13-tridecanediamine, **9** (*31*), 2-(*N*-

biotinyl)-4-(*N*′-(13′-*tert*-butoxycarbonylamino)-4′,7′,10′-trioxatridecaneamino)-L-aspartate 1-*O*-*tert*-butyl ester, **10** (*19*), 4-tri-*n*-stannylbenzoate tetrafluorophenyl ester, **12a** (*18*), 4-iodobenzoate tetrafluorophenyl ester, **12b** (*18*), pentynoic acid tetrafluorophenyl ester, **14** (*27*); 3-(*closo*-carboranyl)propionate tetrafluorophenyl ester, and **15** (*27*); *N*-(3-aminophenyl)-3-(*closo*-carboranyl)propionamide, **20** (*27*).

2-(*N*-Biotinyl)-4-(*N*′-(13′-amino-4′,7′,10′-trioxatridecaneamino)-L-aspartate, 11. A 500 mg (0.70 mmol) quantity of **10** was dissolved in 5 mL of trifluoroacetic acid (TFA). The mixture was stirred at room temperature for 30 min, and then the TFA was removed under a stream of nitrogen. The crude residue was washed with anhydrous ether (3 × 20 mL). The TFA salt of **11** was dried under vacuum and was used directly in the next step, yield ~100%. ^{1}H NMR (CD_3OD, 200 MHz) δ 1.39−1.54 (m, 4H), 1.59−1.82 (m, 6H), 1.89−2.01 (m, 2H), 2.24−2.32 (m, 2H), 2.69−2.99 (m, 4H), 3.13 (t, J = 6.3 Hz, 2H), 3.20−3.34 (m, 4H), 3.52 (t, J = 5.9 Hz, 2H), 3.57−3.77 (m, 7H), 4.33 (dd, J = 4.4, 8.1 Hz, 1H), 4.51 (dd, J = 4.4, 8.1 Hz, 1H), 4.78 (dd, J = 5.5, 7.3 Hz, 1H). HRMS (ES$^+$), calcd for $C_{24}H_{44}N_5O_8S$ (M + H)$^+$, 562.2911, found 562.2890; HPLC, t_R = 3.6 min.

2-(*N*-Biotinyl)-4-(*N*′-(13′-(4″-tri-*n*-butylstannylbenzoyl)amino)-4′,7′,10′-trioxatridecaneamino)-L-aspartate, 2a. A 150 mg (0.268 mmol) quantity of **11** and 75 μL of Et_3N were combined in 6 mL of anhydrous DMF. To that mixture was added 152 mg (0.268 mmol) of *p*-tri-*n*-butylstannylbenzoate TFP ester, **12a**, and the resultant mixture was stirred at room temperature for 30 min. The DMF was removed under vacuum on a Kugelrohr apparatus, and the crude product was placed on high vacuum overnight. The residue was placed on a silica gel column (16 g) and was eluted with 50:50 EtOAc/MeOH. The fractions containing product were concentrated and dried under vacuum to yield 180 mg (70%) of **2a**. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 0.87 (t, J = 7.4 Hz, 9H), 1.06 (t, J = 8.0 Hz, 6H), 1.28−1.36 (m, 6H), 1.44−1.57 (m, 10H), 1.61−1.72 (m, 6H), 1.84−1.89 (m, 2H), 2.13−2.31 (m, 2H), 2.60−2.87 (m, 4H), 3.02−3.27 (m, 6H), 3.39−3.63 (m, 9H), 4.22−4.64 (m, 3H), 6.57 (bs, 1H), 7.50 (d, J = 8.0 Hz, 2H), 7.73 (d, J = 8.0 Hz, 2H). HRMS (ES$^+$) calcd for $C_{43}H_{73}N_5NaO_9SSn$ (M + Na)$^+$ 978.4049, found: 978.4079; HPLC, t_R = 16.5 min.

2-(*N*-Biotinyl)-4-(*N*′-(13′-(4″-iodobenzoyl)amino)-4′,7′,10′-trioxatridecaneamino)-L-aspartate, 2b. A 142 mg (0.253 mmol) quantity of **11** and 70 μL (0.505 mmol) of Et_3N were combined in 6 mL of anhydrous DMF. To that mixture was added 100 mg (0.253 mmol) of *p*-iodobenzoate TFP ester, **12b**, and the resultant mixture was stirred at room temperature for 1 h. The DMF was removed on a Kugelrohr apparatus, and the residue was placed on a silica gel column. The column was eluted with 50:50 EtOAc/MeOH. The fractions containing product were combined and dried under high vacuum to yield 159 mg (80%) of the iodobenzamidyl biotin derivative **2b** (*32*).

1-*N*-(Biotinyl)-5-*N*-(*tert*-butyloxycarbonyl)-L-lysine, 17a. Biotin tetrafluorophenyl ester **6** (1.64 g, 4.18 mmol) was added to a solution of *N*-ϵ-*tert*-Boc-L-lysine **16** (1.0 g, 4.06 mmol), $NaHCO_3$ (1.13 g, 13.40 mmol), H_2O (40 mL), and acetone (40 mL) at room temperature. The reaction mixture was stirred at room temperature for 16 h, and then volatile materials were evaporated under vacuum. The residue was washed with 60 mL of EtOAc and neutralized with 14.0 mL of 1.0 N HCl. After standing at 5 °C overnight, the product was filtered, washed with cold water, and dried under vacuum to yield 1.91 g (87%) of compound **17a** as a white solid: mp 156.8−157.5 °C. ^{1}H NMR (CD_3OD): δ 1.43 (s, 9 H), 1.48−1.90 (m, 10 H), 2.26 (t, J = 7.2 Hz, 2 H), 2.69 (d, J = 12.8 Hz, 1 H), 2.89−3.05 (m, 3 H), 3.16−3.26 (m, 1 H), 3.29−3.34 (m, 2 H), 4.26−4.34 (m, 2 H), 4.49 (dd, J = 4.8, 8.1 Hz, 1 H). HRMS (FAB$^+$) calcd for $C_{21}H_{36}N_4O_6SNa$ (M + Na)$^+$ 495.2253, found: 495.2240; HPLC: t_R = 10.3 min.

1-*N*-(Biotinyl)-L-lysine, 17b. A 1.0 g quantity (2.12 mmol) of **17a** was dissolved in 8 mL of TFA. The solution was stirred for 30 min at room temperature, and the excess TFA was removed using a gentle stream of air. The crude residue was washed 2× with 15 mL of ether. The resultant solid was dissolved in a minimum amount of MeOH, made basic with Et_3N (8 mL), and stirred for 30 min at room temperature. The MeOH and excess Et_3N were removed under a stream of air and then under vacuum to yield 772 mg (98%) of **17b** as a colorless solid. mp > 250 °C (dec); ^{1}H NMR (CD_3OD, 500 MHz) δ 1.41−1.53 (m, 4H), 1.57−1.78 (m, 6H), 1.88−1.95 (m, 1H), 2.23−2.34 (m, 2H), 2.68−2.71 (m, 1H), 2.91−2.94 (m, 3H), 3.19−3.23 (m, 1H), 3.30−3.31 (m, 1H), 4.31 (dd, J = 4.3, 8.0 Hz, 1H), 4.39 (dd, J = 4.3, 8.0 Hz, 1H), 4.50 (dd, J = 5.0, 8.0 Hz, 1H). HRMS (ES$^+$) calcd for $C_{16}H_{29}N_4O_4S$ (M + H)$^+$ 373.1910, found 373.1915; HPLC: t_R = 2.7 min.

1-*N*-(Biotinyl)-5-*N*-(3′-(*closo*-carboranyl)propionyl)-L-lysine, 18. A 750 mg quantity of **17b** (2.02 mmol) and Et_3N (285 μL, 2.02 mmol) were dissolved into 4 mL of anhydrous DMF. To the solution was added **15** (743 mg, 2.20 mmol), and the reaction mixture was stirred for 1.5 h at room temperature. The reaction solution was diluted with 10 mL of H_2O and then washed with EtOAc (2 × 25 mL). The H_2O and DMF were removed under vacuum (Kugelrohr). The residue was further dried under high vacuum to yield 966 mg (84%) of **18** as a colorless solid: mp 176−179 °C; ^{1}H NMR (CD_3OD, 200 MHz) δ 1.36−1.85 (m, 17H), 2.23−2.45 (m, 5H), 2.54−2.73 (m, 4H), 2.93 (dd, J = 5.1, 12.8 Hz, 1H), 3.12−3.26 (m, 4H), 3.29−3.32 (m, 1H), 4.27−4.38 (m, 2H), 4.49 (dd, J = 5.0, 8.0 Hz, 1H), 4.55 (bs, 1H); ^{11}B NMR (CD_3OD, decoupled, 64 MHz) δ −8.33 (4B), −10.49 (6B). HRMS (ES$^+$) calcd for $C_{21}H_{43}B_{10}N_4O_5S$ (M + H)$^+$ 573.3885, found 573.3914; HPLC: t_R= 13.2 min.

1-*N*-(Biotinyl)-5-*N*-(3′-(*nido*-carboranyl)propionyl)-L-lysine, 3a. A 50 mg quantity (0.088 mmol) of **18** was dissolved in pyrrolidine (1 mL) cooled in an ice/H_2O bath. This mixture was allowed to warm to room temperature over 30 min. H_2O (5 mL) and diethyl ether (5 mL) were added to the mixture. The ether was separated, and the H_2O layer was washed with ether (4 × 5 mL). The H_2O was removed under vacuum, and the crude residue was dissolved in a 5:4:1 mixture of H_2O:CH_3CN:MeOH (1 mL). This solution was loaded onto an ion exchange column, which was prepared as follows. The ion exchange column was prepared by connecting two Alltech IC-H ion exchange columns in series and washing them with 10 mL of 1 N NaOH. Following this, the columns were washed with H_2O until column reached neutral pH. The columns were then washed with 20 mL of 5:4:1 H_2O:CH_3CN:MeOH solution. Crude product was eluted in 1 mL fractions (20×). Fractions containing product were combined, and solvents were removed under vacuum to yield 42 mg (83%) of **3a** as a tacky solid; ^{1}H NMR (CD_3OD, 300 MHz) δ 1.33−1.91 (m, 16H), 1.98−2.02 (m, 5H), 2.25−2.31 (m, 4H), 2.69 (d, J = 12.5 Hz, 1H), 2.96 (dd, J = 5.2, 12.5 Hz, 1H), 3.15 (t, J = 6.7 Hz, 2H), 3.22−3.32 (m, 5H), 4.22 (dd, J = 4.3, 8.0 Hz, 1H), 4.33 (dd, J = 4.3, 8.0 Hz, 1H), 4.50 (dd, J = 5.0, 8.0 Hz, 1H); ^{11}B NMR (CD_3OD, decoupled, 96 MHz) δ −10.52 (2B), −13.11 (1B), −16.05 (1B), −17.82 (1B), −20.91 (1B), −32.73 (2B),

−37.04 (1B). HRMS (ES^-) calcd for $C_{21}H_{41}B_9N_4O_5S$ $(M)^-$ 560.3635, found 560.3663; HPLC: t_R= 7.9 min.

3-(3′-(*closo*-Carboranyl)propionyl)amino-1-aminobenzene, 20. A 1.0 g quantity (2.72 mmol) of **15** was dissolved in 20 mL of anhydrous DMF. In a separate flask, **19** (0.59 g, 5.43 mmol) was dissolved in 20 mL of anhydrous DMF. The solution containing **15** was added dropwise to the solution containing **19** over a 1 h period. After the addition was complete, the reaction mixture was stirred at room temperature for 2.5 h. DMF was removed under vacuum at 50 °C (Kugelrohr). The residue was dissolved in 50 mL of diethyl ether and was washed with 1% HOAc/H_2O (2 × 25 mL) and then H_2O (25 mL). The ether layer was removed under vacuum, and the colorless solid was dried under vacuum to yield 0.790 g (95%) of **20**: mp 136−137 °C; ^{1}H NMR ($CDCl_3$, 500 MHz) δ 1.57−2.51 (m, 12H), 2.57 (t, J = 7.1 Hz, 2H), 2.68 (t, J = 7.1 Hz, 2H), 3.85 (s, 1H), 6.47 (d, J = 8.0 Hz, 1H), 6.65 (d, J = 8.0 Hz, 1H), 7.06 (s, 1H), 7.09 (t, J = 8.0 Hz, 1H), 7.14 (s, 1H); ^{11}B NMR ($CDCl_3$, decoupled, 160 MHz) δ −8.66 (2B), −9.63 (2B), −10.76 (1B), −12.02 (3B), −12.98 (2B). HRMS (ES^+) calcd for $C_{11}H_{23}B_{10}N_2O$ $(M + H)^+$ 309.2741, found 309.2734; HPLC: t_R = 13.5 min.

3-(3′-(*closo*-Carboranyl)propionyl)amino-1-isothiocyanatobenzene, 21. A 81 mg quantity (0.263 mmol) of **20** was dissolved into 3 mL of DMF. To this solution was added 1,1-thiocarbonyldiimidazole (47 mg, 2.63 mmol), and the reaction mixture was stirred at room temperature for 30 min. DMF was removed under vacuum (Kugelrohr). The residue was dissolved in MeOH (0.5 mL), and 3 mL of H_2O was added. The mixture was stirred for 30 min, and the H_2O was decanted. The solid was washed with another 3 mL of H_2O and dried under vacuum to yield 50 mg (54%) of **21** as a tacky solid. ^{1}H NMR (CD_3OD, 300 MHz) δ 1.27−2.56 (m, 10H), 2.61−2.73 (m, 4H), 4.59 (bs, 1H), 6.98−7.02 (m, 1H), 7.34 (t, J = 8.0 Hz, 1H), 7.39−7.43 (m, 1H), 7.64 (t, J = 2.1 Hz, 1H); ^{11}B NMR (CD_3OD, decoupled, 96 MHz) δ −1.60 (1B), −4.89 (1B), −8.72 (2B), −10.85 (6B). HRMS (ES^+) calcd for $C_{12}H_{20}B_{10}N_2ONaS$ $(M + Na)^+$ 373.2124, found 373.2125; HPLC: t_R = 15.7 min.

3-(3′-(*closo*-Carboranyl)propionyl)amino-1-*N*-(1′-(*N*-biotinyl)-5′-lysyl-thiourea)benzene, 22. A 50 mg quantity (0.14 mmol) of **21**, **17b** (58 mg, 0.16 mmol), and Et_3N (100 μL, 0.71 mmol) were dissolved in 5 mL of DMF. The reaction mixture was stirred for 30 min, and the DMF was removed under vacuum. The residue was dissolved in minimum amount of MeOH, loaded onto a silica gel (20 g) column (1.5 cm × 26 cm), and eluted with an EtOAc/MeOH mixture (50:50). The solvents were removed from the fractions containing the product, and the colorless solid was dried under vacuum to yield 67 mg (65%) of **22**: mp 178−181 °C; ^{1}H NMR (CD_3OD, 500 MHz) δ 1.29 (s, 1H), 1.40−1.46 (m, 4H), 1.55−1.78 (m, 12H), 1.85−1.92 (m, 2H), 2.26−2.29 (m, 4H), 2.67−2.69 (m, 1H), 2.92 (dd, J = 5.0, 13.0 Hz, 1H), 3.18−3.22 (m, 2H), 3.30−3.31 (m, 5H), 3.57 (bs, 1H), 4.28−4.33 (m, 2H), 4.47 (dd, J = 5.0, 8.0 Hz, 1H), 4.61 (bs, 1H), 7.02 (d, J = 8.0 Hz, 1H), 7.29 (t, J = 8.0 Hz, 1H), 7.39 (d, J = 8.0 Hz, 1H), 7.59 (s, 1H); ^{11}B NMR (CD_3OD, decoupled, 160 MHz) δ −1.00 (2B), −8.08 (2B), −10.10 (4B), −11.40 (2B). HRMS (ES^+) calcd for $C_{28}H_{47}N_6O_5S_2B_{10}Na_2$ $(M - H + 2Na)^+$ 767.3775, found 767.3776; HPLC: t_R = 13.3 min.

3-(3′-(*nido*-Carboranyl)propionyl)amino-1-*N*-(1′-(*N*-biotinyl)-5′-lysyl-thiourea)benzene, 4a. A 44 mg quantity (0.06 mmol) of **22** was dissolved in pyrrolidine (1 mL), and the resultant mixture was stirred at room temperature for 1 h. Pyrrolidine was evaporated from the reaction mixture in a fume hood under gentle stream of air. The residue was rinsed with ether (2 × 10 mL), and the ether was decanted. The crude product was dissolved in a 5:4:1 mixture of H_2O:CH_3CN:MeOH (1 mL) and was loaded on an ion exchange column (prepared as described in the synthesis of **3a**). The column was eluted with 1 mL fractions (20×). Fractions containing **4a** were combined, and solvents were removed under vacuum to yield 28 mg (67%) of **4a** as a pale yellow solid: mp 161−163 °C; ^{1}H NMR (CD_3OD, 300 MHz) δ 1.33−1.45 (m, 3H), 1.53−1.71 (m, 6H), 1.78−1.93 (m, 11H), 2.24 (t, J = 7.3 Hz, 2H), 2.47 (t, J = 7.8 Hz, 2H), 2.64 (d, J = 12.5 Hz, 1H), 2.90 (dd, J = 5.0, 13.0 Hz, 1H), 3.06−3.11 (m, 5H), 3.24−3.29 (m, 2H), 3.49−3.57 (m, 1H), 4.20 (dd, J = 4.7, 8.3 Hz, 1H), 4.27 (dd, J = 4.3, 8.0 Hz, 1H), 4.46 (dd, J = 4.3, 8.0 Hz, 1H), 7.03 (d, J = 8.0 Hz, 1H), 7.27 (t, J = 8.0 Hz, 1H), 7.38 (d, J = 8.0 Hz, 1H), 7.57 (t, J = 2.1 Hz, 1H); ^{11}B NMR (CD_3OD, decoupled, 96 MHz) δ −10.42 (2B), −12.68 (1B), −15.92 (1B), −17.72 (1B), −32.63 (2B), −36.78 (2B). HRMS (ES^-) calcd for $C_{28}H_{47}N_6O_5S_2B_9$ $(M)^-$ 710.3887, found 710.3895; HPLC: t_R = 10.0 min.

3-(3′-(*closo*-Carboranyl)propionyl)amino-5-aminobenzoic acid, 24. 3,5-Diaminobenzoic acid dihydrochloride (**23**) (3.7 g, 16.3 mmol) and Et_3N (3.41 mL, 24.5 mmol) were dissolved in 20 mL of DMF under argon atmosphere. A 3 g quantity (8.1 mmol) of TFP ester **15** was dissolved in 20 mL of DMF and was added dropwise over 30 min. The reaction was stirred at room temperature for 1 h. the DMF was removed under vacuum. The crude product was dissolved in hexane/ethyl acetate (4:1), loaded onto a silica column (100 g), and eluted with gradient of starting with hexane/ethyl acetate (4:1). The product eluted with 100% EtOAc. Fractions containing **24** were collected, and solvent was removed under vacuum. The isolated product was dried under vacuum to yield 2.6 g (91%) of **24** as a colorless solid: mp 123−125 °C; ^{1}H NMR (CD_3OD, 500 MHz) δ 1.56−2.55 (m, 10H), 2.58−2.61 (m, 2H), 2.65−2.68 (m, 2H), 4.56 (bs, 1H), 7.11 (s, 1H), 7.24 (s, 1H), 7.41 (s, 1H); ^{11}B NMR (CD_3OD, decoupled, 160 MHz) δ −1.11 (1B), −4.32 (1B), −8.06 (2B), −10.15 (4B), −11.37 (2B). HRMS (ES^+) calcd for $C_{12}H_{22}B_{10}N_2O_3Na$ $(M + Na)^+$ 375.2459, found 375.2454; HPLC: t_R = 13.4 min.

3-(3′-(*closo*-Carboranyl)propionyl)amino-5-(*N*-*tert*-butyloxycarbonyl)aminobenzoic Acid, 25. A 1.0 g quantity (2.84 mmol) of **24** and NaOH (142 mg, 3.55 mmol) were dissolved in 20 mL of DMF/H_2O (1:1). Di-*tert*-butyl dicarbonate (776 mg, 3.55 mmol) was added to the reaction flask, and the reaction mixture was stirred for 16 h at room temperature. The solvent was removed under vacuum. Crude product was dissolved into 10 mL of water and was acidified with 4 mL of 1 N HCl. The precipitate was collected by filtration and was dried under vacuum to yield 920 mg (72%) **25** as a colorless solid: mp 185−186 °C; ^{1}H NMR (CD_3OD, 500 MHz) δ 1.52 (s, 9H), 1.58−2.54 (m, 10H), 2.61−2.64 (m, 2H), 2.66−2.70 (m, 2H), 4.58 (bs, 1H), 7.78 (s, 1H), 7.84 (s, 1H), 7.99 (s, 1H); ^{11}B NMR (CD_3OD, decoupled, 160 MHz) δ −1.11 (1B), −4.41 (1B), −8.11 (2B), −10.21 (4B), −11.41 (2B). HRMS (ES^+) calcd for $C_{17}H_{30}B_{10}N_2O_5Na$ $(M + Na)^+$ 475.2983, found 475.2995; HPLC: t_R = 14.5 min.

3-(3′-(*closo*-Carboranyl)propionyl)amino-5-(*N*-*tert*-butyloxycarbonyl)aminobenzoic Acid Tetrafluorophenyl Ester, 26. A100 mg quantity (0.22 mmol) of **25** and Et_3N (276 μL, 1.3 mmol) were dissolved into 3 mL of anhydrous DMF. The solution was cooled to 4 °C in an ice/H_2O bath. TFP-OTFA (129 μL, 0.67 mmol) was added, the reaction mixture was stirred at 4 °C for 30 min, and then 30 mL of H_2O was added. The precipitate was filtered, washed with water (4 × 10 mL), and dried

under vacuum to yield 115 mg (87%) of **26** as a colorless solid: mp 122−125 °C; ^{1}H NMR (CD_3OD, 500 MHz) δ 1.57 (s, 9H), 1.66−2.61 (m, 10H), 2.67−2.75 (m, 4H), 4.64 (bs, 1H), 7.48−7.55 (m, 1H), 8.05 (s, 1H), 8.12 (s, 1H), 8.14 (s, 1H); ^{11}B NMR (CD_3OD, decoupled, 160 MHz) δ −1.17 (1B), −4.23 (1B), −7.94 (2B), −10.04 (4B), −11.27 (2B). HRMS (ES^+) calcd for $C_{23}H_{30}B_{10}N_2O_5F_4Na$ $(M + Na)^+$ 623.2919, found 623.2929; HPLC: t_R = 15.4 min.

3-(3′-(*closo*-Carboranyl)propionyl)amino-5-(*N*-*tert*-butyloxycarbonyl)amino-1-(3′-dimethyl-aminopropyl)benzamide, 27. 3-(Dimethylamino)propylamine (49 μL, 3.84 mmol) and Et_3N (33 μL, 0.23 mmol) were dissolved in 4 mL of anhydrous DMF. To that solution was added **26** (115 mg, 0.19 mmol). The reaction mixture was stirred for 1 h at room temperature, 50 mL of water was added, and this mixture was stirred for an additional 1 h. The precipitate was filtered, washed with water (4 × 20 mL), and dried under vacuum to yield 90 mg (88%) of **27** as a colorless solid: mp 111−112 °C. ^{1}H NMR (CD_3OD, 500 MHz) δ 1.24−1.45 (m, 4H), 1.52 (s, 9H), 1.64−1.72 (m, 2H), 1.79−1.84 (m, 2H), 1.87−2.25 (m, 4H), 2.32 (s, 6H), 2.49 (t, J = 7.4 Hz, 2H), 2.61−2.64 (m, 2H), 2.66−2.70 (m, 2H), 3.39 (t, J = 7.4 Hz, 2H), 4.59 (bs, 1H), 7.54 (s, 1H), 7.62 (s, 1H), 7.81 (s, 1H); ^{11}B NMR (CD_3OD, decoupled, 160 MHz) δ −1.25 (1B), −4.09 (1B), −7.32 (1B), −8.26 (1B), −9.37 (1B), −10.45 (3B), −11.62 (2B). HRMS (ES^+) calcd for $C_{22}H_{43}B_{10}N_4O_4$ $(M + H)^+$ 537.4215, found 537.4220; HPLC: t_R = 16.4 min.

3-(3′-(*closo*-Carboranyl)propionyl)amino-5-amino-1-(3′-dimethylaminopropyl)benzamide, 28. A 73 mg quantity (0.14 mmol) of **27** was dissolved in TFA (2 mL). The solution was stirred for 30 min at room temperature, and the excess TFA was removed using a gentle stream of air in a fume hood. The crude residue was washed 2× with 3 mL of ether, and then the residue was dried under high vacuum to yield the TFA salt of **28** as a colorless tacky solid, which was used directly in the next reaction step. ^{1}H NMR (CD_3OD, 200 MHz) δ 0.74−1.47 (m, 8H), 1.61−1.76 (m, 2H), 2.17 (s, 6H), 2.28−2.35 (m, 3H), 2.45−2.61 (m, 5H), 3.27 (t, J = 7.4 Hz, 2H), 4.48 (bs, 1H), 6.71 (s, 1H), 6.98 (s, 1H), 7.08 (s, 1H); ^{11}B NMR (CD_3OD, decoupled, 96 MHz) δ −1.77 (1B), −5.30 (1B), −8.72 (2B), −10.80 (4B), −11.86 (2B). HRMS (ES^+) calcd for $C_{17}H_{35}B_{10}N_4O_2$ $(M + H)^+$ 437.3691, found 437.3698; HPLC: t_R = 12.5 min.

3-(3′-(*closo*-Carboranyl)propionyl)amino-5-(1′-(*N*-biotinyl)-5′-lysylthiourea)(3′-dimethylaminopropyl)-benzamide, 29. The crude **28** (0.14 mmol) was dissolved in a minimum amount of MeOH, made basic with Et_3N (2 mL), and stirred for 30 min at room temperature. The MeOH and excess Et_3N were removed under a stream of air and then under vacuum to yield a colorless oil. The oily residue and 1,1-thiocarbonyldiimidazole (22 mg, 0.14 mmol) were dissolved in 3 mL of anhydrous DMF. Reaction progress for formation of the phenyl isothiocyanate was followed by HPLC (1 h). Upon complete formation of the isothiocyanate, the biotin-lysine adduct **17b** (56 mg, 0.15 mmol) and Et_3N (57 μL, 0.41 mmol) were added, and then the reaction mixture was stirred for 3 h at room temperature. DMF was removed under vacuum, and the residue was dissolved in a minimum amount of MeOH. The crude reaction mixture was loaded onto a silica gel column (20 g, 2.5 cm × 35 cm) and was eluted using 1% Et_3N/MeOH. The purified product was dried under vacuum to yield 85 mg (74%) of **29** as a colorless oil: ^{1}H NMR (CD_3OD, 500 MHz) δ 1.24−1.46 (m, 4H), 1.53−1.74 (m, 6H), 1.79−1.90 (m, 4H), 2.25−2.31 (m, 3H), 2.34 (s, 6H), 2.79−2.84 (m, 4H), 2.91 (dd, J = 5.0, 13.0 Hz, 1H), 3.16−3.21 (m, 1H), 3.30−3.32 (m, 2H), 3.34−3.43 (m, 3H), 3.58 (bs, 1H), 4.25−4.30 (m, 2H), 4.45−4.49 (m, 1H), 4.62 (bs, 1H), 7.05 (s, 1H), 7.43−7.90 (m, 2H); ^{11}B NMR (CD_3OD, decoupled, 160 MHz) δ −1.08 (1B), −4.41 (1B), −8.09 (2B), −10.16 (4B), −11.40 (2B). HRMS (ES^+) calcd for $C_{34}H_{61}B_{10}N_8O_6S_2$ $(M + H)^+$ 851.5086, found 851.5083; HPLC: t_R = 12.6 min.

3-(3′-(*nido*-Carboranyl)propionyl)amino-5-(1′-(*N*-biotinyl)-5′-lysylthiourea)(3′-dimethylaminopropyl)-benzamide, 5a. A 60 mg quantity (0.07 mmol) of **29** was dissolved in pyrrolidine (1 mL) and was stirred for 30 min at room temperature. Excess pyrrolidine was removed under a gentle stream of air in a fume hood. The residue was rinsed with ether (2 × 10 mL), and the ether was decanted. The crude product was dissolved in a 5:4:1 mixture of H_2O:CH_3CN:MeOH (1 mL) and was loaded on an ion exchange column (prepared as described in the synthesis of **3a**). The column was eluted with 1 mL fractions (20×). Fractions containing **5a** were combined, and solvents were removed under vacuum to yield 40 mg (68%) of **5a** as a tacky light-yellow solid: ^{1}H NMR (CD_3OD/DMSO-d_6, 500 MHz) δ 1.11−1.27 (m, 3H), 1.51−1.60 (m, 3H), 1.65−1.74 (m, 2H), 1.80−1.84 (m, 2H), 1.87−2.01 (m, 2H), 2.08−2.22 (m, 2H), 2.25 (s, 6H), 2.26−2.32 (m, 1H), 2.53 (t, J = 7.4 Hz, 2H), 2.77 (t, J = 7.8 Hz, 2H), 2.88−2.97 (m, 2H), 3.41−3.49 (m, 2H), 3.55−3.56 (m, 2H), 3.69−3.89 (m, 4H), 4.54−4.75 (m, 4H), 7.92−8.27 (m, 3H); ^{11}B NMR (CD_3OD, decoupled, 160 MHz) δ −10.04 (2B), −12.29 (1B), −15.14 (1B), −17.13 (2B), −20.02 (1B), −31.63 (1B), −35.76 (1B). HRMS (ES^-) calcd for $C_{34}H_{59}B_9N_8O_6S_2$ $(M - H)^-$ 838.4836, found 838.4869; HPLC: t_R = 9.8 min.

General Procedure for Iodination of *nido*-Carborane Derivatives, 3a, 4a, and 5a. To a 500 μL quantity of a 2 mg/mL solution of *nido*-carborane derivative in MeOH/1% HOAc was added an appropriate microliter quantity of a 22 mg/mL solution of NaI in H_2O to introduce 0.5 mol equiv of iodide. Immediately following this, an appropriate microliter quantity of a 22 mg/mL solution of *N*-chlorosuccinimide (NCS) in MeOH was added to introduce 0.5 mol equiv. The reaction mixture generally turned light brown as the NCS was added but returned to colorless almost immediately. After 30 s, the reaction was quenched by the addition of 10 μL of a 22 mg/mL solution of sodium metabisulfite in H_2O.

Iodinated *nido*-carboranyl species were used for radio-HPLC peak identification. HPLC analysis of the reaction mixtures showed both starting material and an iodinated product. To obtain pure samples, the HPLC peak corresponding to the iodinated product was collected from HPLC effluent. Identity of the collected material was obtained from high-resolution mass spectral analysis.

1-*N*-(Biotinyl)-5-*N*-(3′-(iodo-*nido*-Carboranyl)propionyl)-L-lysine, 3b. HRMS calcd for $C_{21}H_{40}B_9N_4O_5SI$ (M^-) 686.2594, found 686.2602; HPLC: t_R = 9.8 min.

3-(3′-(Iodo-*nido*-Carboranyl)propionyl)amino-1-*N*-(1′-(*N*-biotinyl)-5′-lysylthiourea)-benzene, 4b. HRMS calcd for $C_{28}H_{46}N_6O_5S_2B_9I$ (M^-) 836.2889, found 836.2853; HPLC: t_R = 10.7 min.

3-(3′-(Iodo-*nido*-carboranyl)propionyl)amino-5-(1′-(*N*-biotinyl)-5′-lysylthiourea)(3′dimethylaminopropyl)benzamide, 5b. HRMS calcd for $C_{34}H_{58}B_9IN_8O_6S_2$ (M^-) 964.3791, found 964.3803; HPLC: t_R = 11.0 min.

General Procedure for Radiohalogenation of Arylstannanes, 1a and 2a. To a 50−100 μL aliquot of a 1 mg/mL of the aryl stannanes (**1a** or **2a**) in MeOH/5% HOAc was added 3−10 μL of Na[^{125}I]I, Na[^{131}I] in 0.1 N NaOH or Na[^{211}At] in 0.05 N NaOH. Following this, 10 μL of a 1 mg/mL solution of NCS in MeOH was added.

The reaction was allowed to proceed for 1−10 min, and then 10 μL of 1 mg/mL solution of $Na_2S_2O_5$ in H_2O was added to quench the reaction. The radiohalogenated aryl halide derivatives were isolated from reversed-phase HPLC effluent. After isolation, the MeOH and HOAc was removed under a stream of nitrogen (vented through charcoal containing syringe).

The radiohalogenation reactions can also be conducted using chloramine-T (ChT) in H_2O as described below for **2c**.

***N′*-(13-(4″-[^{131}I]iodobenzamido)-4,7,10-trioxatridecanyl)-*N*-methylglycylbiotinamide, [^{131}I]1b.** Reaction was conducted with 3 μL of Na[^{131}I] (2.14 mCi) in 0.1 N NaOH. [^{131}I]**1b** was isolated from the HPLC effluent and radio-HPLC analysis indicated that the reaction provided 95% yield, and 69% was isolated from the HPLC: t_R = 16.7 min.

***N′*-(13-(4″-[^{211}At]astatobenzamido)-4,7,10-trioxatridecanyl)-*N*-methylglycylbiotinamide, [^{211}At]1c.** Reaction was conducted with 10 μL of Na[^{211}At] (547 μCi) in 0.05 N NaOH with a 10 min reaction time. The reaction mixture containing [^{211}At]**1c** was purified by radio-HPLC to give 64% isolated yield: t_R = 12.6 min (Note: this was a different HPLC column from that used for the radioiodinated product listed above).

2-(*N*-Biotinyl)-4-(*N′*-(13′-(4″-[^{125}I]iodobenzoyl)amino)-4′,7′,10′-trioxatridecaneamino)-L-aspartate,[^{125}I]-2b. Reaction was conducted with 5 μL of Na[^{125}I] (2.76 mCi) in 0.1 N NaOH. [^{125}I]**2b** was isolated from the HPLC effluent. Radio-HPLC analysis indicated that the reaction provided 90% yield, but only 22% was isolated from the HPLC: t_R = 15.2 min. In four other experiments, 37%, 43%, 45%, and 49% (isolated) radiochemical yields were obtained.

2-(*N*-Biotinyl)-4-(*N′*-(13′-(4″-[^{211}At]astatobenzoyl)-amino)-4′,7′,10′-trioxatridecaneamino)-L-aspartate, [^{211}At]2c. Reaction was conducted with 100 μL of Na[^{211}At] (1.39 mCi) in 0.1 N NaOH. [^{211}At]**2c** was isolated from the HPLC effluent. Radio-HPLC analysis indicated that the reaction provided ∼100% yield, and 41% was isolated from the HPLC: t_R = 14.6 min.

In another experiment, 100 μL of **2a** in H_2O (1 mg/mL) and 20 μL of ChT (1 mg/mL) were reacted in Na phosphate buffer, pH 7.4 (100 μL), with 50 μL of (295 μCi) Na[^{211}At]At in 1:1 0.05 N NaOH/MeOH for 5 min at room temperature to give 23% isolated yield of [^{211}At]**2c**.

General Procedure for Radiohalogenation of *nido*-Carborane Derivatives, 3a, 4a, and 5a. To a solution containing 50−100 μL of 1 mg/mL solution of *nido*-carborane derivative (**3a**, **4a**, or **5a**) in MeOH/5%HOAc was added 1−5 μL of Na[^{125}I]I, Na[^{131}I]I, or 20−100 μL of Na[^{211}At]At in 0.05N NaOH. To the resultant solution was added 10−20 μL of a 1 mg/mL solution of NCS in MeOH or ChT in H_2O. The reaction was quenched after 30 s with 10−20 μL of a 1 mg/mL solution of $Na_2S_2O_5$ in H_2O.

Alternatively, 100 μL of a 1 mg/mL solution of *nido*-carborane derivative, **5b**, was reacted with 15−20 μg of a 1 mg/mL solution of ChT in H_2O and 5−15 μL (1.5−1.9 mCi) of Na[^{125}I]I in 0.05 N NaOH. After 1 min reaction time, the reaction was quenched with 15−20 μL of a 1 mg/mL solution of $Na_2S_2O_5$ in H_2O.

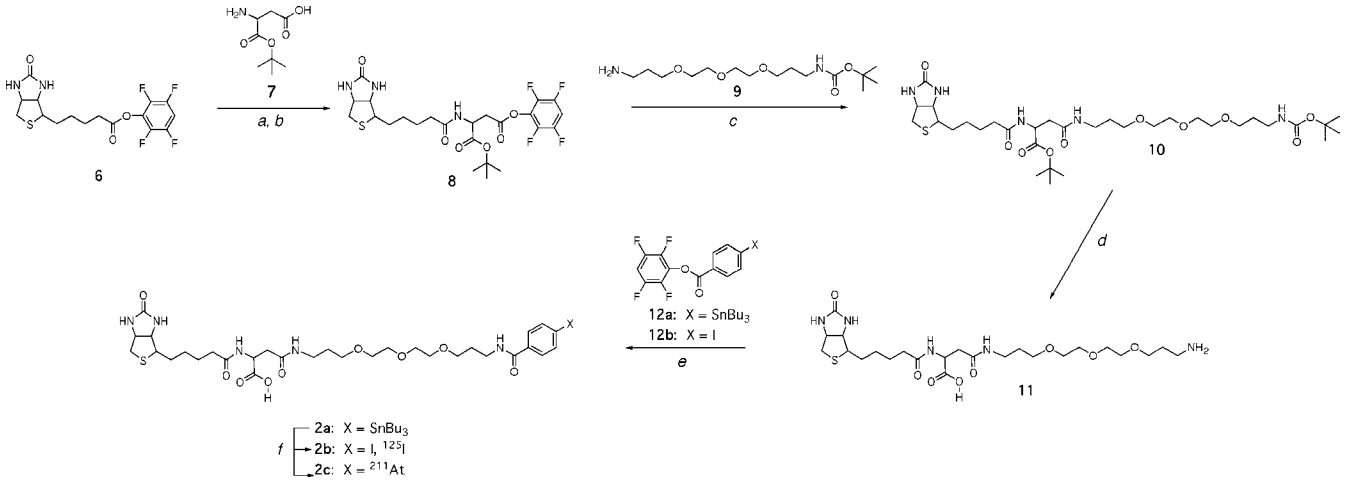
The radiohalogenated *nido*-carborane derivatives were isolated from reversed-phase HPLC effluent. After isolation, the MeOH and HOAc was removed under a stream of nitrogen (vented through charcoal containing syringe). Due to the propensity of the *nido*-carborane compounds to adhere to glass surfaces, plastic vials are routinely used. The radiohalogenated derivatives used in animal studies were diluted with a solution of 1% BSA in PBS after the MeOH/HOAc (or H_2O) was removed. This was necessary to keep the labeled material from adhering to the surfaces in the vial and syringe.

1-*N*-(Biotinyl)-5-*N*-(3′-([^{125}I]iodo-*nido*-carboranyl)-propionyl)-L-lysine, [^{125}I]3b. Reaction was conducted with 3 μL of Na[^{125}I]I (853 μCi) in 0.1 N NaOH. [^{125}I]**3b** was isolated from the HPLC effluent. Radio-HPLC indicated that the reaction provided >75% yield, and 67% was isolated from the HPLC: t_R = 14.0 min.

3-(3′-([^{125}I]Iodo-*nido*-carboranyl)propionyl)amino-1-*N*-(1′-(*N*-biotinyl)-5′-lysylthiourea)-benzene, [^{125}I]-4b. Reaction was conducted with 3 μL of Na[^{125}I]I (766 μCi) in 0.1 N NaOH. [^{125}I]**4b** was isolated from the HPLC effluent. Radio-HPLC indicated that the reaction provided 61% yield. HPLC: t_R = 16.7 min. In a separate reaction, a 59% yield was obtained.

3-(3′-([^{125}I]Iodo-*nido*-carboranyl)propionyl)amino-5-(1′-(*N*-biotinyl)-5′-lysylthiourea)(3′dimethylamino-propyl)benzamide, [^{125}I]5b. Reaction was conducted with 5 μL of Na[^{125}I]I (2.38 mCi) in 0.1 N NaOH. Radio-HPLC indicated that the reaction provided ∼61% [^{125}I]-**5b**, and 50% was isolated from the HPLC: t_R = 14.9 min. In another reaction employing NCS as the oxidant, an 83% (HPLC) yield was obtained. In two other reactions employing ChT in H_2O, 72% and 86% (HPLC) yields were obtained.

3-(3′-([^{211}At]Astato-*nido*-carboranyl)propionyl)-amino-1-*N*-(1′-(*N*-biotinyl)-5′-lysylthiourea)benzene, [^{211}At]4c. Reaction of 20 μL (160 μCi) of Na[^{211}At]-At with **4a** provided 60% radiochemical yield. The product was isolated from the HPLC effluent: t_R= 16.7 min. In a separate reaction, 40 μL (210 μCi) of Na[^{211}At]-At in a 1:1 mixture of 0.05 N NaOH/MeOH provided a 36% isolated yield.



3-(3′-([^{211}At]Astato-*nido*-carboranyl)propionyl)-amino-5-(1′-(*N*-biotinyl)-5′-lysylthiourea)(3′dimethyl-aminopropyl)benzamide, [^{211}At]5c. Reaction of 3 μL of Na[^{211}At]At (853 μCi) in 0.1 N NaOH provided 23% radiochemical yield of [^{211}At]**5c**. The product was isolated from the HPLC effluent. t_R= 14.0 min. In a separate reaction, 25 μL (125 μCi) of Na[^{211}At]At in a 1:1 mixture of 0.05 N NaOH/MeOH was reacted with NCS to provide a 57% isolated yield.

Biodistribution Studies. The animal studies were approved by the University of Washington's Institutional Animal Care and Use Committee prior to being conducted. Animal care and use was conducted in accordance with the NIH guidelines.[4] Mice were placed on a biotin deficient diet for 5−7 days prior to the start of each investigation. This was done to mimic the conditions used in the pretargeting studies.

Male athymic mice (BALB/c nu/nu), 4−5 weeks of age were obtained from Simonsen Laboratories (Gilroy, CA). Mice were housed for 1 week in the animal facility prior to beginning the study. All injections of reagents were administered to mice in a total volume of approximately 100 μL (injectate weighed) via the lateral tail vein. Animals were sacrificed at 1, 4, and 24 h postinjection of the radiolabeled materials. These times correspond to 9%, 32%, and 90% decay of ^{211}At. The data for tissues excised are shown in the Tables S1−S6 in the Supporting Information, and the average animal weight in a biodistribution, and average tumor weights for groups involving mice bearing tumor xenografts are provided in the table legends. Blood samples were obtained by cardiac

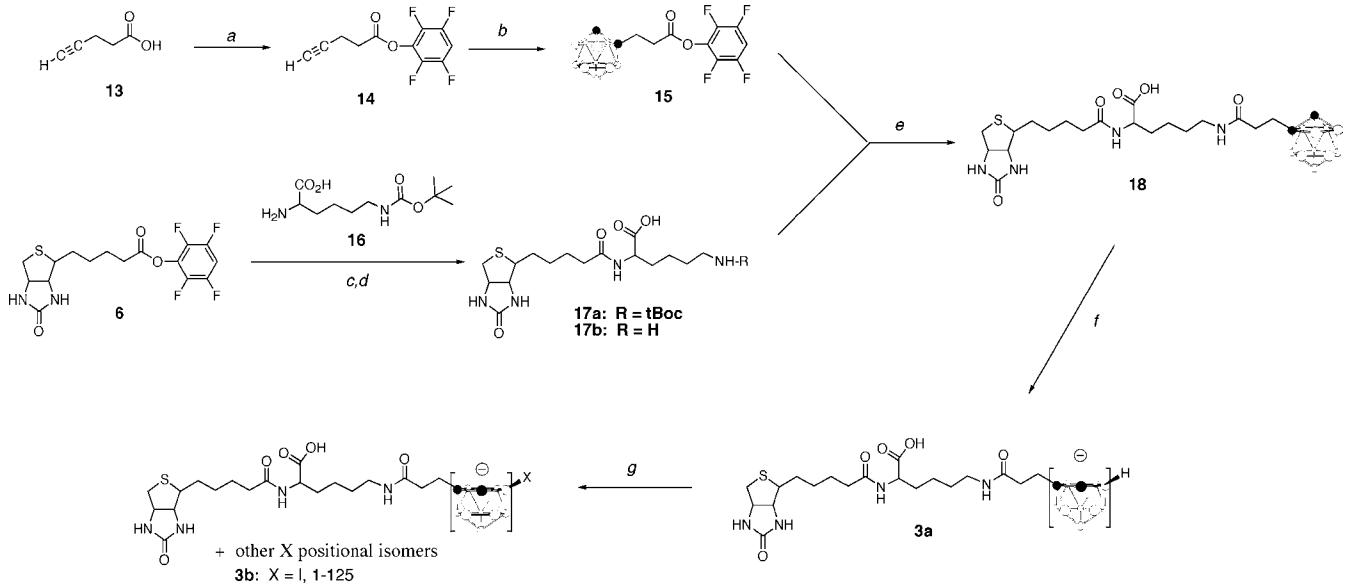
[4] NIH guidelines are described in NIH Publication 86-23: "Guide for the Care and Use of Laboratory Animals".

Scheme 1. Synthesis and Radiohalogenation of 2-(*N*-Biotinyl)-4-(*N′*-(13′-*p*-(tri-*n*-butylstannyl)benzoylamino)-4′,7′,10′-trioxatridecaneamino-L-aspartate, 2a

[a] Reagents and conditions: (a) H_2O, acetone, $NaHCO_3$, rt, 6 h; (b) TFP−OTFA, Et_3N, rt, 20 min; (c) Et_3N, DMF, 4 °C−rt, 1 h; (d) TFA, rt, 30 min, ∼100%; (e) Et_3N, DMF, **12a** or **12b**, rt, 30 min to 1 h, 70% (**2a**), 80% (**2b**); (f) MeOH/5% HOAc, NaX (X = ^{125}I or ^{211}At), NCS, rt, 1−10 min.

puncture immediately before sacrifice. Urine samples were obtained by syringe bladder tap at the time the tissues were excised. Excised tissues were blotted free of blood, weighed, and counted. Calculation of the percent injected dose (%ID) and percent injected dose per gram (% ID/g) in the tissues was based on internal standards containing 1 μL of the injected dose. The standards were prepared by mixing 10 μL of the injectate with 990 μL of saline. After mixing thoroughly, four 100 μL aliquots were placed in tubes and counted as standards. Standards were counted with tissues obtained at each time point, and an average value for the four standards were used in the calculations. The ^{211}At counts were compensated for decay, and where dual radionuclide counting was required, the ^{125}I counts were compensated (13.5%) for spillover counts from the ^{131}I. Total blood volume was estimated to be 8% of body weight for the calculations (*10*). Statistical analysis of the data was conducted using the paired student's *t*-test. Differences were considered statistically significant when the $p < 0.05$.

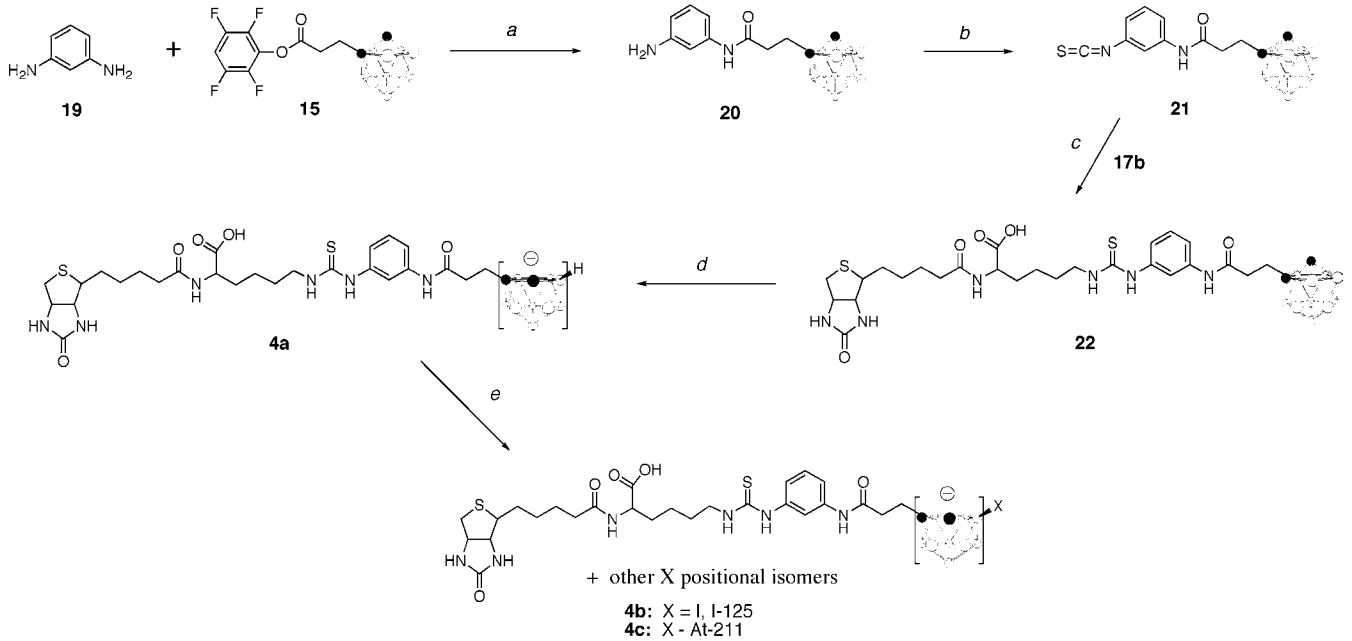
RESULTS



Synthesis of Biotin Compounds Containing Arylstannanes, 1a/2a, and Aryl Iodides, 1b/2b. Syntheses of **1a** and **1b** were conducted as previously described (*18*). Syntheses of **2a** and **2b** were conducted as shown in Scheme 1. Both syntheses were conducted through the common intermediate, biotin derivative **11**. The synthesis of compound **11** has been previously reported (*19*). Briefly, the synthesis started with reaction of biotin TFP ester, **6**, with aspartate α-*tert*-butyl ester, **7**, to form an adduct containing a free carboxylate. The carboxylate was subsequently esterified using TFP-OTFA to provide the TFP ester **8**. Reaction of **8** with the mono-Boc protected 4,7,10-trioxatridecane-1,13-diamine **9** gave the adduct **10**. In the previous studies, **10** was deprotected with neat trifluoroacetic acid (TFA) to provide **11**, which was then reacted with *p*-[^{125}I]iodobenzoate *N*-hydroxysuccinimide ester to form [^{125}I]**2b**. In these studies, the aryl stannanes **2a** was sought as an intermediate to prepare both [^{125}I]**2b** and [^{211}At]**2c**. To prepare **2a**, biotin derivative **11** was isolated as the TFA salt after treatment of **10** with neat TFA. Reaction of the TFA salt of **11** with *p*-(tri-*n*-butylstannyl)benzoate TFP ester **12a** and Et_3N provided **2a** in 70% yield. Similarly, reaction the TFA salt of **11** with *p*-iodobenzoate TFP ester **12b** and Et_3N provided **2b** in 80% yield.

Synthesis of Biotin Compounds 3a, 4a, and 5a, Containing *nido*-Carborane Moieties. The reactions employed to obtain the biotin-*nido*-carborane derivative **3a** are shown in Scheme 2. The synthesis of the 3-(*closo*-carboranyl)propionate TFP ester, **15**, was conducted as previously described (*27*). Briefly, the TFP ester of pentynoic acid **14** was prepared by reaction of 4-pentynoic acid with dicyclohexylcarbodiimide (DCC) and tetrafluorophenol (TFP-OH). Formation of the *closo*-carborane moiety to produce **15** was accomplished by reaction of the acetylenic group with decaborane ($B_{10}H_{14}$). It should be noted that the TFP ester was used in the reaction as free carboxylates are problematic in reactions with decaborane. Preparation of the biotin-lysine adduct **17a** was accomplished in 87% yield by reaction of biotin TFP ester **6** with ϵ-*N*-(*tert*-butoxycarbonyl)-L-lysine, **16**, and sodium bicarbonate in aqueous acetone at room temperature. Removal of the *t*-Boc protecting group from **17a** was facile in neat TFA, providing **17b** in 98% yield. Reaction of biotin-lysine adduct **17b** with **15** and Et_3N in anhydrous DMF provided the biotin derivative containing a *closo*-carborane moiety, **18**, in 84% yield. The *closo*-carborane moiety in **18** was readily converted into the *nido*-carborane by boron abstraction reaction with pyrrolidine to provide the 3-(*nido*-carboranyl)propionic acid, **3a** in 83% yield.

The synthesis employed to obtain **4a** is shown in Scheme 3. The synthesis is similar to that employed to prepare **3a**, except it incorporates 1,3-diaminobenzene, **19**, into the structure. Reaction of an excess of **19** with the 3-(*closo*-carboranyl)propionate TFP ester, **15**, in anhydrous DMF provided the *closo*-carborane adduct **20** in 95% yield. The aniline amine in **20** was converted to an isothiocyanate derivative **21** in 54% (isolated) yield by reaction with thiocarbonyldiimidazole in DMF at room temperature. The isothiocyanate **21** was reacted with the biotin-lysine adduct **17b** and Et_3N in anhydrous DMF at room temperature to provide the biotin derivative **22**, containing a *closo*-carborane moiety, in 65% yield. The targeted *nido*-carboranyl-biotin derivative **4a** was prepared in 67% yield by reaction of **22** with pyrrolidine.



Synthesis of the biotin derivative **5a**, containing a trialkylamine moiety, is shown in Scheme 4. 3,5-Diami-

Scheme 2. Synthesis and Radioiodination of 1-*N*-(Biotinyl)-5-*N*−(3′-(*nido*-carboranyl)propionyl)-L-lysine, 3a

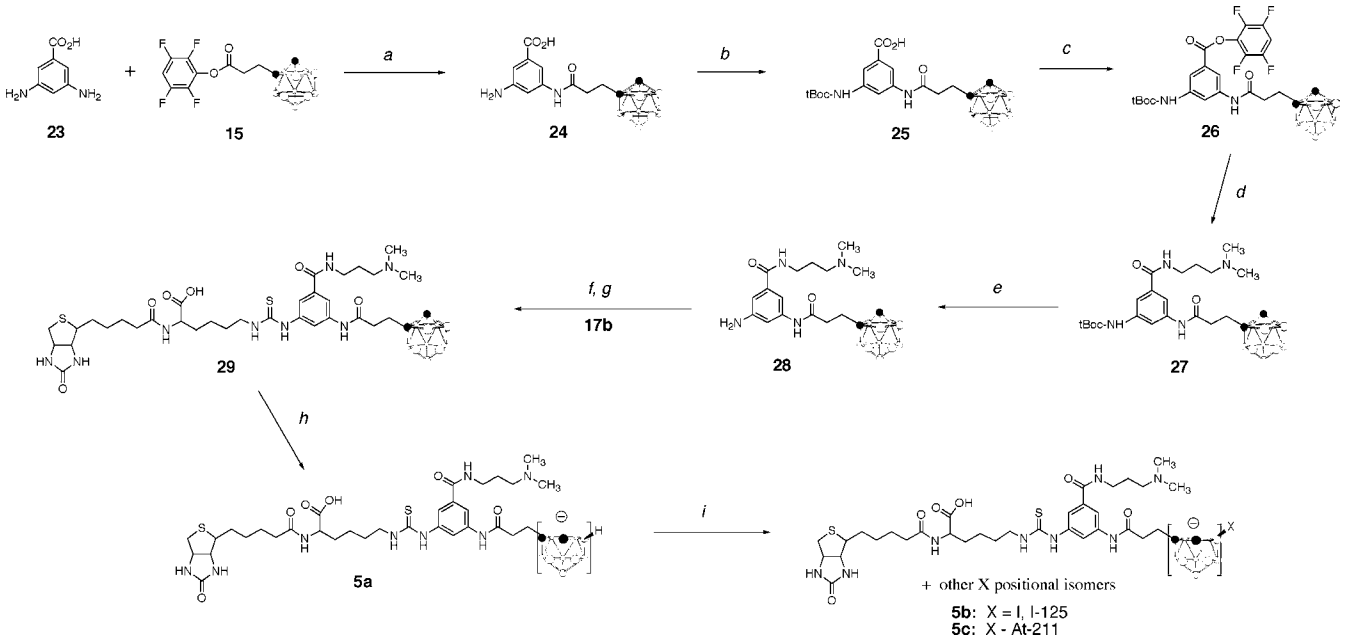
Scheme 3. Synthesis and Radiohalogenation of 3-(3′-(*nido*-Carboranyl)propionyl)amino-1-*N*-(1′-(*N*-biotinyl)-5′-lysyl-thiourea)benzene, 4a



[a] Reagents and conditions: (In carborane structures, open circles represent boron or B−H atoms and closed circles represent carbon atoms) (a) DMF, rt, 3.5 h, 95%; (b) DMF, TCDI, rt, 30 min, 54%; (c) DMF, Et_3N, rt, 30 min, 65%; (d) pyrrolidine, rt, 1 h, 67%; (e) MeOH/5% HOAc, NaX (X = ^{125}I or ^{211}At), NCS, rt, 1 min.

nobenzoic acid, **23**, was used to provide a trifunctional aryl moiety for introducing a trialkylamine moiety. Reaction of an excess of **23** and Et_3N with **15** in DMF at room temperature provided the *closo*-carborane adduct **24** in 91% yield. Protection of the aniline amine of **24** to give **25** was accomplished in 72% yield by reaction with di-*tert*-butyl dicarbonate in a mixture of DMF and H_2O at room temperature. Subsequent formation of the TFP ester derivative **26** was accomplished in 87% yield by reaction of **25** with TFP-OTFA in DMF at 4 °C. Reaction of **26** with 3-(dimethylamine)propylamine and Et_3N in DMF at room temperature provided **27** in 88% yield. Removal of the *t*-Boc group from **27** with neat TFA gave the aniline **28** in nearly quantitative yield. Conversion of the aniline amine in **28** to an isothiocyanate functionality using thiocarbonyldiimidazole in anhydrous DMF was followed by reaction with the biotin-lysine adduct **17b** to provide the *closo*-carboranyl-biotin derivative **29** in 74% overall yield. Reaction of the *closo*-carborane in **29** with pyrrolidine provided the *nido*-carborane derivative **5a** in 95% yield.

Radiohalogenation Reactions of Biotin Derivatives 1a, 2a, 3a, 4a, and 5a. The product mixtures for the radiohalogenation reactions were assessed by reversed-phase HPLC using nonradioactive iodinated derivatives (**1b**, **2b**, **3b**, **4b**, **5b**) as HPLC standards. All radiolabeled

Scheme 4. Synthesis and Radiohalogenation of 3-(3′-(*nido*-Carboranyl)propionyl)amino-5-(1′-(*N*-biotinyl)-5′-lysylthiourea)−(3′dimethylaminopropyl)benzamide, 5a

[a] Reagents and conditions: (In carborane structures, open circles represent boron or B−H atoms and closed circles represent carbon atoms) (a) DMF, Et_3N, rt, 1.5 h, 91%; (b) NaOH, DMF, H_2O, DTDC, rt, 16 h, 72%; (c) DMF, Et_3N, TFP-OTFA, 4 °C, 30 min, 87%; (d) 3-(dimethylamino)propylamine, DMF, Et_3N, rt, 1 h, 88%; (e) TFA, rt, 30 min, ∼100%; (f) DMF, TCDI, 1 h (not isolated); (g) **17b**, DMF, Et_3N, rt, 3 h, 74%; (h) pyrrolidine, rt, 30 min, 95%; (i) MeOH/5% HOAc, NaX (X = ^{125}I or ^{211}At), NCS, rt, 1 min.

samples were obtained pure by collection of radioactivity from the HPLC effluent. Astatinated compounds had retention times slightly longer than that of the iodinated standard. Under the elution conditions employed, biotin derivatives containing aryl moieties had narrow HPLC peaks (sometimes as doublets), whereas, biotin derivatives containing *nido*-carboranyl moieties had much broader HPLC peaks. In most cases, radioiodination reactions were conducted multiple times. Due to the cost and quantity of ^{211}At, astatinations were (generally) conducted only at the time of the labeling for the animal study. No optimization studies of the radiohalogen labeling conditions were conducted.

Radioiodination and astatination of biotin derivatives containing aryl stannane moieties, **1a** and **2a** (50−100 μg), were conducted by reaction of *N*-chlorosuccinimide (NCS) (10 μg) and Na[^{125}I]I or Na[^{211}At]At in MeOH containing 1−5% HOAc at room temperature for 1−10 min. The reaction was then stopped by the addition of (10 μg) sodium metabisulfite. Radioiodination of **1a** has been conducted several times as the resultant compound, [$^{125/131}$I]**1b**, is used as a control in studies of biotinidase stability. As an example, isolated yields of 34%, 35%, 39%, and 69% were obtained in four radioiodination experiments. Astatination of **1a** was conducted using the same reaction conditions, giving yields of 22% after 3 min reaction time, and in a second reaction 64% after 10 min. Radioiodination of **2a** has also been conducted a number of times under the same reaction conditions. In four radioiodination experiments with **2a**, isolated yields of 37%, 43%, 45%, and 49% for [^{125}I]**2b** were obtained. Astatination of **2a** was conducted twice. One experiment was conducted using NCS as the oxidant, and the other experiment used ChT as the oxidant. The NCS reaction provided 41% isolated yield of [^{211}At]**2c**, and the ChT reaction provided 23% isolated yield.

Radioiodination was conducted on all three biotin derivatives **3a**, **4a** and **5a**, containing a *nido*-carborane moiety, whereas astatination was only conducted on **4a** and **5a**. Radioiodination of **3a**, **4a**, and **5a** were conducted by reaction of NCS and Na[^{125}I]I in MeOH containing 1−5% HOAc at room temperature for 30 s to 5 min. Following that, sodium metabisulfite was added to quench the reaction. The radiochemical yields obtained under these reaction conditions were [^{125}I]**3b**, 67%; [^{125}I]-**4b**, 82% and 59% (isolated); and [^{125}I]**5b**, 83%. Radioiodination of **5a** was also conducted by reaction of ChT and Na[^{125}I]I in H_2O at room temperature for 1 min. The radiochemical yields (HPLC) of [^{125}I]**5b** obtained in those reactions were 72% and 86%. Astatinations of **4a** and **5a** were conducted using NCS as the oxidant to give 36% and 23% isolated radiochemical yields of [^{211}At]**4c** and [^{211}At]**5c**, respectively. Astatination of **5a** was also conducted using ChT in H_2O and that reaction gave [^{211}At]-**5c** in 57% isolated yield.

Biodistributions of Radiohalogenated Biotin-lysine-*nido*-carborane Derivatives [^{125}I]1b, [^{125}I]2b, [^{211}At]2c, [^{125}I]3b, [^{125}I]4b, [^{211}At]4c, [^{125}I]5b, and [^{211}At]5c. A total of six biodistributions of radiohalogenated biotin derivatives were conducted in the investigation. Due to the propensity of the *nido*-carboranes to adhere to glass and metal surfaces, 1% BSA was added to the radiolabeled compounds when diluted from the (rotoevaporator) concentrated HPLC effluent. All studies evaluated the tissue distribution of radiolabeled compounds at 1, 4, and 24 h postinjection in athymic mice. The complete tissue distribution data are provided in the Supporting Information as Tables S1−S6.

Three biodistribution studies utilized coinjected, dual-labeled (^{125}I and ^{131}I) compounds to compare the in vivo tissue distributions of biotin derivatives that have different structures. In an initial animal study, the distribution of radioiodinated biotin derivatives [^{125}I]**2b** and [^{131}I]**1b**, containing aryl labeling moieties, were evaluated. The biodistribution data is provided as Table S1 in Supporting Information. Although the data has a fairly large spread, evaluation of concentrations of the two radionuclides in individual tissues by the Student's t-test

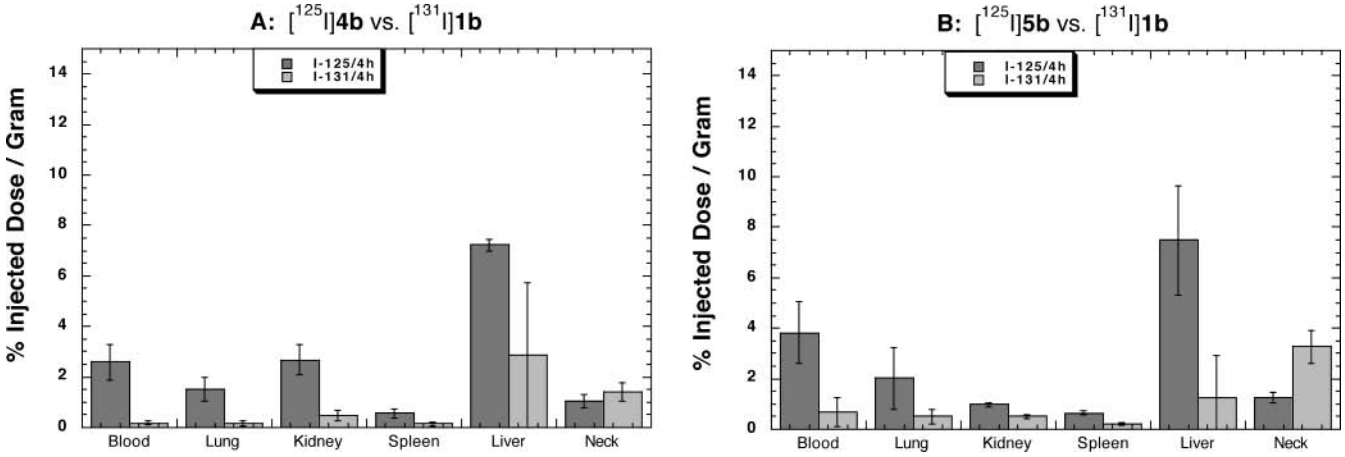


Figure 1. Concentrations of ^{125}I and ^{131}I in selected tissues at 4 h pi for the radiolabeled compounds listed (top of panels A and B). Note that the *Y*-axis range for the percent injected dose/gram has been set at 0−15 to correlate with graphs in Figure 2. Complete data sets are provided as (A) Table S3 and (B) Table S5 in the Supporting Information.

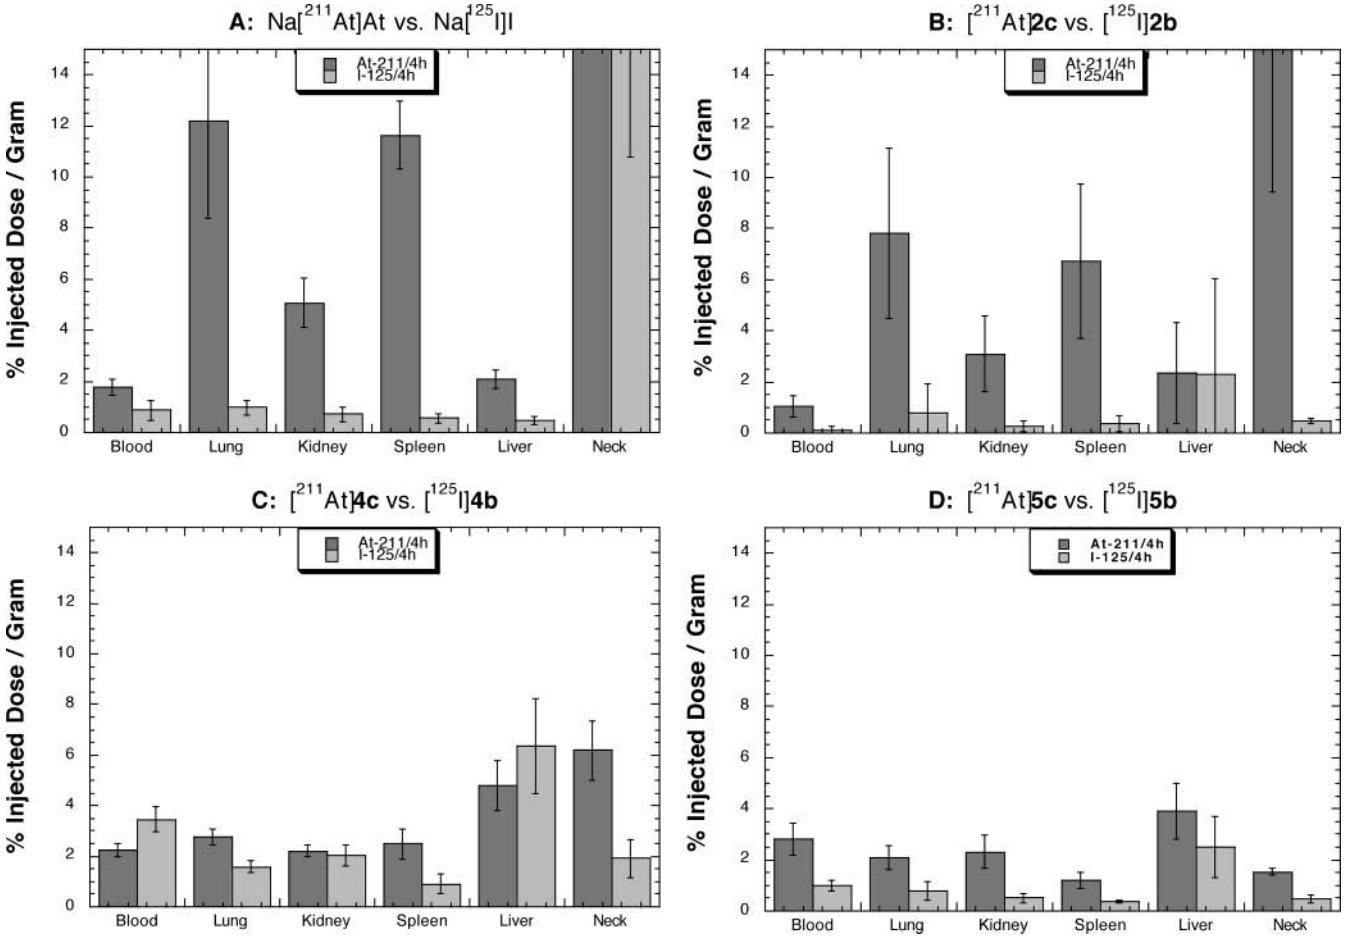

Figure 2. Concentrations of ^{211}At and ^{125}I in selected tissues at 4 h pi for the radiolabeled compounds listed (top of panels A thru D). Data for the graph in panel A was obtained from the literature (*27*) (with permission). Complete data sets are provided as (B) Table S2, (C) Table S4, and (D) Table S6 in the Supporting Information.

indicates that there is little difference between the two in vivo. The two other studies involving radioiodinated biotin derivatives compared the in vivo distribution of a biotin derivative containing an aryl moiety [^{131}I]**1b** with the biotin derivatives [^{125}I]**4b** or [^{125}I]**5b**. Both biotin derivatives **4b** and **5b** contain an aryl group and a *nido*-carborane moiety, and **5b** also contains a dimethylamine moiety. From the data obtained, it is readily apparent that the *nido*-carborane containing biotin derivative, [^{125}I]-**4b**, is cleared from blood, lung, kidney, and liver much slower than [^{131}I]**1b.** These differences are observed at all time points (Table S3, Supporting Information) and can be readily seen in the concentration of radionuclides in selected tissues at 4 h postinjection, which are plotted in Figure 1, panel A. Similar results were obtained in the comparison of [^{125}I]**5b** and [^{131}I]**1b**. The data obtained in that study are provided as Table S5 and tissue concentrations in selected tissues at 4 h postinjection are plotted in Figure 1, panel B.

Three studies were conducted to evaluate the distribution of radionuclides in mice for biotin derivatives (**2b/c**, **4b/c**, and **5b/c**), which were dual labeled with ^{211}At and

^{125}I (Figure 2, panels B−D). To use as a reference, a plot of data from a previous evaluation of free Na[^{211}At]At and Na[^{125}I]I in selected tissues of mice[27] is provided as Figure 2, panel A. The results of [^{211}At]**2c** vs [^{125}I]**2b** are provided as Table S2 in Supporting Information, and data obtained at 4 h postinjection in selected tissues are plotted in Figure 2, panel B. Unfortunately, the high concentrations of ^{211}At and large differences between ^{211}At and ^{125}I in lung, spleen, and neck indicate that [^{211}At]**2c** undergoes considerable deastatination. Indeed, comparison of the pattern of tissue concentrations in graphs provided in panels A and B of Figure 2 provides strong evidence that large amounts of free astatide are present in the animals injected with [^{211}At]**2c**.

Biodistribution data for biotin derivatives [^{211}At]**4c** and [^{125}I]**4b**, that contain a radiohalogenated *nido*-carborane moiety, are provided in Table S4 in Supporting Information, and data obtained at 4 h postinjection for selected tissues are plotted in Figure 2, panel C. Much smaller differences in the lung and spleen concentrations of the two radionuclides is observed at the three time points, indicating that the deastatination is much lower than observed for [^{211}At]**2c**. Unfortunately, while the *nido*-carborane appears to provide a more stable attachment for astatine, it also prolongs the blood residence time. The biodistribution data for the biotin derivatives [^{211}At]**5c** and [^{125}I]**5b**, containing a *nido*-carborane and a trialkylammonium moiety, are provided in Table S6 in Supporting Information, and the 4 h data for selected tissues are plotted in Figure 2, panel D. It is apparent that some deastatination also occurs with this compound because of the differences observed in the concentrations of the two radionuclides in lung, spleen, and neck.

DISCUSSION

The high cytotoxicity of radionuclides that emit α-particles makes them attractive for developing new radiopharmaceuticals for targeted radionuclide therapy (TRT) of cancer. Further, the short path length (e.g. 50−80 μm) of the emitted α-particles makes these radionuclides particularly well suited for therapy of micrometastatic disease, disease in compartmental spaces (e.g. ovarian carcinoma), and cancer cells remaining in surgical tumor resection areas. One of the most promising α-emitting radionuclides is ^{211}At. It is particularly attractive because it can be readily prepared in high radionuclidic purity and does not produce α-emitting daughter radionuclides. While its short half-life ($t_{1/2}$ = 7.21 h) is problematic for use with intact monoclonal antibodies, smaller tumor targeting agents, such as biotin derivatives or peptides, may provide good carrier molecules for this radionuclide.

There are many reagents and approaches that may be taken in TRT of cancer. One approach that utilizes the proven tumor targeting of monoclonal antibodies (mAb), is termed "pretargeting" (*13*, *14*, *33*−*35*). The pretargeting approach is particularly attractive as it employs a two- or three-step procedure to separate the pharmacokinetics of the molecule carrying the radionuclide (e.g. mAb) from the pharmacokinetics of the tumor targeting monoclonal antibody. This fact makes it attractive for use with short half-lived radionuclides such as ^{211}At. Although several different pretargeting approaches have been described, we have chosen to investigate the use of antibody-streptavidin (mAb−SAv) conjugates in combination with radiolabeled biotin derivatives. This combination of reagents using other radionuclides has been successfully applied to treatment of human tumor xenografts in athymic mice (*15*, *16*, *36*) and has undergone clinical study (*14*, *17*, *37*). The success of the approach is due, in part, to the extremely high binding affinity of biotin with streptavidin (*38*), which provides high tumor targeting efficiency and long retention at the tumor site. Further, the small size of biotin derivatives provides rapid renal clearance of radiolabeled biotin derivatives, eliminating much of the irradiation of nontarget tissues.

While a variety of biotin derivatives containing metal radionuclides have been successfully targeted to tumors in mouse models (*34*, *36*, *39*, *40*), no examples of successful cancer targeting of radiohalogenated biotin derivatives have appeared in the literature. We hypothesized that the lack of examples of pretargeting with radiohalogens was due to the structural and lipophilic differences between biotin derivatives that bind metal radionuclides and those that bind radiohalogens. On the basis of this hypothesis, we have conducted a large number of studies to optimize the structural features of biotin derivatives so the in vivo characteristics of radiohalogenated biotin derivatives are improved. Unlike radiometal-containing biotin derivatives, radiohalogenated biotin derivatives can be quite insoluble in aqueous medium, so many of the compounds that have been investigated include ether containing linkers between the biotin moiety and the radiohalogen bonding moiety. Because all biotin derivatives are subject to in vivo degradation by the enzyme biotinidase (*41*−*43*), we (*19*, *44*) and other investigators (*45*) have conducted studies to determine which structural features will block the biotinamide hydrolysis reaction of that enzyme. In addition to determining whether biotinidase cleaved biotin from radiohalogenated biotin derivatives, we also investigated the effect of structural features on biotin binding with avidin and streptavidin (*46*). We believe that it is important to retain the high binding affinity of biotin with these proteins for optimal in vivo tumor targeting. An outcome of those studies was identification of biotin derivatives which have a carboxylate functionality α to the biotinamide bond as an optimal structural feature. The α-carboxylate is optimal because it blocks biotinidase cleavage while retaining high binding affinity. Thus, all of the biotin derivatives investigated in vivo contain a carboxylate functionality α to the biotinamide bond.

The design of the biotin derivatives for carrying the radioiodine and astatine must include a moiety for radiohalogens to react with. It is very important that radiohalogenation reactions are rapid and efficient and that the radiohalogenated moiety be stable to in vivo dehalogenation. Due to the presence of deiodinase enzymes (*47*), radioiodinations of small molecules for in vivo applications are generally conducted on deactivated aryl moieties or vinyl moieties. To facilitate rapid incorporation of radiohalogens, organometallic intermediates are generally used (*48*, *49*). In these studies, stannylbenzamides and *nido*-carboranyl moieties were included in the biotin derivatives as functional moieties for reacting with radiohalogens. Aryl stannanes are very reactive toward electrophilic radiohalogens, producing site-specific incorporation. Aryl stannanes have been used extensively as intermediates for radioiodination and for astatination of molecules. Similarly, high reactivity of *nido*-carboranes with electrophilic radioiodine and astatine has been demonstrated. Pioneering work of Hawthorne and coworkers (*50*−*52*) and our previous studies (*24*, *25*, *53*) have shown radiohalogenation of *nido*-carboranes can occur in excellent radiolabeling yields under mild reaction conditions. Unlike the aryl stannanes, halogenation of *nido*-carboranes is not site-specific, with substitution potentially occurring on any boron atom of the *nido*-

carborane moiety. However, it seems most likely that when only one halogen is substituted, halogenation occurs on a boron atom in the open rim. Hawthorne et al. have reported crystal structures of two iodo-*nido*-carboranes, wherein the iodine atom substituted on the open rim α to a carbon atom (*50*, *54*). Thus, while the structures shown in Schemes 2−4 depict only one of the potential halogenated regioisomers, it is likely to be a major one. Significantly, the presence of halogenated regioisomers is not an important factor in the compounds studied, since it is very unlikely that biotin binding with streptavidin will be affected by substitution on the *nido*-carborane. Biotin binding can be affected if any of the three contiguous, all-cis, chiral centers on the thiophane ring are altered. Importantly, the all-cis (+) configuration of biotin stereocenters is retained under the reaction conditions used. A fourth chiral center is present in the aspartyl group of compound **2** and the lysine groups of compounds **3**−**5**. The presence of this chiral center does not appear to affect biotin binding (*18*−*20*). The presence of chiral centers and iodinated carboranyl regioisomers can, however, result in diasteriomeric pairs of compounds that complicate the NMR spectra and are observable as doublets in HPLC chromatograms.

In vivo stability of the ^{211}At bond to the carrier molecule is absolutely critical to its successful application in TRT. On the basis of our previous experiences, we anticipated some instability of ^{211}At in the biotin derivatives prepared. Fortunately, the release of ^{211}At from carrier molecules in vivo is easily monitored, as free ^{211}At (astatide) localizes in lung, spleen, stomach, and thyroid. Localization of ^{211}At in those tissues can be estimated by comparing its concentration against that of free radioiodine (or a radioiodinated compound). This comparison was first reported by Hamilton et al. (*55*) in an extensive study of the localization of ^{211}At (vs ^{131}I) in rats and monkeys. We have used the comparison of tissue concentrations to demonstrate that ^{211}At-labeled mAb Fab′ fragments are unstable to in vivo deastatination (*56*) and more recently to show stability of astatinated benzamides, and *nido*-carboranyl derivatives in vivo (*27*). The graphs provided as panels in Figures 1 and 2 include the ^{211}At-localizing tissues: lung, spleen, and neck (thyroid). The graphs also include concentration data from blood and the excretory tissues, kidney, and liver. Only the 4 h data for the tissues is provided in the graphs, as that data is adequate to point out the important differences between the biotin derivatives or between ^{211}At and ^{125}I. For comparison purposes, a graph of the tissue concentrations of [^{211}At]astatide and [^{125}I]iodide in the selected tissues, from data previously published, has been included as Figure 2, panel A.

The primary objective of the investigation was to determine the in vivo stability of the astatinated biotin derivatives. The biotin derivative **1a** was the first prepared for astatination and evaluation. Astatination of **1a** was fairly efficient, providing 64% isolated radiochemical yield after reaction for 10 min at room temperature. However, the astatinated compound, [^{211}At]**1c** was not evaluated in vivo, as it was subsequently shown that the biotinidase-blocking *N*-methyl group dramatically decreases binding with avidin and streptavidin (*20*). Therefore, the biotin derivative **2b**, which has a carboxylate group α to the biotinamide bond, was prepared and evaluated. In an vivo experiment, [^{125}I]**2b** and [^{131}I]**1b** were co-injected and tissue concentrations were evaluated at 1, 4, and 24 h postinjection. The results from the experiment (Table S1) indicated that there was little difference between the two compounds in vivo. Therefore, **2a** was chosen for astatination and in vivo study. In the experiment, [^{211}At]**2c** and [^{125}I]**2b** were co-injected, and their biodistribution was evaluated. The data obtained (Table S2) clearly show that [^{211}At]**2c** is unstable to in vivo deastatination based on the observed differences in ^{211}At and ^{125}I concentrations in lung, spleen, and neck (thyroid) (compare Figure 2, panels A and B). The magnitude of difference between the concentrations of ^{211}At and ^{125}I in those tissues suggests that the deastatination is very rapid.

The rationale for evaluating *nido*-carboranes as radiohalogen-binding moieties in biotin derivatives was that these moieties may provide higher in vivo stability of ^{211}At. Because boron−halogen bonds are generally stronger than aryl−halogen bonds (*57*), it seemed possible that boron−halogen bonding would be more stable in vivo. Further, our studies with structurally simple benzamide derivatives and *nido*-carboranyl derivatives appeared to indicate some in vivo stability could be gained by using astatinated *nido*-carborane derivatives (*27*). Our initial study of an astatinated biotin derivative with a *nido*-carborane moiety demonstrated that it could be rapidly astatinated; however, an in vivo evaluation was not conducted as the compound was not stable to biotinidase. The biotin derivative employed contained a methyl group α to the biotinamide moiety (*26*). In vitro studies later demonstrated that this structural feature slowed the biotinidase cleavage rate (to ∼25% of an unaltered biotinamide) but did not block it (*18*). Once it was established that an α carboxylate could be used to completely block biotinidase, a biotin-lysine adduct, **3b**, containing the *nido*-carborane moiety, was prepared and radioiodinated. However, preparation of **3b** was also premature, as other studies demonstrated that inclusion of an aryl moiety decreased the in vivo release of ^{211}At over simpler *nido*-carboranyl compounds (*27*). Therefore, a biotin derivative, **4a**, that contains a phenyl group and a *nido*-carborane, was prepared and evaluated in vivo. In an initial study, [^{125}I]**4b** was co-injected with [^{131}I]**1b** to compare the radioiodinated *nido*-carboranyl-biotin derivative with a biotin derivative containing an aryl halide. The results show that [^{125}I]**4b** is cleared much slower from blood, lung, and kidney than [^{131}I]**1b**. This was consistent with the data previously obtained with similar derivatives that did not include biotin moieties (*27*). Following that experiment, [^{211}At]**4c** and [^{125}I]**4b** were co-injected and evaluated in vivo. The differences in concentration of ^{211}At and ^{125}I in lung, spleen, and neck are much smaller, indicating that less free ^{211}At was present. This is very encouraging, but the high concentrations of astatinated and radioiodinated biotin derivatives remaining in blood and tissues makes this biotin derivative not optimal.

The cause of the longer blood residence time of the *nido*-carborane-containing compounds is not known, but it may be due to their binding with serum proteins. In our studies, it has been noted that the concentration of radiolabeled biotin derivative in aqueous solution could decrease dramatically over a short period of time, with the radioactivity being bound to the surfaces of the container. Additionally, injection or transfer of the solutions via syringes were complicated by adsorption to the metal syringe needle. We found that preparations containing *nido*-carboranes were easier to handle and quantify when a 1% BSA solution was added prior to isolation. These observations led to a conclusion that the adsorption may be due to the *nido*-carborane moiety's interaction with cationic ions on surfaces and on BSA. If this were true, it seemed that one way to potentially improve the

in vivo characteristics of biotin derivatives containing *nido*-carborane moieties would be to incorporate a trialkylamine that, when protonated, could act as an intramolecular counterion. Thus, a *nido*-carboranyl-biotin derivative which contained a trialkylamine functionality, **5a**, was prepared and tested in vivo. An initial in vivo study compared [^{125}I]**5b** with [^{131}I]**1b**. Interestingly, the tissue concentrations of [^{125}I]**5b** did not appear to be very different from that of [^{125}I]**4b**, with the exception of the kidney, which appeared to have a considerably lower concentration at the 1 and 4 h time points (compare Tables S3 and S5).

The biodistribution of [^{211}At]**5c** is very similar to that of [^{211}At]**4c** (compare Figure 2, panels C and D; Tables S4 and S6). The rationale for preparing **5a** was that this compound might have decreased blood concentration due to a lower propensity to bind with serum proteins. In the study comparing co-injected [^{211}At]**5c** and [^{125}I]**5b** (Table S6) there appeared to be a large decrease in blood concentration for [^{125}I]**5b** but not for [^{211}At]**5c**. However, the biodistribution data for [^{125}I]**5b** in the initial study (Table S5) did not show a low blood concentration. Therefore, the question of whether the intermolecular trialkylammonium counterion actually decreased the propensity to bind with serum proteins has not been answered from our data. Some differences in tissue concentrations of [^{211}At]**5c** and [^{125}I]**5b** are most likely due to having free ^{211}At present (i.e. deastatination occurred). Importantly, it appears that the deastatination is of the same magnitude as that observed for [^{211}At]**4c**, so the addition of the trialkylammonium counterion had little effect on the deastatination.

In conclusion, we have investigated the synthesis, radiohalogenation, and in vivo tissue distribution of some biotin derivatives containing aryl stannanes or *nido*-carboranes for radiohalogenation. The studies have shown that biotin derivatives containing *nido*-carboranyl moieties can be readily prepared using standard synthetic organic chemistry methods. The studies have provided data that indicate the biotin derivatives containing astatinated *nido*-carborane moieties are more stable to in vivo deastatination than aryl astatine derivatives. This is a significant improvement over the use of astatinated aryl moieties; however, the astatinated *nido*-carboranyl derivatives do undergo some deastatination. The fact that the *nido*-carboranyl biotin derivatives are not completely stable toward in vivo deastatination, along with their long retention in blood, makes these derivatives nonoptimal. Continuing studies will investigate biotin derivatives with other borane cage molecules, and different charged functionalities, in an attempt to further improve them for use in pretargeting protocols.

ACKNOWLEDGMENT

We thank Dr. Ruedi Risler for his efforts in the preparation of ^{211}At, and Kent Buhler for his participation in animal studies. We are grateful for the financial support provided by the Department of Energy, Medical Applications and Biophysical Research Division, Office of Health and Environmental Research, under grant number DE-FG06-95ER62029.

Supporting Information Available: Tables containing biodistribution data for compounds studied in vivo are included as Tables S1−S6. HPLC chromatograms, ^{1}H NMR spectra, and mass spectra are provided for new compounds (**11, 2a, 17a, 17b, 18, 3a, 20, 21, 22, 4a, 24, 25, 26, 27, 28, 29, 5a**) prepared in the research described in this manuscript. This material is available free of charge via the Internet at http://pubs.acs.org.

[a]Values shown are % injected dose / gram ± standard deviation. [b]Time of sacrifice from injection of halogenated biotin derivatives. [c]Data were obtained for $n = 5$ mice at 1 h, 4 h and 24 h; average animal weight, 27.91 ± 1.97 g; Injectate for each animal had 25 μCi of [^{125}I]**2b** and 13 μCi of [^{131}I]**1b** in approximately 100 μL of 0.9% sterile saline. [b,d]Urine was collected by syringe bladder tap after sacrifice. Those tissues that had a significant difference ($p < 0.05$)in radionuclide concentrations by paired Student's t-test are marked with an asterisk (*). The data in the 24 h time point was not analyzed as the values are very small.

[a]Values shown are % injected dose / gram ± standard deviation. [b]Time of sacrifice from injection of halogenated *nido*-carborane derivatives. [c]Data were obtained for $n = 5$ mice at 1 h, 4 h and 24 h; average animal weight, 25.69 ± 0.93 g; Injectate for each animal had 20 μCi of [^{211}At]**2c** and 20 μCi of [^{125}I]**2b** in approximately 100 μL of 0.9% sterile saline. [b,d]Urine was collected by syringe bladder tap after sacrifice. Those tissues that have radionuclide concentrations that *are not* significantly different ($p > 0.05$) are marked with an asterisk (*).

Table S3: Distribution of Radioactivity for Co-injected [^{125}I]4b and [^{131}I]1b in BALB/c mice.[a]

Design and Synthesis of a New [^{18}F]Fluoropyridine-Based Haloacetamide Reagent for the Labeling of Oligonucleotides: 2-Bromo-*N*-[3-(2-[^{18}F]fluoropyridin-3-yloxy)propyl]acetamide

Bertrand Kuhnast,[†] Béatrice de Bruin,[†] Françoise Hinnen,[†] Bertrand Tavitian,[†,‡] and Frédéric Dollé*[,†]

Service Hospitalier Frédéric Joliot, Département de Recherche Médicale, CEA/DSV, 4 place du Général Leclerc, F-91401 Orsay, France, and INSERM ERM 0103, Service Hospitalier Frédéric Joliot, Département de Recherche Médicale, CEA/DSV, 4 place du Général Leclerc, F-91401 Orsay, France. Received January 7, 2004; Revised Manuscript Received February 24, 2004

Based on the recently highlighted potential of nucleophilic heteroaromatic ortho-radiofluorinations in the preparation of fluorine-18-labeled radiotracers and radiopharmaceuticals for PET, a [^{18}F]-fluoropyridine-based bromoacetamide reagent has been prepared and used in prosthetic group introduction for the labeling of oligonucleotides. [^{18}F]FPyBrA (2-bromo-*N*-[3-(2-[^{18}F]fluoropyridin-3-yloxy)propyl]acetamide) was designed as a radiochemically feasible reagent, its pyridinyl moiety both carrying the radioactive halogen (fluorine-18) and allowing its efficient incorporation via a nucleophilic heteroaromatic substitution, and its 2-bromoacetamide function, ensuring the efficient alkylation of a phosphorothioate monoester group born at the 3′- or 5′-end of single-stranded oligonucleotides. [^{18}F]-FPyBrA (HPLC-purified) was efficiently prepared in 18−20% non-decay-corrected yield (based on starting [^{18}F]fluoride) using a three-step radiochemical pathway in 80−85 min. The developed procedure involves (1) a high-yield nucleophilic heteroaromatic ortho-radiofluorination as the fluorine-18 incorporation-step (70−85% radiochemical yield) and uses [3-(3-*tert*-butoxycarbonylaminopropoxy)-pyridin-2-yl]trimethylammonium trifluoromethanesulfonate as precursor for labeling, followed by (2) rapid and quantitative TFA-removal of the *N*-Boc-protective group and (3) condensation with 2-bromoacetyl bromide (45−65% radiochemical yield). Typically, 3.3−3.7 GBq (90−100 mCi) of HPLC-purified [^{18}F]FPyBrA could be obtained in 80−85 min, starting from 18.5 GBq (500 mCi) of a cyclotron production batch of [^{18}F]fluoride. [^{18}F]FPyBrA was regioselectively conjugated with 9-mer and 18-mer single-stranded oligonucleotides, provided with a phosphorothioate monoester group at their 3′-end. Both natural phosphodiester DNAs and in vivo-stable 2′-methoxy and -fluoro-modified RNAs were used. Conjugation uses optimized, short-time reaction conditions (MeOH/0.1 M PBS pH 7.4, 15 min, 120 °C), both compatible with the chemical stability of the oligonucleotides (ONs) and the half-life of fluorine-18. Conjugated [^{18}F]ONs were finally purified by RP-HPLC and desalted using a Sephadex NAP-10 column. The whole radiosynthetic procedure, including the preparation of the fluorine-18-labeled reagent, the conjugation with the oligonucleotide, and the HPLC purification and formulation lasted 140−160 min. [^{18}F]FPyBrA represents a valuable alternative to the already reported *N*-(4-[^{18}F]fluorobenzyl)-2-bromoacetamide for the design and development of oligonucleotide-based radiopharmaceuticals for PET.

INTRODUCTION

Positron emission tomography (PET) is a high-resolution, sensitive, molecular and functional imaging technique that permits repeated, noninvasive assessment and quantification of specific biological and pharmacological processes in humans. PET is also the most advanced technology currently available for studying in vivo molecular interactions and therefore can advantageously play a key role in both drug discovery and development of pharmaceuticals, by assessing their in vivo distribution, pharmacokinetics, and dynamics, once labeled with a positron-emitter. Recent advances in positron-emitter labeling of bioconjugates now allow the design and development of complex high-molecular-weight bioactive chemical structures as radiopharmaceuticals *(1−4)*, including single-stranded oligonucleotides *(5)*.

Fluorine-18 appears often as the radionuclide of choice for the preparation of short-lived positron-emitter radiotracers and radiopharmaceuticals. In regard to its physical and nuclear characteristics, fluorine-18 displays simple decay and emission properties with a high positron abundance (97%). Compared with the other conventional short-lived positron-emitting radionuclides carbon-11, nitrogen-13, and oxygen-15, fluorine-18 has a relatively low positron emission energy (maximum 635 keV) and the shortest positron linear range in tissue (2.3 mm), resulting in the highest resolution in PET imaging. Its half-life (109.8 min) is long enough to give access to relatively extended imaging protocols compared to what is possible with carbon-11 (therefore facilitating kinetic studies and high-quality metabolite and plasma analysis) and from a chemical point of view, allows multistep synthetic approaches that can be extended over hours. This distinctive advantage, combined with its reliable multi-Curie production on widely implemented biomedical cyclotrons, has been effectively used for the labeling of various chemical structures *(1−4)*.

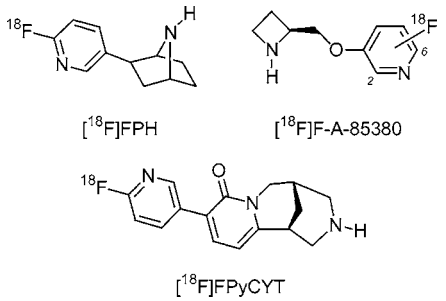

Figure 1. Chemical structures of norchloro[^{18}F]fluoroepibatidine ([^{18}F]FPH), 2- and 6-[^{18}F]fluoro-A-85380, and (−)-9-(2-[^{18}F]-fluoropyridinyl)cytisine ([^{18}F]FPyCYT).

In the macromolecule field, fluorine-18-labeling of single-stranded oligonucleotides has already been described in the literature *(6*−*16)*. It is usually performed by conjugation of a prosthetic group, carrying the radioisotope, with a reactive function of the macromolecule. This strategy has the advantage of offering a wide choice of chemical routes, including drastic chemical conditions, for the preparation of the labeled prosthetic group entity, followed by the conjugation of the latter with a macromolecule using mild conditions needed to preserve its integrity.

From a radiochemical point of view, all fluorine-18-labeled prosthetic groups described so far have been prepared using the relatively restricted labeling strategies offered by homoaromatic and aliphatic nucleophilic substitution reactions *(2, 3)*. Recently, the scope of these nucleophilic radiofluorinations has been opened to heteroaromatic substitutions, particularly in the pyridine series *(17)*. After having been evaluated and validated on the radiosynthesis of 2- and 4-[^{18}F]fluoropyridine as a model reaction *(18, 19)*, these nucleophilic heteroaromatic substitutions have since been applied successfully to the preparation of various PET radiotracers and radiopharmaceuticals, for example in the field of cholinergic $\alpha_4\beta_2$-subtype selective nicotinic radioligands, notably norchloro[^{18}F]fluoroepibatidine ([^{18}F]FPH, (±)-*exo*-2-(6-[^{18}F]fluoro-3-pyridyl)-7-azabicyclo[2.2.1]heptane) *(20*−*26)*, 2- and 6-[^{18}F]fluoro-A-85380 (2- and 6-[^{18}F]F−A-85380, 2- and 6-[^{18}F]fluoro-3-[2(*S*)-2-azetidinylmethoxy]-pyridine) *(27*−*34)*, and more recently (−)-9-(2-[^{18}F]fluoropyridinyl)cytisine ([^{18}F]FPyCYT, (−)-(1*R*,5*S*)-9-(2-[^{18}F]-fluoro-5-pyridyl)-1,2,3,4,5,6-hexahydro-1,5-methanopyrido-[1,2-*a*][1,5]diazocin-8-one) *(35)* (Figure 1).

Considering chemical structures showing a fluoropyridinyl moiety, nucleophilic heteroaromatic substitution at the ortho-position with no-carrier-added [^{18}F]fluoride appears today as the most efficient method for the radiosynthesis of radiotracers and radiopharmaceuticals of high specific radioactivity when compared to homoaromatic or aliphatic, nucleophilic radiofluorination. On the basis of these recent advances, we have designed a new [^{18}F]fluoropyridine-based haloacetamide reagent, [^{18}F]-**1** (2-bromo-*N*-[3-(2-[^{18}F]fluoropyridin-3-yloxy)propyl]-acetamide, coded [^{18}F]FPyBrA, Figure 2) as a new fluorine-18-labeled prosthetic group for the specific radioactive alkylation of (5′- or 3′-end) phosphorothioate-bearing single-stranded oligonucleotides. We herein report the synthesis of the nonlabeled fluoropyridinyl reagent (**1**, FPyBrA) as a reference, as well as the synthesis of the corresponding nitro- and trimethylammonium trifluoromethanesulfonate derivatives as precursors for labeling with fluorine-18. We also present the radiosynthesis of [^{18}F]FPyBrA ([^{18}F]-**1**) using an efficient three-step radiosynthesis, involving a nucleophilic heteroaromatic ortho-radiofluorination as the fluorine-18 incorporation-step. Finally, we describe the conjugation of this bromoacetamide reagent (FPyBrA) with various 9- and 18-mer single-stranded oligonucleotides as well as the efficient preparation of the corresponding fluorine-18-labeled oligonucleotide conjugates (Figure 2).

RESULTS AND DISCUSSION

Chemistry. The synthesis of FPyBrA (**1**, 2-bromo-*N*-[3-(2-fluoropyridin-3-yloxy)propyl]acetamide) is outlined in Schemes 1 and 2.

[3-(2-Fluoropyridin-3-yloxy)propyl]carbamic acid *tert*-butyl ester (**3a**) was prepared in 49% yield via a Mitsunobu coupling reaction *(36)* from commercially available (3-hydroxypropyl)carbamic acid *tert*-butyl ester (**2**) and 2-fluoro-3-hydroxypyridine *(27, 29)*, in THF at room temperature, using triphenylphosphine (0.8 equiv) and diisopropylazodicarboxylate (1.4 equiv) (Scheme 1). Trifluoroacetic acid (TFA) removal of the *tert*-butoxycarbonyl function of derivative **3a** was performed in dichloromethane at room temperature and gave the desired free amine **4** in 96% yield (Scheme 2). Treatment of **4** with 2-bromoacetyl bromide in the presence of *N*-methylmorpholine in dichloromethane at 0 °C gave the acetamide **1** (FPyBrA) in 24% yield (nonoptimized).

The synthesis of the *N*-Boc-protected nitro- and trimethylammonium precursors for labeling (**3c** and **3d**) is described in Schemes 1 and 3. The choice of these nitro- and trimethylammonium functions will be discussed in the radiochemistry section below.

The dimethylamino and nitro derivatives **3b** and **3c** were prepared in 43% and 40% yield, respectively, from

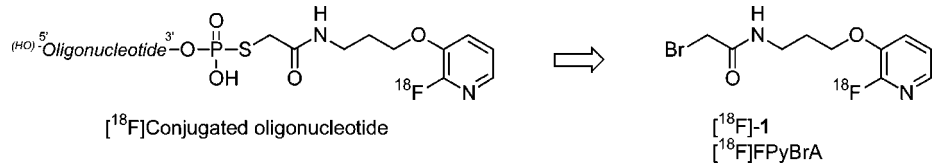

Figure 2. Fluorine-18-labeling design of phosphorothioate-bearing single-stranded oligonucleotides using 2-bromo-*N*-[3-(2-[^{18}F]-fluoropyridin-3-yloxy)propyl]acetamide ([^{18}F]FPyBrA, [^{18}F]-**1**).

Scheme 2. Preparation of 2-Bromo-*N*-[3-(2-fluoropyridin-3-yloxy)propyl]acetamide (1)

Scheme 3. Preparation of [3-(3-*tert*-Butoxycarbonylaminopropoxy)pyridin-2-yl]trimethylammonium Trifluoromethanesulfonate (3d)

the corresponding 2-(dimethylamino)-3-hydroxypyridine *(27, 29)* and 2-nitro-3-hydroxypyridine (commercially available) under Mitsunobu conditions similar to those described above for the synthesis of **3a** (Scheme 1). The trimethylammonium derivative **3d** was cleanly obtained in 93% yield by methylation of the dimethylamine **3b** using methyl trifluoromethanesulfonate (1.3 equiv) in toluene at 0 °C (Scheme 3).

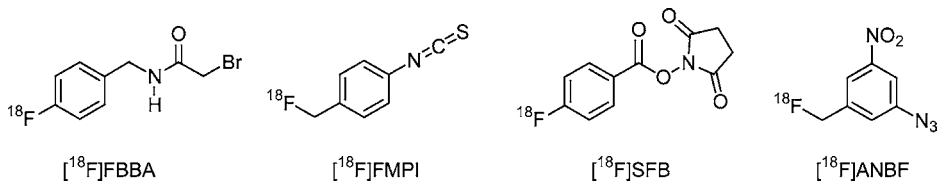
The synthetic procedure of conjugation of oligonucleotides described below uses preparative-scale commercially available 3′-end phosphorothioate oligonucleotides. It is based on the efficient coupling reaction of these oligonucleotides, containing a single phosphorothioate monoester moiety, with an electrophilic reagent such as the 2-halo-*N*-substituted acetamides *(37, 38)*. Table 1 summarizes the principal characteristics of the oligonucleotides (**OL1**, **OL2a**, **OL2b**, and **OL3**) used as starting material in the present study and the corresponding conjugated oligonucleotides (C-**OL1**, C-**OL2a**, C-**OL2b**, and C-**OL3**) that we have synthesized. Sequences, lengths, chemistry (DNA, 2′-OMe-RNA, and mixed 2′-fluoropyrimidines-RNA/DNA) as well as analytical data obtained for these conjugated oligonucleotides are indicated.

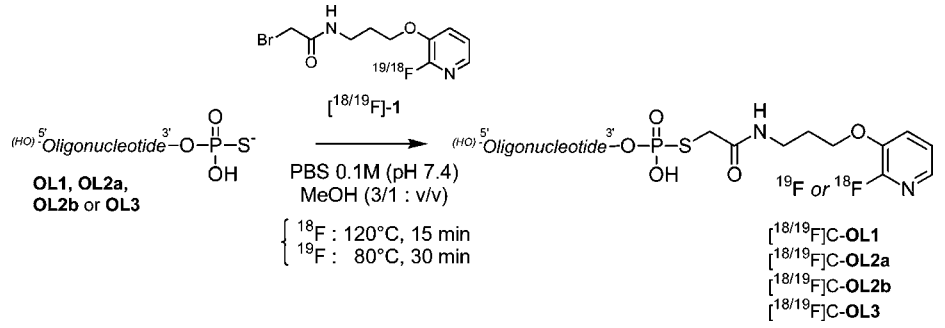
The conjugation of the oligonucleotides (**OL1**, **OL2a**, **OL2b**, and **OL3**) was carried out using 10 equiv of FPyBrA (**1**) in a mixture of methanol and 0.1 M phosphate buffer saline (PBS, pH 7.4) at 80 °C for 30 min (Scheme 4). The conjugation yields were determined by HPLC (based on starting oligonucleotides) and were high: 70% to 75% for the 18-mer C-**OL2a**, C-**OL2b**, and C-**OL3** and up to 95% for the 9-mer C-**OL1**. The nonlabeled conjugated oligonucleotides (C-**OL1**, C-**OL2a**, C-**OL2b**, and C-**OL3**) were separated from the nonreacted material by semipreparative RP-HPLC and desalted using a Sephadex NAP-10 column before characterization.

The regioselectivity of the coupling was verified by ^{31}P NMR (Table 1). The chemical shift of the 3′-end phosphorus atom had moved from +42.00 ppm (single phosphorothioate monoester) to +14.44 ppm (*S*-alkyl phosphorothioate) for C-**OL1**, and analogously from +39.00 ppm to +14.53 ppm for C-**OL2a**, from +39.65 ppm to +13.94 ppm for C-**OL2b**, and from +40.97 ppm to +13.94 ppm for C-**OL3**, after alkylation (Table 1). These results are fully in agreement with published ^{31}P NMR tables *(39−43)* and previously reported data for oligonucleotides having a phosphodiester or a chemically modified backbone *(6, 11, 12, 15, 16)*. Mass spectrometry gave the expected calculated mass for all conjugated oligonucleotides (See Table 1) and higher molecular weight species could not be detected. These results clearly confirmed in all cases the monoconjugation with the 2-bromoacetamide reagent.

Radiochemistry. [18F]FPyBrA ([18F]-**1**) was synthesized in three steps from the NO_2 precursor **3c** (Scheme 5) or from the N^+Me_3 precursor **3d**. The nitro function was selected for its high potential as leaving group in comparison with the corresponding halo substituents *(18, 19)* and for its ease of preparation from commercially available starting materials. The trimethylammonium function was also chosen as leaving group for this substitution, not only for its excellent potential as leaving group *(44)* but also for the expected superior precursor separation (using HPLC or SPE-cartridge) from the reaction product (the fluoro derivative [18F]-**3a**) due to the large differences in the physicochemical properties.

The first radiochemical step in the process is the introduction of fluorine-18 into the pyridine ring, by nucleophilic heteroaromatic substitution, using the no-





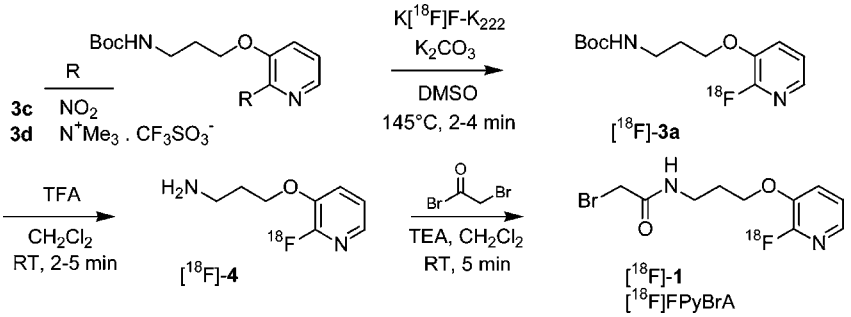


Figure 3. Chemical structures of *N*-(4-[^{18}F]fluorobenzyl)-2-bromoacetamide ([^{18}F]FBBA), 4-([^{18}F]fluoromethyl)phenyl isothiocyanate ([^{18}F]FMPI), *N*-succinimidyl 4-[^{18}F]fluorobenzoate ([^{18}F]SFB), and 3-azido-5-nitrobenzyl [^{18}F]fluoride ([^{18}F]ANBF).

Scheme 5. Preparation of 2-Bromo-*N*-[3-(2-[^{18}F]fluoropyridin-3-yloxy)propyl]acetamide ([^{18}F]-1)

carrier-added naked [^{18}F]fluoride anion as its activated K[^{18}F]F-Kryptofix222 complex *(45)* (Kryptofix222 (K_{222}): 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane) and conventional heating in DMSO at 145 °C for 2−4 min. These nucleophilic heteroaromatic substitutions, like the aliphatic nucleophilic radiofluorinations, only require a good leaving group (a nitro in this case), and there is no need for an additional strong electron-withdrawing substituent for activation of the aromatic ring such as in the homoaromatic nucleophilic radiofluorinations. By use of the NO_2 precursor **3c**, the fluoro derivative [^{18}F]-**3a** was obtained in 45−70% radiochemical yield and purified on a C-18 cartridge. The second radiochemical step is the rapid removal of the *N*-Boc protective group (2−5 min), performed in a mixture of TFA and dichloromethane (1/50, v:v) at room temperature, quantitatively yielding the free amine [^{18}F]-**4**. The third and final step is the condensation with 2-bromoacetyl bromide, performed at room temperature for 5 min in dichloromethane containing triethylamine, giving the desired acetamide [^{18}F]-**1** in 45−65% radiochemical yield. [^{18}F]FPyBrA ([^{18}F]-**1**) was also synthesized using a similar three-step approach, but from the N^+Me_3-precursor **3d**. The nucleophilic heteroaromatic substitution with fluorine-18 was performed using again K[^{18}F]F-K_{222} and conventional heating in DMSO at 145 °C for only 2 min and gave the fluoro derivative [^{18}F]-**3a** in 70−85% radiochemical yield. Typically, 3.3−3.7 GBq (90−100 mCi) of radiochemically pure 2-bromo-*N*-[3-(2-[^{18}F]-fluoropyridin-3-yloxy)propyl]acetamide ([^{18}F]-**1**) could be obtained after semipreparative HPLC in 80−85 min starting from a 18.5 GBq (500 mCi) of a cyclotron production batch of [^{18}F]fluoride (overall radiochemical yields, based on starting [^{18}F]fluoride: 30−34% decay-corrected and 18−20% non-decay-corrected).

According to the available literature, only four fluorine-18-labeling reagents have been successfully prepared and used for prosthetic conjugation with a single-stranded oligonucleotide *(6, 7, 9, 11, 12, 14−16)* (Figure 3).

First, *N*-(4-[^{18}F]fluorobenzyl)-2-bromoacetamide ([^{18}F]-FBBA) was designed as a general and radiochemically feasible reagent, the benzyl function carrying the radioactive halogen, fluorine-18, and the 2-bromoacetamide moiety, offering the opportunity of an efficient and regioselective conjugation with an oligonucleotide provided with a phosphorothioate monoester group at its 3′- or 5′-end *(6, 11, 12, 15, 16)*. Besides natural phosphodiester DNA oligodeoxyribonucleotides, the strategy has been reliably and routinely applied to all the popular chemical modifications of oligonucleotides, such as full-length phosphorothioate diester internucleosidic-bond deoxyribonucleotides, hybrid methylphosphonate/phosphodiester internucleosidic-bond deoxyribonucleotides, and 2′-*O*-methyl-modified oligoribonucleotides *(6, 8, 10−13, 15)*. It has also been successfully applied to the labeling of Spiegelmers *(16)* (L-RNA or L-DNA *(46, 47)*) and peptide nucleic acids (PNAs) *(48, 49)*, another unique class of synthetic macromolecules (the deoxyribose phosphate backbone of DNA is replaced by a pseudo-peptide *N*-(2-aminoethyl)glycyl backbone, while retaining the nucleobases of DNA *(50, 51)*), originally designed as ligands for the recognition of double-stranded DNA. 4-([^{18}F]Fluoromethyl)phenyl isothiocyanate ([^{18}F]FMPI) is another fluorine-18-labeled reagent, which was con-

jugated with a single-stranded 18-mer oligonucleotide provided with a hexylamine linker at the 5′-end *(7)*. However, major loss of [18F]fluoride from the labeled macromolecule was observed, presumably by solvolysis *(7)*. *N*-Succinimidyl 4-[18F]fluorobenzoate ([18F]SFB), an already well-known fluorine-18-labeled reagent used in the conjugation of proteins and peptides using an amino function (α− or ϵ-NH_2-Lys) *(52*−*54)*, and 3-azido-5-nitrobenzyl [18F]fluoride ([18F]ANBF), a photosensitive fluorine-18-labeled reagent, have also been conjugated with single-stranded 18-mer oligonucleotides provided with a hexylamine linker at the 5′-end *(9, 14)*.

Even though its radiosynthesis equally uses a three-step radiochemical pathway, the yields obtained for the preparation of [18F]FPyBrA ([18F]-**1**) are higher than those described for the previously reported *N*-(4-[18F]fluorobenzyl)-2-bromoacetamide ([18F]FBBA). [18F]FBBA was obtained in only 16−25% decay-corrected overall radiochemical yield in 90 min total synthesis time (typical preparations, 2.2−2.9 GBq (60−80 mCi) of HPLC-purified [18F]FBBA starting from 20.3 to 24.0 GBq (550−650 mCi) of [18F]fluoride) *(6, 15)*. The yields obtained for the preparation of [18F]FPyBrA ([18F]-**1**) are also higher than those described for 4-([18F]fluoromethyl)phenyl isothiocyanate ([18F]FMPI) and *N*-succinimidyl 4-[18F]fluorobenzoate ([18F]SFB). 4-([18F]Fluoromethyl)phenyl isothiocyanate ([18F]FMPI) was synthesized in one radiochemical step, but obtained in only 13−15% decay-corrected overall radiochemical yield in 40 min total synthesis time *(7)*. *N*-Succinimidyl 4-[18F]fluorobenzoate ([18F]SFB) was synthesized in four radiochemical steps and obtained in 9−32% decay-corrected overall radiochemical yield in 100 min total synthesis time *(9)*. Only 3-azido-5-nitrobenzyl [18F]fluoride ([18F]ANBF), also synthesized in only one radiochemical step, was obtained in a higher overall radiochemical yield (30−50% decay-corrected) and in a shorter total synthesis time (50 min) *(14)*.

Conjugation of the 3′-phosphorothioate-oligonucleotides (**OL1**, **OL2a**, **OL2b**, and **OL3**) with the HPLC-purified [18F]FPyBrA ([18F]-**1**) (Scheme 4) was carried out in a mixture of methanol and 0.1 M phosphate buffer saline (PBS, pH 7.4) for 15 min at 120 °C. The labeled conjugated oligonucleotides [18F]C-**OL1**, [18F]C-**OL2a**, [18F]C-**OL2b**, and [18F]C-**OL3** were obtained in 50% to 75% yield (determined by HPLC and based on starting [18F]FPyBrA ([18F]-**1**)), separated from starting oligonucleotides and nonreacted [18F]-**1** by semipreparative RP-HPLC and desalted using a Sephadex NAP-10 column as mentioned above. Typically, 0.37−0.55 GBq (10−15 mCi) of pure conjugated [18F]oligonucleotides (specific activity: 37−74 GBq/μmol) could be obtained in 60−75 min starting from 1.85 GBq (50 mCi) of [18F]FPyBrA ([18F]-**1**) (20−30% non-decay-corrected isolated yield). The whole synthetic procedure has been fully automated on our Zymate robot system and lasted 140−160 min. As demonstrated by HPLC analysis, radiosynthesized, labeled, conjugated oligonucleotides ([18F]C-**OL1**, [18F]C-**OL2a**, [18F]C-**OL2b**, and [18F]C-**OL3**) coeluted with the authentic synthesized reference compounds. The fluorine-18-labeled oligonucleotides were found to be >95% chemically and radiochemically pure. The preparations were shown to be free of nonradioactive starting material and radiochemically stable for at least 120 min.

The reaction conditions and yields obtained for the conjugation of [18F]FPyBrA ([18F]-**1**) with oligonucleotides bearing a single phosphorothioate monoester at its 3′-end are comparable to those reported with *N*-(4-[18F]-fluorobenzyl)-2-bromoacetamide ([18F]FBBA) *(6, 11, 12)*. In the case of [18F]FBBA, HPLC-purified, desalted, [18F]-labeled, conjugated oligonucleotides were obtained in 90 min (reaction conditions: 120 °C, 10 min in a 1/1 mixture of methanol and 0.1 M phosphate buffer saline at pH 8) in 50% to 80% yield (determined by HPLC and based on starting [18F]FBBA). The yields obtained with [18F]-FPyBrA ([18F]-**1**) are also much higher, with shorter synthesis time, than those obtained for the conjugation of the other fluorine-18-labeled reagents mentioned above, with oligonucleotide provided with an hexylamine linker at the 5′-end. Using 3-azido-5-nitrobenzyl [18F]-fluoride ([18F]ANBF), 7−20% yield could be obtained for the photochemical-conjugation step (at 0 °C, using a 275 W Mercury lamp for 10 min, in a 10 mM potassium phosphate buffer at pH 7.4, total synthesis time 80−90 min) *(14)*. Using *N*-succinimidyl 4-[18F]fluorobenzoate ([18F]SFB), 7−23% yield could be obtained for the conjugation step (at 40 °C for 30 min, in a 1/4 mixture of DMF and 0.05 M borate buffer at pH 8.5) *(9)*. By use of 4-([18F]fluoromethyl)phenyl isothiocyanate ([18F]FMPI), only up to 8% yield could be obtained for the conjugation step (35 °C for 80 min, in a 1/2 mixture of DMF and 0.1 M NaH_2PO_4/Na_2HPO_4 buffer, pH not indicated) *(7)*. In the latter two examples, the total synthesis time was not indicated but can easily be estimated superior to 80−100 min, when only considering the 30−80 min of reaction time as well as the HPLC purification and desalting process.

Finally, five other fluorine-18-labeled reagents (chemical structures not shown) have recently been synthesized and evaluated (in comparaison with resynthesized *N*-(4-[18F]fluorobenzyl)-2-bromoacetamide [18F]FBBA) as alkylating reagents for the labeling of oligonucleotides in a model reaction using the monomer adenosine 5′-*O*-monophosphorothioate *(55)*. From this comparative study, the author concluded that 2-bromoacetamide reagents, (*N*-(4-[18F]fluorobenzyl)-2-bromoacetamide [18F]FBBA in the cited study) were the more attractive reagents for the labeling of these extremely expensive oligonucleotides, even though their preparation required a longer multistep radiosynthesis *(55)*. In this respect, [18F]FPyBrA ([18F]-**1**), both presenting the 2-bromoacetamide function for optimized conjugations to oligonucleotides and using an efficient radiosynthesis pathway for its preparation, is clearly a new valuable fluorine-18-labeled reagent.

CONCLUSION

For several years now, intense efforts have been devoted to the design and development of oligonucleotide-based radiopharmaceuticals for PET. Based on antisense strategies (specific binding of an oligonucleotide to a complementary DNA or RNA sequence via Watson−Crick base pairing), single-stranded oligonucleotides labeled with a positron-emitter could be in principle used to visualize specific gene expression, by imaging their hybridizations to target mRNAs *(5)*. In this respect, we previously demonstrated that the addition of an *N*-substituted-acetamide-based prosthetic group at the 3′-end of single-stranded oligonucleotide does not hamper the physicochemical properties of the parent oligonucleotide in vitro, including its hybridization to the complementary target *(8, 56)*. Aptamers *(57)* are another class of high-affinity oligonucleotide ligands that do not hybridize to RNA by Watson−Crick base pairing but instead are evolved and selected in vitro for their properties to recognize and bind structurally to a variety of selected molecular targets. Aptamers are an exciting approach to the creation of new contrast agents for PET imaging, and this has been claimed for Spiegelmers, a man-made, highly stable, both in vitro and in vivo, class

of single-stranded mirror-image oligonucleotides (L-RNA or L-DNA) *(46, 47)* with potential for therapeutic and diagnostic applications *(58−62)*.

The objective of the present work was to develop a [^{18}F]-fluoropyridine-based new haloacetamide reagent for the prosthetic labeling with fluorine-18 of phosphorothioate-bearing single-stranded oligonucleotides. [^{18}F]FPyBrA (2-bromo-*N*-[3-(2-[^{18}F]fluoro-pyridin-3-yloxy)propyl]acetamide) was designed as a radiochemically feasible reagent, its pyridinyl moiety both carrying the radioactive halogen (fluorine-18) and allowing its efficient incorporation via a nucleophilic heteroaromatic substitution, and its 2-bromoacetamide function, ensuring the efficient alkylation of a phosphorothioate monoester group born at the 3′- or 5′-end of single-stranded oligonucleotides. [^{18}F]FPyBrA ([^{18}F]-**1**, HPLC-purified) was efficiently prepared in 18−20% non-decay-corrected yield (based on starting [^{18}F]-fluoride) in 80−85 min using a three-step radiochemical pathway. The developed procedure involves a high-yield nucleophilic heteroaromatic ortho-radiofluorination as the fluorine-18 incorporation step and uses a trimethylammonium trifluoromethane sulfonate as the most efficient precursor leaving group for labeling (when compared to the parallely tested nitro precursor). [^{18}F]-FPyBrA ([^{18}F]-**1**) was regioselectively conjugated with 9-mer and 18-mer single-stranded oligonucleotides, provided with a phosphorothioate monoester group at their 3′-end. Both natural phosphodiester DNA oligodeoxyribonucleotides and in vivo-stable 2′-methoxy- and 2′-fluoro-modified oligoribonucleotides were used in the present work. Conjugation was achieved in high yields (50−75%) and uses optimized, short-time reaction conditions, both compatible with the chemical stability of the oligonucleotides and the relatively short half-life of the radioisotope concerned (the whole radiosynthetic procedure, including the preparation of the fluorine-18-labeled reagent, the conjugation with the oligonucleotide, and the HPLC-purification lasted 140−160 min).

Given the high radiosynthetic yields obtained using nucleophilic heteroaromatic substitutions in the pyridine series, [^{18}F]FPyBrA ([^{18}F]-**1**) represents a valuable alternative to the already reported *N*-(4-[^{18}F]fluorobenzyl)-2-bromoacetamide ([^{18}F]FBBA) *(6)* for the design and development of oligonucleotide-based radiopharmaceuticals for PET.

EXPERIMENTAL SECTION

General. Chemicals. Chemicals were purchased from standard commercial sources (Aldrich, Fluka, or Sigma, France) and were used without further purification, unless stated otherwise. Oxygen-18-enriched water ([^{18}O]H_2O, >95%) was purchased from CortecNet (Paris, France). Lyophilized, HPLC-RP-purified 3′-phosphorothioate-oligonucleotides were purchased from Genset (Paris, France) or Eurogentec (Seraing, Belgium). The oligonucleotides purchased differ either in length, in sequence, or in chemistry of the sugar−phosphate backbone: (i) **OL1**, a 9mer natural phosphodiester oligodeoxyribonucleotide (oligo-9mer-PO-3′ps); (ii) **OL2a**, an 18mer natural phosphodiester oligodeoxyribonucleotide (oligo-18mer-PO-3′ps); (iii) **OL2b**, an 18mer 2′methoxy-modified oligoribonucleotide (oligo-18mer-2′OMe-3′ps) with an identical sequence as **OL2a**; (iv) **OL3**, an 18mer with 2′ fluoro-modified pyrimidines (oligo-18mer-2′F-3′ps). Sequences of all oligonucleotides (**OL1**, **OL2a**, **OL2b**, and **OL3**) are summarized in Table 1.

Analytical Methods. Thin layer chromatography (TLC) was run on precoated plates of silica gel 60F_{254} (Merck). The compounds were localized (1) when possible at 254 nm using a UV lamp and/or (2) by dipping the TLC plates in a 1% ethanolic ninhydrin solution and heating on a hot plate. Radioactive spots were detected using a Berthold TraceMaster 20 automatic TLC linear analyzer. Flash chromatography was conducted on silica gel 63−200 μm (Merck) at 0.3 bar (compressed air).

HPLCs (Equipment: Waters or Shimadzu systems). [HPLC A]: Equipment: a Waters Prep LC 3000 system, a Shimadzu SPD10-AVP UV-multiwavelength detector; column: preparative SiO_2 Lichrosorb, Merck (250 × 27.0 mm; porosity: 7 μm); solvents and conditions: isocratic elution with heptane/EtOAc; temperature: RT; absorbance detection at λ = 254 nm. [HPLC B]: Equipment: a Waters 600 Controller Gradient system, a Waters 490E UV-multiwavelength detector and a Geiger-Müller detector; column: semipreparative C18 μBondapak, Waters (300 × 7.8 mm; porosity: 10 μm); solvents and conditions: triethylammonium acetate, 50 mM, pH 7 (TEAA) and acetonitrile; gradient elution: linear 5 min from 95/5 to 90/10 (TEAA/acetonitrile, v:v) then linear 10 min from 90/10 to 70/30 (v:v) and wash-out 10 min at 50/50 (v:v); flow rate: 6 mL/min; temperature: RT; absorbance detection at λ = 254 nm. [HPLC C]: Equipment: a Waters 510 pump, a Shimadzu SPD10-AVP UV-multiwavelength detector, and a Geiger-Müller detector; column: semipreparative SiO_2 Zorbax Rx-SIL, Hewlett-Packard (250 × 9.4 mm; porosity: 5 μm); solvents and conditions: isocratic elution with CH_2Cl_2/EtOAc: 50/50 (v:v); flow rate: 5 mL/min; temperature: RT; absorbance detection at λ = 254 nm. [HPLC D]: Equipment: a Waters 600 Controller Gradient system, a Hewlett-Packard 1100 series UV-multiwavelength detector and a Packard Flow One Scintillation Analyzer equipped with a positron-dedicated cell for radioactivity monitoring; column: analytical C18 μBondapak, Waters (300 × 3.9 mm; porosity: 10 μm); solvents and conditions: triethylammonium acetate, 50 mM, pH 7 (TEAA), and acetonitrile; gradient elution: linear 5 min from 95/5 to 90/10 (TEAA/acetonitrile, v:v) then linear 15 min from 90/10 to 60/40 (v:v) and wash-out 10 min at 50/50 (v:v), flow rate: 1.5 mL/min; temperature: RT; absorbance detection at λ = 254 nm.

NMR spectra were recorded on a Bruker AMX (300 MHz) apparatus using the hydrogenated residue of the deuterated solvents (DMSO-d_6, δ = 2.50 ppm; CD_2Cl_2, δ = 5.32 ppm; CD_3OD, δ = 3.30 and 4.78 ppm) and/or TMS as internal standards for ^{1}H NMR as well as the deuterated solvents (DMSO-d_6, δ = 39.5 ppm; CD_2Cl_2, δ = 53.8 ppm; CD_3OD, δ = 49.0 ppm) and/or TMS as internal standards for ^{13}C NMR. ^{31}P NMR were recorded in nondeuterated water using TMP as internal standard. The chemical shifts are reported in ppm, downfield from TMS (^{1}H and ^{13}C) or TMP (^{31}P) (s, d, t, q, q^5, dd, td, m, b for singlet, doublet, triplet, quadruplet, quintuplet, doublet of doublet, triplet of doublet, multiplet (or multi sharp-peak system), and broad, respectively). The mass spectra were measured on a Nermag R10−10 apparatus or a MALDI-TOF spectrometer (GSG, Karlsruhe, Germany).

Miscellaneous. Radiosyntheses using fluorine-18, including the HPLC purifications, were performed in a 7.5-cm-lead shielded cell using a computer-assisted Zymate robot system (Zymark Corporation, Paris, France). Specific radioactivity was determined as follows: the area of the absorbance peak corresponding to the radiolabeled product was measured on the HPLC chromatogram and compared to a standard curve relating mass to absorbance.

Radioisotope Production. No-carrier-added aqueous [18F]fluoride ion was produced on a CGR-MeV 520 cyclotron by irradiation of a 2 mL water target using a 17 MeV proton beam on 95% enriched [18O]water by the $[^{18}O(p,n)^{18}F]$ nuclear reaction and was transferred to the appropriate hot cell. Typical production: 20.3−24.0 GBq (550−650 mCi) of $[^{18}F]F^-$ at the end of bombardment for a 20 μA, 30 min (36 000 μC) irradiation.

Chemistry. [3-(2-Fluoropyridin-3-yloxy)propyl]-carbamic Acid *tert*-Butyl Ester (3a). To a solution of (3-hydroxypropyl)carbamic acid *tert*-butyl ester (**2**, 2.00 g, 11.4 mmol) in THF (122 mL) were added 2.39 g of triphenylphosphine (MW: 262.29, 9.1 mmol, 0.8 equiv), 1.03 g of 2-fluoro-3-hydroxypyridine (MW: 113.09, 9.1 mmol, 0.8 equiv), and dropwise 3.1 mL of diisopropyl azodicarboxylate (DIAD; MW: 202.21, d: 1.027, 15.7 mmol, 1.38 equiv). After addition, the reaction mixture was stirred at room temperature for 24 h. The reaction mixture was concentrated to dryness, and the residue was purified on silica gel. Elution with heptane/EtOAc (60/40 v/v) gave 1.51 g of **3a** as a yellow oil (49%). For analytical purposes, an aliquot was further purified by HPLC. R_f (EtOAc/heptane: 50/50 v/v): 0.44. R_t (HPLC A, heptane/EtOAc: 60/40 (v/v), flow rate: 25 mL/min): 10.2 min. ^{1}H NMR (CD_2Cl_2, 298 K): δ: 7.68 (dt, J = 3.0, 1.5 Hz, 1H); 7.28 (td, J = 7.8, 1.5 Hz, 1H); 7.10 (dd, J = 8.1, 5.1 Hz, 1H); 4.07 (t, J = 6.3 Hz, 2H); 3.27 (q, J = 6.3 Hz, 1H); 1.98 (q^5, J = 6.4 Hz, 2H); 1.39 (s, 9H). ^{13}C NMR (CD_2Cl_2, 298 K): δ: 156.3 [C]; 154.1 [d, J^1_{F-C} = 237 Hz, C]; 142.5 [d, J^2_{F-C} = 27 Hz, C]; 137.5 [d, J^3_{F-C} = 15 Hz, CH]; 123.0 [CH]; 122.2 [CH]; 79.2 [C]; 67.3 [CH_2]; 38.0 [CH_2]; 29.8 [CH_2]; 28.5 [3×CH_3]. MS (DCI/NH_4^+) $C_{13}H_{19}F_1N_2O_3$: 271 [M + H^+].

[3-(2-Dimethylaminopyridin-3-yloxy)propyl]carbamic Acid *tert*-Butyl Ester (3b). To a solution of (3-hydroxypropyl)carbamic acid *tert*-butyl ester (**2**, 0.31 g, 1.8 mmol) in THF (20 mL) were added 0.47 g of triphenylphosphine (MW: 262.29, 1.8 mmol, 1.0 equiv), 0.25 g of 2-(dimethylamino)-3-hydroxypyridine (MW: 138.00, 1.81 mmol, 1.0 equiv), and dropwise 0.35 mL of diisopropyl azodicarboxylate (DIAD; MW: 202.21, d: 1.027, 1.8 mmol, 1.0 equiv). After being stirred at room temperature for 24 h, the reaction mixture was concentrated to dryness and the residue was purified by column chromatography on silica gel. Elution with heptane/EtOAc (70/30 v/v) gave 0.23 g of **3b** as a yellow oil (43%). For analytical purposes, an aliquot was further purified by HPLC. R_f (EtOAc/heptane: 50/50 v/v): 0.35. R_t (HPLC A, heptane/EtOAc: 60/40 (v/v), flow rate: 35 mL/min): 8.6 min. ^{1}H NMR (CD_2Cl_2, 298 K): δ: 7.77 (dd, J = 4.8 Hz, 1H); 7.00 (dd, J = 7.8 Hz, J < 1.5 Hz, 1H); 6.72 (dd, J = 7.8, 4.8 Hz, 1H); 4.02 (t, J = 6.0 Hz, 2H); 3.30 (q, J = 6.0 Hz, 2H); 2.93 (s, 6H); 2.00 (q^5, J = 6.0 Hz, 2H); 1.42 (s, 9H). ^{13}C NMR (CD_2Cl_2, 298 K): δ: 156.6 [C]; 153.7 [C]; 146.2 [C]; 139.0 [CH]; 118.8 [CH]; 115.9 [CH]; 79.1 [C]; 67.4 [CH_2]; 41.1 [2×CH_3]; 38.8 [CH_2]; 32.3 [CH_2]; 28.5 [3×CH_3]. MS (DCI/NH_4^+) $C_{15}H_{25}N_3O_3$: 296 [M + H^+].

[3-(2-Nitropyridin-3-yloxy)propyl]carbamic Acid *tert*-Butyl Ester (3c). To a solution of (3-hydroxypropyl)-carbamic acid *tert*-butyl ester (**2**, 2.00 g, 11.4 mmol) in THF (122 mL) were added 2.27 g of triphenylphosphine (MW: 262.29, 8.65 mmol, 0.8 equiv), 1.23 g of 2-nitro-3-hydroxypyridine (MW: 139.01, 8.85 mmol, 0.8 equiv), and dropwise 3.1 mL of diisopropyl azodicarboxylate (DIAD; MW: 202.21, d: 1.027, 15.7 mmol, 1.38 equiv). After addition, the reaction mixture was stirred at room temperature for 24 h. The reaction mixture was concentrated to dryness and the residue was purified on silica gel. Elution with heptane/EtOAc (60/40 v/v) gave 1.37 g of **3c** as a yellow oil (40%). For analytical purposes, an aliquot was further purified by HPLC. R_f (EtOAc/heptane: 50/50 v/v): 0.19. R_t (HPLC A, heptane/EtOAc: 50/50 (v/v), flow rate: 25 mL/min): 11.5 min. ^{1}H NMR (CD_2Cl_2, 298 K): δ: 8.06 (t, J = 3.3 Hz, 1H); 7.55 (d, J = 3.0 Hz, 2H); 4.20 (t, J = 5.7 Hz, 2H); 3.28 (q, J = 6.3 Hz, 2H); 2.03 (q^5, J = 6.3 Hz, 2H); 1.41 (s, 9H). ^{13}C NMR (CD_2Cl_2, 298 K): δ: 156.3 [C]; 149.2 [C]; 147.3 [C]; 139.5 [CH]; 129.2 [CH]; 124.0 [CH]; 79.2 [C]; 68.3 [CH_2]; 37.9 [CH_2]; 29.5 [CH_2]; 28.4 [3×CH_3]. MS (DCI/NH_4^+) $C_{13}H_{19}N_3O_5$: 298 [M + H^+].

[3-(3-*tert*-Butoxycarbonylaminopropoxy)pyridin-2-yl]trimethylammonium Trifluoromethanesulfonate (3d). To a 0−3 °C solution of [3-(2-(dimethylamino)-pyridin-3-yloxy)propyl]carbamic acid *tert*-butyl ester (**3b**, 0.4 g, 1.35 mmol) in toluene was added 0.2 mL of methyl trifluoromethanesulfonate (MW: 164.10, d: 1.45, 1.77 mmol, 1.3 equiv). After 3 min, a precipitate was obtained and the reaction mixture was stirred at room temperature for 1 h. The precipitate was filtered and washed with Et_2O to give 0.58 g of **3d** as a white powder (93%). ^{1}H NMR (CD_2Cl_2, 298 K): δ: 8.10 (bd, J = 3.3 Hz, 1H); 7.66 (d, J = 8.1 Hz, 1H); 7.60 (dd, J = 6.1, 4.2 Hz, 1H); 4.31 (t, J = 6.3 Hz, 2H); 3.71 (s, 9H); 3.31 (q, J = 6.3 Hz, 2H); 2.12 (q^5, J = 6.3 Hz, 2H); 1.38 (s, 9H).^{13}C NMR (CD_2Cl_2, 298 K): δ: 156.6 [C]; 147.7 [C]; 142.6 [C]; 139.0 [CH]; 129.0 [CH]; 124.6 [CH]; 121.2 [q, J = 319 Hz, CF_3]; 79.3 [C]; 68.1 [CH_2]; 37.5 [CH_2]; 30.0 [CH_2]; 28.4 [3×CH_3].

[3-(2-Fluoropyridin-3-yloxy)]propylamine (4). To a 0−3 °C solution of [3-(2-fluoropyridin-3-yloxy)propyl]-carbamic acid *tert*-butyl ester (**3a**, 0.04 g, 0.15 mmol) in CH_2Cl_2 (1 mL) was added TFA (100 μL). After being stirred at room temperature for 1 h, the reaction mixture was concentrated to dryness to give 0.05 g of **3** as its TFA salt (quantitative). ^{1}H NMR (CD_3OD, 298 K): δ: 7.51 (bs, $w_{1/2}$ = 5.0 Hz, 1H); 7.36 (bt, $w_{1/2}$ = 25.0 Hz, 1H); 7.04 (bd, $w_{1/2}$ = 15.0 Hz, 1H); 4.03 (bt, $w_{1/2}$ = 15.0 Hz, 2H); 2.99 (bt, $w_{1/2}$ = 15.0 Hz, 2H); 2.01 (bq, $w_{1/2}$ = 15.0 Hz, 2H). ^{13}C NMR (CD_3OD, 298 K): δ: 155.3 [d, J^1_{F-C} = 237 Hz, C]; 144.3 [d, J^2_{F-C} = 24 Hz, C]; 138.5 [d, J^3_{F-C} = 13 Hz, CH]; 125.1 [CH]; 123.8 [CH]; 67.9 [CH_2]; 38.6 [CH_2]; 28.4 [CH_2]. MS (DCI/NH_4^+) $C_8H_{11}F_1N_2O_1$: 171 [M + H^+].

2-Bromo-*N*-[3-(2-fluoropyridin-3-yloxy)propyl]-acetamide (1). To a 0−3 °C solution of 3-(2-fluoropyridin-3-yloxy)propylamine (**4**, 2.90 g, 17.05 mmol) in CH_2Cl_2 (20 mL) were added 5 mL of *N*-methylmorpholine (54.5 mmol, 3.2 equiv) and 5 mL of bromoacetylbromide (MW: 201.86, d: 2.317, 57.4 mmol, 3.4 equiv). After stirring at room temperature for 1 h, H_2O was added to the reaction mixture. The solution was then transferred into a separatory funnel and extracted with CH_2Cl_2. The organic layer was dried with Na_2SO_4 and the reaction mixture was concentrated to dryness to give a residue which was purified on silica gel. Elution with CH_2Cl_2/EtOAc (80/20 to 60/40 v/v) gave 1.00 g of **1** as a yellow powder (24%). R_f (heptane/EtOAc: 70/30 v/v): 0.29. ^{1}H NMR (CD_2Cl_2, 298 K): δ: 7.73 (dd, J = 3.3, 1.8 Hz, 1H); 7.32 (td, J = 7.8 Hz, J < 1.5 Hz, 1H); 7.14 (dd, J = 7.8, 4.8 Hz, 1H); 4.12 (t, J = 6.0 Hz, 2H); 3.85 (s, 2H); 3.49 (q, J = 6.3 Hz, 2H); 2.05 (q^5, J = 6.3 Hz, 2H). ^{13}C NMR (CD_2Cl_2, 298 K): δ: 166.2 [C]; 153.8 [d, J^1_{F-C} = 235 Hz, C]; 142.3 [d, J^2_{F-C} = 25 Hz, C]; 137.5 [d, J^3_{F-C} = 13 Hz, CH]; 123.0 [CH]; 122.3 [CH]; 67.7 [CH_2]; 37.8 [CH_2]; 29.5 [CH_2]; 28.9 [CH_2]. MS (DCI/NH_4^+) $C_{10}H_{12}Br_1F_1N_2O_2$: 292 [M + H^+]; 290 [M + H^+].

Conjugation of Oligonucleotides with 2-Bromo-*N*-[3-(2-fluoropyridin-3-yloxy)propyl]acetamide (1). General Procedure for Preparation of Nonlabeled

Conjugated Oligonucleotides (C-OL1, C-OL2a, C-OL2b, and C-OL3). 50 OD of oligonucleotide (**OL1**, **OL2a**, **OL2b**, or **OL3**) (1 OD is the UV absorbance of 38 μg of an oligonucleotide regardless of the sequence of bases) dissolved in 300 μL of PBS (phosphate-buffered saline) (100 mM, pH 7.4) was mixed with an excess (10 equiv) of 2-bromo-*N*-[3-(2-fluoropyridin-3-yloxy)propyl]-acetamide (**1**), dissolved in 100 μL of MeOH, and reacted for 30 min at 80 °C. Yields of conjugation were determined by HPLC (ratio between conjugated and nonconjugated oligonucleotides). The solvents were evaporated and nonlabeled conjugated oligonucleotides (C-**OL1**, C-**OL2a**, C-**OL2b**, and C-**OL3**) were purified by semipreparative RP-HPLC (HPLC B). Conjugated oligonucleotides were desalted using a NAP-10 G25 Sephadex column (Amersham Pharmacia Biotech) before characterization. Yields of isolated conjugated oligonucleotides were determined by UV measurements and are based on starting oligonucleotides. Chemical purity of the conjugated oligonucleotides was determined using analytical RP-HPLC (HPLC D).

***N*-[3-(2-Fluoropyridin-3-yloxy)propyl]-2-(oligo-9mer-PO-3′ps)acetamide (C-OL1)**. Conjugation yield: 95% (determined by HPLC). Isolated yield: 90% (determined by UV). R_t(C-**OL1**): 10.0−10.5 min and R_t(**OL1**): 8.5−9.0 min (HPLC B). R_t(C-**OL1**): 14.0 min (>99%) (HPLC D). MS (electrospray): 2990.0 (theor), 2989.0 (exp). ^{31}P NMR (D_2O, 298 K): δ: +14.44 (OP(O)(OH)(S-acetamide)).

***N*-[3-(2-Fluoropyridin-3-yloxy)propyl]-2-(oligo-18mer-PO-3′ps)acetamide (C-OL2a)**. Conjugation yield: 70% (determined by HPLC). Isolated yield: 66% (determined by UV). R_t(C-**OL2a**): 10.0−10.5 min and R_t-(**OL2a**): 9.0−9.5 min (HPLC B). R_t(C-**OL2a**): 14.1 min (>95%) (HPLC D). MS (electrospray): 5846.9 (theor), 5847.8 (exp). ^{31}P NMR (D_2O, 298 K): δ: +14.53 (OP(O)-(OH)(S-acetamide)).

***N*-[3-(2-Fluoropyridin-3-yloxy)propyl]-2-(oligo-18mer-2′OMe-3′ps)acetamide (C-OL2b)**. Conjugation yield: 75% (determined by HPLC). Isolated yield: 62% (determined by UV). R_t(C-**OL2b**): 11.5−12.0 min and R_t-(**OL2b**): 10.5−11.0 min (HPLC B). R_t(C-**OL2b**): 15.4 min (>99%) (HPLC D). MS (electrospray): 6345.3 (theor), 6346.7 (exp). ^{31}P NMR (D_2O, 298 K): δ: +13.94 (OP(O)-(OH)(S-acetamide)).

***N*-[3-(2-Fluoropyridin-3-yloxy)propyl]-2-(oligo-18mer-2′F-3′ps)acetamide (C-OL3)**. Conjugation yield: 70% (determined by HPLC). Isolated yield: 53% (determined by UV). R_t(C-**OL3**): 11.5−12.0 min and R_t(**OL3**): 10.0−10.5 min (HPLC B). R_t(C-**OL3**): 15.3 min (>95%) (HPLC D). MS (electrospray): 5991.0 (theor), 5989.7 (exp.). ^{31}P NMR (D_2O, 298 K): δ: +13.94 (OP(O)(OH)-(S-acetamide)).

Radiochemistry. Preparation of the K[^{18}F]F−K_{222} Complex. To recover and recycle the target [^{18}O]water, the 2 mL of aqueous [^{18}F]fluoride from the target holder were passed through an anion-exchange resin (Sep-Pak Light Waters Accell Plus QMA Cartridge in the chloride form, washed with 5 mL of 1 M aq $NaHCO_3$, and then rinsed with 50 mL of water) by He pressure (1.5−2.0 bar). Helium is blown through the column to maximally extract the [^{18}O]water. The [^{18}F]fluoride ion is then eluted from the resin using 1.0 mL of a 4.5 mg/mL aqueous K_2CO_3 solution into a Vacutainer tube containing 12.0 to 15.0 mg of Kryptofix222 (K_{222}: 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane). The resulting solution was then gently concentrated to dryness at 145−150 °C under a nitrogen stream for 10 min to give no-carrier-added K[^{18}F]F−K_{222} complex as a white semisolid residue.

Preparation of 2-Bromo-*N*-[3-(2-[^{18}F]fluoropyridin-3-yloxy)propyl]acetamide ([^{18}F]-1). Procedure Using [3-(2-nitropyridin-3-yloxy)propyl]carbamic Acid *tert*-Butyl Ester (3c) as Precursor for Labeling. Freshly distilled DMSO (600 μL) containing 5.0 mg of the precursor for labeling ([3-(2-nitropyridin-3-yloxy)-propyl]carbamic acid *tert*-butyl ester, **3c**) was directly added into the Vacutainer tube containing the dried K[^{18}F]F−K_{222} complex. The tube (not sealed) was then thoroughly vortexed (15 s) and then placed in a heating block at 145 °C for 4 min without stirring the contents. The reaction vessel was then cooled using an ice−water bath, and the remaining radioactivity was measured. Initial radioactivity (90−95%) placed in the vessel was still present. The resulting dark-colored reaction mixture was then analyzed by radiochromatography. The reaction yield was calculated from the TLC radiochromatogram and defined as the radioactivity area of [3-(2-[^{18}F]fluoropyridin-3-yloxy)propyl]carbamic acid *tert*-butyl ester ([^{18}F]-**3a**) over total fluorine-18 radioactivity area ratio. (SiO_2 TLC, eluent: EtOAc, R_f: [^{18}F]-**3a**: 0.75 and R_f: [^{18}F]fluoride ion: 0.0). Radiosynthesized [^{18}F]-**3a** comigrated with an authentic sample of fluorine-19-synthesized **3a**. The reaction mixture was diluted with 1 mL of water and transferred on the top of a C18 cartridge (PrepSep R-C18, Fisher Scientific, beforehand activated with 2 mL of EtOH and then rinsed with 10 mL of water). The tube was rinsed twice with 1 mL of water which was also transferred and added to the diluted reaction mixture on top of the cartridge. After addition of another 2 mL of water, the whole was passed through the cartridge. The cartridge was washed with 1 mL of water and partially dried for 0.5 min by applying a nitrogen stream. The [3-(2-[^{18}F]fluoropyridin-3-yloxy)propyl]carbamic acid *tert*-butyl ester ([^{18}F]-**3a**) was eluted from the cartridge with 3 mL of dichloromethane into a 5 mL reaction vial containing 0.1 mL of TFA. Twice 1 mL of dichloromethane was used to wash the cartridge and to completely transfer [^{18}F]-**3a** (5% of the total radioactivity amount engaged in the fluorination process was left on the cartridge). The fluorine-18 incorporation yield was also confirmed after the C18 cartridge elution by the CH_2Cl_2-eluted radioactivity over total eluted radioactivity ($DMSO/H_2O + CH_2Cl_2$) counting ratio. The resulting CH_2Cl_2/TFA solution (50/1, v/v) was concentrated to dryness (at 65−75 °C under a gentle nitrogen stream for 4−6 min). The yield of deprotection was quantitative, and no Boc-protected [^{18}F]-**3a** could be detected by radiochromatography (SiO_2 TLC, eluent: EtOAc, R_f: [^{18}F]-**3a**: 0.75). The above residue, containing 3-(2-[^{18}F]fluoropyridin-3-yloxy)propylamine ([^{18}F]-**4**, SiO_2 TLC, eluent: EtOAc, R_f: [^{18}F]-**4**: 0.0) was redissolved in 2 mL of CH_2Cl_2 and concentrated again to dryness to minimize TFA presence (at 65−75 °C under a gentle nitrogen stream for another 2−3 min). The residue, containing [^{18}F]-**4**, was then redissolved in 600 μL of a solution of TEA in CH_2Cl_2 (40 μL/mL or 170 μmol of TEA). After addition of 400 μL of a solution of bromoacetyl bromide in CH_2Cl_2 (50 μL/mL or 230 μmol of $BrCOCH_2Br$), the reaction mixture was allowed to react for 5 min at room temperature with a smooth air-bubbling agitation. Finally, the clear solution was diluted with 200−500 μL of the HPLC solvent used for the purification, and the crude was injected onto a semipreparative HPLC. Isocratic elution (HPLC C) gave pure labeled 2-bromo-*N*-[3-(2-[^{18}F]fluoropyridin-3-yloxy)propyl]acetamide ([^{18}F]-**1**), R_t: 7.0−8.0 min.

Procedure Using [3-(3-*tert*-Butoxycarbonylaminopropoxy)pyridin-2-yl]trimethylammonium Trifluoromethanesulfonate (3d) as Precursor for Labeling. Freshly distilled DMSO (600 μL) containing 4.0 mg of the precursor for labeling ([3-(3-*tert*-butoxycarbonylaminopropoxy)-pyridin-2-yl]-trimethylammonium trifluoromethanesulfonate, **3d**) was directly added into the Vacutainer tube containing the dried K[18F]F−K_{222} complex. The tube (not sealed) was then thoroughly vortexed (15 s) and then placed in a heating block at 145 °C for 2 min without stirring the contents. The remainder of the preparation used the same procedure as described above.

Conjugation of Oligonucleotides with 2-Bromo-*N*-[3-(2-[18F]fluoropyridin-3-yloxy)propyl]acetamide ([18F]-1). General Procedure for Preparation of Labeled Conjugated Oligonucleotides ([18F]C-OL1, [18F]C-OL2a, [18F]C-OL2b, and [18F]C-OL3). 25 OD of oligonucleotides **OL1**, **OL2a**, **OL2b**, or **OL3** dissolved in 300 μL of PBS (100 mM, pH 7.4) were mixed with the HPLC-purified 2-bromo-*N*-[3-(2-[18F]fluoropyridin-3-yloxy)propyl]acetamide ([18F]-**1**), dissolved in 100 μL of MeOH, and reacted for 15 min at 120 °C in a sealed vial. The yields of conjugation of the oligonucleotides with [18F]-**1** reached 50−75% (calculated from the HPLC chromatogram). The solvents were evaporated, and the labeled conjugated oligonucleotides [18F]C-**OL1**, [18F]C-**OL2a**, [18F]C-**OL2b**, and [18F]C-**OL3** were separated from starting oligonucleotides and nonreacted [18F]-**1** by semipreparative HPLC (HPLC B). The HPLC fraction containing the labeled conjugated oligonucleotides ([18F]C-**OL1**, [18F]C-**OL2a**, [18F]C-**OL2b**, and [18F]C-**OL3**) was concentrated under reduced pressure and transferred in a volume of 1 mL onto a NAP10 G25 Sephadex column and eluted in 1.5 mL of water or buffer according to manufacturer's instructions. Typically, 0.37−0.55 GBq (10−15 mCi) of pure conjugated [18F]oligonucleotides could be obtained in 60−75 min starting from 1.85 GBq (50 mCi) of 2-bromo-*N*-[3-(2-[18F]fluoropyridin-3-yloxy)propyl]acetamide ([18F]-**1**) (20−30% non-decay-corrected yield). The whole synthetic procedure has been fully automated on our Zymate robot system and lasted 140−160 min. Quality control (radiochemical and chemical purity) was performed by HPLC (HPLC D).

***N*-[3-(2-[18F]Fluoropyridin-3-yloxy)propyl]-2-(oligo-9mer-PO-3′ps)acetamide ([18F]C-OL1).** R_t([18F]C-**OL1**): 10.0−10.5 min (HPLC B); R_t([18F]C-**OL1**): 14.0 min (>99%) (HPLC D).

***N*-[3-(2-[18F]Fluoropyridin-3-yloxy)propyl]-2-(oligo-18mer-PO-3′ps)acetamide ([18F]C-OL2a).** R_t([18F]C-**OL2a**): 10.0−10.5 min (HPLC B); R_t([18F]C-**OL2a**): 14.1 min (>99%) (HPLC D).

***N*-[3-(2-[18F]Fluoropyridin-3-yloxy)propyl]-2-(oligo-18mer-2′OMe-3′ps)acetamide ([18F]C-OL2b).** R_t([18F]C-**OL2b**): 11.5−12.0 min (HPLC B); R_t([18F]C-**OL2b**): 15.4 min (>99%) (HPLC D).

***N*-[3-(2-[18F]Fluoropyridin-3-yloxy)propyl]-2-(oligo-18mer-2′F-3′ps)acetamide ([18F]C-OL3).** R_t([18F]C-**OL3**): 11.5−12.0 min (HPLC B); R_t([18F]C-**OL3**): 15.3 min (>99%) (HPLC D).

ACKNOWLEDGMENT

The authors wish to thank the cyclotron operators Mr. Daniel Gouel, Mr. Christophe Peronne, and Mr. Christophe Lechêne for performing the irradiations, as well as Ms Badia Amekraz (Laboratoire de Spéciation des Radionucléides et des Molécules, CEA-Saclay, Gif-sur-Yvette, France) and Dr Stefan Vonhoff and Mr Kai Gottsche (Noxxon Pharma AG, Berlin, Germany) for recording the MS spectra. The authors also wish to thank Dr Dirk Roeda for proofreading the manuscript and suggesting linguistic corrections. This work was supported in part by EU contract No QLG1-CT-2000-00562.

Synthesis, Characterization, and Biological Evaluation of Neutral Nitrido Technetium(V) Mixed Ligand Complexes Containing Dithiolates and Aminodiphosphines. A Novel System for Linking Technetium to Biomolecules

Cristina Bolzati,*[,‡] Elisa Benini,[†] Emiliano Cazzola,[†] Christian Jung,[§] Francesco Tisato,*[,‡] Fiorenzo Refosco,[‡] Hans-Jürgen Pietzsch,[§] Hartmut Spies,[§] Licia Uccelli,[†] and Adriano Duatti[†]

ICIS - CNR, Corso Stati Uniti 4, 35127 Padova, Italy, Laboratory of Nuclear Medicine, Department of Clinical & Experimental Medicine, University of Ferrara, Via Borsari 46, 44100 Ferrara, Italy, and Forschungszentrum Rossendorf, Institut für Bioanorganische und Radiopharmazeutische Chemie, PF 510 119, D-01314 Dresden, Germany. Received January 8, 2004; Revised Manuscript Received February 16, 2004

A new biomolecule labeling method that utilizes the $[^{99m}Tc(N)(PNP)]^{2+}$ metal fragment is presented. Thus, a series of nitrido mixed-ligand M(V) complexes (M = ^{99m}Tc, ^{99g}Tc, Re), [M(N)(Ln)(PNP)], where Ln is the dianionic form of a dithiolate or substituted-dithiolate ligand and PNP is an aminodiphosphine, is described. ^{99m}Tc complexes can be prepared using either a two-step or a three-step procedure starting from generator-eluted pertechnetate through a prereduced mixture of [^{99m}Tc(N)]-containing species, followed by sequential or contemporary addition of the relevant dithiolate and aminodiphosphine. The reactions of 2,3-dimercaptopropionic acid (H_2L1) with $[Tc(N)(PNP)]^{2+}$ were investigated in detail. It was found that this bidentate ligand coordinated the metal fragment through the [S^-,S^-] donor atom pair, to yield neutral mixed-ligand complexes [^{99m}Tc(N)(L1)(PNP)] in high specific activity. The additional carboxylic functional group was not involved in metal coordination, thus remaining available for conjugation to target-specific molecules. Dithiolates incorporating pendant functional group(s) gave rise to a 1:1 diastereoisomeric mixture of *syn*-[M(N)(Ln)(PNP)] and *anti*-[M(N)(Ln)-(PNP)] derivatives, depending on the relative orientation of the dithiolate substituent(s) with respect to the terminal nitrido group, and no isomeric conversion was detected. ^{99m}Tc species had been proven to be identical with the ^{99g}Tc complexes prepared at the macroscopic level by comparison of the corresponding radiometric and UV/vis HPLC profiles. Challenge experiments with cysteine or glutathione indicated that these physiological agents had no effect on the stability of this class of mixed-ligand ^{99m}Tc-complexes. Biodistribution studies in rats of selected ^{99m}Tc-complexes showed a rapid clearance from the blood and tissues after 60 min pi.

INTRODUCTION

In the past few years, the design of technetium and rhenium model compounds potentially useful for the development of new radiopharmaceuticals has taken advantage of the introduction of efficient methods for the production of ^{99m}Tc-species (*1*) and ^{188}Re-species (*2*) containing a terminal $[M(N)]^{2+}$ group at the non carrier added (NCA) level. Nitrido-containing complexes offer the advantage to be virtually red-ox inert and stable over a wide range of pH values (*3*), thereby constituting a class of interesting candidates for nuclear medicine applications.

Pioneering investigation on nitrido technetium chemistry performed by Baldas and co-workers in the 1980s (*4*) have been sharply tuned into nuclear medicine applications with the synthesis of the *neutral* myocardial imaging agent [^{99m}Tc−N−NOET] (*5*), an unexpected mimic of the $^{201}Tl^+$ agent (*6*). The [^{99m}Tc−N−NOET] is a simple bis-substituted dithiocarbamate nitrido technetium complex adopting a distorted square pyramidal configuration with the terminal nitride group at the apex and the four (*N*-ethoxy-*N*-ethyl)dithiocarbamate sulfurs at the base of the pyramid. Despite the high stability of the [Tc(N)] group and the variety of nitrido complexes reported (*7*), little effort has been made in the past to use the [Tc(N)] core for the labeling of biomolecules.

Looking for additional stable configurations including the terminal $[M(N)]^{2+}$ group, we have recently developed a synthetic strategy aiming at the incorporation of a bioactive molecule into a stable nitrido containing Tc complex (*8*). This strategy is based on the application of the so-called 'metal fragment' approach (*9*) and requires the synthesis of an asymmetrical nitrido compound characterized by the presence of two different polydentate ligands bound to the same $[Tc(N)]^{2+}$ core. It utilizes the coordination ability of π-acceptor PNP type heterodiphosphines (diphosphine including a tertiary amine nitrogen in a five-member spacer, see Figure 1) to produce the $[M(N)(PNP)]^{2+}$ metal-fragment. This strongly electrophilic synthon selectively reacts with electron rich, π-donor chelating ligands to yield monocationic or neutral asymmetrical compounds of the type $[M(N)(X-Y)(PNP)]^{+/0}$. X−Y ligands are bidentate homoatomic or heteroatomic

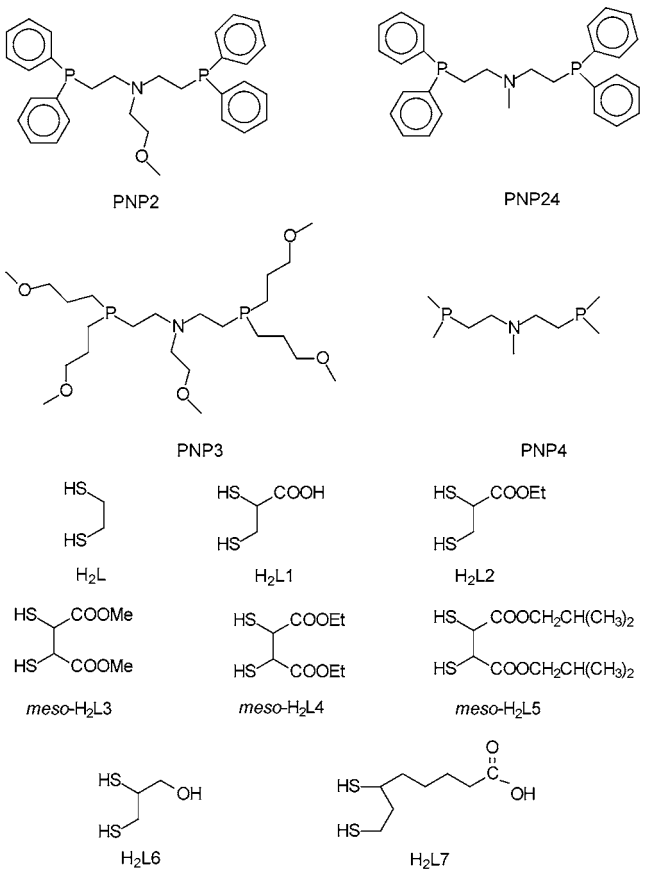

Figure 1. Aminodiphosphines (PNP) and dithiols (H_2Ln) ligands utilized in this study.

chelates having the property to become a bifunctional chelating agent (BFCA) by insertion of an additional functional group for conjugation with bioactive fragments.

Examples of mixed nitrido heterocomplexes already synthesized and thoroughly characterized include monocationic $[M(N)(DTC)(PNP)]^+$ (DTC = various dithiocarbamates) (*10*), $[M(N)(DTCZ)(PNP)]^+$ (DTCZ = S-methyl 2-methyldithiocarbazate), $[M(N)(N,S\text{-cys})(PNP)]^+$ (N,S-cys = L-cysteine ethyl ester) (*11*), and neutral [M(N)(O,S-cys)(PNP)] (O,S-cys = *N*-acetyl-L-cysteine) and [M(N)-(O,S-ma)(PNP)] (O,S-ma = mercaptoacetate) complexes (*11*). It is worth noting that the $[M(N)(PNP)]^{2+}$ moieties are stabilized by a variety of donor atom combinations (i.e. S,S^-, S,NH^-, O^-,S^-), all giving heterocomplexes in which the original, substitution-inert *fac*-$[M(N)(PNP)]^{2+}$ building-block is retained, and the incoming bidentate ligand is accommodated on the equatorial plane, cis-positioned with respect to the terminal nitride group.

A reasonable extension of the above series of ligands able to stabilize the $[M(N)(PNP)]^{2+}$ moieties comprise homoatomic dithiolate ligands for the double reason that thiolate sulfur is among the best donor for group 7 metals (*7*) and dithiolate backbones are prone to derivatization with appropriate functional groups. A wide number of thiolato mono-oxo Tc(V) model compounds including tetradentate diamine-dithiolate in $[Tc(O)(DADT)]^-$ complexes (*12*), tridentate amine-dithiolate and monodentate thiolate in [Tc(O)(SNS)(SR)] '3 + 1' complexes (*13*), and bidentate dimercaptosuccinic acid in bis-substituted [Tc-$(O)(DMSA)_2$] compounds (*14*) have been already produced. DADT, SNS, and SR frameworks have also been in turn conjugated with bioactive molecules (*15*), indicating that thiol-containing BFCAs are suitable substrates for the production of ^{99m}Tc-based receptor-specific agents under mild conditions (*15*). By using the BFCA strategy, Kung and co-workers developed the first ^{99m}Tc dopamine transporter imaging agent by conjugation of a tropane analogue onto one nitrogen of a DADT framework (*16*), and, more recently, the P829 somatostatin analogue conjugate to a N_3S-momoamine diamidethiol chelating unit formed by the (B-Dap)-Lys-Cys tripeptide sequence (*17*) has been approved by FDA as a new radiopharmaceutical for tumor imaging.

For the reasons outlined above, we thought to combine in a unique molecular system the substitution-inert property of $[M(N)(PNP)]^{2+}$ moieties with the well recognized coordination ability toward Tc and Re of dithiolates, to form neutral mixed nitrido heterocomplexes of the type [M(N)(S−S)(PNP)], aiming eventually at the design of a new system useful for the development of receptor-based radiopharmaceuticals. Hence, in this study we report on the preparation and biological evaluation of several mixed nitrido ^{99m}Tc heterocomplexes of the type [^{99m}Tc-(N)(S−S)(PNP)], along with the synthesis and physicochemical characterization of some Re and ^{99g}Tc analogues.

EXPERIMENTAL PROCEDURES

Caution! ^{99g}Tc is a weak β-emitter ($E_{\beta^-} = 0.292$ MeV, $t_{1/2} = 2.13 \times 10^5$ years). All manipulations were carried out in laboratories approved for low-level radioactivity using monitored hoods and gloveboxes. When handled in milligram amounts, ^{99g}Tc does not present a serious health hazard since common laboratory glassware provides adequate shielding. Bremsstrahlung is not a significant problem due to the low energy of the β^- particles. However, normal radiation safety procedure must be used at all times, especially with a solid samples, to prevent contamination and inhalation.

General. All common chemicals were purchased from Aldrich Chemicals. Common solvents were reagent grade and used without further purification. The aminodiphosphine ligands PNP24, PNP3, and PNP4 utilized in this study and sketched in Figure 1, were prepared according to the literature methods (*18*) or purchased from Argus Chemicals (Prato, Italy). Due to the high tendency of the alkyl bis-phosphine ligands to oxidize, all the solvent involved in the reactions with PNP3 and PNP4 were previously degassed. The dithiol ligands H_2L, H_2L1, H_2-L6, and H_2L7 were purchased from Sigma Aldrich Chemicals while the remaining dithiol ligands were synthesized as previously reported (*19*). ^{99m}Tc as Na-[$^{99m}TcO_4$] was eluted from a ^{99}Mo/^{99m}Tc generator provided by Nycomed Amersham-Sorin (Saluggia, Italy). Commercially available $NH_4[^{99g}TcO_4]$ (Oak Ridge National Lab) was purified from a black contaminant ($^{99g}TcO_2 \times nH_2O$) by addition of H_2O_2 and NH_4OH solutions followed by recrystallization from hot water. [^{99g}Tc(N)$Cl_2(PPh_3)_2$] was prepared according to the literature (*20*). [Re(N)Cl_2(PNP2)] and [Re(N)Cl_2(PNP24)] intermediate complexes were prepared as reported previously (*9*).

Elemental analyses (C, H, N, S) were performed on a Carlo Erba 1106 elemental analyzer. FT IR spectra were recorded on a Nicolet 510P Fourier transform spectrometer, in the range 4000−400 cm^{-1} and in KBr mixture using a Spectra-Tec diffuse-reflectance collector accessory. ^{1}H, ^{13}C, and ^{31}P NMR spectra were collected on a Bruker 300 instrument, using $SiMe_4$ as internal reference (^{1}H and ^{13}C) and 85% aqueous H_3PO_4 as external reference (^{31}P).

Thin-layer chromatography (TLC) and/or high performance liquid chromatography (HPLC) analyses were

used to evaluate radiochemical yield (RCY), radiochemical purity (RCP), and stability of the compounds. TLC analyses were performed using silica gel F_{254S} or C18 F_{254S} plates (Merck). The activity on the plates were located and measured using a Cyclone Instrument equipped with a phosphorus imaging screen and an OptiQuant image analysis software (Packard, Meridian, CT). HPLC was performed on a Beckman System Gold instrument equipped with a programmable solvent Model 126, a sample injection valve 210A, a scanning detector Module 166, and a radioisotope detector Model 170. HPLC analysis was carried out using a reversed-phase Beckman ODS precolumn (45 × 4.6 mm) and a reversed-phase Beckman ODS column (250 × 16 mm) at the flow rate of 1 mL/min. Chromatographic data are reported in Table 1.

Preparation of [^{99m}Tc(N)(Ln)(PNP)]: *Method 1*. Na-[$^{99m}TcO_4$] (0.250 mL, 50.0 MBq − 2.2 GBq) was added to a vial containing 5.0 mg of SDH (SDH = succinic dihydrazide), 0.1 mg of $SnCl_2$ suspended in 0.1 mL of saline, and 1.0 mL of ethanol. The vial was kept at room temperature for 15 min giving a mixture of ^{99m}Tc-nitrido precursors, $[Tc{\equiv}N]_{mix}^{2+}$. Then, 1.0 mg of the appropriate diphosphine ligand (PNP3 or PNP4 or PNP24) dissolved in 0.1 mL of ethanol was added, and the solution was left standing for 30 min at room temperature. The resulting $[^{99m}Tc(N)(PNP)]^{2+}$ intermediate complex was converted into the final product by addition of 0.1 mL of an ethanol solution containing 0.5 mg of the relevant dithiol (H_2L1, H_2L3−7) at 50 °C for 1 h (in the PNP24/H_2L2 case, 0.2 mL of an ethanol solution containing 1.0 mg of H_2L2 were added at 100 °C for 30 min, followed by 0.25 mL of phosphate buffer (1 M, pH 7.4); in the PNP4/H_2L case, 0.1 mL of an ethanol solution containing 2.5 mg of H_2L were added at 50 °C for 1 h, followed by 0.25 mL of carbonate buffer (0.5 M, pH 9.0)). In all preparations, TLC characterization showed the presence of two separate radioactive spots (1:1 ratio), which resulted from the formation of two distinct isomers (**a** and **b**) of the complexes [^{99m}Tc(N)(Ln)(PNP)] (vide infra). The total radiochemical yield (RCY) determined by TLC chromatography for the two isomers was >93%.

*Method 2***.** To a mixture of $[Tc{\equiv}N]_{mix}^{2+}$ prepared as above were simultaneously added 1.0 mg of the appropriate diphosphine ligand (PNP) dissolved in 0.1 mL of ethanol and 0.5 mg of the proper dithiol ligand dissolved in 0.1 mL of ethanol to the reaction vial and heated at 50 °C for 1 h (in the PNP24/H_2L2 case, 1.0 mg of H_2L2 was added at 100 °C for 30 min followed by 0.25 mL of phosphate buffer (1M, pH 7.4)). In all cases, total RCY determined by TLC and HPLC chromatography was 90%.

Purification of [^{99m}Tc(N)(Ln)(PNP)] Compounds. [^{99m}Tc(N)(L1)(PNP3)] and [^{99m}Tc(N)(L1)(PNP4)] were purified by HPLC, concentrated on a Sep pack C18 cartridge previously activated with 95% ethanol (5 mL) and water (5 mL), rinsed with H_2O (10 mL), and eluted using EtOH (3 × 0.5 mL). The second fraction containing all the activity was diluted with saline (1/10 EtOH/saline) and utilized for in vitro and in vivo studies. For remaining ^{99m}Tc-derivatives, the reaction mixture was diluted with 25 mL of water (50 mL for PNP4/L) and loaded onto a Sep pack C18 cartridge previously activated with 95% ethanol (5 mL) and water (5 mL). The cartridge was rinsed with water (20 mL) followed by 10% ethanol (5 mL) and 20% ethanol (0.4 mL) for [^{99m}Tc(N)(L)(PNP4)], 10% ethanol (3 mL) for [^{99m}Tc(N)(L3/L4)(PNP4)], and 30% ethanol (3 mL) for [^{99m}Tc(N)(L5)(PNP4)]. Finally, [^{99m}Tc-(N)(L)(PNP4)] was eluted with 30% ethanol (2 × 1 mL), [^{99m}Tc(N)(L3/L4)(PNP4)] was eluted with 30% ethanol (0.250 mL) followed by 60% ethanol (1 mL), and [^{99m}Tc-(N)(L5)(PNP4)] was eluted with 80% ethanol (1 × 0.4 mL; 3 × 1 mL). The second fractions eluted were utilized, after 1/10 EtOH/saline dilution, for stability studies and in vivo biodistribution studies. After purification, the radiochemical purity (RCP), evaluated by TLC chromatography, was >95%.

Preparation of [^{99g}Tc(N)(Ln)(PNP)] Complexes. To an orange-pink suspension containing 0.05 mmol of [$^{99g}TcNCl_2(PPh_3)_2$] in 5 mL of CH_2Cl_2 was added a slight excess of the relevant PNP ligand (0.060 mmol) dissolved

in 5 mL of EtOH. The reaction mixture was stirred to reflux under dinitrogen atmosphere for 30 min. Rapidly the solution became clear and the color turned to yellow. Then, an excess of Et_3N (10 drops) was added followed by 0.11 mmol of H_2Ln dissolved in 2 mL of EtOH. The mixture was heated to reflux for an additional 1 h. After cooling, the solvents were evaporated and the crude material was washed with Et_2O and *n*-hexane. Except for [^{99g}Tc(N)(L1)(PNP4)], all the derivatives were redissolved in CH_2Cl_2 (5 mL) and treated with an equal volume of water (3 × 5 mL) to remove the hydrophilic species. The organic layer was dried over anhydrous $MgSO_4$, the solvent eliminated, and the resulting residue triturated with Et_2O. A yellow solid was recovered for [^{99g}Tc(N)(L1)(PNP3)] and [^{99g}Tc(N)(L3)(PNP4)], which was dried under gentle dinitrogen stream. A yellow oil was instead collected for [^{99g}Tc(N)(L6/L7)(PNP3)]. TLC analyses, carried out on C18 or in silica, revealed the formation of two species (**a**, **b**) in an approximately 1:1 ratio.

Crude [^{99g}Tc(N)(L1)(PNP4)] was instead dissolved in the minimum amount of $CHCl_3$ (0.5 mL) and loaded onto a silica column (Ø 1 cm, l 10 cm) conditioned with $CHCl_3$. The column was eluted with $CHCl_3$ (50 mL) followed by mixtures of $CHCl_3$/MeOH 98/2 (50 mL) and $CHCl_3$/MeOH 95/5 (100 mL). Two yellow bands were separated and isolated, as yellow oily residues for [^{99g}Tc(N)(L1)(PNP4)]. The first fraction was identified as the syn isomer (**a**) and the second fraction as the anti isomer (**b**). All of the compounds are soluble in chlorinated solvents and in alcohols, insoluble in diethyl ether and *n*-hexane.

[^{99g}Tc(N)(L1)(PNP3)] (a + b). Yield: 65%. Anal. ($C_{26}H_{55}N_2O_7P_2S_2Tc$ Mw = 732.79): calcd C, 42.61; H 7.56; N 3.84; S 8.75. Preparation of [Re(N)(Ln)(PNP)] Complexes. To a yellow solution containing the [Re(N)Cl$_2$(PNP)] precursor (0.1 mmol) dissolved in $CHCl_3$/EtOH (1.1) (20 mL), a slight excess of the appropriate H_2Ln dithiol (0.11 mmol) and an excess of Et_3N (10 drops) were added. The reaction mixture was refluxed for 2 h. After cooling, the solvents were evaporated under a gentle dinitrogen stream and the residue was dissolved in water (10 mL) and neutralized with 2 M citric acid. The aqueous phase was extracted three times with $CHCl_3$. The combined organic phases were washed with saline (3 × 10 mL) and dried over $MgSO_4$, and the solvent was stripped in vacuo. The oily residue was triturated with Et_2O giving a yellow powder. For [Re(N)(L7)(PNP24)], the oily residue was redissolved in $CHCl_3$ and purified by column chromatography on silica. Elution with a $CHCl_3$/MeOH mixture (10:1) gave a large yellow band. This fraction was collected and reloaded onto a silica column which was eluted with a $CHCl_3$/MeOH/acetone mixture (10:1:1). The first yellow band was collected and, after solvent removal, triturated with Et_2O giving a yellow powder as above.

[Re(N)(L)(PNP2)]. Yield 52%. Anal. ($C_{33}H_{39}N_2OP_2S_2$-Re Mw = 791.92): calcd C, 50.04; H 4.96; N 3.53; S 8.09. Found C, 49.85; H 5.01; N 3.65; S 7.86. Labeling Efficiency of H_2L1 Ligand. Ligand concentration that is required for metal complexation was determined by mixing different concentrations of H_2L1 with freshly prepared [^{99m}Tc(N)(PNP3/PNP4)]$^{2+}$ intermediate complexes following Method 1, using carrier free [Na^{99m}TcO$_4$] generator eluate containing 2.2 GBq in 0.250 mL of saline. The mixture was incubated at 50 °C or alternatively at 100 °C for 1 h. The final volume of the reaction solution was always kept within 1.5 mL by addition of ethanol. The final labeling yield was determined by HPLC and TLC analysis.

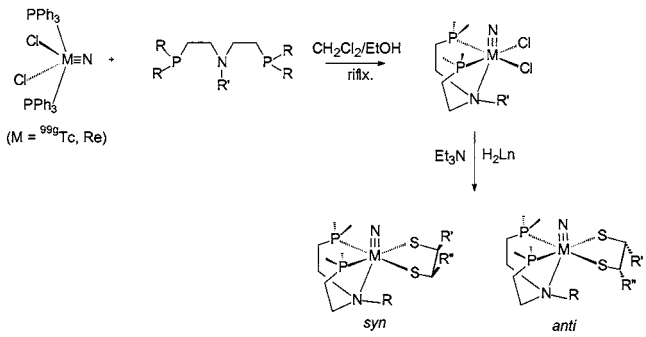
Stability Studies. Each ^{99m}Tc-complex (100 μL) was added to a propylene test tube (5 mL) containing rat

Scheme 1. Synthesis of [^{99m}Tc(Ln)(PNP)] Complexes

PNP = PNP24, PNP2, PNP3, PNP4

serum (900 μL), or alternatively saline (900 μL). The resulting mixture was incubated at 37 °C for 2 h and assayed by TLC for any changes in RCP at 15, 30, 60, and 120 min.



Glutathione (GSH) and Cysteine Challenge. In a propylene test tube (5 mL) containing 0.2 M phosphate buffer (250.0 μL, pH = 7.4), water (100.0 μL), and the ^{99m}Tc complex (100.0 μL), an aliquot (50.0 μL) of a 10.0 mM stock aqueous solution of GSH was added. The mixture was vortexed and incubated at 37 °C for 2 h. A blank reaction containing an equal volume of water instead of GSH was also accomplished. At 15, 30, 60, and 120 min, aliquots of the reaction mixture were withdrawn and analyzed by TLC and HPLC chromatography. All the complexes were found to be inert toward substitution by GSH. A similar procedure was applied using cysteine hydrochloride (10.0 mM and 1.0 mM) as the challenge ligand. The complexes were found to be stable toward cysteine transchelation.

Animal Studies. Biodistribution studies have been carried out in rats. After purification, the recovered activity was diluted with phosphate buffer (0.1 M, pH 7.4) to ensure that the final solution was 10% in ethanol content. Female, Sprague−Dawley rats weighing 200−250 g were anesthetized with an intramuscular injection of a mixture of ketamine (80 mg kg^{-1}) and xilazine (19 mg kg^{-1}). The ^{99m}Tc complexes (100 μL; 300−370 kBq) were injected into the jugular vein. The animals (n = 3) were sacrificed at 0, 2, 10, 20, 60 min time-intervals postinjection. The blood was withdrawn from the heart through a syringe immediately after sacrifice and counted. Organs were excised, rinsed with saline, weighed, and counted in a NaI well counter. The percent injected dose per gram (%ID g^{-1}) for each organ and blood was calculated, and the results are reported in Tables 2, 3 and 4.

RESULTS

Preparation and Characterization of ^{99m}Tc Complexes. Two different procedures were employed for preparing neutral nitrido ^{99m}Tc complexes of the type [^{99m}Tc(N)(Ln)(PNP)]. The optimal labeling procedure (Method 1, three-step synthesis) entailed the preliminary formation of a mixture of nitrido Tc-99m precursors, all containing the $[Tc{\equiv}N]^{2+}$ core, through the reduction of ^{99m}Tc pertechnetate with tin(II) chloride in the presence of SDH as donor of nitrido nitrogen. In the second step, the mixture was converted into the intermediate monosubstituted species [^{99m}Tc(N)X$_2$(PNP)] (11) (X = monodentate groups such as halides or hydroxyl) by reaction with the aminodiphosphine ligand (PNP) at room temperature. In the last step the preparation was completed by addition of the appropriate bidentate dithiol ligand (H_2Ln) to afford the final mixed nitrido complex in high RCY. Alternatively, a two-step procedure (Method 2), which required the simultaneous addition of the two polydentate ligands to the reaction vial containing the mixture of nitrido ^{99m}Tc precursors, was applied. A schematic drawing of the two synthetic methods and the hypothetical structure of the resulting complexes are illustrated in Scheme 1.

Scheme 2. Synthesis of [M(Ln)(PNP)] Complexes (M = ^{99g}Tc, Re)

The chemical identity of the ^{99m}Tc complexes was assessed by comparing their HPLC chromatograms with those of the corresponding ^{99g}Tc or Re compounds. Except for H_2L containing complexes, both TLC and HPLC techniques (Table 1) revealed the existence of two different compounds in 1:1 ratio, identified as the syn/anti isomeric forms of the mixed asymmetrical complexes (vide infra), irrespective of the aminodiphosphine or dithiol used, and of the experimental condition employed.

Preparation and Characterization of ^{99g}Tc and Re Mixed Complexes. Nitrido ^{99g}Tc and Re mixed complexes were prepared by ligand exchange reactions according to the pathway outlined in Scheme 2. Reactions of labile [M(N)Cl$_2$(PPh$_3$)$_2$] precursors with a slight excess of the appropriate aminodiphosphine ligand in dichloromethane/ethanol solutions led to the formation of the monosubstituted intermediate complexes [M(N)Cl$_2$(PNP)]. Subsequent addition of the relevant dithiol ligand in basic media by Et$_3$N produced the final neutral mixed compounds [M(N)(Ln)(PNP)]. Isolation of the [Re(N)Cl$_2$-(PNP)] intermediate complexes (*9*) was necessary to avoid formation of intractable byproducts.

Elemental analyses of all of the mixed complexes [M(N)(Ln)(PNP)], as shown in the Experimental Section, were in good agreement with the proposed formulation. Multinuclear NMR characterization (^{1}H, ^{13}C and ^{31}P)

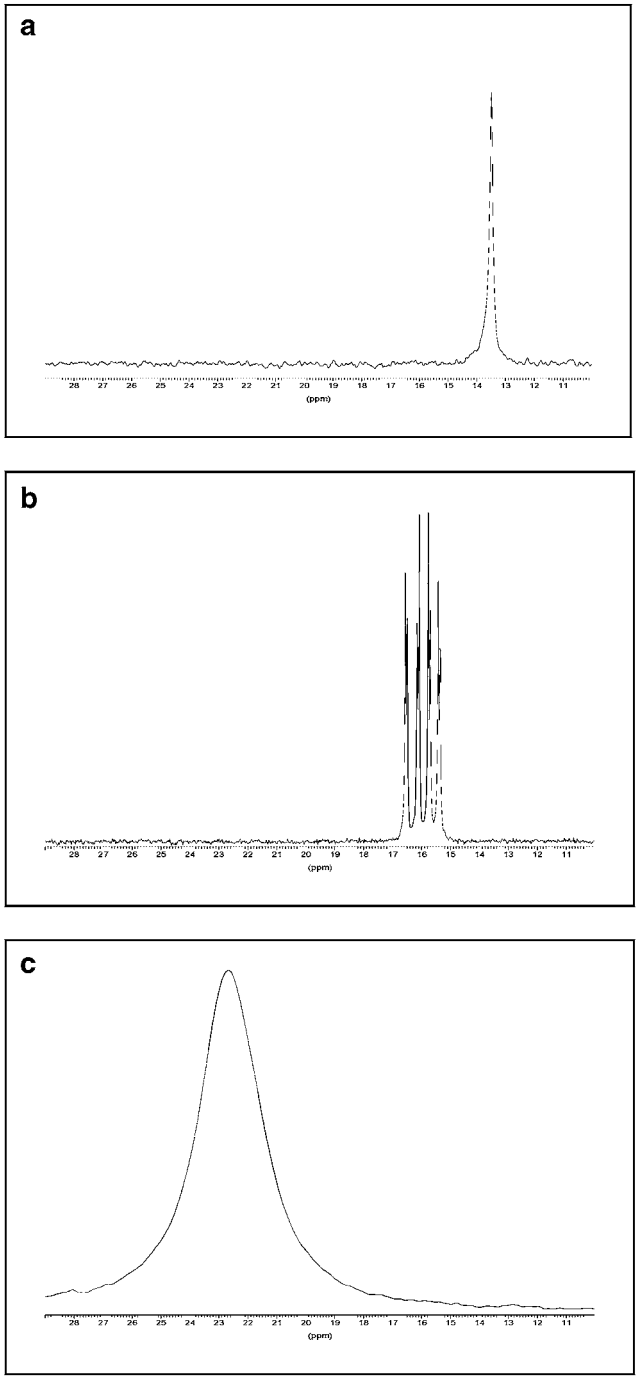


Figure 2. ^{31}P NMR spectra of selected Re and ^{99g}Tc complexes: (A) a singlet for [Re(N)(L)(pnp2)], (B) two doublets of doublets for [Re(N)(L2)(pnp24)], (C) a broad singlet for [^{99g}Tc-(N)(L6)(pnp4)].

allowed the identification of this class of dithiolate-containing species in the solution state. In particular, the ^{31}P NMR signal was diagnostic of diphosphine coordination, the associated signal being deshielded from negative ppm values in uncoordinated ligands (in the range from − 21.5 [pnp2 and pnp24] to − 52.8 ppm [pnp4]) to positive ones in coordinated compounds (in the range from 22.6 [Tc(N)(L6)(pnp3)] to 9.3 ppm [Tc(N)(L3)(pnp4)]). The ^{31}P signal is relatively sharp for rhenium complexes (half line width ($\nu_{1/2}$) of ca. 25 Hz) and broadens to $\nu_{1/2}$ = ca. 300 Hz for technetium species (Figure 2c). Such broadening was observed previously by other authors in similar diamagnetic Tc(V) compounds and attributed to the coupling of the ^{31}P nuclei with the quadrupolar ^{99}Tc center (*20*). In the complex [Re(N)(L)(PNP2)], the diphosphine phosphorus were found to be magnetically equivalent, facing the simplest symmetric dithiolato ligand of the series, thereby showing a singlet at δ = 13.5 ppm (Figure 2a). The magnetic equivalence of coordinated Ps was removed in other rhenium complexes due to the introduction of a pendant substituent onto the dithiolate framework that caused the split of the signal into two doublets of doublets. In addition, the orientation of such substituent (syn or anti positioned with respect to the terminal nitride group) induced a further split of the ^{31}P signal into two equally populated doublets of doublets (Figure 2b).

For technetium complexes, formation of the isomer pairs was detected by chromatographic methods. Both TLC and HPLC showed two distinct peaks of equal intensity in their chromatographic profiles, corroborating the view that reaction of monosubstituted dithiolate ligands onto [M(N)(PNP)] moieties is not regiospecific. For the identification of the two isomers, separation of the diastereoisomeric mixture was accomplished by column chromatography on silica on the representative [Tc(N)(L1)(pnp4)] complex. Proton NMR spectra of the two isolated fractions displayed similar patterns except for the dithiolate networks. The more lipophilic isomer (T_R = 20.12 min) identified via two-dimensional ^{1}H−^{1}H COSY-45 maps by the methyne proton at 3.60 ppm coupled with the diastereotopic methylene ones at 3.19 and 3.01 ppm, was assigned as the syn isomer by analogy with previously reported pairs of mixed nitrido heterocomplexes containing N-substituted cysteine (*21*). The less lipophilic isomer (T_R = 18.59 min.), displaying the dithiolate network spread over a wider ppm region (δ = 3.74, 3.27 and 2.66 ppm for methyne and methylene protons, respectively) was assigned as the anti isomer. The presence of diastereotopic methylene protons in the dithiolato backbone of both isomers supports the view that coordination of the dithiolate ligand occurs via the [S$^-$,S$^-$] donor set, leaving the carboxylic group out of the coordination sphere available for coupling with biomolecules. Hence, as depicted in Scheme 2, these complexes are composed by a Tc≡N group coordinated to a facially arranged aminodiphosphine ligand, the phosphorus donors of which face the dithiolato sulfurs on the equatorial plane.

Finally, a close matching of HPLC retention times of corresponding pairs of ^{99m}Tc and ^{99g}Tc complexes (see the chromatographic profiles of the diastereisomeric mixture of [Tc(N)(L1)(pnp4)] reported in Figure 3) attested the chemical identity of the species produced at nca and macroscopic levels.

Labeling Efficiency of H_2L1 ligand. The design of new ^{99m}Tc receptor-based radiopharmaceuticals requires the choice of an efficient BFCA. The main factor influencing the ^{99m}Tc-labeling kinetics is the nature of the donor atoms and the radiolabeling conditions. In addition, the use of large amount of BFCA conjugate may result in receptor site saturation, blocking the docking of the ^{99m}Tc-labeled BFCA conjugate, as well as in unwanted side effects. Consequently, the concentration of the BFCA conjugate in each kit has to be very low, usually in the 10^{-5} to 10^{-6} M range (*22*).

For these reasons, we investigated the influence of the aminodiphosphine (PNP3 or PNP4)/dithiol molar ratio on the radiochemical yield (RCY) of the resulting heterocomplexes. In detail, bidentate H_2L1 was labeled at different concentrations under standardized conditions, by adding the dithiol solution to freshly prepared [^{99m}Tc-(N)(PNP3/4)]$^{2+}$ intermediate species synthesized using different amounts of aminodiphosphine. The dependence

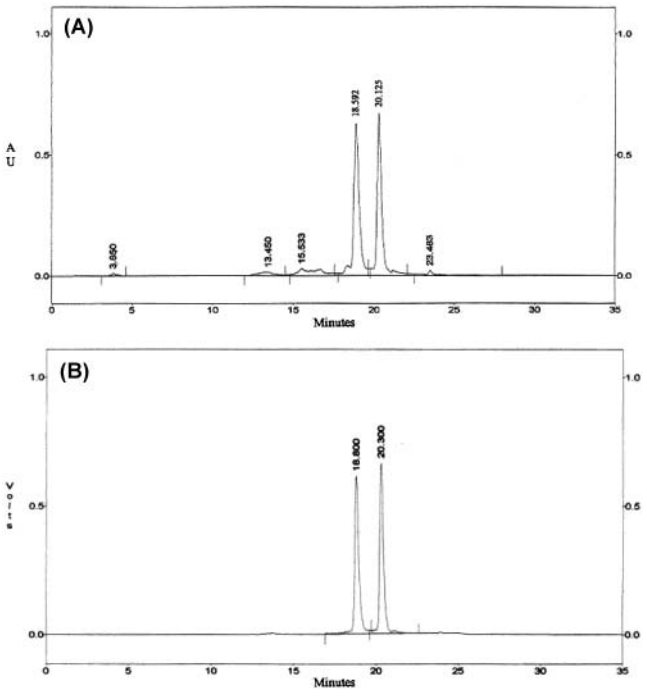

Figure 3. HPLC chromatographic profiles of the diastereomeric mixture of *syn*/*anti*-[Tc(N)(L1)(pnp4)] complexes: (A) UV−vis trace, (B) radiometric trace.

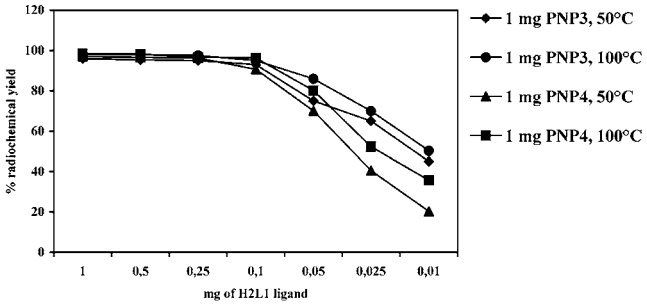

Figure 4. Radiochemical yields of [^{99m}Tc(N)(L1)(PNP)] complexes as a function of H_2L1 concentration at 50 °C and 100 °C.

of RCY of heterocomplex formation, as a function of H_2L1 concentration (1 mg − 15μg) at different temperature (50° or 100 °C), is illustrated in Figure 4. The analysis of the diagram revealed that highest RCY was achieved with a PNP/H_2L1 ratio of approximately 3.5:1, irrespective of the PNP and of the temperature used. A strictly similar behavior was detected in a related mixed system including PNP3 and substituted cysteine ligands (N,S-cys, O,S-cys), demonstrating that the ^{99m}Tc labeling efficiency of [S^-,S^-] coordinating pair was comparable with [N,S^-]-cys and/or [O^-,S^-]-cys ones (*11*). Moreover, by fixing a 3.5:1 PNP/H_2L1 molar ratio, and progressively reducing the amount (in terms of mg) of the two ligands, quantitative formation of the final complex was obtained after 1 h heating at 50 °C using 0.5 mg of PNP4 and 0.125 mg of H_2L1. The time-activity curves are reported in Figure 5a. As expected, higher RCY (>95%) was obtained at 100 °C at earlier times (30 min), using a lower amount of the two chelating ligands (PNP4 = 0.125 mg; H_2L1 = 0.03 mg) (see Figure 5b). An identical behavior was observed at 50 °C with PNP3 (data not shown), while highest labeling efficiency was detected at 100 °C reducing the amount of PNP3 at 0.062 mg and H_2L1 at 0.006 mg (3 μM) (Figure 5c).

These studies evidenced that the radio-labeling efficiency of the bidentate ligand H_2L1 is function of several

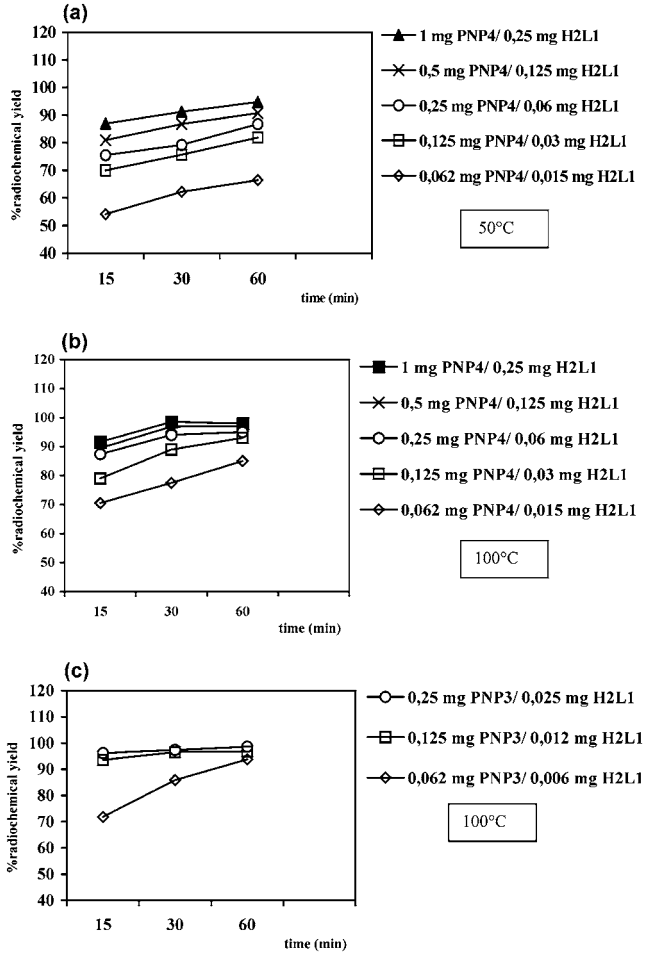

Figure 5. Time−activity curves of [^{99m}Tc(N)(L1)(PNP)] complexes.

factors, including the identity of the [^{99m}TcN(PNP)]$^{2+}$ metal fragment. In fact, by increasing the bulkiness at the aminodiphosphine substituents (PNP4 → PNP3), the radiolabeling efficiency improves by a factor of 5. Studies aiming at the comprehension of the role of different substituents, especially those at the tertiary amine nitrogen, on the overall stability of the resulting intermediate and final mixed compounds are under investigation.

Stability. Serum stability and the stability toward transchelation with GSH and cysteine of ^{99m}Tc-complexes were investigated. No significant change of radiochemical purity (RCP) was observed after 2 h of incubation at 37 °C with excess GSH or cysteine, indicating that all of these compounds are inert toward substitution. On the contrary, slight difference in serum stability was observed. Those complexes containing ester group(s) in the dithiolate backbone were rapidly transformed into more hydrophilic species, due to hydrolysis to the corresponding ionizable acid forms, a well-recognized phenomenon occurring in-vivo catalyzed by serum enzymes, and extensively reported by Seifert and co-workers (*23*). Hydrolysis proceeded with different rates, depending on the steric hindrance of the ester group(s), but, in all cases, it was completed after 60 min of incubation. On the contrary, ^{99m}Tc complexes not incorporating ester group-(s) in the dithiolate framework were found to be stable after 2 h of incubation in rat serum.

Biodistribution. The tissue distribution data of [^{99m}Tc(N)(L)(PNP4)], [^{99m}Tc(N)(L1)(PNP4)], and [^{99m}Tc-(N)(L1)(PNP3)] complexes are summarized in Tables 2,

3, and 4. Before injection, the complexes were purified using the procedures outlined in the Experimental Section. RCP and stability of the purified complexes were verified before in vivo administration. PNP4 containing complexes showed an efficient clearance from the blood and target and nontarget tissues within 1h postinjection. The excretion of the radioactivity from the body occurred via both the renal and the hepatobillary (liver and intestines) systems. Even faster blood and tissues clearances were observed for the PNP3 containing complex, except for a high intestinal uptake (14.62%dose/g) at 2 min postinjection.

DISCUSSION

Dithiols and substituted dithiols ligands (H_2Ln) have been proven to be efficient chelating systems for [M(N)(PNP)] moieties (M = ^{99m}Tc, ^{99g}Tc and Re) giving neutral asymmetrical heterocomplexes of the type [M(N)(Ln)(PNP)] in high yield. According to the general synthetic pathways presented in Schemes 1 and 2, these heterocomplexes can be prepared using either a two-step or a three-step procedure involving the preliminary formation of prereduced species containing the terminal [M(N)] group, followed by contemporary or sequential addition of the relevant aminodiphosphine (PNP) and dithiol. Under the synthetic conditions utilized in this study, no detectable formation of the corresponding symmetrical nitrido compounds comprising two identical polydentate ligands (i.e. [Tc(N)$(PNP)_2$] and/or [Tc(N)$(Ln)_2$]) was observed.

The molecular structure of these mixed complexes contains the [M(N)(PNP)] metal fragment composed by the multiply bonded nitrido group and a facially arranged aminodiphosphine, to which the two sulfur of the dithiolate ligand are coordinated on the remaining equatorial sites (see Scheme 2). When pendant group(s) are introduced in the dithiolate framework, an equimolar mixture of *syn*-[M(N)(Ln)(PNP)] and *anti*-[M(N)(Ln)(PNP)] isomers was always collected. The formation of the isomer pairs depends on the orientation of the pendant dithiolate group(s) relative to the terminal [M(N)] core.

Dithiol ligands such as H_2L1 and H_2L7, which incorporate an additional potentially coordinative carboxylic function, behave as described above, giving a diastereoisomeric mixture of syn and antispecies. Also in this case, spectroscopic data (for example, the presence of diastereotopic methylene protons in the L1 backbone of the ^{1}H NMR spectrum of [^{99g}Tc(N)(L1)(PNP4)]) suggest that coordination of the substituted dithiolate occurred via the [S^-,S^-] coordinating atoms, leaving the carboxylic function outside from the metal coordination sphere, thereby offering a convenient site on which to append other molecule designed to target specific tissue or receptor.

Dithiolate-containing [^{99m}Tc(N)(Ln)(PNP)] species were found to be stable toward transchelation reactions with excess of physiologically relevant cysteine and glutathione, and incubation in rat serum revealed hydrolysis of the outer ester functions in those complexes containing ester-substituted dithiolate only, without affecting the inner coordination sphere. These data suggest high stability of the mixed [M(N)(Ln)(PNP)] configuration. Moreover, no isomeric conversion between syn and anti forms was observed under a wide range of experimental conditions (room temperature and 100 °C, pH from 5 to 9) indicating a superior chelating power of the S,S-dithiolate pairs compared to the S,O-cysteine one included in similar [M(N)(O,S-cys)(PNP)] complexes, in which conversion of the syn into the anti form was found to occur through a dissociative mechanism implying

release of the carboxylate oxygen of the O,S-cys ligand from the metal (*21*).

Dithiolates showed a radiolabeling efficiency toward the [^{99m}Tc(N)(PNP)] synthons in the micromolar range, values comparable to those exhibited by different bidentate donors such as O,S-cys and N,S-cys. This behavior is likely attributed to the peculiar electronic and steric properties of the [Tc(N)(PNP)] metal fragment. Its strong electrophilic character induces selective reactions with π-donor atoms to achieve mixed ligand arrangements, which are well tailored for the [Tc(N)] core. In addition, the facial arrangement of the PNP ligand grants the best steric configuration for the substitution of labile halides with incoming bidentate ligands. Hence, substituted dithiolates carrying further functional groups (i.e. H_2L1 and H_2L7) constitute alternative chelating systems for incorporating bioactive molecule into nitrido-containing ^{99m}Tc compounds.

Biodistribution studies in rats performed using the three representative [^{99m}Tc(N)(L)(PNP4)], [^{99m}Tc(N)(L1)-(PNP4)], and [^{99m}Tc(N)(L1)(PNP3)] showed that they were efficiently cleared from the blood, and no specific uptake or long-term retention was observed in other organs to reduce the background activity, except for a gastrointestinal tract accumulation of the PNP3 derivative. The latter behavior was already observed in a series of related nitrido ^{99m}Tc-complexes containing terminal methoxy and/or ethoxy pendant groups in the aminodiphosphine framework (*24*). This could be associated with a faster hepatobillary excretory pathway and/or with an aspecific intestinal uptake. Studies focused on the comprehension of the biological mechanism underlying this process are in progress.

The chemical flexibility of the [Tc(N)(Ln)(PNP)] system, which allows subtle tuning of the lipophilicity by insertion of variable groups onto the PNP framework of the [Tc(N)(PNP)] synthon on one side, and the possibility to conjugate biologically active fragments onto the dithiolate backbone make this class of compounds interesting candidates for the design of new receptor-based ^{99m}Tc agents.

CONCLUSION

Micromolar concentrations of dithiolate and substituted dithiolate ligands have successfully chelated [^{99m}Tc-(N)(PNP)] moieties giving neutral, mixed-ligand complexes of the type [^{99m}Tc(N)(Ln)(PNP)]. Comparison of their chromatographic profiles with those of the corresponding [M(N)(Ln)(PNP)] compounds (M = ^{99g}Tc, Re) indicated an identical molecular structure at nca and macroscopic levels. The substituent(s) incorporated in the dithiolate backbone promoted the formation of equally populated syn and anti isomers, depending on the relative orientation of the substituent(s) with respect to the terminal nitrido group. Mixture of the two isomers of each ^{99m}Tc-compound was found to be substitution-inert toward transchelation reaction when incubated with excess of cysteine or glutathione. In vivo studies in rats showed that they were efficiently cleared from the blood, and no specific uptake or long-term retention was observed in the kidneys and in other organs. The combination of the biological properties exhibited by this class of nitrido mixed-ligand compounds, along with the possibility to conjugate biologically active fragments onto the dithiolate carboxylic or hydroxylic pendant groups, make this novel molecules interesting candidates for the development of receptor-specific ^{99m}Tc-radiopharmaceuticals.

Synthesis and Fluorescence Studies of Multiple Labeled Oligonucleotides Containing Dansyl Fluorophore Covalently Attached at 2′-Terminus of Cytidine via Carbamate Linkage

Arvind Misra,† Satyendra Mishra, and Krishna Misra*

Nucleic Acids Research Laboratory, Department of Chemistry, University of Allahabad, Allahabad- 211 002, India Received January 11, 2004; Revised Manuscript Received March 2, 2004

Synthesis of modified oligonucleotides in which the specific cytidine nucleoside analogues linked at 2′-OH position via a carbamate bond with an amino ethyl derivative of dansyl fluorophore is reported. For the multiple labeling of oligonucleotides, a strategy involving prelabeling at the monomeric level followed by solid phase assembly of oligonucleotides to obtain regiospecifically labeled probes has been described. The labeled monomer was phosphitylated using 2-cyanoethyl- *N*,*N*,*N*′,*N*′-tetraisopropyl-phosphoramidite (Bis-reagent) and pyridiniumtrifluoro acetate (Py·TFA) as an activator. To ascertain the minimal number of labeled monomers required for a specific length of oligonucleotide for detection and also to assess the effect of carbamate linkage on hybridization, hexamer and 20-mer sequences were selected. Both were labeled with 1, 2, and 3 monomers at the 5′-end and hybridized with normal (unmodified) complementary sequences. As compared to midsequence or 3′-terminal labeling reported earlier, the 5′-terminal labeling has been found to have minimal contact-mediated quenching on duplex formation. This may be due to complementary deoxyguanosine (dG) rich oligonucleotide sequences or CG base pairs at a terminus that is known to yield stronger binding. This is one reason for selecting cytidine for labeling. The results may aid rational design of multiple fluorescent DNA probes for nonradioactive detection of nucleic acids.

INTRODUCTION

Fluorescent labeling of oligonucleotides has been attracting current interest in connection with the development of new methods for distinguishing and detecting nucleic acids sequences for diagnostics and homogeneous hybridization assays. Being dependent on the local environment fluorescence has proved an indispensable tool for the study of molecular interactions and several cellular functions. Fluorescently labeled oligonucleotide probes are nowadays in much regular use for nucleic acid sequencing (*1*), sequencing by hybridization (SBH) (*2*), fluorescence in situ hybridization (FISH) (*3*), fluorescence resonance energy transfer (FRET) (*4*−*6*), molecular beacons (*7*−*8*), taqman probes (*9*), and chip-based DNA arrays (*10*−*11*). This has made fluorescent probes an important tool for clinical diagnostics and made possible real-time monitoring of oligonucleotide hybridization. Furthermore, fluorescent-based diagnostics avoids the problem of storage, stability, and disposal of radioactive labels (*12*).

Application of techniques mentioned above requires appropriately labeled nucleic acids and/or oligonucleotides. Labeling techniques for the incorporation of different fluorophores at different functional positions has been very well established. The multiple functionalization may be another alternative approach for the enhancement of sensitivity of detection. Most of the synthetic strategies involving synthesis of nucleic acids incorporated with modified bases carrying nucleophilic handles such as alkylamines, hydroxyl, and sulfydryls followed by labeling reactions has been extensively reviewed (*13*). However, in the case of ribonucleotides, 2′-OH function of the ribose ring can be utilized for the covalent attachment of ligands such as fluorophores. Attachment of ligands at this position may not cause any steric hindrance and thereby any destabilization in the stable duplex formation. Few approaches to link fluorophores at the 2′-end have been addressed for particular analytical needs (*14*−*19*).

It has been reported that nucleobases in ribozyme core regions are often in a different kind of noncovalent interaction which is important for maintaining structure and function (*20*−*21*). 2′-End ligand functionalization has already proved valuable in applications such as fluorescence monitoring of tertiary folding of oligoribonucleotides (*22*). An alternative opportunity for 2′-OH functionalization is via a carbamate function which can be easily generated by reaction with *N*,*N*′-carbonyldiimidazole (CDI). This chemistry has been used successfully for 5′-modification of oligoribonucleotides (*23*), 3′-modifications (*24*), and 2′-modifications (*25*−*27*).

The present report describes the preparation of cytidine-2′-yl carbamate and its subsequent attachment with 5-*N*,*N*-dimethylaminonaphthalene sulfonyl (dansyl) ethylamine derivative to get a fluorescent analogue for its further incorporation into the oligonucleotides for multiple labeling and their hybridization with complementary sequences. The oligonucleotides were synthesized using a standard phosphoramidite protocol, and the modified fluorescent cytidine analogue was placed in the last coupling step to get terminally 5′-O-mono, di, and tridansylated oligonucleotides. The modified oligonucle-

otide probes have shown remarkable enhancement in the fluorescence intensity vis-à-vis the dansyl fluorophore. It is reported that placement of dansyl fluorophore in the hydrophobic environment causes a significant increase in the fluorescence intensity, quantum yield, and blue shift in the emission (*28*−*30*). Therefore, it is proposed that such labeled probes may be exploited for the characterization of the nucleobases present in ribozymes core regions because such nucleobases are important for maintaining structure and function of ribozymes. These can also be used similarly in other cases in which a hydrophobic environment exists. However, upon duplex formation with the complementary deoxyguanosine (dG) base present at the terminal 5′-position, a minimal quenching termed "contact mediated quenching" has been observed. This quenching is relatively insignificant as compared to the already reported cases in which labeling is at 3′-termini or in the middle of the sequence. The binding affinity with complementary strands has been assessed by taking UV-melting profiles. The results not only demonstrated the feasibility of covalent attachment of the fluorophore via carbamate linkage but also defines necessary requirements for achieving optimum enhancement of fluorescence intensity.

EXPERIMENTAL PROCEDURES

General. 1,3-Dichloro-1,1,3,3-tetraisopropyldisiloxane (TIPDSCl) was from Merck-Schchdart, Germany; dansyl chloride, 4,4′-dimethoxytrityl chloride (DMTr-Cl), (dimethylamino)pyridine (DMAP), and carbonydiimidazole (CDI) were from Aldrich; tetrabutylammonium fluoride (TBAF)/THF, 2-cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphoramidite (Bis-reagent), Py·TFA, LCAA-CPG loaded nucleosides of Perseptive Biosystem Gmbh (LCAA-CPG, 500 Å, 39 mmol/g), and different amidites were obtained as a generous gift from ISIS Pharmaceutical, USA. Oligonucleotide synthesis grade acetonitrile, 1*H*-tetrazole were purchased from Applied Biosystem, Perkin-Elmer, Switzerland. UV−visible spectra was recorded on Hitachi 220S UV−visible spectrophotometer. Thermal denaturation experiments with oligonucleotides were performed on a Perkin-Elmer Lambda Bio 20 UV−visible spectrometer with PTP 1 (Peltier Temperature programmer). Fluorescence spectra were recorded on Kontron SFM 25 spectrofluorometer. Purification of oligonucleotides was carried on a Shimadzu HPLC using an RP C18 Lichrosphere column employing a UV−visible detector. Synthetic grade solvents used were from Qualigens and were purified and dried prior to use. ^{1}HNMR and ^{31}P NMR were recorded on a DRX300 instrument. All the oligomers were synthesized on a ABI 392 DNA/RNA synthesizer.

***N*^{4}-Benzoyl Cytidine 2.** To the solution of cytidine (10 mmol, 2.43 g) in dry pyridine (25 mL) and DMF (10 mL) benzoic anhydride (15 mmol, 3.39 g) was added, and the reaction mixture was stirred overnight at room temperature in the presence of nitrogen. Reaction mixture was poured in water with stirring. The solvents were evaporated with anhydrous toluene to remove excess pyridine in a vacuum to leave a white solid which was extracted with diethyl ether (4 × 40 mL) to remove BzOH. Yield 92% (3.2 g). R_f 0.55 ($CHCl_3$/MeOH: 8:2 v/v) mp 218 °C. UV λ_{max} (MeOH): 305, 260 nm. IR (cm^{-1}) 1730. ^{1}HNMR (DMSO) δ ppm: 1.9−2.4 (m, 2H), 3.6 (m, 2H, H5′), 3.83 (m,1H, H4′), 4.1 (m, 1H, H3′), 4.8−5.4 (m, 2H), 6.1 (t, 1H, H1′), 7.1−7.4 (m, 4H, *J* 7.5 Hz, Ar+H-5), 8.1 (m,2H,Ar-H′ ortho to carbonyl), 8.2 (1H, *J* 7.5, H-6). Anal. Calc. $C_{16}H_{17}O_6N_3$: C 55.04%, H 4.89%, N 12.3%. Found: C 55.09%, H 4.97, N 12.37.

***N*^{4}-nCbz Cytidine 2a.** To the well-stirred solution of cytidine (10 mmol, 2.43 g) in dry THF, reagent *o*-nitrobenzyl-*p*-nitrophenyl carbonate (15 mmol, 4.8 g) in THF (15 mL) and 2 N NaOH (3 mL) was added. The reaction mixture was stirred for 3 h at r.t. TLC showed the completion of the reaction by the consumption of starting substrate into the single predominant product. Solvents were evaporated under reduced pressure. Residue obtained was dissolved in diethyl ether and washed with 1 M aqueous solution of $NaHCO_3$. The pH of the aqueous phase was made to 5.8 with 1 N HCl and extracted with diethyl ether. The combined organic layer was washed with water (3 × 15 mL), saturated brine solution, and water, and kept over anhydrous sodium sulfate, filtered, and evaporated in a vacuum to yield a white crystalline compound. Yield 70% (2.83 g). R_f 0.53 (dichloromethane/methanol: 9:1, v/v). UV λ_{max} (MeOH); 235, 255, 262, 307, 390 nm. Anal. Calc. $C_{17}H_{18}O_9N_4$: C 48.34, H 4.25, N 13.3. Found: C 48.24, H 4.35, N 13.75%. ^{1}HNMR ($CDCl_3$) δ ppm; 8.74 (br s, 1H, NH), 8.32 (d, 1H, H-6, $J_{6,5}$ 7.8 Hz), 8.71 (d, 2H, Bz, J 8.5 Hz), 5.65−5.85 (m, 1H, H1′), 3.75−3.91 (m, 1H, H4′), 4.35−4.44 (m, 1H, H2′), 3.72−3.85 (m, 3H, H3′,5′).

3′,5′-*O*-(Tetraisopropyldisiloxane-1,3-diyl)-*N*^{4}-Benzoyl Cytidine 3. To an ice-cold solution of **2** (5.8 mmol, 2.0 g) in anhydrous pyridine (10 mL) 1,1,3,3-tetraisopropyldisiloxane-1,3-dichloride (6.67 mmol, 2.1 g), dissolved in 1,2-dichloroethane (3 mL) was added dropwise with constant stirring for 30 min. After complete addition the reaction mixture was allowed to stir for another 2 h at room temperature. TLC showed the completion of the reaction in EtOH/$CHCl_3$ (1:9, v/v). Dry methanol (2 mL) was added to quench the reaction, and solvents were evaporated in a vacuum. The residue was dissolved in dichloromethane (20 mL) and washed with 1 M aq. $NaHCO_3$ (5 × 5 mL). The organic phase was dried over anhydrous $NaSO_4$, filtered, and evaporated in vacuum to afford the title compound as a white solid foam. Yield 90% (3.6 g). R_f 0.48. Anal. Calc. $C_{28}H_{43}O_7N_3Si_2$: C 57.03, H 7.29, N 7.12%. Found: C 57.15, H 7.33, N 7.23%. MALDI-TOF (2,4,6-THAP+citrate) $[M+Na]^+$, calc. 612, found 612.1, $[M+K]^+$ calc. 628.0 found 628.1. ^{1}HNMR (δ ppm) 7.4−7.7 (m, 4H), 8.1 (m, 2H), 8.2 (1H, *J* 7.6, H-6), 8.9 (s,1H, NH), 5.74 (s,1H, H1′), 5.67 (d,1H, H2′), 5.55 (d,1H, H-5), 4.71 (m,1H, H-5′), 4.38−3.96 (m, 3H, H4′, H5′), 1.2−0.9 (m, 28H, ^{i}Pr′).

3′,5′-*O*-(Tetraisopropyldisiloxane-1,3-diyl)-*N*^{4}-nCbz Cytidine 3. Compound **3a** was synthesized following the above same procedure. Yield 92% (3.48 g). R_f 0.45. Anal. Calc. $C_{28}H_{42}O_{10}N_4Si_2$: C 51.7, H 6.46, N 8.61%. Found: C 51.91, H 6.83, N 9.13%. MALDI-TOF (2,4,6-THAP+citrate) $[M+Na]^+$, Calc. 673.5 found 673.6, $[M+K]^+$ calc. 689.6 found 689.7 ^{1}HNMR ($CDCl_3$; δ ppm); 10.1 (b s, 1H, NH), 8.71 (d, 2H, J 8.75 Hz, Bz), 8.24 (d, 1H, *J* 7.3 Hz, H-6), 8.2 (d, 2H, *J* 8.79, Bz), 7.12 (1H, J 7.5 Hz, C-5) 5.74 (s, 1H, H1′), 4.87 (m, 1H, H2′), 4.38 (m, 1H, H3′), 4.15−4.59 (m, 3H, H4′, H5′), 0.9−1.2 (m, 28H, ^{i}Pr′).

2′-*O*-(Imidazol 1-yl carbonyl)-3′,5′-*O*-(Tetraisopropyldisiloxane-1,3-diyl)-*N*^{4}-benzoyl Cytidine 4. Compound **3** (3.4 mmol, 2.0 g) was taken in dry dichloromethane (30 mL), and *N*,*N*′-carbonyldiimidazole (CDI) (3.7 mmol, 0.6 g) was added. The reaction mixture was stirred for 1.5−2 h and monitored on TLC. The completion of the reaction was observed by the conversion of starting substrate into the product of lower mobility. The solution was washed with water (3 × 25 mL). The organic layer was kept over Na_2SO_4, filtered, and evaporated in a vacuum to get imidazolyl derivative in the crystalline

form. Yield 85% (2.2 g) R_f 0.4 (EtOAc). MALDI-TOF (2,4,6 THAP+citrate): $[M+Na]^+$ 706.7 expected 706.6, $[M+K]^+$ 722.8 expected 722.7.

2′-*O*-(Imidazol 1-yl carbonyl)-3′,5′-*O*-(Tetraisopropyldisiloxane-1,3-diyl)-*N*⁴-nCbz Cytidine 4a. Yield 80% (2.74 g) R_f 0.37 (EtOAc). MALDI-TOF (2,4,6 THAP+citrate): $[M+Na]^+$ 769.1 expected 768.5, $[M+K]^+$ 784.7, expected 784.6.

5-Dimethylamino-*N*-ethylamine-1-naphthalene Sulfonamide 5. To the ice-cold solution of freshly distilled ethylenediamine (25 mmol, 1.5 g) in 10% sodium bicarbonate (20 mL), dansyl chloride (5 mmol, 1.35 g) in THF (25 mL) was added dropwise in 1 h. The reaction mixture was stirred for 2 h and monitored on TLC. The solvents were evaporated in a vacuum. The residue was poured in water extracted with ethyl acetate (3 × 25 mL). The organic layer was concentrated and chromatographed using EtOAc/hexane (2:8) as eluent to afford an ethylamine derivative of dansyl as a fluorescent green oil which was solidified at −20 °C. Yield 78% (2.33 g). R_f 0.34 (8:2: EDC(1,2 dichloroethane)/MeOH). IR (cm^{-1}) 3300, 3052, 1586, 1574, 1464. UV λ_{max} (MeOH): 220, 251, 334, 385 nm. ^{1}HNMR (δ ppm); 1.38 (m, J 7.5 Hz, CH_2-CH_2NH_2), 2.89 (s, 6H, $(CH_3)_2N$), 4.62 (bt, 1H, J 5.2 Hz, SO_2NH), 8.21 (d, 1H, J 8.1 Hz, 2H). Fluorescence (MeOH, λ_{ex} 335 nm, λ_{em} 510 nm).

2′-*O*-(Dansyl-2-sulfonamido-ethylamino-carbonyl)-3′,5′-*O*-(tetraisopropyldisiloxane-1,3-diyl)-*N*⁴-benzoyl Cytidine 6. To the imidazole derivative of cytidine **4** dissolved in dry DCM (30 mL), compound **5** (3.4 mmol, 1.0 g) in dry DCM was added dropwise with constant stirring for a period of 1 h under argon. After complete addition the reaction was allowed to stir overnight. TLC showed the formation of single predominant product. The reaction mixture was washed sequentially with water, 3% citric acid, and again with water. The organic layer was kept over Na_2SO_4 and concentrated. The residue was chromatographed on a silica gel column using an increasing gradient of ethyl acetate in chloroform. Fractions containing products pooled and evaporated to dryness in a vacuum to afford the title compound as a foamy mass. Yield 73.5% (2.22 g) R_f 0.45 (DCM/MeOH: 7:3 v/v). MALDI-TOF (2,5 DHBA); [M+Na and M+K]$^+$ calc. 931.7, and 947.8, found; 932.2 and 947.9, respectively. Anal. Calc. $C_{43}H_{60}N_6O_{10}Si_2S$; C 56.83, H 6.61, N 9.25%. Found C 56.21, H 7.16, N 10.21%. ^{1}HNMR ($CDCl_3$ δ ppm); 11.2 (b s, 1H, NH), 7.40−7.48 (m, 4H, Bz, H-5), 8.29−8.36 (m, 4H, benzoyl, naphthoyl, H-6), 8.01 (t, 1H, naphthoyl), 8.42−7.67 (m, 3H, naphthoyl, *J* 9.1 Hz), 7.13 (t, 1H, NHCOO, J 5.9 Hz), 6.44−6.50 (m, 2H, H1′, naphthoyl), 5.12−5.15 (m, 1H, H2′), 4.17−4.21 (m, 1H, H3′), 3.91−3.94 (m, 2H, H4′, H5′), 3.28−3.34 (m, 4H, -$NHCH_2CH_2$-NH-), 2.85 (s, 6H, -NCH_3), 0.92−1.35 (m, 28H, ^{i}Pr′).

2′-*O*-(Dansyl-2-sulfonamido ethylamino carbonyl)-3′,5′-*O*-(tetraisopropyldisiloxane-1,3-diyl)-*N*⁴-nCbz Cytidine 6a. Yield 70% (2.17 g) R_f 0.42 (DCM/MeOH: 7:3 v/v). MALDI-TOF (2,5 DHBA); [M+Na and M+K]$^+$ calc. 931.8 and 947.9, found; 932.2 and 948.1, respectively. Anal. Calc. $C_{43}H_{60}N_6O_{10}Si_2S$; C 56.83, H 6.61, N 9.25%. Found C 56.21, H 7.16, N 10.21%. ^{1}HNMR ($CDCl_3$ δ ppm); 11.2 (b s, 1H, NH), 8.68 (d, 1H, J 8.8 Hz, Bz), 8.72 (d, 1H, J 8.9, ortho to NO_2), 7.40−7.48 (m, 3H, Bz, H-5), 8.29−8.36 (m, 3H, benzoyl, naphthoyl, H-6), 8.01 (t, 1H, naphthoyl), 8.42−7.67 (m, 3H, naphthoyl, *J* 9.1 Hz), 7.13 (t, 1H, NHCOO, J 5.9 Hz), 5.83−5.93 (m, 2H, H1′, naphthoyl), 4.98−5.12 (m, 1H, H2′), 4.15−4.17 (m, 1H, H3′), 3.89−3.92 (m, 2H, H4′, H5′), 3.29−3.36 (m, 4H, -$NHCH_2CH_2$NH-), 2.75 (s, 6H, -NCH_3), 0.9−1.25 (m, 28H, ^{i}Pr′).

2′-*O*-(Dansyl-2-sulfonamido-ethylamino-carbonyl)-*N*⁴-benzoyl Cytidine 7. Compound **6** (2.23 mmol, 2 g) was dissolved in THF (10 mL) and a 1 M solution of terabutylammonium fluoride in THF (8.8 equiv 6.0 mL) was added to it. The reaction was stirred for 15 min at room temperature and monitored on TLC (CH_3OH/$CHCl_3$: 1:4 v/v), then diluted with EtOAc (30 mL) and washed with 5% aq. $NaHCO_3$ (30 mL) solution. The aqueous layer was back triturated with EtOAc (3 × 30 mL). The organic phase was combined concentrated and again washed with brine solution (2 × 30 mL) and dried over anhydrous $MgSO_4$. The crude oily product was purified with column chromatography. The column was first eluted with EtOAc/petroleum ether (4:1 v/v) and then with 40% methanol in EtOAc. The product which was eluted with a second solvent system was pooled and evaporated in a vacuum to afford the title compound as reddish yellow gum. Yield 95% (1.43 g). R_f 0.43 ($CHCl_3$/MeOH: 8:2 v/v). UV λ_{max}(MeOH): 220, 236, 256, 336 nm. MALDI-TOF (2,5 DHBA); [M+Na and M+K]$^+$ calc. 689.4, and 705.5, found; 690.2 and 705.9, respectively. Anal. Calc. $C_{31}H_{34}N_6O_9S$; C 55.87, H 5.11, N 12.61%. Found C 55.55, H 5.51, N 13.05%. ^{1}HNMR ($CDCl_3$ δ ppm); 10.34 (s, 1H, NH), 8.27 (d, 1H, J 7.5 Hz, H-6), 8.01 (d, 2H, J 8.2 Hz, Ar), 7.37−7.43 (m, 4H, Bz, C-5), 7.53 (t, 1H, NHCOO, J 5.9 Hz), 6.24 (m, 1H, H1′), 5.02−5.06 (m, 1H, H2′), 4.16−4.19 (m, 1H, H3′), 3.87−3.92 (m, 1H, H4′), 3.64−3.68 (m, 2H, H5′), 5.31 (t, 1H, 5′-OH, J 4.7 Hz), 8.05 (t, 1H, naphthoyl), 8.52−7.87 (m, 3H, naphthoyl, *J* 9.2 Hz), 6.34−6.40 (m, 2H, H1′, naphthoyl), 3.38−3.44 (m, 4H, -$NHCH_2CH_2NH$-), 2.95 (s, 6H, -NCH_3).

2′-*O*-(Dansyl-2-sulfonamido-ethylamino-carbonyl)-*N*⁴-nCbz Cytidine 7a. Yield 95% (1.21 g). R_f 0.38 ($CHCl_3$/MeOH: 8:2 v/v). UV λ_{max}(MeOH): 220, 236, 256, 307, 336, 390 nm. MALDI-TOF (2,5 DHBA); [M+Na and M+K]$^+$ calc. 750.5, and 766.6, found; 750.9 and 707.5, respectively. Anal. Calc. $C_{31}H_{33}N_7O_{12}S$; C 51.2, H 4.54, N 13.5%. Found C 51.35, H 5.15, N 14.2%.

***N*⁴-Benzoyl-5-*O*-(4,4′-dimethoytrityl)-2′-*O*-{(2-dansyl Sulfonamido) Ethyl Carbamoyl} Cytidine 8.** Cytidin-2′-yl carbamate **7** (1.8 mmol, 1.15 g) was dried by addition and evaporation of tolune and pyridine (3 × 20 mL). To residue anhydrous pyridine (20 mL), triethylamine (2 mL), DMAP (0.02 eq 0.024 g), and 4,4′-dimethoxytrityl chloride (3.55 mmol, 1.2 g) were added under argon. The reaction mixture was stirred for 2.5 h at room temperature. TLC showed the completion of the reaction (CH_3OH/$CHCl_3$/TEA; 1:8.5:0.5); the excess of DMTr was quenched with methanol (2 mL), and solvents were evaporated in a vacuum. Syrupy mass was dissolved in chloroform (100 mL) and washed with water, 5% $NaHCO_3$, and again with water. Organic layer was pooled, kept over anhydrous Na_2SO_4, filtered, and co-evaporated with toluene to remove residual pyridine. The crude product was purified by a silica gel column using a 10% stepwise gradient of methanol in chloroform, containing 1% triethylamine as eluent. Fractions containing products were pooled and evaporated in a vacuum to get the title compound as amorphous solids. Yield 77% (1.32 g). R_f 0.57 (MeOH/$CHCl_3$/TEA). UV λ_{max}(MeOH): 220, 238, 256, 335 nm. MALDI-TOF (2,4,6 THAP) $[M+Na]^+$; calc. 976.6, found 976.6 $[M+K]^+$; calc. 995.7, found 995.9. ^{1}HNMR (DMSO) δ; 11.42 (s, 1H, NH), 8.39 (d, 1H, J 9.1 naphthoyl), 8.22−8.27 (m, 4H, 2H Bz + 1H naphthoyl+ 1H, H-6), 7.59−7.96 (d, 2H J 9.0 Hz, naphthoyl), 7.28−7.37 (m, 10H, 3H Bz + 1H naphthoyl,1H, C-5, 5H, Ar), 7.08−7.78 (d, 8H, J 8.5, DMTr), 7.53 (t, 1H, NHCOO, J 5.9 Hz), 6.65 (d, 1H, J 9.0 Hz, naphthoyl), 6.39−6.43 (m, 1H, H1′), 5.03 (m, 1H, H2′), 4.14−4.17 (m,

Pyridinium trifluoroacetate (Py·TFA) (3.0 mmol, 0.7 g) was added to the reaction mixture and stirred for 3 h. After complete consumption of starting material (TLC), methanol (2 mL) was added, and the resulting solution was washed with 10% $NaHCO_3$ (3 × 10 mL). Organic layer was dried over sodium sulfate and directly applied to a silica gel column. Compound was eluted with dichloromethane/ethyl acetate/Et_3N (4.5:4.5:1, v/v). The desired fractions were pooled and dried under reduced pressure to afford title compound as amorphous yellow powder. Yield 80% (1.0 g). R_f 0.63 (CH_2Cl_2/EtOAc/Et_3A: 4.5:4.5:1, v/v), λmax 260, 333 nm, ^{31}PNMR (CH_3CN) 150.3, 149.9 ppm (diastereoisomers).

Synthesis of Oligonucleotides. All the oligomers were synthesized at 0.2 μmol scale on an ABI 392 model DNA/RNA synthesizer using nucleoside analogues (**9**) with only benzoyl group on exocyclic amino function. The last coupling cycle was increased by 10 min. All the oligomers were mixed type. Three 6-mers and three 20-mer sequences were synthesized in which the number of fluorophore was successively increased as one, two, and three by coupling modified analogues (**9**) (Table 1). All the oligomers were treated with 30% aqueous ammonia for 15 h at 65 °C to remove protecting groups from the bases and internucleotide phosphates and also to cleave oligomer from the solid support. The ammoniacal solution was concentrated under a vacuum in a speed vac, and the residue was subjected to desalting on a reverse phase silica gel column. The oligomers were purified on anion exchange FPLC and then analyzed on reverse phase HPLC with a Merck lichrosphere RP-18 column using 0.1 M ammonium acetate buffer at pH 7.1 and acetonitrile solvent. In the case of the dansyl derivative, it was very hard to separate the desired peaks. However, the desired collected portion was reinjected in 25 μL to get the 90−95% purified oligonucleotides. HPLC graph and retention time of the fluorescently labeled 20-mer oligomers have been shown in Figure 1. In the case of 2′-*O*-carbamate modified oligonucleotides, the carbamate and sulfonamide bonds were found completely stable to the condition of oligonucleotide synthesis as well as under deprotection conditions at the desired temperature. The λ max for monolabeled, dilabeled, and trilabeled 20-mers (ON7, ON8, and ON11) was 260, 295, 333 nm with the intensity of the peaks increasing, respectively.

Conditions: column, Lichrosphere RP-18 (Merc, Germany); buffer A, 0.1 M NH_4OAc, pH 7.1; solvent B, acetonotrile; flow rate, 1.0 mL/min; gradient, 0−50% B in 30 min; aufs, 0.05.

RESULTS AND DISCUSSION

To assess (i) the minimum number of dansyl labeled nucleosides required for a specific length of oligonucleotide to act as probe, (ii) the appropriate linkage for covalent linking of fluorophore to oligonucleotide, and (iii) the specific site in the oligonucleotide for incorporation of fluorophore for stability of duplex, cytidine has been used as the 2′-O-labeled monomer. A general method for the preparation of cytidin-2′-yl-carbamate and its corresponding phosphoramidite is outlined in Scheme 1. Phosphoramidite of 2′-O-labeled cytidine (**9**) has been synthesized from N-acyl cytidine (**2**) by first protecting 3′,5′-OH with 1,3-dichloro-1,1,3,3-tetraisopropyl disiloxane as reported earlier (*31*). The crude product was purified by column chromatography in silica gel using EtOH−$CHCl_3$ to afford **3** as a white solid foam. This was then treated with CDI in dry dichloromethane (DCM) to get in situ carbamate derivative, *N*-acyl-2′-*O*-(imidazol-1-ylcarbonyl)-3′,5′-*O*-tetraisopropyldisiloxane1,3-diyl) cytidine (**4**) in quantitative yield. The imidazolide derivative **4** was not isolated and was subsequently reacted with an excess of aminoethyl dansyl derivative **5** in dry DCM to get compound **6** after stirring the reaction mixture for 2 h at r.t. which was finally purified by column chromatography. Compound **5** was synthesized by treating ethylenediamine in 10% $NaHCO_3$ with dansyl chloride in THF, in an ice bath. Monitoring on TLC showed the total conversion of starting material into the product (**5**) in 3 h. On illuminating the fluorescent plate with a UV torch at 354 nm wavelength, bright fluorescence of the dansyl derivative was observed, which was further confirmed by ninhydrin spray. Markiewicz 3′,5′-O-silyl group was removed by treating compound **6** with tetrabutylammoniumfluoride (TBAF) in THF for 15 min. The crude product was purified by column chromatography. Compound **7** was obtained as a reddish yellow gum with needlelike crystals, which was tritylated with 4,4′-dimethoxytrityl chloride in dry pyridine in the presence of DMAP and TEA to get derivative **8** in 77% yield. Phophitylation at the 3′-OH position was done using 2-cyanoethyl-*N*,*N*,*N*′,*N*′-tetraisopropyl phosphoramidite (Bis-reagent) and activator pyridinium trifluoroacetate (Py·TFA) in dry 1,2-dichloroethane. Py·TFA was used, in place of more conventional 1H-tetrazole or 4,5-dicyano imidazole (DCI) because it is an excellent activator,

cheaper, stable at r.t., less acidic, less toxic, and has a higher pK_a (5.23) than those (4.4−5.1) of other activating reagents (*32*). After the completion of the reaction, the crude product was immediately transferred onto a short silica column and eluted with ethyl acetate and dichloromethane (1% triethylamine) to furnish the 2′-O-carbamate amidite of cytosine (**9**), the protected monomer to be used for further synthesis of oligonucleotides.

All the cytidine derivatives from **2**−**9** were prepared with either benzoyl or *o*-nitrobenzyloxycarbonyl (nCbz), a photolabile group on the exocyclic amino function of the nucleoside. All the derivatives were properly characterized by their elemental analysis, UV, NMR, and MALDI−TOF. This photolabile group viz. (nCbz) was used by synthesizing the reagent *o*-nitrobenzyl-*p*-nitrophenyl carbonate which releases the nCbz group in the presence of NaOH, and it is then employed for the N-acylation as reported previously (*33*) by our laboratory. The advantage of the group lies in that it can be cleaved by photoirradiation at 354 nm wavelength of UV light. However, in the present case, use of the nCBz group for custom synthesis of oligonucleotide probes failed, because on photoirradiation to deprotect the photolabile group (*34*) the dansyl fluorophore was also cleaved.

Synthesis of Oligonucleotides. Three labeled hexamers and three labeled 20-mers were synthesized on an ABI 392 DNA synthesizer using CPG as support and the phosphoramidite approach, using labeled cytidine analogue (**9**) in the last coupling step to incorporate one, two, or three labeled monomers at the 5′-prime. Out of the three labeled 20-mers, two were identical sequences having one and two labeled monomers, while one had a different sequence. This was invariably done to ascertain the effect of variation in the sequence on the resulting

fluorescence quantum, if any. However, it was found that one-labeled monomer is sufficient for diagnostic requirement for any 20-mer sequence. The corresponding unmodified hexamer and 20-mers having similar sequence as the labeled ones and their complementary sequences were also synthesized to study the effect of hybridization on the resulting fluorescence quantum. In the case of labeled oligonucleotides, the carbamate and sulfonamide bonds were found stable to the condition of oligonucleotide synthesis as well as the deprotection conditions. UV-spectra have shown the retention of the fluorophore in the labeled oligomers. The absorbance at ∼333−340 nm and at 260 nm due to fluorophore and DNA respectively and fluorescence emission spectra at ∼500−520 nm wavelength clearly confirmed the retention of the chromophore in the oligonucleotides. The relative enhancement in the intensity of peak due to the fluorophore was observed in the mono, di, and trilabeled oligonucleotides.

Thermal Denaturation Studies. The thermal denaturation studies of labeled oligonucleotides, i.e., three hexamers and three 20-mers with the complementary normal oligomer strands, were carried out in phosphate buffer of 0.1 M concentration having 1 M NaCl by adjusting the pH at 7.0. There was a little difference in the T_m value (in the range of ∼1.79−2.01 °C) of the normal hexamer duplex (T_m 31.13 °C) and of labeled duplexes (T_m 29.44, 29.33, 29.12 °C of monodansyl, didansyl, tridansyl labeled hexamer strands, respectively) (Table 2). The difference in the T_m value clearly showed the little bit of destablization in the duplex formation. In the case of 20-mer oligonucleotides, there was a decrease in the T_m value of about 1.5−1.7 °C as compared to the normal unmodified oligomers, thus further confirming the pattern of destabilization of the oligonucleotides (Table 2). The decrease in the T_m values may be attributed to the use of linker arm (ethylenediamine) and type of bond formations between the labeled fluorophore (sulfonamide) and the nucleoside (carbamate) at the 2′-OH end. It has been reported by Gait et al. (*25*) that most of the carbamate modifications at the 2′-end position when introduced at the terminal fraying or near the terminal end fraying or the middle of the oligomers result in a considerable decrease in the T_m values of the duplexes. The negative effect of a 2′-O-carbamate modification on the thermal stability in the case of an DNA·RNA duplex was also reported (*35*). Since we have introduced modifications at the 5′-terminal position of the oligonucleotides, destabilizations were comparatively less than placing the modifications at the middle or 3′-end terminal of the oligonucleotides. However, as the number of 2′-O-modified carbamate nucleotides increase to make oligonucleotides multiple labeled the destabilization effect seems to be functionally positive as was evident by a further decrease in the T_m values of the respective duplexes chosen in the present case. However, it would show further destabilization if such a modification was introduced in the internal positions in accordance with the earlier reported works.

Fluorescence Studies. In the present study, dansyl fluorophore has been selected because it has a large Stokes shift and its fluorescent intensity depends much on the neighboring environment such as hydrophobicity and hydrophilicity, ligand binding, etc. Such alteration in the spectral property of the dansyl fluorophore has been used to detect the substrate binding to protein (*36*) and to study the interaction of DNA with Klenow fragment of DNA polymerase I (*37*). 4-Dansylamino-1,8-naphthalimido-*N*-pentanol has also been developed for the covalent labeling of oilgonucleotides (*38*).

Furthermore, covalent attachment of dansyl group with oligonucleotides with a relatively shorter linker arm at pyrimidine C-5 position exhibits little or no change in the fluorescence intensity on duplex formation with the complementary DNA segment (*39*−*42*). However, placing nucleoside analogues at the internal or middle position by attaching a dansyl group at C-8 position of a purine nucleobase results enhancement in the fluorescence intensity as well as the quantum yield (*43*).

UV-spectra have shown the retention of the fluorophore in the modified oligomers. The 20-mer oligonucleotide-bound dansyl conjugate was spectrally distinct from the labeled monomer. The absorbance at ∼333−340 nm and at 260 nm due to fluorophore and DNA respectively and fluorescence emission spectra at ∼500−520 nm wavelength clearly confirmed the retention of the chromophore in the oligonucleotides. The relative enhancement in the intensity of peak due to the fluorophore was observed in the mono, di, and trilabeled oligonucleotides.

All the fluorescence spectra were recorded in 0.1 M phosphate buffer containing 1.0 M NaCl by exciting the molecules at 333 nm and scanning the emission spectra in the range of 220−650 nm wavelength (Figures 2and 3). The fluorescence spectra of dansyl attached modified single-stranded oligonucleotides were recorded at 2.0 OD concentration and for homogeneous hybridization studies

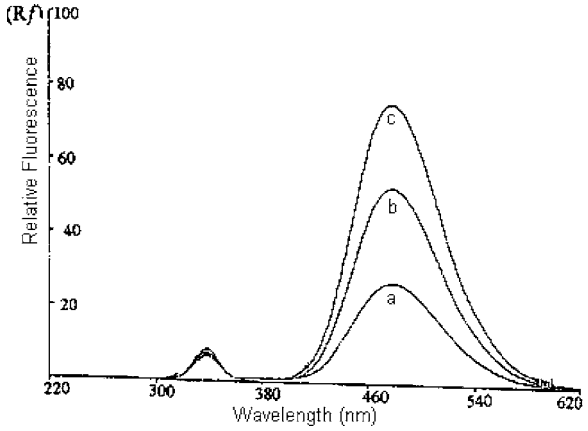

Figure 3. Fluorescence spectra of 20-mers in 0.1 M phosphate buffer containing 1.0 M NaCl by exciting at 333 nm, (a) ON7, (b) ON8, (c) ON11.

an sample containing an equimolar concentration of complementary strands was vortexed and heated at 90 °C for 15 min and was then gradually cooled at 5 °C. The process was repeated 2−3 times to ensure complete hybridization of the duplexes, and then the fluorescence spectra were recorded at 25 °C. It was observed that as the number of 2′-O-modified dansyl labeled monomer increased there was relative enhancement in the fluorescence intensity of oligonucleotides.

To observe the fluorescence pattern of duplexes of modified labeled probe with its complementary strand a model experiment was done by taking target complementary oligonucleotide of 5×10^{-5} M concentration (~1.50 OD) in phosphate buffer and the single-labeled modified 20-mer oligonucleotide of different molar concentrations was added sequentially stepwise in the order 5×10^{-6} M (0.15 OD); 1×10^{-5} M (0.3 OD); 2×10^{-5} M (0.6 OD); 3×10^{-5} M (0.9 OD); 4×10^{-5} M (1.2 OD); and 5×10^{-5} M (1.5 OD). On increasing the concentration of labeled oligonucleotide to the target DNA strand stepwise, there was relative enhancement in the relative fluorescence intensity and after reaching the equimolar concentration there was no further increase in the relative fluorescence intensity (Figure 4). The observation clearly indicated that on complete duplex formation, the dansyl fluorophore gets transferred into a less polar environment henceforth resulting in enhancement in the fluorescence intensity.

However, quenching was also observed while comparing the fluorescence intensity of individual labeled oligomers with their duplexes (Figure 5). This is may be due to the nature of interaction leading to partial compensation of carbamate and sulfonamide (electron sinker) linkages and also a stacking effect between two adjacent base pairs, i.e., intercalation and/or minor groove binding affinity may be feasible for 2′-O-modified substituents. The decrease in fluorescence intensity may also be attributed to the dansyl group, which may not remain entirely passive in duplex formation when present on the terminal nucleosides because of stacking effects at the ends of the duplex. Although the ligand intercalation and stacking effects stabilize the duplex, they may not be advantageous when the ligand is employed as a fluorophore probe. However, there is no such report about the intercalating characteristic of the dansyl fluorophore. Because dansyl is a nonplanar bulky substituent, it should be incorporated into the sugar moiety at the terminal fraying end of the oligonucleotides rather than at internal positions to retain the normal binding affinity

of the complementary DNA strand and consequently enhancement in the fluorescence intensity.

Further quenching may also be due to presence of guanosine nucleotides in the complementary strand. It has been reported very well that nucleotides, especially guanosine, have the ability to quench the fluorescence intensity of the fluorophores (*44*−*46*). However, the quenching efficiency of nucleotides is not as high as with the use of standard quencher molecules. The quenching efficiency of nucleotides are in the order guanosine > adenosine > cytidine > thymidine. The same effect of guanosine nucleotides was observed in the present case, which was just complementary to the labeled modified cytidine base of the oligonucleotide strand. The quenching efficiency in the present case was found to be in the range of 30−40%. Thus, the result also demonstrated a very good example of resonance energy transfer. The results also clearly showed that nucleosides such as guanosine have the ability to quench the fluorescence intensity of the fluorophore significantly.

CONCLUSION

In this paper, a viable strategy for multiple labeling of oligonucleotide via premodified monomers has been described. Most interesting properties were demonstrated by the 2′-*O*-(dansyl ethylcarbamoyl)-cytidine containing DNA oligomers. The dansyl modification was able to stabilize selectively a duplex with a deoxyguanosine directly opposite to the carbamate-modified nucleoside. It is applicable for homogeneous hybridization assays. To avoid adverse effects of the label or the modified base on the desired hybridization characteristics, fluorophore has been incorporated regiospecifically at 2′-end of a pyrimidine base residue. This particular region of the pyrimidine base, which does not take part in base pairing, is expected to be buried in the more hydrophobic interior of the duplex on binding to the complementary DNA fragment, thereby resulting in the enhancement of the fluorescence intensity. The 5′-prime of an oligonucleotide appears to be the most suitable site for linking of a fluorophore vis-à-vis 3′-prime or midsequence.

Moreover, the fluorophore showed characteristically a considerable enhancement in the fluorescence intensity upon hybridization with complementary "G" rich DNA sequence. The 2′-*O*-carbamate modification affords a convenient way to place various ligands in the minor groove of a DNA·DNA duplex. Other possible applications include the specific minor groove delivery of reactive functions such as directed cross-linking on conjugation with peptides, modifications of a flexible part of structured RNA molecules, possible detection of point mutation in DNA, and access of the FRET phenomenon.

ACKNOWLEDGMENT

Arvind Misra is indebted to the Department of Biotechnology, New Delhi, for financial support. We are grateful to Dr. Yogesh S. Sanghvi, ISIS Pharmaceuticals, USA, for providing Bis-reagent, Py·TFA, and phosphoramidites for oligonucleotide synthesis. Thanks are due to RSIC, Lucknow, for providing all spectral data and IGIB, Delhi, for MALDI-TOF spectral analysis.

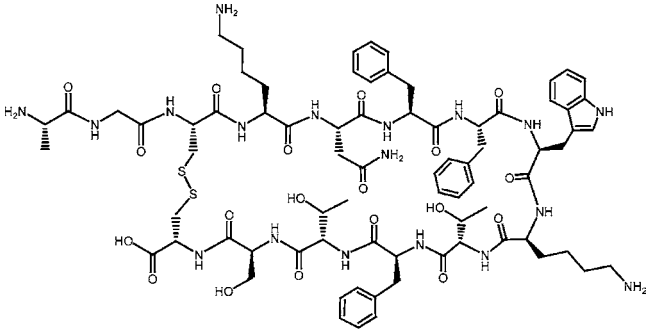
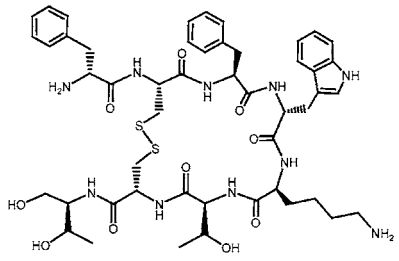
Radioligand targeting of somatostatin receptor subtype 2 (sstr2)-positive tumors with synthetic somatostatin analogues such as octreotide is subject to improvement in tumor to nontumor biodistribution, in part because internalization of such somatostatin analogues is limited by sstr2 recycling to the cell surface. We reasoned that it might be possible to prepare probe-carrying somatostatin analogues that would escape recycling, efficiently depositing probe molecules inside cells and ultimately increasing their intracellular concentration. We have incorporated cathepsin-B-cleavable linkers into (Tyr^3)-octreotate chelate conjugates and examined these constructs as to cellular uptake, externalization, subcellular localization, and cleavage in the rat pancreatic tumor cell line AR42J in culture. Comparison of the cleavable radioligands with a noncleavable control indicates that scission of the constituent cathepsin B substrate occurs at a rate faster than ligand externalization, depositing virtually all internalized cleaved radiochelates within lysosomal compartments.



INTRODUCTION

Long-lived synthetic somatostatin analogues such as octreotide (Chart 1) are useful in targeting radiolabels to type 2 somatostatin receptor-positive tumors, for medical imaging and therapy (*1*−*3*). Their effectiveness, particularly in therapeutic applications, is limited by the balance between radiation delivered to the target and to the kidney. This situation might be improved either by facilitating kidney clearance or by enhancing tumor retention of the radiolabels. A variety of methods designed to reduce kidney accumulation of radioactivity have been examined with some success (*4*−*18*); however, we have been unable to find any reports focused on increasing the residence time of radioactivity in tumors.



For the octreotide/sstr2 interaction, tumor retention of radioactivity is limited by receptor recycling mechanisms that involve vesicular packaging of receptor−ligand complexes and ultimately lead to radioligand externalization (*19*−*22*). It has been reported that the uptake of receptor ligands (^{111}In-DTPA-D-Phe^1)-octreotide and (^{111}In-DTPA)-sst-14 (Chart 1) in sstr-positive organs is determined predominantly by sstr2 (*23*), which efficiently internalizes these ligands. Since affinity profiling of several octreotate and octreotide derivatives demonstrated (DOTA-Tyr^3)-octreotate[1] to have the highest affinity for sstr2 of those examined (*24*), we chose this ligand as our model to study the effect of intracellular cleavage.

Experiments with conjugated antibodies have indicated that cleavably linked radiochelates do not clear subcellular compartments efficiently (*25*); however, noncleavable radiochelates conjugated to synthetic somatostatin analogues do (*19*, *20*). We reasoned that synthesis of a (DOTA-Tyr^3)-octreotate analogue with a cleavable peptide linker between chelate and (Tyr^3)-octreotate could allow vesicular proteases to separate the two during

internalization of the receptor-bound radiolabeled peptide. This separation could cause the radiolabel to remain inside the cell, enhancing tumor retention.

Peterson and Meares previously prepared a peptide combinatorial library and screened it to identify several excellent substrates for the intracellular proteases cathepsins B and D (*26*, *27*). Here, we have designed (Tyr^3)-octreotate derivatives that incorporate labile peptide sequences based on the decapeptide GFGSVQFAGF, which has the highest cathepsin B cleavability of those reported (*26*). To reduce the hydrophobicity of the conjugates, we investigated the pentapeptide fragments GSVQF (P_4-P_1') and SVQFA (P_3-P_2') of the GFGSVQFAGF 10-mer (Scheme 1). DOTA, a chelator that forms stable complexes with many metals useful for medicine (*6*, *28*−*37*), was used in conjunction with (Tyr^3)-octreotate, whose derivatives often show good biodistribution (*14*, *34*−*41*). In this study we synthetically incorporated the two cathepsin-B-labile peptide sequences into (Tyr^3)-octreotate conjugates and evaluated their behavior in cultured rat pancreatic tumor AR42J cells.

MATERIALS AND METHODS

Wang (*p*-benzyloxybenzyl alcohol) resin, Fmoc-amino acids, amino acid derivatives, and analogues were purchased from Novabiochem (San Diego, CA). DOTA-tris(*tert*-butyl ester) was purchased from Macrocyclics (Dallas, TX). Human liver cathepsin B was purchased from Sigma (St Louis, MO). Analytical HPLC was performed on an Alltech (Deerfield, IL) Alltima C18 column (5 μm, 250 × 4.6 mm), eluted with a linear gradient of 0.075% CF_3COOH/CH_3CN (Solvent B) in 0.1% CF_3COOH/H_2O (Solvent A) at a flow rate of 1 mL/min. Semipreparative HPLC was performed on an Alltech Alltima C18 column (5 μm, 250 × 22 mm), eluted with a linear gradient of

[1] Abbreviations: Acm, acetamidomethyl; Ahx, ϵ-aminohexanoic acid; AMC, 7-amino-4-methylcoumarin; AMCA, 7-amino-4-methyl-3-coumarinylacetic acid; CBZ, benzyloxycarbonyl; CPM, counts per minute; DIEA, *N*,*N*-diisopropylethylamine; DIPCDI, *N*,*N*′-diisopropylcarbodiimide; DMAP, 4-(dimethylamino)pyridine; DMF, *N*,*N*-dimethylformamide; DMSO, dimethyl sulfoxide; DOTA, 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid; DTPA, diethylenetriaminepentaacetic acid; DTT, dithiothreitol; EDTA, *N*,*N*′-ethylenediaminetetraacetic acid; ESI-MS, electrospray ionization mass spectrometry; FBS, fetal bovine serum; Fmoc, 9-fluorenylmethoxycarbonyl; HEPES, 2-[4-(2-hydroxyethyl)-1-piperazinyl]-ethanesulfonic acid; HOBt, *N*-hydroxybenzotriazole; PyBOP, benzotriazole-1-yloxytrispyrrolidinophosphonium hexafluorophosphate; sst, somatostatin; sstr2, somatostatin receptor subtype II; TIS, triisopropylsilane; Tris, tris(hydroxymethyl)-aminomethane.

Solvent B in Solvent A at a flow rate of 6 mL/min. All solvent gradient programs are provided in Supporting Information. Effluent was monitored by detection of its optical absorption at 350 nm for AMCA-conjugated peptide or 280 nm for non-AMCA-conjugated peptides; the absorption at 214 nm was also measured for all effluents. ESI-MS was performed on a Thermo Finnigan (San Jose, CA) LCQ Deca instrument. Thin-layer chromatography was performed with EM Science (Gibbstown, NJ) silica gel 60 F_{254} plastic backed plates (cat. no. 5735), or with the nonfluorescent equivalent (cat. no. 5748).

Peptide Synthesis. All DOTA- and AMCA-conjugated peptides were synthesized on Wang resin (loading capacity 1.2 mmol/g) by Fmoc solid-phase peptide synthetic techniques according to Scheme 1.

Initial loading of the Fmoc-Thr(tBu)-OH amino acid onto the resin was accomplished via symmetric anhydride activation. Fmoc-Thr(tBu)-OH (5 equiv to resin, 2.385 g) was dissolved in anhydrous CH_2Cl_2 (10 mL), DIPCDI (2.5 equiv, 470 μL) was added, and the mixture was stirred for 20 min at 0 °C on ice. The CH_2Cl_2 was removed by evaporation under reduced pressure, and the residue resuspended in DMF (4.5 mL) and added along with 0.1 M DMAP in DMF solution (0.05 equiv, 0.6 mL) to preswollen resin. The mixture was then agitated by bubbling Ar gas through the resin slurry at room temperature for 2 h. After the resin was washed and dried, the loading yield was estimated by measuring the amount of Fmoc released from the resin upon piperidine treatment. Two aliquots of resin (about 1−2 mg each) were weighed into test tubes, and 20% piperidine in DMF (3 mL) was added to each. After agitation for 3 min, the absorbance at 290 nm of each solution was compared to the 20% piperidine reference solution and loading yield was estimated at 0.269 mmol/g from the equation: $\text{mmol/g} = (\text{Abs}_{\text{sample}} - \text{Abs}_{\text{ref}})/(1.65 \times \text{mg of resin})$. The remaining hydroxyl functionality on the resin was blocked by reaction with acetic anhydride (2.5 equiv, 566 μL) and 0.1 M DMAP/DMF solution (0.05 equiv, 0.6 mL) in DMF.

After the initial loading, peptides were extended in a batch-wise manner: Fmoc was removed from resin-bound N-terminal amines with 20% piperidine in DMF, and amide couplings were performed by addition of a solution containing 3 mol equiv of protected amino acid, HOBt, PyBOP, and DIEA in DMF (10 mL/g resin). Removal of the Fmoc group and completion of the conjugation reaction were monitored by the quantitative ninhydrin test (*42*).

Upon completion of the (Tyr³)-octreotate sequence (Fmoc-D-Phe-Cys(Acm)-Tyr(Boc)-D-Trp(Boc)-Lys(Boc)-Thr-($\psi^{\text{Me,Me}}$pro)-Cys(Acm)-Thr(tBu)-Wang resin), peptide cyclization was performed on the resin by concurrent oxidative removal of cysteine Acm protection and formation of the cystine bond. A solution of $Tl^{3+}(CF_3COO^-)_3$ in DMF (0.1 M, 2.5 equiv to peptide) was added and the slurry mixed by bubbling through Ar gas for 2 h (*40*, *43*−*45*). An Fmoc-aminohexanoic acid spacer was appended to the N-terminus of the (Tyr³)-octreotate peptide, after which either the cleavable linker, DOTA(tBu)$_3$, or AMCA was conjugated to the N-terminus using PyBOP and HOBt activation.

The peptide-resin was washed thoroughly and dried under reduced pressure overnight. Cleavage and deprotection of the peptide was afforded by treatment of the resin with a mixture of 95% CF_3COOH, 2.5% H_2O, and 2.5% TIS (10 mL/g peptide-resin) in a stoppered flask left to stand at room temperature for 2.5 h with occasional swirling. The resin was removed by filtration and rinsed twice with cleavage mixture, the filtrates were combined, and CF_3COOH was evaporated under reduced pressure. Cold Et_2O was added to the residue, and the resultant precipitate was extracted into water. Crude peptides were >85% pure by analytical HPLC. Following purification by semipreparative HPLC, peptides of >97% purity were lyophilized and stored at −80 °C. Peptide identities were confirmed by ESI-MS: (Tyr³)-octreotate ($C_{49}H_{65}N_{10}O_{12}S_2$), calcd $(M + H)^+$ m/z 1049.421, found 1049.7; (DOTA-Ahx-Tyr³)-octreotate ($C_{71}H_{102}N_{15}O_{20}S_2$), calcd $(M + H)^+$ m/z 1548.684, found 1548.8; (DOTA-Ahx-P_3−P_2'-Ahx-Tyr³)-octreotate ($C_{102}H_{149}N_{22}O_{28}S_2$), calcd $(M + H)^+$ m/z 2194.032, $(M + 2H)^{++}$, 1097.5, found $(M + 2H)^{++}$, 1098.3; (DOTA-Ahx-P_4−P_1'-Ahx-Tyr³)-octreotate ($C_{101}H_{147}N_{22}O_{28}S_2$), calcd $(M + H)^+$ m/z 2180.016, $(M + 2H)^{++}$, 1090.5, found $(M + 2H)^{++}$, 1091.1; (AMCA-Ahx-Tyr³)-octreotate ($C_{67}H_{85}N_{12}O_{16}S_2$), calcd $(M + H)^+$ m/z 1377.563, found 1377.6; (AMCA-Ahx-P_3−P_2'-Ahx-Tyr³)-octreotate ($C_{98}H_{132}N_{19}O_{24}S_2$), calcd $(M + H)^+$ m/z 2022.91, $(M + 2H)^{++}$, 1012.0, found $(M + 2H)^{++}$, 1012.6; (AMCA-Ahx-P_4−P_1'-Ahx-Tyr³)-octreotate ($C_{97}H_{130}N_{19}O_{24}S_2$), calcd $(M + H)^+$ m/z 2008.895, $(M + 2H)^{++}$, 1005.0, found $(M + 2H)^{++}$, 1005.4.

Radiolabeling of DOTA-Conjugated Peptides. Peptides were dissolved into 10% DMSO in 0.1 M NH_4OAc (pH 6.0) at approximate concentrations of 5 mM by mass. The true concentration of each peptide−chelate solution was then measured by radiometric assay with a standardized solution of ^{57}Co(II) (*46*, *47*).

For all cell culture experiments, the chelates and peptide chelates were radiolabeled with either ^{111}In or ^{90}Y. Indium-111 metalations were performed in 5% DMSO, 0.1 M NH_4OAc buffer (pH 5.5) with radiometal and DOTA-peptides at final concentrations of 3.3 mCi/mL and 25 μM, respectively; yields were >95%. Yttrium-90 metalations were performed in 5% DMSO, 0.4 M NH_4OAc buffer (pH 6.0) at identical concentrations; yields were >80%. Radiometal was added to the peptide−chelate solution, and the mixture vortexed and incubated at 70 °C for 45 min. To ensure that each treatment contained a single peptide species, each metalation reaction was chased with 1 equiv of cold metal ($InCl_3$ or YCl_3) to fully metalate the peptide−chelate conjugate. To then allay the toxic effects that free metal may have had upon cell culture, DTPA (10 mM, final) was added, and to then prevent free chelate from removing other minerals from the medium, $CaCl_2$ (10 mM, final) was added. After each addition, the mixture was incubated at 37 °C for 1 h. Radiochemical purity was examined by TLC (EM Science 5735), which was developed in 0.1% CF_3COOH/H_2O: 0.1% of CF_3COOH/CH_3CN (1:1). After TLC development, plates were visualized with X-ray film and cut and counted in a Beckman γ-counter. In instances where the radiolabeling of the peptide−chelate was not quantitative, final concentration of the radiopeptide was normalized to the TLC count data. Since control experiments demonstrated that the uptake of ^{111}In-DTPA and ^{90}Y-DTPA by cells was negligible, radiolabeled peptide solutions were used without further purification in all cell experiments.

Cathepsin B Cleavage in Vitro (*27*). For all peptides, experiments were performed in triplicate. To human liver cathepsin B (50 μL, about 123 units/mL in 50 mM NaOAc, 1 mM EDTA) was added 4 μL of 1 M DTT, and the mixture was preactivated at 37 °C for 30 min. A 2 μL aliquot of this preactivated solution was added to each AMCA-peptide solution (25 μL, 50 μM) in 10% DMSO, 0.1 M Me_4NOAc buffer (pH 4.8), and the mixture was incubated at 37 °C. Aliquots of this solution were removed at 15, 30, 60, 80 min, and AMCA-conjugated peptides were applied to nonfluorescent silica

gel TLC plates (EM Science 5748). The TLC was developed in 10% aqueous NH_4OAc:methanol (2:1). At the same time, cathepsin B activity was measured using the commercial substrate CBZ-Arg-Arg-AMC. To 100 μL of a 5 μM CBZ-Arg-Arg-AMC solution in 10% DMSO, 0.1 M Me_4NOAc buffer (pH 4.8) was added 8 μL of the same preactivated cathepsin B solution, and fluorescence of released AMC was measured every 30 s for 30 min (λ_{ex}= 348 nm; λ_{em}= 440−480 nm). The amount of released AMC was calculated using the calibration curve found from the fluorescence of standard AMC solutions.

Similar experiments were performed using ^{111}In-labeled DOTA-peptides. After developing TLC plates (EM Science 5735) in 0.1% CF_3COOH/H_2O: 0.1% CF_3COOH/CH_3CN (1:1), the plates were imaged by exposure to film, and then cut and counted for quantitation.

Cell Culture. AR42J (ATCC, Manassas, VA) rat pancreatic tumor cells were cultured in high glucose Dulbecco's modified Eagle's medium with 2 mM glutamine and 1.5 g/L $NaHCO_3$ (DMEM, GibcoBRL), supplemented by 10% (v/v) FBS, 100 U/mL penicillin, and 100 μg/mL streptomycin. Cultures were maintained in a humidified incubator at 37 °C, 5% CO_2. Subculturing was performed employing a 0.25% trypsin−0.1% EDTA solution.

Internalization and Externalization Experiments in Cultured AR42J Cells. Internalization experiments were performed in triplicate. AR42J cells (5×10^5/well) were distributed in 12-well plates and incubated at 37 °C for 2 days in cell culture medium (DMEM containing 10% FBS). Medium was removed, and cells were washed with Dulbecco's phosphate-buffered saline (1 mL × 1) and incubated at 37 °C in 1 mL internalization medium (DMEM containing 0.1% FBS). After 2 h, 0.5 mL of a dual-labeled radiopeptide mixture, containing equimolar amounts of (^{90}Y-DOTA-Ahx-Tyr^3)-octreotate and either (^{111}In-DOTA-Ahx-P_3−P_2′-Ahx-Tyr^3)-octreotate or (^{111}In-DOTA-Ahx-P_4−P_1′-Ahx-Tyr^3)-octreotate, were added (final total concentration: 1 nM), and the incubation was continued. At 0.5, 1, 2, and 4 h, incubation medium was removed and cells were washed and harvested. After removal of the radiolabel-containing medium, cells were washed consecutively with 1 mL of DMEM containing 10% FBS and 1 mL of Dulbecco's phosphate-buffered saline to remove free radioligand and protein. Cells were solubilized in 1 mL of 0.1% Triton X-100/0.3 M NaOH, and 0.5 mL of each cell lysate was transferred to a scintillation vial for counting both β- and γ-emissions. For each cell lysate sample, protein concentration was determined by microBCA assay (Pierce) using bovine serum albumin as a protein standard.

Competitive inhibition of radiolabel uptake was examined by repeating the internalization experiment in the presence of unmodified (Tyr^3)-octreotate at concentrations ranging from 100 pM to 10 μM. Data were numerically fit and IC_{50} values calculated with a sigmoidal dose−response regression analysis using GraphPad Prism version 3.00 for Windows (www.graphpad.com).

Externalization experiments were performed with eight replicates per sample. After 4 h internalization incubation with dual (^{90}Y and ^{111}In)-labeled peptides, cells were washed with 1 mL of DMEM containing 10% FBS. The internalization medium was replaced with DMEM containing 10% FBS and 1 μM (Tyr^3)-octreotate, added to prevent reinternalization of externalized radiolabels, and again incubated at 37 °C. At 0, 6, and 24 h, cells were washed and solubilized, and lysates assayed for radioactivity and protein concentration by the same methods used for internalization experiments.

For both internalization and externalization experiments, cell viability was assayed before and after treatment with the radiolabeled peptides using trypan blue stain. A single replicate from each treatment was treated with a 0.4% (w/v) solution of trypan blue in Dulbecco's phosphate-buffered saline and examined at 10× magnification with a microscope fitted with a 10 mm × 10 mm (0.5 mm × 0.5 mm squares) eyepiece grid reticle. Stained cells were deemed nonviable, while refractile cells were considered viable. Tallies of each species within the four central grid squares were taken, and the percentage of viable cells was calculated.

Analysis of Radiopeptide Cleavage in Cultured AR42J Cells. After internalization incubation of cultured AR42J cells with ^{90}Y-labeled peptides, cell lysates were analyzed by TLC (EM Science 5735) to evaluate whether the inserted linkers had been cleaved. For each radiopeptide at each time point, the lysates of three replicate wells of a 12-well plate were combined and used in the analysis (combination was necessary in order to obtain sufficient radioactivity for TLC visualization). Similarly to internalization experiments, 1 nM (final concentration) radiopeptide was incubated with cells. At 0.5, 1, 2, and 4 h, incubation medium (supernatant) was removed and set aside. Cells were washed with 1 mL of DMEM containing 10% FBS and 1 mL of Dulbecco's phosphate-buffered saline. Cells in one replicate well were solubilized in 200 μL of 0.1% Triton X-100/0.3 M NaOH; after complete solubilization of cells, the lysate was consecutively transferred to the next replicate well and solubilization repeated until three replicates were combined. Proteins in the cell lysates were precipitated by the addition of 200 μL of CH_3CN, and soluble portions were retained (all radioactivity remained in the soluble portion). Samples of each radiolabel in medium, cell supernatant, and cell lysate were spotted onto a silica gel TLC plate. The activity (CPM/mL) of the three solutions—medium, supernatant, and lysate—were estimated using a handheld Geiger counter and adjusted so that the amounts spotted on the TLC would yield approximately the same number of counts per sample. Four microliters (2 μL × 2) of each sample was applied to the TLC plate. Plates were developed using 0.1% CF_3COOH/H_2O: 0.1% CF_3COOH/CH_3CN (1:1) and visualized using a phosphorimaging device (Molecular Dynamics Typhoon 8600), and the spots were quantified using ImageQuant software (Molecular Dynamics, ver 5.1).

Subcellular Localization of Radioactivity in Cultured AR42J Cells. Through the application of Percoll-sucrose density gradient centrifugation (*48*, *49*), the subcellular localization of radioactivity in cultured AR42J cells immediately following radiolabel uptake, as well as in cells following 24 h of externalization, was determined. Cells were seeded at a density of 1.25×10^7 cells per dish in tissue culture Petri dishes (5 cm radius) and incubated at 37 °C for 2 days in cell culture medium (DMEM containing 10% FBS). Similarly to internalization and externalization experiments, after 2 h preincubation with DMEM containing 0.1% FBS, cells were incubated with a dual-labeled radiopeptide mixture, containing (^{90}Y-DOTA-Tyr^3)-octreotate and either (^{111}In-DOTA-Ahx-P_3−P_2′-Ahx-Tyr^3)-octreotate or (^{111}In-DOTA-Ahx-P_4−P_1′-Ahx-Tyr^3)-octreotate (final total concentration: 1 nM).

The application of dual-labeling, i.e., having both cleavable and noncleavable radiopeptides present in the same batch of cells, eliminated the necessity of normalizing the data to protein content, since the amount of each radiolabel within each fraction was directly comparable to the other.

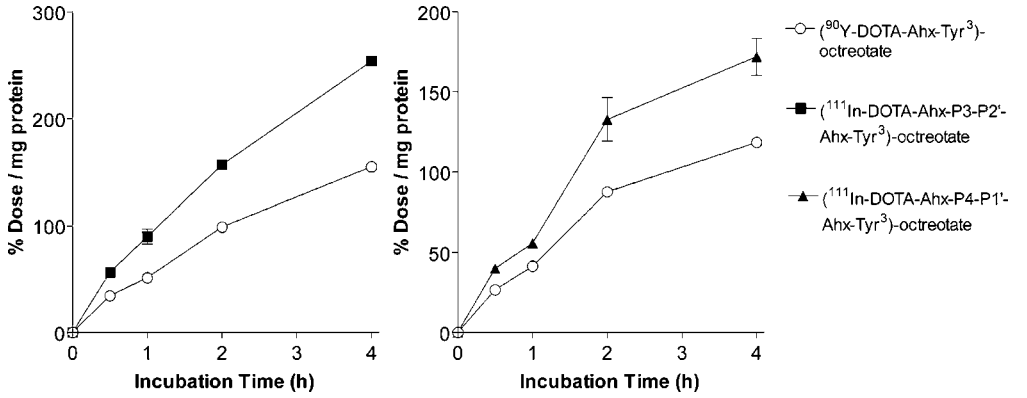

Figure 1. Internalization of mixture of (^{90}Y-DOTA-Ahx-Tyr^3)-octreotate (circle) and (^{111}In-DOTA-Ahx-P_3-P_2'-Ahx-Tyr^3)-octreotate (square) or (^{111}In-DOTA-Ahx-P_4-P_1'-Ahx-Tyr^3)-octreotate (triangle) into AR42J. SEM values indicated for all data points.

After 4 h internalization incubation, cells were washed with DMEM containing 10% FBS and Dulbecco's phosphate-buffered saline. Cells were incubated in and washed first with ice-cold glycine buffer (pH 2.8) to remove cell-surface-bound peptides (*50*) and then with Dulbecco's phosphate-buffered saline. The procedures for Percoll density gradient fractionation were performed on ice or at 4 °C (*48*, *49*). Cells were scraped off the Petri dish with a rubber policeman into 1 mL of 0.25 M sucrose/10 mM HEPES, pH 7.4, and transferred to a Dounce homogenizer (15 mL, Type A, Wheaton) with an additional 1 mL of 0.25 M sucrose/10 mM HEPES, pH 7.4. After cells were homogenized with 30 strokes, the homogenate was transferred to a falcon centrifuge tube (15 mL), diluted with an additional 1 mL of 0.25 M sucrose/10 mM HEPES, pH 7.4, and centrifuged at 500 × *g* for 5 min to pellet unbroken cells and nuclei. Postnuclear supernatant was transferred to another falcon centrifuge tube (15 mL). After the pellet was resuspended with 2 mL of 0.25 M sucrose/10 mM HEPES, pH 7.4, the suspension was centrifuged at 500 × *g* for 5 min and added to the first postnuclear supernatant fraction. The combined supernatant fractions were diluted to 10 mL with 0.25 M sucrose/10 mM HEPES, pH 7.4, and adjusted to a final concentration of 27% Percoll in 0.25 M sucrose using a 90% Percoll solution (9 parts Percoll and 1 part 2.5 M sucrose/100 mM HEPES, pH 7.4). This solution was layered over a 1 mL sucrose cushion consisting of 10 × homogenization buffer (2.5 M sucrose, 100 mM HEPES, pH 7.4) in a 16-mL round-bottom centrifuge tube (polycarbonate, 18 × 101 mm, Nalge Nunc International). Samples were centrifuged without braking at 20 000 × *g* for 120 min in a Sorvall SS-34 fixed-angle rotor (Sorvall Instruments, Newtown, CT) equipped with adaptors (Kendro) to fit the centrifuge tubes. Twenty fractions were collected starting from the top of the gradient, and the radioactivity in each dual-labeled fraction was measured by γ- and β- counters for ^{111}In and ^{90}Y, respectively.

The late endosome and lysosome marker enzyme, β-hexosaminidase, and the plasma membrane marker enzyme, alkaline phosphodiesterase I, were also assayed for each fraction (*51*). In this study, alkaline phosphodiesterase I serves as a marker of the early endosome fraction, since with this centrifugation protocol the early endosome fraction sediments with the plasma membrane fraction, and the plasma membrane has been stripped of radioligand. Enzyme assays were performed in 96-well plates, and absorbances were measured by an EL 311 microplate reader (Bio-Tek instruments) connected to Macintosh computer equipped with Deltasoft 3 (2.22 Biotek PlateReader). β-Hexosaminidase activity was measured by adding 100 μL of 10 mM *p*-nitrophenyl-*N*-acetyl-β-D-glucosaminide in 0.1 M NaOAc buffer, 0.1% Triton X-100, pH 4.1, to wells containing 10 μL of the sample. After incubation at 37 °C for 90 min, 100 μL of 1 M Na_2CO_3(aq) was added to stop the reaction. Precipitated Percoll was removed by centrifugation at 3000 × *g* for 10 min, and 150 μL of the supernatant was transferred to another 96-well plate and its absorbance read at 405 nm. Alkaline phosphodiesterase I activity was measured by adding 100 μL of 2 mM thymidine 5′-monophosphate *p*-nitrophenyl ester in 0.1 M Tris-HCl buffer, 0.1% Triton X-100, pH 8.9, to wells containing 10 μL of the sample. After incubation at 37 °C for 60 min, 100 μL of 0.1 M NaOH was added to stop the reaction, and the absorbance at 405 nm was measured.

Subcellular Localization after 24 h Externalization of the Radiolabel. After identical treatment for radiolabel internalization, cells were washed with DMEM containing 10% FBS (10 mL) and Dulbecco's phosphate-buffered saline (10 mL) and then incubated with DMEM containing 10% FBS and 1 μM (Tyr^3)-octreotate for 24 h, after which the assay for subcellular localization was performed as above.

RESULTS

In Vitro Cleavage. To verify the cathepsin B cleavage of (Tyr^3)-octreotate conjugates incorporating the P_3-P_2' and P_4-P_1' sequences, AMCA-conjugates were incubated with human liver cathepsin B in vitro. At 15 min, the CBZ-Arg-Arg-AMC control was cleaved 95±2%, the AMCA-conjugate containing P_3-P_2' 27 ± 3%, the conjugate containing P_4-P_1' 18 ± 3%, while the noncleavable AMCA-conjugate showed no cleavage. In the case of ^{111}In-labeled DOTA-peptides, similar results were observed: 24 ± 3% and 16 ± 5% cleavage, respectively, for the P_3-P_2' and P_4-P_1' containing peptides, with no cleavage of the DOTA-(Tyr^3)-octreotate peptide.

Internalization/Externalization. The uptake of radiolabeled DOTA-peptides by somatostatin receptor-positive AR42J cells was measured using dual-radiolabeling methods. Mixtures containing not only the ^{90}Y-labeled noncleavable peptide but also one of the ^{111}In-labeled cleavable peptides were incubated with cells. Although all peptides showed time-dependent uptake, cleavable linker-peptides displayed higher uptake rates than the noncleavable peptide by 64 ± 3% and 45 ± 17% for P_3-P_2' and P_4-P_1' sequences, respectively (Figure 1). Control experiments showed that switching the metal labels so that the noncleavable peptide contained ^{111}In and the cleavable contained ^{90}Y did not affect the outcome.

Uptake inhibition was also examined. Each ^{111}In-radiolabeled DOTA-(Tyr^3)-octreotate peptide (1 nM) was

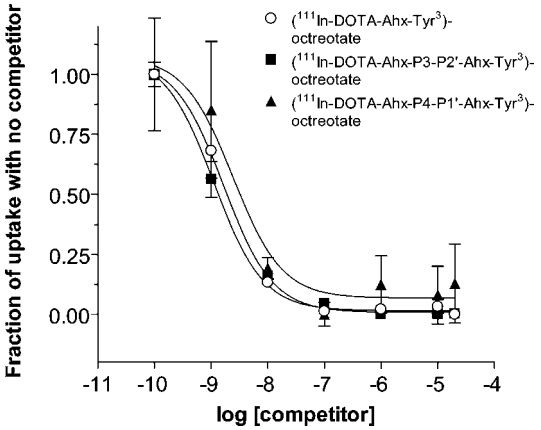

Figure 2. Internalization of (^{111}In-DOTA-Ahx-Tyr^3)-octreotate (circle), (^{111}In-DOTA-Ahx-P_3-P_2'-Ahx-Tyr^3)-octreotate (square), and (^{111}In-DOTA-Ahx-P_4-P_1'-Ahx-Tyr^3)-octreotate (triangle) in the presence of (Tyr^3)-octreotate as a competitor. Values are expressed as % of maximal uptake (i.e. uptake without inhibitor) ± SEM.

Table 1. IC_{50} Values for Rat Sstr2 of Somatostatin Analogues[a]

peptide	IC_{50} ± SEM (nM)
(DOTA-Ahx-Tyr^3)-octreotate	1.6 ± 0.4
(DOTA-Ahx-P_3-P_2'-Ahx-Tyr^3)-octreotate	1.1 ± 0.4
(DOTA-Ahx-P_4-P_1'-Ahx-Tyr^3)-octreotate	2.4 ± 0.8

[a] Determined by competitive binding with (Tyr^3)-octreotate, IC_{50} = 1.5 ± 0.4 nM (*24*).

challenged with varying concentrations of unlabeled (Tyr^3)-octreotate during incubation with AR42J. In each case, 50% inhibition of uptake was observed at approximately equimolar concentrations of (Tyr^3)-octreotate inhibitor and ^{111}In-peptide (Figure 2). At (Tyr^3)-octreotate concentrations greater than or equal to 100 nM, radiolabel uptake was almost completely inhibited. Numerical curve fitting yielded IC_{50} values (Table 1) in agreement with published values for (^{90}Y-DOTA-Tyr^3)-octreotate (*24*).

Externalization experiments were performed to examine the degree to which the internalized radioactivity was retained within AR42J cells over time. After allowing radiolabels to internalize within cells over 4 h, cells were washed and incubated with culture medium containing 1 μM unlabeled (Tyr^3)-octreotate (to prevent re-uptake of externalized peptides), and cell cultures were monitored over 24 h for loss of radioactivity. After the 24 h incubation, the noncleavable peptide showed about 40% secretion of its initial uptake, while both cleavable peptides maintained near 100% of their initial uptake (Figure 3). Ratios of cleavable to noncleavable for each of the dual-radiolabeled experiments are shown in Figure 4.

In both internalization and externalization studies, cells were assayed for viability both before and after radioligand treatment; in all cases cell viability exceeded 95%.

Intracellular Radioligand Proteolysis. The extent of peptide cleavage in cell culture was examined by TLC after incubation with ^{90}Y-labeled peptides (Figure 5). Intact peptides were compared with peptides in cell-treatment supernatant and with peptides contained in cell lysates. No cleavage of any of the peptides was apparent in culture medium either before or after incubation with cells, while both cleavable and noncleavable peptides were degraded within cells, as evidenced by changes in their R_f-values. After 4 h of incubation, the cell lysates showed less than 3% of the radioactivity from cleavable peptides migrating at the R_f of the parent peptide, while more than 80% of the noncleavable peptide remained intact.

Subcellular Localization of Radioactivity. We examined the subcellular distribution of radioactivity after cellular internalization of a mixture of ^{90}Y-labeled noncleavable and ^{111}In-labeled cleavable peptides (Figure 6). Fractionation of cell homogenate immediately following the 4 h internalization of the radiolabels showed a marked difference in subcellular localization between the cleavable and noncleavable peptide−chelates. At 4 h, lysosomal fractions contained a significantly larger percentage of the radioactivity derived from cleavable peptides than from the noncleavable peptides, which appeared in early endosomes. A two-tailed unpaired *t*-test comparison of the values observed within fractions 4 and 17 of the 4 h treatments (Figure 6, panels A and C) indicates that the observed differences between the cleavable and noncleavable peptides are significant with *P*-values of less than 0.0001. However, after 4 h of internalization followed by an additional 24 h incubation, the radioactivity from either cleavable or noncleavable peptide−chelates was located predominantly within lysosomes, with no statistical difference between the two radiolabels.

DISCUSSION

Our aim in this study was to increase the amount of radiolabeled somatostatin derivatives within tumor cells by increasing the intracellular residence time of the radiolabel. We designed and synthesized DOTA-conjugated (Tyr^3)-octreotate, that incorporated cathepsin-B-

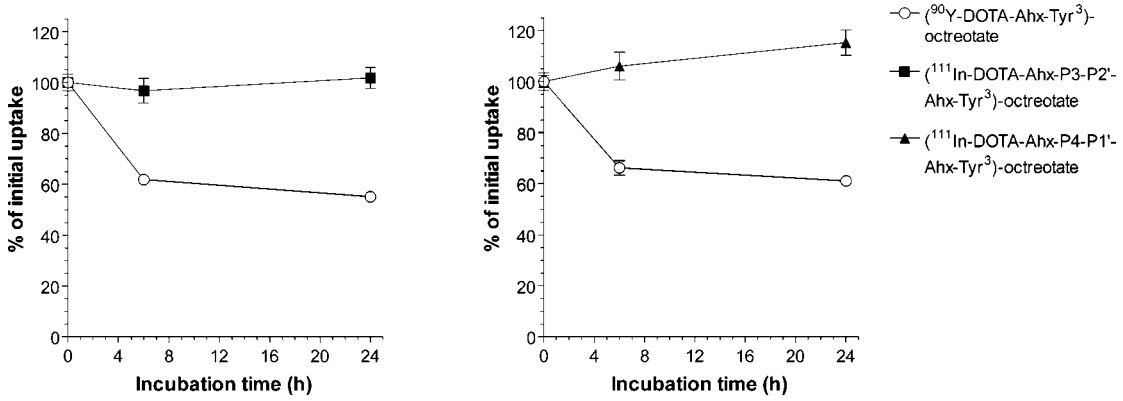

Figure 3. Externalization of mixture of (^{90}Y-DOTA-Ahx-Tyr^3)-octreotate (circle) and (^{111}In-DOTA-Ahx-P_3-P_2'-Ahx-Tyr^3)-octreotate (square) or (^{111}In-DOTA-Ahx-P_4-P_1'-Ahx-Tyr^3)-octreotate (triangle) from AR42J. *Y*-axes are expressed as % of initial content ± SEM.

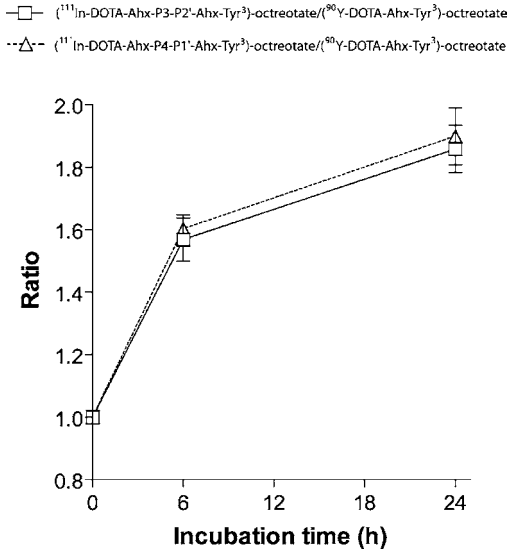

Figure 4. Externalization of mixture of (^{90}Y-DOTA-Ahx-Tyr^3)-octreotate and (^{111}In-DOTA-Ahx-P_3-P_2'-Ahx-Tyr^3)-octreotate (square) or (^{111}In-DOTA-Ahx-P_4-P_1'-Ahx-Tyr^3)-octreotate (triangle) from AR42J. *Y*-axes are expressed as the ratio of ^{111}In CPM to ^{90}Y CPM, without protein normalization. Errors indicated are SEM.

Lane 1: loaded sample before incubation; lane 2: loaded sample after incubation; lane 3: CH_3CN-soluble portion of cell lysate. Y-oct: (^{90}Y-DOTA-Ahx-Tyr^3)-octreotate; Y-P3: (^{90}Y-DOTA-Ahx-P_3-P_2'-Ahx-Tyr^3)-octreotate; Y-P4: (^{90}Y-DOTA-Ahx-P_4-P_1'-Ahx-Tyr^3)-octreotate.

labile peptides (Scheme 1), and examined their behavior in vitro and in cell culture.

After receptor-mediated endocytosis, stable synthetic somatostatin analogues are externalized by receptor recycling mechanisms in which receptor−ligand complexes are packaged in endosomal vesicles within the recycling pathway and shunted back to the cell surface (*19*, *20*). We hypothesized that since internalized metal chelates tend to remain within cells, intravesicular cleavage of the radiochelate moiety from the receptor-binding somatostatin analogue might increase radiochelate retention within the cell. Assuming that low levels of proteolytic enzyme activity would be present in early endosomes or other vesicles involved in recycling somatostatin analogues, we incorporated excellent cathepsin B substrates between the chelate and (Tyr^3)-octreotate, using a previously identified peptide substrate as our model (*26*, *27*). Truncating that substrate's decapeptide sequence to the five internal residues P_3-P_2' or P_4-P_1' afforded final constructs that were significantly more water-soluble than the GFGSVQFAGF parent decapeptide. Insertion of ϵ-aminohexanoic acid spacers between the chelate and the linker, and between the linker and (Tyr^3)-octreotate, was done to maximize accessibility of the cathepsin B substrate to the enzyme and to maintain optimal affinity of the resultant peptide for the somatostatin receptor (*44*).

Linker cleavage by cathepsin B was confirmed in vitro. Both AMCA- and ^{111}In-DOTA-labeled peptides containing the P_3-P_2' or P_4-P_1' sequence (Scheme 1) were incubated in vitro with human liver cathepsin B along with positive and negative controls; examination by TLC indicated that both linkers cleaved with rates approximately 20% that of the commercial substrate CBZ-Arg-Arg-AMC. The (Tyr^3)-octreotate peptides without linker were not cleaved under these conditions. The P_3-P_2' linker cleaved slightly faster than P_4-P_1', a result consistent with the report by Portaro et al., indicating that the P_3-P_2' residues are those primarily responsible for enzyme recognition (*52*).

Cleavage in AR42J cell culture was also confirmed and was shown only to occur intracellularly. Peptide cleavage was not observed in the cell culture medium—either before or after incubation in cell culture—but was only seen in cell lysate. While all peptides, including the nonlinker control, were cleaved intracellularly, the peptide without the cleavable linker was still >80% intact after 4 h of incubation, at which time <3% of the cleavable peptides remained intact (Figure 5). Indeed, cleavage appears to be rapid compared to the recycling process, since even at 30 min of incubation in cell culture, the scissile peptides were mostly cleaved. The small difference in cleavage rate between the two cleavable substrates observed in vitro does not affect their behavior in cell culture, corroborating the hypothesis that the rate of intracellular cleavage is more rapid than the externalization process.

Figure 1 shows internalization curves. After 4 h of internalization incubation, compared to the noncleavable peptide, the P_3-P_2'- and P_4-P_1'-containing peptides displayed significantly higher uptake. Meir et al. demonstrated that N-terminal extension of the ligand peptidyl chain should not significantly change the receptor-affinity of the compound (*44*). Since the IC_{50} values for all three peptides were in the low nM range (Table 1), demonstrating that the incorporated cleavable linkers do not increase affinity, the most likely cause for the increased uptake of radioactivity is the rapid cleavage of the linkers upon internalization.

Externalization studies confirmed the net increase in internalization seen for the cleavable ligands. Cleavage not only prevents recycling of the ligand by detaching the chelate from the ligand−receptor complex, but also produces a radiolabeled product that is not membrane-permeable. While the noncleavable peptide showed a gradual decrease of intracellular radioactivity to about

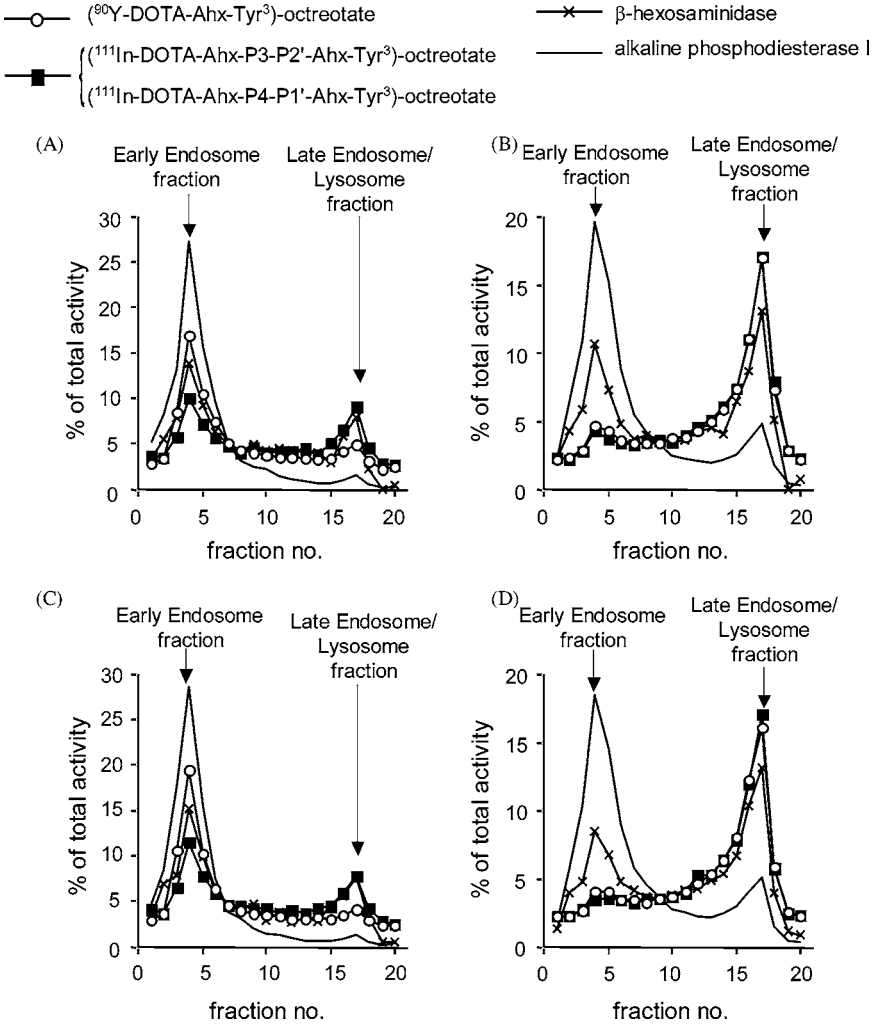

Figure 6. Subcellular localization of radioactivity after 4 h internalization (A) and 24 h externalization incubation (B) with mixture of (^{90}Y-DOTA-Ahx-Tyr^3)-octreotate (circle) and (^{111}In-DOTA-Ahx-P_3-P_2'-Ahx-Tyr^3)-octreotate (square) and after 4 h internalization (C) and 24 h externalization incubation (D) with mixture of (^{90}Y-DOTA-Ahx-Tyr^3)-octreotate (circle) and (^{111}In-DOTA-Ahx-P_4-P_1'-Ahx-Tyr^3)-octreotate (square). x: β-hexosaminidase (lysosome marker enzyme); solid line: alkaline phosphodiesterase I (plasma membrane marker enzyme). Error bars indicating ± 2 standard deviations, in all instances, are smaller than the datapoints on the graph and thus do not appear.

60% of the initial value after 24 h, the cleavable peptides maintained near 100% of initial uptake over this period (Figure 3). The P_4-P_1'-(Tyr^3)-octreotate data showed over 100% residence, but this can be attributed to an error in normalization to protein content; if the ratio of cleavable peptide to noncleavable in these double-label experiments is plotted versus time, the error resultant from normalization is removed and it becomes evident that the cleavable linker increases resident radioactivity about 2-fold over the noncleavable ligand after 24 h. Plots of the CPM ratios of each P_3-P_2' and P_4-P_1' peptide against the (DOTA-Ahx-Tyr^3)-octreotate control show identical response (Figure 4).

Investigation of the subcellular localization of radioactivity also distinguished the behavior of the cleavable peptides from the control. After 4 h internalization, the radioactivity from the noncleavable peptide remained primarily in early endosomes, while that resulting from either of the cleavable peptides was seen significantly in lysosomes. Twenty-four hours after cell loading, all intracellular radioactivity was localized in lysosomes (Figure 6), consistent with previous reports (*51*, *53*, *54*). The presence of the lysosomal marker enzyme β-hexosaminidase within both early and late fractions has been noted by others (*51*). We believe that its presence in the light fractions of the Percoll gradient is due to the enzyme's presence within early endosomes in this cell line, and thus the enzyme is acting as a marker for both early and late endosomes; as such it does not present a problem in interpreting the data. While β-hexosaminidase is seen consistently in both the early and late endosome fractions in all four panels of Figure 6 (i.e. at both 4 and 24 h, and in both experimental treatments with each cleavable peptide), the distribution of radioactivity clearly differs for the noncleavable peptide at 4 and 24 h.

We interpret the difference in localization between the two radioligands at 4 h as attributable to the difference in longevity of each ligand−receptor complex. The relatively rapid proteolytic release of the cleavable radiochelate from the ligand−receptor complex prevents its externalization and increases its rate of accumulation within lysosomes. The noncleavable radiochelate, on the other hand, remains in early endosomes as the ligand−receptor complex and is largely externalized. Thus the fast cleavage of the cathepsin-B substrate linker leads to the observed differences in subcellular localization as well as to the increase in cell resident radioactivity of the two species.

While a 2-fold increase in tumor resident radioactivity for the cleavable radioligands presents a significant improvement, the clearance of nontumor resident radioactivity is still of concern. Radiometal-labeled DOTA- or DTPA-conjugated octreotate derivatives typically show nonspecific accumulation of radioactivity within the kidneys. High intralysosomal cathepsin B activity within the kidney (*55*, *56*), should efficiently process the cleavable radiolabels to produce chelate-appended tetra- or tripeptides with a single negative charge. As in tumor cells, this cleavage might be expected to increase the radiochelate residence within the kidney. However, since renal uptake is based on adsorptive endocytosis rather than receptor-mediated endocytosis, ligand re-externalization is not significant and we expect that both cleavable and noncleavable ligands should exhibit similar retention.

This strategy to enhance radioactivity within tumor tissue could lead to improved diagnosis and therapy using radiometal-labeled somatostatin derivatives and may have application to therapy with Auger emitters such as ^{111}In, which are effective when internalized (*57*, *58*).

Direct Production of Proteins with N-Terminal Cysteine for Site-Specific Conjugation

Ian E. Gentle, David P. De Souza, and Manuel Baca*

The Walter and Eliza Hall Institute of Medical Research, 1G Royal Parade, Parkville, Victoria, 3050, Australia.
Received February 3, 2004

Proteins with N-terminal cysteine can undergo native chemical ligation and are useful for site-specific N-terminal labeling or protein semisynthesis. Recombinant production of these has usually been by site-specific cleavage of a precursor fusion protein at an internal cysteine residue. Here we describe a simpler route to producing these proteins. Overexpression in *E. coli* of several proteins containing cysteine as the second amino acid residue yielded products in which the intiating methionine residue had been completely cleaved by endogenous methionine aminopeptidase. While secondary modification of the terminal cysteine was a complicating factor, conditions were identified to eliminate or minimize this problem. Recombinant proteins produced in this way were suitable for site-specific modification of the amino terminus via native chemical ligation technology, as demonstrated by conjugation of a thioester-containing derivative of fluorescein to one such protein. The ability to directly produce proteins with N-terminal cysteine should simplify the application of native chemical ligation technology to recombinant proteins and make the technique more amenable to researchers with limited expertise in protein chemistry.

INTRODUCTION

Over the past decade, a number of new chemical methods have been devised which can be used to site-specifically modify the N-terminus of recombinant proteins (*1*−*3*). The most elegant of these, native chemical ligation (*2*), requires that the recombinant protein contain an N-terminal cysteine residue, which can then react in a specific manner with thioester-containing reagents. This method has been used to site-specifically label proteins with small molecules (*4*, *5*), to generate semisynthetic proteins via ligation of synthetic peptides (*6*) or to link together recombinantly produced protein fragments (*7*). While native chemical ligation has been extensively applied to chemically synthesized peptides (*8*), its application to recombinant proteins has been more limited. Current methods for producing N-terminal cysteine proteins usually involves cleavage of a precursor fusion protein with a site-specific protease in order to expose an internal cysteine residue as the new N-terminus (*4*, *9*). The drawbacks of this approach include possible cleavage at other sites within the protein and the need to repurify the cleaved product. Furthermore, the activity of site-specific proteases are not compatible with high levels of chaotropic agents which might otherwise be used to extract proteins from inclusion bodies and, if necessary, maintain them in solution.

A preferable approach to the production of N-terminal cysteine proteins would be to take advantage of endogenous methionine aminopeptidase (*10*) to cleave the initiating methionine from recombinantly expressed proteins containing cysteine as the second residue. As methionine excision is believed to occur cotranslationally (*11*−*13*), that is, before the completion of synthesis or folding of polypeptide chains, the expressed protein would be isolated with cysteine as the N-terminal residue. The specificity of methionine aminopeptidase is dependent upon the identity of the amino acid residue adjacent to the amino terminus. Methionine is efficiently removed from proteins when the second residue is a small side chain amino acid, even when these proteins are overexpressed (*14*−*16*). However, methionine is not cleaved when a large side chain amino acid is the adjacent residue. Variable degrees of cleavage have been reported to occur when the second residue is an intermediate sized amino acid such as cysteine (*14*, *15*). This appears to have limited attempts to produce N-terminal cysteine proteins by this route, due to a widely held belief that methionine excision will be incomplete (e.g. reference (*4*)), although at least one report has made use of this strategy (*17*).

Given the usefulness of proteins with N-terminal cysteine for site-specific modification or protein semisynthesis, we have investigated the direct production of such proteins in *E. coli* by expression of constructs containing Met-Cys- amino terminii. We report conditions for optimizing the yield of the processed product and demonstrate its utility for site-specific modification of the N-terminus.

EXPERIMENTAL PROCEDURES

Construction of Protein Expression Vectors. For expression of proteins containing an N-terminal polyhistidine tag, a modified pET15b vector (Novagen) was used. Proteins produced corresponded to fragments from suppressor of cytokine signaling (SOCS)-7 (amino acids 378−512) and SHP2 (amino acids 1−105 or 109−220). Each of the pET15b-based constructs encoded polypeptide products with either a MCSHHHHHHGARQ or MCRHHHHHHGARQ N-terminal sequence, followed by the fragments defined above. For expression of proteins containing a C-terminal polyhistidine tag, a pET22b vector (Novagen) was used. Proteins produced with this construct corresponded to fragments from SOCS7 (amino

acids 378−512) and SHP2 (amino acids 3−105 or 110−220). Each of the pET22b constructs encoded protein products that contained a common MC N-terminal sequence, followed by the fragments defined above.

Expression, Purification, and Characterization of Protein Products. BL21 DE3 pLysS *E. coli* harboring the expression construct of interest were grown overnight in media containing ampicillin and chloramphenicol antibiotics. The overnight culture (20 mL) was used to inoculate 400 mL of super broth containing ampicillin, with or without 2% v/v glucose. Cultures were incubated with shaking at 37 °C until the optical density at 600 nm reached approximately 0.8 (typically 1.5−2 h). Protein expression was then induced by addition of isopropyl β-D-thiogalactopyranoside (IPTG)[1] to a final concentration of 200 μM, and cultures were incubated a further 2−4 h. For cultures grown in media supplemented with cysteine, 4 mL of a freshly prepared 1 M cysteine stock (pH 7.0) was added approximately 45 min prior to IPTG induction, and another 2 mL at the time of IPTG induction. Cell pellets were stored at −20 °C prior to lysis.

The frozen cell pellets were resuspended in 10 mL of lysis buffer (100 mM sodium phosphate, 10 mM Tris-HCl, pH 8.1, containing 7 M guanidine·HCl) to which methyl methanethiosulfonate had been added (10 mM final). After being stirred on ice for 30 min, the cell lysate was clarified by centrifugation and filtration, applied to a Hi-Trap Chelating HP column (Amersham-Pharmacia) precharged with nickel, and preequilibrated in lysis buffer. Following washing with lysis buffer adjusted to pH 6.3, the protein was eluted with the same buffer at pH 4.5. Samples were adjusted to pH 8.0 and reduced with DTT prior to analysis by HPLC. Reduced samples were also analyzed by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) after desalting of samples with a C4 ZipTip pipet tip (Millipore).

Chemical Reversal of N-Terminal Cysteine Modification. Lyophilized protein was solubilized in 400 mM unbuffered *O*-methylhydroxylamine hydrochloride (∼pH 3), and 0.1 volumes of 200 mM aqueous tris(2-carboxyethyl)phosphine was added. Samples were incubated at room temperature and then removed at various time points for analysis by HPLC and/or MALDI-TOF MS (after desalting with a C4 ZipTip).

Preparation of Fluorescein 2-Mercaptoethanesulfonate Thioester (fluorescein-2MES). 5- (and 6-)-Carboxyfluorescein succinimidyl ester (96 mg) was combined with sodium 2-mercaptoethanesulfonate (375 mg) and solubilized in 10 mL of 0.1 M sodium borate buffer, pH 8.7. After being stirred at room temperature for 2 h, the thioester product was purified by reverse phase HPLC and lyophilized to yield 69 mg of fluorescein-2MES.

Site-Specific Ligation. Lyophilized protein was solubilized in unbuffered water at 5 mg/mL. To 13 μL of this sample were added 2.5 μL of 2 mg/mL fluorescein-2MES (in water), 1 μL of 200 mM sodium 2-mercaptoethanesulfonate (in water), and 4 μL of 500 mM sodium phosphate (pH 7.5). After 4.5 h incubation at room temperature, an equal volume of 100 mM DTT in water was added and the sample was incubated for a further 30 min. An aliquot of the reaction was then analyzed by HPLC and MALDI-TOF MS (after desalting).

RESULTS

Production of an N-Terminal Cysteine Protein. To determine whether the initiating methionine residue would be cleaved from a protein expressed in *E. coli* containing cysteine as the adjacent amino acid, we expressed the C-terminal Src homology 2 (SH2) domain from SHP2 (amino acids 109−220), a dual SH2 domain-containing protein phosphatase that we have previously studied in our laboratory (*18*). The expressed protein (SHP2C) contained the N-terminal tag sequence MCSH-HHHHHGARQ, thereby allowing purification of the recombinant product by nickel affinity chromatography. To protect the terminal and internal cysteine side chains from unwanted reactions during purification, the protein was extracted from *E. coli* by denaturing lysis buffer containing methyl methanethiosulfonate, a reagent which oxidizes sulfhydryl groups into the methyl disulfide derivative (*4*). The yield of purified protein obtained after affinity chromatography was 19 mg from a 400 mL *E. coli* culture.

To determine whether the N-terminal methionine residue had been cleaved, a sample of the protein was reduced with DTT and desalted prior to analysis by MALDI-TOF MS. The parent molecular ion observed by MALDI-TOF MS was broad, suggesting product heterogeneity, but was centered on 14 056 Da which is 110 Da lower than that of the full length methionine-containing product, but 21 Da higher than the methionine-cleaved product (Figure 1A). The MALDI-TOF MS data was not consistent with a mixture of processed and methionine-containing proteins because of an absence of defined molecular species with masses 14 035 and 14 166 Da. Rather, it suggested that the initiating methionine residue had been cleaved, but that low molecular weight modifications of the protein had also taken place. One defined species, present at a low level, was of mass 13 932 Da which is within 1 Da of that expected for a protein lacking both the N-terminal methionine and adjacent cysteine residues.

To better analyze the source of heterogeneity, a sample of the nonreduced protein was digested with trypsin, and the peptide fragments were analyzed by HPLC and MALDI-TOF MS (Figure 1B, 1C). On the basis of a comparison of the experimental versus predicted tryptic peptide masses, three peptide fragments appeared to be derived from the N-terminus of the protein. The masses of these peptides (1212, 1361, 1385 Da) were consistent with N-terminal peptide fragments SHHHHHHGAR, the methyl disulfide derivative of CSHHHHHHGAR (as expected from treatment of the protein with methyl methanethiosulfonate), and a +70 Da adduct of CSHH-HHHHGAR. The mass spectrum for the 1385 Da peptide also showed fragment ions at M − 46, M − 58, and M − 70 Da (Figure 1C). There was no tryptic fragment detected corresponding to an N-terminal methionine-containing peptide. The presence of three N-terminal tryptic peptides, in addition to the tendency for one of these to fragment in the mass spectrometer, explained why the MALDI-TOF MS data for the undigested protein showed a broad molecular ion (Figure 1A). Treatment of the tryptic mixture with the reducing agent tris(2-carboxyethyl)phosphine only affected the 1361 Da peptide, suggesting that the cysteine residue in the 1385 Da peptide was not modified by a disulfide adduct. We did not perform further characterization of the 1385 Da

[1] Abbreviations used: DTT, dithiothreitol; fluorescein-2MES, fluorescein 2-mercaptoethanesulfonate thioester; IPTG, isopropyl β-D-thiogalactopyranoside; MALDI-TOF MS, matrix-assisted laser desorption/ionization time-of-flight mass spectrometry; SH2, Src homology 2.

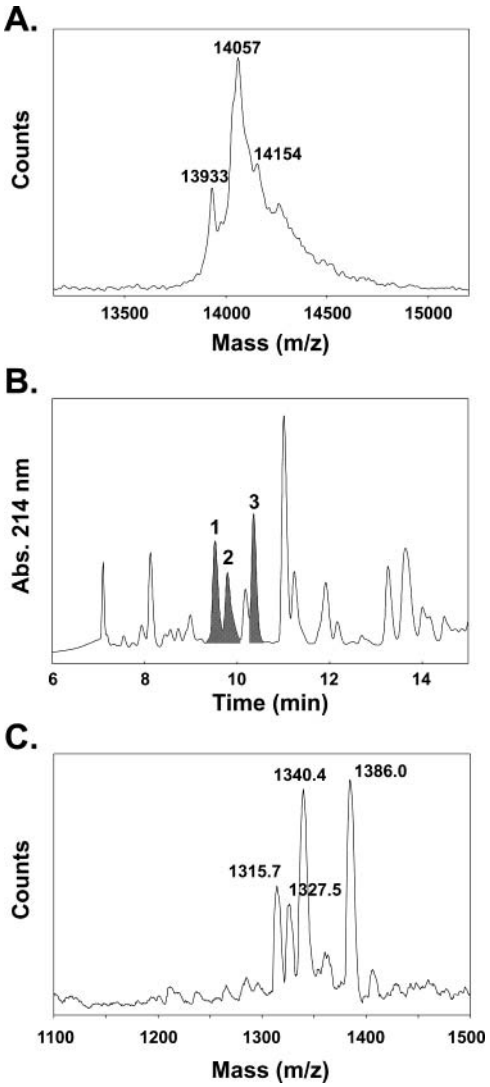

Figure 1. Analysis of modifications to N-terminal cysteine protein. Recombinantly produced SHP2C, containing the N-terminal tag sequence MCSHHHHHHGARQ, was analyzed for cleavage of the terminal methionine residue and other N-terminal modifications. (A) MALDI-TOF MS analysis of affinity-purified protein, after reduction with DTT and desalting. Labeled peaks correspond to singly charged $[M + H]^+$ ions. The expected masses for full length, des-Met[1], and des-Met[1]-Cys[2] protein products are 14 166, 14 035, and 13 392 Da, respectively (average masses, unprotonated state). (B) HPLC analysis of tryptic digest of SHP2C. The sample analyzed in (A) was digested with trypsin (without DTT reduction), and the products were separated by reverse phase HPLC. Each HPLC peak was collected and analyzed by MALDI-TOF MS. Peaks labeled 1, 2, 3 were of masses 1212, 1385, and 1361 Da, respectively. (C) MALDI-TOF analysis of N-terminal tryptic peptide 2, showing the tendency for the $[M + H]^+$ parent ion to fragment into various daughter ions.

peptide; however, this mass is consistent with the formation of a thiazolidine product by condensation of the N-terminal cysteine residue with pyruvic acid, an abundant *E. coli* metabolite.

Optimization of Culture Conditions for Producing N-Terminal Cysteine Proteins. In an attempt to minimize the formation of secondary products following cleavage of the terminal methionine residue, several modifications were made to the expression protocol. The culture time after IPTG induction was reduced from 4 to 2 h, and cysteine was added to the media to act as a scavenger of potentially reactive metabolites. We also omitted glucose from the medium to remove this as a source of pyruvic acid formation. In addition, acting on the suspicion that methionine aminopeptidase was causing some secondary cleavage of N-terminal cysteine, we replaced the small side chain amino acid at position 3 in the sequence (serine) with a large side chain amino acid (arginine).

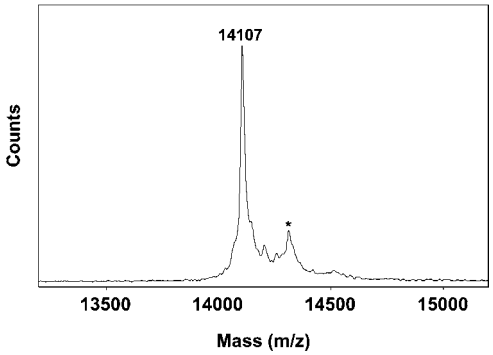

Figure 2. MALDI-TOF analysis of an N-terminal cysteine protein produced under optimized conditions. Recombinantly produced His6-SHP2C, containing the N-terminal tag sequence MCRHHHHHHGARQ, was expressed using the optimized conditions described in the text. Following affinity purification, reduction with DTT and desalting, a sample was analyzed by MALDI-TOF MS. The expected masses for full length and des-Met[1] protein products are 14235 and 14104 Da, respectively (average masses, unprotonated state). The peak marked with an asterisk (14 316 Da) is a matrix adduct of the 14 107 Da species.

Table 1. N-Terminal Cysteine Proteins Produced with a Common N-Terminal Tag[a]

protein expressed	calculated mass (Da)	observed mass (Da)
His6-SHP2C	14 235 (14 104)	14 106
His6-SHP2N	13 501 (13 370)	13 370
His6-SOCS7	17 461 (17 330)	17 328

[a] Each expressed protein encoded the common N-terminal sequence MCRHHHHHHGARQ. Calculated average masses are shown for protein products with the N-terminal methionine residue and without (in parentheses).

The alternate culture conditions were used to express an SHP2C construct containing the modified N-terminal tag sequence MCRHHHHHHGARQ (hereafter referred to as His6-SHP2C to distinguish it from the earlier sample). Following affinity purification of the protein, analysis of the product by MALDI-TOF MS showed that the terminal methionine residue had been completely removed (Figure 2). Moreover, the optimized expression protocol and modified N-terminal sequence led to a dramatic improvement in the homogeneity of the purified product. Although the yield of purified protein was lower than previously attained (7 mg from a 400 mL culture), most likely due to the shorter culture time and absence of glucose supplement, there was no detectable evidence of chemical modification to the N-terminal cysteine, nor of its cleavage from the protein.

To determine whether methionine would be cleaved from other proteins produced in the same way, we expressed two additional SH2 domain-containing protein fragments with the same N-terminal tag sequence (Table 1). Each protein was affinity purified from bacterial lysates and analyzed by HPLC and MALDI-TOF MS following reduction with DTT (Table 1). Methionine was completely excised for each of these proteins, and there was no detectable modification or cleavage of the N-terminal cysteine residue. Thus, the N-terminal methionine residue was cleaved for three different proteins produced in *E. coli* with cysteine as the second amino acid.

Table 2. Production of N-Terminal Cysteine Native Sequence Proteins

protein expressed	N-terminal sequence	calculated mass (Da)[a]	observed masses (Da)
SHP2C-His6	MCERWFHG	13 879 (13 747)	13 746, 13 777,[b] 13 819
SHP2N-His6	MCSRRWFH	13 057 (12 925)	12 829, 12 931, 12 960,[b] 13 002
SOCS7-His6	MCLYRPDS	17 249 (17 118)	17 129

[a] Calculated average masses are shown for protein products with the N-terminal methionine residue and without (in parentheses). [b] Observed ion was broad, centered on the mass indicated.

Production of N-Terminal Cysteine Native Sequence Proteins. While proteins containing N-terminal cysteine and polyhistidine tag sequences would be suitable for many applications requiring site-specific labeling, they would not be suitable for protein semisynthesis. For this application, proteins or protein fragments with native sequence downstream of an N-terminal cysteine residue are required. To determine whether methionine cleavage would occur for proteins containing native sequence downstream of methionine and cysteine as the first two amino acids, we recloned the proteins from Table 1 into a vector lacking the N-terminal polyhistidine tag. The new constructs encoded protein products with native sequences beginning at codon 3, that is, downstream of Met-Cys- in the first two positions (Table 2). These expression constructs contained a C-terminal hexahistidine tag to aid in purification of the recombinant products.

Following expression in *E. coli* using the optimized conditions previously described, proteins were affinity purified and analyzed by MALDI-TOF MS after DTT reduction (Table 2). We did not detect any retention of methionine for each of the three proteins. However, in additional to the N-terminal cysteine products, there was evidence of significant low molecular weight modification for two of the proteins, similar to that observed in our initial studies. Analysis of these two samples by reverse phase HPLC, which partially resolved modified from unmodified proteins, indicated that 40−60% of each protein was modified. Mass analysis of the modified species showed a similar profile to that seen earlier, that is, a prominent broad molecular ion centered on a mass approximately 30 Da higher than that of the N-terminal cysteine product. In addition to this modification, we detected minor secondary cleavage of the N-terminal cysteine residue in the case of the SHP2N-His6 protein, but not of the other two proteins. This was again consistent with the substrate specificity of methionine aminopeptidase. While the third amino acid was small in the case of SHP2N-His6 (Ser), the other two proteins contained bulkier amino acids at this position (Glu and Leu).

Reversal of N-Terminal Cysteine Modification. Chemical modification of the amino terminus appeared to be a recurring problem limiting the direct production of N-terminal cysteine proteins. While careful optimization of the culture conditions could be used to limit or eliminate this side reaction, we investigated whether the cysteine modification could be chemically reversed.

Formation of thiazolidines by condensation of ketones or aldehydes with the 1,2-amino thiol group of N-terminal cysteine is a reversible reaction, and the free cysteine moiety can be regenerated by covalent trapping of the ketone/aldehyde compound. Thus, if the modification observed in these studies was due to reaction with a metabolite such as pyruvic acid, then treatment with a trapping reagent should regenerate the terminal cysteine residue. To test this, an HPLC-enriched fraction of the modified SHP2N-His6 protein was treated with *O*-methylhydroxylamine, an aminoxy-containing reagent that reacts with ketones and aldehydes to form oximes. Incubation at room temperature for several hours resulted in significant conversion of the modified protein into the free cysteine-containing product (Figure 3). This result demonstrated two important points. First, that the chemical modification was most likely due to reaction of the N-terminal cysteine residue with a ketone (or aldehyde)-containing metabolite. Second, the modification can be reversed to regenerate the N-terminal cysteine. Treatment with *O*-methylhydroxylamine therefore provides a facile way of reversing the amino terminal modification and increasing the yield of N-terminal cysteine protein.

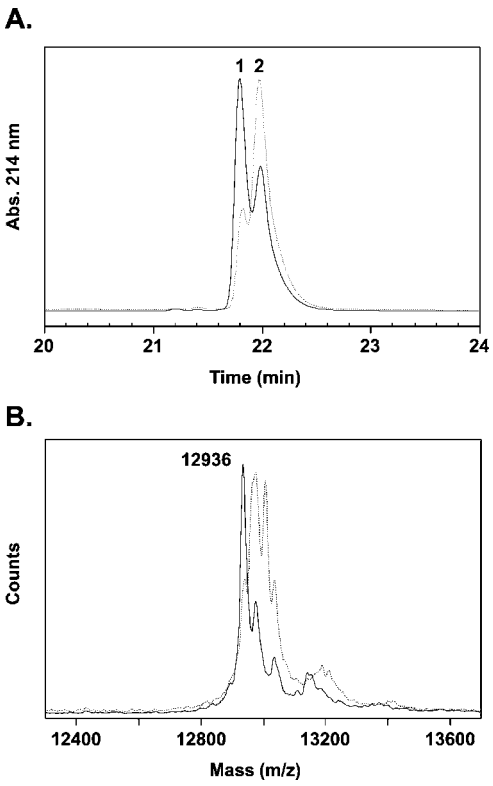

Figure 3. Chemical reversal of N-terminal cysteine modification. A sample of modified SHP2N-His6 protein was partially purified by HPLC and treated with *O*-methylhydroxylamine for 5 h to reverse the modification to the N-terminal cysteine residue. (A) Analytical HPLC traces of untreated (dashed trace) and treated (unbroken trace) protein samples. Peak 1 corresponds to the N-terminal cysteine protein, while peak 2 is the modified species. (B) MALDI-TOF MS analysis of untreated (dashed trace) and treated (unbroken trace) samples. The *O*-methylhydroxylamine-treated sample was analyzed after desalting a small aliquot of the crude reaction mixture with a C4 ZipTip pipet tip.

Site-Specific N-Terminal Labeling with Fluorescein. To confirm that N-terminal cysteine proteins generated in this way are able to react with thioester-containing compounds via native chemical ligation, we prepared a water soluble thioester derivative of fluorescein, a fluorescent agent commonly used to label proteins. Commercially available carboxyfluorescein succinimidyl ester was converted to the ethylsulfonate thioester (fluorescein-2MES) by treatment with sodium 2-mercaptoethanesulfonate. Treatment of the N-terminal cysteine-containing protein His6-SHP2C (Table 1) with fluorescein-

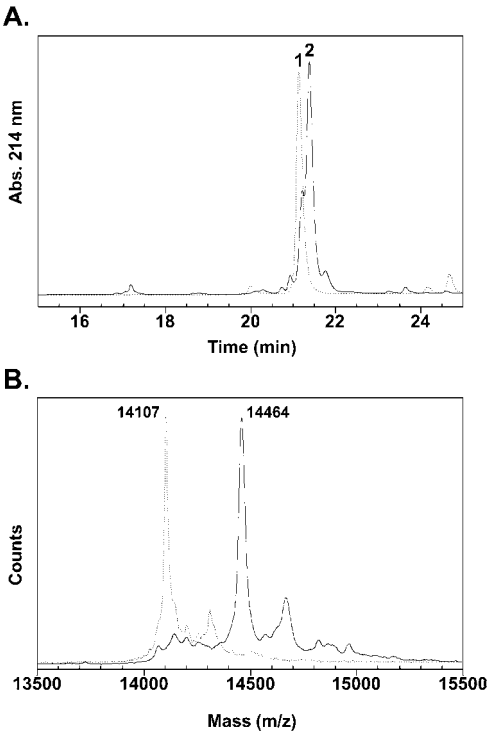

Figure 4. Native chemical ligation of a thioester-containing fluorescein derivative. Fluorescein-2MES, a thioester containing derivative of fluorescein, was ligated onto the amino terminus of the N-terminal cysteine protein His6-SHP2C. (A) Analytical HPLC trace of the ligation mixture after 5 h reaction (unbroken trace). For comparison, the HPLC trace of an unligated protein sample is also shown (dashed line). Peak 1 corresponds to the starting N-terminal cysteine protein, while peak 2 is the ligation product. (B) MALDI-TOF MS analysis of fluorescein-ligated His6-SHP2C. A sample of the crude ligation mixture was desalted with a C4 ZipTip pipet tip after 5 h reaction time and analyzed by MALDI-TOF MS. The observed mass of the major product (14464 Da, $[M + H]^+$ ion), corresponds to the addition of a single carboxyfluorescein molecule. The MALDI-TOF MS spectrum of the unligated protein is shown by dashed trace.

2MES resulted in rapid and specific labeling with a single molecule of fluorescein (Figure 4). Interestingly, we did not find it necessary to add thiol cofactors such a thiophenol or benzylmercaptan to this reaction mixture (*2*), suggesting that the ethylsulfonate thioester was sufficiently activated to achieve an adequate ligation rate, at least for this small molecule reactant. We did detect some side reactions which we attributed to formation of unwanted disulfides and/or thioester adducts; however, these were easily reversed upon addition of DTT (data not shown). Digestion of the ligated product with trypsin, followed by mass spectrometric analysis, confirmed that the modifying fluorescein group was located on the amino terminal Cys-Arg dipeptide tryptic fragment as expected (data not shown).

DISCUSSION

In this study, we found that heterologous expression in *E. coli* of proteins containing cysteine as the penultimate amino acid yielded mature products devoid of the initiating methionine residue. The side chain of cysteine is intermediate in size among the 20 amino acids found in proteins, and there have been conflicting reports as to the degree of methionine cleavage for proteins containing an adjacent cysteine residue. While one study claimed that processing efficiency was 100% (*14*), another claimed that cleavage was only partial (*15*). While these differences may have been specific to the proteins and/or expression systems under investigation, it is important to note that the latter study used Edman sequencing to quantitate the extent of methionine excision. Given we observed partial chemical modification of the N-terminal residue cysteine, it is possible that Edman sequencing would underestimate the amount of methionine excision.

Although we observed complete cleavage of N-terminal methionine for the proteins studied here, two side reactions initially limited the yield of target N-terminal cysteine protein. The first of these was a low level of additional N-terminal processing when the third amino acid residue was a serine. While there are no reports of methionine aminopeptidase having this activity, we suspect this enzyme was responsible for N-terminal cysteine cleavage, as excision only occurred for expressed proteins containing serine as the third encoded amino acid, but not the larger amino acids arginine, leucine, or glutamic acid. This may be a general problem when the third residue is a small side chain amino acid. Indeed Iwai et al. (*17*) noted partial cleavage of N-terminal cysteine for a protein containing an adjacent alanine residue. The second side reaction appeared to result from modification of the N-terminal cysteine residue by a low molecular weight metabolite. While it may be difficult to completely eliminate this side reaction, we found that optimization of the media and culture conditions suppressed the degree of modification. In addition, treatment of the recombinant product with *O*-methylhydroxylamine was shown to reverse the modification. While some degree of N-terminal heterogeneity may be acceptable depending on the application, the purity of the N-terminal cysteine product can be improved by use of optimized culture conditions, selection of protein sequences containing a large side chain amino acid at the third position, and/or treatment with a ketone trapping agent such as *O*-methylhydroxylamine. In addition, covalent capture chromatography using aldehyde-derivatized resin could also be used to selectively purify the N-terminal cysteine protein if highly pure preparations are required (*19*).

We did not investigate whether the expressed proteins were being produced in a soluble or insoluble form in *E. coli*; thus, we cannot comment on the dependence of methionine excision on the solubility of the protein. However, methionine processing has been reported to occur cotranslationally, that is, before synthesis of the protein chain is complete (*11*−*13*). Thus, the solubility of the final protein product is unlikely to have an effect on methionine excision. This fact may be of considerable advantage in using native chemical ligation for the semisynthesis of proteins. Subdomain protein fragments, which may have low intrinsic solubility, could be directly produced with the requisite N-terminal cysteine residue following extraction from inclusion bodies and purification under denaturing conditions. This product could then be ligated to a synthetic peptide fragment under denaturing conditions. By contrast, production of the same fragment by proteolytic cleavage of a fusion protein precursor may be difficult if this molecule has poor solubility in buffers compatible with the site-specific protease.

In conclusion, we have demonstrated the feasibility of directly producing N-terminal cysteine proteins in *E. coli*. This represents a significant advantage over methods which involve cleavage of fusion proteins and will hopefully make chemical ligation methods more amenable to recombinantly produced proteins.

Received February 13, 2004

The bacterial cell surface layer (S-layer) protein of *Bacillus sphaericus* CCM 2177 assembles into a square lattice structure and recognizes a distinct type of secondary cell wall polymer (SCWP) as the proper anchoring structure in the rigid cell wall layer. For generating a nanopatterend sensing layer with high density and well defined distance of the ligand on the outermost surface, an S-layer fusion protein incorporating the sequence of a variable domain of a heavy chain camel antibody directed against prostate-specific antigen (PSA) was constructed, produced, and recrystallized on gold chips precoated with thiolated SCWP. The S-layer protein moiety consisted of the N-terminal part which specifically recognized the SCWP as binding site and the self-assembly domain. The PSA-specific variable domain of the camel heavy chain antibody was selected by several rounds of panning from a phage display library of an immunized dromedary, and was produced by heterologous expression in *Escherichia coli*. For construction of the S-layer fusion protein, the 3′-end of the sequence encoding the C-terminally truncated form $rSbpA_{31-1068}$ was fused via a short linker to the 5′-end of the sequence encoding cAb-PSA-N7. The S-layer fusion protein had retained the ability to self-assemble into the square lattice structure. According to the selected fusion site in the SbpA sequence, the cAb-PSA-N7 moiety remained located on the outer surface of the protein lattice. After recrystallization of the S-layer fusion protein on gold chips precoated with thiolated SCWP, the monomolecular protein lattice was exploited as sensing layer in surface plasmon resonance biochips to detect PSA.

INTRODUCTION

Crystalline bacterial cell surface layers (S-layers) can be considered one of the most common surface structures in prokaryotic cells (*1*−*5*). S-Layers of bacteria and archaea are composed of identical protein or glycoprotein subunits, which completely cover the cell surface during all stages of bacterial growth and division. The S-layer subunits can be aligned in lattices with oblique, square, or hexagonal symmetry with a center-to-center spacing of the morphological units of approximately 3 to 35 nm. In bacteria, the S-layer subunits are linked to each other and to the underlying cell envelope layer by noncovalent interactions. In the case of *Bacillaceae*, the N-terminal part is involved in anchoring the S-layer subunits to the rigid cell wall layer via a distinct type of secondary cell wall polymer (SCWP) (*5*−*10*). The polymer chains are covalently linked to the peptidoglycan backbone. Because many S-layer subunits self-assemble in suspension or recrystallize into regularly structured monolayers on solid supports, such as noble metals, plastics, or silicon wafers, as well as on Langmuir lipid films, on liposomes, and at the air−water interphase, they can be considered as unique biomaterials with properties most relevant for applications in molecular nanotechnology, nanobiotechnology, and biomimetics (*1*−*3*).

The S-layer protein of *Bacillus sphaericus* CCM 2177 assembles into a square lattice with a center-to-center spacing of the morphological units of 13.1 nm. On SDS-gels, this S-layer protein migrates as a single band with an apparent relative molecular mass of 127 000. The gene encoding SbpA has been sequenced, cloned in plasmid pET28a, and expressed in *Escherichia coli* HMS174(DE3) (*11*). The protein precursor includes a 30 amino acid long typical Gram-positive signal peptide and consists of total of 1268 amino acids. Since the N-terminal part of SbpA carries an S-layer homologous (SLH)-domain which is required for binding of the S-layer subunits to the SCWP, the surface accessibility of selected amino acid positions in the C-terminal part was investigated after fusion of the short affinity peptide *Strep*-tag I (STI) for binding of streptavidin. In comparison to the entire SbpA ($rSbpA_{31-1268}$), the C-terminally truncated form $rSbpA_{31-1068}$ showed a significantly increased accessibility of the C-terminal end. Despite the deletion of 200 C-terminal amino acids, $rSbpA_{31-1068}$/STI was still capable of self-assembling into the square lattice structure. Since the fused *Strep*-tag I remained located on the outer surface

of the protein lattice, $rSbpA_{31-1068}$ was used as base form for the construction of various S-layer fusion proteins.

The S-layer protein SbpA recognizes a distinct type of SCWP consisting of eight to nine disaccharide repeating units as the proper anchoring structure in the rigid cell wall layer. As described in a previous study, the SCWP can be exploited for an oriented binding of rSbpA-fusion proteins on solid supports to generate regularly structured functional protein lattices (*12*).

The *Camelidae* is the only taxonomic family known to possess functional heavy chain antibodies lacking light chains. These unique antibody isotypes interact with the antigen by virtue of a single variable domain, termed VHH. The variable domain of a camel heavy chain antibody is the smallest known complete antigen binding fragment from a functional immunoglobulin. The single domain nature of VHHs gives rise to several unique features as compared to antigen-binding derivatives of conventional antibodies. Besides the advantage of single gene cloning and selection from an in vivo matured library, recombinant VHHs have other technological, functional, and physicochemical advantages, such as (i) high expression yields and ease of purification, (ii) a highly soluble and stable single domain immunoglobulin fold, (iii) the generation of antigen-specific, high-affinity binders, (iv) the recognition of unique conformational epitopes with the dominant involvement of its enlarged variable region CDR3, and (v) the close homology to human VH fragments (*13, 14*). These features can be expected to lead to a number of applications in which VHHs perform better than conventional antibody fragments, e.g., as enzyme inhibitors, as modular building units for multivalent or multifunctional constructs or as immunoadsorbents and detection units in biosensors (*13, 14*).

The prostate-specific antigen (PSA) is a useful marker to screen potential prostate cancer patients. The current diagnostic test systems determine the concentration of total PSA with monoclonal antibodies that recognize free as well as PSA complexed with α-1-anti-chymotrypsin (ACT). For the employment of a VHH in a PSA biosensor, VHHs that recognize free and complexed PSA are required. Moreover, the kinetic requirements in the biosensor impose a high probe density that can probably only be obtained with single domain VHHs.

For generating a monomolecular protein lattice capable of binding PSA on the outermost surface in high density, an S-layer fusion protein incorporating the VHH domain of a heavy chain camel antibody directed against PSA was constructed and the sequence encoding the fusion protein heterologously expressed in *E. coli*. After recrystallization of the S-layer fusion protein on gold chips precoated with thiolated SCWP, the monomolecular protein lattice was exploited as sensing layer in surface plasmon resonance (SPR) biochips.

MATERIALS AND METHODS

Immunization of a Dromedary for Generating PSA Binding Antibodies and Fractionation of IgG Subclasses. One male dromedary (*Camelus dromedarius*) kept at the Central Veterinary Research Laboratories (Dubai, United Arabic Emirates) was injected seven times subcutaneously at weekly intervals with 500 μg of highly purified PSA, mixed in Gerbu adjuvans. Forty-five days after beginning of immunization, 100 mL of anticoagulated blood was collected, from which plasma and peripheral blood lymphocytes were isolated with a lymphocyte preparation kit from WAK (WAK, Chemie, Steinbach, Germany).

Separation of the different plasma immunoglobulin G (IgG) subclasses was performed by differential adsorption on Hitrap-proteinA and Hitrap-proteinG columns (Pharmacia). The IgG3 and IgG1 subclasses were eluted from the proteinG column with sodium acetate buffer (pH 3.5) and glycine-HCl buffer (pH 2.7), respectively. The flow-through was subsequently loaded onto the Hitrap-proteinA column to recover the IgG2 subclass during elution with acetate buffer (pH 3.5).

Construction of a Library and Selection of PSA Specific Antibody Fragments. The mRNA was extracted from the peripheral blood lymphocytes (*15*). In a subsequent step, the cDNA was prepared using Ready-to-Go beads (Pharmacia). The gene fragments encoding the variable domain until the CH2 domain were amplified with the specific primers CALL001 (5′-GTC CTG GCT CTC TTC TAC AAG G-3′) and CALL002 (5′-GGT ACG TGC TGT TGA ACT GTT CC-3′), which anneal at the leader sequence and at the CH2 exon of the heavy chains of all dromedary immunoglobulins, respectively. After reamplification of the VHH gene fragments with nested primers annealing at the framework1 and framework4 regions (*15*), the final PCR fragments were cloned into the phagemid vector pHEN4, using the restriction sites *Pst*I and *Not*I. The VHH library was expressed on phages after infection with M13K07 helper phages. Specific VHHs against PSA were enriched by three consecutive rounds of in vitro selection on biotinylated PSA captured on an ELISA plate coated with 10 μg of Neutravidin (PIERCE) per well. Bound phage particles were eluted with 100 mM triethylamine (TEA, pH 10.0). Solutions containing eluted particles were immediately neutralized with 1 M Tris-HCl buffer (pH 7.4) and used to infect exponentially growing *E. coli* TG1 cells. The enrichment of phage particles carrying the antigen-specific VHHs was assessed by comparing the number of eluted phages from antigen-coated versus non-antigen-coated wells. After the second and third round of panning, individual colonies were picked up and expression of genes encoding VHHs was induced by the addition of 1 mM isopropyl-β-D-thiogalactopyranoside (IPTG). The recombinant VHH extract from the periplasm was tested for antigen recognition in ELISA (*15*).

Expression and Purification of Antibody Fragments. The VHH genes of the clones that scored positive in ELISA were recloned into the expression vector pHEN6, using the restriction enzymes *Pst*I and *BstE*II. The plasmid constructs were transformed into *E. coli* WK6(su^-) cells. Production of recombinant VHHs was performed in shaking flasks by growing the bacterial culture in Terrific Broth supplemented with 0.1% glucose and ampicillin. When the optical density measured at 600 nm was between 0.6 and 0.9, expression was induced by the addition of 1 mM IPTG. Cultures were then incubated for 16 h at 28 °C. After pelleting the cells, the periplasmic proteins were extracted by osmotic shock and the extract was loaded onto a Ni-nitrilotriacetic acid (Ni−NTA) Superflow Sepharose column (Qiagen). After being washed, the bound proteins were eluted with sodium acetate buffer (pH 4.7). The eluted fraction was concentrated on Vivaspin concentrators with a molecular mass cut off of 5 kDa (Vivascience), and the purity was checked by SDS−PAGE.

Solid-Phase ELISA for the Detection of PSA-Specific Phages. Maxisorb 96-well plates (Nunc, Maxisorb) were coated with Neutravidin or the PSA-specific monoclonal antibody 3E6 (DIAMED) at a concentration of 5 μg/mL in phosphate-buffered saline (PBS) overnight at 4 °C. Residual sites were blocked for 2 h at room

temperature with 1% (wt/vol) casein in PBS. After incubation with biotinylated PSA (1 μg/mL), serial dilutions of purified IgG subclasses, phages from different rounds of panning, or soluble VHHs were added. Detection was performed with a rabbit anti-dromedary IgG antiserum, a horseradish peroxidase-anti-M13 conjugate (Pharmacia), a mouse anti-hemagglutinin decapeptide tag (BAbCO), or an anti-His tag antiserum (Serotec), respectively. The absorption at 405 nm was measured 15 min after the addition of the substrate *p*-nitrophenyl phosphate (p-NPP, Sigma).

Further Characterization of cAb-PSA-N7 by Epitope Mapping by Means of ELISA and Affinity Measurements by Surface Plasmon Resonance (SPR). Either Neutravidin (5 μg/mL) or the PSA-specific monoclonal antibody 3E6 (5 μg/mL) were coated on ELISA plates, followed by the addition of 1 μg/mL biotinylated or nonbiotinylated PSA or PSA−ACT complex. Bound VHHs were detected with an anti-His tag monoclonal antibody or Nickel Express Doctor (Killguard Laboratories), respectively.

Affinity measurements were assessed by the addition of different concentrations of PSA to purified His-tailed VHHs coated on a Ni−NTA-biochip (Biacore) according to the manufacturer's descriptions. The kinetic parameters and K_D were determined with the BIAevaluation software (Biacore).

Cloning of the Chimeric Gene Encoding the Fusion Protein rSbpA$_{31-1068}$/cAb-PSA-N7. All PCR reactions were performed as described by Jarosch et al. (*16*). The sequence encoding the C-terminally truncated form rSbpA$_{31-1068}$ was PCR amplified from chromosomal DNA of *B. sphaericus* CCM 2177 by using the oligonucleotide primers *sbpA*/*Nco*I [5'-CG GAT T**CC ATG G**CG CAA GTA AAC GAC TAT AAC AAA ATC-3'] and *sbpA*/*Nhe*I [5'-GAC CGC **GCT AGC** TTC TGA ATA TGC AGT AGT TGC TGC C-3'], which introduced the restriction sites (bold) *Nco*I or *Nhe*I. The *cAb-PSA-N7* sequence was amplified from plasmid *cAb-PSA-N7*-pHEN6 by using the oligonucleotide primers *cAb*/*Nhe*I [5'-CGG ATT **GCT AGC** GAT GTG CAG CTG CAG GAG-3'] and *cAb*/*Xho*I [5'-GAC CG**C TCG AG**T TAT GAG GAG ACG GTG ACC TGG G-3'], which introduced the restriction sites *Nhe*I or *Xho*I. To obtain plasmid pET28a−*sbpA*$_{(93-3204)}$, the gel-purified PCR product *sbpA*$_{(93-3204)}$ was ligated into the corresponding restriction sites of plasmid pET28a, which was established in *E. coli* TG1. For generating the chimeric *sbpA*$_{(93-3204)}$/*cAb-PSA-N7* gene, the gel-purified PCR product *cAb-PSA-N7,* encoding the VHH domain of the camel antibody directed against PSA, was ligated into the corresponding restriction sites of plasmid pET28a−*sbpA*$_{(93-3204)}$. This was used for transformation of *E. coli* TG1.

Expression of the Chimeric *sbpA*$_{(93-3204)}$/*cAb-PSA-N7* Gene and Isolation of the S-Layer Fusion Protein from the Host Cells. The plasmid stability test and heterologous expression of the *sbpA*$_{(93-3204)}$/*cAb-PSA-N7* gene in *E. coli* One Shot BL21 Star (DE3) (Invitrogen) were performed as described by Jarosch et al. (*16*). Samples of the *E. coli* One Shot BL21 Star cultures were taken 1 to 5 h after induction of *sbpA*$_{(93-3204)}$/*cAb-PSA-N7* gene expression by the addition of 1 mM IPTG (Gerbu). Preparation of samples for SDS−PAGE analysis was carried out as described by Laemmli (*17*). For electron microscopic investigation, whole cells of *E. coli* One Shot BL21 Star (DE3) were prepared as described (*18*).

Isolation of the S-layer fusion protein from *E. coli* One Shot BL21 Star (DE3) cells induced to express the *sbpA*$_{(93-3204)}$/*cAb-PSA-N7* gene and purification by gel permeation chromatography (GPC) was performed as described (*19*) except that DNA was degraded by DNAse treatment. For that purpose, the insoluble pellet obtained after sonification of whole cells and centrifugation of the suspension was treated with a solution of 1 mg/mL DNAseI (Roche) in 100 mM $MgCl_2 \cdot 7H_2O$ in MilliQ-water. For removal of residual DNAseI, the pellet was washed twice with 1% Triton X-100 in 50 mM Tris-HCl buffer (pH 7.2) and 50 mM Tris-HCl buffer (pH 7.2). After the pellet was resuspended in 4 mL of 5 M guanidine hydrochloride (GHCl) in 50 mM Tris-HCl buffer (pH 7.2) and centrifugation, the clear supernatant was subjected to GPC. Fractions eluting at a molecular mass of ~123 000 Da expected for rSbpA$_{31-1068}$/cAb-PSA-N7 were pooled, dialyzed against distilled water for 18 h at 4 °C, lyophilized, and stored at −20 °C. Immunoblotting using a polyclonal rabbit antiserum raised against the S-layer protein of *B. sphaericus* CCM 2177 and a polyclonal rabbit anti-camel antiserum (Sigma C7540) was performed as described (*19, 20*).

Investigation of the Self-Assembly Properties of the S-Layer Fusion Protein and Recrystallization on Peptidoglycan-Containing Sacculi. The production of self-assembly products as well as recrystallization of the S-layer fusion protein on peptidoglycan-containing sacculi was performed as described (*19*). Peptidoglycan-containing sacculi carrying a monolayer of recrystallized S-layer fusion protein are referred to as recrystallization products in all further experiments. To keep the S-layer fusion protein water-soluble, the GHCl-extract was dialyzed against 1 mM 1,4-dithio-DL-threitol (DTT) in MillQ-water.

Dot Blot Assays for Investigating the Accessibility of the Fused cAb-PSA-N7. To investigate the accessibility of the fused cAb-PSA-N7 in the water-soluble, self-assembled, or recrystallized S-layer fusion protein, 5 μL samples with an S-layer protein content of 1 mg/mL were dried onto a nitrocellulose membrane. Plain rSbpA (1 mg/mL) was taken as blank and patient serum containing PSA (diluted 1:20 in TBS) was used as positive control. Dot blot assays were carried out as described in a previous study (*19*). For binding of PSA, the membrane was incubated with 20 ng of PSA from patient serum in 20 mL of blocking solution (2% Top Block (Fluka) in TBS) for 1 h at 20 °C. To detect PSA, the monoclonal mouse antibody 3E6 raised against PSA (1.38 mg/mL; diluted 1:2000 in blocking solution) was used.

Binding of cAb-PSA-N7 and the S-Layer Fusion Protein rSbpA$_{31-1068}$/cAb-PSA-N7 to a CM5 SPR Sensor Chip with Immobilized PSA. SPR experiments were performed using a Biacore 2000 system (Biacore, Sweden). For covalent binding of PSA on a CM5 sensor chip (Biacore, Sweden), the carboxylic groups on the CM5 matrix were activated by injecting a mixture containing 0.1 M *N*-hydroxysuccinimide (NHS, Fluka) and 0.4 M 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (EDC, Sigma) for 7 min at a flow rate of 5 μL/min. Subsequently, a PSA (Scipac, UK) solution was passed over the surface with an appropriate reaction time, followed by a 7 min injection of 1 M ethanolamine-HCl solution (pH 8.5) to block nonreacted activated groups. The amount of covalently bound PSA was expressed in terms of resonance units (RU; 1000 RU correspond to approximately 1 ng/mm^2). For investigation of the affinity to immobilized PSA, cAb-PSA-N7 and the S-layer fusion protein, 1 μg/mL and 100 μg/mL, respectively, in HBS buffer (10 mM Hepes, 150 mM NaCl, 3

mM EDTA, 0.005% Tween) pH 7.2, were conducted over the chip with a flow rate of 2 μL/min. Afterward, four steps of regeneration with 10 mM glycine-HCl buffer (pH 2.2) were performed to ensure the removal of noncovalently bound proteins. To generate reference surfaces, all experiments were performed as described above with the exception that no PSA was supplied.

Recrystallization of rSbpA$_{31-1068}$/cAb-PSA-N7 on Gold Chips Precoated with Thiolated SCWP and Evaluation by Atomic Force Microscopy (AFM). Coating of gold chips (silicon ⟨100⟩ , coated with 1 nm Ti and 60 nm Au) with an area of 1 cm^2 with thiolated SCWP and recrystallization of the S-layer fusion protein was done as described (*19*). A Nanoscope III AFM (Digital Instruments, Santa Barbara, CA) equipped with a liquid cell and a 120 μm scanner and oxide-sharpened Si_3N_4 tips (NanoProbes, Digital Instruments, Santa Barbara, CA) with a nominal spring constant of 0.06 N/m was used for all AFM investigations. Imaging of recrystallized rSbpA$_{31-1068}$/cAb-PSA-N7 was carried out in contact mode in liquid (100 mM NaCl). Height and deflection signals were recorded simultaneously (error signal mode). The applied force was kept at a minimum in order not to destroy the sample. The scan rate was 5.1 Hz at a scan size of 1 by 1 μm.

Investigation of the PSA Binding Capacity of the rSbpA$_{31-1068}$/cAb-PSA-N7 Monolayer Obtained by Recrystallization of this S-Layer Fusion Protein on SCWP-Coated Gold Chips by SPR. The S-layer fusion protein was recrystallized on SCWP-coated gold chips (Biacore, Sweden) at a concentration of 100 μg/mL for 25 min at a flow rate of 1 μL/min. For reference studies, rSbpA$_{31-1068}$ was used. Patients' sera containing PSA (diluted 1:5 in HBS buffer to obtain a final concentration of 20 ng/mL) were injected. To verify specific binding of PSA, a solution of female blood serum (200 μL) was injected. During the reaction time, a continuous flow of HBS buffer (10 μL/min) was maintained over the sensor surface. The contact and dissociation time for PSA was 40 min and 800 s, respectively.

RESULTS

Immunization of a Dromedary with PSA for Provoking a Humoral Response. A dromedary received seven injections with purified PSA. Forty-five days after the first injection, blood was drawn and the immunoglobulins were purified from its plasma by differential adsorption on proteinA and proteinG columns. The immune response in subclasses IgG1, IgG2, and IgG3 was assessed by ELISA. Starting from 5 μg/mL, serial dilutions of purified IgG1, IgG2, and IgG3 were used in a solid-phase ELISA with biotinylated PSA captured onto a Neutravidin coat. Bound IgG was subsequently detected with rabbit anti-dromedary IgG antiserum (Figure 1).

An antigen-specific response was observed for heavy chain antibodies (IgG2 and IgG3) and conventional antibodies (IgG1) (*21*).

Construction of a Library and Selection of PSA Specific Antibody Fragments. A library was constructed starting from 1.5 $\times$ 10^7 lymphocytes. After extraction of mRNA, cDNA was prepared and the genes coding for the variable domains of the immunoglobulins were amplified. The final *VHH* gene product was ligated into the phagemid vector pHEN4. A *VHH* library of 1.5 $\times$ 10^7 individual transformants was obtained when 3 μg of vector was transformed. As determined by PCR, 90% of the clones within the library carried a *VHH* gene insert

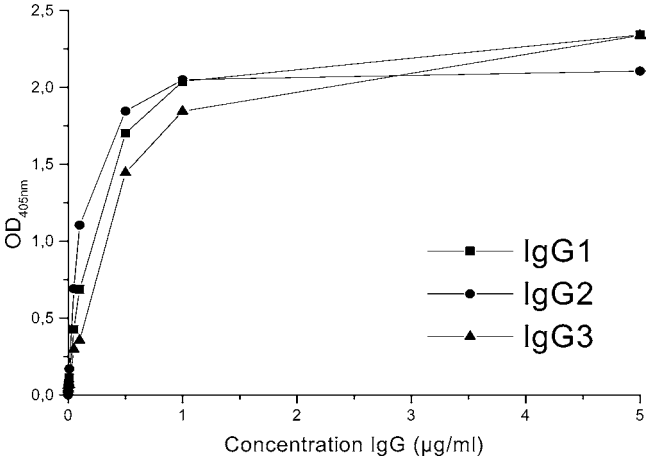

Figure 1. Analysis of antigen-specific antibodies. Solid-phase ELISA for detection of serial dilutions of fractionated IgG against PSA. Biotinylated PSA (1 μg/mL) was captured onto 5 μg/mL Neutravidin coating. Bound IgG1 (■), IgG2 (●), and IgG3 (▲) was detected with rabbit anti-dromedary IgG antiserum.

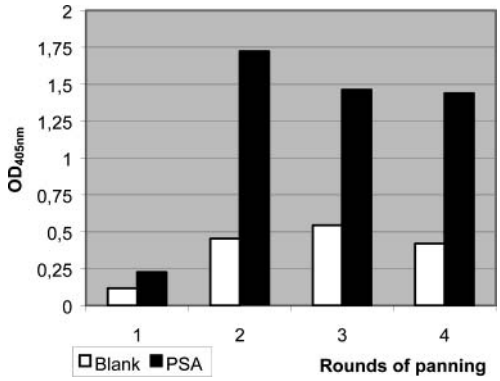

Figure 2. Enrichment of PSA-specific virons by consecutive rounds of in vitro selection. Solid-phase ELISA for detection of antigen-specific phages from different rounds of panning. Biotinylated PSA (1 μg/mL) was captured on 5 μg/mL Neutravidin coating. Virons (10^9) of the library (1), after the first (2), after the second (3) and the third round (4) of panning were loaded onto the antigen. Bound phages were detected with anti-M13 horse-radish peroxidase conjugate.

of proper size. The *VHH* repertoire from the library was expressed on phages after infection with helper phages M13K07. Three rounds of in vitro selection or panning were performed on biotinylated PSA captured by a Neutravidin coat. After being extensively washed, bound phages were eluted with TEA. The enrichment factors were calculated in two different ways. First, it was calculated as the ratio of the number of PSA specific colonies to the number of nonspecific colonies. An enrichment was observed in the second round, with the maximum enrichment after the last round of selection. Second, the enrichment was also assessed in solid-phase phage ELISA adding 10^9 virons per well (Figure 2).

From the corrected signals ($OD_{PSA} - OD_{Blank}$), the best ratio (specific to nonspecific) was found after the second round of panning. In total, 25 different VHHs binding specifically to PSA were isolated. For the present study, the specific binder cAb-PSA-N7 was selected.

Further Characterization of cAb-PSA-N7 by Epitope Mapping and Affinity Measurements. The epitope region recognized by cAb-PSA-N7 was mapped in ELISA. Binding of the VHH was tested on different forms of PSA, such as free PSA and PSA complexed with ACT. Both forms were captured onto either the 3E6

Table 1. Different Characteristics of the PSA-Specific Single Domain Antibody, cAb-PSA-N7[a]

	binding to free PSA	binding to PSA−ACT	binding to biotinylated PSA	K_D (nM)
cAb-PSA-N7	+	+	+	0.09

[a] Recognition of free PSA, PSA complexed with ACT (PSA−ACT), and biotinylated PSA by cAb-PSA-N7 was assessed by solid-phase ELISA. The dissociation constant (K_D) was calculated from the kinetic constants measurements by SPR.

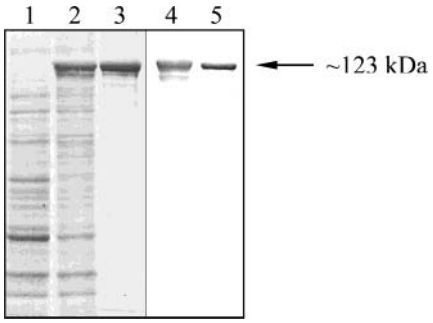

Figure 3. SDS−PAGE patterns (lanes 1−3) of SDS-extracts of whole cells of *E. coli* One Shot BL21 Star cells harboring the vector pET28a containing the *sbpA*$_{(93-3204)}$*/cAb-PSA-N7* gene construct, before (lane 1) and 5 h (lane 2) after induction of gene expression. Lane 3: SDS-extracts of GPC purified rSbpA$_{31-1068}$/cAb-PSA-N7. Immunoblot analysis (lanes 4 and 5) of SDS-extracts of GPC purified rSbpA$_{31-1068}$/cAb-PSA-N7. The presence of the SbpA-portion was detected with anti-SbpA antiserum and anti-rabbit IgG-alkaline phosphatase conjugate (lane 4). The presence of the cAb-PSA-N7 moiety was checked with anti-dromedary IgG antiserum and anti-rabbit IgG-alkaline phosphatase conjugate (lane 5).

monoclonal antibody or after biotinylation onto Neutravidin. Since binding of cAb-PSA-N7 was observed on PSA captured by 3E6 as well as on the PSA-ACT complex (Table 1), the results indicated binding onto a region of PSA different from its interaction site with ACT and from the epitope region recognized by 3E6. To further characterize its binding properties, the kinetic constants of cAb-PSA-N7 for PSA were measured by SPR on Biacore 3000 and the dissociation constant (K_D) was calculated accordingly (Table 1). Because of its high affinity, the specific binder cAb-PSA-N7 was selected out of 25 different binders (Saerens et al., unpublished data).

Cloning and Expression of the Gene Encoding rSbpA$_{31-1068}$/cAb-PSA-N7 and Isolation of the S-Layer Fusion Protein from the Host Cells. The PCR product obtained by amplification of the *sbpA* gene using the primers *sbpA*/*Nco*I and *sbpA*/*Nhe*I which encoded the truncated form of the S-layer protein SbpA (rSbpA$_{31-1068}$) was ligated into the pET28a vector. After transformation of *E. coli* TG1, amplification and isolation of the plasmid pET28a−*sbpA*$_{(93-3204)}$, the gene encoding cAb-PSA-N7 was ligated into this plasmid via the corresponding restriction sites. The resulting vector pET28a−*sbpA*$_{(93-3204)}$*/cAb-PSA-N7* was established in *E. coli* One Shot BL21 Star and expression was induced by the addition of IPTG. Biomass samples were harvested at various points of time and subjected to SDS−PAGE analysis and ultrathin sectioning. In comparison to *E. coli* cells harvested before the addition of IPTG (Figure 3; lane 1), an additional high molecular mass protein band with an apparent molecular mass of 123 000 Da was observed on SDS-gels in samples from *E. coli* cultures induced to express the chimeric *sbpA*$_{(93-3204)}$*/cAb-PSA-N7* gene (Figure 3; lane 2).

As derived from SDS−PAGE, the S-layer fusion protein had accumulated in the insoluble fraction of the lysed *E. coli* One Shot BL21 Star cells. This was in agreement with data from ultrathin-sectioned preparations of whole cells, which revealed the presence of inclusion bodies in the cytoplasm of the host cells (not shown). The insoluble fraction of the lysed *E. coli* cells was extracted with 5 M GHCl and subjected to GPC. After unifying the fractions from the second peak and removing GHCl by dialysis, only a single major protein band with an apparent molecular mass of 123 000 Da was observed on SDS-gels (Figure 3; lane 3). On immunoblots, a strong cross reaction was observed between the high molecular mass protein band and the polyclonal rabbit antiserum raised against the S-layer protein SbpA of *B. sphaericus* CCM 2177, as well as with the polyclonal rabbit antiserum raised against dromedary IgG (Figure 3; lanes 4 and 5, respectively).

Investigation of the Self-Assembly and Recrystallization Properties of the S-Layer Fusion Protein and of the Accessibility of the Fused cAb-PSA-N7 Moiety by Dot Blot Immunoassay. To investigate the self-assembly properties, purified and lyophilized rSbpA$_{31-1068}$/cAb-PSA-N7 was denatured in 5 M GHCl, and the solution was dialyzed against 10 mM $CaCl_2$ in 1 mM DTT. Negative-staining confirmed that the S-layer fusion protein had self-assembled into flat double layer sheets, which clearly exhibited the square lattice structure (not shown). The S-layer fusion protein recognized peptidoglycan-containing sacculi of *B. sphaericus* CCM 2177 as binding site and recrystallized into the square lattice type (Figure 4 A).

Dot blot assays were performed in order to investigate the accessibility of the fused cAb-PSA-N7 moiety in the water-soluble, self-assembled, and recrystallized S-layer fusion protein. Patient's serum containing PSA used as positive control (Figure 5; spot 1) led to a strong reaction with a monoclonal mouse antibody raised against PSA, whereas no reaction was observed with plain rSbpA taken as negative control (Figure 5; spot 2). As shown in Figure 5 (spots 3−5), the reaction toward PSA was independent of the state of the S-layer fusion protein and comparable for all samples.

Assuming an identical functionality of cAb-PSA-N7 in all S-layer fusion protein samples, these findings indicated that the accessibility of the fused functional sequence for the antigen was not reduced in the self-assembled or recrystallized state of the S-layer fusion protein.

Binding of cAb-PSA-N7 and the S-Layer Fusion Protein rSbpA$_{31-1068}$/cAb-PSA-N7 to a CM5 SPR Sensor Chip with Immobilized PSA. To compare the affinity of cAb-PSA-N7 and the chimeric S-layer fusion protein to PSA by SPR, PSA was covalently bound to the activated carboxylic acid groups of a CM5 sensor chip (Figure 6). This lead to an increase in 916 RU which corresponded to 3.05×10^{-5} nM/mm^2. By passing cAb-PSA-N7 over the sensor surface, an increase in 197 RU was measured which corresponded to 1.29×10^{-5} nM/mm^2, or to a molar ratio between bound cAb-PSA-N7 and PSA of 0.43. In the case of rSbpA$_{31-1068}$/cAb-PSA-N7, an increase in 570 RU was measured. This value corresponded to 4.6×10^{-6} nM/mm^2, or to a molar ratio between bound S-layer fusion protein and immobilized PSA of 0.16. The lower molar ratio as determined for the binding of the S-layer fusion protein to immobilized PSA can be explained by the 8-fold higher molecular mass of rSbpA$_{31-1068}$/cAb-PSA-N7 in comparison to cAb-PSA-N7.

Investigation of the PSA Binding Capacity of the rSbpA$_{31-1068}$/cAb-PSA-N7 Monolayer Obtained by Recrystallization of This S-Layer Fusion Protein

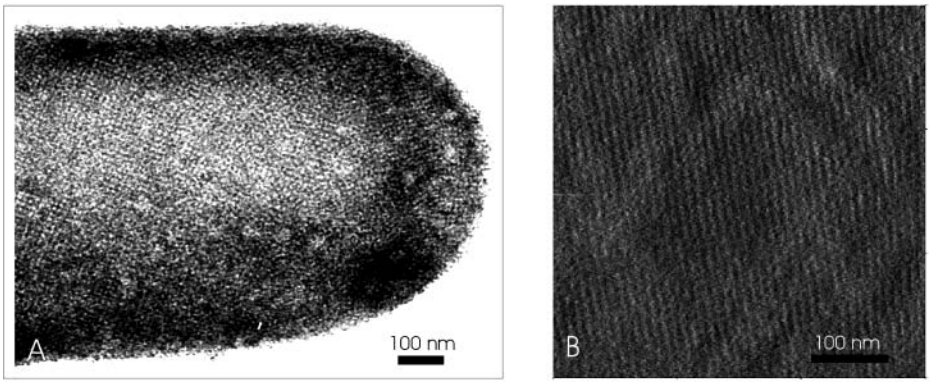

Figure 4. (A) Electron micrograph of a negatively stained preparation of recrystallization products obtained with $rSbpA_{31-1068}$/cAb-PSA-N7 exhibiting the square S-layer lattice type. (B) AFM image of the S-layer fusion protein $rSbpA_{31-1068}$/cAb-PSA-N7 recrystallized on a gold chip precoated with thiolated SCWP.

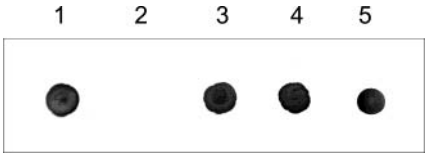

Figure 5. Dot blot assay indicating the accessibility of the cAb-PSA-N7 moiety in the water-soluble, self-assembled, and recrystallized S-layer fusion protein. Spot 1: patient serum containing PSA (diluted 1:20 in TBS) used as positive control; spot 2: rSbpA used as negative control; spot 3: water-soluble $rSbpA_{31-1068}$/cAb-PSA-N7; spot 4: self-assembly products formed by $rSbpA_{31-1068}$/cAb-PSA-N7; spot 5: recrystallization products obtained with $rSbpA_{31-1068}$/cAb-PSA-N7.

on SCWP-Coated Gold Chips by SPR. As shown by AFM analysis, the S-layer fusion protein was capable of recrystallizing into the square lattice structure on gold chips precoated with thiolated SCWP (Figure 4 B). For generating a sensing layer with well defined arrangement of the ligand on the outer surface of a monomolecular protein lattice, the S-layer fusion protein was conducted over an SPR gold chip precoated with thiolated SCWP. Recrystallization of the S-layer fusion protein led to an increase in the SPR signal to 5770 RU, which corresponded to 4.6×10^{-5} nM/mm^2, and therefore to a monolayer of the S-layer fusion protein. When a solution of PSA containing patient serum diluted 1:5 in HBS buffer was conducted over the $rSbpA_{31-1068}$/cAb-PSA-N7 monolayer, specific binding of the antigen was observed. For female blood serum, no specific binding was observed (data not shown). In Figure 7, the sensorgram of a $rSbpA_{31-1068}$ monolayer used as the reference was subtracted from that obtained with the S-layer fusion protein.

By this subtraction, a value of 1074 RU could be calculated for bound PSA, which corresponded to 3.6×10^{-5} nM/mm^2. When this value was correlated to the value of 4.6×10^{-5} nM/mm^2 calculated for the $rSbpA_{31-1068}$/cAb-PSA-N7 monolayer, a molar ratio of 0.78 PSA molecules per S-layer fusion protein was obtained. These measurements reveal that at least three PSA molecules were bound per morphological unit of the square S-layer lattice consisting of four S-layer fusion protein subunits. Since PSA showed no affinity to $rSbpA_{31-1068}$ at all, it was confirmed that binding of PSA to the S-layer fusion protein was due to specific interactions with the cAb-PSA-N7 moiety.

DISCUSSION

Studies on the structure−function−relationship of the S-layer protein SbpA revealed that the N-terminal part is required for anchoring the S-layer subunits via a distinct type of SCWP to the rigid cell wall layer and that 200 C-terminal amino acids could be deleted without interfering with the self-assembly properties (*11*, *12*). Since the SCWP could be exploited to achieve an oriented binding of the S-layer subunits via their N-terminal region to solid supports, amino acid positions in the C-terminal part of the SbpA sequence were screened in order to identify potential fusion sites that were located on the outer surface of the protein lattice. For that purpose, the sequence encoding *Strep*-Tag I was fused to the 5′-end of the sequence encoding various C-terminally truncated rSbpA forms. Since after recrystallization of $rSbpA_{31-1068}$/STI on peptidoglycan-containing sacculi the fused *Strep*-Tag I was accessible to streptavidin binding on the outer surface of the protein lattice to a significantly higher extent than in the case of the entire rSbpA (*11*), the sequence encoding $rSbpA_{31-1068}$ was exploited for the construction of various S-layer fusion proteins. Such fusion proteins comprised either the sequence of the major birch pollen allergen (*11*), the Fc-binding ZZ-domains (*22*), or the VHH of a heavy chain camel antibody directed against lysozyme (*19*). Depending on the fused functional sequence, the S-layer fusion proteins were either used for the development of an anti-allergic vaccine (*23*, *24*), or as immunoadsorbent to remove autoantibodies from patients' sera suffering from autoimmune disease (*22*). Due to the stability properties of heavy chain camel antibodies, appropriate S-layer fusion proteins were constructed for the development of novel diagnostic test systems (*19*). The S-layer fusion protein carrying the heavy chain camel antibody directed against lysozyme ($rSbpA_{31-1068}$/cAb-Lys3) was recrystallized on ELISA plates to provide a surface with a well-defined number and distance of the ligand. According to the construction principle of this S-layer fusion protein, each subunit carried one cAb-Lys3 moiety. The monolayer generated by recrystallization of the S-layer fusion protein on ELISA plates showed the same performance as the rSbpA monolayer to which cAb-Lys3 had been immobilized by chemical coupling. In this case, eight to nine cAb-Lys3 molecules were available per morphological unit of the square S-layer lattice, which was twice as much as in the case of the monolayer consisting of the S-layer fusion protein (*19*). Although several studies indicated that the S-layer fusion protein had attached with the inner surface to the ELISA plates, this orientation was guaranteed when solid supports carrying the SCWP were used for recrystallization. Besides peptidoglycan-containing sacculi of *B. sphaericus* CCM 2177, gold chips precoated with thiolated SCWP fulfilled such

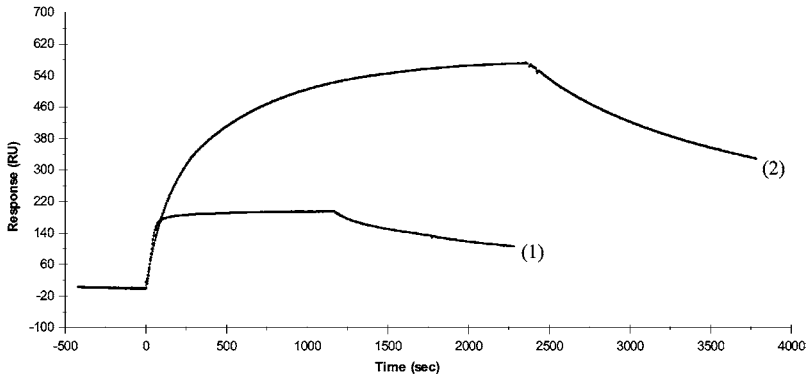

Figure 6. Sensorgrams obtained by binding of cAb-PSA-N7 (1) and the chimeric S-layer protein rSbpA$_{31-1068}$/cAb-PSA-N7 (2) to PSA covalently bound to a CM5 sensor chip. The sensorgrams were obtained by subtracting the respective blank sensorgram from flow cell 1.

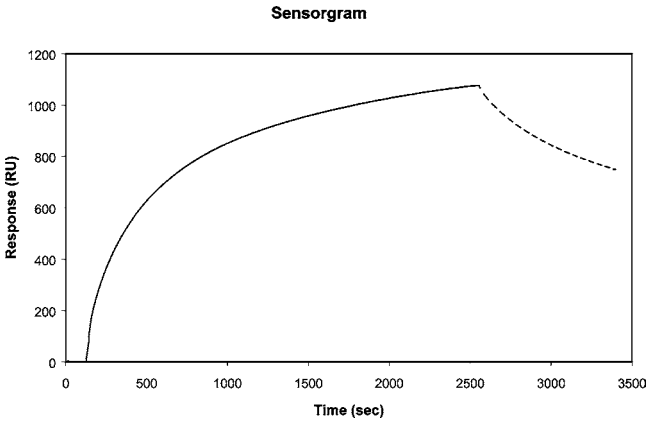

Figure 7. Sensorgram showing association (—) and dissociation (- - -) between PSA and rSbpA$_{31-1068}$/cAb-PSA-N7 recrystallized on a gold chip precoated with thiolated SCWP. The sensorgram indicated specific binding of PSA to the S-layer fusion protein.

requirements. The latter were exploited for the recrystallization of the S-layer fusion protein rSbpA$_{31-1068}$/cAb-PSA-N7 which comprised the sequence of a heavy chain camel antibody that specifically recognized PSA. For isolation of genes encoding appropriate heavy chain camel antibodies, a dromedary was immunized with purified PSA. This proved to be successful since all IgG subclasses reacted positive on PSA. The genes encoding VHHs were amplified from the purified lymphocytes and cloned into a phage vector resulting in a VHH immune library. After panning on biotinylated PSA, we identified more than 20 different binders, characterized by ELISA, and the kinetic parameters were investigated by SPR. The VHH cAb-PSA-N7 with the highest affinity to PSA (K_D 0.09 nM) was chosen for further analysis to enable highly sensitive detection of the analyte.

The S-layer fusion protein rSbpA$_{31-1068}$/cAb-PSA-N7 formed self-assembly products and recrystallized on peptidoglycan-containing sacculi of *B. sphaericus* CCM 2177. In both cases, the S-layer lattice exhibited the square structure with a center-to-center spacing of the morphological units of 13.1 nm. The accessibility of the fused cAb-PSA-N7 moiety for PSA was proved for the water-soluble, self-assembled, and recrystallized S-layer fusion protein, which independent of its state led to comparably strong reactions in dot blot immunoassays.

To generate a PSA-specific sensing layer for SPR measurements, the S-layer fusion protein rSbpA$_{31-1068}$/cAb-PSA-N7 was recrystallized on gold chips precoated with thiolated SCWP. The formation of the monomolecular protein lattice was confirmed by AFM analysis, as well as by the level of the measured SPR signal. As derived from the response levels measured for binding of PSA to the rSbpA$_{31-1068}$ /cAb-PSA-N7 monolayer, the molar ratio between bound PSA and the S-layer fusion protein was 0.78, which means that at least three PSA molecules were bound per morphological unit of the square S-layer lattice. Comparative studies with an rSbpA monolayer confirmed that the measured response levels were specific for PSA binding.

To summarize, by using the SCWP as biomimetic linker to gold chips, a sensing layer for SPR could be generated by recrystallization of an S-layer fusion protein. Due to the crystalline structure of the S-layer lattice, the fused ligand sequences show a well defined distance in the protein lattice, and according to the selected fusion site in the S-layer protein, they are located on the outermost surface, which will reduce diffusion limited reactions. A further advantage can be seen in the constant and low distance of the ligands from the optically active gold layer, which is exclusively determined by the thickness of the S-layer and lies in the range of only 10 to 15 nm. Thus, S-layer fusion proteins can be considered as key element for the development of label free detection systems such as SPR, surface acoustic wave (SAW), or quartz crystal microbalance (QCM-D), in which the binding event can be measured directly by a mass increase without the need of any labeled molecule.

ACKNOWLEDGMENT

This work was supported by the Austrian Science Foundation, project P14689-MOB, by the Competence Center “Biomolecular Therapeutics” and by the EU project PAMELA. We thank Jacqueline Friedmann for excellent technical assistance concerning the AFM studies and Prof. Dr. Georg Steiner from the AKH for providing us with PSA-containing serum samples from patients. This work was supported by a predoctoral grant from the Institute for the promotion of Innovation by Science and Technology in Flanders (IWT-Flanders) to Dirk Saerens.

Poly(ethylene glycol)-Supported Enzyme Inactivators. Efficient Identification of the Site of Covalent Attachment to α-Chymotrypsin by PEG-TPCK

Christine A. Schering, Boyu Zhong,[‡] Jonathan C. G. Woo,[†] and Richard B. Silverman*

Department of Chemistry, Department of Biochemistry, Molecular Biology, and Cell Biology, and the Drug Discovery Program, Northwestern University, 2145 Sheridan Road, Evanston, Illinois 60208-3113. Received March 9, 2004; Revised Manuscript Received May 6, 2004

A new methodology utilizing an enzyme inactivator covalently attached to poly(ethylene glycol) (PEG) is described in which the PEG affords facile and mild quantification, isolation, and identification of the site of enzyme inactivation. As proof of concept, the known affinity labeling agent for α-chymotrypsin, *N*-tosyl-L-phenylalanine chloromethyl ketone (TPCK), was linked to PEG. The synthesis of the PEG-bound inactivator PEG-TPCK was carried out in good yields using standard solution-phase chemistry. Inactivation of α-chymotrypsin with PEG-TPCK was monitored via UV−vis spectroscopy in aqueous conditions, which resulted in less than 3% remaining activity, indicating that 97% of the α-chymotrypsin was covalently modified with PEG-TPCK. The MALDI-TOF mass spectrum showed only one new peak that was distinct in shape and corresponded to the mass of PEG-TPCK−α-chymotrypsin. Following proteolytic digestion, the PEG-TPCK−peptide was easily discernible from the rest of the digest in a HPLC trace because of its characteristic prolonged retention time and broad polymer shape. MALDI-TOF MS was used to determine the mass of the PEGylated peptide. Without prior removal of the PEG, the amino acid site to which PEG-TPCK covalently bound was determined via Edman sequencing. In comparison to other methods, the PEG-supported inactivator system is significantly cheaper and safer than the synthesis of radiolabeled compounds; furthermore, isolation of the PEGylated peptide is milder and more selective than standard affinity binding columns. Edman sequencing provides an exact determination of the site of inactivator covalent attachment without extensive, tedious LC-MS analysis of a complex peptide mixture. The method described here could be applied to a variety of enzymes as an alternative to current techniques.

The assessment of enzyme inactivators is an important tool to understand the catalytic mechanism and active site topology of enzymes. The traditional method to identify the site of covalent attachment involves synthesizing a radiolabeled inactivator (*1*). Because of the high cost of radiolabeled starting materials, the difficulty in synthesis, and many federal regulations, alternative methods are desirable. Site-directed mutagenesis has been used to determine the importance of an active-site residue, but this method lacks definitive support for

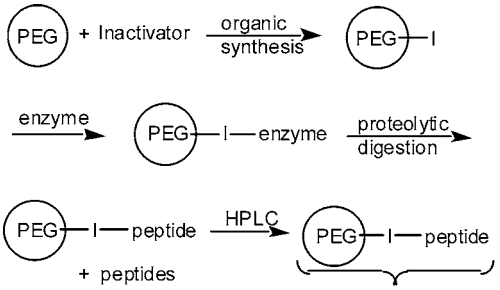

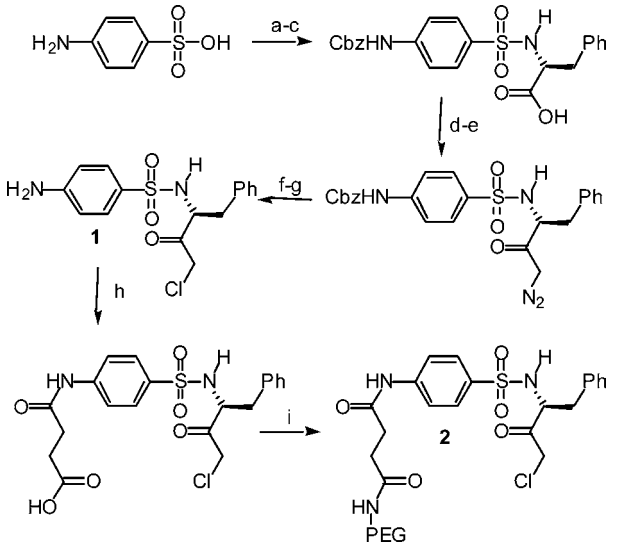

Figure 1. PEG-supported inactivator methodology.

inactivator binding (*2*). Affinity techniques, such as biotin/avidin, vary in selectivity and many times require nonaqueous incubation systems and harsh cleavage conditions (*3*). Recently, mass spectrometry has been used to analyze digested inactivated enzymes; however, the quality and complexity of the digest greatly influence the degree of difficulty and methodological approach of the subsequent MS analysis, and it does not always provide convenient identification of the site of inactivator binding (*3, 4*). An alternative method that would retain the positive features but overcome the failings of current approaches would facilitate the assessment of enzyme inactivators.

Poly(ethylene glycol) (PEG) is a water- and organic-soluble polymer utilized in chemistry because its homogeneous reaction conditions contribute to fast kinetics and high loading levels, while PEG's propensity to precipitate in ether aids in facile purification during PEG-supported synthesis of small molecules and biopolymers (*5*−*10*). PEGylation, the biological technique of covalently attaching PEG to nucleophilic amino acids of enzymes and peptides, produces new pharmaceutical agents and organic catalysts with enhanced stability and performance (*11*−*14*).

PEG's ability to impart its physiochemical properties on other molecules in both chemical and biological systems could allow it to overcome the above-mentioned failings of current approaches to identify the enzyme inactivator covalent binding site (Figure 1). Synthesis of a PEG-supported inactivator through standard solution-phase organic synthesis would be simpler and cheaper than synthesis of a radiolabeled molecule, with the added benefit that the PEG-supported inactivator could be subsequently characterized via NMR and MALDI-TOF MS (*15*). Because of the homogeneous aqueous reaction conditions and the flexible PEG framework, the PEG-bound inactivator should be capable of inactivating the enzyme similarly to that of the unmodified inactivator (*16*). The inactivation of the enzyme and the concurrent formation of the PEGylated proteins can be quantified by the same assays used on the unmodified inactivator. The inactivated PEGylated enzyme can be quickly purified by size-exclusion chromatography and identified by MALDI-TOF MS because of the drastically altered retention time, molecular weight, and broad peak shape of PEGylated peptides and proteins (*17, 18*). Furthermore, a variety of proteolytic enzymes are known to cleave PEGylated proteins (*12*). Once digested, PEG alters the properties of the PEGylated peptide from those of the unmodified peptides, aiding in HPLC purification and identification of the PEGylated peptide by MALDI-TOF MS (*19*). Finally, MALDI-TOF MS and Edman sequencing are both amenable for use with PEGylated peptides, allowing determination of the covalent attachment site

Scheme 1. Synthesis of PEG-TPCK[a]

without prior cleavage of the PEG handle (*12*−*17*). A PEG-supported inactivator would behave as both a tag to identify any polymer covalently modified species as well as a handle to isolate the PEGylated moieties. Exact determination of the site of inactivator covalent attachment would be possible at low cost, in mild and standard conditions, without harsh cleavage conditions to remove the polymer or analysis of a complicated digestion mixture.

This new methodology utilizing a PEG-supported inactivator was developed using the known affinity labeling agent for α-chymotrypsin, *N*-tosyl-L-phenylalanine chloromethyl ketone (TPCK) (*20*). TPCK is known to bind covalently to His 57, part of the catalytic triad of α-chymotrypsin, with both time and concentration dependence (*20*−*22*). An analogue of TPCK, *S*-1-[1-*N*-(4-amino benzenesulfonyl)aminophenethyl] chloromethyl ketone (**1**, Scheme 1), was synthesized (*23*−*24*). Replacement of the methyl group with the isosteric amino group provided a handle to link the PEG. Monomethoxyamino PEG (MW 5000) and the TPCK analogue were linked via succinic anhydride, resulting in a stable and UV-active diamide linker (**2**, Scheme 1).

As with TPCK, the time and concentration dependent inactivation of α-chymotrypsin with PEG-TPCK (**2**) was monitored by the cleavage of L-benzyltyrosine methyl ester until less than 3% of the activity remained (24 h), implying 97% linkage of the PEG-TPCK to the α-chymotrypsin. Dialysis (MWCO 10 000 Da) was used to remove unreacted PEG-TPCK and buffer salts prior to MALDI-TOF MS analysis. Comparison of the molecular weight of the inactivated α-chymotrypsin (31 060 Da, broad) with those of the control α-chymotrypsin (25 230 Da, sharp) clearly indicated that the PEG-TPCK (approximately 5400 Da) was covalently bound to the α-chymotrypsin. The peak shapes also supported complete covalent binding of PEG-TPCK to α-chymotrypsin; the control is a sharp peak as would be expected for a single protein whereas the inactivated enzyme is a uniquely shaped broad peak caused by the polydisperse PEG covalently bound to the enzyme.(Figure 2).

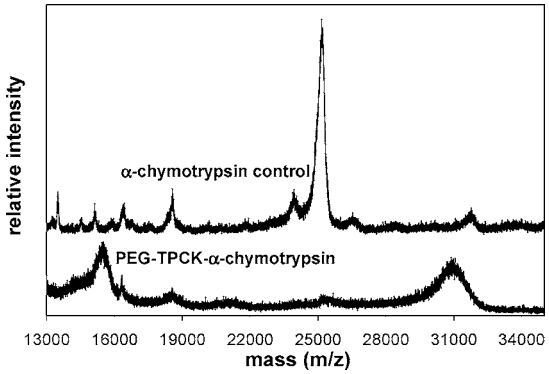

Figure 2. MALDI-TOF MS of α-chymotrypsin and PEG-TPCK−α-chymotrypsin (positive mode, CHCA matrix). The unique peak shape and large mass difference clearly indicate covalent attachment of the polydisperse PEG-TPCK (MW ∼ 5450, g/mol) to α-chymotrypsin.

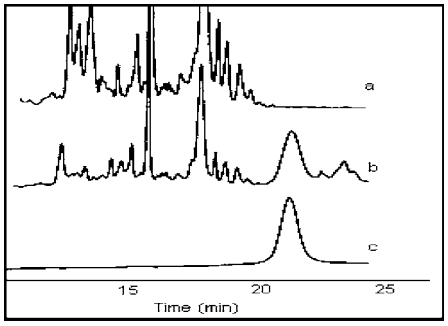

Figure 3. HPLC analysis (Vydac C8, A:H2O, 0.1% TFA, B: ACN, 0.1% TFA, 20−80% in 40 min) of digested (a) α-chymotrypsin control, (b) PEG-TPCK−α-chymotrypsin, and (c) purified PEG-TPCK−peptide. The prolonged retention time and unique peak shape aid in immediate identification of the modified peptide and facile isolation of the peak.

PEG-TPCK-α-chymotrypsin (900 μM) was denatured, reduced, alkylated, and then subsequently digested with α-chymotrypsin. The digestion was stopped by allowing the mixture to run through a PD-10 desalting column. The PEG-TPCK−peptide peak in the HPLC (Figure 3b) was easily identified because it appears as a distinct broad peak as the result of the polydispersity of the PEG not present in the digested control (Figure 3a). It is known that PEGylated peptides and proteins elute as polydisperse peaks following the nonPEGylated moieties because of an increase in size and decrease in polarity (*18, 25*). This new peak was isolated by HPLC (Figure 3c) and characterized by MALDI-TOF MS to be a PEGylated peptide because of the distinct polydispersed peak centered around 7400 g/mol (Figure 4).

Gas-phase Edman sequencing identified only two peptides, offset by three amino acids because of partial cleavage after Thr 54; the sequence of one peptide was VVTAA**X**C′GVTTSD- - -A and the sequence of the other was AA**X**C′GVTTSDVVVAGEF. Both sequences correlate to the known primary sequence of α-chymotrypsin with the indeterminable amino acid (**X**) corresponding to His 57, the known site of TPCK covalent binding to α-chymotrypsin. The expected molecular weight for each sequence through Phe 71 is 2017.98 g/mol and 1718.79 g/mol, respectively. If the molecular weights of the inactivator (MW 450.92 g/mol) and PEG (MW 5000 g/mol) are added to these, then the expected molecular weights of the PEG-TPCK−peptides would be 7468.89 and 7169.71 g/mol. These masses agree with the broad peak seen by MALDI-TOF MS (Figure 4). No other free or PEG-TPCK-bound peptide sequences were detected by Edman sequencing or mass spectrometry.

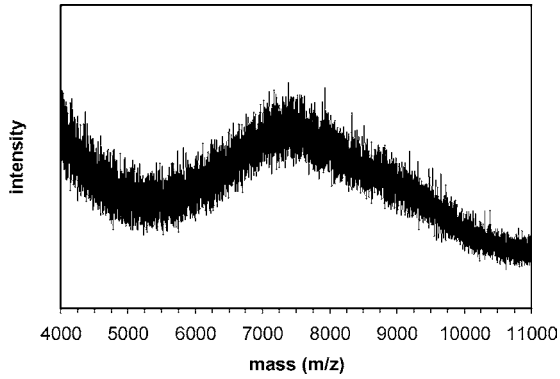

Figure 4. MALDI-TOF MS on the purified PEG-TPCK−peptide (negative mode, DHB matrix). The distinct shape is indicative of a PEGylated peptide.

This new methodology utilizing an enzyme inactivator covalently bound to PEG enabled facile, mild, and selective isolation and identification of the site of PEG-TPCK covalent attachment to α-chymotrypsin, the same residue to which unmodified TPCK binds. The polydisperse nature of the PEG aided in visualization and subsequent isolation of the PEGylated enzyme and peptide. Inexpensive starting materials were used to synthesize PEG-TPCK. The inactivation occurred in aqueous conditions and thereby could be easily monitored and purified via standard techniques. The PEGylated enzyme was fragmented into small peptides via proteolytic digestion. HPLC was used to easily identify and then purify the PEG-TPCK−peptide from the digested mixture. The peptide sequence was determined by Edman sequencing without prior cleavage of the PEG, indicating without ambiguity the site of PEG-TPCK attachment. Because of its facile and mild nature, this method could be applied to a variety of enzymes instead of currently used techniques.

ACKNOWLEDGMENT

This research was supported by NIH (GM32634). Edman sequencing was performed by the Protein Separations and Analysis Laboratory at Purdue University.

Physicochemical and Biological Characterization of Polyethylenimine-graft-Poly(ethylene glycol) Block Copolymers as a Delivery System for Oligonucleotides and Ribozymes

Carola Brus,[†] Holger Petersen,[†] Achim Aigner,[‡] Frank Czubayko,[‡] and Thomas Kissel*[,†]

Department of Pharmaceutics and Biopharmacy, Philipps-University, Ketzerbach 63, 35037 Marburg, Germany, and Department of Pharmacology and Toxicology, School of Medicine, Philipps-University, Karl-von-Frisch-Strasse 1, 35033 Marburg, Germany. Received September 9, 2003; Revised Manuscript Received April 28, 2004

Two different series of polyethylenimine (PEI) block copolymers grafted with linear poly(ethylene glycol) (PEG) were investigated as delivery systems for oligodeoxynucleotides (ODN) and ribozymes. The resulting interpolyelectrolyte complexes were characterized with respect to their physicochemical properties, protection efficiency against enzymatic degradation, complement activation, and biological activity under in vitro conditions. The effect of PEG molecular weight and the graft density of PEG blocks on complex characteristics was studied with two different series of block copolymers. The resulting ODN complexes were characterized by photon correlation spectroscopy (PCS) and laser Doppler anemometry (LDA) to determine complex size and zeta potential. Electrophoresis was performed to study the protective effects of the different block copolymers against enzymatic degradation of ODN. Intact ODN was quantified via densitometric analysis. Ribozymes, a particularly unstable type of oligonucleotides, were used to examine the influence of block copolymer structure on biological activity. The stabilization of ribozymes was also characterized in a cell culture model. Within the first series of block copolymers, the grafted PEG chains (5 kDa) had marginal influence on the complex size. Two grafted PEG chains were sufficient to achieve a neutral zeta potential. Within the second series, size and zeta potential increased with an increasing number of PEG chains. A high number of short PEG chains resulted in a decrease in complex size to values comparable to that of the homopolymer PEI 25 kDa and a neutral zeta potential, indicating a complete shielding of the charges. Complement activation decreased with an increasing number of short PEG 550 Da chains. Ribozyme complexes with PEG-PEI block copolymers achieved a 50% down-regulation of the target mRNA. This effect demonstrated an efficient stabilization and biological activity of the ribozyme, which was comparable to that of PEI 25 kDa. PEGylated PEI block copolymers represent a promising new class of drug delivery systems for ODN and ribozymes with increased biocompatibility and physical stability.

INTRODUCTION

Oligodeoxynucleotides (ODN) and ribozymes have stimulated significant interest as tools for sequence-specific down-regulation of gene expression (*1*−*3*). To improve limited cellular uptake and poor stability of ODN, several carrier systems are currently under investigation, e.g., cationic lipids (*4*) and cationic polymers (*5*). Recently, important discoveries have led to a deeper understanding of the self-assembly processes between cationic polymers and DNA (*6*−*10*). Complexation with polycations by electrostatic interactions causes condensation of the DNA (*11*). The ratio of DNA to polymer, expressed as the N/P ratio, determines the extent of condensation (*12*). Furthermore, DNA stability against enzymatic degradation is increased by complexation with the polycations (*13*). Although, similar mechanisms have been proposed for polyplexes containing ODN (*10*, *14*), they are considered to be one of the most difficult classes of polynucleotides to be complexed by and delivered with polycations. It has been postulated that the limited number of negative charges presented by ODN may be insufficient for cooperative binding (*15*). Additionally, such interpolyelectrolyte complexes often suffer from a poor stability in solution leading to rapid aggregation (*14*, *16*, *17*). To overcome this problem, block copolymers containing a water-soluble nonionic segment, such as poly(ethylene glycol) (PEG), have been recently introduced. These include PEG-polyspermine (*14*), PEG-polylysine (PLL) (*9*, *10*), and di- or trimethylammonioethyl methacrylate (DMAEMA or TMAEMA)-based copolymers coupled to PEG or other hydrophilic polymers such as poly[*N*-(2-hydroxypropyl)methacrylamide] (pHPMA) (*18*, *19*), PLL-pHPMA (*18*), PLL-dextran (*20*), and PEG-polyethylenimine (PEI) (*7*). Promising results were reported using

these water-soluble block copolymers for ODN complexation, indicating an increased solubility and stability against enzymatic degradation (*7*). Cell culture and in vivo experiments have also demonstrated a decreased cytotoxicity (*14*) and high antisense activity (*21*−*23*). A possible explanation for these positive features of ODN copolymer complexes could be the arrangement of the ODN. It is hypothesized that the ODN is trapped within a polycationic core with the hydrophilic polymer chains oriented to the surrounding aqueous environment, creating a hydrophilic shell (*16*). This core shell structure possibly prevents aggregation due to steric repulsion, thus stabilizing the particles in solution. Furthermore, enzymatic attacks are prevented by the surrounding hydrophilic shell, leading to increased nuclease resistance (*7*, *10*). The degree of PEG substitution was found to influence physicochemical properties of the resulting complexes such as complex size, nuclease resistance (*9*), and even complement activation (*24*), posing restrictions for intravenous application of these delivery systems, as demonstrated by the appearance of serious side effects under in vivo conditions (*25*). Studies using plasmid DNA further revealed an influence of PEG molecular weight on condensation properties, biocompatibility, and biological activity (*26*).

The aim of this study was to establish the structure−property relationships of block copolymer ODN and ribozyme complexes. The influence of PEGylation degree and PEG molecular weight on physicochemical and biological properties was systematically investigated.

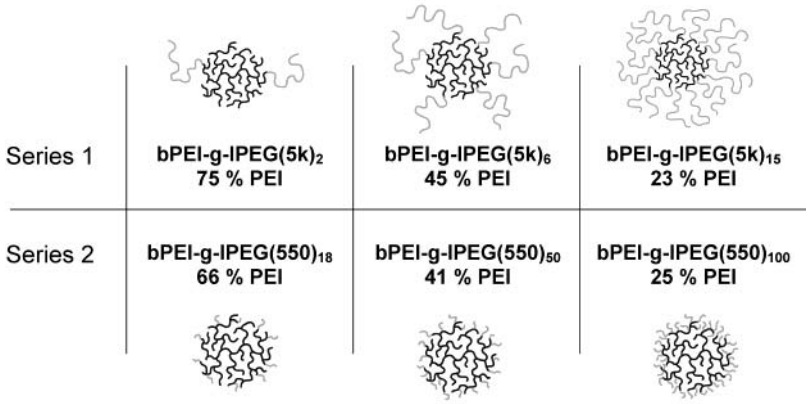
MATERIALS AND METHODS

Materials. The 20 mer DNA oligodeoxynucleotide (ODN) with the sequence 5′ TTC CAA TAC AGA AAC TCT CT- 3′ was purchased from Biospring (Frankfurt, Germany), dissolved in sterile water and stored at −20 °C until use. The 40 mer ribozyme Luc Rz 227 with the sequence 5′-ACU GCA UAC CUG AUG AGU CCG UUA GGA CGA AAC GAU UCU G-3′, directed against the luciferase mRNA, was purchased from GENSET S.A (Paris, France). PEI 25 kDa (Polymin water free, 99%) was a gift from BASF (Ludwigshafen, Germany). PEG-monomethyl ether (mPEG) 550 and mPEG 5000 were obtained from Aldrich (Taufkirchen, Germany). Block copolymers were synthesized by grafting linear PEG onto branched PEI using a diisocyanate linker as described in detail previously (*27*, *28*). Polymers were used as sterile filtered aqueous stock solutions (0.9 mg/mL) of pH 7.4. All other materials were of analytical grade.

Preparation of Polymer−ODN Complexes. Complexes were prepared as previously published by diluting the appropriate amount of ODN stock solution (100 μg/mL in sterile water), as well as polymer stock solution (0.9 mg/mL in sterile water, pH 7.4) in 50 μL of 150 mM NaCl, vortexing and incubating for 10 min (*13*). The polymer solution was added to the ODN solution, vortexed again, and incubated for a further 10 min. The polymer/DNA ratio was expressed as the nitrogen/phosphate (N/P) ratio and calculated on the basis that 1 μg of DNA corresponds to 3 nmol of phosphate, while 1 μL of PEI stock solution contains 10 nmol of nitrogen (*13*). For photon correlation spectroscopy and transfection experiments complexes were prepared in 150 mM NaCl. For atomic force microscopy, 10 mM NaCl was used to prevent salt crystal formation.

Photon Correlation Spectroscopy (PCS). The hydrodynamic diameter of freshly prepared complexes with a ODN concentration of 40 μg/mL were measured using a Zetasizer 3000 HS form Malvern Instruments (Herrenberg, Germany) equipped with a 10 mW HeNe laser at a wavelength of 633 nm at 25 °C. Scattered light was detected at 90° angle through a 400 μm pinhole, and the viscosity and refractive index of pure water at 25 °C were used for data analysis. Measurements were analyzed using the CONTIN algorithm. Values given are the means of 10 runs of 60 s ± standard deviation. The instrument was routinely calibrated with Standard Reference Latex Particles (AZ 55 Electrophoresis Standard Kit, Malvern Instruments).

Laser Doppler Anemometry (LDA). The zeta potential of freshly prepared complexes with an ODN concentration of 40 μg/mL was determined using the standard capillary electrophoresis cell of the Zetasizer 3000 HS form Malvern Instruments at position 17.0 at 25 °C. Average values were calculated with the data of 10 runs ± standard deviation.



Atomic Force Microscopy (AFM). AFM images were conducted on a Dimension3000 Scanning Probe Microscope from Digital Instruments (Santa Barbara, CA) with a Nanoscope IIIa controller. All imaging was carried out in the tapping mode at a scan speed of approximately 2 Hz with 512 × 512 pixel data acquisition. V-shaped cantilevers with a pyramidal tip of silicon nitride were used (Park Scientific, CA).

Nuclease Stability. Freshly prepared complexes were incubated with 5 units DNase 1 (Roche Diagnostics GmbH, Mannheim, Germany) per μg DNA for 3 h at 37 °C. The samples were then transferred to a water bath of 70 °C for 30 min to inactivate the nuclease. The ODN was displaced from the complex by adding 8 μL 10% (w/v) sodium dodecyl sulfate (SDS) in water, vortexing, and incubating for a further 10 min. A 10 μL volume of each sample was loaded onto a 15% polyacrylamide gel containing 7 M urea, corresponding to total amount of 0.2 μg of ODN. Electrophoresis was carried out at 200 V for approximately 50 min (Consort E332 power supply, Roth, Karlsruhe, Germany). Afterward, gels were stained for 5 min in a 1:1000 dilution of SYBR Gold (MoBiTech GmbH, Göttingen, Germany) in water and digitalized using the BioDocAnalyze gel documenting system (Biometra, Göttingen, Germany) with an excitation wavelength of 312 nm.

Densitometric Analysis. Electrophoretic gels were analyzed using the software program Scion Image 4.0.2. beta (Scion Corporation, Frederick, MD). The amount of intact ODN was calculated via a four point standard curve on every single gel using three ODN dilutions of 0.2, 0.1, and 0.05 μg, respectively, plus the point of origin. Values given are the difference between the calculated ODN amount of each sample and the intact amount of the noncomplexed ODN control and are expressed as the percentage which was protected by the complex. The linear relationship between the amount of the ODN and the optical density of the bands was previously proven by a calibration curve. Five independent calibration curves using nine different dilutions were measured. Linear regression of the means exhibited a correlation coefficient of 0.9947. Differences were considered significant for $P \leq 0.05$ based on One-way ANOVA using Origin software package (Microcal Software, Inc. Northampton, MD).

Complement Activation. The principle of the hemolytic assay is based on the concentration-dependent consumption of complement components by complement-activating agents when serum is preincubated with these agents (*24*). The subsequent hemolysis of antibody-sensitized sheep erythrocytes by the so-called membrane

Table 1. Nomenclature of the Two Grafted PEI-*g*-PEG Block Copolymer Series. It Is Further Given the Average PEI Content and the Schematic Structure of the Single Copolymers. The Black Part of the Structure Represents the Branched PEI 25 KDa, and the Gray Part Represents the Nonionic Linear PEG Segments

attack complex formed by the remaining complement components is decreased as compared to that of untreated serum. Gelatin veronal buffer (GBV) and antibody-sensitized sheep erythrocytes were both purchased from Sigma-Aldrich (Taufkirchen, Germany). The required serum dilution of 1:10 in GBV, necessary for the lysis of 50% of the erythrocytes, was determined using the Krogh equation as described (*29*) and expressed as $CH50_{max}$ value. The procedure was performed according to the protocol by Plank et al. (*24*). Briefly, five different concentrations (25 mg/L; 12.5 mg/L; 6.25 mg/L; 1.56 mg/L and 0.39 mg/L) of freshly prepared bPEI-*g*-lPEG−ODN complexes at N/P ratio 20 were preincubated with serum. The resulting CH50 of the serum, after preincubation with complexes, was compared to $CH50_{max}$ and expressed as percentage of $CH50_{max}$ = (CH50 sample/$CH50_{max}$) × 100 (*24*).

Cell Culture. SKOV-3 ovarian carcinoma cells (American Type Culture Collection, Manassas, VA), stably transfected with the luciferase gene, were cultured in Iscove's modified Dulbecco's medium IMDM (PAA Laboratories, Cölbe, Germany) supplemented with 10% FCS at 37 °C and 5% CO_2 (v/v).

Ribozyme Activity Assay. SKOV-3 cells, stably transfected with the luciferase gene (Aigner and Urban-Klein, unpublished results), were seeded at a density of 34 000 (Figure 6a and b) or 70 000 (Figure 6c) cell/well in 24-well plates, respectively. After 6 h, medium was exchanged and the cells were incubated with freshly prepared complexes. Ribozyme−PEI complexes were prepared according to the standard protocol containing 0.25 μg of ribozyme directed against the luciferase mRNA and unrelated ribozyme as a control where indicated. Experiments were carried out at two different N/P ratios of 6.7 and 20 for PEI homopolymers and all PEI-*g*-PEG block copolymers. Cells incubated with 0.25 μg of non-complexed ribozyme were used as a control. Medium was exchanged after 4 h. Luciferase activity was determined after a further 44 h using the Luciferase Assay System from Promega according to the manufacturer's instructions. All experiments were performed in triplicates. The protein concentration in each sample was determined using a BCA assay (*30*).

RESULTS AND DISCUSSION

Two series of block copolymers were chosen to study the influence of PEGylation on the physicochemical properties and biological activity of the resulting interpolyelectrolyte complexes with ODN and ribozymes. In both series, branched (b) PEI 25 kDa was grafted with an increasing number of linear (l) PEG chains, with a molecular weight of 5 kDa within the first and 550 Da within the second series, respectively (Table 1). These graft (*g*) copolymers were designated using the following nomenclature: bPEI(25k)-*g*-lPEG(x)$_n$ with b and l denoting a branched or linear structure, respectively. The number in brackets (25k or x, where x = 5k or 550) represent the MW of the PEI or the PEG block, and the index n is the average number of PEG blocks per PEI molecule. This number was calculated based on ^{1}H NMR spectra as described previously (*27*).

Photon Correlation Spectroscopy (PCS). The hydrodynamic diameters of ODN−PEG-PEI complexes were determined at two different nitrogen to phosphate (N/P) ratios of 6.7 and 20 (Figure 1). All PEG-PEIs formed very small complexes in the range of 7 to 40 nm. No specific trend could be observed within the first series (Figure 1a). The complex size was only marginally influenced by the increasing degree of PEG substitution with 5 kDa PEG chains. At both N/P ratios, the average diameters were below 30 nm. bPEI(25k)-*g*-lPEG(5k)$_{15}$ formed larger complexes of 40 nm at N/P 6.7, possibly due to a decreased condensation efficiency of this highly grafted derivative. At N/P 20, small complex sizees were also observed. A decrease in complex size at higher N/P ratios using PEI 25 kDa has been previously reported for unmodified ODN and a phosphorothioate oligonucleotide previously (*31*). Petersen et al. also found smaller complex sizes when using five different PEI-*g*-PEG block copolymers with plasmid DNA at different N/P ratios (*26*). In the second series, polymer grafted with shorter 550 Da PEG chains, up to a substitution degree of 50, showed increases in complex size (Figure 1b). Complexes at an N/P ratio 6.7 exhibited in all cases larger average diameters, which suggest that the ability of these polymers to condense ODN at this N/P ratio is impaired. Interestingly, PEG-PEI copolymers with 100 PEG chains of 550 Da exhibited complex sizes, which were comparable to those of the homopolymer PEI 25 kDa. PEG-PEI complexes with ODN are generally found to yield small diameters and narrow size distributions (*15*). Vinogradov et al. described a copolymer composed of a PEI 2 kDa grafted with an average number of 1.7 PEG (8 kDa) chains, which produced complexes with a phosphorothioate (PS) ODN of 32 nm (*7*). While experimental conditions and especially chemical modifications of the ODN seem

to have a great influence on complex formation of PEI 25 kDa complexes (*31*), further studies are necessary to determine the influence of chemical modification on the complexation with block copolymers.

Laser Doppler Anemometry (LDA). The surface charge of PEG-PEI complexes was determined at the two different N/P ratios, 6.7 and 20, using LDA. The results are shown in Figure 3. PEI 25 kDa complexes revealed high positive surface charges of +35 mV at N/P 6.7 and +25 mV at N/P 20. A decrease in the zeta potential with increasing N/P ratio has been previously reported for plasmid PEI complexes, as well (*26*, *32*). Zeta potentials of the block copolymer complexes were reduced to nearly neutral values as documented for both series 1 (Figure 2a) and 2 (Figure 2b). Our results are compatible with a core−shell structure, in which hydrophilic PEG chains are oriented toward the surface. Hence, the positive charge of the PEI core is shielded as previously discussed (*10*, *15*). Full shielding was already achieved at the lowest degree of PEGylation investigated in this study of PEG-$(5k)_2$ or PEG$(550)_{18}$, respectively. A further increase of the PEGylation degree had only marginal effects on the zeta potential. The net charge of plasmid DNA complexes could be fully shielded only with block copolymers containing more than six PEG (5 kDa) chains or one very long PEG chain of 20 kDa (*26*). The substantial difference in DNA size seems to be responsible for the lower degree of condensation of plasmid DNA within the polycationic core (*15*). Surprisingly, under our experimental conditions only bPEI(25k)-*g*-lPEG$(550)_{50}$ led to a clear positive surface charge possibly caused by a difference in stoichiometry of ODN to polymer which is also reflected by the increased complex size.

Atomic Force Microscopy (AFM). To visualize the shape of the PEG-PEI complexes, we performed atomic force microscopy studies with ODN−PEI 25 kDa complexes and the block copolymer, bPEI(25k)-*g*-lPEG$(550)_{100}$ (Figure 3). AFM imaging was performed directly in solution; however, a lower salt concentration of 10 mM NaCl, pH 7.4, was necessary to prevent salt crystal formation (*26*). Complexes were imaged at an N/P ratio of 6.7. PEI 25 kDa showed images of very small, compact, homogeneously distributed complexes with a nearly spherical shape (Figure 3a,b). PEGylation affected the condensation of the complexes, as is shown for the block copolymer complexes of bPEI(25k)-*g*-lPEG$(550)_{100}$ (Figure 3c,d). This has been previously reported for plasmid DNA complexes as well (*26*). The complexes lost their spherical, well-defined shape and appeared to be more "fuzzy". Wolfert et al. reported a similar phenomenon for PEGylated PLL (*8*). The reason for the decreased condensation efficiency of PEGylated derivatives is not yet clear. It might be the result of a reduced ability to collapse into small particles, due to hydrogen bonding of the PEG with water (*8*, *15*).

Nuclease Stability. It is well established that complexation with polycations leads to protection of DNA from enzymatic digestion (*6*, *13*). PEG-PEI have demonstrated a high protection efficiency for ODN (*7*, *9*). However, it remains to be investigated whether the degree of PEGylation and PEG molecular weight have an impact on the stabilization efficiency of block copolymers. Both ODN complex series were incubated with

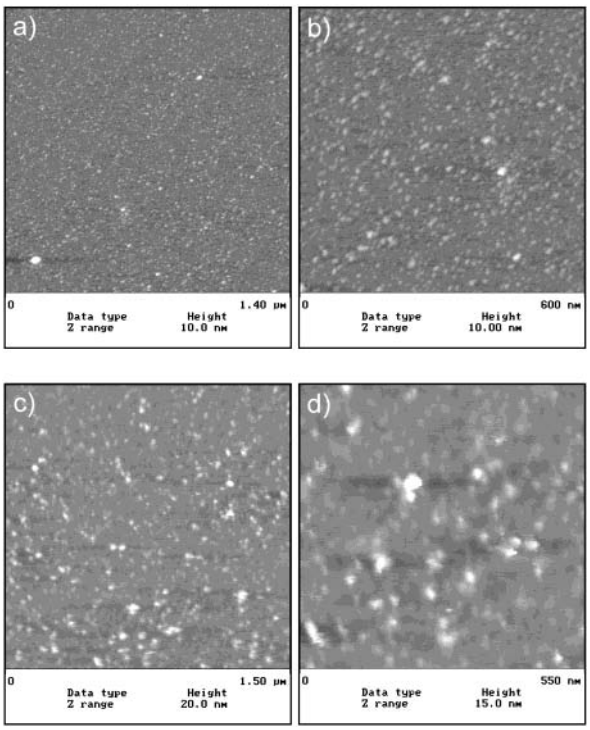

Figure 3. AFM images of ODN complexes of PEI 25 kDa (a and b) in two different resolutions and bPEI(25k)-*g*-lPEG(550)$_{100}$ (c and d) in two different resolutions at N/P ratio 6.

DNase 1 for 3 h. Afterward the nuclease was denatured and the ODN displaced from the complex. DNase 1 is a double-strand-specific endonuclease, which also cleaves single stranded ODN, albeit more slowly. Accordingly, nearly 75% of the noncomplexed control was degraded after 3 h in contrast to plasmid DNA which is totally degraded within this period. The percentage of nondegraded control was subtracted from the intact amount of the single samples in order to obtain the real protected fraction, as shown in Figure 4. All block copolymers revealed a protection equal to that of PEI 25 kDa. In contrast, Dash et al. achieved a higher protection of plasmid DNA by a PEGylated PLL in comparison to the non-PEGylated derivative (*33*). This effect could be explained by steric hindrance of the nucleolytic attack by the PEG shell (*7, 9*). Under our experimental conditions, however, no specific trend could be distinguished within both series 1 (Figure 4a) and 2 (Figure 4b), suggesting a more complete protection of the ODN by entrapment within the polycationic core. Similarly, Harada et al. reported that an increased degree of polymerization of PEG-PLL block copolymers positively influenced the protection efficiency, which likewise provided evidence for protection via the polycationic segment (*9*).

Complement Activation. The interaction of interpolyelectrolyte complexes with blood and blood components seems to be a major obstacle for their intravenous administration (*17, 34*). Components of the complement system, as part of the nonadaptive immune system of vertebrate species, have been demonstrated to interact with non viral vectors (*24*). The binding of complement proteins to DNA complexes leads inevitable to complement-dependent phagocytosis as demonstrated for liposomes (*25*). Clearance by the reticuloendothelial system reduces the complex half-life within the blood stream. Plank et al. studied the complement activation of commonly used nonviral vectors (*24*). They reported that a high degree of PEGylation decreased complement activation. In this study, the influence of the PEGylation degree, as well as that of PEG molecular weight, on complement activation was systematically investigated. Dilutions of the two series of ODN block copolymer complexes were examined according to the protocol of Plank et al. (*24*). The appropriate initial serum dilution required for 50% hemolysis was determined and expressed as $CH50_{max}$. In theory, binding of complement components to the PEG-PEI/ODN complexes during incubation with serum results in a consumption of these complement factors. Thus, they are no longer available for the following hemolysis, leading to a concentration dependent decrease of $CH50_{max}$. The PEG-PEI complexes of the first series consumed complements component to the same extent as PEI 25 kDa (Figure 5a). Thus, it may be concluded that the shielding obtained by PEGylation with 5 kDa PEG does not necessarily result in decreased complement activation. Increasing PEGylation up to 77% PEG content did not show any positive effects. This is in line with the results of Plank et al. who did not observe a decrease in complement activation of PEGylated PLL when investigating copolymers with up to 20 PEG chains and molecular weights ranging from 1 to 12 kDa. Only larger PEGylation degrees finally led to decreased complement activation (*24*). On the other hand, PEGylation with 550 Da PEG (Series 2) achieved decreased complement activation (Figure 5b). A correlation between the increase in $CH50_{max}$ and the PEGylation degree was observed. The fact that the PEG-PEIs with 100 chains of PEG 550 Da and 15 chains of PEG 5 kDa contain approximately the same amount of PEG, suggests that not the total PEG content, but rather the PEG molecular weight and, hence, the degree of substitution influences complement activa-

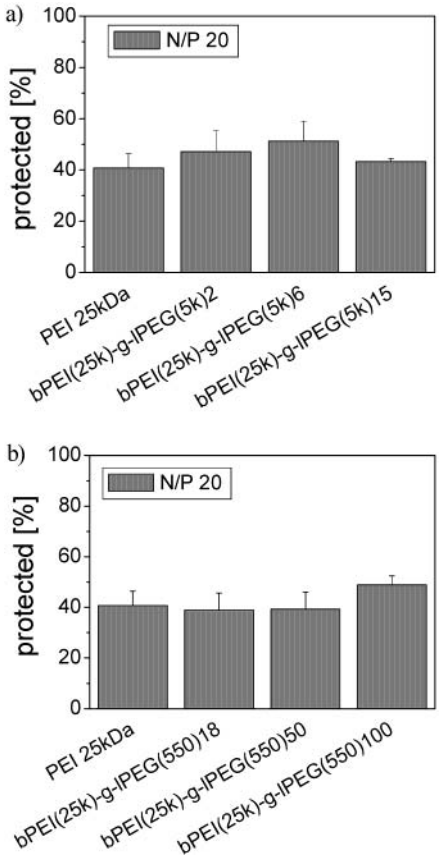

Figure 4. Nuclease stability of ODN−PEI 25 kDa and block copolymer complexes (a) of Series 1 and (b) of Series 2, at N/P ratio 20. All experiments were run in triplicate. (One-way ANOVA statistic test revealed no significant difference).

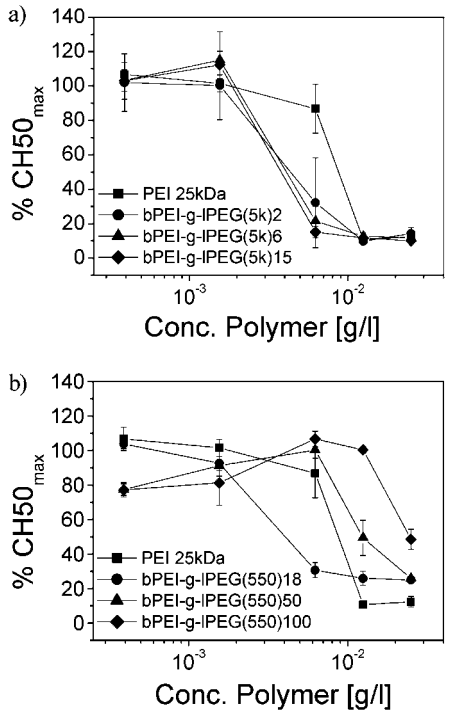

Figure 5. Complement activation of ODN−PEI 25 kDa and block copolymer complexes (a) of Series 1 and (b) of Series 2, at N/P ratio 20. All experiments were run in triplicate.

tion. We hypothesize that a high degree of substitution leads to a brushlike PEG coverage of the polycationic surface. This "crew-cut" micelle structure, achieved only when using the small 550 Da PEG chains, is better capable of preventing complement activation. Movement of the smaller number of longer PEG chains possibly enables contact with the polycationic core. The zeta potential values of all block copolymer complexes suggest that simple shielding of the surface charge is not sufficient to prevent complement activation.

Biological Activity of Ribozymes. Ribozymes are short single-stranded RNA−ODN capable of cleaving their target mRNA in a sequence-specific manner (*35*). Due to the RNA structure, these molecules are even more accessible to enzymatic degradation than the corresponding DNA-ODN (*36*). It could be previously demonstrated that PEI is able to stabilize ribozymes even under in vivo conditions (*37*). The ribozyme-based assay used in this study, therefore, was designed to investigate the influence of PEI-*g*-PEG block copolymer structure on two effects simultaneously: First, the ability to protect ribozymes under cell culture conditions and, second, the biological activity of the ribozyme, therefore, representing very drastic conditions. Ribozymes directed against the luciferase mRNA in stably transfected SKOV-3 cells cause sequence-specific cleavage of the target mRNA, resulting in a decrease of luciferase activity. When cells were incubated with noncomplexed ribozyme as a control, no ribozyme activity could be observed, due to degradation of the ribozyme by the 10% FCS supplement in the cell culture medium. Luciferase activity was comparable to untreated cells, as seen in Figure 6a. Also an unrelated ribozyme, not complementary to the luciferase mRNA, did not affect luciferase activity. In contrast, exposure of cells to ribozyme PEG-PEI complexes led to approximately a 50% down-regulation of the luciferase activity. The interpolyelectrolyte complexes of series 1 (Figure 6b) as well as of series 2 (Figure 6c), demonstrated ribozyme activity comparable to that of PEI 25

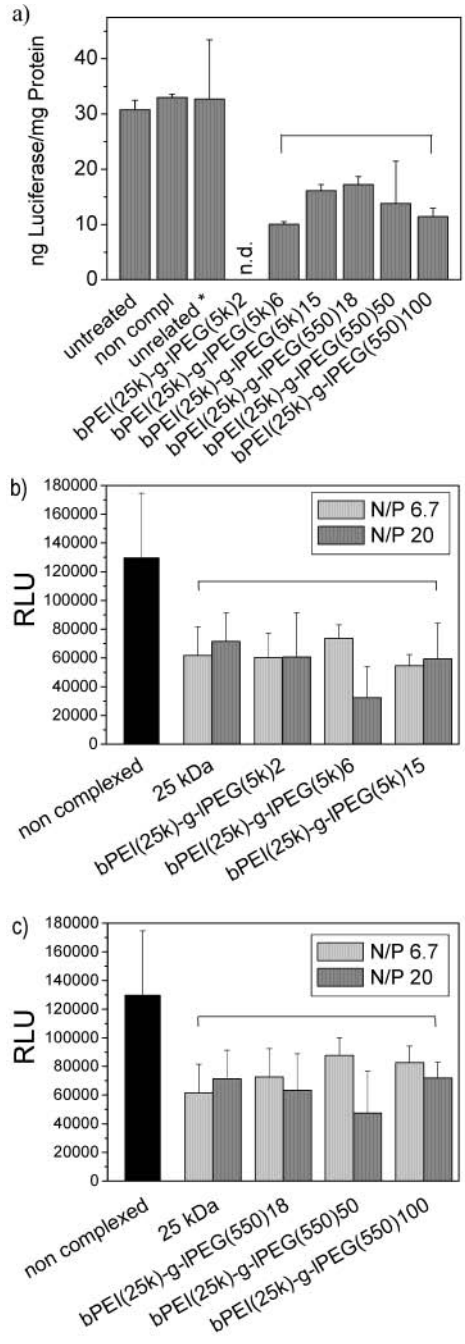

Figure 6. Biological activity (a) as ng luciferase/mg protein of ribozyme block copolymer complexes at the N/P ratio of 20 in comparison to unrelated ribozyme (* complexed to bPEI(25k)-*g*-lPEG(5k)6) and noncomplexed ribozyme and as relative light units (RLU) of ribozyme block copolymer complexes (b) of Series 1 and (c) of Series 2, at the N/P ratios 6.7 and 20 in comparison to PEI 25 kDa. All experiments were run in triplicate. One-way ANOVA statistic test revealed no significant difference between biological activity of PEI 25 kDa complexes and block copolymer complexes.

kDa. Furthermore, no influence of increasing PEGylation on the activity could be distinguished. Surprisingly, the N/P ratio of 6 and 20, respectively, had only a marginal effect on ribozyme activity. In contrast to our observations with ribozyme, it has been reported that the delivery of plasmid DNA using PEG modified PEI often caused a dramatic decrease of transfection efficiency (*38*, *39*). Recently, the transfection activity of five different PEI-*g*-PEG block copolymers used for plasmid delivery was studied systematically (*26*). It was found that trans-

fection was negatively influenced by an increasing degree of PEGylation. This was explained by the differences in cytotoxicity and zeta potential of the various complexes. Under our experimental conditions, only marginal differences in the zeta potentials of the different PEI-*g*-PEG block copolymer complexes could be observed, which correlates well with the similar biological activity observed. It was speculated that the small ribozyme could be condensed more effectively and the shielding of the positive surface charges could be achieved with lower degrees of PEGylation. It has been reported that the transfection efficiency of PEG-PEI complexes with pSV-β-gal plasmid was slightly decreased with an increase in PEG content. However, PEGylation did not affect the transfection efficiency of the complex for 48 h transfection in the presence of serum (*40*), analogous to the observation period in this study. Only limited results are available reporting successful ODN transfection using block copolymers (*14*, *21*, *22*). An antisense effect directed against amphiphysin was achieved at a very low ODN concentration using a PEGylated polyspermin (*22*). However, this provides evidence that PEG-PEI copolymers do have potential for an efficient ODN delivery. Under our experimental conditions, ODN transfer was as effective as with PEI 25 kDa. This trend might be further increased using even higher N/P ratios, as demonstrated for plasmid DNA. bPEI(25k)-*g*-lPEG(550)35 at N/P 50 achieved transfection rates 1 order of magnitude higher than that of PEI 25 kDa at N/P 20, possibly due to the decreased toxicity of PEGylated PEI derivatives (*26*). Whether this trend in transfection efficiency of plasmid DNA and ODN are comparable remains to be resolved.

CONCLUSIONS

The results of this study demonstrate that PEI-*g*-PEG block copolymers formed very small, homogeneously distributed nucleic acid complexes with high nuclease protection and transfection efficiency. Block copolymers with a high number of short PEG chains (550 Da) achieved a decreased activation of the complement system without losses in biological activity. Therefore, the favorable characteristics of highly grafted copolymers with low molecular weighted PEG are suitable for the delivery of ODN and ribozymes. These new insights into the structure−property relationships of ODN copolymer complexes are valuable for the optimization of hydrophilic nonviral carriers for an efficient ODN delivery.

Synthesis and Characterization of Bioconjugates of S-Layer Proteins

Parthasarathy Sampathkumar and M. Lane Gilchrist, Jr.*

Departments of Chemical and Biomedical Engineering, The City College of the City University of New York, New York, New York 10031. Received November 6, 2003; Revised Manuscript Received February 11, 2004

The self-assembling proteins that form crystalline surface layers (S-layers) on many microbial species have found numerous applications due to their nanostructured nature. To devise a new method to construct surface displays that exploit S-layer self-assembly activity and nanostructural properties, we have constructed polymer bioconjugates of S-layer proteins. The conjugates formed are similar in function to the monomer alkanethiols that form self-assembled monolayers (SAMs) on gold surfaces. However, the self-assembly is driven by the protein "headgroup" that positions polymer-tethered endgroups on a surface. This paper examines the integration of protein purification, conjugation, and surface assembly that has led to the development of this new method for the formation of nanostructured surfaces. Purified S-layer proteins from *Lactobacillus brevis* were conjugated with small molecule probes and polymers using amine-based reactions. To keep multiple labeling of protein amine groups to acceptable levels, the conjugations were performed at pH 6.5, allowing for limited yields (24−39%) as determined by mass spectrometry and SDS-polyacrylamide gel electrophoresis. As the presence of high levels of unlabeled S-layer proteins is undesired, we have developed a protocol for further purification that employs monomeric avidin affinity chromatography. The surface self-assembly of the polymer bioconjugates onto amine-terminated microspheres was studied using epi-fluorescence, confocal, and scanning electron microscopy. The surfaces obtained exhibited homogeneous distributions of tethered molecules. Also, in cases where the modular assembly of two distinct types of tethered endgroups was accomplished, there was no evidence for phase separation in the surfaces. The modular assembly method will provide a potential route to controlling surface display density as the starting assembly conditions guide displayed endgroup concentrations in mixed molecular monolayers.

INTRODUCTION

Microorganisms often employ crystalline surface monolayers of self-assembling proteins for molecular display, exozyme binding, and other extracellular functions (*1*). These protein monolayers, collectively known as the crystalline surface layer or S-layer, contain subunits with molecular weights ranging from 40 to 200 kDa, depending on the species (*1*−*8*). In the assembled form, the S-layer proteins form porous crystalline molecular monolayers with unit cell dimensions on the order of 4−15 nm (*5*). The regular nanostructure and high degree of long-range order provides favorable attributes for potential uses of the assembled S-layer in nanostructured materials (*1*, *2*, *7*, *9*). This study concerns the development of a new method to be used for building nanostructured, self-assembled monolayers based on S-layer bioconjugates.

Various subtypes of S-layer proteins have been used in wide ranging applications such as ultrafiltration membranes (*2*), solid supports for lipid bilayer membranes (*10*), and nanoparticle arrays (*11*). S-Layer proteins that associate with the peptidoglycan layer of the microbial cell wall, can in general, be disassembled, but not denatured, by treatment with chaotropic agents such as LiCl or guanidine HCl. These proteins can be separated from cells and media by centrifugation and then reassembled in vitro by dialyzing out the chaotrope or salt. Thus, successive steps of disassembly and reassembly can be used to obtain gram quantities of highly purified S-layer proteins. The reassembly of these proteins onto interfaces can be controlled via surface charge or hydrophobicity. This process has been studied extensively by Sleytr and co-workers (*1*, *2*, *9*). These advances in purification and reassembly have facilitated the ultrastructural analysis of the assembled layers and paved the way for nano- and biotechnological applications (*2*, *5*).

The crystalline nanostructure of the S-layer gives rise to protein surface sites that repeat regularly in two dimensions over the structure assembled onto an interface. The arrays of protein reactive sites provided by surfaces of assembled S-layer proteins have been used for the conjugation of antibodies, vaccine adjuvants, and other molecules. Thus, the proteins produce a very high-density array of displayed molecules that retain the underlying regular spacing of the S-layer (*2*, *9*). A recent major advance involved the successful construction of S-layer fusion proteins containing antibody fragments and streptavidin monomers that have been assembled onto surfaces (*12*, *13*). In previous studies involving surface chemical modification, the conjugation was carried out by first assembling the S-layer and then conjugating a single moiety (*9*).

In contrast, the aim of the research described here is to first build individual bioconjugates of various functionalities tethered by highly hydrophilic poly(ethylene glycol) (PEG) linkers and then assemble them in a modular fashion onto surfaces. The driving force for self-assembly is provided by the S-layer protein, and, in essence, the S-layer proteins serve as headgroups in molecules designed to form self-assembled monolayers (SAMs). The PEG tethers are included so as to provide

Published on Web 07/03/2004

passivation from nonspecific protein adsorption (*14*−*17*). The important aspect of SAM formation by this method is that a new route to form surfaces of controlled surface density that contain mixtures of displayed functional groups is envisioned. As this system is built upon the nanometer spacing of the S-layer, larger molecules such as polymers are displayed in adjacent lattice sites with imposed separation. This spacing imparts two major favorable characteristics to such self-assembled monolayers. First, phase separation during assembly of mixed monolayers would be suppressed, leading to uniform surface distributions of displayed molecules of disparate sizes or functionalities (*18*−*20*). Second, the intrinsic separation between neighboring endgroups would curb steric hindrance of molecular recognition and block interendgroup interactions that could result in aggregation and loss of functional activity. The overall consequence would be the placement of more active and accessible endgroup molecules per unit area, leading to optimized molecular recognition at interfaces and increased miniaturization and complexity of the resulting molecular array.

This paper provides a detailed description of the synthesis and characterization of S-layer protein bioconjugates, spanning from small molecule probes to biotinylated polymers. Reversed-phase high performance chromatography/mass spectrometry (RP-HPLC-MS) and polyacrylamide gel electrophoresis (SDS−PAGE) were used to obtain bioconjugation reaction yields. Gel filtration and monomeric avidin affinity chromatography was used to purify the bioconjugates. S-Layer bioconjugates were assembled onto amine-terminated polystyrene beads, and ligand display and surface distribution were studied using epi-fluorescence, confocal, and electron microscopy.

MATERIALS AND METHODS

Materials. S-Layer proteins (SLP) were extracted from the surface of the bacteria *Lactobacillus brevis* ATCC 8287 that were purchased from ATCC, Manassas, VA. Biotin-PEG_{3400}-*N*-hydroxysuccinimide (Bio-PEG-NHS), fluorescein-PEG_{2000}-*N*-hydroxysuccinimide (Fl-PEG-NHS), and vinyl sulfone-PEG_{3400}-*N*-hydroxysuccinimide (VS-PEG-NHS) were purchased from Shearwater Polymers (Huntsville, AL). Fluoroscein isothiocyanate (FITC) was obtained from Sigma, St. Louis, MO. BODIPY 558/568-*N*-hydroxysuccinimide (Bodipy558), D(+)-biotin, and NeutrAvidin-coated TransFluoSpheres fluorescent nanospheres (100 nm nominal size; 488 nm excitation/605 nm emission) were obtained from Molecular Probes, Eugene, OR. Monomeric avidin affinity column gels and Sephadex G-50 and G-25 gel supports were purchased from Sigma, St. Louis, MO. Biotin-*N*-hydroxysuccinimide (Bio-NHS) and BS^3 (bis(sulfosuccinimidyl) suberate) were obtained from Pierce Chemical, Rockford, IL. All other chemicals used to make buffers were purchased from Sigma except for glycine (BioRad Laboratories, Hercules, CA). The regenerated cellulose dialysis tubing used during purification was purchased from Fisher Scientific (nominal molecular weight cut off between 12 000 and 14 000).

S-Layer Protein Purification. The bacteria (*L. brevis* ATCC 8287) were grown unstirred in MRS broth (Difco Laboratories, Sparks, MD) at 37 °C for 2 days after inoculation with 3% (v/v) 2 day culture. The extraction and purification steps are similar to that performed by Lortal and co-workers (*21*). Exponential-phase cells were recovered by centrifugation at 14 000*g* for 20 min. The cell pellets were resuspended in distilled water to wash the remaining broth and centrifuged again at 14 000 g for 20 min. After two such wash cycles, 10−15 mg of moist pellet was suspended per milliliter of 5 M lithium chloride (LiCl) (Sigma) and incubated for 30 min at 4 °C to extract the S-layer protein. The extract was then centrifuged at 14 000*g* for 20 min, and the supernatant was designated as crude extract.

The crude extract was purified using a gel filtration chromatography column, 2.5 × 50 cm, with a uniform packing of Sephacryl S200 HR (Sigma) gel, equilibrated with 5 M LiCl. The protein was eluted at 30 mL/h, and 1.5 mL fractions were collected. In some runs, the crude extract was concentrated prior to injection into the column. They were concentrated 10-fold using Millipore Ultrafree-15 centrifugal filter device (Sigma) having a 30 kDa cut off. The device was first washed for 10 min with deionized water, and then the protein was added (in 5 M LiCl solution) and spin-filtered at 4000*g* until the final concentration was reached. In some other runs, the protein was first dialyzed against water overnight, and the assembled protein was resuspended in 5 M LiCl before injection.

Construction of Bioconjugate Modules. Purified protein suspended in 5 M LiCl was dialyzed overnight against water. The assembled proteins were dissolved separately in 50 mM sodium phosphate buffers at pH 6.5 to obtain a final protein concentration of 5−10 mg/mL. The probes were then dissolved in deionized water and immediately added to the protein solution for conjugation. All reactions were carried out at 4 °C in darkness, in a flask shaker. Twenty-fold molar excess of small molecule probes (FITC, Bodipy558, and Bio-NHS) and 10 molar fold excess of Fl-PEG-NHS, Bio-PEG-NHS, and VS-PEG-NHS were used for conjugation, with 24 and 12 h reaction times, respectively. The reactions were terminated with 150 mM hydroxylamine (Sigma) at pH 7. Unreacted probes were removed by gel filtration either through Sephadex G-25 (Sigma) (small molecule probes) or Sephadex G-50 (PEG-tethered probes) gravity columns that have been equilibrated with 50 mM, pH 6.5 sodium phosphate buffer. The gels were hydrated for 1 h and 3 h, respectively, and decanted for any floating particles prior to loading. The S-layer protein small molecule probe conjugates were analyzed with HPLC in tandem with mass spectrometry (HPLC-MS) to identify their respective yields. PEGylated S-layer protein yields were obtained from gel desitomograms of 4−15% Tris SDS−PAGE (Bio-Rad Laboratories, Hercules CA) runs carried out in a minigel apparatus with Coomassie protein staining. Gel densitomograms were obtained using a 16 bit Umax flatbed scanner, with image processing carried out using Igor Pro 4.0.

Monomeric Avidin Affinity Column Purification. To separate the biotinylated conjugates from the unlabeled S-layer protein, we used affinity columns containing monomeric avidin. These columns selectively retain the biotinylated proteins during disassembly process or 5 M LiCl wash. The required biotinylated and fluorescently labeled protein monomers were eluted with free biotin buffer (50 mM sodium phosphate, 150 mM sodium chloride containing 1 mg/mL D(+)-biotin).

The affinity gels after packing were washed with four column volumes of 50 mM sodium phosphate with 1 mg/mL of D-biotin, pH 7. Subsequently, the columns were washed with 8 to 10 volumes of 100 mM glycine·HCl, pH 2, to displace biotin from exchangeable sites. The resins were then reequilibrated with 50 mM sodium phosphate, 150 mM sodium chloride, pH 7, prior to sample injection. Samples of volume approximately 10% the column volume were injected to saturate the resin. The resins were

mildly agitated once to ensure proper mixing of the contents and incubated in dark for 30 min. The buffer was then replaced with 5 M LiCl, and the resin was again incubated in dark for 1 h to facilitate complete disassembly of the S-layer protein multimers. Following the incubation, there was 5 M LiCl wash to remove unlabeled S-layer proteins, followed by a neutral buffer wash and free biotin elution of the conjugates at 15 mL/h flow rate with all the fractions being collected. The affinity-purified biotinylated conjugate is recovered during the free biotin buffer elution (50 mM sodium phosphate with 1 mg/mL of D-biotin, pH 7). All the peak fractions were pooled and collected for further analysis.

Microsphere Surface Assembly Experiments. Purified S-layer bioconjugates were assembled onto amine-terminated polystyrene microspheres (6 μm nominal size; Polysciences, Inc, Warrington, PA) using the following procedure. Purified S-layer bioconjugates at 2 mg/mL concentration were centrifuged at 14 000*g* to remove assembled fragments. The resulting supernatant containing disassembled S-layer conjugates and unlabeled S-layer protein was used in surface assembly. To conduct modular self-assembly, desired proportions of individual conjugates were mixed and added to amine-terminated S-layers in large excess to total surface area. The self-assembly was conducted at pH 8 in phosphate buffer for 24 h at 4 °C. Subsequently, the assembly solution was removed by 50*g* centrifugation-induced settling of the microspheres. The microspheres were then gently washed with pH 8 buffer to remove any remaining unassembled protein, and then the amine-reactive homobifunctional cross-linker BS^3 was added at a concentration of 10 mM for a 30-min reaction in 50 mM sodium phosphate buffer, pH 8 at 4 °C. The cross-linking reaction was quenched with hydroxylamine (150 mM), followed by a washing step with pH 8 buffer to remove any remaining deactivated BS^3. At this stage the microspheres assembled with biotin-PEG_{3400}−S-layer conjugates were incubated overnight with and excess of NeutrAvidin-coated TransFluoSpheres fluorescent nanospheres at 4 °C, followed by washing with pH 8 buffer to remove any excess unbound nanospheres.

Mass Spectrometry. S-Layer protein samples and their small fluorophore bioconjugates were analyzed using reversed-phase HPLC (C-18 column) in line with an electrospray ionization mass spectrometer. The studies were carried out using an HPLC-ESI-MS Agilent Chem Station at the Hunter College of the City University of New York Mass Spectrometry facility. The samples were prepared to give an average protein content of 10−15 μg in a 10% acetic acid solution. The samples injected into the C18 column of the HPLC-MS were eluted at the rate of 0.5 mL/min with a gradient flow of acetonitrile.

Confocal, Epi-Fluorescence, and Electron Microscopy. Samples were imaged using a Leica TCS-SP four channel confocal microscope at the Mt. Sinai School of Medicine, using 488 nm excitation for fluorescein and 568 nm for the TransFluoSpheres fluorescent nanospheres. The transmitted light channel was used to position the imaging plane at the center of the microspheres. Epi-fluorescence microscopy was conducted using a Nikon TE300 inverted microscope with B-2A and G-2E/C filter cubes for fluorescein and TransFluoSpheres fluorescent nanospheres, respectively. Samples for scanning electron microscopy were dried, sputter-coated with gold, and observed with a JEOL 35 scanning electron microscope at the Mt. Sinai School of Medicine. Image analysis, including fluorescence emission intensity profiling, was accomplished with IgorPro 4.0 and NIH Image 1.63.

RESULTS AND DISCUSSION

Purification of *Lactobacillus brevis* S-Layer Protein. Surface layer proteins range in size from 40 to 200 kDa, depending on the species of origin. Our rationale for the choice of the smaller *Lactobacillus* variant S-layer protein for these studies was based on suitability for facile characterization by both mass spectrometry and eventually high-resolution solid-state NMR. The *Lactobacillus brevis* S-layer protein was obtained at yield of greater than 100 mg/L of microaerobic culture in MRS broth. At these high yields a 10 g pellet of the bacterial cells will conservatively yield ∼0.5 g of S-layer protein. The protein purification was monitored using SDS−PAGE, shown in Figure 1A. The S-layer protein crude extract is run through two cycles of (1) dialysis (assembly: 30 kDa Mw cutoff), (2) 5 M LiCl disassembly, and (3) dialysis once again to bring the purity up to >50%, shown in Figure 1, Lane 2. Three main impurities remain with estimated molecular weights of 23, 27, and 35 kDa. Gel permeation chromatography was used to isolate the *L. brevis* S layer protein with a final purity of >95%, shown in Lane 3. The target protein for the bioconjugation studies was first cloned and sequenced by Vidgren and Palva (*22*). Their nucleic acid sequence analysis revealed a 465 residue open reading frame with a capacity to encode a 48 159 Da protein. This sequence contains a 30 residue signal peptide common to Gram-positive species. Analysis of the purified protein with reversed-phase HPLC electrospray mass spectrometry (RP-HPLC-MS) gave a molecular weight of 45 238 Da. The molecular mass of the *L. brevis* S-layer protein corresponds to the 465 residue open reading frame with the 30 residue signal peptide removed, resulting in a 435 residue protein. This purified S-layer protein is the starting material for the bioconjugation studies outlined below.

Construction of *Lactobacillus brevis* S-Layer Protein Bioconjugates. The goal of this work was to produce functional S-layer bioconjugates by tethering molecules of various sizes while retaining the self-assembly "activity" of the S-layer protein. As this protein contains no cysteines and many (over 30 each) primary amines, carboxylates, and hydroxyls, when using standard coupling strategies, the challenge is to limit multiple labeling. To achieve this outcome, we have used amine-based coupling chemistry, targeting the α-amino group of the amine terminus by running the coupling reaction at below neutral pH to suppress ϵ-amino lysine reactivity. An additional, S-layer specific consideration in the conjugation is the multimeric state of the protein. In these studies the S-layer protein is undergoing the bioconjugation reaction in the assembled form. Thus, the majority of the protein is assembled into multimeric sheet structures with up to micron length scales (as evidenced by visual light scattering and fluorescence microscopy; data not shown). In this state, the larger multimers in the solid state are in dynamic equilibrum with a soluble form of the protein, likely composed of monomers or smaller multimers. Conjugation in the assembled form is dictated by the fact that the fully disassembled or soluble form of the protein is obtained only at high concentrations of LiCl or guanidine hydrochloride, solution conditions incompatible with bioconjugation reactions. An inherent advantage is that reactive sites left exposed when the protein is in the assembled form will most likely lead to conjugates that retain the ability to self-assemble.

To initiate the studies and probe the reactivity of the S-layer protein amines at lower pH, we have employed number of amine-reactive labels for bioconjugation, rang-

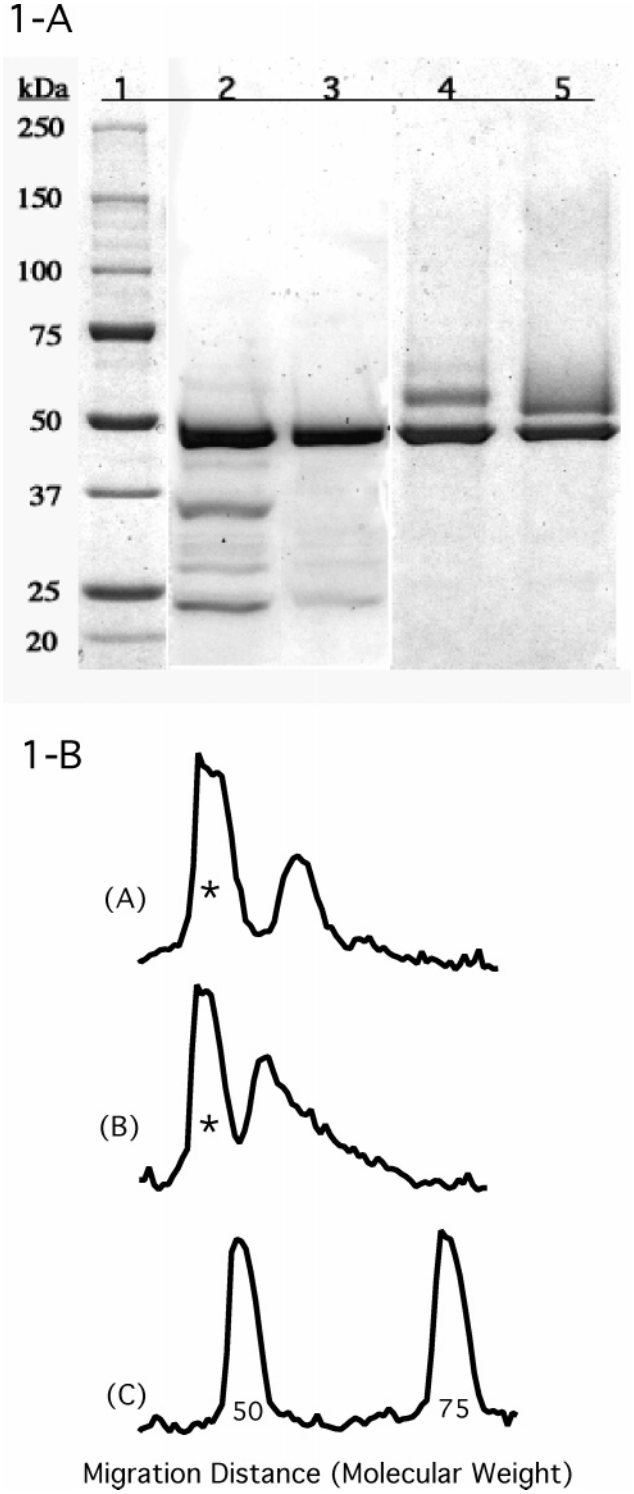

Figure 1. Gel electrophoresis results for the purification of *L. Brevis* S-layer protein and synthesis of poly(ethylene glycol)-based bioconjugates (SDS−PAGE 4−15% Gel). Lane 1 is from the molecular weight markers. Lane 2 is from proteins extracted from the surface of the cells after two cycles of: (1) dialysis (30 kDa Mw cutoff), (2) washing, (3) 5 M LiCl disassembly followed by concentration to give 10 mg/mL. Lane 3 is after prep-scale gel permeation chromatography using sephacryl SH-200 as the support. Lanes 4 and 5 were obtained after conjugation of vinyl sulfone-PEG_{3400} and fluorescein-PEG_{2000}, respectively. The bottom figure shows gel densitomograms of lanes 4 and 5 in traces A and B, respectively, zoomed into the relevant molecular weight range.

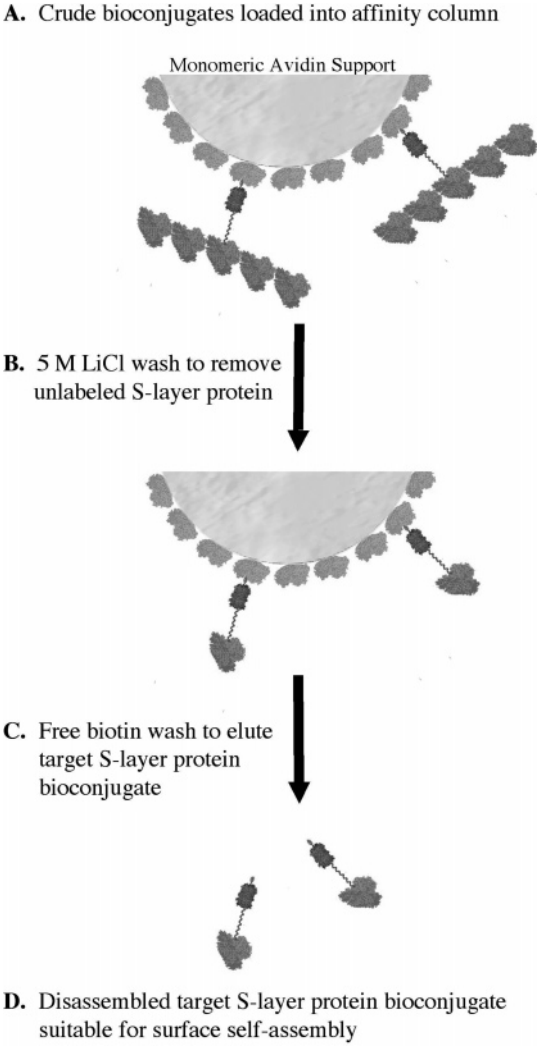

ing from fluorescent probes to polymers. RP-HPLC-MS was used to calculate the yields for the fluorescent probes; for the polymer conjugates, SDS−PAGE densitometry was employed. After exploring a range of conditions in preliminary bioconjugation studies, we converged upon two sets of conditions for low molecular weight probes and polymers. The results of bioconjugation at these two sets of conditions are tabulated in Table 1. In general, the reactions were conducted at S-layer protein concentrations of greater than 5 mg/mL with 20-fold and 10-fold molar excess of reactant for low molecular weight probes and polymers, respectively. However, presumably only low levels of reactive *N*-hydroxysucccinimate and isothiocyanate moieties remained at these 12−24 h long reaction times. For all cases, the yields of singly labeled bioconjugates ranged 24−39%. In all cases except for the FITC coupling, doubly labeled species were obtained, with yields ranging from 4 to 16%. While formed in substantial amounts, these multiply labeled bioconjugates are not expected to limit the applicability of the method as long as self-assembly activity is maintained. For the polymer bioconjugates, the yield of the reactions was estimated from gel densitomograms, shown in Figure 1B. Trace A, obtained from the vinyl sulfone-PEG_{3400}−SLP bioconjugates, contains the unlabeled protein (denoted with an asterisk) and two peaks of successively smaller areas from the bioconjugates. The peaks are Gaussian in line shape, leading to straightforward peak fitting to calculate the yields. For the case of the fluorescein-PEG_{2000}−SLP bioconjugate, the peak resulting from the conjugates is more complex and complicated by the fact that the migration in the gel is less for the smaller polymer bioconjugate (2000 vs 3400 Da for the vinyl sulfone-PEG) (*23*).

To limit the yield of multiply labeled species, we have conducted the conjugation at pH 6.5 in order to protonate the ϵ-amino groups of surface lysines and thus lower their reactivity. One consequence of this reaction condition is that the majority of the protein remains unlabeled and thus must be separated from the conjugates. In the more common conjugation scenario where multiple labeling is desired, repeated cycles of labeling are carried out to increase the yield. However, in this case this strategy is expected to give unwanted higher levels of multiple site labeling that could potentially affect self-assembly. Since the conjugation is conducted while the S-layer protein is in the multimeric assembled form, this provides an added purification obstacle. The conjugated proteins are likely to be present in multimeric structures and surrounded by unreacted protein monomers. The logical separation strategy would be to disassemble and purify; however, the conditions for disassembly are expected to have deleterious effects on the conjugated target protein or group. For the case of the poly(ethylene glycol) conjugates, our observation is that precipitation or "salting out" occurs at levels of LiCl necessary for disassembly. To explore a means for obtaining high purity S-layer protein bioconjugates, we have employed avidin affinity chromatography, in which the specific binding of biotin ligands to the protein avidin is used to bind the target biotinylated bioconjugate to the column via the formation of an high-affinity ligand−protein complex ($K_D \approx 10^{-15}$ M). The monomeric avidin support was selected over tetrameric avidin as the conditions for retrieving the final product are milder and higher yields can be obtained. The method we have employed is shown schematically in Scheme 1. In the first step, crude S-layer bioconjugates are loaded onto the support. As shown in panel A, the conjugates bind to the column via biotins on the surface of target protein (or polymer). This is followed by a washing step to remove the unlabeled S-layer protein

Table 1. Types and Yields of S-Layer Protein Bioconjugates Constructed

Scheme 1. Affinity Purification of S-Layer Protein Bioconjugates[a]

[a] To remove the unlabeled S-layer proteins, monomeric avidin supports were used to bind the biotinylated conjugates, followed by elution of the unlabeled proteins in 5 M LiCl disassembly solution. For fragile tethered functionalities, an extended buffer wash is used to remove the unlabeled S-layer protein. To obtain the purified conjugates, a free biotin (1 mg/mL) elution step is employed

(panel B). In the case where the conjugated group is robust under conditions of high salt, a 5 M LiCl wash is used to disassemble and remove the unlabeled S-layer protein. In other cases an extended washing with pH 7 phosphate buffer is employed. As the assembled, unlabeled proteins are in exchange with the soluble form, over longer elution times the unlabeled proteins will be removed, leaving behind the biotinylated conjugates. In addition, conjugates formed from the PEG labels without biotin, ~20% of the activated PEG reactant, are also

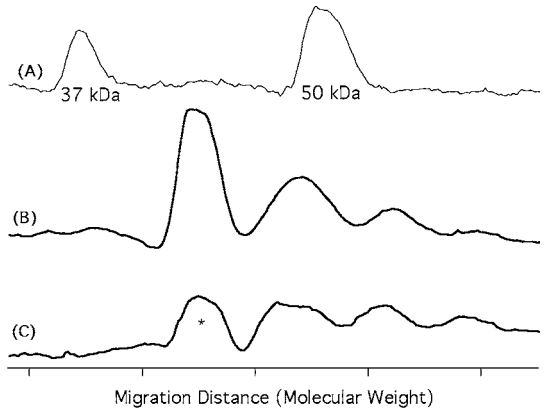

Figure 2. Gel densitometry results for biotin PEG_{2000} S-layer protein bioconjugate purified via monomeric avidin affinity chromatography. Trace A is the molecular weight marker. Trace B is from the unpurified biotin-PEG_{2000}−S-layer protein bioconjugate. Trace C was obtained after monomeric affinity purification (Scheme 2) of the biotin-PEG_{2000}−S-layer protein bioconjugate (trace B was the starting material for the purification).

removed during this step. In the final step the purified bioconjugates are eluted from the support with a free biotin wash. The amount of protein eluted can be adjusted by varying the amount of loaded affinity support bead volume. This protocol provides a precise means of controlling the concentration of S-layer bioconjugates used for assembling surfaces in a modular fashion.

Figure 2 displays the results of the monomeric avidin affinity chromatography conducted on the biotin PEG_{3400} S-layer protein bioconjugate, displayed as SDS−PAGE densitomograms. Trace A was obtained from the molecular weight marker, trace B is from the biotin-PEG_{3400}−S-layer protein bioconjugate, the starting material. The affinity purified conjugate is shown in trace C, eluted from the column with a free biotin wash. Comparison of traces B and C shows a dramatic decrease in the unlabeled S-layer protein, labeled with an asterisk (*); peak analysis gives an approximate 50% decrease in unlabeled S-layer protein. We also obtain higher yields of the multiply biotinylated S-layer proteins since they bind to the monomeric avidin support with higher efficiency.

Surface Assembly of S-Layer Protein Bioconjugates. Thus far we have produced sets of S-layer bioconjugates with PEG tethers for modular assembly onto surfaces; the following section details surface self-assembly. It has been previously established that S-layers from Gram-positive microorganisms assemble in vitro onto surfaces that are positively charged (*2*, *6*, *21*, *24*). Thus, we have conducted assembly experiments using 6 μm amine-terminated polystyrene beads as the assembly substrate. Figure 3, panel 3-A, displays a confocal image of the S-layer−PEG_{2000}−fluorescein bioconjugate assembled onto a 6 μm amine-terminated polystyrene bead, taken as 2D XY slice through the center of the bead. The

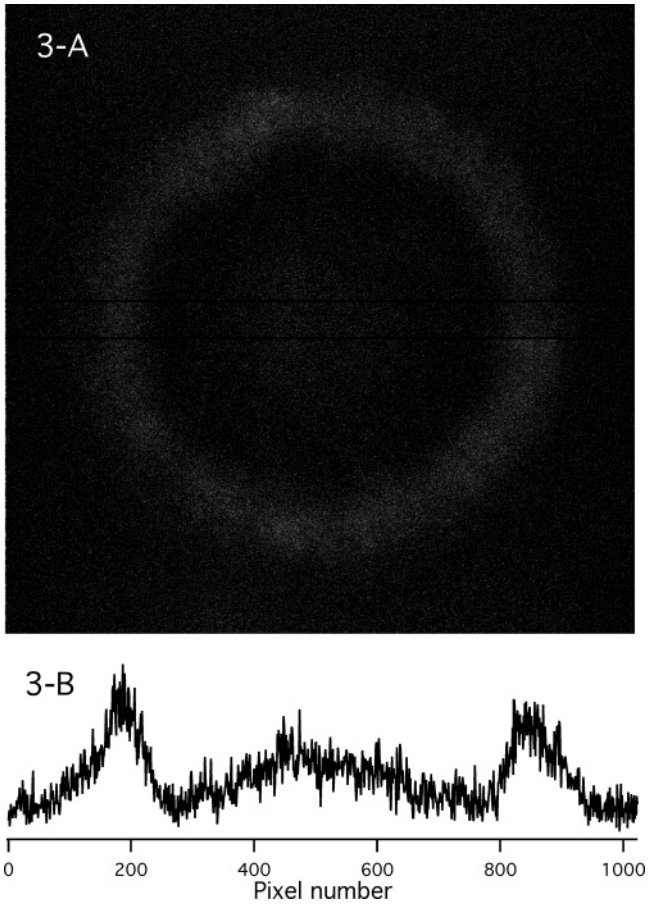

Figure 3. Confocal micrograph of S-layer−PEG_{2000}−fluorescein bioconjugate assembled onto a 6 μm amine-terminated polystyrene microsphere. The top panel (3-A) was obtained from the XY plane that intersects center of the bead. The fluorescence emission intensity profile shown in panel 3-B was obtained from image analysis inside the area bounded by the horizontal lines in 3-A.

light area exhibited symmetrically around the particle is the emission of green (515 nm) fluorescence that has been converted to gray scale in the image. The bottom panel 3-B shows the fluorescence emission intensity profile taken through the center of the image, highlighting the annular distribution of fluorescence intensity arising from the conjugate assembled at the membrane surface. As can be seen from inspection of this image, fluorescence intensity profiles obtained from other angles relative to horizontal gave similar results. This image provides direct evidence that the fluorescence is emitted evenly over this microsphere within the resolution of this image. In other microspheres in the sample a similar even surface distribution was seen (data not shown). This confocal data is consistent with complete coverage of the microspheres with a surface layer of S-layer proteins and S-layer−PEG_{2000}-fluorescein bioconjugates. We note that before the microsphere self-assembly stage the NHS-PEG_{2000}-fluorescein reactant has been carefully removed via gel filtration to preclude nonspecific adsorption artifacts. Furthermore, the highly hydrophilic nature of the polymer retards adsorption of any residual reactant.

As a test system for the assessment of the display capabilities of our S-layer bioconjugates, we have used biotin, in this case, specifically biotin tethered to the S-layer proteins via PEG_{3400} linkages. To detect the surface display of tethered biotin positioned on the surface resulting from modular self-assembly of the S-layer protein conjugates, 100 nm sized avidin-coated,

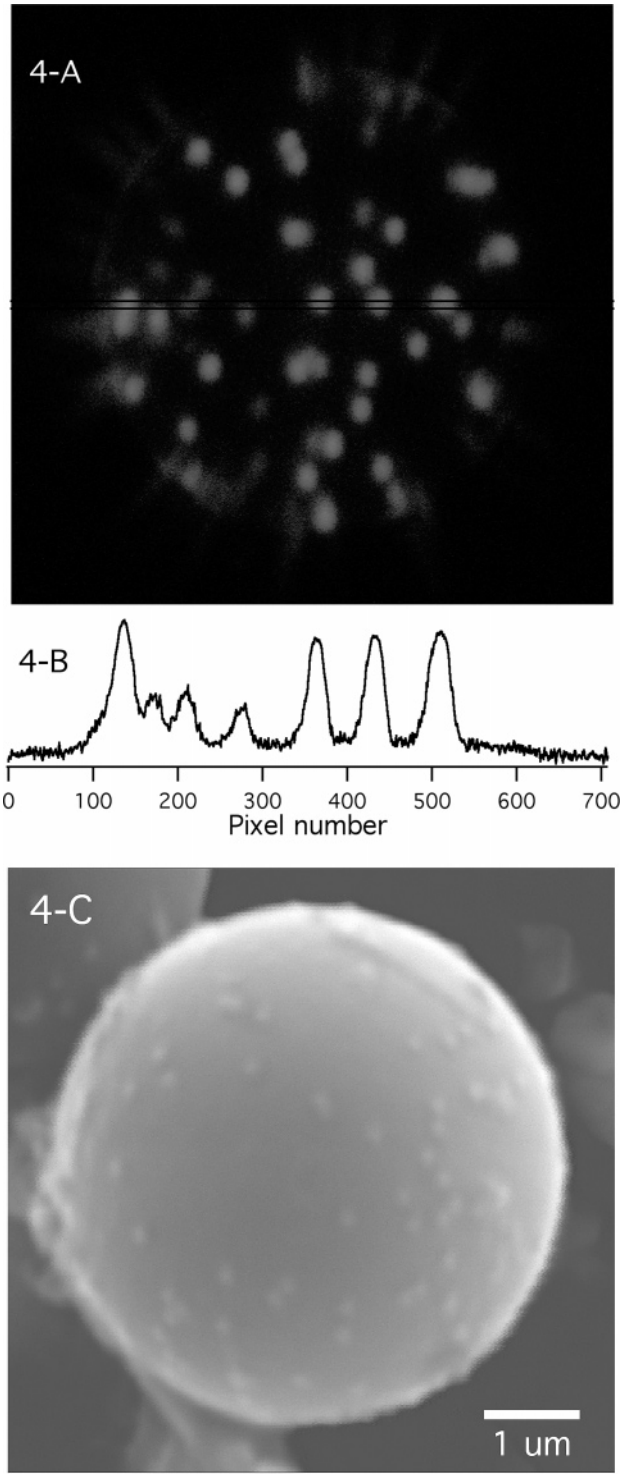

Figure 4. Confocal micrograph of monomeric avidin affinity purified S-layer−PEG_{3400}-biotin bioconjugate assembled onto a 6 μm amine-terminated polystyrene microsphere, followed by biotin−avidin complex formation with 100 nm avidin-coated nanospheres. The top panel, 4-A, was obtained from averaging over 20 XY sections. The fluorescence emission intensity profile shown in panel 4-B was obtained from image analysis inside the area bounded by the horizontal lines in 4-A. The relative intensities of the nanospheres were affected somewhat by photobleaching and scattering artifacts; however, this did not preclude accurate measurements of nanosphere binding. Panel 4-C is a scanning electron micrograph taken of a microsphere from the same sample that was sputter-coated with gold.

fluorescent nanospheres (nanospheres) were used. Figure 4 shows the results obtained from the self-assembly of avidin-affinity purified S-layer−PEG_{3400}-biotin conjugates

onto 6 μm amine-terminated polystyrene beads. Panel 4-A was obtained from the average of confocal images taken as 2D slices in the XY plane, detecting the red fluorescence emission of the nanospheres (here shown in gray scale as dots). This image gives the localization of nanospheres over the entire surface of the larger microsphere. The nanospheres appear to be evenly distributed, thus the PEGylated and unlabeled S-layer proteins are not assembled onto the surface in separate domains (i.e. phase separation in SAM research). The middle graph (Panel 4-B) shows the image line profile taken through a section of the image as indicated, highlighting, in this case, the nanospheres. As expected, at the edges of the microsphere no peak in fluorescence emission intensity is evidenced; even intensity that potentially originates from the scattering of emitted light of the highly fluorescent nanospheres is absent (as is often seen in epi-fluorescence images). To further assess the surface features of the biotin-PEG_{3400}−S-layer bioconjugates assembled on the microspheres, scanning electron micrographs (SEM) were obtained from the same samples (Panels 4-A, 4-B) that were sputter-coated with a thin layer of gold atoms. An SEM image of a microsphere with avidin-affinity purified S-layer−PEG_{3400}-biotin conjugates assembled on the surface is shown in Panel 4-C (prepared from the same sample from Panel 4-A). Over the predominantly smooth surface of the microsphere (at >50 nm resolution) faint yet evident bump-like features are seen from the avidin nanospheres bound to surface-displayed biotin. At this resolution level it appears that the microspheres are completely covered with an even monolayer of assembled S-layer bioconjugates. Furthermore, there is no evidence for multiple layers or for uneven coverage over the surface. Thus far we have produced sets of S-layer bioconjugates with PEG tethers for modular self-assembly onto surfaces.

Our work provides a new route for the formation of surfaces that contain homogeneous displays of mixtures of molecular functionalities. To first demonstrate the concept, we have performed modular self-assembly of S-layer−PEG_{3400}-biotin and S-layer−PEG_{2000}−fluorescein onto 6 μm amine-terminated polystyrene beads. Figure 5, panel A, shows a confocal microscopy image in which both the green (fluorescein) and red (nanosphere) fluorescence emission from multiple 2D confocal XY planes were averaged into a single image and converted to gray scale. The nanospheres are seen as prominent gray dots, and the fluorescein conjugate emission is seen as the background microsphere fluorescence with a peak in emission intensity distributed around the rim of the microsphere. This is emphasized by the emission intensity profile in which the features from the nanosphere are seen as sharp peaks bounded on each side by smaller peaks at the edge of the microsphere. In this image, in contrast to Figure 3, panel 3-B, the fluorescein emission intensity is also substantial in the middle of the image line profile of the microsphere as this is an average over multiple 2D confocal slices over the whole microsphere. Upon inspection of the Figure 5 confocal image, it is apparent that the modular self-assembly resulted in a relatively sparse yet homogeneous surface, as no evidence of phase separation was seen. This is to be expected, as the tether differences in the two conjugates are slight (77 vs 45); studies involving more disparate endgroups are in progress.

It is evident from comparison of the avidin nanosphere coverage in Figures 4A and 5A that differences in the assembly conditions in terms of the starting concentration of S-layer−PEG_{3400}-biotin conjugates led to markedly disparate surface displays of biotin. To further examine

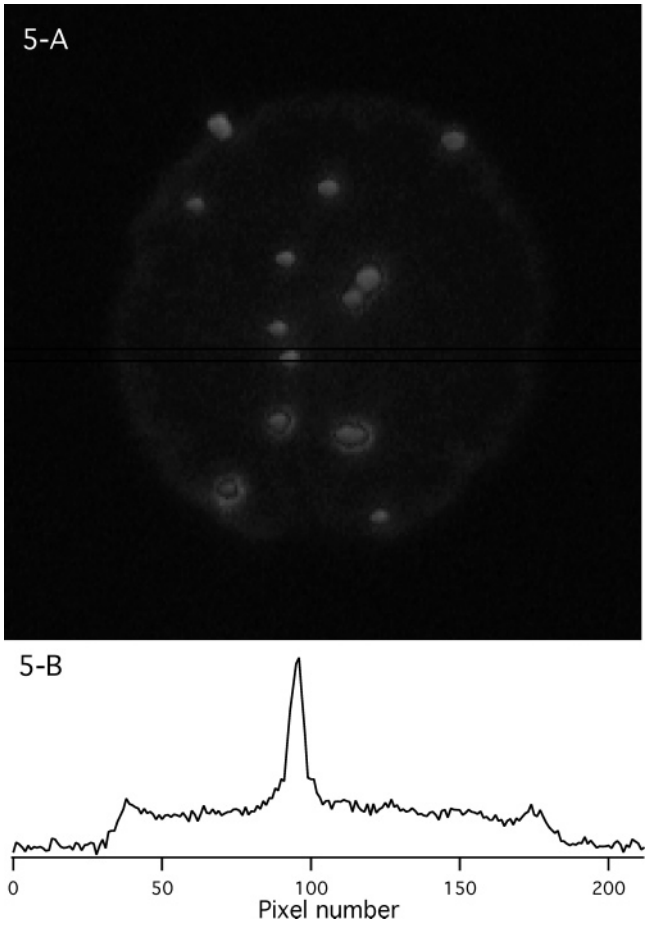

Figure 5. Confocal micrograph of S-layer−PEG_{2000}−fluorescein and S-layer−PEG_{3400}-biotin bioconjugates coassembled onto a 6 μm amine-terminated polystyrene microsphere from a 1:1 mixture, followed by biotin−avidin complex formation with 100 nm avidin-coated nanospheres. The top panel, 4-A, was obtained from averaging over 20 XY sections. The fluorescence emission intensity profile shown in panel 5-B was obtained from image analysis inside the area bounded by the horizontal lines in 5-A.

this difference, the average number of nanospheres bound per microsphere was determined using epi-fluorescence microscopy. Figure 6 shows comparative results of average surface coverage obtained from four samples (20 microspheres averaged): (A) control amine-terminated polystyrene microspheres, (B) microspheres formed from S-layer−PEG_{2000}−fluorescein conjugates, (C) microspheres formed from the modular assembly of S-layer−PEG_{2000}−fluorescein and S-layer−PEG_{3400}-biotin conjugates and (D) microspheres formed from affinity-purified S-layer−PEG_{3400}-biotin conjugates. In the control samples that did not contain biotin, nonspecific adsorption of nanospheres was observed at low levels (A and B). Specifically for the S-layer−PEG_{2000}−fluorescein sample (B), the presence of polymer endgroups gave rise to significant suppression of this nonspecific adsorption of avidin-coated nanospheres. Studies to further examine this suggested inhibition of nonspecific protein adsorption by displayed polymer endgroups are underway.

When biotin-PEG_{3400}−S-Layer conjugates are assembled onto microsphere surfaces, greater numbers of nanospheres bind to the microspheres due to the formation of avidin-biotin complexes. This is shown in the average surface coverage results for C and D of Figure 6, acquired from the samples that were used to obtain the confocal images in Figures 5A and 4A, respectively. As these samples were prepared at different times, only

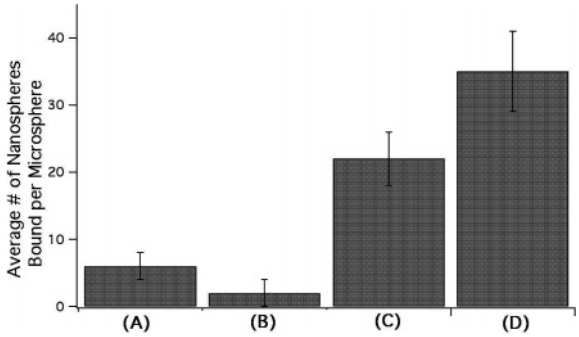

Figure 6. Average number of nanospheres bound per microsphere obtained from epi-fluorescence microscopy. Each data point was derived from the average of 20 microspheres, with error bars set from approximately the full width half-maximum of histograms from the data. Data from experimental controls (without biotin) are shown in sample A, amine-terminated microspheres, and sample B, from assembly of S-layer−PEG_{2000}−fluorescein conjugates onto 6 μm amine-terminated polystyrene microspheres. Sample C was obtained from a 1:1 mixture of S-layer−PEG_{2000}−fluorescein and S-layer−PEG_{3400}-biotin bioconjugates coassembled onto 6 μm amine-terminated polystyrene microspheres. Sample D was obtained from monomeric avidin affinity purified S-layer−PEG_{3400}-biotin bioconjugates assembled onto 6 μm amine-terminated polystyrene microspheres.

qualitative comparison of the nanosphere binding is intended here. However, an important trend is apparent in that the surface density of displayed biotin can be manipulated by increasing the starting concentration of biotin-PEG_{3400}−S-layer conjugates in the surface assembly. In these samples the levels of nanosphere coverage obtained from biotin-PEG_{3400}−S-layer conjugates are far below that of complete coverage based on surface geometry arguments, approximately <1−5% of total coverage. We are currently conducting the assembly using high purity S-layer bioconjugates to fully exploit the methodology. At the purity levels used in these studies, the surface assembly and coverage is dominated by unlabeled S-layer protein monomers. These were present at higher concentrations and in addition are likely to have faster assembly kinetics than the polymer conjugates. We are currently investigating these effects in detailed studies of S-layer bioconjugate assembly kinetics.

CONCLUSIONS

The construction of assembly competent S-layer bioconjugates was described, based on the conjugation of small molecule and poly(ethylene glycol)-based probes to the S-layer protein from *L. brevis*. The purification of the S-layer protein was accomplished using successive cycles of assembly/disassembly followed by gel permeation chromatography, allowing for the production of copious amounts of starting material for the conjugation. Limited conjugation yields were obtained via pH 6.5 reaction conditions; however SDS−PAGE gel densitometry results provided evidence for predominantly single site labeling as was desired. To provide a route to obtain high purity conjugates free of unlabeled protein, avidin affinity chromatography was employed, leading to a method to control surface assembly conditions and a means for potential scale-up.

The S-layer bioconjugates were assembled onto amine-terminated polystyrene beads to probe surface self-assembly. The surface coverage of polymer conjugates was found to be homogeneous in nature, with no evidence of phase separation of polymer-conjugated S-layer with unlabeled S-layer on the surfaces as assessed using fluorescence and electron microscopy. A reduction in nonspecific binding of avidin-coated nanospheres was obtained with polymer endgroups displayed via S-layer−PEG_{2000}−fluorescein bioconjugates assembled on the microspheres. Modular surface assembly was achieved using S-layer−PEG_{2000}−fluorescein and S-layer−PEG_{3400}-biotin conjugates, also resulting in homogeneous coverage and no detectable phase separation. With this approach, we have also shown that the surface densities of mixed displays can be controlled by changing the relative bulk concentrations of S-layer bioconjugate self-assembly suspensions.

A significant feature of this method is that the mixed monolayers formed would retain the underlying natural nanostructure of the S-layer array. Thus, the spacing of the functional endgroups will be dictated by the underlying S-layer protein matrix. Another potential significant feature of our method is that self-assembled monolayers could be formed using monomer units with larger functional endgroups than is possible with current technologies, such as for example, proteins, polymers, or nanoparticles. This potential benefit stems from the fact that the headgroup protein size is substantially larger than most functional endgroups and the highly stable S-layer structure is energetically favored due to protein−protein and protein−substrate interactions. This could significantly advance self-assembled monolayer technology, providing a new route for the display of intact proteins and other large molecules at an interface.

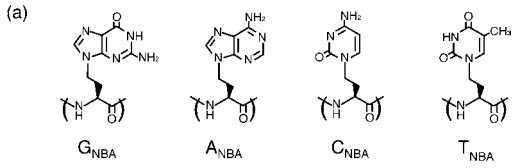
De Novo Design of Peptides with L-α-Nucleobase Amino Acids and Their Binding Properties to the P22 boxB RNA and Its Mutants

Hideo Miyanishi, Tsuyoshi Takahashi,* and Hisakazu Mihara

Department of Bioengineering, Graduate School of Bioscience and Biotechnology, Tokyo Institute of Technology, 4259 Nagatsuta, Yokohama 226-8501, Japan. Received November 12, 2003;
Revised Manuscript Received April 26, 2004



A method to design novel molecules that specifically recognize a structured RNA would be a promising tool for the development of drugs or probes targeting RNA. In this study, the de novo design of the α-helical peptides having L-α-amino acids with nucleobases (nucleobase amino acids, NBAs) was carried out. Binding affinities of the peptides for a hairpin RNA derived from P22 phage were dependent on the types and positions of the NBA units they have. Some NBA peptides bound to the wild-type RNA or its mutant with high affinity and high specificity compared with the native P22 N peptide. These results indicate that the NBA units on the peptides interact with the RNA bases in a specific manner. It is demonstrated that the de novo design of peptides with the NBA units is an effective way to construct novel RNA-binding molecules.

INTRODUCTION

RNA−protein interactions play important roles in organisms. The specific interaction between proteins and RNA regulates many biological functions, including transcription, RNA splicing, translation and so on (*1*). In many cases, RNA-binding proteins recognize a specific site of RNA such as hairpin loops, internal loops, and bulges (*1*). Therefore, construction of the novel molecules that specifically recognize a structured RNA could lead to the development of drug design and specific probes against RNA. However, construction of RNA-binding molecules is difficult compared to that of DNA-binding molecules because of the structural diversity of RNA (*2*).

On the other hand, we utilized artificial amino acids having nucleobases in their side chain (nucleobase amino acids, NBAs) (Figure 1a) for constructing novel functional peptides and proteins (*3*−*5*). It has been reported that the NBA units were incorporated into the designed α-helix peptides and the nucleobase interaction on the peptides can regulate the peptide−peptide recognition effectively (*3*). In the design of RNA-binding molecules, NBAs were studied as building blocks capable of interacting with RNA bases specifically (*4*, *5*). For instance, NBA units were incorporated into the HIV-1 nucleocapsid protein NCp7, and their binding affinities for the HIV-1 Ψ-RNA SL3 region were evaluated (*5*). An NCp7 protein containing two NBA units at the specific sites showed a higher binding affinity and specificity than the wild-type NCp7. The study demonstrated the applicability of the NBA units as building blocks for constructing RNA-binding molecules. The peptide and protein engineering studies derived from native proteins showed an advantage for designing more specific molecules than the natural counterparts.

However, this protein-engineering strategy has the limitation that a lot of proteins with NBAs are difficult to be prepared easily with chemical methods. Furthermore, it is hard to design RNA-binding molecules targeting a variety of RNAs by using natural proteins. On this standpoint, we have attempted to start the de novo design of artificial NBA peptides with simple amino acid sequences in short length. A variety of peptides with various sequences are more easily synthesized than the larger protein. Four kinds of NBA units (adenine, guanine, thymine, and cytosine) could be placed on various positions of peptides capable of forming secondary structures, such as an α-helix and a *β*-structure. A strategy using de novo design has a high probability of constructing the molecules targeting a variety of structures and sequences of RNA. To approach this goal, in this study, we have performed de novo design of the NBA peptides

that have high binding affinities and specificities for a hairpin RNA. The findings in this study lead to a way for constructing novel molecules working against RNAs.

MATERIALS AND METHODS

Chemicals and Reagents. All chemicals and solvents were of reagent or HPLC grade. Amino acid derivatives and reagents for peptide synthesis were purchased from Watanabe Chemical (Hiroshima, Japan). MALDI-TOF MS was measured on a Shimadzu MALDI III mass spectrometer by using 3,5-dimethoxy-4-hydroxycinnamic acid as a matrix. HPLC was carried out on a YMC ODS A-302 5C18 column (4.6 mm × 150 mm; YMC, Tokyo, Japan) or a YMC ODS A-323 5C18 column (10 mm × 250 mm) by employing a Hitachi L-7000 HPLC system. Amino acid analyses were performed by using the phenyl isothiocyanate (PTC) method on a Wakopak WS-PTC column (Wako Chemical; Osaka, Japan). Synthetic DNA templates were purchased from Sigma Genosys (Ishikari, Japan). Fluorescein-labeled DNA was purchased from Espec Oligo Service (Tsukuba, Japan). A RiboMAX large-scale RNA production system T7 was purchased from Promega (Tokyo, Japan). T4 RNA ligase was purchased from Takara Bio (Osaka, Japan).

Peptide Synthesis. Fmoc-protected NBA monomers (Fmoc-G_{NBA}-OH, Fmoc-C_{NBA}(Z)-OH, Fmoc-A_{NBA}(Z)-OH, Fmoc-T_{NBA}-OH) were synthesized according to the reported methods (*4b*). The peptides were synthesized by the solid-phase method using the Fmoc strategy with *O*-(7-azabezotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU) or 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) and 1-hydroxybenzotriazole hydrate (HOBt·H_2O) as the coupling reagents (*6*). To synthesize the acetylated-peptide resin, the Fmoc-deprotected peptide resin was reacted with acetic anhydride (10 equiv) in *N*-methylpyrrolidone (NMP) for 20 min. To remove the resin and the protecting groups, the peptide resin was treated with trifluoroacetic acid (TFA) containing *m*-cresol, triethylsilane, and thioanisole as scavengers for 1 h at room temperature. For the peptide resin with the Z groups on A_{NBA} and C_{NBA}, the reaction was carried out for 2.5 h. The product was solidified with diethyl ether in an ice bath. All crude peptides were purified with RP-HPLC on a YMC ODS A-323 column using a linear gradient of 8−38% acetonitrile/0.1% TFA (30 min) to give the purified peptides. Peptides were identified by their molecular ion peak $(M + H)^+$ on MALDI-TOF MS: *m*/*z* found (calcd) P22N, 2234.0 (2232.6); A9R4, 1324.7 (1324.7); GCG, 1774.8 (1774.0); GTG, 1788.0 (1788.0); GAG, 1797.8 (1798.0); GGG, 1812.9 (1814.0); CGG, 1774.3 (1774.0); TGG, 1789.0 (1788.0); AGG, 1796.7 (1798.0); GGA, 1796.9 (1798.0); AlaGG, 1649.9 (1650.9); GAlaG, 1652.1 (1650.9); GGAla, 1652.7 (1650.9).

Preparation of Fluorescein-Labeled P22 boxB RNA and Mutants. The P22 boxB RNA was prepared by transcription of a synthetic DNA template (5′-AATTTAATACGACTCACTATAGGTGCGCTGACAAAGCGCGCC-3′ and 5′-GGCGCGCTTTGTCAGCGCACCTATAGTGAGTCGTATTAAATT-3′) by using the RiboMAX large-scale RNA production system T7 (Promega). The template DNA was degraded by RNase-free DNase I, and then the RNA was purified by polyacrylamide gel electrophoresis (PAGE) (15% acrylamide). The fluorescein-labeled DNA oligomer was incorporated into the product RNA using T4 RNA ligase in Tris-HCl buffer (50 mM, pH 7.5) that contained $MgCl_2$ (10 mM), 1,4-dithiothreitol (DTT, 10 mM), adenosine triphosphate (ATP, 1 mM), bovine serum albumin (BSA, 0.05%), and dimethyl sulfoxide (DMSO, 10%). The solution was incubated at 15 °C for 16 h. The fluorescein-labeled boxB RNA was purified by ethanol precipitation and PAGE. The mutant RNAs were also prepared using the same method. Concentrations of RNAs were determined by the absorbance at 260 nm.

CD Measurements. CD spectra of the peptides were measured on a Jasco J-720WI spectropolarimeter using a quartz cell with 1.0 mm path length in the region of 195−250 nm. Peptides were dissolved in 10 mM Tris-HCl buffer (pH 7.5) containing 100 mM KCl and 1 mM $MgCl_2$ or trifluoroethanol (TFE) solution (peptide concentration of 10 μM).

Fluorescence Anisotropy Measurements. Fluorescence anisotropy measurements were carried on a Shimadzu RF-5300PC spectrofluorophotometer using a quartz cell with a 1.0 cm path length at 10 °C in *N*-(2-hydroxylethyl)piperazine-*N*-(2-ethanesulfonic acid) (HEPES)−KOH buffer (10 mM, pH 7.5) containing KCl (100 mM), $MgCl_2$ (1 mM), and EDTA (0.5 mM). Fluorescence anisotropy was calculated by the intensities at 520 nm excited at 480 nm.

Determination of Dissociation Constants between Peptides and RNAs. The binding affinities of the peptides for the RNA were determined by fluorescence anisotropy measurements. The fluorescein-labeled RNA (5.0 nM) in the buffer solution was titrated with a peptide solution. After each addition of a peptide, samples were stirred for 30 s and equilibrated for 4.5 min at 10°C, and then fluorescence anisotropy was measured. The dissociation constants of the peptides and RNAs were calculated using eq 1 and Kaleida Graph (Synergy Software), assuming a 1:1 stoichiometry:

$$A = \frac{(A_b - A_f)\{[F]_0 + [P]_0 + K_d - (([F]_0 + [P]_0 + K_d)^2 - 4([F]_0[P]_0)^{1/2})\}}{2[F]_0} \quad (1)$$

$[F]_0$ and $[P]_0$ represent the initial concentrations of the fluorescent RNA and a peptide, respectively. A, A_b, and A_f are the anisotropy values of each solution, the bound fluorescent RNA, and the free fluorescent RNA, respectively. K_d is the dissociation constant between the peptide and RNA.

RESULTS AND DISCUSSION

Design and Synthesis of the Peptides. To achieve the de novo design of NBA peptides that interact with a hairpin RNA, four kinds of NBA units, alanine, and arginine residues were used. A hairpin RNA was selected as a target molecule because of its important functions in nature such as that in some viral RNAs (HIV-1 TAR, λ phage boxB) and ribosomal RNAs (*7*). A hairpin RNA studied here is derived from the boxB region of phage P22 RNA that contains a stable GNRA-like (G, guanine; N, any bases; R, guanine and adenine; A, adenine) tetraloop structure (Figure 2a) (*8*, *9*). For the design of the NBA peptides targeting the P22 RNA, NBA units were incorporated into positions 3, 6, and 11 of the peptides (Figure 1b). It was expected that the NBA at position 3 could interact with the stem region of the RNA (Figure 2a). In addition, the NBA units at positions 6 and 11 were expected to interact with the bases of the loop region of the RNA. These expectations were based on the structure of the complex between the boxB RNA and P22 N peptide (*8*), the N-terminal region of P22 phage N protein (*10*). In this peptide−RNA complex, the peptide forms an α-helical conformation, the amino acid residue

Table 1. α-Helix Content of the Peptides in TFE Solution

peptide	α-helicity (%)	peptide	α-helicity (%)
GCG	58	TGG	50
GTG	67	AGG	58
GAG	58	GGA	72
GGG	71	P22N	62
CGG	57	A9R4	55

at position 3 is located in the major groove region, and the residues at positions 6 and 11 are located near the bases of the loop region of the boxB RNA. According to the findings, a variety of NBA peptides (13AA) with three NBA units at positions 3, 6, and 11 were designed. Each peptide has six alanine and four arginine residues in addition to the NBA units (Figure 1b). Alanine was selected to generate a high ability to form an α-helical structure (*11*). Arginine residues were incorporated into the positions expected to interact with phosphate groups electrostatically. In addition to these NBA peptides, the peptides with two guanine NBA units and one alanine residue at these positions were designed. These peptides were expected to clarify the contribution of the NBA unit at each position to the RNA-binding. The A9R4 peptide having three alanine residues at positions 3, 6, and 11 was also designed as a reference molecule for evaluating the NBA function.

Peptides were synthesized using the Fmoc solid-phase method (*6*) and purified by reversed-phase HPLC with high purity. The P22 N peptide was also synthesized as a reference molecule (Figure 2b). All peptides were identified by matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS), and peptide concentrations were determined by amino acid analyses.

Circular Dichroism Study. The designed peptides were expected to form an α-helical conformation when the peptide bound to the RNA. Circular dichroism (CD) spectra of the peptides were measured in 10 mM Tris-HCl buffer (pH 7.5) containing 100 mM KCl and 1 mM $MgCl_2$ or trifluoroethanol (TFE). In the buffer solution, both the peptides with three NBA units and the P22 N peptide did not form an α-helical structure sufficiently. These results should be due to the repulsions between positively charged residues in the peptides. In contrast, all the peptides with three NBA units showed a typical α-helix CD pattern as well as the P22 N peptide in TFE solution. The α-helicities of the peptides were estimated from the molecular ellipticity at 222 nm (*12*). As shown in Table 1, the α-helix content of the NBA peptides was estimated as around 50−70%. These results indicate that the NBA peptides have potential to form an α-helical structure. The previous study demonstrated that the incorporation of one or two NBA units does not disturb the conformational properties of the peptides and proteins (*3, 5*). Considering that the α-helix content of the A9R4 peptide was estimated as 55%, in this study, incorporations of three NBA units also do not disturb the abilities of the peptides to form an α-helical structure.

Table 2. Dissociation Constants (K_d) of the Peptides with the P22 boxB RNA

peptide	K_d (μM)	relative affinity[a]
GCG	1.2 ± 0.1	100
GTG	1.9 ± 0.1	63
GAG	0.86 ± 0.03	140
GGG	0.27 ± 0.02	444
CGG	0.85 ± 0.04	141
TGG	0.79 ± 0.04	152
AGG	0.93 ± 0.03	129
GGA	0.32 ± 0.01	375
AlaGG	0.53 ± 0.02	226
GAlaG	3.0 ± 0.3	40
GGAla	0.57 ± 0.02	211
P22N	0.88 ± 0.03	129
A9R4	120 ± 10	1.00

[a] The relative affinity represents the ratio of dissociation constants between the A9R4 peptide and other peptides to the P22 boxB RNA.

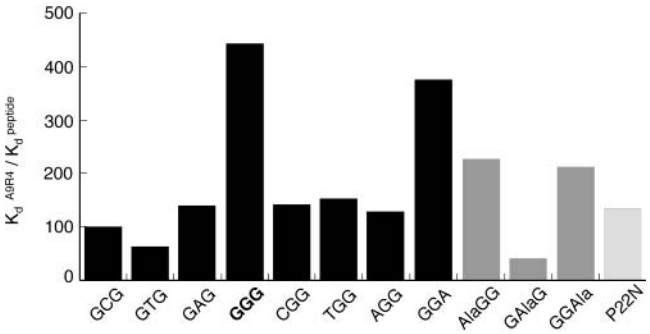

Figure 3. Relative binding affinities between the peptides and the A9R4 peptide with the P22 boxB RNA. $K_d^{A9R4}/K_d^{peptide}$ represents the ratio of the dissociation constants between the A9R4 peptide and each peptide to the P22 boxB RNA.

Binding Analyses of the NBA Peptides with the P22 boxB RNA. To evaluate the binding affinities of the NBA peptides for the boxB RNA, the fluorescein moiety was incorporated into the RNA using T4 RNA ligase (Figure 2b) (*13*). Dissociation constants (K_d) of the peptides with the RNA were determined by fluorescent anisotropy measurements. In this method, the binding affinity of the A9R4 peptide for the RNA was estimated as the K_d value of 120 μM. Binding affinity of each peptide was compared with that of A9R4 (Table 2 and Figure 3).

At first, the binding affinities of the NBA peptides with G_{NBA} at positions 3 and 11 and the several types of the NBA units at position 6 were compared. The GGG peptide having three G_{NBA} units showed a binding affinity with $K_d = 0.27$ μM, a value that indicates affinity ca. 450-fold higher than that of the A9R4 peptide. Furthermore, the GGG peptide showed a higher affinity (3.5-fold) than the natural counterpart P22 N peptide, which is known to bind to the P22 boxB RNA. In contrast, the peptides having other types of NBA units at position 6 (A, T, and C bases) bound to the target RNA at a similar or lower level of the P22 N peptide. These results strongly suggested that $G_{NBA}6$ could work more effectively in the interaction with the boxB RNA than the other types of nucleobases.

Next, the binding affinities of the peptides with the various NBA units at position 3 for the boxB RNA were also compared. In this case, the GGG peptide bound to the target RNA more strongly than the other peptides having adenine, thymine, and cytosine NBA units at position 3. These results indicated that $G_{NBA}3$ could interact with the RNA base more effectively than the other types of NBA units at its position. $G_{NBA}11$ was also evaluated to interact with the RNA effectively by a comparison of the binding affinities between the GGG and GGA peptides for the RNA. Therefore, the GGG peptide showed the highest affinity for the P22 boxB RNA in the series of de novo peptides. These results indicated that three guanine bases of the GGG peptide could work effectively for the RNA binding. Generally in RNA, guanine base can interact with not only cytosine base by making the Watson−Crick type base pairing but also guanine by making the Hoogsteen type pairing. Therefore, it seems that three guanines of the GGG peptide are able to interact with a G−C base pair on the stem region of the P22 boxB RNA and guanine and cytosine bases on the loop region. The specific interaction may include not only hydrogen bonding but also hydrophobic interaction. The NMR analysis of the P22 N peptide−boxB RNA complex revealed that the amino acid residues of the peptide at positions 3, 6, and 11 are located near the C7-G15, G9, and C11 bases of the boxB RNA, respectively (*7*). Along with these data, it was estimated that the de novo designed NBA peptides might be located at a position similar to that of the P22 N peptide in the peptide−RNA complex when the NBA peptides could take the α-helical conformation by binding to the RNA. In addition, the other peptides with two guanine bases also showed higher binding affinities than the A9R4. This finding indicates that the two guanine moieties interact with the RNA bases in a manner similar to the case of GGG, and another base (A, T, or C) might interact weakly with RNA by a nonspecific manner.

To investigate the contribution of each G_{NBA} unit to the RNA-binding, one of the G_{NBA} units of the GGG peptide was replaced by an alanine residue (Figure 1). As a result, the AlaGG and GGAla peptides showed the binding affinities with $K_d = 0.53$ and 0.57 μM, respectively, which is ca. 2-fold lower than the GGG peptide. In contrast, the GAlaG peptide that has the alanine residue at position 6 showed significantly lower binding affinity ($K_d = 3.0$ μM) than the other peptides. It was implied that $G_{NBA}6$ contributed to the RNA-binding to a larger extent than the G_{NBA} units at the other positions. These results do not contradict the facts that the GGG peptide with G at position 6 shows significantly higher affinity for the RNA than the peptides with the A, T, and C bases at the position. Moreover, considering that the binding affinities of the AlaGG and the GGAla peptides were decreased compared with the GGG peptide, $G_{NBA}3$ and $G_{NBA}11$ are also important for the RNA-binding. Consequently, since three guanine moieties of the GGG peptide interacted with RNA bases effectively, the GGG peptide showed the higher binding affinity for the P22 boxB RNA than the other peptides including P22 N.

Binding Analyses of the NBA Peptides with the Mutant RNAs. By using the NBA units and the de novo designed α-helical peptides, we have successfully demonstrated the construction of the novel RNA-binding molecules. For the evaluation of the specificity of the NBA peptides with the P22 boxB RNA, two types of the mutant RNAs (7A15U and C11U) were prepared (Figure 2a). It was expected that the peptide with the NBA units corresponding to the bases of the mutant RNA showed a higher affinity for the mutants than for the wild-type boxB RNA.

Table 3. Dissociation Constants of the Peptides with the C11U Mutant RNA

peptide	K_d (μM)	K_d^{P22}/K_d^{C11U} [a]
GGG	0.41 ± 0.02	0.66
GGA	0.18 ± 0.02	1.78
P22N	0.92 ± 0.03	0.96

[a] K_d^{P22}/K_d^{C11U} represents the ratio of the dissociation constants of each peptide to P22 boxB RNA and the C11U mutant RNA.

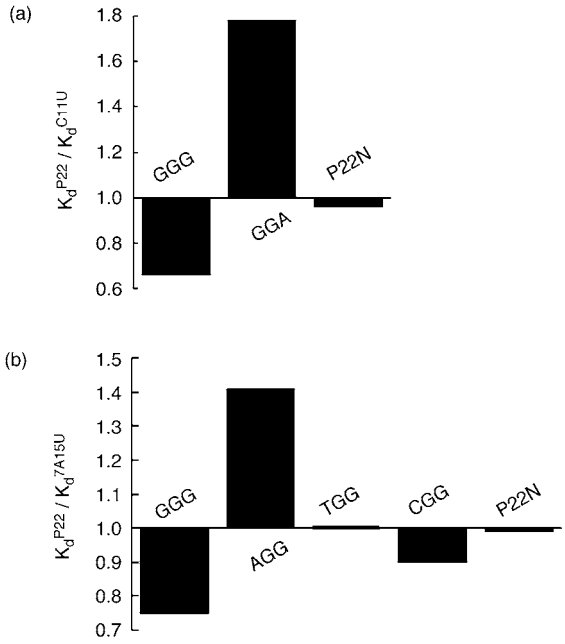

Figure 4. (a) Relative binding affinities of the peptides for the P22 boxB RNA and the C11A mutant RNA. K_d^{P22}/K_d^{C11U} represents the ratio of the dissociation constants of each peptide to P22 boxB RNA and the C11U mutant RNA. (b) Relative binding affinities of the peptides for the P22 boxB RNA and the 7A15U mutant RNA. K_d^{P22}/K_d^{7A15U} represents the ratio of the dissociation constants of each peptide to P22 boxB RNA and the 7A15U mutant RNA.
